Abstract. Decline in soil physical health and crop productivity are the major concerns in wheat-maize cropping system of northwest India. Depending on objective, conservation and deep tillage are the potential solutions. Therefore, a field study was conducted to investigate the interactive effects of land management practices and irrigation regimes on soil properties and wheat-maize productivity. The tillage treatments comprised of no-tillage, strip tillage, conventional tillage and deep tillage, while the irrigation regimes included three levels based on irrigation water over pan evaporation (IW/PAN-E) ratios i.e. $I_{0.6}$, $I_{0.9}$ and $I_{1.2}$ for both wheat and maize crops. By shattering soil up to 45 cm depth, the deep tillage helped in improving infiltration rate by 31 % over conventional tillage. However, the no-tillage improved soil aggregation by 38 % than deep tillage. At subsurface depth (15-30 cm) the soil bulk density and penetration resistance were found to be significantly lower under deep tillage (1.52 Mg m^{-3} and 1.9 MPa) than conventional tillage (1.68 Mg m^{-3} and 2.8 MPa), respectively. The deep tillage enhanced root proliferation by increasing root length density by 44 % and 34 % than conventional tillage in maize and wheat, respectively. The grain yields (Mg ha^{-1}) of maize and wheat were 14 % and 12 % more under deep tillage than conventional tillage, respectively. The water productivity varied significantly under different irrigation regimes and was found to be highest at $I_{0.9}$ in maize and $I_{1.2}$ in wheat.
Keywords: *soil compaction, mechanical resistance, water transmission, root proliferation, crop productivity*

Introduction

Alternate tillage practices and excessive use of machinery leads to soil compaction and hard pan formation in subsurface soil layer (Kukal and Aggarwal, 2003; Singh et al., 2009) this may affect the growth of wheat and maize due to reduced water transmission and root proliferation (Gajri et al., 1994). The deep tillage (DT) enhances rooting system by lowering soil strength which helps in better uptake of water and nutrients from the deeper layers (Gajri et al., 1994). On the other hand, conservation tillage i.e. no-tillage with residue retention (NT) provide favorable soil environment by improving soil water transmission, moisture storage, aggregation, carbon sequestration and crop productivity (Tessier et al., 1990). This practice also improves economic performance, energy use efficiency and reduces production risks (Zentner et al., 2002; Lal, 2003). The area under NT has been substantially increased in South Asia and particularly Indo-Gangetic plains (Derpsch et al., 2010). Continuous use of NT can cause measurable changes in soil hydrological, mechanical, physical, chemical and biological properties (Lal and Elder, 2008). The other conservation tillage practice i.e. strip till (ST) disturbs the soil minimally and it also manages to keep the previous crop residue in between the rows. However, the conventional tillage (CT) practices lead to breakdown of soil structure which subsequently affects soil water transmission characteristics, soil organic matter depletion, microbial activity and crop productivity

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_001013

(Ramos et al., 2011). The CT, including intensive soil cultivation and crop residue removal and burning, have exacerbated soil erosion and degradation, thus contributing to the development of soils with low organic matter contents and a fragile physical structure. There is thus an urgent need to identify land management practice which would help in sustaining soil physical health as well as crop productivity. Since, it is difficult to sow wheat and maize directly in the standing stubbles and the loose residue of previous crops, the farmers, mostly, burn them for seed bed preparation. The crop residue burning or removal can cause huge loss to soil fertility, physical health and environmental issues such as aerosols (Sidhu et al., 2007). However, with the help of NT practices, residue management problem can be solved to a great extent (Afzalinia and Zabihi, 2014). Water stress (both due to excessive and deficient soil moisture conditions) at any growth stage of wheat and maize can reduce crop and water productivity (Paudyal et al., 2001). Thus, optimum irrigation is a solution to this problem. The knowledge of wheat and maize performance at various irrigation regimes is of utmost importance in a semi-arid environment to improve water productivity. Water scarcity and uneven distribution are considered to be the primary limiting factors affecting wheat and maize production in the semiarid region (Kang et al., 2002; Wang et al., 2009). There are few reports on the interactive effects of straw mulching and DT in relation to irrigation regimes on crop yield. There is thus, dire need to find out a suitable land management practice along with optimum irrigation to resolve soil physical constraints and improve crop productivity. This study examined the combined effects of tillage and irrigation on soil water transmission characteristics, yield and water productivity of wheat and maize in a semi-arid sub-tropical environment of Punjab in northwest India.

Materials and methods

A field study was conducted at research farm of Department of Soil Science, Punjab Agricultural University, Ludhiana (30° 56’ N, 75° 52’ E, 247 m above the mean sea level), Punjab, India. The area is characterized by sub-tropical and semi-arid type of climate with hot and dry summer from April to June followed by hot and humid period during July to September and cold winters from November to January. The average rainfall of the area is 600-700 mm, of which about 80 percent is received during July to September. The soil was non calcareous, non-saline, neutral with medium organic carbon content.

The treatments includes four tillage practices i.e. no-tillage with residue (NT), strip tillage (ST), conventional tillage (CT) and deep tillage (DT). In NT practice, the surface residue was retained and sowing of both wheat and maize was done directly in standing stubbles and loose straw of previous crop, however, in ST, the seedbed is tilled in strips leaving the residue in between undisturbed. The conventional tillage (CT) involved five field operations i.e. two disks, two cultivator followed by one planking operation, whereas in DT the deep ploughing of soil was done up to 45 cm followed by CT. The irrigation treatments include three irrigation water over pan evaporation (IW/PAN-E) ratios, 1.2, 0.9 and 0.6. The experiment was conducted in split plot design with three replications. The tillage treatments were kept in main plots and irrigation in sub plots. The recommended dose of fertilizers as per Punjab Agricultural University package of practices were applied at the rate of 125 kg N ha^{-1} in the form of urea, 62.5 kg P_2O_5 ha^{-1} in the form of single superphosphate and 30 kg K_2O ha^{-1} in the form of muriate of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_001013

potash to both the crops. The wheat and maize crops were sown with the recommended seed rate of 100 and 20 kg ha^{-1}, respectively. Weeds were kept under check with use of recommended herbicides and hand weeding. The manual harvesting of wheat was performed in mid April, while decobbing of harvested maize crop was done mechanically after sun drying and the seed yield was recorded from each plot.

Infiltration was measured, *in-situ* at the end of cropping cycle by double ring infiltrometer method according to Reynolds et al. (2002). Water was filled in both the outer and inner rings and the fall of water levels in the inner ring was recorded at different time intervals till the water intake rate becomes constant. The saturated hydraulic conductivity (K_s) was determined using constant head method (Reynolds et al., 2002). Undisturbed soil cores (8 cm diameter and 7.5 cm length) were collected from 0-7.5 and 7.5-15 cm depths. Samples were saturated in the laboratory by placing on cloth covered perforated disks in 25 cm deep tray containing 5 cm of water. Saturated soil sample along with core was connected with another core and to avoid the water leakage grease was applied in the jointing place on the top of previous core. A thin layer of water was slowly poured on top of the sample by using siphons connected to a constant head device (Mariotte apparatus). The volume of water that percolates through the sample was measured at definite intervals of time. The K_s was calculated using the following equation:

$$K_s = (Q/At) \times \{L/(H+L)\} \quad \text{(Eq.1)}$$

where,
Ks = saturated hydraulic conductivity (cm h^{-1}),
Q = volume of percolate collected (cm^3),
L = length of soil column (cm),
A = cross sectional area of soil column (cm^2),
t = time (h),
H = depth of water above soil (cm).

For determining soil bulk density (ρ_b) the undisturbed soil cores were taken at the end of cropping cycle upto 30 cm depth (0-7.5, 7.5-15, 15-22.5 and 22.5-30 cm) with the help of cylindrical core (7.5 cm height and 8.0 cm diameter) and dried in an oven at 105 °C till the weight of the soil becomes constant. The ratio of dry soil mass (M_s) and internal volume (V_t) of the cylindrical ring is expressed as bulk density (ρ_b) of soil (Mg m^{-3}) (Blake and Hartge, 1986).

$$\text{Bulk density } (\rho_b) = M_s/V_t \quad \text{(Eq.2)}$$

The penetration resistance (PR) was measured by a hand-held digital cone penetrometer (CP40II; Rimik electronics, RFM Australia) at three randomly selected locations within a plot. The soil PR readings were recorded up to 60 cm depth. The measurements were made at the end of the cropping cycle along with simultaneous measurements of soil moisture content.

Soil moisture samples were taken for entire soil profile (0-120 cm soil depth with 15 cm increments) with screw auger. Moisture storage in different layer was computed by multiplying the mass water content depth of a particular layer and bulk density. It was summed up for all the layers to get profile moisture storage in cm. Surface soil (0-15 cm) samples were collected for aggregate size analysis Aggregate status of soil was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_001013

determined by wet sieving method (Yoder, 1936). The air-dried soil peds were passed through 8-mm sieve and were retained on 4-mm sieve. Yoder's wet sieving apparatus, comprising of 4 sieve sets, each having nest of 5 sieves of 12.7 cm diameter and 5 cm height and with hole sizes of 2.0, 1.0, 0.5, 0.25 and 0.1 mm (with mesh numbers of 8, 16, 32, 64 and 150 respectively), were used for this purpose. The samples were evenly distributed over the top sieve of the sieve sets and pre-wetted by capillarity for 10 minutes. The nest of sieves was then allowed to move up and down for 30 minutes. Following this, the sieves were drawn out of water and the oven-dried weight of aggregates retained on each sieve was recorded after drying these in an oven at 105 °C till the constant weight achieved. Mean weight diameter (MWD) and water stable aggregates (WSA) were calculated using the formula:

$$\mathrm{MWD} = \sum_{i=1}^{n} d_i \times w_i \quad \text{(Eq.3)}$$

$$\mathrm{WSA} > 0.25\ \mathrm{mm}(\%) = \frac{\sum_{i=1}^{n} w_i}{\text{weight of sample}} \times 100 \quad \text{(Eq.4)}$$

where, n is number of size fractions (the finest fraction that passes through the finest sieve inclusive), d_i is the mean diameter of each size range, w_i is the weight of aggregates in that size range as a fraction of the total dry weight of the sample analysed. Oxidizable soil organic carbon was estimated using (Walkley and Black, 1934) rapid titration method, using a diphenyl amine indicator.

The plant height of ten randomly selected plants in each plot was measured with the help of meter scale from ground surface to apex of the plant at 70 days after sowing (DAS) in maize and 100 DAS in wheat. The root distribution was measured at 70 DAS in maize and 100 DAS in wheat. The root samples were collected from 0-15, 15-30, 30-45 and 45-60 cm soil layers. For root sampling, the soil cores were taken with the help of core sampler of 5 cm diameter. Samples were taken in between the plant rows. The root-soil cores were then collected and washed in plastic nets. Roots were carefully separated from the soil by washing the nets under water. The washed roots were further cleaned to remove any leftover weed roots, seed and other organic debris. The root length density (RLD) (cm cm^{-3}) was calculated from the total length of roots measured by scanner to the volume of the core. A representative sample of one thousand grains of maize from each plot was counted manually and weighed on a precision balance and expressed in grams. However, a representative sample of one thousand grains of wheat from each plot was counted with the help of automatic seed counter (SLY-C Automatic Seed Counter, Shailron Technology Pvt. Ltd.) and weighed on a precision balance and expressed in grams.

The crop biomass determination was made by taking all the above ground plant parts at time of harvesting. The samples were allowed to dried and then weighed to express in Mg ha^{-1}. The harvested crop produced from each plot was thrashed in case of wheat and decobbed in maize. Grain yields of both the crops were recorded in kg from 24 m^2 area in each plot and finally expressed in Mg ha^{-1}. The water productivity was calculated by dividing the grain yield of corresponding treatments of both the crops with the total water use (irrigation water + rainfall + profile water use) in particular treatment. The data

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_001013

collected on various aspects of the investigations were statistically analyzed as prescribed by Cochran and Cox (1967) and adapted by Cheema and Singh (1991) in statistical package CPCS-I. The treatment comparisons were made at 5 per cent level of significance.

Results and discussion

Bulk density (ρ_b) and penetration resistance (PR)

Soil mechanical characteristics including ρ_b and PR affect other soil properties as well as the crop productivity. The data presented in *Figure 1* showed that at subsurface soil depth (15-30 cm), where the chances of occurrence of hard pan were prominent yielded highest ρ_b (Mg cm^{-3}) under CT (1.68) and minimum under in DT (1.52). Similar observations were recorded for other soil depths. The other two tillage systems recorded in between values. The use of heavy machinery and intensive tillage in CT for performing five field operations (twice disc, twice cultivators and one planking operation) can increase soil ρ_b at the ploughing depth (15 to 30 cm). Whereas, in case of DT the soils was shattered up to 45 cm depth, which break down the compaction and reduces ρ_b of soil. The DT experienced an all-time low ρ_b. However, the lower ρ_b in NT plots may be associated with greater soil biological activates, especially earthworms (Lal, 1976; Kahlon et al., 2012a). Jin et al. (2011) also reported that the mean ρ_b at 0-10 and 10-20 cm soil layers under NT practice was 2.1 per cent and 4.7 per cent significantly ($P< 0.05$) lower than under CT. In general with increase in depth there was an increase in ρ_b. The PR determines the soil strength which effect root proliferation. The PR measurements of soil can be used to assess the need for tillage operations, which will help in maintaining effective plant rooting and facilitate good water and nutrient uptake. In general, root tips are unable to penetrate pores narrower than their diameter. They can exert a vertical pressure ranging from 0.7 to 2.5 MPa, depending on crop species. Likewise soil ρ_b, the PR also showed maximum value in CT (2.8 MPa) and minimum in DT (1.9 MPa) at subsurface soil depth (15-30 cm) (*Figure 1*). This indicates the formation of hard pan, which restricts the downward movement of water and root penetration. Since the PR linked with the soil moisture content, its value decreased at lower soil depths. Maximum difference in PR values were observed between DT and CT at subsurface soil depth i.e. 15-30 cm. Kahlon et al. (2012b) reported higher soil PR in CT than NT. Penetrometer values greater than 2 MPa are generally reported to reduce root growth significantly (Atwell, 1993). In well-structured soils or those in which biochannels are preserved (as in non-tilled soils); roots continue to extend at greater penetrometer readings because they can grow in integrated space.

Water transmission characteristics

Soil management practices affect water transmission characteristics to such an extent that they may cause considerable loss to crop and water productivity. Significant differences ($P< 0.05$) in K_s were observed among tillage practices for 0-7.5 and 7.5-15 cm depths (*Figure 2*). The highest K_s (cm h^{-1}) were observed in DT (4.9 and 3.7) and the least under CT (3.8 and 2.2) at 0-7.5 and 7.5-15 cm depths, respectively. The higher K_s under DT may be due to more macro porosity. However, the NT plots showed more K_s than CT and ST. The presence of abundant roots and biochannels are responsible for rapid conduit of water through the soil under NT. The pore continuity maintained due to better aggregate stability and pore geometry also leads to higher K_s under NT. The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_001013

activity and population of soil organisms may also have played an important role in increasing pore continuity. The pores were more continuous under NT plots, probably because of more soil fauna and preceding crop root channels (Singh et al., 1995; Bhattacharyya et al., 2006; Kahlon et al., 2012b). In general, K_s decreased with increase in depth in all tillage practices. Due to more soil disturbance and trafficking the macro pores reduced under CT which leads to lowest K_s.

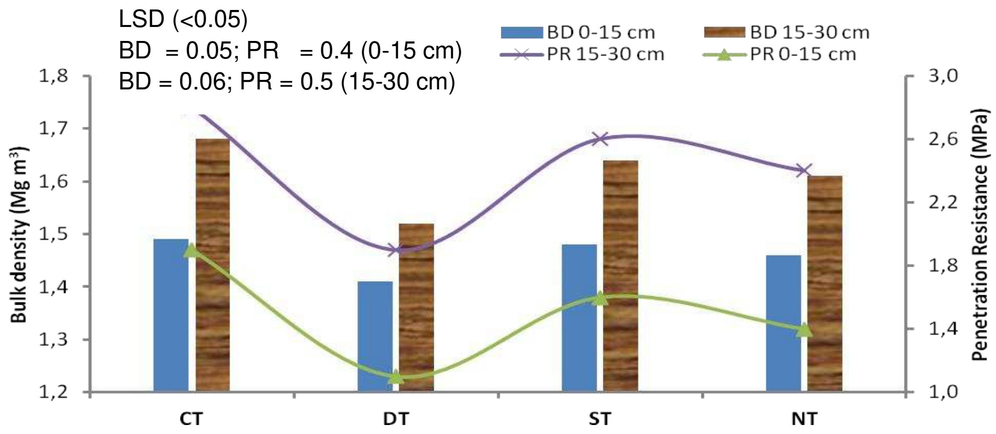

Figure 1. *Effect of tillage practices on soil bulk density and penetration resistance recorded at the end of wheat-maize cropping system (DT = deep tillage; CT = conventional tillage; ST = strip tillage; NT = no-tillage)*

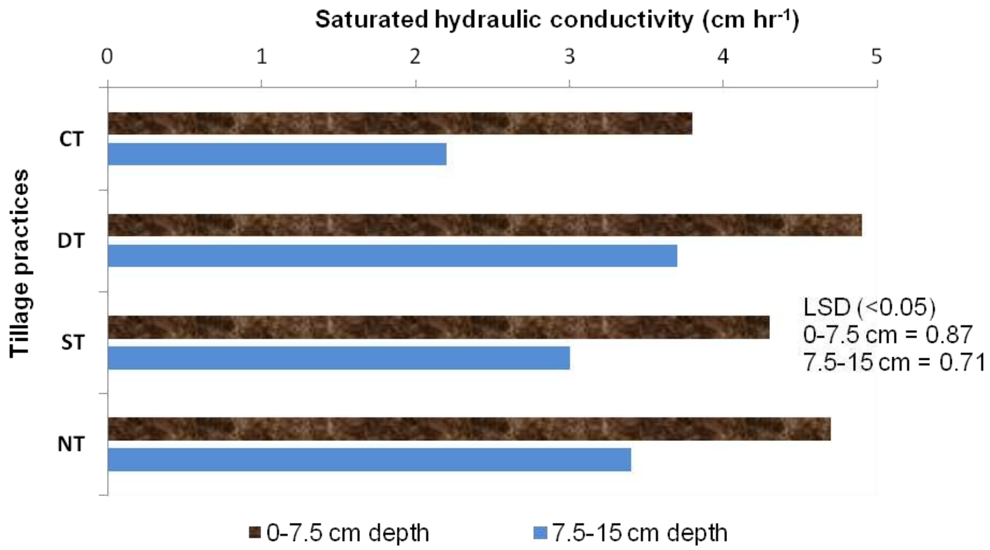

Figure 2. *Saturated hydraulic conductivity as affected by tillage practices at 0-7.5 and 7.5-15 cm soil depth measured in wheat-maize cropping system (DT = deep tillage; CT = conventional tillage; ST = strip tillage; NT = no-tillage)*

Final infiltration rate (IR) was also found to be significantly affected by tillage practices (*Table 1*). Mean highest IR (cm h^{-1}) was observed under DT (3.9), followed by NT (3.5), ST (3.1) and CT (2.7). The higher infiltration recorded under DT attributes to more macro porosity which leads to fast entry of water into the soil profile. The NT still

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_001013

recorded more IR than CT and ST. The reason cited for higher IR under NT than CT may be due to higher SOC content, continuity of water conducting pores, biochannels and MWD which led to a better pore size distribution (Azooz et al., 1996; Jabro et al., 2008). In pattern of IR the maximum cumulative infiltration (CI) was observed under DT (30.6 cm) followed by NT (24.3 cm), ST (21.7 cm) and CT (18.2 cm) (*Table 1*). The higher IR observed under DT reflect the breakdown of hard pan which restricts downward entry of water into the soil. As concluded by Shaver et al. (2002), more number of macropore channels in DT aided in better water transmission characteristics as compared to other tillage treatments. This may also be due to less stable aggregates in the CT practice which upon intense rainfall event clogs the soil pores through slaking of aggregates leading to decrease in water transmission through the soil as also reported by Mbagwu and Auerswald (1999). Further, less soil disturbance in the NT also kept pore structure continuous which aids greater water transmission through the soil. Another reason cited by the researchers to support conservation tillage is that the crop residues left on the soil surface limit evaporation, soil sealing and crusting and thereby increase soil infiltration (Gangwar et al., 2006). Water transmission through the soil profile also depends on the antecedent water content, aggregation and the presence of macropore channels. Least value was observed under CT might be due to relatively smaller pore heterogeneity, discontinuity of pores and less stable aggregates. Maximum water holding capacity (%) and soil moisture storage (cm) was observed in NT (41.8 and 9.6), respectively. Whereas, the minimum values of both were recorded under CT (*Table 1*).

Table 1. *Soil physical characteristics under different tillage practices in wheat- maize system*

Tillage practices	MWD (mm)	WSA (>0.25 mm, %)	IR (cm h^{-1})	CI (cm)	WHC (%)	SMS (cm)
CT	0.39	28.9	2.7	18.2	39.8	8.7
ST	0.48	36.1	3.1	21.7	41.4	9.3
NT	0.58	41.6	3.5	24.3	41.8	9.6
DT	0.36	27.4	3.9	30.6	40.3	8.8
Mean	0.45	33.5	3.3	23.7	40.8	9.1
LSD (<0.05)	0.19	2.8	0.5	4.2	1.6	0.6

CT: conventional tillage; ST: strip tillage; NT: no-tillage; DT: deep tillage; MWD: mean weight diameter; WSA: water stable aggregates; IR: infiltration rate; CI; cumulative infiltration; WHC: water holding capacity; SMS: soil moisture storage

Mean weight diameter (MWD), water stable aggregates (WSA > 0.25 mm) and soil organic carbon

Tillage practices experienced a significant effect on soil aggregation as observed from the data for both the indicators i.e. MWD and WSA (>0.25 mm) (*Table 1*). Among tillage practices, the mean highest MWD (mm) of 0.58 was found under NT followed by ST (0.48), CT (0.39) and least under DT (0.36). Mathematical representation foretells that the mean highest WSA (> 0.25 mm, %) of 41.6 was observed in NT followed by ST (36.1), CT (28.9) and DT (27.4). The DT showed significantly lower values of MWD and WSA in comparison to other treatments. The higher soil aggregation observed in NT attributes to the non disturbed soil conditions and retention of crop residue on soil surface, which helps the aggregates to break from direct raindrop

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_001013

impacts as well as with addition of organic matter in the soil. Different aggregate size fractions (per cent) as affected by tillage practices are presented in *Figure 3*. The data on aggregate size distribution indicate that greater proportion of smaller particles with size < 0.25 mm was found in DT as compared with other tillage treatments. However, the proportion of larger size aggregates (> 1.0 mm) follows the order NT > ST > CT > DT (*Figure 3*). It is well established fact that soil aggregation correlated significantly with the organic carbon content of soil. The same was reported in present study, where, the SOC content was more i.e. under NT practice the bigger size aggregates were also recorded in that treatment. The NT recorded 28 % more SOC than DT (*Figure 4*).

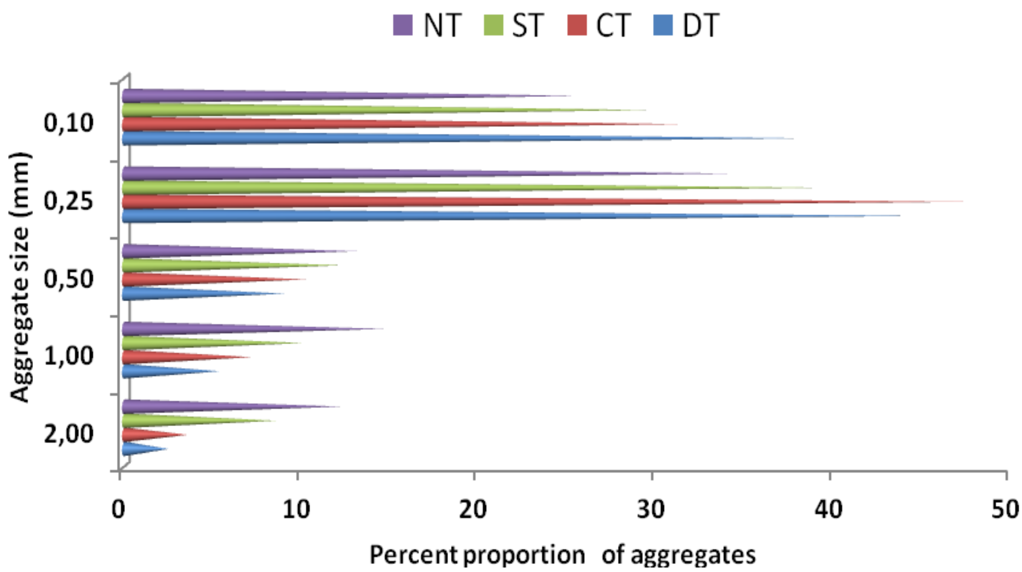

Figure 3. *Percent proportion of aggregate size fractions under different tillage practices in wheat-maize cropping system (DT = deep tillage; CT = conventional tillage; ST = strip tillage; NT = no-tillage)*

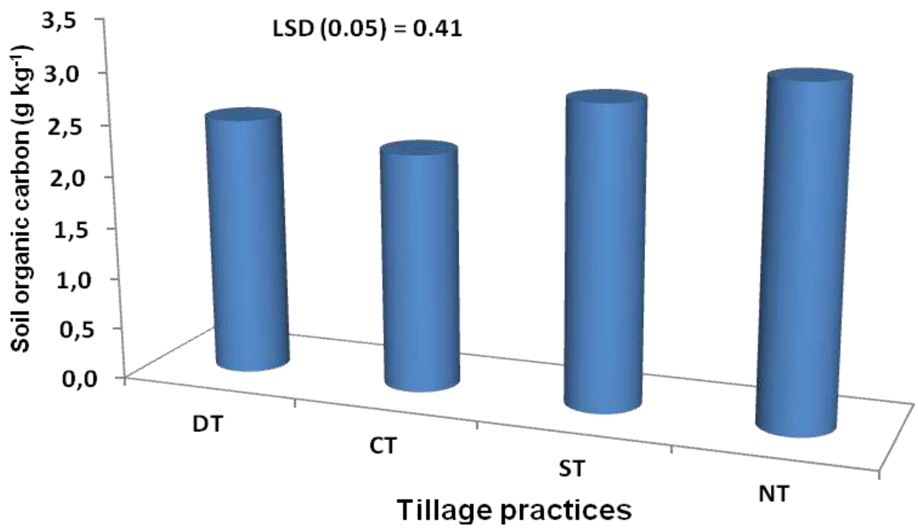

Figure 4. *Soil organic carbon under different tillage practices in wheat-maize system (DT = deep tillage; CT = conventional tillage; ST = strip tillage; NT = no-tillage)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_001013

Root length density (RLD)

In general, the increase in subsoil compaction resulted in reduced rooting system. According to the data presented in *Table 2*, it was observed that due to high soil ρ_b and PR in subsurface soil layer (15-30 cm), CT recorded the least RLD while its maximum value was recorded in DT. However, due to more availability of soil moisture and nutrients in surface layer (0-15 cm) the NT had more RLD than CT and ST. Alternatively, the main reason for higher RLD in DT is the removal of compact hard pan below surface soil layer which otherwise restrict the root proliferation to lower soil depths. Similar observations were recorded for the wheat crop (*Table 2*). The higher root concentration observed in NT attributes to formation of bio channels. However, under CT the presence of plow pan does not allow easy root penetration. Arora et al. (1991) reported that increased tillage reduces soil strength in tilled zone which results in better growth of maize as strength is negatively correlated with root growth. Kumar (2005) studied the effect of tillage on root development of maize and reported that depth of roots at harvest was maximum under DT as compared to CT.

Plant parameters and productivity of maize and wheat

The data pertaining to tillage effects on plant parameters and productivity of maize and wheat is presented in *Table 3*. It depicts that DT outperformed the other tillage treatments with respect to plant height, thousand grain weight and crop biomass for both the crops. The highest maize grain yield (Mg ha^{-1}) was recorded in DT (6.4) followed by NT (6.3), ST (5.9) and CT (5.5). The same yield pattern was observed for wheat crop. The water productivity (kg ha^{-1} mm^{-1}) was also observed to be maximum in DT (8.8) and least in CT (7.2) for maize crop. The WP of wheat followed the similar trend. The irrigation regimes also significantly affect the plant parameters and crop productivity of both the crops (*Table 4*). Maximum maize grain yield (Mg ha^{-1}) was recorded at irrigation regime $I_{0.9}$ (6.5) followed by $I_{1.2}$ (6.2) and least under $I_{0.6}$ (6.1). Irrigation regimes also showed significant effect on water productivity (WP). The mean highest water productivity (kg ha^{-1} mm^{-1}) was found under $I_{0.9}$ (8.7) and the lowest under $I_{0.6}$ (7.8) for maize. The water productivity decreased with increase in IW/PAN-E ratio (0.6 to 1.2). Memon et al. 2013 also reported higher maize grain yield in DT than NT and CT treatments. The increase in yield with increase in number of irrigations is because of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_001013

more availability of water for plant physiological processes. Mojid et al. (2009) also reported decrease in water productivity with increase in irrigation level.

Mean	0.95	2.46	38.3	277.5	13.7	16.1	4.0	6.3	20.3	8.2
LSD (<0.05)	0.09	0.21	2.2	7.4	0.7	0.6	0.3	0.3	0.9	0.4

I1: IW/ PAN-E ratio 1.2; I2: IW/ PAN-E ratio 0.9; I3: IW/ PAN-E ratio 0.6 (for both wheat and maize)

It is concluded that under compaction or hard pan formation at subsurface soil layer the deep tillage (DT) is most appropriate practice while under water stress situation the no-tillage with residue retention (NT) is viable option for achieving higher crop and water productivity in maize-wheat system in northwest India.

Abstract. In this study, we used both culture-dependent physiological profiling and culture-independent DNA-based approaches to characterize the bacterial communities of tobacco rhizospheric soils affected by different pre-crops (soybean, maize and tobacco). Using Biology-Eco plates, we found that the bacterial metabolic activity in soybean-tobacco and maize-tobacco rotation soils were higher than in tobacco monocropping soil. Across all soil samples, bacterial communities were dominated by *Proteobacteria*, *Acidobacteria* and *Actinobacteria* at the phylum level. However, the diversity and composition of the bacterial communities varied significantly between tobacco rotations and monocropping soil. The estimated bacterial diversity (Shannon diversity index) was higher in the maize-tobacco and soybean-tobacco soils than in tobacco monocropping soil. The populations of *Proteobacteria*, *Acidobacteria*, *Actinobacteria* and *Bacteroidetes* were found in variable proportions, depending on the different pre-crops. The highest percentages of *Proteobacteria*, *Actinobacteria* and *Bacteroidetes* were found in soybean-tobacco soil, whereas *Acidobacteria* occurred at higher percentages in tobacco monocropping soil. Collectively, crop rotation influenced soil biodiversity by change of composition and abundance of individual species, and soils under cereal-tobacco rations had higher bacterial activity and diversity than soils under tobacco monocropping.
Keywords: *soybean*, *maize*, *monocropping*, *rotation*, *bacterial community structure*, *bacterial community function*

Introduction

Microorganisms are ubiquitous in the environment and play an essential role in the biogeochemical cycles that sustain all life on Earth (Zarraonaindia et al., 2013; Su et al., 2012). Soil microbial communities are responsible for soil structure maintenance,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_015030

organic matter decomposition, nitrogen fixation, the breakdown of toxic compounds, and inorganic compound transformation (Dick, 1992; Nannipieri et al., 2003). Previous studies have shown that the community structure, abundance and activity of soil microorganisms can be affected by various physical disturbances in the soil (Dick, 1992; Lienhard et al., 2013). Thus, land-use management practices, including crop rotation and tillage (Quadros et al., 2012), fertilizer regime (Qiu et al., 2012), irrigation (Qiu et al., 2012), and continuous cropping (Li et al., 2010) are logical case studies for soil microbial diversity studies.

Tobacco (*Nicotiana tabacum* L.) is among the most important economic crops in the world, and one million acres of tobacco are planted each year in China (Hecht et al., 1984). Tobacco quality is determined by genetic factors, environmental factors and cultivation measures. Cereal-tobacco rotation is the dominant practice in the northeast of China. Soybean (*Glycine max* L.) and maize (*Zea mays* L.) are the major cereal crops grown most often in rotation with tobacco. However, research on the relative effects of the preceding crops on the soil quality of subsequent tobacco in cereal-tobacco rotation systems is rare. It is well known that rotation improves soil quality, including soil biota structure, organic matter content and moisture retention capacity (Ponge et al., 2013). Soils under crop rotation with a high input and diversity of organic materials contain high microbial biomass content and enzyme activity compared with monoculture soils (Trasar-Cepeda et al., 2008). Many studies have found that crop sequence plays a major role in soil C retention (Morari et al., 2006; Varvel, 2008; Wright and Hons, 2005). In particular, the effects of preceding crops on subsequent crops can relate to residual nutrients and water as well as to disease control (Kirkegaard et al., 2008). The decomposition rate of plant debris was found to be mainly governed by the C/N ratio. There is growing evidence that the variety of pre-crops can become factors in the microbial population and enzymes in the soils for subsequent crops.

In this study, two different techniques (Biolog-Eco and 454 pyrosequencing) for estimating the soil bacterial community were adopted. To build a sustainable crop-tobacco rotation sequence, the objective was to investigate the bacterial community structure and function of subsequent tobacco in soils in response to three preceding crops (soybean, maize and tobacco) and to observe differences among bacterial communities.

Materials and Methods

Field plots and sample collection

Soil sampling was performed in September 2011, at Tobacco Research Institute of Mudanjiang, Ningan city of Heilongjiang province (latitude, 44°85′N; longitude, 129°60′E, Northeast China). The average annual temperature in the region is 4°C. The mean annual precipitation is 427.50 mm, and the evaporation is 1635 mm per year. The soil is classified as a river silt soil. Selected soil properties were as follows: pH 6.85; organic matter 27.70 $g \cdot kg^{-1}$; total nitrogen 1.90 $g \cdot kg^{-1}$; total phosphorus 1.62 $g \cdot kg^{-1}$; total potassium 1.61 $g \cdot kg^{-1}$; available nitrogen 86.50 $mg \cdot kg^{-1}$; available phosphorus 36.40 $mg \cdot kg^{-1}$; available potassium 300.00 $mg \cdot kg^{-1}$.

The experimental design consisted of three blocks. Each block was divided into three plots representing the three plantation systems. Each plot comprised 8 rows that were 6.00 m long and 8.80 m wide; thus, each was 52.80 m^2 in size. Treatments levels included (1) tobacco monocropping, (2) soybean-tobacco rotation and (3) maize-tobacco rotation. The cultivars of tobacco, soybean and maize were Longjiang 911, Heinong 34 and Kenfeng 1, respectively. Soil samples were collected from all

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_015030

plots, three individual rhizosphere soils randomly collected for each treatment in a plot. Tobacco rhizosphere soils, which adhered to the roots (Nazih et al., 2001), were collected by shaking the soil off the roots. After removal of the vegetation, roots, and stone (>2 mm), samples were placed into sterile centrifuge tubes under ice and transported to the laboratory within 24 hours. Finally, samples were stored at 4°C prior to microbial functional (Biolog™ ECO technic) and structural (454 pyrosequencing) analyses.

Substrate utilization patterns and data analysis

Substrate utilization patterns were measured using Biolog™ ECO plates (BIOLOG, Inc.). A 10^{-1} microbial suspension was prepared by suspending 10 g of fresh soil in 100 mL 0.85% NaCl solution. The slurry was processed with a Vortex mixer for 1 min at maximum speed and centrifuged for 10 min at 500×g (Rutgers et al. 2006). Tenfold serial dilutions were performed, and 150 μL of the 10^{-3} dilutions were pipetted into microplates using an 8-channel micropipette. Microplates were incubated at 28°C for 216 h. The color development at OD_{578} nm was read for each well at 24-h intervals. Negative values were set to zero. The average well color development (AWCD) value of the Biolog data was calculated for each sample at each time point by dividing the sum of the optical density data by 31 (number of substrates), as described by Garland (1996).

The 96-h data were used to measure the functional and species diversity of the soil microbial community, and the following parameters were calculated using the equations below:

Shannon-Wiener index $$H=-\sum Pi\times\ln(Pi)$$ (Eq.1)

Simpson index $$D=1-\sum(Pi)^2$$ (Eq.2)

McIntosh index $$U=\sqrt{\left(\quad Ni^2\right)}$$ (Eq.3)

where Ni is the relative OD in each carbon source well, and Pi is calculated by subtracting the control from the absorbance of each substrate and then by dividing this value by the total color change recorded for all 31 substrates.

DNA extraction, amplification of 16S rRNA genes, and pyrosequencing

Total microbial community DNA was isolated from 0.25 g of soil per sample using soil DNA extraction kit (Omega Bio-Tek, Atlanta, USA). The extracted DNA was examined following electrophoresis in 1% agarose gel, and the DNA was normalized to the same concentration prior to amplification. A ~455 bp region of the 16S rRNA gene covering the V1-V3 region was selected to construct the community library through tag pyrosequencing. The V1-V3 region was amplified using the universal primers 8F (5'-AGAGTTTGATCCTGGCTCAG-3') and 533R (5'-TTACCGCGGCTGCTGGCAC-3') containing the A and B sequencing adaptors (454 Life Sciences). The PCR mixture (final volume, 50 μL) contained 5 μM of each primer, ~5 ng of template DNA, 5×FastPfu PCR buffer, and 2.5 U of FastPfu DNA Polymerase (MBI, Fermentas, USA). The amplification conditions consisted of an

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_015030

initial denaturation at 95°C for 2 min and 25 cycles of denaturation at 95°C at 30 s, annealing at 55°C for 30 s, and extension at 72°C for 30 s, followed by a final extension period at 72°C for 5 min. During amplification, negative control reactions lacking template DNA were also performed to check for experimental contamination. The amplicons were then purified once by gel electrophoresis/isolation and twice more using the Wizard SV Geland PCR Clean-Up System (Promega, Madison, Wisconsin, USA). Next, 454 pyrosequencing was conducted on a Roche massively parallel 454 GS-FlX sequencer according to standard protocols.

454 Pyrosequencing and data analysis

Pyrosequencing flowgrams were converted to sequence reads using the MOTHUR software (http://www.mothur.org) and analyzed. The acquired sequences were filtered by evaluating data quality and removing primers and barcodes. Sequences were filtered by the following methods: (1) selecting sequences that contained the barcode and forward primer and eliminating sequences with even a single base pair; (2) removing sequences shorter than 150 bp, with ambiguous base pairs, or with more than two wrong matches in the primer; and (3) eliminating barcodes and forward primers. After filtering, the effective sequences were clustered into operational taxonomic units (OTUs) based on phylum, class, order, family, genus and species levels using MOTHUR.

Data analysis

To detect OTUs, optimized sequences were reduced to 300 bp in length and compared using silva108. Rarefaction curves based on an identified OTU, the species richness estimator Chao 1, were generated for each sample using MOTHUR. The taxonomic assignment of sequences was performed using the Ribosomal Database Project (RDP) classifier (minimum confidence of 80%). After phylogenetic allocation of the sequences to the phylum and genus levels, the relative abundance of a given phylogenetic group was set to the number of sequences per sample. Hierarchical cluster (Heatmap) analyses were generated in MOTHUR using the gplots package of R. We used SPSS for windows (version 19) to test for significance (P<0.05) between treatments of relative abundances, Alpha diversity and richness of bacterial communities were analyzed using Duncan post-hoc test at 95% confidence level. The Duncan test method was conducted for multiple comparisons to assess the significance level of substrate utilization among treatments.

Results

Community level physiological profile

As expected, the average well color development (AWCD) increased with incubation period (*Fig. 1*). The soybean-tobacco rotation consistently exhibited the highest AWCD at all periods, followed by maize-tobacco rotation. There was no significant difference in soil bacterial functional diversity between the soybean-tobacco and maize-tobacco treatments. The tobacco monocropping treatment constantly had the lowest AWCD throughout all period. The soil bacterial functional diversity index (H, D and S) was significantly affected by the pre-crop treatment (*Table 1*). Among rotation treatments, there was no significant difference between the soybean-tobacco and maize-tobacco treatments.

Principal component analysis of bacterial community

Microbial consumption of polymers, amino acids, amines/amides and miscellaneous compounds were significantly higher in soybean-tobacco rotation soils compared to that found in tobacco monocropping soil (*Fig. 2*). On the contrary, the consumption of carbohydrates was lower in soybean-tobacco soils than in tobacco monocropping soil. However, similarly to soybean-tobacco rotation treatment, soil microbial communities of maize-tobacco rotation treatment showed large polymers utilization.

The principal component analysis (PCA) of bacterial substrate utilization patterns (*Fig. 3*) explained 79.42% of the total variance, with the first principle component having the greatest power of separation (70.21%). The PCA score plot revealed that the soybean-tobacco and maize-tobacco rotation treatments were clustered together and separated from the tobacco monocropping treatment.

Bacterial community analysis using pyrosequencing

In this study, we assessed and compared the composition of soil bacterial communities derived from the soybean-tobacco, maize-tobacco and tobacco monocropping libraries through the pyrosequencing-based analysis of 16S rRNA gene sequences. Pyrosequencing analysis of the V1-V3 region of the 16S rRNA genes resulted in 57,084 high-quality sequences reads with a read length of ≥300 bp across all samples. The average read length was 434 bp. The read numbers were uneven per sample, ranging from 18,343 to 19,911, with an average of 19,028 (*Table 2*). All samples were randomly reduced to the same size using MOTHUR based on the sample with the smallest number of reads.

Table 2. *Number of 16S rRNA gene sequences derived from three libraries. Treatment: SB-TC, soybean-tobacco; MZ-TC, maize-tobacco; and TC-TC, tobacco monocropping*

Treatment	No. obtained sequences ≥400 bp	Bases (bp)	Average length (bp)
SB-TC	18,343	5,934,166	426.2
MZ-TC	19,911	6,243,854	436.3
TC-TC	18,830	6,091,675	439.7

Bacterial alpha-diversity

To determine rarefaction curves and other measures of diversity, OTUs (operational taxonomic units) were identified at 3% genetic distance. The rarefaction curves indicated consistent differences among the three libraries (*Fig. 4*). At 3% genetic distance, the rarefaction curves suggested that the sequencing effort was not large enough to capture the complete diversity of these communities, as the curves did not reach the asymptote with increasing sample size. The same conclusion was observed in terms of coverage (*Table 3*). The coverage from the three libraries was below 95%, indicating that the sequencing reads were not sufficient for this analysis.

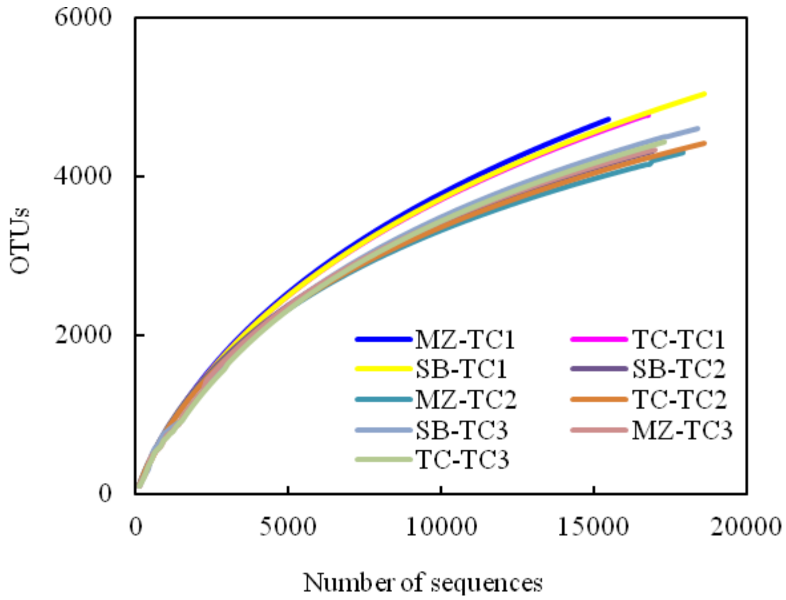

Figure 4. *Rarefaction curves indicating the observed number of OTUs at genetic distances of 3% in all libraries. SB-TC, soybean-tobacco; MZ-TC, maize-tobacco; and TC-TC, tobacco monocropping*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_015030

Table 3. *Sequencing information and diversity estimated for three samples obtained by 454 pyrosequencing. Treatment: SB-TC, soybean-tobacco; MZ-TC, maize-tobacco; and TC-TC, tobacco monocropping*

Treatment	3% Genetic distance			
	Ace	Chao1	Shannon	Coverage (%)
SB-TC	8,806	7,221	7.78	86.6
MZ-TC	9,812	7,892	7.91	86.3
TC-TC	7,589	7,563	7.86	86.9

Comparing the mean Shannon diversity index of the three libraries revealed that the highest bacterial diversity at the analyzed genetic distances was found in the maize-tobacco soil, followed by the tobacco monocropping and soybean-tobacco soils. The Chao1 index varied among the three libraries, although not significantly. In addition, the Ace index increased significantly in tobacco rotations soils compared to the tobacco monocropping soil.

Distribution of bacterial composition at the phylum level

The 57,084 classifiable sequences were affiliated with 15 bacterial phyla (*Fig. 5*).The dominant phyla across all samples were *Proteobacteria*, *Acidobacteria*, *Actinobacteria*, *Chloroflexi*, *Gemmatimonadetes*, and *Bacteroidetes*, representing 28.10, 18.90, 17.50, 11.00, 7.59, and 5.47%, respectively, of all sequences that were classified below the domain level. These dominant bacterial phyla were found in all samples (*Fig. 6*). Other sequences belonged to *Nitrospirae*, *Armatimonaddetes*, *Firmicutes*, *Fibrobacteres*, *Chlorobi*, *Verrucomicrobia* and other bacteria, and they were always found in very low proportions (<5%).

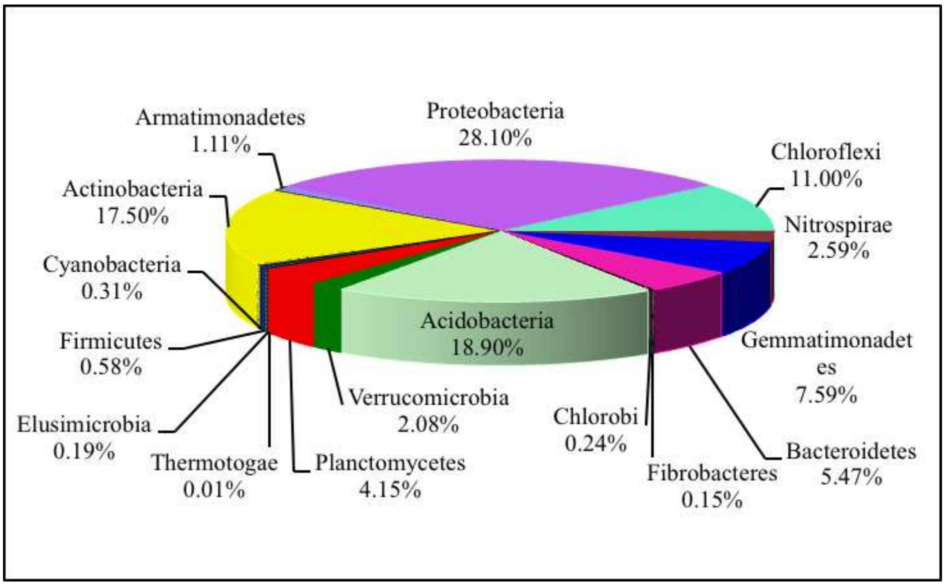

Figure 5. *Proportional distribution of different phyla.*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_015030

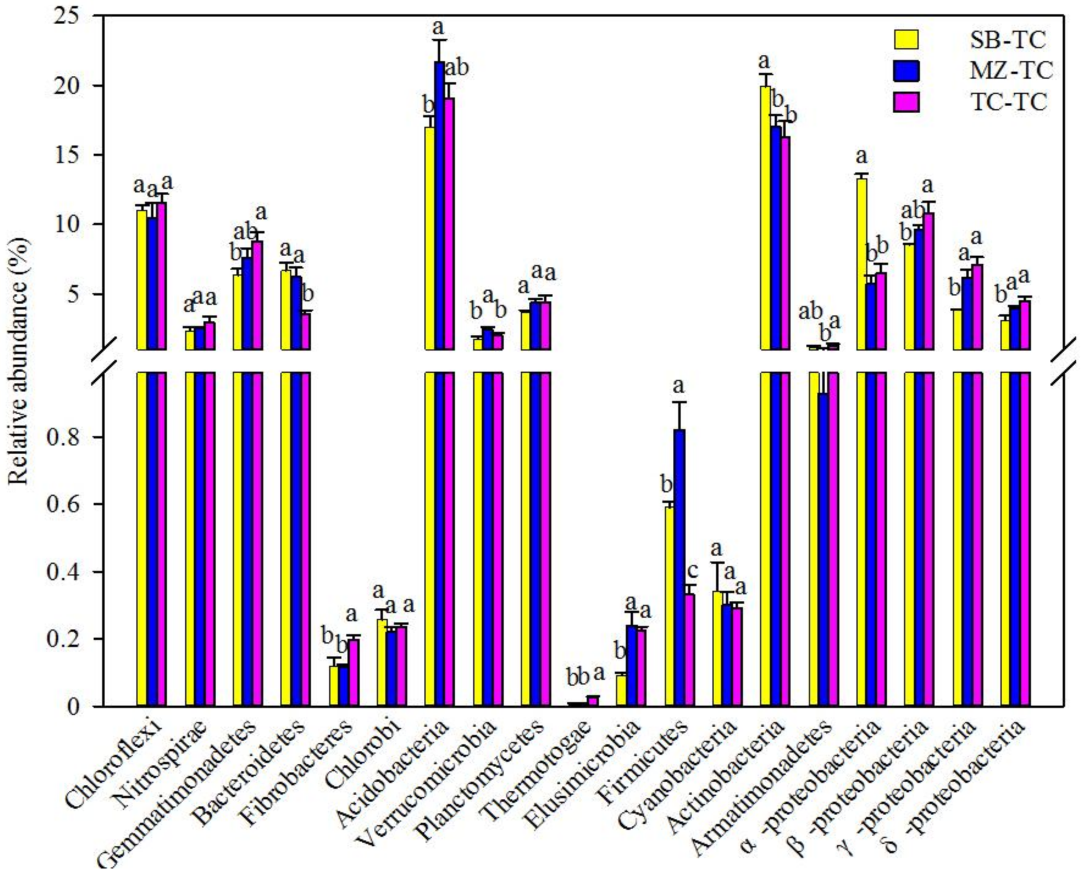

Figure 6. *Relative abundance of bacterial phyla and classes of Proteobacteria for each soil library. SB-TC, soybean-tobacco; MZ-TC, maize-tobacco; and TC-TC, tobacco monocropping*

The bacterial composition at the phylum level differed between the rotations (soybean-tobacco and maize-tobacco) and the monocropping system. The major phyla were shared by all samples, but in different relative abundances (*Fig. 6*). In the maize-tobacco and tobacco monocropping soils, *Proteobacteria* and *Acidobacteria* were the most abundant phyla, representing 26.58%, 28.02% and 20.63%, 19.05%, respectively. However, the soybean-tobacco rotation systems were dominated by the phyla *Proteobacteria* and *Actinobacteria*, representing 29.20% and 19.91%, respectively.

Among the *Proteobacteria*, *α*-, *β*-, *γ*-and *δ-proteobacteria* were found in all soil libraries (*Fig. 6*). In the maize-tobacco and tobacco monocropping systems, *β-proteobacteria* showed the highest relative abundance (9.74% and 10.48%), followed by *γ-proteobacteria* (6.96% and 6.89%), *α-proteobacteria* (5.82% and 6.26%) and *δ-proteobacteria* (4.06% and 4.39%). The insignificant differences between the maize-tobacco and tobacco monocropping soils indicated that maize as a pre-crop did not significantly impact *Proteobacteria* in subsequent tobacco soil (P>0.05). Compared with the tobacco monocropping system, *Proteobacteria* showed significant differences in the soybean-tobacco rotation soil (P<0.05). The relative abundances of *Proteobacterial* sequences were 13.57% for *α-proteobacteria*, 8.67% for *β-proteobacteria*, 3.92% for *γ-proteobacteria* and 3.04% for *δ-proteobacteria*.

Considering the bacterial distribution in tobacco rotations and monocropping systems,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_015030

variations in relative abundances were also observed for the phyla *Acidobacteria*, *Actinobacteria*, *Gemmatimonadetes* and *Bacteroidetes* (*Fig. 6*). The *Acidobacteria* showed relative abundances of 19.05% in tobacco monocropping soil, 16.98% in the soybean-tobacco rotation soil, and 20.63% in the maize-tobacco rotation soil. A statistical comparison across soil libraries revealed that the relative abundances of *Bacteroidetes* in soybean-tobacco and maize-tobacco rotation soils, amounting to 6.62% and 6.23%, respectively, were significantly higher than in tobacco monocropping soil (3.56%)($P<0.05$). In contrast, the relative abundance of *Gemmatimonadetes* revealed a significant decrease in the soybean-tobacco (6.33%) rotation soils compared to the tobacco monocropping soil (8.80%)($P<0.05$). Among the *Actinobacteria*, we observed no significant differences between the soybean-tobacco (19.91%) and maize-tobacco (17.02%) soils ($P>0.05$).

Distribution of bacterial composition at the genus level

Hierarchically clustered heatmap analysis based on 100 predominant bacterial communities at the genus level was used to identify the different compositions of these soil libraries (*Fig. 7*). Variations at the genus level were observed between soil from tobacco rotations and tobacco monocropping soils. Overall, among the *Proteobacteria*, the genera *Rhodoplanes* (0.41%), *Phenylobacterium* (0.53%) and *Sphingobium* (0.86%) revealed a significant increase in soybean-tobacco rotation soil compared to the corresponding genera in the tobacco monocropping soil (0.13%, 0.23% and 0.18%, respectively). In contrast, the relative abundances of *Nitrosomonadaceae* (1.90% and 2.83%), *Sorangium* (0.22% and 0.30%), *Lysobacter* (0.4% and 0.33%) and *Arenimonas* (0.12% and 0.25%) were lower in soybean-tobacco and maize-tobacco soils than in tobacco monocropping soil (3.29%, 0.36%, 0.60% and 0.32%, respectively). The phylum *Actinobacteria*, which contains the genera *Solirubrobacter*, *Aeromicrobium* and *Microbacterium*, showed significant abundance differences between tobacco rotations and tobacco monocropping soils. *Aeromicrobium* showed a higher relative abundance in the soybean-tobacco soil, and *Solirubrobacter* was present at lower relative abundances in the soybean-tobacco and maize-tobacco soils compared with the tobacco monocropping soil. The comparison of the relative abundances of *Solirubrobacter* revealed no significant difference between the soybean-tobacco and maize-tobacco soils. Within the *Bacteroidetes* and *Acidobacteria*, representatives of the genera *Adhaeribacter* and *Candidatus_Chloracidobacterium* were variational in the three libraries. Their relative abundances were significantly higher in the soybean-tobacco and maize-tobacco soils than in tobacco monocropping soil. Other genera, *Bacillaceae_Bacillus* (affiliated with *Firmicutes*), *Zavarzinella* (affiliated with *Planctomycetes*) and *Anaerolineaceae* (affiliated with *Chloroflexi*), showed higher relative abundances in the maize-tobacco soil compared to tobacco monocropping soil.

Discussion

The residue of the preceding crops has been found to strongly influence soil characteristics, including physic-chemical properties and enzyme activities, which are important for subsequent crops (Urbatzka et al., 2009; Preissel et al., 2015). Numerous bacteria have been known to flourish in the rhizosphere, which is mostly due to the supply of nutrients and the platform supplied by plant residues (Mendes et al., 2013; Bakker et al., 2012; Sugiyama and Yazaki, 2012). In this study, the rhizosphere bacterial communities for the tobacco crop (with pre-crops of soybean, maize and tobacco) were studied using both culture-dependent physiological profiling (Biolog-Eco) and culture-independent 16S rRNA metagenomics (454 pyrosequencing). Using the Biolog-Eco plates, we found that the bacterial activity and diversity in soil from tobacco rotations (soybean and maize) were higher than in the tobacco monocropping soil (*Fig. 1* and *Table 1*). This result was consistent with the findings of Yue (2013) that continuous monocropping in tobacco cultivation led to a decrease in soil bacterial abundance. Meanwhile, some studies have found that rotation systems stimulate soil microbial biomass, enzyme activities and functional diversity and abundance in the soil community structure (Orr et al., 2012; Insam et al., 2015; Plaza et al., 2004). Thus, we speculated that pre-crops of soybean and maize affected the rhizospheric bacterial communities of subsequent tobacco. Moreover, the results of principal component analysis suggested that the soybean-tobacco and maize-tobacco rotation treatments had similar rhizospheric bacterial communities, whereas the continuous cropping of tobacco showed different bacterial communities. The preceding crop effect of grain legumes providing nitrogen has been demonstrated (Hauggaard-Nielsen et al., 2009). As a consequence, this effect varies the bacterial communities for subsequent crops in the soil. In addition to legumes, many broad-leaved crops or summer cereals produce similar rotational benefits (Preissel et al., 2015). The bacterial activity and diversity data showed no significant differences between the soybean-tobacco and maize-tobacco rotation systems, although maize and soybean leave different residues in the field after the crops have been harvested. These results suggested that the plant species planted in the current year was more important in determining the bacterial community in soils than the pre-crop species.

The 454 pyrosequencing analyses revealed 57,084 sequences obtained from the three soil libraries in this study, and *Proteobacteria*, *Acidobacteria* and *Actinobacteria* were the most abundant phyla, which generally agreed with several previous studies reporting that these phyla are capable of having various effects on plant health, including both beneficial and pathogenic interactions (Lee et al., 2008; Berendsen et al., 2012; Li et al., 2016). The rarefaction curves for these samples did not reach the asymptote. Therefore, the deeper sequencing may be required to avoid underestimation of microbial diversity in our samples. But the coverage values for all libraries were not too low (i.e. over *C*. 85%), and provide a basis for comparison with other studies. Indeed, our coverage values were largely over reported in oil-contaminated sediment (C=61%-83%). Our rarefaction curves based on 454 pyrosequencing did not saturate but we consider, on the basis of the above comparisons, that the majority of the bacterial diversity in our samples was correctly sampled.

Significant differences in bacterial community composition systems were observed between tobacco rotations and tobacco monocropping. The largest shifts in relative abundance were found for *Proteobacteria* and *Acidobacteria*. The increase in the relative abundance of *α-proteobacteria* in the soybean-tobacco rotation soil was driven by the increases in the genera *Rhodoplanes*, *Sphingobium* and *Phenylobacterium* (*Fig. 7*), suggesting that these genera are enriched by soybean as a pre-crop. The pH was the highest in the soybean-tobacco (7.02) soil compared to the tobacco monocropping (6.60)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_015030

and maize-tobacco (6.87) soils. Previous research has demonstrated that *α-proteobacteria* and *γ-proteobacteria* showed positive relationships to soil pH (Rousk et al., 2010). The phylum *Chloroflexi* is ubiquitous in various soil samples, and its relative abundance was frequently higher than the abundance of *Bacteroidetes* (Roesch et al., 2007). This finding was further supported by the changes in our study. The relative abundance of *Acidobacteria* increased significantly in the maize-tobacco rotation soil compared to the soybean-tobacco soil. The abundance of the phylum *Acidobacteria* correlates with the soil pH (Hartman et al., 2008; Jones et al., 2009), and acidobacterial subgroups 1 and 2 decreased with increasing pH (Lauber et al., 2009), which is in consistent to our study. The biological functions of *Acidobacteria* are not well known because most microorganisms of this phylum have not been cultured (Yamada and Sekiguchi, 2009). However, as recent study found that *Acidobacteria* are capable of degrading plant litter in soils (Eichorst et al., 2011), the presence of maize residues in the maize-tobacco rotation soil may have contributed to the observed differences. Symbiotically fixed N may contribute to the nutrient availability, soil structure, and microbial activities of subsequent crops in rotation via the N mineralization of plant residues (Urbatzka et al., 2009). The relative abundance of *Actinobacteria* was strongly shaped by the pre-crop, and a significant increase was observed in the soybean-tobacco rotation soil compared to the tobacco monocropping soil. *Actinobacteria* members play an important role in the degradation of recalcitrant compounds and prevent infection with pathogenic microorganisms by secreting various antibiotics (Nour et al., 2003). In addition, previous studies have demonstrated that the *Bacillaceae_Bacillus* genus (affiliated with *Firmicutes*) was primarily involved in biological control against different soil-borne pathogens (Pal et al., 2004). Since the *Bacillaceae_Bacillus* genus showed higher relative abundances in soil from tobacco rotations with (soybean and maize) than in tobacco monocropping soil. The higher abundance of *Bacillaceae_Bacillus* in the tobacco rotation systems may contribute to disease suppression, and soybean as a pre-crop resulted in the highest bacterial community diversity and activity compared with maize and tobacco. Such results suggest that the soybean-tobacco rotation system, from a biological perspective, may represent a good strategy for enhancing microbial diversity and maintaining soil biological fertility.

Conclusion

Our research shows that the bacterial communities in the soybean-tobacco and maize-tobacco rotation soils are diverse, and various members can apparently be attributed to the pre-crops (compared to the corresponding bacterial communities in the tobacco monocropping system soil). The results obtained from the present field investigations, by using Biolog-Eco platess and next-generation sequencing from the three treatments, showed that (i) the bacterial activity and diversity in soil from tobacco rotations (soybean and maize) were higher than in tobacco monocropping soil; (ii) there were increased relative abundances of *Actinobacteria* and *Bacteroidetes*, particularly of the genera of *Rhodoplanes*, *Adhaeribacter*, and *Bacillaceae_Bacillus* in the soybean-tobacco and maize-tobacco rotation soils compared with the tobacco monocropping soil.

Abstract. Hypertension and hyperlipidemia are two main causes of cardiovascular diseases with rapidly increasing pervasiveness worldwide. Complimentary alternative medicines provide an effective choice to these highly prevalent global health issues. *Nigella sativa* has diverse range of traditional and pharmacological potential with established safety profile. This study was carried out in 163 mild-moderate hypertensive and hyperlipidemic patients. Patients were selected randomly of both genders. The patient's age ranges between 20-65 years. This clinical study was conducted to evaluate the clinical effect of *Nigella sativa* virgin oil in hypertension and hyperlipidemic patients of the selected region and also assess its antioxidative potential. The results conferred that *N. sativa* has significant (< 0.05) effect on controlling hypertension and hyperlipidemia as compared to standards used. Moreover, *N. sativa* conferred excellent antioxidant potential as compared to other commercially available edible oils.
Keywords: *alternative medicines, pharmacological, antioxidants, virgin oil, edible oils*

Introduction

Hypertension is the major cause of cardiovascular diseases (CVD) which is significantly increasing day by day and according to an estimate by the end of 2025 it will go up to 1.4 billion of the world's adult population (Kearney et al., 2005). Hypertension is defined as a systolic blood pressure greater than 140 mmHg and/or diastolic 90 mmHg or greater, and any record of serum lipid abnormality is defined as hyperlipidaemia. There are number of known cardiovascular disease, renal disease, liver disease, obesity, high cholesterol and stressful conditions; an unknown reasons of high blood pressure (essential hypertension). Hypertension is a silent killer disease as it may go undiagnosed for years and when detected had developed chronic heart disease, cardiovascular disease, diabetes mellitus, renal disease, etc. However, if properly diagnose and treat would reduce the morbidity and mortality (Schuman and Emerson, 1998). Hypertension in long terms impairs the renal function and resulted to failure in

DOI: http://dx.doi.org/10.15666/aeer/1504_031048

majority of the cases (Klag et al., 1996) and these all causes cardiovascular complication (Rostand et al., 1991). Clinical studies demonstrated that a reduction in hypertension can control 42% risk of stroke and 14% coronary heart disease (Hobbs, 2004). In the struggle of modernization and exposure to globalization the population of low income countries greatly affected their lives to pursue their high living standards. Although some get well succeed status but many deprived in hands of cultural and social adjustments that may cause increase in hypertension. Hypertension has long been thought of Western world disease but now it is equally the part of poor countries. In addition to organic causes lifestyle play major role in this regard. The lifestyle of many people has become more westernized. Several studies hypothesized its contribution to hypertension in urban populations when compared to rural populations (Ma et al., 2012). Within the non-communicable diseases hypertension plays leading role posing threats of disabilities (WHO, 2013) and this is because of unawareness to these conditions by a high number of hypertensive individuals (Kayima et al., 2013). In a study of prevalence of hypertension, in low and middle income countries the blood pressure found in more than half of population higher than in US (Fuentes et al., 2000). Although hypertension is the cause of mortality and morbidity in world (Rodger et al., 2004) but stroke in urban East-African countries is five times higher than in Britain (Walker et al., 2000).

Nigella sativa is an annual herb belonging to family *Ranunculaceae* with huge medicinal potential. Its seeds and seeds extracts has been used medicinally for centuries especially in Mediterranean region, Middle-East and Southeast Asia (Rchid et al., 2004; Najmi, et al., 2008). It has tremendous traditional and pharmacological potential in curing a wide range of ailments particularly hypotension (Aqel, 1992), hypoglycaemia (Bamosa et al., 1997; Meral et al., 2001; Bamosa et al., 2010), oxidative stress (Burits and Bucar, 2000) and cardio protective (Tasawar et al., 2011). *N. sativa* plant has strong antihypertensive effect that significantly lowered down blood pressure and cholesterol (Dehkordi and Kamkhah, 2008). Reinhart et al. (2008) also reported its hypotensive, hypercholesterolemic, hypoglycaemic and antioxidative activities. *N. sativa* significantly reduces intracellular cholesterol by regulating LDL, HDL and triglycerides blood levels (El-Dakhakhany, 2000). Obesity is the main cause of metabolic syndrome (Vega, 2001). BMI is also an important indicator of metabolic syndrome (Najmi et al., 2008). *N. sativa* showed a significant reduction in the body weight when administered to a experimental model of rats (Zaoui et al., 2002). More than 100 bioactive compounds had been reported in the *N. sativa* seeds (Ramadan, 2007). The therapeutic potential of medicinal plants is mainly due to the antioxidative properties of some active components (El-Saleh et al., 2004). The seeds of *N. sativa* contains two active components in its oils i.e. Thymoquinone and dihydrothymoquinone, revealed enormous potential of free radical scavenging capabilities (Khalife and Lupidi, 2007). These biological active compounds considered largely as chemo protective (Badary et al., 1999 and Badary et al., 2007), gastro protective (El-Abhar et al., 2003; Kanter et al., 2005) and immuno protective (Gilani et al., 2004). The foods rich in fats after absorption through intestine intensify the hepatic detoxification, enhance lipid peroxidation and resulted debris cause cellular modifications. Cholesterol in the blood vessels also constructs fibrosis plaque along the walls. These plaques are atherosclerotic proliferation of the extra cellular matrix formed due to extensive biochemical and molecular changes within the vessels (Glass and Witztum, 2001; Tiwari et al., 2008). Oxidation by free radicals is an imperative incident cause aging and human diseases.

DOI: http://dx.doi.org/10.15666/aeer/1504_031048

The antioxidant screening of plants and their phytochemicals through comparing commercial antioxidants could help to find new source of expected innate antioxidants. *N. sativa* and its active components have tremendous potential of nutraceutical and pharmaceutical applications. This needs to be explored through more clinical studies in metabolic syndrome that is the challenge of future to medical professionals. The present study was undertaken to explore probable antioxidant potential of *N. sativa* found in its different parts which is responsible for lowering high blood pressure, serum cholesterol and plasma sugar. The data on the evaluation of *N. sativa* clinically and as antioxidant are scanty. This was the first ever study for validating the therapeutic potential of *N. sativa* in the state of Azad Kashmir, Pakistan.

Methodology and Materials

Patient Selecting Criterion

Patients with mild-moderate hypertension were selected from outpatient departments (OPD) of Abbass Institute of Medical Sciences (AIMS) Muzaffarabad and from medical camps organized through AIMS cardiology department. Before starting the study an approval from hospital ethical committee was taken. After explaining all the outcomes of the treatment and taken written consent from all participants (*Supplementary Figure 3*), pathological history was recorded through questionnaire (*Supplementary Figure 1*). During selection every aspect of patient interest focussed so that satisfies his convenience in perfection of better compliance. A total of 180 patients were registered for this clinical study which was divided in to two groups, each comprising 90 individuals. All patients were selected from the same geographical area randomly with a male and female ratio of 43:57. Selection of Patients were based on category, Mild-Moderate Hypertension, Systolic Blood Pressure 130-159 mmHg; Diastolic Blood Pressure 80-99 mmHg, Abdominal obesity (Waist circumference): >102 cm in males and >88 cm in females, Total Cholesterol: ≥ 200 mg/dL, Serum Triglycerides: > 150 mg/dL, LDL: > 120 mg/dL, HDL: < 40 mg/dl (male) or HDL < 50 mg/dL (female). Serum Glucose: ≥ 110 mg/ dL.

Patient's weight and height were measured for Body Mass Index calculation BMI (Kg/m²). Patient's systolic and diastolic blood pressure was recorded by using mercury Sphygmomanometer (Tycos Japan). Fasting blood samples (Venus) were taken in the hospital pathological laboratory and analysed for all biochemical tests using principal biochemistry analyzer and enzyme assays. Adverse events report proformas (*Supplementary Figure 2*) to report any adverse event and laboratory proformas (*Supplementary Figure 4*) to file all base line tests reports were prepared. A copy of each was given to patient for record. Patients were divided randomly including male and female's age ranged from 20-65 years into *N. sativa* and standard statin groups. One group was started with *N. sativa* oil treatment while second on statin standard treatment (atorvastatin 10 mg tablet once a day) and metformin 500 mg tablet one twice a day added to diabetics after taking a baseline data of all biochemical parameters. All the patients were strictly advised to follow the guide lines regarding physical activities, diet and maintained it regularly in routine life style. *N. sativa* seeds virgin oil (NsVO) administered orally twice a day in a dose of 0.5 ml before breakfast and going to bed for sleeping at night. During the study period patients were closely monitored through telephone calls, personal visits and every fortnight calls on hospital visits for blood

DOI: http://dx.doi.org/10.15666/aeer/1504_031048

pressure examination. After 45 days patient's blood samples taken in the hospital pathological laboratory and data were analyzed statistically by using paired t-test.

The Antioxidant Assay

Antioxidant potential of *N. sativa* and edible oils was evaluated by using free radical scavenging DPPH assay (2,2-diphenyl-1-picrylhydrazyl) as described by Amarowicz et al. (2004). The absorbance was recorded at 517 nm through ultrospec-4000 (Pharmacia-LKB) UV-visible spectrophotometer. The radical scavenging activity was expressed as $IC_{50.}$ Ascorbic acid was used as standard. The percentage scavenging activity was calculated by using the following formula:

$$\text{Percentage Inhibition} = \frac{(\text{A control} - \text{A extract})}{(\text{A control})} \times 100$$

where A control is the absorbance of the control reaction, A extract is the absorbance of the test sample.

Results and Discussion

The study was undertaken with the aim to compare the antihypertensive and antihyperlipidemic effect of *N. sativa* virgin oil and standard statin treatments with their respective baseline data's in selected area. For this purpose 180 patients was screened out. Out of 180 patients 163 comply while 17 did not due to personal reasons. Statistical analysis showed that *N. sativa* has significant (P-value = < 0.05) effect on controlling hypertension (Systolic Bp P=3.079e-07; Diastolic Bp P=2.136e-06) and hyperlipidemia (Total cholesterol P = 2.2e-16, LDLc P = 2.2e-16, HDLc P = 4.739e-12 and TGs P = 0.05706) as compared to standard group (Systolic Bp P=5.505e-07; Diastolic Bp P = 1.005e-07; Total cholesterol P = 4.805e-13, LDLc P = 4.803e-10, HDLc P = 4.049e-06 and TGs P = 1.441e-07) through its antioxidative activities (Table 4, 5). The patients receiving *N. sativa* treatment after 45 days the mean systolic (154.35 mmHg) and diastolic (95.20 mmHg) blood pressure at baselines was reduced to 142.80 mmHg and 88.15 mmHg respectively (*Table 1; Fig. 1, 3*). Among the 83 patients 59 (71%) showed a significant decreased in blood pressure, 13 (16%) increased and 11 (13%) showed no effect of the treatment (*Fig. 2*). In comparison to the 2nd group of standard treatment after 45 days the mean systolic (153.60 mmHg) and diastolic (95.18 mmHg) blood pressure at baselines was also reduced to 146.60 mmHg and 90.30 mmHg respectively (*Table 1, Fig. 4*) but it was less than *N. sativa* group. Among the 80 patients receiving standard treatment 46 (57%) showed a decreased in blood pressure, 16 (20%) increased and 18 (23%) showed no effect of the treatment (*Fig. 3*). The percent effect of *N. sativa* (71%) at individual levels was also better compared to standard group (57%). Various traditional and animal studies report the promising hypotensive action of the seeds and extracts of *N. sativa*. Rahman et al. (1990) described the antihypertensive effect of the methanolic seeds extracts of *N. sativa* in the normal and adrenaline induced hypertension. Dehkordi and Kamkhah (2008) suggested that 200 mg *N. sativa* seeds extract twice daily for 8 weeks significantly lowered down the systolic and diastolic blood pressure.

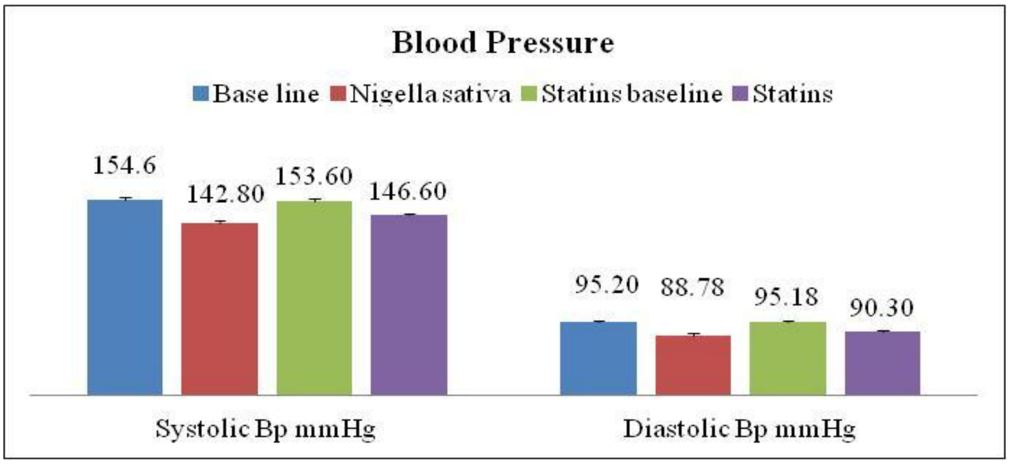

Figure 1. *Mean comparison of N. sativa patients vs. standard statin at baseline after 45 days treatment*

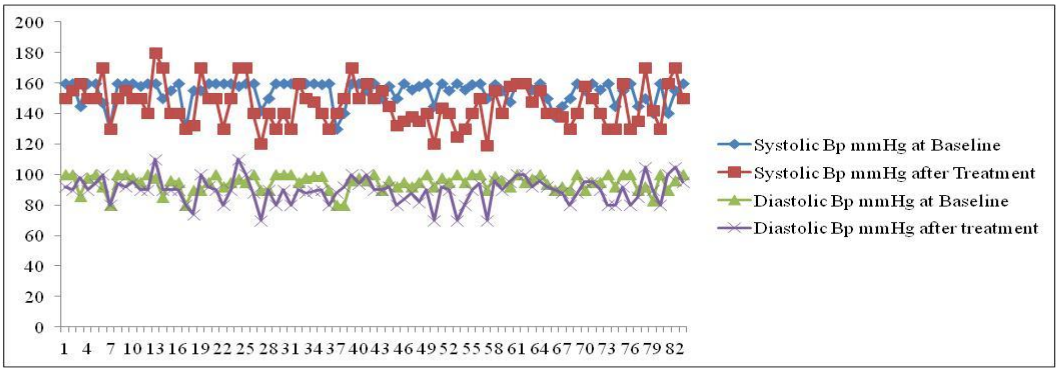

Figure 2. *Pattern of systolic and diastolic blood pressure of the individuals after N. sativa treatment at baseline*

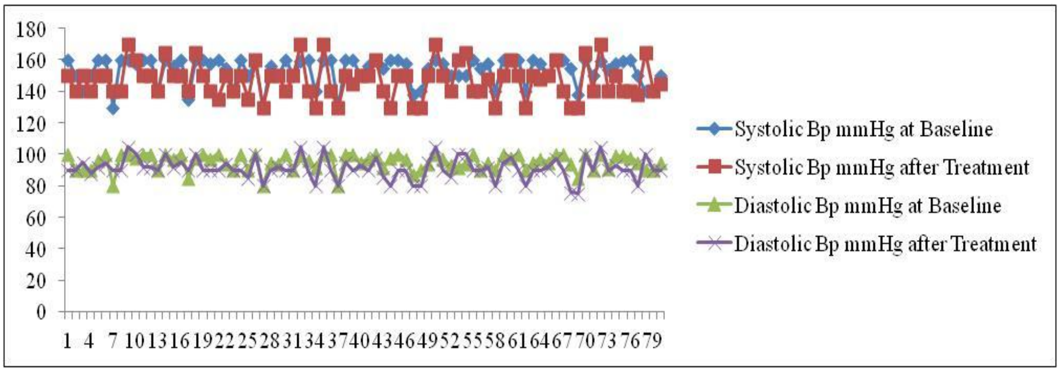

Figure 3. *Pattern of systolic and diastolic blood pressure of the individuals after standard treatment at baseline*

The *N. sativa* treatment showed a considerable reduction in the total cholesterol (~218-205 mg/dl), LDLc (~135-122 mg/dl) and triglycerides (~204-194 mg/dl) levels at their baselines as compared to the standard treatment which were ~222-215 mg/dl, ~136-130 mg/dl and ~190-180 mg/dl respectively. There was found a significant

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_031048

reduction in the mean total cholesterol (P = 2.2e-16) and LDLc (P = 2.2e-16) in *N. sativa* group as compared to standard group (P = 4.805e-13 and P = 4.803e-10). The effect of seeds extract in animal model (for 12 weeks) has been evaluated by Zaoui et al. (2002) which showed a decrease in the levels of cholesterol, triglycerides and blood glucose. Dekhordi and Kamkhah (2008) depicted that 100 or 200 mg twice daily doses of *N. sativa* significantly reduced the total and LDL cholesterol in a dose dependent manner. Pourghassem-Gargari et al. (2009) and Nader et al. (2010) reported that if black seeds used in diet supplements can effectively decrease the total cholesterol (43.7 %), LDLc (42.8 %) and TGs (34.9 %) after one month of treatment as compared to control. The improvement in HDLc is although low (37.7 3-39.50 mg/dl), however better than in case of standard therapy (39.18-39.5 mg/dl). The results are in agreement reported by Najmi et al. (2008) and Le et al. (2004).

Reduction in BMI has positive effect on obesity. The treatment with *N. sativa* showed the reduction of BMI (26.22-25.52 kg/m²) as compared to standard group (27.90-27.38 kg/m²) however waist in both cases (~92-91 and ~98-97 cm) were comparable (*Table 1*). The reduction in triglyceride levels were also found same in both groups (204-194 mg/dl and 190-180 mg/dl). Similar results were reported by Najmi, et al. (2008) while working with *N. Sativa.* Datau et al. (2010) found a reduction in the body mass index when used *N. sativa* seeds in a dose of 1.5 g/day for three months in obese individuals. Although their study conferred that the reduction in BMI and waist was not much significant but it had good impact on improving cholesterol. Moreover, In the *N. sativa* group the HDLc was raised 37.73-39.50 mg/dl while in standard group the value was 39.18-39.50 mg/dl which showed a significant (P = 4.739e-12) augment due to the *N. sativa* treatment. It has also been observed the high impact of the *N. sativa* treatment on the reduction of fasting blood glucose levels (~150-128 mg/dl) in comparison to the standard treatment (~147-144 mg/dl) at baseline (*Table 1; Fig. 4, 5*). The studies of Bamosa et al. (2002) and Najmi, et al. (2008) also supported the findings of the present study on total cholesterol, LDL, HDL, Triglyceride and fasting blood sugar.

Table 1. *Mean comparison of N. sativa vs. standard treatment at their respective baselines*

Biochemical Parameters	**Control vs. NsVO**		**Control vs. Statin**	
	Before Treatment Means Value	After Treatment Means Value	Before Treatment Means Value	After Treatment Means Value
Systolic Bp (mmHg)	154.35	142.80	153.60	146.60
Diastolic Bp (mmHg)	95.20	88.78	95.18	90.30
BMI (Kg/m²)	26.22	25.52	27.90	27.38

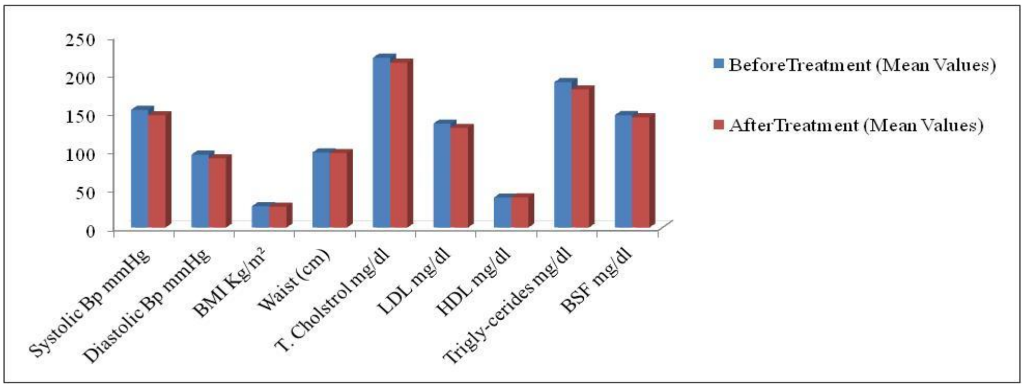

Figure 5. *Mean comparison of standard vs. baseline after 45 days treatment*

Furthermore, when cholesterol and sugar levels were undertaken resulted lowered down along with blood pressure which also controlled due the fact that an increase in blood pressure found to be linked with increased cholesterol and sugar levels (Siok-Koon et al., 2009). The systolic and diastolic blood pressure significantly lowered down with the increased in duration of the *N. sativa* treatment. The systolic blood pressure was decreased to ~134 mmHg after 90 days and ~127 mmHg after 180 days of *N. sativa* treatment at baseline of ~155 mmHg followed by decrease in diastolic blood pressure as ~83 mmHg and ~76 mmHg after 90 and 180 days at baseline of ~94 mmHg respectively (*Table 2; Fig. 6*). In case of standard treatment the systolic (~153 mmHg) blood pressure was decreased to ~145 and 138 mmHg after 90 and 180 days while the diastolic (~94 mmHg) was decreased to ~90 and ~84 mmHg after 90 and 180 days respectively (*Table 3; Fig. 7*). Similarly patients receiving *N. sativa* showed a remarkable reduction in the mean total cholesterol, LDLc and triglycerides with the increase in HDLc after six month of treatment. The *N. sativa* group significantly reduced the cholesterol (199 and 186 mg/dl), LDLc (113 and 99 mg/dl), triglyceride (168 and 154 mg/dl) and fasting blood sugar (112 and 94 mg/dl) after 90 and 180 days of treatment at baselines of 220 mg/dl, 136 mg/dl, 191 mg/dl and 150 mg/dl respectively. The HDLc was increased to 40.80 mg/dl and 42.13 mg/dl at the baseline of 39.05 mg/dl after 90 and 180 days of *N. sativa* treatment respectively (*Table 2; Fig. 6*).

The systolic and diastolic Bp significantly (P-value = < 0.05) decreased when treatment of *N. sativa* was continued for another 45 days. The systolic and diastolic blood pressure was raised from ~143-148 mmHg and ~88-94 mmHg respectively when that group of patients was treated with placebo however, the total cholesterol was increased from ~200-209 mg/dl and LDLc ~102-125 mg/dl while no significant change was recorded in the levels of HDLc and triglycerides. Moreover a little change conferred in BMI (25.52-25.33 kg/m²) and waist circumference (91.32-90.12 cm) while blood sugar was raised from 128 – 146 mg/dl (*Table 6*).

Table 6. *Comparison of variables before and after placebo treatment using paired t-test*

The antioxidant activity of the extracts of all lines of *N. sativa* was assessed by using DPPH assay and IC_{50} value recorded was tabulated in Table 7. Among seven lines tested, the N1 sample was found to be potent (*Table 7; Fig. 8*). When compared different solvents extracts, the ethyl acetate was found to be a potent solvent for the extraction of potential compound with IC_{50} values for N1 (0.0022), N2 (0.0033), N3 (0.0030) and N7 (0.4476) while methanol, chloroform and acetone extracts showed least activity (*Table 7; Fig. 8*). Due to the factual antioxidant potential of seeds of *N. sativa*, a detail screening of all parts was carried out. Here also the N7 line was found to be potent. The IC_{50} value recorded for ripen seeds was 0.000415 followed by unripe (green seeds) i.e. 3.510731 as compared to the standard used (*Table 8; Fig. 9a* and *3c*). Other parts were found to be rubbished (*Table 8; Fig. 9b*). Vinha et al. (2005) reported that variation in antioxidant potential among all parts of same genotype was due to variation in secondary metabolites in different parts or may be due to extraction procedures, which is adopted for the extraction of active constituents. Commercially available edible oils were also screened with the purpose to compare their potential with selected genotype. It was found that *N. sativa* had great antioxidant potential as compared to the edible oils tested (*Table 9; Fig. 9d*). According to Skerget et al. (2005) sometime sampling of the same plant from the same ecological zone may deviate to the potential behavior because of mishandling of sampling procedures that could immediately oxidized the active metabolites and the antioxidant ability of the plants.

Yoruk et al. (2010) also reported significant antioxidant potential of *N. sativa* preventing oxidative stress by scavenging reactive oxygen species. The current results were in harmony with the previous studies.

In the present findings of clinical studies the use of *N. sativa* virgin oil (N7) revealed a significant reduction in the blood pressure and other biochemical parameters. The evidence from literature also supports the findings that the antioxidants protect the body against the development of atherosclerosis and provide putative hypotensive effects (Rohdewald, 2002; Paulis and Simko, 2007). Antioxidants contained melatonin (Flavonoids) can effectively be used in reducing blood pressure, lipid profile, body weight and plasma glucose (Hussein et al., 2007). Antioxidants have strong impact of reducing the blood pressure which is also supported by a recent study (Rezzani et al., 2010) that described the protective role of antioxidants against the initiation of atherosclerosis in hypertensive animal model. Houghton et al. (1995) reported that the biologically active constituents of *N. sativa* had potent quenching capabilities for free radicals. On the basis of present findings it is conferred that the poor antioxidant effects in treating various pathological conditions are more or less due to improper dosage, methods of extraction, selection of the seeds cultivar and the selection of the seeds lots. So it is suggested that only an intellectual approach could succeed in achieving the desired results while implementing any treatment of plant material consisting these oxidants. Moreover the oxidative stress promptly impregnate its harmful effects on the arterial vasculature that require long time to correct in a smoothly manner. Allopathic drugs although provide to some instant relieve to the inflammation of the endothelial linings of the vasculature but could not be the sole solution to the whole imploratory process of atherosclerosis.

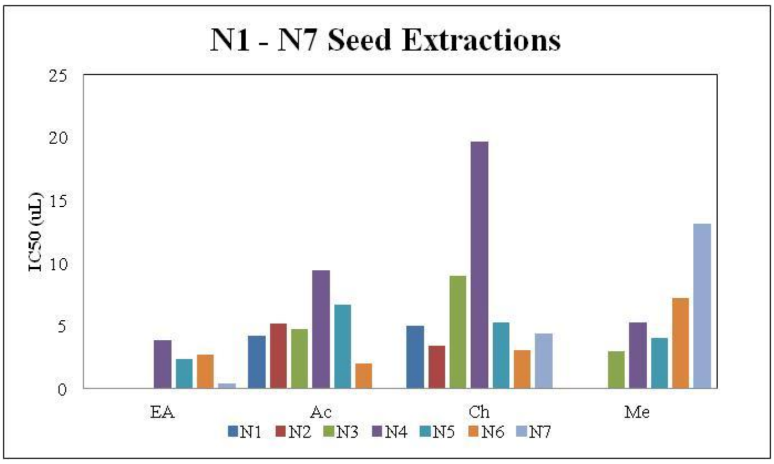

Figure 8. *Comparison of antioxidant activities of N. sativa seeds in four solvent extracts of seven lines in different concentrations and IC50 values*

Conclusion

On the basis of the current investigations it is concluded that *N. sativa* seeds and oil should be considered routinely in the management of diabetic and hypercholesterolemic disorders as remedy was found to be potent hypotensive, antihyperlipidemic and hypoglycaemic with strong antioxidative activities without any adverse effect. *Nigella sativa* proved to be the best alternatives remedial source to cure these fatal ailments with

DOI: http://dx.doi.org/10.15666/aeer/1504_031048

remarkable benefits of many other concomitant cures. However more investigations are needed to isolate bioactive compounds that are responsible of managing high blood pressure and other biochemical disorders.

The beneficial effects of *N. sativa* in diabetic's subjects with fasting sugar, LDL, triglycerides, total cholesterol, BMI and high blood pressure were investigated and found highly significant (P = < 0.05) although the *N. sativa* was comparable to standards in short term but in longer therapy *N. sativa* revealed excellent role in controlling biochemical disorders. Maintaining serum glucose, serum cholesterol and high blood pressure at optimum reduces atherosclerosis and subsequently the risk of coronary heart diseases, a major threat to diabetic and hyperlipidemic patients. The potent antioxidative activities of *N. sativa* played a central role in functional optimization of biochemical parameters.

(Received 13th Dec 2016; accepted 24th Mar 2017)

Abstract. Sulfosulfuron, a new sulfonylurea herbicide, is used to control certain broadleaf and grass weed species in wheat fields. Herbicides, when applied to the field may leave unwanted residues in the soil. Bioassay and chemical assay techniques are main methods for monitoring herbicides levels in agricultural soils. Thus, a set of field and greenhouse experiments was established to evaluate the reliability and accuracy of HPLC and bioassay techniques to detect sulfosulfuron residues in the soil of the wheat field. The experiment was conducted in a randomized complete block design with three treatments in three replications for each treatment in 2014-2015 and 2015-2016 growing seasons at Marvdasht location. Herbicide treatments included: sulfosulfuron (apirus) at 26.6 and 53.2 g a.i. ha^{-1} rates and no-herbicide control. Herbicide was sprayed at the end of tillering stage of wheat in a field experiment. Samples were collected randomly with an auger from 0-10 cm depth at different times i.e. 0, 3, 10, 20, 30, 60, 90 and 125 days after herbicide spray. The bioassay experiment showed that root parameter was more sensitive to sulfosulfuron as compared with the shoot. According to the results, among the studied plants, garden cress was recognized as the most sensitive plant to different rates of sulfosulfuron herbicide. At recommended (26.6 g a.i. ha−1) and double (53.2 g a.i. ha^{-1}) rates of application sulfosulfuron residues were detected up to 60 and 90 days after treatment by HPLC and bioassay techniques in both years, respectively. According to the bioassay and HPLC techniques at two rates of application, residues decreased with time in 2014 and 2015.

Introduction

Most farming systems extensively use herbicides. When applied to the field, herbicides control targeted weeds and leave unwanted residues in the soil that are harmful ecologically (Haney et al., 2000; Derksen et al., 2002). Despite the great efficacy of herbicide for controlling weeds, its residual effect should be taken into account for the safety of the environment. Ideal herbicides should have good efficacy and minimum adverse effects on crops, ecology and the environment (Faheed and Abd-Elfattah, 2007).

The most important crop in Iran is wheat which can be considered as the main food for the entire population (Vahedi-Sheikhhasan et al., 2012; Rahman et al., 2008). The second crops such as cotton, corn, soybean, canola and sunflower are sown after wheat is harvested as rotation crops. Good weed control is a necessary component of wheat yield (Hasanuzzaman et al., 2009). To do this, in wheat fields, the application of herbicides especially sulfonylurea is common. In the 1970s, sulfonylurea herbicides were introduced, which are a class of herbicides that were used as control chemicals for the majority of broad-leaved weeds and common grasses in agriculture (Coly and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_049065

Aaron, 1999; Guibiao et al., 2006). These herbicides reside in the acetolactate synthase enzyme which is the main enzyme in the biosynthesis of branched-chain amino acids and is characterized by a high herbicidal activity that leads to application at low rates (Nystrom and Blanck, 1998; Brown, 1990; Ye et al., 2003). Sulfonylurea herbicides apply post-emergence in cereal specially wheat therefore there was short period between herbicide application and next planting which caused adverse effects on crops in rotation with wheat (Menne and Berger, 2001). Of sulfonylurea herbicides, sulfosulfuron (1- (4,6-Dimethoxypyrimidin-2-yl) -3- (2-ethylsulfonylimidazol [1,2-a] pyridin-3-ylsulfonyl) urea), has been suggested for weed control in wheat fields (Nurse et al., 2007). Sulfosulfuron which is a new sulfonylurea herbicide, is used to control weeds in different agricultural crops and wheat (Parrish et al., 1995). These new herbicides have an extensive range of soil residual characteristics that must help with meeting specific agricultural requirements (Maheshwari and Ramesh, 2007). Sulfonylurea herbicides consist of 3 distinct parts: a sulfonylurea bridge, an aryl group and an S-triazine group. Of the reasons they were quickly accepted include a very low animal toxicity, low application rate and a broad-spectrum weed control. The removal of sulfonylurea herbicides can be done in three ways in the environment and these methods are: chemical hydrolysis, microbial degradation and photodegradation. Potential transformation in sulfonylurease is the cleavage of the sulfonylurea bridge yielding sulfonamide, S-triazine and Striazinurea bridge contraction and ring opening which forms triurets (Sarmah et al., 1998).

Soil pH, organic matter, moisture and temperature are the major factors that affect sulfonylurea chemical hydrolysis and microbial degradation. In soil, sulfonylurea hydrolysis is primarily pH dependent and its rate goes up with decreasing soil pH (Beyer et al., 1988). Recent studies have proven a similar pH dependence of sulfosulfuron hydrolysis in soil incubation research (Saha and Kulshrestha, 2002). The study of Pusino et al. (2003) which was done on the desorption and the adsorption of a sulfonylurea herbicide triasulfuron in three different soils, revealed that, pH was the main cause which affected the absorption level and also showed that, adsorption in soils, was negatively correlated with pH. The highest amount of adsorption was measured in soils which had low pH and high organic carbon content. In specific conditions like highly alkaline soils with low temperatures and organic matter contents in dry regions, sulfonylurea herbicides might persist at phytotoxic rates in soils to have negative impacts on sensitive crops in the subsequent season (Stork, 1995).

The main methods for monitoring herbicide levels in agricultural soils are Bioassay and Chemical assay techniques such as high performance liquid chromatography (HPLC) and gas chromatography (GC) (Tchan et al., 1975; Johnson et al., 2005; Watson and Checkel, 2005). Because the application of chemical techniques was limited due to higher costs, the bioassay technique is a useful tool to detect residues herbicides. Moreover, chemical assay techniques are able to determine herbicide residues rates but cannot determine that these rates are really toxic to plants (Szmigielski et al., 2008). Alonso-Prados et al. (2002) showed that the European Commission Guidance Document on Residue Analytical Methods has accepted and suggested bioassays as suitable screening tests that can be good for excluding the occurrence of low levels of residues of phytotoxic compounds in soils. Many researchers used bioassay methods to discover herbicide residues in soil (Alonso-Prados et al., 2002; Blacklow and Pheloung, 1991; Gunther et al., 1993; Hernandez-Sevillano, 2001; Stork and Hannah, 1996).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_049065

The chemical extraction method cannot distinguish between available and unavailable herbicide. Also, a chemical extraction will not show an indication of potential plant response. As a replacement to chemical extraction methods, bioassay is the most accurate method available for the detection and quantification of sulfonylurea residues in soil (Beyer et al., 1988). Based on the study of Ferris and Haigh (1992), bioassay is the level of a plant's response to the total herbicide residue in the soil at a site-specific location.

As far as we know, little or no research has been done to detect sulfosulfuron residues in the soil. The objectives of this research were to: 1) determine half-life of sulfosulfuron in soil, 2) determine the most sensitive plant species to sulfosulfuron, 3) and to compare analytical and bioassay techniques for monitoring sulfosulfuron herbicide level in soil.

Material and Methods

Field Experiment

The study were conducted in two consecutive years 2014-2015 and 2015-2016 at Marvdasht location (Fars province, Iran) that situated in 29°52'43.46" N (Latitude DMS) and 52°49'13.99" E (Longitude DMS) (*Fig. 1*). Before sowing, soil samples were taken from 0 to 30 cm depth and physicochemical properties of the experimental site were determined (*Table 1*). The field at the test site had lain fallow the year before the start of our study. To prepare the seedbed, deep plowing (20-25 cm) with a moldboard plough were carried each year in autumn, followed by disking in the spring. The soil fertility was increased by using diammonium phosphate (18-46-0 N-P-K) and urea at the rate of 250 and 150 kg a.i. ha^{-1}, respectively, each year in spring before planting. Moreover, 200 kg a.i. ha^{-1} N (as urea) was added at the 6-8 leaf growing stage of wheat along with irrigation. The wheat hybrid "Singles Cross 704" was sown at desired density (7 plants a.i. m^{-2}), seeds spaced 18.5 cm apart in rows spaced 20 cm apart on 15 May 2014 and 22 May 2015. The experimental design at two years was a randomized complete block with three replications. Sulfosulfuron was applied as POST (Post-emergence application) at 26.6 g a.i. ha^{-1} (recommended rate) and 53.2 g a.i. ha^{-1} (double rate) with a knapsack sprayer using flat fan nozzle at four-leaf stage in each year. Three plots were sprayed with water without any herbicide and considered as the control plots. The experimental fields were 9 plots 10 m×3 m size with a buffer of 0.5 m between adjacent plots to avoid spray overlap.

Figure 1. *Location of Marvdasht in Fars province*

Sampling and Storage

Soil samples were collected randomly throughout each plot from 0–10 cm depth using a tube auger 0 (2 h), 3, 10, 20, 30, 60, 90 and 125 days after treatment. Samples were air dried and ground to pass through a 2-mm sieve, mixed thoroughly and subsamples were taken from each plot for the bioassay and HPLC studies. Samples were kept in a deep freezer at -20 °C until they were subjected to the bioassay and HPLC analysis.

Greenhouse Experiment

Bioassay Technique

Determination of test plant for bioassay study: Greenhouse experiments were conducted to select the most sensitive plant species to evaluate sulfosulfuron residues in soil. Eight different plant species including lentil (*Lens culinaris* Medik.), garden cress (*Lepidium sativum* L.), mung bean (*Vigna radiata* L.), cucumber (*Cucumis sativus* L.), corn (*Zea mays* L.), sugar beet (*Beta vulgaris* L.), canola (*Brassica rapa* L.) and chick pea (*Cicer arietinum* L.) were screened by measuring their shoot and root responses to soil-incorporated. The pots (10 cmID ×10 cm length) were filled with 500 g of soil and treated with sulfosulfuron at 5, 10, 20, 50, 75 and 100% of recommended rate (26.6 g a.i. ha^{-1}), five pre-germinated seeds of each test-plant were planted at 2–3 mm depth in each pot. The pots were arranged on greenhouse in a completely randomized design with four replicates along with untreated control pots. The pots were sub-irrigated as needed during the experiment. The plants were uprooted to measure the sulfosulfuron effects on plants root and shoot length at 15 days after planting (Paul et al., 2009). During the experiment, temperature and relative humidity were fluctuated between 18–25 °C and 58–85%, respectively.

Preparation of standard curve by bioassay and analysis of field samples: To establish a standard curve, the samples soils (500g) fortified with sulfosulfuron concentration (5, 10, 20, 50, 75 and 100% of recommended rate (26.6 g a.i. ha^{-1}) were filled in the plastic pots with four replicates along with untreated controls. Five pre-germinated garden cress seeds (*Lepidium sativum* L.) were sown as the indicator species in each pot. The experiment was conducted under greenhouse conditions as completely randomized design. The pots were irrigated as needed to retain the soil moisture. 15 days after sowing, all plants were uprooted and washed carefully with water to remove the soil. Then, root length for garden cress plants were measured as sensitive parameter and the percentage reduction in root length relative to the control plants was calculated for each concentration. A standard curve was drawn by plotting the percentage root inhibition on a vertical linear (y) axis versus the corresponding sulfosulfuron concentration on horizontal logarithmic (x) axis. The soil samples which were taken at different intervals from wheat field were placed in pots, and five pregerminated garden cress seeds were planted into these pots as described above. After 15 days, all plants were uprooted and percentage root inhibition was calculated for each interval. Finally, the herbicide residues were determined under field conditions by fitting the data correspond to percentage root inhibition into the regression equation (Paul et al., 2009).

HPLC Technique

Chemicals

Analytical-grade sulfosulfuron (97% purity) with chromatographically (TLC and HPLC) pure was supplied by Sigma–Aldrich (Steinheim, Germany). The chemical structure of sulfosulfuron herbicide is given in *Figure 2*. All solvents, such as acetonitril and dichloromethane were HPLC grade and purchased from Merck (Darmstadt, Germany).

DOI: http://dx.doi.org/10.15666/aeer/1504_049065

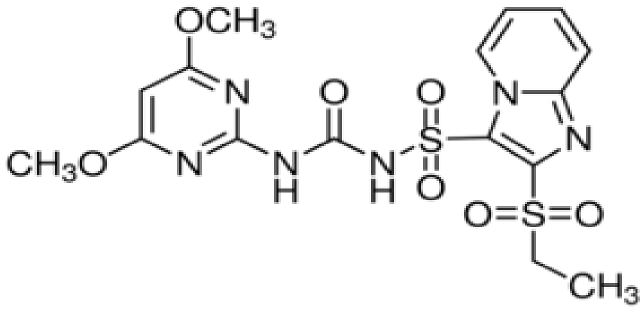

Figure 2. *The structure of sulfosulfuron herbicide (1-(4,6-Dimethoxypyrimidin-2-yl)-3-(2-ethylsulfonylimidazol[1,2-a]pyridin-3-ylsulfonyl)urea)*

Soil Extraction and Clean-up

Fifty g of soil were put in a conical flask and 50 ml of acetonitrile and ammonium carbonate (9:1 v/v) was added to it. The filled flask was shaken for 30 min and its contents were partitioned. We separated and filtered the upper organic layer. The soil was shaken with 50 ml of acetonitrile: ammonium-carbonate (9:1 v/v) once again. next, the upper organic phase were separated and mixed with the first fraction. The mixed extract was gathered and dried at 40°C on a rotary evaporator and then decreased to 20 ml. Next, it was dissolved in 50 ml of saline water (1 M NaCl). The solution was put in the separating funnel and partitioned twice with 50 ml of dichloromethane. The mixed dichloromethane extract was then collected and passed through anhydrous sodium sulfate which was packed in a 30 cm column to remove all traces of moisture. Then filtrate was collected, pooled and almost completely dried at 40 °C on a flash evaporator. At the end, the residue was dissolved in 2 ml of HPLC grade acetonitrile and filtered through 0.45 μm Millipore system before being injected into the HPLC system (Saha et al, 2003).

Preparation of Standard Curve by HPLC

A stock solution (1000 μg a.i. mL^{-1}) of sulfosulfuron was prepared in acetonitrile and different concentrations including 0.01, 0.05, 0.1, 0.5, 1.0, 5.0 and 10.0 μg a.i. mL^{-1}) of sulfosulfuron were made by diluting the stock solution. A volume of 15 μL of each standard solution was injected into the HPLC and the peak area measured. Each run was repeated twice and the calibration curve was created by drawing the known concentrations of sulfosulfuron on the x-axis and the average peak area corresponding to each concentration on the y-axis.

Apparatus Conditions

Sulfosulfuron was detected with a HPLC equipped with a photodiode array detector, a C18 column (250 mm × 4 mm ID), a mobile phase of acidic water + acetonitrile + o-phosphoric acid, 20 + 80 + 0.1 (v/v), a flow rate of 1 mL a.i. min^{-1}, a UV – detector set at a wavelength of 225 nm. A volume of injection was 15 μL for each standard solution and the retention time was 2.9 min. Samples were filtered before injection by a 0.45 μm membrane using a millipore filtration syringe.

DOI: http://dx.doi.org/10.15666/aeer/1504_049065

Data Analysis

Data analysis was performed by using the Statistical Analysis System (SAS). Means were compared by the least significant difference (LSD) test at $\alpha = 0.05$. The three-parameter sigmoidal model was used to determine dissipation time (DT50) of sulfosulfuron herbicide in Marvdasht location: $f = a/(1 + \exp(-(x - x_0) / b))$, where the parameter a is maximum dissipation of herbicide, b is the slope of the curve around the X_0 and X_0 donates time required for 50% dissipation. Figures were drawn by using the microsoft excel software.

Results

Determination of Test Plant for Bioassay Study

The bioassay experiment showed that root parameter was more sensitive to sulfosulfuron as compared with shoot. As shown in *Figures 3* and *4*, the percentage root length reduction was within the approximate range of 40 to 71% for the bioassay plants, while the shoot length inhibition for bioassay crops was lower (25 to 60%). Since the roots are directly exposed to the herbicide residues, it seems that the influence of the herbicide residues on roots is higher than shoots. These results revealed the differential sensitivities of plant species to sulfosulfuron. Among the eight crops tested, garden cress had the maximum percentage decrease in root length with root length inhibition of approximately 71% at recommended rate which was followed by lentil, canola, sugar beet, cucumber, mung bean, chick pea and corn (*Fig. 3*). Thus, garden cress was considered as the test species for planting in the field soil samples in bioassay experiments and the percentage root length inhibition was found as the standard parameter. This finding is consistent with findings of Paul et al. (2009). Szmigielski et al. (2009) developed the sugar beet bioassay to study the soil-incorporated sulfentrazone.

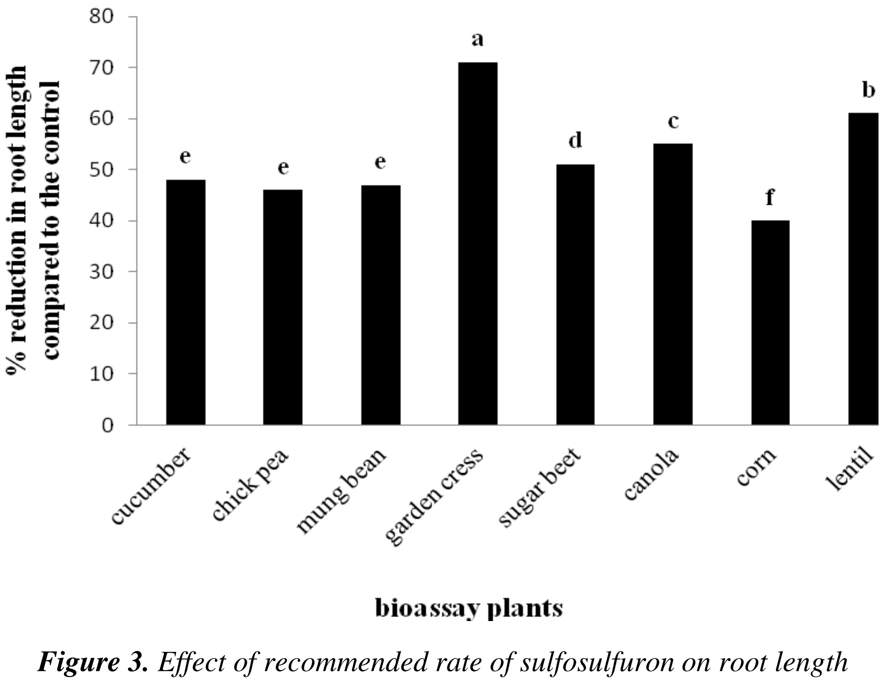

Figure 3. *Effect of recommended rate of sulfosulfuron on root length in different bioassay plants*

DOI: http://dx.doi.org/10.15666/aeer/1504_049065

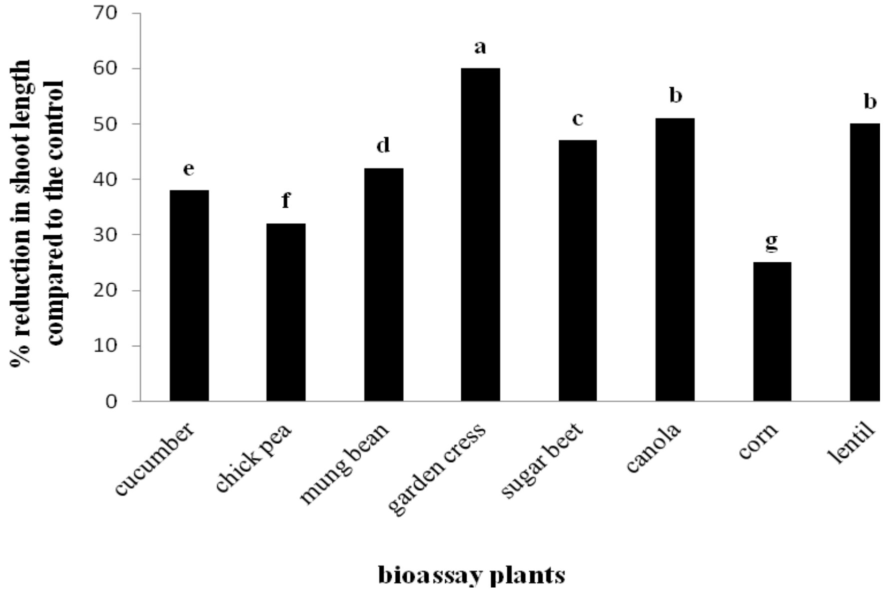

Figure 4. *Effect of recommended rate of sulfosulfuron on shoot length in different bioassay plants*

Calibration Curve

To establish a standard curve, soil samples treated with six different levels of sulfosulfuron (5, 10, 20, 50, 75 and %100 of recommended rate) were filled in pots with four replicates for each concentration and five pregerminated garden cress seeds (in each pot) were planted as the indicator species. After 15 days of planting, the percentage reduction in root length of garden cress plants versus different concentrations of sulfosulfuron was measured and the respective calibration curve was drawn. At the recommended rate of application (26.6 g a.i. ha^{-1}), the best regression equation fitted was linear as Y = 7.3781X + 4.0174 with R^2 = 0.97 (*Fig. 5*). At the double rate of application (53.2 g a.i. ha^{-1}), the best regression equation fitted was linear as Y = 4.4272X+13.494 with R^2 = 0.98 (*Fig. 6*). 15 days after planting, the percentage inhibition of garden cress root length of the field samples, were entered into the standard equation to determine the herbicide concentration that was bioavailable.

For HPLC, a series of standard solutions containing different concentrations of sulfosulfuron (0.01, 0.05, 0.1, 0.5, 1.0, 5.0 and 10.0 µg a.i. mL^{-1}) were prepared in acetonitrile by diluting the stock solution (1000 µg a.i. mL^{-1}). 15 microliters of each concentration was injected and the calibration curve was established based on the sulfosulfuron concentration versus corresponding peak. The best fitted regression equation was Y = 177947X + 40771 with R^2 = 0.99.

Recovery and Limit of Quantification (LOQ)

The accuracy and precision of the method was performed by recovery study. Recovery study was conducted for soil by extraction and analysis of five replicates at three different levels (0.01, 0.05 and 0.1 mg a.i. kg^{-1}). The average recoveries of sulfosulfuron in soil were varied from 78 to 85%. The limit of quantification of sulfosulfuron was detected to be 1 µg a.i. kg^{-1}.

Persistence of Sulfosulfuron in Wheat Field Soil

HPLC Method

The results of extracted herbicide concentration in the soil for different rates are shown in *Table 2*. Results of the sulfosulfuron dissipation in the wheat field soil displayed that initial concentration of sulfosulfuron residues in the surface soil (0-10 cm) were 9.8 and 10.1 µg a.i. kg^{-1} for recommended rate (26.6 g a.i. ha^{-1}) and 19 and 18.5 µg a.i. kg^{-1} for double rate (53.2 g a.i. ha^{-1}) application in 2014 and 2015, respectively. 3 days after application (DAA), dissipation of sulfosulfuron was 17.19 and 18.1 % for 26.6 g a.i. ha^{-1} and 15.37 and 17.19 % for 53.2 g a.i. ha^{-1} application in 2014 and 2015, respectively. 20 days after application, the residues decreased to 5.2 and 6.8

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_049065

µg a.i. kg^{-1} for recommended rate and 10.6 and 12.4 µg a.i. kg^{-1} for double rate in 2014 and 2015, respectively. After 60 days of application, the residues decreased to 1.5 and 1.2 µg a.i. kg^{-1} with 86.35 and 89.1 % dissipation for recommended rate and 7.2 and 4.0 µg a.i. kg^{-1} with 67.24 and 81.8 % dissipation for double rate in 2014 and 2015, respectively. 90 days after application, the sulfosulfuron residues were found to be below detectable level at recommended rate. However, 1.6 and 2.1 µg a.i. kg^{-1} residues were detected at double rate in 2014 and 2015, respectively (*Table 2*). At recommended rate of application, the half-life of sulfosulfuron by the chemical extraction method were 17.28 and 19.42 days in 2014 and 2015, respectively.

Bioassay Method

Data obtained in the study of sulfosulfuron persistence by the garden cress seed bioassay technique, calculated using the regression equation $Y = 7.3781X + 4.0174$, indicated that the residues of sulfosulfuron were detected up to 90 DAA in 2014 and 2015 at the recommended rate of application (*Table 3*). At day 0, the decreases in garden cress root length were 78.3 and 80.4% for recommended rate and 82.17 and 79.2% for double rate in 2014 and 2015, respectively (*Tables 3* and *4*). At the recommended rate of application, the initial deposit of 10.06 and 10.35 µg a.i. kg^{-1} in 2014 and 2015 decreased to 8.41 and 9.05 µg a.i. kg^{-1} at 10 DAA in 2014 and 2015, respectively (*Table 3*). At the double rate of application, the initial deposit of 15.51 and 14.84 µg a.i. kg^{-1} in 2014 and 2015 decreased to 12.44 and 12.76 µg a.i. kg^{-1} at 10 DAA in 2014 and 2015, respectively (*Table 4*).

In 2015, the residues of sulfosulfuron dissipated with a slow rate so that the residues were detected up to 90 DAA at the recommended rate of application whereas the residues were below detectable level at 125 DAA (*Table 3*). Moreover, the residues were detected up to 90 DAA at the double rate in both years (*Table 4*). At the recommended rate of application, Fitting data of the percentage dissipation of herbicide at different intervals to a three -parameter sigmoidal model indicated that X_0 value, which is the half-life of herbicide and estimated based on the percentage of sulfosulfuron dissipation versus different day intervals, were found to be 20.31 days in 2014 and 21.78 days in 2015 by the bioassay method (*Table 5*).

Table 5. *The three-parameter sigmoidal model f= (a/ (1+exp (-(x-x₀)/b)) to determine dissipation time (DT 50) of sulfosulfuron herbicide at the recommended rate of application (26.6 g a.i. ha⁻¹) by bioassay and HPLC techniques*

Model parameters	Technique			
	Bioassay		**HPLC**	
	2014	**2015**	**2014**	**2015**
A	89.87 (0.801)	86.85(0.920)	94.00 (0.99)	96.55 (0.94)
B	8.97 (0.290)	8.62 (0.321)	10.20 (0.29)	9.44 (0.23)
X_0	20.31(0.396)	21.78 (0.450)	17.28(01.02)	19.42(01.21)
R^2	0.97	0.96	0.98	0.96
RMSE	9.21	7.71	5.30	8.95
P-value	<0.0001	<0.0001	<0.0001	<0.0001

Values in parentheses indicate ±SE (standard error).
A = maximum dissipation of herbicide.
B = the slope of the curve around the X_0.
X_0 = is time required for 50% dissipation.

Discussion

Bioassay Analysis of Soil-Bound Herbicides

According to the bioassay experiment, root parameter was more sensitive to sulfosulfuron as compared with shoot. A root length inhibition bioassay is an effective tool to detect small amounts of phytotoxic compounds in the soil, however it may not necessarily reflect yields observed in field. Several bioassays have been developed for the detection of soil residual herbicides. A bioassay involves assessing some component of plant growth such as root length, shoot length, or yield as a function of herbicide concentrations in soil. A bioassay can be used as a quantitative procedure to determine the total amount of a certain herbicide residue present in a soil sample or to assess phytotoxicity (Sunderland et al., 1991). The application of bioassays to measure ALS inhibiting herbicides in the soil is an effective method as these compounds are potent inhibitors of root and shoot growth of susceptible plants (Brown, 1990). This method has proven useful and valid for the detection of several different herbicide residues (Szmigielska et al., 1998; Sunderland et al., 1991).

Comparison of Sulfosulfuron Persistence in Field Soil By HPLC and Bioassay Methods

At the recommended rate of application (26.6 g a.i. ha^{-1}), the initial deposit observed on day 0 was 10.06 and 10.35 μg a.i. kg^{-1} by the bioassay in 2014 and 2015 versus 9.8 and 10.1 μg a.i. kg^{-1} by HPLC in 2014 and 2015, respectively. The differences between

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_049065

residues detected by the two techniques were more obvious with time, so that on 3 DAA for recommended rate the residues detected by HPLC was 9.1 and 9.0 μg a.i. kg^{-1} in 2014 and 2015 versus 9.81 and 9.93 μg a.i. kg^{-1} detected by bioassay in 2014 and 2015, respectively. The dissipation rate of residues estimated by HPLC was more than bioassay. On 20 DAA for recommended rate, dissipation of herbicide was 40.85 and 37.30% by bioassay technique, in 2014 and 2015 versus 52.68 and 38.12% by HPLC technique in 2014 and 2015, respectively. At the recommended rate of application, sulfosulfuron residues were detected up to 60 days after treatment by HPLC method in both years, whereas residues were detected up to 90 days after treatment by bioassay method in 2014 and 2015. It has demonstrated that the herbicide residues are adsorbed tightly to soil particles with time, consequently the extraction technique is inadequate for detecting the residues. In contrast, the bound residues of herbicide can be released from the soil matrix during plant growth and thus the bioassay technique is more sensitive technique than HPLC and can detect more residues (Paul et al., 2009). The major advantage of the bioassay over the HPLC is, its relative simplicity. The HPLC assay is moderately labor-intensive and requires expensive equipment whereas the bioassay is easy to perform and requires no special equipment. According to Ranft et al. (2010), the chemical extraction measures the concentration of herbicide, but not the rate influencing the crop, while the bioassay method measures amount of herbicide available to the plant, but not unavailable active herbicide in the soil.

Our study highlighted that the estimated half-life of herbicide by HPLC was lower than that of bioassay (*Table 5*). At the recommended rate of application (26.6 g a.i. ha^{-1}), estimated half-life of herbicide by bioassay and HPLC were 20.31 and 17.28 days in 2014 and 21.78 and 19.42 days in 2015, respectively. In a study by Paul et al. (2009), the half-lives of metsulfuron-methyl by HPLC and bioassay were found to be 6.3–7.8 and 17.5 days, respectively. The ability of a soil residual herbicide to have a phytotoxic effect on a sensitive crop depends on the half-life of the herbicide being used. The half-life of herbicides in soil varies with the chemical structure and soil conditions that affect degradation. According to Sarmah et al. (1999), the half-life of a sulfonylurea herbicide in soil can vary significantly depending on pH, temperature, moisture, texture and organic matter content of the soil (Blacklow and Pheloung, 1991; Sarmah et al., 1999). Sulfosulfuron, with a field half-life of 14 to 75 days, is often one of the more persistent herbicides (Vencill, 2002).

According to the bioassay and HPLC results, at two rates of application (26.6 and 53.2 g a.i. ha^{-1}), Sulfosulfuron residues decreased with time in 2014 and 2015. This may be due to various causes. Once a herbicide is applied, there are eight possible routes that may affect its dissipation: 1. adsorption to clay and organic matter, 2. leaching with the downward percolation of water, 3. volatilization to the atmosphere, 4.uptake by plants and/or soil organisms, 5. movement with runoff water or eroded soil, 6. microbial degradation, 7. chemical degradation, and 8. photolysis (McEwen and Stephenson, 1979). These processes are affected by the adsorption of a herbicide to soil colloids and soil organic matter. The greater the adsorption of a herbicide to a particular soil, the less the losses from leaching and volatilization (Smith, 1982). Depending on the chemical nature of the herbicide the importance of each of these routes can be quite different. One of the properties of some ALS inhibiting herbicides such as Sulfosulfuron, is soil residual activity that can result in weed control throughout the growing season. However, this characteristic can also cause crop damage and an economic loss due to a phytotoxic effect on sensitive rotational crops (O'Sullivan et al., 1998). The degree to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_049065

which a residual herbicide can persist and cause damage is influenced by three factors including soil properties, environmental conditions and landscape position (Moyer and Hamman, 2001; Schoenau et al., 2005).

According to the bioassay and HPLC results, at two rates of application, Sulfosulfuron had different soil persistence in 2014 and 2015. This may be due to various environmental conditions. The environment has a large influence on herbicide residue persistence. Many herbicides that have residual activity are degraded in soil by hydrolysis and/or microbial degradation (Beckie and McKercher, 1989; Vencill, 2002). The relative importance of microbial degradation as compared to chemical hydrolysis is dependant on many factors. Joshi et al. (1985) found that a sulfonylurea herbicide degraded faster in acidic soils because both forms of degradation took place. In alkaline soils however, microbial degradation was the primary source of degradation, resulting in a slower rate of dissipation. Temperature and soil moisture levels have a significant effect on soil microbial populations and activity. Beckie and McKercher (1989) found that lower temperatures and drier soils resulted in the ability to detect herbicide residues with a bioassay for a longer time period after application. Experimental sites, which received a higher level of precipitation, had lower amounts of phytotoxic residues of sulfonylurea herbicides present the year after application (Shinn et al., 1998). Hill et al. (1998) found that yearly precipitation levels had a significant effect on the persistence of quinclorac, with drier conditions increasing the soil residual half-life of the herbicide. This suggests that in years of lower than average growing season temperatures and/or lower precipitation, residual herbicides may persist longer in the soil. This can have negative effects on sensitive rotational crop species, resulting in reduced yield and/or later maturing crops.

Conclusion

In this study, the reliability and accuracy of HPLC and bioassay methods were evaluated to detect sulfosulfuron residues at macro quantitative levels. Results revealed that the bioassay was more sensitive than HPLC for the determination of sulfosulfuron residues. According to the bioassay experiment, root parameter was more sensitive to sulfosulfuron as compared with the shoot. Root length inhibition bioassay was a useful tool to detect small amounts of sulfosulfuron residues in the soil. So the residues of sulfosulfuron herbicide were detected up to 60 and 90 days after application by HPLC and bioassay techniques, respectively. These findings can be applicable for agriculture since knowledge on the degradation rates of herbicides usage, and their possible effects on sensitive rotational crops can help for making effective management decisions. Further studies need to be carried out for a better understanding of the sulfosulfuron behavior in different soil and meteorological conditions.

Abstract. The main objective of this study was to compare the removal efficiency of nutrients using *Lactuca sativa, Medicago sativa* and *Phragmites australis* in subsurface flow constructed wetlands with horizontal flow. In order to test water quality, fabricated reactors designed and the plants cultivated in the soil while their root were inside the wastewater. A long time study carried out from spring till end of autumn (9 months) in order to evaluate the difference in removal rate based on the seasonal changes. The highest removal rate was during summer which followed by spring and autumn. Thus, the effect of plants on the removal efficiency of organic matter (COD, BOD), TSS and nutrient (P and TN) appeared to be dependent on the seasonal growth. *Phragmites australis* the most sensitive species in order the removal of nutrient from wastewater.
Keywords: *subsurface flow constructed wetland, nutrient removal, wastewater treatment; Lactuca sativa, Medicago sativa, Phragmites australis*

Introduction

Today, constructed wetlands are recognized as a reliable wastewater treatment technology and they represent a suitable solution for the treatment of many types of wastewater. Constructed wetlands have been used extensively across the world for treating wastewater due to its low cost and efficiency in removal of pollutants (Vymazal, 2010). Wastewater treatment in wetland occurred by a process named phytoremediation that is a moderately late innovation and is seen as practical, proficient, novel, eco-friendly technology, still in its initial improvement stages and full scale applications are still constrained (Rezania et al., 2015). Wide range of wastewaters such as municipal, industrial, agricultural, and storm water can be remediated in constructed wetland (CWs) (Pedescoll et al., 2015; Qasaimeh et al., 2015). In addition, CWs is a flexible and effective method for treating and reusing wastewater with less greenhouse gas emission (Chen et al., 2011).

Generally, the major functions of plants in CWs is to create conditions suitable for removal of pollutants and the direct role of plants is limited to uptake of nutrients and heavy metals (Marchand et al., 2010). Brisson and Chazarenc (2009) showed that some environmental factors like temperature, pH, solar radiation and water salinity can influence plant growth and its performance in phytoremediation. The importance of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_067076

these parameters are related to size, weight and growth rate of aquatic plants (Lissy and Madhu, 2010).

Based on Tanner (2001), wetland plants provide only small improvements in biological oxygen demand (BOD), chemical oxygen demand (COD) and faecal bacterial indicator removal but provide measurable enhancement of nutrient removal, mainly by promoting transformations to gaseous forms and sequestration in accumulating organic matter. As extensively reviewed by Engloner (Engloner, 2009), considering the worldwide distribution, Phragmites dominated wetlands may have a considerable effect on climate change. Because of this issue, the significance of common reed in scientific research will be on-going in the future studies. *Phragmites australis* is the most often used plant in CWs although a large diversity of species can be used and the genus *Typha* and *Scirpus* are commonly used (Vymazal, 2013). As described by Engloner (2004), water availability is an important factor in shoot which is longer in wetter than drier habitats (with maximum water depths 40-0 and -30 cm, respectively).

In the Czech Republic, horizontal subsurface flow CWs are mostly planted with *Phragmites australis* (Common reed) or *Phalaris arundinacea* (Reed canarygrass) or with a combination of these two species. Some factors like: (1) excellent germination from the seeds, (2) easy planting, (3) fast growth, creating full cover of the surface during the first growing season if planted in spring, and (4) provision of good insulation during the winter (Vymazal, 2013). *P. australis* aboveground biomass in HF CWs varies widely between the values < 1000 g m -2 to more than 11,000 (g/m-2) on dry matter basis and growing in natural stands also varies greatly within the similar range as in constructed wetlands (Vymazal and Březinová, 2016). As the nitrogen and phosphorus are essential elements for plants and living beings, meanwhile domestic and industrial wastewater which is not fully treated can be among the most important factors that threatens the water quality (Chang et al., 2006). There has been a growing evidence that constructed wetlands with emergent vegetation are more efficient as compared to unplanted filters and that some species are more efficient than the other ones (Zhang et al., 2010).

The objective of this study was to determine the effect of nutrient removal by *Medicago sativa*, *Lactuca sativa*, *Phragmites australis* and mixture of (*Medicago sativa* and *Lactuca sativa*) while they grew in municipal wastewater as the first treatment system. Also, the removal efficiency of these plants during 9 months experiments was compared.

Experiment

Pilot experimental set-up

A pilot experimental system was established in Ekbatan wastewater treatment plan and the study was carried out from April 2015 to December 2015. In Iran, the spring begin on April while the summer and autumn begin on July and October, respectively. The system was comprised of five horizontal subsurface flow CW units in parallel with a different plant species each: CW1 (unplanted), CW2 (*Medicago sativa*) CW3 (*Lactuca sativa*), CW4 (*Phragmites australis*) and CW5 (Mixture of *Medicago sativa* and *Lactuca sativa*) as shown in *Figure 1*.

Figure 1. *Plant cultivation in separate reactors*

Each CW unit has length of 1.15, width of 0.75 and depth of 0.6 meters. Inside the reactor was completed with stones of various diameters as larger stones (15-32 mm) were placed at the bottom, medium (9.5-15 mm) and small (6-9 mm) placed at the middle and the top. The wastewater was entered with a flow rate of (0.093 L/day) to the system continually. The length of *M. sativa* root was inside the sand 10 cm while it was 6 cm for *L. sativa* is 6 cm (in a radius way). In the case of *P. australis*, the bushy root reached to the bottom of the soil. The overall design of pilot study is shown in *Figure 2.*

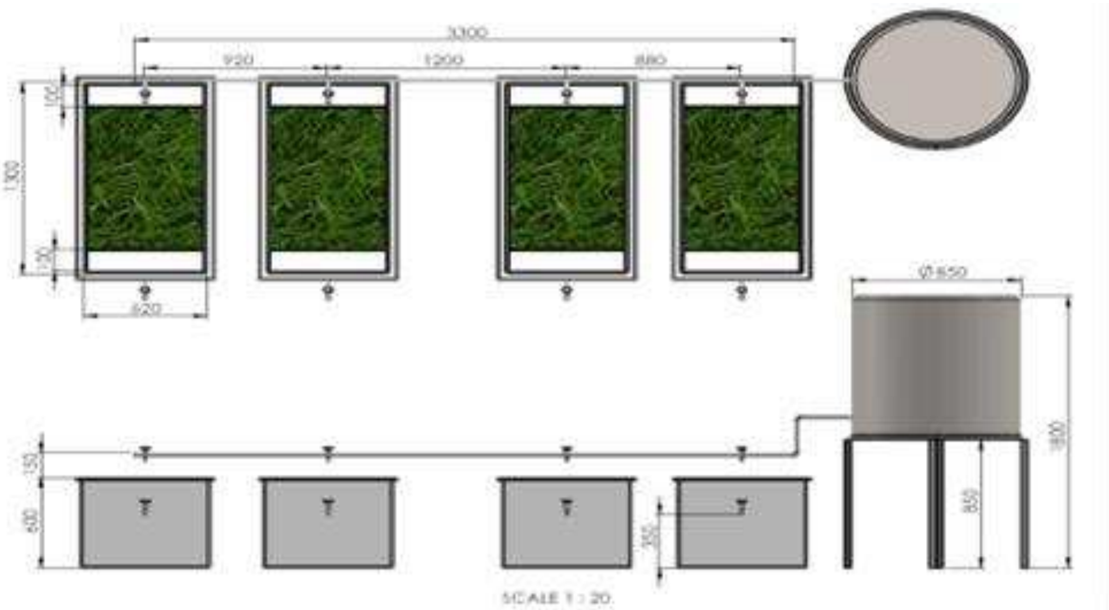

Figure 2. *Design of horizontal subsurface flow constructed wetland in the study*

Water sampling and analysis

The influent comes from raw wastewater as first treatment system which located at Ekbatan township in Tehran. The samples were collected from influent and effluent of each CWs daily for the analyses. The sampling last for 10 days of each month (standard deviation) and each test was conducted in triplicates. All the parameters were investigated in accordance to APHA (2005) BOD, COD and TSS were measured by

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_067076

following methods: BOD_5 determined using 5-Day BOD test method, COD by colorimetric method (5220-D) and TSS by using Method No. 2540D. The total P was measured using the vanado-molybdate colorimetric method by measuring the absorbance at a wavelength of 420 nm (Fiske and Subbarow, 1925). Kjeldahl nitrogen was measured using APHA (2005).

Results and discussion

The removal efficiency of each plant in CWs during 9 months in different seasons was investigated and discussed as shows in *Table 1*.

Table 1. *Removal efficiency based on different CWs*

CWs	**Plant species**	**Removal efficiency**		
		Spring	Summer	Autumn
1	*Medicago Sativa*	low	high	moderate
2	*Lactuca sativa*	moderate	high	moderate
3	*Phragmites Australis*	moderate	high	moderate
4	*Medicago Sativa & Lactuca sativa*	moderate	high	moderate

Medicago sativa

As shown in *Figure 3* during the first months of plant operation, COD decreased gradually which the lowest was 385 on 5 month in the summer. It showed the linear and stable reduction till end of the experiment. The reduction was around 50% using *Medicago sativa* for the treatment of municipal wastewater. Similarly, BOD showed same reduction while after month 5 (35%), small increases observed which may related to biomass growth and seasonal changes. In regard to nutrient removal like P and TN, the reduction occurred till 4 month (summer). In summer, the amount of P and TN increased slightly while was fluctuated for TN. During autumn, P values in water decreased proportionally while TN showed lesser reduction rate by 25%. In regard to TSS, it increased sharply till from spring till end of summer (6 months) which the highest was by 120% on 6 months. Then, it decrease during autumn till end of experiment.

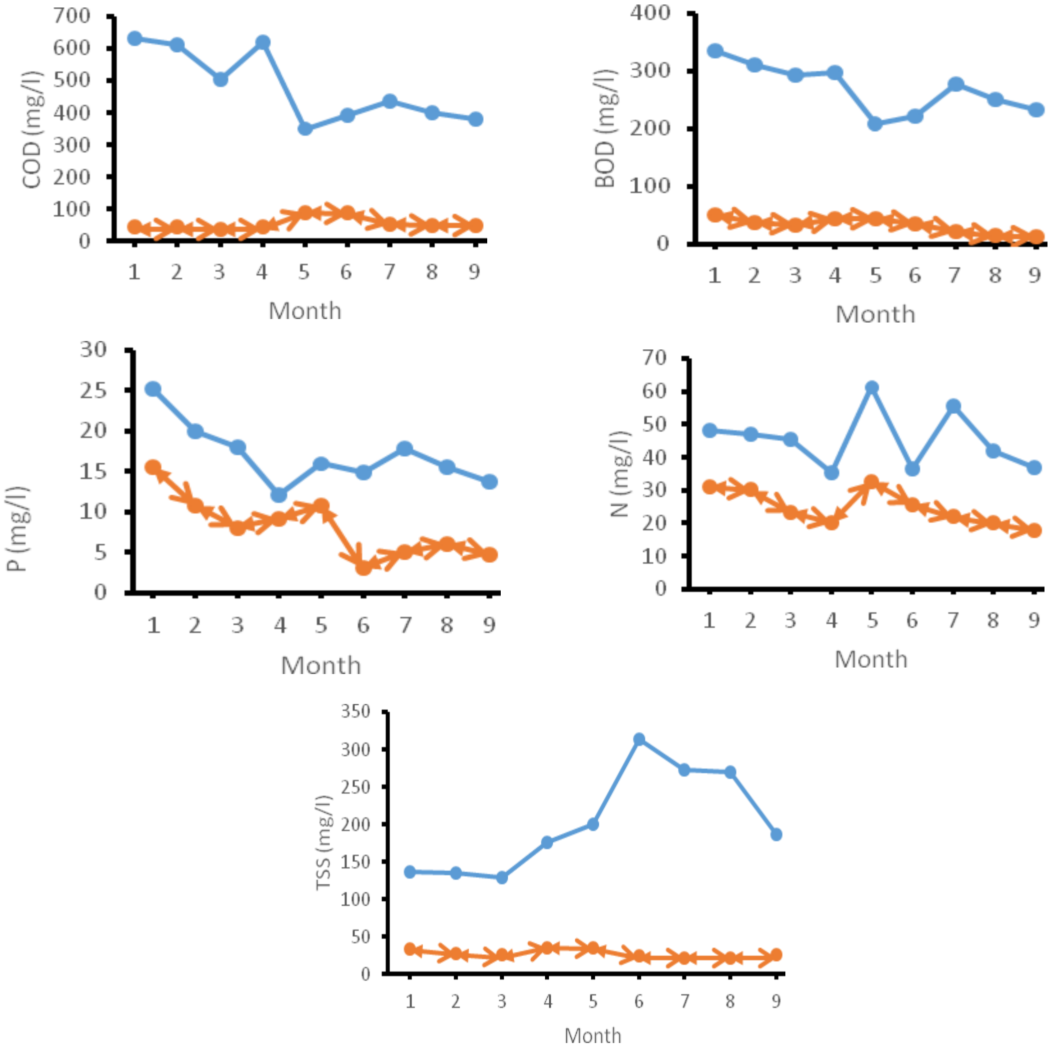

Figure 3. *Nutrient removal by M. sativa*

Lactuca sativa

There is no studies which used *Lactuca sativa* for wastewater treatment. This plant reduced COD by 40% during first five months of the experiment. Then, COD increased during autumn till end of the experiment. In regard to BOD, similar reduction occurred which was highest by 35% on middle of summer after 5 months of the experiment. *L. sativa* had similar removal reduction pattern for T and TN which reduced after 4 months of the experiment. The highest removal was 60% and 30% for P and TN, respectively. By using *Lactuca sativa*, TSS was increased till end of summer by 100% and then decreased till end of autumn (*Figure 4*).

DOI: http://dx.doi.org/10.15666/aeer/1504_067076

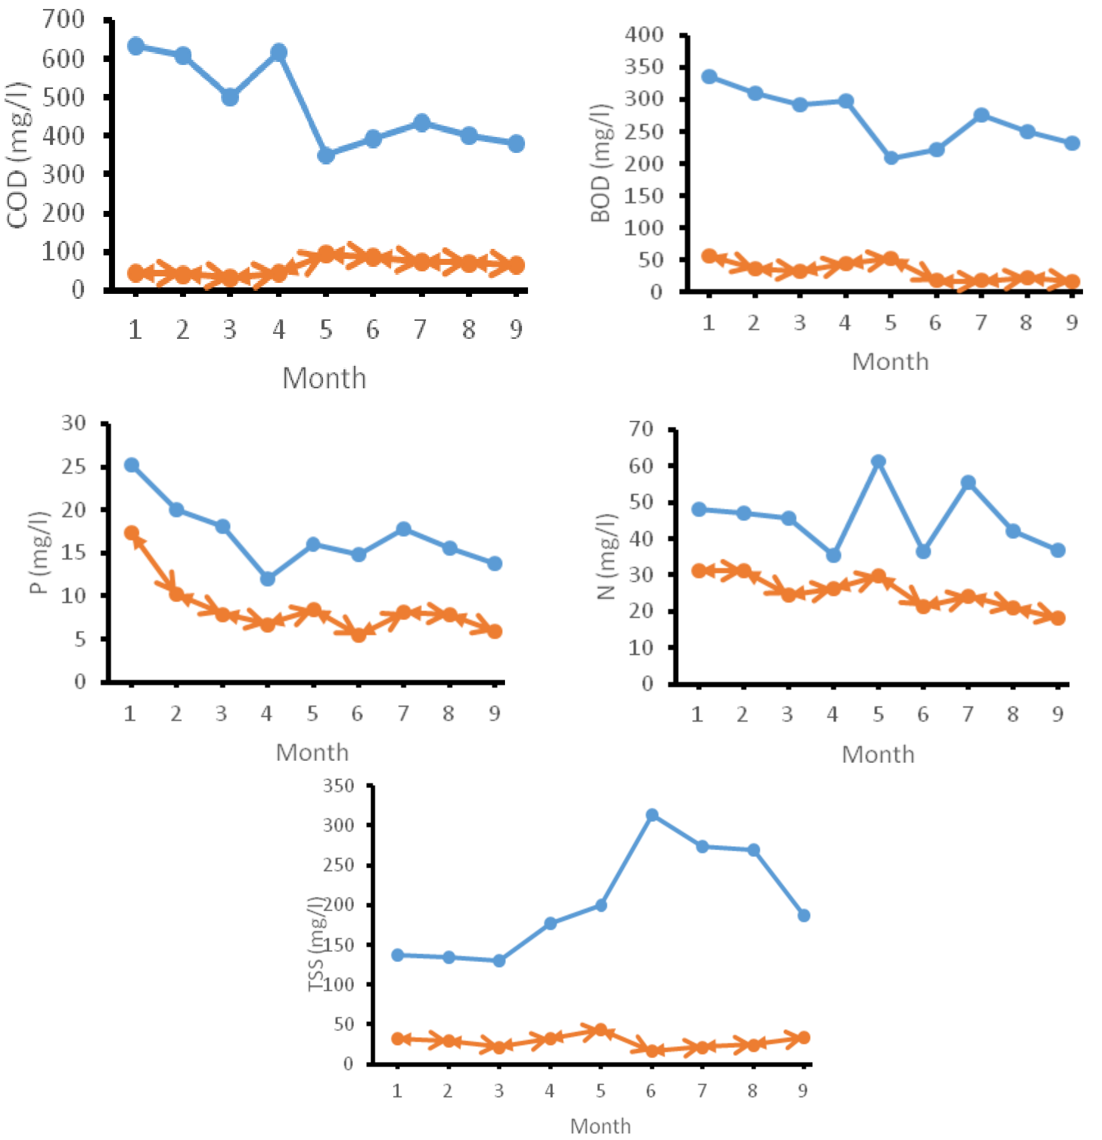

Figure 4. *Nutrient removal by L. sativa*

Phragmites australis

Many studies showed the efficiency of *P. australis* in removal of nutrient from different types of wastewater. This plant was effective in removal of BOD and COD over the five years (Březinová and Vymazal, 2014). Although, Carballeira et al. (2016) found that the high increases in TSS by using *P. australis*. In this study, *P. australis* removed COD and BOD by 40% and 30% till end of summer, respectively. Similarly, P and TN removed significantly till starting of summer by 65% and 30% respectively. Fuchs et al. (2011) found lesser removal rate of TN and P using *Phragmites australis* which was as 35.6 % and 31% respectively. As indicated by Carballeira et al. (2016), *P. australis* had an intermediate biomass production rate and an increased nitrogen removal rate by approximately 30% in comparison with the control. As shown in *Figure 5*, TSS increased till end of summer and was decreased during autumn proportionally.

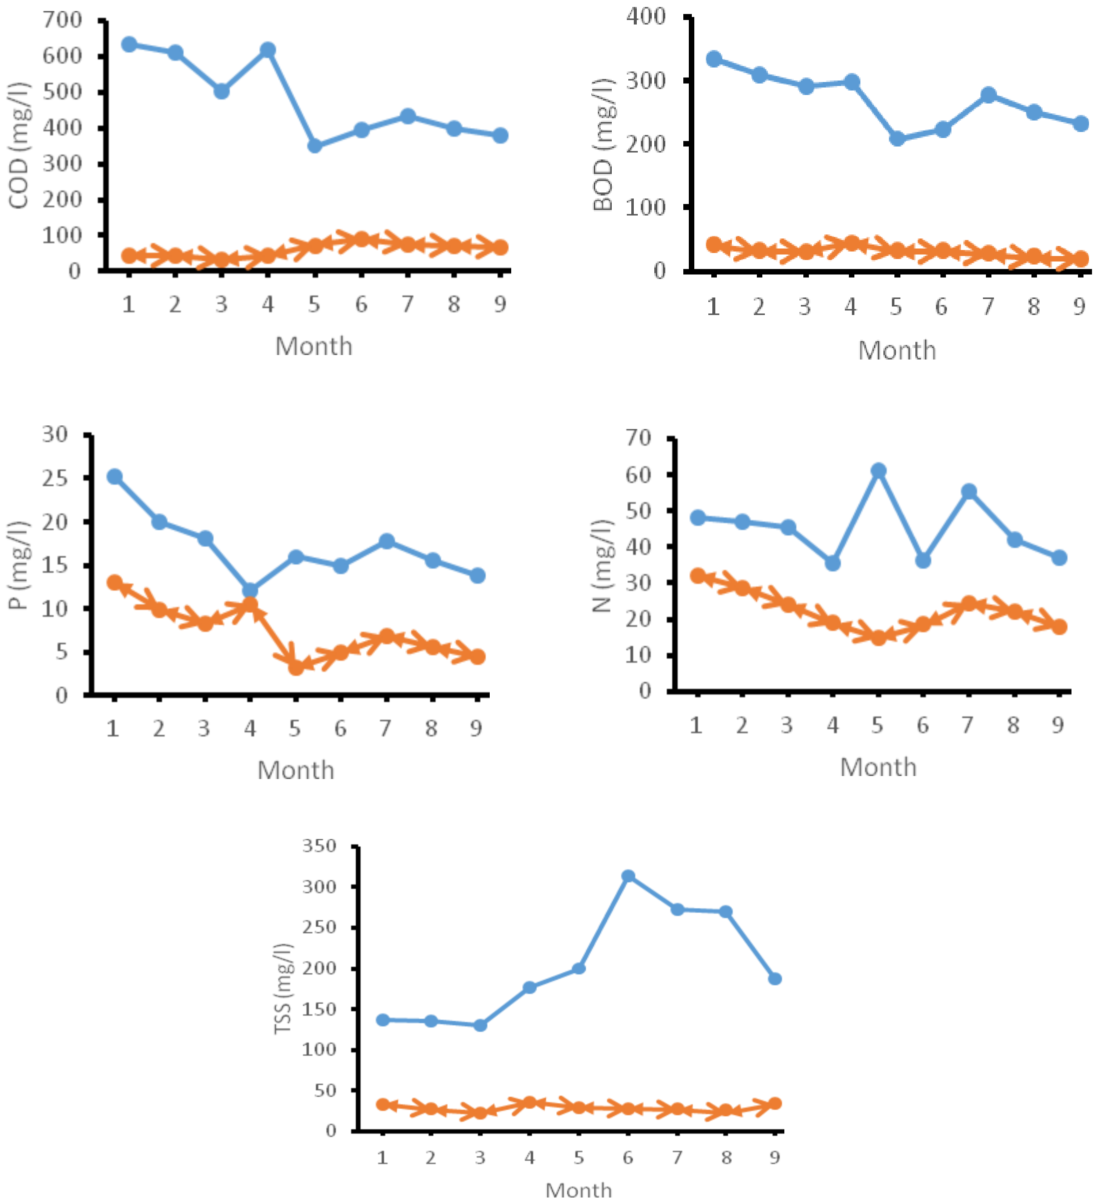

Figure 5. *Nutrient removal by P. Australis*

Mix of L. sativa and M. sativa

As shown in *Figure 6*, in the CWs contains mixture of *L. sativa* and *M. sativa*, similar observation of reduction was observed. The obtained results showed in was inconsistence with reduction of these plants when they culture in CWs alone. Most of the reduction occurred during summer while it was lesser during autumn. Highest removal of most of the parameters was in summer which followed by autumn and the lowest was in spring (*Figure 6*). It shows that the duration and season are the important factors which influenced removal efficiency.

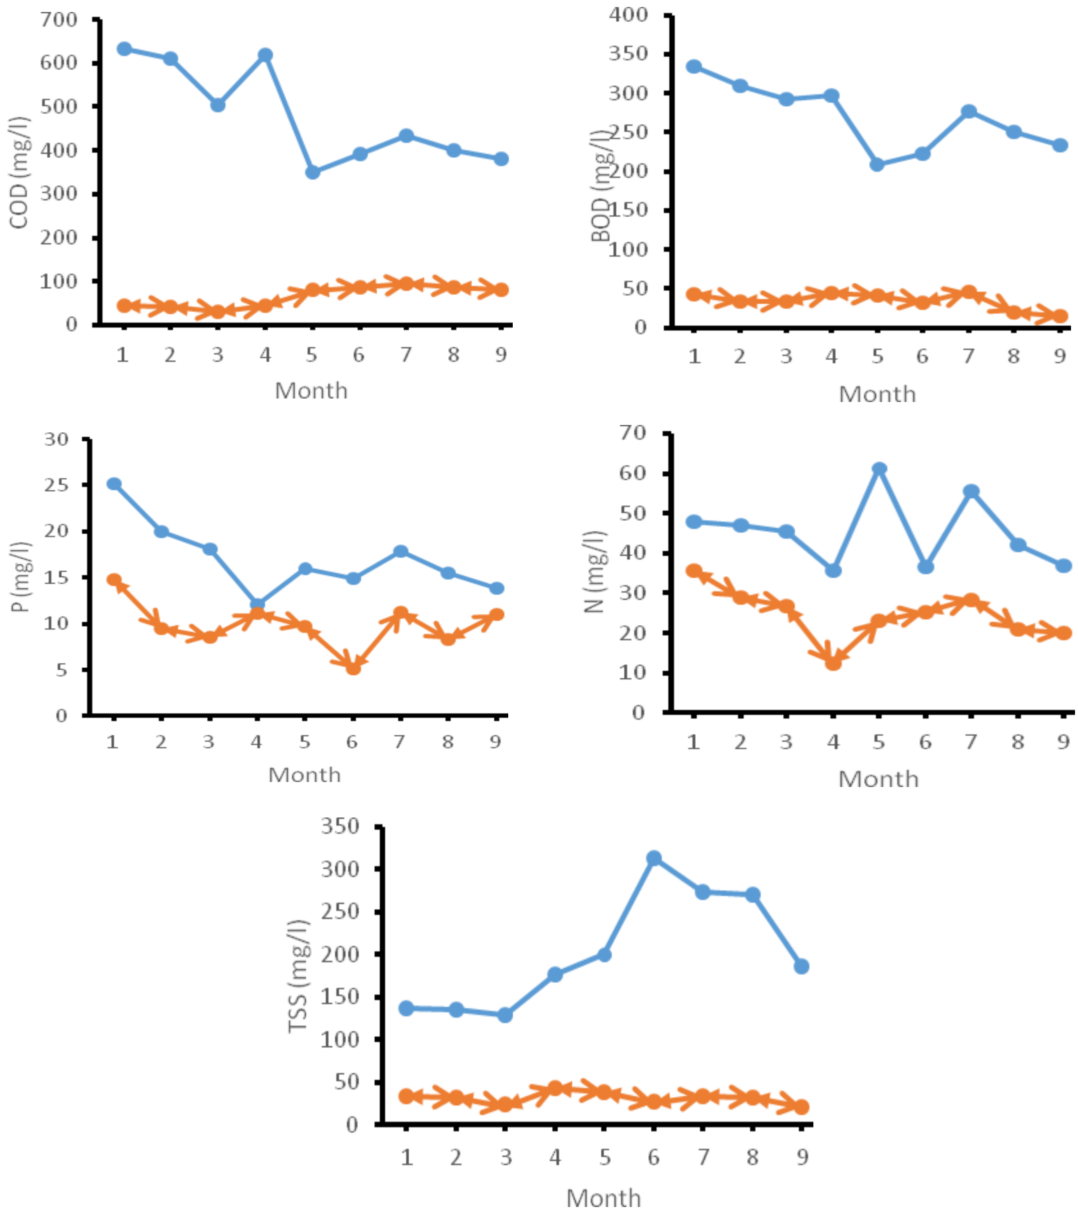

Figure 6. *Nutrient removal by mix of L. sativa & M sativa*

Conclusion

In this study, the effectiveness of nutrient removal by *Medicago sativa*, *Lactuca sativa*, *Phragmites australis* and mixture of (*Medicago sativa* and *Lactuca sativa*) in farictaed CWs was investigated. Different parameters like COD, BOD, TSS, P and TN measured during 9 months treatment system of municipal wastewater. Similar reduction pattern was observed during experiment while the highest reduction occurred during summer which followed by spring and autumn, respectively. In terms of removal efficiency in CWs, the highest reduction obtained using *Phragmites australis* which followed by (*Medicago sativa* and *Lactuca sativa*), *Medicago sativa* and *Lactuca sativa*. The average of removal rate was for COD (40-65%), BOD (30-50%), TSS (100-120% increase), P (40-60%) and TN (25-35%). This study proved that the horizontal

Abstract. Due to increasing demands for agricultural products and the problems to generate new data, using proper models to predict the performance of agricultural products seems necessary. The objective of this study was to assess the ability of artificial neural networks (ANN) for yield prediction of wheat, barley and maize to determine the most important soil properties for land production potential in Varamin region, Iran. In this study, potential production was calculated using the AEZ model. ANN model inputs were soil characteristics, including the percentage of calcium carbonate, coarse fragments, gypsum, clay, silt and sand, electrical conductivity, sodium absorption ratio and pH. ANN model output was production potential. Mean absolute error, root means square error and coefficient of determination criteria were used to evaluate the performance of the ANN. The obtained results showed that the ANN models with two hidden layers provided the most accurate prediction of production potential. Mean land production potentials for wheat, barley and maize, using ANN models were predicted respectively, as 7417.73, 6810.41 and 8922.48 kg/ha. Sensitivity analysis of models showed that wheat production potential has the most dependence on sodium absorption ratio and clay percent. Sand and coarse fragments rates were the most important parameters for predicting the barley production potential. The sodium absorption ratio and electrical conductivity were determined as the relevant and effective soil properties on maize production potential. Also, the optimum model for maize production potential prediction has less accuracy than wheat and barley. The reason of this may be differences in the environmental compatibility of various products to adverse conditions.
Keywords: *FAO method, sensitivity analysis, land production potential*, *gross biomass production, climatic and plant parameters*

Introduction

Crop yield prediction has an important role in agricultural policies such as specification of the crop price. Nowadays, using suitable models to predict the performance of agricultural products is vital, since demands for agricultural products are increasing and water and land resources are limited. Crop yield is a function of several plant agents, climatic conditions, and soil and water management (Qian et al., 2009). Therefore, the calculation of crop yield and its related indicators follow up the complex nonlinear relationships that are modeled difficulty.

In recent years, crop growth models have become increasingly important as major components of agriculture related decision support systems. Crop growth and yield models are based on a combination of soil, crop and climatic variables. Crop models and decision tools are increasingly used in the agricultural field to improve production efficiency. The combination of advance technology and agriculture to improve the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_077090

production of crop yield is becoming more interesting recently. Due to the rapid development of new higher technology, crop models and predictive tools might be expected to become a crucial element of precision agriculture (Shearer et al., 2000).

Land production potential (LPP) estimation is considered as a prerequisite for land use planning. LPP is determined based on land characteristics for specific land use for increment of production per surface area unit. In this regard, first, radiation thermal production potential (RTPP) is calculated, using different models such as FAO model. This potential is a genetical one which is not affected by water, soil and management limitations. If soil limitations are exerted in the radiation thermal production potential, LPP is resulted.

Some adaptive and non-parametric models have been recently introduced in environmental science for predictive purposes. ANN models are a powerful empirical modeling approach and yet relatively simple compared with mechanistic models. (Bishop, 1995), the method is gaining popularity for research areas where there is little or incomplete understanding of the problem to be solved, but where training data are available. The ANN can be used to develop empirically based agronomic models. The ANN structure is based on the human brain's biological neural processes. Interrelationships of correlated variables that symbolically represent the interconnected processing neurons or nodes of the human brain are used to develop models. ANN models find relationships by observing a large number of input and output examples to develop a formula that can be used for predictions (Pachepsky et al., 1996).

Safa et al. (2015) showed that the ANN model can predict wheat production based on farm conditions (wheat area and irrigation frequency), machinery condition and farm inputs (N and fungicides consumption) in Canterbury, New Zealand, with an error margin of ±9%. Drummond et al. (2003) evaluated the predictive ability of representative linear, nonlinear, and neural network techniques on a multiple site–year data set of grain yield and site and soil characteristics. The results showed that significant over fitting had occurred and indicated that a much larger number of climatologically unique site–years would be required in this type of analysis. Kaul et al. (2005) reported that ANN models consistently produced more accurate yield predictions than regression models for corn and soybean yield prediction under typical Maryland climatic conditions. Norouzi et al. (2010) predicted the biomass, grain yield, and grain protein in wheat grown in hilly regions using an ANN model under rainfed conditions in the semiarid and hilly regions of western Iran. The results indicated that the ANN models could explain 89–95% of the total variability in wheat biomass, grain yield, and grain protein content. Bagheri et al. (2012) determined the least important computer input parameters which affecting the silage maize yield using ANN. The results showed that adding the solar radiation and average relative humidity to the input parameter cause reduction in MSE and increasing the accuracy of the model in the process network training. Kitchen et al. (2003) and Safa et al. (2003) suggested that the feed forward back propagation neural network is the most commonly used neural network, which can approximate any function with arbitrary precision. The objective of this study was to assess the ability of artificial neural networks (ANN) for wheat, barley and maize production potential prediction and determination of the most important soil properties affecting land production potential in Varamin area, Tehran province, Iran.

Materials and methods

Study area and data compilation

The study area with an approximate area of 2000 hectares is located between latitude 35° 20′ and 35° 24′ N and longitude 54° 38′ and 54° 42′ E in the Varamin area, Tehran province, Iran. The area has a mean annual rainfall of 170 mm and mean annual temperature of 17.4°C with a mean altitude of 972 m a.s.l. The ground water table depth is more than 10 m. Based on U.S. Soil Taxonomy (Soil Survey Staff, 2014), the soil moisture and temperature regimes of the area are aridic and thermic, respectively.

Some of the plant characteristics such as leaf area index and harvest index were measured in the laboratory. The maximum leaf photosynthesis rate was estimated from the graph according to the crop group (Sys et al., 1991). Required climatic data for land suitability evaluation were obtained from Varamin Synoptic Meteorological Station for a 20 years period (1994–2014).

In this research based on semi-detailed soil survey, a regular grid sampling method was designed; consequently 50 soil profiles with 600 m intervals were investigated. Soil samples were collected from different horizons of the profiles. Prepared samples were subsequently analyzed for required soil properties in land suitability evaluation (Sys et al., 1993) using standard methods (Soil Survey Staff, 1996). For determining the mean values of the soil physical and chemical properties for the upper 1 m of the soil depth, the profile was subdivided into 4 equal sections and weighting factors of 1.75, 1.25, 0.75, and 0.25 were attributed for each section, respectively (Sys et al., 1991).

The land characteristics, i.e., climatic data and soil properties, with studied plant requirement tables presented by Sys et al. (1993), were matched. Consequently, the square root formula was used to calculate the soil index (SI). Soil index reflects the soil, topography and drainage limitations for irrigated farming. The relevant equation is as follows:

$$SI = R_{min} \times \sqrt{\frac{A}{100} \times \frac{B}{100} \times \ldots} \quad \text{(Eq.1)}$$

where, SI, is the specified soil index; A, B, etc., are different ratings for each soil characteristic and R_{min} is the minimum rank or value (Sys et al., 1991).

To calculate the radiation-thermal production potential of wheat, barley and maize based on FAO model (Sys et al., 1991), the following were measured or calculated:

- Respiration coefficient was calculated as follows:

$$Ct = C30(0.044 + 0.0019t + 0.001t^2) \quad \text{(Eq.2)}$$

where, Ct, respiration coefficient; C30 of 0.0108 for non-legumes and t, mean daily temperature of the growing cycle (°C).

- Maximum gross biomass production ratio was calculated according to:

$$bgm = f \times bo(1 + 0.002\,y) + (1 - f) \times bc(1 + 0.005\,y) \quad \text{(Eq.3)}$$

$$y = \left|(Pm - 20) \times 5\right| \quad \text{(Eq.4)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_077090

where, bgm, maximum gross biomass production rate (kg CH_2O/ha.hr); f, fraction of the daytime that the sky is overcast; bo, maximum gross biomass production on overcast days (kg CH_2O/ha.day); bc, maximum gross biomass production on clear days (kg CH_2O/ha.day) and Pm, maximum leaf photosynthesis rate (kg CH_2O/ha.hr).

- Radiation-thermal production potential was calculated as follows:

$$Y = (0.36 \times bgm \times KLAI \times Hi) / \left[1/_L \times 0.25Ct \right] \quad \text{(Eq.5)}$$

where, Y, radiation-thermal production potential (kg/ha); bgm, maximum gross biomass production rate (kg CH_2O/ha.day); KLAI, leaf area index at maximum growth rate; Hi, harvest index; L, growth cycle (day) and Ct, respiration coefficient.

Finally, LPP was calculated according to:

$$LPP = Y \times SI \quad \text{(Eq.6)}$$

where, LPP, the land production potential (kg/ha); Y, radiation-thermal production potential (kg/ha) and SI, the soil index.

Land and soil characteristics were included topography, wetness and drainage conditions, soil texture and structure, the percentage of coarse fragments, equivalent $CaCO_3$ percent, gypsum percent, soil depth, electrical conductivity (EC), sodium absorption ratio (SAR) and pH. The growing period was determined based on climatic data (i.e., rainfall, temperature, relative humidity, hours of bright sunshine and wind speed) using graphical method. To calculate the evapotranspiration, CropWat software was used.

Artificial neural network model development

In this paper, the feed forward back propagation neural network as the most commonly used neural network architecture was applied. The first term, “feed forward” describes how this neural network processes and recalls patterns. “Back-propagation” is a form of supervised learning where the error rate is sent back through the network to alter the weights to improve prediction and decrease error. Supervised learning, which applies known outputs to train the ANN, is more commonly used than unsupervised learning (Wieland and Mirsche, 2008).

Since, the climatic characteristics and topographic conditions were entirely equal within the study area; they were not considered as the ANN inputs. ANNs can identify and learn correlated patterns between input data sets and corresponding target values through training. The trained network is then tested with a separate data set with its output information omitted. Training data sets were used to develop models including field-specific: equivalent $CaCO_3$ percent, percentage of coarse fragments, gypsum, clay silt and sand percent, EC, SAR and pH as inputs with associated land production potential as output. The training and testing process have been carried out for around 80% and 20% of the sample data set respectively in each of the cases under study.

Since, the sigmoid threshold function was used in the hidden layer and its output values are between 0 and 1, therefore the data sets were normalized using the following equation (Montazar et al., 2009):

$$X_n = 0.5\left(\frac{X_o - X_{ave}}{X_{max} - X_{min}}\right) + 0.5 \quad \text{(Eq.7)}$$

DOI: http://dx.doi.org/10.15666/aeer/1504_077090

where X_n, the normalized data; X_o, the input data; X_{ave}, the average of data, X_{min} and X_{max}, the minimum and maximum data value, respectively.

Training neural network models was founded on the basis of trial and error. Adjustment of ANN parameters were included the number of hidden nodes and hidden layers, learning rate, training function type and training tolerance. So that, the optimum neural network architecture was obtained from changing the mentioned parameters. For each step, multiple linear regression models between the actual and predicted yields were applied. The coefficient of determination (R^2) and root mean square error (RMSE) were calculated to find the optimum neural network architecture. The different threshold functions such as logarithmic sigmoid function, linear and hyperbolic tangent functions were used to improve neural network performance. Finally, the best neural network architecture was obtained for prediction of wheat, barley and maize land production potential. The performance of developed models was evaluated using by mean absolute error (MAE), RMES and R^2 (Tang et al., 1997). The ANN models were developed in MATLAB 10.1 software.

The sensitivity analysis must be conducted to detect the robustness of every ANN model because different choices of function and parameters in ANN models would influence the performance of simulation (Zhang et al., 2007). In this research, sensitivity analysis was done using Statfsoft method (StatSoft, 2004). The sensitivity coefficient values of the inputs obtained by dividing the total network error in the absence of one variable on the total network error in the presence of all the variables. According to this, if the sensitivity coefficient value of variable is more than 1, the variable has a great impression in the variability of the components of yield (Norouzi, 2010).

Results and discussion

Required plant and climatic characteristics for calculation of wheat, barley and maize radiation-thermal production potential were presented in *Table 1*. Regarding to FAO model, the radiation-thermal production potential of wheat, barley and maize were obtained 7417.73, 6810.41, and 8922.48 (kg/ha), respectively. Of course, it is impossible to achieve such production because anyway, there are soil and management limiting factors in irrigated farming. In other words, the difference between the LPP and farmer yield is due to these limitations. *Table 2* shows summary statistics of the studied soil attributes used in the training and testing process. The studied soils have a wide range of EC, SAR and particle size distribution (*Table 2*).

The designed ANN models

In this study, one and two hidden layer structure and one to 14 numbers of neurons in hidden layers was applied in network training. Eight optimized ANN models for wheat and maize and seven optimized models for barley production potential predication were achieved. *Table 3* shows the characteristics of ANN models. The efficiency of models for estimation of LPP was compared with R^2, RMSE and MAE statistics (*Table 4*).

The ANN models were ranked based on the highest R^2 and the lowest RMSE and MAE for selection the best one. Numerical values were assigned to the best and worst models (1 to 8 for wheat and maize and 1 to 7 for barley). Based on the sum of these values, ANN models were ranked: the models with the lowest and the highest sum of scores had the highest and lowest worthiness, respectively. Ranking of models for selection of the optimum model was presented in *Table 5*. The results for each crop were as follows:

Wheat production potential prediction by proposed ANN model

Model No. 7 in *Table 3* as the best ANN model for estimation of wheat production potential, has 10 input layers and one output layer. The number of neurons in two hidden layers has been taken as 9 and 12. This model has the lowest sum of the scores and the highest ranking in training process (*Table 5*). *Fig. 1* shows high correlations between calculated FAO production potential and predicted ANN production potential (R^2= 0.924). High coefficient of determination reflects the ability of ANN for estimation of the wheat production potential. Also, R^2 of 0.780, RMSE of 0.310 and MAE of 0.245 in training stage confirm the efficiency of the proposed ANN model

Table 6. *Summary statistics of actual and predicted production potential by artificial neural networks*

Crop	Production potential (kg/ha)	Minimum	Maximum	Mean
Wheat	Actual production potential	101	5080	2503
	Predicted production potential by ANN	749	5013	2617
Barley	Actual production potential	95	4769	2350
	Predicted production potential by ANN	252	4764	2389
Maize	Actual production potential	124	6234	3072
	Predicted production potential by ANN	667	6083	3354

According to *Table 7*, SAR and clay percent, which have the coefficient of sensitivity: 6.12 and 5.96, respectively, were as the most effective factors for wheat production potential prediction. The reason for the yield decline due to salinity has been attributed to competition between sodium and chloride ions in nutrient uptake. In saline soil, the balance in nutrient uptake was disturbed (Hosseinifard et al., 2005). In coarse soil texture, high percentage of nitrogen was leached out of the root zone. Although in fine soil texture, nitrogen leaching is more limited than sandy soils, but more nitrogen volatilization was occurred (Salehi et al., 2009).So, mineral soil particles (sand, silt and clay) as the effective factors on soil fertility are very important in crop yield. The finding results of this research also confirm it.

Barley production potential prediction by proposed ANN model

Model No. 7 as the best ANN model (*Table 5*) for estimation of barley production potential, has 10 input layers and one output layer. The number of neurons in two hidden layers has been taken as 5 and 11. *Fig. 2* shows the correlation between the calculated FAO production potential and the predicted ANN production potential for

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_077090

barley (R^2 = 0.866). This model estimated the highest and the lowest barley production potential of 4764 and 252 (kg/ha), respectively (*Table 6*). The results of coefficient of determination, RMSE and MAE, which are 0.892, 0.299 and 0.235, respectively; confirmed the effectiveness of proposed model (*Table 4*).

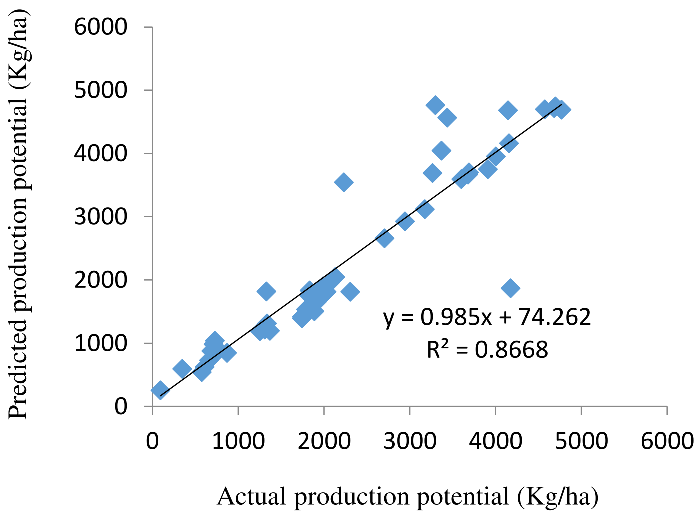

Figure 2. *Relationship between actual and predicted production potential for barley by neural network*

The results of sensitivity analysis indicate that the percentage of sand with the coefficient of sensitivity of 6.45 is the most important parameter for predicting of barley production and after that is the coarse fragment percent with the sensitivity coefficient of 4.86 (*Table 7*). Since, the studied soils with sand and coarse fragments of 75.3% and 23.6%, respectively (*Table* 2) are gravelly soils, therefore these factors are the main constraint for barley production in the study area. The reason for this could be a direct or indirect impact of these factors on the supply and maintenance of required air, water and nutrients for plant. Ranjbar et al. (2015) have reported similar findings about the influence of some soil physical properties included percentage of coarse fragments, mineral soil particles (sand, silt and clay) and weighted mean diameter of aggregates on nutrient uptake. Also, according to the growing requirements of barley (Sys et al., 1993), coarse soil textures are unsuitable for barley production.

Maize production potential prediction by proposed ANN model

Model No. 5 with two hidden layers and a network structure of 9-6-8-1 (*Table 3*) shows the highest ranking in training process (*Table 5*). *Fig. 3* shows high correlations between calculated FAO production potential and predicted ANN production potential for maize (R^2 = 0.868). The highest and the lowest estimated maize production potential by optimum model were: 6083 and 667 (kg/ha), respectively (*Table 6*). The results of coefficient of determination, RMSE and MAE, which are 0.746, 0.426 and 0.352, respectively; confirmed the effectiveness of proposed Ann model (*Table* 4). According to *Table 7*, SAR and electrical conductivity, which have the coefficient of sensitivity: 7.26 and 6.25, respectively, were the most effective factors for maize production

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_077090

potential prediction. Available information about the growing requirements of maize (Sys et al., 1993) shows the more sensitivity of maize to soil salinity and sodium content than wheat and barley. The results of studies by Khaghani et al. (2012) showed that the toxicity of chloride and sodium ions compared to chloride and magnesium ions in equal osmotic pressure led to the more reduction of maize performance.

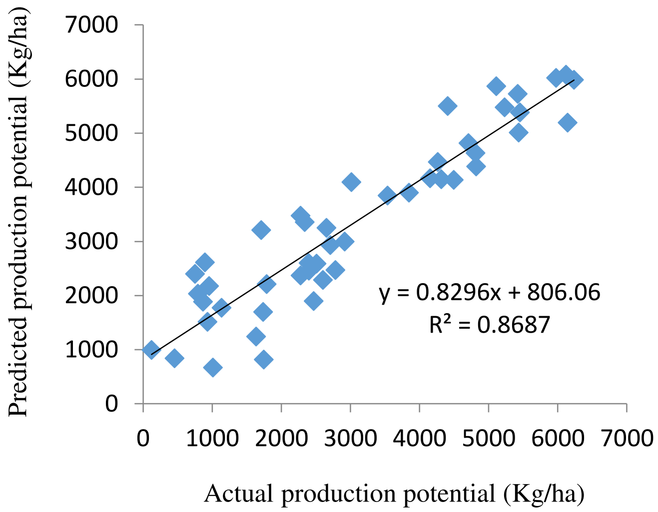

***Figure 3.** Relationship between actual and predicted production potential for maize by neural network*

RMSE, MAE and R^2 statistics of suggested models show that ANN models with two hidden layers have higher efficient than those with one hidden layer for production potential prediction of all three products (*Tables 4* and *5*). Safa et al. (2003), Kaul et al. (2005), Alvarez (2009) and Bagheri et al. (2012) showed that the efficiency of ANN model is increasing with the increment of hidden layer numbers. Although these models with two hidden layers were the most efficient model for estimation of wheat, barley and maize production potential, but the number of neurons in each hidden layer for each crop is different (*Table 3*). The reason of this can be the difference between climatic and soil requirements of each crop. Askari et al. (2009) investigated the efficiency of ANN for estimation of wheat, barley and maize yields. He found similar results in terms of the number of hidden layers and the number of neurons in the hidden layers of the optimum ANN models.

RMSE, MAE and R^2 statistics in the testing process (*Table 4*) show the higher efficiency of model for barley predicts yield (model 7) than wheat (model 7) and maize (model 5) and also the higher efficiency of model for wheat yield prediction compared to maize. The reason of this may be differences in the environmental compatibility of various products to adverse conditions. So that, barley has higher environmental compatibility compared to wheat and maize. It is also true about wheat compared to maize. Drummond et al. (2003) mentioned the more capability of ANN for yield prediction of crops with more resistance and environmental comparability.

High correlations between calculated FAO production potential and predicted ANN production potential for studied crops demonstrated that that the reliability of ANN for

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_077090

production potential prediction is acceptable in this research. This proves the high accuracy of ANN method in accordance with the nonlinear performance of crops and the influence of many factors such as climate, soil and management on it. The ability of neural network method in describing the nonlinear relation of variables for yield prediction was reported by Zare Abyaneh (2012).

Conclusions

The ANN can predict the crop production potential by land characteristics in the study area. The ANN models with two hidden layers provided the most accurate prediction of crop yield. Also, the optimum model for maize production potential has less accuracy than wheat and barley. It may be due to differences in the environmental compatibility of various crops to adverse conditions. Therefore, it can be said that the higher environmental compatibility affects the efficiency level of ANN for production potential prediction. Generally, the results of this research show that ANN method has high capability to predict the land production potential. It can be attributed to the nonlinear relation of the production potential with effective variables and the ability of neural networks in nonlinear mapping. It should be noted that using climatic and plant parameters must be considered in neural networks modeling in areas with different agricultural, ecological zones.

(Received 16th Jan 2017; accepted 2nd Jun 2017)

Abstract. Not only in developing countries has remained land-filling the most customarily used method despite the increased attention to development of the Municipal Solid Waste (MSW) management. There is a worldwide need to find the right management of MSW and this research is developing an strategy for landfill sites in Iran. We first determine the characteristics of the ten landfill sites in western part of Mazandaran province, northern Iran, using seven different landfill site sitting approaches. After reviewing each waste deposit site, considering all the criteria in each one of the seven methods applied in the present study, the incoherence in suitability was apparent in first phase. The second phase was to address the locally preferred criteria for landfill site evaluation. The aims of the present research were to show the unsuitability of the current landfill sites in western part of Mazandaran province and therefore, addressing locally preferred criteria for landfill site evaluation in northern Iran, commonly referred to as the Caspian Landfill Criteria (CLC), using which the most suitable areas for landfill sites were formerly chosen. The most principal parts in the CLC model were the importance of the weights of the criteria and the preferred weights of them. This model with eighteen effective and native criteria provides the suitable evaluation technique for municipal landfill sites. The final aim of this project was to apply the obtained results to illustrate the lack of suitable regions for MSW landfill sites in studied area.
Keywords: *Evaluation method, Caspian Landfill Criteria, Iran, GIS, AHP*

Introduction

During the last decade improvements about how to manage the solid waste in the cities was developed. Landfills have been a quick and efficient solution but still there are many improvements to be done (Adamcová et al., 2016; Cassinari et al., 2016; Chen et al., 2015; Wong et al., 2016a, 2016b). Solid waste management is a challenging issue (Guerrero et al., 2013) as waste disposal in developing countries is one of the significant environmental challenges (Baun and Christensen, 2004; Sharholy et al., 2008). Waste generation has grown rapidly over the recent years in Iran. It has been shown that new capabilities and capacities are required to address the crisis of growing waste production in Iran, as well as new disposal centres. The location of a disposal centre is an important factor, which should be considered in construction of any new centre (Shahabi, 2008). Although, the municipal solid waste (MSW) management has been developed worldwide, it is still in a critical status in Iran (Abdoli, 2005; Yazdani et al., 2013). In most Iranian cities, landfills are not used. About less than 50% of the municipal solid waste disposal methods in Iranian cities is still confined to pile-up or other unsafe methods of disposal (Rahim et al., 2005). Open dumping is a common method of waste

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_091110

disposal in most Iranian cities (Yazdani et al., 2015a). Numerous problems are seen in the landfill sites in Iran including those in Mazandaran province. Open-air waste burning, open-pit dumping and unsafe disposal considerations are common procedures in this province which can result in irreparable damages in the environment and also on society health (Yazdani et al., 2013 and 2015a; Calvo et al., 2005; Calvo et al., 2007; Diaz et al., 2005). Some land degradations caused by landfills have been previously reported, for instance, the impacts of landfills on soil quality. It has been shown that the leachate from landfills causes the soil degradation (Hernandez et al., 1998; Raman and Narayanan, 2008; Shaylor et al., 2009). The important environmental problems affiliated with open dumps are the infiltration and ground water pollution and the subsequent contamination of the land (Kale et al., 2010; Fatta et al., 1999). The leachate from municipal solid waste (MSW) landfills is a chemical compound. Therefore, small amounts of leachate can pollute soil which can contaminate a large amount of groundwater (Nema et al., 2009; Dimitriou et al., 2008; Mor et al., 2006). For example, leachate changes the nitrate level of soil. Nitrates are easily transported with water and therefore it pollutes surface and subsurface waters (Novara et al., 2013). Uncontrolled waste incineration resulted from the degradation process is one of the other important issues in the open dumping sites (Yazdani et al., 2015b). In the present studied area, uncontrolled waste incineration is the common process in most of the 10-landfill sites. Some studies have reported the negative impacts of the fire, resulted from waste incineration, on soil quality by affecting the chemical and microbiological properties of the soil (Martínez-Murillo et al., 2016; Pereira et al., 2016) In natural ecosystems, such as existing landfill sites in the studied area, restoration of the degraded soil is achieved by returning the microbiota activity and plant community recovery. Soil development is dependent on the erosion severity, total nitrogen and pH (Yazdani et al., 2015b), since these parameters in soil texture is determined the soil typicality (Pallavicini et al., 2014).

Therefore, the attempt of the present study was to understand the quality of existent landfill sites. During the last decades multiple methods have been applied to develop more suitable municipal solid waste landfill sites. Some relevant studies have integrated GIS with MCDA (Multi Criterai Decision Making) on landfill site sitting in several procedures, some of which are mentioned below.

Alanbari et al. (2014) and Sureshkumar et al. (2017) have used Multi Criteria Decision Analysis and GIS for municipal solid waste landfill site sitting. Elahi et al. (2014) have applied Multi Criteria Decision Analysis after preparing the data and evaluating the criteria according to the geographic situation of the studied area and have overlaid the map layers with the relevant criterion in ArcGIS. This recent study finally presented 3 places in Tafresh city for municipal landfill site sitting.

Moeinaddini et al. (2010) have used spatial cluster analysis (SCA) method and weighted linear combination (WLC) to choose the proper options for MSW landfill site in Karaj city. The most preferred site was then identified by Analytical Hierarchy Process (AHP). This study has indicated that WLC was useful for identification of the criteria and AHP was useful for prioritization.

In another research carried out by Eskandari et al. (2012) a methodology based on socio-cultural and economical-ecological aspects using multi criteria evaluation integrated with GIS has been suggested to choose a proper MSW landfill site in Marvdasht city. Delgado et al. (2008) have presented three spatial analysis models (overlay analysis, Boolean logic, binary evidence) for MSW landfill site sitting.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_091110

Furthermore, available MSW landfills are evaluated by some procedures, such as Monavari 95-2 (Monavari and Shariat, 2000; Farzaneh, 2003; Ghanbari et al., 2011), Oleckno method (Salimi et al., 2013; Monavari and Arbab, 2005), Drastic (Wang, 2007), USEPA method (Christensen, 1992) and regional and locally screening (Davami et al., 2014; Aliowsati et al., 2013).

Human beings critically influence their environment, therefore, disorder in any element of a municipal system may cause a deficiency in the entire system (Meshkini et al., 2007). Although, various waste disposal approaches have significantly been developed worldwide, land-filling as yet is the most popularly applied procedure in third world countries (Yazdani et al., 2015b; Sumathi et al., 2008). In Iran, MSW land-filling is expanded day by day because of the rapid urban population growth and the changes in consumption patterns (Davami et al., 2014; Eskandari et al., 2012).

The aims of the present research were to show the unsuitability of the current landfill sites in studied area and therefore, addressing the locally preferred criteria for landfill site evaluation in the northern Iran, commonly referred to as the Caspian Landfill Criteria (CLC), using which the most suitable areas for landfill sites were formerly chosen. The final aim of this project was to apply the obtained results to illustrate the lack of suitable regions for MSW landfill.

The landfill sites are serious issues in the western part of Mazandaran due to the geographic conditions, including the proximity of forests and the sea, high groundwater levels and high tourists in holiday seasons, this region is in a more sensitive condition than the other parts of Mazandaran province (Yazdani et al., 2013). After the evaluation of landfill sites and showing the indications of land degradation, it is essential to restore these lands. Numerous researches have been carried out on land recovery after degradation using different methods which can be used in the future. For instance, there has been a report on restoration of mine dunes with fungi species (de Suza et al., 2011). Furthermore, in another study, limestone quarries has been resorted using three approaches; tree and shrub planting, no herb layer and hyseed (Gillardeli et al., 2013). (Pallavicini et al., 2014) have emphasised that environmental factors are very important for soil quality and development. It has also been shown that to forestation on degraded land (Haigh et al., 2013). Moreover, further researches have been carried out on forest restoration as well (Quinonero et al., 2016; Davies et al., 2010). Few studies have been conducted in Iran in the land restoration field (Sadeghi et al., 2015; Fallahzadeh et al., 2015). As to the sustainable municipal solid waste management, a wise plan in the western part of Mazandaran province should be prepared and performed.

Materials and methods

Study area

The studied area (8761.5 km^2) is located in the western part of Mazandaran, Iran, which is situated in the southern coast of the Caspian Sea in northern edge of Iran. In a region consisting about 36.88 percent of the total area of this province about 20.87 percent of the population of Mazandaran province is concentrated (Iranian Statistic Centre, 2010). The 610120 inhabitants of this area generate about 181040 tons of waste per year. The elevation of the studied area varies from 27 meters below sea level to almost 4800 meters above sea level because of locating between the Alborz mountain range and the Caspian Sea. There are three distinct geomorphologic conditions with different weather conditions in the studies area;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_091110

coastal plains and foothills with temperate and humid weather and mountains with cold weather (Mazandaran Governor, 2014).

In Iran, similarly to the other developing countries, landfilling has continued as customarily used procedure despite the increased attention to develop the MSW management (Yazdani et al., 2013; Eskandari et al., 2012; Sumathi et al., 2008). Landfilling sanitary municipal solid waste, just like any other engineering project, requires basic information and planning. The landfill in every area has important effects on environment.

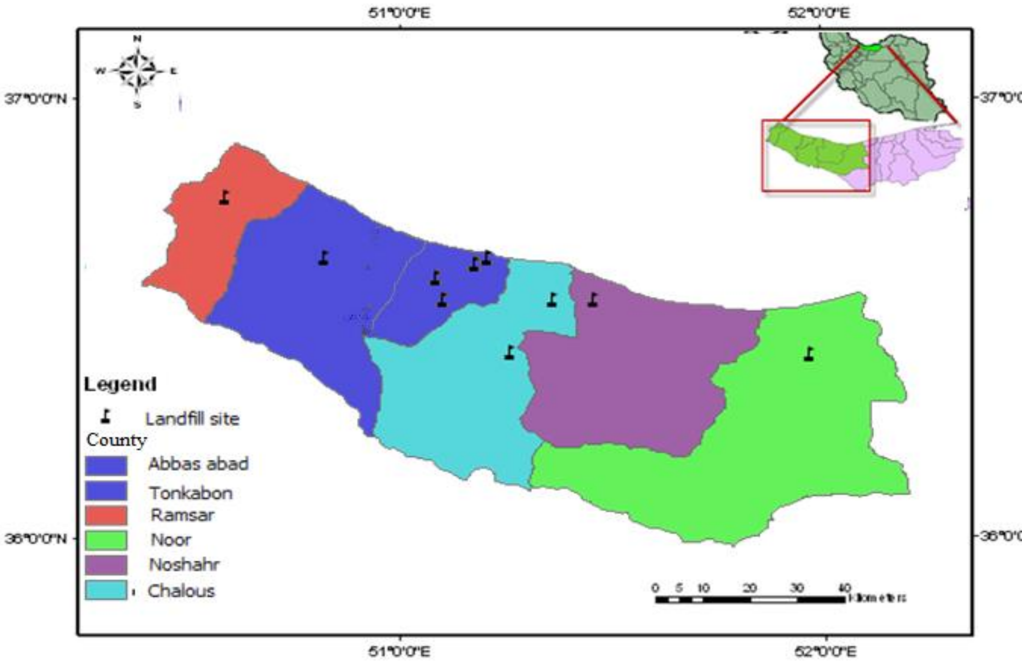

***Figure 1.** Landfill sites in the study area*

Evaluation of the landfill sites using seven standards

The preliminary phase in the environmental impact assessment of landfill site is to know the sensitive parameters. Various methods have been introduced in literatures describing how to select a landfill site (Koshik et al., 2014; Alanbari et al., 2014; Elahi et al., 2014; Salimi et al., 2013; Eskandari et al., 2012; Moeinaddini et al., 2010; Shahabi et al., 2008; Sumathi et al., 2008; Hatzichristos and Giaoutzi, 2006; Heydarzadeh, 2001). The present study applied these methods to evaluate current municipal landfill sites situated in the studied area. In this study, 10 municipal waste landfills (Ramsar, Tonekabon, Abbas Abad, Kelardasht, Salmanshahr, Kelar Abad, Chalous, Marzan Abad, Noshahr, Noor) in 12 municipal districts were initially evaluated using the approved standards based upon the guidelines of British Columbia (BC), Environmental Protection Agency (EPA), Oleckno method, MPCA (Minnesota Pollution Control Agency), Regional Screening, Management and Programming Organization of Iran (MPO) and Iran Department of Environment (DOE). Each method and its criteria are mentioned and compared with each other in *Table 1*, however, the Oleckno index determination is mentioned separately in *Table 2*. In the Oleckno method, the annual average rainfall, soil type and soil depth are the three important

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_091110

factors which are considered to determine the rank of each landfill site. For this purpose the following equation was used (Monavari and Arbab, 2005; Salimi et al., 2013):

Oleckno Index Method Score = rainfall (mm/year) + soil type + ground water table (m)

Table 1. *Comparing the seven methods and their criteria*

Criteria methods	Distance to fault	Soil	Groundwater sources of drinking water	Distance to airports	Flood plain, flood basin	Land use
British Colombia			The distance between the discharged MSW and the nearest residence, water supply well, water supply intake, is to be a minimum of 300 meters.	The distance between an airport utilized by commercial aircraft and a landfill containing food wastes which may attract birds is to be a minimum of 8.0 kilometers.	Landfills proposed for locations within the 200 years floodplain and the associated floodway are not to be sited without adequate protection to prevent washouts.	The distance between the discharged MSW and public park is to be a minimum of 300 meters.
DOE			In areas where the water level is high ,it should be a2-meter-deep layer(made of silt and clay)and maximum permeability millionths of a centimeter per second must be provided	Minimum of 8 kilometers		Landfills should not be in conflict with Populated areas or other land uses distance to farmland 500metres, distance to the major cultural, archaeological and historical sites must be suitable
MPO	Minimum distance of 300 meters		Minimum distance of400 meters from the municipal water wells	Minimum of 3 kilometers		
MPCA (Determinative criteria)				Do not cumulate birds in sensitive area around airport	Distance from area with 100 years retention period flood	
EPA	The distance from faults must be at least 60 meters	Distance to areas with unstable soil		Distance within 3048 meters of runway airports turbojet aircraft, the distance of 1524 m from the runway airports piston aircraft	Distance from area with 100 retention period flood	

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_091110

Regional screening	The distance from faults must be at least 61 meters	The areas with shortage supply of heavy clay and fine grained soil for using coating layers are not suitable for municipal solid waste landfill sitting.	Regions with high underground water levels are not compatible for MSW sites, if the hydraulic trap method is used. At least 300 meters distance from water wells	At least 3 km distance from the airport.		At least distance of 150 m from, commercial, educational and residential centers and at least 80 m from industrial applications. The agricultural land use can be suitable for solid waste landfill sites

Continue ***Table 1.***

Criteria	Surface water (lake, river, lagoon)	Geology	Distance to residential areas	Distance to road	Preserve and bird habitat
BC	The distance between the discharged MSW and the nearest surface water is to be a minimum of 100 meters.	Landfills are not to be located within 100 meters of an unstable area	The distance between the discharged MSW and the nearest residence, hotel, restaurant, food processing facility, school, church or public park is to be a minimum of 300 meters.		The buffer zone between the discharged MSW and the property boundary should be at least 50 meters of which the 15 meters closest to the property boundary must be reserved for natural or landscaped screening (berms or vegetative screens)
DOE	Landfills should not be located in the wetlands and unique habitats Minimum distance of 2000 meters to surface waters	Not to be Placed on faults, underground mines, subsidence and collapse of cavities	Distance of 10-15 kilometers from the city	Distance of 3-5 kilometers to main road	
MPO	Wetlands should not be selected as the burial place ,landfills must be away from lakes ponds more than300meters.Minimum distance of 100 meters to rivers			Minimum distance of 300 meters	

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_091110

MPCA	Minimum 305 meters distance from any lake or pool, Minimum92meters distance from any river or channel, Avoiding from wetlands	Distance from area with limestone caves			
EPA	Landfills should not be located in the wetlands	Distance to high seismic areas, (displacement of rocks and karst areas)			
Regional screening	The MSW landfill sites should not be sited near the surface water (minimum distance of 61 m should be observed).	The regions with slide risk potential and sensitive clays are not suitable for landfill sites. The regions with high sensitive soils such as limestone and fragile soils are not suitable for landfill sites. The MSW landfill site should not be sited in the ravines		A proper distance from the main road should be considered. (Less than one kilometer is ideal)(economic)	

Table 2. *The indices of rank determining in Oleckno method*

The annual average rainfall (mm/year)	**Less than 250 (mm/year)**	**255-760 (mm/year)**	**765-1780 (mm/year)**	
Score	21	7	6	
Soil type	Clay silt or clay and sand	Silt and soft sand	Mud	Gravel and cobble
	12	5	4	0
Soil depth(m)	1.5 - 3	3 - 6	6 - 9	9 <
Score	3	7	9	9
Oleckno rank	Good	Acceptable	Unacceptable	
Score	24 - 42	21-23	>20	

The present study consisted of two phases; first phase included determining the characteristics of the 10 landfill sites by reviewing the library data, previously published literatures and using the ArcGIS software maps (version 10.2). The second phase is to address the locally preferred criteria for landfill site evaluation in the northern Iran for Caspian Landfill Criteria (CLC) model.

Most of the information was obtained from the Mazandaran Management and Planning Office of the Governor with a scale of 1:100000. The hydrology and hydrogeology maps (surface and groundwater maps) with a scale of 1:250000 were

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_091110

obtained from the Geographic Information Centre of the Mazandaran Regional Water Organization. By locating the GPS coordinates of the available landfill sites in field view and entering them as latitude and longitude in the GIS software database the landfill site map layer was prepared. The gathered data were then converted into a point data. Thematic maps, characterizing the affecting factors, were generated for landfill sites evaluation (Yazdani et al., 2013). The map layers of the evaluation criteria in the study area are shown in *Fig. 2*. The steps of the first phase of the present research are illustrated in *Fig. 3*. All the mentioned steps are considered in each of the seven evaluation methods for total research area.

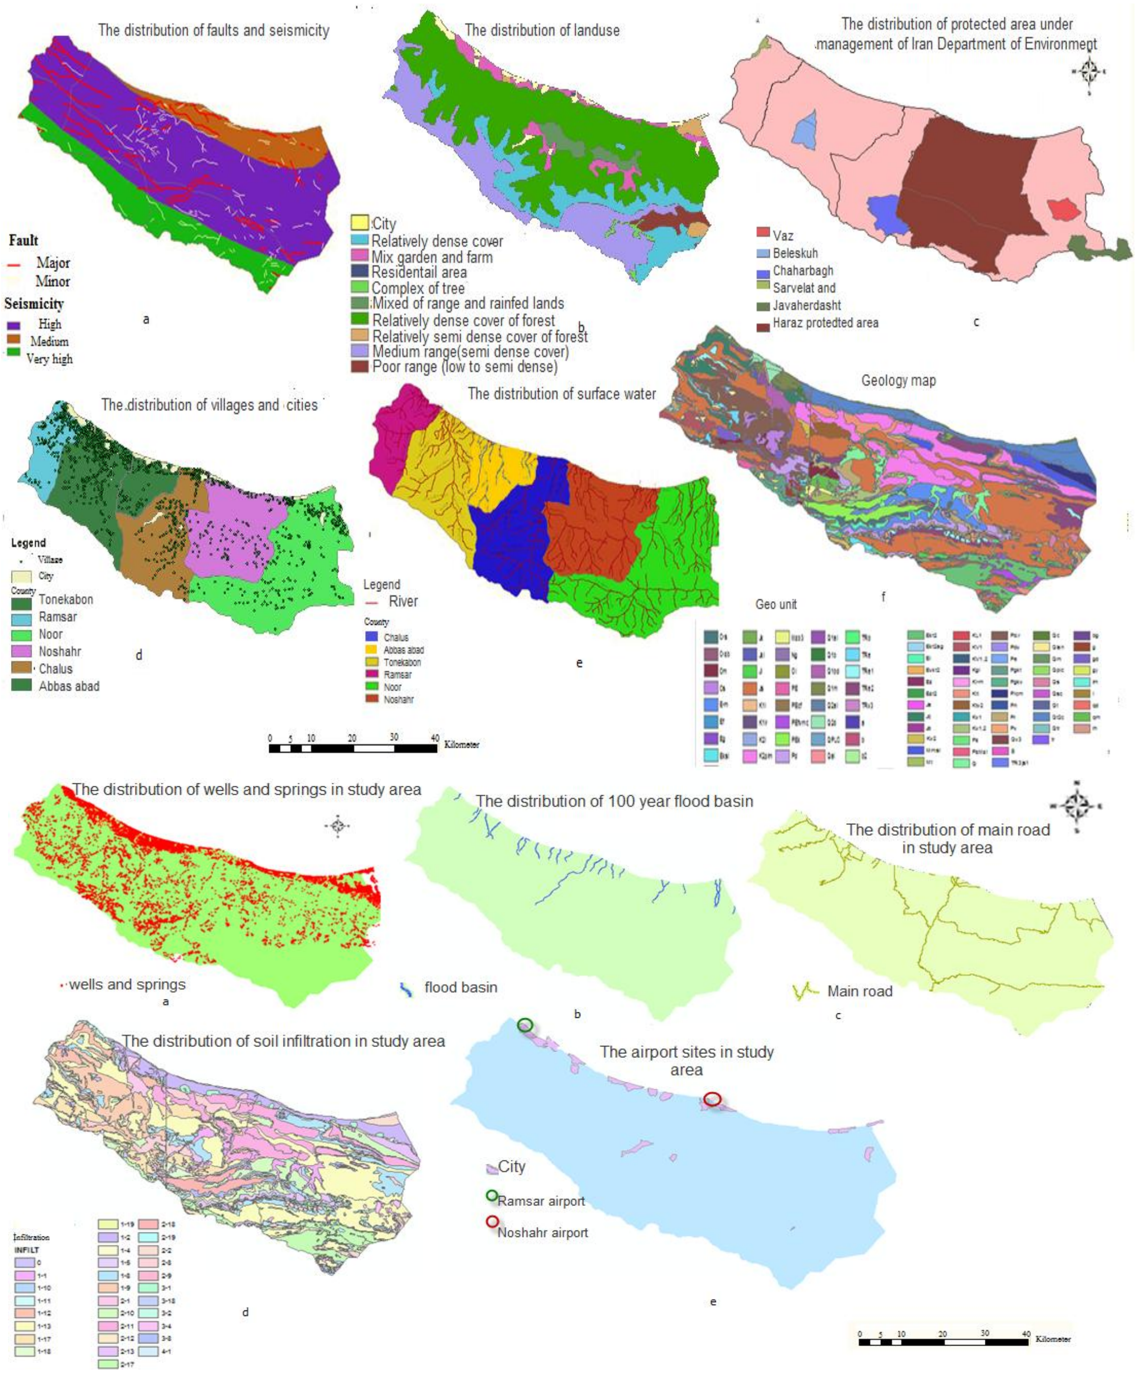

***Figure 2.** Criteria maps in the study area*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_091110

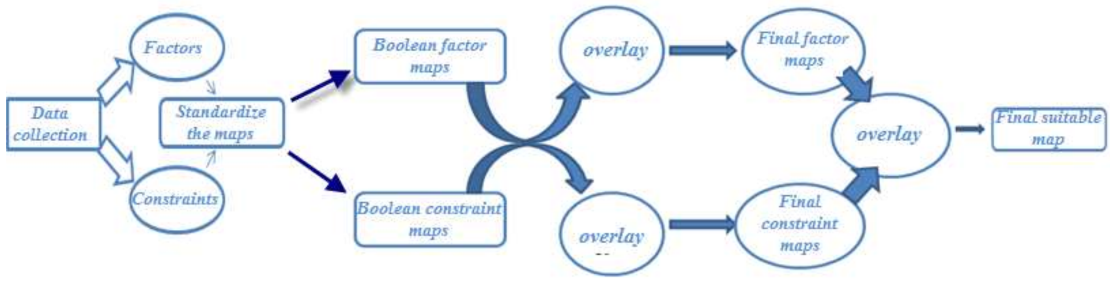

Figure 3. *The research steps in first phase (Yazdani et al., 2015a)*

There were two types of map in first phase of the study; factors (such as faults map and landuse), constraints (such as distance to spring, distance to road, distance to rivers and distance to protected areas). Since there are some regulations applying these seven methods to evaluate landfill sites, Boolean logic was used to standardize the constraint and factor of the map layers. Therefore, all the areas that are impermissible for landfill site sitting according to the 7 guidelines and their principals (constraints) as well as whole areas that fall inside the restricted area (buffers) which landfill site development is prohibited in ArcGIS software with the reclassified module were determined. In map layers the value of the restricted area (unsuitable area) was 0 and that of the other area was 1 (suitable area) (Yazdani et al., 2015a). Different criteria map layers were prepared according to the extant standards which are mentioned in *Table 1*. Buffer maps using the buffer option in ArcGIS were prepared for various criteria. The areas falling inside the buffer areas are unsuitable for municipal solid waste landfill site sitting.

The GIS-based constraint mapping technique was then used to evaluate the suitability of each existing landfill site in studied area considering all the mentioned criteria in each method. The results are shown in *Table 3*.

The overlaying of Boolean factor maps is shown in *Fig. 4* and *Fig. 5* shows the overlaying of Boolean constraint maps in Iran Department of Environment (DOE) method. The final suitable map according to DOE method is shown in *Fig. 6*.

Evaluation criteria for Caspian Landfill Criteria (CLC) model

The second phase of the study consisted of four main stages to select and evaluate landfill site based on the Caspian Landfill Criteria (CLC) model; choosing evaluation criteria using Delphi method, standardizing map layers with Boolean logic and fuzzy

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_091110

functions, application of Analytical Hierarchy Process (AHP) method to identify the importance of the selected criteria and finally combining the information gathered from various criteria to combine a single evaluation index with Multi Criteria Evaluation (MCE).

Table 3. *The suitability of landfill sites with 7 methods in first phase*

Landfill site name	Regional screening suitability	BC suitability	EPA suitability	MPO suitability	DOE suitability	MPCA suitability	Oleckno suitability
Ramsar	Unsuitable	Suitable	Unsuitable	Unsuitable	Unsuitable	Suitable	Suitable
Tonekabon	Unsuitable	Suitable	Unsuitable	Unsuitable	Unsuitable	Suitable	Suitable
Abbas abad	Unsuitable	Suitable	Unsuitable	Unsuitable	Unsuitable	Suitable	Suitable
Kelardasht	Unsuitable	Suitable	Unsuitable	Unsuitable	Unsuitable	Suitable	Suitable

Suitability percent of the total study area	58.17	62.38	77.9	48.5	20	95.32	38.9

Choosing the evaluation criteria

At first, the Delphi technique was used to identify the suitable criteria. This method is an effective tool to achieve a well-thought-through consensus among experts. Delphi technique has been applied in MSW landfill site sitting in the past (Sumathi et al., 2008; Hatzichristos et al., 2006; Koshik et al., 2014). Therefore, the findings of twenty experts in the field, with the most relevant experience, have been included to determine which factors should be considered for alternative ranking. This was accomplished using questionnaire form. A list of criteria based on the 7 mentioned guidelines, as well as a review of the scientific periodicals on previously works was conducted in the questionnaire form. The experts who were familiar with the studied area and participated in the study were requested to supply a list of the preferred evaluation criteria for landfill site selection and evaluation. To data, 18 important criteria have been determined to evaluate landfill sites, and thus, were prepared as input map layers.

Standardizing map layers

Considering the fact that to measure the criteria a variety of scales are used, therefore, it is necessary that the values present in layers of different criteria could be changed into proportional and comparable units. The map layers were standardized in a GIS environment using fuzzy and Boolean logic functions. Boolean logic was used to standardize the constraint map layers. Therefore, in ArcGIS software with the reclassified module was determined. In map layers the value of the restricted area (unsuitable area) was 0 and that of the other area was 1 (suitable area) (Yazdani et al., 2015a). To standardize the factor map layers the criteria-related fuzzy approach was used. To make fuzzy factor maps the threshold should be determined for the values of the criteria, the type and shape of the membership function which are shown in *Table 4* are required.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_091110

The maps were standardized in the 0-255 range for each criterion with 0 as the least and 255 as the maximum suitability range. The linear function which is provided using IDRISI software is applied in the present study.

Due to its high capabilities, IDRISI software was applied to calculate the weights of the criteria, to standardize the criteria by fuzzy functions and also to merge the criteria by MCE model. Therefore, IDRISI software is a suitable option for decision-making using spatial information (Moeinaddini et al., 2010). To quantify the fuzzy diagrams (membership functions), linear scale conversion method was used based on minimum and maximum values as scaling points. In monotonically increasing functions, the linear scale transformation method was used as shown in equation (1) (Eastman, 2012).

$$X_i = 1 - \frac{(Ri - Rmin)}{(R_{max} - R_{min})} * \text{standardized\_range} \quad \text{(Eq.1)}$$

$$X_i = \frac{(Ri - Rmin)}{(R_{max} - R_{min})} * \text{standardized\_range} \quad \text{(Eq.2)}$$

where:
X_i is pixel value after standardization,
R_i is pixel value before standardization,
R min is minimum point in factor,
R max is maximum point in factor,
Standardized _range is range standardization (on a scale of 255 bytes).

In monotonically decreasing linear functions, linear scale transformation method was sued based on equation (2). In symmetric (trapezoidal) functions, a combination of equations (1) and (2) was used. All these steps were carried out in the ArcGIS and IDRISI software with Con conditional statement. In the case of discontinuous functions, such as land use and geological factors, the fuzzy values associated with each class were determined using equation (1).

Table 4. *Factors used to form the landfill site sitting suitability map, with indications on their endpoints (the 2nd one shows to the highest suitability value and the 1st endpoint to the lowest) and their comparative weight, M.I (Monotonically increasing), M.D (Monotonically decreasing) and S (symmetric)*

Criteria [unit of measurement]	End point 1	End point 2	Weight	Fuzzy function

* are mentioned in *Table 5*.

Application of AHP method

After the GIS database for landfill site sitting and the thematic map layers for each criterion were prepared and their importance were identified, a relative classification was carried out for each factor based on the relative influence of each criterion. In this study, analytical hierarchy process (AHP) was applied for pair-wise comparison to create comparative weights. In the AHP, the first step is the decomposition of a difficult complex decision into the easier decision subject to form a hierarchical model. In each hierarchical model, the upside level is the final goal (in this study the goal is landfill site evaluation). In analysis step, simultaneous pair wise comparisons between each both criteria and their relative values was carried out using the Expert Choice software for a simple classification. The comparison matrix was developed for eighteen criteria. The criteria weights are shown in *Table 4*.

Combining criteria using MCE (Multi Criteria Evaluation)

Multi criteria evaluation is mainly used to incorporate the different criteria to form a single evaluation index (Voogd, 1983). After standardization of criteria maps (factors and constraints) and determining the weights factors, the next step was to perform multi-criteria evaluation process. The Boolean intersection logic, AND logic or the multiplied or logic function according to equation (3) were used to integrate layers of constraints and provide the final layer. All criteria weights were considered equal (Eastmen, 2012).

$$C = \Pi c_j \qquad \text{(Eq.3)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_091110

where C is final constraints, Π is multiplied index, cj is constraints criterion j score.

Considering the fact that, the Weighted Linear Combination (WLC) is one of the best and useful methods of multi-criteria decision making (Heydarzadeh 2001), was used throughout this study. In order to perform the assessment process using this method in the present study, each factor (criterion) was multiplied by its corresponding weight according to the equation (4).

The unsuitable areas were omitted by summing the gathered results and multiplying the constraints. Consequently, the suitable area(s) for landfill sitting was obtained.

$$S = \Sigma \, WiXi\Pi cj \qquad \text{(Eq.4)}$$

where S is suitability, Wi is weight of factor i, Xi is fuzzy value of factor i, Π is multiplied index, Cjis is constraints criterion j score.

WLC approach was applied in IDRISI software according to equation (2). After generating a raster map in ArcGIS software (this map is based on the pixel level) using the "Re class" command, (Re class), the final plotted map was divided to 5 sections from 0 as the minimum to 250 as the maximum suitability rate.

Results

After reviewing each waste deposit site, considering all the criteria in every 7 methods applied in the present study, the incoherence in suitability was apparent in first phase. For example, some sites were suitable using one method, but unsuitable using another. The suitability report of the studied landfill sites is shown in *Table 3*. Thus, presenting unique locally parameters suited to particular ecological conditions, seems necessary for evaluating all landfill sites. To achieve a comprehensive and applicable evaluation, the criteria should be defined in accordance with the locally condition of the studies area. The review of all existing methods has shown that none of them have considered the distance from sea, which is critically important for the entire region. Considering the importance of high priority data layers in MCE, the weighting of these layers and the fact that each of these criteria and their importance changes in accordance with the special environmental conditions, it is necessary to localize the criteria for different environmental zones. Therefore, 18 factors were used for alternative ranking (shown in *Table 4*) in CLC model. The map layers of each of these 18 factors are essential to be thought out. Consequently, the eighteen essential evaluation criteria including their regulations and constraints were prepared based on the prior inspections, present regulations, point of view and questionnaires answered by twenty specialists familiar with the field of study and also familiar to studied area (the Delphi method).

Based on the availability of the data, these 18 important criteria were modified in order to evaluate the landfill sites, as input map layers. In the present study, a GIS/MCE integrated method has been used for the data analysis. Furthermore, the results were compared and the accuracy was checked using an AHP/Fuzzy integrated method. *Table 4* indicates that the fuzzy approach was applied for standardization and the weights of each criterion (preferred value). The description of qualitative criteria is indicated in *Table 5*. Five standard maps out of eighteen are showed as samples in *Fig. 7*. The standardized maps were divided into 5 classes in the 0-255 range for each criterion with 0 (unsuitable) to 255 (most suitable areas). In this study, a multi-criteria evaluation approach integrated with Arc GIS overlay analysis was used to choose the most

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_091110

preferable landfill site in studied area. The suitable regions were recognized for landfilling considering the final map layer. In executing the CLC model, the important of the weights and the preferred value of each of the criterion are critical.

In the present study, parameters and their prioritization includes distance to river, distance to population centres, distance to springs and wells, distance to sea, flood plains, distance to lakes and lagoons, the rate of soil infiltration, soil texture and underground level, distance from the airports and main roads, the depth of soil, distance from sensitive habitats and land use, distance from fault and, the least important one, the stone material of context and slope.

The results of this study have been achieved using fuzzy multi-criteria decision making and analytic hierarchy process, which are similar to that used in researches on locating and evaluating landfill sites. This integrated method can be used in areas similar to those in this study or, to be more general, in the coastal regions of the Caspian Sea.

Table 5. *Qualitative criteria description*

Criteria	1	2	3	4	5
Suitability range	Very unsuitable	Unsuitable	Low suitability	Suitable	Very suitable
Bed rock material	Permeable flood basin floor	Sand, stone, limestone, dolomite, deposits range, conglomerates, alluvial fans, alluvial present covenant	Igneous and metamorphic rocks with low breakage and silt	Schist, clay ,tuff, evaporated rock, clay and mud, fine loss	Shale, marl and clay
Soil type (depth and texture)	Shallow to moderately deep soils with limestone, or with gravel bearing	Shallow to moderately deep soils, medium to heavy pebble texture on the rocks, moderately deep to deep loamy to gravelly soil	Deep heavy texture soils in some areas with limestone floor concentration	Deep soil with moderate to heavy texture	Deep soil with heavy texture, moderately deep to deep soils
Land use	Forest, dense range, populated area, river floor	Very low densities of forest ,agricultural lands, Gardens	Semi dense range, agricultural land, incorporating gardens	Poor range, low density other land	Land without vegetation, rocky protrusions
Infiltration	Very high	High	Medium	Low	Very low

Discussion

Unfortunately in Iran, similar to other developing countries, there have been few studies carried out on evaluating current landfill sites. Municipalities rarely consider the ecological properties of an area, adequately, in accordance to the governmental organizations and international standards and the pre-defined criteria before depositing the waste material at the edges of the cities and degrading the valuable natural ecosystems. Therefore, the applicable criteria are hardly used in most of the MSW landfill sites. Comparing the applied criteria indicated that all the criteria have some similar aspects in common. According to the previously studies, some parameters are joined in all methods. These common parameters have been considered in the present study. Parameters such as hydrology, distance form roads and airports and preserving special habitats are some of the factors taken into account in most of the methods due to their crucial significance. The studied parameters and their prioritization can be different based on the ecological characteristics. Choosing a set of effective parameters for selecting the location and evaluation of the landfill sites in relation to the environmental conditions of the studied area is critical and has a direct effect on prioritizing parameters (Sener, 2004). For instance, one study has shown that the highest prioritised parameters in landfill site selection are distance from urban and rural areas, surface water, geology, land use and fundamental instalments and roads, respectively (Khan and Anjaneyulu, 2003). In another study the priority of parameters was distance from geologic faults and the depth of earth, distance to the airports, distance to urban areas, distance to lakes, dams and slope of the soil, land use, paths network and in final run the least priority belonged to instalments and telecommunication (Delgado et al., 2008). In this study, preservation of the ecosystems of the vast water resources, both underground and surface, as well as the Caspian Sea was the preeminent concern. (Tajziehchi and Monavari, 2013) mentioned in their research that geographical features and special environment in this region are the main reasons for the complex landfill site sitting process. All of the considered criteria in this study and previously researches are

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_091110

to prevent land degradation and protect the environment. To evaluate the landfill sites in the studied area in the present research, which is situated in western part of Mazandaran province, noble approaches are required because of its special topographic conditions (closeness to the forest and the sea), high level of underground water and high rate of tourism (especially in spring and summer). Considering the importance of prioritizing the data layers in multi-criteria evaluation and defining the value of the layers based on their specific ecological conditions, the criteria and their importance can be changed. Therefore, locally criteria—Caspian landfill criteria—appropriate to the ecological condition of the area has been presented.

Conclusion

This research shows the incoherence in suitability status of the 10 current landfill sites in west area of Mazandaran province with using seven different landfill site sitting approaches. In second phase, the proposed Caspian Landfill Criteria with effective and native criteria has been used to determine the status and (un)suitabilty of the current landfills and the studied area. The suitability of the CLC (Caspian Landfill Criteria) model for landfill site sitting and evaluation of the current landfill sites were considered through field observations. Finally, only about 0.4% of the whole studied area was appropriate for landfilling. The most principal parts in the CLC model were the importance of the weights of the criteria and the preferred weights of them which in this research, distance to residential area parameter has the highest and slope has the least weight. As the findings of the present study have revealed, there are insufficient suitable areas in the western part of Mazandaran province for landfill site sitting. Furthermore, landfilling is not an appropriate approach for waste disposal in this region. There for other approaches should be considered for waste disposal with regard to the environmental characteristic of this specific region. The results of this study have been achieved using the same method applied for processing the consequent and phasic analysis in multi-criteria decision making in researches on locating and evaluating the landfill sites. The Caspian Landfill Criteria model with effective and native criteria has been used to determine the status of the current landfills and recognize the ruined areas, which are a good illustration of land degradation, in order to achieve an optimal management approach to convert the land into a sustainable natural ecosystem of the southern coast of the Caspian Sea.

(Received 23rd Feb 2017; accepted 19th May 2017)

Abstract. The use of mineral fertilisers causes soil degradation; however, there are alternative systems such as the application of effective microorganisms (EM), although this technology is not fully studied in Africa. The objective of this greenhouse experiment was to assess the response of Swiss chard (*Beta vulgaris* subsp. cicla) and soil chemical properties to EM. The crop was harvested twice - after eight and sixteen weeks. The experimental design was randomised complete block design, treatments were: control, EM, recommended fertilizer (RF), RF + EM, compost, compost + EM, 1/2 RF + compost, 1/2 RF + compost + EM, goat manure (GM), GM + EM, 1/2 RF + GM, and 1/2 RF + GM + EM, with six replications and each pot represented an experimental unit. The first yield was higher than the yield from the second harvest, except for the GM treatments due to nitrogen immobilisation. Yield was improved by 32.5% for the second harvest where GM was applied owing to improved nutrient availability. The application of fertiliser doubled the yields, which were not reduced when half of the recommended fertiliser was applied with GM or compost. The results confirm that EM's application had inconsistent effects on Swiss chard yields and soil properties.
Keywords: *Beta vulgaris subsp. cicla, mineral fertiliser, organic manure, effective microorganisms, soil properties*

Introduction

The use of effective microorganisms (EM) in agricultural soils as an amendment for disease control and maintenance of healthy resilient soils was reported by Daly and Stewart (1999), and Hu et al. (2013). EM are a microbial culture of a naturally occurring assortment of beneficial microorganisms such as photosynthetic bacteria (*Rhodopseudomonas plastris* and *Rhodobacter sphacrodes*), lactic acid bacteria (*Lactobacillus plantarum*, L. casei, and *Streptococcus lactis*), yeast (*Saccharomyces* spp), actinomycetes (*Strptomyces* spp.) and fermenting fungi that coexist together (Bell et al., 2013; Hu and Qi, 2013; Boga et al., 2014; Daur et al., 2015). EM are used as an inoculant to increase the microbial biomass diversity of soils through a rapid proliferation of their constituents (Javaid and Bajwa, 2011; Bhalla et al., 2013; Khan et al., 2013). Application of EM solution to soils enhances the growth of other microorganisms and a colony forming units (CFU) of 110000000 per gram on TS agar has been recorded (Javaid and Bajwa, 2011).

EM improve crop quality, growth and yield through effective mineralisation of soil organic matter (Megali et al., 2014; Daur, 2015, 2016; Xu et al., 2016) and are applied

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_10091022

with a carbon and energy source of molasses for the microorganisms (Mayer et al., 2010; Ahn et al., 2014). The integrated use of EM with organic amendments is an effective technique for enhancing nutrient release and supply from the sources. The mechanism of EM activities for rapid nutrient release from organic amendments involves a rapid proliferation of its effective and beneficial microorganism content within the soil system (Bouws and Finckh, 2008; Gabhane et al., 2012).

Some studies have shown that the inoculation of soils with EM can improve soil and crop quality (Javaid and Bajwa, 2011; Megali et al., 2014; Javaid and Bajwa, 2016). Research and field testing of EM were conducted in the Asia Pacific region (Bajwa et al., 1995; Bajwa et al., 1999; Hussain et al., 1999; Iwaishi, 2000; Hu and Qi, 2013; Daur, 2015, 2016; Xu et al., 2016), Switzerland (Mayer et al., 2010; Megal et al., 2013), Africa (Ncube et al., 2011; Ncube and Brutsch, 2012) and New Zealand (Daly and Stewart, 1999) where the application of EM to onions, peas and sweet corn increased yields by 29%, 31% and 23%, respectively. Khaliq et al. (2006) reported that the integrated use of compost with EM increased seed cotton by 44% over the control treatment. The application of EM with 50 Mg ha^{-1} of animal manure and 30 mg ha^{-1} of a combination of various green crop residues and weeds separately, increased the production of polysaccharides, alkaline phosphatase and esterase enzymes (Valarini et al., 2002). The application of compost A with EM resulted in the highest strawberry yield and quality (Hammad et al., 2014). In a study conducted by Megali et al. (2014), application of EM increased plant growth fruit production by 61% and plants sustained 25% higher insect survival.

EM are effective in improving plant and soil quality, but studies conducted at the University of Fort Hare (Ncube et al., 2011; Ncube and Brutsch, 2012) did not detect a substantial contribution to crop yield by the recommended application of EM in combination with commercial compost. This was attributed to the low-quality C constituents in the compost used, which is typical of most compost that have matured. Composted organic wastes are low in soluble C, because microorganisms use most of it during the composting process (Groenestein and van Faassen, 1996; Boechat et al., 2013). Therefore, mature compost such as the one used in the earlier study may not be able to effectively support proliferation of the decomposer community, including EM.

The objective of the study was to evaluate the single and integrated application of EM with fresh and composted organic sources of nutrients on the yield of Swiss chard (*Beta vulgaris* subsp. cicla) grown in Oakleaf soil in pots.

Materials and methods

Soil, goat manure and the compost characteristics

The soil used in this study was from the research farm of the University of Fort Hare in Alice, Eastern Cape, South Africa. The farm is located at 32° 47′ S and 26° 50′ E and 535 m above sea level (asl.). The farm is situated in a semi-arid ecological zone that has an average annual rainfall of approximately 575 mm during the summer and a mean daily temperature of 22.5°C during the day and 18.8°C at night. In winter the temperatures are about 13.6°C during the day and below 10.3°C at night (Marais and Brutsch, 1994). The soils are of an Oakleaf form (Oa), belonging to the Jozini series (Soil Working Group, 1991). The soil characteristics are as shown in Table 1. An equivalent of 30 t ha^{-1} of goat manure was applied (which supplied 657, 30, 135 kg ha^{-1} of N, phosphate (P), and potassium (K), respectively) (*Table 1*). Thirty t ha^{-1} of nature's

grow compost were applied (which supplied 60, 15 and 12 kg ha^{-1} of N, P, and K, respectively) (*Table 1*).

Treatments and experimental design

The experiment was conducted in a glasshouse whose conditions are controlled at the University of Fort Hare, South Africa, and was laid as a randomised complete block (RCB) with six replicates. Treatments were: control (T1), EM alone (EM) (T2), recommended fertiliser (RF) (N 150: P 90 kg ha^{-1}) (T3), RF + EM (T4), compost (Comp) (T5), comp + EM (T6), 1/2 RF (N 75: P 45 kg ha^{-1}) + comp (T7), 1/2 RF + comp + EM (T8), goat manure (GM) (T9), GM + EM (T10), 1/2 RF + GM (T11) and 1/2 RF + GM + EM (T12). Two plants of Swiss chard were planted in each pot with a depth of 30 cm containing 15 kg of soil as an individual experimental unit. The soil moisture was kept at field capacity during the course of the experiment. Swiss chard was used in this study due to an increasing awareness on the importance of leafy vegetables in the daily diet which has prompted an increasing demand for the fresh vegetable crops such as Swiss chard throughout the year in South Africa (Abdel-Rahman et al., 2014). Moreover, Swiss chard is known for its high nutritional value due to its high levels of antioxidants and vitamins (Mitic et al., 2013). The crop was harvested at the eighth and the sixteenth week. Inorganic fertiliser was incorporated into the soil, with N applied in the form of NPK prior to planting and as LAN three weeks after transplanting.

Effective microorganisms (EM)

Multiplied - EM, EM - F.P.E, EM 3-in-1 and EM -5 were the EM products used. The Multiplied-EM was dissolved in water in a ratio of 1:300 and applied as a soil drench at a rate of 200 L per experimental unit, 7 days prior to transplanting of Swiss chard.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_10091022

During the experiment, multiplied - EM solution, in a ratio of 1: 500, was applied to respective EM - treated units at a rate of 50 L per week. Mixtures of EM - FPE, EM 3-in-1 and EM - 5, mixed at a ratio of 1: 1: 1, then diluted with water at a ratio of 1: 800 were sprayed to control diseases and pests in EM treated units (Ncube et al., 2011).

Soil and leaf analysis

Soil and leaf samples were taken at harvest to assess the treatment effects on soil and plant nutrient content. For leaf sampling, the youngest mature leaves were taken from the top of plants (Hue et al., 2012). The leaf dry matters were dried in an oven at 65 °C and were ground in a hammer mill to pass through a 1 mm mesh sieve. Total P and K contents were determined as described by Okalebo et al. (2002). Total nitrogen was determined using a LECO TruSpec C/N auto analyser (LECO Corporation, 2003).

Crude protein is an estimate for total protein. Crude Protein (CP) is based on a laboratory nitrogen analysis, from which the total protein content can be calculated by multiplying the nitrogen figure by 100/16 or 6.25. This is from the assumption that nitrogen is derived from protein containing 16 % nitrogen (Okalebo et al., 2002). Therefore, crude protein was calculated by multiplying total N x 6.25.

Soil samples were air-dried for two weeks and then were ground to pass through a 2 mm mesh sieve. Soil pH and EC were determined in water extracts as described by Okalebo et al. (2002). Total N and C were determined using a LECO TruSpec C/N auto analyser (LECO Corporation, 2003) and extractable P and K were determined following the Ambic - 2 extraction method (Non-Affiliated Soil Analysis Work Committee, 1990).

Data analysis

The data were subjected to analysis of variance (ANOVA) using the SAS statistical package and means were compared with Tukey test ($p \leq 0.05$).

Results and discussion

Effects of amendments on dry matter yield of Swiss chard

Yield obtained during the second harvest was lower than yield obtained during the first harvest. Yield decreased by 46.2%, 44.2%, 51.3%, 56.6%, 44.1%, 44.3%, 68.0%, 67%, 43.3% and 57.9% for T1, T2, T3, T4, T5, T6, T7, T8, T11 and T12, respectively (*Figure 1*). The application of goat manure with or without EM significantly increased yield for the second harvest. An increase in yield of 61.3% and 84.3% for the second harvest was observed with T9 and T10 relative to the control (*Figure 1*). The positive effects of incorporating goat manure with or without EM observed during the second cropping suggests that soil production was better maintained under goat manure treatment, possibly as a result of nutrients being slowly released over a period of time as suggested by Cooke (1972; Neina et al., 2016a). Application of goat manure to soil decreases nutrients sorption capacity and increases their availability to plants. This is thought to result from the cumulative effects of various processes such as preliminary soil incubation, soil microbial activities, moisture content, incubation temperature, soil pH, N mineralisation and ammendment biochemistry. The immobilisation of nutrients by native soil microbial biomass in response to added manure may also increase its availability to plants. Native microbial biomass apparently increases nutrients

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_10091022

availability by immobilizing soil inorganic nutrients and releasing them at a later stage through mineralization during microbial biomass turnover. The nutrients is released slowly and taken up by the crop more efficiently and may account, at least in part, for the observed synergistic effects on crop growth observed (Gichangi et al., 2010; Calvalho et al., 2013; Neina et al., 2016b). Therefore, nutrients contained in manure are primarily organic and must be mineralised before they are used by plants.

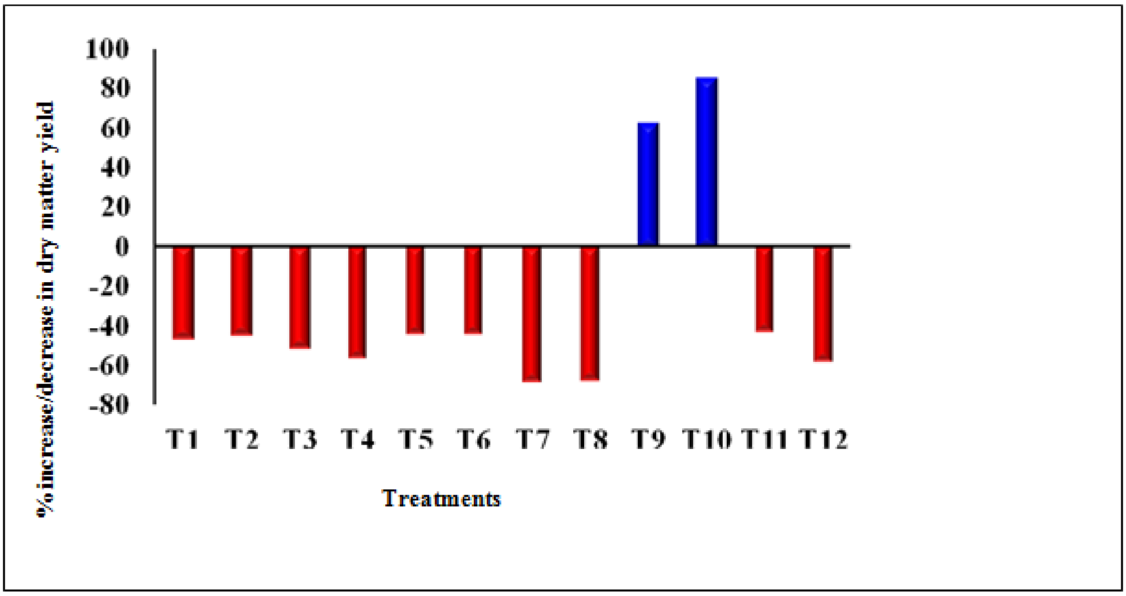

Figure 1. *Effects of amendments on dry matter yield of Swiss chard*

The performance of EM and compost was not as expected when applied alone or in combination (*Figure 2*) and their performance was speculated to have been affected by the soil organic C, which was low (0.6%). In soils with low organic C, release of nutrients from compost materials is relatively low and cannot increase yield to the same level as the mineral fertilisers. The added compost in soils with low organic C could be first utilised by native soil microbes, as plants and microbes compete for applied N (Khaliq et al., 2006). Unlike microbes, plants require more energy for nutrient absorption and uptake so that microorganisms become successful in utilising most of the applied N. The release of nutrients from compost materials, their absorption by plants and the remineralisation of immobilised nutrients require time and might not be attained within a few weeks (Hussain et al., 1999).

With regards to the performance of EM, researchers have shown that it is difficult to establish the predominance of EM cultures in soil within a few weeks. Indigenous soil microbes often affect the establishment of EM negatively (Bajwa et al., 1995). However, the problem can be overcome through prolonged, repeated applications of EM (Javaid et al., 2000). Soil type, the source and amount of soil nutrients, as well as the test crop can also affect the establishment and performance of EM (Bajwa et al.,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_10091022

1999; Javaid et al., 2002; Javaid, 2010). In a 4-year field experiment under organic management (2003–2006) in Zurich, Switzerland, application of EM did not improve yields and soil quality (Mayer et al., 2010).

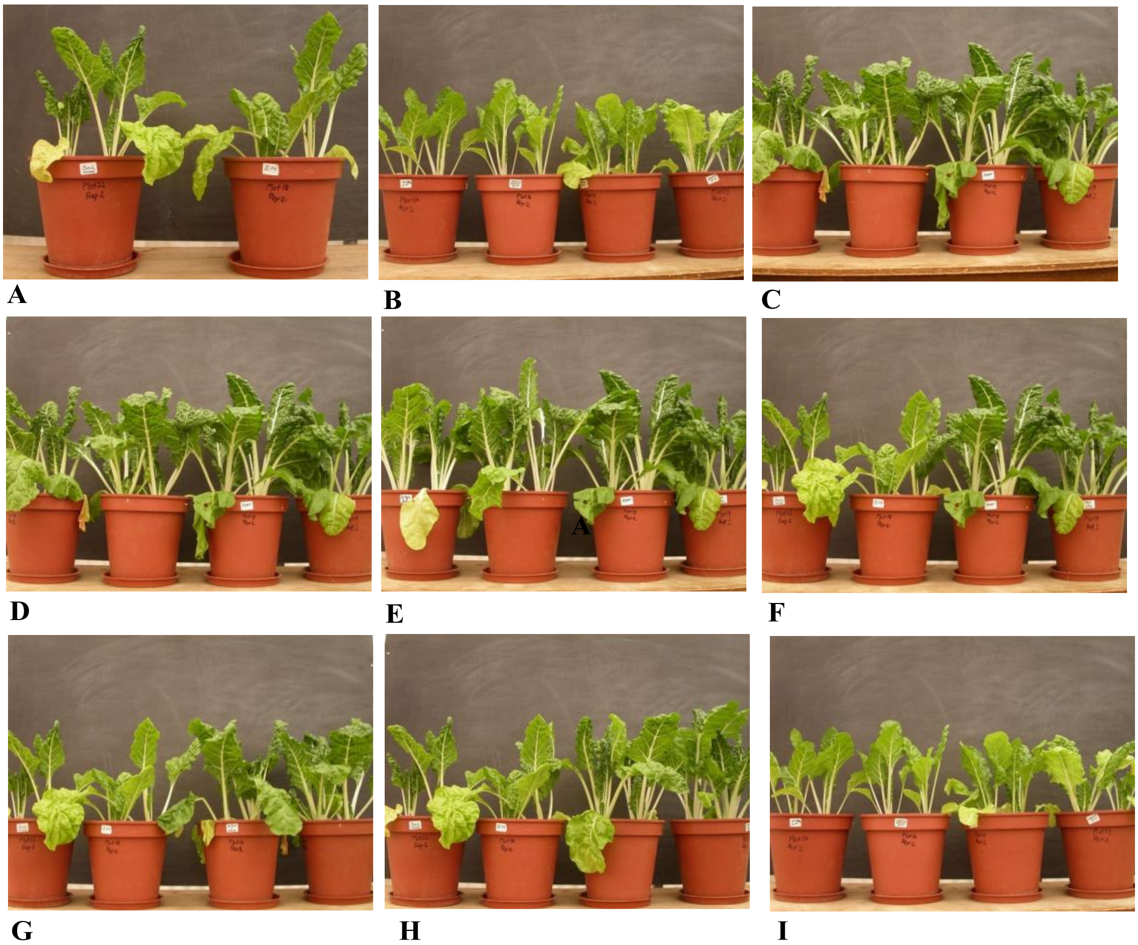

Figure 2. *Swiss chard plants growing in the greenhouse*

The application of the reference fertilisers (T3 and T4) caused a significant increase in yield for both the first and the second harvests (*Figure 3*), possibly due to the immediate release of nutrients from the added reference fertiliser. The application of T7, T8, T11 and T12 resulted in yield that was equivalent to that obtained with the application of the reference fertiliser (T3 and T4). These results indicate that half of the required mineral fertilisers can substitute half of the required fertiliser amount, possibly because of greater amounts of N and P supplied to the soil. Similar results were obtained by Khaliq et al. (2006), where the application of OM + EM + 1/2 mineral NPK

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_10091022

yielded 2 091 kg ha^{-1} of seed compared to 2 165 kg ha^{-1} obtained from the recommended mineral NPK.

It is noteworthy that yield obtained from the control and treatments other than goat manure declined in the second harvest (*Figure 3*). This could be attributed to a decline in nutrient content as a result of nutrient removal by the first crop. The removal of nutrients by the first crop is confirmed by higher levels of leaf N content and subsequent N uptake by the first crop compared to the second crop (*Table 2*). Leaf P content increased during the second cropping and this ruled out the possibility of P limiting plant growth during the second cropping. These results are similar to those obtained by Tanner and Mugwira (1984). In their study, the application of manure to soil resulted in an increase in nutrient uptake by the second crop rather than the immediate crop. The implication of these results is that farmers should take measures to ensure that nutrients in organic material become available before plants begin their rapid development. Similar results were also obtained by Zhao et al. (2014).

Effects of amendments on leaf nutrient content

Leaf nutrient contents is a good predictor of plant responses to nutrients supplied through soil applied fertilisers. Nutrient management in organically managed soils is fundamentally different to soils managed conventionally, however, the underlying processes supporting soil fertility are not. This suggests that, although soil fertility is theoretically better in organic management, if there is a balanced supply of nutrients, i.e. there are no deficiencies or excesses of a nutrient that cause excessive consumption, the plant will take the nutrients in proportion to their needs (Herencia and Maqueda, 2016).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_10091022

There were significant ($p \leq 0.05$) treatment effects on leaf N content of both harvests (*Table 2*). Leaf N content ranged from 1.34 g kg^{-1} to 3.79 g kg^{-1} in the first harvest and 1.12 to 1.73 g kg^{-1} in the second harvest. The application of reference fertiliser significantly increased leaf N content of both the first and the second harvests as compared to the control. The highest leaf N concentration was observed with respect to the application of the reference fertiliser with EM in both the first and the second harvests. The application of half the reference fertiliser with compost resulted in a significant increase (18%) in leaf N content as compared to the control in the first harvest. Nitrogen is a critical component of proteins and biomolecules such as chlorophyll in plants (Fu et al., 2017). A similar trend was observed with respect to leaf N uptake, with the highest leaf N uptake being observed with reference fertiliser + EM treatment in both harvests. Due to the close relationship between N and protein, a similar trend was observed with crude protein in both harvests.

Leaf P content ranged from 0.06 g kg^{-1} to 0.14 g kg^{-1} in the first harvest and from 0.10 g kg^{-1} to 0.25 g kg^{-1} in the second harvest. Leaf P content remarkably increased from a depressed state in the first harvest to a significantly higher figure in the second harvest. The application of goat manure caused a significant ($p \leq 0.05$) increase in leaf P content relative to the control treatment (*Table 2*). It is known that with the addition of organic nutrients, the supply and availability of P is high in soils (Herencia et al., 2008). Manure application rates are routinely based on crop N requirements, which might have resulted in more P than is needed by the crop and this can cause a buildup of P in the soil (Edmeades, 2003) and consequently in plants. The P/N relationships for adequate crop development are usually 1/10 (Herencia and Maqueda, 2016), however, in the goat manure used in the current study, the P/N relationship was about 1/21.9. This amount would be in excess of the crop's needs. The application of goat manure with EM resulted in leaf P content that was significantly lower than that of the control.

Effects of EM, goat manure, compost and mineral fertiliser on selected soil properties

Post-cropping soil pH was significantly ($p \leq 0.05$) affected by different soil amendments (*Table 3*). The application of the reference fertiliser significantly depressed post-cropping pH, which declined to levels that were moderately acidic (*Table 3*). A similar trend was observed with the application of half reference fertiliser with compost (T7) and half reference fertiliser with compost and EM (T8).

The application of goat manure alone (T9) or with half the reference fertiliser (T11), without or with EM (T12), significantly increased post-cropping soil pH relative to the control treatment. The highest post-cropping pH was observed with the sole application of goat manure (T9). These results indicate that goat manure has a liming effect, whereas the mineral fertiliser has acidifying effects. The liming effects of goat manure can be of great value in areas like the Eastern Cape, South Africa, parts of which have critically low soil pH (Mandiringana et al., 2005). Similar results were obtained by Mhlontlo et al. (2007), in whose study the application of sheep kraal manure at rates greater than 2.5 t ha^{-1} resulted in higher pH values compared to the control and the mineral fertiliser treatments.

Means in a column with a different letter are statistically different (LSD test; $p \leq 0.05$)

The highest EC value was observed in plots where the reference fertiliser was applied. A similar pattern was observed in respect of the application of sole goat manure or goat manure in combination with half the reference fertiliser, with or without EM.

There were significant ($p \leq 0.05$) treatment effects on residual soil N concentration (*Table 4*), although the values did not significantly differ from the initial concentration. Soil N levels associated with the reference fertiliser, half the reference fertiliser + compost + EM, goat manure, goat manure + EM, half the reference fertiliser + goat manure, and half the reference fertiliser + goat manure + EM were significantly higher than those of the control treatment, suggesting that the plants did not exhaust N from these added amendments (*Table 3*). The increase in N that was observed could possibly be due to the slow release of nutrients through mineralisation from these organic materials. The application of goat manure + EM resulted in the highest soil N and C contents, suggesting that EM increased the mineralisation of goat manure applied to the soil.

A similar trend was observed with soil C, and the greatest amounts of soil N and C were observed in soils treated with goat manure and EM together. The observed decrease in the soil C:N ratio indicated a build-up of the N pool in the soil. The application of different amendments decreased extractable soil P to below initial levels. The highest extractable P was observed in respect of the application of reference fertiliser, suggesting that the crop had not exhausted the soil P from the fertiliser that had been applied.

Soil residual K in pots treated with goat manure, goat manure + EM and half the reference fertiliser + goat manure, and EM was significantly higher than that of the control treatment. The highest soil residual K was observed in pots where goat manure

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_10091022

was applied with EM, although the manure used had a relatively low concentration of K. Kraal manure has, on average, about 2% K, which is far higher than the 0.5 % contained in the goat manure used (Bornman et al. 1989; Kizzar et al., 2010; Materechera and Mkhabela, 2016). General residual soil K in all the amendments exceeded the critical level of 80–120 mg kg^{-1} suggested by Bornman et al. (1989). Results from this study are consistent with what was reported by Laker (1976) and Ayanda et al. (2016), namely, that most South African soils are not deficient in K.

Conclusion

EM application had inconsistent effects on Swiss chard yields. The use of goat manure with a narrower C:N ratio than the compost used in earlier studies did not improve EM effectiveness, indicating that the observed ineffectiveness of EM was not related to the quality of the organic material used. However, the results of this study show the benefits of the combined application of organic amendments with half of the recommended mineral fertiliser over the separate full application of inorganic fertiliser or organic amendment.

(Received 15th Mar 2017; accepted 31st May 2017)

Abstract. Migration often leads to the loss of what is known as the "healthy immigrant effect" due to the adoption of unhealthy eating habits upon resettlement in host countries. A descriptive study was conducted to assess the current food practices of sub-Saharan immigrants residing in Gauteng Province, South Africa. Questionnaires were administered to 194 female participants residing in Gauteng. Data relating to socioeconomic factors, the adoption of South African food culture in general and specific food items that have been adopted were collected. The association between food adoption and socioeconomic factors was tested. Among the households polled, 78.4% had adopted South African food to varying degrees. Four adoption patterns emerged: strict continuity with traditional food; very limited adoption; limited adoption; and complete adoption of South African food culture. With regard to the association between food adoption and factors tested, the region of origin (p<0.000) was highly significant, while money spent on food was marginally significant (p<0.077). Dietary acculturation was characterised by a high intake of energy-dense, high-fat and low-micronutrient foods. Culturally appropriate nutrition education studies are required. Future studies should assess the impact of these dietary patterns on health outcomes among immigrants living in South Africa.
Keywords: *dietary acculturation, dietary patterns, food culture, food adoption patterns*

Introduction and background

Recent immigration trends indicate that 70% of all international migration is interregional and takes place within the African continent (Adepoju, 2008). Consequently, ever since the apartheid dispensation ended in 1994, South Africa has seen an increase in the number of sub-Saharan immigrants due to unstable economic conditions, soaring ethnic conflicts, volatile political situations and drought situations in most African countries (Njomo, 2013; Statistics South Africa, 2014a). However, research has shown that immigrants undergo dietary acculturation upon settlement in new countries (Garnweidner et al., 2012; Njomo, 2013) due to unavailability and inaccessibility of their traditional ingredients in the host countries (Garnweidner et al., 2012; Deng et al., 2013). Dietary acculturation is defined as the process by which immigrant minority groups adopt the dietary habits of the host society (Deng et al., 2013).

Dietary acculturation often results in the adoption of unhealthy eating habits (Okafor et al., 2014; Terragni et al., 2014) and subsequent loss of what is known as the "healthy immigrant effect" (HIE) (Sanou et al., 2014). HIE is defined as a situation whereby immigrants are usually healthier than native-born population when they first arrive in host countries due to medical screening they are subjected to as part of the selection

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_10231038

processes (Sanou et al., 2014). However, upon settlement in host countries, previous studies indicate (Lesser et al., 2014; Sanou et al., 2014) that immigrants loose the Healthy Immigrants Effect due to, among other factors dietary acculturation. Evidence suggests that African immigrants are at risk of weight gain and poor health outcomes owing to their poor food choices, when compared with immigrants from other continents (Venters and Gany, 2011; Okafor et al., 2014). According to Venters and Gany (2011), this could explain why the leading chronic diseases among African immigrants are hypertension and diabetes, which are lifestyle diseases.

It is reported that immigrants tend to increase their intake of ready-to-eat processed foods because they are unfamiliar with new foods and cooking items (Deng et al., 2013). According to a study that was conducted among Somali refugees in the United States of America (USA), the intake of snacks and sugary beverages increased significantly in this group of immigrants upon resettlement (Dharod et al., 2011). Replacing high-nutritive food with high-fat and calorie-dense food was also reported in a study that was conducted among Latin American immigrants residing in Toronto (Vahabi and Damba, 2013). Higher dietary acculturation characterised by increased consumption of fast foods and meat and a decrease in the consumption of fruits and vegetables was reported in a study that was conducted in the USA among African immigrants (Okafor et al., 2014). This places immigrants at a higher risk of developing lifestyle diseases – a situation which, if left unattended, could place an enormous burden on the health system of the host country. Sanou et al. (2014), in a review of acculturation studies conducted among immigrants living in Canada, argue that the burden of lifestyle diseases increases consistently after immigrants' settlement in host countries.

Although most studies on dietary acculturation have been conducted on immigrants moving from developing to developed countries, an increase in the intake of sweets, sweet baked goods and sweetened fruit drinks was reported in a study on Liberian immigrants residing in Ghana (Ross et al., 2016). This suggests that immigrants moving from one developing country to another are not immune to these unhealthy dietary changes when settling in developing host countries. Two past studies conducted in South Africa showed that sub-Saharan immigrants consume their indigenous foods at least three times a week (Njomo, 2012, 2013). The question, then, is what happens during the others days of the week? It is possible that some level of dietary acculturation is taking place among this group. Furthermore, what could be the possible implications of this dietary acculturation on the “Health Immigrant Effect”? However, there is no evidence of studies that have investigated dietary acculturation or factors that affect dietary acculturation among sub-Saharan immigrants living in South Africa.

The authors of this paper had three objectives: (1) to assess the dietary patterns of sub-Saharan immigrants residing in Gauteng; (2) to identify patterns of dietary acculturation among sub-Saharan immigrants upon resettlement; and (3) to identify factors that significantly affect the adoption of South African food.

Methods

Research design

A descriptive survey study design was adopted to obtain responses that would fulfil the objectives of this study. The study was conducted in Tshwane and Johannesburg

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_10231038

because these two metropolitan municipalities together host the largest number of immigrants (Landau and Gindrey, 2008; Njomo, 2013).

Study area

South Africa does not have statistics on all immigrants currently residing in the country (Statistics South Africa, 2013). Therefore, information on the number of permits that were issued by the Department of Home Affairs in 2011 and 2013 was considered (Statistics South Africa, 2013, 2014a) when determining the regions to be included in this study. According to Statistics South Africa (2016), the majority of immigrants are from Southern Africa, followed by Central Africa and then East Africa. Therefore, for the purposes of this study, only immigrants from these regions were considered for this study.

Development of questionnaire

Literature from previous research informed the objectives of the study, which were used to develop the survey questionnaire. Gaps in the literature indicated the need to gain a greater understanding of the dietary patterns, acculturation and factors that affect dietary acculturation of sub-Saharan immigrants in South Africa. For the purposes of clarity, relevance, language and cultural appropriateness, the first draft of the questionnaire was reviewed independently by four sub-Saharan immigrant academics that have been residing in the country for over 15 years. Feedback was discussed by all authors to reach consensus before changes were effected.

The following changes were introduced, based on the recommendations of the reviewers: An option for self-employment was added; categories of income levels were created, rather than making this question open-ended; possible reasons for wanting to continue with the traditional food culture were added, from which respondents could choose; the wording of some questions was revised to make them more relevant to the target community (e.g. the term “food safety” was deemed to be unclear and was therefore changed to “quality of the food”); and owing to the diverse origin of immigrants, the question on the country of origin was changed to region of origin. The final draft questionnaire was then circulated to a group of 20 academics for final review.

The questionnaire was piloted on 34 female participants representing households from Southern, Central, East and West African regions. Two major changes were made, based on the results of the pilot study. Among the Southern African immigrants, the highest number of immigrants were from Zimbabwe, accounting for approximately 42.2% of the permits that were issued (Statistics South Africa, 2013, 2014b, 2016). During the pilot study, it was discovered that there was not much difference between South African and Zimbabwean food culture; therefore, the Southern African region was dropped from the main study. The question about the immigration status was also excluded, as most respondents were not comfortable answering that question. The final questionnaire had 4 sections aimed at capturing data on: socio-demographic and economic details of the respondents, adoption of the South African food, food items that have been adopted since settled in South Africa and 3-day food recall.

Selection of participants

The study targeted women, who are habitually responsible for food preparation in most households in African societies (Garnweidner et al., 2012; Njomo, 2013). In this

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_10231038

study, owing to the lack of a sampling frame, it was not possible to adopt random sampling, which is known to yield representative samples. Furthermore, since relatively little is known about the phenomenon under investigation, snowball sampling was considered the most appropriate sampling technique for the study. Churches that host highest numbers of immigrants, businesses that employ immigrants, personal contacts of data collectors, referrals from academic staff members and networking were used to identify and recruit the first six participants of the study (two from each region). Each participant was then requested to identify two other immigrant households. This process was repeated until a statistically significant number of participants was reached. One hundred and ninety-four (n=194) female participants representing households from Central, East and West African regions were identified and invited to participate in the study.

Data collection

Four university students of sub-Saharan African descent were recruited and trained as data collectors. The data were collected between August 2015 and January 2016. A structured questionnaire consisting of both closed and open-ended questions was used to gather data on socio-demographic characteristics, dietary patterns and dietary acculturation. A three-day food recall was also used at the end of each questionnaire to triangulate the information gathered on the food items that have been adopted since the immigrants' arrival in South Africa. In cases where the responses were deemed insufficient or unclear, probing questions were used to elicit more information.

Data analysis

Quantitative data were coded and entered into a Microsoft Excel® worksheet. The data were then checked for any inconsistencies and missing values before analysis was performed using the statistical package IBM SPSS version 23 (2015). Data were summarised and descriptive statistics presented as graphs and tables. The probit model was used to identify associations between the adoption of South African food and socio-demographic and economic factors of the households. In this study, households that had adopted South African food culture were coded as 1, whereas those that had not adopted the South African food culture were denoted as 0.

Assumption of general probit model: $Y = \Pr(Y=1 \mid X) = \Phi(X' \beta)$,

where Pr denotes probability; Φ is the cumulative distribution function (CDF) and β is the parameters

The probit model, as a latent variable model with an auxiliary random variable, is expressed as: $Y^{*} = \beta' X + \varepsilon$,

where $\varepsilon \sim N(0,1)$. Then Y can be viewed as an indicator of whether this latent variable is positive:

$$Y = 1_{\{Y^{*}>0\}} = \begin{cases} 1 \text{ if } Y^{*} > 0 \text{ i.e. } -\varepsilon < X'\beta, \\ 0 \text{ otherwise} \end{cases} \quad \text{(Eq. 1)}$$

Specific regression model: $ASFC = \beta_0 + \beta_1 A + \beta_2 G + \beta_3 Edc + \beta_4 B + \beta 5DR + \beta_6 P + \beta_7 MS + \beta_8 R + \beta_9 ES + \beta_{10} Y + \beta_{11} MSF$

Ethical considerations

Ethical clearance (2014/CAES/113) for the study was obtained from the College of Agriculture and Environmental Science, University of South Africa before the study could commence. After study objectives were explained to the participants, only those who granted informed consent participated in the study.

Results

Socioeconomic results

As shown in *Table 1*, the majority of the respondents (79%; n=153) were aged between 20 and 39 years. Most respondents (53.6%; n=104) were single and 56.7% (n=110) had tertiary education, while 43.3% had only a high school education or lower. More than half (62.9%; n=122) of the respondents had lived in South Africa for more than four years. Most respondents (41%; n=80) were from West Africa, while 30% (n=58) were from Central Africa and 29% (n=56) were from East Africa.

Adoption of the South African food culture

Out of 194 respondents, 78.4 % (n=152) indicated that they had adopted the South African food culture (*Table 3*). Among those who had adopted South African foods, the level of adoption varied considerably. Based on the findings of this study, the following four (4) patterns of dietary acculturation emerged: strict continuity with their traditional food (21.6%; n=42); very limited adoption (21.1%; n=39); limited adoption (50.5%; n=98); and complete adoption of South African food culture (7.7%; n=15). Complete adoption of South African food was explained as eating South African food during all mealtimes and eating traditional food only on special occasions, such as at cultural gatherings, weddings and naming ceremonies. Limited adoption meant eating South African food in combination with traditional food; very limited adoption was used to describe eating traditional food at all mealtimes, while eating South African foods only when visiting friends or dining out. Strict continuity with traditional food meant that the respondents always eat traditional food for all meals.

Table 3. *Adoption of South African food*

My kids prefer it	4	2.1
Reasons for not adopting		
Not applicable	152	78.4
Unfamiliar taste	33	17.0
Inability to cook SA food	6	3.1
SA food is unhealthy	3	1.5

During the interviews, it became clear that immigrants did not distinguish food that was part of the South African cuisine from globalised or westernised foods. They considered all food – including fast food – to be part of the traditional South African food culture, as long as it fell outside their original food culture.

Respondents gave various reasons for adopting South African food (see *Table 3*). Among the households that reported adopting the South African food culture, the most common reason was that the price of traditional food was too high (50%; n=76), followed by the unavailability of the traditional food (32.2%; n=49).

Of the 42 respondents that have not adopted South African food, the main reason given was the unfamiliar taste (79%; n=33). Other reasons included inability to cook South African food (14.2%; n=6) and the fact that other immigrants believed the food is unhealthy (7%; n=3).

Food items that have been adopted since resettlement

An assessment of the food items that the respondents had started eating after settling in South Africa revealed the following to be the most common: pap (84.5%; n=164); fried potato chips (43.8%; n=85); cold drinks (42.8%; n=83), fast foods (37.6%;n=73); *sphathlo* (30.9%; n=60); *vetkoek* (fat cakes) (30.4%; n=59); and spinach (24.2%;n=47). Pap is a typical South African staple food made from maize meal, while *sphathlo* (sometimes known as *kota*) is an African burger made of a quarter loaf of bread and usually filled with at least five ingredients, including potato chips, cheese, polony, Russians (spicy sausages), atchar (a spicy condiment), fried eggs and tomato sauce. Other items that are sometimes also included in *sphathlo* are chakalaka (a spicy vegetable relish), braai meat, samp (coarsely ground mealie meal) and beans. *Sphathlo* is commonly consumed in the townships of Gauteng.

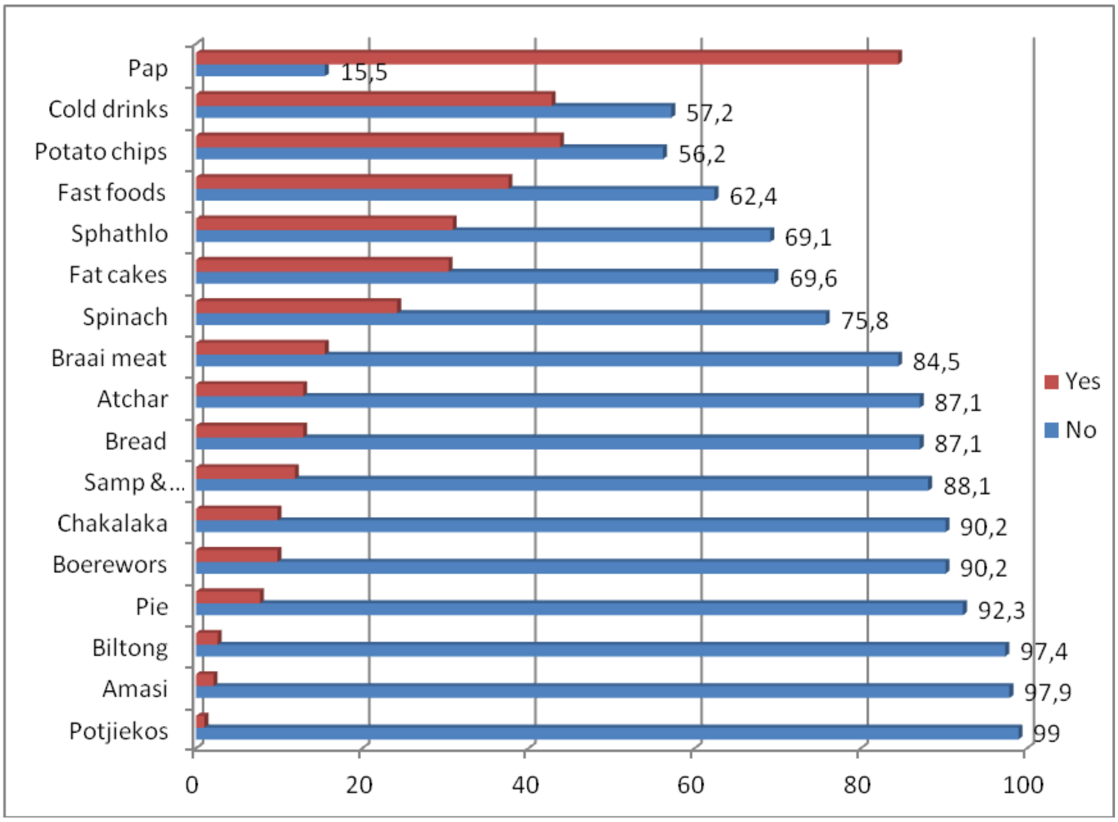

Figure 1. *South African food adoption showing different food items that have been adopted by immigrants since their re-settlement in South Africa*

Consumption of fizzy drinks was also common among immigrants, with most respondents consuming at least one fizzy drink every day. The leading fast food outlets mentioned by respondents were Kentucky Fried Chicken, MacDonald’s, Steers, Nando's and Roman's Pizza.

Factors associated with the adoption of South African food

At 0.05 cut off significance level, the region of origin was highly significant ($p<0.000$), while money spent on food was marginally significant ($p<0.077$). No statistically significant associations were observed for the rest of the factors that were tested.

Discussion

Results on the age of the respondents confirm findings that the majority of the immigrants are young (Vahabi and Damba, 2013; Anderson et al., 2014) and have probably moved in search of better economic conditions. While most immigrants participating in our study were fairly educated (56.7%; n=110), the low-income categories (i.e. below ZAR15 000 per month) into which the majority of respondents (74.8%; n=145) fell suggest that our study population falls into the low-income bracket. This income is below the South African average monthly income of ZAR17 517(Statistics South Africa, 2016). Low incomes and the fact that only 31.4% of immigrants are in full-time jobs suggest that they are finding it difficult to secure decent jobs. The prevalence of low socioeconomic status among the respondents in this study was consistent with the results of similar studies of sub-Saharan immigrants that have resettled in other countries (Vahabi and Damba, 2013; Anderson et al., 2014; Ross et al., 2016). As a result, their dietary acculturation is likely to be characterised by negative dietary changes (Kiptinness et al., 2011). Difficulty in finding employment among well-educated immigrants was associated with language barriers (Vahabi and Damba, 2013) and employment restrictions imposed on foreign nationals (Shackelford, 2010). In the current study, the low employment level could be aggravated by the high unemployment rate in South Africa, which is currently at 26.6% (Statistics South Africa, 2016).

Consistent with previous studies, the current study revealed that even though the majority of immigrants try to preserve their traditional food culture upon resettlement, some level of dietary acculturation takes place (Garnweidner et al., 2012; Njomo, 2013; Sanou et al., 2014). For example, in a Norwegian study on African and Asian immigrants conducted by Garnweidner et al. (2012), different patterns of dietary acculturation were observed. Therefore, the authors of the current study are of the view that dietary acculturation does not move in a linear process. This view is supported by Deng et al. (2013), who contends that Chinese immigrants residing in North America do not just change their diets from traditional to strictly new foods upon resettlement. Instead, immigrants retain traditional foods, find new ways of incorporating their traditional ingredients and exclude others, while adopting new ones (Satia, 2010).

While Garnweidner et al. (2012) identified three patterns of dietary acculturation, the authors of the current study observed four patterns. However, in the same study by Garnweidner et al. (2012), none of the participants had completely adopted the host country's food culture.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_10231038

In the case of South Africa, the fact that immigrants are able to continue with their traditional or ethnic diets could be attributed to traditional foods' being available and sold by small ethnic shops (Njomo, 2012). However, these ethnic shops are reportedly very expensive when compared with the mainstream supermarkets (Njomo, 2012; Dharod et al., 2013). This situation could lead to food inaccessibility and hence accelerated dietary acculturation.

As was observed in previous studies (Garnweidner et al., 2012; Deng et al., 2013), high prices and unavailability of traditional food were the main reasons given by respondents for adopting South African foods. In view of this, adopting the South African food culture suggests that dietary change is not voluntary and might happen haphazardly before immigrants get a chance to familiarise themselves with the local food culture. This has important policy implications because of evidence suggesting that most immigrants often replace pricey, nutrient-rich foods with cheaper, energy-dense but low-micronutrient foods (Anderson et al., 2014). According Deng et al. (2013), when dietary acculturation occurs, breakfast is the first meal to be replaced by food items such as oatmeal, milk, bagels and cream cheese, a transition that predisposes the consumers to obesity and type 2 diabetes. Although there are dietary guidelines for the general South African population (Vorster et al., 2013), there is no record of nutrition education programmes that target immigrants in South Africa. The authors are therefore of the view that welfare resettlement and nutrition education programmes are required to help minimise the negative impact of acculturation among immigrants settling in the country.

Studies show that taste is associated with resistance to adopting the new food culture (Garnweidner et al., 2012; Dharod et al., 2013; Vahabi and Damba, 2013). This is consistent with the findings of this study, which showed that unfamiliar taste contributed to some immigrants' not adopting South Africa’s food culture. A similar observation was made by Vahambi and Damba (2013) in a study they conducted in Toronto among Latin American immigrants. There, too, they concluded that difference in the taste of food resulted in a rejection of the new food culture.

In examining the changes in food habits, the results of our study indicated that the intake of energy-dense, highly processed food among immigrants had increased significantly after they had settled in South Africa. These findings are consistent with the findings of previous studies (Deng et al., 2013; Lesser et al., 2014; Okafor et al., 2014). Okafor et al. (2014) also reported that dietary changes among African immigrants in the United States were characterised by foods high in fat, sugar and cholesterol. An increase in the intake of convenience foods, fizzy drinks, desserts, candy and dining out among Asian immigrants residing in Canada was also reported by Lesser et al. (2014). Deng et al. (2013) argue that as Chinese immigrants settle in the United States, their diets tend to become more westernised. These dietary behaviours are highly discouraged as they are associated with lifestyle diseases such as obesity and type 2 diabetes (Deng et al., 2013; Okafor et al., 2014).

The unhealthy food choices observed among immigrants have been attributed to their low socioeconomic status. This is because these poor-quality food items are usually less costly than more nutritious food (Dharod et al., 2011; Okafor et al., 2014). In addition, Okafor et al. (2014) suggest that since most immigrants live below the poverty line in their new home countries, they are usually forced to work multiple low-paying jobs, thus reducing food accessibility and time to prepare traditional food dishes. In view of the fact that the current study also indicated that the majority of the immigrants (76.3%)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_10231038

live below the average monthly gross income of ZAR17 517(Statistics South Africa, 2016), they are likely to experience difficulty in accessing nutritious food, which tends to be more costly. Apart from economic constraints, the increase in the consumption of unhealthy fast foods could also be due to a lack of knowledge on how to prepare new food items. Meanwhile, unhealthy nutrition transitions have also been associated with lifestyle factors, such as urbanisation and globalisation, which result in the high accessibility of fast foods and fizzy drinks (Satia, 2010). Furthermore, it is reported that prior to immigration, most immigrants are accustomed to small shops, open markets and fresh foods (Njomo, 2012; Terragni et al., 2014); therefore, moving to a place like Johannesburg or Pretoria – where there are many large supermarkets – could curtail their shopping capabilities. This could explain why immigrants resort to fast, cheap, energy-dense foods.

It is not always the case that immigrants respond negatively when faced with the challenges of adopting new food cultures. Some authors have found that immigrants sometimes make positive dietary changes (Lesser et al., 2014; Sanou et al., 2014). The question, then, is what causes these immigrants to make positive changes, while others do not? Is it a lack of knowledge of nutrition and unfamiliarity with the cooking methods and new foods that prevent immigrants from making healthy food choices? Available evidence suggests that positive dietary changes are associated with nutrition education initiatives (Lesser et al., 2014).

Consistent with the observation by Okafor et al. (2014), the region of origin in the current study was highly significant (*P=.000)* at the confidence level of 5%. Okafor et al. (2014) observed in their study that immigrants from Ethiopia and Nigeria were more acculturated than immigrants from other sub-Saharan countries. Moreover, Okafor et al. (2014) observed that the diets of the more acculturated immigrants were characterised by an increased consumption of fast foods and a decreased consumption of fruits and vegetables.

The other factor that was marginally associated with the adoption of South African foods was the money spent on food. This was expected, given that the majority of immigrants (76.3%) who participated in this study indicated that they lived on less than the average national monthly gross income of South Africa, namely ZAR17 517(Statistics South Africa, 2016).

In previous studies, factors such as age, education level, income (Deng et al., 2013; Okafor et al., 2014) and the duration of residence (Dharod et al., 2011; Okafor et al., 2014) had a significant influence on food adoption, whereas in the current study these factors did not prove to be significantly associated with the adoption of South Africa food culture. The fact that there are differences between the current study and the studies reported on above in terms of geographical location of the studies and methodologies adopted could explain the differences in the findings.

In the literature, length of residence has been associated with dietary acculturation (Deng et al., 2013; Lesser et al., 2014). For example, Deng et al. (2013), observed that a longer duration of stay by Korean immigrants in the USA resulted in higher acculturation among younger immigrants (Deng et al., 2013). In contrast, length of residence was not associated with dietary acculturation in the current study. However, the findings of the current study are in agreement with what Ross et al. (2016) reported with regard to factors associated with dietary patterns, namely that duration of stay was not associated with the adoption of the host country's food culture among Liberian immigrants living in Ghana. In fact, these same authors observed that dietary patterns

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_10231038

among Liberian immigrants remained different from those of the local population, irrespective of the number of years they had stayed in Ghana. The explanation for these contradictions could be attributed to the fact that these other studies (e.g. Deng et al., 2013; Lesser et al., 2014) were conducted on other continents, where circumstances are different.

In their study, Lesser et al. (2014) observed a different scenario from what our study and other studies have observed. Lesser et al. (2014) observed that a longer stay was associated with both negative and positive dietary changes. Positive changes included improved cooking methods, while negative dietary changes included increased consumption of red meat, fizzy drinks and desserts (Deng et al., 2013).

Limitations of the current study

The current study has a number of limitations. The use of non-probability sampling to select respondents for this study and the location where the study was conducted preclude any generalisation of the results. Therefore, the results reported here remain valid for the respondents involved and may be indicative of the problems experienced by sub-Saharan immigrants residing in South Africa. Consequently, validating these results in a different context and using a different sampling method would be valuable for further research. Another limitation of this study is that it did not measure food insecurity. Research has shown that there is high prevalence of food insecurity among immigrant groups, especially recent immigrants (Vahabi and Damba, 2013; Anderson et al., 2014). Thirdly, immigrants in this study were not grouped according to their immigration status. Research has shown that refugees and recent immigrants are highly vulnerable to food insecurity (Dharod et al., 2013). Lastly, the three-day food recall used in this study did not collect information on portion sizes, nor did it collect information on cooking methods and the ingredients used, especially for the traditional immigrant foods.

Conclusion and recommendations

To the best of our knowledge, the current study is the first of its kind to investigate dietary changes of immigrants in South Africa. An important finding of this study is that traditional food features very prominently in the dietary patterns of sub-Saharan immigrants. However, owing to high prices and unavailability of traditional ingredients, involuntary dietary acculturation takes place, forcing immigrants into bicultural eating patterns. High prices and unavailability of traditional ingredients could also make immigrants vulnerable to food insecurity. Therefore, further studies to identify similar-tasting, nutritious food items from the South African food culture – as substitutes for unavailable traditional ingredients – might be useful in preventing food rejection and informing culture-specific nutrition education programmes, which could contribute to positive nutritional transitions. Furthermore, our findings confirm that when dietary acculturation occurs, immigrant populations tend to adopt less healthy dietary patterns. In the long run, these unhealthy eating patterns could have negative implications, not only for the health of the immigrants themselves, but also for the health system in South Africa. This suggests the need to design targeted food security and culture-appropriate nutrition education programmes. Further studies to improve understanding of the severity and implications of unhealthy eating patterns among sub-Saharan immigrants in South Africa could help to inform policy and programmes aimed at improving the resettlement of immigrants.

Finally, the findings of this study suggest that there is no association between marital status, age, household income, duration of residence and the adoption of the South African food culture.

(Received 23rd Mar 2017; accepted 24th Aug 2017)

Abstract. Plant migration is a well-known adaptation strategy of plant groups or species with evidence from historical to present observation and monitoring studies. Importance of N_2-fixing plants has increased in last decades. *Alnus* (alder) is an important plant group because of its nitrogen fixation ability. Alders are generally distributed in humid locations of boreal, temperate and tropical climate zones, where the nitrogen fixation is an important nitrogen source for other plants. To model the nitrogen fixation by alder, data about the global distribution of alder is absolutely required. In this study, a new method and model (Alnus-Distribution-Model (ADM)) are presented to predict the distribution of N_2-fixing genus on global scale and its migration in the future by using climate change scenarios up to 2300. Results of the study showed that the potential distribution of *Alnus spp.* not only depending on solitary use of climate variables, soil types and vegetation groups but on combined effect of all tree influencing variables. The ADM also presented that the *Alnus spp.* potentially will migrate mainly northwards in the northern hemisphere. This study covered basic approaches to understand the combine effect of climate, soil and vegetation on modelling of plant distribution and migration.
Keywords: *Alnus, plant distribution, plant migration, nitrogen fixation, climate change, RCP scenarios*

Introduction

Since the nitrogen is a key factor for carbon uptake processes by photosynthetic organisms, and the main resource of the available nitrogen for biogeochemical processes in ecosystems is the N_2 fixation by the symbiotic pathways between the host plants and N_2-fixing bacteria, the determination of distribution of the host plants has been gaining very important meaning and role in modelling of biogeochemical cycles in the ecosystems. Numerous biogeochemical and biome models use empirical or statistical methods to predict the nitrogen fixation by N_2 fixing plants (Prentice et al., 1992; Vitousek et al., 2002; Galloway et al., 2004; Esser et al., 2011). However, none of them considers the N_2 fixation by alders since there is limited information about the distribution of alder species on global scale. It makes difficult to implement the fixation process in biogeochemical, biome models to investigate the interactions between the carbon and nitrogen biogeochemical cycles. It is well known that plants can change their distribution with time, when environmental conditions (i.e. soil, climate etc.) and biological factors (i.e. plant–plant interaction) change in their distributed regions (Sauer, 1988; Dawis and Zabinski, 1992; Iverson and Prasad, 2002). Overpeck et al. (1991) and Bartlein et al. (1997) published new data about widening capability of trees due to the change in environmental conditions. Climate change in the 21st and 23rd centuries that mainly driven by emission change and its impacts on different sectors has been addressed by numerous studies and projects. It is also documented that rapid climate change may put some species at risk of extinction, and possibly reduce the functionality of ecosystems, which could have consequences for ecosystem processes such as global

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_10391070

carbon storage and biodiversity (Thomas et al., 2003). Furthermore, a change in the land cover due to migration of plant species can also affect greenhouse gas concentration in the atmosphere, since for instance a migration of nitrogen fixing plants can influence the carbon uptake and nitrogen availability in soil (Kurz and Apps, 1999). In recent years, the importance of the nitrogen cycle for the sequestration of atmospheric carbon dioxide in the terrestrial biosphere has become obvious (Vitousek et al., 2002; Galloway et al., 2004; Reich et al., 2006; Wang et al., 2007; Esser et al., 2011). While the fixation of CO_2 by photosynthesis produces carbohydrates, nitrogen is required to bind carbon into phytomass. If the biospheric carbon pools increases, an adequate increase of the biospheric nitrogen pools is required. Atmospheric N_2 may be incorporated in the biosphere, but only a limited number of organisms are able to fix it, because of the high activation energy for the decomposition. These organisms are free-living or symbiotic cyanobacteria, actinomycetes, and bacteria in roots of host plants (Galloway, 2002). Not only N_2-fixing bacteria but also host plants that supply required energy for the fixation to the bacteria have enormous importance for the ecosystems. Most of the host plants belong to the families Fabaceae, Mimosaceae, Caesalpiniaceae (legumes) as well as to the *Betulaceae* (alder spp.), and they are called N_2-fixing plants (Saikia and Jain, 2007; Lepper and Fleschner, 1977). Because of their participation in the N_2 fixation, the modelling of distribution of the N_2-fixing plant species plays a key role in earth system and ecosystem modelling. A spatial change in distribution areas of the nitrogen fixers affects directly available nitrogen in soil, carbon uptake and allocations in the biosphere (Galloway et al., 2004). Numerous ecosystem and biogeochemical models aim to predict the nitrogen fixation by using empirical functions (Vitousek et al., 2002; Wang et al., 2007; Galloway, 2002; Esser, 2007). Still, the modelling of nitrogen fixation by alders is missing in most of the models. To predict the amount of fixed nitrogen under global climate change conditions, it is indispensable to have a mechanistic description of the N_2 fixation. And also, the description of the distribution of the symbiont's host plants, their density distribution in the vegetation types in which they occur, the type and the number of root nodules, and the activity of the nitrogen fixing enzyme systems in the nodules are needed. For instance, the density of alders in their native locations in Europe is mainly between 0 and 40% of total plant biomass (Skjøth et al., 2008). These percentage provide a possibility for a modelling the distribution and alders' biomass density according total plant biomass in a location by using models like Nitrogen–Carbon-Interaction-Model (NCIM) (Esser et al., 2011). Alder roots are generally infected with the symbiotic endophytic genus Frankia. As a symbiont, Frankia can convert atmospheric N_2 into reactive nitrogen usable by using the supplied carbohydrates from alders as energy source (Myrold and Huss-Dannel, 1994; Schwintzer and Tjepkema, 1990; Binkley, 1994). Thus, the N_2 fixation by alders can range from 20 kg·ha−1·yr−1 (Binkley, 1994) to 320 kg·ha−1·yr−1 (Van Miegroet et al., 1989). Therefore, alders play an important role in the respective ecosystems due to its ability to enrich poor soils with reactive nitrogen compounds. About 30 species belong to the genus alder, and to the family Betulaceae. The species are mainly distributed in the northern boreal and temperate zones e.g. *Alnus glutinosa* (L.) Gaerten, *A. incana* (L.) Moench, *A. viridis* (Chaix) D. C., *A. rubra* Bong., *A. oblongifolia Torr*, and *A. serrulata* (Ait.) Willd (Tutin et al., 2001). Some species extend into the subpolar zones, including A. hirsuta (Fischer) C.K. Schneider, *A. viridis* (Chaix) DC (Wiedmer and Senn-Irlet, 2006). In the Mediterranean zone occurs for example *A. cordata* (Loisel.) Duby. (Quézel et al., 1999). Numerous species are native to the mountains of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_10391070

subtropical and tropical zones. *A. nitida* (Spach) Endl. occurs in the temperate Himalayas in altitudes from 1000 to 2900 m (Nasir, 1975). *A. nepalensis* D. Don is widely distributed in southeast Asia from subtropical China, Indochina, the Burmese (Shin) Hills, to the Himalayas in altitudes between 300 and 3000 m (Dai et al., 2004). Some alder species also distribute in the southern temperate zone, e.g. *A. acuminata* HBK, and the evergreen *A. jorullensis* Kunth are found in the Chilean Andes at high altitude (Reese, 2003). Within the distribution area of the alders the mean annual temperature is reported to range from −14 ºC to more than 20 ºC (NACS, 1980). The annual precipitation probably ranges from less than 150 mm (WRCC, 2009; Hagenstein and Rickets, 2001) to more than 5600 mm (Harrington, 1991). Alder species prefer poor soils of various particle sizes from gravel and sand to silt, loam, and even clay as well as organic soils. Most species occur on fenlands, in swamp areas, along brooks, rivers, and streams in bogs, but regularly not in riparian areas with highly varying water levels. However, some species such as *A. firma* Sieb. & Zucc. and *A. crispa* (Dryand. in Ait.) Pursh are distribute steep slopes. Several studies show that the main factors that influence the distribution of plant species in their natural ecosystem are climatic factors like temperature and precipitation (Woodward, 1996; Dukes and Mooney, 1999; Walther et al., 2002). Not only the climate change is a critical factor for plant distribution, but also the soil units via their different physical or/and chemical conditions can influence plant distribution (Brown, 1984; Min and Kim, 1999; Wu et al., 2011). Therefore, the soil units should be considered in the modelling studies about the prediction of plant distribution. Also, the occurrence of a plant species in its natural area is depending on plant–plant interactions. Plant species often favor to grow with specific other species (Pyke and Archer, 1991; Brooker, 2006). Several models like NCIM (Esser et al., 2011), LPJ-GUESS (Smith et al., 2001), and EMEP (Simpson et al., 2012) consider plant–plant interactions due to use potential natural vegetation groups or biome units in the model simulations.

In this paper, the aims were reported for modelling the global distribution of the N_2 fixing host genus alder, and then the effect of climate change effect on the globally *Alnus* distribution. To predict the global distribution of alders, an available gridded data sets on climate, soil units and potential natural vegetation groups will be used. The individual contribution of each data type was tested for the correctness of the predicted distribution. This work should be a first step to predict the potential occurrence and distribution of alders depending on their climate requirements, soil conditions, and plant–plant interactions. This study should also give the basic information for implementation of N_2-fixation by alders in biogeochemical and ecosystem models since N_2 fixation is directly depending on the occurrence of N_2-fixing plants in the terrestrial ecosystem.

Materials and methods

In this paper, a new model based on four progress steps was developed for the predicting of the potential distribution of alder spp. on the global scale. This new model is called “Alnus-Distribution-Model (ADM)”. In the first step, the values of annual average temperature and precipitation were used from Leemans and Cramer 0.5º degree grid element global climate database (Cramer and Leemans, 1991) to define a bioclimatic niche of *Alnus spp*. The climate database includes 30 years (1961–1990) average of the climate parameters for 0.5º resolution on the global scale. In the second

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_10391070

step, the climate based ADM was extended with soil units by using the FAO soil classification (1974) in "Soil Types of the World" (FAO-Unesco, 1974). In the third step, the climate parameters based ADM was extended with potential natural vegetation groups after Esser et al. (2011). The vegetation data set is our own digitized database from the "Atlas for Biogeography" after Schmithüşsen (1976). The vegetation map after Schmithüsen comprises 176 vegetation units globally. These 176 vegetation units were aggregated in 31 potential natural vegetation groups in the research group at the institute, and it published in the study Esser et al. (2011). In the fourth step, all three methods were merged to predict the potential alders' distribution by the ADM. The used climate, soil, and vegetation data sets are on identical global grid resolution, i.e. half degree longitude and latitude as commonly used by global vegetation models. 62483 grid elements are characterized for the land areas excluding Antarctica. Each grid element is characterized by its lower left (south–east) corner coordinate in decimal degrees.

Distribution data for alders

For the construction of ADM, the global distribution data for of the *Alnus spp*. were extracted from seven databases (Tropicos.org, 2009; eFloras, 2008; WWF, 2009; Tutin et al., 2001; US Forest Service, 2008; USDA-NRCS, 2009; Li and Skvortsov, 1999). The number of data for alder occurrence is very unevenly distributed worldwide. The name of the alders' species, the altitude, and the coordinates of the origin place were collected. A total of 308 locations including the data were extracted. All species of genus *Alnus* Mill. of *Table 1* are represented in the 308 locations. The lifespan of alders ranges between 40-100 years (Harrington et al., 1994; Claessens et al., 2010). It is assumed that a change in the 30-year annual average of climate conditions (i.e. temperature and precipitation) can change the suitable climate conditions in the distribution area and force the migration of alder species. Unfortunately, there is data for validation of this assumption in the academic literature databases. Therefore the 30-year period was used for the prediction of alder distribution and migration. This is a weak point of the model, and may be changed in the future by long-term observation studies.

Table 1. *The global distributed 34 alder species, which were used for selection of the locations and the relevant climate, soil, and vegetation parameters. The species names are according to the publication from Chen and Li (2004).*

"Clim"

I determined the grid elements, in which alders occur in the 308 sites. All further analyses were made by using the gridded data sets. First, the mean annual temperature (T_{ann}) and annual total amounts of precipitation (P_{ann}) were extracted from the gridded climate data set for the sites of alders. The altitudes of the alder locations within a grid element may deviate from the mean altitude of the grid element. Therefore, corrections of the gridded climate data were sometimes necessary. For this purpose, the altitude of the site that was given in the original databases was used. If altitudes were lacking, it was determined from the GTOPO30 global elevation dataset (GTOPO30, 2010). If the altitude could not be determined, the side was eliminated. The nearby climate stations were selected from Walter and Lieth (1961–1967), Müller (1982) and Mitchell and Jones (2005). The arrays of T_{ann} and P_{ann} were plotted for the 308 alder sites. Three linear functions were then determined which envelop the field of climate data of the alder sites. The T_{ann} and P_{ann} values of the 308 locations were presented in the *Fig. 2*. three linear functions F1–F3 were fitted to the six cardinal points P1–P6:

F1(P1, P2); F2(P3, P4); F3(P5, P6). The three linear functions that form the borderlines of alder distribution in the temperature–precipitation matrix are:

$$F_1(x) = -2.04 * x + 172.58 \quad \text{(Eq. 1)}$$

$$F_2(x) = -561.58 * x + 16141.87 \quad \text{(Eq. 2)}$$

$$F_3(x) = 110.67 * x + 1658.64 \quad \text{(Eq. 3)}$$

The *x* equals to T_{ann} (ºC) and $F_{(1,2,3)}(x)$ to P_{ann} (mm). In *Figure 2* plot of these functions can also be found.

To determine the potential distribution areas for alders, the following climate based method was used:

$$D_{Clim,i} = \begin{cases} true, if\ Clim_{T_{ann},P_{ann},i}\ inside\ climate\ matrix\ field \\ false, else \end{cases} \quad \text{(Eq. 4)}$$

where *i* is grid number of half degree grid element, T_{ann} (ºC) is mean annual temperature, and P_{ann} (mm) is annual total amounts of precipitation of the grid element, respectively. The distribution of alder species based on climate parameter ($D_{Clim,i}$) is true in a grid element if the certain criteria of the grid element are fulfilled (see *Eq. 4*).

"Soil"

For this aim, the FAO soil units from the "Soil Types of the World" database, which

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_10391070

includes 129 soil units for the 0.5º grid cells of the terrestrial biosphere (excl. Antarctic) (FAO-Unesco, 1974) were used to enhance the climate based ADM for prediction of potential alders distribution. The soil units of the 308 study sites, in which the alders natively occur were recorded as suitable soil types for the alder distribution. Thereby, the soil units were used as additional determinants for the alder occurrence. If a soil unit were present in only one grid element, it was not considered in the modelling study. Grid elements were marked as potential alder habitats, if they were within the climate field limited by the three linear functions of the temperature–precipitation field, and have suitable soil unit, which occurs in more than one grid elements with alder distribution. For this step, the following equation was used:

$$D_{Soil,i} = \begin{cases} true, if \begin{cases} Soil_i = Soil_a \\ D_{Clim,i} = true \end{cases} \\ false, else \end{cases} \quad \text{(Eq. 5)}$$

where i is grid number of half degree grid element, $Soil_i$ is the soil unit of the grid element, and $Soil_a$ is the soil unit of the grid elements with data record about alder distribution in 308 study sites, respectively.

"Veg"

In this step, the 31 potential natural vegetation groups according to the study from Esser et al. (2011) were used to investigate the correlation between the alder distribution and climate–vegetation aspect in this study. The potential natural vegetation groups, in which alders occur natively were marked as suitable vegetation groups for alder distribution. Thereby, these potential natural vegetation groups were used as additional determinants for alder distribution. If a vegetation group was recorded in only one grid element, it was not considered in the modelling study. Grid elements were marked as potential alder habitats if they were within the climate field limited by the three linear functions of the temperature–precipitation field, and have suitable potential natural vegetation group which occurs in more than one grid elements with alder distribution. For this step, the following equation was used:

$$D_{Veg,i} = \begin{cases} true, if \begin{cases} Veg_i = Veg_a \\ D_{Clim,i} = true \end{cases} \\ false, else \end{cases} \quad \text{(Eq. 6)}$$

where i is grid number of half degree grid element, Veg_i is the vegetation type of the grid element, and Veg_a is the vegetation type of the grid elements with data record about alder distribution in 308 study sites, respectively.

"All"

In this step, all three method were combined for modelling of potential alder distribution. The verified the soil units, and the potential natural vegetation groups which occur in the grid elements with alder sites were used together as additional determinants for alder occurrence. The equation of this step is as follows:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_10391070

$$D_{All,i} = \begin{cases} true, if \begin{cases} D_{Clim,i} = true \\ D_{Soil,i} = true \\ D_{Veg,i} = true \end{cases} \\ false, else \end{cases} \quad \text{(Eq. 7)}$$

where *i* is grid number of half degree grid element.

Migration of alder species in 2100 and 2300

To predict the migration of alder species up to 2300, data for T_{ann} and P_{ann} were needed. For this step, the mean annual value of temperature and precipitation of four RCP (Representative Concentration Pathway) scenarios (i.e. RCP 2.6, RCP 4.5, RCP 6.0 and RCP 8.5) were selected from the CCSM4 data model outputs for the period between 2000 and 2300. The climate data of the four different RCP scenarios was used for checking the potential effect of variability in temperature and precipitation on plant distribution (i.e. *Alnus spp*.) due to change in anthropogenic emission of greenhouse gases, technology and population density according to the RCP scenarios. Since the used climate data for the prediction of alder distribution in the “Clim” stage were the 30-year annual average data from Leemans and Cramer data base, 30-year annual average value of T_{ann} and P_{ann} from 2071 to 2100, and from 2271 to 2300 were used for prediction of alder distribution in 2100 and 2300, respectively. The 30-year periods give plants the possibility for adaptation to the climate change in a location. To avoid the jump of alder species over long distance (i.e. more than one grid cell), it is also assumed that the alder cannot migrate to a grid cell if at least one of the neighbor grid cell was not marked as a potential distribution grid cell.

Observations and statistical analyses

The Global Biodiversity Occurrence Data Base (GBIF) (GBIF, 2010) was used for the evaluation of the model results. The database includes 237178 data records about the alder occurrence worldwide. Majority of these observations crowds together in a few regions of the world, while data in other regions are very scarce, so that the global coverage is very uneven. The database includes a global distribution map as well as the opportunity to download information amongst others the coordinate, name of the occurred alder species, and basis of records (unknown, herbarium, observed or specimen) in the locations. In the *Table 4*, 49 countries were presented, which were extracted from the database with data records about the alder distribution. Countries with just one data record for alder distribution or data records without the coordinate of the location or with the “unknown” basis of records were not considered in this study. Therefore, 215444 of 237178 were selected as useful data records in the 49 countries (see *Table 4*).

The prediction of the ADM model was validated with the data from the GBIF database for each step as well as for analyzing correlations between the observed and predicted data by calculation regression coefficient, index of agreement d (Willmott, 1982) (see *Eq.* 9), mean absolute error (*MAE*) (see *Eq. 8*) to determine the best method for the prediction of the alder distribution. The used *MAE* and d equations are:

$$MAE = \frac{1}{n}\sum_{i=1}^{n} |P_i - O_i| \quad \text{(Eq. 8)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_10391070

$$d = 1 - \frac{\sum_{i=1}^{n}(P_i-O_i)^2}{\sum_{i=1}^{n}((|P_i-\bar{O}_i|)+(|O_i-\bar{O}|))} \quad \text{(Eq. 9)}$$

where P is the number of the simulated grid cells with potential alder distribution in related locations and O is the number of the observed grid cells with alder distribution, i a sample, n the number of samples, overbar represents mean values, and d is the index of agreement, respectively.

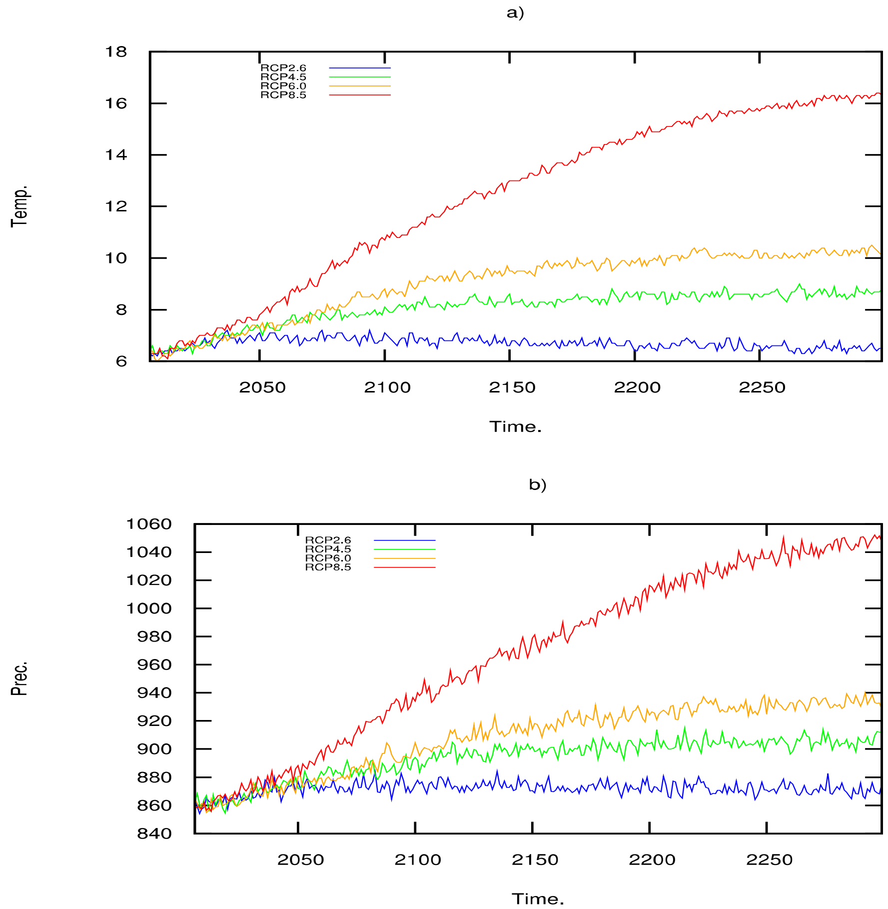

Figure 1. *The change in global average temperature and precipitation (2006–2300) of CCSM4 model which driven by four RCP emission scenarios.*

Results

Evaluation of distribution methods

In *Figure 2*, the distribution of the 308 data points in the field of T_{ann} and P_{ann} is shown. In the distribution regions, there is a lower limit of annual precipitation, which excludes the occurrence of alders. This lower limit depends also on T_{ann}. At the alder distribution sides, when the T_{ann} around −10 ºC or colder, P_{ann} limit is about at 190 mm. When T_{ann} is around 28ºC, the alders need about 115 mm annual precipitation for their existence. Since alders occur at low precipitation values mainly along rivers and brooks, it is assumed that the occurrence of alders in areas with low P_{ann} is due to the probability of the suitable soil water content.

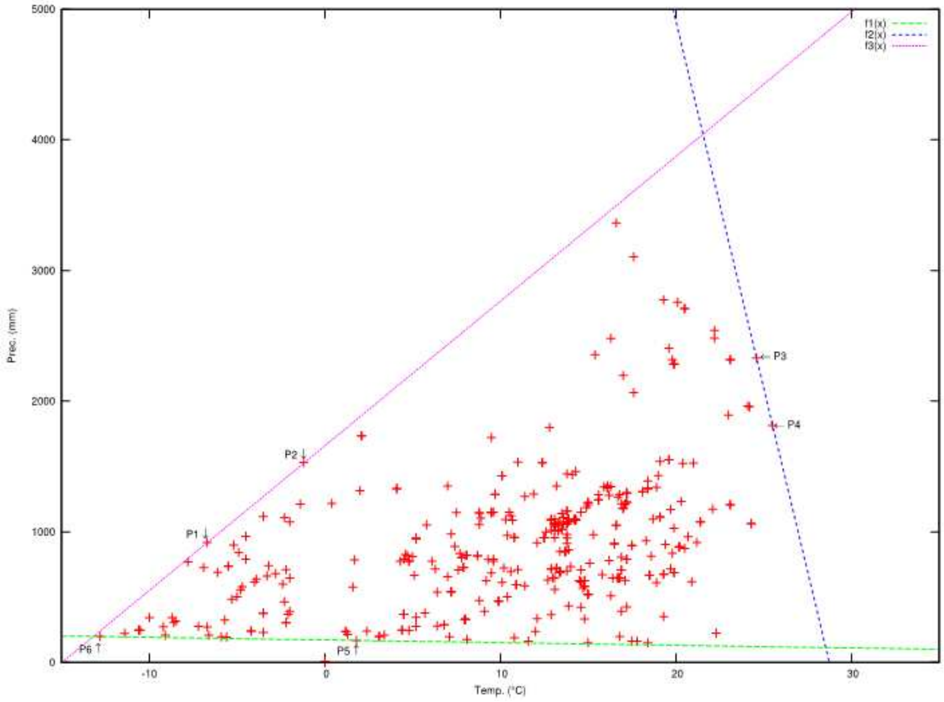

Figure 2. *The temperature–precipitation field of the 308 data points which were extracted from seven data bases (Tropicos.org, 2009; eFloras, 2008; WWF, 2009; Tutin et al., 2001; US Forest Service, 2008; USDA-NRCS, 2009; Li and Skvortsov, 1999) as sites of alder occurrence. The cardinal points P1,...,P6 define the borderline of the distribution of alder in this field. They define the three linear functions 1 through 3 which were used to select appropriate grid elements from a global 0.5° grid of climate data (Cramer and Leemans, 1991).*

From the selected six cardinal points P1...P6 to define the borderline of the alder distribution in a matrix (see *Figure 2*), the point P1, P2 and P6 refers to *Alnus viridis*, which occurs in the northern boreal regions of Asia, Europe, and North America. In temperate regions, *A. viridis* may occur at high elevations (Kamruzzahan, 2003). P_{ann} range for *A. viridis*. is between 150 and 3000 mm yr^{-1} in its native distribution areas (Racine et al., 2001). The points P3 and P4 belong to the two species *Alnus acuminata* the Andean alder, and *Alnus jorullensis* the Mexican alder, which are native to the mountains of Central and South America. Their distribution defines the upper temperature limit of the alder distribution, which seems to be below 30 ºC average annual temperature. In the regions, P_{ann} may range from 500 to 4000 mm yr^{-1}. The point P5 refers to *Alnus rhombifolia*, which occurs in the lower areas of the northern Pacific coast of North America from humid to per-humid climates (USDA-NRCS, 2009). The P_{ann} within the distribution areas of *A. rhombifolia* varies from 508 to 3175 mm per year, and the lowest temperature is −4.4ºC (USDA-NRCS, 2009).

Further stages of the model

The climate based ADM was refined by means of the soil units. The soil units that recorded in the 308 grid elements are shown in *Table 2*. The considered alder distribution areas involve 53 of 130 FAO soil units. Lithosols and Cambisols are the dominated soil units in the 308 distribution areas. About half the grid elements include the two soil units. Although, most of the alder species prefer to distribute in wet soils

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_10391070

and in soils with high water availability, the Gleysols were found only in 21 of 308 grid elements. Gleysols are wetland soils and categorized in FAO-UNESCO soil database as a hydromorphic soil group, which are influenced by groundwater for a long period to develop a characteristics gleyic pattern, and are mainly covered by swamp vegetation (FAO-Unesco, 1974). The soil units, which were present in only one grid element, were not considered in this work.

Table 2. *Soil units related to Soil Map of the World of FAO-UNESCO (1974) which dominate in the 0.5° grid elements where alder species occur according to the GBIF database. The bold lines are the main groups of the related sub group for soil types according to FAO-UNESCO Soil Map of the World.*

In *Table 3*, the potential natural vegetation groups of the 308 grid elements after Esser et al. (2011) and their vegetation units which occur in digitized version of the atlas for bio-geography after Schmithüsen (1976) were shown. 50 of 176 vegetation units according to Schmithüsen (1976) were recorded in the 308 grid elements. The most common vegetation units in the distribution areas was the potential natural vegetation group "Temperate deciduous forests" (68 of 308 grid elements). In 97 locations, the tropical and subtropical potential natural vegetation groups were recorded. In 32 locations, dry vegetation units ("Open conif. dry woodland", "Conif. dry forest", "Puna dry steppe", "Drought-deciduous and part evergreen thorn bush formation", "Artemisia dry steppe", and "Trop. lowland dry forest") were found. In those locations, the alders may distribute in moist areas along rivers and streams. For instance, the "drought-deciduous and part evergreen thorn bush formation" (7 sites) occurs on the east slopes of the Argentinian and southern Bolivian Andes, where a number of brooks and rivers are present. There are also 33 grid elements with sclerophyllous formations of Mediterranean type climates. These sites may also be supported by water currents occurring in these formations.

Table 3. *The potential natural vegetation groups according to the study from Esser et al. (2011) (name with bold character) and the vegetation units according to Schmithüsen (1976) which occur in the 0.5° grid elements which include the data records about alder occurrence. The left column gives the respective number of grid elements.*

Observed alder distribution

In *Table 4*, data about the 49 countries with data records for alder distribution in GBIF database were presented. The 49 countries include 215444 data records with coordinates of the locations, name of the occurred alder species, and the basis of the records for alder occurrences. The countries were ordered after having most data records (i.e. countries with most data records first). The first 20 countries in the *Table 4* included the most data records for alder distribution in the GBIF database (see *Table 4* column "Rec."). The total number of records in these countries is 208181 of 215444 in 1866 of 4098 half degree grid elements (see *Table 4* columns "Rec.", and GBIF 05"). Also, the first 20 countries (14 in Europe, 3 in South America, 2 in Asia, and 1 in Central America,) in the *Table 4* include 97% of the useful data records and the most data density for alder distribution. Each country has over 100 data records, and also 5 data records per half degree GBIF grid cell. Thus, these 20 countries were used for the validation of model prediction about alder distribution. The other 29 countries in the *Table 4* included the rest of data records for the alder distribution in GBIF database. Two countries after the middle line the table (US and Canada) have indeed high data records but less data density (records number per grid elements). Therefore, these countries were not considered within the 20 countries. Countries with only one data record in GBIF data base were also not considered and not presented in this paper.

Table 4. *Analysis of the data distribution in the GBIF database (GBIF, 2010) which was used for the validation of the ADM model results for 49 countries with data records for alder distribution.*

Meaning of the columns: (Country) name of the countries; (Rec.) Number of data records for alder distribution in each country (countries with just one data record are not shown); (Grid 0.5) Number of half degree grid elements of the country; (GBIF 0.5) Number of half degree grid elements with data records about the alder distribution. The first 20 countries have in the GBIF grid cells minimum 100 data records and five data records per grid.

Validation of the methods

Since the 20 countries had the most density for data records about the alder distribution in GBIF database, a statistical analysis between the observed and predicted alder distribution was done in these countries to find out, which method of the four methods (“Clim”, “Soil”, “Veg”, and “All”) is more suitable for the modelling of alder distribution. In the *Figure 3* the results of the correlation and statistical analyses

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_10391070

between the observed and predicted number of half degree grid elements with data records about alder distribution were presented. The correlation functions (f (x)), 1:1 lines, correlation coefficients (r^2), index of agreement (d), and mean absolute error (*MAE*) were also presented in the scatter plots. The actual data of the scatter plots may be found in the *Table 5* columns "Grid", "Soil" "Veg", and "All" respectively. The r^2 values of the correlation analyses ranged between 6 and 84%. The lowest correlation was found between the observed and "Clim" method based ADM results with r^2 = 6%. The d and *MAE* values of this correlation analysis were 0.36 and 117, respectively (see *Figure 3a*). The "Clim" method shown also a large intercept with 117 grid elements. The "Soil" method shown similar correlation with the observed data as the "Clim" method (see *Figure 3b*). The correlation coefficients r^2 between this method and observed data were 11%. The value of d for this method was 0.5, where the *MAE* value was 86. The method "Veg" provided a better correlation with the observed data (see *Figure 3c*). The values of index of agreement and mean absolute error shown quite good results with d = 0.93, and *MAE* = 28, respectively. But the best correlation coefficient (r^2= 84%) were found between the observed and "All" method based ADM results (see *Figure 3d*). And also the highest d value with 0.96, and the lowest *MAE* value with 27 were found between the "All" method based ADM and observed data. The intercept of this method was around 27 grid elements. Thus, the correlation analyses shown the best performance between the "All" method based ADM results and the observed data in the high relevant 20 countries. Because of the best r^2, d, *intercept*, and *MAE* values, the "All" method based ADM was used to predict the potential alder distribution areas globally.

The figures in the *Appendix* give an overview about the statistical analyses between the results of ADM by using each single parameter and observation in the 20 countries, and about the results of "CLIM", "Soil" and "Veg" methods on global scale.

Table 5. *Analysis of the data distribution in the GBIF database (GBIF, 2010) which was used for the validation of the ADM model results for 49 countries with data records for alder distribution, and comparison with model results using different constraints besides climate.*

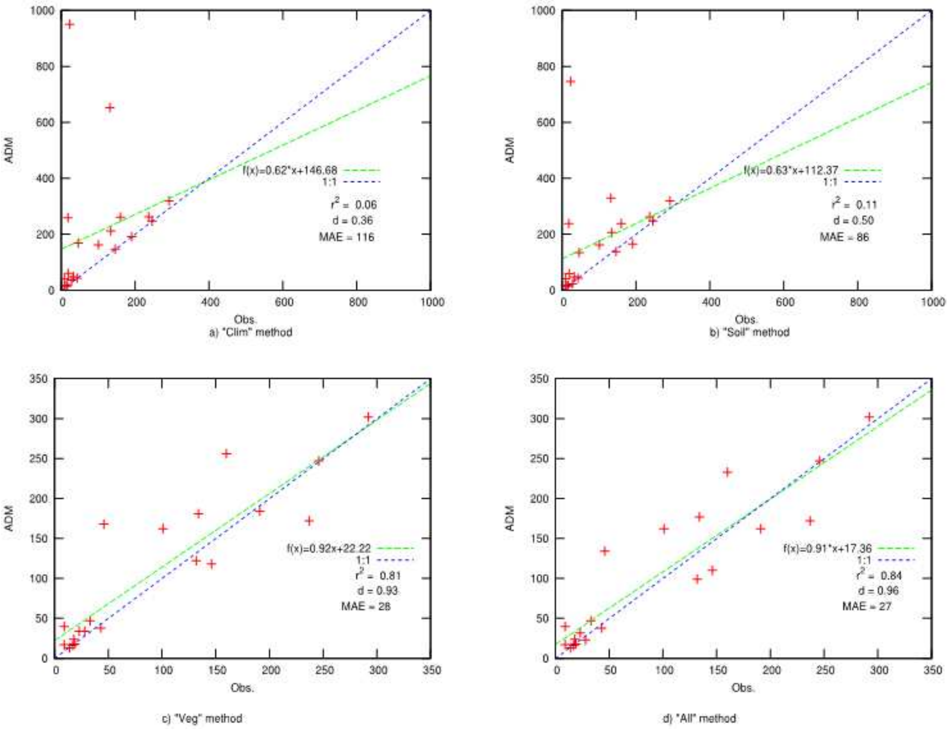

***Figure 3.** The correlation between the observed and predicted alder distribution in half degree grid elements in 20 countries. Countries from the Table 4 with minimum 100 data records and five data records per each noted half degree grid cell were considered. The regression and 1 : 1 lines are shown along with correlation coefficient (r), index of agreement (d), mean absolute error (MAE).*

Global potential alder distribution

The predicted alder distribution by using "All" method based ADM was shown in *Figure 5*. It is to see that alder has a large potential distribution areas in Asia and North America. In comparison to the global alder distribution on GBIF map (see *Figure 4*) the ADM also predicted the potential distribution in several grid elements of South America, Africa, and Australia (see *Figure 5*). The ADM predicted the alder distribution in 1898 grid elements in the 20 countries where the GBIF database has records in 2066 grid elements (see *Table 5* columns "Grid" and "All"). Most of the eliminated grid elements have suitable soil units but not vegetation types for the potential alder distribution in these countries. For example, eliminated grid elements in Norway have the soil unit "Lithosols" and the vegetation type "Mountain vegetation above the tree line". "Lithosols" are the second largest occurred soil units in the 308 grid elements (75 of 308) of the evaluation's grid elements (see *Table 2*). These grid elements have the suitable climate conditions and soil units but not the vegetation types. Most eliminated grid elements in the 20 countries after using "Soil" and "Veg" methods in ADM were found in Mexico. The dominant soil units in Mexico are "Leptosols", "Regrosols", and "Calcisols" (FAO-Unesco, 1974). Only "Regrosols" were presented in 308 evaluation's grid elements (see *Table 2*). Also, the dominated vegetation types are "Shrub desert", "Thorn savanna", and the "Open deciduous small leafed" in Mexico. Only the vegetation units "Thorn savanna" were recorded in one of 308 grid elements. In Russia and China, the ADM has shown the potential alder distribution in 67, and 460

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_10391070

times more grid elements than the GBIF database records. In Russia, grid elements with potential alder distribution have the suitable climate conditions, soil units ("Lithosols" and "Cambisols") as well as the potential natural vegetation groups ("Boreal coniferous forest" and "Boreal woodlands"). These two soil units were recorded in 45 of the 308 evaluation's grid elements (see *Table 2*) and the vegetation types in 75 of the 308 grid elements (see *Table 3*). In China, same vegetation types are also the dominant vegetation types in potential distribution areas. However, the mostly coming soil units in those areas are the "Cambisols", "Gleysols" and "Acrisols". The three soil units were found in 121 of 308 grid elements. In comparison to the 20 countries, the US and Canada have also large data records but appreciably low data density per grid elements. The ADM predicted the alder distribution in 499 grid elements more in US and in 1613 in Canada than the GBIF database. In the regions, "Lithosols", "Podzols", "Luvisols", and "Phaozems" are mostly recorded soil units (FAO-Unesco, 1974). The potential natural vegetation groups are mainly "Temperate deciduous forests", and "Mediterranean sclerophyll formations" in the US, "Boreal evergreen conif. forests" in Canada.

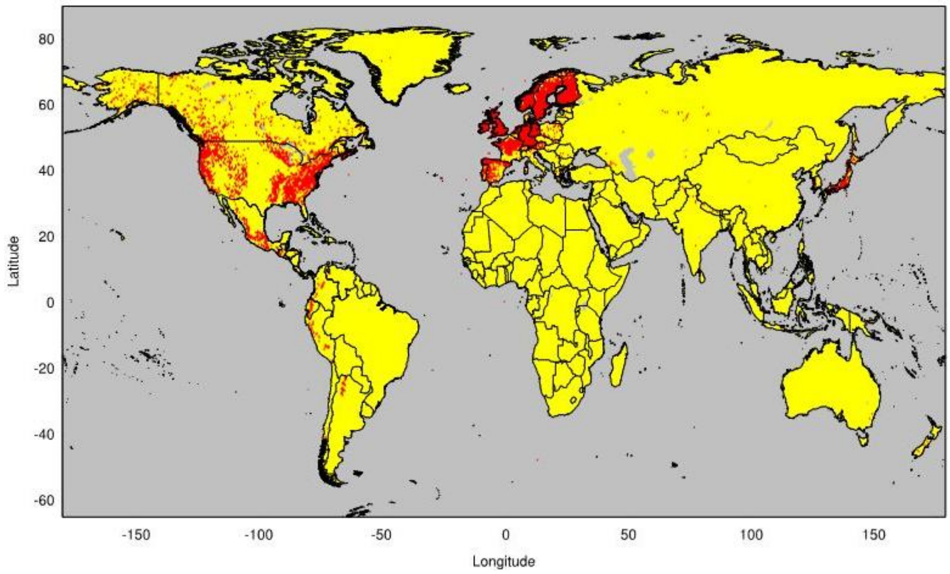

Figure 4. *Distribution of alders (red) according to the GBIF database (GBIF, 2010). For the locations with yellow colour there is no data record in the database.*

It is generally to see that the "Veg" method eliminated more grid elements than the "Soil" method in 12 of the 20 countries as well as in Russia, in China, and in the US. In France, Germany, Poland, Austria, and Canada more grid elements were eliminated by using the "Soil" method than the "Veg" method.

The results shown that the existence of alders in natural ecosystems is not only depending on climate conditions but also on soil types, and vegetation units. The potential distribution of alders mainly occurs in Northern Hemisphere, but also occurs in quite few locations in south hemisphere with adequate climate conditions, soil types and vegetation units (see *Figure 5*). Since the alders can fix atmospheric nitrogen, consideration of the nitrogen fixation by alders in their distributional areas in ecosystem and biogeochemical models gives the opportunity to investigate and predict the nitrogen

APPLIED ECOLOGY AND ENVIRONMENTAL RESEARCH 15(4):1039-1070.
http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_10391070

fixation impacts on CO_2 uptake, and carbon storage in the.

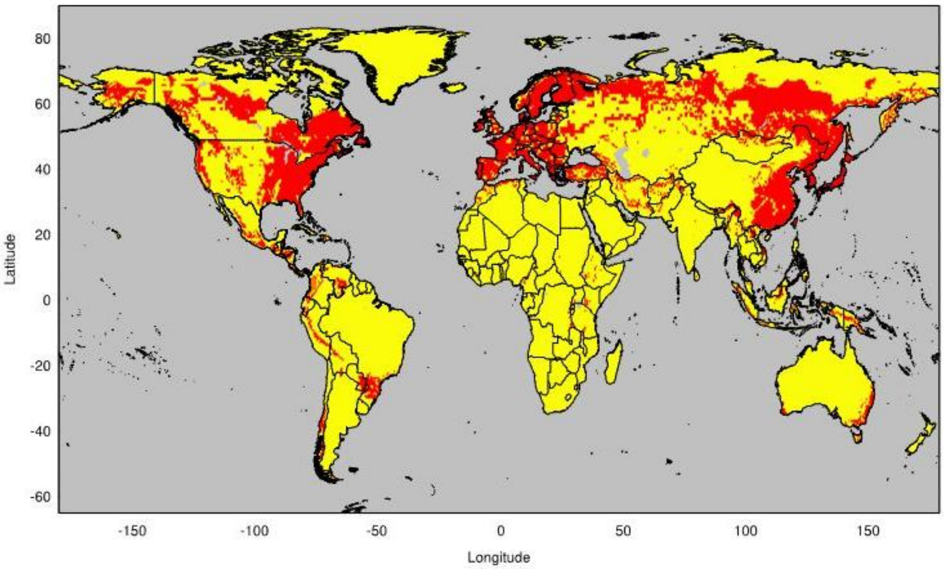

Figure 5. *Distribution of grid elements (red) that were identified as potential sites with alder based on the climate functions 1...3 (see also Figure 2). In this version of the model, restriction by vegetation types (see Table 3) and by soil units as found in Table 2 was applied. Yellow: grid elements were not identified as potential distribution area for alder.*

Potential distribution and migration of alder in 2100 and 2300

The absence of alders in the natural ecosystems can also cause an extreme decrease in nitrogen input by N_2 fixation of this plants group, and as a result can have gravely consequences for the nitrogen availability in soil of the areas. Therefore, it is important to model the migration of the N_2 fixing plants on global scale. To investigate this, the climate data of CCSM4 by driven four IPCC RCP scenarios up to 2300 were used. The rising of atmospheric CO_2 has enormous impact on climate change in the future. The using of climate data by driven different RCP scenarios enables to understand the effects of changed climate parameter (i.e. the T_{ann} and P_{ann}) by rising CO_2 on plant migration (in this study for alders). An increase in CO_2 in the atmosphere can also influence plant distribution by e.g. CO_2 fertilization, CO_2 partial pressure, water use efficiency (Johnson et al., 1993; Collatz et al., 1998). In this study, this type of impacts from CO_2 on the alder distribution was not considered.

For this step of the study, it was assumed that the soil unit and the potential natural vegetation groups of a grid element will not be changed in 2100 and 2300. The migration of alder species for those two prediction periods by using the ADM was shown in the *Figures 6* and 7. The results show that the alders can extend its distribution northwards. Especially the alder species may be frequently occurring furthermore in Northern Russia and Alaska at all scenarios of the climate models (see the blue areas in *Figure 6*). Few grid elements in Norway, Finland, the US and Canada may also additionally to be suited for the alder distribution in all scenarios in 2100. On the other hand, a range of grid elements close to coast in Europe, Southern US and Southern China may not have proper conditions anymore for alder distribution in 2300 (see the red areas in *Figure 7*). It is further to see that most of the grid elements in Africa,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_10391070

Indonesia and middle and south America may be eliminated for the alder distribution by all scenarios of the climate models in 2100 and 2300.

The prediction of potential migration of *Alnus spp*. by using the climate parameter of four RCP scenarios shown differences on global scale for the two projection periods (2100 and 2300).

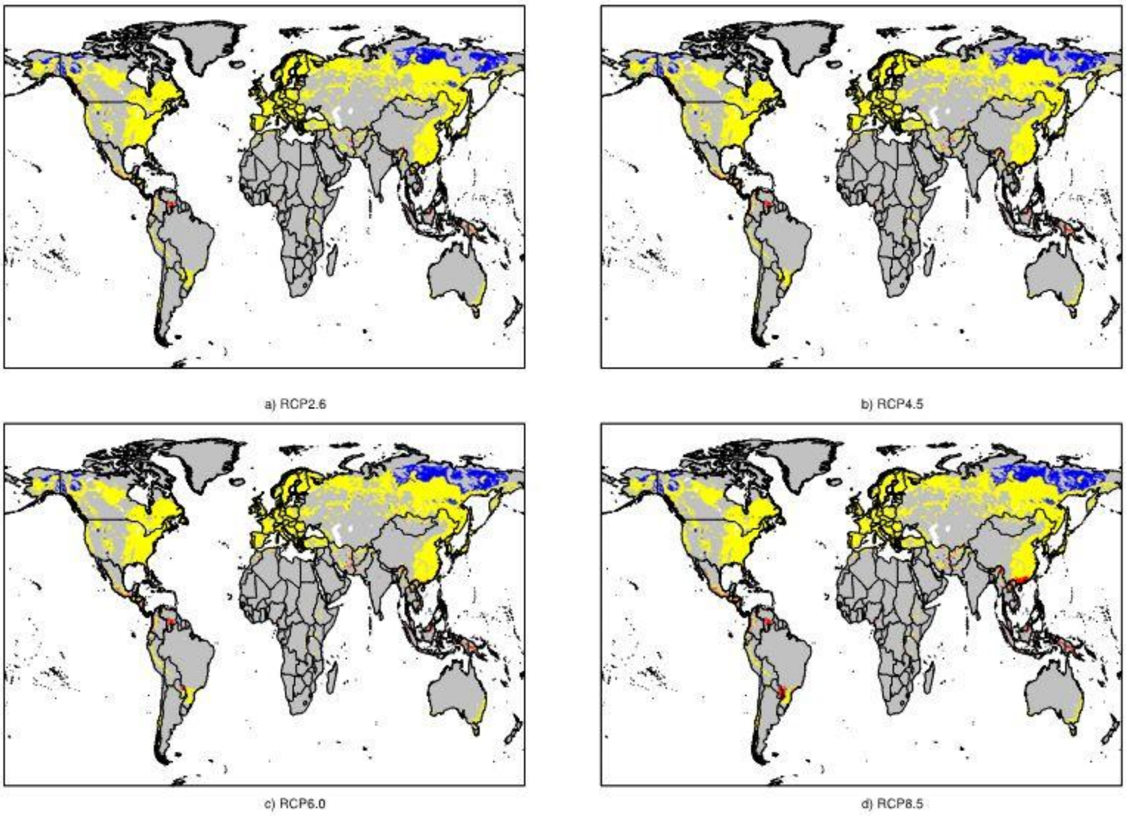

Figure 6. *Distribution of grid elements which were identified as potential sites for alder distribution based on the "All" method in ADM by using the climate data from CCSM4 data model which was driven by four RCPs emission scenarios. The colour "yellow" represents the potential distribution areas both present and in 2100, where the colour "red" shows the grid elements with present potential distribution but not in 2100, and also the colour "blue" the grid elements with potential distribution in 2100 but not present.*

The results indicated that only a change in two climate parameters (i.e. T_{ann} and P_{ann}) can affect the existence and distribution of plants in terrestrial ecosystems in the end of the 21th century. The validation of the methods also pointed out that the changes of soil types and vegetation compositions have enormous influences on the distribution of alders, and this should be considered in modelling studies about plant distribution.

The changes of the climate parameters within the four RCP scenarios have quite similar impacts on the alder distribution at global level in 2100 (see *Figure 6 a, b, c* and *d*). In 2300, the alder distribution was more affected by the change of the climate parameters in RCP8.5 scenario in the tropical and sub-tropical regions than other three RCP scenarios (see *Figure 7-d*).

Discussion

The records for the distribution of the world's vegetation types was started by foundations of plant geography ca. 200 years ago (Humboldt, 1807). Also at the beginning of 18th century the scientist started to investigate about the potential effect of climate on plant distribution (Schouw, 1823; Meyen, 1846). Nowadays, numerous models use the climate conditions for the prediction of plant species distribution, and for the modelling of phenological processes of plants (Prentice et al., 1992; Brovkin et al., 1997; Smith et al., 2001; Skjøth et al., 2008; Sakalli and Simpson, 2012). Lantz et al. (2010) investigated the regional temperature impacts on the *Alnus viridis* subsp. *fruticosa* (green alder) patch dynamics and plant community (Lantz et al., 2010). They found out that the regional temperature influence the cover, growth, reproduction and age distributions of the green alder. Martínez-Meyer and Peterson (2006) worked on niche models to determine the distribution of eight taxa including *A. incana* and *A. viridis* in North America by using pollen distribution data on present day, and climate data from the Palaeoclimate Modelling Intercomparison Project in Last Glacial Maximum (LGM). They found a similar temperature-precipitation demand for the distribution of *A. incana* (see *Figure 3* in the paper). The using of only climate

DOI: http://dx.doi.org/10.15666/aeer/1504_10391070

parameter in ADM predicted the distribution of all alder species almost in whole Australia, Middle and South Africa, where there is no or very poor record about the distribution of alder (see *Appendix Figure 1*). Also, the statistical analysis of the “Clim” methods has the poorest correlation in the 20 countries with high density records about the alder distribution. Sykes et al. (1996) developed a bioclimatic model based on climatic geography of the European plants to predict the distribution of northern Europe’s dominant trees including the alder species *A. incana*. They used the bioclimatic factors as winter cold tolerance, summer heat and winter cold requirements, and drought tolerance (soil moisture) of the species. Although the bioclimatic model supplied quite good result for the *A. incana* distribution, it also showed that the distribution of plants was not only depending on the climate factors but also the soil conditions could play a crucial role in the prediction. Like most of the models, the bioclimatic model could be used for prediction of the distribution of specific alder species (not for all species of genus *Alnus*) on regional scales and needs predefined parameter for each species. Compared to the bioclimatic model, the ADM has the advantage to predict the distribution of all alder species on global and regional scale.

Since, the selected climate factors were alone inadequately to predict the distributions of alder species, and it is well known that the components of each plant community are influenced by soil units, and the alders prefer some specific soil conditions for the occurring in a natural ecosystems (Bean, 1989; Wheeler and Miller, 1990; Claessens et al., 2010), the soil units were used as additionally determinant to the selected climate factors for the modelling of potential alder distribution areas. The addition of the soil units to the “Clim” method showed its impacts mostly in East Europe, Australia, Central and South Africa as well as in North America. But in comparison to the distribution Map from GBIF and the literature data, quite a lot areas were still selected as potential distribution locations for the alder species in that areas (see *Figure 4* and *Appendix Figure 2*). Also, the statistical analysis between the observed and predicted data in the 20 countries resulted a rare correlation (see *Figure 3b*).

In the natural ecosystems plants are living in a species compositions which are called plant communities (Schmithüsen, 1968). Each plant species belongs to a community and is related to other species of the community (Breckle, 2002). Therefore, the relations of the species in plant communities, and the using of the relations were quite important in modelling of distribution of plant species. Woodward and Williams (1987) investigated the effect of climate on plant distribution on global and local scales. Their predictions of the distribution of the vegetation were based on temperature, precipitation and annual water balance of the distribution areas. They enhanced also that the climate conditions are not sufficiently for the modelling of the distribution of vegetation or species, and in such modelling studies, the population dynamics (plant–plant interactions) should be also considered. Therefore, the potential natural vegetation groups after Schmithüsen (1976) were used as additional determinant to the “Clim method” for the prediction of the potential distribution areas for alder species. Although the statistical of the results in the 20 countries showed quite good correlation with the observed data from the GBIF database (see *Figure 3c*), on the global scale, the comparing of the results (see *Appendix Figure 3*) with the distribution map from GBIF database (see *Figure 4*) presented noticeable differences in East Europe, in Canada, Southeast Australia and America. In some local studies, the scientist tried to find out the interspecific relationships between plant species in plant communities, and the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_10391070

relationships between the dispersal of the species and the environmental, biological, and geological factors. Jones et al. (2008); Flinn et al. (2010); Aiba et al. (2012); Lin et al. (2013) pointed out that plant dispersal is not depending on environmental factors. They found a poor correlation between the environmental factors and plant dispersal. On the other hand, they also did not use the combination of annual average temperature and sum of the precipitation as determinant in their studies. The used parameters (Wind, NO3, soil humus content etc.) were also dynamic parameters, which can have strong seasonality. The ADM considered the average of 30 years of the climate data (1961–1990). That eliminated the uncertainties regarding to the dynamic seasonality of climate parameters.

Although, only 6% of the alder distribution can be explained by using the climate data in this study (see *Figure 3*), results of this study showed that the distribution of plant species was not only depending on the climate factors but also on the soil types, and the vegetation units should be considered together. The additions of soil units and potential natural vegetation groups to the "Clim" method pointed out that both determinants can influence the prediction of the potential distribution areas of alder species in different regions. Therefore, all determinants were merged in one method for the modelling of the potential distribution areas of alder species. The "All" method of the ADM shows a new kind of modelling issue for plant distribution. The statistical analysis of the "All" method results showed quite good correlation and the best value of index of agreement as well as the lowest *MAE* (see *Figure 3d*). The predicted potential distribution areas for alder species using the "All" method was presented in the *Figure 5*. In comparison to the potential distribution maps of the "Clim", "Soil" and "Veg" methods, there is a further improvement of the predicted distribution especially in Central and Eastern Asia, and in America. But there are still differences between the observed and predicted distribution areas in Asia, Africa, Southeast Australia and America. It is well known that alder grows well on acid soils and its growth can be restricted under the alkaline or neutral conditions. "Lithosols" are typical soil unit in temperate climate zone under coniferous forests, and the "Camsbisols" are well represented in boreal and temperate regions. The two soil units are well represented in Russia and known as acid soils. Suitable climate conditions and vegetation groups make possible to distribute the alders in large areas in Russia. Murai (1968) published the potential distribution areas of alder species (*A. viridis* and *A. crispa*) in Russia in a vegetation map (Murai, 1968). It shows that the distribution of *A. viridis* and *A. crispa* stretches in most vegetation zones of Russia. Also, Kajba and Gracan (2003) illustrated a map for the distribution of *A. glutinosa* in Europe (Kajba and Gracan, 2003). It showed that *A. glutinosa* also distribute in several locations in Russia. These maps confirm that the results of ADM prediction for Russia are acceptable. Furthermore, the GBIF database does not indicate the absence of alders. Therefore, grid elements with no data records may indicate either the absence of alders or the absence of observations. Because of the suitable climate, soil, and vegetation conditions, it is highly probable that alders can distribute in these areas (Czerepanov, 1995). Globally, ADM may provide better results for the distribution of this genus. The discussion of this results also shows the importance to improve the GBIF database for validation of such model results. In China, the alder distribution was recorded in only three grid elements (see *Table 4*). But "All" method based ADM predicted the distribution in 1376 grid elements more than the GBIF database. Likewise, it is well known that *A. nepalensiss* distributes in moist, cool, subtropical monsoon climates with a dry season of 4–8 months in Guangxi,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_10391070

Guizhou, SW Sichuan, Xizang, Yunnan of China (Furlow, 1979; Sharma and Ambasht, 1991; Chen, 1994; Jackson, 1994; Dorthe, 2000; Chen and Li, 2004). It also shows that the prediction of ADM for alder distribution is more reliable than GBIF database in China. Furthermore, some regions in Central Africa and southeast Australia still remain. The regions in Central Africa are known to be suitable for alder cultivation, however, no natural occurrence of alders is recorded in the areas. Such plantations of alder species are also recorded in African highlands (Wajja-Musukwe et al., 2008; Muthuri et al., 2009; Siriri et al, 2013). Niang et al. (1996) published data about the adapted alder species (*A. acuminata* HBK) to the highlands of Rwanda in Central Africa. The average annual rainfall is 1500 mm and the annual mean temperature is 14.6 ºC in the study site. The values of the climate parameters are in the climate field (see *Figure 2*). The dominant soil unit is a “Podzols” and the vegetation group is a “tropical forests of higher elevation”. Both the soil unit and the vegetation type are presented in the 308 evaluation’s data (see *Tables 2* and *3*). This result shows that the alder species can well distribute in some areas of Central Africa, and the prediction of ADM can be right in Central Africa. In southeast Australia, 8 records in totally 3 grid elements were recorded in GBIF data base (see Table 4). But the model results shown that alders potentially can distribute in 157 grid elements in this area. The T_{ann} and P_{ann} values in the regions range 8–15 ºC and 500–1100 mm, respectively. The dominant vegetation unit is “Laurel mountain forests” as well as “Laurel forest w. conf. trees”, and “Luvisols” are the most recorded soil types in southeast Australia. The values of the climate parameter in the 157 grid elements are found in the climate matrix field in the *Figure 2* as well as the vegetation units and the soil types are appropriate units and types for a potential alder distribution. Therefore, it is quite possible that the alders can have larger distribution than as recorded in GBIF database for southeast Australia. Hnatiuk (1990) also recorded an alder species (*A. glutinosa*) in Australia, and indicated that four related species have also naturalized in Australia. But, there is no information about the distribution locations of the alders in his study.

A visible and an important difference between the predicted and observed alder distribution is to see in South American lowland and Araucaria forests in Brazil and Paraguay (see *Figure 5*). The ADM show the potential alder distribution in 168 of 1 653 grid elements in Brazil and in 40 of 143 in Paraguay where the GBIF database does not include data records about the alder distribution. But, Ledru et al. (2007) and Behring (1997) published data about the pollen distribution of some alder species in Araucaria forests in South Brazil. Also, Marchant et al. (2002) presented data about pollen distribution of alder in several Middle and South American countries. They found alder pollen in gallery forests and forests with *Quercus–Pinus* species. These pollen data show that alder species have distributed in the regions of South America with suitable climate conditions, soil units and vegetation groups. But, data records about current occurrence of alders with coordinate data are still needed in the regions for a reliable comparison of the model results.

The pollen records of the alder species in some areas, where the alders currently do not represent show that the alders have potential for migration. Van Minnen et al. (2000) reported that the alders need between 50 and 200 years to change its distribution areas due to the climate change. The migration of nitrogen fixers will certainly influence the natural nitrogen fixation in the ecosystems. Esser et al. (2011) showed the effect of nitrogen fixation on carbon biogeochemical cycle by switching off and on the nitrogen fixation fluxes in the nitrogen carbon interaction model (NCIM) (see model scenarios in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_10391070

Esser et al., 2011). They presented a three times carbon storage with a nitrogen availability than without in the biosphere. Since a migration of N_2-fixing plants changes the amount of available nitrogen in soil for soil microorganisms and plants, as important N_2-fixing group, the investigation of the spatial and temporal alder migration is quite important.

The using climate parameters from different climate models and scenarios gives important indications of climate change effects on alder distribution and migration in the future. As it presented in *Figure 1*, CCSM4 provides variously T_{ann} and P_{ann} by using four IPCC RCP scenarios. There is quite difference between the values of the T_{ann} as well as P_{ann} of the models, and the difference between the four scenarios of the models are quite large (ca. 16 ºC for T_{ann} and ca. 250 mm for P_{ann} in 2300). Though, the effects of the climate parameter of the models, and scenarios on the alder distribution on global scale are quite similar (see *Figure 7*). There is unfortunately no similar study to compare the results of the ADM by using values of the climate parameter from the four IPCC RCP scenarios of a GCM model. Therefore, it is assumed that the prediction of the potential alder distribution (migration) in the future is quite reasonable according to the results of this study.

Conclusion

In this paper, a new methodology for predicting of potential distribution of alder species on global scale is presented. The new methodology of ADM gives the scientist the possibility to understand the climatological and ecological requirements of alder species to distribute in natural areas and the opportunity to implement a simple method to predict the potential distribution locations of the alder species on each resolution. The using simplified approaches as in "All" method of the model allows the scientist to understand the functionality of plant distribution by considering the environmental and geological factors. The model shows that combine effect of the all three parameters (i.e. climate, soil, vegetation) is the predictor for the identification of potential habitats for the alders. Climate alone may not predict the range of alders correctly. By using soil units and potential natural vegetation groups as additional predictors, the identification of potential alder sites is much closer to the presented distribution map of GBIF database. In this paper, the temporal and spatial change of alder distribution was modeled by using the climate variables from the CCSM4, which was driven with four RCP scenarios (RCP2.6, RCP4.5, RCP6.0, RCP8.5) up to 2300. The using of climate variables should give an overview of the sensitivity of the methodology for modelling of plant distribution according to climate models. The using of the climate variables of four RCP scenarios in this study allows the scientists the investigation of the sensitivity of plant distribution by considering the different emission scenarios on global scale up to 2100 and 2300, respectively. Because of the missing dynamic vegetation data and dynamic soil unit data for 2300, only the climate parameters were dynamically changed in the ADM for predicting the potential distribution of alder species in 2300. The results of the ADM show that numerous regions in Northern Hemisphere will get the suitable conditions for the migration of alder species. But also, a lot of grid elements in Southern Hemisphere will not be suitable for alder occurrence.

Although clearly dynamic datasets for soil units and vegetation groups are needed for a testimonial evidence, the simple requirements of the ADM methodology might make it suitable for use in other biogeochemical models and other modelling systems.

(Received 19th Mar 2017; accepted 1st Aug 2017)

Abstract. In this study, the spray pyrolysis and hydrothermal production processes of nanostructured zinc oxide were compared in terms of health and environmental risk on a semi-industrial scale with a capacity of 2000 kg/year. For this, environmental release and human exposure to identified sources of pollution in each production process were modeled using the Chemical Screening Tool for Exposure and Environmental Release (ChemSTEER) software. Spray pyrolysis and hydrothermal were compared pair-wisely by analytic hierarchy process (AHP), which is a multi-criteria decision-making model using health and environmental indicators. According to AHP results and box plot chart, hydrothermal process leads to a higher health and environmental median inverse risk compared with spray pyrolysis. Thus the synthesis of nanostructured zinc oxide by hydrothermal process is safer than spray pyrolysis. Due to the growing development of the various methods of the nanomaterials, we need to apply the safer methods and to have the least ecological risks in the production of the nanomaterials. These findings could be helpful for modifying the operation and reducing the ecological potential risks to scale up the existing pilot plant to an industrial unit.
Keywords: *ecological aspects*, *environmental release, nanotechnology, process design, analytic hierarchy process*

Introduction

Environment and ecological risk assessment

The word “Ecology” literally means the mutual effects of the environment on the living organisms, and the living organisms on the environments along with interrelationships between organisms. (Michener, 2006) A branch of the ecology is to understand the relationship between man and the environment and their consequences on the environment. The experts have hardly emphasized on the effect of the human activities on the features of the ecosystem up to now. However, to figure out the structural changes in the ecosystem, we need to have a comprehensive understanding of the stressors and their impacts on the environment and the ecosystem. (Jounston et al., 2015) It should be noted that the chemical pollution is one of the stressors that we can find everywhere, and it can make some changes in the process of the ecosystem. (Mc Mahon et al., 2012). Pollutions from many sources in various formats can go to the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_10711082

ecosystem, besides they can cause many environmental risks. Therefore, the environmental risk assessment of the chemical contamination can be a step towards a reduction of the dangers and the protection of the environment. The risk assessment is a rational way to determine the size of the quantitative and qualitative hazards, and the possible consequences of the hazards on people, materials, equipment and the environment (ISO/IEC, 1998). It has four stages.

- The description and identification of the hazards.
- The exposure assessment (e.g. the emission or environmental fate).
- The risk assessment.
- The risk management (Ostertag and Husing, 2008). The results of the risk assessment can effectively lead to changes in the environmental management policies. (Vall-llosera and Sol, 2009). We consider the nanotechnology as an applicable technology in recent decades. This technology comes from the convergence of physics, chemistry and biology.

Some studies consider nanotechnology the next industrial revolution (Scrinis and Miller, 2006), as it is changing other industries, including health, environment, agriculture, energy, materials, and communication sciences (Rickerbya and Morrison, 2007).

Nanotechnology has been able to make some significant changes in various industries, for instance, using carbon nanotubes which have been able to upgrade the mechanical properties of tires, or the nanoparticles are used as the catalysts for the petrochemical industry. Nevertheless, the particles have the potential to cause the ecological hazards. Moreover, several factors can make the nanoparticles go to the environment through the air, soil and groundwater. They can be a threat to the organisms in the environment or vicinity of the environment. The key aspects of the risk assessment in the field of the nanomaterials are the identification of the physical and chemical properties of nanomaterials, the identification of the environmental hazards, the identification of the hazards, and how humans face with ecosystem risks and their effects (Colvin, 2003; Maynard, 2006). The results of the risk assessment are the important components to ensure various industries in the safety of their industry (Drobne, 2007). In this way, we can determine the efficiency of the inventory controlling procedures; moreover, we can prepare some valuable data for making decision on the reduction of the risks, hazards, upgrading the control systems and planning to respond to them.

Ecological impact and nano technology

Nanotechnology provides the ability to fabricate smaller materials with a significantly reduced volume of active materials, a high surface area to volume ratio, and increased performance (Moore, 2006; Gregory, 2010).

The high-level reactivity of the nanomaterials can be a threat to humans and the environment. This increased reactivity gets the nanoparticles to have an uncontrollable and unpredictable high potential in the reaction with many molecules found in the nature, cells and organisms. On the other hand, the very small size of the nanoparticles reinforces the hypothesis that particles can pass through the immune system. Some inhaled particles can enter the lungs; consequently, they can enter the bloodstream. (Moghimi and Hunter, 2001)

Due to the increasing consumption of these materials industries, for instance, the nanoparticles such as titanium dioxide are some of the air pollutants which can cause

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_10711082

inflammation and lesions of the mucous, and accumulate in the lungs (Moghimi and Hunter, 2001). In addition, the nanoparticles of the titanium dioxide and zinc oxide in sunscreens can cause free radicals in skin cells and damage DNA. Damaging to DNA can also make some changes in the structure of the proteins and their functions; subsequently, they can lead to the cell cancer, the metastasis and tumors (Poirier, 2004). Titanium dioxide nanoparticles have some other applications including cleaning the environment, soil, water and air. Hence, these particles can easily enter the environment, and they can enter to the food chain through vegetarian and fish, owing to it, they can spread out in organisms in ecosystem. The processed carbon nanoparticles gluten causes the depletion and the oxidation in fish's brains and changes in the functions of genes. The substance can also be transmitted through the soil, as a result of it, earthworms can absorb these substances, and then they enter to the food chain (Oberdorster et al., 2004). The miners and workers exposed to the nanoparticles of quartz (the carcinogenic materials) are susceptible to the dangerous diseases. The researches show that the impacts of the carbon nanotubes are more toxic than the quartz dusts on mice's lungs in the laboratories (Lam et al., 2004). The high surface reactivity of quartz and carbon nanoparticles can make free radicals; consequently, it can cause the oxidation of the white blood cells and immune cells.

The formation of carbon nanotubes and nanocrystals are accumulated in the air.

Nanocrystals composed of the carbon particles are more dangerous than the individuals not the accumulated ones to the living organisms. The researches also show that the unprocessed carbon nanotubes, which are either displaced or aroused enough, can form the dust particles (Maynard et al., 2004). Carrying the carbon nanotubes is somehow hazardous to the health. Furthermore, the factories which are either the manufacturers or the consumers of the carbon nanotubes-based products endanger the health of workers (Oberdorster et al., 2004).

Increasing use of nanotechnology and nanomaterials has significantly increased exposure of workers to nanomaterials, increasing threats to employee health and to the environment (Savolainen et al., 2010). This necessitates the need for increased global research on the use of nanotechnology to combat unsanitary living conditions (Nowack and Bacheli, 2007).

The unclear adverse effects of nanotechnology on humans and the environment (Ostertag and Husing, 2008) have led many organizations in the world, such as the national institute of health, national nanotechnology initiative, nanomedicine roadmap initiative in the USA, center of nanotechnology, institute of nanotechnology, nanoscale science and nanotechnology group, manufactory engineering center, and other similar organizations in Europe to invest heavily in nanotechnology research.

This study is also done to promote research in the field of nanotechnology and nanoparticles as an emerging technology. Studies on the ecological effects of the chemicals often occur in the early stages of the materials consumption and their disposal. In addition to the ecological assessments in the consumption and disposal, we can do these studies in the stages of production of materials. In this case, the manufacturing processes and the ecological effects are less developed by the result. Many studies have been done about the assessment of the biological environment and health during the production process of a substance. In 2010a, Hasim and Hurmeh evaluated and compared the methyl methacrylate production based on the health indices through the six stages. In the same year (2010b), they introduce a method known as the health quotient index (HQI) in another study. The HQI method presents a simple

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_10711082

approach to assess the people's health which some hazardous factors may expose their health; moreover, this method can present the ranking of the manufacturing process risks. Their method has been tested in six different- production process of the methyl methacrylate.

These authors also estimated the chemical concentration of fugitive emissions during chemical process design (Hassim, Perez and Hurme, 2010). Similar studies have been conducted by Srinivasan and Trong (2010). Gupta and Edward (2003) introduced some indices such as the Inherent Safety Design index. In another study, Rahman, Heikkila and Hurme (2005) compared inherent safety index methods and discussed their properties and limitations. A case study of methyl methacrylate process routes was conducted in 2005. In the same year, Faisal khan and Paul Amyotte presented the conceptual framework of the inherent safety index. Risza and Azmi (2010) proposed a methodology that integrated the hazard review technique with inherent safety, which is useful for identifying risks at an early stage of the production process

Objectives

This study aims to introduce a suitable method of zinc oxide nanostructure production with regard to health and environmental parameters.

In this study, spray pyrolysis and hydrothermal processes for producing nanostructured zinc oxide were compared under normal operating conditions with regard to health and environmental risks.

The high strength of zinc oxide under the harsh conditions of industrial processes and its high activity at the nanoscale (Rajendran et al., 2010) in comparison to the microscale (Zhang et al., 2009), low toxicity, good thermal stability, good oxidation resistibility, good biocompatibility, large specific surface area and high electron mobility (Pan and Huang, 2011) suggests the importance of using the material in different industries. The high consumption rate of zinc oxide in various industries on one hand, and the ability to produce zinc from domestic sources on the other hand, are encouraging factors for the study on health and environmental risks of producing nanostructured zinc oxide.

Spray pyrolysis is based on the liquid atomization technique (Madler, 2004). It is an economical, easy, and continuous technique *(*Charp et al., 2015*)*. In the spray pyrolysis process, a solution of zinc salt [Zn $(NO_3)_2.6H_2O$] are placed under a pressure and temperature of 20 bar and 80 °C, respectively. The decomposed droplet as resulting mixture was pumped as feedstock into a spray dryer reactor at a temperature of 500-800 °C (Ghaffarian et al., 2011). The product was subsequently fed into a cyclone to separate the particles based on their sizes. A scrubber and caustic soda were used to neutralize NO_x emitted from filtering process.

The hydrothermal method is based on crystal synthesis at temperatures above 100°C and pressures above 1 atom (Hayesh and Hakuta, 2010). It uses simple equipment, is catalyst free and low cost (Aneesh, Vanaja and Javaraj, 2007), and constitutes a batch method. In this study the crystals of zincsalt [$Zn(NO_3)_2.6H_2O$] is used. Leached solution from reactor will be cold rapidly and then filtered.

In this study, we compared, for the first time, the spray pyrolysis and hydrothermal production processes of nanostructured zinc oxide under normal operating conditions in terms of health and environmental risks at Iran's Research Institute of Petroleum Industry (RIPI) in 2015.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_10711082

Environmental release and the exposure level to chemicals during each of the processes with the same production capacity was determined separately for each pollutant sources. Subsequently, spray pyrolysis and hydrothermal processes were compared pair-wisely using analytical hierarchy process based on respiratory harms, skin harms, and environmental damages such as air, water, and soil pollution to determine the optimal method in terms of health and environmental risks.

Materials and methods

As already mentioned this study aims to introduce a suitable method of zinc oxide nanostructure production with regard to health and environmental parameters. For this purpose, pollution sources in zinc oxide nanostructure spray pyrolysis and hydrothermal processes were identified. The Chemical Screening Tool for Exposure and Environmental Release (ChemSTEER) was used to model the release of possible pollutants and the amount of human exposure in each process.

ChemSTEER software, developed by the United States American Environmental Protection Agency (US EPA) was used to model the release of possible pollutants and the degree of human exposure in each process. The software is capable of estimating the extent of respiration and skin contact with chemicals during industrial and commercial production processes. It can also estimate the amount of chemicals released into the environment during industrial production (EPA, 2014).

According to the results of ChemSTEER, the spray pyrolysis and hydrothermal process were compared pairwise using the analytic hierarchy process (AHP) in Expert Choice based on five criteria. Respiratory and skin damage as the health subcriteria and air, water, and soil pollution as the environmental subcriteria to investigate suitable zinc oxide nanostructure production methods with regard to the environment and health. Criteria mentioned are the most important criteria in health (Hassim and Hurme, 2010c) and environmental assessment (Kweku et al., 2008; Som et al., 2011*)* which have frequently been used by researchers.

AHP method was performed by weighting of criteria and prioritizing of alternatives using eigenvector technique. This is one of the most comprehensive systems designed for decision making with multiple criteria by which it is possible to formulate the problem as a hierarchy. It also offers the possibility of involving qualitative and quantitative criteria in decision making (Saaty, 1986, 2008).

According to AHP results the box plot diagram of inverse risk has been drawn, and the optimal production process of nanostructured zinc oxide was introduced

Results

As mentioned earlier, each of the two processes has been studied from health and environmental aspects. For this, following the investigation of spray pyrolysis and hydrothermal processes and identification of pollution sources in each process, skin and respiratory exposure to chemicals released into the environment were modeled by ChemSTEER software.

The pollution sources of spray pyrolysis under normal operating conditions includes NO_x fumes from the feeder, spray dryer, and scrubber and sodium nitrate solid waste from filtration. Pollution sources of hydrothermal process under normal operating

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_10711082

conditions include NOx fumes from the reactor and waste water include sodium nitrate and different kind of solvent.

In this study, the emission sources and human exposure of spray pyrolysis and hydrothermal methods used in two semi-scale nanostructured zinc oxide production processes with a capacity of 2000 kg/year were modeled by ChemSTEER software. To run this software, the chemical properties of primary substances, including their vapor pressure, molecular weight, density, and solubility in water, were required. Next, operation parameters and polluting sources or activities were determined. ChemSTEER has provided default models. The estimation of the environmental release and chemical exposure occurs according to the operation process and polluting sources. Spray pyrolysis is a continuous process; hydrothermal is a batch process. The duration is eight hours for the former and one hour for the latter. Production per process of each is 100kg; the number of individuals exposed to the emissions in each working shift is 5 people.

According to the results, the average daily exposure resulting from respiratory contact with NO_x emitted from the feeder, spray dryer, and scrubber in the spray pyrolysis process are 0.00012, 0.00096, and 0.00004 mg/kg/d, respectively. While the average daily exposures from inhalation and skin contact with the waste storage tank in the spray pyrolysis process containing sodium nitrate are 0.039 and 0.8088 mg/kg/d, respectively. The environmental release of NO_x emitted from the feeder, spray dryer and scrubber in the spray pyrolysis process are 0.012, 0.1, 0.004 μg/m³, respectively. Moreover, the possible daily release rate of sodium nitrate from waste storage tank is 0.161 kg/day.

The average daily exposure resulting from respiratory contact with NO_x emitted from the reactor in the hydrothermal process is 0.02 mg/kg/d. While the average daily exposures skin contact with the waste water in the hydrothermal process containing sodium nitrate and different kind of solvent is 1.2 mg/kg/d. The environmental release of NOx emitted from reactor in the hydrothermal process is 0.16μg/m³.

Tables 1 and *2* present the results of respiratory and skin contact along with environmental release modeling for each of the pollution sources in spray pyrolysis and hydrothermal.

Table 1. *Inhalation and skin contact*

	Type of Contact	**Pollution Sources**	**Potential Dose Rate (mg/d)**	**Life Time Average Daily Dose (mg/kg/d)**	**Average Daily Dose (mg/kg/d)**	**Exposure Limit TWA (8 h)**	**Acute Potential Dose (mg/kg/d)**
Spray Pyrolysis Method	Inhalation	No_x emission from feeder	0.1546	0.000069	0.00012	5 ppm	0.0022
		No_x emission from spray dryer	1.2328	0.00055	0.00096		0.018
		No_x emission from scrubber	0.061	0.000027	0.000048		0.0009

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_10711082

		Waste storage (sodium nitrate)	49.99	0.022	0.039	5 mg/m^3 or 1.438ppm	0.7142
	Skin	Waste storage	1033.23	0.4622	0.8088	5 mg/m^3 or 1.438ppm	14.7604
Hydrothermal	Inhalation	No_x emission	4.98	0.0022	0.02	5 ppm	0.56
	Skin	Waste water	202.45	0.091	1.2	-	22.4

Table 2. *Environmental release*

Method	Pollution Sources	Media	Daily Release Rate (kg/site-day)	Annual Release Rate (kg/year-all site)	Annual Concentration (μg/m³)	Annual Standard
Spray Pyrolysis	No_x emission from feeder	air	0.012	0.026	0.012	0.053 ppm (100 μg/m³)
	No_x emission from spray dryer	air	0.01	0.2	0.1	
	No_x emission from Scrubber	air	0.0005	0.01	0.004	
	waste storage (sodium nitrate)	soil	0.161	0	-	-
Hydrothermal	No_x emission from reactor	air	0.002	0.051	0.16	0.053 ppm (100 μg/m³) annual
	Waste water	soil/water	0.5	10	-	-

According to *Table 1*, the average daily exposure to NO_x and solid particles in a sodium nitrate waste storage tank during spray pyrolysis and the average daily exposure to NOx from reactor during the hydrothermal process are below the 8-hour occupational exposure limit. Also, the average daily exposure of skin contact to sodium nitrate during spray pyrolysis is 0.8088 mg/kg/d, which is below the 8-hour occupational exposure limit, regardless of the acute potential dose

According to *Table 2*, the emissions from feeder, spray dryer, scrubber during spray pyrolysis and reactor during hydrothermal process are below the standard.

To introduce a suitable method of zinc oxide nanostructure production with regard to health and environmental parameters, the spray pyrolysis and hydrothermal techniques were compared pair wisely using AHP in expert choice software based on respiratory harms, skin harms, air, water, and soil pollution according to the results of ChemSTEER. The criteria were weighted by averaging the scores in the structured questionnaires given by industrial and academic experts in environment, health, ecology, chemistry and nanotechnology.

The obtained results indicate that the hydrothermal process with 0.61 wt % has a lower health and environmental risk than the spray pyrolysis process with a 0.39 wt %.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_10711082

Thus, it can be concluded that the hydrothermal process would be a more health and environment- friendly process for the production of nanostructured zinc oxide (*Table 3*).

Table 3. *Pair wise comparison of spray pyrolysis and hydrothermal*

	Health criteria		**Environmental criteria**			**Final result**
	respiratory harms	**skin harms**	**air pollution**	**soil pollution**	**water pollution**	
Spray pyrolysis	0.125	0.5	0.25	0.5	0.5	0.39
Hydrothermal	0.875	0.5	0.75	0.5	0.5	0.61

Also the box plot diagram of inverse risk has been drawn according to AHP results (*Figure 1*). Box plot diagram indicated that hydrothermal process leads to a higher health and environmental median inverse risk compared with spray pyrolysis. Obviously, higher inverse risk leads to a safer health and environmental condition. Thus it can be concluded that the hydrothermal process with higher inverse risk would be a more health- and environment-friendly process for the production of nanostructured zinc oxide.

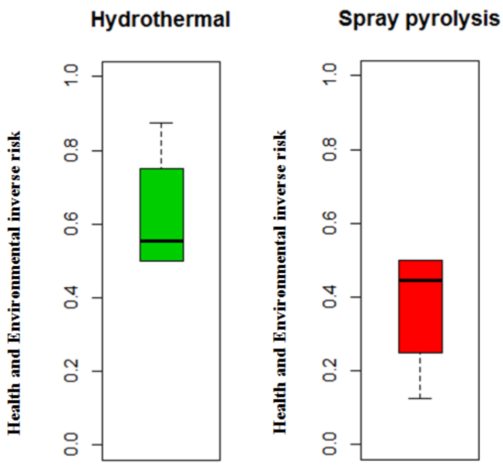

Figure 1. *Box plot diagram of inverse risk*

Discussion

Prior works have been carried out on the health and environmental impacts of nanotechnology (Gregory, 2010; Dreher, 2004; Moore, 2006; Steffi and Jurgen, 2007),

Studies on the ecological effects of the chemicals are often done in the early stages of material consumption and its disposal. In addition to the ecological assessments in the consumption and disposal, we need to study them in the production of materials. Thus, we can control the manufacturing processes and the ecological effects through the analysis of the results. several Studies on ecological and environmental risk assessment in production processes, especially during the early stages of the production process, except nano-materials, have also been conducted (Hassim and Hurme 2010a; Rahman et al., 2005; Srinivasan and Trong, 2008).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_10711082

What we can get from the similar surveys of the risk assessments of the chemicals in manufacturing processes is the lack of comprehensive studies on the nanomaterials production processes. Due to the growing development of the various methods of the nanomaterials and the development of the products based on nanoparticles, we need to apply the safer methods and to have the least ecological risks in the production of the nanomaterials. In this case, we are able to step in reducing the environmental risks associated with the development of this modern technology.

The above-mentioned results are based on health and environmental risk assessment of spray pyrolysis and hydrothermal synthesis of nanostructured zinc oxide on a semi-industrial scale. These findings could be helpful to mitigate ecological risk and scale up the existing pilot plant to an industrial unit with minimum environmental impacts.

The increasing use of nanoparticles as an attractive tool in the industry, as well as difficulties controlling the size and shape of nanomaterials, suggest the optimal method of nanomaterial production. This is despite the health and environmental consequences of nanomaterial production, which may be irreversible.

Studies on adverse health and environmental effects during the early stages of technology development and industrialization could effectively mitigate ecological risks. Process modification, substitution of hazardous chemicals with safer compounds, and presenting risk mitigation strategies are important topics, especially in nanomaterial production processes. These studies could be useful in identifying and reducing risks during the initial stages of the development process.

To this end, this study was conducted to identify the health and environmental risks of nanostructured zinc oxide production processes, which have received relatively little attention. The distinguishing feature of this study is to analyze the risks of nanomaterial production on a semi-industrial scale for the first time.

In this study the emission sources and human exposure of spray pyrolysis and hydrothermal methods used in two semi-scale nanostructured zinc oxide production processes were modeled by ChemSTEER software. Using ChemSTEER, spray pyrolysis, and hydrothermal techniques were compared pair-wise using AHP on respiratory harm, skin harms, air, water, and soil pollution indices.

According to the result the hydrothermal process with 0.61 wt % has a lower health and environmental risk than the spray pyrolysis process with a 0.39 wt %, so the production of nanostructured zinc oxide by hydrothermal processes is less risky than spray pyrolysis from health and environmental viewpoints.

On the one hand there is the management of the environmental and ecological risks; on the other hand we need to take some necessary measures to improve the performance of the method in the early stages, because the development of the production processes could be much more efficient and cheaper.

It is therefore recommended that–to develop a safer industry and to prevent irreparable events and environmental impact–further research is required on this topic**.**

Evaluating the other processes in the production of nano-materials disposal, we can use either other models such as fuzzy models of high accuracy or the neural network models which are capable of making new structures for the information processing system. We can compare the results of the hierarchical models which are accessible, functional and reliable by them. It is clear that these studies could help both to develop more secure industries and to prevent the devastating effects of the ecological and environmental factors.

(Received 19th Mar 2017; accepted 1st Aug 2017)

Abstract. Sustainable development refers to interactions between different aspects of economic, social and environmental features that are designed to improve the quality of human life. The aim of this study is to evaluate urban sustainability in different urban areas of the Kermanshah city of Iran. An important city in western Iran, Kermanshah faces several social, economic and environmental problems, thus confirming the need for this research. This study was completed using multi-criteria decision making (MCDM) methods, including SAW, ELECTRE and TOPSIS. The results of these three methods indicated that different urban areas in Kermanshah city have different sustainability levels and among the six urban areas, area 4 was designated as first priority. In addition, this paper offers some necessary strategies on the issues relating to the planning and management of Kermanshah city. Furthermore, the results of three methods were compared with each other. The findings of the Friedman Test showed that there is no meaningful difference between the applied methods.
Keywords: *MCDM, sustainable development, SAW, ELECTRE, TOPSIS*

Introduction

Presently, over 50% of the world’s population lives in cities. Cities form the core of social, economic, and environmental development and are also the most probable places to suffer setbacks (Connelly, 2007; Oliver, 2008; Varol et al., 2010). The statistics on the urban growth rate in the world show a significant increase in the rate of 3% in 1800 to 50% in 2008. On this basis, it is expected to increase up to 60% and 70% by 2030 and 2050, respectively (Khazaei et al., 2013). These changes have an impact on economic, social, and environmental conditions and can create problems such as social injustice, inappropriate population settlements, and climate change (Rasoolimanesh et al., 2011; Hassan et al., 2015; Huang et al., 2015). In order to face the aforementioned changes, new approaches and solutions, such as sustainable development, environmental justice, modern city lifestyle, and recently, smart development have been introduced (Taghvaei, 2013; Haikio, 2014). Sustainability was introduced for the first time in 1972 at The United Nations

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_10831100

Conference on the Human Environment held in Stockholm. Also, the Agenda 21 was approved in 1992 among The United Nations Conference on Environment and Development in Rio de Janeiro (Whitehead, 2003). The concept of sustainable development was advanced to solve economic, social, and environmental problems; it is one of the most important debates worldwide, one that sees collaboration from international environmental organizations as well as the United Nations (Rotmansa et al., 2000; Rasoolimanesh et al., 2011; Maleki, 2013). Today, the proposed practical plan considers 21 fundamentals that provide the three necessities of our time, the environmental preservation of water, soil and biodiversity, which our lives are dependent upon (Willis, 2006). There are many definitions of sustainable development. Sustainable development is ‘a kind of development by which today’s generation can achieve their basic needs without limiting the future generation’s resources’. This cannot be achieved till all the factors and criteria have been defined and designed in detail (Leghaee, 1999; Berke, 2000; Jansen, 2003).

Also, the different aspects of sustainable development including, economic, social and environmental should be considered. If any aspects of sustainable development are weak, the system will be unsustainable. Urban sustainable development has the ability to develop the cities and provide the urban future generations and community's needs (Hall, 1993).

Since urban sustainable development comes from the knowledge of the conditions in urban areas, the study and review of the status of such areas is essential. In earlier research, the sustainable development level of Weifang city, of Shandong province, was studied by the AHP method. The result of this study showed that the Weifang sustainability index has been increasing in the last few years due to the environmental infrastructure improvement (Wang et al., 2012). The development of urbanization under the ecological environment restriction in the western region was done by Duan (2012). This study presents the corresponding solutions to increase the urban sustainable development quality. Different methods of multi-criteria decision making (MCDM) systems, such as SAWM, ELECTRE, TOPSIS and PROMETHEE, were used while studying the sustainability of different provinces in India (Sen et al., 2014). Evaluation of urban sustainability in 287 cities in China using TOPSIS-Entropy method has been done. Since, the level of urban sustainability in China was not high and much difference between cities exist, some strategies at urban and regional scale have been proposed (Ding et al., 2016). In another study performed by Zarrabi (2014), the social sustainability of Tehran city in Iran was assessed using factor analysis, and the level of sustainability in each urban area was defined. The same research had been done in Ilam, Iran (2009), Ahwaz, Iran (2013) by Maleki, and Orumieh, Iran (2013) by Mobaraki. Several other studies have also been conducted using MCDM methods (Viteikiene et al., 2007; Rajak et al., 2015; Zhang et al., 2016; Mokhtari Malek-Abadi et al., 2016; Liang et al., 2016; Hsueh et al., 2017).

These studies have been done by various methods and various indicators at different cities with different problems and different conditions. They indicate that there are many differences between areas in a city in terms of social, economic and environmental sustainability indicators and high inequality exist among different urban areas. According to the literatures, the cities have a trouble with legal authority and financial resources to deal with urban problems. These studies have also provided useful information on increasing the sustainable development level of cities and agreed that the urban development should be done by sustainable plans and good management and three

important objectives should be considered including, social equality, economic development and environmental protection. While, community participation is a key role in promoting quality of urban sustainable environment.

As a country, Iran has consistently struggled with economic, social and environmental issues. Therefore, paying attention to sustainable development is essential for the nation's present and future. Several cities in Iran have developed in unsuitable ways, leading to different issues like pollution and chaos. This is particularly challenging on metropolises, which are usually focal points of population, trade, economy, culture, as well as pollution. Despite being one of the most important cities in western Iran, Kermanshah is highly unsustainable due to rapid population growth, high migration rate and increase in trade and economic activities, all of which lead to different problems. Even with the appropriate facilities, services are unevenly distributed among different parts of the city. This study aims to assess the sustainability of urban areas in Kermanshah by using the SAW, ELECTRE, and TOPSIS methods, as well as explore necessary policies to promote the sustainability level in the different areas.

Materials and methods

The study area

Kermanshah is located between latitudes 33°N and 35°N and longitudes 45°E and 47°E. The city, comprising 1.5% of Iran's total area, is located in the west and has a shared boundary with Iraq. Kermanshah Province is limited by Kurdistan in the north, Lorestan and Ilam provinces in the south, Hamedan in the east, to the country of Iraq in the west. The city of Kermanshah is the capital of the province, with a population of 818,719 people within the area of 9564 km^2 (Statistical Center of Iran, 2011). According to the population and housing census from 1966 to 2011, the population of Kermanshah city has increased from 192,072 people in 1966 to 850700 in 2011, with a positive population growth rate of 3.36%. Despite fluctuations, the city's population has always exhibited a positive growth trend (Zinatizadeh, 2013; Shirazi, 2013). Kermanshah has six urban areas, which are defined in *Table 1* and *Figure 1*.

Table 1. *Specification of each area of Kermanshah city (Statistical Center of Iran, 2015)*

Urban areas	Population	Area (Hectare)
Area 1	80689	1442
Area 2	100900	1135
Area 3	164254	1654
Area 4	151376	1469
Area 5	177408	1711
Area 6	144092	2153

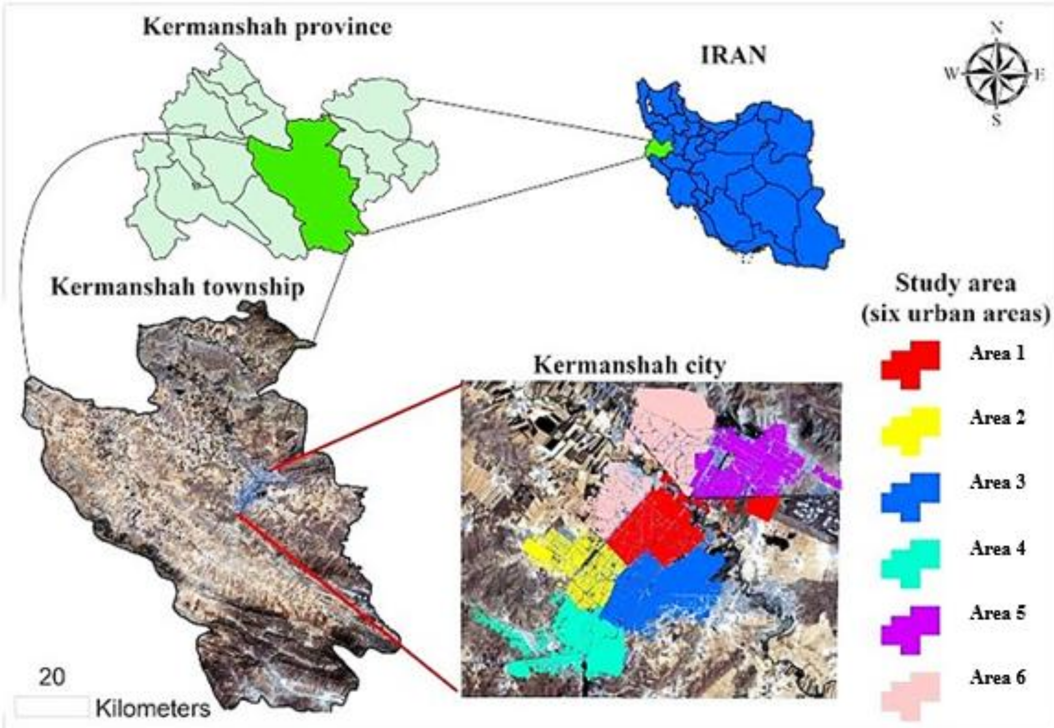

Figure 1. *Location of the study area*

In order to investigate sustainability of six urban areas in Kermanshah, a list of 44 indicators was prepared. The selection of indicators was based on expert opinions, conditions in Kermanshah city, access to the required data, and literature review (Mousavi, 2005; Zakerian, 2010; Jafaei, 2011; Aboubakri, 2012; Bahari, 2012; Raz-Dasht, 2012; Azani, 2013; Saraei, 2013; Saeedi Mafar, 2013; Akbari Nasab, 2014; Mokhtari, 2014; Li-Yin, 2011; Singh, 2009) (*Table 2*). The required data were gathered from different centres viz. province hall, municipality, department of environment, municipal water and wastewater company, waste management organizations, traffic and transportation organizations, renovation and reconstruction organizations, and statistics and information technology center. Additionally, Shannon's entropy method (Shannon, 1948) was used to determine the weight of indicators (*Table 2*).

Table 2. *List of the indicators studied and their weights in Kermanshah city (Social and welfare (1-23) Economic growth (24-31) Environmental protection (32-44))*

Indicator	Weight
(1) Population density	0.002006
(2) Literacy rate	0.000917
(3) Family size	0.008309
(4) Number of Fire station per 1000 people	0.011512
(5) Number of gas station per 1000 people	0.031225
(6) Number of toilets per 1000 people	0.023562

(34) Percent of Population Water network coverage	0.000461
(35) Percent of Population network wastewater coverage	0.000921
(36) Percent of source separation of solid waste	0.216273
(37)Waste production per capita	0.0043
(38) Percent of Semi-mechanized collection of household waste	0.004441
(39) Number of industrial centers per 1000 people	0.191567
(40) Number of database associated with environment per 1000 people	0.14267
(41) Green space per capita	0.111328
(42) Number of traffic jams per 1000 people	0.053538
(43) Percent of travel at peak hours	0.045457
(44) Percent of old area	0.09757

Source: (Mousavi 2005, Zakerian 2010, Jafaei 2011, Aboubakri 2012, Bahari 2012, Raz-Dasht 2012, Azani 2013, Saraei 2013, Saeedi Mafar 2013, Akbari Nasab 2014, Mokhtari 2014, Li-Yin 2011 and Singh 2009)

Following this, the MCDM methods were used for prioritizing the urban areas. The MCDM method is a branch of operations research models which cope with decision problems that have a number of criteria (Pohekar et al., 2004). In this study, one method from each subgroup of the MCDM methods was chosen. The selective methods include Elimination and Choice Expressing Reality (ELECTRE) from the concordance sub-group, the Technique for Order Preference by Similarity to Ideal Solutions (TOPSIS) from the compromising sub-group, and Simple Additive Weighting (SAW) from the scoring sub-group of the MCDM methods. These methods are further described in the following sections.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_10831100

SAW

The simple additive weighting (SAW) is one of the simplest methods of the MCDM methods (Churchman et al., 1954):

Normalize the decision matrix (N):

According to the *Eq. 1*, the decision matrix is normalized using of linear method.

$$n_{ij} = \frac{a_{ij}}{Max\ aij} \quad i = 1, \ldots, m, \quad j = 1, \ldots, n \qquad \text{(Eq. 1)}$$

Calculate the weighted normalized decision matrix (V):

The weighted normalized value (v_{ij}) is obtained according to *Eq. 2*.

$$V_{ij} = N_{ij}W_j \quad i = 1, \ldots, m, \quad j = 1, \ldots, n \qquad \text{(Eq. 2)}$$

Where w_j is the weight of the *i*th indicator.

Select the alternative with the highest overall performance value (A):*

$$A^* = \{A_i Max \sum n_{ij} w_j\} \qquad \text{(Eq. 3)}$$

ELECTRE

ELECTRE was introduced at the end of 1980th (Roy 1968). ELECTRE Is an outranking method based on outranking relation and concordance analysis. So, this method does not necessarily results in ranking the alternatives (Velasquez et al 2013; Taha et al 2013).

Normalize the decision matrix (N):

The normalized value (n_{ij}) is obtained according to the *Eq. 4*.

$$n_{ij} = \frac{x_{ij}}{\left[\sum_{i=1}^{m} x_{ij}^2\right]^{\frac{1}{2}}} \quad i = 1, \ldots, m, \quad j = 1, \ldots, n \qquad \text{(Eq. 4)}$$

Calculate the weighted normalized decision matrix (V):

The weighted normalized value (v_{ij}) is obtained according to *Eq. 5*.

$$V_{ij} = N_{ij}W_j \quad i = 1, \ldots, m, \quad j = 1, \ldots, n \qquad \text{(Eq. 5)}$$

Where w_j is the weight of the *i*th indicator.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_10831100

Formation the concordance matrix set

$$S_{k,l} = \{j \mid Vkj \geq Vij\}\ , \quad j = 1, \ldots, m$$

$$S_{k,l} = \{j \mid Vkj \leq Vij\}\ , \quad j = 1, \ldots, m$$

Formation the discordance matrix set

$$D_{k,l} = \{j \mid Vkj < Vij\}, \quad j = 1, \ldots, m$$

$$D_{k,l} = \{j \mid Vkj > Vij\}, \quad j = 1, \ldots, m$$

Determine of concordance matrix (I_{kl})

In this stage, the concordance matrix is calculated using *Eq. 6*. This matrix is an m*m matrix, which diameter of that, does not have any element. The other elements (entries) of this matrix can be calculated via summation of indicator weights that belong to concordance group.

$$I_{kl} = \sum w_j\ ,\quad j \in A_{k,l} \qquad \text{(Eq. 6)}$$

Determine of discordance matrix (NI):

In this stage, the discordance matrix is calculated using *Eq. 7*. This matrix is an m*m matrix. The diameter of this matrix does not have any elements and other elements can be calculated from weighted normalized matrix according to *Eq. 7*.

$$NI_{kl} = \frac{Max\left|V_{ij} - V_{lj}\right|, j \in D_{k,l}}{Max\left|V_{ij} - V_{lj}\right|, j \in all\ indicators} \qquad \text{(Eq. 7)}$$

Calculate the effective concordance matrix (H):

To create this matrix, first we need to determine a threshold. If each element of matrix I, be bigger or equal to that, that factor in matrix H, will be equal one, otherwise 0. From the *Eq. 8*, the threshold for the matrix is calculated.

$$I = \sum_{i=1}^{m} \sum_{k=1}^{m} I_{k_l} / m(m-1) \qquad \text{(Eq. 8)}$$

If, $I_{ki} \geq \bar{I}$, $H_{ki} = 1$ *and* *If,* $I_{ki} < \bar{I}$, $H_{ki} = 0$

Calculate the effective discordance matrix (G):

In this stage, the effective discordance matrix can be calculated based on the *Eq. 9*

$$\overline{NI} = \sum_{i=1}^{m} \sum_{k=1}^{m} NI_{k_l} / m(m-1) \qquad \text{(Eq. 9)}$$

http://www.aloki.hu • ISSN 1589 1623 (Print) • ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_10831100

$$If, \quad NI_{ki} \geq \overline{NI}, \quad G_{ki} = 0 \qquad and \qquad If, \quad NI_{ki} < \overline{NI}, \quad G_{ki} = 1$$

Determine the effective final matrix (F):

The effective final matrix can be calculated by combination of effective concordance and effective discordance matrix based on the *Eq. 10*.

$$F_{kl} = H_{kl} G_{kl} \qquad \text{(Eq. 10)}$$

TOPSIS

TOPSIS was proposed by Hwang and Yoon in 1981. The basic concept of this method is that, the chosen alternative should have the closest distance from the ideal solution (Velasquez et al., 2013; Taha et al., 2013).

Normalize the decision matrix (N):

The normalized value (n_{ij}) is obtained according to *Eq. 11*.

$$n_{ij} = \frac{x_{ij}}{\left[\sum_{i=1}^{m} {x_{ij}}^2\right]^{\frac{1}{2}}} \qquad i = 1, \ldots, m, \quad j = 1, \ldots, n \qquad \text{(Eq. 11)}$$

Calculate the weighted normalized decision matrix (V):

The weighted normalized value (v_{ij}) is obtained according to *Eq. 12*.

$$V_{ij} = N_{ij} W_j \qquad i = 1, \ldots, m, \quad j = 1, \ldots, n \qquad \text{(Eq. 12)}$$

Where w_j is the weight of the *i*th indicator.

Determine of positive ideal solution and negative ideal solution

Positive ideal solution (V_j+) =vector of the best values of each indicator (*V*)
Negative ideal solution (V_j^-) = vector of the worst values of each indicator (*V*)
The best values for the positive indicators are the biggest and for the negative indicators are lowest values.

Determine of Euclidean distance to positive and negative ideals:

Euclidean distance of each alternative from positive ideal (d_j^+) and negative ideal (d_j^-) can be calculated based on *Eq. 13* and *14*.

$$d_i^+ = \sqrt{\sum_{j=1}^{n} \left(V_{ij} - V_j^+\right)^2} \quad , \ i = 1,2, \ldots, m \qquad \text{(Eq. 13)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_10831100

$$d_i^- = \sqrt{\sum_{j=1}^{n}\left(V_{ij} - V_j^-\right)^2} \quad , \ i = 1,2,\ldots,m \qquad \text{(Eq. 14)}$$

Determine the relative closeness to ideal solution (CL):*

Determination of relative closeness of each alternative to an ideal solution can be calculated based on *Eq. 15*.

$$CL_i^* = \frac{d_i^-}{d_i^- + d_i^+} \quad , \quad i = 1,2 \ldots,n, \quad 0 \leq CL_i^* \leq 1 \qquad \text{(Eq. 15)}$$

Ranking the preference order

Alternatives having bigger CL, are better. According to relative closeness of each alternative to an ideal solution, the ranking order of alternatives can be determined and the best alternative is selected.

Results

Based on the data obtained, the sustainability levels of six urban areas were evaluated using three methods under the MCDM, and three aspects of sustainability, including social, economic and environmental.

Urban areas ranking by SAW

The results obtained from SAW in three categories (social, economic, and environmental) are shown in *Table 3*. The best alternative selected is the one where the sum of the weighted normalized values is greater than other values.

Table 3. *Results obtained from SAW method*

Area	Sum of environmental indicators values	Rank	Sum of economic indicators values	Rank	Sum of social indicators values	Rank	Sum of indicators values	Rank
1	0.764	1	0.817	1	0.471	4	2.052	4
2	0.362	5	0.695	2	0.489	3	1.555	3
3	0.538	3	0.547	4	0.626	1	1.711	1
4	0.602	2	0.560	3	0.600	2	1.762	2
5	0.330	6	0	5	0.290	6	0.62	6
6	0.368	4	0	5	0.392	5	0.76	5

According to the results, Area 1, with a value of 2.052, is more sustainable than the others. Three areas (4, 3, and 2) are ranked in the second, third, and fourth place, with

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_10831100

values of 1.762, 1.711 and 1.555, respectively. Areas 6 and 5 are graded as fifth and sixth, with 0.76 and 0.62, respectively.

Urban areas ranking by ELECTRE

The results of urban area ranking in three categories (social, economic, and environmental) using the ELECTRE method are shown in *Tables 4, 5, and 6*.

Table 4. *The final dominance matrix of social indicators*

Final dominancy	Area 1	Area 2	Area 3	Area 4	Area 5	Area 6
Area 1	-	0	0	0	1	1
Area 2	0	-	0	0	1	1
Area 3	0	1	-	0	1	1
Area 4	0	1	0	-	1	1
Area 5	0	0	.	0	-	0
Area 6	0	0	0	0	1	-

Table 5. *The final dominance matrix of economic indicators*

Final dominancy	Area 1	Area 2	Area 3	Area 4	Area 5	Area 6
Area 1	-	1	0	0	0	1
Area 2	0	-	0	0	0	1
Area 3	0	0	-	0	0	1
Area 4	1	1	1	-	1	1
Area 5	0	1	0	0	-	1
Area 6	0	0	0	0	0	-

Table 6. *The final dominance matrix of environmental indicators*

Final dominancy	Area 1	Area 2	Area 3	Area 4	Area 5	Area 6
Area 1	-	1	1	0	1	1
Area 2	0	-	0	0	0	0
Area 3	0	0	-	0	1	0
Area 4	0	1	0	-	1	1
Area 5	0	0	0	0	-	0
Area 6	0	0	0	0	0	-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_10831100

Based on the results, two areas (4 and 1) have the maximum dominance, followed by areas 3, 2, 5, and 6, in that order.

Urban areas ranking by TOPSIS

For the current study, the relative closeness of each alternative to the ideal solution, in three categories (social, economic, and environmental), was calculated (*Table 7*).

Table 7. *Relative closeness of each alternative to an ideal solution*

Alternatives	Social indicators	Economic indicators	Environmental indicators	Overall closeness to ideal solution
Area 1	0.437	0.52	0.627	1.594
Area 2	0.437	0.349	0.207	1.083
Area 3	0.575	0.578	0.449	1.602
Area 4	0.537	0.913	0.579	2.029
Area 5	0.197	0.557	0.21	0.964
Area 6	0.319	0.196	0.361	0.876

According to the results obtained by this approach, Area 4, with a score of 2.029, is in better condition when compared to the others. Three urban areas (3, 1, and 2) are ranked second, third and fourth, with scores of 1.602, 1.594 and 1.083, respectively. The remaining areas (5 and 6), with scores of 0.964 and 0.876 scores, are ranked fifth and sixth grade, respectively.

Final ranking of urban areas

The final ranking result is based on the average of the ranks obtained from different methods (Momeni 2013). Accordingly, the final rankings of the six urban areas are shown in *Table 8*.

Table 8. *Final ranking results*

Area	MCDM methods			Averaged rank
	SAW	ELECTRE	TOPSIS	
Area 1	1	2	3	2
Area 2	4	4	4	4
Area 3	3	3	2	2.6
Area 4	2	1	1	1.3
Area 5	6	5	5	5.3
Area 6	5	6	6	5.6
Area 4 > area 1 > area 3 > area 2 > area 5 > area 6				

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_10831100

Discussion

Based on this study, it is evident that different urban areas of Kermanshah city have different sustainability levels. Area 4 is listed as the first priority, followed by areas 1, 3, 2, 5 and 6, respectively. Due to the centrality of area 4, more social and public services, including health, culture, education, entertainment, sports, as well as city infrastructure and administrative buildings are located here. Area 1, which is predominantly occupied by the wealthy, is characterized by high economy; collaboration on environmental projects receives particular attention in this area (due to the location of the administrative section), and it is therefore more sustainable. In comparison, in two areas (2 and 3), the disorganized structure of streets and alleys leads to traffic problems, water and sewage-network-related accidents and difficulties in municipal waste management. Furthermore, Areas 5 and 6 are not well-developed due to rural migration, cheap land price and semi-rural structure. Overall, the main factors contributing to unsustainable conditions in six urban areas of Kermanshah are high unemployment rate, high solid waste production, unequal distribution of city services and infrastructures, the old structure of the city, inefficient public transportation system, lack of attention to renovation projects in older areas and social discrepancies.

Based on these limited factors, particular strategies need to be considered. These include the provision of basic services, decentralization, promoting public participation in urban planning, infrastructure establishment for proper development, building recreation and tourism centers in the city, enhancing relationship with Iraq, improving economic prosperity and reducing marginal jobs. It is further important to draw the attention of local, regional, and national planners towards creating a special economic zone in Kermanshah province, which can create various employment opportunities, and assist in the development of waste management programs and wastewater treatment plants, as well as improve public transportation, and increase green spaces across the city.

In the present study, the results from SAW, ELECTRE, and TOPSIS methods were compared using the Friedman test. Based on the sig (0/93) value, no meaningful difference was found among the methods. As seen in *Table 8*, areas 5 and 6, with the lowest sustainability levels are ranked similarly in all three methods. Areas 1, 3, and 4, with comparably superior sustainability levels were ranked high in all methods, while area 2 in ranked fourth in all of the methods. In the other words, all three applied methods have resulted in similar rankings.

It is probable that due to the use of a single method for weighting (Shannon’s entropy), the results achieved from all three methods were similar. This suggests that in the process of alternatives prioritization, the weight of indicators is more important than the method being used (Janic et al., 2002; Zareie et al., 2011). On the other hand, the three methods applied in this study belong to compensatory MCDM methods. These refer to methods where trade-offs between the indicators are allowed (XU et al., 2001); that is, a decline in one indicator's attributes is acceptable if it is compensated by an increase in another indicator's attribute. Thus, one of the characteristics of compensatory methods is the closeness among the rankings (Ebrahimi et al., 2014). Many previous studies have shown similar results in final rankings with the use of different MCDM methods, which corresponds to the current study (Chu et al., 2007; Hoshyar et al., 2011; Momeni et al., 2011; Shirouyehzad et al., 2011; Bordbar, 2013).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_10831100

Despite the similarity between the results obtained from the three different methods, the authors propose TOPSIS as the most suitable and practical method. This selection is based on the advantages and characteristics of this method as compared to the rest. The benefits of TOPSIS are listed below - (Srdjevici, 2004; Falsoleiman et al., 2013; Kolios et al., 2016):

- It is capable of merging several quality and quantity indicators simultaneously.
- The method is characterized by simplicity and high speed.
- The system function is desirable and acceptable.
- The desirability of applied indicators in solving a problem can be steadily increasing (or decreasing).
- The method allows changing the primary data, and subsequently, changing the functions and outcome.
- Prioritizing in this method is done based on similarity to the ideal solution, such that the final option will be close to the ideal answer and far from the wrong answer.
- In case some of the indicators are not desirable and need to be decreased, or some others are desirable and can be increased, TOPSIS can easily calculate the ideal solution through a combination of the best values obtained from all criteria.
- TOPSIS considers the best and the worst answers simultaneously, based on closeness to the ideal solution.
- The outcomes can express the priorities quantitatively.
- *Table 9* compares the specifications for the different methods.

Table 9. *Comparison of characteristics of methods (SAW, ELECTRE, and TOPSIS)*

Conclusion

Multi-criteria decision making methods were applied to assess the sustainability of urban areas in Kermanshah city. In this research, the authors applied the ELECTRE, TOPSIS and SAW methods for the evaluation of sustainability of urban areas using 44 indicators at three social, economic and environmental aspects. In addition, The Friedman test showed there is no significant difference between these MCDM methods. The results showed that among the six urban areas, areas 4, 1 and 3 are more sustainable than the other areas. Totally, Kermanshah city is not at good condition and is far from sustainability. Therefore, in order to achieve sustainability, especially in more deprived areas, some strategies should be done such as creating jobs, more attention to economic in undeveloped areas, cultural solution and collaboration of people in environmental issues. Equal distribution and decentralization of services and allocating funds to poor areas must be considered. The study also pointed out the advantages and disadvantages related to the application of the selected methods and the TOPSIS method was preferred due to its advantages over the other methods.

Acknowledgments. The authors are grateful to the Kermanshah Department of Environment for providing facilities to conduct and accomplish this study.

(Received 29th Mar 2017; accepted 1st Aug 2017)

Abstract. Intensification of sedimentation process has resulted in shallower river, thus increasing their vulnerability to natural hazards (i.e. climate change, floods). Considering the impact of soil erosion to the sedimentation, identification of the main source of erosion is critical to watershed management. Stable isotope of carbon (δ^{13}C) and nitrogen (^{15}N) were carried out in Kelantan catchment. Results from δ^{13}C showed that C_3 type plant represents as major plant (-29.10‰ to -23.60‰) in the river. While for δ^{15}N, the isotopic variations demonstrate distinct pattern of dry (Southwest Monsoon, SWM) and wet (Northeast Monsoon, NEM) seasons, suggesting significant pollutants washout from terrestrial (due to agricultural activities) to the water bodies. In addition, the Kelantan river system is an autochthonous as determined by carbon to nitrogen (C:N) ratio. Essentially, this study will serve as a precursor of future study to understand the impact of anthropogenic activities on carbon and nitrogen cycles in tropical catchment.
Keywords: *erosion, sedimentation, carbon, nitrogen, cycle, tropical, deforestation, stable isotopes, agriculture, land use, C_3 plants, C:N ratio, water quality, sediment yield*

Introduction

Kelantan basin is located in northeast of Peninsular Malaysia. The main river is known as Kelantan river with the total length of 248 km, with draining that flows northwards in the direction of the South China Sea. The catchment area is approximately 11,900 km^2 (Yen and Rohasliney, 2013) occupying more than 85% of Kelantan state. Along the river, the topography is comprised of rain forested hills, lowland forests and limestone caves. Currently, the type of activities that occur around the area include deforestation, vegetation and urbanization (Basarudin et al., 2014).

Land use activities that degrade natural landscape through clearing of tropical rainforests, unsustainable agriculture and rapid urban expansion have had significant impacts to hydrological conditions and ecological processes (Adnan et al., 2014; Hadi et

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11011119

al., 2017) in the Kelantan watershed. It is also vulnerable to climate change (Huang and Lo, 2015; Zafirah et al, 2017). Changes in geographical area leads to alteration of hydrological process. Impact of various land use activities include flowing of fine sediment into the river, due to soil surface erosion (Chen et al., 2015). Soil erosion is the result of overland flow as rainfall occurs, which in turn results in serious environmental problem if not properly controlled (Mahabaleshwara and Nagabhushan, 2014). Increasing sedimentation in the river can cause extensive catchment flooding due to overflow at the river, water pollution and poor drainage system (Kithiia, 2012; Zafirah et al., 2017). Mitigation process is often delayed due to lack of capability to identify the cause and source of erosion. This paper will discuss the application of environmental isotopes technique to identify the source of erosion in Kelantan catchment. Sediments in the Kelantan rivers were collected and analyzed by using Isotopic Ratio Mass Spectrometer (IRMS) to measure the δ^{13}C and δ^{15}N and Perkin Elmer 2400 Series II CHN Elemental Analyzer for C:N analysis in the sample.

Soil erosion and sedimentation mechanism

Soil erosion requires three steps to trigger the process: (i) detachment, (ii) transport and (iii) deposition (Pidwirny, 2008; Zafirah et al., 2017). Detachment process is defined as a particle that is disengaged from the main subject. It requires the procedure of breaking the bond that binds the particle together. Factors of weathering in physical, chemical and biological state causes the bond particle in the subject to weaken and detach.

It is then followed by transportation process, whereby the particle moves with the presence of the medium or agent at high velocity. This step depends on mass of particle, size, shape, surface configuration and medium type to undergo the process (Pidwirny, 2008; Safaei et al., 2014). Finally, it ends with deposition process, whereby the velocity of the medium reduces or increases in particle resistance (Stephen, 2016).

Sedimentation is a result of erosion process where it refers to the accumulation of particle that is carried out by a medium such as water, wind or ice for transportation. Sedimentation process is a natural process, although it may be influenced by anthropogenic factors. Transported sediments can be chemical, organic material or inorganic, mineral matter and pollutants. Increase in sediments and siltation have threatened the surrounding ecology, irrigation of river and aquatic habitat (Huggins et. al., 2007; Kjelland et al., 2015). It also makes the river to become more shallow and easier to overflow.

Stable isotope as tool in fingerprint detection

Stable isotope analysis is one of the potential tool to detect and trace the fingerprint of organic matter in the environment (Liu et al., 2017) such as aquatic, water and sediment, terrestrial, soil, plant and others. The stable isotope carbon and nitrogen were used to analyze the values, therefore determining the categories and understanding the process of sedimentation in the catchment (Tue et al., 2011). Carbon isotope were used to differentiate the type of plants present in the selected area. δ^{13}C have been used to determine the C_3 and C_4 plants, which indicates the photosynthesis process that plants undergo (Boullion et al., 2003a; Tue et al., 2011).

The ranges of C_3 plants are from -32 to -22‰ and -16 to -9 for C_4 (Medina et al., 1999; Kendall et al., 2001; Schaal et al., 2008; Kohn, 2010), hence it is useful as an

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11011119

ecosystem components tracer (Bouillon and Boschker 2006; Werner and Máguas, 2010; Gilbert et al., 2012). Variations of δ^{13}C provide clues for further investigation on environmental condition and land use activities in the watershed (Cravotta, 2001; Fushan et al., 2014).

Stable nitrogen isotope is commonly used to detect the sources of pollution, and it is made up of several of classes such as soil organics, fertilizers, animal or sewage waste and precipitation (Heaton, 1986; Lim et al., 2010; Zhao et al., 2016). Different of δ^{15}N is determined by fractionation process, which consist of four types, including equilibrium, kinetic, mass independent or transient kinetic isotope fractionation (Heaton, 1986; Dähnke and Thamdrup, 2013; Ryabenko, 2013). From different values, it will then be used to classify the possible sources based on the fingerprint, as well as the activities nearby the sampling location. Therefore, this approach is used to identify the possible sources of sedimentation in Kelantan catchments.

Material and Methods

Study area

Malaysia is located near the equator and is one of the tropical countries that is hot and humid all year round. The average temperature is about 27^{0}C and receives rainfall on average 2500 mm annually. Peninsular climate differs from Malaysian Borneo as the peninsular is directly affected by wind and is exposed to the El Niño effect. The phenomena cause dry season as it reduces the amount of rainfall. Climate change has a significant impact on Malaysia as it is crucial in determining the sea level as well as amount of precipitation, which results either in drought or extensive rainfall, which increases the flood risks. In addition, Malaysia also experiences monsoon seasons, Northeast Monsoon (NEM) from November to March and Southeast Monsoon (SEM) from May to September. Monsoon occurs due to atmospheric pressure patterns in Southeast Asia that results from different pressure between Asia continent and land mass in Australia, known as Inter-Tropical Convergence Zone (ITCZ). NEM hit Peninsular Malaysia during northern hemisphere during winter seasons, together with high pressure from China and low pressure in Australia thus combination of forces the ITCZ in south areas. Opposite circulation occurs when northern hemisphere experience summer seasons, low pressure in Asia and high pressure in Australia forcing the ITCZ in northwards resulting SWM in Peninsular Malaysia. Both seasons, NEM and SWM play the main factors in determining the amount of precipitation in Malaysia (Loo et al., 2015). However, between these two monsoons, NEM give extra rainfall events compared to SWM (Suhaila et al., 2010).

This study focuses in Kelantan catchment area, located at east coast of Peninsular Malaysia (*Figure 1*). The Peninsular Malaysia lies between 1^0 and 7^0 North and 99^0 to 105^0 East, extending 748 km SSE-NNW and 322 km ENE-WSW. The landscapes of peninsular at inland areas are mainly from denudation terrains of bedrocks, resulting from weathering and erosion process. The range of Titiwangsa (highland) located somewhat at the middle of Peninsular region, separates the eastern and western part of the region. In addition, it is composed mainly of granite with some regions of metasedimentary rocks (Ishak, 2014). These series of mountain ranges play a crucial role in creating the streams and rivers network pattern (Hutchison and Tan, 2009).

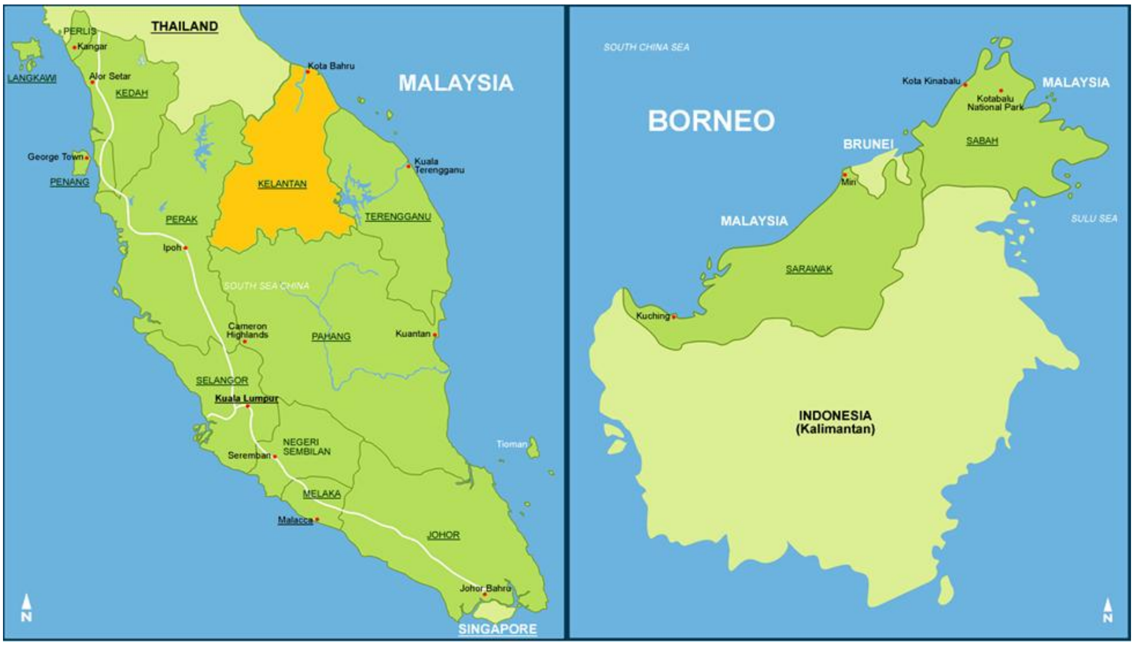

Figure 1. *Malaysia map (World Map, 2017)*

Kelantan Basin

The study area covers the catchment around Kelantan state which is located in the northeast of Peninsular Malaysia lies between 4^0 40’ and 6^0 12’ North and 101^0 20’ and 102 20’ East (*Figure 2*). Kelantan catchment comprises an area about 11,900 km², (Yen and Rohasline, 2013). Three main rivers at Gua Musang District which are Nenggiri River, Betis River and Broke River were selected. The dominant land use of this area is agriculture, native forest and countryside native. The next river is Lebir River located at Kuala Krai district. Pergau River which is located in Jeli district, has one of the highest waterfalls in Southeast Asia. The river merges with Galas River. The land use of this area comprises of croplands and new settlements. Kelantan river, which is the third longest river in Peninsular Malaysia, is also included in this study.

Climate and hydrology of Kelantan Basin

The regional climate of Kelantan state has temperatures ranging between 21 to 32 ^{o}C and recurrent rain throughout the year. However, it is exposed with extra rainfall in Northeast Monsoon from November to March every year. The average rainfall is about 2062 to 2543 mm per year and humidity is constantly high on the lowlands ranging between 82% and 86% annually (Irwan et al., 2013).

Vegetation and land use in Kelantan watershed

Majority of Kelantan’s land cover consist of forest. Its economy constitutes mainly from agriculture industries dominated by oil palm plantation, rubber, paddy and other cash crops.

DOI: http://dx.doi.org/10.15666/aeer/1504_11011119

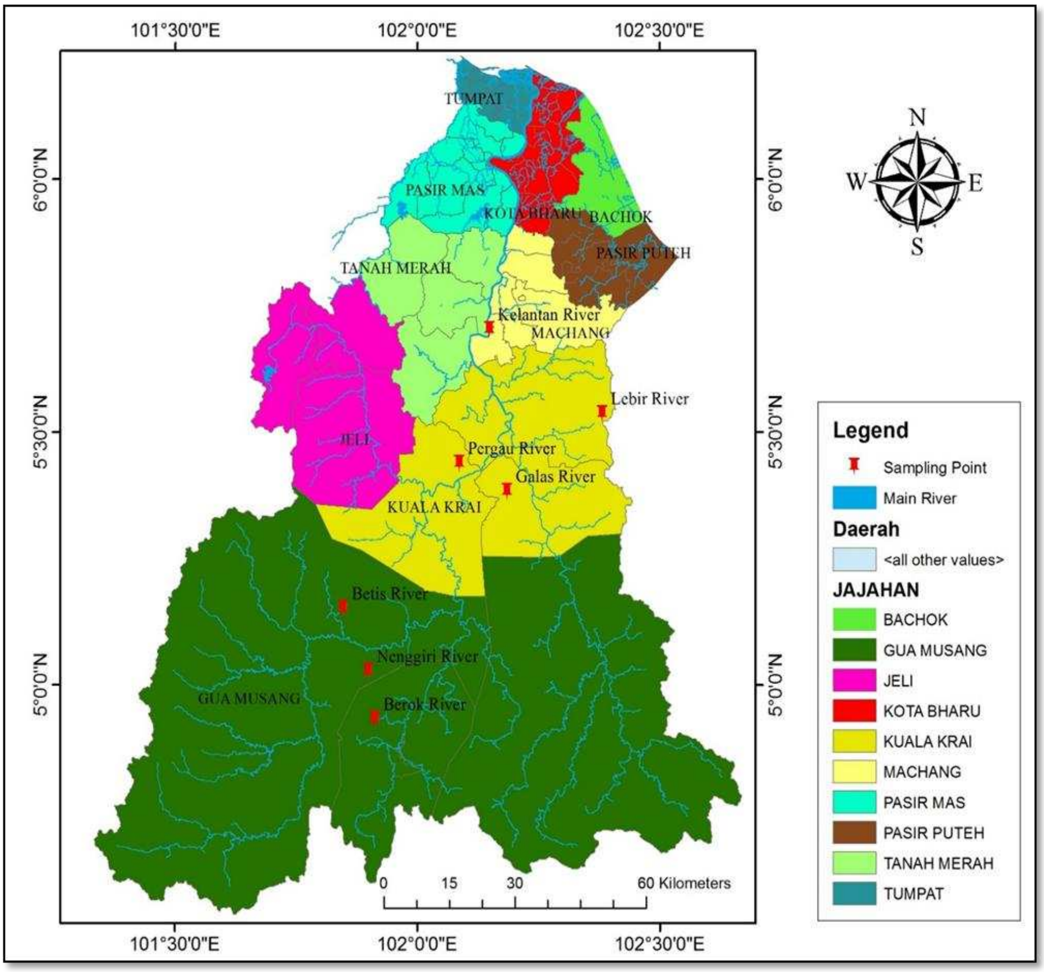

Figure 2. *Map of the Kelantan river and study sites*

Sample collection and analytical procedures

Sediment sample collection was carried out in July 2015 and January 2016. The sediments were sampled at seven selected stations; Broke, Betis, Nenggiri, Lebir, Galas, Pergau and Kelantan river. The sediment was sampled at 10" of top sediment, with approximately 100 g per sediment sample by using grab sampler and subsequently packed into zipper bag, and is preserved in a cold storage box. Samples were stored in the laboratory accordingly (Shanbehzadeh et al., 2014).

Sample preparation

In the laboratory, 50 g of sediment samples were washed by using 10% of hydrochloric acid prior to remove carbonates (Kennedy et al., 2005) and rinsed with distilled water for three times. The samples were then dried at 80 to 90 ºC to remove moisture. The subsample was then grounded into powder form. Grinding was performed using a mortar and pestle. The sample were finally sieved through a 425µm sieve and stored in glass jars.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11011119

Stable isotope analysis

Each sediment sample was weighed into small tin capsule (8 x 5 mm) for 12mg in triplicates. The sample was folded and compressed into a tight ball before being loaded into an auto-sampler. All the replicated samples were analysed for stable carbon ($\delta^{13}C$) and nitrogen ($\delta^{15}N$) isotopic composition using Flash EA 2000 elemental analyser (ThermoScientific, Waltham, MA) coupled to a Delta V Advantage isotope ratio mass spectrometer (Thermo, Milan, Italy).

Raw isotope ratios from the analysis were normalized to the international scales using USGS-40 and USGS-41 reference materials (~0.5 mg, respectively) assayed with the unknown samples. For quality control material, Urea (IVA-Analysentechnik GmbH & Co., Germany) was used to correct for drift. It was measured for every 12 samples with known values of $\delta^{13}C$ = -40.81‰ and $\delta^{15}N$ = -0.49‰. Variations in stable isotope ratios were reported as parts per thousand (‰) deviations from internationally accepted standards which are Vienna Pee Dee Belemnite (VPDB) for carbon, atmospheric nitrogen (AIR) for nitrogen, in the delta (δ) notation.

The δ notation is defined using the following Equation (1):

$$\delta\ (‰) = (\ R\text{sample} \ /\ R\text{standard}\ -\ 1) \qquad \text{(Eq.1)}$$

where R_{sample} is the isotope ratio ($^{13}C/^{12}C$ or $^{15}N/^{14}N$) of the sample, and $R_{standard}$ is the isotopic ratio of the international reference materials.

Carbon Nitrogen Ratio (C:N Ratio) Analysis

Same as isotope analysis, each sediment sample was weighed into small tin capsule (8 x 5 mm) for 2 mg in triplicates. The sample was folded and compressed into a tight ball before being loaded into an auto-sampler. All the replicated samples were analyzed for carbon and nitrogen composition using Perkin Elmer 2400 Series II CHN Elemental Analyzer (Perkin Elmer).

Samples were introduced from an autosampler into a combustion furnace with a temperature of 925°C. The resulting gases (CO_2, NOx, and H_2O) were passed through combustion and reduction columns, mixed, and separated through thermal conductivity detector (TCD) gas chromatography column (Stephen et al., 2011). Acetanilide standards were run every triplicates samples to ensure proper instrument operation.

The C:N ratios is defined using the following Equation (2):

$$\frac{C}{N} ratio = (\frac{(\%C/\%N)}{(14/12)} \qquad \text{(Eq.2)}$$

Water quality and sediment yields data

Water quality data (2004 - 2014) were provided by Department of Environment (DOE). The parameters include chemical oxygen demand (COD), biochemical oxygen demand (BOD), suspended solids (SS), pH, dissolved oxygen (DO), and Ammoniacal nitrogen (NH3-N). Besides, data of sediment yields in Kelantan were also retrieved from Department of Irrigation and Drainage (DID) Kelantan. The data is a 30-year dataset that ranges from 1980 to 2009. Both secondary data were analyzed using Principal Component Analysis (PCA).

Results and Discussion

Stable isotopes analysis of $\delta^{13}C$ and $\delta^{15}N$ in sediment at different catchment area in Kelantan

Plant types can be divided into three categories; C_3, C_4 and Crassulacean acid metabolism (CAM) based on carbon fixation of carbon dioxide during photosynthesis process. Every plant group will produce different $\delta^{13}C$ signatures of the organic carbon. C_3 plant is ranged from approximately -34‰ to -23‰, C_4 -18‰ to -12‰ and CAM -32‰ to -12‰, (Brand, 1996; Faure and Mensing, 2005). In Malaysia, there are less number of CAM plants, as it is usually found in dry or arid condition (Masrahi et al., 2012), which allows stomata to remain shut during the day.

A distinct inclination of $\delta^{13}C$ sediment values emerged in all seven studied locations were plotted in *Figure 3*. In overall, the mean value for $\delta^{13}C$ for July was -27.05 ± 1.02‰ followed by January, -26.80 ± 1.76‰ (*Table 1*). The results from both dry and wet seasons in Kelantan catchment showed that the value ranged from -29.10‰ to -23.60‰, which represent C_3 type plants suggested that terrestrial plants (allochthonous) were the main source of sediment contribution in all seven rivers.

The mean of $\delta^{13}C$ at Brok samples is -26.81 ± 1.46‰ and Betis is -24.90 ± 0.98‰ (*Table 1*). Both are located at Gua Musang district. The major type of vegetation here is rubber (Hevea brasiliensis) (Da Matta et al., 2001), tapioca (*Manihot esculenta*) (Calatayud et al., 2002) and banana (*Musa spp.*) (Janssens et al., 2009), all representing C_3 type plants. Nenggiri is the main river of Betis and Brok tributaries and average of the $\delta^{13}C$ in sediments is -26.08 ± 1.28‰ (*Table 1*). Galas and Pergau have almost the same average of $\delta^{13}C$ in sediments, -27.36 ± 0.60‰ and - 27.12 ± 0.84‰ (*Table 1*) respectively. The rivers are located in Dabong, south of Kelantan. Rubber estate appears as the main land use activity, followed by small farming of banana and tapioca.

Lebir River which is located in Kuala Krai district, with average of $\delta^{13}C$ is -27.99 ± 0.88‰ (*Table 1*), of which palm oil plantation is the main land use activity representing approximately 80% of the catchment area. According to Lamade et al., (2009), $\delta^{13}C$ of oil palm (*Elaeis guineensis*) leaves is around ≈-27‰, which is also categorized as a C_3 plant type. For Kelantan river sediments located at the downstream catchment, the mean value of $\delta^{13}C$ is - 28.22 ± 0.82‰ (*Table 1*). Small farming activities like banana, cocoa, tapioca and rubber estate are present around the catchment area.

Cocoa (*Theobroma cacao*) (Gattward et al., 2012) also represents the C_3 type plant range. However, the result is still tentative, thus, require further investigation using advance technique such as compound specific isotope analysis (CSIA).

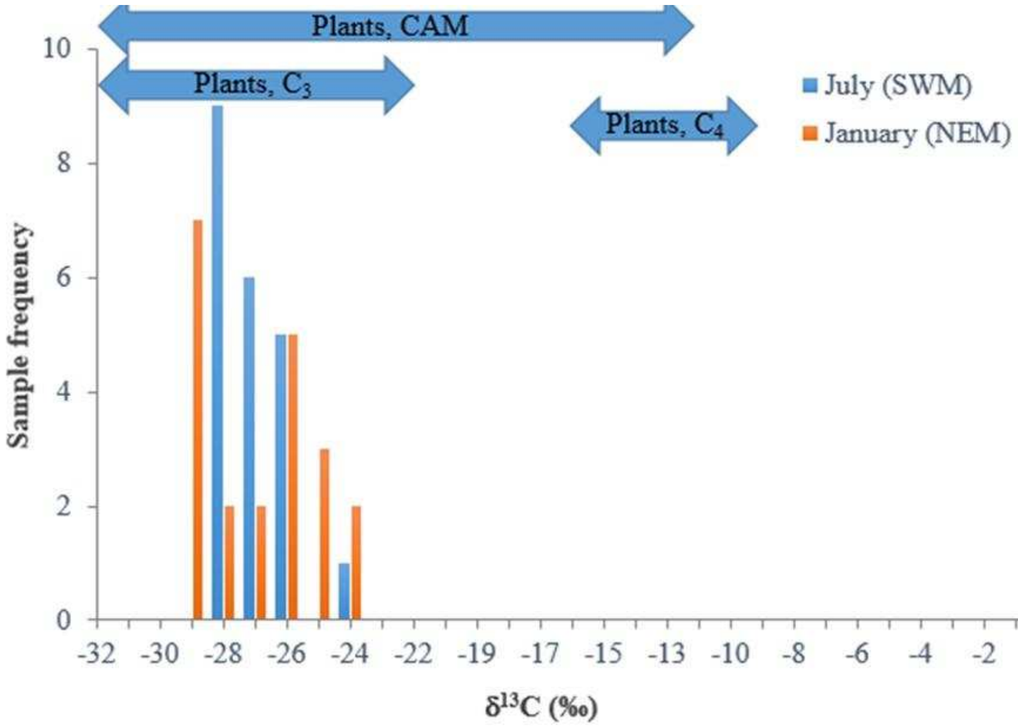

Figure 3. *Bar frequency plot δ^{13}C [‰] sediments in two different seasons*

The range of δ^{13}C could reflect sources of sedimentation, where most of the terrestrial plant that are present along the studied locations, are mainly from C_3 type plant. Theoritically, variations of C_3 values were due to kinetic isotope fractionation process, which includes microbial respiration of organic carbon, assimilation process of residual materials (Thornton and McManus, 1994; Teranes and Bernasconi, 2005) and changes in global carbon cycle (Oehlert and Swart, 2014), thus deposited in the water bodies.

The δ^{15}N sediment values at different study areas were presented in *Figure 4*, with information on organic content resulted from decomposition process. In general, the average value for δ^{15}N in July (SWM) and January (NEM) were +0.65 ± 2.44‰ and +3.35 ± 1.02‰ (*Table 2*) respectively. Both results of the two different seasons showed that δ^{15}N were ranged from -3.98‰ to +5.25‰ (*Table 2*), which demonstrated the dynamic of N cycle.

The average values of δ^{15}N for Brok, Betis, Nenggiri are 1.48 ± 2.48‰, 2.26 ± 1.82‰ and 0.70 ± 2.74‰ (*Table 2*), respectively, enriched in δ^{15}N. The upstream of Betis River is flowing from Lojing and merges with Brok River at the confluence of Nenggiri River. Richness of δ^{15}N indicates more nitrogen source mainly from anthropogenic activities (Dolenec et al., 2006; Brahney et al., 2014). The average values of δ^{15}N for Galas River, Pergau River and Lebir River are 1.51 ± 2.63‰, 2.50 ± 0.90‰ and 3.45 ± 2.63‰ (*Table 3*) respectively. Matured oil palm and rubber plantations are the major land use activities around the catchment areas.

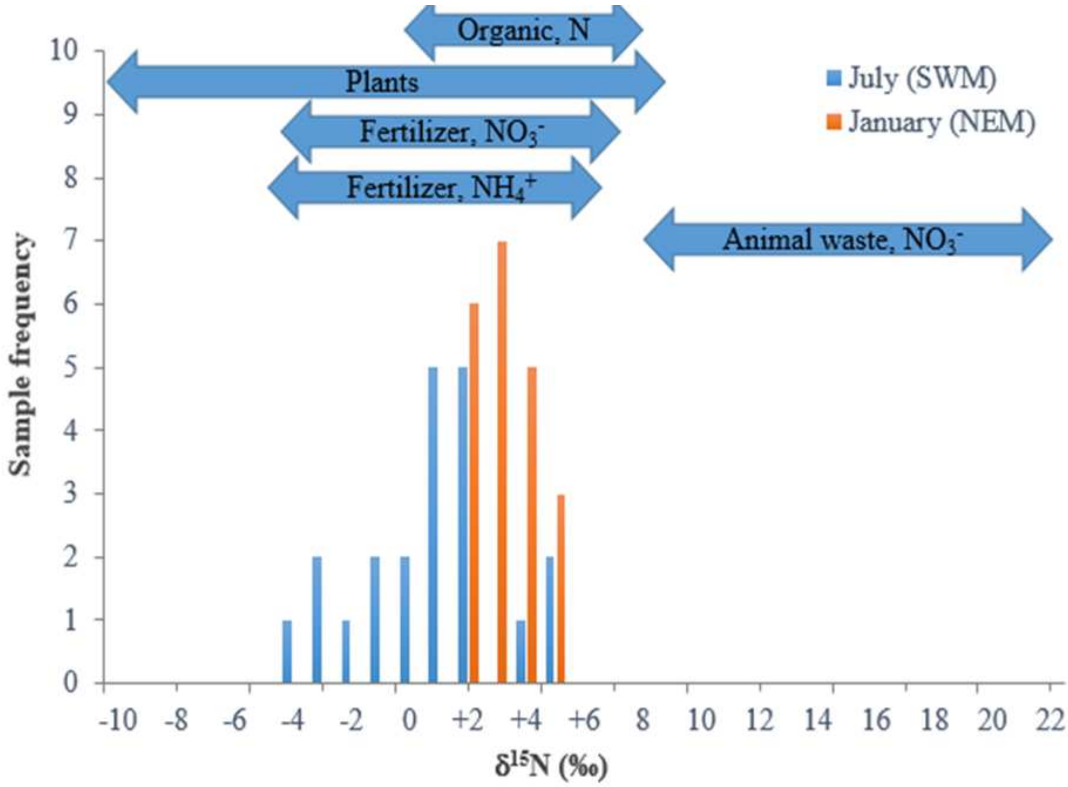

***Figure 4.** Bar frequency $\delta^{15}N$ [‰] sediments at two different seasons, Southwest Monsoon (July) and Northeast Monsoon (January)*

Kelantan river, which is situated at the downstream area, have average values of $\delta^{15}N$ 2.10 ± 2.49‰ (*Table 2*). The villages around the catchment may affect the nitrogen concentration in the sediments due to all the wash out from upstream river. Kelantan river exposed by many land use activities such as mining activity and development around the river area for new residential and towns, thus, posing significant impact on river sedimentation.

Distinct of $\delta^{15}N$ values are due to kinetic isotopic reaction and together with unidirectional reaction in hydrosphere cycle perform by bacteria activities (Heaton, 1986). The overlapping of $\delta^{15}N$ values reflect complex fractionation caused by multiple

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11011119

processes (mineralization, nitrification, plant uptake and denitrification) in nitrogen cycle (Lajtha and Schlesinger, 1986; Ryabenko, 2013).

Fertilizer appears as one of the main "fingerprints" in sediment samples. Both nitrate (NO_3^-) and ammonia (NH_4^+) are common results from industrial fixation of atmospheric nitrogen via measureable process of isotopic fractionation, whereby δ^{15}N depletes (Gunter, 1986). Meanwhile, organic nitrogen in soil undergo mineralization process that causes it to fractionate. It involves steps that can fractionate it and change δ^{15}N values in favorable condition with the aid of bacteria activities (Heaton, 1986).

The isotopic fingerprints of δ^{15}N (*Figure 4*) in sediments (+0 to +9) represent the Soil Organic Matter (SOM), suggesting significant erosion (due to land clearing) during the NEM (An et al., 2008; Chakravarty et al., 2012; Ickowitz et al., 2015).

C:N ratios in sediments

C:N ratio in sediments was analyzed to complement the terrestrial and organic matter sources characterized by δ^{13}C and δ^{13}N (Finlay and Kendall, 2007; Sanderman et al., 2015). *Figure 5* shows a biplot δ^{13}C and C:N ratio presenting various types of terrestrial and aquatic organic matter overlapping from sediment collections in Kelantan. There is absence of C_3 type plant from terrestrial source, which constitutes a ratio of more than 15. However, although the "fingerprint" of terrestrial plants might be present, in our case, the allochthonous component was not clearly identified, perhaps, due to the catchment settings (climate, hydrology, etc) that may speed up the rate of decomposition process in water body (McGill and Cole, 1981). Besides, the C:N ratio too can be changed due to degradation of organic matter during sediment diagenesis (Gao et al., 2012).

In overall, about 95% of C:N ratio were determined <12 (*Figure 5*), indicating the source of sedimentation particularly from aquatic part which is autochthonous (Tue et al., 2011). Even though it is believed that high turbidity and sedimentation in Kelantan catchment causes absence of aquatic macrophytes and seagrass, microalgae were present as autochthonous input. Besides that, it is evident that there are terrestrial, allochthonous input from the river being transported, which is phytoplankton (Tue et al., 2011). The C:N ratios value tend to decrease over time as degradation process release carbon dioxide (CO_2) or methane (CH_4), ammonia and other microbially-associated nitrogen (Gao et al., 2012). Additionaly, low of C:N ratio is caused by abundance of ammonium ions is absorbed into clay minerals (Rumolo et al., 2011).

C:N ratio shows higher in Nenggiri and Kelantan river with a slightly change in δ^{13}C range suggest that post depostional decay in organic sedimentary, might be due to rapid sedimentation process (Sanderman et al., 2015). From this biplot, it shows that the source of sediments was from a mixture of C_3 from terrestrial part, phytoplankton and algae. The input from outside is seemed superimpose to the large river, where it does not give such a vast impact to the ecosystem.

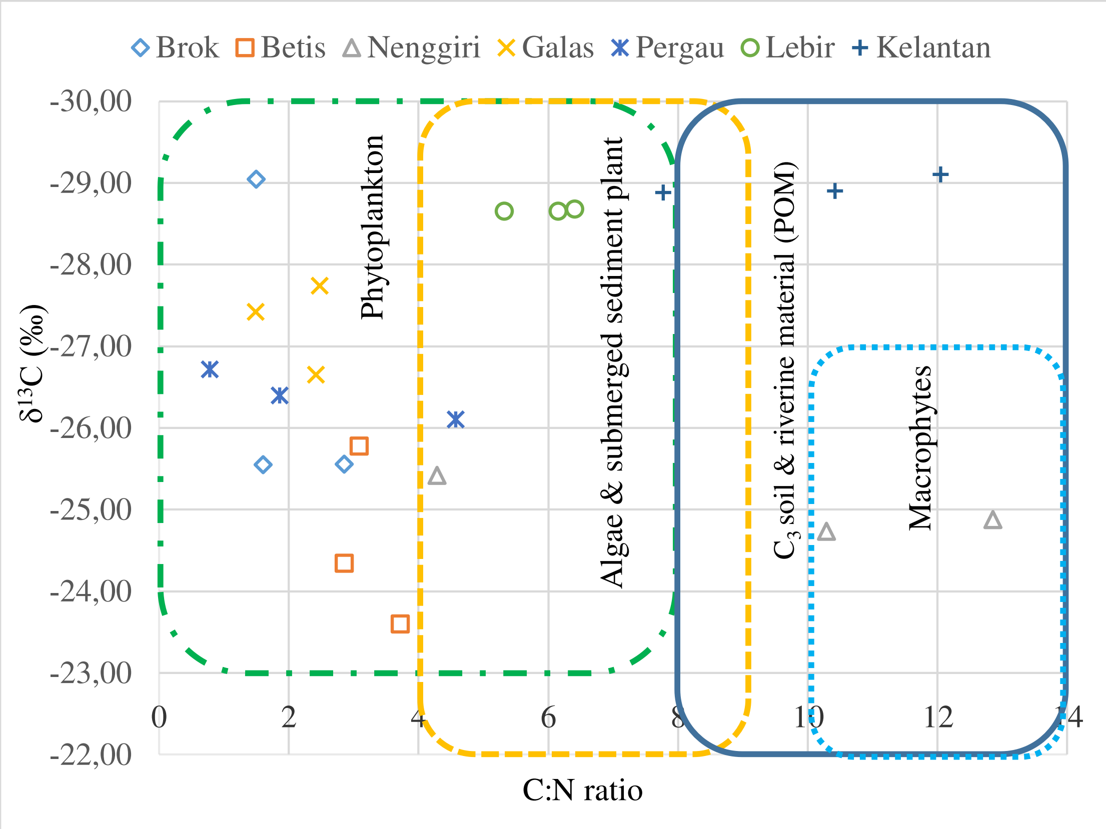

***Figure 5.** The $\delta^{13}C$ and C:N ratio of various types of terrestrial and aquatic organic matter overlap by the sediment range from Kelantan catchments*

Sediment accumulation in Kelantan river networks

Sedimentation in river is one of major flood factors in Kelantan's watershed. As mentioned in methodology, the sediment yield data were analyzed using multivariate principal component analysis (PCA) to determine major factors that are responsible for the sediment accumulation in water bodies. PCA is a technique to reduce large data into small variable number to summarize the data analysis (Pallant, 2001; Wuttichaikitcharoen and Babel, 2014).

***Table 3.** Proposed factor of sediment yields in Kelantan watershed*

Sediment yield	Kelantan catchment	F1	F2
	Component	All	Oct, Nov, Dec
	Eigenvalue	9.66	2.31
	Variability (%)	80.54	19.24
	Cumulative (%)	80.54	99.77
	Factor	Climate	Northeast Monsoon

PCA for sediment yields datasets (*Table 3*) shows that the main component for factor loading (*Table 4*) are characterized by two components with Eigenvalue > 1, which consist of all months throughout the year and component two only on October, November and December. This explains 99% (*Figure 6*) of cumulative variability respectively, reflecting seasonal factor whereby Northeast Monsoon in component

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11011119

factor two in agreement with Butt et al. (2011) and Hua (2014). The reason is because during this period, east coast states such as Kelantan receives extra rainfall, thus triggering erosion process, which results in sediments transport into the water.

Figure 6. *Scree plot Eigenvalue for sediment yield in Kelantan catchment*

Jul	**0.97**	-0.25
Aug	**0.99**	-0.13
Sep	**0.89**	0.46
Oct	**0.67**	**0.74**
Nov	**0.72**	**0.70**
Dec	**0.66**	**0.75**

Moreover, sediments yield show significant results in Nenggiri Rivers, suggesting rampant land use activities which degrades the soil along the river banks. Logging and deforestation activities at upstream of Gua Musang is one of the evidences showing unsustainable land use activities that destroys the ecosystem services (Adnan and Atkinson, 2011). Anthropogenic activities such as deforestation and agriculture are the main factors of erosion process that contributes to sedimentation. Sand mining is also identified as one of the reasons that intensifies sedimentation in Kelantan river (Syahreza, 2012).

Water quality data (Principal Component Analysis, PCA)

Sediment transport have had tremendous impact on water quality of Kelantan river. A water quality set of data provided by Department of Environment (DOE) since 2004 to 2014 was analyzed by using PCA to determine major factors that responsible for the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11011119

degradation of river networks in Kelantan catchment (Berok, Betis, Galas, Kelantan, Lebir, Nenggiri, Pergau).

PCA for water quality parameters datasets (*Table 5*) shows the main factor that plays a crucial role in determining the quality data of Kelantan catchment, which are characterized by two factor components with Eigenvalue > 1. According to Chatfield and Collin (1980) assumption, stated that components with eigenvalue less than 1 should be eliminated. This explains 51% (*Figure 7*) of total variance, due to anthropogenic factor, contributed by urbanization along the river (Ishak, 2014) with superimpose of natural factor.

Principal component analysis results show factor loadings in *Table 6*. Based on these parameters loading, the variables are grouped accordingly with their factors group. Factor loading with value more or equal than 0.60 were bold in the table below. Factor loading 1 consists of three parameters, which are Chemical oxygen demand (COD), Biochemical oxygen demand (BOD) and Suspended solid (SS). While Factor loading 2 are dissolved oxygen (DO) and pH unit followed by Factor loading 3 Ammoniacal nitrogen (NH3-N), Factor loading 4 dissolved oxygen (DO) and Factor loading 5 Suspended solid (SS).

Results showed that chemical oxygen demand (COD) is the most significant parameter in determining water quality of Kelantan river, which reflects the parameters to measure oxygen required to oxidize chemical substance through chemical process (Talib and Amat, 2012). According to Northeast Georgia Regional Development Center, (2001) COD values always have high value compared to BOD. This is because COD measurement only requires a few hours while BOD measurement can lead up to five days. Both COD and BOD are correlated process to each other as oxidation process that occurs during organic matter break down to a more stable form (Talib and Amat, 2012).

The second factor that contributes to COD value is phosphate concentration, as they are directly proportional to each other (Talib and Amat, 2012). The COD value will be high as phosphate concentration increases. The main source of phosphorus is mainly from agriculture fertilizer, manure industrial effluent and sewage. The major factor that causes high concentration of phosphorus in the river is soil erosion especially during flooding event (USGS, 2016).

Furthermore, as BOD is correlated with COD, it suggests that the other factor that influence BOD value is organic waste and detritus from terrestrial part, agriculture and also urban runoff, (Northeast Georgia Regional Development Center, 2001). These are also the same contributing factors of COD. Both COD and BOD play a major role in the deterioration of Kelantan's water quality.

Table 5. *Proposed factor of water parameter in Kelantan catchment*

Water quality	Kelantan catchment	F1	F2
	Component	COD, BOD, SS	pH, DO
	Eigenvalue	1.90	1.17
	Variability (%)	31.68	19.48
	Cumulative (%)	31.68	51.17
	Factor	Anthropogenic	Anthropogenic

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11011119

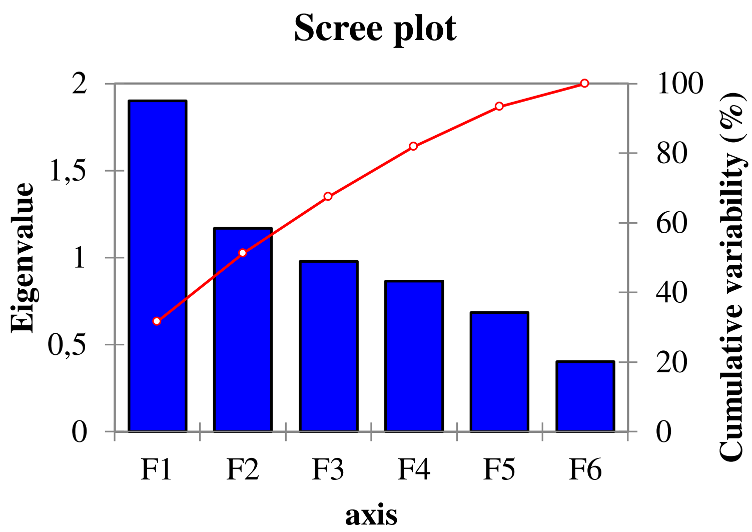

Figure 7. *Scree plot eigenvalue for water quality parameter*

Table 6. *Factor loading of river parameters over two principal component*

Parameter	F1	F2
DO mg/l	-0.32	-0.61
BOD mg/l	**0.74**	-0.39
COD mg/l	**0.84**	0.09
SS mg/l	**0.70**	0.07
pH Unit	-0.11	0.76
NH3-NL mg/l	0.20	0.24

Besides COD and BOD, suspended solids (SS) too, pronounces significantly, in agreement with stable isotopes results. This factor supports the sediment yield data, which was discussed earlier in the erosion mechanism. The other two parameters, which are dissolved oxygen and ammonical nitrogen are not the factors in determining the water quality of Kelantan river. Theoritically, DO depends on the water temperature (temperature depend on COD and BOD), sediment quantity in water flow and aeration. (Northeast Georgia Regional Development Center, 2001)

Conclusions

Stable isotope of $\delta^{13}C$ suggested that C_3 type plant are the dominant plants in Kelantan river with an autochthonous system as depicted in C:N ratio. However, it was evidenced through isotopic fingerprint of $\delta^{15}N$ and multivariate analyses of Water Quality and Sediment Yield datasets, anthropogenic factors have had significant impact on water quality and sedimentation of Kelantan river. Essentially, this research will help stakeholders to develop better strategies in restoring ecosystem services of Kelantan watershed. Balanced ecosystem, therefore, plays significant role in servicing the humanity, makes the ecosystem more resilience to natural disasters.

ANOPLOPHORA CHINENSIS (FORSTER, 1771) (COLEOPTERA: CERAMBYCIDAE) REPORTED AT NEW LOCATION IN TURKEY

YILDIZ, Y.

Bartın University, Faculty of Forestry, Department of Forest Engineering, 74100 Bartın, Turkey, e-mail: yafesyildiz@hotmail.com
phone: +90378-223-51-64; fax: +90378-223-50-66

(Received 31st Jan 2017; accepted 3rd Jul 2017)

Abstract. Invasive alien insect species have fast growth and reproduction, high spreading ability, tolerance tovery different enviromental conditions and ability to feed with many plant species. The increase in importing of the plants in the recent years has been causing the prensence of these species in Turkey. One of the these species, *Anoplophora chinensis* (Forster, 1771) (Coleoptera: Cerambycidae) citrus longhorned beetle was recorded for the first time in Marmara region, Istanbul, Turkey by Hizal et al (2015). This study is a second report for the presence of releated pest in Turkey. The new location (Bartin), in the western Black Sea region, shows that the insect is expanding its distribution area in Turkey.

Keywords: *Anoplophora chinensis, citrus longhorned beetle, Cerambycidae, new location, Turkey*

Introduction

The genus *Anoplophora* (Coleoptera: Cerambycidae) consists of 36 species of longhorned beetles indigenous to the temperate and tropical regions of Asia (Lingafelter and Hoebeke, 2002). Among these species, the citrus longhorned beetle, *Anoplophora chinensis* is a poliphagous woodboring beetle native to Eastern Asia with a host range quite wide causes damage on more than 100 species of trees and shrubs (Peverieri et. al., 2012; EPPO, 2013a). The beetle gets its name from the damage caused to citrus groves in its native China. Unlike many cerambycids that primarily attack dead trees, this beetle attacks apparently healthy trees and sever tissues that carry nutrients, water, and subsequently kill the host tree (Chambers, 2002; Lance, 2002).

The citrus longhorned beetle has been introduced to Europe on several occasions. It was first discovered in Europe in 2000 at Parabiago, Italy and respectively it has been recorded in Netherlands and France (2003) and Switzerland (2006) according to FAO (2009). In Italy more than 18000 plants have been removed for the eradication program and the cost has amounted to about 12 million euros (Jucker and Lupi, 2011). Adults of *A. chinensis* were captured on 12 June 2014 in Sile region of Istanbul province and it was given as a new record to Turkish invasive alien insect species fauna by Hizal et al. (2015).

A. chinensis is a new threat on a wide range of broadleaved trees and shrubs in Turkey. Therefore its distribution areas and the behaviour of the pest in these areas should be investigated.

Materials and Methods

A total number of 28 adult samples were collected from a private nursery in Bartin region on ornamental plants consisting of *Acer palmatum purperea, A. negundo flamingo* and *A. platanoides* by a Japanese umbrella. Specimens were photographed with Samsung Pro-815 digital camera and they were examined under the Olympus

DOI: http://dx.doi.org/10.15666/aeer/1504_111116

SZX7 stereomicroscope. The identification process was carried out using specific literature (Lingafelter and Hoebeke, 2002; Gyeltshen and Hodges, 2005; EPPO, 2013a). The samples are stored in the collection of Bartin University, Faculty of Forestry, Department of Forest Entomology and Protection.

Results and Discussion

Experimental location: Turkey, Bartin, 41˚ 38' 17" N- 32˚ 19' 48" E, 13m, 15.VI. 2014 1♂, 17.VI. 2014, 5 ♂, 10 ♀, 19.VI. 2014, 3 ♂, 9♀

Morphology

The beetle is large, stout, and approximately 21 to 37 mm long with shiny black elytra marked with 10 to 20 white round spots (Lingafelter and Hoebeke, 2002). Generally males are smaller than females, and have their abdomen tip entirely covered by the elytra, in contrast to the partially exposed abdomen of females. Also, the male elytra are distally narrowed compared to the rounded female elytra. Another difference between males and females are antennal sizes. The male's antennae are approximately twice as long as its body compared to the female's antennae which are only slightly longer than the body. Each segment of the long, 11-segmented antennae is basally marked with white or light blue bands (Gyeltshen and Hodges, 2005). The anteriorly and posteriorly narrowed pronotum has a pair of stout spines extending from its sides and some with two blue and white tufts of hair on pronotum (EPPO, 2013a). The base of the elytra has numerous short tubercules/granulae, a morphological character that may help to differentiate *Anoplophora chinensis* from the, *A. glabripennis* (Gyeltshen and Hodges, 2005) (*Figure 1 A-D*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_111116

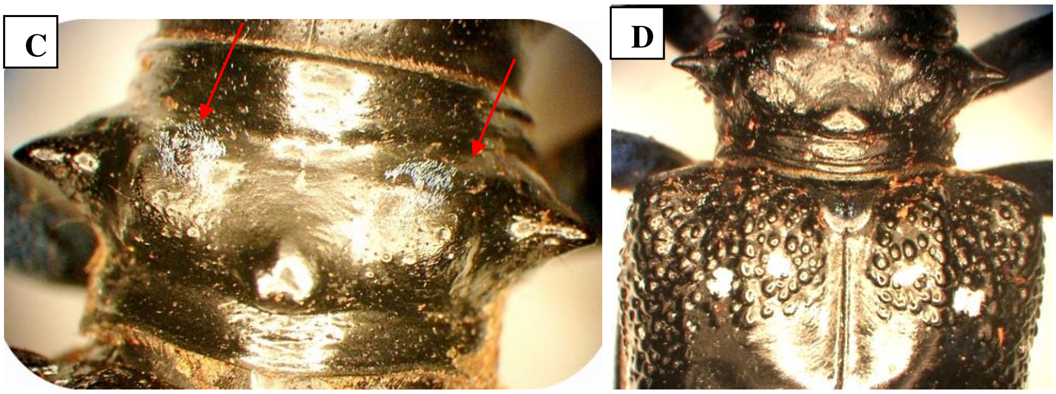

Figure 1. *A. Adult of Anoplophora chinensis B. Antenna with blue-white bands C. Pair of stout spines and two blue-white tufts of hair on pronotum D. Tubercules/granulae on the base of the elytra*

Distribution: The species has been reported China, Croatia, Germany, Guernsey, Hong Kong, Indonesia, Italy, Japan, Korea, Lithuania, Malaysia, Myanmar, Philippines, Switzerland, Taiwan and Vietnam (EPPO, 2014).

Host plants: *Acer* spp., *Aesculus hippocastanum*, *Alnus* spp., *Betula* spp., *Carpinus* spp., *Citrus* spp., *Cornus* spp., *Corylus* spp., *Cotoneaster* spp., *Crataegus* spp., *Fagus* spp., *Lagerstroemia* spp., *Malus* spp., *Platanus* spp., *Populus* spp., *Prunus laurocerasus, Pyrus* spp., *Rosa* spp., *Salix* spp., *Ulmus* spp., *Casuarina* spp., *Cryptomeria* spp., *Ficus* spp., *Hibiscus* spp., *Litchi* spp., *Mallotus* spp., *Melia* spp., *Morus* spp. and other woody plants (EPPO, 2013b).

In the study, adults of *A.chinensis* were detected in private nursery on maple trees (*Acer palmatum purperea*, *A. negundo flamingo* and *A. platanoides*) that imported from China. These beetles were recorded in the same time as it was recorded first time in Istanbul by Hizal et al. (2015). Due to its polyphagous character, host plant is considered under high risk of attack, especially *Acer* species. The pest is a serious problem for the nursery industry, in the production of ornamental trees; it is also a potentially pest of citrus orchards and of many other deciduous trees. Adults feed on the fresh bark of small twigs and branches, and sometimes on leaf petioles. The females also chew from the bark of the host tree to the cambial layer, forming 'egg scars'; then inserts her ovipositor and lays a single egg (Lingafelter and Hoebeke, 2002). Larvae feed and develop in the wood of the main roots and trunks, where they create tunnels. Exit holes have been found only at the base of trees (*Figure 2 A-D*). Heavy infestations can kill the host trees (Maspero et al., 2005).

This species, is placed at the list of 'Unknown presence and harmful organism for importing' as a part of Agricultural Quarantine Regulations Bylaw -1 An Obstacle Harmful Organism for Importing which is prepared in terms of the law no. 5996 Veterinary Services, Plant Health, Food and Feed promulgated on 13 June 2010 on Official Gazette. In addition, as regard to European Union *Anoplophora chinensis* commission decision of 1 March 2012 and law no. 2012/138/EC, specifically, by law is prepared and on 17 June 2014 law no. 29033 promulgated on Official Gazette and entered in force (Anonymous, 2014).

Most of the known host plants of the citrus longhorned beetle exist also in Turkey. With respect to this, discovering of the releated invasive pest and exploring its new distribution areas in Turkey has a very important value for management of Turkish forests. Ayberk et al. (2014) has reported another invasive longhorned beetle, the Asian longhorned beetle, for the first time in Turkey. The authors has reported the adults of *Anoplophora glabripennis* were collected from Istanbul province (Zeytinburnu) damaging on *Acer negundo* trees in July, 2014. For this purpose, as the first step should be to determine real status of invasive *Anoplophora* species in Turkey. And then to eliminate these extremely dangerous quarantina pests is to remove infested trees and destroy them by chipping or burning immediately. To stop the spread of the citrus and Asian longhorned beetles, it should be to follow the quarantine procedures strictly in infested areas.

Abstract. This paper reviews initiatives of Community-Based Natural Resource Management (CBNRM) from 21 case studies in different countries. The study uses Ostrom's design principles and eight objective measures. These are empowerment, public participation, equity, conflict resolution mechanisms, similarities between misuse and establishment of rules for indigenous environments, effective monitoring, collective choice arrangements and sanctioning activities for the use of common resources to evaluate and compare the case studies to examine the cases. Based on the analyses, successes and failures of CBNRM were determined. Successes were evident in the management of water resources in Honduras, India, Kenya, Nepal and St Lucia. CBNRM was also successful in Fiji, in joint forest management in India and other instances such as in Alaska, China, Cambodia, Namibia, Malaysia, Mexico, Washington, and to a small extent in Papua New Guinea. However, CBNRM initiatives failed in managing wildlife conservation in Nepal and Kenya, and in Tanzania wildlife management, Uganda and Zimbabwe. CBNRM failure was attributed to the uneven distribution of the benefits of natural resources, lack of empowerment, low community participation, failure to resolve conflicts, among many factors. In this study, the recommendations is made that similar research should be conducted with a larger sample size and employ other techniques such as Principal Component Analysis for examining the characteristics that achieve effective and sustainable CBNRM initiatives.
Keywords: *community, participation, biodiversity, water management, sustainability, international comparison*

Introduction

The worldwide failure of centralised approaches to managing natural resources led to the search for a viable and sustainable alternative approach by conservationists to achieve sustainable management (Nabane and Matzke, 1997). The approach whereby local communities are given ownership rights to manage natural resources became common in the 1960s when it was named community-based natural resource management (CBNRM). It is also called community-based conservation. According to Songorwa (1999), CBNRM aimed to create conditions under which most members of the community stood to benefit from the sustainable utilisation and management of wildlife resources. This would occur through a bottom-up participatory approach (Songorwa, 1999) based on a number of principles. These principles, which include meeting the basic needs of local people, putting resources under local control rather than the control of the state government, obtaining equal delivery and apportionment of socio-economic benefits and resources, and commitment involving members of the community and the local institutions in managing and conserving natural resources. This would be achieved regardless of their gender and would encompass the defence

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11211143

and legitimisation of local resources and property rights. There would also be a willingness to embrace traditional values and ecological knowledge in the management of present resources and a need to associate and resolve the objectives of social and economic growth for the protection and conservation of natural resources in the environment (Songorwa, 1999; Kellert et al., 2000). Also, CBNRM attempts to integrate the goals of conservation, sustainable development and community participation (UNDP, 2012c). This is performed by applying Ostrom's 1990 design principles (*Table 1*) on governing the common elements concerning empowerment, public participation, equity, conflict resolution mechanisms, congruence between appropriation and provision of rules for local conditions, effective monitoring, collective choice arrangements and sanctioning activities for the use of common resources. Ostrom design principles were based on extensive studies of long-enduring governing institutions of common-pool resource management across different systems such as wildlife, fisheries, and forests (Ostrom 1990, 2009; Dell'Angelo et al., 2016). The eight design principles that were identified by Ostrom (1990) include opportunities for collective choice and local self-determination, approaches to monitoring, congruence with local conditions, sanctions, and conflict resolution. It included the incorporation of multiple, nested layers of organisation, shows the best practices, and describes the rules and structures of robust institutions associated with the sustainable governance of common pool resources. This study employed Ostrom's (1990) design principles for natural resource management as a diagnostic framework to analyse the CBNRM initiatives in the 21 case studies.

Table 1. *Ostrom's 8 design principles for natural resource management of common-pool [Adapted from Ostrom (1990)]*

Ostrom's design principles	Operationalisation
1. Clear boundaries	Individuals or households who have the right to use the common-pool resource are clearly defined
2. Congruence with local conditions	Rules restricting time, place, technology, and quantity of resource use are well adapted to local conditions
3. Collective-choice arrangements	Most individuals affected by the rules can participate in modifying them
4. Monitoring	Common-pool resource conditions and use are monitored by the users themselves or by people accountable to the users
5. Graduated sanctions	Users who violate resource-related rules are likely to be assessed penalties that correspond to the seriousness and context of the offense

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11211143

6. Conflict-resolution mechanisms	Users and officials have rapid access to low-cost local arenas for resolving conflicts among users and conflicts between users and officials
7. Recognition of the right to organization	The rights of users to devise their own organisations are not challenged by external government authorities
8. Nested governance	Appropriation, provision, monitoring, enforcement, conflict resolution, and governance are organized in multiple, nested layers

CBNRM as a concept emerged and gained popularity in the early 1980s as an alternative to resource regimes that were perceived to be failing (Gibson and Mark, 1995; Matzke and Nabane, 1996). CBNRM has been extensively promoted in recent years as a method for investigating natural conservation and socio-economic goals. Examples such as forests, wetlands and grasslands are among several projects that involve local communities in managing natural resources in protected areas. Despite variation in forms of CBNRM such as the management by communities of wildlife, grassland, forests, water resources and many others, they share common features, including the involvement of local people in the management of their resources. This implies a willingness to devolve power and authority from central government to local institutions and people. This happens because of their belief and desire to integrate traditional ecological knowledge in balancing socio-economic and environmental goals in the conservation and protection of natural resources (Kellert et al., 2000).

CBNRM syntheses that has been conducted (Agrawal and Gibson, 1999; Allan and Curtis, 2005; Barkes, 2004; Campbell and Vainio-Mattila, 2003; Child, 2007; Deker et al., 2002; Gruber, 2010; Kellert et al., 2000; St. Jacques, 2009; Measham and Lumbasi, 2013) has been consistent with Ostrom's 1990 design principles for governing the common elements. Agrawal and Gibson (1999) proposed focusing on institutions rather than the community if CBNRM programmes are to be successful. Allan and Curtis (2005), in their study on adaptive management, found that using both passive and active adaptive management may be inhibited by deeply rooted social norms and institutional structures. Barkes (2004) proposes the need for greater consideration of the nature of people, communities and institutions, and how they interrelate at several levels in CBNRM programmes. In their synthesis of CBNRM, Kellert et al. (2000) note that the success of a CBNRM programme may depend on the structure of institutions, socio-economic development and scientific considerations. They also observed that the main and consistent obstacle was a failure to control and monitor the behaviour of complex organisations, mostly bureaucratic and local institutions. Measham and Lumbasi (2013) further observed that communities with high level of ownership tend to have effective CBNRM programmes.

Assistance in the analysis of the current state of CBNRM initiatives was provided by Gruber (2010) who tried to develop wide organisational principles and main characteristics of effective and sustainable CBNRM. However, he could not recognise the key characteristics that were most critical in attaining long-term effective and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11211143

sustainable CBNRM. Further, in his CBNRM synthesis, St. Jacques (2009) observes that participation needs to be flexible, not only to meet project phase objectives but also to allow for content-specific needs. He also observes that the most democratic form of participation is one that facilitates social learning and maximises the opportunity for information flows between stakeholders. Campbell and Vainio-Matilla (2003) also note in their study that lessons learned in participatory development have not been used in community-based conservation. This was partly because of the different emphasis on means versus ends in participatory development and community-based conservation. Furthermore, scholars such as Brooks et al. (2013) observed that Community-based conservation promoted the idea that long-term conservation success required engaging with and providing benefits for local communities. This was in line with Gurneya et al. (2016) who found that individuals' level of participation in marine protected areas (MPA) management was related to socioeconomic factors. In short, success in conservation is often predicated by local support for conservation which is influenced by perceptions of the impacts that are experienced by local communities and opinions of management and governance (Bannett and Dearden, 2014).

This review paper examined critically the success and failure of CBNRM that occurred in various case studies from 21 different countries based on the eight design principles developed by Ostrom (1990) that are displayed in *Table 1* above.

Methods

To determine the relative success of CBNRM of the 21 case studies from the different countries, each variable was first given a score that was entered into a spread sheet. The scores were either 0 for no evidence or evidence not deemed useful or 1 for the existence of evidence provided in the case study. Second, the scores were then added to give a total value out of 8. The higher the number, the greater was the relative success of the CBNRM initiative in each of the resources being managed in the 21 case studies. Third, the cross-tabulation analysis was performed using the variables scored in the spread sheet. Fisher's Exact Test in the cross-tabulation was used to analyse the relationship between each variable and the success of CBNRM. Fisher's Exact Test was appropriate for this study because of the small sample size used (21 cases). Data reduction techniques such as principal component analysis (PCA) could therefore not be used as it is recommended for a sample size of at least 50 and above (Hair et al., 2010).

Results

In *Table 2*, the countries where the case studies were done, as well as the name of the case study are shown. An indication is also given of the resource being managed and the source of data where the case study was reported. The resources managed in the case studies analysed included water, forest, wildlife, fish and wetlands. The case studies examined were drawn from different countries. *Table 3* indicates the CBNRM performance criteria and the totals for the various case studies analysed. The CBNRM performance criteria analysed in the study include equity, empowerment, community participation, monitoring of biological diversity, conflict resolution, collective choice, and local condition rules. *Table 3* indicates the total score for CBNRM performance criteria in each country, too.

Spread sheet scores for cases studies examined are shown in *Table 3*. The table shows that for cases from Honduras up to Namibia, the total score for all the variables was 8, while Alaska, Washington, China and Papua New Guinea scored 7, but Botswana scored 2, with Nepal, Kenya, Zimbabwe and Tanzania scoring 0 for all the eight variables examined.

Cross-tabulation of the variables and CBNRM are shown in *Appendix 1*. The cross-tabulation analysis was performed using scores from the spread sheet. The Fisher's Exact Test in the cross-tabulation reviews the relationship between each variable and the success of CBNRM. The Fisher exact test value = 17.008 is significant at 5% level ($p < 0.05$). We therefore reject the null hypothesis that there is no association between CBNRM and equity. This shows that for CBNRM initiative programme was successful, and equity needs met. From the cross tabulation *Table 3* of CBNRM versus equity, it can be seen that if equity is absent, then CBNRM is not achieved. However, the table further shows that CBNRM can only be successful if equity is partially or fully achieved. The Fisher exact test is significant for the subsequent test of association between CBNRM and other variables examined. All the variables are important if CBNRM initiate is to be achieved (*Table 3*). For the entire cross tabulations for the variables assessed, Fisher exact test value is 0.00 indicating that all the variables need to be achieved to have a successful CBNRM initiative.

Discussion

We analysed CBNRM initiatives in 21 case studies from different countries using Ostrom's (1990) eight design principles of natural-resource management and eight

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11211143

objective measures. We found that some CBNRM initiatives show that their institutional structures reflect the eight design principles while others are not as discussed below. Those that were aligned with the design principles were successful while those that were not were unsuccessful. This is discussed more as follows.

Gender and equity

CBNRM advocates equal opportunities for men and women in natural resource management. Involving women in natural resource management programmes leads to positive outcomes, as women have a key influence on the environment (Songorwa, 1999). Gender balance has resulted in the success of most CBNRM initiatives where this was maintained. For example, the involvement of women in the management of forests in India led to success in that the first president of Vana Samarakshana Samith (VSS) is a woman and half of the members of the managing committee of VSS are women, too. The high involvement of women in India's forest management is attributed to the local demography of the area, which favours women (D'silva and Nagnath, 2002; Pathak and Gour-Broome, 1999). In Cambodia, a case study in the Monk Community Forest shows that women are actively encouraged to participate in CBNRM programmes; they are encouraged to take part in increasing awareness about activities in villages and to participate in the seven village sub-committees (UNDP, 2012a). In Mexico, there is strong participation of women in the management of activities in forests, such as bottling of water and tapping of resin (Bray, 2003). Gender balance is also a priority in the Fiji case study about a locally managed marine area network. There is a gender programme in which meetings are held with local women's groups that are encouraged to discuss the progress of the CBNRM initiative. This empowers women to make decisions on the management of their natural resources.

In the Honduras case study, dealing with the community-based supply of water and sanitation, sustainability is demonstrated through capacity building of the local community in water management, as water committees are established in the area. It is important to note that representation by women involved in decision-making did increase to 30% of the total number of individuals participating in the process of management (St. Jaques, 2009). This has led to an improvement in access to potable water and sanitation services in the area.

Some CBNRM initiatives, however, pays less attention to gender balance in their management of natural resources. This is the case in Zimbabwe's CAMPFIRE programme, where the participation of females is low (Mutandwa and Gadzirayi, 2007). Furthermore, in Nepal and Kenya women are marginalised (Kellert et al., 2000). In Botswana, Uganda and Tanzania the case studies did not provide information on how gender was addressed in their CBNRM initiatives.

Equal distribution of natural resource benefits to resource users motivates them to manage their resources sustainably. In Cambodia motivation to protect the forest emanates from the material benefits the forest offered to the local people, which are distributed equally to all the resource users (UNDP, 2012b). In Washington, the CBNRM initiative is a success because of the benefits from the natural resources that are distributed equally, which is evident from the lower number of conflicts that are registered in the case study (Kellert et al., 2000). When natural resource benefits are not distributed equally to all resource users, it tends to lead to conflicts. In Papua New Guinea, the CBNRM initiative provides benefits to the community in the form of economic benefits from the wetland resources hence it is a success (UNDP, 2012d). In

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11211143

India, local communities have equal access to forests and have employment opportunities in the forest work, therefore, they are motivated to protect the forest (Pathak and Gour-Broome, 1999). In their study on the effect of equity in benefit sharing in Nepal community forest programme, Luintel et al. (2017) noted that equity has been crucial in motivating forest managing communities.

In some case studies, however, equal distribution of natural resource benefits to all beneficiaries is a failure, and this leads to deficiencies in managing the natural resources effectively and in a sustainable manner. For example, case studies from Kenya, Nepal, Tanzania, Uganda and Zimbabwe reflect the unequal distribution of natural resource benefits. In Kenya, only a small minority received monetary benefits, while in Nepal there is uneven allocation of natural resources. This is because local people living closer to CBNRM headquarters receive more development benefits than those who live further from the headquarters in both Annapurna conservation areas (ACA) and Makulu barun conservation area (MBCA) (Kellert et al., 2000). In Zimbabwe's CAMPFIRE programme, the local community receives no economic benefits from their natural resources (Mutandwa and Gadzirayi, 2007). In Botswana unequal distribution of benefits occurs, as only 40% of the locals benefit from the wildlife resources (Boggs, 2000). Failure to distribute resource benefits equally to all beneficiaries leads to conflicts in the community and also reduces interest in managing natural resources effectively.

Monitoring

Ostrom's 1990 design principles advocate effective monitoring procedures in the management of common pool regimes. In the Mexico case study, effective monitoring is demonstrated by the expansion of canopy from 1982 to 1993, where the communities place four hectares under strict protection for the conservation of the endangered species Hickel's fir (*Adies hickelii).* The certification of 502,656 ha of forest in 2002 in 25 communities under the criteria of the forest stewardship council and the declaration of 500,000 ha in 1980 by the state of Quintana Roo as permanent forest areas demonstrates an increase in re-afforestation by the community, with limits being placed on agricultural activities in the forest area. Other monitoring indicators in Mexico include prohibiting all hunting activities in forest areas and willingness to reduce the logging volume in the Quintana Roo community and Laguna Kana' from 29% and 37% respectively (Bray, 2003). Effective monitoring procedures are also observed in Puget Sound in the State of Washington where ecological information on various salmon stocks has improved, and coordination of conservation efforts is enhanced among stakeholders (Kellert et al., 2000). The same happened in India, where a reduction in the demand for firewood is noted (D'silva and Nagnath, 2002). In the case of community water resources management in India, the programme has an ecological impact, namely an increase in the availability of water, as several rivers became perennial. There is also an increase in agricultural productivity where wheat yields are doubling (Islam and Jain, 2011).

However, in some case studies, there are no effective procedures to monitor natural resources. In Kenya for example, there is insufficient monitoring of observations of the wildlife resource because patrols by game scouts are highly sporadic. Data collected on the wildlife population and their habitats and on ecologically threatened and endangered species are insufficient. Moreover, little data collection on the dynamics of wildlife populations in the area and encroachment on the habitats of wildlife resources in parts

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11211143

of the Kimani community wildlife sanctuary (KCWS), take place (Kellert et al., 2000). In Nepal, a case study in the Annapuna and Makalu-Barun areas reveals that little time is being devoted to monitoring and protecting biological diversity, as most of the work is focused on building and local communities (Kellert et al., 2000). There is also insufficient monitoring of wildlife resources in Botswana and Zimbabwe, as no information is available to indicate the dynamics of resources in the study areas (Mbaiwa, 2012). The picture is similar in Tanzania and Uganda for their wildlife management case studies.

In summary, gender balance, equity and effective monitoring of natural resources are important for the success of a CBNRM initiative. This is because they all lead to the sustainability of natural resources.

Devolution and empowerment

Design principles developed by Ostrom in 1990 also advocate defined membership and rights in the management of common pool regimes. This is because devolution empowers resources (Armitage, 2005; Child, 2007; Grumbine, 1994). Measham and Lumbasi (2013) observe that communities with high level of ownership tend to have effective CBNRM programmes. Therefore, local communities will only be empowered if devolution is fully achieved. Empowering local communities builds commitment in the users of natural resources to manage such resources effectively (Bannett and Dearden (2014). Unfortunately, where local communities are not empowered to manage their natural resources, they usually remain unmotivated, and this has a negative effect on the well-being of the natural resources that are available. In all the case studies that are examined, attempts are made to devolve authority from the state to the local power, but the effectiveness of that devolution is variable. For example, in Kenya devolution of authority usually results in power being concentrated in certain groups or members, with others being excluded, and in Nepal people of a low caste and women are under-represented in conducting the management of natural resources (Kellert et al., 2000). Empowerment is also lacking in Zimbabwe's CAMPFIRE programme, where Mutandwa and Gadzirayi, 2007) observes partial devolution of natural resources and the exclusion of the local people in decision-making and management. In Botswana, too, despite job creation related to wildlife activities, no empowerment is seen among the local people (Mbaiwa, 2012), as the management of the resources is entirely in the hands of the government (Boggs, 2000).

In Fiji, the locally managed marine area within the network was established in 1997 in the Ucinivanua community, where the local community are empowered through the building of on-going capacity with the necessary knowledge to reverse the decline in their natural resources. Also, the emphasis is placed on the importance of collecting data as a tool for learning, alongside on-site training workshops and encouragement in the use of adaptive management as a key to achieving best practices. Moreover, a network has been developed that recognises the autonomy of the local communities' management of their marine resources, while providing support and guidance to help them achieve the best results and take responsibility for planning and facilitating the programme, while decision-making, implementation and evaluation are undertaken on ground level by the individual groups (Gruber, 2010).

The situation concerning empowerment is different in Alaska, Cambodia, China, Fiji, India, Japan, Malaysia, Mexico, Namibia, Papua New Guinea, St Lucia and Washington. In Alaska's Kuskokwim River watershed the local community is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11211143

empowered to manage their salmon resource. In Cambodia, the programme for the management of natural resources has empowered the participants to have a voice in the management of the community forest through their representatives on the central management committee and the sub-committees (UNDP, 2012b). In China, the Kanghua community placed a strong emphasis on ownership of the natural resource by the local people, giving the community a strong sense of engagement and commitment that leads to the success of the initiative. The management programme for sika deer in Japan also empowers the local community, as they are involved in the decision-making process through the Nishiokoppe Wildlife Steering Committee (Decker et al., 2002). The same happens in Cambodia, where the participants have a voice in the management of the community forest through their representatives on the central management committee and the sub-committees. The importance of empowerment is further demonstrated by the Malaysian case where the World Wide Fund for Nature (WWF) withdrew its support in 2004. They also withdrew funding for the initiative of the Regional Environmental Awareness of Cameroon Highlands (REACH). Thereafter, funding was entirely depended on membership fees, donations and fundraising ventures (St Jacques, 2009). This confirms the empowerment of the local community to manage their resources by a non-governmental organisation because the initiative continues even after support is withdrawn.

In Mexico, devolution of responsibility for forest resources to the local communities is about 80% (Bray, 2003). The Mexican case also clearly shows that large numbers of communities are managing common property forests for commercial production of timber and finished timber products in some areas in Mexico, unlike in less developed countries where community forest management usually entails the management of non-timber forest products or wood for domestic use on government land (Bray, 2003). In St Lucia's water catchment project, community empowerment is demonstrated by the full participation of the local community and through capacity building in the various awareness programmes that are offered. Examples of this are technical training sessions and exchange programmes with similar community-based organisations, both in St Lucia and elsewhere (St Jacques, 2009). In Washington, the indigenous people are empowered through a partnership with the fisheries department, which gives them sufficient legal rights and authority to manage their local fisheries (Kellert et al., 2000).

Conflict resolution

Cheap or accessible conflict resolution mechanisms are one of the key principles designed by Ostrom (1990) in the management of common pool regimes. Conflicts in CBNRM programmes cannot be avoided, as management involves many stakeholders who have an interest in the natural resources. It is therefore important for CBNRM to factor in conflict resolution strategies at the start of the programmes (Ostrom, 1990). In the cases analysed, conflict resolution is addressed well in all of the water cases mentioned. In case studies of wildlife management in Kenya, Tanzania, Botswana, Zimbabwe China, and Nepal, however, conflicts are rarely resolved. For example, in all of these case studies, natural resource conflicts frequently occur, although the sources of conflict vary from place to place. In Kenya conflicts arise from wildlife depredation and disputes with neighbouring group ranches over boundary delineations and those related to institutional posts (Kellert et al., 2000. These cases are rarely resolved by management in the area, and little or no compensation is provided for damage caused by wildlife. In Nepal, the causes of conflicts are mostly related to power struggles among

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11211143

members and members of the institutions, especially the elite. Local conflicts in institutions also occur in the area as a result of overlapping jurisdictions and mandates (Heines and Mehta, 1999). In Tanzania, conflicts did arise from serious crop damage, usually caused by wildlife in the study area, but no compensation is paid for the damage that occurs (Emerton, 1999). The case is the same in Botswana and Zimbabwe, where community conflicts are on the increase but rarely resolved and no compensation for wildlife damage is paid (Mutandwa and Gadzirayi, 2007; Mbaiwa, 2012). Empowerment and conflict resolution lead to the sustainability of natural resources, and therefore CBNRM programmes could be successful.

Participation

Another of Ostrom (1990)'s key principles for enduring common pool institutions is collective choice arrangements. This allows the local community to participate in the decision-making process through village institutions and several committees. Community participation in natural resource management is one of the pillars of CBNRM (Mbaiwa, 2012) and is usually the outcome of sustainable CBNRM. When resource users can derive economic benefits from their resources, they tend to develop positive attitudes to natural resources and therefore use them sustainably, and this promotes participation among them (Gurneya et al., 2016). However, if the benefits are not realised by the local community, they usually become demotivated, and this frequently destroys participation, since the unsustainable use of resources is the outcome. The holistic watershed management in Sukhomojri, India shows that active participation of the local community is needed for the conservation and management of extraction of timber for firewood, brought about by its increased scarcity. It demonstrates that the local community should take an active part in the management of their natural resources (Pathek and Gour-Broone, 1999). The motivation to participate in natural resource management derives from benefits that the resource users receive from the natural resource (UNDP, 2012e). In water resources management in India, the local community in village assemblies is fully involved in determining the management of the watershed, distribution of water, rules about annual repairs as well as penalties for users of unsustainable natural resources Islam and Jain, 2011). Effective participation is also shown in a water case in India where villagers are allowed to make decisions on the management of their water resource through village institutions; several committees are democratically formed in the area. Participation of the local community in the St Lucia water case is sustained by encouragement from the management of the responsible use of natural resources, as well as direct and indirect monetary incentives. Awareness and demonstrations offered to the local community in the study area are important, too (St Jacques, 2009). Often, local community participation in the case studies is low. In Tanzania, Uganda, Nepal and Kenya local participation is also low in the cases examined (Emerton and Mfunda, 1999; Kellert et al., 2000). However, in Botswana, the situation is different, as local community participation is observed (Mbaiwa, 2012). Active participation of the local community in natural resource management is an important element of a successful CBNRM initiative. The sustainability of natural resources is therefore guaranteed if the local community is actively involved in the management of the resources through various committees and village institutions where they are free to make decisions on matters related to their natural resources.

Fisher's Exact Test analysis of the cross-tabulation of the variables further indicates that for a CBNRM initiative to be successful, all eight variables are important. Of the 21 cases analysed, 11 are successful in their CBNRM programmes, five are partially successful while the last five are not successful (*Table 2*). This is because the Fisher's Exact Test P-value in all the variables analysed was .00, which was less than .5, indicating a significant relationship between each variable and the success of the CBNRM initiative (*Appendix 1*). This shows that all the variables assessed in the review, are all important for CBNRM initiative to be successful.

Conclusion

This study analysed CBNRM initiatives in 21 case studies from different countries based on the application of Ostrom (1990)'s eight design principles of common pool regimes to the management of natural resources. The various aspects of the 21 case studies were examined and grouped into the sustainability of natural resources, social institutions sustainability and livelihood sustainability. To ascertain the sustainability of the CBNRM programme in each of the case studies mentioned above, all three areas were examined. All three aspects of sustainability are evident in the successful cases. Most of the dimensions of social institutions' sustainability are achieved by the case studies, such as equity, participation, sense of community ownership, social coherence and encouraging diversity in the community. Livelihood sustainability is also achieved by the cases that achieved a high scoring. Dimensions of livelihood sustainability that were examined include economic and indirect benefits, for example in the areas of education and health, where infrastructure was built to ensure that the community would satisfy its basic needs so as to foster good quality of life in the communities. Natural resource sustainability was achieved in a few cases, as there seemed to be a challenge in balancing the social and natural aspects of sustainability. However, cases from North America seem to have no problem with that, as evidenced by the study. Natural resource sustainability is a major problem in cases from Africa and Asia. Dimensions examined include monitoring and proof of biodiversity protection. Cases that did not score high in the social sustainability and livelihood sustainability dimensions seem to have problems in protecting their natural resources. A successful CBNRM programme is possible when the resource users are motivated to take care of their resources. When the resource users are not motivated, the result is the unsustainable use of resources, which leads to failure in the CBNRM initiative. It is therefore important to promote the social and livelihood aspects of sustainability, such as equity, participation, rights and empowerment, collective choice and conflict mechanisms, to have a successful CBNRM programme. It is recommended that further studies be conducted with larger sample sizes utilising different techniques for increasing the understanding of multiple factors that are essential for achieving effective and sustainable CBNRM initiatives.

(Received 10th Apr 2017; accepted 11th Aug 2017)

Abstract. With the shortage of water resource being more and more serious day by day, reclaimed water irrigation is an effective approach to solve this problem. In this article, field experiment is conducted to research and analyze the effects of different proportions of rural domestic sewage reclaimed water drip irrigation on characteristics of rhizosphere soil, using groundwater drip irrigation as sample comparison. The results show that: As for soil physical and chemical characteristics, the soluble salt concentration (EC value) of soil solution under reclaimed water drip irrigation is higher than that under groundwater drip irrigation. However, the pH values of soil solution under both conditions are similar. As for soil nutrients, compared with sample comparison, reclaimed water irrigation increases the amounts of organic matter in soil and available phosphorus in soil layer, but has no effect on the contents of available nitrogen and available k. The higher the concentration of reclaimed water in irrigation water is, the more obvious the effect on soil respiration is. Under the condition of drip irrigation, with proper agronomic measure and irrigation system, the adoption of certain proportion of rural domestic sewage reclaimed water irrigation is an effective way to reduce reclaimed water pollution.
Keywords: *soil characteristics; EC value; nutrients*

Intrduction

Reclaimed water resource is a kind of recycled water source, which has great potential value. In China, we are short of water source, especially agricultural water source (Yadav et al., 2002; Ramirez et al., 2002; Lu et al., 2016a). In order to relieve the present situation of water shortage, reclaiming rural domestic sewage and using it for agricultural irrigation is an important way to solve the problem of agricultural water shortage. The effects of reclaimed water on soil physical features change according to the soil characteristics and they mainly show in N, P and salinity contents. The contents of other elements in reclaimed water are similar to that of tap water (Smol et al., 2015; Lu et al., 2016b; Cui and Ouyang, 2015). It has been proved that heavy metals and other organic matters in reclaimed water do not pollute soil obviously. Waste water irrigation, which contains lots of nutrients, helps to increase soil fertility. Since there are traces of saline matters in reclaimed sewage, long-term irrational irrigation can affect soil permeability, for example, excessive salinity

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11451155

may accumulate at plant roots, which will change soil components and cause soil to harden; some ions in salinity are poisonous, which can cause physical environment changes; the increase of sodium can reduce soil porosity, which decreases soil's capacity to keep nutrient elements (Lu et al., 2015; Wiśniewska-Kadżajan et al., 2017).The effects of both fertility and pollution of reclaimed water determine that effects of sewage irrigation on physical and chemical characteristics especially the fertile of soil is a hot research topic in reclaimed water irrigation. However, the complexity of migration and transmission of irrigation water source in soil system makes the effects of reclaimed water on the fertile of soil a much difficult topic.

Drip irrigation is an effective way to reduce the pollution of reclaimed water. Drip irrigation is a modern irrigation method that allows water and fluid fertilizer to drip in small flow, long time, and high frequency to the soil with crops roots, on the basis of water and fertilizer requirement law of the crops (Badruzzaman et al., 2013; Rao et al., 2017). It can save increase production, save water, fertilizer, labor and energy and adopt well to different kinds of landform and soil, which helps to improve utilization efficiency of water and nutrients and reduce agricultural non-point source pollution while ensures high yield and grade (Jennings and Ma, 2008; Lu et al., 2016c; Lu et al., 2017). The severe control irrigation time and amount and soil moisture area in drip irrigation allows it to adjust soil moisture and nutrients according to the physical property, crop root system distribution and crop water consumption. Recycling rural domestic sewage by drip irrigation can improve the utilization efficiency of N, P and other nutrients in reclaimed water, save fertilizer and water, improve production and reduce pollutants that might be put into environmental ecosystem. This is significant for relieving water shortage crisis, controlling agricultural non-point source pollution and promoting circular economy development.

Reusing sewage, applying and promoting reclaimed water is an effective way to increase income and reduce expenditure, important support to construct the economic society, an important measure of harmonious development of realizing economic benefits, society benefits and environment benefits (Becerra-Castro et al., 2015; Islam et al., 2015; Lu et al., 2016d; Lu and Shang, 2017). By using reclaimed water, we can save regular water source, keep and replenish groundwater, and relieve the conflict between water supply and demand in countries, which brings remarkable economy benefits. This article researches and compares effects of rural domestic sewage reclaimed water and groundwater drip irrigation on the characteristics of crop rhizosphere soil, with other conditions being the same (Dragović et al., 2014; Lu et al., 2016b). In this article, field experiment is conducted, and "Agricultural surface pollution control integrated demonstration in the south to North Water Diversion Project", in the southern mountain area, Maojian district, Shiyan city, Hubei province, is used as testing area. By measuring related indexes of harvest soil, it shows that recycling rural domestic sewage by drip irrigation can improve the utilization efficiency of N, P and other nutrients in reclaimed water, save fertilizer and water, improve production and reduce pollutants that may be put to environmental ecosystem. It is significant for relieving water shortage crisis, controlling agricultural non-point source pollution and promoting circular economy development. With other conditions same, by comparing the pH value and EC value of rural domestic sewage reclaimed water irrigation (Frantz et al., 2012), this experiment analyzes the effects of nutrients contents in soil on soil respiration, and researches and compares the effects of rural domestic sewage reclaimed water and groundwater drip irrigation on characteristics of crop rhizosphere soil. It provides evidences for evaluation of reclaimed water irrigation effects on soil environment and making secure control method.

Material and method

Experimental field situation

The experimental area is "Agricultural surface pollution control integrated demonstration in the south to North Water Diversion Project", which is established by Institute of Geographical Sciences and Natural Resource Research, Chinese Academy of Sciences and The Policy and Technology Research Center of South-north Water Diversion Project Office of the State Council. This area is located in the southern mountain area, Maojian district, Shiyan city, Hubei province in the subtropical monsoon climate area. The four seasons there are distinct, and winter period is long while spring is short. In spring, the temperature rises rapidly. In autumn there are lots of rains. In winter, there are few rains and snows and it is not very cold. The annual amount of solar radiation is 106.6 Kcal/cm^2, physiological radiation is 50.4 Kcal/cm^2, and average annual sunshine duration is 1925.8 hours. Annual average temperature is 15.3 °C, with extreme low temperature -14.9 °Cand extreme high temperature 41 °C. The annual accumulated temperature (≥10°C) is 4936.5 °C. There are 246 frost-free days a year. Multi-year average precipitation is 855mm and the precipitations in different year are very different. The precipitation of flood season (from May, 1st to Dec. 20th) takes up about 58%-62% of the whole year, with features of great intensity, short duration and limited infiltration capacity, which can easily scour and erode soil surface. The experimental soil in research is yellow-brown soil and the volume weight of it is 1.56 -1.71g/cm^3.

The reclaimed water used in test station is from the village, in Maojian southern mountain area, Shiyan city, Hubei Province, which is secondary treated reclaimed water. The water quality is stable and the water is just get when used.

Experimental arrangement

The experiment is conducted from May to September, 2011, the growing season of spinach. The cultivation method of spinach is ridge planting: ridge shoulder width: 40cm; center space of two ridges: 100cm; ridge height: 10cm, two lines of plants per ridge; planting space: 20cm. They are irrigated by 5 kinds of irrigation water, labeled as following: T1 (full reclaimed water), T2 (joint irrigation of reclaimed water and groundwater with reclaimed water taking up 70%), T3 (joint irrigation of reclaimed water and groundwater with reclaimed water taking up 50%), T4 (joint irrigation of reclaimed water and groundwater with reclaimed water taking up 20%) and C (full groundwater), as shown in *Table 1*. There are three small areas for each treatment, with 3 ridges of 4m long for each small area, that is 4 m×3 m for each small area. The irrigation method is gravity drip irrigation. Drip tapes are placed at the center of each ridge, the spacing of each dripper is 20cm, same distance as row spacing, dripper discharge is 0.6 L/h, and that is to say each plant has a dripper near root to provide water. Each treatment (including three small areas) is provided with water by a barrel (volume: 180 L). The barrel is put about 2.0 m high from ground. In the second small test area of each treatment, install a set of suction gauge. When the suction gauge shows that soil water potential is under -25 kPa, the plant will be irrigated, 5mm every time, 7 times during growth period, 35mm in total.

Before planting spinach, the field is fertilized with DAP fertilizer, 20kg per mu. During experiment, the area with treatment of reclaimed water irrigation (T1, T2, T3 and T4) will not be fertilized again. But for the area with treatment of full groundwater irrigation (C), 100g urea is dissolved in the water of the irrigation barrel before irrigation, and then the area will be fertilized with it.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11451155

Determination indexes and methods

At the end of spinach growing season, use soil auger to get soil samples under drippers. The sample depth is 0-30 cm and 30-60 cm. The samples from the three areas with same treatment are mixed as one soil sample. After being dried naturally and triturated, the soil is sorted by 1mm sieve. Take exact 20.0g soil, add 100mm deionized-distilled water, sufficiently oscillate, shake up and filter, take supernatant liquid, under 25 ℃, use “DDS-307 type” conductivity meter to measure EC value and meanwhile use "pHS-2C type" meter to measure EC value. Available nitrogen amount in soil is measured by alkaline hydrolysis diffusion method; Available phosphorus amount is measured by 0.05 mol·L-1 $NaHCO_3$ method; Available k amount is measured by NH_4OAc extraction and flare photometer method; Organic matter amount is measured by the potassium dichromate method. Soil respiration is measured by soil partitioning respiration of Li-6400-09 Portable Photosynthesis System produced by American company Li-cor. The measuring position is under dripper, and the period is three days during growing season , at the time 11:00-12:00, three times repeatedly.

Besides, *Table 2* shows the quality of the following water: experimental reclaimed water, which originates from rural domestic sewage, filtered by multi-layer soil infiltration system, groundwater, domestic sewage and reclaimed water. The effects of multi-layer soil infiltration system on treatment of domestic sewage are not obvious. There are many upper limits of indexes in reclaimed water that exceed the upper limits of country’s irrigation standard (Lu et al., 2016b; Khamisi et al., 2013; Furumai, 2008). Under reclaimed irrigation, soil-plant system will digest and absorb pollutants in reclaimed water. Under the condition of drip irrigation, if the water volume of a single time is less, the leaching loss of pollutants will be less. With effective coordination of reclaimed water quality and irrigation volume, we can ensure the high production of crops and prevent pollutants from leaching into water body.

Table 1. *Treatments of reclaimed water drip irrigation with rural domestic sewage*

No.	Treatment	Irrigation water quality

Results

Effects of rural domestic sewage reclaimed water drip irrigation on pH value and EC value of soil

Soil pH value is an index of soil acidity-alkalinity, and it is also an important index of critical value of trace elements in soil. The proper pH value for soil is 7.5~8.4. It is generally acknowledged that reclaimed water irrigation will not cause the increase of soil pHvalue (Yi et al., 2011; Gaydon et al., 2012). In this research, in 0~30cm deep soil layer, the pH value decreases gradually with the increasing proportion of reclaimed water in irrigation water. Compared with C treatment, the reductions of T1-T4 are only 5.4%, 2.3%, 1.9% and 1.5% respectively (refer to *Figure 1*). As for 30~60cm deepsoil layer, the difference of soil pH is not obvious. This indicates that compared with full groundwater irrigation, different proportions of rural domestic sewage reclaimed water drip irrigation does not have great effect on soil pH value.

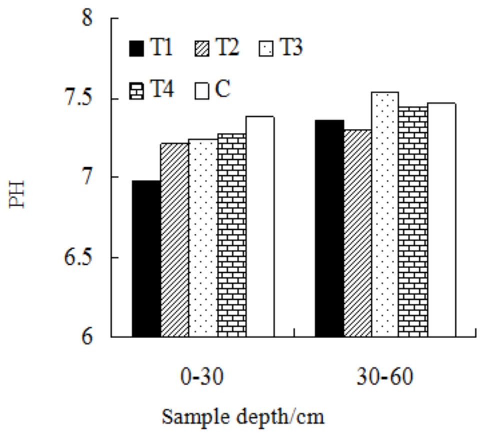

Figure 1. *Effects of rural domestic sewage reclaimed water drip irrigation on soil pH value*

Soil EC value is an index of soluble salt content in soil solution. High concentration of soluble salt will damage plants and cause the death of plant roots. As shown in *Figure 2*, rural domestic sewage reclaimed water irrigation has significant effect on soil EC value. Compared with groundwater drip irrigation, the EC values of upper and lower soil layer under T1 treatment and full reclaimed water drip irrigation are higher. However, the soil EC value under 20% and 50% reclaimed water drip irrigation increases little, especially

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11451155

for the lower soil layer, which shows no obvious difference (Darouich et al., 2012; Mouri et al., 2013). In conclusion, high proportion of reclaimed water drip irrigation significantly increases EC value of upper soil layer.

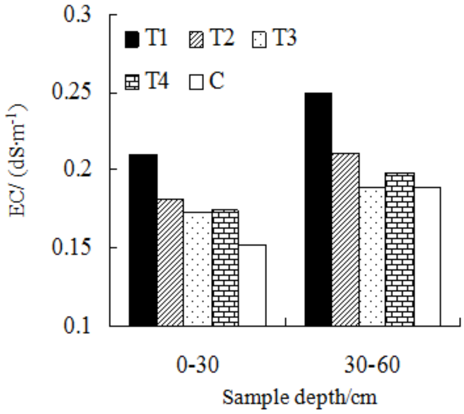

***Figure 2.** Effects of rural domestic sewage reclaimed water drip irrigation on soil EC value*

Effects of rural domestic sewage reclaimed water drip irrigation on soil nutrition content

Soil can provide everlasting and low-dose available nutrients (Nayak and Prasanna, 2007;). A lot of domestic and overseas researches on soil fertility levels after reclaimed water irrigation are made, and one coincident conclusion is made as following: reclaimed water irrigation can significantly improve soil fertility and long-term irrigation can reduce artificial fertilization (Sidhu et al., 2013; Hooper et al., 2014; Samsó and García, 2013).The potassium amount increases more in reclaimed water irrigation area, which is caused by its absorption and transformation in soil. Soil organic matter content is an important index of assessing soil fertility, which is relevant to various kinds of soil nutrients and has significant effect on soil physical property such as water retention and supply capacity, porosity and aggregate degree, etc (Lu et al., 2016a). As shown in *Figure 3*, with the increase of reclaimed water proportion in irrigation water, the organic matter amount increases, and the increasing trend is more obvious in upper layer soil. The organic matter contents in soil under full reclaimed water drip irrigation and 70% reclaimed water drip irrigation are obviously higher than other, which indicates that reclaimed water drip irrigation can increase organic matter contents in soil.

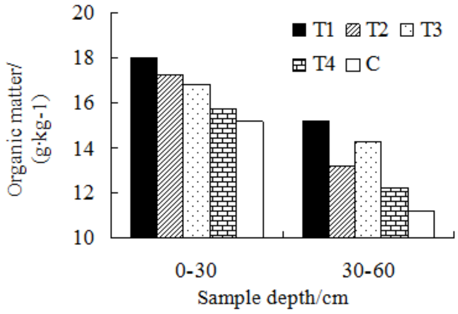

***Figure 3.** Effects of rural domestic sewage reclaimed*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11451155

In upper soil layer of 0~30cm deep, the available nitrogen contents in soil under T1 (full reclaimed water irrigation) and C (additional nitrogen) treatment are much higher than others (refer to *Figure 4*). In 30~60cm deep soil layer, the nitrogen content in soil under T1 treatment is higher, and no obvious difference under other treatments. Generally speaking, except for soil under full reclaimed water irrigation, the increase of available nitrogen is not obvious for soil under different proportion of reclaimed water drip irrigation. The reason may be that reclaimed water drip irrigation increases the organic matter contents which increases the growth of plant and then promotes the consumption of nitrogen in soil, so that there is no obvious difference of nitrogen under T2, T3 and T4 treatments.

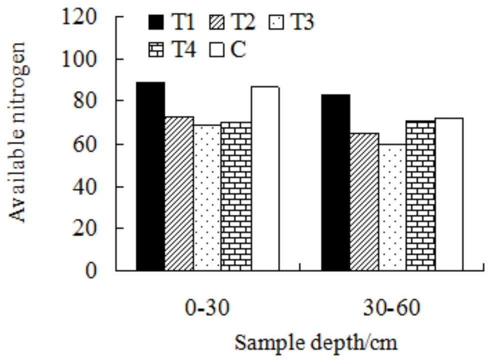

Figure 4. *Effects of rural domestic sewage*

Different proportions of reclaimed water drip irrigation have great effect on available phosphorus contents in spinach rhizosphere soil (refer to *Figure 5*). In 0~30cm deep soil layer, except for soil under T4 treatment (20% reclaimed water drip irrigation), the available phosphorus contents in soil under T1, T2, T3 treatments are higher than soil under full underground water drip irrigation. In lower soil layer (30~60cm), available phosphorus contents in soil under T1 and T2 treatments are obviously higher than other treatments. There is no obvious difference between other three kinds of treatments. It indicates that high proportion of reclaimed water drip irrigation can greatly increase available phosphorus content in soil.

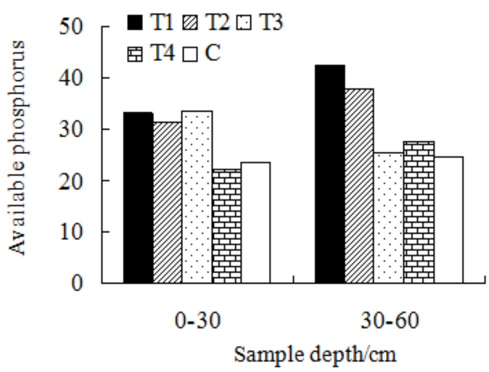

Figure 5. *Effects of rural domestic sewage reclaimed*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11451155

As shown in *Figure 6*, different proportions of reclaimed water drip irrigation have little effect on available K content in spinach rhizosphere soil. In 0~30cm deep soil layer, with increase of reclaimed water proportion in irrigation water, the available K content increases gradually, but the difference is not obvious. In lower soil layer (30~60cm), available K contents in soil with full reclaimed water drip irrigation and 70% reclaimed water drip irrigation are a little higher than full groundwater drip irrigation. There is no obvious difference among other treatments. Generally speaking, rural domestic sewage reclaimed water drip irrigation has little effect on available K contents in spinach rhizosphere soil. Bajaj and Singh (2015) considers that reclaimed water drip irrigation can provide nutrients for soil, especial potassium fertilizer, so that we can use 24．5～97．8kg / hm^2 less potassium fertilizer than regular irrigation.

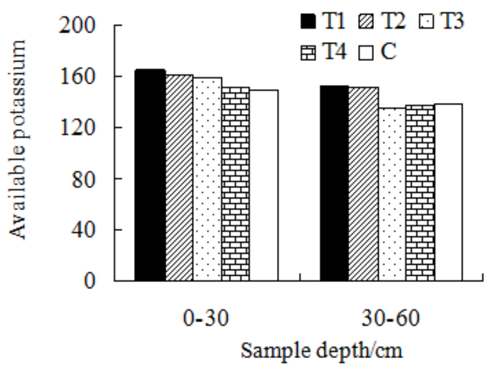

Figure 6. *Effects of rural domestic sewage reclaimed*

From the experimental results, under combined effects of internal and external factors, such as physiological activity of plant root cells, maintenance and management practice, change of climate conditions, etc., if irrigating spinach field by slightly alkaline (pH>7) reclaimed water, the pH value of the soil will decrease a little, which means the acid is enhanced. The enhanced soil acid will accelerate the humification process of organic matter, which will enhance soil acid and accelerate the liberalization and ionization process of N, P, and Ketc. This makes them in an existential state that is easy to run off with water, and digest and use by plant. So that elements, such as N, P, K, etc., will not accumulate in soil and neither will growth failure or large-area death happens because of the accumulation of N, P, K, etc.

Effects of rural domestic sewage reclaimed water drip irrigation on soil respiration

Soil respiration refers to all the metabolic activities in soil that can produce carbon dioxide (Yang et al., 2015; Rezgui et al., 2016). It mainly includes respiration of plant roots (part of autotrophic respiration), heterotrophic respiration of soil microbes and animal, and it is an import index that reflects the soil fertility characteristics. *Figure 7* shows effects of different proportion of reclaimed water drip irrigation on soil respiration. As shown in *Figure 7*, different proportions of reclaimed water drip irrigation can all promote soil respiration. The larger the proportion is, the more obvious the promotion and the faster the respiratory rate is. This is because reclaimed water drip irrigation does not only increase nutrients in soil such as organic matter, but also increases the amount of various kinds of microbes in soil. Microbes in soil use organic matters as energy

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11451155

substance, decompose them step by step and release them in form of CO_2 and mineral nutrients, which provides plants with available nutrients.

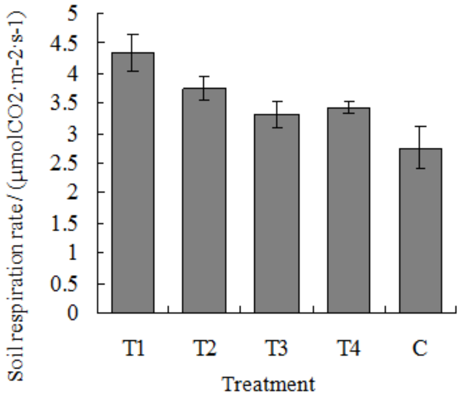

Figure 7. *Effects of rural domestic sewage reclaimed water*

Conclusion

Rural domestic sewage reclaimed water drip irrigation will not cause obvious or anomalous change of soil pH value, but high proportion of reclaimed water drip irrigation can increase EC value of upper soil layer. Relatively speaking, rural domestic sewage reclaimed water drip irrigation has little effect on available nitrogen and available K, but has significant effects on organic matter andavailable phosphorus. Besides, there is no anomalous change in plant growth because of sewage pollutants accumulation in soil; it indicates that reclaimed water, used as irrigation water, can improve soil fertilizer to some extent, and in the aspect of heavy metal, reclaimed water irrigation is safe. Reclaimed water drip irrigation can promote soil respiration. The larger the proportion of reclaimed water is, the faster the respiratory rate is.

Therefore, under the condition of drip irrigation, with proper agronomic measure and irrigation system, certain proportion of rural domestic sewage reclaimed water can be adopted to irrigate crops. The results also show that, to some extent, the pollutants in reclaimed water still accumulate in soil, and they have effect on plant growth. As for the effect degree and period, we need to make long-term experiments and do further observation and research.

Abstract. In this study, Poyang Lake catchment with frequent drought and flood disasters in recent years was chosen as the study area. Due to the influence of global climate changes, great changes have taken place in the hydrological and climatic process of Poyang Lake in the past half a century, leading to the increase of extreme weather and hydrological events, shrinkage of water, threat to wetland ecosystem and other problems. First, historical climate data simulated by Atmosphere-Ocean General Circulation Models CCSM4 and ECHAM5 were obtained, which were then applied to Poyang Lake catchment with down-scaling method. The hydrological model WATLAC can be driven by upper climate data along with other data so that we get the runoff series in this catchment for the past one thousand years. Based on the research, it was found that the runoff series were in significant positive correlation with precipitation series. The frequency of extreme runoff was consistent with that of precipitation in both models. The peak value was 0.03, indicating the period was 30 years. The wavelet power spectrum contours of runoff and precipitation series generate significant signals in 20～40-year scale. The signal is the strongest in a scale of about 30 years, which further confirms the runoff of Poyang Lake catchment has a macro cycle of about 30 years.
Keywords: *millennial time scale; climate model; runoff changes; hydrological cycle; Poyang Lake catchment*

Introduction

The Poyang Lake, located in the middle and lower reaches of Yangtze River, is the largest fresh-water lake in China. As one of the few large lakes linking to the river, Poyang Lake plays an important role in water conservation, flood control, climate regulation, ecological protection, etc (Zhu and Zhang, 1997). Due to the influence of global climate change (Guo et al., 2006), great changes have taken place in the hydrological and climatic process of Poyang Lake in the past half a century, leading to the increase of extreme weather and hydrological events (Liu and Ren, 2014), shrinkage of water (Yu and Hu, 2010), threat to wetland ecosystem and other problems (Jiang et al., 2010). Will this situation continue to deteriorate in the future under the influence of climate changes? This paper, based on statistical down-scaling method, thus analyzes

DOI: http://dx.doi.org/10.15666/aeer/1504_11571166

runoff changes of Poyang Lake in the past millennium under the extreme climatic conditions, aiming to offer scientific guidance for the flood and drought control, ecological protection, development and utilization of water resources and to ensure the coordinated development of the economy and society in this area.

Overview of Research Area

Poyang Lake is located on the south side of the lower Yangtze River. It is the largest lake connected with Yangtze River. The length from south to north of Poyang Lake is 173 km and the average width from east to west is 16.9 km, with the width of the widest part at about 74 km. The narrowest part of Poyang Lake is only about 2.8 km wide. The total length of the lake circle is 1200 km (Jiang et al., 2007). There are five rivers which contribute to Poyang Lake, namely Ganjiang River, Fuhe River, Xinjiang River, Raohe River and Xiuhe River. After regulation and storage, water in Poyang Lake runs into Yangtze River, which is an important characteristic of seasonal influent-effluent lakes. There are significant periodic variations in water levels of Poyang Lake within the year and among different years. In the wet season, the water level is high and the lake surface is large, with the highest lake surface area being 4070 km^2; in dry seasons, the water level is low, with the lowest lake surface area being no more than 150 km^2 and the lake water being contained in the channels. The maximum water surface area ever recorded in the wet season is about 27 times of the minimum ever recorded in the dry season, which makes Poyang Lake a lake in wet seasons and several rivers in dry seasons. Variation of water level is mainly induced by the effects of the five rivers mentioned above and the Yangtze River. The main flood season of the 5 rivers is from April to June, when the water level in Yangtze River is comparatively low and the flood water into Poyang Lake can be discharged into the Yangtze River rapidly and the water level in Poyang Lake can be maintained; from July to September, incoming water volume from the five rivers decreases, but water level in Yangtze River is high, which makes the water level in Poyang Lake high; after the end of September, water level in Yangtze River decreases, dry season of the five rivers is coming and the water level in Poyang Lake gradually becomes lower and lower. According to statistical data, the water level variation of Poyang Lake within a year is up to 10 m, which is unique in large lakes (Xu and Chen, 2009).

Research Methodologies

Climate Model

Climate model usually refers to general circulation model (GCM), a mathematical-physical model of the earth system, which determines the characteristics of the Earth's atmosphere based on mathematical equations formed in dynamic, physical, chemical and biological process of the earth system. The climate model used to simulate changes of the climate system, the response time and process, and the spatial features is a key method to study climate changes on seasonal and interdecadal scale. Climate model involves the simple energy-balance equation and the complex earth system model. Currently the earth system model (ESMs) couples atmosphere, ocean, land and sea ice, with some part of the model even coupling aerosol, carbon cycle, dynamic vegetation and atmospheric chemical process (Liu and Zhang, 2009). Atmosphere-ocean general

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11571166

circulation model (AOGCMs) couples the dynamic changes of atmosphere, ocean, land, ice and snow in the climate system. The Coupled Model Intercomparison Project Phase 5（CMIP5） develops a research plan to simulate climate in the past millennium. More than 20 climate model organizations drive the climate field through the same indicators like solar radiation, volcanic ash, greenhouse gases and etc. And results of near-surface temperature, upper atmosphere and atmospheric circulation characteristics are calculated through physical model like dynamics, heat, and water volume of climate model (Liu, 2011). The USA general climate model: The Community Climate System Model 4 (CCSM4) and European Centre Hamburg Model (ECHAM5) are adopted in this paper to simulate climate (Qin et al., 2014).

The CCSM4 and ECHAM5 are used in the paper as hydrological drive, for they can better simulate the climate in East Asia (Yu and Harrison, 1996). CCSM4 climate model developed by National Center for Atmospheric Research is well received in China (Blackmon et al., 2001). Recently, Tian et al. (2012), Tian and Jiang (2013) have proved that CCSM4 model can better simulate climate features of East Asia and China. Thus it is suitable for long-time climate model researches. The ECHAM5 model proposed by the Max Planck Institute for Meteorology improves the dynamic coupling function of atmosphere, ocean, land and ice and snow, based on ECHAM4 model. The improved model has better simulation (Yu et al., 2009). In recent years, Bueh and Lin (2003) have used ECHAM4 to simulate East Asian monsoon circulation and predict its future changes. Zhai et al. (2009) use ECHAM5 to forecast distribution of drought and flood in China before the year 2050. These researches show that the two models can better simulate regional climate system in China.

So far, most coupled models (AOGCMs) have a relatively low spatial resolution. It is therefore difficult to make reasonable predictions about climate changes on regional scale. The down-scaling methods then come into being, and have since been widely applied to overcome AOGCM's weakness. Statistical down-scaling method is a powerful tool to obtain small-scale climate data from large-scale climate data. Firstly, empirical relationship between large-scale climate factors (predictors) and regional climate factors (predictors) should be established. Then the relationship is used as the output of global climate model or regional climate model and corresponding information of any place can be obtained (Fan et al., 2005).The paper gets related information of Poyang Lake based on the simulation of CCSM4 and ECHAM5 within the framework of IPCC-CMIP5. And monthly temperature and rainfall series of Poyang Lake in the past millennium are obtained through down-scaling methods. Yu et al. (2013) use historical literature and facts from archaeology study to verify the simulation results. The verification shows that GAMs' simulation of rainfall is acceptable. Modern climate data are obtained from monthly temperature and rainfall records of 17 stations of National Secondary Meteorological Station between the year 1951 and 2015, as well as the station positions.

Hydrological Data

Hydrological model: A Water Flow Model for Lake Catchements (WATLAC) is a mathematical model that simulates surface water and underground water of lake catchment. Unlike most hydrological models with a general summary of underground runoff, WATLAC is improved in this aspect and can better simulate the hydraulic relationship between lakes and inland rivers (Zhang, 2007). Driven by rainfall and evaporation, the model involves two simulation processes: surface runoff and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11571166

underground runoff. It takes into consideration major hydraulic process, such as canopy interception, catchment evapotranspiration, soil water storage, slope runoff, groundwater recharge and runoff, and river runoff. Surface runoff is simulated by spatial discrete raster (Zhang, 2009). Each raster has different hydrogeological parameters and input data by remote sensing interpretation. In view of different characteristics of saturated soil and unsaturated soil, for underground runoff, finite difference is used to disperse saturated zone and analytic equation is used to simulate unsaturated soil (Liu and Zhang, 2009).

Input data like Digital Elevation Model (DEM), land use, evapotranspiration, soil characteristics, daily rainfall, and a large quantity of information including soil moisture, soil and underground water recharge, and lake runoff can be outputted. The main structure of the model is shown in *Figure 1*.

Researches on Poyang Lake based on WATLAC model have been recognized all over the world. For example, Fan et al. (2005) verify the model based on measured data between 1960 and 1989 of Waizhou Station and Xiajiang Station. During the calibration period, the annual runoff of the two stations has an error less than 8%. This shows that the model has better simulation. Ye et al. (2011) combine ECHAM5 and WATLAC to predict the runoff of Poyang Lake in the context of future climate. Compared with the measured data of six hydraulic stations, the predicted result has a certainty factor above 0.7, indicating a better simulation of the model. Li et al. (2014) use measured data of lake runoff, lake level, outlet volume and etc. to verify the model. The certainty factor is above 0.75, showing a better simulation of the model. These researches show that distributed hydrological model WATLAC has been successfully applied in the research of Poyang Lake. The paper therefore, adopts the model to establish runoff series of Poyang Lake in the past millennium.

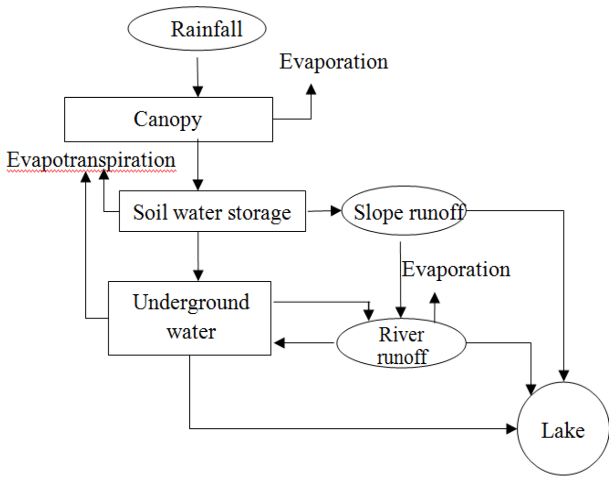

Figure 1. *The simulated hydrology process of Model WATLAC*

Result Analysis

Features of Rainfall-Runoff Changes

This paper focuses on the features of interannual-interdecadal changes based on an understanding of rainfall-runoff series in the past millennium obtained from the mean value of rainfall-runoff at different time scale of 1 year, 5-year, 10-year, 20-year, 30-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11571166

year. Simulation results of rainfall series based on CCSM4 and ECHAM5 are shown in *Figure 2*. *Figure 2* respectively shows simulating changes of 10-year average anomaly for depth of rainfall runoff of Poyang Lake in the past millennium based on CCSM4 and ECHAM5. CCSM4 model includes the runoff series between 1040 and 1850, 810 years in all. ECHAM5 model includes the runoff series between 1000 and 1959, 960 years in all. The two models differ a little in the simulation of dry-wet changes during the MWP and LIA periods.

For the MWP period, CCSM4 model shows that runoff ranges around the mean value and that dry and wet situation appear alternatively. In terms of the rainfall, 45% of the years have a dry weather, and 38% have runoff. The distribution is relatively even. For the LIA period, dry-wet situation changes drastically and easily causes extreme drought or flood. 53% of the years have rainfall and 41% have runoff. Both appear in the dry years. The wet years appear alternatively with dry years. The dry-wet situation changes significantly. On the whole, according to CCSM4 model, dry and wet situation appear alternatively and the changes of rainfall and runoff are similar. For the MWP period, ECHAM5 shows that 56% of the years have a low rainfall and 49% have a low runoff. For the LIA period, 59% of the years have a low rainfall and 55% have a low runoff. According to this model, dry-wet situation remains for a long time.

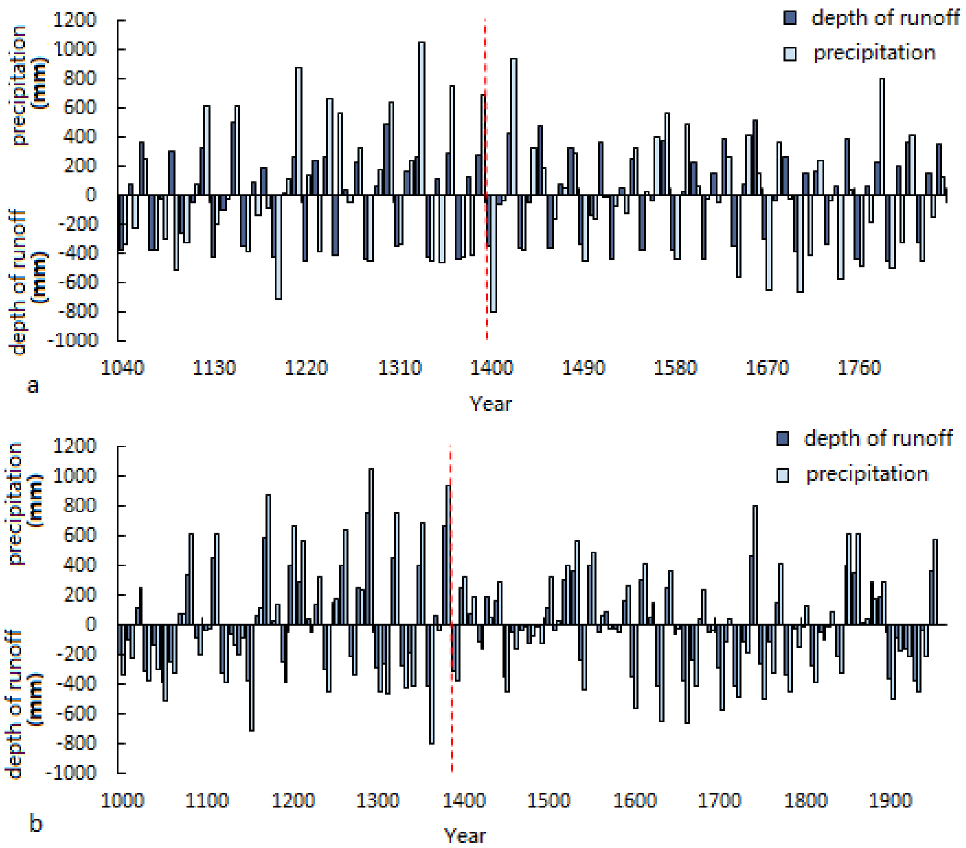

Figure 2. *Variances of anomaly of precipitation and runoff on 30-year time scale. Picture (a) represents the model CCSM4 and (b) is ECHAM5. The red dash line divided the picture into period MWP and period LIA*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11571166

Periodic Changes of Rainfall-Runoff

The periodical changes of rainfall-runoff depth series based on CCSM4 and ECHAM5 are shown in *Figure 3*. Fast Fourier Transform (FFT) results can easily identify strong and weak changes of time series on different scales. *Figure a* and *b* in *Figure 3* show that both models have several peak values, indicating the strongest vibration at certain frequency. Corresponding frequency of rainfall-runoff depth series at the peak value has a higher matching level. This indicates that rainfall and depth of runoff have the same vibration period on the time scale. In CCSM4 model frequency above confidence curve involves 0.033, 0.101 and 0.133. In ECHAM5 model frequency above confidence curve involves 0.034, 0.066 and 0.133. The recurrence intervals of rainfall-runoff series in the two models are similar, suggesting the synchronous changes of runoff process and rainfall process. In view of the statistical meaning of the period, here listed are the first three periods.

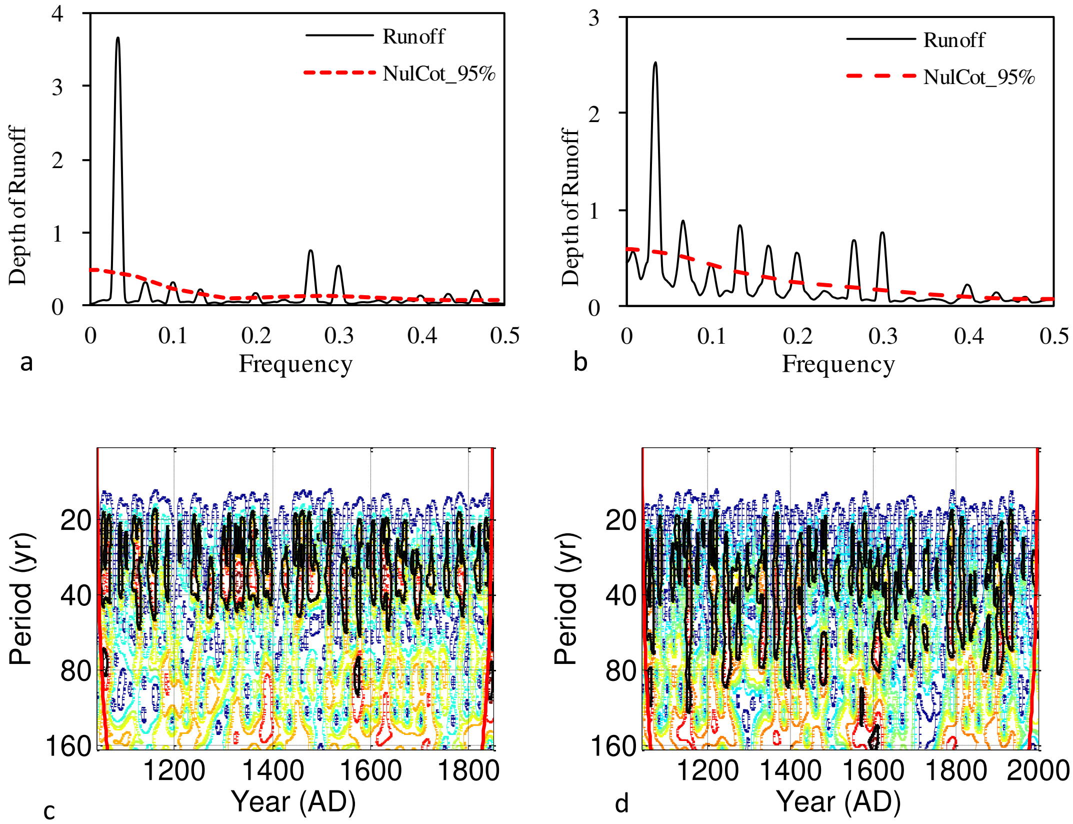

Figure 3. *(a and b) Fast Fourier transform spectral power spectrum of depth of runoff. The black full line and dash line indicate spectral power of precipitation and depth of runoff respectively. And the red ones mean their own 95% confidence line. (c and d) Wavelet power spectrum contours of depth of runoff for CCSM4 model and ECHAM5. It was plotted by time series against periods, in which the 95% confidence contour was in black part and the red full line meant cone of influence. Any part below the red line is not reliable.*

Period distribution in Wavelet Transform module square time frequency distribution contour is similar to that in FFT. *Figure 3c* shows that in CCSM4 model both rainfall and depth of runoff are strongest on time scale of 20 to 40-year, with the energy center

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11571166

around 30-year. According to *Figure 3*, in ECHAM5 model confidence region is at 20 to 80-year, but the energy center with continuous changes is basically around 30-year. Power spectrum contours of rainfall and runoff series in both models are basically the same. This further shows that though flow process is influenced by some factors, it mainly changes with rainfall process on time scale. According to the analysis results of the models, the period of rainfall-runoff change of Poyang Lake in the past millennium is around 30-year.

Hydrological and Meteorological Series and Frequency and Period of Extreme Events

Figure 4a and *4b* are FFT power spectrums of rainfall based on CCSM4 and ECHAM5 respectively. For the sake of comparison, *Figure 4c* and *4d* show FFT power spectrum of rainfall-runoff respectively based on the two models.

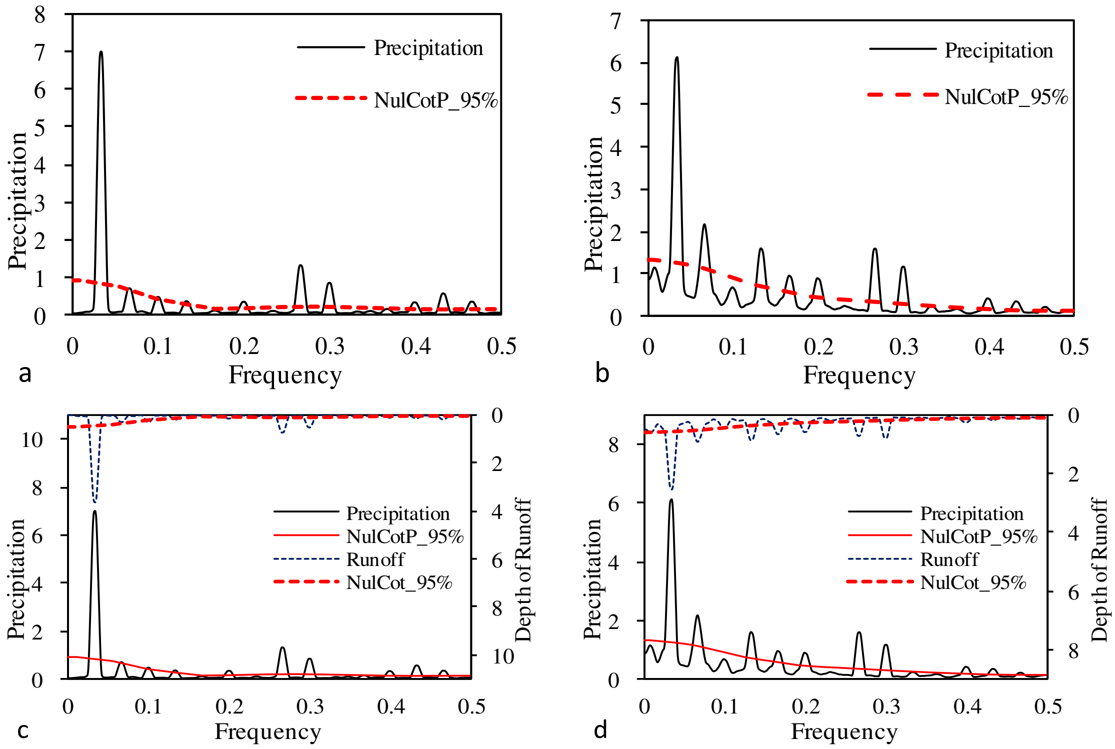

Figure 4. *(a and b) Fast Fourier transform spectral power spectrum of precipitation and depth of runoff. (c and d) Spectral power spectrum between precipitation and depth of runoff. The black full line and dash line indicate spectral power of precipitation and depth of runoff respectively. And the red ones mean their own 95% confidence line*

According to *Figure 4*, power spectrum change distribution of rainfall series and runoff series are basically the same. The peak value of rainfall series is bigger, indicating a high frequency of extreme rainfall events. Similar power spectra reflect the corresponding relationship between the extreme runoff and the climate.

Figure 5a is Wavelet Transform module square time frequency distribution of rainfall anomaly based on CCSM4 model. *Figure 5b* is Wavelet Transform module square time frequency distribution of rainfall anomaly based on ECHAM5 model.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11571166

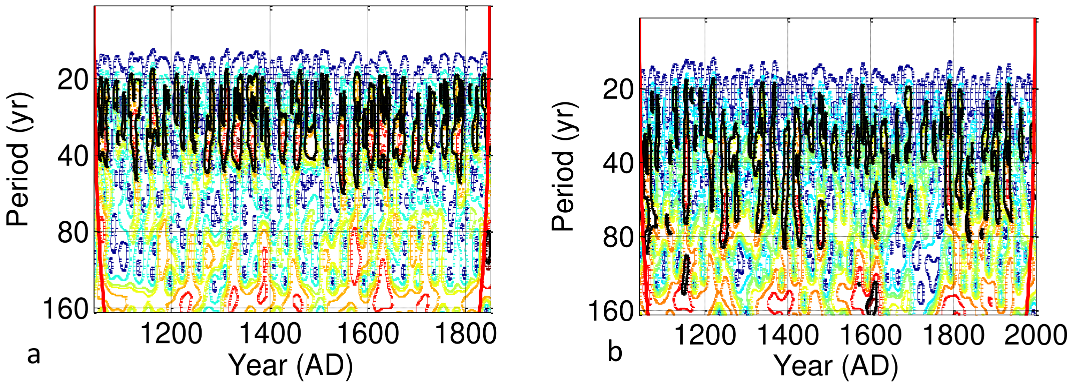

Figure 5. *(a and b) Wavelet Transform module square time frequency distribution of depth of precipitation for CCSM4 model and ECHAM5 model. It was plotted by time series against periods, in which the 95% confidence contour was in black part and the red full line meant cone of influence. Any part below the red line is not reliable*

Rainfall period shown in *Figure 5* is similar to that in FFT, and to module square distribution of runoff depth in *Figure 3*. In CCSM4 model rainfall has the strongest energy between 20-40 year, with the energy center at around 30-year. .ECHAM5 model has confidence region between 20 and 80-year, but the energy center with continuous changes basically remains at 30-year. According to the figure, both models show that in the past millennium Poyang Lake had similar rainfall process and runoff process, with 30-year being the period. This again displays the corresponding relationship between the runoff and the climate.

Conclusion

This paper simulates the runoff series of Poyang Lake in the past millennium and explains the hydrological changes, features and dynamic mechanism of this area under the influences of climate changes. Nowadays extreme hydrological events happening in Poyang Lake area are mainly caused by rainfall and surface confluence. And a regression analysis of historical situation can offer reliable scientific proof for predicting future extreme hydrological events. The runoff period of Poyang Lake in the past millennium is 30 years, similar to the current runoff research results of Poyang Lake. This further proves the influence of climate changes on hydrological process in the area on the time scale.

- Rainfall and runoff of Poyang Lake in the past millennium have a similar variation trend based on CCSM4 and ECHAM5 models through down-scaling methods. This shows the basic characteristics of atmosphere circulation under the influence of radiation and the formation of basic rainfall pattern. Runoff changes a little differently based on the two models. In ECHAM5 model there is a longer time of dry years, while in CCSM4 model dry years and wet years appear alternatively. In both models, dry years in LIA period is more than those in MWP period.
- According to the FFT analysis of runoff series based on CCSM4 and ECHAM5 models, the runoff series shows main period 30 years and 29 years with peak value, secondary period between 10 and 15 years, and the 3rd period around 7 years. The analysis shows that the main period is related to atmospheric

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11571166

oscillation and Pacific decadal oscillation; the secondary period is related to solar activity; and the 3rd period is related to El Nino influenced by radiation and atmospheric action. Changes of atmospheric oscillation reflect the macro features of a regional climate. In terms of changes on interdecadal and interannual scale, what matters is interior vibration of climate system and air-sea-land interaction. According to the wavelet analysis, relatively strong signals appear between 20 and 40 years in CCSM4 model and between 20 and 80 years in ECHAM5 model, but the peak value of energy appears around 30 years. The results are similar to FFT results. Within the same model, module square distribution of rainfall-runoff series has a similar energy distribution. This indicates that rainfall and runoff have the same vibration changes on the millennium scale. This phenomenon reveals the atmospheric oscillation in the millennium, which is helpful in understanding features and rules of regional climate changes against the natural climate changes.

Abstract: Information on the species composition and community structure of vegetation at different successional stages is useful for understanding successional mechanisms and for selecting species for vegetation recovery. We investigated the composition and structure of plant community in different succession stages by setting 270 sample plots in all 5 types stony desertification areas of Guizhou province, China. The results show that: (1) in the early succession stage of karst rocky desertification area, the environment adaptable species mainly are pioneer species of light-demanding and drought-tolerant. With the succession, species change following a variation trend of "increasing-decreasing-increasing", Shrub stage had the largest number of plant species. (2) There is difference in plant composition in different succession stages of 5 types stony desertification areas. (3) During natural succession stages, the cover degree, predominance degree, and density of plant community represents the horizontal structural feature of karst stony desertification area. The difference in predominance degree and density is considerable, and in certain proportion relation. (4) In early-mid succession stages of plant community, plants are in contagious distribution, while in climax community succession stage, most plants are in random distribution and less are in contagious distribution. From above results, it can be concluded that the variation feature of plant communication in karst stony desertification areas follows certain natural succession law, therefore, species collocation and optimal configuration should be arranged according to natural succession law for control of stony desertification.
Keywords: *community succession; life form; type of stony desertification; plant arrangement*

Introduction

The total carbonatite outcrop area of China is about 1,300,000 km^2, which is distributed in most provinces of China. China's southern region (including Guangxi, Yunnan, Sichuan, Chongqing, Hubei and Hunan provinces based on Guizhou as center) has carbonatite outcrop area of over 540,000 km^2, which is featured by the largest outcrop area in 3 linked karst regions, the strongest karst development, the most landscape types, and the most complex ecological environment (Yang et al., 2014; Zhang et al., 2014). Moreover, the aforesaid southern region is the major area where subtropical karst forest locate. Being different from foreign karst regions, the southern karst region of China is mainly composed of hard carbonate rock before triassic period,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11671183

in which the limestone porosity in all geologic ages is lower than 2%, dolomite porosity is generally lower than 4% with compressive strength under 1000kpa/cm^2 (Jiang et al., 2014). All these characteristics exert great influence to karst development. With the substantial rise of Cenozoic quaternary tectonic movement, the karst topography of carbonate development in all geologic ages becomes more comprehensive, which is distributed in different altitudes, forming the karst landform with world's longest time span and best spatial continuity. Moreover, the karst forest grown in this area has its own particularity in global range, therefore, the ecological study on karst forest in this area is of more important scientific value (Wen et al., 2015).

In the fragile karst ecologic environment, human irrational social economic activities cause prominent human-earth system conflict, vegetation deterioration, water and soil loss, bare rock, land productivity decline or even loss, making ground surface manifested in desert landscape. Such evolution process and outcome is called stony desertification (Jiang et al., 2014). In karst region, stony desertification brings severe impact on the survival, production, and life of rural people, and seriously hinder the sustainable socioeconomic development of this area. However, stony desertification is an inherent and zonal landscape in karst region. For example, the development of karst forest vegetation in Maolan of Guizhou province, which is a primordial forest vegetation, provides references for the recovery of forest vegetation in karst stony desertification area. It is of great significance for stony desertification control to use water, soil, gas, heat in a balance and skillful way in such harsh environment and figure out the succession law and interspecific competitions of plant community in karst region (Liu et al., 2011). Therefore, the species composition and spatial structure of plant community in natural succession stages in karst region should be clearly understood, which provides theoretical basis for species selection in early stage and optimization allocation of stony desertification control.

Profile of Research Area

Located in eastern part of the Yunnan-Guizhou Plateau, Guizhou province of China has an area of 176,167km^2 including mountainous region and hilly land accounting for 92.5% of total province area, which is an inland plateau mountainous area with karst development, crosses of mountains and rivers, abundant resources, various nationalities and no plains (*Fig. 1*). The karst outcrop area of Guizhou province is 109,084.58km^2, accounting for 61.92% of total province area. In 2011, the stony desertification area of Guizhou province is about 30,200 km^2, accounting for 17.16% of total province area. The rock combination characteristics of Guizhou province can be categorized into 3 major combination types including homogenous carbonate rock combination, combination of carbonate rock intercalated with clastic rock, and interbedded combination of carbonate rock and clastic rock. The homogenous carbonate rock combination can be further divided into homogenous limestone, homogenous dolomite, and mixed combination of limestone and dolomite. The homogenous limestone is mainly distributed in the south, northwest, southwest of Guizhou province, with area 30, 676km2, accounting for 17.4% of total province area. The homogenous dolomite is mainly developed in the northeast of Guizhou province, with area of 22,990km2, accounting for 13.1% of total province area (Tan, 2006).

Research areas were selected in Libo county, Luodian county, Puding county, Wudang district, Xiuwen county, Pan county, Jinsha county, Bijie county, Weining

Research Method

Sample-plot survey of plant community

Ecosystem evolution is a long-term course. A natural recovery from degraded grass slope back to climax evergreen and deciduous broad-leaved mixed forest will takes tens or even hundreds of years (Yu, 1998). By setting 270 sample plots in 5 desertification

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11671183

areas of Guizhou province, this paper presents investigation on phytocoenology of plant community in different succession stages (Yu et al., 2011) [herbosa succession stage (I), shrub-grass community succession stage(II), brush-shrub community succession stage (III), shrub community succession stage (IV), tree-shrub community succession stage (V), high-forest community succession stage or climax community stage (VI), investigations were conducted 3 times for each stage] using method of substituting spatial sequence for time sequence (Muellerdombois and Ellenberg, 1974). The sample plot areas can be $20m^2$, $100m^2$, $100m^2$, $100m^2$, $160m^2$, $400m^2$. In each square sample plot, there arranges a 2m×2m shrub layer quadrat and a 1m×1m herb layer quadrat. Record the species, quantity, DBH (diameter at breast height), ground diameter, height, crown diameter, cover degree of arbors, shrubs, young trees in each quadrat, and judge whether each plant seeds or sprouts. The species, abundance, height, and cover degree of *herbaceous* plant were investigated as well.

Annotation: According to the outline of rocky desertification in karst region comprehensive treatment planning (2006y to 2015y), China will be divided into eight desertification control type area, among them, there are five rocky desertification in Guizhou province.

Determination of plant life forms

Life form: According to life-form system proposed by Raunkiaer, terrestrial plant can be divided into 5 life forms by taking growing height and location of dormant bud and renewal bud in bad seasons as division criterion.

Phanerophyte (Ph): the dormant bud is at least 25cm high above the group, which can be divided into 4 sub-forms according to plant height:

Macrophanerophyte (Ma): height>30m, for instance megaphanerophyte.

Mesophanerophyte (Me): height 8-30m, for instance microphanerophyte.

Microphanerophyte(Mi): height 2-8m, including microphanerophyte and shrub.

Nanophanerophyte (N): 2m>height>25cm, including shrub and undershrub.

Chamaephyte (Ch): the renewal bud locates above soil surface while under 25cm, mainly include subshrub *herbaceous* plants.

Hemicryptophyte (H): the renewal bud locates in soil layer, which will be partially or fully dead on winter ground, mainly including renascent herb.

Cryptophyte (Cr): the renewal bud locates deeply in soil or water, mainly including aquatic renascent herb plant in bulbous, tuberous or rhizomatic types

Therophyte (T): overwintering as a seed. In this paper, phanerophyte was further divided into Evergreen plant (E) and Deciduous plant, (D). For the convenience of distinguishing, Epiphytic plant (Ep) is listed separately in category system

Division method of adapted species

Community succession is a process where dominant community species changing from one to another. In karst area with complex habitat, there is not one but multiple species that can be adapted to the habitat during the same succession stage (Zhu, 2003). According to the variation of dominant position of main compositional species of deteriorated community during natural recovery process, the adaption level of species can be classified. Specific methods are shown as below:

Based on population as entity, degree of dominance (i.e. important value of population) as attribute, dominance matrix of population during community restoration was established, which means establishing 141×421 original data matrix using quantity index of 421 plant species in141 quadrats.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11671183

$$y = \begin{bmatrix} x_{11} & x_{12} & x_{13} & x_{14} & x_{15} & x_{16} & x_{17} & x_{1j} \\ x_{21} & x_{22} & x_{23} & x_{24} & x_{25} & x_{26} & x_{27} & x_{2j} \\ x_{31} & x_{32} & x_{33} & x_{34} & x_{35} & x_{36} & x_{37} & x_{3j} \\ x_{41} & x_{42} & x_{43} & x_{44} & x_{45} & x_{46} & x_{47} & x_{4j} \\ x_{51} & x_{52} & x_{53} & x_{54} & x_{55} & x_{56} & x_{57} & x_{5j} \\ x_{61} & x_{62} & x_{63} & x_{64} & x_{65} & x_{66} & x_{67} & x_{6j} \\ x_{71} & x_{72} & x_{73} & x_{74} & x_{75} & x_{76} & x_{77} & x_{7j} \\ x_{i1} & x_{i2} & x_{i3} & x_{i4} & x_{i5} & x_{i6} & x_{i7} & x_{ij} \end{bmatrix} = \begin{bmatrix} x_{11} & & x_{1j} \\ & & \\ x_{i1} & & x_{ij} \end{bmatrix} \quad \text{(Eq. 1)}$$

Where i represents sample plot, j represents species, x_{ij} represents dominance (important value) of the j th species in the i th quadrat.

After establishing dominance matrix, DCA (Detrended Correspondence Analysis) was adopted for sorting using eigenvector modified based on CA/RA. The primary shaft was divided by DCA into a series of intervals, in which the mean value was set as zero to adjust the coordinate value of the second shaft. This method was effective method for vegetation analysis, which overcame the arch effect of CA/RA, improved sorting accuracy, and realized the results that were the most consistent with Gaussian community model (Zhang, 2004). After that, CANOCO4.5 analysis software was used for analysis and drawing (Zhang et al., 2000). The results aggregated together were merged into a group.

Study on species diversity

Species diversity was measured using Shannon-wiener diversity index (D):

$$D = 3.3219\left[\lg N - \frac{1}{N}\left(\sum n_i \lg n_i\right)\right] \quad \text{(Eq. 2)}$$

community dominance was measured using Simpson index (C):

$$C = \sum n_i \frac{(n_i - 1)}{N(N-1)} \quad \text{(Eq. 3)}$$

Uniformity was measured by uniform index based on Shannon-Wiene diversity index (J):

$$J = \frac{\lg N - \frac{1}{N}\left(\sum n_i \lg n_i\right)}{\left[\lg N - \frac{\alpha(S-\beta)\lg\alpha + \beta(\alpha+1)\lg(\alpha+1)}{N}\right]} \quad \text{(Eq. 4)}$$

Where N is the number of species individuals; n_i is the number of individuals of the ith species; S is the number of species, βremainder after dividing N by S, αis (N-β)/S (ShaoLin, 1996).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11671183

Heterogeneity of community space

According to geostatistics research method, set 30m×30m quadrats on main sample plots of herb community, shrub community, high-forest community, and climax community, and then partition quardrats into 1m×1m adjacent grids. The habitat variables and heterogeneity in each grid was investigated, including mean soil thickness of various microhabitat types (stone-drain, swallet, stone cavern, stone cistern, soil surface, stone surface), as well as mean soil thickness, soil moisture, litter depth and litter coverage in each quadrat. In addition, collect soil sample from each grid, test the pH value of soil sample, and draw biotope distribution map by measuring scale of 1:500. The investigation was finished at August to September of 2009. The habitat index of soil capacity was proposed in this research, of which the definition is the actual soil volume that can be held in habitat. The soil capacity of each quadrat is the sum of soil capacities of all microhabitats. The soil capacity of each microhabitat is balanced by the product of mean soil thickness and microhabitat distribution area. The distribution area of microhabitat was calculated by paper weighing method according to the distribution map. Soil moisture was measured in field using TDR300 soil-moisture content analyzer, and the soil pH value was measured in door using PHS-3C acidometer in October, 2009.

As different constants normally have different units and variation degrees, which makes it difficult for practical variable explanation. Therefore, after standardization of variable data by standard deviation, the geostatisticcal common software GS+7.0 was used for variogram analysis, Moran's I analysis, and fractal dimension analysis.

Results and Analysis

Species composition of plant community in karst stony desertification area during natural succession stage

Species composition is a necessary element of biotic community. Interspecific coordinated development is related to community succession. The species quantity and composition are very important indexes for evaluating the species diversity, and also the foundation for the stable development of community and ecosystem.

With the succession of community, the species of herb commmunity gradually decrease during recovery stages, while slowly increases in succession stage of high-forest, with generally a V-shape variation tendency. In the early recovery stage of community when the environment condition is harsh, species that can be adapted to harsh conditions are mainly light drought-enduring pioneer species, including *Pteridium revolutum*, *Imperata cylindrica* var. major, *Senecio scandens*, *Trifolium*, *Miscanthus si nensis Anderss*, *Bidens pilosa*, *Erigeron annuus*, *Arthraxon hispidus.* With the change of environment, there are considerable light drought-enduring woody pioneer species migrating here and settling down. In climax community, succession stage, many light Annual herb species are eliminated by the competition, while some shade-tolerant herb plants are more adapted to such environment, developing into stable climax community and settling down, such as Through investigation, the types of species of herb community in peak-cluster depression of stony desertification area are always in leading position during all recovery stages, wherein the highest value is 76, while the lowest value is 56. In plateau, trough valley, canyon, fault basin of stony desertification area, there types of species of herb community can be as much as 75, 61, 63, 56, and as less as 37, 31, 34 and 23, respectively (See *Fig. 2*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11671183

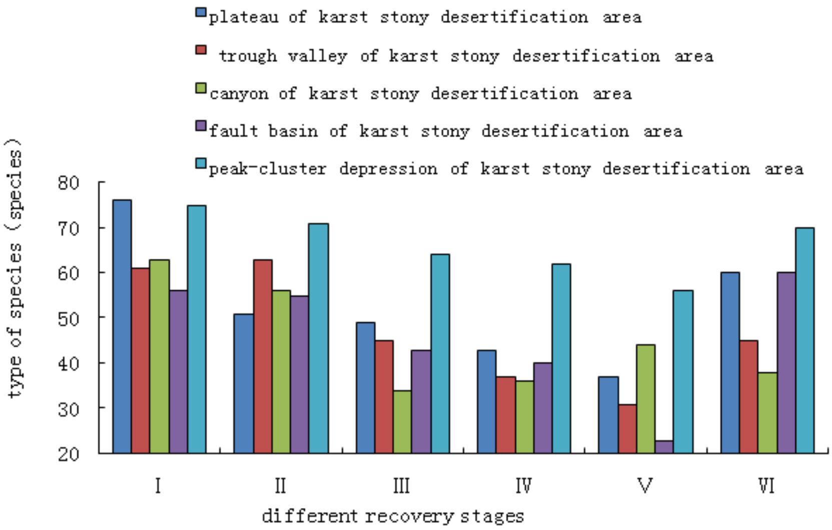

Figure 2. *Variation of species of herb plants in karst stony desertification area during different recovery stages*

With the succession of community, the species of woody plant shows a variation tendency of "increasing-decreasing-increasing". This is mainly because that in the early recovery stage, the species are less, while with the change of environment, the species of woody plant start to increase and reach saturation in shrub stage. After that due to the limitation of vegetation space, some species are eliminated by competition. In tree-shrub transition stage where species competition is the most significant, the early stage of arbor-shrub-grass is also formed, and many species are eliminated because of inadaptation to the transition from light role to shade-tolerance role. In high-forest succession stage, the arbor-shrub-grass layer has been fully formed, shade-tolerance species migrate in and settle down, leading to the increase of species.

According to statistic data, in plateau, trough valley, canyon, fault basin, and peak-cluster depression of karst stony desertification area, the species of woody plant can be as much as 118, 113, 77, 42, 161, respectively, wherein the type of species of wood plant in fault basin is relatively less, which is 42. However, the least number of types of wood plant species in plateau, trough valley, canyon, fault basin, and peak-cluster depression of karst stony desertification are 20, 26, 25, 17, 36, respectively (*Fig. 3*).

The change law of the entire community is consistent with that of woody plant communities (*Fig. 4*). The more the type of species is, the more complex the species composition is, the more stable the ecosystem is, and the stronger the resistance to disease and pest is. Therefore, there are diversity of species during disposition of species, including the *rosaceous* plants, *rutaceous* plants, and *hamamelidaceae* plants in early stage as well as *fagaceae* plant, canella, *magnoliaceae* plants, *theaceae* plants in late stage. In the early vegetation recovery stage, it should focus on species selection during artificial disposition of species, while in the mid-late stage, it should focus on species conserving during structural adjustment.

Life-form composition of plant community in karst stony desertification area during natural succession stage

Life-form plants at different stony desertification areas include therophyte (T), cryptophyte (Cr),hemicryptophyte (H), chamaephyte (Ch), nanophanerophyte Ph(N), microphanerophytes Ph(Mi), mesophanerophyte Ph(Me), megaphanerophyte Ph(Ma), Vine plants (EP), evergreen plant (E), deciduous plant (D). However, there is difference

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11671183

in life form composition ratio at different stony desertification areas during different succession stages.

In the early succession stage, woody plants are dominant species. With the succession of community, woody plants gradually reduce, and then start to increase by a slight rate in climax community stage. This is because that in the early succession stage where the environment condition is harsh, there is lack of water and severe drought, species that can be adapted to such environment condition are mainly plants with short life span, which is overwintering as a seed, followed by dried-up overground part and underground part regeneration. The therophyte herb plant is featured by large quantity, small individual, and short life span, which is adapted to environment by R-strategy and change in large extent. In the mid-late succession stage, most tree and shrub plants migrate hear, while herb plants gradually decrease, and most remained species are shade-tolerant herb plants, such as pilea notata, pteridophyta and Carex plants. With the successions of community, phanerophyte (Ph) gradually increase, which mainly include Ph(N) and Ph(Mi) in early stage as well as Ph(Mi) and Ph(Me) in mid-late stage. The variation tendencies of Ph(N) and Ph(Mi) are consistent, both of which are first increasing and then decrease; the variation tendency of Ph(Me) is basically identical to that of Ph(Ma), both of which are gradually increasing.

In the early succession stage, life form components are mainly *herbaceous* plant, Ph(N), and Ph(Mi), with ratio of 6:3:1; In the middle succession stage, life form components are mainly *herbaceous* plant, Ph(N), and Ph(Mi), with ratio of 3:3:4; In the late succession stage, life form components are mainly *herbaceous* plant, Ph(N), Ph(Mi), and Ph(Me), with ratio of 2:3:3:2 (See *Table 2*).

Table 2. *Life form composition ratio of community at different stony desertification areas at early, mid, and late stage of natural succession*

Stony desertification area	Early stage		Middle stage		Late stage	
Plateau of karst stony desertification area	C:Ph(N):Ph(Mi)	6:3:1	C:Ph(N):Ph(Mi)	3:3:4	C:Ph(N):Ph(Mi):Ph(Me)	2:3:3:2
Trough valley of karst stony desertification area	C:Ph(N):Ph(Mi)	6:2:2	C:Ph(N):Ph(Mi)	3:3:4	C:Ph(N):Ph(Mi):Ph(Me)	2:3:2:3
Canyon of karst stony desertification area	C:Ph(N):Ph(Mi)	6:3:1	C:Ph(N):Ph(Mi)	3:3:4	C:Ph(N):Ph(Mi):Ph(Me)	3:3:2:2
Fault basin of karst stony desertification area	C:Ph(N):Ph(Mi)	6:3:1	C:Ph(N):Ph(Mi)	3:4:3	C:Ph(N):Ph(Mi):Ph(Me)	2:3:3:2
peak-cluster depression of karst stony desertification area	C:Ph(N):Ph(Mi)	5:3:2	C:Ph(N):Ph(Mi)	3:3:4	C:Ph(N):Ph(Mi):Ph(Me)	2:2:3:3

Note: C represents *herbaceous* plant, Ph(N) represents nanophanerophyte, Ph(Mi) represents microphanerophyte，Ph(Me) is mesophanerophyte.

Structural feature of plant community at karst stony desertification area during natural succession stages

Due to the influence of topographic relief, illumination, and humidity, different species are normally distributed at different areas with different density and cover degree, leading to the difference in horizontal structure of whole community. This paper mainly studied the horizontal structure feature and variation of plant community at karst stony desertification area during different succession stages in term of cover degree, predominance degree, and density.

Herbaceous layer community gradually reduces from grass slope stage to high-forest stage; shrub layer first increases and then decreases, while tree layer gradually increases from V to VI stage. The cover degree of plant community is insignificantly changed, with small difference and basically identical variation tendency among different species, which is generally over 80%. The *herbaceous* layer, shrub layer, tree layer reach the largest cover degrees of their own when they are at constructive layer.

Although the cover degree of community is merely changed, the cover degrees of herb, shrub, tree layer are significantly changed. The cover degree of herb layer community gradually decreases from 90.6%-79% in grass slope stage to 32-10% in high-forest stage. In bare rock stage, the cover degree of herb community is even lower, which ranges from 5% to 20%; In grass-slope stage, the cover degree of shrub community ranges from 3.9% to 17%; In shrub community succession stage, the cover degree of shrub layer is the highest, which are 81.7%, 80%, 85%, 80% and 82.5% in plateau, trough valley, canyon, fault basin, peak-cluster depression of karst stony desertification area, respectively; the cover degree of high-forest layer is the highest during high-forest succession stage, which are respectively 73.3%, 80%, 80%, 75% and 71.7% in above areas, with very small difference (*Fig. 5*).

The predominance degree of community is mainly manifested by variation of plant thickness accumulation in horizontal direction. The predominance degree of shrub layer community is manifested by variation of plant ground diameter accumulation in horizontal direction, while that of tree layer community is mainly manifested by variation of plant DBH (at breast height) diameter accumulation in horizontal direction.

In trough valley, fault basin, and plateau of karst stony desertification area, the predominance degree of plant community shows variation tendency of "increasing-decreasing"; while in canyon and peak-cluster depression of karst stony desertification area, the variation of predominance degree of plant community is "increasing-decreasing-decreasing". At canyon of karst stony desertification area in high-forest stage, the predominance degree of shrub layer is high, while the predominance degree of tree layer is low, which indicates such area is dominant by small diameter species during shrub succession stage, while is dominant by large diameter species during tree succession stage. At peak-cluster depression of karst stony desertification area, the predominance degrees of shrub layer and tree layer are both high during high-forest recovery stage, which indicates the large diameter species and small diameter species are both in substantial quantity, and both biomass and stand volume per unit area are in high level (*Fig. 6*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11671183

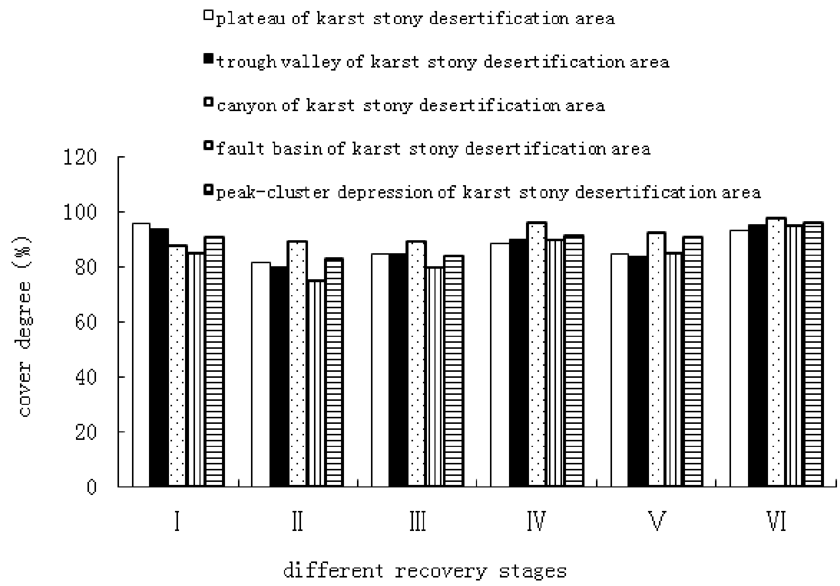

Figure 5. *Cover degree of plant community at karst stony desertification area during different succession stages*

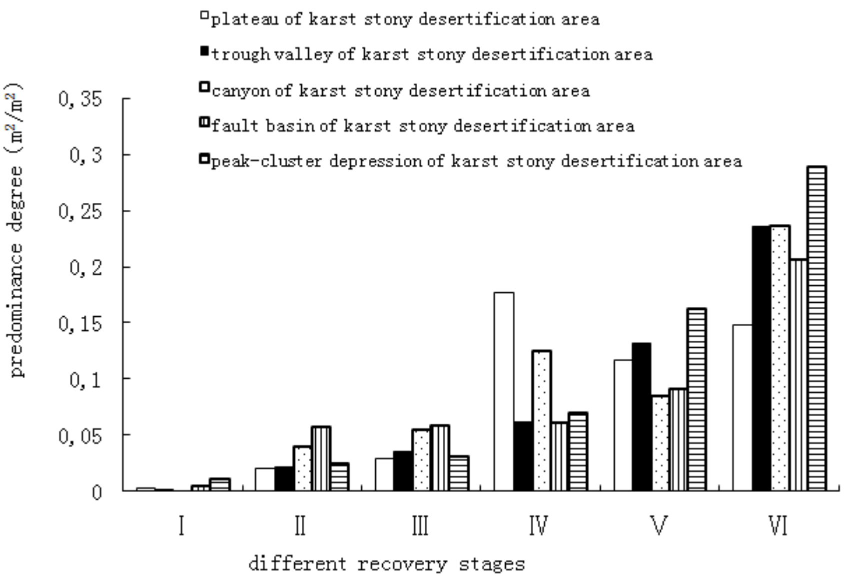

Figure 6. *Predominance degree of plant community at karst stony desertification area during different succession stages*

In early succession stage, the variation range of predominance of plant community are respectively 0.0019-0.02m2/m2, 0.0012-0.021m2/m2, 0.001-0.0396m2/m2, 0.0053-0.569m2/m2, 0.011-0.0253m2/m2 in plateau, trough valley, canyon, fault basin, peak-cluster depression of karst stony desertification area.

The density variation of shrub layer is "increasing-decreasing-increasing" with the succession of community. This is due to that in grass slope stage, herb plant is the dominant species; with the migration of woody plants, the herb plants start to decrease while woody plants gradually increase. After reaching a certain quantity, some species

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11671183

will be naturally reduced or eliminated due to interspecific competition of vegetation space, while those with strong competence start to enter into tree layer, use large amount of vegetation space, cover the illumination, making the light plants gradually eliminated due to the inadaptation to shady and cool environment. Therefore, the density of community during tree-shrub transition stage is smaller than that during shrub succession stage. After reaching high-forest succession stage, some shade-tolerant species will migrate in, breed on lower light, and species quantity in shrub layer gradually grow. This is the reason why shrub layer density show variation of "increasing-decreasing-increasing". While the density of tree layer at karst stony desertification area shows an increasing tendency.

The density variation of the whole community is consistent with that of shrub layer, which is "increasing-decreasing-increasing"(*Fig. 7*). This indicates the increase of tree layer is slow, which does not change the variation tendency of the whole community density. Many small shrubs are in aggregated distribution or in clustered distribution, such as *myrsine*, *berberis aggregata*, *rhamnus heterophylla*, chinese *spiraea*, *C.horizontalis perpusillus*. In particular, the *berberis aggregata* in one cluster can be as much as 178 plants. If all plants in one cluster are taken into density, thhen the lowest density of shrub layer in grass-slope stage can account for about 1/4 of the highest density of tree layer in tree succession stage. In addition, there are some sprouting plants including Sichuan hazel, *platycarya longipes*, *Vitex negundo* L., bamboo leaves pepper, and small fruit rose root, which are normally in quantity of several plants or dozens of plants. Plants in clustered distribution which are mainly small shrubs show advantage in density.

In this paper, the number of genet of plants in clustered distribution is regarded as 1. Therefore, in early succession stage, the density of community is relatively smaller, and then gradually increases with the successions, finally reaches the maximum value in the late succession stage. This indicates during community collocation, plant community is in small-density distribution in early succession stage, and then in large-density (including the total density of shrub and tree) distribution in mid-late succession stage. If community structural adjustment is carried out in the late succession stage, it should focus on the density of tree layer, which is 0.48-0.97 plant/m^2, averaging at 0.65 plant/m^2 in the early stage; 2.16-2.97 plant/m^2, averaging at 2.41 plant/m^2 in the middle stage; 0.11-0.42 plant/m^2, averaging at 0.21 plant/m^2 in the late stage (*Table 3*).

Table 3. *Densities of constructive species layer at different karst stony desertification areas in the early, mid, late natural succession stage*

Stony desertification areas	Early stage	Middle stage	Late stage
Plateau of karst stony desertification area	0.56	2.25	0.14
Trough valley of karst stony desertification area	0.95	2.16	0.11
Canyon of karst stony desertification area	0.76	2.27	0.26
Fault basin of karst stony desertification area	0.50	2.97	0.13
Peak-cluster depression of karst stony desertification area	0.48	2.38	0.42

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11671183

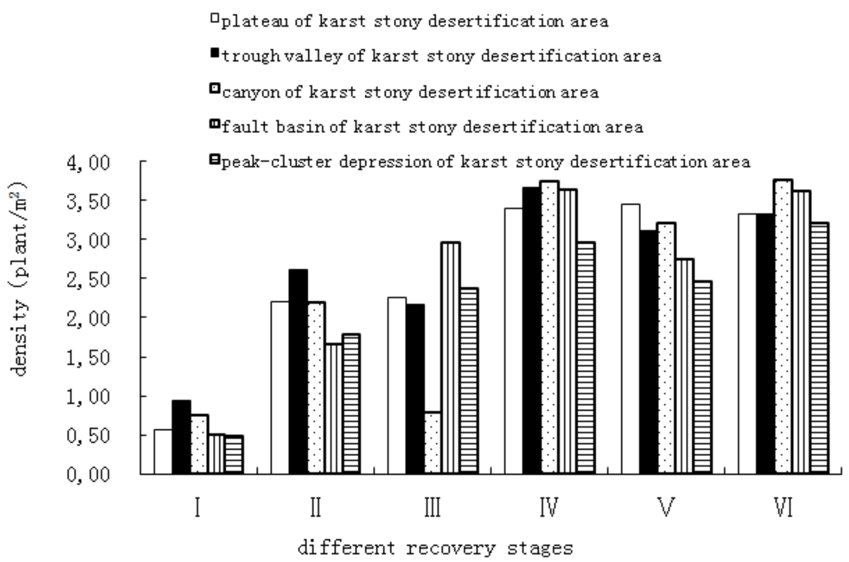

Figure 7. *Community densities in karst stony desertification areas at different recovery stages*

Through investigating the characteristics of spatial distribution of dominant species at different community layers during different succession stages, it can find that the dominant species in all layers are in aggregated distribution in herb and shrub succession stages, while the dominant species in all community layers during high-forest stage is generally in aggregated distribution, but with weaken aggregation intensity and smaller aggregation scale as compared with two former stages, showing variation from aggregated distribution to random distribution in certain degree. In climax succession stage, the dominant species at all community layers is generally in randomly distribution (*Figs. 8* and *9*).

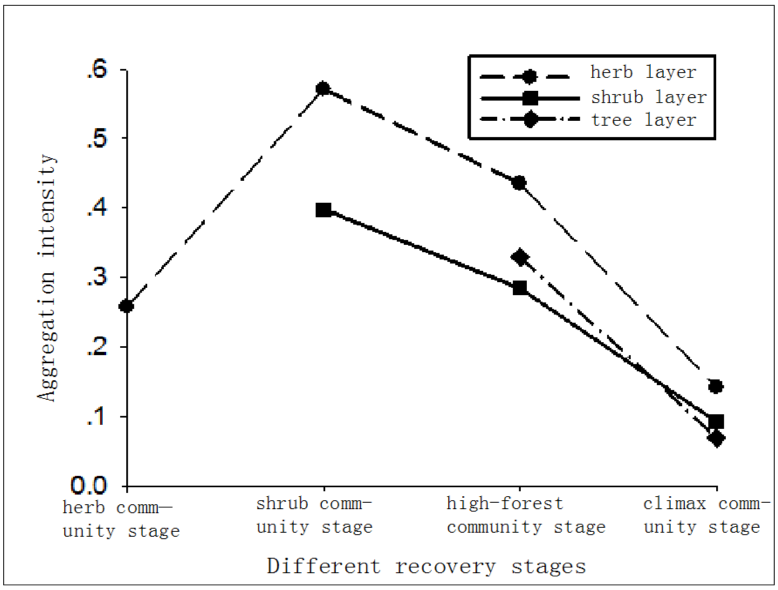

Figure 8. *Variation of aggregation intensity of dominant species*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11671183

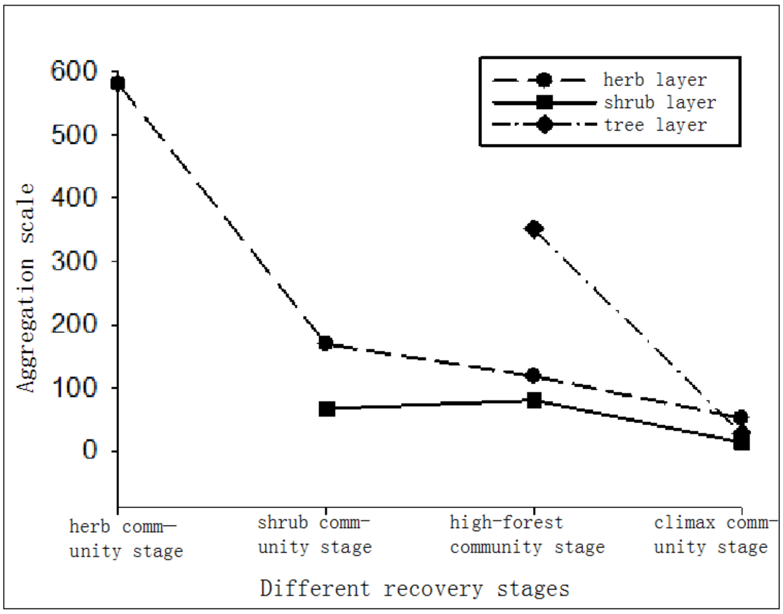

Figure 9. *Variation of aggregation scale of dominant species*

Therefore, the dominant species at constructive layer in early-mid succession stages are mainly in aggregated distribution, while in the late climax succession stage, they are mainly in random distribution and less are in aggregated distribution. This reveals that the dominant species of plant community at karst stony desertification areas in early stage has small aggregation scale, but larger aggregation intensity which gradually decreases with the succession. The largest aggregation scale of dominant species is relative smaller, therefore the allocation scale of plant community at karst stony desertification areas should be set small.

Disscussions

The natural succession of plant community follows certain law. The species composition and structure of plant community vary among different stony desertification areas. It has long been suggested that afforestation should be carried out according to local field condition. Through site classification and plant community investigation, it is believed that stony desertification control can be realized by closing the land for reforestation, but also by establishing artificial plant community with consideration on environment condition (site condition), plant ecological adaptability, community composition, community horizontal structure, and community vertical structure.

Liu Xin-ding studied the community composition in red-earth region of southern china during different recovery stages, finding that "the vegetation type and quantity both increase with the succession of recovery stages"(Liu, 2014), which is different from the situation at karst stony desertification area where the species vary in tendency of "increasing-decreasing-increasing". The major different is that the species quantity shows decreasing tendency in tree-shrub recovery stage, which is may be due to ecological environment difference as Guizhou belongs to krast stony desertification area with subtropical humid monsoon climate.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11671183

Similar to karst stony desertification areas, the Loess Plateau of China include therophyte (T), cryptophyte (Cr),hemicryptophyte (H), chamaephyte (Ch), nanophanerophyte Ph(N), microphanerophytes Ph(Mi), mesophanerophyte Ph(Me), megaphanerophyte Ph(Ma), Vine plants (EP), evergreen plant (E)，deciduous plant (D). However, the dominant speice at Loess Plateau of China in the early recovery stage is perennial hemicryptophyte, which is different from therophyte at karst stony desertification areas. This indicates that the vegetation at Loess Plateau of China is influenced by typical temperate climate (Zhang, 2007). Due to the difference in climate and habitat characteristics, the adaptive ways of plant to environment between two area are significantly different, therefore, different vegetation restoration ways should be implemented.

Conclusions

At karst stony desertification area during early recovery stage when the environment is harsh, species that can be adapted to the environment are mainly light, drought-tolerant pioneer species, such as annual herb plants; with the successions of stages, woody plants gradually increase in a variation tendency of "increasing-decreasing-increasing". Till to shrub forest stage, the quantity of woody plants reach the maximum value, and the variation of species composition of whole community is identical to variation of species composition of woody plants.

Five different stony desertification areas all include therophyte (T), cryptophyte (Cr), hemicryptophyte (H), chamaephyte (Ch), nanophanerophyte Ph(N), microphanerophytes Ph(Mi), mesophanerophyte Ph(Me), megaphanerophyte Ph(Ma), Vine plants (EP), evergreen plant (E)， deciduous plant (D). However, there is difference in life form composition ratio during different succession stages. In the early succession stage, *herbaceous* plant is the dominant species; with the succession of stage, the *herbaceous* plant gradually decreases, and then increases slowly in climax stage.

During natural succession stages, the cover degree, predominance degree, and density of plant community represents the horizontal structural feature of karst stony desertification area. The cover degrees of plant community at all stony desertification areas are insignificantly different, which is around 80%. Moreover, the cover degrees of herb, shrub, tree layer all reach the maximum when they are in constructive layer. The predominance degrees of community at rough valley, fault basin, and plateau of karst stony desertification area are in variation of "increasing-decreasing" while that at canyon and peak-cluster depression of karst stony desertification are in variation of "increasing-decreasing-increasing". The density of shrub layer is in variation of "increasing-decreasing-increasing", while that of tree layer in increasing variation.

The dominant species at constructive layer in early-mid succession stages are mainly in aggregated distribution, while in the late climax succession stage, they are mainly in random distribution and less are in aggregated distribution. This reveals that the dominant species of plant community at karst stony desertification areas in early stage has small aggregation scale, but larger aggregation intensity which gradually decreases with the succession. The largest aggregation scale of dominant species is relative smaller, therefore the allocation scale of plant community at karst stony desertification areas should be set small.

(Received 2nd Feb 2017; accepted 18th May 2017)

Abstract. Information on the crossbreeding parameter estimates involving Nigerian Indigenous pigs and exotic breeds are rare, as well as the best combination for improved growth and conformation traits. A 3×3 diallel cross was conducted among three breeds of pigs – Large White (WW), Landrace (RR) and Nigerian Indigenous pig (NN) breeds. Growth traits measured were body weight at birth (BWB), weaning (BWW at 6 weeks), maturity of 20 weeks (BW20) and average daily gain (ADG up to 20 weeks), while conformation traits were heart girth (HG), height-at-withers (HW), and body length (BL) all at 20 weeks of age. Significant heterotic and maternal effects were reported for BWW, BW20 and ADG. Also significant specific heterosis was recorded only for BW20, with no significant reciprocal effect for the other growth traits measured. Significant heterotic effects for HG and BL were also recorded, while maternal effect was significant only for BL. Significant specific heterosis was recorded for HG, while reciprocal effect was significant only for HW and B. This implies that for growth traits, RR, WW and NN breeds had the best combining ability for BWW, BW20 and ADG respectively with a high positive average heterosis of 0.06, 2.53 and 1.58. This shows that NN breed could elicit attractive economic and environmental benefits when crossbred with exotic ones, in terms of growth traits, as shown by the significant crossbreeding parameter values reported.
Keywords: *diallel cross, heterosis, maternal effect, reciprocal effects, pig production*

Introduction

Various attempts had been made to improve pig strains by identifying the best combining ability in terms of heterosis, maternal and reciprocal effects using diallel cross (Fernandez et al., 2002; Garcia-Casco et al., 2012; Ibanez-Escriche et al., 2014). The main purpose of crossing is to produce superior crosses to improve fitness, conformation and fertility traits, and to combine different characteristics in which the crossbreds were valuable (Balaguer, 2014). Improvement of different traits in pigs have been attempted using cross breeding estimates; such as carcass characteristics (Sutha et al., 2015), semen qualities (Gonzalez-Pena et al., 2015), reproduction and growth traits (Hsu and Johnson, 2014), fat deposition and fatty acid profiles (Ibanez-Escriche et al., 2016). The estimation of crossbreeding effects (direct genetic effect, heterotic effect, maternal effect and reciprocal effect, combining ability - General (GCA) and Specific (SCA)) therefore are of major importance. The testing of populations to attain evaluation of their combining ability requires systematic crossbreeding design. The diallel crossing is one such design. A diallel cross is a set of possible combinations between lines, breeds or general populations (Jakubec et al., 1987). Desirable characteristics of different breeds can be utilized if some breeds can be identified as good maternal breeds and others as good paternal breeds.

There is dearth of information on the crossbreeding effects of Nigerian indigenous pigs with exotic ones, particularly on estimates of crossbreeding parameters in such mating scheme. Duro et al. (2015) attempted the use of diallel cross method involving Nigerian indigenous pig and two exotic breeds to evaluate the effects of cross, parity and sex on bodyweight and morphometric traits among them and these estimates lacked information on crossbreeding parameters. This study is, therefore, aimed at estimating the crossbreeding parameters on growth and conformation traits in a complete diallel cross involving Nigerian indigenous, Large white and Landrace breeds, which are used mainly for production in Nigeria.

Materials and Methods

Study location

This research was carried out at the piggery unit of the Teaching and Research Farm of the Federal University of Technology Owerri, Imo State Nigeria between 2009 and 2014. The facility lies between Latitudes 4^0 04' and 6^0 03' N and Longitudes 6^0 15' and 8^0 15' W. The mean annual rainfall is 2500mm, temperature ranges from 26.5 to 27.5^0 C, and humidity ranges from 70 to 80%.

Animals and experimental design

A complete 3 × 3 diallel cross involving three breeds of pigs, namely Large White (WW), Landrace (RR) and Nigerian Indigenous pig (NN) breeds was conducted. The resultant possible mating combinations included 3 purebreds (WW, RR and NN) and 6 crossbreds (WR, WN, RW, RN, NW, and NR). The base population includes 5 sires per breed and 10 dams per breed which resulted in a total of 148 offsprings farrowed (*Table 1*).

The method of identification was through the use of ear notching identical for each pure bred and cross bred genetic groups. The initial crossbred population was generated between 2009 and 2011 (Okoro, 2012), while the pure population was generated between 2011 and 2014. The data used were records from 2 parities per cross in the experiment from the population bred at the Teaching and Research farm. The number of records, cross distribution and the summary statistics for all the traits measured are shown in *Tables 1* and *2*.

[1]BW20 = Bodyweight at 20 weeks maturity, HG = Heart girth at 20 weeks, HW = Height at withers at 20 weeks, BL = Body length at 20 weeks, SEM = Standard error of mean.
[2]Breed of boar x Breed of sow, W= Large White, R= Landrace, N = Nigerian Indigenous.
[3]Parity 1 = first parity, Parity 2 = second parity.
[4]Sex 1 = Female, Sex 2 = Male.

Management of experimental animals

The parent animals were fed *ad libitum* on concentrates containing 17% crude protein (CP) and 2,480 Kcal/kg energy. A concentrate feed containing 24% CP and 2,500 Kcal/kg energy was also used to flush the sows during the gestation period to enhance nutrients for embryonic and foetal development. Other management practices of animals in the study are in accordance with descriptions in study by (Duro et al., 2015).

Parameters measured

The parameters measured were growth traits and conformation traits taken from the purebreds and the crossbred progenies at the various stages of growth which includes:
1) Growth traits
   i) Birth weight taken at birth of the piglets using 50 kg weighing scale ® Salter England);
   ii) Weaning weight taken at 6 weeks after birth using 200kg bridge weighing scale ® Global Universal, England);

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_117128

iii) Maturity weight taken at 20 weeks post birth using 200kg bridge weighing scale ® Global Universal, England);
iv) Average Daily gain taken daily as the difference between initial weight and current weight taken from birth to maturity at 20 weeks.

2) The conformation traits taken at 20 weeks post birth which includes:
i) Heart Girth (HG): Measured as the circumference of the animal body taken immediately posterior to the shoulder, using a tailor's tape;
ii) Height at Withers (HW): Measured as the distance from the highest point on the dorsum of the animal to the ground surface, at the level of the front feet, using a tailor's tape;
iii) Body length (BL): Measured as the distance from the point of the scapular to the pin bone of the tail base, using a tailor's tape.

Statistical analysis

The following statistical model according to (Jakubec et al., 1987) was used to analyse the diallel cross:

$$y_{hijk} = \mu^B + a_h^B + p_{lii}^B + g_{2i}^B + g_{2j}^B + c_{2ij}^B + m_{2j}^B + r_{2ij}^B + e_{ijk}^B \qquad \text{(Eq.1)}$$

Where

y_{hijk} = the k-th observation on the progeny of a mating of a dam from the j-th line with a sire of the i-th line in the h-th type of breeding (purebred or crossbred, h = 1,2), μ^B= mean of the purebred and crossbreds, a_h^B = effects common to all progeny of the h-th type of breeding (purebred or crossbreds); similar to average heterosis ($\bar{h}^A$) in model A (Eisen et al., 1983), p_{lii}^B = effect common to all progeny of a mating between a dam of the i-th line and a sire of the i-th line; g_{2i}^B= general combining ability of the i-th line, c_{2ij}^B= specific combining ability of the ij-th line cross, m_{2j}^B = maternal genetic effect of the j-th line, r_{2ij}^B = residual reciprocal effect in the cross ij, e_{ijk}^B = random error. The subscript 1 denotes that the effects are measured only among the purebred progeny, while the subscript 2 denotes that the effects are measured only among the crossbred progeny.

Restrictions imposed on the parameter estimates are:

$$\sum_h a_h^B = \sum_i p_{lii}^B = \sum_i g_{2i}^B = \sum_j m_{2j}^B = \sum_i c_{2ij}^B = \sum_j c_{2ji}^B = \sum_i r_{2ij}^B = \sum_j r_{2ji}^B = r_{2ij}^B + r_{2ji}^B = 0 \qquad \text{(Eq. 2)}$$

The least squares estimators of the parameters are as shown in (Jakubec et al., 1987), where model A is the model developed by (Eisen et al., 1983) while model B is developed by (Harvey, 1960) and extended by (Jakubec et al., 1987). The choice of this model (Model B) is because it is the most appropriate when the parental lines are less than 4. With all the crossbreeding parameters being the major interest in this study, relating some aspects of model A to model B according to (Jakubec et al., 1987) was necessary in order to capture all the parameters of heterosis (direct, line and specific heterosis) and maternal effects (direct and maternal genetic effects). The equations that relate parameters in model A to model B are as shown below:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_117128

$$\bar{\mu}^B = \bar{\mu}^A + {}^1/_2\,\bar{h}^A \quad \text{(Eq.3)}$$

$$\bar{a}_1^B = -\,{}^1/_2\,\bar{h}^A \quad \text{(Eq.4)}$$

$$\bar{a}_2^B = {}^1/_2\,\bar{h}^A \quad \text{(Eq.5)}$$

$$\bar{p}_{1ii}^B = \bar{v}_i^A + \bar{m}_i^A \quad \text{(Eq.6)}$$

$$\bar{g}_{2i}^B = {}^1/_2\,\bar{v}_i^A + \bar{h}_i^A \quad \text{(Eq.7)}$$

$$\bar{c}_{2ij}^B = \bar{s}_{ij}^A \quad \text{(Eq.8)}$$

$$\bar{m}_{2j}^B = \bar{m}_j^A \quad \text{(Eq.9)}$$

$$\bar{r}_{ij}^B = \bar{r}_{ij}^A \quad \text{(Eq.10)}$$

The simple difference in the two models is in the estimation of the direct genetic effect and line heterosis in model A which are substituted with the term general combining ability in model B. The model A parameters for heterosis $\bar{h}^A$ and $\bar{h}_i^A$ were derived from model B parameters according to (Jakubec et al., 1987) thus;

$$\bar{h}^A = \bar{a}_2^B - \bar{a}_1^B \text{ or } \bar{h}^A = 2\,\bar{a}_2^B \text{ and } \bar{h}_i^A = \bar{g}_{2i}^B - \frac{\bar{p}_{1ii}^B - \bar{m}_{2i}^B}{2} \quad \text{(Eq.11)}$$

Therefore, heterosis and maternal effects were estimated from these expressions based on the number of parental lines, which is three, leading to all the parameters for heterosis captured. Where there were significant least squares estimate, the least significant difference (LSD) method was used to separate the means (SAS Institute, 2010).

Results

There were significant effects due to direct and maternal genetic effects, GCA, line heterosis and maternal effects on growth traits as estimated from equations 7, 8 and 9, at a probability levels of 95% and 99% (P<0.05 and P<0.01) (*Table 3*). However, significant specific heterosis was reported only for BW20 (P<0.01), and no significant reciprocal effect was reported for all the growth traits measured. The significant GCA translates to significant line heterosis on three growth traits measured viz BWW, BW20 and ADG up to 20 weeks (*Table 3*).

However, the values of crossbreeding parameters for the Large White genotype consistently expressed positive values for the growth traits, particularly at weaning, maturity and ADG, except for heterosis and maternal effects which expressed negative values (*Figs. 1B, 1C, 1D, 1E & 1F*).

[#]and[#1]= purebred and crossbred heterosis respectively. [abc] means on the same column within the same parameter but with different superscripts are significantly different. *=P>0.05, **=P>0.01.

For the conformation traits, there were significant direct and maternal genetic effects on HG and HW ($P < 0.05$) but none on BL ($P > 0.05$). GCA was significant on HG ($P < 0.01$) and BL ($P < 0.05$), resulting in a significant line heterosis on the two traits respectively but none significant on HW (*Table 4*). These are based on equations 7 to 11. Meanwhile, maternal effects and specific heterosis were significant on BL ($P < 0.05$) and HG ($P < 0.01$) respectively, while reciprocal effects were significant on HW ($P < 0.05$) and BL ($P < 0.01$) traits, respectively. The conformation traits also showed an inconsistent distribution of values for the crossbreeding parameters measured. Apart from heterosis, GCA and reciprocal effects in the Large White genotype reflected negative values throughout the period of the experiment, while the rest were all positive estimates of crossbreeding parameters (*Figs. 2A, 2B, 2C, 2D, 2E & 2F*).

[#and#1]= purebred and crossbred heterosis respectively, [abc] means on the same column within the same parameter but with different superscripts are significantly different. *=P>0.05, **=P>0.01.

Discussion

The observed average heterosis of -0.27kg, 0.06kg, 2.53kg and 1.58g/day for BWB, BWW, BW20 and ADG, respectively, for the growth traits shows there was effective heterosis in the diallel cross, although BWB exhibited negative heterosis. However, the positive average heterosis exhibited by other traits might explain the mostly significant crossbreeding parameters expressed subsequently in the traits. The significant direct and maternal genetic effects on growth traits imply that these traits are influenced significantly by genotypes. The growth traits BWW, BW20 and ADG were influenced more by genotype in breeds RR, RR and NN respectively due to the high mean values they exhibited. Estimates of genetic effects are useful to evaluate pig breeds and to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_117128

develop efficient crossbreeding systems (Hidalgo et al., 2015). Therefore, when selecting purebred lines for crossbred performance, the potential use of dominance, imprinting and breed-specific effects could be considered an alternative to improve the efficiency of crossbreeding and selection.

Hildago et al. (2015) reported non-significant direct genetic effect on weight at all ages for pure bred cross, whereas maternal genetic effects differed significantly for weight at 14, 28 and 154 days of age for purebreds using genomic breeding value accuracy prediction methods. Meanwhile, the crossbred had a significant effect of direct genetic effect on weight at 56, 70 and 154 days while for the maternal genetic effect; it differed significantly at birth, 28 and 56 days. Hsu and Johnson (2014) reported highly significant direct maternal effects on 180-d weight (WT180) and longissimus muscle area (LMA) and decreased back fat (BF10) in a Large White – Landrace composite population which favored the Large white breed.

For the significant GCA and its composite; line heterosis, it implies that for the growth traits, BWW, BW20 and ADG, the breeds, NN, WW and RR had a positive line heterosis of 0.74, 0.58 and 0.18 for each breed and GCA values of 0.44, 1.69 and 2.54 for RR, WW and NN breeds respectively. Kurnianto et al. (2010) in a diallel study involving Duroc, Yorkshire and Landrace breeds of pigs estimated GCA for growth traits such as birth weight, average daily gain (ADG), post weaning ADG and body weight at 42 days and found it to be significant and in favour of Duroc breed, due to the highest value reported which implies a significant line heterosis. In a similar vein, Garcia-Casco et al. (2012) in a complete diallel cross scheme with 4 ancient lines of Iberian pigs reported a significant heterotic effect on weight at 420 days of age for the different crosses, while a non-significant heterotic effect for daily growth rate inferred in the first 5 combinations, but the remaining combinations had significant heterosis (+66g/d). Sutha et al. (2015) also reported that in a diallel cross involving Duroc, Yorkshire and Landrace gilts, offspring from Duroc boars were most efficient in feed utilization, and a synthetic three way pig cross was achieved with very high lean weight. They also.reported high heterotic gains in carcasses with less loin fat, a thicker loin muscle, a higher estimated lean yield and a better classification index. These results are in agreement with the findings in this study and by Ibanez-Escriche et al. (2016) in which heterosis effects were relevant for the Retinto and Entrepelado pig breed crosses (approximately 16% of the trait), which could be valuable for a crossbreeding system involving these lines.

The significant maternal effects with high positive values of 0.27, 0.22 and 1.75 for RR, WW and NN breeds respectively, implies that the traits BWW, BW20 and ADG are influenced more by the dams respectively. Gonzalez-Pena et al. (2015) in a three and four way crossbreeding for swine production reported a significant maternal effect for average daily gain (ADG) backfat (BF), feed efficiency (FE), and carcass lean % (LEAN) due to semen traits. Silva et al. (1996) estimated the maternal effects on bodyweight at birth, 21, 35, and 77 days in a full diallel crosses involving Duroc, Landrace, Yorkshire and Large White pigs and reported a significant maternal effect at birth, 21 days and 35 days of age. Also, Hsu and Johnson (2014) reported that crossbreeding and selection for growth traits along with litter size selection at 19 to 28 days resulted in responses consistent with the selection applied and the heritability of the trait on maternal effects. Also pig body weights appeared to be positive from weaning to 154days in Yorkshire breed dams, while Duroc dams seemed to perform poorly throughout. The positive influence of Yorkshire gilts on pig size was somewhat

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_117128

unexpected in view of the fact that Yorkshire gilts also had the largest crossbred litters. Thus, Yorkshire gilts not only raised slightly larger litters but also weaned heavier pigs and their advantage carried through to 154-day weight.

Also, the significant specific heterosis for BW20 implies that lines for the best specific heterosis are combinations of W×R and R×N with values of 8.41kg respectively and the worst combination being W×N with -1.62kg. Kurnianto et al. (2010) also reported a significant SCA in favour of Yorkshire × Landrace breed cross for all the growth traits studied in a diallel cross involving Duroc, Yorkshire and Landrace breeds of pigs.

For the conformation traits, significant direct and maternal effects for HG and HW imply that these traits were influenced by the genotype than phenotype. The WW breed exhibited the highest mean value for both traits (3.03kg and 2.38kg) respectively. With the RR breed being phenotypically characterized by longer body frame than WW and NN breeds, it was expected that it would have expressed a significantly higher BL. This may be explained by the inherent expression of the trait which might not be only heterotic, but also epistatic. But for the GCA and its composite - line heterosis; there is significant heterotic effect in HG and BL, with BL having the highest mean value (5.59cm) in W×N cross. In the line heterosis however, BL trait was exhibited more in RR breed, with the highest mean value of 6.67cm, showing that the trait might be inherent in the breed naturally and expressed epistatically instead of in heterosis. Meanwhile, HG trait exhibited negative mean values for both GCA and line heterosis, even though significantly influenced. This might imply that the traits were negatively influenced in the three breeds analyzed. The maternal effects are also significant only in BL trait, while HG and HW were not. This is more exhibited in the WW breed, as shown in its mean value of 11.30cm, which implies that that the dams of this breed enhances the trait in swine. The specific heterosis also showed that only HG trait was significantly influenced while HW and BL were not with the W×R combination exhibiting the highest value (12.14cm) while W×N was the least. This implies that HG trait is more expressed in the W×R combination. Whereas for the reciprocal effect, HW and BL traits were significantly influenced, while HG was not. The combination of R×N was consistently highest in mean values for both HW and BL traits, showing that the reciprocal cross will be influenced in the same way as the main cross.

Conclusion

Effective combination of local breeds of animals such as Nigerian indigenous breeds in crossbreeding programs to improve growth and reproductive traits has been advocated, as shown by the advantage of Chinese breeds used in production due to its high prolificacy (Rothschild, 1996). The Nigerian indigenous pigs in this study have shown its ability to enhance the specific heterosis with the Landrace breed in improving bodyweight at 20 weeks, which could have major underlying advantage in commercial swine production. This study which is aimed to understand the genetic underpinnings of the breeds as well as the best combination to enhance growth and conformation traits, may also enhance the adaptability of the crossbreds in the harsh tropical environment where the exotic breeds are not used to.

Abstract. Precision fertilizer management could help reduce farming costs and maintain production sustainability in current cropping systems. Soybean is a major oil crop and to improve temporal and spatial fertilizer application to demand variations, soybean canopy nutrient status was diagnosed by the hyperspectral remote sensing techonology. First, field canopy spectral reflectance was characterized during key developmental stages with three levels of fertilizer treatments in northeastern China. Then, foliar nitrogen (N), phosphorus (P) and potassium (K) contents were quantified and analyzed for correlation with transformed spectral data formats including reciprocal, logarithm and derivatives, red edge parameters and vegetation index. Last, simulation models for soybean canopy nutrient status (total N, P and K) were constructed. The simulation model (y= -19.153x+3.1114) using second derivatives of spectral data at 432 nm was proved to significantly correlate the predicted value with measured total N content (r=-0.7829, p<0.01; RE=0.1713). The first derivative-derived models y=-0.2939x+0.5889(r=-0.6172, p<0.01; RE=0.2428) at 909 nm and y=-0.4157x+1.874(r=-0.5631, p<0.01; RE=0.1345) at 908 nm produced most accurate prediction for total P and K respectively. Models reported in this work were top selections for the simplicity and practicality in predicting soybean nutrient and growth status.
Keywords: *soybean, nutritional status, predictive modeling, remote sensing, canopy reflectance*

Introduction

To meet increasing needs of food supply from the fast growing global population, high cropping yields have to be achieved and be even further increased. Since plant growth, development and productivity depend on the availability of nutrients, intensive use of fertilizers has become common agronomic practices of current farming systems especially in low productive regions. However, excessive application of fertilizers has caused major detrimental impacts on the ecosystem and increased costs for both producers and consumers. In this regard, there is a clear need of more reasonable and "intelligent" use of fertilizers to help maintain environmental and economic sustainability of the agricultural production (Chen et al., 2014), which is a main aspect of precision agriculture (PA) (Gebbers and Adamchuk, 2010). Precision fertilization allows a finer degree of fertilization responding to intra-field variability in crops such as different soil conditions and the "heterogeneous" plant growth status so that fertilization efficiency can be improved and productivity is "intensified" (Lindblom et al., 2017).

Plant growth status can be reflected by outward structural characteristics and internal chemical compositions. Hyperspectral remote sensing is a technology used for the collection of information of contiguous high-resolution electromagnetic radiation emitted from an object so that to recognize and locate the target and reveal its natural properties. In recent years, the hyperspectral agricultural remote sensing technology has been used to

predict crop water content (Holben et al., 1983; Su et al., 2010; Liu et al., 2012), chlorophyll content (Madeira et al., 2000; Tang et al., 2011; Curran et al., 1999), leaf surface area index (Bouman et al., 1992; Danson and Plummer, 1995; Feng et al., 2009) and other biophysical parameters (Vergara-Díaz et al., 2016) and major nutrient elements of plants (Femandez et al., 1994; Cheng et al., 2011; Yi et al., 2014), monitoring micronutrient and other nutrient status of crops (Masoni et al., 1996; Wang et al., 2012).

A combination of techniques suitable for remotely sensing foliar Nitrogen (N) in semiarid shrublands – a capability that would significantly improve our limited understanding of vegetation functionality in dryland ecosystems (Mitchell et al., 2012). In A. Zerger study introduced that environmental sensor networks for vegetation, animal and soil sciences (Zerger et al., 2010). The ratio vegetation index (RVI) between the spectral reflectance from the near-infrared and visible band ranges can be used to construct a hyperspectral simulation model for soybean leaf area index (Zhang et al., 2005). Advance on application of of hyperapectral technology in detection of crop was proposed (Liu et al., 2013). Findings from these large numbers of research efforts have provided the theoretical bases for incorporating the remote sensing technology in precision fertilization by diagnosing plant nutrient status.

Crop species each may have its own characteristic spectrum; the information from visible light, near infrared light, and short infrared region can be used to produce biomass at high accuracy (Shibayama et al., 1989). Study by a Chinese group discovered that in a soybean crop, the above-ground fresh weight has a strong correlation with the spectral signatures in the range of 760~1050nm, and RVI can be used to accurately predict soybean above-ground biomass yield (Song et al., 2005; Chen et al., 2010). The canopy reflectance indices measured at early flower stage of cotton growth could serve as input to a crop growth model for predicting potential yield loss (Zhao et al., 2007).

Chlorophyll content and leaf spectral characteristics have a very strong correlation (Madeira et al., 2000). Studies found that soybean chlorophyll A, B contents have a negative relationship with canopy reflectance in the visible band range, and in the near-infrared wavelength, and it changed to positive in the red edge band region (Song et al., 2006). At 536, 577, 611, 680, 705 nm wavelengths, the first derivative of spectral reflectance has a significant correlation with chlorophyll content (Chen et al., 2012). In Tang study proposed to use the Neural Network Model to estimate stable soybean canopy chlorophyll content.

Spectral measurements are useful for estimating the nitrogen status of crops, thereby enabling site-specific fertilizing in precision farming systems (Mistele and Schmidhalter, 2008). Soybean is one of the most cultivated oil crop worldwide and especially in northeastern regions of China in terms of land area and production (Zhang et al., 2014). Presently, spectral remote sensing technology is mainly used in soybean field to analyze biomass yield, leaf surface area and chlorophyll content. Plant nutrient diagnosis studies, in particular of P and K, have not been investigated. In this study, the technology and theory in remote sensing and the ground remote sensing were applied to develop models for the evaluation of soybean plants, in combination with the hyperspectral non-invasive monitoring technology and field data synchronization collection method, and with the aid of statistical analysis methods. The objective was to explore the major agronomic parameters, and leaf nutrient contents, and its relationship with reflectance spectrum. The characteristic spectral signatures were extracted for each plant growth parameter, and to construct simulation models for plant growth using canopy reflectance spectral data. Findings from this study will provide theoretical bases for real time diagnosis and accurate management of soybean fields in Northeast China.

Materials and Methods

Materials and Experimental Design

The experiment was performed on the experimental station at Shenyang, China (41°48′11.75″N, 123°25′31.18″E) in 2013. The soil of experimental sites were similar typical cropping soil in northeastern China which contained a total content of 2.65 g kg^{-1} N, 0.083 g kg^{-1} P, 75 mg kg^{-1} alkali-hydrolysable nitrogen, 0.07 mg kg^{-1} available P, 149.56 mg kg^{-1} available K, 18 g kg^{-1} organic matter. Liaoning No.14, a semi-determinate and Liaoning No.15, a determinate cultivar were chosen as experimental varieties. Seeds were sown on the 18^{th} of Maywith a density of 165, 000 plants hm^{-2}. Three P levels (P_2O_5), at 0, 5.5, 11 kg hm^{-2}, were designated as P0, P1, P2 respectively. Each plot (L 7 m x W 4 m) was used for one soybean variety with one P treatment. Every variety and treatment combination was repeated for three times and the total eighteen plots were randomly arranged. The same field management procedures were adopted for all experiments.

Collection of canopy spectral data

A portable spectrometer (ASD, USA) was used to collect canopy spectral reflectance. The instrument was operated with a 512 *element photo-diode array* (PDA) probe within wavelength spectrum of 325 ~ 1075 nm. The scanning was conducted according to the operational instruction for ASD as: spectral resolution was 3 nm; scan time interval was 17 ms; spectral sampling interval was 1.5 nm; the probe was placed vertically over the canopy at a field angle of 10°; the distance from probe to the top of the canopy was 1 m. The instrument was calibrated against internal reference prior to each measurement. Measurements were taken during key soybean developmental stages including branching, early flowering, peak flowering, pod setting and seed bulging stages. To control variation from field conditions, measurements were only taken on sunny days from 10 AM to 14 PM (local time). Each spectral reflectance data was an average of twenty measurements on a single plot.

Analysis of N, P and K contents in soybean leaves

After taking spectral measurements, fully expended leaves from the canopy top were cut without petiole and frozen immediately in liquid nitrogen. On each plot, twelve leaves collected from six plants were oven-dried (105 °C for 0.5 hour followed by 80°C for 2 days) then ground into fine powder for mineral content analysis. Sample digestion was carried out using the H_2SO_4-H_2O_2 method. The total nitrogen content was quantified using the classic Kjeldahl method. The total P content was quantified using the Mo-Sb- Vc- colorimetric method and the atomic absorption spectroscopy was used for K quantification.

(Leaf area index was measured but not included in this manuscript.)

Processing of spectral data

(1). The first and second derivative spectrum

The reflectance spectra were transformed into the first derivative spectral revalues using the following equation:

$$\rho'(\lambda_1) = [\rho(\lambda_{i+1}) - \rho(\lambda_{i-1})]/2\Delta\lambda \quad \text{(Eq.1)}$$

λ_i is the wavelength of each channel (band); $\rho'(\lambda_i)$ is the first derivative spectrum of each band;

$\Delta\lambda$ is the interval difference from λ_{i-1} to λ_i

The second derivative spectrum was calculated by using the first derivatives as input data into the above equation.

(2). Calculation of red edge parameters

The red edge parameters were calculated for bands corresponding to the first derivative spectrum maximum within the red edge range (680 ~ 760 nm). The red edge slope is the first derivative spectra collected from the maximum peak area in the red edge range (680 ~ 760 nm). The red edge peak area is the size of the area surrounded by the first derivative spectra in the 680 ~ 760 nm range.

(3). Calculation of common vegetation indices

Common vegetation indices were calculated according to equations listed in the *Table 1.*

Table 1. *Formula for calculating common vegetation indices.*

Index	Abbreviation	Equation	Reference
Ratio vegetation index	RV	$RVI = \frac{\rho_{NIR}}{\rho_{RED}}$	Pearson et al.（1972）
Difference vegetation index	DVI	$DVI = \rho_{NIR} - \rho_{RED}$	Jordan（1969）
Normalized difference vegetation index	NDVI	$NDVI = \frac{\rho_{NIR} - \rho_{RED}}{\rho_{NIR} + \rho_{RED}} = \frac{RVI - 1}{RVI + 1}$	Rouse et al.（1974）
Re-normalized difference vegetation index	RDVI	$RDVI = \sqrt{NDVI \times DVI}$	Reujean and Breon（1995）

Model simulation

A canopy spectural reflectance data set was input with leaf N content data (from all examined soybean developmental stages) into the EXCEL software to calculate for associated factors across the whole scanning spectrum. The data reflectance data format with highest associated factors was chosen for model construction. The wavelength corresponding to the highest associated factor was chosen as characteristic wavelength to nutrient N. Then, a linear regression model was constructed in EXCEL with the chosen format of data set on the characteristic wavelength. Simulation models for P and K were constructed with the same protocol.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11851198

Software tools

All vegetation indices were calculated with a self-programmed software. All other data processing and analysis were performed with the the EXCEL software.

Results and analysis

Changes of soybean canopy reflectance spectrum at different growth stages

The structure and physiological properties of soybean canopy change as plants grow, and those alterations will affect characteristics of the canopy spectral reflectance. When examining the whole spectral curve in the visible light range of 400~680 nm, it was found that the highest reflectance occurred at the branching stage, it then declined and stabilized at a lower level during seed bulging and maturation stages (*Fig. 1*). This spectral band region is influenced strongly by plant pigments. It is possible that as soybean plants grow, leave accumulate more chlorophyll thus increasing the absorbance capacity for visible light. The same physiological state continues until pod-set stage. Thereafter, plant pigment content gradually declines to a stable low level, thus spectral reflectance rate also stabilizes at a different level. In the near-infrared region (760~1000 nm), the reflectance rate also changed significantly with plant growth. The canopy spectral reflectance was at the highest level at the branching stage. At more mature growth stage, the reflectance rate gradually decreased till reaching the lowest level at the maturation stage (*Fig. 1*). Furthermore, it was also found that from flowering to seed set period, and from seed bulging and maturation period, the spectral reflectance curve had several big fluctuations. It is likely that during the first period from flowering to seed set stages, large amounts of leaf mineral nutrients were transported to seed pods, and then during the second period from seed bulging to maturation stages, plants started to age and deteriorate resulting in physiological functional decline.

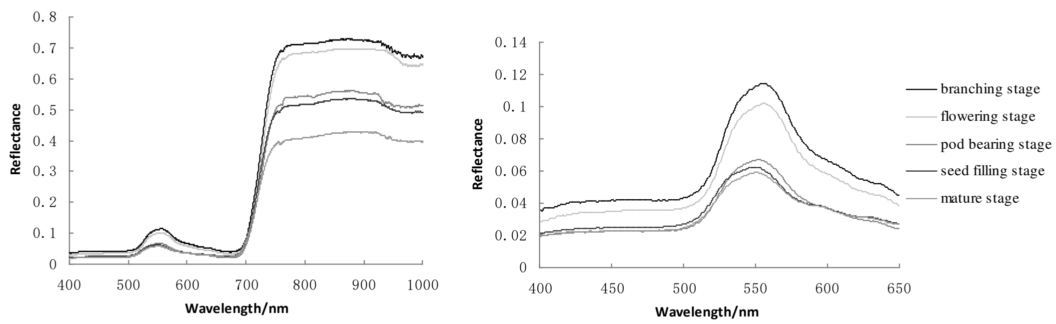

Figure 1. *Hyperspectral reflectance of soybean at different growth stages*

Characteristic changes in soybean canopy total N, P K contents

Changes of soybean leaf mineral nutrients at different growth stages were shown in *Fig. 2*. The total N content decreased as plants grew with a sharp decline from branching to flowering stages then it slowed down at the post-flowering stage. Contents of P and N seem to have positive synergistic effects. The application of P fertilizer treatment had a positive effect on N content. For plants passed the flowering stage, leaf P content was higher for the one that were fed with P fertilizers than those without P

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11851198

fertilizers; P-1 treatment had a more pronounced effect on soybean leaf N content compared to P-2 treatment; leaf total P content decreased gradually from branching to flowering stages, and then declined post the flowering stage. The highest leaf P content was found in high-rate P fertilizer treatment which is significantly higher than the non-P-fertilizer control; soybean leaf K content increased gradually from branching to flowering stages and it started to decline post the flowering stage. Plants receiving P fertilizer treatment also had higher K contents compared to control; but there were no big differences among between different levels of P fertilizers. These results indicate that appropriate use of P fertilizer helps to improve leaf K nutrient status.

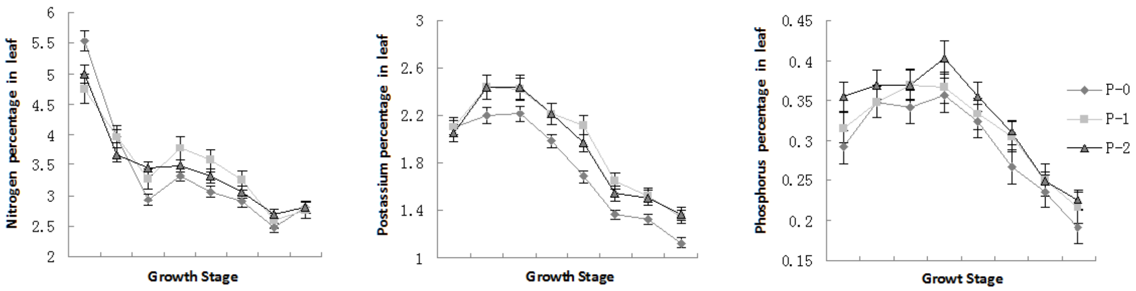

Figure 2. *Variation of total N, P, K content in soybean canopy at different growth stages*

Simulation models for soybean leaf total N, P, K contents

In this study, the original data of canopy spectral reflectance and those transformed by the function of reciprocal, derivative and algorithm, were used to identify the optimal band regions that would produce a good correlation between canopy spectral data and leaf total N, P, K contents, and to establish simulation models of these three mineral nutrients. Results indicate the correlation efficient (r) of the simulation equations depends on data transformation *(Table 2)*. The correlation efficient of the four transformed datasets was at an extremely significant level ($p<0.01$) but from different bands for total N, P and K. The first and second-derivatives of the spectral reflectance had a better correlation with N, P, and K than the other three transformed datasets. These results indicate that the first and second derivatives may be able to eliminate side-effects from soil, the depth of leaf color, and other environmental factors. Thus they are correlated with physiological-chemical properties of chlorophyll and other growth factors (Malthus et al., 1991).

Table 2. *Correlation between soybean leaf essential mineral nutrients and transformed spectral data (N=144)*

Spectral data	Leaf total N (%)		Leaf total P (%)		Leaf total K (%)

Log(ρ) ″	423nm	-0.7138**	680nm	-0.5894**	539nm	-0.5461**

Note:** indicates an extremely significant correlation (P< 0.01), * indicates a significant correlation (P< 0.05).

It was shown that soybean leaf total N content has the best and positive correlation with the second-derivative (ρ″) of the spectral reflectance at the 423 nm band (*Table 2*); the simulation equation is: y=-19.153x+3.1114 (r=-0.7829, p<0.01; RE=0.1713); the measured and analog value predicted from the model is r=0.7908 (p<0.01) (*Fig. 3*). The simulation equation was constructed for the total P content and Log(ρ) ′ of the first-derivative of spectral reflectance at 909 nm as: y=-0.2939x+0.5889 (r=-0.6172, p<0.01; RE=0.2428); The measured and simulated values were significantly correlated (r=0.7386, p<0.01) (*Fig. 4*). To determine the optimal correlation coefficient between soybean leaf total K content and the first derivative of spectral reflectance at 908 nm, a function model was constructed using the derivative data and leaf total K content and it is written as: y=-0.4157x+1.874(r=-0.5631, p<0.01; RE=0.1345) and there was a significant correlation between the measured data and the analog values predicted using the model (r=0.6421 (p<0.01) (*Fig. 5*).

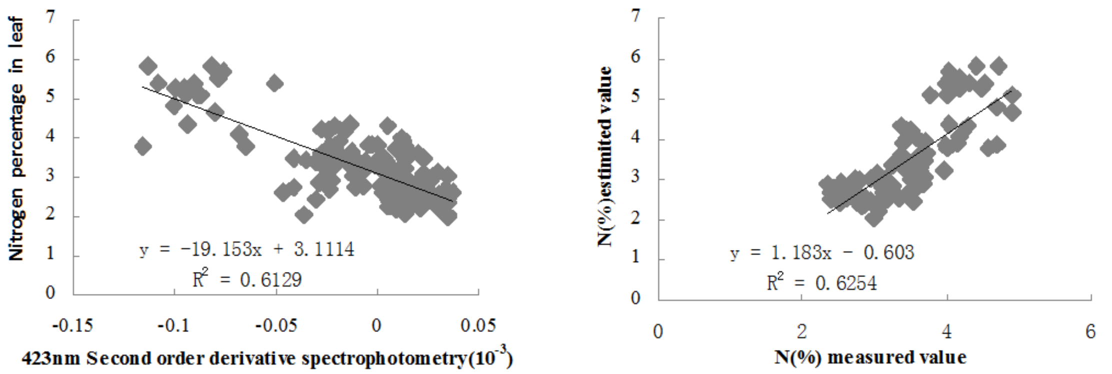

Figure 3. *Correlation analysis between total leaf nitrogen content and optimal transformation of the reflectance spectrum of soybean canopy (N=144)*

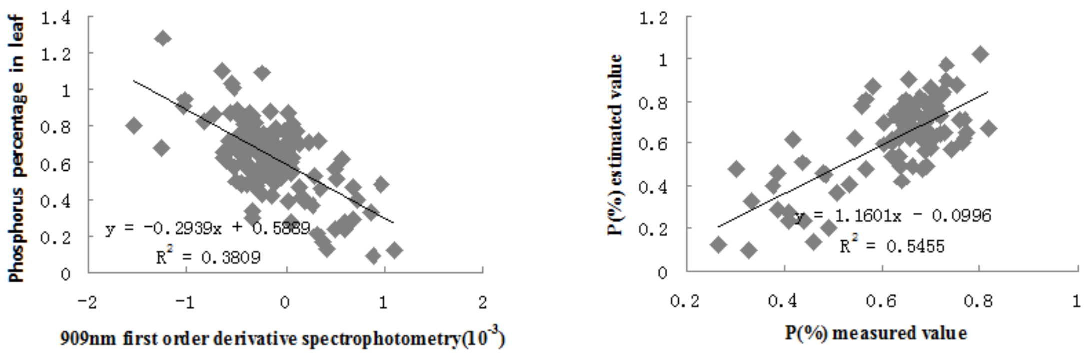

Figure 4. *Correlation analysis between the simulated and the measured total phosphorus content of soybean leaves (N=90)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

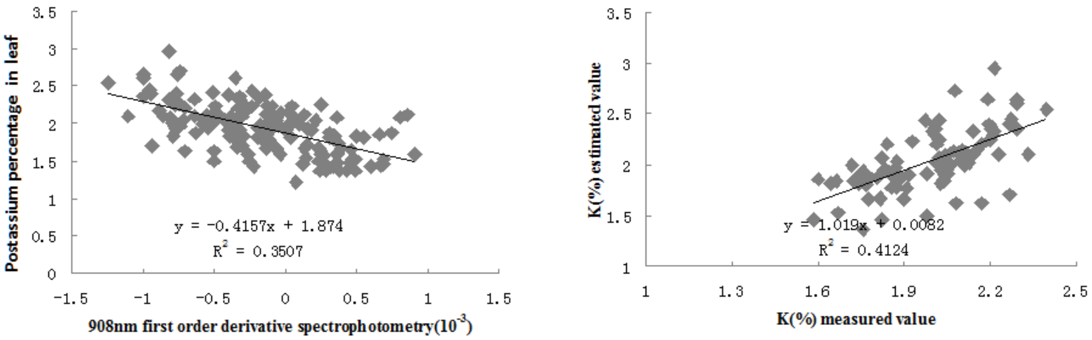

Figure 5. *Correlation analysis between total leaf potassium content and the derivative spectra (N=144) in soybean canopy*

Correlation between red edge parameters and soybean leaf N, P, K contents

Results of the correlation analysis between the red edge parameters including red edge position (λ_{red}), red edge slope ($D\lambda_{red}$) and red edge area (S_{red}) and leaf total N, P, K were contained in *Table 3*. Among the simulation models, the fit equation for red edge area (S_{red}) and soybean leaf total N content is: y=3. 1714x+1.7001(r=0.4676, p<0.01; RE=0.2439). The correlation coefficient between measured and analog values from simulation is: r=0.7088 (p<0.01) (*Fig. 6*). The simulation equation for the red edge slope ($D\lambda_{red}$) and total P content is: y=20.204x+0.3811(r=0.3981, p<0.01; RE=0.2739); the correlation coefficient between the measured and analog values is r=0.5918 (p<0.01) (*Fig. 7*). The simulation equation for the red edge area (S_{red}) and leaf total K is: y=1.009x+1.589 (r=0.4121, p<0.01; RE=0.1506); The correlation coefficient between measured and analog values is r=0.5791 (p<0.01) (*Fig. 8*). These results indicate that red edge area (S_{red}) and the slope ($D\lambda_{red}$) and the position (λ_{red}) each have lower correlation with leaf total N, P and K contents. Therefore these red edge parameters are not suitable for the purpose of predicting leaf total N, P, K contents under the experimental conditions.

Table 3. *Correlation between soybean canopy red edge parameters and leaf nutrient contents*

Red edge parameters	Leaf total N (%)	Leaf total P (%)	Leaf total K (%)
Red edge position λred	0.2582**	0.0964	0.0964
Red edge slope Dλred	0.4590**	0.3981**	0.3608**
Red edge area Sred	0.4674**	0.3641**	0.4120**

Note:** indicates an extremely significant correlation (P< 0.01), * indicates a significant correlation (P< 0.05), (N=144).

Vegetation index simulation model

Data of spectral reflectance from a selection of optimal bands were used to construct simulation models for vegetation indices and leaf total N, P and P content. The four generally used vegetation indices, DVI, RVI, NDVI and RDVI, were calculated to select the optimal spectral bands (*Table 4*), and then soybean LAI simulation model were constructed for these growth parameters. After simulation test, the equations giving the best correlation coefficient (r) and smallest average relative error (RE) was selected as the optimal simulation model.

Table 4. *Soybean leaf mineral nutrients and vegetation index simulation model analysis (N=144)*

	Vegetation index	Spectral band regions (nm)		The fitted equation	Correlation coefficient	Average relative error (RE)

Leaf total K content (% in dry weight)	DVI	762	734	y=3.2464x+1.5448	0.4755**	0.1468
	RVI	762	742	y =3.3287x-1.82	0.4207**	0.1534
	NDVI	761	735	y =4.2976x+1.4181	0.4591**	0.1471
	RDVI	762	722	y = 2.3962x+1.2782	0.5318**	0.1402

Note:** indicates an extremely significant correlation (P< 0.01), * indicates a significant correlation (P< 0.05); x is vegetation index

The simulation equation for leaf N content was constructed using the difference vegetation index (DVI) [762,743]. It is described as: y=22.006x+2.0303(r=0.6242, p<0.01; RE=0.1195). The measured data and simulated analog values have a significant correlation (r=0.7678, p<0.01) (*Fig. 9*). The simulation equation for DVI [771,757] and leaf total P is written as: y=16.62x+0.2946(r=0.5750, p<0.01; RE=0.2292), with a significant r (r=0.7572, p<0.01) between the predicted analog values and the measured data (*Fig.10*). The simulation equation using the normalized difference vegetation index (NDVI) [762,722] is: y = 2.3962x+1.2782(r=0.5318, p<0.01; RE=0. 1402). The measured data and simulated analog value has a significant correlation (r=0.6303, p<0.01) (*Fig. 11*).

Conclusion and discussion

The following conclusions have been *drawn* from this study:

- *Models for hyperspectral simulation* of major mineral nutrient contents (leaf total N, total P, total K) were constructed using the original data and those *transformed* by the *reciprocal* function, logarithm, derivative, of *spectral*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11851198

reflectance, the red edge parameters, and the four vegetation indices *of soybean canopy. It was* found that the first derivative and the second *derivative of spectral reflectance* at 423nm *can reliably predicate leaf total N content using the* following equation: y=-19.153x+3.1114 (r=-0.7829 RE=0.17130). The predicted data using this modes is well- correlated value (r=0.7908**) with measured data, thus the model has competitively high predictive power.

- Among model equations developed using the l*ogarithmic spectrum* data, the first *and* the second *derivatives and* DVI were able to predict leaf total P content at a degree of high accuracy. At the 909nm wavelength, *the equation for* the first *derivative of logarithmic spectrum is:* y=-0.2939x+0.5889(r=-0.6172 RE=0.2428),which produces a significant correlation coefficient (r=0.7386**, p<0.01),between measured and analog values and it is the best among the three models.
- The derivative- transformed and renormalized difference vegetation index (RDVI) can both accurately predict leaf total K content. At 908nm, the equation using the first derivatives of spectral data is: y=-0.4157x+1.874 (r=-0.5631 RE=0.1345). The correlation coefficient between measured and analog values is r=0.6298**, therefore it is the most powerful equation for modeling leaf K content.
- In summary, in this study, the reflectance spectral data from soybean canopy were collected and processed to develop simulation models for leaf growth parameters and mineral nutrient contents. A wide application of these models is expected in crop management. An extremely strong correlation was found between content of major nutrients (total N, P K) and the transformed data of canopy spectral reflectance. The sensitive bands for total leaf N, P K contents are 423nm, 909nm and 908nm. Several highly accurate simulation equations were developed for these bands. But during the process of screening for the optimal band range, it was found that a large number of bands had an extremely significant correlation (p<0.01) with leaf mineral contents, furthermore, the differences between those bands were very small.
- The hyperspectral features within the visible light region (400~700nm) are sensitive to N status in the canopy of cotton (Wang and Li, 2012). The 350~730 nm and 1420~1800 nm are the wavelength ranges that are sensitive to P contents in maize plants (Wang et al., 2007). These researches consistently have demonstrated that there is no single band that can produce enough spectral data to simulate a plant growth parameter, instead, data from "a range of optimal wavelengths" have to be used to develop the spectral signatures. More studies will be conducted to establish and validate the most stable and most effective wavelengths for each of the plant growth parameters for soybean crop.

(Received 10th Apr 2017; accepted 20th Jul 2017)

Abstract. In most cases, there is no positive strong relation (correlation > +0.95) between germination percentage (G) and individual seedling dry weight (W) over treatment levels, which indicates the different response of GW to treatment. In such cases, it is difficult to choose/recommend a treatment level as a best one. Artificial neural network-based optimization (interpolation of treatment levels for possible simultaneous maximum increase in both GW) is the solution to such difficulties. This study aimed at optimizing ultrasonication (pre-soaking duration, temperature and duration of irradiation) of *Phaseolus vulgaris* L. seeds. Treatments were factorial arrangement of 5 pre-soaking durations (2, 4, 6, 8 and 12 hours), 5 irradiation durations (0, 3, 6, 9 and 12 minutes), and 4 irradiation temperatures (temperature of ultrasound device:17, 22, 27, and 32 ^{o}C). The results indicated that the structure 3:4:4:2 of neural network appeared to be appropriate for predicting GW responses. This structure showed higher R^2 in both learning and test phases, when the model was based on Secant Hyperbolic function. The optimized combination of treatments was irradiation temperature of 26.99 ^{o}C, irradiation duration of 5.91 minutes, and pre-soaking duration of 3.20 hours.
Keywords: *pre-soaking duration, irradiation temperature, irradiation duration, seedling dry weight, prediction.*

Introduction

Several methods have been used for seed pre-sowing treatment in order to increase the germination and uniformity i.e. gibberellic acid, sulphuric acid, and hot water treatment (Machikowa et al., 2013). However, seeds treated by these methods have to be rapidly grown and cannot be storaged. Therefore, the methods that increase seed germination but do not affect their viability during the storage are much needed. Applications of ultrasound have been used to induce faster and greater seed germination of the Norway spruce, barley, orchids and other crops. It has been reported that the optimum condition of treated seeds lead to uniform and rapid germination (Machikowa et al., 2013). Ultrasonication not only promotes germination rate (Gordon et al., 1963; Shimomura, 1990; Keshvari et al., 2008; Yaldagard et al., 2008), but also accelerates water uptake and seed coat permeability via creating temperature and mechanical effects on cell membrane and hence promotes germination (Yıldırım and Mehmet, 2015; Gavrilo et al., 1996).

Ultrasonic waves have various applications ranging from seed treatment and elimination of pests and pathogens to genetic engineering and gene transfer (Yaldagard et al., 2008). The first research on the field of biological effects of ultrasound was reported by Harvey and Loomis (1928). In a research conducted on seed germination of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11991209

Assa foetida L., the 0, 4, 8 and 12 minutes ultrasonication resulted in germination rates of 5, 35, 57.75 and 62.5 day^{-1}, respectively; in this study, the 4-minute irradiation was selected as the best treatment (Abdali et al., 2010). Machikowa et al. (2013) reported that seed irradiation with ultrasound waves enhances seedling vigor; this positive effect of ultrasound on seed germination results from change in cellulosic membrane and enhancement of nutrient uptake and transfer to inside of seed and growing seedling. Faryabi et al. (2008) studied effects of ultrasound waves on physiological and morphological processes of capsicum pepper (*Capsicum annuum*) and radish (*Rhaphanus sativus*); in their experiment, the seeds were treated under ultrasound waves of 42 KHz for 0, 4, 6 and 8 minutes at 25 ^{o}C under cool light; results indicated that the best treatment for radish was sonication for 6 minutes.

It should be noted that the amplitude of ultrasound plays critical role in activation/inactivation of enzymes. Many reports confirm enhancement of enzymatic activity of free enzymes under slight radiation of ultrasound; for example, activity of alpha-chymotrypsin on casein is enhanced under slight amplitude of ultrasound; while the activity of this enzyme is reduced at higher amplitudes (Ishimori et al., 1981).

Artificial neural network is a data analysis system inspired from human brain that analyzes the data using a large number of small processors. These processors are arranged as a consistent network and act in parallel to solve a problem. In such networks, a data structure is designed to act like a neuron. An artificial neuron is system which consists of many inputs and one or a few outputs. The network includes layers and weights components. Network behavior depends on the interrelations among the members. In general, there are three types of neuron layers in neural networks:

- Input layer (regressor): reception of raw material (R_1, …, R_n) entering the network.
- Hidden layer(s): performance of these layers is determined by inputs and the weights of their relations (Z_1, …, Z_2). The weights between input and hidden units determine when a hidden unit should be active.
- Output layer: function of output layer depends on function of hidden unit and the weight of relation between hidden and output layer (Y_1, …, Y_n).

Neural networks have many applications such as prediction of continuous variables such as soil moisture (Chang and Islam, 2000), sampling (Zhang and Barrion, 2006), estimation of grain biomass and yield (Drummond et al., 2003). Using neural network, Gholipoor et al. (2013) optimized the traits affecting barley seed and suggested that genetic improvement of barley seeds based on the optimized seeds can significantly improve seed yield. By optimization of mineral concentration in sugar beet tuber using artificial neural network, the optimal concentration of calcium, magnesium, nitrogen, potassium and sodium was estimated as 0.37%, 0.35%, 0.97%, 4.67 mili equivalent/100 g, and 0.33%, respectively. Under optimized concentration of minerals, potential yield of tuber and sugar was enhanced by about 17% (Gholipoor, 2012).

To the best of our knowledge, there has been no report about possible interaction of pre-soaking duration and ultrasonication temperature with ultrasonication duration on seedling growth and germination percentage of red bean. Regarding these issues, the main objective of this study was to find the best ultrasonication duration, pre-soaking duration and ultrasonication temperature to have highest germination percentage and seedling growth.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11991209

Due to the fact that in most cases, there is no positive strong relation (correlation > +0.95) between germination percentage and individual seedling dry weight over treatment levels (Golipoor et al., not published), these traits tend to have different response to a treatment. In such cases, it is difficult to choose/recommend a treatment level as a best one. Artificial neural network-based optimization (interpolation of treatment levels for possible simultaneous maximum increase in both germination percentage and individual seedling dry weight), which was used here, is the solution to such difficulties.

Materials and Methods

Laboratory experiment

An experiment, as completely randomized design with three replications, was carried out on red bean (*Phaseolus vulgaris* L.) seeds in Seed Technology Center of Shahrood University of Technology in 2015. Treatments were factorial arrangement of five pre-soaking durations (2, 4, 6, 8 and 12 hours), five ultrasonication durations {0 (control), 3, 6, 9 and 12 minutes}, and four ultrasonication temperatures (temperature of ultrasound device: 17, 22, 27, and 32 ^{o}C). The ultrasonic bath (digital ultrasonic, Model 4820-CD) with constant frequency of 24 kHz of ultrasonic waves was used for irradiating the seeds.

Twenty five seeds were selected for each petri dish. The germinated seedlings were counted on daily basis until it was found no change in number of germinated seedlings for two consecutive days. The germinated seedlings were multiplied by four to get the germination percent. The seedlings were separated form seeds and dried in oven for 48 hours at 70 ^{o}C. Then they were weighed. The individual seedling dry weight and germination percentage were subjected to analysis of variance, using the SAS software (version 9.1).

Optimization of regressors using artificial neural network

Data of input (regressors or independent variables; pre-soaking duration, ultrasonication duration, and ultrasonication temperature) and output variables (dependent variables; individual seedling dry weight and germination percentage) were first arranged consecutively and divided into two learning (70%) and test (30%) parts. Then, they were standardized using the following formula (Rohani et al., 2011):

$$Y_i = 0.8 \times \frac{X_i - X_{min}}{X_{max} - X_{min}} + 0.1 \quad \text{(Eq.1)}$$

where, Y_i represents standardized data, X_i denotes non-standardized data, X_{min} stands for the smallest data and X_{max} denotes the largest data. Using this formula, the input data are placed between 0.1 and 0.9. Perceptron multilayer neural network was used in this research. Using QNET software, back propagation algorithm was used for network learning. Various numbers of hidden layers and following four activation (transfer) functions were tested:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11991209

- Sigmoid function:

$$f\left(\sum W_{ij}X_i\right) = \frac{1}{1+e^{-\left(\sum_{i=1;j=1}^{n} W_{ij}X_i\right)}} \quad \text{(Eq. 2)}$$

- Hyperbolic tangent function:

$$f\left(\sum W_{ij}X_i\right) = \frac{e^{\left(\sum_{i=1;j=1}^{n} W_{ij}X_i\right)} - e^{-\left(\sum_{i=1;j=1}^{n} W_{ij}X_i\right)}}{e^{\left(\sum_{i=1;j=1}^{n} W_{ij}X_i\right)} + e^{-\left(\sum_{i=1;j=1}^{n} W_{ij}X_i\right)}} \quad \text{(Eq. 3)}$$

- Hyperbolic secant function:

$$f\left(\sum W_{ij}X_i\right) = \frac{2e^{\left(\sum_{i=1;j=1}^{n} W_{ij}X_i\right)}}{e^{2\left(\sum_{i=1;j=1}^{n} W_{ij}X_i\right)} + 1} \quad \text{(Eq. 4)}$$

- Gaussian function:

$$f\left(\sum W_{ij}X_i\right) = \frac{1}{\sqrt{2\Pi\sigma}} e^{\frac{-\left[\left(\sum_{i=1;j=1}^{n} W_{ij}X_i\right)-\Pi\right]^2}{2\sigma^2}} \quad \text{(Eq. 5)}$$

where W is weight, X regressor, σ standard error, and Π pi value.

For evaluation of efficacy of perceptron neural network in predicting variation of seedling dry weight and germination percentage, the correlation coefficient (r), mean of absolute error (MAE) (eqation 6), root-mean-square error (RMSE) (eqation 7) and relative standard deviation (RSE) (eqation 8) were used:

$$\text{MAE}=\frac{1}{n}\sum_{i=1}^{n}\left|Y_i - \hat{Y}_i\right| \quad \text{(Eq. 6)}$$

$$\text{RMSE}=\sqrt{\frac{1}{n}\sum_{i=1}^{n}\left(Y_i - \hat{Y}_i\right)^2} \quad \text{(Eq. 7)}$$

$$\text{RSE}=\frac{\sqrt{\frac{1}{n}\sum_{i=1}^{n}\left(Y_i - \hat{Y}_i\right)^2}}{Ybar} \quad \text{(Eq. 8)}$$

where, Y_i stands for observed output, Ybar denotes mean of observed output, $\hat{Y}_i$ is estimated output and Ybar stands for mean of observed output. Optimization of the regressors was performed through following three steps (Gholipoor et al., 2012), using QNET software:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11991209

Step 1

Out of the regressors, a regressor (irradiation temperature) with strong relation with seedling dry weight and germination percentage was put in the model as the output. Seedling dry weight and germination percentage were considered as model inputs. Data were randomly arranged in line and divided in to two learning (70%) and (30%) parts. Different scenarios were tested and the superior model was selected for each output variable. Based on the superior model, irradiation temperatures were estimated. Each of these estimated values can be potentially the optimal temperature of irradiation for achieving maximum seedling dry weight and germination percentage. The temperature values within tested temperature range were selected (*Table 1*).

Step 2

Using original and estimated data in previous step, other regressors were individually put in the model as output. Model inputs include seedling dry weight, germination percentage and irradiation temperature. Like previous step, data were divided into two groups, different scenarios were tested and superior model was selected. Using this superior model, output was estimated. The values within the tested values range were selected (*Table 1*).

Step 3

For prediction of seedling dry weight and germination percentage using estimated regressors, the neural network model developed earlier was used. The predicted values of seedling dry weight and germination percentage were presented in *Table 1*.

Table 1. *The values of input layer and output layer obtained during 3 steps of optimization*

Irradiation temperature (°C)	Pre-soaking duration (hour)	Irradiation duration (minute)	Seedling dry weight (mg.seedling^{-1})	Germination percentage
17.09954	2.10646	0.24924	0.21596	87.60438

Results and Discussion

The substantial differences in treatments produced a wide range of variation in the values of the output layer (*Table 2*). For instance, the maximum value of seedling dry weight was almost twice of minimum value; such variations are necessary for successful learning and predicting processes of neural network. Specially, when there is no strong relation ($r>+0.95$) between output variables; the relation of seedling dry weight with germination percentage was 0.34 which confirms the different response of these traits to treatments.

The result of analysis of variance indicated that in addition to simple effects, the double and triple interactive effects of factors pre-soaking duration, temperature regime, and irradiation duration were significant on both seedling dry weight and germination percentage traits (data not shown). This shows that the effect of one factor on these traits tends to be changed with changing the level of other two factors. Such interactive effects, on one hand, and not significant relation between traits, on the other hand, indicate the complicate relation between regressors and output variables. Neural network-based optimization is capable of solving such multi-response complicate problems.

The performance of the MLP tended to improve as the number of hidden neurons increased. However, too many neurons in the hidden layer caused over-fitting problems. This situation allowed good network learning and data memorization but also produced a lack of any ability to generalize. However, the network was unable to learn if a small number of neurons were used in the hidden layer. Usually the number of layers and neurons nodes of hidden layer (s) is typically determined by trial-and-error. The best structure of neural network was 3:4:4:2.

Statistical indices were used for evaluation of neural network models for (1) different activation functions, (2) number of hidden layers, and (3) number of neurons in each hidden layer. Combination of these factors can generate more than 50 scenarios and presenting statistical indices for all of these scenarios provides an unnecessary and bulky table. Therefore, after selection of the best number of hidden layer and neuron number in the hidden layer, only statistical indices for activation functions are presented (*Table 2*). According to these indices, higher accuracy of a neural network is obtained when the model not only has higher coefficient of determination, but also has lower absolute error mean, lower relative standard deviation, and lower root-mean-square error. This is the case for hyperbolic tangent activation function as is evident in *Table 3* and *Figs. 1 and 2*.

Table 2. *Statistical properties of input and output layers of neural network model*

Input+output	Range	Mean	Maximum	minimum
Irradiation temperature (°C)	15.0000	24.5758	32.0000	17.0000
Pre-soaking duration (hour)	10.0000	6.3434	12.0000	2.0000
Irradiation duration (minute)	12.0000	6.0303	12.0000	0.0000
Seedling dry weight (mg. seedling^{-1})	0.2601	0.2966	0.4056	0.1905
Germination percentage	23.3333	90.2862	100.0000	76.6667

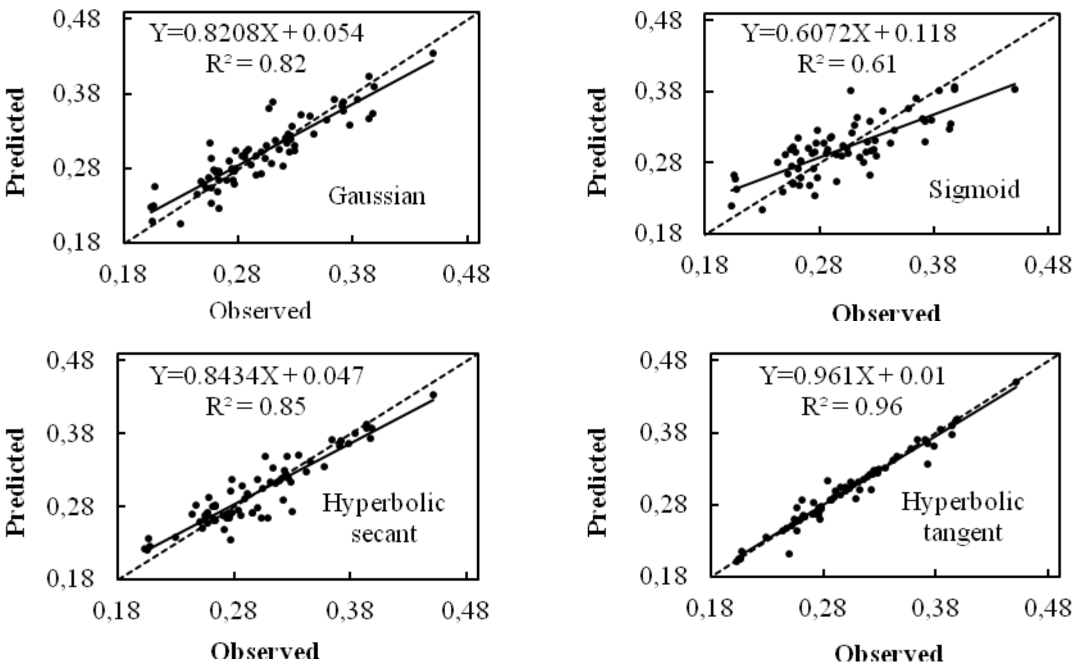

Figure 1. *Sensitivity analysis of neural network using four activation functions for prediction of seedling dry weight of red bean in learning phase*

Optimization results indicated that the highest germination percentage and seedling growth optimized by neural network were 100% and 0.48892 g, respectively (*Table 1*), which is about 19% higher than the observed maximum dry weight of seedling. These values were obtained under treatment with irradiation temperature of 26.99 °C,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_11991209

irradiation duration of 5.91 minutes and pre-soaking for 3.20 hours. This combination resulting from neural network is different from treatment combination in routine analyses (temperature of 32 ^oC, pre-soaking for 12 hours and irradiation duration of 12 minutes).

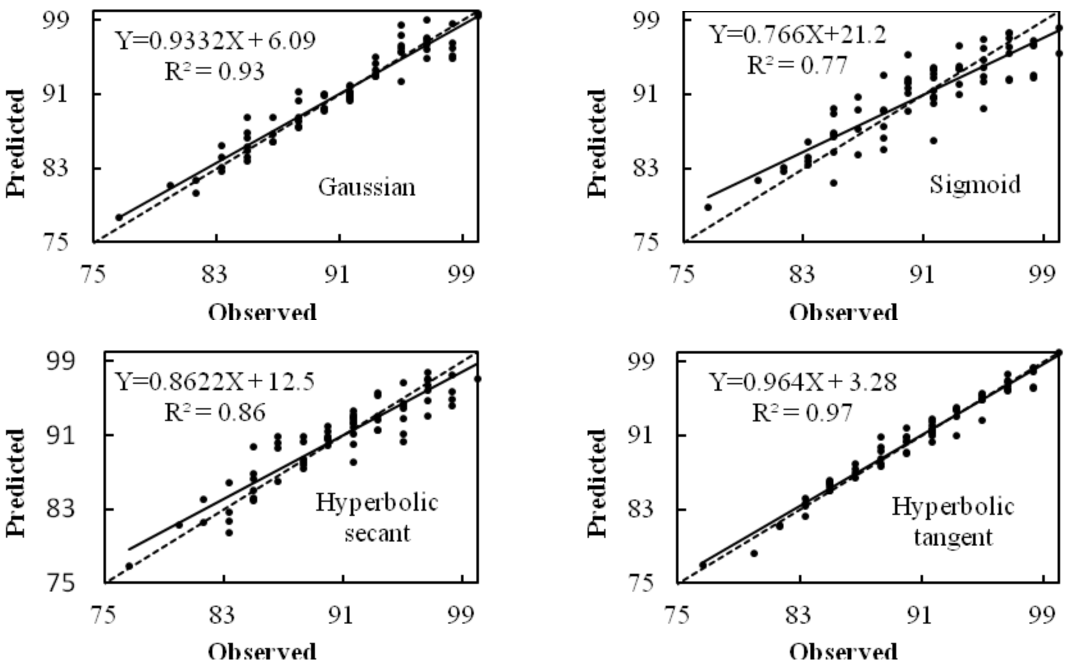

Figure 2. *Sensitivity analysis of neural network using four activation functions for prediction of germination percentage of red bean in learning phase*

The best irradiation level obtained here for *Phaseolus vulgaris* L. , 5.91 minutes, is similar to 6 minues for *Capsicum annuum* L. and *Rhaphanus sativus* L. (Faryabi et al., 2008), but inconsistent with 4 minutes for *Assa foetida* L. (Abdali et al., 2010). Such differences or similarities imply the expectedly direct relation between hardness of seed coat and exposure duration; in another words, the exposure duration is highly dependent on texture of seed covers. This is because of the fact that the machanical impact of ultrasound is higher than other priming methods like hydro priming, hormon priming, and magnetic field (Majd et al., 2010), as ultrasonication could fragment the seed shell and produce larger porosity on the surface of seeds by captivation of ultrasound (shock waves). Shell fragmentation and enlargement of the pore size of seeds lead to more water retention capacity in dry grains and result in better hydration (Yaldagard et al., 2008).

Table 3. *Statistical indices of various transfer functions*

Transfer function	Dependent variable	RMSE	MAE	RSE	r
Gaussian	Seedling dry weight	0.00567	0.01645	0.01889	0.90550
	Germination percentage	0.04410	1.06378	0.00049	0.96424
Sigmoid	Seedling dry weight	0.00788	0.02642	0.02626	0.78187
	Germination percentage	0.14344	2.03956	0.00158	0.87762
Hyperbolic tangent	Seedling dry weight	0.00191	0.00570	0.00636	0.98012
	Germination percentage	0.11125	0.67271	0.00123	0.98508
Hyperbolic secant	Seedling dry weight	0.00013	0.01521	0.00045	0.92348
	Germination percentage	0.04628	1.55737	0.00051	0.92583

Regarding contribution of regressors in explaining variation of seedling dry weight and germination percentage, irradiation temperature, irradiation duration and pre-soaking duration have the higher priority, respectively; however their difference was not considerable (*Fig. 3*). This result indicates importance of all the three factors and implies that ignoring one factor may result in unfavorable result. This is an exact and unique property of neural network for optimization (Kashi et al., 2013; Huang et al., 2010; Green et al., 2007; Park et al., 2005; Kaul et al., 2005). There is no published report about relative importance of these factors. Regarding different response of plant species to irradiation it is necessary to study impressionability of other species from these factors.

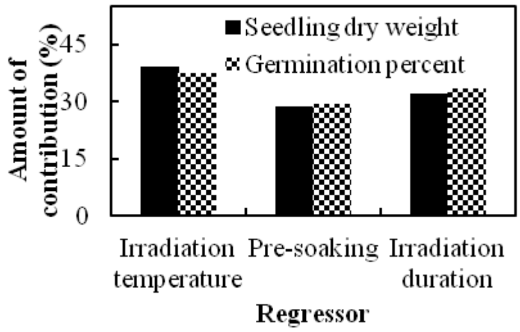

Figure 3. *Contribution of regressors in explaining variation of seedling dry weight and germination percentage*

If ultrasonication is used at optimal conditions (temperature and pre-soaking duration), it will provide positive effects. Irradiation effects result from cavitation phenomenon which causes alteration in cell membrane (Bommannan et al., 1992). One of the reasons for positive effect of ultrasonication on seedling dry weight might be due to reduction in soaking time, as it has been reported for chickpeas (Yildirim et al., 2010), sorghum (Patero and Augusto, 2014) and navy beans (Ghafoor et al., 2015). This improvement has been attributed to a greater reduction of internal resistance than external resistance (Cunningham et al., 2008), as well as possible changes in microstructure by cavitation (micro-channel formation) and/or the so called "sponge effect", causing inertial flow (Patero and Augusto, 2014). The enhanced movement of liquid medium, increase of mass transfer among the organelles within cells and enhanced rate of biochemical reactions are also regarded as the positive effects of irradiation (Bar, 1998).

Conclusion

The results indicated that seedling dry weight and germination percentage tend to differ in terms of response to treatment level (combination of temperature regime, pre-soaking and irradiation duration), as their correlation was not significant. Therefore, selecting each level of treatment does not necessarily increase both traits. Therefore, interpolation of treatment level for possible simultaneous increase in both seedling dry weight and germination percentage, say optimization, was carried out to solve the problems. The optimized values of treatment levels (ultrasonication

DOI: http://dx.doi.org/10.15666/aeer/1504_11991209

components) were temperature of 26.99 °C, irradiation duration of 5.91 minutes and pre-soaking for 3.20 hours. This procedure could be used in all agricultural researches in which the multi-response investigations, like response of grain yield and grain protein content, are common.

(Received 27th Apr 2017; accepted 1st Aug 2017)

Abstract. Boron-tolerant bacteria fall in the category of extremophilic organisms as they have the ability to survive in high boron environments. Such bacterial species needs to be characterized to identify new extremophilic organisms from the ecology for biotechnological benefits. In this study, five boron-tolerant bacterial strains, designated as NCCP-132, NCCP-133, NCCP-134, NCCP-135 and NCCP-136 were isolated from sewage sludge treatment pond of Islamabad, Pakistan. These strains grew on media containing 200 to more than 450 mM of boron concentration. However, the microbial growth is found high at low boron concentration. The isolated boron-tolerant bacterial strains were either extremely boron-tolerant or moderately boron-tolerant. The 16S rRNA gene sequences and phylogenetic analyses delineated that all strains were found to be closely related to species belonging to different genera: *Bacillus, Oceanobacillus* and *Lentibacillus*. Strains NCCP-132, NCCP-134 and NCCP-135 are found to be novel species, while NCCP-133 and NCCP-136 are revealed to be previously identified bacterial species. Morphological, physiological and biochemical characteristics of these strains were studied at their optimal growth conditions. Our study inferred that the sewage treatment pond of Islamabad, Pakistan is rich in boron-tolerant extremophilic bacterial population with diverse bacterial communities having a potential to be utilized in various biotechnological applications in future.
Keywords: *boron, 16S rRNA, phylogeny, Bacillus, Lentibacillus, Oceanobacillus*

Introduction

Boron is concentrated in the earth's crust in the form of borate minerals. The largest known boron deposits have been found in Turkey (Col and Col, 2003). Microbes, plants and animals require boron as micronutrient for their growth (Stanier et al., 1966; Goldbach et al., 2010), but the level of required concentration varies among different organisms (Saleem et al., 2011). Boron in lesser concentration has been declared useful for the treatment of candidal vulvovaginitis (Swate and Weed, 1974; Otero et al., 2002), food preservation against different microbes (Nielsen, 2004), and an insecticide against cockroaches (Cochran, 1995). Although boron is an essential micronutrient but a very

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_12111226

narrow range exists between its sufficiency and toxicity (Nable et al., 1997). Boron toxicity to microbes, plants and animals usually cause growth retardation and deleterious effects on reproductive functions (Col and Col, 2003). In contrary, boron essentiality has been considered good for growing specific types of bacteria such as *Bacillus boroniphilus* (Ahmed et al., 2007a).

Extremophilic organisms possess great capacity to inhabit hostile conditions of salinity, drought, temperature, radiation, etc. (Rampelotto, 2010). During the last decade, boron toxicity has been studied as a new frontier in extremophiles and several novel species have been reported as tolerant to toxic concentrations of boron (Ahmed et al., 2007a, 2007b, 2007c, 2007d). Few bacterial species like *Bacillus boroniphilus, Gracilibacillus boraciitolerans, Chimaereicella boritolerans, Lysinibacillus boronitoleran, Variovorax boronicumulans, Lysinibacillus parviboronicapiens*, have shown various levels of boron tolerance (Ahmed et al., 2007a, 2007b, 2007c, 2007d; Miwa et al., 2008, 2009). *Bacillus boroniphilus* can tolerate >450 mM of boron but also it is reported to require boron for its normal growth. Some strains are reported to accomulate boron in their cells (Miwa et al., 2008, 2009) and found to be comparatively low in boron-tolerance. Boron-tolerant bacterial species maintain lower boron concentration in cells by an efflux mechanism (Ahmed and Fujiwara, 2010). These findings can be exploited for their applications in biotechnology.

Boron-tolerant bacteria needs to be explored in different ecologies worldwide, such as in salt mines and sewage treatment ponds. The objective of current study was to isolate and identify novel boron-tolerant bacterial strains from Pakistani ecology. These studies comprised of isolation and identification of boron-tolerant bacteria using 16S rRNA gene sequencing, and their phenotypic characteristics including morphological, physiological and biochemical characterization. The findings of these studies may provide useful information for basic and applied sciences under extreme conditions of elemental boron toxicity.

Materials and methods

Sample Collection

Samples for isolation of boron-tolerant bacterial strains were collected in sterile bottles from sewage treatment pond of Sector I-9/1, Islamabad, Pakistan (location is shown in *Figure 1*) and then stored at 4°C until isolation of strains.

Isolation and Enrichment

Procedures of isolation and enrichment of cultures were performed to recover boron-tolerant bacterial strains on tryptic soy agar (TSA, Difco^{TM}) medium. Serial dilution of samples was carried out in phosphate buffer saline (PBS) in an appropriate volume. The diluted samples were streaked on TSA medium containing 50 mM boron and incubated at 28 °C for 2-3 days. Isolated strains were sub-cultured many times under similar conditions. Later on, the pure cultures of morphologically different bacteria were obtained and used for further characterization. All of isolated strains were preserved at 4 °C, and also in glycerol (35 % w/v) stocks at -80 °C.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_12111226

Growth Optimization

Growth conditions of isolated strains were evaluated at different pH (4.0-10.0), temperature (4-50 °C), and NaCl [0-16 % (v/v)] by allowing bacterial strains to grow in a shaking incubator at 28 °C for 2-5 days. TSB medium was used for optimization of growth conditions at OD_{600}.

Morphological Observation

Morphological observations and comparisons were made using microbiological standard. Bergey's manual was used to characterize pure bacterial colonies on the basis of color, shape, margin, elevation, texture, size, etc. Gram staining and visualization of colony morphology of pure bacterial strains was done by light microscope (Nikon E600, Japan).

Boron-tolerance Assay

Boron-tolerance of each strain was performed by growing the bacterial strains at 28 °C in a shaking incubator using tryptic soy broth (TSB; Bacto^{TM}) medium containing various concentrations of boron from 0-450 mM. Bacterial growth was evaluated using spectrophotometer at 600 nm (OD_{600}) for 3-7 days.

Identification using 16S rRNA Gene Sequencing

Genomic DNA extraction was performed following Ahmed et al. (2007a). It involved suspension of 2-3 well isolated bacterial colonies in 20 µL of Tris EDTA (TE) buffer in a micro-PCR tube. After heating the cells at 95 °C for 10 min, centrifugation was carried out at 6000 rpm for 2-3 min. The pellet was discarded and the supernatant obtained was used as a template DNA for amplification of 16S rRNA gene. Polymerase chain reaction (PCR) was performed using 9F (5'-GAGTTTGATCCTGGCTCAG-3') and 1510R (5'-GGCTACCTTGTTACGA-3') primers and PreMix ExTaq (Takara, Japan) to amplify the 16S rRNA gene of the isolated strains according to previous protocol (Ahmed et al., 2007a) using ABI Veriti PCR Machine (Applied Biosystems, USA) with the optimized PCR program, i.e., initial denaturation at 94 °C for 2 min, 30 cycles of denaturation at 94 °C for 1 min, annealing at 50 °C for 1 min, extension at 72 °C for 1:30 min, and final extension at 72 °C for 5 min. Amplification of 16S rRNA gene was confirmed on 0.8% agarose gel. Documentation system (UVIPro Platinum, England) was used for viewing the DNA image. The purification and sequencing of amplified PCR products was performed using 27F (5'-AGAGTTTGATCMTGGCTCAG-3') and 1492R (5'-ACCTTGTTACGACTT-3') primers and commercial service of Macrogen Inc. Korea (www.dna.macrogen.com).

Phylogenetic Analysis

Sequences were aligned using Clustal X software and the fragment sequences of 16S rRNA gene were assembled by BioEdit. Later on, 16S rRNA gene sequences were submitted to DDBJ (http://www.ddbj.nig.ac.jp/) (*Table 1*). Bacterial strains were identified by BLAST search using 16S rRNA gene sequences. Ez-Taxon server was used to retrieve the sequences of closely related type strains in order to construct phylogenetic trees. MEGA software Version 7 was used for phylogenetic and molecular evolutionary analyses.

Biochemical Characterization

Biochemical analysis of the isolated strains was performed using API ZYM, API 20E and API 50CH (bioMérieux, France) according to the manufactured protocols, whereas oxidase and catalase tests were performed according to the procedure of Cowan and Steel (2004). The suspension medium of API was utilized for inoculation of strips in all tests. API ZYM test was conducted for elucidation of enzymatic activities, and API 50CH strips were used for carbohydrate utilization and other biochemical analysis.

Results and Discussion

Isolation and Identification of Boron-tolerant Bacteria

The bacterial strains isolated from sewage treatment pond (shown in *Figure 1*) were found extremely and moderately boron-tolerant (tolerated up to 450 mM of boron). This site was selected for sampling because it is reported that sewage treatment ponds are rich in bacteria that can grow in environment having high concentrations of boron element. A total of five bacterial strains were isolated because it is recommended that the number of strains studied for each taxon should be at least five, and ideally ten or more; observations on a minimum of three strains are necessary to have some indication of natural variability (Logan et al., 2009). This difference in strains could be due to the environmental changes occurring in different sites of the sewage treatment pond.

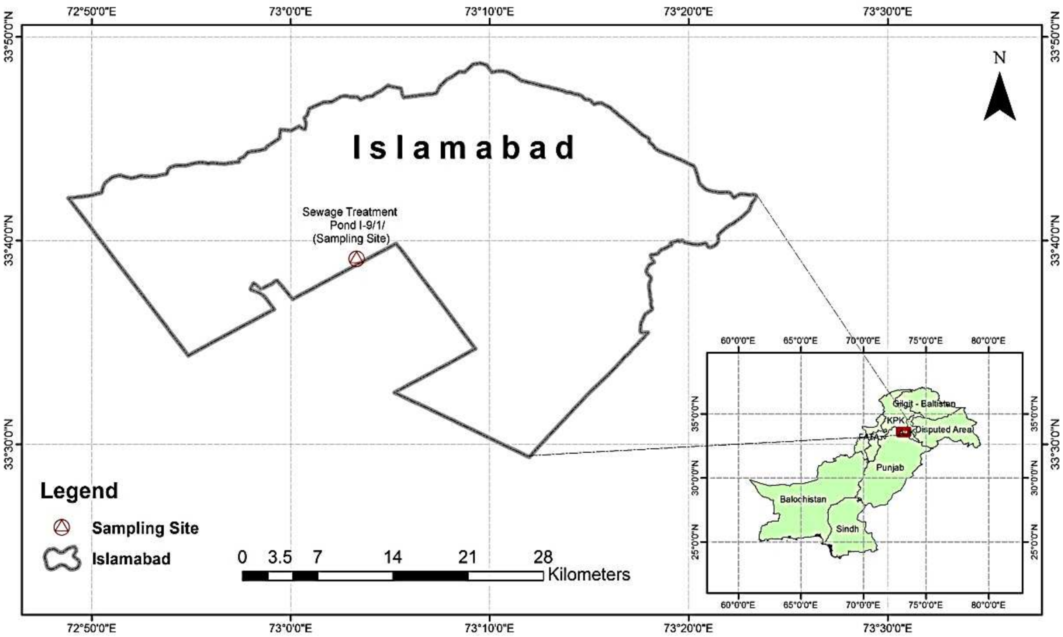

Figure 1. *Map of Pakistan showing sampling site of Islamabad.*

Taxonomic identification of five bacterial isolates was conducted by using the robust method of 16S rRNA gene sequencing (*Table 1*). Thereafter, the phylogenetic position of each strain was determined by the construction of phylogenetic trees (*Figures 1 and 2*). Phylogenetic analysis delineated that the isolated strains belonged to *Virgibacillus*, *Oceanobacillus,* and *Bacillus* (*Table 1*). Two out of five strains (belonging to genus

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_12111226

Bacillus) shared > 97 % identity with their closest phylogenetic relatives. These result showed that NCCP-133 and NCCP-136 may belong to the known species of *Bacillus oceanisediminis* H2^T (GQ292772) and *Bacillus oryzaecorticis* R1^T (KF548480), respectively, whereas the other three strains (belonging to genera *Bacillus, Virgibacillus* and *Oceanobacillus*) sharing < 97 % sequence similarity confirmed that these strain belong to new species, however further taxonomic characterization experiments need to be performed to delineate these strains as novel species.

Table 1. *Identification of isolated boron-tolerant bacterial strains based on 16S rRNA gene sequence and their accession numbers published in DNA database.*

Strain ID	Strain / Genus	No. of nucleotides of 16S rRNA gene	Accession No. of 16S rRNA gene	Closely related validly published species	Sequence similarity (%) of 16S rRNA gene
NCCP-132	*Bacillus* sp.	1557	AB562920	*Bacillus pakistanensis* NCCP-168^T (AB618147)	96.66
NCCP-133	*Bacillus* sp.	1477	AB562921	*Bacillus oceanisediminis* H2^T (GQ292772)	99.35
NCCP-134	*Ornithinibacillus* sp.	1538	AB562922	*Ornithinibacillus contaminans* CCUG 53201^T (FN597064)	96.41
NCCP-135	*Oceanobacillus* sp.	1499	AB562923	*Oceanobacillus profundus* CL-MP28^T (DQ386635)	96.75
NCCP-136	*Bacillus* sp.	1436	AB562924	*Bacillus oryzaecorticis* R1^T (KF548480)	98.00

Phylogenetic Analysis of Identified Strains

The strains NCCP-132, NCCP-133 and NCCP-136 belong to genus *Bacillus* based on 16S rRNA gene sequence data as depicted in the phylogenetic tree (*Figure 2*). Strain NCCP-132 showed 96.66 % similarity with *Bacillus pakistanensis* NCCP-168^T (*Table 1*), whereas NCCP-133 and NCCP-136 have sequence similarity of 99.35 % and 98.0 % with *Bacillus oceanisediminis* H2^T and *Bacillus oryzaecorticis* R1^T, respectively. Based on 16S rRNA gene sequence data, the strains NCCP-134 and NCCP-135 belonged to genera *Ornithinibacillus* and *Oceanobacillus* (*Figure 3*) and showed sequence similarity of 96.41 % and 96.75 % with *Ornithinibacillus contaminans* CCUG 53201^T (FN597064) and *Oceanobacillus profundus* CL-MP28^T (DQ386635), respectively. As the similarity with pre-identified species was less than 97 %, suggesting these two strains can be further studied taxonomically to delineate these strains as novel species.

The G+C content of the DNA of the type strain should be determined by high performance liquid chromatography (HPLC) and is recommended for the description of novel species, and essential for the description of new genera (Logan et al., 2009). As identical or highly similar 16S rRNA gene sequences do not guarantee species identity, DNA-DNA hybridization is essential in case of species description when 16S rRNA gene sequences of the novel strains show < 97 % or less similarity with existing taxa. Several widely used methods do not allow the determination of thermal stability (expressed as ΔTm) of the hybrid, but differences in ΔTm between the hybrid and the homologous duplex are important and can be decisive for taxonomic conclusions. Hence, determination of ΔTm is recommended (Logan et al., 2009).

Nucleic acid fingerprinting is also recommended because DNA fingerprinting methods provide information at the subspecies and strain level. Examples are amplified fragment-length polymorphism (AFLP) analysis, macrorestriction analysis after pulsed-field gel electrophoresis (PFGE), random amplified polymorphic DNA (RAPD) analysis, rep-PCR (repetitive element-primed PCR, directed to naturally occurring, highly conserved, repetitive DNA sequences, present in multiple copies in the genome), including REP-PCR (repetitive extragenic palindromic-PCR), ERIC-PCR (enterobacterial repetitive intergenic consensus sequences PCR), BOX-PCR (derived from the boxA element) and $(GTG)_5$-PCR, and ribotyping (Logan et al., 2009). DNA-DNA hybridization study, together with DNA fingerprinting and 16S rRNA sequence analysis clearly demonstrate the strains to be novel or already identified and more work has to be done on the phenotypic and genotypic level.

Colony Morphology of Bacterial Strains

The isolated five bacterial strains were grown at 28 °C for 3 days on TSA medium containing 100 mM boron concentration. Phase-contrast microscopy showed colony morphology of isolated strains. Gram staining of bacterial isolates was also performed (*Table 2*). Colonial pigmentation of the isolates included pale yellow, creamy and orange coloration. The colonies were round and punctiform in shape and circular in form. Colony surfaces were smooth and margins were entire. Colonies had raised, flat, and convex elevations. The colonies possessed moist and mucoid texture, whereas the opacity of colonies was found to be translucent and opaque.

Table 2. *Colony morphology of bacterial strains observed 3 days after inoculation and incubation at 28 °C. The medium used was Tryptic Soy Agar (TSA) containing 100 mM boron.*

Phase-contrast microscopy at x1000 magnification is superior to bright-field microscopy of stained smears, including spore staining, and is much more convenient (Logan et al., 2009). Electron microscopy could be done to reveal additional morphological information like flagellation, and sporangial appearance could also be checked.

Optimization of growth conditions for all strains was carried out regarding pH, temperature and NaCl tolerance (*Table 3*). The boron-tolerant bacterial strains were found to grow best at 7-9 pH, 16-37 °C temperature and 0-4% (v/v) NaCl concentration. All bacterial isolates were oxidase and catalase positive as well as Gram-positive. Positive, negative, weakly positive, moderately positive, and strongly positive observations were recorded via tests of API ZYM and API 50CH kits (*Table 4a, b*).

Table 3. *Physiological characteristics of boron tolerant isolated bacterial strains.*

Optimization of Conditions for Bacterial Growth and Biochemical Characterization

Chemotaxonomic fingerprinting techniques applied to aerobic endospore-formers include fatty acid methyl ester (FAME) profiling, PAGE analysis of whole-cell proteins, polar lipid analysis, quinone content, cell-wall diamino acid content, pyrolysis mass spectrometry, Fourier-transform infrared spectroscopy, Raman spectroscopy and matrix-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_12111226

assisted laser desorption/ionization-time-of-flight (MALDI-TOF) mass spectrometry. Fatty acid profiles are very useful in descriptions of new taxa, and it is recommended that the fatty acid profile should be available and the minor compounds that are characteristics of a novel taxon should be stated in the description (Logan et al., 2009).

Description of NCCP-132 and NCCP-136

Phylogenetic analysis revealed that NCCP-132 and NCCP-136 belong to the *Bacillus* genus, and are similar to *B. marisflavi*, *B. aquimaris* and *B. vietnamensis*, based on comparison of 16S rRNA gene sequence. On TSA medium, colonies of NCCP-132 are cream in colour, round, circular, smooth, having entire margins, having convex surface, moist, translucent and 2.5mm in size after 3 days at 28 °C. Cells are gram-positive, catalase-positive and oxidase-positive. In API ZYM gallery, alkaline phosphatase, esterase, esterase lipase, lipase, trypsin, acid phosphatase and β-glucuronidase tests are negative. Leucine arylamidase, valine arylamidase, cystine arylamidase, α-chymotrypsin, α-galactosidase, β-galactosidase, α-glucosidase, β-glucosidase, N-acetyl-β-glucosaminidase, α-mannosidase, α-fucosidase tests are weakly positive. Naphthol-AS-B1-phosphohydrolase test is strongly positive. In API 50CH gallery, glycerol, erythritol, D-arabinose, L-arabinose, D-ribose, D-xylose, D-adonitol, methyl-βD-xylopyranoside, D-galactose, D-glucose, D-fructose, D-mannose, L-sorbose, L-rhamnose, dulcitol, inositol, D-mannitol, D-sorbitol, methyl-αD-mannopyranoside, methyl-αD-glucopyranoside, N-acetylglucosamine, amygdalin, arbutin, esculin, salicin, D-cellobiose, D-maltose, D-lactose, D-melibiose, D-saccharose, D-trehalose, inulin, D-melezitose, D-raffinose, amidon, glycogen, xylitol, gentiobiose, D-turanose, D-lyxose, D-tagatose, D-fucose, L-fucose, D-arabitol, L-arabitol, potassium gluconate, potassium-2-ketogluconate tests are negative. Potassium-5-ketogluconate test is positive. Optimum boron concentration needed for growth is 0mM and boron range for growth is 0-450 mM. Optimum growth pH is 7.0, thus, neutrophilic. pH range for growth is 7.0-8.0. Optimum growth temperature is 37 °C, thus, mesophilic. The temperature range for growth is 10-45 °C. Optimum NaCl concentration needed for growth is 0-2 %, thus, slightly halotolerant. The growth range for NaCl concentration is 0-3 %.

On TSA medium, colonies of NCCP-136 are orange in colour, punctiform, circular, smooth, having entire margins, having raised surface, moist, opaque and 1.0mm in size after 3 days at 28°C. Cells are gram-positive, catalase-positive and oxidase-positive. In API ZYM gallery, alkaline phosphatase, esterase, esterase lipase, lipase, trypsin, acid phosphatase, leucine arylamidase, α-galactosidase, β-galactosidase, naphthol-AS-B1-phosphohydrolase, α-mannosidase, α-fucosidase, N-acetyl-β-glucosaminidase, α-glucosidase, β-glucosidase and β-glucuronidase tests are negative. Valine arylamidase, cystine arylamidase, α-chymotrypsin tests are weakly positive. In API 50CH gallery, glycerol, erythritol, D-arabinose, L-arabinose, D-ribose, D-xylose, D-adonitol, methyl-βD-xylopyranoside, D-galactose, D-glucose, D-fructose, D-mannose, L-sorbose, L-rhamnose, dulcitol, inositol, D-mannitol, D-sorbitol, methyl-αD-mannopyranoside, methyl-αD-glucopyranoside, N-acetylglucosamine, amygdalin, arbutin, esculin, salicin, D-cellobiose, D-maltose, D-lactose, D-melibiose, D-saccharose, D-trehalose, inulin, D-melezitose, D-raffinose, amidon, glycogen, xylitol, gentiobiose, D-turanose, D-lyxose, D-tagatose, D-fucose, L-fucose, D-arabitol, L-arabitol, potassium gluconate, potassium-2-ketogluconate and potassium-5-ketogluconate tests are negative. Optimum boron concentration needed for growth is 0mM and boron range for growth is 0-200mM. Optimum growth pH is 8.5, thus, alkaliphilic. pH range for growth is 7.0-9.0. Optimum

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

growth temperature is 28-37°C, thus, mesophilic. The temperature range for growth is 10-45°C. Optimum NaCl concentration needed for growth is 0%, thus, non-halotolerant. The growth range for NaCl concentration is 0-7%.

Description of NCCP-133

Phylogenetic analysis revealed that NCCP-133 belongs to the *Bacillus* genus, and is similar to *B. firmus*, based on comparison of 16S rRNA gene sequence. On TSA medium, colonies of NCCP-133 are yellow in colour, round, circular, smooth, having entire margins, having raised surface, mucoid, translucent and 1.5mm in size after 3 days at 28°C. Cells are gram-positive, catalase-positive and oxidase-positive. In API ZYM gallery, alkaline phosphatase, esterase, esterase lipase, lipase, trypsin, acid phosphatase, leucine arylamidase, valine arylamidase, α-galactosidase, β-galactosidase, naphthol-AS-B1-phosphohydrolase, α-mannosidase, α-fucosidase, N-acetyl-β-glucosaminidase, α-glucosidase, β-glucosidase and β-glucuronidase tests are negative. Cystine arylamidase and α-chymotrypsin tests are weakly positive. In API 50CH gallery, glycerol, erythritol, D-arabinose, L-arabinose, D-ribose, D-xylose, D-adonitol, methyl-βD-xylopyranoside, D-galactose, D-glucose, D-fructose, D-mannose, L-sorbose, L-rhamnose, dulcitol, inositol, D-mannitol, D-sorbitol, methyl-αD-mannopyranoside, methyl-αD-glucopyranoside, N-acetylglucosamine, amygdalin, arbutin, esculin, salicin, D-cellobiose, D-maltose, D-lactose, D-melibiose, D-saccharose, D-trehalose, inulin, D-melezitose, D-raffinose, amidon, glycogen, xylitol, gentiobiose, D-turanose, D-lyxose, D-tagatose, D-fucose, L-fucose, D-arabitol, L-arabitol, potassium gluconate, potassium-2-ketogluconate and potassium-5-ketogluconate tests are negative. Boron range for growth is 0-450mM. Optimum pH is 8.5-9.0, thus, alkaliphilic. pH range for growth is 7.0-9.0. Optimum temperature is 16-32°C, thus, psychrophilic and mesophilic. The temperature range for growth is 10-45°C. Optimum NaCl concentration is 0-4%, thus moderately halotolerant. The growth range for NaCl concentration is 0-5%.

Description of NCCP-134

Phylogenetic analysis revealed that NCCP-134 belongs to *Lentibacillus* genus, and is similar to *L. garicola*, based on comparison of 16S rRNA gene sequence. On TSA medium, colonies of NCCP-134 are cream in colour, punctiform, circular, smooth, having entire margins, having flat surface, mucoid, translucent and 0.5mm in size after 3 days at 28°C. Cells are gram-positive, catalase-positive and oxidase-positive. In API ZYM gallery, esterase, lipase, trypsin, leucine arylamidase, valine arylamidase, naphthol-AS-B1-phosphohydrolase, α-galactosidase, α-glucosidase, β-glucosidase, α-mannosidase, α-fucosidase and β-glucuronidase tests are negative. Alkaline phosphatase and N-acetyl-β- glucosaminidase tests are strongly positive. Esterase lipase test is weakly positive. Cystine arylamidase, α-chymotrypsin and β-galactosidase tests are moderately positive. In API 50CH gallery, erythritol, D-arabinose, D-xylose, L-xylose, D-adonitol, methyl-βD-xylopyranoside, D-galactose, L-sorbose, L-rhamnose, dulcitol, inositol, methyl-αD-mannopyranoside, methyl-αD-glucopyranoside, amygdalin, arbutin, D-maltose, D-lactose, D-saccharose, D-trehalose, inulin, D-melezitose, D-raffinose, amidon, glycogen, xylitol, gentiobiose, D-turanose, D-lyxose, D-fucose, L-fucose, potassium-2-ketogluconate tests are negative. Glycerol, L-arabinose, D-ribose, D-glucose, D-fructose, D-mannose, D-mannitol, D-sorbitol, N-acetylglucosamine, salicin, D-cellobiose, D-tagatose, D-arabitol, L-arabitol and potassium gluconate tests are weakly positive. D-melibiose test is positive. Esculin test is strongly positive. Optimum

boron concentration needed for growth is 0mM and boron range for growth is 0-450mM. Optimum pH is 8.0, thus, alkaliphilic. pH range for growth is 7.0-8.0. Optimum temperature is 37°C, thus, mesophilic. The temperature range for growth is 10-37°C. Optimum NaCl concentration is 0%, thus, non-halotolerant. The growth range for NaCl concentration is 0-14%.

Description of NCCP-135

Phylogenetic analysis revealed that NCCP-135 belongs to the *Oceanobacillus* genus, and is similar to *O. profundus*, based on comparison of 16S rRNA gene sequence. On TSA medium, colonies of NCCP-135 are yellow in colour, round, circular, smooth, having entire margins, having raised surface, moist, translucent and 1.0mm in size after 3 days at 28°C. Cells are gram-positive, catalase-positive and oxidase-positive. In API ZYM gallery, alkaline phosphatase, esterase, lipase, acid phosphatase, trypsin, valine arylamidase, naphthol-AS-B1-phosphohydrolase, α-galactosidase, α-glucosidase, β-glucosidase, α-fucosidase and β-glucuronidase, β-galactosidase tests are negative. Esterase lipase and leucine arylamidase, α-mannosidase, N-acetyl-β-glucosaminidase tests are weakly positive. Cystine arylamidase, α-chymotrypsin and tests are moderately positive. In API 50CH gallery, glycerol, L-arabinose, D-ribose, D-glucose, D-fructose, D-mannose, D-mannitol, D-sorbitol, esculin, salicin, D-melibiose, erythritol, D-arabitol, L-arabitol, potassium gluconate, D-arabinose, D-xylose, D-adonitol, methyl-βD-xylopyranoside, D-galactose, L-sorbose, L-rhamnose, dulcitol, inositol, methyl-αD-mannopyranoside, methyl-αD-glucopyranoside, amygdalin, arbutin, D-maltose, D-lactose, D-saccharose, D-trehalose, inulin, D-melezitose, D-raffinose, gentiobiose, D-turanose, D-lyxose, D-fucose, L-fucose, L-xylose potassium-2-ketogluconate tests are negative. Potassium-5-ketogluconate, D-cellobiose, D-tagatose, amidon, glycogen, xylitol and tests are weakly positive. N-acetylglucosamine test is positive. Optimum boron concentration needed for growth is 0-50 mM and boron range for growth is 0-450mM. Optimum pH is 8.0, thus, alkaliphilic. pH range for growth is 5.0-9.0. Optimum temperature is 37 °C, thus, mesophilic. The temperature range for growth is 10-37°C. Optimum NaCl concentration is 1-2%, but its tolerance to NaCl ranges 0-14%, thus, slightly halotolerant.

Conclusion

Bacterial isolates having high biological diversity were found from the sewage samples taken from different sites of sewage treatment pond. Biological diversity is evident from the data depicting morphology of these isolates. As phenotypic characterization was not enough for microbial identification so different factors like pH, temperature and NaCl were optimized for growing boron-tolerant bacteria. Furthermore, biochemical testing showed different biochemical properties of bacterial isolates. However, the accurate taxonomic position of bacterial strains was confirmed by the conventional method for microbial identification, i.e., phylogenetic analysis using comparative sequence analysis of 16S rRNA gene. Out of the five bacterial isolates, four were highly boron-tolerant and one was moderately boron-tolerant strain. NCCP-133 and NCCP-136 were found to be pre-identified strains as these shared > 97 % similarity of 16S rRNA gene sequence with their closest relatives. NCCP-132 (*Bacillus* sp.), NCCP-134 (*Lentibacillus* sp.) and NCCP-135 (*Oceanobacillus* sp.) were found to be novel species based on phylogenetic analysis, however further taxonomic

DOI: http://dx.doi.org/10.15666/aeer/1504_12111226

characterization particularly chemotaxonomic profiling is required to meet the minimum standards for delineation of these isolates as a novel species.

The present study is the first study from Pakistan exploring a new aspect of extremophiles. Finding out the boron tolerance and essentiality level for novel bacterial strains would provide a genetic resource to identify the genes responsible for mechanisms of boron-tolerance and boron-requirement in bacteria. Gene identification would help in the successful management of boron in agriculture and such genes might be useful for cloning in other organisms especially the crop species that are grown on high boron soils. Moreover, it will provide information to study the biochemistry of boron in living cells.

Abstract. The objective of this work was to characterize the seasonal variation in the community of Histerid beetles (Histeridae) of different ecosystems in the Brazilian Amazon, ranging from primary or secondary forests with different stages of regeneration to cocoa farms and pastures. Pitfall traps were distributed within the monitored ecosystems during different periods of the year. A total of 1945 Histerid beetles, belonging to five genera and 14 species were captured. Higher diversities were observed during the rainy season, although with differences among ecosystems. The genera *Phelister* and *Hister* were ubiquitous in all ecosystems, constituting 71% of all the specimens captured. Histerid beetle communities, discriminated by ordination methods, change gradually from the most conserved ecosystems to more disturbed ones. Moreover, the results showed that disturbed ecosystems, namely cocoa farms and pastures, have detrimental effects on the occurrence of Histerid beetles, which are considered forest specialists, while enhancing generalist species.
Keywords: *Amazon rainforest, biodiversity, soil insect, fluctuation, tropical forest*

Introduction

Currently, there is enormous concern and speculation about the effects of anthropogenic disturbance on the biodiversity of tropical ecosystems, including the effects on species composition and the modifications in the ecological services provided (e.g. Morris, 2010; Aerts and Honnay, 2011; Cajaiba et al., 2017a). Deforestation in the Neotropics, particularly in the Brazilian Amazon (Amazonia), has been causing a sharp erosion of biodiversity and disruption of the complex global climate phenomena (e.g. Hassan et al., 2005; Morris, 2010). Therefore, the conservation of the Amazonian ecosystems represents a growing core challenge for sustaining earth´s functioning and ultimately that of mankind (e.g. Viana and Pinheiro, 1988; Viegas et al., 2014).

Predicting the ecological consequences of land use/land cover (LU/LC) changes is therefore a subject of scientific and political interest in order to support strategic options for sustainable development, land use planning and natural resources management

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_12271237

(Turner et al., 2007). In this context, ecological assessment and monitoring are important tools to support effective management of ecosystems and natural resources, in which the use of pertinent indicators is crucial for measuring and evaluating the status and trends of target environmental systems (Cajaiba and Silva, 2017).

Ecological integrity is a key concept in natural resource management, and researchers have been trying to improve public understanding of this concept by using simple scientific measures known as ecological indicators (Andreasen et al., 2001). In fact, ecological integrity can be measured and interpreted by changes in abundance, diversity, and composition of groups of indicator organisms that ultimately depend on system resources and conditions. Correlates of integrity in terrestrial landscapes have been proposed, along with many specific indicators that measure various aspects of the ecosystems (Cajaiba and Silva, 2017). Among the various indicators, terrestrial invertebrates, and particularly insects, play a crucial role in most ecological processes, and they are key components of ecosystem structure and functioning (Bicknell et al., 2014; Viegas et al., 2014; Cajaiba and Silva, 2015; Cajaiba et al., 2015; Campos and Hernández, 2015). Insect abundance and richness are related with other taxa, climate, and soil characteristics, thus representing potential target indicators of environmental changes (e.g. Nichols et al., 2008; Cajaiba et al., 2015). Therefore, a better understanding of the ecological relevance of insects in the humid tropics could support decision-making and robust management/recovery of imperilled ecosystems in the scope of the need for rapid, standardised, and cost-effective assessment methodologies (Godfray et al., 1999).

Beetles have characteristics that make them appropriate for ecological studies (Vasquez-Velez et al., 2010; Paoletti et al., 2010; Cajaiba and Silva, 2015) monitoring different compartments of the system (Marinoni, 2001). Among beetles, those of the family Histeridae (Histerid beetles - HB) are known as generalist predators, with wide range of habitats, which may occur in faeces, fungi, tree trunks, decomposing fruit, roots of trees, bird nests, burrows of mammals or reptiles, and in decaying vegetation. In addition, they are important predators of eggs and larvae, particularly of Diptera (Cyclorrhapha). Some groups are related to other animals, particularly social insects such ants and termites (Leivas et al., 2013). Despite its ecological importance, few studies have been conducted in Brazil using this group, and the published ones focused on the systematics (Degallier et al., 2011; Corrêa et al., 2012; Leivas et al., 2012a, b; Leivas et al., 2015).

In the present study, we aimed to characterize the seasonal communities of HB of different ecosystems in the Brazilian Amazon, ranging from primary or secondary forests with different stages of regeneration, to cocoa farms and pastures. These ecosystems, characterized by dissimilar structure and complexity, could be associated with divergent seasonal patterns in richness and diversity. Specifically, we addressed the following questions: 1) does the composition of Histerid beetle communities vary among the different ecosystems and 2) does the diversity of Histeridae assemblies in the Amazon biome differ among seasons?

Material and methods

Study area

This study was performed near the city of Uruará, state of Pará, northern Brazil (*Fig. 1*). The territorial extension of the municipality is 10796 km² and its population encompasses circa 44789 inhabitants. The dominant land use/ land cover (LU/LC) is natural forest (69% of the area) and deforestation is concentrated mainly in the south-central part of territory and near the main roads. Extensive livestock production and the exploitation of timber at a large scale (mostly illegal) are currently considered the most serious environmental threats (Cajaiba and Silva, 2017). The studied areas contain the pertinent gradients, in terms of biophysical and ecological characteristics, for testing the response of Histerid beetle communities (Cajaiba and Silva, 2017) facing the main anthropogenic drivers. These gradients encompass: Native Vegetation - NV, Early Secondary succession – ES (vegetation with five years of regeneration), Mature Secondary succession - MS (vegetation with 15 years of regeneration), Agriculture - Ag (cocoa plantations, Theobroma cacao L.) and Pasture for extensive livestock - Pa. The climate of the study area is classified as Aw (Köppen), hot and humid and the average annual rainfall is 2000 mm (Cajaiba et al., 2017b).

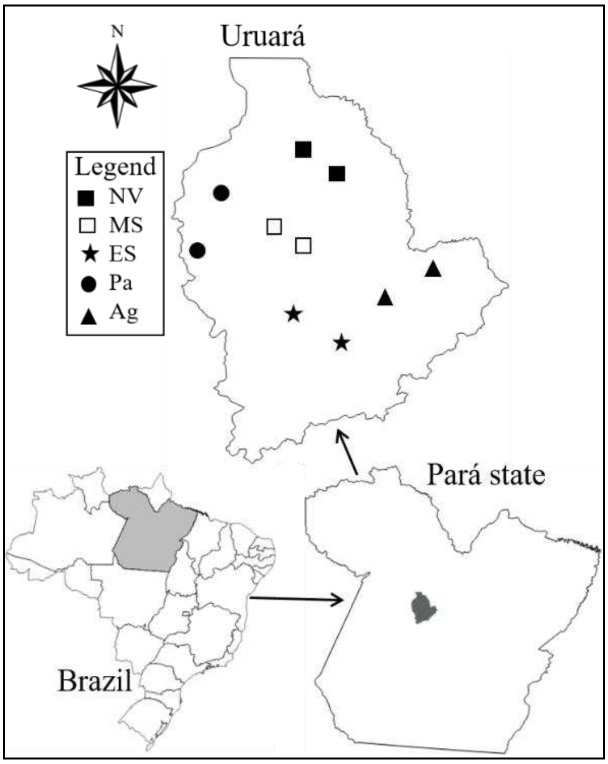

Figure 1. Location of the study region in the municipality of Uruará, state of Pará, northern Brazil. Location of the sampling areas: NV, Native vegetation; MS, Mature secondary succession; ES, Early secondary succession; Ag, Agriculture; Pa, Pasture.

Histerid beetles sampling

Sampling was carried out during the year 2015, in the months of February/ March (rainy season), June (final of rainy season and early dry season) and September/ October (dry season). This allowed integrating eventual seasonal differences in the diversity of Histerid beetles (HB). The sample points were placed at a minimum distance of 100 meters from ecotones, to ensure that most HB captured were associated to the ecosystem in study. Pitfall traps with 75 mm diameter and 110 mm deep were filled with preservative liquid consisting of formalin, alcohol, water and a few drops of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_12271237

detergent to break the surface tension. A roof was attached to each trap to prevent rainwater from entering the trap, remaining installed for 48 h prior to collection. Each pitfall contained different baits such as human faeces, meat and banana in order to attract different species according to their feeding habits (non-baited pitfalls were used as control).

In each studied ecosystem (NV, MS, ES, Ag and Pa) seven sample points were placed 100 m apart. Each sample point contained four pitfall traps including the different baits (faeces, carrion, banana and non-baited), separated by 5 meters. The distance between pitfall traps allowed individuals to choose their preferential food resource (Almeida and Louzada, 2009). This protocol was applied to all areas and periods of collections, totalizing a sampling effort of 840 traps. In order to complement the pitfall derived information (Cajaiba et al., 2014), specific methods were used to collect leaf litter invertebrates. Ten random sampling points of 1 m^2 were selected in each ecosystem and sampling period. At each collection point ('litter-only'), only the loose soil was gently scraped with a metal trowel, to include those HB into the samples that fell out of the leaf litter during this collection procedure. We refrained from simply separating leaf litter and soil, considering that when we remove the litter, HB might flee the litter and hide in the loose topsoil.

Assemblage analysis

Richness and abundance of HB were measured in each sampling site and differences among ecosystems were gauged using One-Way-Analysis-of-Variance (ANOVA). ANOVA was also applied to find possible differences in HB along the year. When the ANOVA indicated differences in the average among ecosystems and/or seasonality, a Tukey's post-hoc test was performed to find specific difference(s). The normality of the data was verified by the Shapiro-Wilk test.

The taxonomic composition of HB communities between ecosystems was compared using Permutational Multivariate Analysis of Variance (PERMANOVA). Non-metric Multidimensional Scaling (NMDS) plots were used to help interpret the results found with the PERMANOVAs (see Anderson, 2001 for similar procedure). In order to check for environmental variables with influence on the HB communities, associated with periods of the year, a correlation analysis (Pearson correlation) was applied between HB abundance and richness and meteorological data - temperature, humidity and precipitation. All analyses were performed using PAST software version 3.14 (Hammer et al., 2001).

Results

Composition of Histeridae

A total of 1945 individuals Histerid beetles (HB) were captured, distributed by five genera and 14 species/ morphospecies (species). All species (14 species, 682 individuals) were monitored in the native vegetation (NV), 12 species (513 individuals) in the Mature Secondary succession (MS), 13 species (180 individuals) in Early Secondary succession (ES), 11 species (232 individuals) in Agriculture (Ag) and 13 species (338 individuals) in Pasture (Pa). The most abundant species were *Phelister* sp1 (302 individuals), *Phelister* sp4 (257 individuals), *Hister* sp1 (246 individuals) and *Phelister* sp2 (184 individuals). These four species represent more than 50 percent of all specimens collected. The genera *Phelister* and *Hister* were prevalent in all communities, with more 71 percent of all specimens captured (*Table 1*).

Table 1. *Total numbers of Histerid beetles species in the environments different in the Brazilian Amazon. NV = Native Vegetation; MS = Mature Secondary succession (15 years of regeneration); ES = Early Secondary succession (5 years of regeneration); Ag = Agriculture (Cocoa); Pa = Pasture. R = Rainy Season; Intermediary Season; D = Dry Season.*

Histerid beetles (HB) richness and abundance presented significant differences between ecosystems ($F_{4,114} = 111.3$, $p<0.001$; $F_{4,114} = 346$, $p<0.001$) (*Figs. 2a and 2b*). Generally, less disturbed ecosystems had higher values of both indexes, although with exceptions: higher richness and abundance depicted in Pastures when comparing with Cocoa farms (Ag) and Early secondary succession (ES).

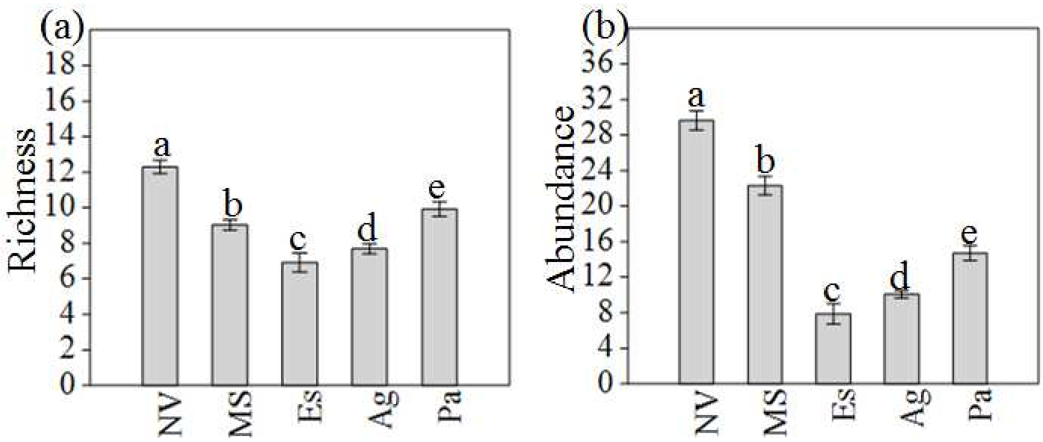

Figure 2. *Differences in the projected values for (a) Richness (± SE), and (b) Abundance (± SE) of Histerid beetles (HB) community in the different ecosystems considered. The values followed by the same letters are not significantly different according to Tukey test. NV, Vegetation native; MS, Mature Secondary succession (vegetation with 15 years of regeneration); ES, Early Secondary succession (vegetation with five years of regeneration); Ag, Agriculture; Pa, Pasture.*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_12271237

NV presented all species while *Phelister haemorrhous* was not captured in MS, ES and Ag; *Operclipygus* sp was not captured in MS, Ag and Pa; *Hister* sp2 and *Omalodes* sp2, were not found in ES and Ag, respectively.

The results of the NMDS showed that the HB assemblages of different ecosystems could be separated from each other by ordination of the species composition, suggesting that these assemblages change gradually from the most pristine to more disturbed ecosystems. The composition of the HB of NV and MS were more similar to each other than HB assemblages of other habitats: ES, Ag and Pa could be discriminated from NV and MS (*Fig. 3*). In fact, the Permutational Multivariate Analysis of Variance (PERMANOVA) showed that HB taxonomic composition of the ecosystems studied was significantly different ($F_{4,114} = 28.44$, $p<0.0001$).

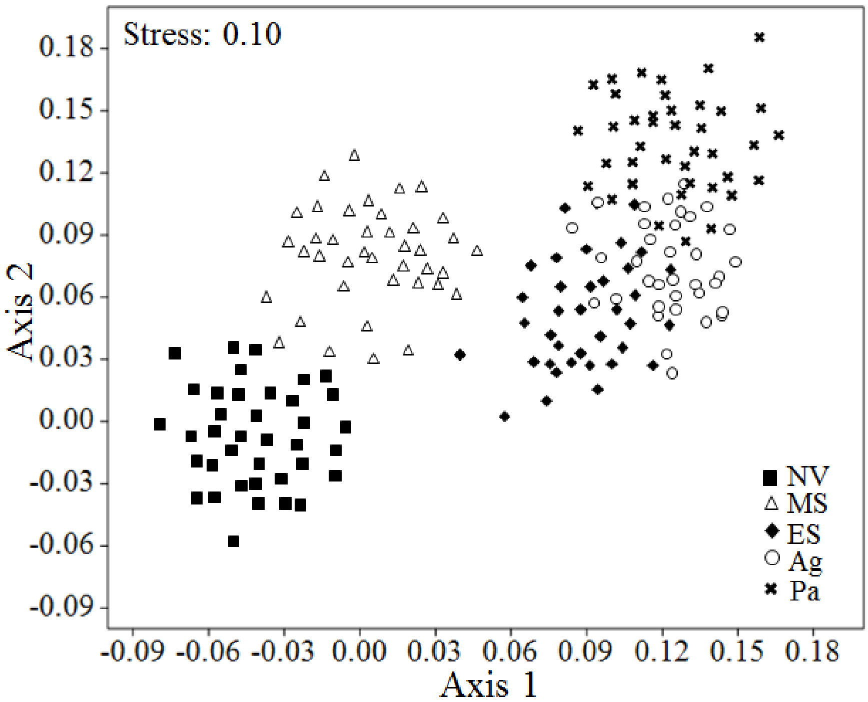

Figure 3. *Non-metric multidimensional scaling (NMDS) showing Histerid beetles grouped in accordance with the ecosystems (using Bray-Curtis similarity). NV, Vegetation native; MS, Mature Secondary succession (vegetation with 15 years of regeneration); ES, Early Secondary succession (vegetation with five years of regeneration); Ag, Agriculture (Cocoa); Pa, Pasture.*

Seasonality patterns in Histerid beetles assemblages

With respect to the relation between the period of the year and HB assemblages, statistical differences in abundance and richness were identified ($F_{2,342} = 11.71$, $p<0.001$; $F_{2,342} = 13.29$, $p<0.001$): significant differences in abundance were found between the averages of the rainy and dry seasons (Tuckey test: Q=6.76, p<0.001), and the intermediary and dry seasons (Tuckey test: Q=5.64, p<0.05); significant differences in richness were found between averages of rainy and intermediary seasons (Tuckey test: Q=3.17, p<0.01), and intermediary and dry seasons (Tuckey test: Q=4.09, p<0.05) (*Fig. 4a*).

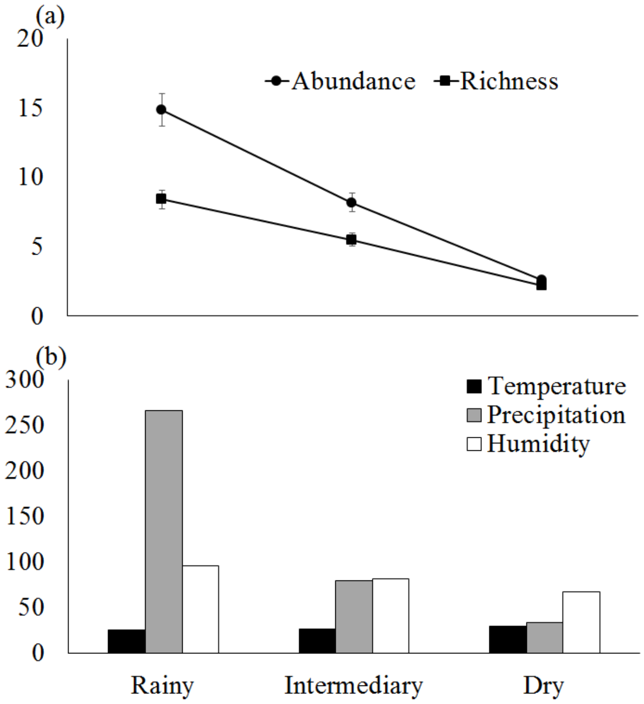

Figure 4. *Abundance and richness of Histerid beetles (a) and distribution of environmental variables during the study period (b).*

Among the climatic variables evaluated (*Figure 4b*), humidity and precipitation were positively correlated with the abundance and richness of Histeridae. In contrast, the air temperature negatively influenced these indexes (*Table 2*).

Table 2. *Pearson correlation between environmental variables and ecological indices (abundance and richness) of Histeridae collected in Uruará, Pará, northing Brazil. Asterisks indicate statistical significance at level of * p<0.05; ** p<0.01;*** p<0.001.*

Environmental variables	Abundance	Richness
Humidity	0.57***	0.49***
Temperature	-0.29*	-0.29**
Precipitation	0.48***	0.44***

Discussion

Composition

Degallier et al. (2011) highlighted the shortage of information on Histerid beetles (HB) in Neotropical areas, where environmental and ecological conditions should enhance their biodiversity. In fact, there is a lack of specific collections and specialized taxonomists for this group. Despite the lack of HB collections, the results obtained provide clues on the diversity of the group in the Amazon region (Leivas et al., 2013).

The genus *Phelister* (Marseul, 1853), which was the most abundant in the present study, represents a varied genus with 88 species described with mostly Neotropical distribution (Mazur, 2011). These species can be found on diverse substrates like faeces, carcasses, decomposing plants, plants, mammal burrows, bird nests, and in debris piles

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_12271237

of leaf-cutting ants. Some species, associated with carcasses, have been considered relevant for forensic entomological studies (Almeida and Mise, 2009; Leivas et al., 2013). The enormous diversity, lack of taxonomic studies, and the possibility of description of many new taxa hinders the identification of species (Leivas et al., 2013). The genus *Hister* (Linnaeus, 1758), which was the second most abundant in the present study, is the most diverse genus of HB, with approximately 195 described species distributed across all zoogeographic regions (Mazur, 2011). These species occur in faeces, carcasses, decomposing plants and fungi, mammal burrows, and in debris piles of leaf-cutting ants. The small number of species recorded in Brazil suggests that new taxa and new records might be described in future (Leivas et al., 2013, 2015).

In the present study, both richness and abundance were the highest in the most pristine and/or conserved ecosystems (e.g. NV and MS). These results suggest the presence of differences among HB communities associated with specific ecosystems, probably related with the environmental conditions and bioecology of species (Moraes et al., 2013). Summerlin (1989) mentions a trend starting from low dominance and high richness of HB communities in pristine ecosystems to higher abundances and reduced richness of HB communities in open and degraded ones. Thus, diversity and abundance of HB communities are intimately related with differences in environmental characteristics of these ecosystems (Lopes et al., 2005).

Biotic and abiotic factors associated with most pristine/ heterogeneous environments, are, for example, mild climates, high canopy cover, and complex ground cover that provide environments for hibernation and more diverse prey, and better conditions for larvae and adults. Cattle treading on pasture areas or the use of machinery in agriculture areas contribute to soil compaction, resulting in changes in the soil structure, reduction of soil litter and water, thereby decreasing and/or eliminating many species (Kruess and Tscharntke, 2002).

Seasonality

In the present study, the abundance and richness of HB collected at different times of the year (rainy season, intermediary season, and dry season) depicted a trend with higher diversity during the rainy season, corroborating the hypothesis that the abundance, richness, and diversity are associated with climatic conditions (Andresen, 2005). Nonetheless, microclimatic factors are not necessarily correlated with climatic conditions, but they play an important part in the activity of HB and associated taxa in different climates (Moraes et al., 2013).

The positive correlation between air moisture and the diversity of HB is expected, because higher air moisture may produce favourable microclimates for HB. Previous studies demonstrated that vegetation structure and its effects on microclimate (e.g. temperature and air moisture) might be one of the most important factors controlling and structuring the distribution of beetles (Magura et al., 2000). Apparently, the evolutionary life cycle strategy of beetles is optimized and synchronized with seasonal changes of microclimatic environmental conditions (Kotze et al., 2011; Wang et al., 2014).

Although temperature was negatively correlated with abundance and richness in the present study, annual temperature variation in this region is small, suggesting that rain and humidity are probably the main drivers affecting the dynamics of invertebrates (Andresen, 2008). Silva et al. (2010) presented two hypotheses to explain the lower abundance and richness of adult beetles in the dry season: (1) adults are sensitive to the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_12271237

effects of drought and remain underground during this period, or (2) adults die in the dry season and only the immature beetles survive in the nest, reaching the adult stage at the beginning of the wet season. Nevertheless, temperature is a major factor affecting activity, flight, foraging behaviour, and metabolism of beetles (Saska et al., 2010).

Additional studies are necessary to document the extent of sensitivity to microclimate and climate, and they could be particularly relevant in the light of the potential effects of climate change (Williams et al., 2007; Maveety et al., 2014). Understanding seasonal patterns of beetles in a given region is important for several reasons. Firstly, seasonal variations in abundance, richness, and species composition emphasize the role of phenology and the effect of survey timing on the results obtained for studying the association of HB with ecosystems. Further, seasonal information of HB might be a relevant ecological indicator, which might have importance in the management of ecosystems.

Conclusion

The Histerid beetles collected in this study demonstrate patterns of habitat preference and marked seasonal variations. In addition, the results indicate factors and conditions that might affect overall biodiversity distribution in the Brazilian Amazon. In fact, the present study should be complemented with studies linking Histerid beetles with other taxa for understanding and assessing the state of conservation of the diverse ecosystems of the studied region.

Abstract. Nitrogen dioxide (NO_2) is considered as one of the most important ambient air pollutants in gas refineries. In this study, AERMOD dispersion model was applied for prediction of NO_2 ambient concentrations and dispersion patterns from point sources, including 13 stacks and six flares in a gas refinery located in Asaluyeh, Iran. For this purpose, the NO_2 concentrations exhausted from the stacks were measured by a portable emission analyzer and the NO_2 concentrations resulted from the flares were estimated using the emission factors. Moreover, the amounts of ambient NO_2 concentrations in 10 monitoring stations were measured in four seasons. Then, the ambient NO_2 concentrations and dispersion patterns were predicted using the AERMOD model within a domain of 10 × 10 km^2, in 1-hr and 12 months averages and the unhealthy zones in the study area were defined. The results revealed that for both annual observed and predicted values, ambient NO_2 concentrations were higher than WHO standard limits but they did not exceed the US EPA standard limits. However, the hourly observed and predicted concentrations were lower than the standard levels. Statistical methods were used for comparing the predicted and observed NO_2 concentrations. Simulation results indicated that the predicted concentrations were underestimated by a factor of 20 % in comparison to the measured ones which revealed the estimated contribution of other sources including mobile sources and neighbor sources located in the vicinity of the gas refinery.
Keywords: *AERMOD, air quality, emission, performance, point source*

Introduction

Air pollution will adversely affect the quality of life and human health. Therefore, it has been widely concerned by environmental experts in the world.

The World Health Organization (WHO) has reported that about 2.7 million people die due to the health effects of air pollution annually (WHO, 2014). The minimum concentrations of gasses in the atmosphere could be essential in determining the health status of the societies (Shooter et al., 1993). Meanwhile, the air quality management policies are important in order to reduce the acute effects of air pollutants. Identifying the emissions due to different sources and assessing their adverse effects are important for appropriate air quality management (Bhanarkar et al., 2005).

The NO_x concentrations exhausted from the gas refinery usually increase with rising ignition temperature that leads to producing NO, and then oxidized to nitrogen dioxide (NO_2) in the presence of oxygen in the atmosphere. NO_2 is an air pollutant with a 1–3 days

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_12391254

lifetime in mesoscale. Ambient NO_2 concentrations have been regulated by the U.S. EPA as one of the six primary air pollutants. Respiratory tract infections due to the pollutant's interaction with the immune system may be increased by NO_2 exposure. Furthermore, it has been associated with slight respiratory symptoms at low NO_2 concentrations and with death in indoor locations (Chen et. al, 2007). It is caused throat, eyes and nose irritation for inhalation in human (Perkins, 1974). Direct effects of nitrogen oxides can be considered as the creation of smog and photochemical ozone components (Akdemir et al., 2013). The U.S. EPA (2010) has determined that the hourly average ambient NO_2 concentrations should not exceed 200 $\mu g/m^3$. In order to meet the regulation goals and for minimizing the adverse effects of air pollutants, it is essential to study the dispersions of air pollutants which are affected by several factors including atmospheric stability, orography, obstacles, roughness, maximum mixing height, wind speed and wind direction, and height of the release above ground level (Crowl and Louvar, 2002; Seangkiatiyuth et al., 2011).

Various methods including measurement, emission inventory and simulation studies are applied to assess air pollution impacts due to pollutants released into the atmosphere and to monitor whether pollutants' concentrations exceed the standard limits (Capelli et al., 2013). Air quality dispersion modeling is important for predicting the pollutants' concentrations, simulating the emission distribution patterns and the spatial allocation of outdoor air pollutants (Holmes and Morawska, 2006; Zhang et al., 2010). On the other hand, dispersion models are effective tools for predicting the contributions of emissions due to various pollutant sources including traffic, industry, residential and commercial sectors (Cimorelli et al., 2005). Advanced dispersion models such as American Meteorological Society/Environmental Protection Agency Regulatory Model (AERMOD) were often applied for predicting the air quality after a long time, e.g. at least 10 years (Ma et al., 2013).

As AERMOD model can combine various concepts and complex algorithms, it has been used for evaluating the ambient concentrations and dispersion patterns of some pollutants, including SO_2, PM_{10}, VOCs, hydrogen cyanide (HCN),and sulfur hexafluoride (SF_6) (Bhardwaj et al., 2005; Orloff et al., 2006; Venkatram et al., 2001, 2004, 2009; Zou et al., 2009, 2010).

Moreover, AERMOD can be used for simulating the dispersion of heavy metals, such as chromium and mercury (Sax and Isakov, 2003; Mazur et al., 2009). When upper climatological data are not accessible, AERMOD can be integrated with meteorological models such as MM5, WRF, and RAMS, etc (Caputo et al., 2003; Isakov et al., 2007; Kesarkar, 2007).

Some studies were carried out regarding prediction of NO_2 concentrations and dispersion patterns with AERMOD. The dispersion of NO_2 emitted from four cement plants in Thailand were studied using AERMOD model. In this study, the predicted ambient NO_2 concentrations were compared with the observed values in 12 receptors. The results showed that simulated and observed concentrations were in better agreement within 1-5 km than those at receptors situated in 5km further away from the reference point. Moreover, the results revealed that both observed predicted ambient NO_2 concentrations were not exceed the limit values set by the National Ambient Air Quality Standards (Seangkiatiyuth et al., 2011). Furthermore, AERMOD was used for modeling of NO_x , $PM_{2.5}$ and SO_2 emissions from point and line sources in Halifax, Nova Scotia, Canada in 50 × 50 km^2 domains over 1-hr, monthly and annual periods averages. The evaluation of model performance was done by applying

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_12391254

statistical parameters and the results showed poor agreement among the observed and simulated results (Gibson et al., 2013). In another study, Cohan et al. (2011) examined the dispersion and predicted concentrations of NO_x and $PM_{2.5}$ in port communities in California using AERMOD. The correlation coefficients for NO_x and $PM_{2.5}$ were 50% and 43%, respectively (Cohan et al., 2011). AERMOD model was also used to simulate the NO_2 and SO_2 concentration in Beilun area. The results demonstrated that the ambient average concentrations of NO_2 and SO_2 were equivalent to 16.7%~58.3% and 26.7%~53.3% of the clean air quality standard respectively. However, concentrations of NO_2 and SO_2 were relatively higher in the upper air of Beilun region. NO_2 and SO_2 gasses in the upper air were a reason for the high potential of acid rain on Beilun region (Hasson et al., 2013).

In order to study the performance of applying emission control devices, AERMOD modeling system was applied for predicting the air pollution in Xuanwei, an important industrial city in China, and it was concluded that AERMOD can be used properly for simulating NO_x and SO_2 emissions (Ma et al., 2013). The emission, transport, dispersion, and concentration analysis of PM emitted from a big industrial complex in Malagueño city, Argentina, were also conducted using AERMOD model. The model was applied to 224 emission sources. The performance of the model was evaluated by comparing the simulated results with the observed Total Suspended Particulate matters (TSP) at two monitoring sites for 62 continuous days in winter. The results showed the impact of the industrial activities on the local PM concentrations, from which stockpiles and unpaved industrial roads were the main emission sources, straightly affecting two of the nearest neighborhoods in the study area (Abril et al., 2016). In another study, AERMOD model was used to predict SO_2, CO, NO_x and PM_{10} emissions impacts at receptors due to calcining processes including handling and storage of raw petroleum coke in Argentina. The observed and predicted ambient pollutants' concentration levels were compared with public health standards. The results revealed that the exposures of the simulated NO_x, CO, PM_{10} and SO_2 concentrations were lower than the air quality standards. However, the PM concentration level was higher than the standard limits (Singh et al., 2015).

The exposures of various pollutants including NH_3, CH_4, CO, CO_2, H_2S, NO_2, N_2O, SO_2 and organic dust were estimated for populations residing in close vicinity to ten poultry concentrated animal feeding operations (CAFOs) located in Central Poland. AERMOD model was used to predict the pollutants' concentrations in order to compute the Hazard Index (HI) for a mixture of chemicals. Results presented that the estimated hazard indexes which were less than unity; therefore there was low potential for adverse health consequences for the surrounding society for the combined mixture of chemicals (Pohl et al., 2016).

A comparative study regarding the health effects of emissions due to vehicles and industries were conducted in China and Pakistan. In this study, ambient CO, NO_2, and SO_2 concentrations were measured and compared with U.S. EPA, WHO and national clean air standards in China and Pakistan (Niaz et al., 2015).

The performances of ISCST-3, AERMOD, and CALPUFF models for NO_x and CO emissions in point, line and area sources were compared together using statistical analysis in Körfez. The results revealed that AERMOD predictions for NO_x concentrations were lower than those predicted by ISCST-3, and CALPUFF models. Meanwhile, CO concentrations predicted by AERMOD were among the concentration levels simulated by CALPUFF and ISCST-3 (Demirarslan and Doğruparmak, 2016).

DOI: http://dx.doi.org/10.15666/aeer/1504_12391254

The main goal of the present study was to simulate the ambient concentrations and dispersion patterns of NO_2 emitted from stacks and flares in a sour gas refinery located in a complex industrial region with special climatological and topographical conditions and to determine the contribution of the gas refinery in NO_2 emissions using AERMOD dispersion model.

In this study, ambient NO_2 concentrations in a gas refinery situated in Asaluyeh was measured seasonally in 10 receptors in and around the refinery from June 2014 to May 2015. Thereafter, the 1-hr and annual ambient concentrations and dispersion patterns of NO_2 were simulated by applying AERMOD dispersion model in the area of 10×10 km^2. Moreover, the predicted concentrations in receptors were compared with the measured ones using statistical methods. Then, unhealthy zones were determined in the study region using contour plots of the seasonal NO_2 distribution patterns. Finally, the contribution of emissions due to point sources in this refinery was determined.

Materials and Methods

Study Area

Asaluyeh, a sub-city of Kangan, belongs to Boushehr Province, which locates in the southwest of Iran. The desired gas refinery as shown in *Figure 1*, is situated on 27° 30’ to 27° 31’ north latitude and 52° 34’ to 52° 36’ east longitude in Asaluyeh. It was commissioned with a refining 50 million cubic meters per day sour gas and 80,000 barrel per day gas condensate to supply for the Iran’s local strategic demand.

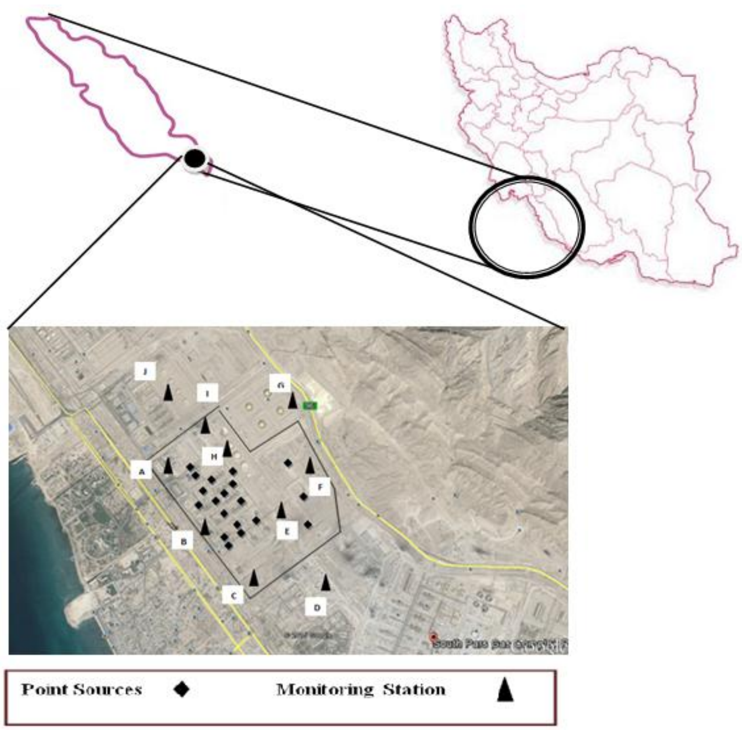

***Figure 1.** The study area, the point sources and monitoring stations*

Field Measurements

Emission Sources

The point sources in the gas refinery included 13 stacks and six flares. The exit velocity of the flue gas and concentrations of NO_2 emitted from the stacks were measured by a portable emission analyzer (TESTO 350 XL), in four seasons (June 2014 - May 2015) and four times in each season (ASTM, 2011a). The emission rate of NO_2 resulting from the flares was also determined by emission factors according to EPA/AP-42 method.

The required AERMOD inputs data were including emission height (m), flue gas temperature (°C), inner diameter of stack (m), flue gas velocity (m/s), geographical coordinates (X,Y) and elevation above the ground level (m) (*Table 2*). The locations of point sources are illustrated in *Figure 1*. In the current study, the maximum NO_x emission for the continuous operation has been considered. The total NO_2 emission rate from 19 point sources which evaluated according to Tier2 in AERMOD guidelines (US EPA, 2009, 2010a) was 270 g/s.

Ambient NO_2 Concentrations

Measurements of 1-hr average of ambient NO_2 concentrations were performed using a mobile device (LSI-Lastem Babuc A) in four seasons and four times in each season from June 2014 to May 2015 in 10 receptors (ASTM, 2011b). The locations of receptors from reference point (BO-1) have been presented in *Table 3*.

Meteorological Data

All Surface and upper-air weather data (wind speed, wind direction, temperature, cloud cover, dew point temperature, pressure at sea level, rainfall and humidity, solar radiation) in eight time steps (0:00, 3:00, 6:00, 9:00,12:00, 15:00, 18:00, 21:00) in a day were provided as meteorological inputs for AERMOD from June 2014 to May 2015 (IRIMO, 2015).

The annual wind rose was produced based on data received from Asaluyeh Weather Station (*Figure 2*). The prevailing wind direction in this station was from NW to SE in all seasons. The AERMET was employed to simulate the climatically conditions using the values of Bowen ratio, surface roughness length and Albedo parameters based on the types of the surrounding vegetation and land use in the study area. The values of these parameters have been presented in *Table 1*.

Table 1. *The surface specifications according to meteorological data*

Elevation Data

In order to predict the NO_2 concentrations at receptors, elevation data was required as model input. In this study, the required digital elevation files were provided from Iran National Cartographic Center. The 3D view of topography in the study region produced by GIS with a resolution of 90 m has been shown in *Figure 3*.

AERMOD Modeling System

AERMOD dispersion model developed by the U.S. EPA is a steady-state Gaussian model for predicting air pollutants' concentrations and dispersion patterns due to various emission sources. AERMOD model consists of three sections: Meteorological Preprocessor (AERMET), Terrain Preprocessor (AERMAP) and AERMOD Gaussian Plume Model (US EPA, 2004a, 2004b, 2009). It is necessary to provide all emission rates due to various sources (point, line, area, and volume sources) and the meteorological and topographical data to predict pollutants' concentrations and dispersion patterns in rural and urban areas, calculating building downwash effect, terrain adjustment, etc. at short-range (up to 50 km) (Cimorelli et al., 2005; Perry et al., 2005). AERMOD makes distribution estimations by utilizing the meteorological characteristics of the study region, including stack diameter and height; stack temperature, flue gas velocity, wind direction and wind speed (Mokhtar et al., 2014; Huertas et al., 2014; Stein et al., 2007).

In this study, simulations for NO_2 ambient concentrations and dispersion patterns were performed for the total study area of 100 km^2, where a grid of 50 m × 50 m was built.

Evaluation of AERMOD Performance

In order to evaluate the model performance, the results of field measurement and model simulation were compared together using statistical methods. Statistical Parameters suggested by U.S. EPA (U.S. EPA, 2003, 2005) including: "correlation coefficient (COR) ", Normal Mean Bias (NMB)", "Normal Mean Error (NME), "fractional bias (FB)," and also "Index of Agreement (IOA)" (Luhar, 2003) were applied (*Equations 1 ~ 5*). According to *Eq. (1)*, parameter COR indicates the relationship between the Simulated and the measured results. The more the value of COR is closer to 1, the performance of the model is more satisfactory.

$$COR = \frac{\sum_{i=1}^{N}(S_i-\bar{S})(M-\bar{M})}{\left(\sum_{i=1}^{N}(S-\bar{S})^2\sum_{i=1}^{N}(M_i-\bar{M})^2\right)^{1/2}} \quad \text{(Eq. 1)}$$

NMB and NME parameters were applied to evaluate the model performance for simulating NO_2 concentrations. The variation ranges for COR, NMB and NME were (-1 ~ + 1), (-1 ~ + ∞), (0 ~ + ∞), respectively (U.S. EPA, 2003).

$$NMB = \frac{\sum_{i=1}^{N}(S_i-M_i)}{\sum_{i=1}^{N}M_i} \times 100 \quad \text{(Eq. 2)}$$

$$NME = \frac{\sum_{i=1}^{N}|S_i-M_i|}{\sum_{i=1}^{N}M_i} \times 100 \quad \text{(Eq. 3)}$$

FB indicates the tendency of the model to predict values more or less than the measured concentrations in this study (Olesen, 2001). The acceptable value for FB was less than 0.3 (Ghannam and El-Fadel, 2013).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_12391254

$$FB = \frac{(\overline{M_i} - \overline{S_i})}{0.5(\overline{M_i} + \overline{S_i})} \quad \text{(Eq. 4)}$$

IOA is sensitive to differences between the measured and simulated results means as well as to certain changes in proportionality (Luhar, 2003). The variation range for IOA was (0,1).

$$IOA = 1 - \left[\frac{\sum_1^N (S-M)^2}{\sum_1^n (|S-\overline{M}| + |M-\overline{M}|)^2}\right] \quad \text{(Eq. 5)}$$

Where, S_i: simulated concentrations, M_i: measured concentrations, $\overline{S}$: average simulated concentrations, $\overline{M}$: average measured concentrations, N: the total number of measurements.

Results and Discussion

Experimental Results

The 1-hr averages of ambient NO_2 concentrations in 10 receptors in four seasons from June 2014 to May 2015 have been illustrated in *Figure 4*. For all receptors except B in summer 2014, the measured ambient NO_2 concentrations were lower than the clean air U.S. EPA standard for 1-hr ambient concentration levels. However, in all seasons the simulated ambient NO_2 concentrations in all receptors were lower than the standard limit (200$\mu g/m^3$). Based on the safety regulation for hourly NO_2 concentrations (200 $\mu g/m^3$) published by the WHO Guideline, NO_2 emissions from the gas refinery showed no significant health effects on personnel. However, the average annual concentration was 87 $\mu g/m^3$ which was higher than the WHO standard limit (40 $\mu g/m^3$) and they have not exceeded the U.S. EPA standard limits (100 $\mu g/m^3$) (WHO, 2017; U.S. EPA, 2010b).

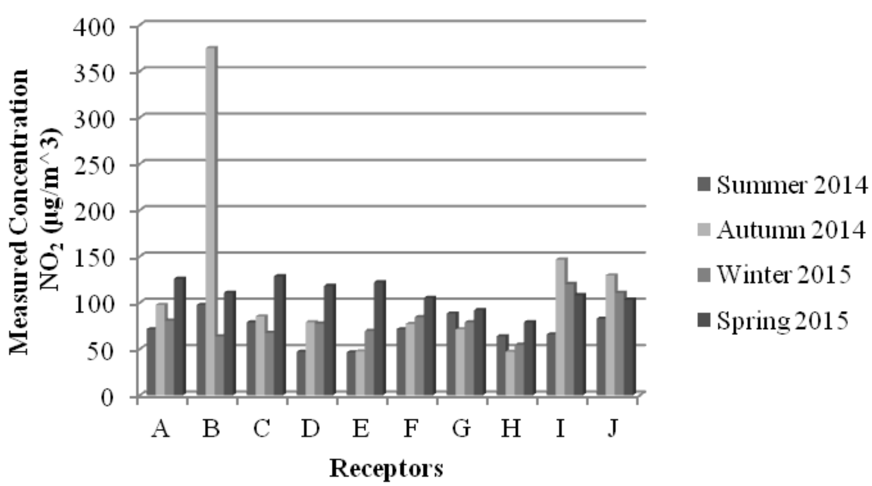

Figure 4. *Ambient NO_2 concentrations in 10 receptors at 1-hr average period*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_12391254

The 1-hr averages of ambient NO_2 concentrations measured in 10 receptors varied from 46.4 to 97.6 $\mu g/m^3$ in summer 2014, from 47 to 375 $\mu g/m^3$ in autumn 2014, from 54.5 to 120.2 $\mu g/m^3$ in winter 2015 and from 78.9 to 125.8 $\mu g/m^3$ in spring 2015. As a result, the highest observed NO_2 ambient concentration was measured in autumn and the lowest amount was measured in summer for 1-hr average period. However, in all seasons the predicted ambient SO_2 concentrations in all receptors were lower than the US EPA clean air standard levels except for B monitoring stations in autumn 2014, due to the direction of prevailing wind (from NW to SE) and the neighboring refineries.

The simulated results also showed that the variations of NO_2 concentrations were ranged from 21.2 to 83.03 $\mu g/m^3$ in summer 2014, from 35.7 to 162 $\mu g/m^3$ in autumn 2014, from 34.5 to 87 $\mu g/m^3$ in winter 2015, and from 73 to 114.5 $\mu g/m^3$ in spring 2015, which presented the highest concentration in the autumn and the lowest value in the summer. Meanwhile, in all seasons the simulated ambient NO_2 concentrations in all receptors were lower than the clean air standard levels.

A comparison among the results of measured 1-hr average NO_2 concentrations and the simulated values for 10 monitoring stations (receptors) in four seasons in the study area is presented in *Figure 5*. As shown, the simulated ambient NO_2 concentrations were less than the measured ones for all receptors. The variations among the simulated and measured ambient NO_2 concentrations in D, I and J receptors were higher than those in other receptors. These receptors were situated on the border of the study area with other refineries and it might be resulted from emissions due to other neighboring refineries and other industries. The observed and simulated results were in good agreement. The values and locations of maximum simulated ambient NO_2 concentrations at 1-hr and annual averages are presented in *Table 4*.

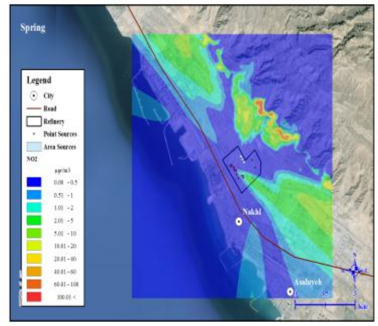
c) Winter 2015



d) Spring 2015

Figure 6. *NO_2 distribution maps for the simulated results in the study area*

1-hr maximum concentrations of the simulated and measured values were used for the statistical analysis for evaluating the model performance. The values of correlation coefficients (COR) for NO_2 concentrations were 0.89 in summer 2014, about 0.87 in autumn 2014, about 0.67 in winter 2015 and about 0.73 in spring 2015. The results are shown in *Table 5*. As a result, there were acceptable ranges for statistical parameters and the model simulation indicated that the simulated concentrations were underestimated in compare to the measured ones.

Table 5. *The results of statistical analysis*

Season	**COR (0,1)**	**NMB ≤%15**	**NME ≤%30**	**IOA (0,1)**	**FB <0.3**
Summer (2014)	0.89	-16	16	0.86	-0.017
Autumn (2014)	0.87	-38	28	0.70	-0.047
Winter (2015)	0.67	-21	25	0.61	-0.023
Spring (2015)	0.73	-22	22	0.63	-0.025

Since there are some limitations for applying AERMOD modeling system, the simulation results may not be quite accurate. The limitations are such as: lack of module for considering NO_2 deposition reactions; high sensitivity of AERMOD to various time scales (Zou et al., 2010; Bhardwaj, 2005); lack of considering the dynamic emission rates (U.S. EPA, 2009); lack of considering the substantial time intervals for wind velocities less than 1 m/s; errors due to monitoring devices (Drew et al., 2007); complexity in topographical structure of the study area (El-Fadel et al., 2009), coastal evaporation, and the geographical effects (Yao et al., 2011).

DOI: http://dx.doi.org/10.15666/aeer/1504_12391254

A comparison made among the measured and predicted ambient NO_2 concentrations. The results indicated that the predicted concentrations were underestimated by a factor of 20 % in comparison to the measured ones which indicated the contribution of other sources including mobile sources and the neighboring gas refineries and other industries.

Conclusions

In the present study, ambient NO_2 concentrations in a gas refinery located in Asaluyeh was measured in 10 receptors in and around the refinery and the 1-hr and annual ambient NO_2 concentrations and dispersion patterns were simulated by AERMOD model in 10×10 km^2 domain. Then the unhealthy zones were determined in the study area using contour plots of the seasonal NO_2 distribution patterns. It was found that the hourly observed and predicted concentrations of NO_2 were lower than the U.S. EPA clean air standard except in receptor B in autumn 2014. However, there was no health risk due to NO_2 emissions for short time (1-hr) exposure in the gas refinery. Furthermore, a comparison made among the measured and the simulated NO_2 concentrations in 10 receptors. The results indicated the performance of the modeling was quite satisfactory with little disagreement in the values of predicted results. The discrepancy between the average simulated and measured concentrations varied from 2% to 56%; however the average predicted concentrations were underestimated by a factor of 20 % in comparison to the measured ones.

Abstract. The Agricultural Water-saving Potential (AWP) has important influences on water-saving technology development, regional irrigation water management, agricultural production and water ecological balance protection. The study aims to design a reasonable methodology to calculate the AWP and analysis the AWP of Guanzhong irrigation area, in Weihe River Basin of China. The AWP was divided into resource-based AWP and efficiency-based AWP. The former was calculated according to the coefficient of water transmission in canals and irrigation in the field. The latter was estimated on the basis of the field evapotranspiration. The guaranteed rates of precipitation were chosen as the hydrologic conditions. Under the guaranteed rates of 25%, 50%, 75%, 90% and 95%, the annual total AWPs of the Guanzhong irrigation areas reached 30.69×106 m^3, 111.67×106 m^3, 11.75×106 m^3, 12.52×106 m^3, and 14.76×106 m^3 respectively. The efficiency-based AWP occupied a proportion of more than 50% in each condition, which indicated that the improvement of water utilization efficiency should be in preference to improvement of water conveyance efficiency in technology innovation. Summer maize, fruit tree and cotton made the largest contribution to efficiency-based AWP while there was not a big difference among the 3 crops in various irrigated areas when it came to the AWP per unit area, and their average values were 9.4, 6.3 and 4.3 mm respectively. Then the study comes up with measures and suggestions to improve the AWP according to the planting structures and features of the 9 irrigated areas. This method takes into account the water consumption during the processes of irrigation and crop growth. It can provide the support for water saving agriculture. The accurate calculation of water dissipation coefficient is the key to the efficiency of the AWP method, and the stability of the measurement coefficient will be improved in the future.
Keywords: *resource-based water-saving, efficiency-based water-saving, Weihe River Basin, precipitation insurance rate, water utilization efficiency*

Introduction

Both water resources per capita and water resources per area are low in China (Yang et al., 2012). Particularly, the distribution of water resources in the country is seriously uneven, with large amount of freshwater resources concentrating in the south. By contrast, the total amount of water resources in the north of the Yangtze River (covering the Haihe River Basin, Huaihe River Basin, Yellow River Basin, and Northwest and Northeast China) is about 546 billion m^3, accounting for only 19% of the national total (Hu et al., 2010). According to the International Water Management Institute (IWMI), water shortage in most countries and regions in the world is correlated to agriculture. The research (Yang et al., 2012) indicates that, if irrigation water used in global food production could be reduced by 10%, people’s water demands for all other purposes

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_12551274

wouldbe met. Accounting for the largest part of the total water use, agricultural water is the most important factor in regional water balance and sustainable utilization of water resources (Belder et al., 2004). Yang and Tian (2009) and Fan et al. (2010) studied the relation between agricultural irrigation water and surface runoff in typical water basins in North China (NC), and the results show that agricultural production may be the major reason for decrease in surface runoff and exhaustion of rivers in most northern river basins. Moreover, groundwater overdraft has resulted in the generation of the world's largest underground cone of depression, sharp drop of underground water level, river blanking, and continuously decreasing water flow in NC; these phenomena indicate that water resources have become increasingly scarce in semi-humid and semi-arid regions and arid regions in China (Moiwo et al., 2009; Zhang et al., 2013; Yin et al., 2016).

Currently, the overall utilization efficiency of irrigation water in China is relatively low, and the biggest water loss is percolation and evapotranspiration in the process of water transmission (Wang et al., 2012a). In addition, farmlands are still the key link of agricultural water saving. The core of agricultural water saving is to reduce and effectively control water use throughout three processes of water transmission and loss in farmlands, which are respectively soil water evaporation, plant transpiration, and soil water percolation (Nair et al., 2013). Because percolating water could be reused through nearby water transfer, the most important factors influencing water consumption on the scale of irrigation area are soil water evaporation and plant transpiration (Yan et al., 2015).

After years of expansion, studies on "agricultural water-saving" have covered all links of agricultural production, and one of the important contents of these studies is to improve the overall utilization efficiency of agricultural water resources (Kifle and Gebretsadikan, 2016). In terms of scale, agricultural water-saving has gone far beyond the concept of "farmland" and was gradually employed 3 scales: plant – farm – area (irrigation area in most cases) (Yang et al., 2012; Nair et al., 2013). The studies are aimed to develop theories and technologies for realizing agricultural water-saving, and strategies on the utilization of water resources. In the next place, except for agricultural water-saving at the technical level, water-saving at the management level is receiving more and more attention as well (Huffaker and Whittlesey, 2003; Hu et al., 2010; Yan et al., 2015; Damerau et al., 2016). In this respect, Agriculture Water-saving Potential, AWP, is an important index for water resources management, which can be used to evaluate the amount of water-saving in a certain area (Horst et al., 2005; Yan et al., 2015). Calculating AWP on the scale of irrigation area has certain practical meaning in both agricultural water-saving and water resource security (Zhang and Guo, 2016).

The concept of "Water-saving Potential" was first proposed in researches on urban and residential water management. Dixon et al. (1999) evaluated cities' water-saving potentials in studying the effect of reclaimed water reuse and rainwater utilization on cities' water-saving capacity. Based on investigations, Yurdusev and Kumanlıoğlu (2008) divided domestic water into different categories of water used respectively in washroom, toilet, bathroom, kitchen, washing machine, dishwasher, and for watering flowers outside, washing cars, etc., and defined water-saving potential as the sum of water-saving amounts achieved under all the categories. By using the concept of agricultural water-saving for reference, researches on estimation of AWP play a more and more important role in water resources management. Karimov et al. (2012) calculated the water-saving potential of Fergana Valley using the "water accounting procedures", which are based on the principle of water balance. According to the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_12551274

method, they first analyzed the using condition of the water resources in the study area, then worked out the amount of ineffective water consumption, namely the water-saving potential, and finally proposed some measures to reduce the ineffective water consumption, such as evapotranspiration reduction and depression detention, and to increase effective utilization, such as expansion of planting area. With the geo-information system (GIS) and remote sensing (RS) technologies being widely used in the calculation of water resources potential, AWP on a regional scale has been gradually introduced to various studies. Horst et al. (2005) analyzed the water saving potential through the application efficiency, the distribution uniformity and total applied irrigation depths with furrow irrigation in Fergana, Aral Sea basin, to assess the potential for improving the performance of furrow irrigation in the central part of the Fergana Valley, Uzbekistan. Yan et al. (2015) project the results of such experiments for winter wheat, maize, and cotton to basin scale to assess their potential in restoring sustainable water consumption. The study employed the remote sensing model-ETWatch (Wu et al., 2012) for calculating the crop water comsuption in planting area, and found that the mulching, which would reduce the over-consumption by 25%, is the most promising option for farmers in Hai River Basin.

China has great AWP (Yang et al., 2009; Damerau et al., 2016), and the utilization efficiency of agricultural water resources in China will be finally improved by relying on reasonable irrigation methods, adopting advanced irrigation technologies, establishing perfect irrigation managing system and institution, and improving biological attributes of fields and crops, so as to effectively alleviate the pressure from water resource shortage (Yan et al., 2015). The Guanzhong region in Weihe River Basin serve as the bond and bridge connecting the western and eastern regions in North China. The Guangzhong region includes nine main irrigation areas, which are the major grain-producing areas in this region. In recent years, the economic and social development in this region has been limited by the serious situation of water shortage. Although the local government devotes itself to adjusting water utilization structure, agriculture is always the largest source of water use (Tang et al., 2016). The total amount of water resources in the Weihe River Basin is 10.683 billion m^3, with total surface water resources being 9.012 billion m^3. By 2015, the overall utilization ratio of surface water resources in the river basin reached to near 30%, but the potential was low, with no potential left in some tributaries; the total amount of groundwater resources is 4.506 billion m^3, but the exploitation rate has exceeded 62%, indicating this region is a seriously overdraft area (Ministry of Water resources of the P. R. China 2015). The water deficit is expected to be more than 2.4 billion m^3 by 2020, and more than 3.0 billion m^3 by 2030 (Tang et al., 2016). Meanwhile, the productivity of agricultural water resources in the irrigation areas is low, being 1 $kg \cdot m^{-3}$ on average, much lower than that other agriculturally advanced countries (Tang et al., 2014a). The causes for the low water resource efficiency mainly include lack of water-saving hi-tech applications, low lining rate of water conveyance canals, and insufficient researches on the irrigation areas' actual carrying capacity of water resources (Tang et al., 2014b). So, there is a great potential in exploiting water resources in this region, but the question is: how much is the potential after applying agronomic measures and water-saving irrigation technologies? Reasonable analysis of AWP has great practical and referential significance in developing agricultural water-saving and making water-saving policies and water resources utilizing plans.

DOI: http://dx.doi.org/10.15666/aeer/1504_12551274

Considering that water dissipation mainly occurs in two different processes: water transmission (Tang et al., 2014a) and field evapotranspiration (Wu et al., 2012; Pereira, 2017), water consumption could be influenced directly by changing the two links (Wang et al., 2011). The two processes were discussed separately in this study. The amount of water that can be saved in the process of water transmission is denoted as resource-based saving amount, and the amount of water that can be saved in the field is denoted as efficiency-based saving amount (Wang et al., 2011). In addition, at different precipitation levels, the amounts of irrigation water are different from each other (Bennett et al., 2014; Siderius et al., 2015), so precipitation has to be considered in discussions on water-saving potential and the potential shall be estimated at different Guaranteed Rate of Precipitation (GRP) (Zhang et al., 2007).

By selecting the climate condition (precipitation), in which the GRP was respectively 25%, 50%, 75%, and 90%, the water-saving potentials of the main irrigation areas in the Guanzhong region were analyzed. The water-saving potentials of main crops (winter wheat, summer corn, cotton, fruit tree, cole) in the irrigation areas under the extreme drought condition, in which the GRP was 95%, were analyzed emphatically. Finally, some suggestions on agricultural water-saving modes were proposed according to the current water-saving technologies and the features of planting structure in the nine irrigation areas. This study aims to establish a method to estimate water saving potential, as a theoretical basis for effective utilization of water resources in the irrigation areas and comprehensive development and utilization of water resources in the Weihe River Basin.

Materials and Methods

The Study Area

Guanzhong irrigation areas are located in Shaanxi Province, and involve 5 prefecture-level cities: Baoji, Xi'an, Xianyang, Tongchuan, and Weinan. Agricultural irrigation water in Shaanxi Province concentrates in the areas. Including 9 major irrigation areas and covering a total area of 22,000 km^2, Guanzhong irrigation areas are mainly distributed in the Weihe Valley and valleys of its tributaries (*Fig. 1*). The irrigation areas are located in the continental monsoon climate zone. with a multi-year average precipitation of 600 mm. The mean annual temperature varies from 7.2 °C to 15.2 °C (Wu and Sun, 2016). Precipitation concentrates in July and August, and the precipitation in the two months accounts for nearly 50% of the annual total (Wu et al., 2017). The irrigation areas enjoy abundant sunshine, with a multi-year average sunshine duration of 1,900-2,400 h. Annual actural evapotranspiration in the irrigation areas is 900-1200 mm (Wu et al., 2017). The difference between annual evapotranspiration and precipitation is relatively great, with the highest in summer and lowest in winter and the difference in spring is higher than that in autumn. Defined as semi-arid and semi-humid irrigated agricultural areas in warm temperature zone, Guanzhong irrigation areas are suitable for planting a variety of crops. Guanzhong irrigation areas account for 1/3 of the total grain production in Shaanxi Province (Wang et al., 2011). In addition, vegetables, fruits, and other commercial crops are widely grown in the areas as well, and multiple-cropping index is high. The main food crops in the irrigation areas include wheat, maize, and beans, and the commercial crops include cotton, oil plants, fruits, vegetables, etc. Fruit-planting areas

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_12551274

are mainly located in Baojixia, Luohuiqu, Yangmaowan, Shibaochuan, Taoqupo irrigation areas (Wang et al., 2012b; Yin et al., 2013).

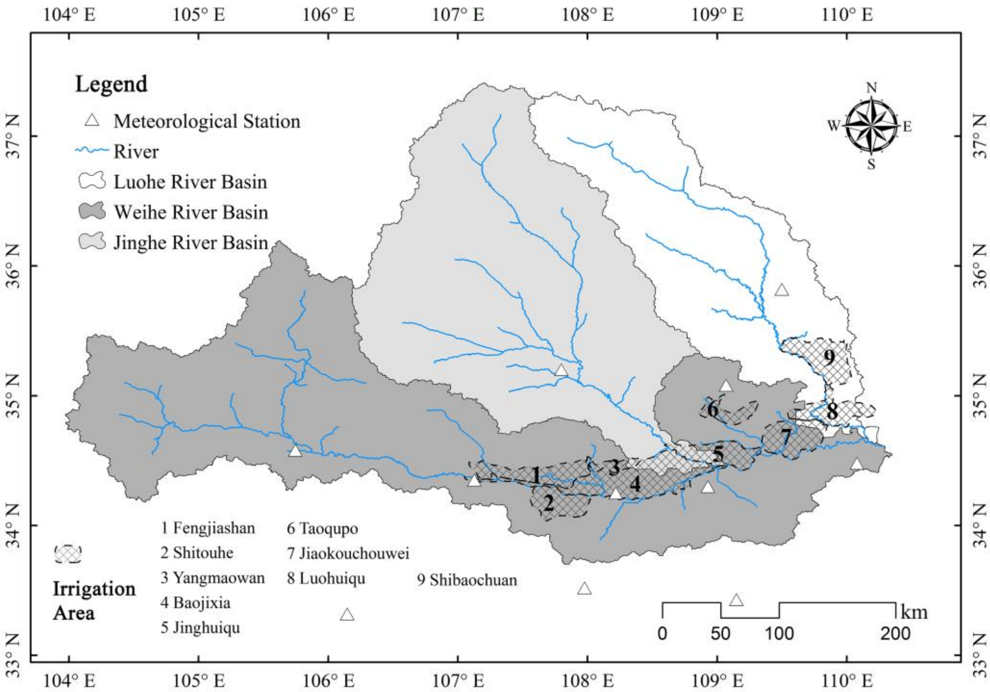

Figure 1. *Map of the 9 irrigation areas in Guanzhong area*

Over the years, the average annual amount of diverted water in the irrigation areas is 1.787 billion m^3, 82.65% of which is diverted by means of ground channel system; the other water is drawn from on-site wells (Yin et al., 2013). The irrigation water for the irrigation areas is mainly taken from Jinghe River, Luohe River, and Weihe River, but the runoff of these rivers is distributed unevenly throughout the year, with the runoff from June to October accounting for 50-70% of the annual runoff (Wang et al., 2011).

Data sources

Meteorological and hydrological data used in this study includes precipitation, temperature, relative humidity, wind speed, sunshine duration, air pressure, vapor pressure, and evapotranspiration data recorded by a number of meteorological stations in the Guanzhong region over 35 years (1981-2015) and provided by China Meteorological Data Sharing Service System (http://data.cma.cn/) (the distribution of the meteorological stations is shown in *Fig. 1*). Other data includes social and economic data (mainly about agricultural water and crop structure, such as the area of main crops in Guanzhong irrigation areas, and irrigation water use), which was collected from statistical yearbooks of Shaanxi Province and official reports on water resources of the Weihe River Basin. After collecting natural and social original data, spatial interpolation method was then used to obtain the mean value of Guanzhong irrigation areas.

Methodology

Theoretical AWP

In the study, we divided AWP into two types, namely resource-based water-saving potential and efficiency-based water-saving potential. The resource-based water-saving potential refers to the saving amount that is achieved by reforming or adjusting water supply to reduce water evapotranspiration and deep percolation; the efficiency-based water-saving potential refers to the saving amount that is achieved by controlling the soil water required for crop growth. The total water-saving potential is the sum of resource-based water-saving potential, W_r, and efficiency-based water-saving potential, W_e, as shown in (Eq.1):

$$W = W_r + W_e \quad \text{(Eq.1)}$$

where, W represents the water-saving potential of an irrigation area, and the subscripts indicate the types of water-saving potential.

The equation for calculating the maximum water-saving potential of a region, $W_{r,m}$ is written as:

$$W_{r,m} = D_c + D_f = (1-\xi_c)I_g + \xi_f(1-\xi_c)I_g = (1+\xi_f)(1-\xi_c)I_g \quad \text{(Eq.2)}$$

where, D respectively represent water loss in the process of water transmission by channels (D_c) and deep percolation in the field (D_f), which can be calculated by using the gross irrigation water amount I_g, the coefficient of water transmission by channels ξ_c, and the coefficient of irrigation in the field ξ_f, From being drawn from water sources to being assimilated by crops, irrigation water is first converted to soil water after being transported to farmlands through channels, and then used by crops through transpiration to generate biomass. Meanwhile, some of irrigation water would lose in forms of soil evaporation, deep percolation, and surface runoff. Therefore, the actual amount of irrigation water needed by crops is much higher than the net irrigation water demand.

The resource-based water-saving coefficient ξ_r is the ratio of resource-based water-saving amount to the gross irrigation water amount, written as:

$$\xi_r = W_{r,m} / I_g = (1+\xi_r)(1- \xi_r) \quad \text{(Eq.3)}$$

The resource-based water utilization coefficient, ζ_r, is written as:

$$\zeta_r = 1- \xi_r = 1- (1+\xi_r)(1- \xi_r) \quad \text{(Eq.4)}$$

If the coefficient of water transmission by channels and the coefficient of irrigation in the field are known, the resource-based water utilization coefficient could be calculated.

Efficiency-based water saving includes two aspects: reducing ineffective water consumption in the growing process of crops, and reducing water consumption by adjusting crops' water consumption process based on crops' physiological characteristics. Thus, efficiency-based water-saving potential includes the potential from reduction of ineffective water consumption and the potential from reduction of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_12551274

crop evapotranspiration. The equation for calculating efficiency-based water-saving amount is written as:

$$W_{e,m} = ET_{ine} + \varphi_1 (ET - ET_{ine}) = \varphi_2 ET + \varphi_1 (ET - \varphi_2 ET) = ET(\varphi_1 + \varphi_2 - \varphi_1 \varphi_2) \quad \text{(Eq.5)}$$

where, E_{ine} represents the ineffective water consumption in the field, which is mainly the reduced evaporation from soil and can be expressed as a percentage of crop water consumption (evapotranspiration, ET); φ_1 represents the percentage of water consumption reduction in farmlands achieved by adjusting crops' physiological process; φ_2 represents the percentage of water consumption reduction in farmlands achieved by adopting covering technologies and other agronomic measures.

The efficiency-based water-saving coefficient ξ_e is the ratio of the water-saving amount to evapotranspiration, written as:

$$\xi_e = W_{e,m} / ET = (\varphi_1 + \varphi_2 - \varphi_1 \varphi_2) \quad \text{(Eq.6)}$$

The efficiency-based water utilization coefficient ζ_e is written as:

$$\zeta_e = 1 - \xi_e = 1 - (\varphi_1 + \varphi_2 - \varphi_1 \varphi_2) \quad \text{(Eq.7)}$$

If the evapotranspiration percentage under the condition of less land coverage and the percentage of reduction achieved by sacrificing some yield are known, the efficiency-based water utilization coefficient could be calculated.

Actual AWP

The following assumptions are made in the analysis of maximum water-saving potential of the irrigation areas. For resource-based water-saving potential, assume the maximum utilization coefficient of irrigation water is 1 (the utilization coefficient of channel water is 1, and the utilization coefficient of field water is 1). For efficiency-based water-saving potential, assume the current water consumption of crops is the maximum water consumption. In practice, the utilization coefficient of irrigation water is generally less than 1. With respect to efficiency-based water saving, though crop water consumption could be reduced by using covering technologies and other measures and optimal irrigation water amount and other variables could be determined by water generation function and efficiency curve, the irrigation water for the irrigation areas is relatively less in actual production and can hardly meet crops' water demand, thus making the evapotranspiration in actual water consumption less than the maximum one.

The equation for calculating actual potential water saving amount W_p of the irrigation areas is written as:

$$W_p = I_d / \zeta_2 - I_d / \zeta_1 \quad \text{(Eq.8)}$$

where, ζ_1 and ζ_2 respectively represent the resource-based water utilization coefficients before and after applying water-saving technologies, equal to the product of the utilization coefficient of channel water, ξ_c, and the utilization coefficient of field water, ξ_f, I_d represents the net irrigation water demand of crops in the irrigation areas, which

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_12551274

depends on crops' evapotranspiration (E), precipitation (P), effective utilization coefficient of precipitation α, and crop planting area A:

$$I_d = \sum_{i=1}^{n} A_i (E_i - P\alpha - G) \quad \text{(Eq.9)}$$

where, the subscript, i, represents crop variety; A_i and E_i respectively represent the planting area and evapotranspiration of the ith crop; P and α are respectively the precipitation and the effective utilization coefficient of precipitation in the region. Because the groundwater level in the Guanzhong region is relatively deep, the influence of groundwater contribution G on the crops could be neglected and the value could be approximated as 0.

The equation for calculating the resource-based water utilization coefficient, namely the utilization coefficient of irrigation water, is written as:

$$\zeta_1 = \xi_{c,1} \times \xi_{f,1},\ \zeta_2 = \xi_{c,2} \times \xi_{f,2} \quad \text{(Eq.10)}$$

The utilization coefficient of channel water could be increased by canal lining and other measures, and the utilization coefficient of field water could be increased by land leveling, ridged field improvement, and applications of water-saving irrigation technologies. If the irrigation area of the irrigation areas and irrigation water (I) stay unchanged, and the utilization coefficient of field water is improved to $\xi_{f,2}$, then the resource-based water-saving amount is:

$$W_{r,p} = I(\zeta_2 - \zeta_1) = I \times \xi_{r,p} \quad \text{(Eq.11)}$$

where $\xi_{r,p}$ represents the resource-based water-saving coefficient, which can be written as:

$$\xi_{r,p} = \xi_c \times \xi_{f,2} - \xi_c \times \xi_{f,1} \quad \text{(Eq.12)}$$

Efficiency-based water saving mainly includes two aspects: reducing ineffective water consumption in the growing process of crops, and reducing water consumption by adjusting crops' water consumption process based on crops' physiological characteristics. The equation for calculating the efficiency-based water-saving potential, $W_{e,p}$, is written as:

$$W_{e,p} = \Delta ET / \zeta_2 = ET_b(\varphi_1 + \varphi_2 - \varphi_1\varphi_2)/\zeta_2 \quad \text{(Eq.13)}$$

where, ΔET is the reduction in crop evapotranspiration; ET_b is the water consumption of crops in the base year, which can be obtained by using the Penman-Monteith equation, recommended by FAO56 and various crop coefficients (Pereira et al., 2015).

Results

AWP with different GRP

Resource-based water-saving amount is reduced water percolation and evaporation, which are saved by implementing water-saving projects. After implementing water-saving projects in Guanzhong irrigation areas, the utilization coefficient of channel water and the utilization coefficient of irrigation water were increased to 0.65 and 0.50 respectively. According to on-site investigations, the water utilization efficiency in Guanzhong irrigation areas has been improved to 0.55. Thus, if taking ξ_c as 0.65, then ξ_f would reach to 0.85 (Wang et al., 2012b). According to the technical specification for water–saving irrigation engineering (GB/T 50363-2006) (Ministry of Housing and Urban-Rural Development of the P. R. China, 2006), the irrigation water utilization coefficient and the canal conveyance coefficient in large irrigation areas shall be no less than 0.50 and 0.55, and the utilization coefficient of field water in irrigation areas for growing rain-fed crops shall be no less than 0.90 (*Table 1*). Through comparison with the specifications, we can learn that, after implementing water-saving projects in Guanzhong irrigation areas, the utilization coefficient of irrigation water and the canal conveyance coefficient have met the requirements of the specifications, but the utilization coefficient of field water is still at a low level. Therefore, the resource-based water-saving potential is mainly from improving the utilization coefficient of field water, which can be improved by applying land leveling technology, ridged field improving technology, surge flow irrigation technology, and conduit conveyance-based sprinkling and micro-irrigation technologies.

Table 1. *Water utilization coefficient in the specification*

Technical specification for irrigation projects with low pressure pipe conveyance (GB/T 20203-2006) (Standardization Administration of the P. R. China 2006)	**The utilization coefficient of canal water ≥ 0.95**	**The utilization coefficient of field water ≥ 0.85**	**The utilization coefficient of irrigation water ≥ 0.80**
Technical specification for water–saving irrigation engineering (GB/T 50363-2006) (Ministry of Housing and Urban-Rural Development of the P. R. China 2006)	Large-scale irrigation ≥ 0.55 Medium-sized irrigation ≥ 0.65 Small-scale irrigation ≥ 0.75 Canal seepage control ≥ 0.90 Pipeline convey water ≥ 0.95	Rice based irrigation ≥ 0.95 Dry crops based irrigation ≥ 0.90	Large-scale irrigation ≥ 0.50 Medium-sized irrigation ≥ 0.60 Small-scale irrigation ≥ 0.70 Well irrigation ≥ 0.80 Drip irrigation ≥ 0.90

Meanwhile, some of Guanzhong irrigation areas are well-canal combined irrigation areas, in which the regional conduit conveyance coefficient (the percentage of conduit conveyance ≥ 0.95) could be greatly increased through implementing conduit conveyance, thus improving the utilization coefficient of irrigation water in the irrigation areas. If the conduit conveyance coefficient of the conduit-based irrigation areas (such as sprinkling irrigation areas, micro-irrigation areas, and trickle-irrigation areas) is 0.95 and the utilization coefficient of field water is 0.90, then the utilization

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_12551274

coefficient of irrigation water in the irrigation areas could reach up to 0.855, greatly improving the utilization efficiency of irrigation water. If total water demand stays unchanged, saving of irrigation water could be achieved by increasing conduit conveyance coefficient. Possible resource-based water-saving amount in different situations could be calculated according to crop planting structure and water consumption structure in different Guanzhong irrigation areas.

Resource-based AWP of typical irrigation area

In order to determine the precipitation at the GRP of 25%, 50%, 75%, and 90% respectively, we carried out a precipitation frequency analysis by using the irrigation areas' meteorological data from 1955 to 2015 through Pearson type III curve (Bobée, 1975; Feng et al., 2014), and further calculated the AWPs of the irrigation areas in the corresponding years. *Table 2* shows the resource-based AWP of the Baojixia irrigation area.

Table 2. *The resource-based AWP of Baojixia Irrigation Area in different hydrological years*

Hydrological year (GRP)	Water withdrawal (10^4m^3)	Utilization coefficient of irrigation water		Water-saving amount (10^4m^3)
		Current situations	Using water-saving technologies	
25%	14 893	0.55	0.585	891
50%	33 609	0.55	0.585	2 011
75%	33 609	0.55	0.585	2 011
90%	48 897	0.55	0.585	2 925

*Through the actual investigation, we have learned that under the current conditions of irrigation water use coefficient is 0.55, higher than the target value 0.50 of the transformation of Guanzhong Irrigation Area. After using of water-saving technology, the water use coefficient is raised to 0.585, in which channel water use efficiency is 0.65 with reference to the condition of Guanzhong Irrigation Area reconstruction. According to TSWI (GB/T 50363-2006), the field-water use coefficient is 0.90.

Efficiency-based AWP of typical irrigation area

A covering layer can significantly reduce crops' water consumption. In Guanzhong irrigation areas, covering materials are lacking in the planting season of winter wheat, and covering technologies are seldom used at that time. Therefore, in the growing period of winter wheat, φ_2=0. Large combines are generally used to harvest wheat in Guanzhong irrigation areas. When harvesting, the combines would only take wheat grains away, leaving straw on the soil surface. In addition, wheat-maize continuous cropping system is generally employed in Guanzhong irrigation areas, so summer maize is often covered by wheat straw and stubble during its growing period. According to the studies(Chen et al., 2004; Li et al., 2012), thanks to the covering layer formed by wheat stubble, the evapotranspiration of summer maize would decrease by 10-20% to about 30-50 mm. In addition, straw mulching can increase the water utilization efficiency of fruit trees by 20-30% (Liu et al., 2013) in general, and according to the equation for calculating water utilization efficiency, the water consumption of the trees would decrease by 15-25% with little change in yield. If fruit trees' annual water consumption is 600 mm, then their water consumption would decrease by 90-150 mm after applying covering technologies. In Guanzhong irrigation areas, single cropping system is generally used for planting cotton. Due to soil preparation and other factors, there is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_12551274

little possibility that the stubble of the previous crop is used as the covering layer. Therefore, it is more likely to implement plastic film mulching. As indicated by literature, plastic film mulching can decrease the water consumption of cotton by 13-18% in general (15% on average) (Zuo et al., 2010; Liu et al., 2013). The growing period of rape in the Guanzhong Plain is generally from September to May of the next year, and covering technologies are seldom used in this period. When calculating efficiency-based water-saving potentials, conditions of using the water-saving measure of covering to improve crops' water utilization efficiency were mainly considered in this study, with the measure of changing crops' physiological structure being put aside. The percentages (φ_2, namely) of reduced water consumption of different crops in the Guanzhong region, which is achieved by using covering technologies, are shown in *Table 3*.

Table 3. *The Efficiency-based AWP under mulching condition of Baojixia Irrigation Area*

On the premise that the yield does not decrease, the reducible irrigation water amount, which is achieved by applying covering technologies, can be regarded as the saved water amount. According to the irrigation habits in the Guanzhong region, winter irrigation, spring irrigation, and summer irrigation would be generally carried out in a year to meet crops' water demands in different seasons. Therefore, it is necessary to fully consider crops' water deficit and local irrigation habits when making irrigation plans for different hydrological years and calculating corresponding water-saving amount. The irrigation systems for crops in the Baojixia irrigation area for different hydrological years and savable irrigation water amount are described in *Table 4*.

Table 4. *The AWP and irrigation schedules of Baojixia Irrigation Area in different hydrological years*

Hydrological year (GRP)	AWP ($10^4 m^3$)			Irrigation schedules (irrigation amount/ irrigation times) (mm/dimensionless)				
	Total	Resource-based	Efficiency-based	Winter wheat	Summer corn	Cotton	Fruit tree	Cole
25%	891	891	0	247/2	0/0	0/0	0/0	0/0
50%	4 165	2 011	2 154	195/2	0/0	0/0	0/0	0/0
75%	4 190	2 011	2 179	268/2	0/0	0/0	0/0	134/1

AWP of each irrigation area

The *Fig. 2* shows the distribution of water-saving potentials of the nine major Guanzhong irrigation areas. It can be seen from total water-saving potentials and unit-area water-saving potentials of all the irrigation areas that total water-saving potentials and unit-area water-saving potentials varied greatly among the irrigation areas. The factors influencing total water-saving potentials include area of irrigation areas, and planting proportion of main crops. It can be seen from *Fig. 2* that the relatively large Baojixia irrigation area had relatively high total water-saving potential, while the relatively small Yangmaowan irrigation area and Taoqupo reservoir irrigation area had relatively low total water-saving potentials. The Jinghuiqu irrigation area, Jiaokouchouwei irrigation area, Luohuiqu irrigation area, and Shibaochuan irrigation area are close in size, but the former three irrigation areas had larger total water-saving potentials than the Shibaochuan irrigation area; that's because the planting area of summer maize and fruit trees in the former three irrigation areas was significantly higher than that in the Shibaochuan irrigation area. *Fig. 3* shows the proportions of resource-based water-saving potentials and efficiency-based water-saving potentials, and it can be seen that the proportions of efficiency-based water-saving potentials of all the irrigation areas were more than 50%.

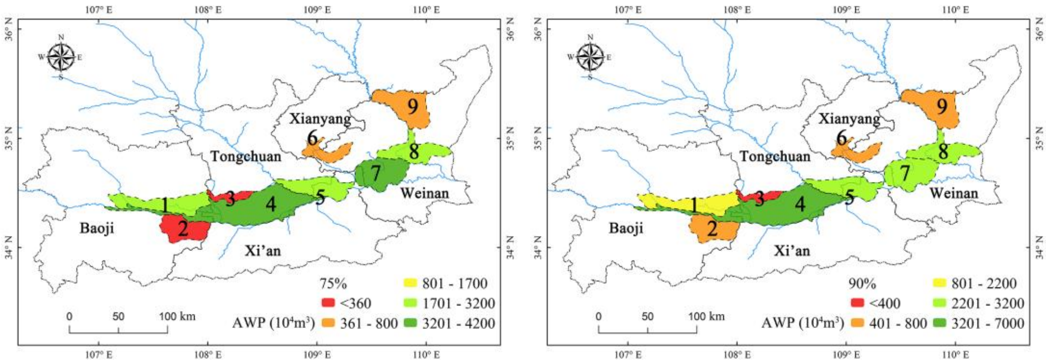

Figure 2. *Map of the total AWP of each irrigations under different GRPs*

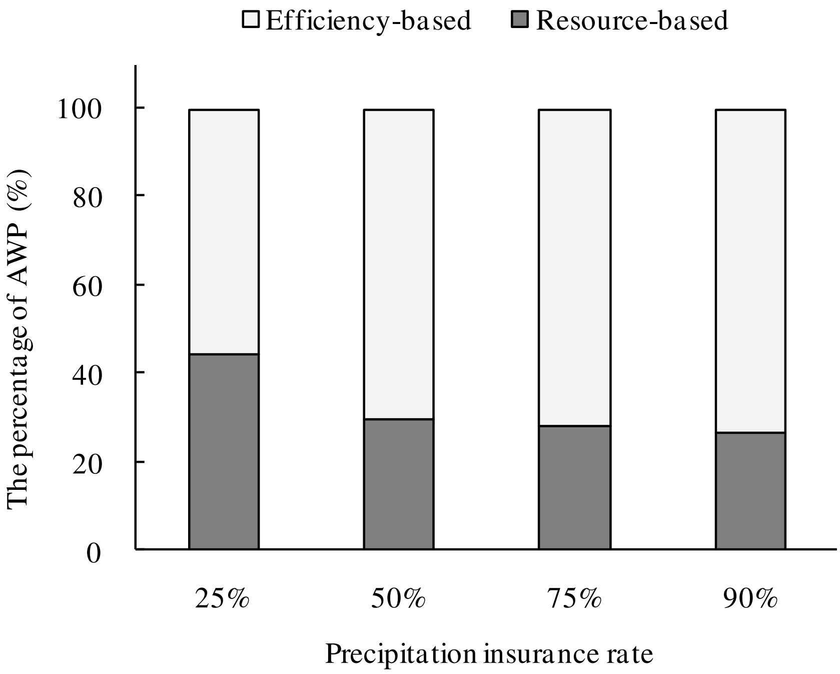

Figure 3. *The proportion of the resource-based (efficiency-based) AWP in Guanzhong Irrigation Area under different GRPs*

AWP in extreme drought condition

In extreme weather conditions, surface evaporation and plant transpiration could be reduced by using covering technologies, and thus irrigation water would be reduced and irrigation water resources would be saved. In the Guanzhong Plain, covering technologies are generally not used in planting wheat; in the growing period of maize, wheat straw is generally used to cover the ground; wheat straw or plastic film mulching could be used in planting fruit trees; plastic film mulching is generally used in planting cotton; covering technologies are generally not used in planting rape. According to relevant data (Wang et al., 2012b), when applying covering technologies, the water-saving percentages (φ_2) of summer maize, fruit trees, and cotton are respectively 15%, 20%, and 15%. Based on the percentages, water-saving amounts of different crops were

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_12551274

calculated. Water-saving potentials of main crops in Guanzhong irrigation areas under extreme drought condition are shown in *Fig. 4* and *Fig. 5*.

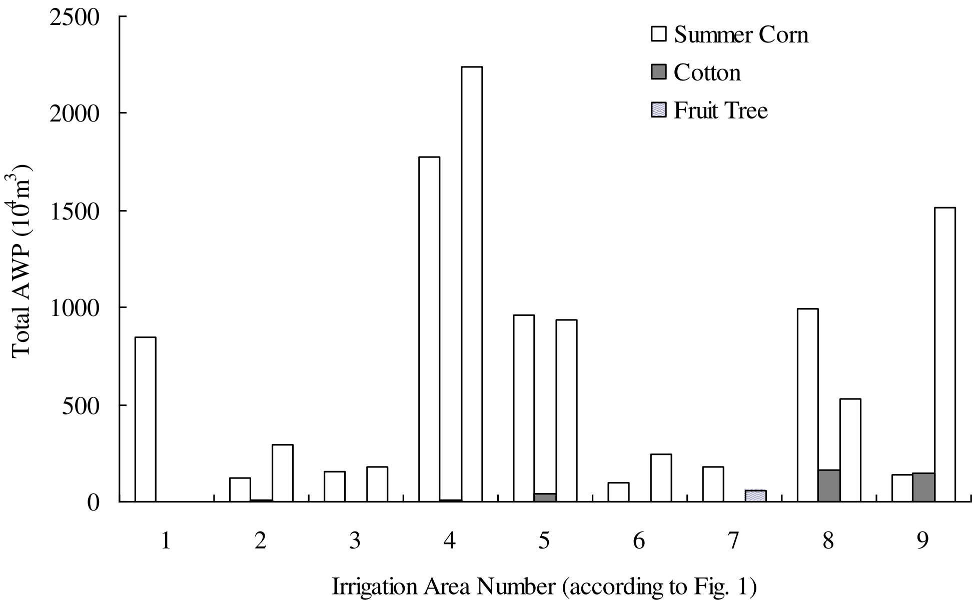

Figure 4. *The total AWP of main crops in Guanzhong irrigation areas in extreme drought condition*

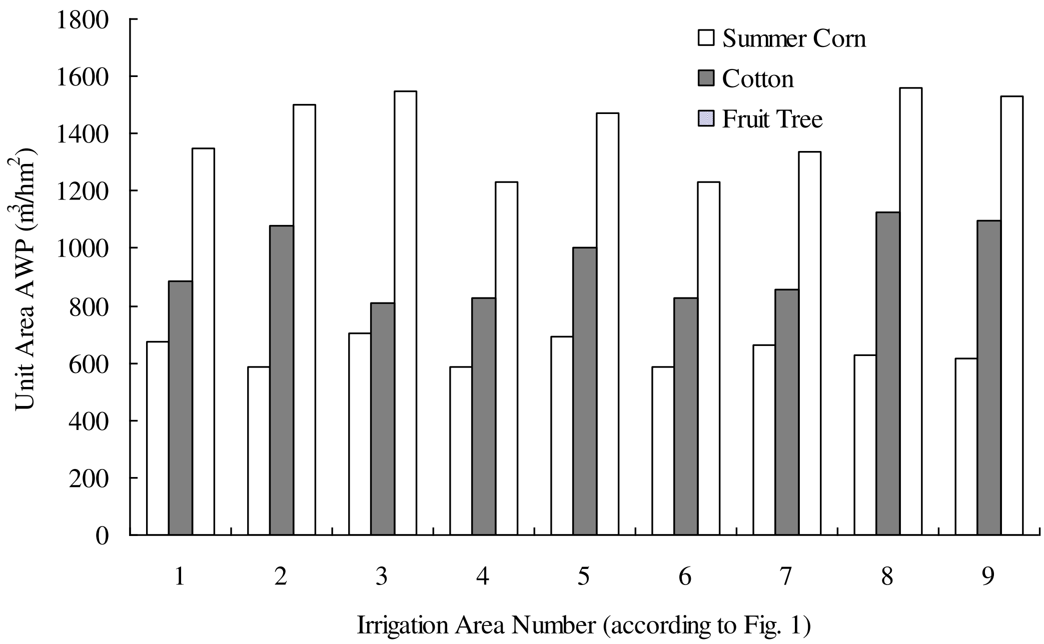

Figure 5. *The unit area AWP of main crops in Guanzhong irrigation areas in extreme drought condition*

From *Fig. 4* and *Fig. 5*, it can be seen that the total water-saving potential of each irrigation area was mainly contributed by summer maize and fruit trees, which accounted for more than 95% of the total water-saving potential. By contrast, winter

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_12551274

wheat and rape had very small water-saving potentials, which are not shown in the figures. In terms of unit-area water-saving amount, fruit trees, cotton, and summer maize had highest water-saving efficiency, much higher than that of rape and winter wheat. The unit-area water-saving amounts of fruit trees, cotton, and summer maize did not vary much among the nine major irrigation areas, with their average values being 9.4, 6.3, and 4.3 mm respectively. This result is consistent with the actual situation that the irrigation areas are located in the same climate zone and were at a similar technical level of agricultural production.

By using the main crops' water-saving potentials, the total water-saving potentials and unit-area water-saving potentials of the Guanzhong irrigation areas were obtained, as shown in *Figs. 6-8*.

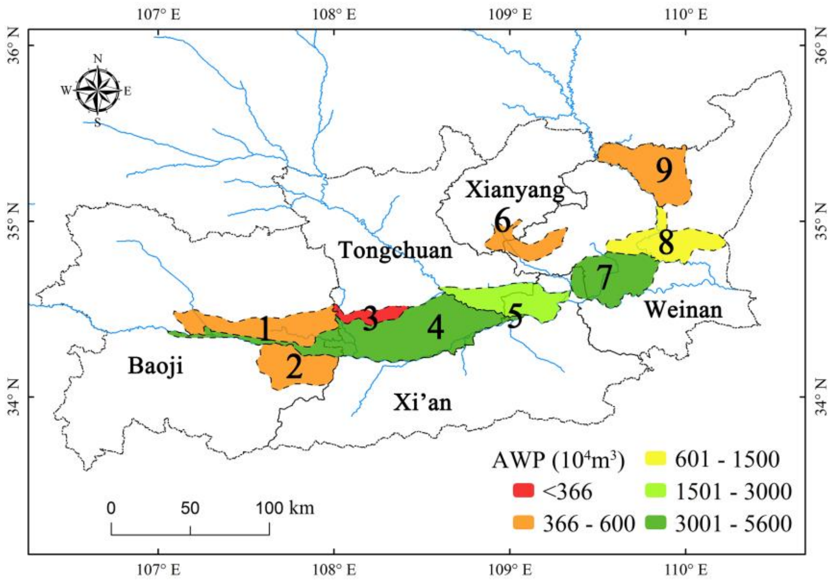

***Figure 6.** The total AWP in each irrigation area in extreme drought condition*

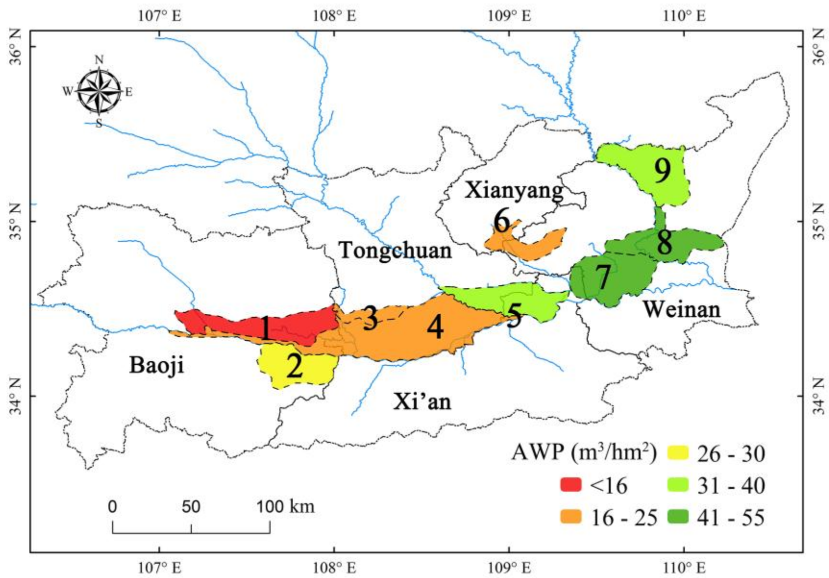

***Figure 7.** The unit area AWP in each irrigation area in extreme drought condition*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_12551274

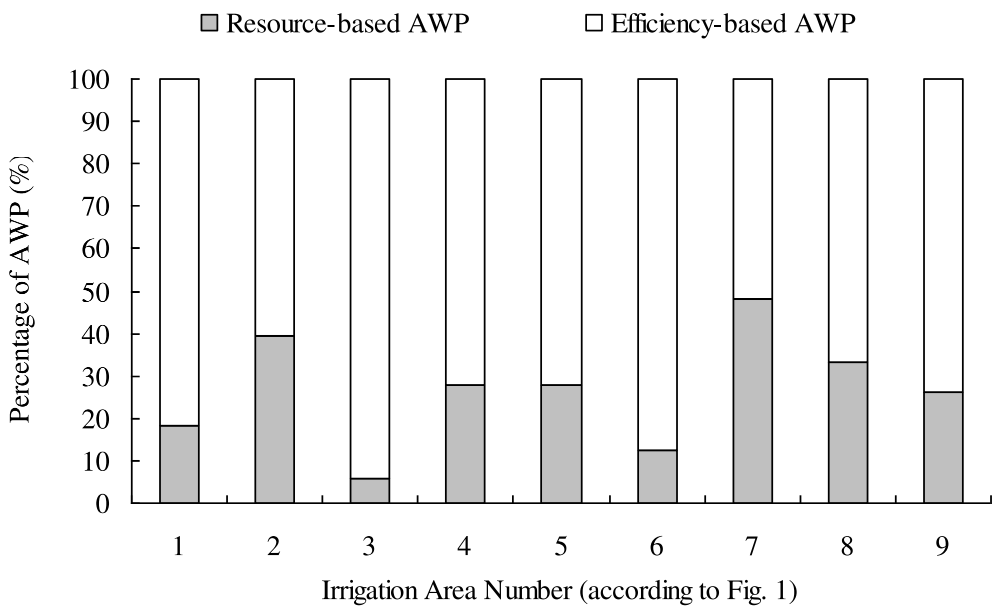

Figure 8. *The percentage of the resource-based (efficiency-based) AWP in each irrigation area in extreme drought condition*

It can be seen from total water-saving potentials and unit-area water-saving potentials of all the irrigation areas in extreme climate conditions that total water-saving potentials and unit-area water-saving potentials varied greatly among the irrigation areas. The factors influencing total water-saving potentials include area of irrigation areas, and planting proportion of main crops. It can be seen from *Fig. 6* that the relatively large Baojixia irrigation area had relatively high total water-saving potential, while the relatively small Yangmaowan irrigation area and Taoqupo reservoir irrigation area had relatively low total water-saving potentials. The Jinghuiqu irrigation area, Jiaokouchouwei irrigation area, Luohuiqu irrigation area, and Shibaochuan irrigation area are close in size, but the former three irrigation areas had larger total water-saving potentials than the Shibaochuan irrigation area; that's because the planting area of summer maize and fruit trees in the former three irrigation areas was significantly higher than that in the Shibaochuan irrigation area.

At different hydrologic conditions (GRP of 25%, 50%, 75%, 90%, and 95%), the proportions of resource-based water-saving potentials and efficiency-based water-saving potentials show that the proportions of efficiency-based water-saving potentials of all the irrigation areas were more than 50%. Thus it can be concluded that improvement of crops' water utilization efficiency should be in preference to improvement of water conveyance efficiency in technology innovation.

Discussion and Conclusions

Concepts and connotations of resource-based water saving and efficiency-based water saving were proposed in this study, and models for calculating water-saving potentials of the two types were established. Key parameters of the calculation models were studied in depth, and the resource-based water-saving coefficient and efficiency-based water-saving coefficient of the main crops in the typical irrigation area (Baojixia)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_12551274

were determined based on water-saving schemes for different crops. Based on the established models for calculating water-saving potentials, water-saving potentials of different crops in different water-saving schemes were calculated. In addition, possible resource-based water-saving potentials and efficiency-based water-saving potentials of the nine major irrigation areas in different hydrological years were calculated respectively.

Based on different irrigation areas' planting structure and planting scale, agricultural water-saving schemes were proposed. For the food crops-oriented Shitouhe irrigation area, it is recommended to mainly apply land leveling technology, surge flow irrigation technology or sprinkling irrigation technology, and straw mulching technology. For the commercial crops-oriented Jiaokou and Shibaochuan irrigation areas, it is recommended to apply micro-irrigation technologies and covering technologies. For the cotton-oriented Luohuiqu irrigation area, it is recommended to apply land leveling technology, surge flow irrigation technology, and covering technologies, and to popularize field sprinkling irrigation and trickle irrigation technologies appropriately. For the Baojixia, Fengjiashan, Jinghuiqu, and Yangmaowan irrigation areas, which are oriented at planting food crops and commercial crops, it is recommended to apply land leveling technology, surge flow irrigation technology, and straw mulching technology according to actual circumstances, to popularize field sprinkling irrigation technology appropriately, and to vigorously popularize trickle irrigation technology in areas for planting commercial crops.

Currently, comprehensive definitions of water-saving agriculture and water-saving potential have not been given authoritatively in the research field. As a result, there are numerous directions in researches on specific issues. Thus, in researches on water utilization efficiency, it is still necessary to find out which calculation model is most practical, particularly in calculating water amount. Water-saving potentials vary greatly among research objects. Currently, researches are mainly carried out on improvements to diversion and irrigation projects and agronomic measures in the field, which actually would bring relatively static potentials. In addition, scale effect problem exists in the process of studying water utilization efficiency and water-saving potential. Regarding components of water amount, many scholars have proposed 3 scales in water balance calculation, which are respectively field scale, mesoscale, and macro-scale. As indicated by this study, resource-based water saving is more suitable for micro-scale and mesoscale, while efficiency-based water saving is more suitable for macro-scale. However, effective and reasonable methods to eliminate scale effect and realize conversion between different scales have not yet been proposed and will be an emphasis in future research.

In recent studies, AWP is generally taken as the difference between irrigation water use in a base year and that in a planned year. However, the base year is often selected at will without a standard, and the concept in this sense is not yet perfect due to the scale effect problem. Water-saving irrigation could be applied not only in irrigation agriculture, but also in dryland agriculture. However, applications in the latter are fewer than in the former, so studies on water-saving potential are mainly targeted at irrigation agriculture. In addition, studies on precipitation accumulation and utilization in the region where irrigation agriculture prevails should be enhanced.

The utilization coefficient of irrigation water is an important indicator for evaluation in water-saving agriculture, which is generally taken as the product of the utilization coefficient of channel water and the utilization coefficient of field water. Loss of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_12551274

irrigation water would directly influence the utilization efficiency of irrigation water. From this perspective, the factors influencing the utilization coefficient of irrigation water mainly include size of irrigation areas, diversion discharge, groundwater level, soil conditions, and types and technologies of anti-percolation works in irrigation areas. The following problems need to be solved in obtaining the coefficients: heavy workload; it is difficult to guarantee stable measuring conditions (that is because irrigation measurement is generally carried out in production period, during which irrigation water flow, length of channels, existence of branches, and other conditions are subject to changes, thus making measurement very difficult); a great deal of talents possessing special technical knowledge are needed in measuring the coefficients; representative evaluation of the determined coefficients is necessary. The above-mentioned problems need to be discussed in future studies.

(Received 2nd May 2017; accepted 17th July 2017)

Abstract. The long-term effect of Bt-maize on soil animals is an important, repeatedly discussed, but a poorly investigated topic. The collembolan *Folsomia candida* is a recognised representative of the mesofauna in the laboratory ecotoxicological experiments. The following questions were addressed in the present experiment: (i) is there any consequence on some life-history traits of *F. candida*, if Bt-maize is provided as food after about 4 years of feeding instead of the near-isogenic counterpart, and (ii) is there any effect on life-history traits, if the near-isogenic and Bt-toxin containing food is changed? Long-term (40-48 generations) feeding on Bt-maize leaf caused alterations in some life-history traits (larger eggs, higher growth rate both in length and width). On the other hand, reproduction (egg size, the total number of eggs, the number of eggs in the first clutch) was influenced, if Bt-toxin containing maize was replaced by its near-isogenic counterpart. Based on currently available methodologies, it is not possible to judge, whether observed differences are due to the Bt-toxin or another component of the maize leaf.
Keywords: *MON810 maize; Cry1Ab toxin; egg size; body growth; sublethal effect*

Introduction

Genetically engineered (GM) crops are cultivated on 179.7 million hectares all over the world from which maize plants are planted on 53.9 million hectares (James, 2015). Side effects of GM plants on soil animals have been studied both in the field as well as laboratory experiments in numerous cases. The results of the field experiments are summarised e.g. by Birch et al. (2007) and currently by Arias-Martín et al. (2016). In general, no severe side-effects on soil animal (Zwahlen et al., 2007; Hönemann et al., 2008) or collembolan (Marvier et al., 2007; Comas et al., 2014) populations and coenosees were found in the field.

Laboratory experiments were performed with GM plants and several non-target soil animal species, like earthworms, woodlouse, nematodes, collembolan, etc. Collembolans occupy a substantial position in plant litter decomposition processes, forming soil microstructure and regulating microbial species composition and biomass (Bakonyi, 1989; Rusek, 1998). That is why collembolan species are used in the laboratory for soil biological studies. The most frequently employed species of them is *Folsomia candida* Willem 1902 (Fountain and Hopkin, 2005). This species have been often in the focus of ecotoxicological studies as well as when the side-effects of the GM plants is examined (Jepson et al., 1994). Besides, this species is recommended as a representative of decomposers, if GM plant and/or Bt-protein effect on non-target organisms is investigated (Römbke et al., 2010; De Schrijver et al., 2016).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_12751286

Studying the side-effects of the GM plants on *F. candida*, short-term laboratory studies were conducted in most cases. Tested material included purified toxin as well as different plant parts as pollen, stalk, root or leaf. Their effects were investigated on different life-history traits of *F. candida*, as mortality, reproduction, and growth.

Four Bt-toxins (Cry1Ab, Cry1Ac, Cry2A, Cry3A) presented in the diet (mixed with Baker's yeast) did not influence adult mortality and the number of juveniles o*f F. candida* (Sims and Martin, 1997). Similarly, in a dietary exposure assay, Cry1C and Cry2A toxin did not influence either the survival, and development of the animals, nor the measured antioxidant-, detoxification-, and digestion-related enzyme activities (Yang et al., 2015). However, Broza et al. (2001) found decreased reproduction if *F. candida* was fed on B. thuringiensis diet.

Yu et al. (1997) studied the effect of the Bt-toxin (Cry1Ab and Cry1Ac) producing cotton on oviposition time, the number of eggs, and final body lengths of the *F. candida*, but the measured traits remained unaffected. Romeis et al. (2003) did not find differences in mortality, clutch size, body weight and duration of egg development when *F. candida* was fed on the KP4-transgenic wheat plant (Golin and Greina varieties) and its near-isogenic counterpart. The effects of Bt and near-isogenic lines of rice were studied in two laboratory experiments. In the first one, Bai et al. (2011) used two Cry1Ab containing Bt-rice lines and their near-isogenic counterpart as food. Growth, reproduction, and superoxide dismutase activity were unaffected both in the Petri-dish and soil microcosm experiment. In the second study, root, stem, and leaf of three Bt and non-Bt-rice were provided as food and survival, reproduction and growth as traits were measured (Yuan et al., 2013). Differences in the measured traits between the treatments were not observed in these two studies.

Regarding the effect of the GM maize consumption on *F. candida*, few studies were published till now. Comparing the effects of near-isogenic and Bt-maize (Bt11 and MON810 varieties), no significant differences were detected as a consequence of feeding on Bt-maize in mortality and offspring number by Clark and Coats (2006). Bakonyi et al. (2006) observed about 30% less fecal pellets around the Bt-maize (MON810) than its near-isogenic counterpart. Recently, Zhang et al. (2017) found no effect of Cry1Ab/Cry2Aj toxin contained maize pollen on *F. candida* survival, development, and reproduction.

As presented above, several short-term experiments with *F. candida* exist, but long-term laboratory studies are scarce. As far as we know, no other research group as ours is working in this research field. In a previous study (Bakonyi et al., 2011) no effect of Bt-maize (MON810) on egg production and food choice of *F. candida* was found if the animals were fed up to 29 months with this plant leaves. Working under similar experimental circumstances as in the mentioned study, the following questions were addressed in the present study: (i) is there any consequence on life-history traits of *F. candida*, if Bt maize is provided as food after about 4 years (40-48 generations) of feeding instead of the near-isogenic counterpart, and (ii) is there any effect on life-history traits, if the food is changed, e.g. near-isogenic maize line is provided after feeding on Bt-maize for 4 years? It was hypothesized that (i) long-term feeding has an impact on life-history traits, because of the different quality of the Bt and near-isogenic plants and (ii) a shift due to the food change will appear in life-history traits of *F. candida*, because this species preferred near-isogenic maize leaves in a previous experiment (Bakonyi et al., 2006).

Material and Methods

Folsomia candida Willem 1902 (Collembola, Isotomidae) used in this study was obtained from the stock population reared in the laboratory of the Szent István University, Department of Zoology and Animal Ecology, Gödöllő (Hungary) since about 20 years. Our animals are belonging to the clade B according to the grouping by Tully et al. (Tully et al., 2006). Collembolans were kept in Petri dishes of a diameter 9 cm based on the method of Goto (1960). Animals in stock culture were kept at a temperature of 20±0.2 °C, with constant humidity (~ 100%) and in total darkness. Dry baker's yeast was given as food ad libitum once a week.

This experiment was started with two stock populations. One of them was fed with MON810 (YieldGard®) maize line and the second one with its near-isogenic counterpart (variety DK-440). Both groups of collembolans were fed with ground leaf of these maize varieties for 4 years. Maize leaves of similar size and position on the plant were collected at harvest than stored dried, in a dark, cool place. Since the embryonic development of our animals takes about 8-10 days, and they arrive their sexual maturity in 10-12 days, its generation time is calculated as roughly one month. Consequently, 10-12 generation per year as a conservative estimation was used for calculating the total number of generations under conditions of our laboratory.

Ground leaf litter was presented as food ad libitum and two grains of baker's yeast to arrange balanced nutrition of the animals. Nitrogen and carbon content of the maize leaf was as follows: N% 0.27 ± 0.02 and 0.29 ± 0.03 and C% 41.9 ± 4.2 and 40.5 ± 4.5 for isogenic and Bt-maize, respectively. Cry1Ab concentration was 8.38 ± 0.19 µg/g dry leaf material, which is in the range presented by Székács et al. (2010). Leaf of MON810 used in this study contained higher Cry1Ab concentration, in comparison with root, stem, anther wall and pollen (Székács et al., 2010).

The experiment was performed with 10-12 days old synchronised *F. candida* individuals. Every treatment of the collembolans was started with 50 animals. They were kept in 5 cm high plastic dishes (the base 5.3 cm and the top 6.6 cm in diameter). Two cm of the mixture of active carbon and plaster of Paris was layered on the bottom in a ratio of 1:10. The top of the wet mixture was scrubbed to arrange smooth surface without holes. The animals were kept individually. Each collembolan got a unique identification number. The experimental animals were kept in total darkness, at a temperature of 20±0.2 °C and with constant humidity (~ 100%). The length of the experiment was 29 days.

Four treatments were set up in the experiment, as follows:

- IsoIso treatment: collembolans consumed the near-isogenic maize (DK-440) for 4 years before the experiment and during the experiment, as well.
- IsoBt treatment: collembolans consumed the near-isogenic maize (DK-440) for 4 years, but MON810 maize during the experiment.
- BtBt treatment: collembolans consumed MON810 maize for 4 years before the experiment and during the experiment, as well.
- BtIso treatment: consumed MON810 maize for 4 years, but near-isogenic maize (DK-440) during the experiment.

Following traits were measured in this study: 1.) final length (mm), 2.) length growth rate, 3.) final width (mm), 4. width growth rate, 5.) number of eggs in the first clutch, 6.) days till first clutch, 7.) total No. of eggs, 8.) No. of eggs/clutch, 9.) egg size (mm).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_12751286

Digital photos were taken from each animal twice a week from 4 to 29 days (Olympus C7070 Wide zoom camera with Olympus C5060 ADL optic). The length of the animals was measured from the frons to the end of the last segment, while the width at the widest part of the metathorax. The length and width for any collembolan at a given time were calculated as the mean of measurements on two consecutive photos to avoid inaccuracy which may cause of collembolan movements. Final body length and width, as well as growth rate, were calculated with the CurveExpert 1.4 software for any animals (Hyams, 2010). The equation Exponential Association (y = a(1-e^-bx; where a = final value of length or with; b = growth rate) was applied. Only those animal's data were regarded which survived until the end of the experiment.

The egg clutches were transferred to Petri dishes which contained a 0.5 cm high mixture of active carbon and plaster of Paris (1:10) on the bottom. The clutches were spread carefully with a wet brush in order to separate eggs from each other and digital photo was taken from them (BTC STM-9T microscope equipped with MicroQ-PRO type camera). The eggs were numbered on the photo. After that, an egg was chosen randomly from all of the clutches. The shortest and longest diameters of the eggs relative at a 90° angle to each other were measured with the aid of the ImageJ software (Schneider et al., 2012). Egg diameters were transformed so that the two diameters were multiplied by each other and the square root of it was extracted, so it gives a diameter as the egg were perfectly round (TD = egg size, hereafter). Egg numbers and the date of egg laying were monitored continuously every day during the experiment.

Final length, length growth rate, final width and width growth rate were compared with ANOVA. If the significant effect was found ($p < 0.05$) than posthoc Bonferroni-Holm test was applied. Effect of treatment on a total number of eggs, the number of eggs in the first clutch, days till the first clutch, the number of eggs/clutch and egg size (TD) was analysed with linear models. The mortality of the animals was analysed with a binomial model (R Core Team, 2012).

Canonical Variate Analysis (CVA) was performed based on the measured traits (the trait "days till the first clutch" was not applied because data distribution was not normal despite transformation). The SynTax2000 statistical program package (Podani, 1993) was used for the analysis.

Results

Long-term feeding effect

At the start of the experiment the body length and width of the 10-12 day old collembolan were significantly different between the treatments ($t = 3.9$, $df = 46$, $p < 0.001$ and $t = 2.8$, $df = 46$ $p < 0.01$, for body length and width, respectively). Growth curves of both length (*Figure 1*) and width (*Figure 2*) showed sigmoid shape type. Measured points fitted well to the curve because correlation coefficients of the fitting were 0.95 or higher in cases of all individuals. Final body length and width of the IsoIso and BtBt animals did not differ significantly from each other (*Table 1*). The length and width of the collembolans ranged from 0.426 to 2.238 mm and 0.080 to 0.583, respectively (data of all treatments). The relationship between body length and width may describe with the equation as follows: width (mm) = 0.27*length (mm) – 0.047 ($r = 0.95$, $t = 88.4$, $df = 1161$, $p < 0.001$). No treatment-related differences in body length and width relationship were found. Growth rates correlated negatively with both final body length ($r = 0.73$, $t = 10.6$, $df = 99$, $p < 0.001$) and width ($r = 0.71$, $t = 10.0$, $df = 99$,

p < 0.001). This relationship is seen very clearly in *Figure 3*. as well. Egg size and a total number of eggs did not correlate each other.

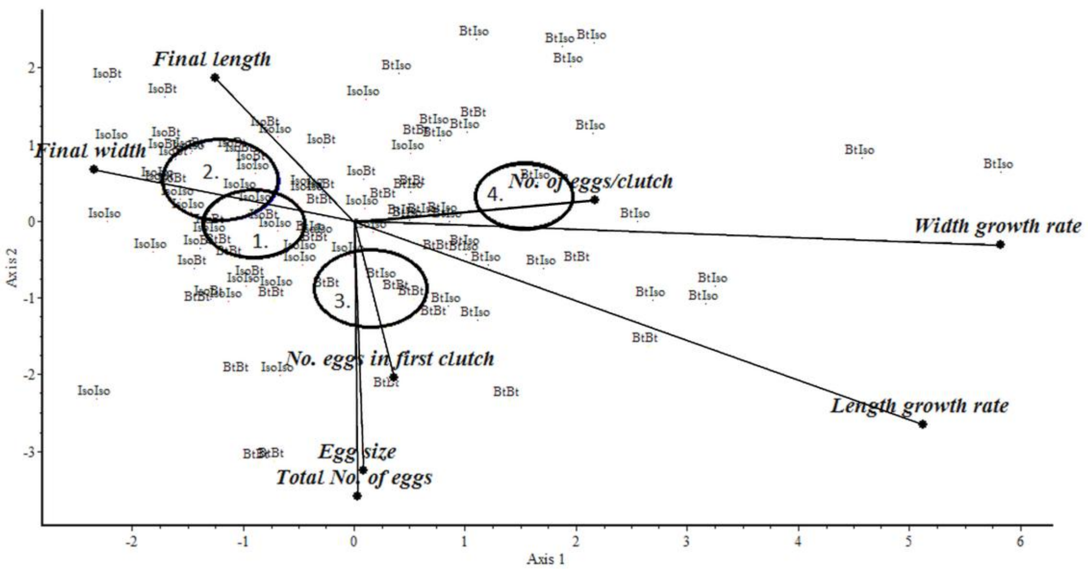

Figure 3. *Results of the CVA analysis. Confidence circles are shown. Numbers of treatments are as follows: 1. IsoIso, 2. IsoBt, 3. BtBt, 4 BtIso.*

The effect of the long-term feeding is demonstrable by comparing data from IsoIso and BtBt treatments. Three out of nine measured traits showed significant differences between these treatments (*Table 1*). Both of the length and with growth rate was higher in the case of the BtBt treatment during the investigated period. Besides, collembolans in BtBt treatment laid significantly larger eggs. No other traits differed between the two treatments (*Table 1*). The mortality of the four treatments was 22, 29, 20 and 28 percent

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_12751286

in IsoIso, IsoBt, Bt Iso, and BtBt treatment, respectively. No significant differences were detected between these values (p= 0.231, z= -1.197).

Food change effect

Changing of food source did not cause significant alteration in any traits measured in the study (*Table 1*). Neither the food change from Iso to Bt nor vice versa has any statistical difference in life-history traits. However, egg size and total number of eggs correlate negatively each other ($r = 0.41$, $t = 2.4$, $p < 0.03$ and $r = 0.32$, $t = 2.1$, $p < 0.05$ for IsoBt and BtIso treatments, respectively).

Results of the CVA analysis show differences between population traits (*Figure 3*). Eigenvalues as a percent of Axis1 and 2 are 78.7 and 16.1, respectively, i.e. the first two axes explain 94.8 percent of the total variance. Both Axis1 and 2 contribute significantly to separation of the groups (chi2 = 107.1, df = 24, $p < 0.001$ and chi2 = 29.6, df: 14, $p < 0.01$ for Axis1 and 2, respectively). Axis1 determines first of all the growth and Axis2 the reproduction of the *F. candida*. The main factors responsible for the separation of all the four groups are final length and width as well as their growth rates. This result coincides with a negative correlation of final size and growth rate of animals, as it was presented before. The traits, "total number of eggs", and "egg size" distinguish between groups, where food change occurred, especially in the case of the BtIso treatment (*Figure 3*).

The mortality of the four treatments was 22, 29, 20 and 28 percent in IsoIso, IsoBt, Bt Iso, and BtBt treatment, respectively. The alteration of the food did not cause a significant difference in mortality (p= 0.1109, z= -1.594), but the interaction of the long-term feeding and the food change was significantly associated with mortality (p= 0.0345, z= 2.114).

Discussion

According to Zwahlen et al. (2003), the Cry1Ab toxin can persist in the soil up to 2 years. In spite of this fact, a long-term investigation of Cry1Ab toxin producing maize on soil fauna is very rare. That is why Heckmann et al. (2006) and Székács and Darvas (2013) emphasise the significance this kind of studies.

In our previous investigation with *F. candida* (Bakonyi et al., 2011), we did not find a relationship between elapsed time from the start of feeding on the Bt-maize and a total number of eggs produced by one individual. This trait was affected neither in the present, a longer experiment where similar maize lines were used.

It has long been known that food limitation (Martin, 1987), as well as the quality of the food (Boersma and Kreutzer, 2002), can considerably influence life history traits. According to the results of the present study, two slightly different life-history strategies seem to emerge due to long-term feeding on two qualitatively different food sources. Our populations have been fed for 40-48 generations on either near-isogenic or Bt-maize. So many generations may be definitely enough for adaptive changes of life-history and adjust to different food sources (Awmack and Leather, 2002; Fricke and Arnqvist, 2007). Probably, as a consequence of accommodation to food, our collembolans in BtBt treatment produced larger eggs than in IsoIso one. Tully and Ferrière (2008) found that there is a positive relationship between egg size and juvenile size, and larger *F. candida* juveniles have improved quality, which means a higher chance to survive and better productivity. Maybe that is why the time until the first

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_12751286

clutch is shorter (although not significantly) and the body growth rate is higher in BtBt treatment and BtBt collembolans reach their maturity earlier. In the case of the IsoIso treatment, all these traits are changing oppositely. However, the final body size is equal in both treatments. The result of all these events is the differently shaped growth curves of collembolans in IsoIso and BtBt treatments (*Figure 4*).

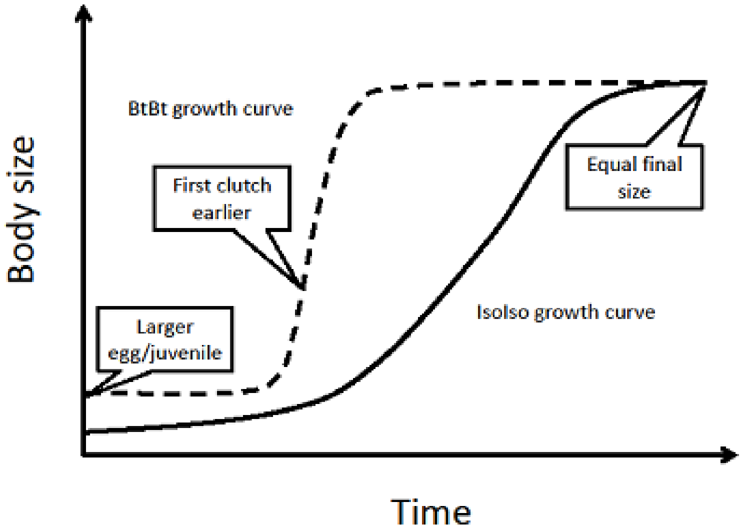

Figure 4. *Schematic presentation of results summary. Differences in body length growth of the IsoIso and BtBt treatments is presented.*

Based on the results of CVA analysis, it was not a noteworthy consequence if the collembolans from the Iso stock breed were fed with Bt-maize during the experiment. Oppositely, considerable modification in reproduction traits was observable, if collembolans from Bt stock breed were fed with near-isogenic leaf during the experiment. Reproduction of the collembolan in the BtIso treatment becomes more similar to IsoIso and IsoBt treatments than to their original BtBt counterparts. Smaller eggs in the BtIso treatment may be a sign of the favorable food (Tully and Ferrière, 2008).

It is well known that food quality has a significant influence on life-history traits of *F. candida* (Jørgensen et al., 2008). So, the contrast between the two life-history strategies observed in this experiment may be the results of the different quality of maize leaves used as food. Nitrogen proved to be one of the main factors, which determine reproduction and growth of *F. candida* in several cases (Booth and Anderson, 1979; Leonard and Anderson, 1991; Kaneda and Kaneko, 2002). However, leaf nitrogen and carbon content were similar in maize leaves in our study. That is why nitrogen was probably not responsible for life-history changes detected in our study.

The higher lignin content of MON810 comparing its near-isogenic counterpart is suggesting as a factor, which can decrease digestibility of this Bt-maize by herbivores (Saxena and Stotzky, 2001). However, they investigated the lignin content of stems and not leaves, and lignin content is different in maize stem and leaf (Johnson et al., 2007). In the case of maize leaf, Tarkalson et al. (2008) did not find differences in lignin content of four maize lines (Pioneer 34N44 Bt, Pioneer 34N43, NC+4990 Bt, NC+4880). Poerschmann et al. (2005) found marginally higher lignin content in the Bt-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_12751286

maize leaf than in its near-isogenic counterpart (Novelis, Valmont Bt and Nobilis, Prelude near-isogenic lines). We did not measure the lignin content of the leaves, so the possible lignin effect remained unanswered. Besides, any undetected factor(s), which influenced *F. candida* food choice (Bakonyi et al., 2006), may also be responsible for alteration in reproductive strategy of the BtBt and IsoIso treatments.

Previous studies suggest that qualitative differences between Bt and near-isogenic lines may occur, which explain detected differences of the life-history strategies of the IsoIso and BtBt populations in this study. Our findings are in line with the results of several studies, which revealed life-history adaptation due to food alteration at *F. candida* (Booth and Anderson, 1979; Stam et al., 1996; Tully and Ferrière, 2008).

The exact effect of Cry toxins on the population biology of *F. candida* and other insect species remained an unresolved issue till now. The central problem is that Cry toxins are embedded in the matrix of plant cell cytoplasm, and their effect could be correctly interpreted only in this context. If pure Cry toxins were examined in any experiments, no effect was found (Sims and Martin, 1997; Yu et al., 1997; Galbraith et al., 2015; Yang et al., 2015). It does not mean that possible harm of the toxin could be excluded with confidence because potentiating effects has never been tested yet. However, it remains questioning, whether such a test developable or not. Moreover, if whole Bt-plant or any plant parts was tested in a study, then the current experimental methods did not separate the only effect of any cell component (including Cry toxin) from the other. New methodologies are required in order solving this problem.

Using functional traits to predict responses to environmental changes is in the focus of several contemporary soil ecological studies (Hedde et al., 2012; Salmon et al., 2014). Collembolan functional traits were involved as markers of biodiversity decline (Vandewalle et al., 2010), climate change (Makkonen et al., 2011; Bokhorst et al., 2012), forest fire (Malmström, 2012) and urbanisation (Santorufo et al., 2014). Moreover, Hawes et al. (2009) applied this approach in order to evaluate effects of genetically modified herbicide-tolerant crops on functional groups of soil invertebrates. It was found that this method is suitable for monitoring effects of the new crops introduction in an area. Correspondingly, our result indicates that *F. candida* egg size and growth are appropriate functional traits for such monitoring work.

Conclusions

Long-term (40-48 generation) feeding of *F. candida* on Cry1Ab toxin producing maize (Mon810, YieldGard®) causes considerable differences in this species compared to the treatment group which was fed with near-isogenic maize. Change of life-history parameters causes a difference in the growth curve of animals. On the other hand, a shift in food source (change from Bt to Iso maize) may initiate changes in reproduction. This shift is a quick process, which is observable even in one generation, as it is proved in this experiment.

Abstract. Two forms of ciprofloxacins (CIP) are used in animal husbandry and veterinary medicine, and may occur in manure-fertilized soil as pollutants: CIP-HCl salt, readily dissolvable in water, and the free base CIP, practically water-insoluble. The aim of this study was to compare the phytotoxicity of both forms of CIP to yellow lupin seedlings (*Lupinus luteus* L.). In eight-day-old lupin seedlings higher amounts of both water-soluble and insoluble CIP were detected in roots, compared to shoots. The amount of CIP in plants treated with CIP-HCl was 1.5 times higher compared to plants treated with the insoluble, free base form. Nevertheless, both forms of the antibiotic caused very similar reduction in lupin shoot length, root length and seedling fresh mass as well as very similar increases in seedling dry mass. Activity of guaiacol peroxidase in control seedlings was 14.09 and 49.25 U in roots and shoots, respectively, and in plants treated with CIPs it was highly dependent on the antibiotic dose. Guaiacol peroxidase activity was stimulated in plants treated with 5 mM CIP of any kind (water-soluble or insoluble), and this activation was particularly visible in roots, while the enzyme activity decreased to nearly zero in both roots and shoots of plants treated with CIPs at the level of or above 20 mM. The activity of superoxide dismutase in roots was severely repressed by even the lowest dose of any CIP, while it was slightly stimulated in shoots by any of the CIPs at the level not exceeding 10 mM. The following carbohydrates were detected in roots of lupin grown in soil contaminated with CIPs (water-soluble and insoluble): D-*chiro*-inositol, D-pinitol, *myo*-inositol, galactose, glucose and sucrose. The content of myo-inositol and sucrose in lupin roots increased with increasing concentrations of soluble and insoluble CIPs. Neither of the forms of the drug clearly affected the content of D-*chiro*-inositol, D-pinitol, glucose and galactose. Both forms of CIP showed very similar effects on lupin seedlings, however, the accumulation of CIP-HCl was a little higher compared to the free base form of this antibiotic.
Keywords: *lupin, plant uptake, guaiacol peroxidase and superoxide dismutase activity, soluble carbohydrates*

Introduction

Antibiotics are widely applied in human and veterinary medicine and industrial animal production. The increased usage of well-known forms of these pharmaceuticals, as well as the launch of new antibiotics and the spread of multi-stand industrial farms have resulted in increased environmental pollution with antibiotics and their metabolites. The environmental impact of the majority of these drugs is unknown or is regarded as low. However, their presence may be linked to ecotoxicological changes with negative effects on ecosystems (Ding and He, 2010; Santos et al., 2010).

DOI: http://dx.doi.org/10.15666/aeer/1504_12871300

Ciprofloxacin (CIP) belongs to the fluoroquinolone group of pharmaceuticals and is one of the most commonly applied antibiotics. It has a broad spectrum of biological activity and is used against both Gram-negative and Gram-positive bacteria. When applied frequently, it infiltrates soil and is detected at the level 6 to 750 µg/kg (Golet et al., 2002; Kemper, 2008; Martínez-Carballo et al., 2007). The mechanism of CIP toxicity towards bacteria involves the inhibition of DNA topoisomerases: topoisomerase II (DNA gyrase) and topoisomerase IV, resulting in an arrest of bacterial DNA replication (Oliphant and Green, 2002). The bioavailability of ciprofloxacin in various mammals is estimated at about 70%. After oral ingestion, about 15% of the drug undergoes transformation into less active metabolites that are detected in urine, while 40-50% is detected as the unchanged form (DrugBank Reports, DB00537).

Drug bioavailability is affected by several factors. These include the properties of the drug itself, as well as the type and quantity of the solvent. Many antibiotics may occur as water soluble salts – hydrochlorides – and water-insoluble, free base forms (Caco et al., 2008). The kinetics of the drug dissolution process affects the drug absorption and accumulation in plants. Plants absorb antibiotics from water and soil and distribute them throughout plant tissues as a result of passive transport in transpiration stream (Liu et al., 2013). Antibiotics in plants may decrease the plant growth rate and activity of biochemical defence reactions (Sikorski at al., 2014). One of the key defence mechanisms in plants is activation of antioxidative enzymes: guaiacol peroxidase (POD, EC 1.11.1.7) and superoxide dismutase (SOD, EC 1.15.1.1). These enzymes are present in nearly all plants and they are important elements of plant antioxidative protection system (Cheng et al., 2012; Passardi et al., 2004; Cesarino et al., 2013). They catalyse the disproportionation of the superoxide O_2^- radical into hydrogen peroxide and molecular oxygen. The reaction occurs in all organisms that metabolise oxygen. Class III peroxidases are secreted glycoproteins that participate in lignin and suberin biosyntheses and deactivate toxic compounds. Moreover, they are involved in the developmental processes by controlling auxin level and cell elongation (Passardi et al., 2004; Bakalovic et al., 2006).

Plant responses to some environmental stresses include the accumulation of soluble carbohydrates, that ensure the right cellular osmotic potential and create a protective layer around macromolecules. They also act as signal substances and take part in antioxidative defence (Noiraud et al., 2001; Rontein et al., 2002; Piotrowicz-Cieślak and Adomas, 2012).

The aim of the study was to compare phytotoxicity of two forms of CIP (water-soluble and insoluble) towards lupin (*Lupinus luteus* L.), cultivar Mister, by assessing selected morphological and biochemical features: seedling growth, the activity of guaiacol peroxidase, superoxide dismutase and the content of soluble carbohydrates as well as quantifying content of both drug forms in lupin roots and shoots.

Material and Methods

Plant material and growth conditions

Seeds of yellow lupin (*Lupinus luteus* L.) cv. Mister were germinated for eight days in Phytotoxkit plates (MicroBio Test, Inc., Belgium). Germination was carried out under controlled climatic conditions with temperature set at 25° C and 90% relative humidity (RH), with a 16h/8h day/night photoperiod and 3.4 klx light intensity. Ninety milliliters of soil (sand, vermiculite, peat 1:0.3:1, v/ v/v) were placed in each plastic

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_12871300

microbiotest plate. The soil was covered with Whatman No. 1 filter paper and watered with 27 ml distilled water supplemented with water-soluble and insoluble CIP (Sigma-Aldrich) at final concentrations of 5; 10; 20; 40, 80 mM. The control plants were watered with pure distilled water. The root length was estimated after eight days of germination using Image Tool for Windows. Fresh weight of seedlings was determined according to standard seed testing recommendations (ISTA, 1999). The experiment was carried out in four replicates, each containing 40 seedlings.

Water-soluble and insoluble ciprofloxacin content in seedlings

CIP was extracted from eight days-old seedlings grown in soil containing CIP-HCl or CIP free base. Plants were first rinsed with distilled water, then manual solid phase extraction (SPE) was carried out by squeezing the sap from plant material with a mortar and pestle and transferring the sap to SPE cartridges (Chromabond®Easy, 3 ml×200 mg^{-1}, Macherey-Nagel, Dtiren, Germany) prewashed with methanol (Rydzyński et al., 2017). After loading the samples to cartridges the antibiotic was eluted with 250 µl methanol. CIP in seedlings was analyzed by HPLC according to Pailler et al. (2009) with small modifications. Briefly, the chromatographic system consisted of a Water Aliance 2695 HPLC system (Waters Corp.) with a binary high-pressure gradient pump, an automatic injector and a column oven. The chromatographic column was an Atlantis T3 column (150×3.0 mm, 3 µm) (Waters Corp.) at 40^oC. The MS–MS analyser consisted of Quattro micro® API MS (Waters Corp.) using electrospray in the positive mode (ESI+). N_2 was used as nebulizer, drying, curtain and collision gas. A chromatographic gradient was applied for the separation of the analytes depending on the ionization mode employed, with a total chromatographic run of 18 min. Gradient elution was carried out with aqueous 0.1% formic acid : 0.1% formic acid in acetonitrile at a flow rate of 4.5 $ml{\times}min^{-1}$. Validation of the method included the assessment of selectivity, linearity (1 to 11 $\mu g{\times}ml^{-1}$), limits of detection (8 $ng{\times}ml^{-1}$) and quantification (26 $ng{\times}ml^{-1}$). Chromatographic system and data collection were controlled with a MassLynx 4.1. chromatographic software interfaced to a personal computer.

Guaiacol peroxidase activity

Extracts used to determine guaiacol peroxidase (POD) activity were prepared on ice. The root and shoot tissues (500 mg) that grew in soil with water or with chlortetracycline were homogenized for 30 minutes in the extraction buffer (0.1 M Tris/HCl, pH 7.8, 8.75% polyvinyl pyrrolidone, 0.1 M KCl, 0.28% Triton X-100). Samples were centrifuged for 30 minutes at 4000×g at 4ºC. The supernatant was passed through membrane filters with 0.45 µm porosity. The protein content in samples was determined with the Lowry et al. (1951) protein assay. POD was determined based on the spectrophotometric detection (Cecil, CE2021 2000 Series) in a mixture containing 100 µl 1% guaiacol, 2 ml 0.1 M KH_2PO_4, 150 µl supernatant and 20 µl 0.18% H_2O_2. The absorption rate increase was measured at room temperature at the wavelength of 470 nm. One unit of activity equals oxidation of 1 µmole H_2O_2/mg protein during 1 minute. POD analysis was carried out in four replications.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_12871300

Superoxide dismutase activity

Extracts used for superoxide dismutase (SOD) activity determination were prepared on ice. The root and shoot tissues (200 mg) were homogenized in the extraction buffer (1ml) consisting of 50 mM phosphate buffer (pH 7.0), 1% polyvinyl pyrrolidone, 0.1 M KCl, 0.1% Triton X-100. Samples were centrifuged for 15 minutes at 15 000×g at 4ºC, and supernatants were used as crude extracts for soluble protein quantification according to Lowry et al. (1951) with bovine serum albumin as the standard. Total SOD activity was assayed by the inhibition of the photochemical reduction of nitroblue tetrazolium (NBT). The reaction mixture (2.2 ml) contained, 0.05 M buffer $Na_2CO_3/NaHCO_3$ (pH 10.2), 0.0001 M EDTA, 0.0001 M xantin, 2.5×10^{-5} M NBT and 50 µl of plant extract. The reduction of NBT by superoxide radicals to blue coloured formazan was followed at 560 nm. One Unit of SOD activity is defined as that amount of enzyme required to inhibit the reduction of NBT by 50% under the specified conditions per 1 g protein.

Soluble carbohydrates contents

Soluble carbohydrates (sucrose, glucose, galactose, *myo*-inositol and D-*chiro*-inositol) content in the seedlings were analyzed by GC chromatography according to Piotrowicz-Cieślak (2005). Tissues (100 mg fresh mass) were homogenized in ethanol : water mix, 1:1 (v/v) containing 300 µg phenyl-α-D-glucose as internal standard. The homogenate and the wash were combined in a 1.5 ml microfuge tube, heated to 75 ºC for 30 min in order to inactivate endogenous enzymes and centrifuged at 15 000×g for 20 min. The supernatant was passed through a 10 000 MW cut-off filter (Lida, Kenosha, WI USA). Aliquots of 0.3 ml filtrate were transferred to silylation vials and evaporated to dryness under a stream of nitrogen. Dry residues were derived from 300 µl of silylation mixture (trimethylsilylimidazole : pyridine, 1:1, v/v) in silylation vials (Thermo Scientific) at 70ºC for 30 min, and then cooled at room temperature. One µl soluble carbohydrate extract was injected into a split-mode injector of a Thermo Scientific gas chromatograph equipped with flame ionisation detector. Soluble carbohydrates were analyzed on a DB-1 capillary column (15 m length, 0.25 mm ID, 0.25 µm film thickness, J&W Scientific) and identified with internal standards as available. Concentrations were calculated from the ratios of peak area, for each analyzed soluble carbohydrates, to the peak area of respective internal standard. Quantities of soluble carbohydrates were expressed as mean ± SD for four replications of each treatment.

Statistical analysis

The experiment was conducted in four replicates. The results were statistically evaluated using Statistica 6.0 software by performing analysis of variance (F test) for two factor experiments (split-plot) at the significance level $p = 0.01$. The mean values of the plots were compared using q SNK test (Student-Newman-Keuls).

Result

The lupin root length was found to decrease due to the presence of the lowest of the tested CIP concentrations, i.e. 5 mM for both drug forms (*Figs 1A, 1B*). CIP at the highest concentration (80 mM), both as the soluble and insoluble form, significantly

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_12871300

inhibited the growth of roots, by 85% and 75%, respectively (*Figs 1A, 1B*). A similar reaction to the drug was observed for lupin shoots. Shoots of lupin growing in soil contaminated with 5 mM of the water-soluble form of the drug were shorter by 7 mm on average than the shoots of plants growing in soil with the insoluble CIP form (*Figs 1A, 1B*). Fresh mass of roots growing in soil contaminated with 5 mM of water-soluble and insoluble CIP was lower by 35 mg, compared with the control sample. On the other hand, the weight of fresh roots of plants growing in soil contaminated with soluble and insoluble CIP at the highest of the concentrations was lower by 116 mg and 97 mg, respectively (*Figs 1C, 1D*). Fresh mass of lupin shoots also decreased, regardless of the drug form.

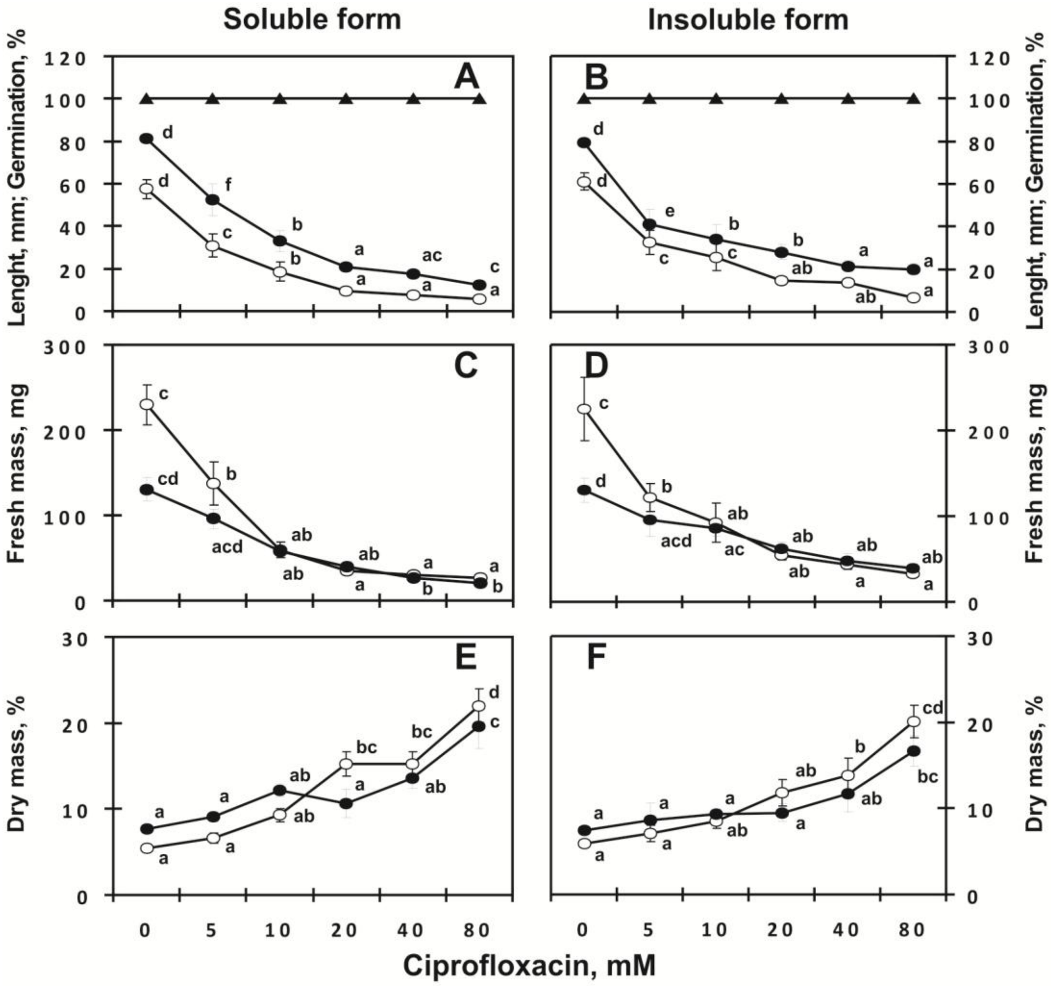

Figure 1. *Panel A and B seedlings length (○ - root, ● - shoot), germination (▲); panel C and D fresh mass (○ - root, ● - shoot); panel E and F dry mass (○ - root, ● - shoot) in yellow lupin after three days on soil supplemented with different soluble and insoluble form of ciprofloxacin concentration (0, 5, 10, 20, 40, 80 mM). Data points represent the means ± SD. Means with the same letter are not significantly different from each other (p≤0.01).*

Control shoots reached a fresh mass of 230 mg, whereas those from plants growing in soil contaminated with the drug water-soluble and insoluble forms at the highest concentrations reached only 27 and 32 mg (*Figs 1C, 1D*). The dry mass of lupin roots

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_12871300

increased with increasing concentrations of both forms of CIP in the soil. The dry mass of roots in the control sample was 7.6%, whereas it was 19.6% and 16.6%, (*Figs 1E, 1F*), in the case of roots of plants growing in soil contaminated with 80 µM of water-soluble and insoluble CIP, respectively. Similarly, the dry mass of shoots increased steadily with increasing contamination of soil with both forms of CIP. With the highest of the concentrations under study, it reached 22% (water-soluble CIP) and 20% (insoluble CIP) (*Figs 1E, 1F*).

CIP was found to be present in roots and shoots of seedlings treated with both CIP-HCl and CIP free base (*Fig. 2*). The roots, in comparison to shoots, accumulated more CIP in both plants treated with the water-soluble and insoluble CIP form. The contents of the drug in roots of plants grown in soil with 5 µM CIP (both CIP-HCl and CIP free base) were similar and averaged 200 $\mu g \times g^{-1}$ fresh mass. Roots grown in soil contaminated with 80 µM drug contained the highest amount of water-soluble CIP (700 $\mu g \times g^{-1}$ fresh mass) and insoluble CIP (400 $\mu g \times g^{-1}$ fresh mass). Compared to shoots, roots contained 1.5 less of both drug forms. Similar to root tissues, the contents of both drug forms in shoots depended on the level of CIP in soil. The maximum level of CIP in shoots was 380 and 180 $\mu g \times g^{-1}$ fresh mass, for soluble and insoluble form, respectively (*Fig. 2*). Lupin roots took up more of the drug than the shoots. The uptake of insoluble CIP from soil by yellow lupin roots and shoots was slower compared to the soluble form. The drug concentration in the lupin organs increased with increasing contamination of the soil with ciprofloxacin (*Fig. 2*).

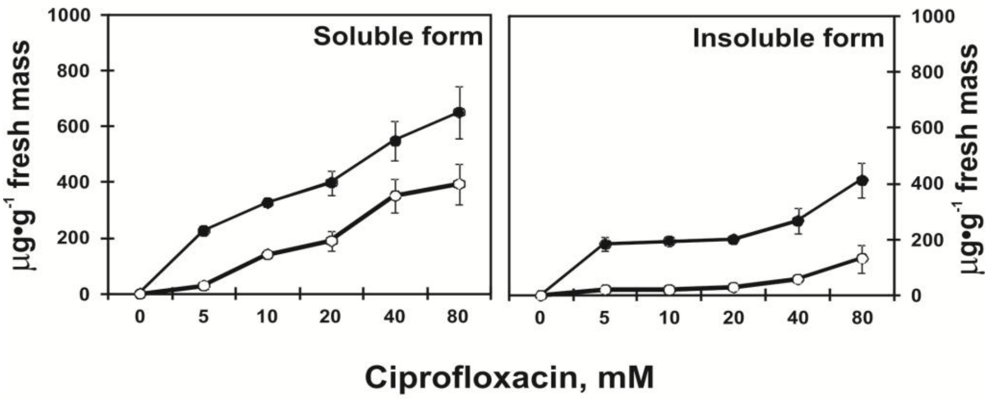

Figure 2. *Ciprofloxacin content in yellow lupin seedlings (○ - root, ● - shoot) growing eight days on soil supplemented with different concentrations (0, 5, 10, 20, 40, 80 mM) of CIP-HCl or free CIP base. Data points represent the means ± SD for three replicate samples.*

The roots and shoots of lupin growing in control soil contained 14.09 and 49.25 U of POD and 31.23 and 127.68 U of SOD, respectively (*Figs 3A, 3C*). The activity of peroxidase increased to 17.59 and 19.23 U in the roots of lupin growing in soil contaminated with the lowest of the concentrations of water-soluble and insoluble CIP (*Figs 3A, 3B*). The activity of the enzyme in roots was 78% lower than in the shoots of lupin exposed to water-soluble CIP (5-10 mM), and 74% lower after exposure to the insoluble form (*Figs 3A, 3B*). The activity of peroxidase in lupin shoots, regardless of the drug concentration, was similar. Its highest level was found in lupin shoots growing in soil contaminated with 5 mM CIP. An increase in POD activity of 38.22 and 31.55 U was recorded in samples growing in soil contaminated with the soluble and insoluble

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_12871300

form of the drug, respectively. Both forms CIP at 20 mM concentration deactivated peroxidase in both the roots and shoots of lupin. The same tendency was observed for higher drug concentrations, i.e. 40 and 80 mM (*Figs 3A, 3B*). Unlike peroxidase, the activity of SOD in lupin shoots was inhibited by water-soluble and insoluble CIP even at the lowest, i.e. 5 mM concentration. The lowest concentrations of both CIP forms decreased the activity in shoots by 14.28 and 55.73 U, respectively. Shoots of plants growing in soil containing 80 mM of soluble CIP showed a higher SOD activity by 17 U compared with shoots growing in soil with insoluble CIP. The SOD activity in shoots of plants growing in soil containing the highest concentration of soluble or insoluble CIP (80 mM) was lower by 58% and 72%, compared with the control shoots (*Figs 3C, 3D*). On the other hand, in the roots, both forms of the drug at 10 mM concentration had a slightly stimulating effect on SOD activity. The highest SOD activity was detected in roots growing in soil containing 10 mM of soluble and insoluble CIP and it was 58.22 and 63.53 U, respectively.

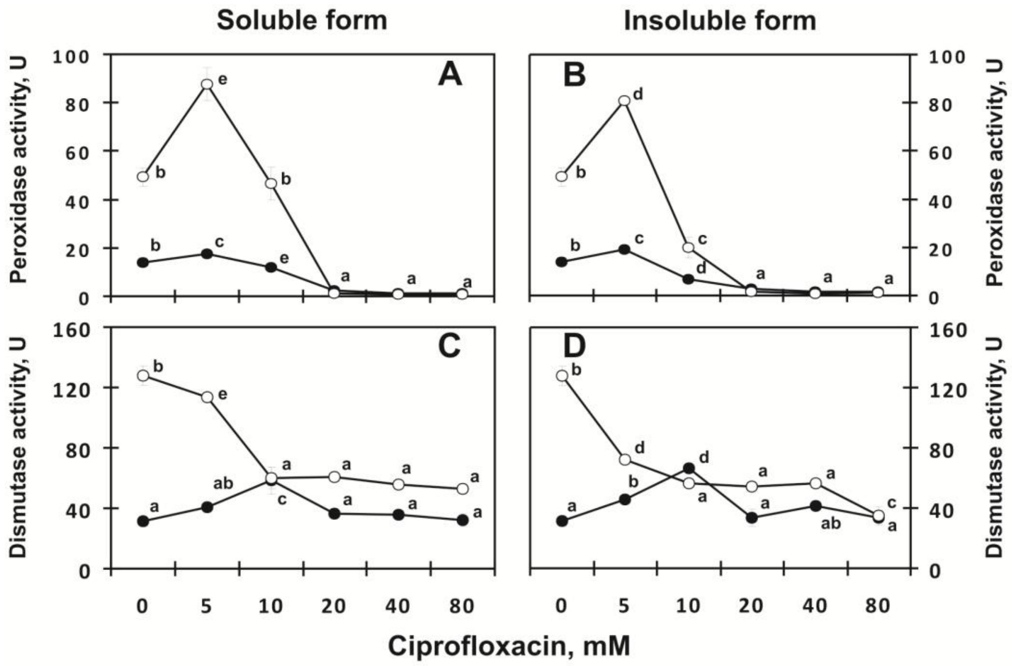

Figure 3. *Panel A and B peroxidase and panel C and D dismutase activity in yellow lupin seedlings (○ - root, ● - shoot) growing eight days on soil supplemented with different soluble and insoluble form of ciprofloxacin concentration (0, 5, 10, 20, 40, 80 mM). Data points represent the means ± SD for three replicate samples. Means with the same letter are not significantly different from each other (p≤0.01).*

Eight-day-old roots and shoots of lupin seedlings growing in soil contaminated with soluble or insoluble CIP were found to contain: D-*chiro*-inositol, D-pinitol, *myo*-inositol, galactose, glucose, and sucrose (*Figs 4A-F*). The content of D-*chiro*-inositol, D-pinitol, *myo*-inositol in control roots increased from 0.08, 0.07 and 0.34 mg×g^{-1} fresh mass to 0.54, 0.45, and 2.17 mg×g^{-1} fresh mass, respectively, in roots of plants growing in soil contaminated with 80 mM of soluble CIP (*Fig. 4A*).

The content of *myo*-inositol in roots growing in soil containing the highest concentration of insoluble CIP increased nearly four times. The roots contained an

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_12871300

average of 10 times more glucose than galactose (*Fig. 4C*). The content of D-*chiro*-inositol and D-pinitol in lupin shoots was not modified by either form of CIP. On the other hand, content of *myo*-inositol increased two-fold with the highest of the CIP concentrations under study (*Figs 4A, 4B*). No galactose was found in the tissues of shoots growing in soil with insoluble CIP at concentrations from 5 to 20 mM, whereas the concentration of glucose increased, and that of sucrose remained unchanged (*Figs 4D, 4F*). Neither the soluble nor the insoluble form of the drug modified the content of D-*chiro*-inositol or D-pinitol. Both of the CIP forms at the highest concentration increased the content of *myo*-inositol by two-fold (*Figs 4A, 4B*).

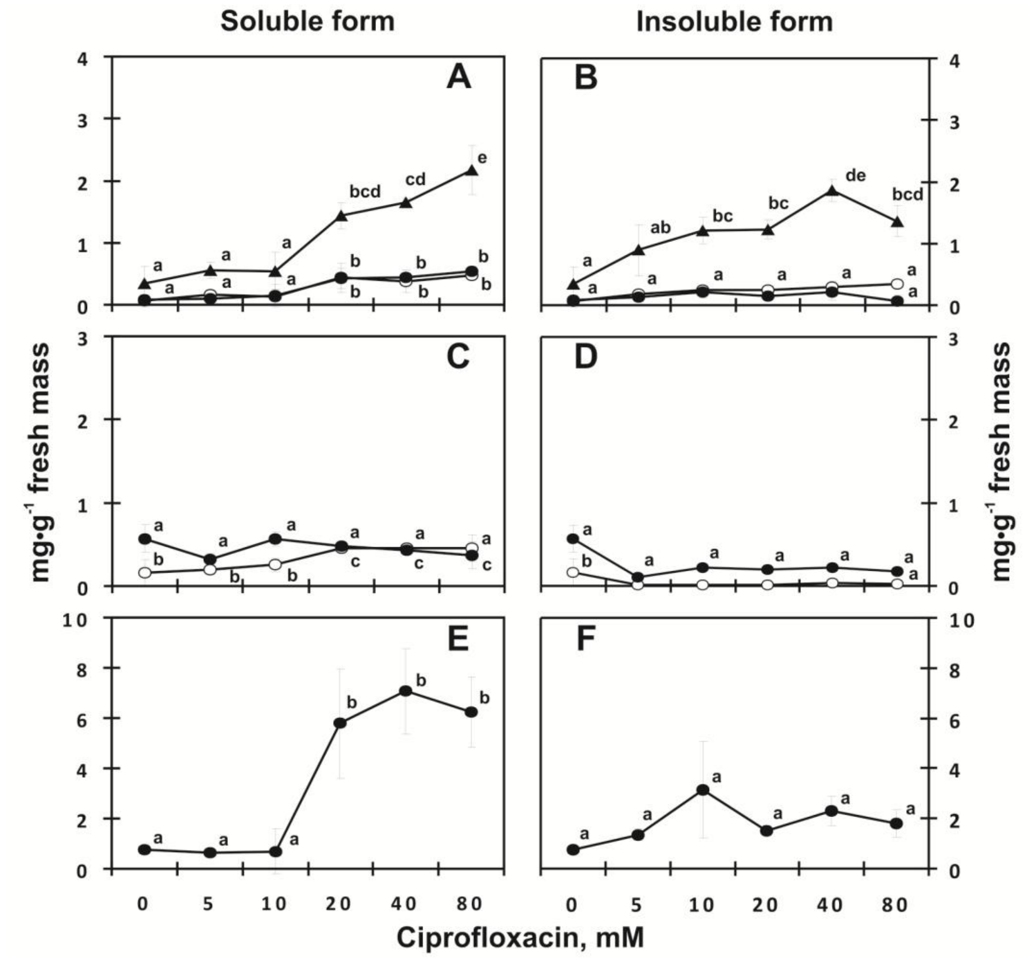

Figure 4. *Panel A and B D-chiro-inositol - ○, D-pinitol- •, myo-inositol-▲ content; panel C and D galactose -•, glucose - ○ content; and panel E and F sucrose-• content in roots of yellow lupin growing eight days on soil supplemented with different soluble and insoluble form of ciprofloxacin concentration (0, 5, 10, 20, 40, 80 mM). Data points represent the means ± SD for three replicate samples. Means with the same letter are not significantly different from each other (p≤0.01).*

Discussion

Fluoroquinolones are absorbed by organic matter in the soil and in manure, as a result of which they degrade slowly and thereby tend to persist in the environment (Kemper, 2008; Lillenberg et al., 2010). When present in the environment, they delay

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_12871300

water supply to seeds and inhibit germination (Jin et al., 2009). In the present study, soluble and insoluble CIP at concentrations from 5 to 80 mM, did not inhibit lupin seed germination (*Figs 1A, 1B*). According to Jin et al. (2009), Adomas et al. (2013), Ziółkowska et al. (2014) and Piotrowicz-Cieślak et al. (2010) seed germination is not a good indicator of the presence of drugs in the environment. Elongation of roots can be a better measure of soil contamination with drugs. Low concentrations of drugs in soil have a positive effect on plants and can even stimulate plant growth (and hormesis occurs at low concentrations) (Migliore et al., 2003). Only 100-fold increase of enroflaxacin concentration (from 50 to 5000 $\mu g \times L^{-1}$) significantly decreases length of roots of plants such as cucumber (by 78%), lettuce (83%), beans (83%), and radish (66%) (Migliore et al., 2003). At the highest of the tested diclofenac concentrations (12 mM), the rate of root growth retardation compared with roots of control seedlings amounts to 85, 83, and 80% for pea, lupin, and lentil, respectively (Ziółkowska et al., 2014). Doxycycline at 25 µg/ml concentration inhibited root elongation of *Arabidopsis thaliana* seedlings by 67% (Moullan et al., 2015).

The presence of soluble or insoluble CIP in soil reduced the length of lupin roots and shoots (*Figs 1A, 1B*). Shoots are shortened on average by 91, 86, and 77% for pea, lupin, and lentil, respectively, exposed to 12 mM diclofenac (Ziółkowska et al., 2014). Shoots of lentil, soybean, adzuki bean, and alfalfa are shortened on average by 85% by 20 mM sulfamethazine (Piotrowicz-Cieślak et al., 2010). Drugs contaminating soil inhibit root elongation, on average by 78-84%, but the extent of inhibition depends on the kind of drug, its concentration, and exposure duration (Jin et al., 2009; Migliore et al., 2003; Moullan et al., 2015; Piotrowicz-Cieślak et al., 2010). Even though that the drug concentrations, compared with their lowest tested values, increased 100-fold (Migliore et al., 2003; Moullan et al., 2015), 200-fold (Ziółkowska et al., 2014), and 16 fold in our study, complete inhibition of root growth is not observed. It indicates that even high drug concentrations do not completely inhibit plant growth and development.

The shortening of the roots and shoots is accompanied by a reduction of their fresh mass (*Figs 1C, 1D*). Leaf biomass of barley and biomass of carrot roots are reduced as a result of exposure of plants to CIP in soil (Eggen et al., 2011). Similarly, oxytetracycline inhibits the biomass of alfalfa shoots and its roots (Kong et al., 2007). Plants growing in soil contaminated with drugs react to the inability of taking up water from soil with tissue dehydration, and consequently a decrease in the dry mass in the analysed under- and above-ground parts of plants. Dry mass of roots and shoots of lupin decreased with increasing concentrations of soluble and insoluble CIP (*Figs 1E, 1F*). The same was observed for dry mass of roots and shoots of narrow-leaved lupin growing in soil contaminated with enrofloxacin (Adomas et al., 2013), sulfamethazine (Piotrowicz-Cieślak et al., 2010) and common red soil contaminated with sulfamethazine, oxytetracycline hydrochloride and ciprofloxacin (Liu et al., 2013). It suggests that plants growing in soil contaminated with drugs take up less water. It may be a result of a different water potential between plants and the environment, which makes water uptake more difficult.

Drugs in the soil are absorbed by plants (Santos et al., 2010). The largest amounts of drugs accumulate in roots and leaves and the smallest amounts accumulate in shoots, as they only transport substances to leaves. Since the root is constantly exposed to contaminants, it takes up and accumulates the largest amounts of drugs (Liu et al., 2013). Eight-day-old lupin seedlings (their roots and shoots) took up soluble and insoluble CIP from soil, and CIP content in the plant tissues increased with increasing

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_12871300

concentrations of the drug in soil. Roots accumulated more soluble and insoluble CIP than shoots. There was 1.5 times more soluble CIP in the analysed organs than its insoluble form (*Fig. 2*). Similar results were observed in an experiment conducted by Liu et al. (2013). Common reed takes up the largest amounts of soluble salts of drugs (sulfamethazine in the basic form and oxytetracycline and ciprofloxacin as hydrochloride), whereas the accumulation of drugs in plant tissues is positively correlated with their concentration in the substrate. The total content of sulfamethazine, oxytetracycline, and ciprofloxacin in tissues of wetland plant on day 62 of the experiment increased from 24, 165 and 345 ng×g^{-1} dry mass to 2047, 6901 and 13.843 ng×g^{-1} of dry mass, in the samples with the lowest and the highest level of contamination, respectively (Liu et al., 2013). It implies that content of drugs in plant tissues depends on the drug type, its concentration in soil and exposure time. Sulfamethazine content in plant tissues increases 85 times, oxytetracycline – 41 times, and ciprofloxacin 40 times. Mol mass of sulfamethazine, oxytetracycline and ciprofloxacin is 300, 460 and 330, respectively, and these values indicate that drug uptake does not depend solely on their mass (Eggen et al., 2011). It is assumed that drug accumulation is the most intensive when they are not too polar or highly hydrophobic. Drug dissolvability and bioaccumulation are defined by index Octanol-Water Partition Coefficient KOW. Log KOW values are generally inversely related to aqueous solubility and directly proportional to molecular weight (U.S. Environmental Protection Agency, 2009). In this study, we used two forms of CIP, soluble and insoluble, that differed in their speed of uptake from soil. We found more of the soluble form in lupin plants but the phytotoxic effect was the same as for the insoluble form. The mol mass for insoluble CIP is 385.82 and for soluble CIP it is 331.34. The log Kow for CIP is from 0.28 to 2.1 (Halling-Sørensen et al., 2000). Plants take up drugs from soil, using and by water transport and passive absorption Liu et al. (2013) are transported to roots, shoots, and seeds. High content of drugs oil seeds can be a risk for animals and people (Eggen et al., 2011).

Taking up and accumulation of drugs results in alteration of the course of numerous biochemical reactions in plants. It has been found that exposing plants to drugs results in inhibition of chlorophyll biosynthesis (Kong et al., 2007), decreases the concentration of carotenoids in leaves, inhibits photosystem II of photosynthesis (Zhu et al., 2001; Liu et al., 2013) and the production of abscisic acid (Pomati et al., 2004). These are not the only responses of plants to the presence of drugs in the environment. In legume plants treated with sulfamethazine, inhibition of root elongation was accompanied by changes in the activity of cytochrome oxidase in mitochondria and in cytosol. Lupin was particularly sensitive to the drug, which is indicative of its ability to detect soil contamination with sulfamethazine (Piotrowicz-Cieślak et al., 2010).

The activity of peroxidase in roots was lower by 78% on average than in lupin shoots exposed to soluble CIP (5mM), and by 74% when plants were exposed to its insoluble form (*Figs 3A, 3B*). Similarly, increasing concentrations of diclofenac in soil reduce the activity of cytochrome oxidase in root mitochondria of lupin, lentil and pea, with a simultaneous increase in the activity of the enzyme in cytosol (Ziółkowska et al., 2014). A change in the activity of antioxidative enzymes in leaves of sugar cane is also brought about by a mixture of sulfamethazine, oxytetracycline, and ciprofloxacin Liu et al., (2013). The highest concentrations of these drugs inhibit the activity of dismutase and catalase by 53% and 54%, respectively (*Figs 3C, 3D*). Although the activity of peroxidase increases at low concentrations, a larger amount of drugs reduces the activity of this

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_12871300

enzyme. An increase of drug concentrations in soil and drug content in plants leads to a more effective antioxidative protection than in the control sample (Liu et al., 2013).

Deactivation of toxic substances and antioxidative protection (Watanabe et al., 2010) are not the only response of plants to soil contamination. The accumulation in plant tissues of compounds with many hydroxyl groups is also a common defence mechanism (Ortbauer and Popp, 2008). Plants react to changes of humidity and temperature by modification of the concentration of soluble carbohydrates, for example, raffinose family oligosaccharides (RFO) and polyhydroxyalcohols, such as their cyclic forms (cyclitols): *myo*-inositol, D-*chiro*-inositol, D-pinitol. Carbohydrates protect cellular structures and proteins with the hydroxyl groups in their structure, which can replace water (Adomas and Piotrowicz-Cieślak, 2004). RFO and galactosyl cyclitols are the basic forms of sugar storage in legume seeds, and their concentration does not usually exceed 20% of the plant dry weight. RFO is accumulated during natural or forced dehydration of seeds (Piotrowicz-Cieślak et al., 2003). Soluble carbohydrates are helpful in determination of the inhibition of germination and growth of plants (Ziółkowska et al., 2014), because complete decomposition of RFO and galactosyl cyclitols takes place during an early phase of lupin germination (Lahuta et al., 2000). The presence of drugs in soil also affects the content and metabolism soluble carbohydrates in plants. Seedlings of lupin, lentil, and pea exposed to diclofenac at 0.06-12 mM, accumulate D-pinitol, raffinose and stachyose, while containing less glucose, fructose and *myo*-inositol (Ziółkowska et al., 2014). Commonly occurring in plants, *myo*-inositol is an important substance in the process of plant growth. It is responsible for signal transduction in plants. Inositol is a precursor of phosphatidylinositol, phytic acid and it is a component of other compounds that take part in alleviating the effects of stress (Loewus and Murthy 2000). Pinitol in fully-hydrated legume plants is the main component of the fraction of soluble carbohydrates (McManus et al., 2000). However, even moderate water stress reduces its concentration, while fructose and sucrose increase their concentration. Sucrose is more effective for membrane protection than reducing sugars (Wang et al., 2013). The current study showed that 8-day old lupin seedlings take up and tolerate higher concentrations of soluble and insoluble CIP than concentrations found in the environment. Inhibition of root and shoot length is probably less harmful to the plants than the increased drug content in the plants that reduces enzyme activity (peroxidise and dismutase), and induces synthesis of D-*chiro*-inositol, D-pinitol and *myo*-inositol in seedling roots and shoots (*Fig. 4*).

Conclusions

The uptake of two forms of ciprofloxacin (water-soluble and insoluble) by plants was different. There was approximately 1.5 times more ciprofloxacin in seedlings treated with the water-soluble CIP compared to plants affected by the insoluble, free base CIP form. Both CIP forms were phytotoxic to lupin seedlings. Contrary to the preliminary assumptions, insoluble CIP inhibited elongation of roots and shoots nearly as severely as the water-soluble form. The study was carried out on reagent grade chemicals, so it depicts antibiotic-plant interaction in a simplified, reductionist model system. The patterns observed here might be confounded under real world, field conditions by partial transformation of the antibiotics in animal bodies and the presence of a plethora of accompanying molecules in manure.

Abstract. In recent years, smart imaging and error detection to achieve optimum performance in water and sewage treatment plants using Artificial Neural Network (ANN) detection technique has had a very active research field and has been regarded as one of the modern methods of modeling. This study has focused on predicting the sludge produced by the oxylator unit of the water treatment plant using an artificial neural network with multilayer Perceptron method. The measured input data: water flow, pH, turbidity, temperature, free residual chlorine, conductivity, consumed lime, coagulant (ferric chloride), and magnum and the sludge produced by the oxylator were examined as output data of the model in two consecutive years 2014 and 2015. At the end, the results of neural network analysis were used to show the effect of each of the parameters in the production of sludge. According to the results, turbidity and pH are the most effective parameters in predicting the sludge produced by the oxylator unit of the water treatment plant. This study indicated that artificial neural network could achieve a 0.99 validity with a regression of 0.9881 and mean square error of 0.006 among the observed and predicted output variables of the model. In addition, artificial neural networks provide an effective tool to analyze the data to understand and simulate the nonlinear behavior of treatment plants.
Keywords: *MLP, clarifier, disposal sludge, sludge quantity, solid wastage*

Introduction

A water treatment plant not only produces drinking water, but is also a generator (inverter and generator) of solid waste. Solid wastages of the treatment plant are generally produced in coagulation and flocculation ponds and backwash filter unit. Sludge management is one of the important issues in water and wastewater treatment plants, including two major objectives of minimizing the sludge production in the treatment plant and treating it, and its user programs. The sludge quantity and properties are two main parameters influencing the management of the methods and costs of sludge treatment and disposal (AWWA, 1981). Modeling many ecological processes that are the effects of the interaction of factors that are firstly high in number and secondly create a complex system through interacting with each other is a difficult but important issue. Simulation of processes of water and waste water treatment plants are not excluded from this rule and usually face problems. Most available models are almost based on assumptions

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_129142

and probability. Lee and Park (1999) simulated the three important stages of water treatment, that are units including coagulation, flocculation, sedimentation and coagulant injection tanks equipped with pump at a pilot scale, Satheesh et al. (2013) equipped it with a feed forward control and measured three qualitative parameters of water including turbidity, electrical conductivity and raw water pH as the input data and the alum required for treatment as the output data, and then compared the results of these two models by modeling the numbers in artificial neural network and fuzzy logic network separately in order to optimize the dosage of coagulant. Results for the values of R and MSE for validation data on the structure of NN, were 0.8861 and 0.3215 respectively in the structure of ANFIS, and 0.8310 and 0.1161. Sengul and Gormez (2013) using neural network TurboProp2 algorithms and data of Büyükçekmece treatment plant in Turkey, modeled the optimal dose of the coagulant. They used the NeuroShell, that normalizes the data and does not need the pre-processing of data. At first they modeled the water qualitative parameters in the initial model, and in the second model, they modeled the optimal dose of coagulant. R and MSE values were 0.95 and 0.02, respectively to predict pH, 0.7 and 0.038 to predict the turbidity, 0.93 and 13.05 to predict electrical conductivity, 0.47 and 1.83 for color parameter, 0.54 and 0.000006 to predict the UV parameter, and 0.19 and 156.67 to predict Aluminum. Noorani et al. (2013) modeled and examined the qualitative parameters of electrical conductivity and TDS of Zarrin Rood water treatment plant, using perspetron neural network. They selected parameters of temperature, turbidity, total hardness, pH and calcium as input to the network, and used FFNN algorithms for modeling. To announce optimum model results, they used the comparison with empirical methods to assess the electrical conductivity and TDS, and found out that empirical equations used to estimate the electrical conductivity is not able to estimate the different variations in temperature, while neural network resists well against these changes and provides optimal results compared to experimental equations. D and RMSE results arising out of them for TDS output, with a structure of 1-5-5, are respectively, 0.81 and 0.028, and for outgoing EC, with a structure of 1-5-5, 0.73 and 0.037, respectively, and for TDS and EC output with a structure of 2-7-5, 0.74 and 0.059, respectively and for TDS output, with a structure of 1-3-1, is 0.98 and 0,007, respectively. Rak (2012) using Perspetron artificial neural network predicted the turbidity of Sosnówka water treatment plant in Poland with input data to models that include turbidity of raw water, tank input water, water level, daily rainfall and tank input water temperature and achieved the desired riteria of R=0.84 and RMSE = 0.49.

CP (clean production) Methods, are integrated approaches to handling wastages and pollution in industries. (Visvanathan and Kumar, 1999). In addition, the importance of CP, has motivated leaders of different countries at different levels of industrial development to adopt national strategies and plan to accelerate the implementation of CP rules (Ghzinoory and Huisingh, 2006). CP principle represents the continuous proactive environmental approach to reduce pollution at the source of production. In addition, the ability of clean production methods is in developing clean systems and creating social and economic benefits (Zarkovic et al., 2011; Giannetti et al., 2008). Management of solid waste from a public health perspective as well as the social, economic and industrial function is very important, because with the constant increase in the quantity of production of dangerous or non-dangerous materials, they should be disposed safely and economically and preferably, with a recycle approach. Large amounts of waste water treatment materials result from drinking water treatment plants every year (Huang et al., 2005). Cleaner production has allowed industrial production to find a place in this vision by recasting negative impacts of polluting industrial processes and products into positive images of news technologies that are materials-conserving, energy- efficient, nonpolluting and low-waste, and that produce ecologically friendly products, like which are responsibly managed throughout their lifecycle (Geiser, 2001).

Materials and methods

The supply source of Jalalieh treatment plant is Karaj River in Beilaghan Basin. Raw water after removing sand and large brooms and preliminary chlorination in the basin is transferred to the treatment plant by two lines of steel pipes with a diameter of 1000 mm and a length of 40 km in gravity manner. Physical and microbiological treatment is performed along with some chemical filtration (refinement and reduction of some gases and heavy metals). Oxylator is a clarification unit under acceleration, which works based on mud workflow. In this clarifier, sludge is kept by the mixer in suspension and in circulation.

Artificial neural networks are information processing models that are inspired from the human brain neural networks. These networks consist of a large number of interconnected processing elements that work with each other in harmony. The idea of artificial neural networks began with the study of human brain cells. The idea of artificial neural networks began with the study of human brain cells. Human brain is made up of millions of unique neurons and these nerve fibers change in different shapes and sizes. Artificial neural networks consist of different parts. Components of an Artificial Neural Network include:

Input signals X1 to Xn, are the equivalents of neural input signals and make up the total neuron input. The input, shown with vector X, can be the output of other layers.

Weight vector Wi1 to Win weights are the equivalents of neuron input synaptic connections values. The effect of input Xi on output y is measured by weight feature. Wi is adjustable and is moderated based on transformation functions and type of learning algorithm.

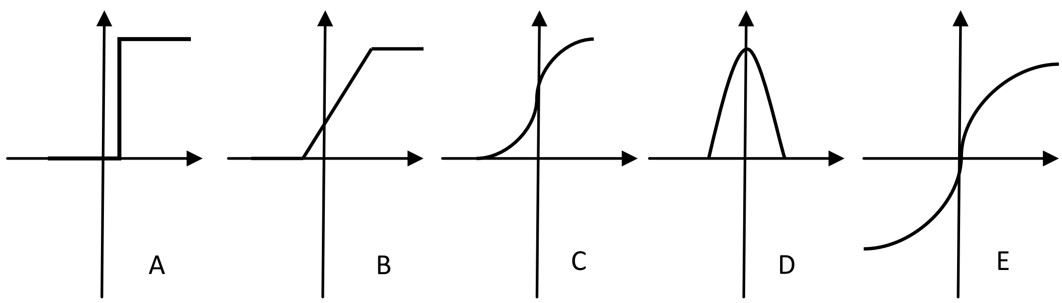

Figure 1. *A) Threshold Function, B) Multi Piece Linear, C) Sigmoid, D) Gaussian, E) Hyperbolic Tangent*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_129142

Aggregation Function defined by the following equation, performs the neuron processing. In one-neuron networks, the aggregation function to some extent determines the output and in multi-neuron networks, the aggregation function determines the level of activity of the neuron j in the inner layers.

$$\text{Net j} = \sum_{j=1}^{n} Wij\ Xi + bi \qquad \text{(Eq.1)}$$

bi: refers to bias, that is actually like a weight, except that its input is a constant 1 (Sun et al., 2016).

Activity Function also called compression function or transformation function; a function that determines the artificial neuron output values. Activation function maps a wide range of input values to a specific amount of output. There are various types of compression functions (*Fig. 1*).

Compression, hyperbolic tangent and sigmoid, functions are used the most. These functions are calculated through the following relationship (Funes et al., 2015):

$$\text{Sigmoid function:}\quad \mathrm{P(t)} = \frac{1}{1+e^{-1}} \qquad \text{(Eq.2)}$$

$$\text{Hyperbolictangentfunction:}\quad Y = \frac{e^{x} - e^{-x}}{e^{x} + e^{-x}} \qquad \text{(Eq.3)}$$

Output refers to the response to the problem. The neuron output is determined by the following function:

$$Yi = \text{ActivationFunction}\left(\sum_{j=1}^{n} Xj\ \ Wij\right) \qquad \text{(Eq.4)}$$

Artificial neural network training process depends on several components and hence, a concept should be defined as network performance measurement. Then, the rules according to which the network performance should be set must also be defined. *(Fig. 2)* displays a schematic of the education network.

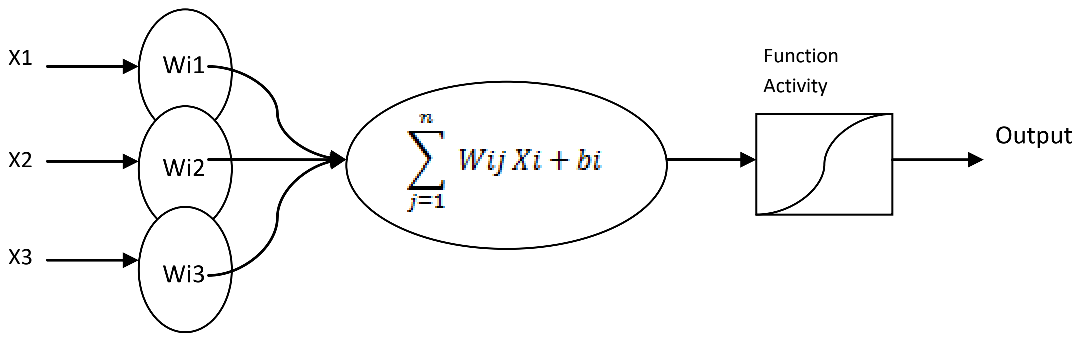

Figure 2. *The structure of an artificial neurons*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_129142

Neural networks can be classified based on the concept of measuring network performance. When the network performance function is based on error measurements, the training is deemed as supervised. Normally, error is defined as the difference between network output and the favorable predefined response (Muthupriya et al., 2011). Common indices used to measure the performance of neural networks are given below (Djeddou and Achour, 2015). In all equations, T represents the actual output, $\overline{T}$ represents the average actual output of the network, O represents the network output, $\overline{O}$ represents the average network output and N is the total number of samples used.

Mean Square Error $$MSE = \frac{1}{N}\sum_{i=1}^{N}(Ti - Oi)^2 \quad \text{(Eq.5)}$$

Root Mean Square Error $$RMSE = \sqrt{\frac{1}{N}\sum_{i=1}^{N}(Ti - Oi)^2} \quad \text{(Eq.6)}$$

Mean Absolute Percentage Error $$MAPE = \frac{1}{N}\sum_{i=1}^{N}\frac{|Ti - Oi|}{Ti} \times 100 \quad \text{(Eq.7)}$$

Absolute Relative Error $$ARE = \frac{1}{N}\sum_{i=1}^{N}\frac{|Ti - Oi|}{Ti} \quad \text{(Eq.8)}$$

The sum of squared errors $$SSE = \sum_{i=1}^{N}(Ti - Oi)^2 \quad \text{(Eq.9)}$$

Regression coefficient $$R = \frac{\sum(Ti - \overline{T}i)(Oi - \overline{O}i)}{\sqrt{\sum_{i=1}^{N}(Ti - \overline{T}i)2 \sum_{i=1}^{N}(Oi - \overline{O}i)2}} \quad \text{(Eq.10)}$$

Coefficient of determination $$R^2 = 1 - \left[\frac{\sum_{i=1}^{N}(Ti - Oi)^2}{\sum_{i=1}^{N}(Ti)^2}\right] \quad \text{(Eq.11)}$$

Clasifications done on different structures of artificial neural networks are based on feedback and advance criteria. If at least one ring can be found in the network, in which one neuron returns to itself or to the past layer, the network is characterized as feedback. Feedback networks have more potential than advance networks and can better show the system time-related behavior characteristics. If in a neural network, the output of each neuron is connected only to the neurons of the next layer, it is deemed as advance. Advance neural network is also known as fully connected neural network, if each cell in each layer is connected to all the neurons in the input layer. But if some synaptic connections are removed, the resulting network is called partly connected *(Fig. 3)*.

Multilayer Perceptron is one of the most commonly used types of neural networks (Vyas al., 2011).

In general, regarding the classification of staticpatterns, a Multilayer Perceptron with two medial layer, is used the most. In other words, separation functions can be used in these networks in any form.

Results and discussion

The recorded data of water flow rate, input turbidity, temperature, electrical conductivity, pH, lime consumption, free residual chlorine, the coagulant consumption and the contribution of the consumed coagulant was received during 22 consecutive months from operation control unit of the company. In addition, the daily production of sludge was extracted using the software SCADA by the operation unit. The Kolmogorov - Smirnov test that determines the normal distribution for the continuous quantitative variables was used with spss software version 19. The results indicate normality of sludge variables, free residual chlorine and the remaining pH, while other variables are not normally distributed. For the normal results of the data, Pearson test was used for the correlation of the normal data, and Spearman correlation coefficient was used for non-normal data. In order to analyze the input data, the correlation between different parameters with each other as well as various parameters with the sludge produced by the oxylator unit was conducted using SPSS version 19. Pierson and Spearman's correlation coefficient was used because of the relativity of the variables used in this study *(Table 1)* (Cronbach, 1951).

Different networks in terms of the number of hidden layer neurons and activation functions were created. Results of the table show that the correlation coefficient of lime consumption variable with ferric chloride is very high. Hence, by entering the variable values of the lime used as input data, the neural network model does not receive new data. Therefore, this parameter is ignored in the present simulation. Results of descriptive figure of the data used in the model are shown in *Table 2*.

Table 2. *Matrix of statistical descriptions of model variables*

	Min	Max	Mean	Std.Dev.
Flow	107800	24000	211547.46	16745.13

In this study, the most commonly used method, which is the Levenberg-Marquardt training method, was used. In order to display the Network training, structure of *(Fig. 4)* was used.

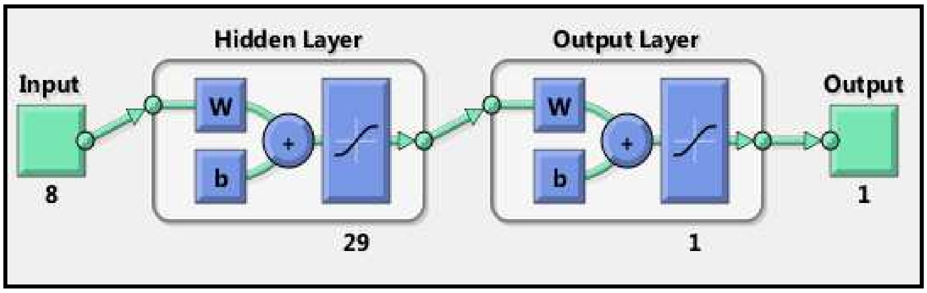

Figure 4. *Structure of network training*

Fig. 5 shows the results of network training to analyze regression coefficients in different structures are 1 to 30 neurons. Activation functions tansig- tansig are given in the order from left to right in the middle layer and output layer. The results including the correlation coefficient (R), the mean squared error (MSE) and root mean square error (RMSE) for each of the three categories (training,validation and testing) for each of the neurons in the middle layer are separated.

Fig. 6 shows network learning results to analyze error coefficients in different structures are 1 to 30 neurons.

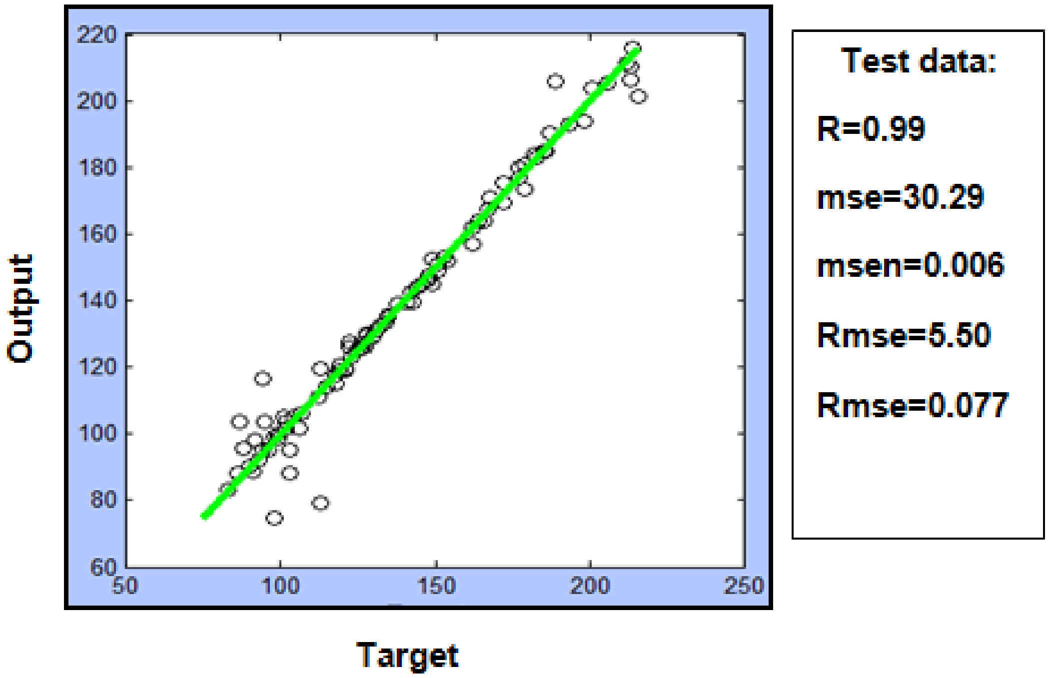

Figure 9. *Values of R - MSE - RMSE for test data set*

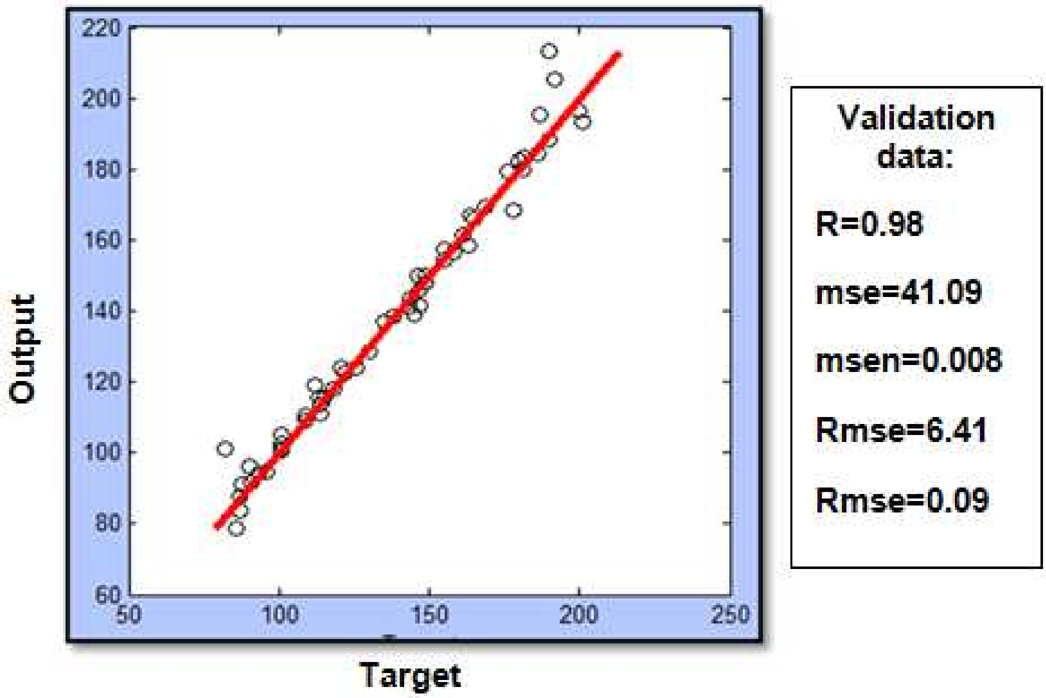

Figure 10. *Values of R - MSE - RMSE for validation data set*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_129142

Since the artificial neural network considers a number of data to learn the networks and some data and some data in order to avoid duplicate network training mode,that is the network validation phase, it also chooses some data in order to extend the network, which is network test data. Model prediction is shown in *(Fig. 11)*.

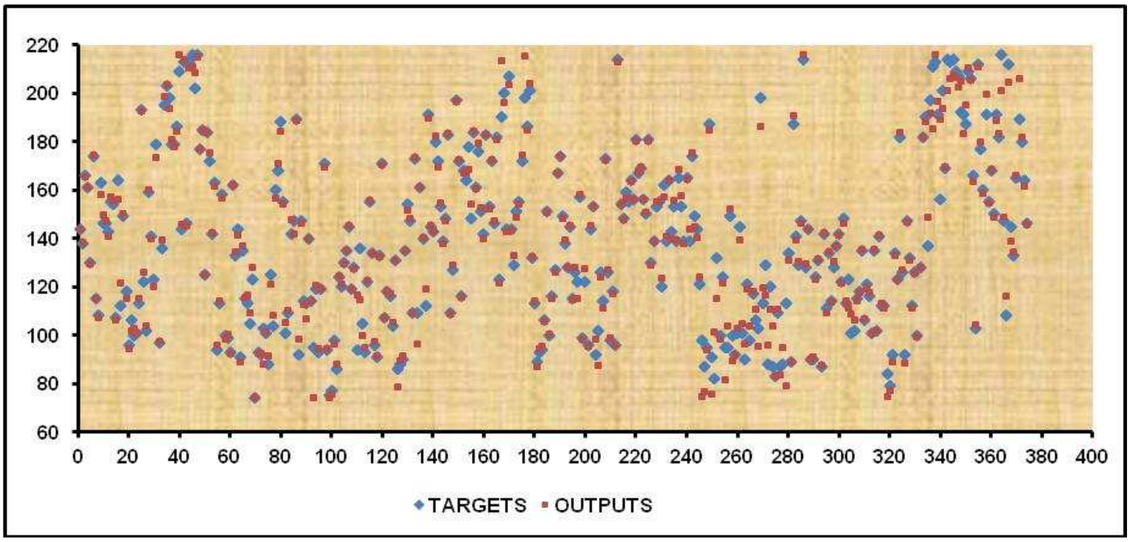

Figure 11. *The results of model prediction against the actual values of the treatment plant*

Sensitivity analysis allows the level of accuracy required for a parameter to be considered so that the model is valuable and useful enough. Sensitivity analysis can also be used to determine what parameter values are reasonable to be in the model (Vilimek, 2014). In this study, because of the complex environmental, physical and chemical process of factors in the treatment plants and the non-linear behavior among them, a decrease or increase in one does not necessarily lead to increases or decreases in output variable. Hence, in order to investigate the role of each of the input parameters in the estimation of the produced sludge, the impact of weight between neurons in the input intermediate and output layer was used in the calculations, according to formula (12) (Montana and Palmer, 2003):

$$Ij = \frac{\sum_{j=1}^{Nh}\left[\frac{|Wij|}{\sum_{r=1}^{Ni}|Wrj|}|Wjk|\right]}{\sum_{i=1}^{Ni}\left[\sum_{j=1}^{Nh}\left[\frac{|Wij|}{\sum_{r=1}^{Ni}|Wrj|}|Wjk|\right]\right]} \quad \text{(Eq.12)}$$

where, Ni is the number of neurons in the input layer,
Nh is the number of neurons in the middle layer,
Wij is the weight between neurons in the input layer and the middle layer (weight between input neurons i and the hidden neuron j),
Wjk is the weight between neurons in the middle layer and output layer (weight between hidden neuron j and the output neuron k),

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_129142

$\sum_{r=1}^{Ni}|Wrj|$: The sum of all weights between the ith input neurons and jth hidden neuron.

The results are provided in *(Table 3)*.

Table 3. *Results of sensitivity analysis on the input data*

Input data	I_j
Turbidity	31.41
pH	30.83
Temprature	15.19
EC	10.91
$FeCl_3$	4.09
Magnom	2.99
Flow	2.32
Cl_2	2.25

As can be seen from the table results, the most effective parameters according to the weighting coefficients between layers, in estimating the daily sludge production of water treatment plant, are, input water turbidity, pH, temperature, electrical conductivity and the coagulant used in the process, respectively.

Conclusion

Given the diverse world-wide applications of sludge from water treatment plants in recent years, which can be used in many different industries, with the approach of clean production methods in order to develop clean systems and to create economic and social benefits for societies, including the production of light-weight bricks by combining the sludge resulting from water treatment plant and rice bran in creating green and eco-friendly future buildings, (Chianga et al., 2009), use of sludge produced by water treatment plants in the structure of clay products such as clay bricks can also be a good alternative instead of clay used in their composition (Hegazy et al., 2012). Use of the sludge from the water treatment plant as an alternative to the cement used in the manufacture of tiles and paving slabs can lead to a significant reduction in the production costs of the industry and also provides a healthy and environmentally friendly option for disposal of sludge from water treatment plants (Wolff et al., 2014). According to various studies on the use of sludge from water treatment plants, it is necessary to accurately predict the daily quantity of the sludge from a water treatment plant with the process governing it. So, it is recommended to use artificial neural network as a powerful mathematical model capable of modeling and creating nonlinear relationships between independent and dependent variables. The results (high regression and low grid error) as well as the self-evaluation and self-monitoringcapability of this software toward generalizability and to prevent its overfitting shows the high capability of artificial neural network as a powerful instrument to predict daily values of sludge produced by water treatment plant oxylator unit. This means, having high functionality and technology has a considerable speed in data analysis. Neural Network Models are

DOI: http://dx.doi.org/10.15666/aeer/1504_129142

used for prediction and classification in cases where classic statistical methods cannot be used because of their limitations. Artificial Neural Networks can be used for modeling water and sewage treatment plants process because of their high accuracy and perfect application in engineering (Neelakantan, 2001).

(Received 10th May 2017; accepted 22nd Jul 2017)

Abstract. The rapid increase in CO_2 emissions has been a hot topic for whole world because of their major contribution to greenhouse gases (GHG) which is an ultimate cause of global warming. This study analyses spatially gridded data from EDGAR (Emissions Database for Global Atmospheric Research) and linear relationship using multiple linear regression model between CO_2 emissions and four economic variables (energy use, urban population, gross capital formation and GDP at market prices) for Pakistan and India. Additionally, four major tools (f-test, t-test, time series analysis, and prediction errors) are used for the purpose of investigating linear relationship and efficiency of the model. EDGAR data shows that about 200 teragram CO_2 has been emitted from Indo-Gangatic plain. Analysis revealed that the most effective predictor for both the Pakistan and India is energy use. The value of f-stat and t-stat showed that the economic variables have joint and individual significance for the regression model at $p<0.05$. Time series revealed that CO_2 emissions increased gradually from 1971 to 2011. Error analysis indicated that regression model for Pakistan is more efficient than that of India. New policies can be devised and decisions can be taken on the basis of information given by this paper.
Keywords: *GHG, Energy use, EDGAR, prediction errors*

Introduction

Economic activities have been increased in the world since the last century. These activities not only promoted the countries in economic development but made an immense increase in CO_2 emissions also. Human activities are adding over 29 billion tons of CO_2 to the environment each year (Goodal, 2007). Contribution of CO_2 to the total greenhouse gases (GHG) is reported to be 58.8% (World Bank, 2007). This rapid increase in CO_2 is so dangerous that it can lead to the severe situations like storms, flood, and other environmental calamities. CO_2 emissions have also caused the sea level to rise to 10-20 cm (Mukhtar, 2004).

It has been noted that due to 30% overall increase in CO_2, the global temperature has also risen by 32.54-33.08 °F (Spence, 2005). There are also some other elements which are contributing to the drastic environmental changes i.e. population, transportation, economic growth, energy consumption and industrial activities (Abdullah, 2015).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13011312

Numerous researches have been conducted to study the relationship among these variables, which clearly indicate the importance of the topic for the whole world (Moran and Gonzalez, 2006; Lozano and Gutierrez, 2007; Ang, 2009; Su et al., 2009; Freitas and Kaneko, 2011; Keat et al., 2015). Bi-variate and multi-variate methods have been used by numbers of researchers to study the relationship between CO_2 and economic variables (Abdullah, 2015).

Four variables; CO_2, population, gross domestic product (GDP), and energy consumption, have been used by Lozano and Gutierrez (2007) through a non-parametric frontier approach to investigate the association between these variables for USA. The study finds a positive relationship between the estimated variables. Moran and Gonzalez (2006) used the methods of linear programming to find the major productive linkage between CO_2 emissions and human activities. This study also found a direct relationship between the variables. Freitas and Kaneko (2011) studied the links between CO_2 emissions and economic growth in Brazil. They concluded that energy intensity, economic activity and demographic pressure increase the emissions. Data for more than 50 years was used by Ang (2009) in order to explore the determinants of CO_2 emissions for China. This study reported a negative relationship between CO_2, research intensity, technical transfer and absorptive capacity in china. On the other hand, a positive relationship was found between energy use, high income, trade openness and CO_2 emissions. Numbers of studies have been conducted to test the comparative relationship of CO_2 emissions and economic variables. Su et al. (2009) used the data of China and Singapore to study the relationship of CO_2 emission and trade. The study concluded that in 40 sectors export is positively correlated with carbon emissions. Martinez and Maruotti (2011) applied STIRPAT model for 88 developing countries from 1975 to 2003 in order to investigate the relationship of CO_2 and urbanization, which showed an inverted U shaped relationship of concerned variables, which means positive relationship existed between urbanization and carbon emissions at 10% level. Aqeel and Butt (2001) determined that the energy consumption is the determinant of economic growth for Pakistan. Energy consumption and pollution has positive relationship for both long and short term (Shahbaz et al., 2010). In an analysis, Keat et al. (2015) examined the correlation between petroleum products and CO_2 emissions by using multiple linear regression model. They found high correlation value (R^2 = 0.9544) among the variables. Mohiuddin et al. (2016) found positive relationship of CO_2 emissions with three parameters i.e. energy consumption (EC), GDP, and electricity production from oil, coal and natural gas over Pakistan.

The trend of carbon dioxide emissions is rising alarmingly in South Asian countries (i.e. India, Pakistan, Bangladesh, Sri Lanka and Nepal) (Sarker et al., 2013). Due to rapid increase in urbanization and industrialization, Pakistan and India are experiencing high amounts of greenhouse gases and air pollutants. Several studies, employing different techniques such as satellite and ground based remote sensing, and *in situ* measurements, have been conducted to monitor greenhouse gases and air pollutants over the sub-continent (Ali et al., 2014; Tariq and Ali, 2015; Tariq et al., 2015; Tariq et al., 2016; Ul-haq, 2014; Ul-Haq, 2015a; 2015b; 2015c; 2015d; Badarinath, 2009). Ang (2009) focused on China, a growing economy, and found that an increase in energy use and trade intensity contributes to higher CO_2 emissions in china. However, in this paper an effort has been made to find the relationship of CO_2 emissions with four economic variables (energy use, urban population, gross capital formation and GDP at market price) over two south Asian countries. Only those economic variables have been

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13011312

considered that are significant ($p<0.05$) determinant of CO_2 emissions in both Pakistan and India. To the best of our knowledge no study has so far been conducted to estimate linear relationship between CO_2 emissions and economic indicators of energy use, urban population, gross capital formation, and GDP at market price for Pakistan and India. The focus of this study is to investigate the relationship between CO_2 emission and the four economic variables for Pakistan and India.

Materials and Methods

Datasets

To investigate spatial distribution of CO_2 emissions we used total CO_2 emissions from EDGAR (Emissions Database for Global Atmospheric Research) version 4.2 data over Pakistan and India during the period 1970-2008. EDGER is a globally gridded database of anthropogenic emissions of greenhouse gases and air pollutants from all the sectors. Same type of economic variables was taken for both the countries for the purpose of easy comparison. Data of CO_2 emissions and four economic variables (energy use, urban population, gross capital formation and GDP at market prices) is sourced from the world data indicator (World Bank, 2016). Data of all the variables were obtained from 1971 to 2011 for both the countries.

Linear relationship of predictors and response variables

Multiple linear regression (MLR) model is used to study linear relationships between the variables. To get interdependencies for a given dataset, the model is widely used to describe the link between the response and predictor variables (Keat et al., 2015). Multiple regressions analysis is most common tool being used in the field of sciences for understanding the results (Courville et al., 2001; Nimon et al., 2010; Zientek et al., 2008).

MLR model is called linear because it forms a straight line when plotted over graph. The functional form of Simple Linear Regression (SLR) is usually written as follows:

$$Y = m + bX \qquad \text{(Eq.1)}$$

where Y is a dependent or response variable for a selected value of X. m represents the Y-intercept and b is a slope of the line. The above equation shows the relationship between one response and one predictor variable. However, there may be a situation in which we need to investigate the relationship of one response variable with multiple predictors. For such kind of relationship MLR model can be used. MLR model is used when we have to study the relationship between one response and several predictors. In MLR model the additional predictor variables (denoted by X1, X2, X3, …., and so on) are used to study the relationship between a dependent and multi independent variables. The general form of MLR equation is:

$$Y = \mathrm{m} + \mathrm{n1X1} + \mathrm{n2X2} + \mathrm{n3X3} + \cdots..\mathrm{nkXk} \qquad \text{(Eq.2)}$$

where m is the Y-intercept and k is any positive integer which is used to represent numbers of predictors in MLR equation. "n_k" is the slope of Y i.e a unit change in n_k with the corresponding change in Y.

Analysis and Results

In order to understand the spatial distribution of CO_2 emissions, we have plotted total CO_2 emissions (see *Figure 1*) from EDGAR data over Pakistan and India during the period 1970-2008. It can be observed from the *Figure 1* that high amounts (about 200 terra gram) of CO_2 have been emitted from Indo-gangatic plain (in north and north eastern parts of India) during the period 1970 to 2008. These high emissions are due to rapidly growing urbanization, industrialization, economic activities and biomass burning. It can further be noted that north eastern parts of Pakistan and almost entire India have emitted almost 20 terra gram of CO_2 in the period from 1970 to 2008.

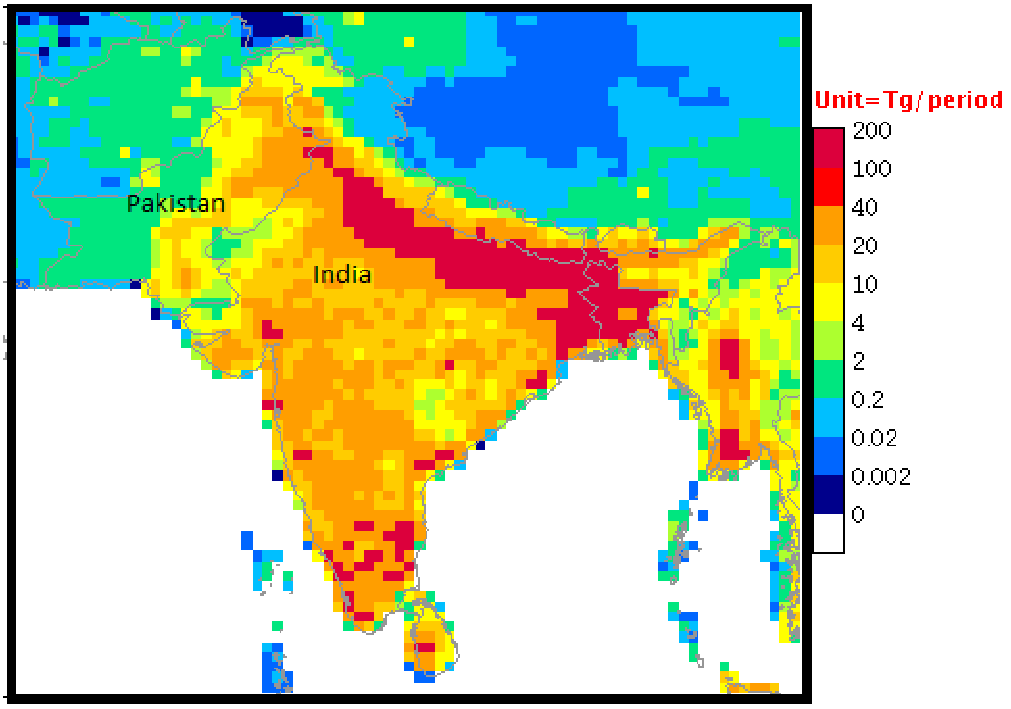

Figure 1. *Spatial distribution of total CO_2 emissions over Pakistan and India in the period 1970-2008.*

Data of CO_2 emissions and economic variables of two developing countries i.e Pakistan and India have been taken for the purpose of studying the linear relationship among them. Data for CO_2 emissions and economic variables have been considered for the period 1971 to 2011 for both the countries. Same type of economic variables was taken for both the countries for the purpose of easy comparison. Data for both dependent and independent variables have been taken from the official website of World Bank (World Bank, 2016). Predictors for Pakistan as well as for India data are energy use, urban population, gross capital formation, GDP at market prices, which are represented as E1, U1, C1, and G1 respectively for Pakistan, whereas the variables for India data are denoted by E2, U2, C2, and G2 respectively. CO_2 emission is a dependent variable which is denoted by Y1 for Pakistan and by Y2 for India. For study purpose the analysis section is divided into four parts which are explained below.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13011312

Excluded predictors

The four predictors that were considered for regression analysis for both India and Pakistan have been shown in the *Tables 1 and 2*. Tables show all the predictors with their corresponding t-values and p-values for Pakistan and India. Regression coefficient analysis shows that all predictors for Pakistan are significant and therefore included in full model because they are significant at 95% level because probability of acceptance is defined at $p<0.05$.

Table 1. *Predictors for Pakistan data*

Model	t-value	Sig(p-value)
Energy Use (E1)	5.043451516	1.31549E-05
Urban Population (U1)	2.706522425	0.010328845
Gross capital formation (C1)	-2.570265226	0.014445252
GDP at market price (G1)	6.4717461	1.63514E-07

Table 2. *Predictors for India data:*

Model	t-value	Sig(p-value)
Energy Use (E2)	6.122963685	4.76218E-07
Urban Population (U2)	3.311246823	0.002120419
Gross capital formation (C2)	-0.977359963	0.334913416
GDP at market price (G2)	1.287407878	0.206167702

Table 2 shows that predictors E2 and U2 are significant only because their significance value (p-value) is less than 0.05 whereas predictors C2 and G2 are insignificant because their significance value (p-value) is more than 0.05. Thus, the predictors C2 and G2 should be excluded from the model of India.

Analysis of variance

After exclusion of insignificant predictors, the selected variables were used to model CO_2 using MLR technique. *Tables 3 and Table 4* show summary results for the MLR model for Pakistan and India data respectively.

Table 3. *MLR test for Pakistan data*

Regression Statistics	
Multiple R	0.997723762
R Square	0.995452705
Adjusted R Square	0.99494745
Standard Error	3376.590289
Observations	41

From the regression statistics of Pakistan, value of R^2 and adjusted R^2 is found to be 0.995452705 and 0.99494745 respectively pointing towards the fact that about 99%

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13011312

variation in CO_2 emission is explained by energy use, urban population, gross capital formation and GDP at market price for Pakistan. This analysis of variance shows that the P-value for the F-test statistics is 3.47144E-47, which is providing strong evidence to reject the null hypothesis. The *Table 4* shows the MLR model for India data.

Table 4. *MLR test for India data*

Regression Statistics	
Multiple R	0.998204755
R Square	0.996412733
Adjusted R Square	0.99622393
Standard Error	33354.1464
Observations	41

ANOVA (Analysis of Variance)

	Df*	SS**	MS***	F****	Significance F
Regression	2	1.17E+13	5.87E+12	5277.51	3.47E-47
Residual	38	42274965109	1112499082		
Total	40	1.17E+13			

* *stands for Degrees of freedom, ** Sum of squares, *** Mean square, **** F statistics*

From the regression statistics of India data, the value of R^2 and adjusted R^2 is found to be 0.996412733 and 0.99622393 respectively indicating that about 99% variation in CO_2 emission is explained by energy use, and urban population for India. ANOVA indicates that the p-value for F-test statistics is 3.47144E-47, which is strong evidence against the null hypothesis. It is also indicated by ANOVA that degree of freedom is 2, indicating minimum number of independent variables for complete system. Sum of square is found to be 1.17×10^{13} which is showing deviation from mean. The ratio of sum of square to the relevant degree of freedom called mean square and is found to be 5.87×10^{12}. It is clear from the above discussion that there exists a linear relation between predictors and CO_2 emission.

Multiple regression equations

Regression coefficients for all the predictors for Pakistan are given in *Table 5*. From the above table it is clear that p-value and coefficients are against rejection region having p-value less than 0.05. It is providing a strong evidence for rejecting then null hypothesis. These results indicate that these four economic variables are good predictors for CO_2 emissions for Pakistan.

Table 5. *Regression coefficients for Pakistan*

	Coefficients	Standard Error	t Stat	P-value	Lower 95%	Upper 95%
Intercept	-63984.7977	8847.997555	-7.23155689	1.63498E-08	-81929.3683	-46040.227
Energy use	262.5086441	52.04940372	5.04345152	1.31549E-05	156.947561	368.069727
Urban Population	0.001005508	0.000371513	2.70652243	0.01032885	0.00025205	0.00175897

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13011312

Gross capital formation	-877.477516	341.3957077	-2.57026523	0.01444525	-1569.8601	-185.09493
GDP at market prices	2.65923E-07	4.10898E-08	6.4717461	1.63514E-07	1.82589E-07	3.4926E-07

The regression equation given below shows that E1 is the best predictor for CO_2 emission in Pakistan. MLR equation for above regression coefficient for Pakistan data is given in equation 3.

$$Y1=63984.79+262.50\ E1+ 0.0010\ U1-877.47\ C1 +0.00000026\ G \qquad \text{(Eq.3)}$$

Table 6. *Regression coefficients for India*

	Coefficients	Standard Error	t Stat	P-value	Lower 95%	Upper 95%
Intercept	-1346910.76	44694.4021	-30.136006	3.8908E-28	-1437389.9	-1256431.7
Energy use	5110.86089	323.755895	15.7861555	2.8098E-18	4455.45136	5766.2704
Urban population	0.00130128	0.00033639	3.86840378	0.00041641	0.00062030	0.0019822

It can be seen from the *Table 6* that p-value for energy use and urban population for India data is less than 0.05, which is a clear indication that these two variables are significant for India. Thus, we can reject the null hypothesis. Therefore we can conclude that the better predictors for CO_2 emissions for India are energy use and urban population. MLR equation of India for above regression coefficients are given in equation 4.

$$Y2 = 1346910.76 + 5110.86\ E2 + 0.0013\ U2 \qquad \text{(Eq.4)}$$

The above equation is showing that E2 is the best predictor for CO_2 emission in India. The value of f-stat and t-stat showed that the economic variables have joint and individual significance for the regression model at $p<0.05$. It can be noted from the regression equations for Pakistan and India that the best predictor against CO_2 emissions is energy use. Our findings are partially consistent with the findings of Wang et al. (2011, 2016) and Ang (2008).

For comparison, the time series data of actual and modeled CO_2 emissions have been plotted together in *Figure 2*. It can be noted from the *Figure 2(a)* that CO_2 increased gradually from 1971 to 2011 over Pakistan. It can further be observed from the figure that actual and modeled CO_2 over Pakistan show a similar pattern indicating the efficiency of regression model. The values of actual CO_2 emissions ranged from 18929 to 163452 while modeled values of CO_2 emissions ranged from 15103.50 to 173441.50. The mean value of actual CO_2 emissions was found to be 77446.32 while mean value of modeled CO_2 emissions is found to be 77446.33 which are very close to each other. It is noted from the *Figure 2(b)* that CO_2 emissions are increasing steadily from 1971 to 2011 for India. Similar pattern of actual and modeled CO_2 is observed which indicates the competence of regression model. The mean value of actual CO_2 emission for India was found to be 849817.23 while mean value of modeled CO_2 emissions is found to be 849817.21. The lowest and highest modeled CO_2 values are 172859 and 2096057

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13011312

respectively. The minimum and maximum values of actual CO_2 emissions are 205869 and 74344 respectively. It can also be observed from *Figures 2a* and *2b* that actual and modeled CO_2 emissions of India (2074344) are greater than the corresponding CO_2 emissions of Pakistan

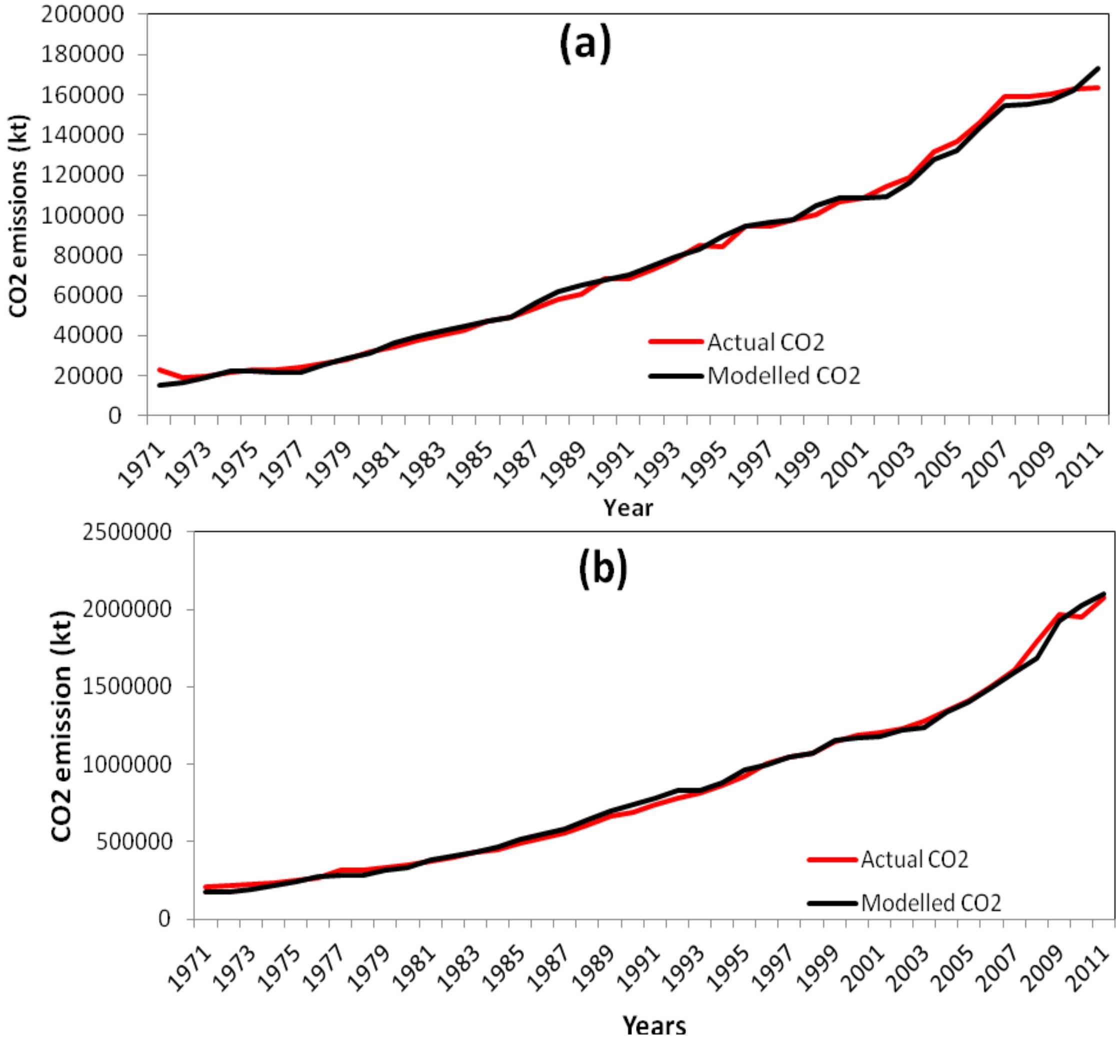

Figure 2. *Time series of modeled and actual CO_2 emissions over (a) Pakistan and (b) India*

Prediction errors

Performance of predictors in the regression model can be measured using two techniques known as MAE (Mean Absolute Error) and RMSE (Rout mean square error). These measures are used to show that how predicted values are performing against the actual values. The difference of actual value and predicted values is called prediction error or deviation error. Equations used to measure predicted error are given below:

$$MAE = \frac{1}{n}\sum_{t=1}^{n} \left|\frac{At - Pt}{At}\right| \quad \text{(Eq.5)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13011312

$$RMSE = \sqrt{\frac{1}{n} \sum_{t=1}^{n} (At - Pt)^2} \quad \text{(Eq.6)}$$

In equations 5 and 6 *At* is representing the actual value, *Pt* is representing predicted value and *n* is representing to the maximum numbers of values in a selected model. *Table 7* is showing the error results of both Pakistan and India model.

Table 7. *Errors for Pakistan and India model*

Model	MAE	RMSE
Pakistan data	0.00676	3164.0088
India data	4.99452	2694012.884

It is quite clear from the above table the model of Pakistan has less error than the model of India. This means that regression model of Pakistan is more efficient than that of India. Pakistan is a populous country and the use of petroleum and natural gas is increasing with the increase in population. A considerable amount of carbon is being emitted from natural gas consumption for electricity use (Alam et al., 2007). Less efficiency of regression model of India is might be due to the fact that predictors considered in this study for India are not enough for prediction of CO_2 emissions. Use of other variables may produce better results for India and is recommended for future research. Furthermore, the prediction of CO_2 emissions in this study may not be consistent with the research conducted at sectoral level data. The use of sectoral data is outside the scope of this study and left for upcoming research.

Per-capita energy consumption (kW h) values of India and Pakistan are 644 and 457 respectively. Higher value of per-capita energy consumption (kW h) for India indicates fast economic growth of India as per-capita energy consumption is proportional to economic growth of a country. India has electricity generation of 1193.48 TW h with 17% share from renewable energy sources while Pakistan has electricity generation of 97.796 TW h having 36% share from renewable energy sources (Ahmad et al., 2016). Contribution of coal in electricity production is much higher in India as compared to Pakistan. India is 3rd largest emitter of CO_2. For both countries solar energy is a good choice as it is cleanest energy source and can help in sustainable economic growth. The overall approximate solar energy potential of India and Pakistan are 5000 trillion kW h and 2900 GW h respectively (Ahmad et al., 2016). Due to poor political infrastructure and the lack of research and development centers, Pakistan had been unable to promote sustainable development goals (Ang, 2008). However, presently Pakistan is paying serious attention towards the use of solar energy and in this regard several projects are underway such as Quaid-e-Azam solar energy park of 1000 MW capacity in Bahawalpur, 300 MW solar plant in Quetta and 3000 solar home systems in Tharparkar (Ahmad et al., 2016). Moreover, twenty two projects with the capacity of 772.99 MW are being installed in the country. Similarly, India has also started solar energy projects such as National Solar Mission (NSM) for installation of 22 GW. During 2015–16, 827.22 MW of solar energy was added to the system that enhanced the installed capacity up to 4579.24 MW (Ministry of New and Renewable Energy India, 2015). Other clean renewable energy sources such as wind, hydro and geothermal are also being installed in both the countries.

Conclusions

In this paper, the multiple linear regression model has been used to investigate the relationship between CO_2 and economic variables for Pakistan and India. The time series of CO_2 emissions for Pakistan and India showed an increasing trend over time especially from 2004 to 2011. Out of the four selected predictors (energy use, urban population, gross capital formation and GDP at market price) only two predictors, energy use and urban population were found to be significant ($p<0.05$) for India, however all the four variables were found to be significant ($p<0.05$) for Pakistan for the prediction of CO_2 emissions. CO_2 emission model for Pakistan showed that four economic variables (E1, U1, C1 and G1) are contributing 99% of the CO_2 emissions in Pakistan. On the other hand, CO_2 emission model for India showed that out of four variables (E2, U2, C2, and G2) only two variables (E2 and G2) are contributing 99% of the CO_2 emissions in India. The regression equation indicated that energy use is the most effective predictor for both Pakistan and India for CO_2 emission. Results from the error of prediction indicated that regression model for Pakistan is more efficient than that of India. Thus, predictors on CO_2 emissions for India are not enough to be considered in prediction of CO_2 emissions. The prediction of CO_2 emissions in this study may not be consistent with the research conducted at sectoral level data. The use of sectoral data is outside the scope of this study and left for upcoming research. Spatially gridded data from EDGER shows that about 200 terra gram CO_2 has been emitted from Indo-Gangatic plain (in north and north eastern parts of India) over the period 1970 to 2008. The results suggest the use of renewable energy resources to reduce the CO_2 emissions. There is a need to enhance the use of clean energy for both countries for sustainable development. On the basis of the information given in this paper new policies can be devised and decisions can be taken.

(Received 12th May 2017; accepted 2nd Aug 2017)

Abstract. Due to massive mining practices and subsequent spurt of human habitation, the East Bokaro coalfield region of Jharkhand in India has faced enormous changes in the landscape. This article aims to study the land cover changes and fragmentation dynamics of the landscape especially forests from 1972 to 2016. Remote sensing based satellite images combined with spatial analysis were used to derive the land cover and fragmentation dynamics over the last 44 years. The results reveal the existence of six primary land cover types namely agriculture, forest, water bodies, mining, settlement and barren land/scrubland. Agriculture and forest which are the dominant categories decreased while mining, settlements and barren lands increased at the expense of forests and agriculture. Fragmentation analysis brings out significant trends in landscape changes that have occurred from 1972 to 2016. The most prominent fragmentation metrics were observed for forests and agriculture classes. Agricultural land has continuously been converted and fragmented into other classes. The forests also show strong fragmentation during 1972-2001 period but in 2016 the level of fragmentation is not very high. This study is a preliminary step towards evaluating the long term impact of mining and its related activities on the landscapestructure.
Keywords: *land cover, coal mining, fragmentation, landscape metrics, forests*

Introduction

A landscape refers to all the visible features of a region of land and their integration with the man made features. Landscape is mostly studied on the basis of composition and configuration of the spatial arrangements of different ecosystems that it is composed of (Tolessa et al., 2016). Composition refers to all the land cover attributes or habitats while configuration refers to the various levels of fragmentation of those habitats. Changes in the composition and configuration of landscapes form the basis of landscape dynamics and fragmentation studies. Fragmentation studies integrated with land cover analysis paves the way for detecting and understanding the spatial patterns of landscape changes (Jansen et al., 2002). There is a lot of research to support that most of the changes in landscapes are brought about by the anthropogenic activities and fragmented landscapes are an indicator of this conspicuous interplay between mankind and the environment (Dupin et al., 2013).

Forests are a very important constituent of the landscape due to their critical role in maintaining biodiversity, regulating climate and providing essential ecological resources. Hence the loss of forest cover from the land raises global concerns on

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13131326

biodiversity, climate change and ecosystem services. However, losing forest cover is not the only concern. Traditional methods document the area of forest lost but the crucial part that needs to be studied is the spatial distribution and fragmentation of the forests and the way these fragmented forests affect the functioning of the ecosystem. Studies on the forest and human health impacts of coal mining are very poorly represented in literature (Upgupta and Singh, 2017). There are a lot of international level studies which have done landscape level fragmentation work for example, Southworth et al. (2002), Armenteras et al. (2003), Millington (2003), Echeverria (2006), Dupin et al. (2013), Tolessa et al. (2016). According to Ritters et al. (2002), fragmentation not only deals with the quantity of habitat loss but also the spatial connection between patches of the habitat. Landscape fragmentation research has mostly been conducted on forests (Cakir et al., 2007) and the majority of forest fragmentation studies have a prime focus on the wildlife habitat as compared to the trees. Various scientists in India have studied forest fragmentation and its impacts on the species diversity like Roy and Tomar (2000) in northeastern India; Jha et al. (2005) in the Vindhyas; Malaviya et al. (2010) in Central India; Behera (2010) in the eastern Himalayas. Roy and Joshi (2001) used remote sensing to study the fragmented landscapes of northeast Indian Himalayan Region. The study emphasized the importance of shape, richness and diversity indices in evaluating spatial distribution of land cover and concluded that fragmentation has led to the lapsed connectivity, corridors and vanishing ecotones as well as meta-populations. De and Tiwari (2008) did research on the Rajaji-Corbett National Parks using LISS III datasets and remote sensing software. They estimated the patchiness of different forest types in the national Parks. The forests of Himalayan foothills were studied by Munsi et al. (2010) using satellite remote sensing and fragmentation analysis. They quantified the landscape structure using landscape based metrics. Giriraj et al. in 2010 used fragmentation to study the forests communities of Southern Western Ghats. The developmental activities like building roads for better connectivity and increasing resource utilization for economic upliftment of local people leads to fragmentation. Therefore fragmentation studies are very important when evaluating changes in forested habitats over a period of time.

Numerous tools are available to estimate a number of fragmentation metrics from remote sensing classified data on land and forest cover. Fragmentation metrics can be computed using different software platforms e.g., FRAGSTAT, SPLAM and Landscape Fragmentation Tool. One of the most widely used and applied tool is the FRAGSTAT which was developed by McGarigal and Marks (1995) to quantify fragmentation. FRAGSTAT gives elaborate statistical information of a variety of landscape levels. Spatial Landscape Modeling (SPLAM) gives landscape parameters like patchiness, interspersion, porosity, juxtaposition, fragmentation and landscape modeling. Landscape Fragmentation Tool maps the types of fragmentation present in a specified land cover type (i.e. forest). It also creates value-added map layers that can be used to quantify and assess the amount and type of fragmentation present in a landscape and runs on ArcToolbox through a Python script. Metrics can be computed at the class level, patch level as well as the landscape level for the whole study area. However class-level metrics are most frequently used in ecological studies as they measure the distribution of one particular habitat within a landscape.

The East Bokaro coalfield region is a predominantly mining area with coal as the major mineral resource being mined. The area was rich in biodiversity and had a large

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13131326

forest cover with fertile cultivable patches. With the advent of coal mining and industrialization, the region witnessed rapid increase in population, economic growth and urbanization. Due to this the original land cover and its rich vegetation cover underwent rapid degradation and the region is subjected to high levels of disturbance and environmental degradation. The goal of this research is to study the changes in land cover during 1972 to 2016 and to assess as how coal mining triggered development and urbanization are driving the fragmentation of the landscape especially forests.

Materials and Methods

Study area

The study area is located in the Bokaro district of the Indian sub-continent. It lies between 23^0 45’ to 23^0 50’ N latitude and 85^0 30’ to 86^0 03’ E longitude (*Figure 1*). It covers an area of 259 sq. km with elevation ranging from 230-300m above mean sea level (MSL). The general slope of the area is from west to east and the area is marked by Lugu Hill (1070m) which is a prominent landmark and also the separation point between the East and West Bokaro coalfields. Tenughat reservoir in the southern part is a tourist attraction. Bokaro thermal power plant is the major industrial set up. This coalfield is in the form of a long narrow strip extending for about 64 km in an east-west direction with a maximum width of about 11 km in the north-south direction.

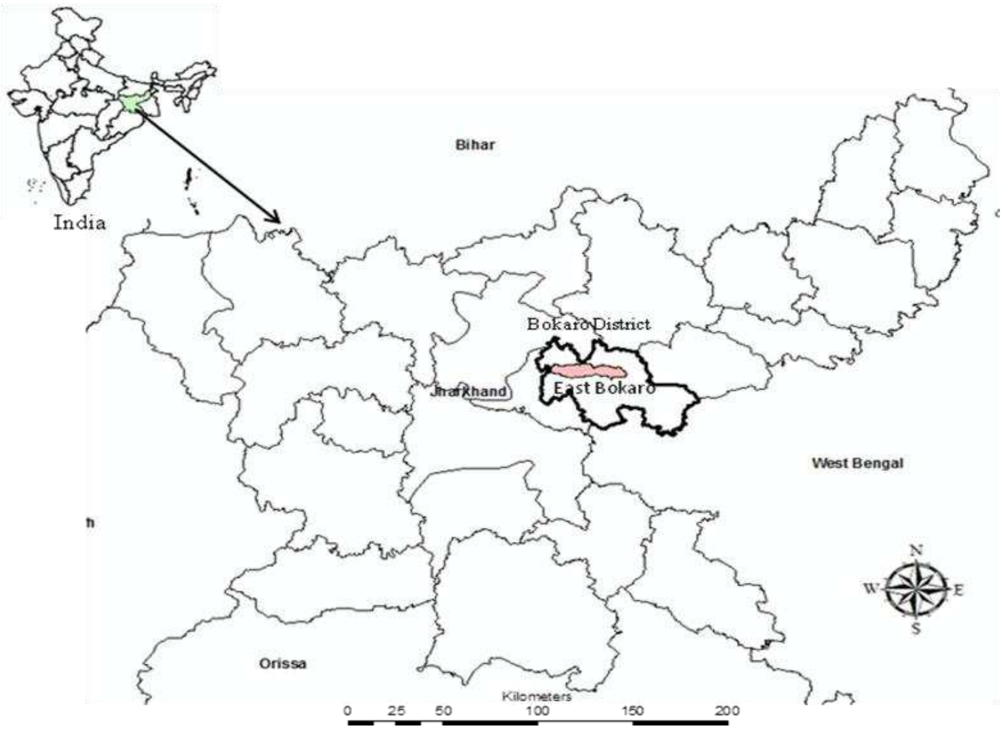

Figure 1. *Location map of East Bokaro, Jharkhand*

The Barkar Formation is the chief coal bearing horizon. Damodar and Bokaro are the primary rivers draining the landscape from north to south. Geologically, the northern part of the area is composed of massive sandstone formation which has resulted in a

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13131326

rugged topography. The East Bokaro is a source of medium coking coal in India. Coal is produced in East Bokaro by underground as well as opencast mining methods by Central Coal Field limited (CCL) a subsidiary of Coal India Limited. The important coal seams found in the coalfield include Jarangdih seam, Kargali seam, Bermo seam and Karo seam.

Climatically, the area has an average temperature of 30 °C during summer season while 20 °C during the winter season. During summer, the maximum temperature rises up to 44 °C while during winter the minimum temperature comes down to 2°C. On an average, the area receives about 1200 mm of rainfall with the bulk of rainfall occurring around the July-September period.

Currently 28.1% of the total geographical area of East Bokaro is under forest cover. Majority of these forests belong to the Tropical Dry Deciduous forest type group. There is 16.6 sq.km, 36.9 sq. km and 21.6 sq.km of the forests having very dense (>70% canopy density), moderately dense (40–70% canopy density) and open forests (10–40% canopy density), respectively [FSI, 2013]. The Bermo subdivision of the area is comparatively rich in forest wealth and the forests are replete with Sal (*Shorea robusta*) along with other trees like mango (*Mangifera indica*, Shisham (*Dalbergia sissoo*, jackfruit (*Artocarpus heterophyllus*) and kendu (*Diospyros melanoxylon*).

Data used

Multi-temporal satellite images of different time periods representing long term and discernible changes were acquired for this analysis. For land cover mapping moderate spatial resolution Landsat images of three time periods 1972 (Landsat 1 reprocessed, Multi-Spectral Scanner), 2001 (Landsat 7, Enhanced Thematic Mapper plus) and 2016 (Landsat 8, Operational Land Imager) at 57m, 28.5m and 30m were used. These images were downloaded from the Earth Explorer USGS image database (Landsat Imagery Archive). The images were chosen based on their availability for the study area, the defined time periods, clarity of data and the season of data capture. Cloud free images were collected for the same season for the month of November 2016. Landsat images are already geo-referenced and were subjected to appropriate atmospheric corrections in the next level of image preprocessing steps to bring out more clarity in the interpretation of the land cover features.

Methods

All the analyses were performed in ArcMap environment. The data for the three time periods were extracted for the study area using the Clip tool in ArcMap 10.2. The delimiting boundary of the East Bokaro coalfield was acquired from the Central Coalfields Limited. FRAGSTAT 4.2 was employed to carry out fragmentation analysis and estimate the various class level metrics.

Land cover classification

Supervised Maximum Likelihood Classifier (MLC) approach was used for land cover classification followed by cleaning of the classified images using majority filters. Six classes namely agriculture, forest, water bodies, mining, settlement and barren/scrub were identified. These classes were based on the land cover classification system developed by National Remote Sensing Centre, Hyderabad in the Manual of Nationwide Land Use/ Land Cover Mapping Using Satellite Imagery" (NRSC, 2006). Majority

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13131326

filters were used to get rid of very small group of pixels below a threshold value of 10 pixels. Ground verification was conducted in the same season as that of satellite image collection. Random points were generated and for every point the existing class in the ground and the corresponding land cover type in the classified image were noted. Accuracy assessment of the classified map of 2016 was performed in Arc Map 10.2 using pivot tables.

Fragmentation analysis

Classified land cover raster datasets were first converted to tiff file format and then used as the inputs into the fragmentation analysis. FRAGSTAT4.2 was used to carry out fragmentation analysis and estimate the various landscape and class level metrics. Landscape metrics were computed at the class level for all the mapped land cover classes of agriculture, forest, water bodies, mining, settlement and barren/scrub. Based on the recently reviewed literature and forest fragmentation studies, the following twelve landscape metrics (*Table 1*) were selected for quantification and comparison.

Table 1. *Landscape metrics used in the analysis*

Level of Analysis	Metric Name	Abbreviation	Description	Valid Range	Units
Class Level	Percentage of landscape	PLAND	Percentage of total landscape area occupied by the largest-sized patch	0 < PLAND < 100	%
	Patch Density	PD	Number of patches on a per unit area		-
	Number of Patches	NP	Total number of patches in the class	N ≥ 1	-
	Largest patch Index	LPI	Percentage of total landscape area occupied by the largest-sized patch of each class	0 < LPI < 100	%
	Mean Patch Size	AREA_AM	Average of patch size in hectares		m2
	Edge Density	ED	Sum of length of all edge segments for the class, divided by total landscape area	ED ≥ 0	m/ha
	Euclidean nearest neighbor	ENN_AM	Mean of minimum edge-to-edge distances to the nearest neighboring patch of the same type of a certain class	ENN ≥ 0	m
	Shape Index	SHAPE	Measures the complexity of patch shape of a particular class	SHAPE≥1	-
	Perimeter to area ratio	PARA	Measure of patch shape	SHAPE≥1	-
	Fractal Dimension	FRAC_AM	Index of the complexity of shapes on the landscape	1 ≤ FRAC ≤ 2	-
	Aggregation Index	AI	Percentage of neighboring pixel of the same class, based on single-count method	0 ≤ AI ≤ 100	%
	Interspersion Juxtaposition Index	IJI	Measure of evenness of patch adjacencies		

These metrics have been widely applied and are the best for the evaluation of spatial properties of fragmented landscapes. Although the analytical outputs were reported for all the land cover classes, forest category was specially emphasized on the spatio-temporal pattern of forest fragmentation during 1972-2016.

Results

Land cover dynamics

The land cover maps representing the spatial pattern of the six identified cover classes of East Bokaro coalfields for the different time periods that is 1972, 2001 and 2016 are shown in *Figure 2*. The area statistics for all the identified classes and for three time periods are shown in *Table 2*. The accuracy assessment for the classified map of 2016 using the ground verification points yielded an overall accuracy of 81% and kappa co-efficient of 0.7. The error matrix for accuracy assessment is shown in *Table 3*.

Table 2. *Comparison of areas and change statistics of Land cover classes between 1972 and 2016*

Sl. No.	Land Cover	1972		2001		2016		Change (1972 to 2016)		Rate of change
		Area (sq.km)	Area (%)	Area (sq.km)	Area (%)	Area (sq.km)	Area (%)	Area (sq.km	Area (%)	(ha/yr)
1	Agriculture	121.48	46.89	114.02	44.08	87.04	33.59	-34.44	-28.35	-78
2	Forest	95.48	36.86	85.46	33.04	92.49	35.70	-2.99	-3.13	-7
3	Water Body	14.02	5.41	13.28	5.13	13.72	5.29	-0.3	-2.14	-1

	Total	259	100	259	100	259	100			

It can be observed from the statistics provided in *Table 2* that in the year 1972, 36.86% of the land was covered by forests and this decreased to 33.04% in the year 2001. But the next decade of 2016 is marked by an increase in forest cover to 35.70%.

Since 1972 to 2016 there is an overall decline of 3.13% in the total forested areas. Similar trend is observed in the water bodies but the change observed is not very significant (*Table 2*). Water bodies also show a decrease in coverage followed by a slight increase. The overall decrease stands at 2.14% since 1972 to 2016.

The agriculture category however depicts a completely different picture. There has been a constant declining trend observed in the agricultural lands from 1972 to 2016 (*Table 2*) indicating land cover transformations from agriculture to other classes like

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13131326

mining, human settlements and barren lands (*Fig. 2*). The decrease accounts for 28.35% reduction in the total area of agricultural lands. Agriculture covered 46.89% of the study area in 1972 which decreased to 44.08% in 2001 and this is followed by a further decrease in 2016 to 33.59% (*Table 2*).

The fourth category of land cover class that is mining has doubled in the last 44 years. The area statistics shows a noticeable increase of 3.72% in 1972 to 5.16% in 2001 and a further increase to 7.42% in 2016 (*Table 2*). There is an overall increase of 99.48% in the total mining sites. *Fig. 2* shows that although few mining sites have been abandoned and reclaimed, there are new sites within the forested areas which have been leased out to the mining companies. There is also expansion of some existing mining projects into bigger mines and into the forested areas.

The remaining classes of settlement and barren lands show an increasing trend in their areas from 1972 to 2016. Most massive increase is in the human settlement areas which increased from 2.99% in 1972 and 7.88% in 2001 to 10.70 in 2016 with an overall increase of more than 200%. The barren lands also show more than 50% increase in their representation.

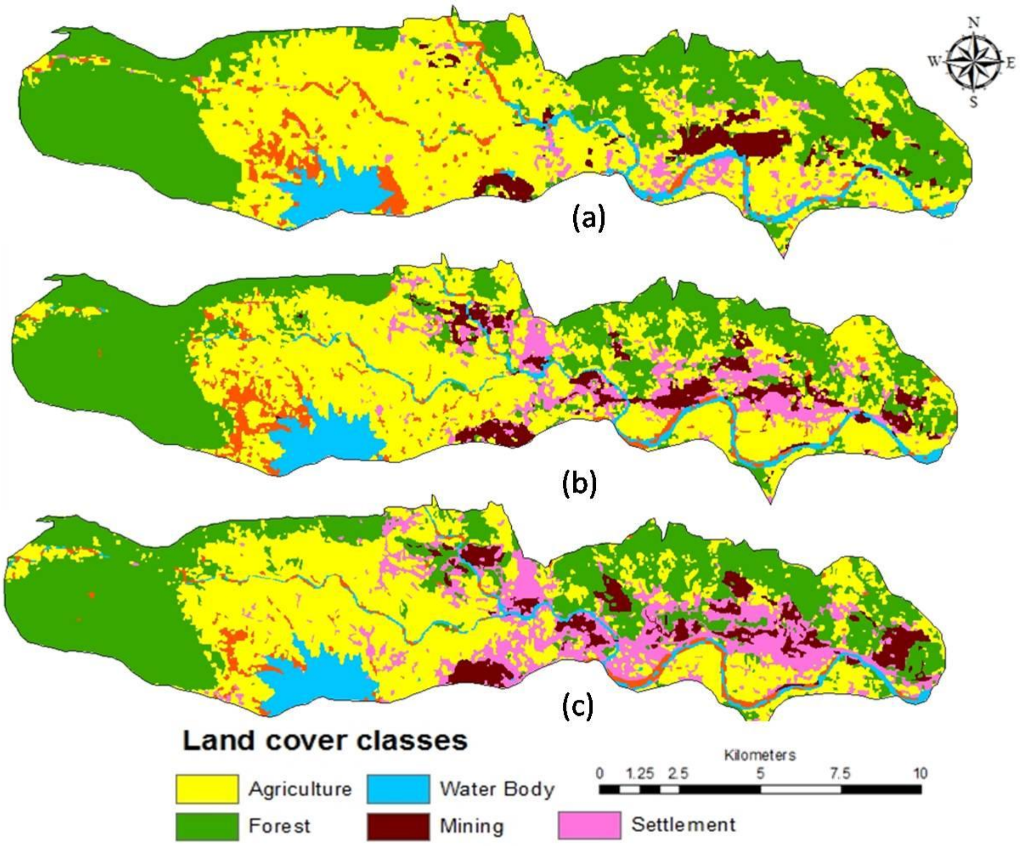

***Figure 2.** Land Cover map 1972 (a), 2001 (b) and 2016 (c)*

Fragmentation dynamics

The fragmentation metrics calculated from the classified images assisted in quantifying the landscape structure and imparted thorough information regarding the configuration changes as well as its impact on the landscape. The analysis revealed that

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13131326

there have been major changes in the density, number, size and the distance between the spatially distributed fragments. The analysis at class level also confirmed that different land cover classes exhibited different patterns of changes. The values estimated for 12 class metrics for the East Bokaro coalfields are represented in *Table 4*. The temporal variations in the class metrics for nine selected class metrics are depicted graphically in *Figure 3* for agriculture and forest classes. The detailed dynamics for each category is discussed below.

Table 4. *Dynamics of class metrics for all the land cover classes for 1972, 2001 and 2016*

*Note: Please refer Table 1 for units and abbreviations.

Agriculture

Agriculture is the dominant land cover category in the study area and it shows significant decrease during the entire study period from 1972 to 2016 (*Table 4*). Among the twelve fragmentation metrics displayed in *Table 4* the parameters that are very important to note are the number of patches, patch density and the largest patch index. Increase in the number of patches signifies that an area of land is continuously being broken into smaller pieces or fragments. The agriculture lands show a very steep rise in the number of patches from 1972 to 2001 followed by a slight decrease. Similar trend was observed for the patch density also wherein the patch density increased highly from 1972 to 2001. The large patch index decreased successively from 29.96 in 1972 to 22.52 in 2016 although the shape complexity has decreased in the agriculture lands over time. The Interspersion and Juxtaposition Index signifies that there was a decrease in patch mixing over time for the agriculture as it changed from 89.52 to 79.58.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13131326

Forest

The period from 1972 to 2001 has also seen an increase in the number of patches as well as patch density for the forest lands (*Figure 3*). The largest patch index shows continuous decline for agriculture category from 1972 to 2016, however the forests depict a slightly improved large patch index (*Figure 3*). The shape indices like SHAPE and PARA show that the patch shape complexity of the forested class has also increased over time (*Table 4*) indicating that the patches are becoming more vulnerable to disturbances. On the other hand the forests show an overall increase in the IJI indicating that the forest patches have mixed over time which explains the increase in the large patch index as well as mean patch size. The mean Eucliden Nearest Neighbour distance of forests decreased continously from 94.77 in 1972 to 72.95 in 2016.

Water bodies

The water bodies have undergone very little changes in their total area within the landscape but their fragmentation metrics have changes significantly. There is a steady increase in the number of patches from 22 in 1972 to 41 in 2016 and the patch density from 0.08 in 1972 to 0.16 in 2016 (*Table 4*). The large patch index improved over time with the index being 2.97 in 1972 to 3.51 in 2016 (*Table 4*). This is explained by the increasing interspersion and juxtaposition index that is from 74.02 to 84.59 as well as the very steep fall in the Euclidean nearest neighbor distance from 245.15 to 86.86 since 2016 (*Table 4*). There was also an increase in the edge density of the water bodies from 4.56 in 1972 to 6.30 in 2016. Although, the shape complexity decreased from 4.88 to 3.17 from 1972-2016 the perimeter to area ration increased from 91.31 to 120.86 (*Table 4*).

Mining

Due to growing mining and developmental activities, the number of patches for mining, settlement and barren lands also increased till 2001 (*Table 4*). This can probably be due to the cropping up of new mining sites and settlement points. The year 2001 onwards has seen a decrease in the number of patches as well as patch density for these categories indicating the expansion of mines and merging of smaller settlements into larger settlement groups by clearing the agricultural lands. The mean patch area for mining has decreased over time and the aggregation index has slightly increased since 1972 to the current period.

Settlements

Patch density and number of patches in the settlement category did not change significantly and they improved in 2016 after an initial increase in 2001. The largest patch Index has also increased to 5.60 (2016) as compared to 0.35 in 1972 (*Table 4*). Edge density is a measure of the per unit edge length and the settlement class has undergone a high change in edge density. The edge density increased from 7.03 to 19.50 in 2016.The shape complexity has increased to a great extent for the settlements with the shape index values ranging from 1.90 in 1972 to 7.20 in 2016 (*Table 4*) but the perimeter to area ration decreased considerably. For the aggregation metrics it was found that there was tendency for the patches to mix which is indicated by the IJI and the AI values increasing steadily. There is also a simultaneous decriease observed in the ENN distance between the similar patches.

DOI: http://dx.doi.org/10.15666/aeer/1504_13131326

Barren lands

For the barren lands and the scrublands, it was observed that though it occupies only 10-18% of landscape area, the number of patches is comparable to the cultivated and the forested lands. The patch density too is the second highest after the settlements. The only important things to note for this category are the mean patch area, PARA and the IJI indices. The perimeter to area ratio increased from 174.94 in 1972 to 241.93 in 2016 while the IJI increased from 45.51 to 69.86 from 1972-2016 (*Table 4*). The mean patch size increased to 151.85 in 2001 but it decreased drastically to 38.58 in 2016.

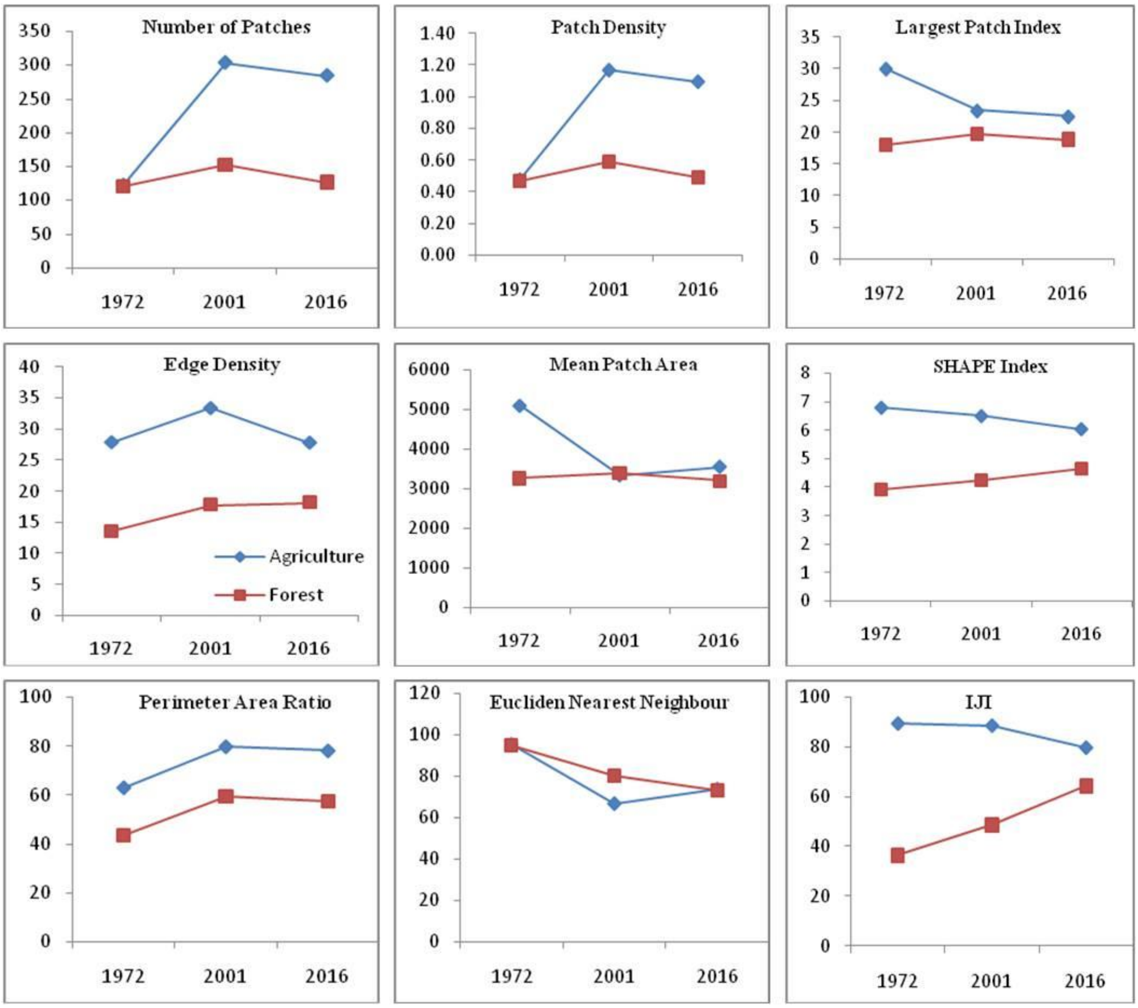

Figure 3. *Temporal changes in the fragmentation metrics of forests and agriculture in the study area*

Discussions

Mining activities extend their ecological footprints beyond the area that is directly impacted. Within the primary impact zone, mining causes complete removal of forest and changes in the composition of any remnant forest while the adjacent areas are the secondary impact zones. The secondary impacts are manifested in the form of land use changes including fragmentation, habitat modifications, wildlife migration and changes in forest types. The developmental activities associated with mining like roads, building,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13131326

and transmission lines lead to forest fragmentation which in turn exposes the interiors of forest to disturbances.

In the current study, the unfolding of the change dynamics of each land cover type, as shown in *Table 2*, *Table 3* and *Figure 3* shows that over the last 44 years the dynamics of evolution are different for the forest and agriculture categories but quite similar for the mining, settlements and barren land categories. Analysis of the trend line revealed that the pattern of land cover changes did not follow a linear pattern and it worked both ways over the 44 year study period. This suggested that the some of the land cover types like forests and water bodies showed increasing and decreasing trends. The forest cover declined at a faster rate from 1992-2001, while the decline rate decreased from 2001-2016. This high decline rate was due to more and more acquisition of forested lands (along with the agricultural lands) by mining projects. However, there is an overall decline in the forest cover but also a substantial increase in the forest cover was observed since 2001. *Figure 2* shows that the increase in forest cover is mostly confined in and around the previously mined and abandoned mines and can be attributed to the vigorous plantation activities being carried out in the reclaimed mine sites and over burden dumps. The subsidiaries of Coal India Limited have carried out extensive tree plantation programmes which include plantations on overburden dumps, plantation around mines, residential colonies and avenue plantations. Coal India planted over 73 millions of plants since 1993-94 covering an estimated land area of over 32000 hectares (CIL). Plantation activities have been integrated into the annual activities of all the existing and new coal subsidiaries.

There was substantial decrease in agricultural land observed in the study area (*Table 2*). This decrease is apparently due to the anthropogenic activities acting in conjunction with the commercial, political and socio-economic factors. The shrinkage of agricultural lands is driven by the diversion of lands for new mining projects, already rugged terrain as well as non profitable agribusiness. This has resulted in shifting the interest of people from conserving the land for agriculture to other more lucrative livelihood options like jobs in mining and allied industries thusultimately ruining the biodiversity. Agriculture and forests have always been the main source of livelihood in the area and some parts are still dependent on agriculture for their livelihoods. The decline in water bodies though not very significant yet the area is suffering from the shortage of availability of clean water for drinking and irrigation purposes.

The area occupied by mining seems to be steadily gaining in appearance from 1972-2016 (*Table 4*). The advent of mining and its increasing representation in the landscape has completely disturbed the ecology which is at high risk of degradation and large scale land use changes. There is a high rate of immigration of people from surrounding regions into the area for livelihood opportunities in the mining sectors. The tremendous mining practices ongoing in the East Bokaro region has led to the evolving new settlements areas concentrating around the mining sites. The settlement areas have increased by more than 250% since 1972 causing a sudden burst in human population and threatening the ecology of the area. The increasing barren lands are an indication of the changing land use practices in the study area.

The framentation outputs depicted the level of landscape configuration changes occurring in East Bokaro. The figures reveal that the different land cover types have undergone varied levels of fragmentation during the study period. The large patch index of agriculture class decreased successively from 1972 to 2016 indicating towards an increasing division of land into other land cover classes. There is observed a high

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13131326

increase in the number of patches as well as the patch density from 1972 to 2001 which signals towards high fragmentation rates (*Table 4*). The decreasing intermixing of the patches as indicated by the fall in IJI values show that over the period of time the patches do not show mixing and this might be due to high human interventions.

The increased patch number and density with improved large patch index of the forest class till 2001 implied that the fragmentation of the forests was strengthened during 1972 to 2001 period but decreased from 2001 onwards. The IJI values show that the forest patches have mixed over time. This is quite evident in 2016, where the level of landscape fragmentation as observed for the forest class is not very high. The decreasing ENN index values is due to new plantation areas which can be credited to the vigorous plantation efforts by the mining companies as a part of their reclamation policies. But the SHAPE and PARA indices show that the increasing complex shape of forest patches with a high perimeter to area ratio points towards higher edge influence and decline in the forest interior. Patch shape and patch size interaction can have important implications for some ecological phenomenon. According to Saunders et al. 1991 and Harris 1984, there are large number of evidences to prove that habitat fragmentation may have deleterious effects on species and lead to substantial loss of local and global biodiversity.

Conclusions

In the current study, a multi-temporal approach integrating remote sensing, geographical information system and ground observations was used to assess the spatial changes in various land use categories and the degree of land cover fragmentation. From the analysis, it was concluded that the East Bokaro coalfields is a highly fragile ecosystem which is vulnerable to degradation and drastic land use changes. Agricultural lands registered a drastic decrease in their representation as compared to any other land use category. The plantation efforts have improved the representation of the forests in the landscape but their ecological role still remains threatened. The other land use categories like mining, settlements and barren lands have also increased considerably. The increasing human disturbance driven by coal mining and associated industries has made the forest patches more vulnerable to fragmentation. The study emphasizes that the increasing mining accompanied by rising anthropogenic activities and unsustainable practices are posing a potential threat to the region's local biodiversity. Fragmentation analysis deals with the detailed dynamics of each land cover category (Uuemaa et al., 2013) and this study gives up-to-date information on the level of fragmentation operating in the area. Remote sensing knowledge information coupled with landscape fragmentation can be very advantageous in evaluating the land cover changes and the process of habitat fragmentation occurring at different locations at different periods of time. Thus it is very important to understand such changes in the landscape composition as well as configuration at different temporal scales and their implications so that they can be utilized in appropriate landscape management planning. Such studies augment the requirement of utilizing a landscape level approach rather than patch level approach for policy and management planning. There is a need to manage entire landscapes, not just the components.

(Received 24th May 2017; accepted 11th Aug 2017)

Abstract. In the present study, the molecular profiles of rhizospheric bacterial communities of *Tagetes terniflora*, *T. remotiflora* and *T. coronopifolia* were analyzed at different times using soil samples under greenhouse conditions. To this end, samples spanning were obtained at 3, 30, 60 and 90 days. Metagenomic DNA was extracted and the 16S rDNA genes were amplified by PCR-touchdown to reduces the formation of spurious by-products. The amplified fragments were run through Denaturing Gradient Gel Electrophoresis (DGGE) to obtain their molecular profiles. Shannon's index showed a decline of bacterial diversity over time. Also, to visualize spatial proximities by species, a non-metric MDS ordination was conducted, generating a stress value of 0.179. A one way-ANOSIM showed significant differences between *T. terniflora* and *T. coronopifolia* ($R = 0.78$, $p < 0.05$), and between *T. remotiflora* and *T. coronopifolia* ($R = 0.791$, $p < 0.05$). Sequencing of some DGGE profiles bands showed that *Pseudomonas* was present at 3, 30 and 60 days in all species of *Tagetes*, while *Chloroflexus* and *Delftia* were present at 3 and 60 days in *T. remotiflora* and *T. coronopifolia*, respectively. The study demonstrated that the beneficial populations were positively selected and sample time and species affect the dynamic succession in the rhizobacteria communities.
Keywords: *nMDS, DGGE, 16S rRNA, V3 hypervariable region, Bray-Curtis similarity index*

Introduction

The term microbial diversity is used to explain the composition, complexity and structure of microbial communities in natural systems. In ecosystems, such as soil and rhizosphere, diverse microbial consortia play an important role in biogeochemical cycles, decomposition and mineralization of organic matter, as well as the formation and maintenance of edaphic structure that confer soil quality (Johnson et al., 2003; Kirk et al., 2004; Ranjard et al., 2010). Besides, the microbial communities influence the nutrition and health of plants through the processes of mineral solubilization, hormone production, and nitrogen fixation at the same time that also antagonizing pathogenic microorganisms (Petersen et al., 1996; Pinton et al., 2001; Prosser, 2002; Nannipieri et al., 2003; Saharan et al., 2011).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13271345

In rhizospheric environments, which are considered a complex example of ecological equilibrium between microbiome and plant roots, most of the environmental changes that occur are attributed to organic substances exuded by the roots, which constitute a nutrient source for microorganisms (Hardoim et al., 2015; Chiarini et al., 1994; Rovira, 1965). However, the composition of rhizospheric exudates is affected by the stage of plant development (Hamlen et al., 1972), which can lead to the selection of specific bacterial genotypes (Picard et al., 2000) that may influence changes in the structure, patterns and activities of rhizobacterial communities (Di Cello et al., 1997; Hamlen et al., 1972; Chen et al., 2014) as has been documented in several microbial communities through an habitat filtering or by interspecific competition (Pontarp et al., 2012; Crits-Cristoph et al., 2013; Zelezniak et al., 2015; Centeno et al., 2016).

Actually, there is a growing interest in the allelopathic properties of plants of the genus *Tagetes* due that, the alternated cultivation of these plants with economically-important crops such as tomato, potato, mulberry, strawberry, soybean, pineapple, cabbage, cauliflower, lettuce, taro and carrot had been successful in the control of plagues (Hooks et al., 2010) mainly by the allelochemical substances produced in flowers, leaves, stems and roots (Weidenhamer et al., 2009). Experimental evidence suggests that certain allelochemical substances, such as α-terthienyles, produce oxygen-free radicals that can significantly reduce populations of root knot nematodes, insects, fungi, bacteria, and some viruses (Tereschuk et al., 1997; Nivsarkar et al., 2001; Tomova et al., 2005). Nevertheless, little is known about the changes in the composition of bacterial communities in the rhizosphere over time. Hence, the aim of this study was to analyze the antagonistic effect of three species of the genus *Tagetes* on changes in rhizosphere bacterial diversity and community structure at different growth stages. To this end, molecular profiles of the V3 hypervariable region of the 16S rRNA gene were obtained using the Denaturalizing Gradient Gel Electrophoresis technique (DGGE) approach.

Materials and Methods

Soil samples

Soil samples were collected in La Vega de Metztitlán region in the state of Hidalgo, Mexico, a zone considered the main agricultural area in the Barranca de Metztitlán Biosphere Reserve located at 20° 42’ 12”; 20° 28’ 04” N and 98° 53’ 20”; 98° 40’ 21” W, at a mean altitude of 1,270 m (4,167 ft.) above sea level (Guzmán et al., 2008). Ten samples were taken randomly in a 5-hectare area (12.4 acres) of agricultural fields planted with chili peppers near the locality of Tres Cruces. First, the upper layer of soil was removed (≈5 cm), then, approximately 50 kg of soil were collected, placed in sterile polyethylene bags, and sealed with elastic bands. After it, in the laboratory, the ten samples were mixed to yield one composite sample, which placed in polypropylene bags in 2 kg quantities and autoclaved for 45 minutes at 121°C, this process was repeated three times with 24 hours of difference.

DOI: http://dx.doi.org/10.15666/aeer/1504_13271345

Tagetes crop

To establish the crop of *Tagetes* plants under greenhouse conditions, seeds of three species were used: *T. terniflora*, *T. remotiflora* and *T. coronopifolia*, all provided by Dr. Miguel Ángel Serrato Cruz of the Department of Plant Science at the Universidad Autónoma de Chapingo, Mexico. Planting the three *Tagetes* species was conducted as follows: 10-12 seeds were germinated in glass Petri dishes using filter paper moistened with distilled water as support. To maintain humidity, the Petri dishes were placed on a plastic tray (20 × 15 × 5 cm) and covered with cellophane plastic that contained moist paper towels. Under these conditions, the seeds were exposed to solar light and environmental temperature until germination. The distilled water was changed every 24 h by adding a fresh volume of 10 mL to prevent the seeds from rotting. At 8-14 days after germination, 10 seedlings of each species were transplanted into plastic boxes (72 × 42 × 66 cm) containing sterile composite soil sample to ¾ of their capacity. The seedlings were separated by 15 cm to obtain better development. Finally, a control with no plants was established.

Samples of rhizospheric soil

To evaluate changes in the composition of the bacterial community, sampling of the rhizospheric soils was performed at 3, 30, 60 and 90 days after transplanting the seedlings. For each specie and stage, was collected and chosen at random, a unique whole plant with adhering soil. The rhizosphere soil was obtained removing the loose soil by careful shaking, after which tightly-adhering soil was sampled from the root surfaces of each plant, we obtained three replicates of approximately 1.5 g of rhizospheric soil, which was placed in 2-ml polypropylene tubes and stored at 4°C.

The physicochemical analysis of the rhizospheric soil collected in La Vega (Metztitlán) was conducted using the Motte Turf Lab Deluxe kit (model TL-2®, Cáceres, Spain) following the protocol provided by the supplier. Analysis consisted in determining nitrogen (N), total phosphorus (P_{tot}), potassium (K) and iron (Fe) content, pH, and soil texture. Determination of the soil texture type was based on data obtained for the percentages of clay, sand and loam, using a triangle of soil texture in accordance with the Official Mexican Norm NOM-021-RECNAT-2000.

Extraction of nucleic acids

Extraction of metagenomic DNA from the rhizospheric soil and controls was carried out using the protocol described by Cullen and Hirsch (1998), the procedure basically was lysis of indigenous soil microorganisms using alkaline-SDS buffer in a bead-beater. Purification of the extracted metagenomic DNA was performed with the commercial Zymo Research ZR Soil Microbe DNA MiniPrep™ kit (Zymo Research Corp, Irvine, CA, U.S.A.), following the manufacturer's instructions. The quality of the DNA was observed in agarose gels at 1% with TAE 1X regulator.

DGGE-PCR

DGGE-PCR amplification of the V3 hypervariable region of the bacterial 16S rRNA gene (193 bp) from the extracted and purified rhizospheric DNA was conducted with the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13271345

universal oligonucleotides *P3* (5'- CCT ACG GGA GGC AGC AG-3'), and *P2* (5'-ATT ACC GCG GCT GG-3'). A GC clamp of 40 nucleotides (5'-CGC CCG CGC GCG GGC GGG GCG GGG GCA CGG GGG G-3') was added to the forward oligonucleotide *P3* at position 5' (Muyzer et al., 1993). Touchdown PCR was performed in a total reaction volume of 100 µl. The concentrations of each component of the reaction mix were 5 ng of DNA, 1X PCR buffer (20 mM Tris-HCl pH 8.0 and 50 mM KCl), 2.5 mM of $MgCl_2$, 250.0 mM of each dNTP, 0.2 mM of each initiator, 0.25 OR/µl of *Taq* DNA polymerase (Invitrogen®) and 250 ng/µl of BSA (Amresco®). The amplification conditions of Touchdown PCR were conducted with an initial cycle at 95°C for 10 min. Next, the alignment temperature was reduced from 65°C to 50°C in intervals of 1°C during 15 cycles. An additional 20 cycles were run at an alignment temperature of 50°C. Each cycle involved a denaturalizing temperature of 94°C for 1 min and an extension temperature of 72°C for 90 s, followed by a final extension at 72°C for 5 min.

Denaturalizing Gradient Gel Electrophoresis (DGGE) was performed following the methodology described by Muyzer et al., (1993). Polyacrylamide gels at 7% were prepared (16 × 16 cm) with a chemical denaturalizing gradient of 0-80% utilizing a urea solution at 5.6 M and formamide at 32% (Sigma-Aldrich, St. Louis, MO, U.S.A.). 20 µl of the Touchdown PCR product were added to each well of the gel, and then run them in an electrophoresis chamber (DGGE-2001, CBS Scientific, San Diego, CA, U.S.A.) that contained TAE 0.5X regulator. Electrophoresis was pre-run for 20 min at 200 V and then for 15 h at 60°C and 70 V. Visualization of the DNA bands was carried out using silver stain from the commercial PageSilver™ Silver Staining Kit (Fermentas, Glen Burnie, Maryland, U.S.A.).

DNA sequencing and phylogenetic reconstruction

The amplified and purified fragments from the V3 region of the 16S rDNA gene were sequenced in both senses using DGGE-PCR initiators (but without the GC clamp) in an automatic 3130 Applied Biosystems® Genetic Analyzer sequencer with 4 capillaries (Foster City, CA, U.S.A.) at the Department of Seed Production at the Colegio de Posgraduados Chapingo. Once the DNA sequences were obtained, they were compared using the BLAST program (http://blast.ncbi.nlm.nih.gov/Blast.cgi) in order to identify similar sequences in the database of nucleotide deposited at the National Center for Biotechnology Information (NCBI). The sequences were edited manually with the help of the BioEdit program V.7.2.5 (http://www.mbio.ncsu.edu/bioedit/bioedit.html), and aligned using the program Clustal X V.2.1 (Thompson et al., 1997). The phylogenetic relationships of the sequences were determined by maximum likelihood analysis (ML) using the PhyML program (http://atgc.lirmm.fr/phyml/) (Guindon et al., 2010). The optimal model of the evolution of our sequence data was obtained using the Akaike Information Criterion (AIC) with Modeltest program V.3.7 (Posada and Crandall, 1998). The support values for each node were estimated using 5,000 bootstrap replicates.

Statistical and DGGE analyses

DGGE gel banding patterns were examined using the 1D gel electrophoresis image analysis software GelAnalyzer (http://www.gelanalyzer.com/index.html). Each band was coded as present (1) or absent (0), and described by its position in the banding profiles.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13271345

Shannon's diversity indexes were estimated for each profile. Also, binary data were transformed mathematically for normalization by the equation x'= log 10 (x + 1) before applying the Bray-Curtis index (Legendre and Legendre, 2012).

The PCR-DGGE-generated banding patterns of the soil samples obtained from the rhizosphere of the three *Tagetes* species and the control at different times were analyzed using a clustering algorithm from the Bray-Curtis index. Additionally, PERMANOVA (Permutational Multivariate Analysis of Variance Using Distance Matrices) with 5000 permutations was performed to test for significant differences between species and development stage in the bacterial community of the rhizosphere. Cluster analysis and dendrogram generation were carried out using PAST software package (PAleontological STatistics) v.3.0. (Hammer et al., 2001).

To state the changes in the bacterial community composition, a one-way ANOSIM analysis with 999 permutations was performed using *Tagetes* species and sampling time as the explanatory variables. This analysis allowed us to evaluate the null hypothesis, H_0, which indicated that there were no significant differences in the structure of the bacterial communities of the three species of *Tagetes*. For each ANOSIM test, we calculated separately the statistical Global R at a significance level of $p < 0.05$ to reject the null hypothesis. Also, species turnover bacterial communities were estimated using the Whittaker Beta Diversity index.

Also, a non-metric multidimensional scaling analysis (nMDS) was performed with 999 bootstraps to avoid minimal local (Legendre and Legendre, 2012). Both multivariate (ANOSIM and nMDS) and beta-diversity analyses were performed using the Bray-Curtis similarity index with the aforementioned PAST software package.

Results

Soil analysis

The physicochemical analysis of the composite soil collected in La Vega de Metztitlán, and used to grow the *Tagetes* plants, was found to contain the following quantities: NO_3-N = 5.60 g/m^2; P_{tot} = 0.56 g/m^2; K = 17.933 g/m^2; and Fe = 1.5 ppm; while pH was 7.0. The analysis of soil texture demonstrated that it was made up of 53.3% sand, 16.7% loam, and 30.0% clay, and so may be considered of the sandy clay loam type.

DGGE patterns and bacterial diversity

Nine samples obtained from the rhizospheres soils of the three *Tagetes* species at different times, plus three control samples, were subjected to electrophoresis in two acrylamide gels under denaturing conditions. Analysis of the gels using GelAnalyzer software (V. 2010a, freeware; Istvan Lazar) showed profiles that were both complex and diverse and that together made it possible to identify a total of 101 bands. The relative intensity or crude volume of each band was calculated after staining with $AgNO_3$, which produced values in the range of 0.43-7.8%. The average number of bands per sample was 37.1. Specifically, for the four sampling times in *T. terniflora*, the average number of bands was 43.6, while the averages calculated for *T. remotiflora* and *T. coronopifolia* were 35.4 and 32.4 bands, respectively. The number of bands in the molecular profiles for each time

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13271345

and species decreased as time increased. Thus, the analysis of triplicate gels showed that at 3 days *T. terniflora* presented, on average, 50 ± 4.3, at 30 days 52 ± 1.7, at 60 days 39 ± 4.7, and at 90 days 35 ± 6.0 bands; *T. remotiflora* at 3 days 42 ± 4.3, at 30 days 31 ± 2.7, at 60 days 34 ± 6.0, and at 90 days 36 ± 6.0 bands; *T. coronopifolia* at 3 days 39 ± 4.0, at 30 days 34 ± 4.0, at 60 days 29 ± 4.3, and at 90 days 29 ± 5.0 bands; and controls at 3 days ± 2.4 33, at 30 days 32 ± 2.4, at 60 days 29 ± 1.4, and at 90 days 23 ± 1.4 bands.

Due to the allelopathic properties of the roots of *Tagetes terniflora*, *T. remotiflora* and *T. coronopifolia*, an analysis of variation of rhizosphere bacterial communities in soil was carried out using the molecular profiles generated by DGGE at 3, 30, 60 and 90 days of growth (*Figure 1A*). The DGGE profiles were reproducible in triplicate, regardless of the DNA extraction process. Profiles were analyzed utilizing a criterion of coincident bands, which allows the construction of dendrograms and calculations of diversity indexes. The dendrogram shown in *Figure 1B* represents the similarity of the relationships among the molecular profiles obtained from the samples of rhizospheric soils at the different times of development for the three species of *Tagetes*. This dendrogram presents a cophenetic correlation coefficient of 0.9054, using a Bray-Curtis similarity measure and 5000 replicates. This analysis made it possible to recover two main clusters, one that included the control and *T. coronipifolia*, and a second with *T. terniflora and T. remotiflora*. In the main cluster, all samples from the same treatment were recovered jointly. In the control, the most similar communities were found between the samples collected at time 3 and 30 (similarity above 96%), while the sample collected at time 90 showed the greatest difference, with a similarity of just 80%. The similarity values calculated for the *T. coronipifolia* samples collected at time 3 and 30 and times 60 and 90 were quite close to each other (≈60%). For *T. terniflora*, the most similar communities were found between times 3 and 30 (≈70%), while the sample taken at time 90 differed most markedly (≈46%). Finally, for *T. remotiflora*, the most similar communities were found between times 30 and 60 (≈56%), and the most different sample was the initial community sampled at time 3 (≈46%).

Whittaker beta diversity (β_w) indexes were estimated to detect changes in bacterial composition among species and over time. All estimated values were above zero, even in the control sample over time. Beta diversity values ranged from $\beta_w = 0.014$ in the control sample between days 3 and 30 to $\beta_w = 0.827$ between the control sample at day 90 and *T. remotiflora* at day 30. The low beta diversity values correspond to the control treatment at the different times.

These Whittaker global beta diversity values show that *T. coronopifolia* had the highest rate of species turnover at $G\beta_w = 1.100$, while *T. terniflora* and *T. remotiflora* showed values of $G\beta_w = 0.847$ and $G\beta_w = 1.040$, respectively. The Mantel test using 9999 permutations suggests that regardless of the changes in bacterial species during the sampling times for each species, the relations between beta diversity and time were statistically-distinct from zero ($r = 0.0049$, $p = 0.4312$).

As a means of measuring alpha diversity, we estimated Shannon's diversity indexes for the electrophoretic profiles generated by the rhizosphere of *T. terniflora*, *T. remotiflora* and *T. coronopifolia* (*Table 1*). The indexes of biodiversity estimated for *T. terniflora* presented a value of 3,573 on day 3, though this decreased at 30 and 60 days to values of 3,345 and 3,445, respectively. However, at day 90 the value increased to 3,468. In the cases of *T.*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13271345

remotiflora and *T. coronopifolia*, observations discerned a downward tendency in the estimated diversity indexes. The boxplot graphs in *Figure 2* show the diversity of the molecular bands in the DGGE profiles. Of the three species of *Tagetes* used, the greatest band diversity was observed in *T. coronopifolia*.

Table 1. *Shannon's diversity indexes*[1]

Sample	Shannon's Diversity Index[1]			
	3 days	**30 days**	**60 days**	**90 days**
Rhizospheric soil from *Tagetes remotiflora*	3.738 (0.043)[2]	3.434 (0.043)	3.526 (0.061)	3.584 (0.053)
Rhizospheric soil from *Tagetes terniflora*	3.912 (0.043)	3.951 (0.017)	3.664 (0.0)	3.555 (0.0)
Rhizospheric soil from *Tagetes coronopifolia*	3.664 (0.031)	3.526 (0.041)	3.367 (0.0)	3.367 (0.050)
Non-rhizospheric soil control	3.497 (0.0)	3.466 (0.0)	3.367 (0.0)	3.135 (0.0)

[1]Biodiversity indexes for repetitions of samples (n=3) estimated using Shannon's Diversity Index. $H = -\Sigma p_i \ln p_i$. Means ($\bar{x}$) and standard deviations (SD) are shown together with the diversity values.

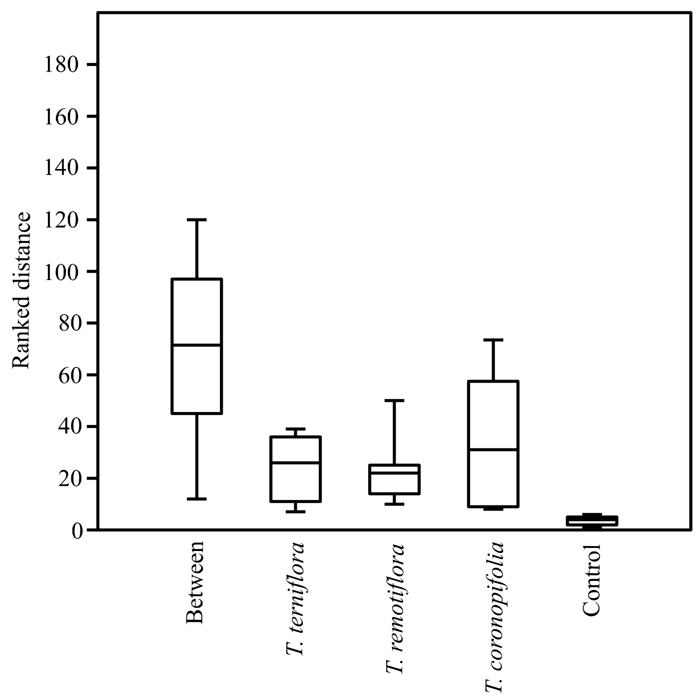

Figure 2. *Boxplot of the mean Bray-Curtis distance measures of DGGE profiles obtained from rhizosphere soil samples of three species of the genus Tagetes*

nMDS analysis of DGGE banding patterns

Analysis with a non-metric MDS ordination in two dimensions and Bray-Curtis similarity measure resulted in a stress value of 0.232. However, adjustment for three dimensions produced a stress value of 0.179, which allowed a better interpretation of the nMDS plot (*Figure 3*). This plot showed the separation of three groups of bacterial populations. The first was located at the top right and corresponds to the control samples.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13271345

The second group was situated on the bottom right and includes the samples taken at 3, 30, 60 and 90 days of the species *Tagetes coronopifolia*. Finally, the overlapping groups of *Tagetes terniflora* and *T. remotiflora* were localized to the left of the graph. These results show that the bacterial communities of the control and three species of *Tagetes* differ clearly, as does *T. coronopifolia* with respect to the other two species.

Analysis of similarities (ANOSIM)

The one-way analysis of similarities (ANOSIM) showed significant differences between *T. terniflora* and *T. coronopifolia* (1-way ANOSIM R = 0.78, p <0.05), between *T. remotiflora* and *T. coronopifolia* (1-way ANOSIM R = 0.79, p <0.05), and between each species of *Tagetes* and the control (*Table 2, Figure 2*). The value of the one-way Global R for the three species of *Tagetes* was $R_{Global} = 0.83$ at *p* = <0.05, which allowed us to reject the null hypothesis and demonstrate that the differences among species were significant. On the other hand, the Global R for the factor time was R_{Global} = - 0.028, and p => 0.05, so we were able to accept the null hypothesis of no significant differences with respect to sampling times. The PERMANOVA test showed a significant effect of the *Tagetes species* on the structure of the bacterial community (***F*** = 5.28; ***p*** < 0.01). Significantly, the greatest differences were found between *T. cornopifolia* and *T. terniflora* with *p* = 0.32; *T. cornopifolia* and *T. remotiflora* with *p* = 0.026; and *T. coronopifolia* and the control with *p* = 0.029. No significant differences were found with respect to time (*F* = 0.67, *p* = 0.86).

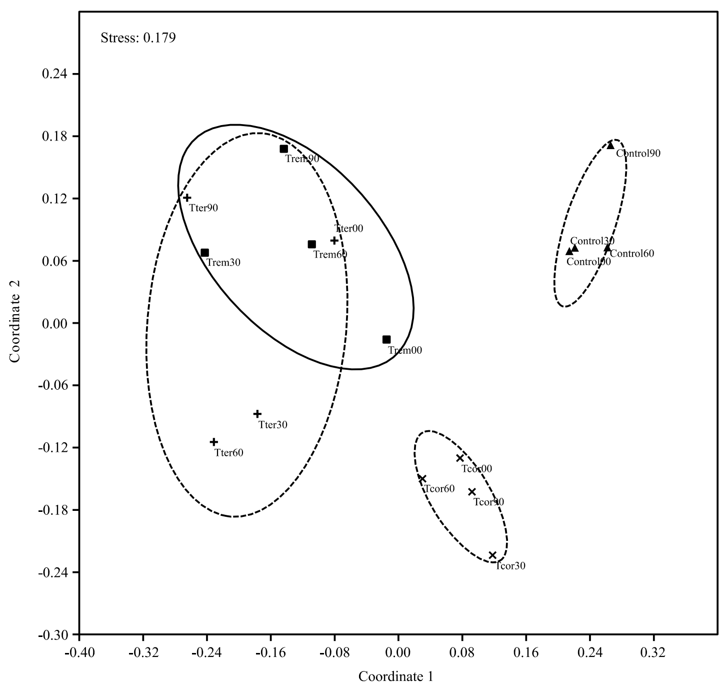

Figure 3. *Two-dimensional plots of nMDS analyses from DGGE patterns to compare differences in bacterial communities taken from rhizosphere soil samples of three species of the genus Tagetes*

DOI: http://dx.doi.org/10.15666/aeer/1504_13271345

Phylogenetic analysis

Six bands from the DGGE profiles of rhizobacteria communities of *T. terniflora*, *T. remotiflora* and *T. coronopifolia* were selected for molecular identification. The criterion utilized in the selection of the bands was basically their atypical or discontinuous presence or absence at the different sampling times. Band B1 was present at 3 and 30 days, absent at 60 days, and reappeared at 90 days. Band B2 was absent at 3, 30 and 90 days, and only present at 60 days. Band B3 was present at 3 days but absent from the later samples taken at 30, 60 and 90 days. Band B4 was present on days 30 and 60, but absent at 3 and 90 days. Band B5 was present at 3 and 30 days, but absent at 60 and 90 days. Finally, Band B6 was absent at 3 and 30 days, but present at 60 and 90 days (*Figure 1A*).

Figure 4 shows a phylogenetic tree constructed on the basis of the band sequences obtained from the DGGE molecular profiles of the rhizobacteria communities from the soil samples of *T. terniflora*, *T. remotiflora* and *T. coronopifolia*. The phylogenetic analysis shows the relations of bands B1, B2, B4 and B5 to the group of the genus *Pseudomonas*; of band B3 to non-cultured bacteria; and of band B6 to microorganisms of the genus *Delftia*.

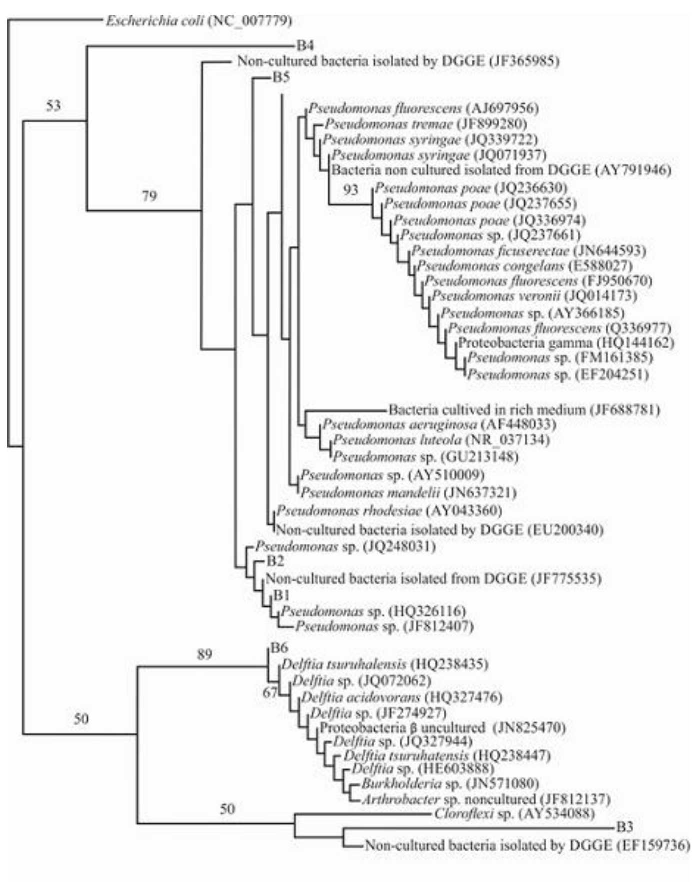

***Figure 4.** Phylogenetic tree constructed on the basis of the sequences from hypervariable region V5 of the 16S rDNA of the bands of interest selected from the molecular profiles of the rhizospheric bacteria in T. terniflora (B1 and B2), T. coronopifolia (B3 and B4) and T. remotiflora (B5 and B6), generated by DGGE*

Discussion

The nature of the changes in structure and diversity of soil bacterial communities that result from the interactive effects of different plant species is a little-studied issue in Microbial Ecology. The use of techniques based on the Polymerase Chain Reaction (PCR) of metagenomic DNA coupled with Denaturalizing Gradient Gel Electrophoresis (DGGE) allow us to analyze the relative abundance of the populations of dominant bacteria and compare the successions or changes in the structure of microbial communities in environmental samples (Muyzer and Smalla, 1998; Brons and van Elsas, 2008; Rodríguez-Lanetty et al., 2013; Chen et al., 2014). Although the usefulness of these techniques is limited by the number of DNA bands and the complexity of the profiles obtained (Nannipieri et al., 2003; Heuer et al., 2001; McCaig et al., 2001; Curtis et al., 2002), when employed over time, these DNA band profiles can help improve our understanding of the succession of microbial soil communities.

This study analyzed the effect of three species of *Tagetes* on the structure of bacterial communities in samples from rhizosphere at different times. These plants are recognized for their allelopathic action because their roots naturally exude components denominated α-terthienyles (Meissner et al., 2013). The results presented here suggest a heterogeneity in the diversity of bacterial communities in the rhizosphere related with plant species. In spite of we failed to detect a selective sweep that leads to a drastic reduction in the alpha diversity estimated through Shannon index we were able to find a drastic change in the bacterial composition trough time.

In relation to the above mentioned results, several earlier studies have suggested a selective effect of microbial populations in plant rhizospheres driven by edaphological characteristics of the soil (Duineveld et al., 1998; Guong et al., 2012) an effect that is highly-specific and reproducible in several vegetable species (Kumar et al., 2016). Nevertheless, recent works have shown that changes in the microbial communities of the rhizosphere could be related with habitat filtering or intraspecific competition. For example, Shi et al. (2015) analyze the changes in microbial rhizosphere communities of the annual grass *Avena fatua* in two growing sessions and found that in spite of the different starting communities in both seasons, the successional patterns were similar and the final communities were very similar. On the other hand, Yuan et al. (2016) analyzed the rhizosphere of the seepweed *Suaeda salsa* and found that both phylogenetic clustering (abiotic factors) and overdispersion (biotic factors) are involved in the high tolerance to salinity in this plant species.

The genus *Tagetes* has been characterized as exuding allelopathic compounds of the thiophenes type which have a nematocide function that has been demonstrated in both field and laboratory (Riga et al., 2005). Once isolated and purified, these allelochemical compounds have been used *in vitro*, where they have shown antiviral, antibacterial, antifungal and insecticide properties as well. Although many tests have demonstrated their allelochemical action, by determining the values of Shannon's diversity indexes obtained from sterilized agricultural soil (*Table 1*), the results of the present study demonstrate a possible selective, species-specific effect of plant rhizospheres on the microbial populations in the soil that develops through exudation during their developmental period as has been proposed in other plant species (Singh and Mukerji 2006; Chaparro et al., 2013).

Topp et al., (1998) analyzed the effect of the roots of *Tagetes* sp. on microbial communities in the soil. Their study considered the suppressor effect of the thiophenes, which are heterocyclic molecules with sulfur atoms that by activating α-terthienyl produce oxygen-free radicals. In this perspective, if the roots of *Tagetes* sp. release a biocide that is activated in the soil, then the microbial populations of the rhizosphere of *Tagetes* sp. should be substantially perturbed. In an effort to demonstrate this, those researchers took measurements of the size of microbial populations and their activity in soils from fields and greenhouses where *Tagetes* sp had been cultivated, and compared them to soils from uncultivated yards (with no vegetation) and fields where rye had been planted (*Secale cereale* L.). The results obtained using extraction-fumigation methods to measure the microbial biomass (MB), epifluorescence microscopy (5-[4,6-dichlorotriazine-2-γl] aminofluorescein) to quantify total bacteria, and heterotrophic bacterial plate counts with different media, the most probable number for the count of nitrifying bacteria demonstrated that the size of microbial populations and their activity in the diverse soils had no significant differences (Topp et al., 1998). Similar results have been found with other methods, such as marking the rye residues with ^{14}C and adding them to soils with the different treatments revealed mineralization activities that were slightly faster in the soil cultivated with rye than in the other treatments. In addition, measurements of the mortality rates of bacterial cells of *Escherichia coli* and *Rhodococcus* TE1 introduced into the soils cultivated with *Tagetes* sp. and the other treatments indicated that there was no accumulation of the biocides. These findings allowed the authors to conclude that the allelochemical exudates released by *Tagetes* sp. did not cause a general decline in the number of microorganisms in the soils and, possibly, that the control of nematodes by this plant might proceed through some other mechanism, and is not due to the release of a biocide into the soil. Analyses of the results of the BoxPlot graph (*Figure 2*), the DGGE gel (*Figure 3A*), and the dendrogram (*Figure 3B*) confirm the phenomenon of a specific, heterogeneous selection of bacterial populations by the species of the plant *Tagetes*.

The phylogenetic tree reveals the presence of three principle groups: the first made up of bacteria of the genus *Delftia* (β-*proteobacteria*), the second of bacteria of the genus *Pseudomonas* (γ-*proteobacteria*), and the third a non-cultured bacterium (*Clorofexi*). Shi et al. (2013) detected significant increases in the relative abundances of rhizobacterias in classes α-*proteobacteria*, β-*proteobacteria*, and γ-*proteobacteria*, which are well known rhizosphere colonizers and have generally been characterized as fast-growing r-strategists, which respond positively to low-molecular-weight substrates abundant in plant root exudates.

The population succession obtained using DGGE demonstrated that bands B1 (3 days, *T.* t*erniflora*), B2 (60 days, *T. terniflora*), B4 (30 days, *T. remotiflora*) and B5 (60 days, *T. coronopifolia*) were variably present at the different times analyzed (*Figure 3A*), while the phylogenetic analysis indicated that these sequenced bands are found in the group of bacteria belonging to the genus *Pseudomonas*. BLAST analysis also demonstrated that all the sequences related to the genus *Pseudomonas* had high similarities to species of *Pseudomonas* isolated from rhizospheric and other environments.

Some species of the genus *Pseudomonas* are often described as plant-growth promoting rhizobacteria (PGPR), due to the fact that they interact with the roots of plants to produce antibiotics, phytohormones, HCN, and siderophores that promote development and protect them from pathogenic microorganisms (Upadhyay and Srivastava, 2010; Subramanian and Saytan, 2014). In this way, together with the use of such techniques as electronic microscopy and genetically-marked strains, studies have shown that the mutual relations entailed in the spatial distribution of the genus *Pseudomonas* are not uniform in the roots of plants, because they prefer to inhabit regions characterized by a higher release of exudation, such as the unions between the epidermal cells of the root, indented parts of the epidermis, or lateral sites on the roots (Chin-A-Woeng et al., 1997; Fukui et al., 1994). On the other hand, observations have also shown that other bacteria –such as *Rhizobium*– prefer the tips of root hairs (Smit et al., 1986; Smit et al., 1987), presumably due to the presence of specific receptors (Swart et al., 1994).

Specific studies of the genus *Pseudomonas* have demonstrated their isolation at high frequencies from soils that suppress black rot in the roots of tobacco plants (*Thielaviopsis basicola*) and most of the fungal diseases that affect wheat (*Gaeumannomyces graminis var. Tritici*). This suppression phenomenon in soils is now well-characterized, and there is strong evidence to indicate that it is the result of the release of the antifungal metabolite 2, 4-diacetilflouroglucinol (PHL) (Walsh et al., 2001). Maize is another crop whose roots promote the colonization of antagonistic groups of *Pseudomonas*, and microbiological quantification has shown that a high proportion (~15%) of the strains of *Pseudomonas* isolated from the rhizoplane contain genes for the biosynthesis of PHL, while non-rhizospheric soils present low levels of this gene (<0.65%) (Picard et al., 2000).

However, in the case of antagonistic plants of the genus *Tagetes*, mutual relationships seem to be more complex, since previous studies have reported the presence and exudation of essential oils with distinct compositions that were common to different species of this genus (Lawrence, 1985; Héthélyi et al., 1986; Marotti et al., 2004). The most remarkable characteristic of the metabolites produced by the genus *Tagetes* is that they have toxic activity on various microorganisms that are pathogenic to plants, animals (Eguaras et al., 2005) and humans (Cestari et al., 2004). Therefore, this genus is a potential option for use in agriculture and medicine as a natural supplier of biocides, biorepellents, or biostatic effects (Díaz-Cedillo and Serrato-Cruz, 2011).

Band B3 is similar to the group of non-cultured bacteria of the genus *Clorofexi*. A recent study (Krzmarzick et al., 2012) demonstrated that in terrestrial environments this genus naturally utilizes organochlorine compounds as final electron-accepters. It is a well-known fact that plants, marine organisms, insects, bacteria, fungi and mammals all naturally produce organochlorine compounds (Öberg, 2002; Öberg and Sandén 2005; Krzmarzick et al., 2012), and this has helped us to better understand that in terrestrial environments the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13271345

transformation of chlorides into organochlorine compounds occurs through the activity of the enzyme chloroperoxidase that results in levels of organochlorine compounds that tend to be higher than those of chloride on the soil surface. As soil depth increases, changes in the speciation of chlorine take place, predominantly from organic-to-inorganic. This suggests that the organochlorines that exist naturally in the organic matter of the soil may be subjected to such biogeochemical processes of chlorination (Krzmarzick et al., 2012).

In the case of plants of the genus *Tagetes*, some 126 secondary metabolites have been identified with diverse carbon skeletons, including the thiophenes, of which 5-(but-l-chloro-2-ol-3-ynyl)-2,2′-bithienyl is characterized as containing a chlorine atom in its R2 (Xu et al., 2012). However, the presence of Band B3 at 3 days after transplanting the *Tagetes* seedlings (time = 3 days) and its subsequent disappearance in the DGGE profiles raises several questions concerning the ecological functions and symbiotic relations between plants and microorganisms.

Finally, the sequence of nucleotides in Band B6 was similar to the group of bacteria of the genus *Delftia*, which has been characterized by its role and capacity to produce D-amino acids in the hemolymph of an insect called the glassy-winged sharpshooter (GWSS) (Bextine et al., 2010). Also, *Delftia* sp., together with other bacteria, such as *Arthrobacter ureafaciens*, *Phyllobacterium myrsinacearum* and *Rhodococcus erythropolis*, have been identified as phosphate-solubilizing bacteria (PSB), thus confirming their ability to solubilize significant amounts of tricalcium phosphate through secretion of organic acids (Chen et al., 2006; Saharan and Nehra, 2011).

Although this band was only observed at 60 and 90 days and exclusively in the rhizosphere of *T. coronopifolia*, this does not preclude its possible existence in the other species of *Tagetes*. Its presence at these times could suggest an association with the process of floral initiation. Serrato-Cruz et al. (1998) determined that floral initiation of *T. patula* and *T. erecta* occurs 56 days after planting, and various studies have reported the use of experimental microorganisms and commercial isolates from rhizospheric soils that have the capacity to solubilize phosphates which positively promote the onset of flowering and an increase in the diameter and length of the flower in ornamental plants such as tuberoses (*nardo*) (Swaminathan et al., 1999), roses (Singh et al., 2003), carnations (Gupta et al., 2004), gladioli (Muzain et al., 2004), gaillardias (Deshmukh et al., 2008), and some varieties of African marigolds (Chandrikapure et al., 1999).

Conclusions

This investigation is a preliminary attempt to study the antagonistic effect of three species of the genus *Tagetes* in the bacterial communities of the rhizosphere. We found no changes in alpha diversity but a drastic change in Beta diversity trough time and among the three species of the genus *Tagetes*. The results presented herein support the selective effect of plant rhizospheres on microbial populations in the soil; an effect that can be highly-specific due that even within *Tagetes* each single species had a unique bacterial community. It is necessary in the future to perform experiments of rhizobacterial succession that imply other molecular techniques and quantification of the allelochemicals exuded by the roots and physicochemicals properties of the soil at different stages of plant development to

evaluate if the community structure is driven by biotic or abiotic factors. The results found in this study could be an important finding due that it makes possible to determine and establish the optimum time for the application of biological controls or biofertilizers on commercial plants.

Acknowledgments. This study was financed by the *Programa de Mejoramiento del Profesorado* (PROMEP) through *Apoyo de Fomento a la Generación y Aplicación Innovadora del Conocimiento* (UPPACH-PTC-079). The authors are also extremely grateful to Dr. Miguel Angel Serrato Cruz for providing the marigold seed included in this work and to Dra. Carla Centeno and Paul Kersey for the kindly review of the translated manuscript.

(Received 13th Jun 2017; accepted 4th Sep 2017)

Abstract. The present study was conducted to identify the response of pepper plants under cadmium stress to gibberellic acid (GA_3) treatments. Plants were exposed to different cadmium chlorine doses (0, 20, 40, 60 ppm) cadmium chloride ($CdCl_2$) and GA_3 (10 ppm) treatments. A resistance scale was used based on symptoms over the leaves and mineral element analyses (K, Cu, Zn, Fe, Mn, Mg and Cd) were performed. Experiments were conducted in hydroponic culture with Demre pepper cultivar under controlled conditions. Present results revealed significant effects of Cd treatments on Cd, Fe, Zn, Cu, Mn, Mg and K concentrations of the plants. Combined treatments of Cd and GA_3 (10 ppm) also increased ion accumulation especially in leaves. It was observed under stress conditions that GA_3 hormone treatments inhibited plant growth to prevent stress, increased ion uptake, well-adjusted ion balance and let the plants avoid from stressors.
Keywords: *cadmium, gibberellic acid, heavy metal stress, ion accumulation, pepper (*Capsicum annuum *L.)*

Introduction

Industrialization and urbanization bring about serious environmental pollution and exert significant threats on nature (Güven et al., 1999).

Even the trace amounts of heavy metals in air, soil and water resources may be dangerous for all living things. Agricultural and industrial activities may significantly increase especially cadmium (Cd) concentrations in the air surrounding us. The presence of heavy metals in trace amounts in soil, water and air can be dangerous to all living things, and the concentration of Cd in the environment is increasing due to agricultural and industrial factors (Foy et al., 1978). Such an increase is mostly resulted from anthropogenic sources and ultimately passed into the agricultural lands through sewage sludge treatments and fertilizer applications (Doğan and Saygıdeğer, 2009).

Cadmium may reduce germination, growth, development, yield and quality of various plants. Several studies were carried out to determine the threshold values and to investigate the morphological and physiological effects of Cd toxicity (Bertin and Averbeck, 2006).

Whether or not being essential element for plant growth, excessive heavy metal accumulation in plant tissues and organs negatively influence vegetative and generative organs of the plants (Gür et al., 2004). With toxic impacts, heavy metals may damage several physiological processes such as transpiration, stomatal conductance, enzyme activity, germination, protein synthesis, membrane stability and hormonal balance (Kennedy and Gonsalves, 1987). Toxicity may vary both from one metal to another and from one organism to another. Positive or negative (toxic) impacts not only depend on element type and concentration, but also closely related to genetic-based physiological responses of different species (Haktanır and Arcak, 1998).

Cadmium stress reduces water and ion uptake of plants and hinders root growth and development. Stomata also close under cadmium stress, thus water loss through transpiration is reduced and cadmium transport is hindered (Salt et al., 1995). Cd accumulation may have toxic impacts on plants and damage mineral nutrition and carbohydrate metabolism of the plants, and then ultimately limits plants growth and development (John et al., 2009). Cadmium also inhibits chlorophyll biosynthesis and reduces total chlorophyll content (Stobart et al., 1985). Zinc and iron are essential micro nutrients for several biochemical processes in plants (Marschner, 1995). Cadmium interacts with these nutrients and directly influences nutrient uptake. Such interactions ultimately influence nutrient distribution, results in nutrient deficiency/imbalance and recesses plant growth and development (Zhang et al., 2002).

There is a consensus on stimulation of internal hormone levels through external application of different growth regulators (El-Shahaby et al., 1992). Rodriguez et al. (2006) indicated that the hormones in EP (extracellular products) produced by Cyanobacteria developed salt-tolerance in paddy seedlings. It was also indicated in the same study that GA treatments stimulated abscisic acid (ABA) production as a response to salt stress and altered and reduced the ratios of growth regulators.

The present study was conducted with pepper plants of Solanaceae family, mostly produced as early grown or summer plant in Turkey, to investigate: a) the effects of cadmium on metabolic activities of the plants; b) the response of plants and adaptation mechanisms developed against this pollutant; c) stress relief through gibberellic acid treatments; d) correlations of plant growth regulators with ion uptake and accumulation in plants.

Materials and Methods

Experiments for stress factors and plant growth were conducted in hydroponic culture in a climate cabin with a split air-conditioner to provide normal atmosphere.

Pepper seeds were sown in pumice-filled plastic germination containers (40x25x5 cm). Following the sowing of 100 seeds to each container, irrigation was performed with tap-water. Containers had 9 holes (0.5 cm) beneath to drain the irrigation water. Pumice was thoroughly wetted and excess irrigation water was drained. Then germination containers were placed in climate cabin with 25^{o}C temperature and 70% relative humidity. Containers were covered with moist paper and regularly controlled. Gradual tap water applications were continued to prevent the drying of pumice. Irrigations were started to be performed with Hoagland nutrient solution when the seedlings had horizontal cotyledon leaves and the first true leaves (Hoagland and Arnon, 1938). The seedlings with the 2nd true leaves were transplanted into hydroponic culture. Plastic cuvettes (25x25x18 cm) filled with Hoagland nutrient solution were used for hydroponic culture. Pepper seedlings were wrapped around with small sponge pieces and placed in specially designed platforms with holes over for each seedling. These platforms were placed over the cuvettes as to have the roots immersed in nutrient solution. Aeration was supplied through the nutrient solution with thin plastic hoses connected to two aquarium pumps.

Following the growth of seedling in hydroponic culture for two weeks, cadmium treatments were initiated. Experiments were conducted by completely randomized design with three replications with 20 plants in each replication. For cadmium treatments, 0, 20, 40, 60 ppm $CdCl_2$ doses were added to nutrient solution (1/2 Hoagland). Solutions were renewed weekly and care was taken to sustain the same

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13471357

cadmium concentrations in each renewal. Together with cadmium, 10 ppm gibberellic acid was applied to plants. Sampling for measurements and analyses were made 15 days after cadmium treatments. Samples were used to determine some plant growth parameters (green herbage fresh weight, number of leaves, plant heights, cadmium resistance scales based on leaf symptoms) and to determine some physico-chemical parameters (Cd, K, Cu, Zn, Fe, Mn, Mg contents).

A total of 8 different treatments were performed (control, cadmium 20, 40, 60 ppm, cadmium 20, 40, 60 ppm + gibberellic acid GA_3 (10 ppm).

Mineral element analysis

Three leaves from tip to downward were taken and they were kept in deep freezer at –40°C. About 200 g samples were taken from the deep freezer and samples were supplemented with 10 ml 0.1 N HNO_3 (Nitric acid). They were then kept in plastic boxes at dark and room temperature for a week. Samples were shaken in a shaker for 24 hours and resultant extract was subjected to K^+, Cu^+, Zn^+, Fe^+, Mn^+, Mg^+, Cd ion analyses in flame photometer (Eppendorf flame photometer). Fresh leaf ion concentrations were expressed in μg/mg fresh weight (Taleisnik et al., 1997).

Experiments were conducted in randomized plots design with 3 replications. Statistical analyses for plant growth parameters, ion and enzyme data were performed with SAS (1985) software.

Results

Data about plant growth parameters are provided in *Table 1*. While the greatest root weight was obtained from the control treatment, the lowest value was obtained from Cd3+GA_3 treatment. The same treatments had the similar characteristics for root lengths. Control treatment had the greatest stem weight and it was followed by GA_3 treatment. As compared to the control treatment, the greatest decrease was observed in Cd+GA_3 treatment, but it was placed in the same statistical group.

There were not any significant differences in stem lengths of the treatments. Control treatment had the greatest leaf weight. As compared to the control treatment, the greatest decrease was observed in Cd3+GA_3 treatment. The results for number of leaves were similar with the results for leaf weight. The greatest plant weight was observed in control treatment and the greatest decrease as compared to control treatment was observed in Cd3+GA_3 treatment. With regard to all growth parameters, it is remarkable that the lowest values were seen in Cd3+GA_3 treatment. Again as compared to the control treatment, leaf weight, number of leaves, total plant weight decreased with increasing cadmium doses.

As compared to control and single Cd treatments, Cd + GA_3 treatments increased root, stem and leaf Cd concentrations. The greatest leaf Cd accumulation in single Cd treatments was observed in leaves (*Table 2*). The greatest root cadmium concentrations were observed in Cd3+ GA_3, Cd2+ GA_3 treatments and they were followed by Cd1+ GA_3 treatment. The greatest stem cadmium concentration was observed in Cd3+ GA_3 treatment and it was followed by Cd2+ GA_3 and Cd1+ GA_3 treatments. The greatest root and stem cadmium concentrations were observed in Cd3+GA_3 treatments and increasing values were observed with increasing treatment doses. The same case was not valid for leaves; the greatest leaf cadmium concentration was obtained from Cd3 treatment and it was followed by Cd2 and Cd1 treatments.

GA_3	1.14 D	0.505 E	0.447 E

Means indicated with the same letters in the same column are not significantly different.

There were remarkable differences in Fe contents of plant organs in different treatments (*Table 3*). While the greatest root Fe content was obtained from the control treatment, the greatest stem Fe content was obtained from GA_3 treatment and the greatest leaf Fe content was obtained from the control and GA_3 treatments. The lowest root and stem Fe contents were obtained from Cd3+GA_3 treatment and the lowest leaf Fe content was obtained from Cd1 treatment.

Considering the Zn contents of the roots, stems and leaves of treated plants, the greatest values were obtained from the control and GA_3 treatments and the lowest values were obtained from single Cd treatments. As compared to control and single GA_3 treatments, Zn contents decreased with Cd + GA_3 treatments, but increased with single Cd treatments (*Table 4*).

With regard to Cu accumulation in roots, stems and leaves of pepper plants, similar with Fe and Zn, the greatest values were observed in control and GA_3 treatments without Cd treatments. As compared to control treatment, decrease was observed with Cd + GA_3 treatments; however Cu accumulation levels were lower in single Cd treatments (*Table 5*).

Considering Mn accumulation in roots, stems and leaves of pepper plants, the greatest values were observed in control and GA_3 treatments. As compared to control treatment, Cd + GA_3 treatments generally decreased Mn contents of roots and leaves, but yielded higher Mn contents than single Cd treatments. Cd+GA_3 treatments yielded the same stem Mn contents with the control treatment, but higher than Cd treatments (*Table 6*).

Control treatments had the greatest root Mg contents. However, contrary to other ion concentrations, single GA_3 treatments had the least Mg accumulation levels. Cd + GA_3 treatments also had lower Cd accumulations than single Cd treatments. With regard to stem Mg contents, Cd+GA_3 treatments were placed in the same statistical group with control treatments, but single Cd treatments had lower stem Cd contents and were places in different statistical group. As it was in other ions, the differences in root, stem and leaf Mg contents of different cadmium doses were not found to be significant (*Table 7*).

Potassium (K) contents of root, stem and leaf samples are provided in *Table 8*. The greatest root K content was obtained from the control treatment and it was respectively followed by Cd+GA_3 treatments and single GA_3 treatment. The least root K content was obtained from single Cd treatments, but the differences between Cd doses were not significant. The differences in stem and leaf K contents of different Cd doses were not also found to be significant. Only the differences between Cd and GA_3 treatments were found to be significant.

Discussion

Current findings revealed that cadmium significantly hindered root, stem and leaf growth of pepper seedlings. However, differences in plant growth parameters of different cadmium doses were not found to be significant. Despite the insignificant differences in stem lengths, Cd + GA_3 treatments inhibited plant growth and development. Current findings about the effects of cadmium comply with results of various earlier studies carried out with different plants. It was previously reported that cadmium inhibited root and stem growth of *Vigna unguiculata* L. var. Pusa falguni plants (Nagor, 1997); cadmium, copper, lead and zinc reduced root and shoot development of *Sorghum bicolour* L. plants (Pandit and Prasannakumar, 1999). Cadmium and nickel reduced root and stem lengths of *Oryza sativa* L. cv. Bahia plants (Moya et al., 1993); zinc reduced stem lengths of Brassica juncea seedlings (Prasad et al., 1999); cadmium also reduced stem and root lengths of *Zea mays* L. Dekalp cv. 73 Sponsor plants (Rascio et al., 1993). Similarly, Zengin and Munzuroğlu (2003) investigated the effects of cadmium ($CdCl_2.H_2O$) on root, stem and leaf growth of bean seedlings and reported that cadmium significantly hindered root, stem and leaf growth and inhibitions were parallel to increasing cadmium doses. As compared to control treatment, plant growth was slow in Cd+GA_3 treatments. Yasar et al. (2016) applied GA_3 to eggplant seedlings under salt stress and reported selective ion uptake of plants. As reported by Ashraf et al (2001), GA_3 might have reduced nitrogen uptake of the plants. Combined application of GA_3 and cytokine-like growth regulators may provide positive contribution in elimination of salt stress (Xiong et al., 2002). Lin and Kao (1995) and Rodriguez et al. (2006) also reported that GA_3 treatments reduced the growth inhibition of paddy and some other plants.

Cd treatments increased root, stem and leaf Cd concentrations as compared to control and single GA_3 treatments. Cd accumulation in roots and stems were higher in Cd + GA_3 treatments than in single Cd treatments. However, an inverse case was valid for leaves. It was observed that GA_3 prevented toxic ion transport to leaves to prevent heavy metal toxicity. Several researchers reported increasing plant Cd concentrations with increasing Cd doses. Bachir et al. (2004) reported increasing plant Cd concentrations with Cd treatments in cotton; Safarzadeh et al. (2013) reported the same case in paddy plants. Tiryakioğlu et al. (2006) reported that increasing Cd doses increased green herbage and especially root Cd concentrations, majority of cadmium taken up by the plants accumulated in roots and slight amounts were transported to green herbage.

Cadmium treatments significantly reduced Fe, Zn and Cu concentrations of all plant organs. However, as compared to single Cd treatments, Cd+GA_3 treatments increased Fe, Zn and Cu accumulations in all three plant organs. Single GA_3 treatments also increased stem and especially leaf Fe, Zn and Cu accumulations as

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13471357

compared to single Cd treatments. Similarly, Bachir et al. (2004) reported that 0.1 and 1 µM Cd treatments increased Fe, Zn and Cu concentrations of cotton plants and indicated a potential synergic effect of Cd on Fe and Zn uptake. Köleli et al. (2004) reported under Zn-deficient conditions that increasing Cd treatments reduced green herbage Fe concentrations; however, Cd treatments did not have significant effects on green herbage Fe concentrations under Zn-sufficient conditions. Safarzadeh et al. (2013) also reported that Cd treatments significantly reduced green herbage Zn and Fe concentrations. Wu et al. (2004) carried out a study about the effects of cadmium on micro element uptake and transport in cotton plants and reported that 0, 0.1 and 1 µM Cd treatments did not change leaf Fe, Zn and Cu concentrations significantly, but 10 µM Cd treatment significantly increased leaf micro element concentrations. Amal et al. (2014) applied GA_3 to barley plants under salt stress and reported decreasing Zn, Fe, Co, Pb, Cr, Cd and Mn ion accumulation under salt stress and indicated that GA_3 treatments relieved the impacts of salt stress and increased ion uptake levels. Akman (2009) also reported similar results for Fe, Zn and Cu ion accumulation in wheat.

As it was in other ion accumulations, Cd and GA_3 treatments yielded similar results for K, Mn and Mg accumulations. Cd treatments reduced the accumulation levels of all ions, except for Cd; GA_3 treatments also yielded slight decreases in accumulation of all ions again except for Cd as compared to control treatment, but increased ion accumulation as compared to single Cd treatments. Mohamed and Gomaa (2012) and Amal et al. (2014) carried out a study with barley plants under salt stress and reported that GA_3 treatments reduced K, Mn and Mg ion accumulation levels in plants and GA_3 treatments also reduced the impacts of salt stress and increased ion uptakes. Similarly, Schachtman and Lio (1999) in barley and Iqbal and Ashraf (2013) in wheat plants under salt stress, reported that salt stress reduced ion uptake in GA_3 treatments, but GA_3 treatments improved ion uptake of plants under salt stress.

It was concluded based on current findings that combined GA_3 and Cd treatments did not have positive contributions to plant growth, but plant under these treatments behaved selectively in ion uptakes to prevent from toxic impacts of Cd. Such impacts of growth regulation hormone GA were also reported by previous researchers. When applied to plants under abiotic stressors, GA inhibited plant growth through synthesis of DELLA proteins. GA treatments increase the activity of this protein and may have positive contributions to stress tolerance of the plants since it inhibits plant growth under abiotic stress conditions (Achard et al., 2006; Achard et al., 2008a; Magome et al., 2008). Increased DELLA activity with GA treatments limits the accumulation of reactive oxygen species (ROS) under Cd stress, thus prevents cell deaths (Achard et al., 2008b). DELLA proteins were reported as behaved like inner-cell suppressors of GA-induced metabolic activities (Peng et al., 1997; Silverstone et al., 1998; Ogawa et al., 2000; Ikeda et al., 2001; Chandler et al., 2002).

Conclusion

When we evaluate the data we obtained without working, we found that the GA_3 application increased ion uptake in plants, GA_3 treatment with Cd inhibited plant growth, but Cd and GA_3 treatments did not cause damage to plants caused by strhenogenesis, even though Cd stress was applied to plants. The reason for this is that it may be originated from DELLA proteins that inhibit enzyme activity when GA_3 is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13471357

applied to plants at the time of stress. Enzyme activities and DELLA proteins should be looked for in order to be fully illuminated. In addition, after application of GA_3 at the time of stress, the levels of organic acid in the cell should be monitored.

(Received 1st May 2017; accepted 25th Jul 2017)

Abstract. Potato is one of the most important crops in Iran and on average, this crop is affected annually by weeds damage which must be prevented by various control methods. Crop residues and other types of mulches are non-chemical methods of weed control in sustainable agricultural systems. The aim of present study was to investigate the effect of chemical and non-chemical control methods on weeds in potato crop. An experiment was conducted in 2015 in two agricultural research stations of Alarogh and Samian in Ardabil city in a randomized complete block design with three replications. The treatments were as follows: 1) Trifluralin herbicide, 2) Metribuzin herbicide, 3) cultivator, 4) wheat straw mulch, 5) canola straw mulch, 6) black plastic mulch, 7) transparent plastic mulch 8) weed infested and 9) weed free. Based on results, all treatments were affected by weed control methods ($P \leq 0.01$), so that Shannon-Wiener index treatment was ($P \leq 0.05$). The greatest diversity of Shannon-Wiener index measured in present experiment was observed in weed infested treatment (average comparison by Duncan test). The treatments of Trifluralin herbicide, cultivator and transparent plastic mulch after the weed infested treatment had the highest species diversity. The lowest density of weeds was related to the wheat straw mulch. Most weeds density was counted as 99.1 plants/m^2 of weed infested treatment. The wheat straw mulch deceased weeds density as 84% compared to weed infested. The canola straw mulch also was deceased weeds density as 79% comparing to weed infested. However, weed biomass in the treatments of transparent and black plastic mulch compared to the weed infested treatment had the highest weeds biomass as 48 and 40%, respectively. The lowest weed biomass was observed in canola and wheat mulch by 16 and 18% after the weed infested. It can be conducted that, the use of plant mulches or residues can provide more proper control of weeds compared to the use of herbicide and the use of plant mulches reduces use of herbicides.
Keywords: *biomass, canola, density, diversity, herbicide, plant mulch, plastic mulch, wheat*

Introduction

In most potato producer countries in the world such as China, India, Russia, Ukraine, America, Germany, Bangladesh, etc. with different climatic conditions, weed control is carried out by agricultural, mechanical and chemical methods or their combination in potato fields. (Hutchinson et al., 2011; Kunz et al., 2015; Weber et al., 2016). Metribuzin (Sencor) is an herbicide belonging to Triazine family that is used in potato fields both

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13591372

before planting and pre-emergence potato, mostly to control annual grass and broad leaf weeds (Zand et al., 2007; Zaki et al., 2014). The use of Trifluralin (Treflan) is effective as pre- emergence in hilling step to control weeds of potato crop (Sheikhi et al., 2012; Borzouei et al., 2013). The use of tillage or cultivator along with herbicide, control of weeds effectively and it is used as one of the major methods of weed control in potato crop (Mohammaddoust et al., 2011). Nowadays, an organic method that is used in weed management is the application of mulches. Moreover, the application of herbal residues or plant mulch has a great importance to develop and expand sustainable farming systems. The need to increase farm productivity and profitability is a factor that stimulates the development of methods based on the ecological management of weeds. Considering that in industrialized countries as well as developing countries, increasing the inputs cost has been more than the products cost, so that has been endangered the economic support for farmers. If the better ecological process is used in weed management, agricultural income will be increased by reducing the inputs cost and this topic helping farmers to provide market friendly agricultural products (Dejam et al., 2010; Jafari et al., 2013; Najafi et al., 2016). Specifically, when using a weed control method, the competition of weeds with crop plants is reduced and as a result the use of other methods (as chemical control) to weed control is reduced. The purpose of this experiment was to determinate the best method that prevents weed growth and competition of weeds with crop.

Materials and Methods

Study area

The present experiment was conducted in 2015 at two stations: 1. Alarogh Agricultural Research Stationin (*Fig. 1*) Ardabil Province, Iran with an altitude of 1350 meters above sea level, a longitude of 48°, 20', a latitude of 38°, 15', a semi-arid and cold climate, and a soil pH of 7.6, and 2. Samian Agricultural Research Station (*Fig. 1*) in Ardabil Province, Iran with an altitude of 1320 meters above sea level, a longitude of 48°, 15', a latitude of 38°, 23', a semi-arid and cold climate, and a soil pH of 7.5-8. Two areas of Alarogh and Samian in Ardabil province are major areas under potato cultivation and many researches are being made on potato crop in these areas. Laboratory measurements were performed at the faculty of agricultural sciences and natural resources, university of Mohaghegh Ardabili, Ardabil, Iran.

Figure 1. *The images of the farm stations in Alarogh (Left) and Samian (Right)*

DOI: http://dx.doi.org/10.15666/aeer/1504_13591372

Experimental design and treatments

The present study employed a randomized complete block design with three replications. The treatments were as follows: 1) Spraying Trifluralin herbicide on the soil between the rows of potato plants (75% EC was formulated with the amount of 2 L/ha by the Matabi model with an 8001 nozzle and the constant speed and pressure of sprayer in all treatments based on the 250 L/ha spraying; thus, the Trifluralin was mixed with soil at the depth of 0-10 cm) immediately after the second hilling of potato plants 45 days after planting the potatoes. 2) Spraying Metribuzin herbicide on the soil between the rows of potato plants with the amount of 1000 g/ha (with the formulation of 70% WP and sprayer specification such as the sprayer used for Trifluralin herbicides) immediately after the second soil hilling of potato plants 45 days after planting the potatoes. 3) Cultivator practice once for 20 days after the second hilling of potato plants 65 days after planting the potatoes. 4) Wheat straw mulch with the amount of 5 ton/ha and thickness of 15 cm immediately after the second soil hilling of potato plants 45 days after planting the potatoes. 5) Canola straw mulch applied similar to WH treatment. 6) The application of black plastic mulch, covering the space between the rows with plastic sheets with the thickness of 50 microns immediately after the second soil hilling of potato plants 45 days after planting the potatoes in the plot or row. 7) The application of transparent plastic mulch was similar to that of BPL treatment. 8) Weed infested or no weed removal in the entire growing season. 9) Weed free or weed removal in the entire growing season in both stations.

Land preparation and planting

The land was prepared for planting by secondary plowing immediately after favorable weather and soil conditions. On 5th June 2015, potato tubers (a variety of Agria) were hand-planted in rows, between which there was a distance of 75 cm and a distance of 25 cm on the ridge (the distance between the tubers planted on the planting row in each plot). Each plot had an area of 3 × 3.5 m.

After selecting the locations of experiment and before the preparation actions, 10 points of each farm soil were randomly sampled to provide composite samples and to analyze soil. Then, based on the results of soil analysis, fertilization was performed with application of phosphate fertilizers (Triple superphosphate with amount of 178 kg.ha^{-1} at two steps based on recommendation of research stations, 50 percent at planting time and 50 percent during the formation of tubers) and nitrogen (urea with amount of 300 kg.ha^{-1} at three times, 25 percent during potato planting, 50 percent during emergence and 25 percent immediately after formation of tubers). Irrigation was also conducted after the first step of soil irrigation and emergence of plants with a 7-day interval. Two potato hilling steps were done for at the base of plants using a hoe at 25 and 45 days after potato planting, respectively.

Potato and weed sampling

At the end of the growing season and a month before harvesting potato tubers (September), the weeds were sampled according to species and were counted. Weed sampling were performed in each plot with dimensions of 0.5 × 0.75 square cm of the soil surface and were transported to the laboratory. After counting the number of plants by

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13591372

species, shoots of weed of each species were separately and put in special bags and placed at oven for 72 hours at 75 ◦C and after drying completely, its were weighed with a balance with precision of 0.001g. Before performing statistical analysis and for data uniformity, conversion of $\sqrt{X+0.5}$ was used for data related to density and dried weight of weed. In order to determine the potato yield, after completion of the growing season and ripening potato tubers, the middle two rows of plants (inside plots) were collected during a meter entirely.

Shannon-Wiener index

In order to estimate weed species diversity, Shannon-Wiener index were used. Shannon-Wiener index was used to calculate the following equation:

$$H' = -\Sigma(n_i/N)(Log_2 n_i/N) \quad \text{(Eq. 1)}$$

In the mentioned equation, H' is Shannon-Wiener index, $(0 \leq H')$, n_i is the number of i-th species and N is the number of peoples (Shannon and Wiener, 1949). The data analysis was finally performed using SAS ver. 9.1 software and graphs were drawn by Excel ver. 2013 software.

Results and Discussion

Weed species diversity and density

In this study, among the 12 weeds species observed in potato field were the seven species annual weeds and five species perennial weeds. The weed species were include Common Amaranth, lamb's quarters, Bindweed, Green foxtail, Prickly lettuce, Russian knapweed and Milk thistle had the highest weed prevalence of dominant (*Table 1*).

Table 1. *The biological and Photosynthetic traits of weed species observed in the sampling units of potato farm*

row	Species name	Scientific name	Family	Life cycle	Photosynthetic cycle
1	Comon Amaranth	*Amaranthus retroflexus*	Amaranthaceae	Annual	C4
2	Russian knapweed	*Acroptilon repens*	Asteraceae	Perennial	C3
3	creeping thistle	*Cirsium arvense*	Asteraceae	Perennial	C3
4	Prickly lettuce	*Lactuca seriola*	Asteraceae	Annual	C3
5	Wild mustard	*Sinapis arvensis*	Brassicaceae	Annual	C3
6	Common Lamb's Quarters	*Chenopodium album*	Chenopodiaceae	Annual	C3
7	Bindweed	*Convolvulus arvensis*	Convolvulaceae	Perennial	C3
8	Pigweed	*Echinochloa crus galli*	Poaceae	Annual	C4

DOI: http://dx.doi.org/10.15666/aeer/1504_13591372

9	Green foxtail	*Setaria viridis*	Poaceae	Annual	C3
10	Licorice	*Glycyrrhiza glabra*	Papilionaceae	Perennial	C3
11	Tumbleweed	*Salsola kali*	Chenopodiaceae	Annual	CAM
12	Milk thistle	*Sonchus arvensis*	Asteraceae	Perennial	C3

In present study the average of Shannon-Wiener diversity index in both stations was changed ($P \leq 0.05$) by changing of management practices for weed management (*Table 2 and Fig. 2*). The greatest diversity of Shannon-Wiener index measured in present experiment was observed in weed infested treatment (*Fig. 2*). Blackwell (2011) stated that failure to weeds control in arable land or fallow cause of increase the density of weeds and also can be effective on weeds species diversity. According to the Shannon-Wiener index the treatments of Trifluralin, cultivators and transparent plastic mulch after the weed infested treatment had the highest species diversity (*Fig. 2*). The light passes through transparent plastic mulch and is likely to stimulate the germination of weeds but because of the low temperature in present region (Experiment locations) could not prevent weeds germination and the result, may be stimulated weed species seeds and causes of weed germination in the amplitude and so may be effective on the composition and diversity of weeds. Majd et al. (2014) also achieved to similar results in this regard.

Table 2. *Combined statistical analysis (ANOVA) of the effects of experimental treatments on weeds biomass, density and Shannon -Wiener diversity index in potato cultivation*

In the farms, the composition, diversity and species richness simultaneously is affected by many factors including climate, soil properties, agricultural products, agricultural operations, tillage, cultivator and farming characteristics (Lososova et al., 2008; Azad et al.,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13591372

2015). The lowest weed species diversity based on Shannon-Wiener index similarly were related to treatments of canola straw mulch, Metribuzin herbicide and black plastic mulch (*Fig. 2*). One reason for the decline of species diversity as a result of the use of mulch, is reducing amount of light reached into weed canopy, because increasing the coverage layer of mulch, more percent of light absorbed by crops or by mulch and therefore the remaining amount of light is reduced to weeds consumption as a result of reduced weed density and diversity (Dvorak et al., 2012; Azad et al., 2015).

Table 3. *Combined statistical analysis (ANOVA) of the effects of experimental treatments on tuber yield of potato*

Brassica plant debris in addition to preventing light from reaching weed seeds and prevent the germination of weed spectrum like some monocots may reduce the species diversity also Allelochemicals released by the organs of these plants (*Brassicas*) may be effective on weed species composition (Pawlonka et al. 2015). The use of herbicides as a result of a specific range of weed control can be reduced weed diversity (Channappaguar et al., 2007; Nikolic et al., 2013). Based on results obtained from the combined statistical analysis of traits in present study, the treatments had a significant effect (P≤ 0.01) on weeds density in both stations (*Table 2*) so that the lowest total weeds density was obtained in wheat straw mulch and then, Metribuzin herbicide. The maximum total weeds density was counted as 99.1 plants per square meter in the weed infested treatment and the lowest total weeds density were related to the wheat straw mulch as 15.5 plants per square meter (*Fig. 3*).

The results showed that the use of wheat straw mulch decreased total weed density by about 84% comparing to weed infested treatment (*Fig. 3*). Canola straw mulch also decreased total weed density comparing to weed infested treatment by about 79% so that weed density difference in canola straw mulch compared to weed infested treatment was significant at (P≤ 0.01) (*Table 2*), however in terms of reducing the number of weeds it was less successful than wheat straw mulch, although this difference between two mentioned treatment was not significant (*Fig. 3*). Weed density reduction in plots where herbal mulch were used, may be because of inhibition of weed germination and growth at this stage of potato growth or as result of the release of Allelopathic substance, the results of the research of many researchers (Dhima et al., 2006; Judice et al., 2007) also showed that plant mulches prevent weed germination or growth with preventing the penetration of light or the release of Allelopathic substances.

Moreover, Dhima et al. (2006) reported when applying the straw mulch of barley, Triticale and Rye in sugar beet crop, the germination of Pigweed (*Echinochloa crus galli*), were 69% less than the plots without plant residues. Herbicides had also a significant impact at (P≤ 0.01) on weeds density of potato cultivation (*Table 2*). *Figure 3* shows that total weed density was lower in Metribuzin and Trifluralin treatments compared to the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13591372

weed infested treatment. At Metribuzin and Trifluralin treatments, total weed density was less than the weed infested treatment as 72 and 69%, respectively. Hence these differences were significant at (P≤ 0.01) (*Table 2*). Although the Metribuzin herbicide after wheat straw mulch had the greatest impact in reducing weed density of potato crop and showed a better performance than the Trifluralin herbicides to prevent from germination and growth of weed during the cultivation period, it had no significant differences with mentioned treatments in terms of reducing weed density. Channappaguar et al. (2007) showed among the herbicides of Alachlor, Pendimethalin, Diuron and Metribuzin, the Metribuzin had maximum efficiency in controlling broadleaf and grass weeds of potato crop because this herbicide effectively prevents of weeds germination and so control weeds. Black and transparent plastic mulch significantly controlled total weed density, the black color of plastic prevents reaching full light to light-dependent weeds for their germination and this point indicates the inhibitory effect of black plastic on the germination and growth of weeds (Majd et al., 2014). Density of broadleaf weeds species, as most important weeds in potato cultivator in all mulch treatments, cultivator and herbicides was reduced compared to weed infested treatment (*Fig. 4*). The maximum density of Comon Amaranth (broadleaf weed specie) has been observed in treatments of black plastic mulch, Trifluralin and transparent plastic mulch, hence the lowest density was observed in treatments of wheat straw mulch and Metribuzin herbicides application (*Fig. 4*). The black plastic mulch in some cases during the growing season is decomposed by sunlight and it may not completely effective to prevent of weed germination as a result of irrigation, wind and other factors, and gives the growth and germination opportunities to weed seeds (Haidar and Sidahmed, 2000; Majd et al., 2014; Zhang et al., 2015). Lamb's quarters weed (broadleaf weed specie) had the highest density in the application of herbicides of Metribuzin and transparent plastic mulch and the minimum density in treatments of cultivator and wheat straw mulch (*Fig. 4*). The use of Poaceae residues as mulch is one of the ecological agriculture components that well prevents of weed seeds germination (Maldonado et al. 2001; Shiyam et al., 2011; Didon et al., 2014). In present experiment the highest grass weed density was related to the treatment of cultivator, however the least one was related to the treatments of black plastic mulch, canola straw mulch and wheat straw mulch (*Fig. 5*). Various experiments have shown that different treatments such as herbicides and plant residues affecting on weed species composition in different ways (Dhima et al., 2006). However in the present study, density of broadleaf weeds was more than grass weeds, in other words, the highest density of weeds was related to the broadleaf weeds. Moreover, all treatments could significantly reduce the level of broadleaf and grass weeds compared to weed infested treatment.

Weed biomass

The results of experiment showed that the use of herbicides had a significant effect on the weeds biomass at (P≤ 0.01) (*Table 2*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13591372

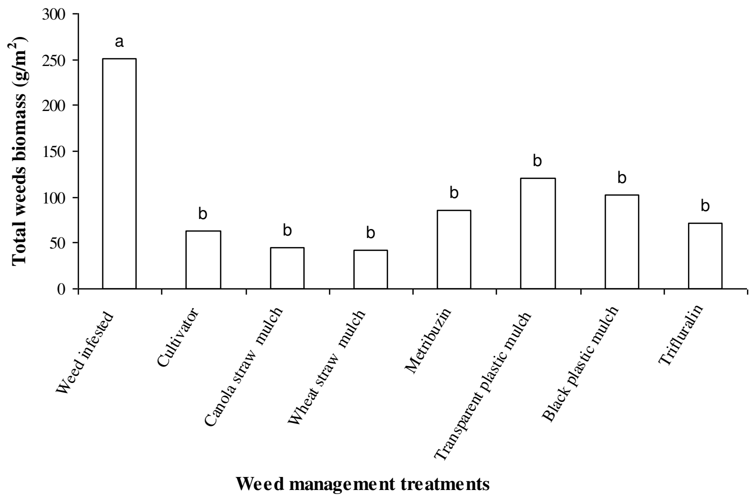

Figure 6. *The effect of different weed management treatments on total weed biomass average (g/m^2) in potato cultivation (The averages of at least one similar letter are not significantly different at* ($P \leq 0.05$)*, using Duncan's multiple range test)*

In present experiment, total weed biomass in the treatments of transparent and black plastics was 120.3 and 101.7 g/m^2, respectively, that showed the maximum biomass value comparing to the weed infested treatment (With biomass of 250.92 g/m^2) comparing to other treatments (*Fig. 6*), although the use of plastic mulches showed no significant difference with the use of herbicides and plant mulchs. However, the least amount of weed biomass was observed in treatments of wheat and canola mulches and it was found that these treatments can reduce weed biomass compared to weed infested treatment by a rate of 83% and 81% decrease, and this reflects the ability of plant residues in suppressing weeds and preventing their growth as well as preventing the spread of weeds and reducing the crop yield (Duppong et al., 2004). Plant residues are not only affect the soil but also can affect the germination, survival, growth and competitive ability of weed and crop plants (Majd et al., 2014; Pawlonka et al., 2015; Azadbakht et al., 2017). Although in current study, the lowest biomass of broadleaf and grass weeds showed a significant difference with the weed infested treatment and broadleaf weeds had more biomass than grass weeds (*Fig. 7* and *8*). Although, all chemical and ecological management treatments could statistically reduce broadleaf weed biomass compared to the weed infested treatment significantly, considering no significant difference between treatments of mulch and herbicides in terms of weeds biomass, it can be noted that the use of plant mulches could be more costly than the use of herbicides due to labor costs and costs related to mulch preparation.

Potato tuber yield

The potato yield was significantly affected (P≤ 0.01) by the applied treatments in the experiment (*Table 3* and *Fig. 9*) except transparent plastic mulch treatment.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13591372

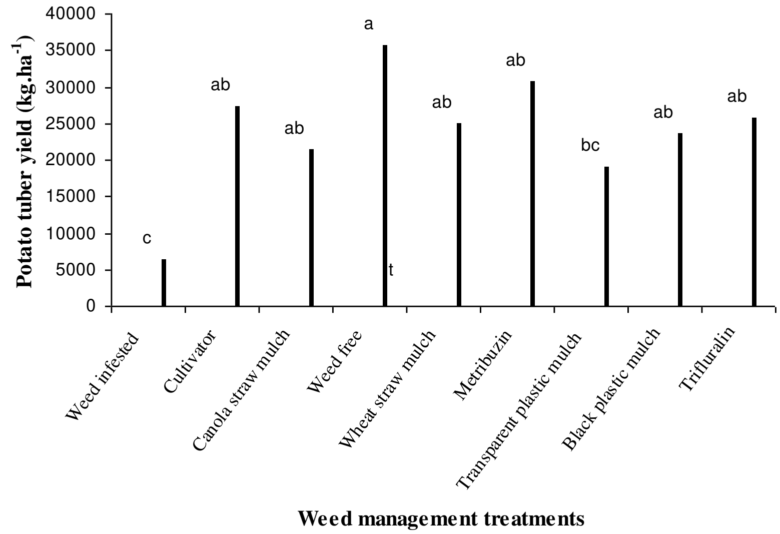

Figure 9. *The effect of different weed management treatments on tuber yield (kg.ha^{-1}) in potato cultivation (The averages of at least one similar letter are not significantly different at* ($P \leq 0.05$)*, using Duncan's multiple range test)*

In present experiment, the highest potato tuber yield was obtained at a rate of 36 ton/ha at weed free treatment that compared with the treatments of plant mulch, cultivator, herbicides and black plastic mulch were not significantly different but the transparent plastic mulch was significantly different compared to weed free treatment and transparent plastic mulch had the lowest tuber yield (19.3 ton/ha) after the weed infested treatment (6.6 ton/ha). The greatest reduction in tuber yield (about 83%) was related to weed infested treatment and then transparent plastic mulch (about 47%), and weed infested treatment was not significantly different with transparent plastic mulch treatment (*Fig. 9),* I seems that this is related to the lack of proper control of transparent plastic mulch to repress weeds in the experiment region in present study (Jafari et al., 2013; Majd et al., 2014).

Majd et al, (2014) applied also plastic mulch, herbicide and cultivator to control weeds and Mohammadduost Chamanabad et al, (2011) used herbal mulch, herbicide and cultivator to control weeds. However all control weed methods in present experiment were used simultaneously, so this experiment completes the results of others. In fact we were able to compare all the methods simultaneously and we developed other experiments mentioned above.

Conclusion

The use of non-chemical treatments of mulches and cultivator had a significant effect on potato weed density in both stations, so that the least amount of weed density was obtained by application of wheat straw mulch. However, the lowest weed biomass was observed in wheat and canola mulches treatments. It is also concluded that ecological treatments can control weeds as much as the herbicides. However, no significant difference between treatments of mulch and herbicides in terms of weeds biomass in present study, because

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13591372

mulches and cultivators can as well as herbicides prevent of germination, growth and development of weeds, both in the initial stage of weeds growth and in the subsequent stages, so it can be concluded that the use of mulches can be more costly than the use of herbicide due to labor costs and costs related to mulch preparation, By ignoring the cost, it can be noted that the ecological methods such as application of plant residues can be more environmental friendly. The presence of herbicides in the ecosystem is harmful for health humans and animals.

Abstract. The aim of this study was to assess the blood parameters and gut histology of broiler and indigenous chickens at different ages. A total of 120 Ross 308 broiler and Venda chickens were assigned in a complete randomized design to assess blood profiles and gut histomorphology in order to determine the immunity and digestive ability of the two breeds. Blood profiles and gut histology of two breeds at ages 42 and 90 days were determined. A measuring tape and RADWAG digital scale (Model PS 750/C/2) were used to measure the lengths and weights, respectively. At 42 days, platelets and serum creatinine were higher ($P<0.05$) for Ross 308 broiler than Venda chickens. Total protein was higher ($P<0.05$) in Venda than Ross 308 broiler chickens. The blood parameters measured at 90 days were higher ($P<0.05$) in Ross 308 broiler. Platelets were higher ($P<0.05$) in Venda than in Ross 308 broiler chickens. Weights and lengths of the gut were higher ($P<0.05$) in Ross 308 broiler than Venda chickens at both 42 and 90 days. Jejunum villus height was higher ($P<0.05$) in Ross 308 broiler than in Venda chickens aged 42 days. Crypt depth was higher ($P<0.05$) in the duodenum and ileum of Ross 308 broiler than in Venda chickens. The villus height/crypt depth ratios were higher ($P<0.05$) in Venda than Ross 308 broiler chickens at both 42 days. Age and breed affects blood profiles of broiler and indigenous chickens. The histomorphology of Ross 308 broiler was superior which reflects better absorption capabilities compared to Venda chickens.
Keywords: *haematology, weights, lengths, villi height, crypt depth*

Introduction

Chickens contribute a lot to social and economic well-being of most rural households of South Africa. The feed intake, digestibility, growth rate and overall productivity of broiler and indigenous chickens vary (Pauwels et al., 2015; Rondelli et al., 2003). Haematological and blood parameters of chickens are reliable indicators of their health status and productivity (Abdi-Hachesoo et al., 2011). Indigenous chickens which are mainly abundant in rural areas are known to be tolerant and resistant to diseases than their counterpart Ross 308 broiler chickens (Abdi-Hachesoo et al., 2013). It is, therefore, important to understand and determine the haematological indices of indigenous chickens in order to better interpret their health status and immune system capability to tolerate poultry

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13731386

diseases. The gastrointestinal tract (GIT) of the chicken and its gut state and condition are accountable for nutrient digestion, metabolism and absorption (Mabelebele et al., 2014). The GIT of fast growing Ross 308 broiler chickens develop and mature faster than those of the slow growing indigenous chickens (Jamroz, 2005). Ross 308 broiler chickens have been selected for high feed conversion ratio and growth rate. This has resulted in changes in the anatomy and function of the digestive system (Krás et al., 2013). The length and weight of the small intestines vary between the different species of birds (Hassouna et al., 2001).

Histologically, villus height and mucosa thickness are normally used as a good index for understanding the intestinal status which is directly linked to the absorptive functions (Incharoen, 2013). Morphology and histology of the gastrointestinal tract of Ross 308 broiler chickens were described and studied previously by Aitken (1958), Calhoun (1954) and Hassouna (2001). However, in more recent studies by Mabelebele et al. (2014), the digestive organ weights and lengths of Ross 308 broiler and indigenous Venda chickens at 90 days of age were compared. These authors observed that although broiler chickens at 90 days of age had heavier and longer digestive organs however, Venda chickens had lower gizzard pH, which might be related with better fibre digestion. As such, not much information on the blood profiles, morphology and histological differences between Ross 308 broiler and indigenous Venda chickens is available. Therefore, the objective of this study was to determine the differences between the blood profiles, morphometric and histological analyses of Ross 308 broiler and indigenous Venda chickens raised under the same conditions and fed a similar diet.

Materials and methods

Study site and experimental design

This study was conducted at the University of Limpopo Animal Unit. The study commenced with 60 Ross 308 broiler and 60 Venda chickens aged 1 day. Ross 308 broilers chickens were acquired from Lufafa hatchery, Tzaneen, South Africa while indigenous Venda chickens were obtained from the University of Limpopo hatchery. The chickens were kept for a period of 90 days on a commercial diet (*Table 1*). Feed and water were provided *ad libitum* and except for the first day when 24 hours of light was provided, 18 hours of lighting and 6 hours of darkness in every 24-hour period was maintained throughout the trial period. Chickens were housed in pens, assigned to a complete randomized design with each breed replicated five times with twelve birds per replicate. All managements of the birds were carried out with the strict accordance of the rules and regulations of the University of Limpopo Animal Ethics Committee with the following ethics approval number (TREC/12/2014:IR).

†The active ingredients contained in the vitamin–mineral premix were as follows (per kg of diet): vitamin A – 12000 IU, vitamin D3 – 3500 IU, vitamin E – 30.0 mg, vitamin K3 – 2.0 mg, thiamine – 2 mg, riboflavin – 6 mg, pyridoxine – 5 mg, vitamin B12 – 0.02 mg, niacin – 50 mg, pantothenate – 12 mg, biotin 0Æ01 mg, folic acid – 2 mg, Fe – 60 mg, Zn – 60 mg, Mn – 80 mg, Cu – 8 mg, Se – 0Æ1 mg, Mo – 1 mg, Co – 0Æ3 mg, I –1

Haematological values

Two chickens per replicate were selected for slaughter at 42 and 90 days of age. Before slaughter, 3 ml of blood samples from both Ross 308 broiler and Venda chickens were collected from a jugular vein into two test tubes per bird, one with ethylenediaminetetraacetic acid (EDTA) as an anticoagulant and the other without EDTA. The blood collection tubes were kept in ice to avoid denaturing of protein, and plasma was stored at -20℃ until further analysis. Blood samples were analysed within 2 hours of collection for haematocrit (HCT), red blood cell (RBC), white blood cell (WBC) and haemoglobin (HBG) according to the methods of Dein (1984). Haemoglobin amount was measured using the Beckman Coulter ACT diff Haematology Analyzer (Beckman-Coulter, USA). Platelet counts were also measured. The HCT was measured as micro haematocrit with 75 × 16 mm capillary tubes and centrifuged at 2500 rpm for 5 minutes. Mean corpuscular volume (MCV), Mean corpuscular haemoglobin (MCH) and Mean corpuscular haemoglobin concentration (MCHC) were calculated according to Ritchie et al. (1994). Serum parameters analysed included total protein, albumen, glucose, cholesterol, triglycerides, calcium, phosphorus, sodium and potassium (Aravind et al., 2003).

Morphology of the gastrointestinal tracts

In order to evaluate organ weights and intestinal morphometrics of the chickens at 42 and 90 days of age, the gizzard, proventriculus, small intestines and the large intestines, including the caeca, were collected and weighed immediately at both 42 and 90 days. A measuring tape and RADWAG digital scale (Model PS 750/C/2) were used to measure the lengths and weights, respectively. The gizzard was weighed after the contents were removed and cleaned. After removal of the contents, the small and large intestines were cut in segments, cleaned, weighed and measured. The small intestines were measured from the site where the duodenum emerges from the gizzard and the beginning of the caeca, and the large intestine length included the length of the colon and the rectum. Chickens were weighed before slaughter.

Digestibility and Histological analysis

Nutrient digestibility at 42 days of age was determined according to the methods of McDonalds et al (1992). At the ages 42 and 90 days, 2 birds per pen were sacrificed by cervical dislocation. The whole small intestine was removed immediately and immersed in 10% buffered formalin. Three small intestine segments measuring approximately 3.0 cm of the duodenum (from the gizzard to pancreatic and bile duct), jejunum (from the bile duct to Meckel's diverticulum) and ileum (from the Meckel's diverticulum to ileo-caecalcolonic junction) were cut according to Samanya and Yamauchi (2002) for each chicken at ages 42 and 90 days. The samples were washed in phosphate buffer solution at 0.1 M (pH 7.4) and fixed in Bouin solution for three days. The samples were then trimmed to eliminate the torn edges, and remained for further 24 hours in the fixing solution. The samples were washed in ethanol at 70% to remove the fixing solutions, dehydrated in graded series of alcohol and cleaned in xylol. Four semi-serial sections with 7-cm thickness were placed in each slide. The slides were dyed using the method of the periodic acid of Schiff (PAS). Using an image capture and analysis system (Image J, 1.47r), villi height and crypt depths were measured in duodenum, jejunum and ileum sections were measured. Villus height was measured from the basal region, which starts at the higher portion of the crypt, until villus tip, whereas crypt depth was measure from the base up to the crypt-villi transition region (Carrijo et al., 2005).

Statistical analysis

Data on haematology, morphology and histology of the GIT of both Ross 308 broiler and Venda chickens were analysed using the General Linear Model (GML) procedure of the statistical analysis of variance (SAS, 2008). Differences were considered significant at $P<0.05$.

Results

Haematological and biochemical parameters of Ross 308 broiler and Venda chickens aged 42 and 90 days

The results of the blood profiles of Ross 308 broiler and Venda chickens aged 42 days are presented in *Table 2*. No significant ($P>0.05$) differences were observed on the complete blood count and biochemical parameters between the chicken breeds except for platelets and serum creatinine. The platelets were higher ($P<0.05$) in Ross 308 broiler than in Venda chickens. Serum creatinine at 42 days of age was higher ($P<0.05$)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13731386

for Ross 308 broiler than Venda chickens. However, the total protein of Venda chickens at 42 days of age were higher (P<0.05) than those of Ross 308 broiler chickens. The results of the blood profiles of Ross 308 broiler and Venda chickens aged 90 days are presented in *Table 3*. The WBC, RBC, HGB, HCT and MCV were lower (P<0.05) in Venda than Ross 308 broiler chickens. However, the platelets were lower (P<0.05) in Ross 308 broiler than Venda chickens. No significant differences (P>0.05) in MCH, MCHC, RDW were observed between Ross 308 broiler and Venda chickens aged 90 days. Serum calcium, creatinine, cholesterol and albumen were higher (P<0.05) in broiler than indigenous chickens. However, sodium, potassium, phosphorus, glucose and total protein were similar in Ross 308 broiler and Venda chickens. Venda chickens had higher (P<0.05) serum triglycerides than those in Ross 308 broiler chickens.

Tables 4 and *5* show the live and carcass weights and gastrointestinal weights of Ross 308 broiler and Venda chickens aged 42 and 90 days. The live and carcass weights were heavier (P<0.05) for Ross 308 broiler than Venda chickens at both ages. The GIT weights of Ross 308 broiler were heavier (P<0.05) than those of the Venda chickens at both ages. The crop, proventriculus and gizzards were heavier (P<0.05) in Ross 308 broiler than in Venda chickens at both ages. Heavier weights (P<0.05) for small intestines, duodenum, jejunum, ileum, large intestines and the caeca were obtained in Ross 308 broiler than Venda chickens at both ages.

The lengths of the gastrointestinal tract are presented in *Tables 6* and *7*. A similar trend observed for GIT weights was also observed for lengths with the entire tract being longer (P<0.05) for Ross 308 broiler than Venda chickens at 42 days of age. The small intestines, duodenum, ileum, large intestines and the caeca were shorter (P<0.05) for Venda than Ross 308 broiler chickens. At 90 days of age, the gastrointestinal lengths of the Venda chickens followed a similar tendency as their weights. The entire GIT length, small intestines and its segments, the large intestines and caeca were longer (P<0.05) for Ross 308 broiler than Venda chickens.

The results of the villus height, crypt depth and villus/crypt depth ratio of small intestine segments between Ross 308 broiler and indigenous Venda chickens are presented in *Tables 8* and *9*. Similar villus heights (P>0.05) were observed on

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13731386

duodenum and ileum of Ross 308 broiler and Venda chickens aged 42 days. However, the jejunal villus height of Ross 308 broiler were higher (P<0.05) than those of Venda chickens aged 42 days. Duodenum and ileum crypt depths of Ross 308 broiler were higher (P<0.05) than those of Venda chickens aged 42 days. Similar (P>0.05) jejunum crypt depths were observed between Ross 308 broiler and Venda chickens. Venda chickens exhibited higher (P<0.05) villus/crypt depth ratios in all segments of the small intestines than Ross 308 broiler chickens at 42 days of age. Villus heights of the duodenum, jejunum and ileum were similar (P>0.05) between Ross 308 broiler and Venda chickens at 90 days. Crypt depths of the duodenum and ileum were higher in Ross 308 broiler chickens than in Venda chickens. However, no differences (P>0.05) in jejunal crypt depths were observed between the two breeds. Venda chickens had higher (P<0.05) ileum villus/crypt depth ratio than Ross 308 broiler chickens at ages 90days. No differences (P>0.05) were recorded on duodenum and jejunum villus/crypt depth ratios of Ross 308 broiler and Venda chickens aged 90 days. The results of nutrient digestibility of a grower diet fed to Ross 308 broiler and Venda chickens are presented in *Table 10*. Ross 308 broiler chickens showed higher (P<0.05) dry matter and crude protein digestibility, metabolisable energy and N retention than in Venda chickens.

Discussion

The blood parameters of chickens are regarded as dependable and good indicators of the bird's health status. Haematological indices are reported not to be consistent in chickens because of a number of reasons including diseases (Fudge, 2000b), stress (Bedonova et al., 2007), season (Hauptmanova et al., 2006) and genotype (Gayathri and Hegde et al., 2006). In the current study Ross 308 broiler and indigenous Venda chickens aged 42 days had similar haematological parameters. The values reported in the present study are within the normal ranges reported for Ross 308 broiler chickens aged 42 days by Tehrani et al. (2012) and Talebi et al. (2005). However, several studies conducted on indigenous chickens in other countries have reported contradicting haematological indices. Higher values of WBC (2.27 - 2.43 × 10^3 cell/µL) and MCH (66-70 pg) were observed in Nigerian local chickens (Peters et al., 2011) than the indigenous chickens in the current study. In the study by Pampori and Iqbal (2007), values of for HCT and Hb were higher in Kashmir native chickens than the values obtained in indigenous chickens in the present study. The platelets in the current study were higher in Ross 308 broiler than indigenous Venda chickens. The results were contrary to those reported by Maxwell et al. (1991) who showed lower thrombocyte (platelets) of Ross 308 broiler chickens at the age of 7 weeks. These cells help in the blood clotting process by promoting homeostasis (Paul et al., 2012) which, therefore, indicates that at 42 days of age in the current study the functioning of these cells were poor in Venda chickens as compared to Ross 308 broiler chickens.

At 90 days of age the WBC, RBC, HCT and MCV were higher for Ross 308 broiler than indigenous Venda chickens. Values in the current study were contrary described by Pampori and Iqbal (2007), Peters et al. (2011) and Albokhadiam et al. (2012) who found that indigenous chickens had higher haematological values or indices than broiler chickens. However, supporting the current findings is a report by El-Safty et al. (2006) which indicated that WBC and MCH were higher in broiler than indigenous chickens. The haemoglobin blood concentrations and platelets were higher for indigenous Venda chickens in the current study than Ross 308 broiler chickens. The higher haemoglobin values of indigenous Venda chickens in the present study are similar to those reported by Orawen and Aengwanich (2007) for indigenous chickens. However, MCH, MCHC and RDW were not influenced by breed in the present study.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13731386

The serum parameters at the ages of 42 days were similar between the chicken breeds. However, the serum total protein was higher in indigenous Venda than in Ross 308 broiler chickens, the levels reported in the current study were still lower (20 g/L for Ross 308 and 25g/L for indigenous Venda chickens) than those reported (33-47g/L in Ross 308 broiler aged 42 days) in a study by Piotrowska et al. (2011). Total serum protein can extremely vary in chickens and its variation depends on internal and external factors and results from physiological roles in blood proteins. This parameter is important to measure the chickens' body condition. Other differences identified where serum creatinine was higher for Ross 308 broiler than indigenous Venda chickens at 42 and 90 days of age. Serum creatinine is an important indicator of protein metabolism, a by-product of phosphocreatine breakdown in skeletal muscles (Piotrowska et al., 2011). Its concentration is directly related to muscle mass and is associated with age and physical activity (Szabo et al., 2005; Rajman et al., 2006). The serum creatinine values for Naked neck and Kashmir indigenous chickens reported in the studies conducted by Peters et al. (2011) and Pampori and Iqbal (2007) were higher (13 and 14 µmol/L, respectively) than values of indigenous Venda chickens in the current study at 42 days of age. Lipid metabolites are associated with energy metabolism and reflect fluctuations occurring during the growth period of chickens. At 42 days of age there were differences observed in the triglycerides concentration between the breeds. However, high triglycerides concentrations levels in indigenous Venda chickens were observed at 90 days of age.

Higher serum triglycerides concentrations, most often, represent intensive lipid metabolism and transport. These results are supported by Piotrowska et al. (2011) who indicated that the serum triglycerides of Ross 308 broiler chicken decrease as they grow in age. However, on the contrary Abdi-Hachesoo et al. (2011) indicated that no serum triglycerides difference was observed between Iranian indigenous and Ross 308 broiler chickens. Higher serum cholesterol levels were observed for Ross 308 broiler in the current study. These findings are similar to those reported by Abdi-Hachesoo et al. (2011) and Simaraks et al. (2004) who showed that serum cholesterol of indigenous chickens is lower than other breeds. The authors went further to hypothesize that this might be because of the high body activity and high energy need in the indigenous chickens.

Minerals are essential for chickens' growth and are involved in many biosynthetic processes in the body. Calcium is mainly needed for ossification of bones, regulation of muscle activity and catalyzation of enzyme and hormonal synthesis (Underwood and Suttle, 1999). On the 90th day serum calcium was higher for Ross 308 broiler than indigenous Venda chickens. Abdi-Hachesoo et al. (2011) reported similar serum calcium values between Ross 308 broiler and Iranian indigenous chickens.

Differences in GIT weights and lengths between the two breeds used in the current study were observed. GIT were heavier and longer in Ross 308 broiler than indigenous Venda chickens. It was clearly evident in the present study that the slow growing indigenous Venda chickens abundant in rural South Africa and with lighter live and carcass weights, had inferior GIT weights and lengths. A study conducted by Borin et al. (2006) indicated that the GIT weights and lengths of indigenous chickens were heavier and longer compared to broiler chickens aged 120 days. The authors explained this by stating that due to the extensive traditional system these chickens are kept under the availability of bulky and fibrous feeds which will contribute to superior GIT weights and lengths than those of the fast growing broiler chickens. These findings are contrary

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13731386

to the current study. The current study is supported by Khempaka et al. (2009), De Verdal et al. (2010) and Mossammi et al. (2011) who indicated that GIT lengths and weights of broiler chickens are superior. A recent study by Mabelebele et al. (2014) conducted on indigenous Venda and broiler chickens noted that broiler chickens with their heavier body weight tended to have heavier and longer GIT and digestive organs, with the exception of the gizzard under an intensive system which supports the current findings.

The intestinal villus and crypt morphology are associated with intestine function and growth in chickens. According to Tivey and Smith (1989), changes in enterocytes development and villi structure determine the digestive and absorptive capacity of the small intestine. The small intestine histomorphology including villus height, crypt depth and their ratio are important pointers of gut health in chickens. Increased villus height and villus height to crypt depth ratio are directly correlated with an increased epithelial turnover and longer villi are associated with activated cell mitosis (Montangne et al., 2003). On the other hand, a decrease in villus to crypt ratio or lower crypt to villus ratio is indicative of a higher rate of enterocyte-cell migration from the crypt to the villus (Adibmoradi et al., 2006; Silva et al., 2009). This can lead to poor nutrient absorption, increased secretion in gastrointestinal tract and reduced performance. In the current study the villus height and crypt depth in the duodenum and ileum were higher for Ross 308 broiler than indigenous Venda chickens. The smallest depth of the crypts was observed from indigenous Venda chickens. Decreasing crypt depth in indigenous chickens might be explained by the fact that the crypt can be regarded as the villus factory and a large crypt indicates rapid tissue turnover and a high demand for new tissues (Choct, 2009). The increased villus height in the small intestines could be associated with higher absorptive intestinal surface (Loddi et al., 2004) which facilitates the nutrient absorption and hence, has a direct impact on growth performance. This indicates that Ross 308 broiler chickens with longer and heavier GIT had better absorptive functions and, therefore, growth as compared to indigenous Venda chickens. At 90 days of age, chickens had similar intestinal villus height. This, however, does not imply that the breeds had similar nutrient absorption potential as the crypt depths are different. Ross 308 broiler chickens had higher crypt depth which is indicative of a higher epithelial cell turn over to permit renewal of the villus as needed (Langhout et al., 1999; Sobayo et al., 2012). Thus, a better absorption potential is evidenced by Ross 308 broiler chickens compared to indigenous Venda chickens. The better intestinal and absorptive functions in Ross 308 broiler chickens, perhaps, can be best interpreted by higher nutrient digestibility and N retention as observed in the current study.

Conclusion and Recommendations

Age affects the blood profiles of both broiler and indigenous chickens. It was observed that at age 42 days, most haematological and biochemical parameters were similar between broiler and indigenous Venda chickens. However, platelets and serum creatinine were higher for Ross 308 broiler chickens at 42 days of age. At 90 days of age, WBC, RBC, Haematocrit, MCV, platelets, serum calcium, creatinine, cholesterol and albumen were higher for Ross 308 broiler chickens. Total protein at 42 days of age, platelets, haemoglobin, serum triglycerides at 90 days of age were higher for Venda chickens. It was expected that indigenous Venda chickens would have superior immunological abilities than broiler chickens in the current study. However, this was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13731386

not the case, debunking the perception that indigenous chickens are hardier and more resistant to diseases than the broiler chickens. Perhaps the immunological abilities of indigenous chickens are superior when kept under extensive conditions, which was not the case in this study. A comparative study should be conducted on the blood profiles of indigenous chickens under intensive and extensive rearing systems.

Breed and age had an influence on the gastrointestinal tract lengths and weights. This was expected as broiler chickens have superior body weights with faster growth rate compared to indigenous chickens. The histology of the small intestine segments varied between breed and age. Higher villus height and deeper crypt depth were observed in Ross 308 broiler than indigenous chickens. This shows the better absorptive functions of the broiler chicken breed which in turn results to faster growth rate.

Acknowledgements. The authors would like to acknowledge and appreciate the funding from National Research Foundation (NRF), South Africa which made this work possible. Special gratitude to (National Health Laboratory Service) NHLS, Polokwane, manager Mr Lucas Kgwetiana for allowing us to use the lab facilities for analyses.

(Received 22nd Mar 2017; accepted 1st Aug 2017)

Abstract. Good structure and function of skeletal system are among the important factors in poultry management. Therefore, understanding the bone parameters of chickens is of paramount importance as they indicate the basic supportive, locomotive and protective functions. The aim of this study was to determine the bone measurements of Ross 308 broiler and Venda chickens aged 90 days. A 2 (breed) × 2 (sex) factorial arrangement in a completely randomised design was used and replicated four times with 20 birds per replicate. A total of 80 Ross 308 broilers and Venda chickens (20 males, 20 females of each breed) were sacrificed to measure the carcass, tibia, femur and fibula characteristics. A digital calliper and electronic scale were used to measure the length, diameter and weight of the bones. Ash contents of the bones were determined. Tibiotarsal, seedor and robusticity indices of the tibia and femur bones were measured. Tibia and femur lengths and widths were shorter in Venda chickens than those of Ross 308 broiler chickens. Ash contents of tibia and femur diaphysis and epiphysis of male and female Ross 308 broiler and Venda chickens varied significantly between the two breeds. Tibia and femur Seedor index were higher in males and females of Ross 308 broiler than Venda chickens. Diaphysis and medullary canal diameter were higher in Ross 308 broiler chickens than Venda chickens. The tibiotarsal index was lower for Ross 308 broiler than Venda chickens. Sex and breed affected the bone length, weight and width of Ross 308 broiler and Venda chickens at 90 days of age.
Keywords: *tibiotarsal index, robusticity, length, ash, seedor index*

Introduction

A fast growing broiler chicken is characterised by higher body weight gain, its skeleton (mainly femur and tibia bones) plays a major role as the supporting structure for its body weight (Applegate and Lilburn, 2002). Proper structure and function of skeletal system are among the important factors in animal management; information on bone morphometric will address this factor. According to Warris (2010), in the life cycle of animals, animal tissue development follows a precise order, the first being maturation of the nervous tissue followed by bone then muscle and lastly fat. Previous studies of Buckner et al. (1959) reported a relationship between body weight and various aspects of the tibia and femur bones in male and female New Hampshire chickens. Regression studies of their data designated that more than 98 % of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13871398

differences in tibia and femur length were a function of the body weight. Itoh and Hatano (1964) who specified that changes in femur ash and mineralisation were a reflective of the total skeletal mineralisation supported this. Study has shown that about 70 to 80% of bone mass is determined genetically, while 20 to 30% can be attributed to external factors in which management and diet are the most important factors (Eastell and Lambert, 2002). These factors also have significant effect on bone mineralization (Huyghebaert, 1997). Apart from the metabolic side-products of digestion and compounds synthesised in the intestine, vitamins, minerals or any other nutrient deficiency or excess are also among the important nutritional factors that may influence bone morphometric changes.

Commercial or intensive production systems (broiler chickens production system) are associated with temperature, photoperiod and light intensity controlled conditions, high energy diets, high plane of nutrition and high feed efficiency rates which encourage rapid growth and the early onset of the fattening phase (Lawrie and Ledward, 2006). Extensive production systems (Venda chicken production system), however, would be exposed to fluctuating temperatures and increased exercise on the forage area (Fanatico et al., 2005). Thus, it would be expected that the animals from the intensive production system would reach maturity at an earlier age and would produce heavier slaughter weight and carcasses with more fat if slaughtered at the same age as the free range animals. Castellini et al. (2002) reported lower growth rates and carcass weights of extensive birds compared to intensive birds. However, studies on morphology of the tibia and femur bones in indigenous chickens have not yet been reported. The densitometric and geometric parameters of the internal structures of the bones are of paramount importance as they indicate the basic supportive, locomotive and protective functions by the chickens (Charuta, 2013a). Bone mineral density in chickens is imperative as it helps to better understand and evaluate the process of bone mineral deposition (Louzada, 1994). Therefore, the objective of this study was to determine the bone characteristics of broiler and indigenous chickens aged 90 days.

Materials and methods

The University of Limpopo Animal Ethics Committee for the care and use of animals approved animal handling procedures for this experiment for scientific purposes with the approval number TREC/12/2014. The study was conducted at the University of Limpopo Experimental Farm, South Africa. The farm is situated 10 km North-west of the Turfloop campus of the University of Limpopo. The ambient temperature around the area is above 30°C during summer and below 25°C in winter. The farm lies at latitude 27.55 S and longitude 24.77 E and receives a mean annual rainfall of less than 400 mm. A total of 80-day-old broiler and indigenous chickens acquired from the University of Limpopo Experimental farm were used in this research. A 2 (breed) × 2 (sex) factorial arrangement in a completely randomised design was used and replicated four times with 20 birds per treatment. The chickens were raised under intensive system and provided with light; feed and water were offered *ad libitum* for the entire period of the experiment (90 days).

A total of 40 birds were slaughtered by cervical dislocation as recommended by the University of Limpopo Animal Science Ethics Committee. A total of 40 tibiotarsal and femoral bones from Ross 308 broiler and indigenous chickens (Ross 308 and Venda) (20 males and 20 females) were obtained and cleaned of the muscles by boiling them in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13871398

deionized water for 10 minutes. For morphometric analysis, the two types of bones from each breed and sex were weighed (g) with a precision scale (RADWAG, Model PS 750/C/2). The length and width of the bones were determined using a measuring tape and a digital calliper (OMNI-TECH, SHA120). Tibia length was measured from the proximal end to the distal end and the width at the medial diaphysis. The widths of the proximal and distal tibia epiphyses were also measured. Femur length was measured from the proximal end of the shaft to lateral condyle and the width at the medial diaphysis (Zhang and Coon, 1997).

Geometric parameters (Tibiotarsal index, Seedor index and robusticity index) of the bones were determined and the thickness of the medial and lateral walls was measured at the midpoint mark using a dial caliper. Medullary canal diameter was calculated by subtracting the thicknesses of the medial and lateral walls from the diameter at the diaphysis while bone weight/length index also known as the Seedor index was obtained by dividing the tibia weight by its length (Seedor et al., 1991). The tibiotarsal and the robusticity indexes were determined using the following formulas (Reisenfeld, 1972), respectively:

$$\text{Tibiotarsal index} = \text{diaphysis diameter} - \text{medullary canal} \frac{\text{diameter}}{\text{diaphysis}} \text{diameter} \times 100 \quad \text{(Eq. 1)}$$

$$\text{Robusticity index} = \text{bone length}/\text{cube root of bone weight} \quad \text{(Eq. 2)}$$

The cleaned bones were taken to Polokwane Veterinary Clinic for X-rays analysis. Bones were oven-dried at 105°C for 24 h, ashed in a muffle furnace at 600°C for 6h, and ashed at 600° C overnight, cooled in a desiccator, and weighed. The samples were then ashed in a muffle furnace at 600°C for 24 h in crucibles (AOAC, 2000). All data was analysed using the General Linear Model procedure of the statistical analysis of systems (SAS, 2008). Analysis of variance was performed and the Duncan's Multiple Range tests were used for mean separation. The level of significance was set at P-value ≤ 0.05. Polynomials of the tibia and femur weights, lengths and widths as a function of the body weight were determined using the PROC REG procedure of statistical analysis of systems (SAS, 2008).

Results

The bone traits of male and female Ross 308 broiler and indigenous Venda chickens are presented in *Table 1* and *Figure 1*. Tibia, femur and fibula lengths were longer (P<0.05) for female Ross 308 broiler than the female Venda chickens. Similarly, male Ross 308 broiler had longer (P<0.05) tibia and femur bones than male Venda chickens. However, the fibula bones were similar (P>0.05) for male Ross 308 broiler and Venda chickens. The tibia and femur weights were heavier (P<0.05) for both male and female Ross 308 broiler compared to those of Venda chickens. Similar fibula weights (P>0.05) were observed for both male and female Ross 308 broiler and Venda chickens. The width of the tibia and femur followed the same trend as observed for the length and weight, with male and female Ross 308 broiler chickens having wider (P<0.05) bones than those observed in male and female Venda chickens. The fibula bone width, however, was not influenced (P>0.05) by either sex or breed of the chickens.

The polynomial regression of tibia and femur length and weight of Ross 308 broiler and indigenous Venda chickens as a function of carcass weight are presented in *Figure 2*. Calculated as a function of carcass weight, 97 % of tibia length and 94 % of femur length in Ross 308 broiler chickens are a result of changes in body weight (*Figure 2A*). However, compared to Venda chickens when polynomial functions were calculated, lower values of 89 % of tibia length and 37 % of femur length were because of variations in carcass weights (*Figure 2C*). When bone weight was determined as a function of carcass weight, 95 % and 88 % of tibia weight of Ross 308 broiler and Venda chickens were observed, respectively. Similar values of 93 % and 91 % of femur weight of Ross 308 broiler and Venda chickens were observed as function of carcass weight, respectively (*Figures 2B* and *2D*).

Tibia and femur geometric parameters of male and female Ross 308 broiler and indigenous Venda chickens are shown in *Table 2*. Tibia Seedor index was higher (P<0.05) in males and females of Ross 308 broiler than their counterparts Venda chickens. The femur Seedor index also followed the similar trend as tibia Seedor index with higher values (P<0.05) reported for male and female of Ross 308 broiler than Venda chickens. No differences (P>0.05) were observed for tibia and femur robusticity indices of male and female Ross 308 broiler and Venda chickens. The tibia diaphysis and medullary canal diameter of male and female Ross 308 broiler chickens were higher (P<0.05) than those in Venda chickens. The tibiotarsal index was higher (P<0.05) for male and female Venda chickens than for Ross 308 broiler chickens.

Ash contents of tibia and femur diaphysis and epiphysis of Ross 308 broiler and indigenous Venda chickens are presented in *Figures 3*. Ash content of the femur epiphysis was higher (P<0.05) in Venda male than the male of Ross 308 broiler chickens. However, female Ross 308 broiler and Venda female chickens exhibited similar (P>0.05) femur epiphysis ash contents. Tibia epiphysis ash contents were not different (P>0.05) between males and females of Ross 308 broiler and Venda chickens. Tibia diaphysis ash content was higher (P<0.05) in Venda males than Ross 308 broiler males. Similar tibia diaphysis ash content (P>0.05) were observed in the females of Venda and Ross 308 broiler chickens. A higher (P<0.05) femur diaphysis ash content was observed in Venda females than males of Ross 308 broiler and Venda chickens. Ross 308 broiler male had lower (P>0.05) femur diaphysis ash content.

Discussion

In recent decades, selection pressure has been applied in poultry for fast growth and high meat production (Breugelmans et al., 2007; Kirkwood et al., 1989). This, in turn, puts pressure on the skeleton of the bird to support the heavier body weights associated with broiler chickens (Breugelmans et al., 2007). The femur bone length in the current study at 90 days for male and female Ross 308 broiler were 96.89 and 92.38 mm, respectively, whereas for male and female Venda chickens they were 85.44 and 82.44 mm, respectively. The values in the present study were lower than those reported by Breugelmans et al. (2007) who indicated that at 98 days of age Ross 308 broiler chickens had a femoral length of 116 mm, this might be due to age differences. The tibia lengths for Ross 308 broiler were 144.90 for males and 126.06 mm for females in the current study. This is similar to the previous results obtained by Latimer (1927) reported similar results for broiler chickens to those observed in the current study. The tibia lengths of male and female Venda chickens were 117.4 and 115.5mm, respectively. These values are lower compared to those of male and female Ross 308 broiler chickens at the same age in the current study. This can be attributed to breed differences. The males in the present study, regardless of the breed, had longer tibia and femur lengths compared to their females. Charuta et al. (2013a) and Rose et al. (1996) who indicated that bone length is related to sexual dimorphism support these results. The lengths of both the tibia and femur of slow growing Venda chickens, irrespective of the sex, were lower compared to those of the fast growing broiler chickens. Therefore, breed had an effect on the bone length of chickens.

Calculated as a function of carcass weight, tibia and femur lengths were compared and R-value of 97 % was a result of the variability in carcass weight of Ross 308 broiler chickens; however, only 89 % was recorded for indigenous Venda chickens. Buckner et al. (1950) observed a > 98 % as differences in tibia bone lengths in male and female New Hampshire chickens aged 196 days. The bone weights of chickens breeds used in this study were significantly higher for males than females. This was similar to the findings of Applegate and Lilburn (2002) who observed that sex had an effect on tibia and femur weights. However, slow growing Venda chickens in the current study with lighter body weight had lower tibia and femur weights compared to their counterparts Ross 308 broiler chickens. Although when the polynomial function of tibia and femur weights was calculated, R-value of 88 % for tibia and 91 % for femur are results of variations of the body weight for indigenous Venda chickens. Applegate and Lilburn (2002) and Buckner et al. (1950) observed that > 98 % of the variations in tibia and femur weights are function of the body weight for broiler chickens aged 43 days and New Hampshire chickens aged 23 weeks. Tibia and femur width of the male and female Ross 308 in the current study tended to follow a similar trend as the bone weights and lengths. Increase in bone length would be expected to correlate with the bone width indicating the overall bone size (Van Wyhe et al., 2012) which was the case with Ross 308 broiler chickens in this study. If the bone length continues to grow and increase without the increase in bone width, this could predispose chickens to increased skeletal problems.

Epiphyseal ash content of the femur was higher for Venda male chickens in the current study. The epiphyseal region of the bone is responsible for the linear increase in bone growth and this process amongst others includes mineralization (Van Wyhe et al., 2012; Applegate and Lilburn, 2002). The percentage of ash in this region would be expected to vary according to nutrition and age. These results are supported by Lin et al.

DOI: http://dx.doi.org/10.15666/aeer/1504_13871398

(2012) indicating that bone ash was higher for Taiwan male chickens at 14 weeks of age. The reasons why both male and female indigenous Venda chickens had higher epiphyseal ash content compared to their counterparts is unclear in the current study. Ash content was higher in the tibia and femur diaphyseal region of male and female indigenous Venda chickens compared to lower percentile values in male and female of Ross 308 broiler chickens. Thorp (1992) compared the ash content at the femur diaphysis with the tibia one and observed that ash content was lower in femur, suggesting that this bone can be a vulnerable point of chickens and can be responsible for long bone abnormalities. Previous studies by Itoh and Hatano (1964); Dilworth and Day (1965) and Moran Junior and Todd (1994) concluded that femur bones in Ross 308 broiler chickens are more sensible to changes in diet than tibia bone.

The Seedor index that is also known as bone weight/bone length index is an indication of bone density (Seedor, 1995; Ameida and Bruno, 2006). Higher bone densities in the current study were observed for male and female Ross 308 broiler chickens than Venda chickens. These higher densities in Ross 308 broiler chickens are an indication of their heavier weight. A low robusticity index is an indication of strong bone structure (Safaeikatouli et al., 2012). Robusticity indexes of both tibia and neither breed nor sex affected femur bones. This was not expected for Venda chickens, as indigenous chickens are known to have stronger bone structure than broiler chickens. Perhaps, the reasons why indigenous chickens in the current study had similar robusticity index with broiler chickens would be the similar rearing systems under which both breeds were reared. Diaphysis and medullary canal diameter of Ross 308 broiler chickens were observed to be higher than in Venda chickens. Tibiotarsal index points out mineralization in the bone, and therefore a higher index indicates higher mineralization level in the bone (Ziaie et al., 2011).

Male and female Venda chickens had higher tibiotarsal index than male and female of Ross 308 broiler chickens. The above findings are supported and confirmed by the higher epiphyseal and diaphyseal ash content of male and female of Venda chickens in the current study. The higher mineralization in male and female Venda chickens is an indication of better bone quality than Ross 308 broiler chickens. Sex and breed affected the bone length, weight and width of Ross 308 broiler and indigenous chickens at 90 days of age. Bone geometry and densitometry analysis varied amongst breed and sex of chickens. Venda chickens had higher epiphyseal and diaphyseal ash content, which was confirmed by the higher tibiotarsal index. On the contrary, Ross 308 broiler chickens had higher femur and tibia Seedor index, which is an indication of denser bones. Although it was expected that indigenous Venda chickens that are hardier would have stronger bone structure than broiler chickens, this was not the case in this study. Perhaps the rearing system could have contributed to similar robusticity indexes that are an indicative of bone strength. This information will have implications when selecting chickens for better bone quality and strength.

Conclusion

In most of the morphometric parameters measured, both the male and female Ross 308 broiler chickens have superior values than the Venda chickens. However, in the ash contents, the male and female Venda chickens had higher values. Tibia and femur lengths were longer for female Ross 308 broiler than the female Venda chickens. Similarly, the tibia and femur weights were heavier for both male and female Ross 308 broiler compared to those of Venda chickens. However, fibula weights were similar for both male and female Ross 308 broiler and Venda chickens. The width of the tibia and femur followed the same trend as observed for the length and weight. Tibia and femur Seedor index were higher in males and females of Ross 308 broiler than the Venda chickens. The tibia diaphysis and medullary canal diameter of male and female Ross 308 broiler chickens were higher than those in Venda chickens. However, the tibiotarsal index was higher for male and female Venda chickens than for Ross 308 broiler chickens. Ash contents of the femur epiphysis and femur and tibia diaphysis were higher in Venda male than the male of Ross 308 broiler chickens. Similarly, tibia diaphysis ash content was higher in Venda males than Ross 308 broiler males. However, tibia and femur epiphysis ash contents were similar in both males and females of Ross 308 broiler and Venda chickens. The tibia diaphysis ash content was also similar in the females of Venda and Ross 308 broiler chickens.

Abstract. Biologically active compounds, sugars, acids and antioxidants are key-important ingredients of healthy tomato food. Objective of the study is to investigate if specific industrial bioeffector products are improving the taste and some quality parameters of tomato fruits and how those results are appearing in pots and among organic field conditions? Spore-forming industrial *Bacillus amyloliquefaciens* FZB42 (RhizoVital) as single inoculums and combinations either with other *Bacillus* strains (Biorex-1), or with N_2-fixing-siderophore-producing strains (Biorex-2) were applied on *Solanum lycopersicon* Mill. var. Mobil test plant. Soil microbial counts, phosphorus availability and fruit quality, such as total soluble solids (TSS), content of some essential organic acids (citric-, maleic) and sugars (glucose, fructose) were assessed. The results found, that single industrial inoculums of FZB42 product had positive effect on P-availability and fruit quality in the pots, combinations of other biofertilizers, however, did not give additional results. Fruit quality parameters, TSS content, soluble sugars and organic acids were significantly improved ($p<0.05$) at both experimental conditions. Such better fruit taste was correlated significantly by the most probable number (MPN) total microbial counts with greater positive values in pot experiment, compared with more variable environmental field condition. The recommendation of using such bioeffector products is supported by the positive interrelation among measured soil characteristics and inside healthy quality parameters of organically grown tomato fruits.
Keywords: *bioeffectors, biofertilizers, phosphate solubilization, tomato quality, organic agriculture, MPN counts, correlation*

Introduction

Sustainable agriculture and healthy food become one of the most important aspects of any food-production systems. An increasing demand exists for fruits and vegetables of originating from ecological farming systems, avoiding the use of chemical fertilizers and pesticides (FIBL 2001; Hesammi et al., 2014; Kocsis et al., 2017). As a direct consequence of intensive agricultural production, deleterious environmental effects on soil-quality and fertility are increasing in parallel loss of the abundance and diversity of living organisms in soil-food-web (Johnston, 1986; Varga et al., 2007). Key important requirements therefore is the needs of reducing the artificial deleterious chemicals and xenobiotic inputs, more particularly among the agri- and horticultural practices (Juhos et al., 2015, 2016). Altogether with those conditions consumers' highlighted expectation for healthy and chemical-free foods are simultaneously required.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13991418

Depending on the variability of environmental conditions 3-15 t microorganisms can be found in each hectare of the soils, not considering other soil-fauna elements of soil-food-web (Fekete et al., 2008; Kotroczó et al., 2008; Veres et al., 2013). For a correct assessment of soil edaphon, several parameters are investigated and variability of methods used, as a function of the aim and applicability of investigations. It is generally accepted, however that biological activity of soil organisms might play a crucial role in mobilization of soil nutrients and make them available and usable for higher plants, crops (Juhos, 2014). Several organisms are known to be involved in soil organic matter degradation and decomposition (Kotroczó et al., 2014a, b; Fekete et al., 2014, 2017; Veres et al., 2015) and giving with this process continuously the available nutrients for higher plants (Tóth et al., 2013). Various microbial diversity and types of microorganisms are living in the soils, including both of bacteria and fungi with known general and/or highly specific nutrient mobilization ability (Schweitzer et al., 2008). In recent decades' chemical fertilization was the most dominant in intensive agricultural production. By contrast active microbial soil characteristics were largely ignored, due to the mainly artificial plant nutrient fertilizing practices among the intensive agriculture production.

Concern for the above mentioned reasons for healthy environment, eco-friendly production methods and chemical-free farming systems are increasing (den Hollander et al., 2007). One of the most accepted and followed alternatives of intensive agricultural practices are the application of living bioeffectors (BE), which might include one or more types and strains of so called "beneficial microorganisms" in many soil-plant systems. Other, so-called non-living bioeffector materials (carriers, soil-ameliorative compounds, natural minerals) can be used in parallel with the generally accepted biofertilizer, bioeffector treatments. Such combined application is providing both living organisms and also soil-improving materials; finally, the survival of microbes and soil functions might be enhanced in one step. The selected beneficial microbes are known to support plant-growth and development, nutrient and water uptake of plants and might suppress damage of harmful soil-borne plant pathogen microorganisms in soil-plant systems. Bioeffectors can successfully integrate into any environmental-friendly agri-horti-, silvi- and viti-cultural practices. Main accepted application of bioeffectors is reducing or diminish fertilizer and high levels of pesticide inputs. Among beneficial microorganisms, the symbiotic connection between plant growth promoting bacteria (PGPB) or -rhizobacteria (PGPR) and their host plants was first described and demonstrated by Kloepper and Schroth (1978). PGPB or PGPR microorganisms have a potentially great impact on plant growth, yield and health with several known mechanisms in soil-plant systems. Those organisms might protect cultivated plants from soil-borne plant pathogens in addition they can improve soil chemical and physical characteristics (Glick et al., 2007). By using PGPB microorganisms as introduced inoculums of soils, nitrogen and phosphorus content, other mezo-micro-elements become available by plants. This mechanism can result harmonized nutrient balance in soils and might heal nutrient disorders in soils. As a direct consequence of inoculation, amount of synthetic fertilizers, furthermore other xenobiotics, toxic agrochemicals will be reduced (Hay et al., 2010).

Direct and indirect beneficial effects and mechanisms of bioeffectors are reported from any soil-plant-microbe systems, with known distinct and well-characterized effects. The combination of those described mechanisms are also possible, and different bacteria or fungal species might have more than one of these functional traits. Schippers

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13991418

et al. (1985) described three different affecting mechanisms in plant-soil-microbe systems:

- increased nutrient supply, nitrogen fixation, nutrient exploration or nutrient transport,
- increased defence mechanisms against some soil-borne plant pathogen fungi and bacteria by inhibiting of their growth; competition for space and for nutrients, antibiosis, parasitism, induced systemic resistance;
- direct enhancement of plant growth, production of several hormone-like, plant growth regulating (PGR) substances.

These protected effects can overlap in many cases and different microorganisms can also have more than one efficient PGPR or plant growth regulating (PGR), hormone-like mechanisms. In several occasions not all of these effects might be developed, due to the fact, that they might be modified during the vegetation periods through the various biotic and abiotic environmental (stress) factors (Biró et al., 2000; Carvalhais et al., 2013). Those particular effects are especially specific for combined "second-generation" of microbial inoculums, where microorganisms as specifically adapted ones were used to certain environment and for certain host plants. Specific bioeffective and stress-tolerant microbes therefore are used efficiently at the practice of amelioration, recultivation and/or at remediation practices (Biró et al., 2000; 2012).

Phosphorus supply is key issue for optimal tomato production. Necessity of P-elements are especially crucial at early stage of plant growth. Presence of phosphorus-mobilizing microorganisms as *Bacillus* spp. bacteria, furthermore the *fluorescens* and *putida* types of *Pseudomonas* spp., which can influence indirectly the uptake of this element is also essential (Khan et al., 2009). Those microorganisms are able to mobilize hardly available phosphorus forms (Bashan et al., 2013) e.g. they can solubilize natural rock phosphates to be available for plants, improving the growth of roots, shoots and plant biomass or fruits. Due to those beneficial properties, bioeffector organisms are successfully involved in ecological farming practices (Hariprasad and Niranjana, 2009; Biró et al., 2012). Among bioeffector (BE) strains, those with spore-forming abilities are more tolerant and survivor at serious environmental stress conditions, therefore their application is highly expanded in industrial microbial inoculum productions (Hartmann et al., 2009).

The *Bacillus amyloliquefaciens* is a non-pathogenic soil bacterium. Similar to other *Bacillus* species it is capable of producing endospores allowing it to survive for extended periods of time. The species also shows some antifungal properties which are influenced by several environmental factors, including nitrogen availability (Caldeira et al., 2008; Choudry et al., 2015). *Bacillus* spp., i.e. *B. subtilis* is known as efficient in cellulose degradation, amylase production and can block phytopathogenic micro-organisms (Yang et al., 2009). *B. thüringiensis* is generally used against soil pests, by creating an alkaline reaction and leading to the serious pest destruction. *B. megaterium* is efficient in phosphate mobilization, the production in growth substances and vitamin B12 and it is also possible to modify the plant residues into humus.

Among beneficial microorganisms the nitrogen(N_2)-fixing bacteria are having the uppermost importance, including as free-living, associative and obligate symbiont forms in soil-plant systems. *Azotobacter chroococcum* bacteria are free-living nitrogen fixing microbes, generally with drought and cold tolerance (about 3-4 °C of soil temperature) ability *Azospirillum lipoferum* is an associative nitrogen fixing bacteria, which secondary interact with the roots of monocots and also known as auxins, gibberellins, cytokinin plant

DOI: http://dx.doi.org/10.15666/aeer/1504_13991418

hormone producer (Biró et al., 2000; Diamantidis et al., 2000). *Pseudomonas putida* as other frequently used biofertilizer species, might produce siderophore-like compounds, efficiently using of iron ions from soil and it creates also some competitive inhibition towards soil-borne plant-pathogen organisms and in addition enhance plant-uptake of macro-, mezo-and micro-nutrients (Timmis, 2002). Among ecological farming production systems, the use of bioeffector treatments, including the biofertilizer and/or the biopesticide effect of microorganisms seems to be the only and highly feasible way of thinking (Rodriguez and Fraga, 1999; Biró et al., 2000).

Tomato is one of the most frequent vegetable grown worldwide and consumed both in freshed and in processed forms (Helyes et al., 2014). This tasty vegetable has important role in healthy lifestyle, sustainable tomato production has therefore an increasing demand nowadays. In order to achieve the highest possible yield, unreasonable tillage and overuse of agrochemicals (pesticides, chemical fertilizers) are applied at intensive growing systems (Glendining et al., 2009). Such breeding practices on the other hand generally reduce the nutritional value of crops, vegetables and also of the fruits. Tomato on the other hand might contain significant amounts of natural health-protecting compounds, such as the organic acids, sugars and antioxidant materials, such as the lycopene, C-vitamins and others (Devi et al., 2008; Helyes et al., 2014).

Soluble sugars and organic acids play crucial role in tomato quality and food taste values. Tomato contains 5.0-7.5 % of dry matter that is mainly constituted of fructose, glucose, citric acid, malic acid, and other organic compounds (Sariyer and Oztokat, 2015; Salles et al., 2003). Major organic acids in tomatoes are citric- and malic acids, with higher dominance of citric-acids (Davies and Hobson, 1981). Levels of organic acids are highly depending on the ripeness and also on the certain cultivars, beside the crucial soil-environmental affecting factors (Baldwin et al., 1991; Béni et al., 2014, 2017). Phosphorus supply of tomato plants influences highly the quantity and quality of biologically active compounds in the fruits (Di Cesare et al., 2010). Several key-important compounds of organic acids and sugars were examined therefore by high performance liquid chromatography (HPLC) beside the total soluble solid (TSS) content from ripe fruits.

Effect of some commercially available microbial fertilizer (bioeffector) inoculations, including spore-forming bacteria was studied on the fruit quality parameters of tomato among controlled light-chamber and at field-conditions. Main focus was given for answering of the following questions: Is *Bacillus* spp. biofertilizer inoculation increasing the soil microbial counts and available P for plants? Is some of inside tomato fruit quality parameters improved by the bioeffector inoculations? Is there any positive correlation between the bioeffector treatments and fruit quality? Is results from pots can be predictable to up-scaled natural field condition?

Materials and methods

Experimental background

Experiments were carried out in pots and also among organic field conditions in 2014. There were 4 different treatments used in the pot experiment of applying 3 dm^3 of pots in 4 replicates (*Table 1*). Among field conditions there were 12 of 4×5m plots used at the Research and Experimental Farm of the Szent István University of Budapest, Horticultural Faculty, Ecological Farming Division in Soroksár, Hungary (N 47°40'; E

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13991418

19°15' at 111 m altitude). Ecological farming practices are carried out since more than ten years on the experimental field site. For nutrient supplementation we applied authorized substances used in organic farming: Viano (13% N; 660 kg ha^{-1}), Patentkali (30% K_2O; 10% MgO; 17% S; 1200 kg ha^{-1}). Regarding plant protection against soil borne plant pathogens during the vegetation periods, we used copper-sulphate-containing fungicide (Cuproxat FW-1) treatment according to the suggestion of suppliers. Experimental area was regularly watered of using drip irrigation system. Some of the soil characteristics and also some data about environmental climatic conditions of the area are shown in *Table 1*. In 2014 it was an excessively rainy growing season with almost 1.5-times higher precipitation than the usual average annual value.

Table 1. *Main characteristics of soil at Soroksár site, Hungary*

Soil parameters	Measured values
pH_{H2O}	7.9
C:N (A horizon)	9.92
NO_2+NO_3-N	8.5 mg kg^{-1} soil
P (CAL)	43 mg (100 g^{-1} soil)
K (CAL)	17 (100 g^{-1} soil)
Mg ($CaCl_2$)	10 (100 g^{-1} soil)
Soil type	slightly hummus sandy soil
Mean annual temperature	11°C
Mean annual precipitation	500 mm

Pot experiment was performed in the light-chamber of Department of Soil Science and Water Management of Corvinus University (now it belongs to Szent István University), Budapest, Hungary. Soil used in the pots, was originated from the field experimental station of Soroksár, Hungary. Light-period of pot experiment was 14 hours in a daily basis in accordance with the requirements of the tomato plants. Pots were placed in a controlled-temperature light room, programmed at a temperature ranging from 17 °C to 28 °C, while the light intensity (Lux) had been 25000 lx (Herrera et al., 2008). Characteristics of applied soil are shown in *Table 2*. Both in pots and in field experiments the tomato (*Solanum lycopersicon* Mill.) Hungarian cultivar of 'Mobil' were used. Seedlings were grown under controlled conditions and planted into their final place after the 14^{th} days, preferably at the same stage of maturity of each. The pot experiment was carried out between 31^{st} of March 2015 and 16^{th} of June 2015. In case of field trials, the seedling was grown up till the 25^{th} of March 2015 in cold plastic house, transplanting of small 2-leaves of seedlings was done to bigger pots at 9^{th} of May 2015. Final seedlings-transplantation to the field condition was performed between 20-26 of May 2015.

Regarding the plant parameters, a biweekly visual inspection of plant-parameters was done during the vegetation periods (data not shown), and a final biomass-production of fresh and dry weight of shoot was estimated. Fruits of tomato was regularly measured from each of the tomato plants, and a summary of the yield was calculated in each plots and in each treatment. In this study we are focusing on the soil- and fruit- quality parameters.

Biofertilizer treatments and estimation of soil-characteristics

Commercially available bioeffectors (BE products), i. e. biofertilizers, were used for both at the pots and the field experiment. On the basis of the results achieved in pot experiment, combinations of BE with other product of biofertilizers were also tested among field conditions according to *Table 2*.

During general set-up of pot experiment, there were 2500 g air-dried soil put in each of the pots and one tomato seedling/pot was planted. Biofertilizers were applied on the basis of supplier suggestions. Bioeffector (BE) strains were used in the rates of 1.33 % (v/v), i.e. 0.2 ml for each plants Hungarian BR1 and BR2 products, as a 2-component-biological fertilizer was also applied according to the supplier's protocol, BR1: 0.1875 $ml.plant^{-1}$; BR2: 0.375 $ml.plant^{-1}$, shown in *Table 2*.

Ammonium lactate method (P-AL) was used to estimate available phosphorus content: 5g of soils were shaken in 100 ml of 0.1 M ammonium lactate and 0.4 M acetic acid (pH 3.75) for 1 hours and phosphorus content was estimated from the filtrate colorimetrically (Egner et al., 1960).

Table 2. *Treatments and density of bioeffector inoculums at the pot and field experiment*

Treatments	Bioeffector strains	Colony forming units in product ($CFU\ g^{-1}$)	Inoculation rates
C (Control)	No inoculums, only water	-	-
BE (Bioeffector)	*Bacillus amyloliquefaciens* FZB42	2.5×10^{10}	1.33 % (v/v), i.e. 0.2 ml/plant
BR1 (Biorex-1)	*Bacillus subtilis; B. thüringiensis; B. megaterium*	2×10^{10}	5L/ha, 0.1875 ml/plant
BR2 (Biorex-2)	*Azotobacter chroococcum: Azospirillum lipoferum; Pseudomonas putida.*	2×10^{10}	10L/ha, 0.375 ml/plants
BE+BR2	Combination of 2 products	$1.25\times10^{10}+1\times10^{10}$	0,2+0,375 ml/plants

Most probable number (MPN) method of sporeforming bacteria in soil capable of growing in nutrient broth (meat extract 3 g; peptone 5 g; pH 7±0.2) (Marshall, 1993; Downes and Ito, 2001) was used by a microplate method. 10-fold serial soil dilutions were made from 10^{-1} to 10^{-8} dilutions as described (Libisch et al., 2010). Average soil samples were collected at the 10^{th} and 14^{th} weeks of tomato growth, with the highest suggested microbial activity in soil-plant system (Biró et al., 2000). From each samples and from each dilution three parallel 20 µl aliquots were transferred to sterile polystyrene 96-well microplates, after 10 minutes stay in water bath at 80 ^{o}C to kill the vegetative cells. Microplates were incubated at 28°C for 1 week. The plates were tested after that for growth using the respiration indicator iodo-nitro-tetrazolium violet (INT) (Sigma-Aldrich) (Johnsen and Henriksen, 2009). 50µl INT solution (3g/L INT dissolved in water) was added to each well, and the plates were incubated overnight at 28°C. Metabolically active bacteria reduce INT to the corresponding formazan forming a purple precipitate. The number of growth-positive wells at each dilution was determined

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13991418

by visual inspection of the plates. The statistical method of Cochran was applied to calculate MPN values using the MPN calculator VB6 (Cochran, 1950). One-way Anova Tukey test with logMPN values and standard logMPN errors was used to determine whether MPN values of various pot experiment and field experiment soil samples were not significantly different at the 95 % confidence level (<0.05) (Mukherjee et al., 2006; Vladar et al., 2008).

Fruit quality assessments

Sugars are the major soluble solids in tomato fruit juice. Soluble solids concentration (Brix or TSS) can be determined in a small sample of fruit juice using a hand held refractometer. Total soluble solid content (TSS) of tomato fruits was determined by Atago® PAL-3 refractometer device (Cavalcanti et al., 2013). The fruits (skins and fruit-pulp) were homogenized with a blender and homogenates were stored at -25 °C until analysis. After hawing 2 g from each fruit puree samples were diluted in 2 ml deionized water, shake for 1 hour in dark and centrifuged for 10 min at 10000 rpm (Hettich Mikro 22R). One ml supernatant was then pipetted off and filtered through a 0.45-µm MILLEX®-HV Syringe Driven Filter Unit (SLHV 013 NL, PVDF Durapore), purchased from Millipore Co. (Bedford, MA, USA). WATERS High Performance Liquid Chromatograph (HPLC, Waters Co., 34 Maple Street, Milford, MA, USA) equipped with 2487 Dual λ Absorbance Detector (for determination of organic acids), 2414 Refractive Index Detector (for the determination of sugars) 1525 Binary HPLC Pump, In-Line Degasser, Column Thermostat (set at 40 °C) and 717 plus Autosampler controlled with EMPOWER™2 software was used for HPLC analysis. For separation of organic acids Shodex KC-811 column (8 mm × 300 mm) with Shodex RSpak KC-G guard column were used. Mobile phase was a 0.1 % aqueous solution of phosphoric acid. Flow rate was adjusted to 1 $ml.min^{-1}$, giving a pressure of 600±25 psi on the column at 40 °C. The volume injected on the column was 20 µl, the detection time was adjusted to 20 min. Detection was carried out at analytical wavelength of 220 nm. Retention times (in min.) of the standards were 7.19 for citric- and 9.10 for malic acids. For separation of sugars a Sugar-PakTM column was used placed in a thermostat at 90 °C. The mobile phase was a 0.0001 M aqueous solution of Ca-EDTA. Flow rate was 0.5 ml min^{-1}, resulting a pressure of 450±10 psi on the column. The 20 µl of injected volume was used, detection took 30 min. for each sample. Retention times of standards were 8.32 for sucrose, 10.93 for glucose and 11.77 for fructose. Two replicates were used. Concentrations were calculated from areas of corresponding peaks and expressed in $mg.100^{-1}$ g.

Statistical analysis

For evaluation of the results one-way ANOVA test was applied. Normality assumption was proven by Kolmogorov-Smirnov test (p>0.05; p=0.200) or Shapiro-Wilk test (p>0.05) and the homogeneity of variances was checked by Levene’s test (p>0.05). As the estimation was proven we applied Tukey HSD post hoc test. If it was not proven the Games-Howell post hoc test was applied. Pearson correlation analysis was used to estimate the interrelation among soil and tomato fruit quality parameters. The analysis is appropriate to know how the involved and studied variables are related to each other. Results are presented in *Figures* and in *Tables*.

Results

Soil parameters with bioeffector application

MPN counts of sporeforming bacteria

Fig 1a is showing the most probable number (MPN) of cultivable microorganisms in the soils, treated or non-treated by bioeffectors in the pot experiments. According to the result of total plate count, normality assumption was proven by the Shapiro-Wilk test ($p>0.05$; $p_1= 0.715$; $p_2=0.883$) and the homogeneity of variances was checked by Levene's test. As the assumption was proven, [$F(7;32)=2.151$; $p1>0.05$; $p=0.066$] we applied Tukey HSD post hoc test. Differences among the treatments were not appeared significantly. However, it is apparent that the number (logMPN) of microorganisms in the BE-treated soils was enhanced tendentiously from April to July in the pot experiment (*Fig. 1a*).

Among the natural field conditions *Fig 1b* is showing the most probable number of microorganisms in the soil of the field experiments after 8 (July) and 14 (September) weeks of growth. According to total plate count results, normality was proven by Shapiro-Wilk test ($p>0.05$; $p1= 0.715$; $p2=0.883$) and homogeneity of variances was checked by Levene's test. The assumption was proven, therefore we used Tukey HSD post hoc test [$F_{July}(7;8)=0.015$; $F_{Sept}(7;19)=0.057$; $p>0.05$]. Differences among the treatments were not appeared significantly either any growing conditions. In case of pot experiment the number of microorganisms in BE-treated soils were increased but the same was not proven among the field conditions, at the studied periods. No differences among the various bioeffector treatments could be found at the sampled time (*Fig. 1b*).

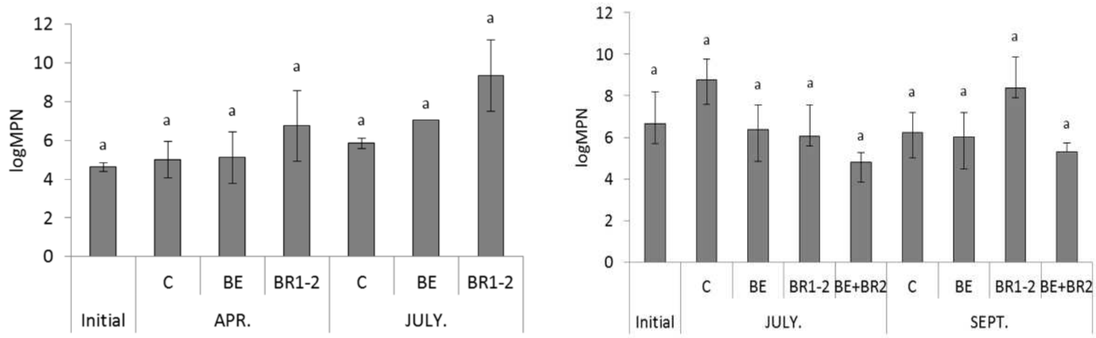

Figure 1a, b. *Most probable number of microorganisms (logMPN) in soils treated or not by various bioeffector products (**a**) and (**b**). Results in pots and in field, respectively (n=4)*

Soil-available phosphorus

Prior to the pot-trial a preliminary soil analysis was performed in soils, originating from the experimental field of Soroksár (Hungary), the site of the field tests on the same year. A specific focus was given for the availability of phosphor (P) doses, due to the fact, that used bioeffector products were predicted of containing mainly the specific P-mobilizing microorganisms. Among the macro elements, examined, phosphor content was found to be increased mainly in the pot experiment. Treatment with the presumably phosphorous-mobilizer *Bacillus* (BE, BR1) strains could increase the available P-content in the soil significantly (*Fig. 2a*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13991418

Among field conditions it was also examined that phosphorus mobilizer *Bacillus* (BE, BR1, BR2) strains could increase the available P-content in soils. Among treated and non-treated soils, however, no significant differences were recorded [F(3;8) = 2.269; p = 0.071] (*Fig. 2b*).

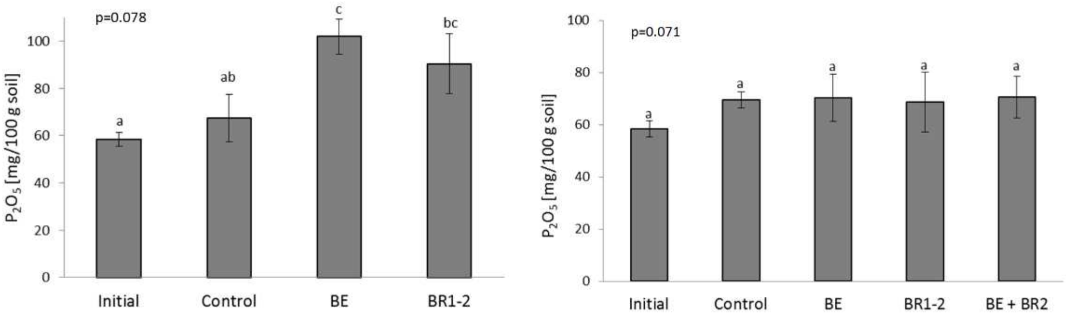

***Figure 2a, b.** Phosphorous, P_2O_5 content of soils after (**a**) 10- (in pots) and (**b**) 14 weeks (in field) growth of tomato (n=4)*

Fruit quality parameters with bioeffector application

Total soluble solids of tomato fruits

Tomato's fruit quality parameters were examined, by assessing the total soluble solid content (TSS). In case of pot experiment TSS value was significantly higher through the effect of used BE industrial product; while in case of BR1-2 treatments TSS value was significantly lower compared to the control. Post hoc comparisons using Games-Howell test indicated, that the mean score of BE (M=9.00; SD=0.608) and the BR1-2 treatment (M=5.2; SD=0.122) were significantly different from the control (M=6.62; SD=0.16) (*Fig. 3a*).

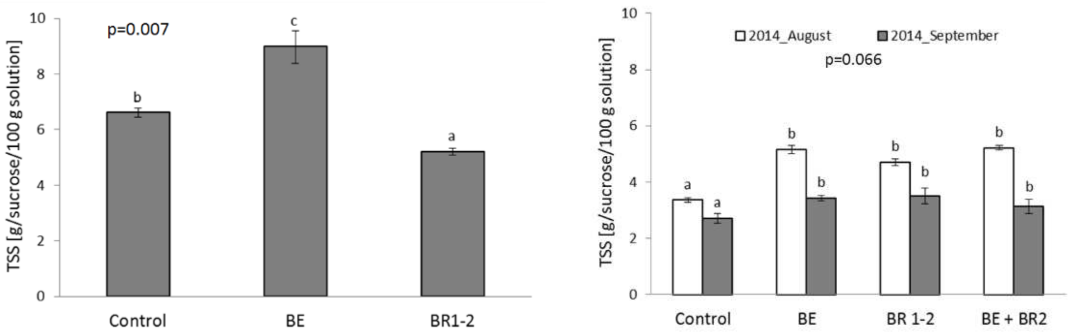

***Figure 3a, b.** Total soluble solid (TSS) content of tomato fruits after (**a**) 10 weeks of growth (in pots) and (**b**) as harvested after 10- (in August) and 14- (in September) weeks of growth (field experiment) (n=4)*

Among field condition beside the single BE treatment, combined effect of bioeffectors (BR1-2 and BE+BR2) was examined. In field the tomato fruits were harvested two times during the vegetation period (after 10 weeks, in August 2014, and after 14 weeks in September 2014). The fruit quality analysis was carried out on average samples after performing both harvests. In case of the field experiment TSS

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13991418

value of fruits from the treated plots were significantly higher than the control at both harvests. Post hoc comparisons using the Tukey HSD test indicated that the mean score of BE (M=5.16, SD=0.15), BR1-2 treatment (M=4.7; SD=0.02) and the BE3+BR2 combination (M=5.22; SD=0.08) were significantly different than the control (M=3.36; SD=0.089). In September the TSS value decreased but the differences have remained similar (*Fig. 3b*).

Sugar and organic acid content of tomato fruits

Among inside fruit quality parameters some of the sugar- (glucose, fructose) and the organic acids (citric-, malic-) components were assessed by high performance liquid chromatography (HPLC) both in pots and in field experiments. In comparison with total soluble solid (TSS) values, similar result appeared with the HPLC-measured sugar components, although those results were found to be lower. Regarding the sugar content in the pot experiment there were no significant differences found in comparison with the control but differences were significantly supported between the two treated groups. TSS value was found to correlate slightly with the concentration of sugar component measured by HPLC. Normality assumption was proven by Kolmogorov-Smirnov test ($p>0.05$; $p1= 0.200$; $p2=0.117$) and the homogeneity of variances was estimated by Levene's test As the assumption was not proven [$F1=F2(3;4)=0.005$; $p<0.05$] a Games-Howell post hoc test was applied (*Fig. 4a*).

The organic acids (citric- and malic) were also assessed by HPLC analysis. Regarding the pot experiment the organic acid content was significantly higher in case of control (M=565.79; SD=3.46) than the BE (M=525.39; SD=2.79) and BR1-2 treatments (M=261.03; SD=3.25) (*Fig. 4b*).

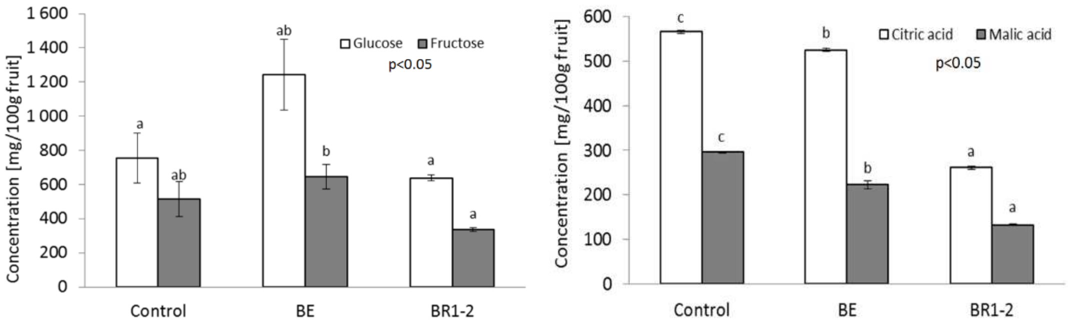

Figure 4a, b. *Sugar (glucose and fructose) (**a**) and organic acid (citric-, malic-) (**b**) content of tomato fruits after 10 weeks of growth in pot experiment (n=4)*

In case of the sugar content in tomato fruits from the field experiment, no significant differences were found in fructose and in glucose contents when single BE treatment was used. When two harvesting periods were compared, the same results were achieved, so no significant differences were found in the sugar concentration. Both normality assumption was proven by Kolmogorov-Smirnov test ($p>0.05$; $p_{Aug}= 0.200$; $p_{Sept}=0.117$) and the homogeneity of variances was estimated by Levene's test. As the assumption was not proven [$F_{Aug}=F_{Sept}(3;4)=0.005$; $p<0.05$] a Games-Howell post hoc test was applied. Post hoc comparisons using the Games-Howell test indicated that the mean score of BE, BR1-2 treatments, and the BE+BR2 combination were not significantly different than the control (*Fig. 4a*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_13991418

The organic acids (citric- and malic) were also assessed by HPLC analysis. In the field experiment two sampling periods and measurement of the organic acids were applied. In September there was an increasing amount of citric acid in tomato fruits, grown in the bioeffector treated soil. The same only tendentiously was supported for malic acid content (*Fig. 5b*).

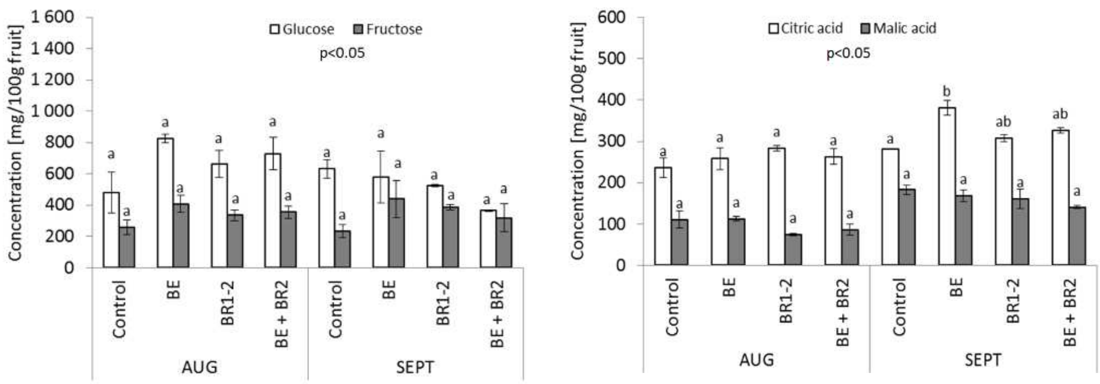

Figure 5a, b. *Sugar (glucose and fructose) (**a**) and organic acid (citric-, malic-) (**b**) concentration of tomato fruits after 10 (August) or 14 (September) weeks of growth in field experiment (n=4)*

Correlation among soil characteristics and tomato fruit quality parameters

Correlation analysis was performed among total cultivable sporeforming microorganisms (*Bacillus* sp.), estimated by MPN (Most Probable Number) method and some of the tomato fruit quality parameters both at pot- and at field experiments.

Correlation results of MPN, measured TSS values and estimated inside fruit quality parameters are shown in *Table 3* and *Table 4*. Interrelation of inside fruit quality with the used biofertilizer application was found to be greater in pot experiment, in comparison with the field experiment with more variable environmental condition.

Results of pot and field experiments are summarized in *Appendix 1*. Measured data of microbial soil and fruit quality parameters are detailed, as the average of 4 replicates, with the standard errors.

Table 3. *Correlation among soil microbial abundance of sporeforming bacteria (MPN), the total soluble sugars (TSS) and inside fruit quality parameters, soluble sugars (glucose, fructose) and organic acids (citric-, malic-) in tomato fruits, grown in pot experiment (n=4)*

Discussion

"Biofector" is an integrated international project with the aim to reduce input of mineral fertilizers in European agriculture by development of specifically adapted bio-effector microorganisms (BEs) to improve the efficiency of alternative fertilization strategies, such as organic and low-input farming, use of fertilizers based on waste recycling products and fertilizer placement technologies. Bioeffectors addressed comprise fungal and bacterial strains (e.g. *Bacillus*, *Trichoderma*, *Pseudomonas* etc.) with well-characterized root growth promoting and nutrient solubilizing potential. In Biofector international project one of the test plants is tomato, which is important in many ways in human consumption. Significant industrial and commercial use is known, exceeding all of the vegetables in terms of both cultivation and consumption in World. The aim of Biofector research project is the development of viable alternatives to conventional mineral fertilization, and contribution to a more efficient management of non-renewable resources of mineral nutrients, energy and water, to preserve soil fertility and to counteract the adverse environmental impact of agricultural production. Our study is part of the above mentioned research.

Tomato is very sensitive to the P supply. It is required relatively high amount of phosphorus, especially at the beginning of its growth (Schmidt et al., 2010). For this reason, some of the marketed bioeffector products were used in this study, which are known to solubilize and mobilize the highly available phosphorus content in the soil. The general use of *Bacillus* spp. strains as P-mobilizing microorganisms are also supported by the fact that those microbes can survive in the soils among several, even at the most serious environmental stress conditions. Due to its spore forming ability the cells of the *Bacillus* spp. can survive long in the soils and at any potential environmental conditions. It is why the individual species and *Bacillus* spp. genus are considered as one of the microbial groups, with specific food-quality and safety importance (Beczner et al., 2004; Dudás et al., 2014; Kocsis and Biró, 2015). Among the marketed products, which are containing spore forming bacteria there were single and combined inoculation treatments used in this study. It was hypothesized that the more types of bacteria, including more than one particular species could produce better performance for the plant growth promotion ability. This idea was already supported by several authors of using different combinations of bacteria or fungal-bacterial consortium, with an uppermost importance of such systems in polluted or environmentally stressed

ecosystems (Kloepper et al., 1989; Biró et al., 1993; Mantelin and Touraine, 2004; Vivas et al., 2006). Among sustainable agricultural practice the synergism of symbiont type of microbes is also demonstrated between arbuscular mycorrhiza fungi and the nitrogen-fixing bacteria. The behaviour of microbes in a consortium is dependent on several environmental factors. It has been reported, that even a beneficial symbiosis is diminished in a short time of periods when the environmental condition, such as the drought, high temperature or reduction of light intensity or heavy metals toxicity become non-tolerable to the macro- and micro-symbionts (the higher plants and the microbes) (Biró et al., 2000, 2015; Füzy et al., 2014). In case of the microbes are tolerable to severe environmental stress-condition, the symbiosis with a joint strategy might be helpful, finally resulting the better survival and growth of host-plants.

The abundance of inoculated microorganisms was followed by the most probable number (MPN) method. The quantity of cultivable spore-forming microbes were estimated, by preliminary kill of the non-spore-bearing vegetative cells from the soil-suspension. Although the presence or absence of those inoculated microorganisms was assessed only occasionally at the beginning and at 2-times during the vegetation periods, there were not greater abundance recorded as the total countable number in the tomato rhizosphere. This result indicates the potential of fast microbial changes in the rhizosphere and the interrelation among microbial colonization with plant growth parameters. Similar conclusion was made by Biró et al. (2015) who found that this effects can be highly dependent on the soil quality, the nutrient content of soils, more particularly focusing on the soil available nutrients during plant growth. On the basis of Kocsis et al. (2015) this type of slightly hummus sandy soil are low in available nutrients and in specific microbes. Significantly increase the microbial abundance is necessary to use soil improvers (e.g. biochar) or organic fertilizer, compost application, which might enhance soil microbial status in one step. We found only in the pot experiment that the abundance of microorganisms is increasing with the plant age. The importance of microbial inoculation is highlighted at early seedling status, when the PGR hormone-effect of inoculated microbes might enhance root-volume, indirectly improve water- and nutrient-uptake of plants (Yang et al., 2009; Biró et al., 2000; Choudry et al., 2015). The connection of microbial presence and activity with plant-necessity was already demonstrated among serious environmental stress conditions in several previous publications (Vivas et al., 2006; Domonkos et al., 2010; Panwar et al., 2011).

Testing the MPN abundance of specific sporeforming microorganisms in the tomato plant rhizosphere, differences among the used treatments were not found significantly in our study. It was apparent, however that the number (logMPN) of studied microbes in the BE treated soils was enhanced tendentiously with plant age (from April to July) in the pot experiment. It was also demonstrated in this study, that the abundance was found parallel with the available phosphorus concentrations in the soil. In connection with this finding Fekete et al. (2011) found, that more organic P can enhance the alkaline phosphatase activities, which finally increase the P-availability in the soil. The alkaline phosphatase is mainly produced by the soil microorganisms and the extent of its synthesis and excretion of it can be coupled to the microbial activity and/or the population size, as it was shown by Kaleeswari (2007) and Garg and Bahl (2008). Due to the presence of BE *Bacillus amyloliquefaciens* FZB42 an increased phosphorus content was found in the treated pots.

DOI: http://dx.doi.org/10.15666/aeer/1504_13991418

Regarding the size and number of fruits there was also an increase in treatment BE and BR1-2 in the pot experiment (data not shown). Richardson et al. (2001) and Idriss et al. (2002) made a similar finding in their experiments in laboratory and field conditions with the same *Bacillus amyloliquefaciens* species. They found that improved phosphorus nutrition is achievable by mobilization of phosphorus fixed as insoluble inorganic polyphosphates which accounts for 20-50 % of the total soil organic phosphorus. It is generally accepted that higher microbial counts can result higher nutrient availability in soil. Contrarily, in case of the combined treatments, where beside the *Bacillus* spp. strains some other microorganisms, as the Nitrogen-fixing *Azospirillum* and *Azotobacter* furthermore the siderophore-producing *Pseudomonas* bacteria (BE+BR-2) were given, no further improved growth parameters were recorded on tomato.

Considering the fruit quality there are also several study of showing the importance of biofertilizer application. According to Bruulsema et al. (2004), phosphorous fertilization is a key component in the metabolism and regulation of several pathways involved in the biosynthesis of secondary plant metabolites. Many of those materials are biologically active compounds. P may increase the level of some acids such as ascorbic acid, although interaction with climatic factors and the growing season growing area may occur. The high level of citric acid concentration was found at a high level of phosphorus concentration by Di Cesare et al. (2010). Tóth et al. (2007), Oke et al. (2005) studied the effect of P fertilizer on the quality of tomato under field conditions for three consecutive years, by evaluating the pH, the acidity, the lycopene, the vitamin C content and also the flavour volatiles. They noted that the influence of P application on several of the quality parameters mentioned above was marginal, while climatic conditions had a more predominant effect. Organic acids and sugar comprise the majority of the total dry matter content of tomatoes (Malundo et al., 1999). The “reducing type” of sugars and organic acids are significant components of fruits, determining the sweet- and the sour taste of the tomatoes, respectively. Their concentration may also affect flavours acceptability (Salles et al., 2003). Tomato fruits harvested at the same time from the bioeffector-treated plots had a more balanced acid-sugar ratio and the control had higher level of organic acid concentration. The well-balanced acid-sugar ratio appreciably increases the food quality and tasty value of the tomato fruits.

On the bases of this study we found that phosphorus mobilizer microorganisms can be successfully used as bio-fertilizers in ecological farming systems, since through applying them soluble phosphorus of the soil might be increased under certain environmental conditions. Phosphorus content of the soil was higher as a result of the used bioeffector inoculation, presumably capable for phosphorus mobilization. As a consequence, the nutritional and food quality and tasty value of tomato fruits (the acid-TSS ratio) have changed to a more favourable, tasteful direction. A tastier, more marketable food was produced by an ecological organic way. Governed by the principles of sustainable farming methods, the application of artificial agrochemicals can be reduced, including also the inorganic phosphorus fertilizer application. Eco-friendly, natural bio-fertilizers and combined bioeffective solutions might play important role in the sustainable agri-/horticultural practices.

Acknowledgements. The project was supported by Eu-Kp7 Biofector (www.biofector.info) „Resource preservation by application of bioeffectors in European crop production” (GA 312117) and the PIAC_13-1-2013-0274 Hungarian “Biochar-EM” projects. Support for providing the bioeffector products are highly acknowledged for the producers.

(Received 10th Apr 2017; accepted 11th Aug 2017)

Abstract. We used spectroradiometry to rapidly and nondestructively predict the nicotine content in flue-cured tobacco leaves and obtained hyperspectral images of tobacco leaves during the squaring development stage at field conditions. We tested the nicotine content in the lab and analyzed correlations between 28 hyperspectral characteristic parameters and the nicotine content of tobacco leaves to establish inversion models. The result showed that (SDr−Sy)/(SDr+Sy), Rg/ Ro, and (Rg−Ro)/(Rg+Ro) provided good correlations for the nicotine content; an inversion model based on (SDr−Sy)/(SDr+Sy) in relation to the nicotine content, $Y=-4.2628+5.8974X_{(SDr-Sy)/(SDr+Sy)} -1.3260X_{(SDr-Sy)/(SDr+Sy)}2$, and a multiple regression model based on Rg/Ro, (SDr− Sy)/(SDr+Sy) in relation to the nicotine content, $Y=-0.4753+1.6982\ X_{(SDr-Sy)/(SDr+Sy)} -0.1616X_{Rg/Ro}$, could be used to predict the nicotine content of flue-cured tobacco leaves during the squaring stage.
Keywords: *flue-cured tobacco, spectral reflectance, chemical composition, inversion model, prediction*

Introduction

Tobacco was used in smoking products and nicotine was the most important chemical that influences the quality of tobacco, and it causes aphysiological dependence (Xu et al., 2003; Li et al., 2007). The nicotine content in tobacco leaves was an important indicator for the quality of the raw tobacco material; thus, it must be monitored to maintain a consistent and stable cigarette quality (Yan et al., 2001; Weeks et al., 1995).

It was a timely, convenient and nondestructive monitoring method to use hyperspectral reflectance to predict nicotine content in tobacco leaves (Xing et al., 2016). Near-infrared analysis was currently the most convenient way to detect the nicotine content after baking (Qiao, 2015). However, there was no monitoring method that can be applied to large tobacco fields. Many studies have examined the biochemical components and nutrient elements based on reflection spectral characteristics (Tang et al., 2003; Tong et al., 1997; Shibayama and Akiyama, 1989, 1991) and accordingly hyperspectral inversion prediction model was established. The results show that the optimum predicted method for nicotine content in tobacco leaves was the linear fitting of the two order differential of 1135nm reflectance (Li et al., 2006a). It was feasible to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_14191426

predict the main chemical composition of a crop using hyperspectral images (Su et al., 2013; Zhao et al., 2014). However, most hyperspectral data was obtained in a controlled environment (Fang et al., 2013; Wang et al., 2011; Zhang and Zhao, 2000) hence, the inversion model and application effect have some limitations. So, there was still no effective and timely monitoring means for large areas of tobacco leaves. We selected a relatively concentrated producing area to examine the relationship between the hyperspectral parameter and the nicotine content in flue-cured tobacco under natural conditions. We set up an inversion model to predict the nicotine content in flue-cured tobacco leaves. We believe that the experiments will provide a good foundation for predicting nicotine content of large-forecast tobacco.

Materials and Methods

Study area

The study was carried out in a relatively concentrated flue-cured tobacco production area of Lin-yi, China. The study area was located in in the northern part of Yishui county, Shandong Province (Latitude35°36′～36°13, longitude 118°13′～119°03′). The topography of study area was relatively unitary, and tobacco planting was carried out by the unified organization of the tobacco companies, unified management, unified planting, unified fertilization. Flue-cured tobacco varieties was NC102.

Sampling design

A total of 100 spatially isolated tobacco plants were sampled to determine their leaf-level nicotine content, of which 70 samples were used for modeling, and 30 samples were used. We identified individual tobacco sample locations by Gridding method. Depended on the green depth of tobacco leaves, locating these points in the field, and then selecting the nearest “suitable” tobacco plant. For the purpose of this study, thesanples divided into three groups based on the color depth, which represents nitrogen under nutrition, normal nutrition,or nitrogen over nutrition. All data were recorded at midday (10:00–14:30, GMT+8) under clear skies and windless conditions.

Live tobacco measurements

Green-leaf samples were collected from each tobacco plant. Reflectance spectra (350～2500 nm) were collected for optically dense ground leaf samples using a high-intensity contact probe attachment (Analytical Spectral Devices (ASD) Inc., Boulder, CO, USA). The spectral resolutions of the instrument are 3 and 10 nm and the sampling intervals are 1.4 and 3.0 nm in the 350～1000 and 1000～2500 nm regions, respectively. The samples were killed at 105 °C for 15 min and then oven dried (60 °C for 72 h), passed through a 1-mm mesh screen, and weighed to the nearest 0.1 mg. The leaf-level nicotine concentrations (grams of N/100 g sample) of the oven dried ground foliage were determined using a LECO TruSpec CN analyzer (St. Joseph, MI, USA).For each sample, a series of twenty replicates were obtained, and the probe was then re-calibrated using a white reflectance cap accessory available from the manufacturer.

DOI: http://dx.doi.org/10.15666/aeer/1504_14191426

Spectral data processing

Leaf-level reflectance data were transformed using standard derivative analysis and continuum removal methodologies (Xiao, 1998). Both transformations were applied directly to the spectrometer data and/or to a smoothed version of the spectrometer data. We opted to smooth the spectrometer data by resampling using coarser HyMap sensor channel configurations (472～2488 nm; 15～20 μm bandpass and sampling interval) because we are familiar with the sensor and the HyMap imagery has been successfully used for remote sensing of foliar biochemistry. Standard derivative analysis was implemented by calculating first derivative reflectance (FDR) values for log-transformed reflectance data (log10 (1/R), where R was reflectance) using the ViewSpec Pro software (version 6.0, ASD).The hyperspectral indices were chosen according to previous studies(Huang et al., 2014; Liang et al., 2013; Li et al., 2006b; Deng et al., 2008; Wang et al., 2011; Xia et al., 2009; Hu et al., 2001; Breuer and Pavan, 1955; Nevalainen et al., 2014; Li et al., 2013; Yang et al., 2011) and are presented in *Table 1*. The related coefficients between the nicotine content and vegetation index were calculated using Data Processing System (DPS) software (Canfield Clinical Systems, Fairfield, New Jersey).A model fitting effect was tested using the relative error (RE), determination coefficient (R^2), and root-mean-square error (RMSE).

Results

Correlation analysis for tobacco leaf nicotine content and high spectral index

A significant correlation was observed between the six indexes of the tobacco leaves and the nicotine content (*Table 1*). The correlation coefficients for five hyperspectral indices and the nicotine content of tobacco leaves were extremely significant. The absolute value of the correlation coefficient between the (SDr−Sy)/(SDr+Sy) index and the tobacco leaf nicotine content was above 0.80. The absolute values of Rg/Ro, (Rg−Ro)/(Rg+Ro), and the nicotine content of the tobacco leaves were all above 0.40.

Establishment and testing of the nicotine content estimation model for tobacco leaves

The parameters for the correlation coefficient of the nicotine content in different growth stages for the tobacco leaves (independent variables) were extremely significant. A linear function ($y=a+bx$), power function ($y=ax^b$), logarithmic function ($y=a+b\ln(x)$), quadratic function ($y=a+bx+cx^2$), exponential function ($y=ae^{bx}$), and negative exponential function ($y=a/(1+\exp(b+cx))$)were chosen as mold functions to establish a tobacco leaf nicotine content inversion model (where y represents the nicotine content of the tobacco leaves and x represents the hyperspectral eigen values; a, b, and c are constants). Then, the Root Mean Square Error (RMSE) and Relative Error (RE) were selected to evaluate the fitting effect between the estimated value and the measured value to verify the accuracy and applicability of the model. Two hyperspectral indices, Rg/Ro and (SDr−Sy)/(SDr+Sy), with high correlation coefficients were chosen as the independent variables for the estimation model to establish the univariate estimation model and multiple regression estimation model.

Establishment and testing of the univariate estimation model for nicotine content in tobacco leaves

The inversion model was established using the hyperspectral indices, Rg/Ro and (SDr−Sy)/(SDr+Sy), as independent variables and nicotine content as the dependent variable (*Table 2*).

Table 2. *Nicotine concentration retrieval model for tobacco leaves during the squaring development stage and the test results*

Index	Estimation model	R^2 (n=70)
(SDr−Sy)/(SDr+Sy)	$y = -1.1977+1.7989x$	0.7582^{**}
	$y = 2.2427/(1+\exp(6.1463-4.7476x))$	0.7955^{**}
	$y = 0.7597x^{1.6421}$	0.7210^{**}
	$y = 0.3258\times\exp(0.9926x)$	0.6667^{**}
	$y = -4.2628+5.8974x-1.3260x^2$	0.8112^{**}
Rg/Ro	$y = 3.0047-0.4399x$	0.1724
	$y = 2.1130/(1+\exp(-4.5275+1.0456x))$	0.1784
	$y = 4.7454x^{-0.9553}$	0.1557
	$y = 4.0603\times\exp(-0.2945x)$	0.1669
	$y = 2.3793-0.0833x-0.0498x^2$	0.1734

From the data in *Table 2*, the decisive coefficients of the univariate inversion model (Eq. 1) and (Eq. 2) with the hyperspectral parameter (SDr−Sy)/(SDr+Sy) as the independent variable were all significant.

$$Y = 2.2427/(1+\exp(6.1463-4.7476X_{(SDr-Sy)/(SDr+Sy)})) \quad \text{(Eq. 1)}$$

$$Y = -4.2628 + 5.8974X_{(SDr-Sy)/(SDr+Sy)} - 1.3260X_{(SDr-Sy)/(SDr+Sy)^2} \quad \text{(Eq. 2)}$$

The estimation model was tested using the nicotine content data from 30 tobacco leaf samples, and the estimated RMSE and RE (%) were used to evaluate the fitting effect of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_14191426

the model. The R^2 value was high and the RMSE and RE (%) values were small for the inversion model (Eq. 1) and (Eq. 2).

Establishment and test of the multiple regression model for nicotine content in tobacco leaves

The multiple regression model was established using Rg/Ro and (SDr−Sy)/(SDr+Sy) models (with higher correlation coefficients) as the independent variables. The regression equation was (Eq. 3).

$$Y = (-0.4753 + 1.6982X_{(SDr-Sy)/(SDr+Sy)} - 0.1616X_{Rg/Ro}) \quad \text{(Eq. 3)}$$

F = 135.7792, p = 0.0000, R = 0.8827, and R^2= 0.7791 (adjusted correlation coefficient, Ra = 0.8794; adjusted coefficient of determination, Ra^2 = 0.7734). The nicotine content of the tobacco leaves was predicted using the model (Eq. 3) and the correlation coefficient between the predicted value and the measured value was 0.8841; RMSE =0.2335 for the prediction equation and RE = 15.47%.

Optimum estimation model of nicotine content in tobacco leaves

Single-variable prediction model

Based on the above analysis, the nicotine content of the tobacco leaves from the single-variable prediction model was Eq.2.

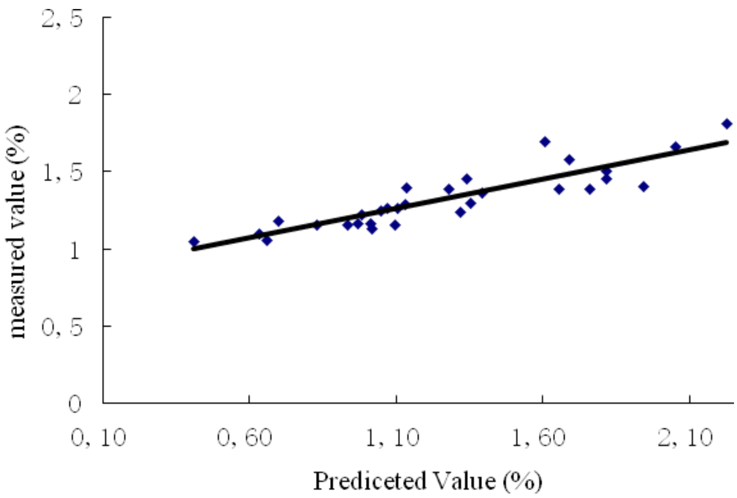

Figure 1. *Validation result of estimation model of nicotine content of tobacco*

The estimated RMSE and RE (%) were used to evaluate the fitting effect of the model. The correlation coefficient of the fitted equation was 0.8148. The RMSE of the fitted equation was 0.2272 and the RE was 14.42%. Further tests for the accuracy of the model (Eq. 2), provided the measured nicotine value and the estimated value of the 1:1 diagram. The correlation coefficient between the predicted value and the measured value was 0.7894. The model provides good precision and can be used to predict the nicotine content in tobacco leaves.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_14191426

Multivariate prediction model

Based on the above analysis, the nicotine content of tobacco leaves from the multivariate prediction model was Eq.3.

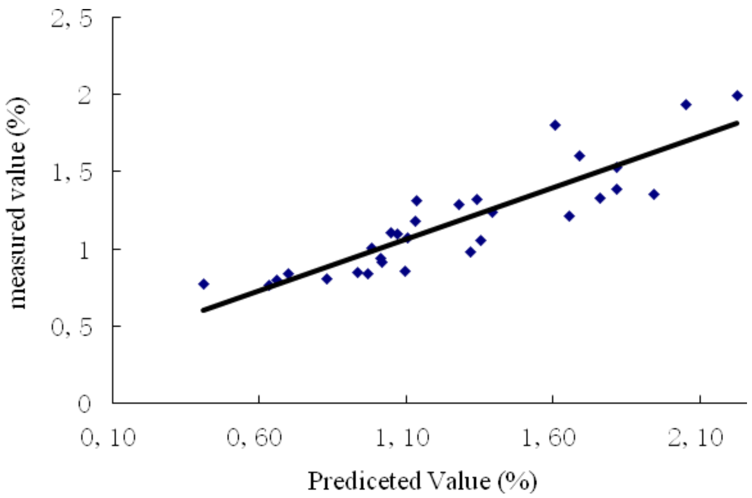

Figure 2. *Validation result of estimation model of nicotine content of tobacco*

The estimated RMSE and RE (%) were used to evaluate the fitting effect of the model. The correlation coefficient of the fitted equation was 0.8841. The RMSE of the fitted equation was 0.2335 and the RE was 15.47%. Further tests for the accuracy of the model (Eq. 3), provided the measured nicotine value and the estimated value of the 1:1 diagram. The correlation coefficient between the predicted value and the measured value was 0.7816. The model provides good precision and can be used to predict the nicotine content in tobacco leaves.

Discussion

Although there are technical standards and uniform requirements for tobacco cultivation in China, annual and regional differences of the nicotine content are significant because of the effects of natural precipitation, soil fertility, and field management measures. Nicotine was the most important tobacco leaf quality factor, and its content determines the intrinsic quality of tobacco leaves and the status of the formula. Industrial enterprises need to predict the main chemical components (especially nicotine content) of tobacco leaves before tobacco procurement, and reduce annual chemical composition differences of tobacco leaves by allocating different tobacco production plans to maintain a stable quality for tobacco brands. This study could only predict the nicotine content of fresh tobacco leaves by screening hyperspectral parameters, establishing models, and optimizing the validation methods. However, we did not establish the relationship between the spectral characteristic parameters and the nicotine content of the initial flue-cured tobacco after preparation. The method could not provide a practical basis for the changes of the cigarette tobacco leaf and recipe directly from the operational level. Future work would include exploring

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_14191426

the precise labeling of hyperspectral tobacco leaves, studying the nicotine content of the first flue-cured tobacco, establishing an estimation model, and predicting the nicotine content of the early flue-cured tobacco to provide the basis for tobacco leaf dispensing and formulation allocation to the tobacco industry.

Conclusion

Using tobacco plants with different nicotine contents growing in natural field conditions, we analysed its hyperspectral characteristics, the Correlation between hyperspectral parameters and nicotine content. Hyperspectral parameters related to nicotine content in tobacco leaves have been preliminarily established and A prediction model of nicotine content of tobacco leaves with high precision was established. The results show that there was a high correlation between the tobacco nicotine content and the (SDr− Sy)/(SDr+Sy), Rg/Ro, and (Rg− Ro)/(Rg+Ro) parameters. The equations for the univariate estimation models (1) and (2), can be used to predict the nicotine content of flue-cured tobacco leaves. The multivariate regressive estimation model equation (3) was established using hyperspectral parameters Rg/Ro and (SDr−Sy)/(SDr+Sy) and can be used to predict the nicotine content in flue-cured tobacco leaves. The results of this study and the estimation model are closer to the actual situation for the flue-cured tobacco growth and development environment, and can provide a reference for the prediction of tobacco nicotine content in large areas.

(Received 15th May 2017; accepted 25th Jul 2017)

Abstract. Out of the 24 genotypes of Indian mustard 63 % showed increase in total seed nitrogen content after 80 kg N (N80) application while 37 % showed a decrease compared to control (N0). In some genotypes the increase in total seed nitrogen content under N80 had no influence on total soluble protein. About 88 % genotypes showed reduction in crude fiber by 1.10 % (GM-2) to 35.6 % (DRMR-IJ-31) and in all 24 genotypes soluble sugars also reduced by 8% (Maya) to 80% (HB-9912) suggesting the influence of N application on digestibility of meal. Profiling of seed storage proteins showed differences in banding patterns in treated samples with prominent changes in α and β chains of cruciferin. In case of SFA and ω6:ω3 ratio, 50% of genotypes showed increase while 50 % genotypes showed a decrease in their SFA and ω6:ω3 ratio compared to control. Oil stability index also increased in 63 % of the genotypes under N80. Undesirable Erucic acid was found to increase in 58 % of the genotypes by 0.98% (DHR-991) to 38.31% (HB-9902) and in rest of the 42 % it reduced by 1.14 % (DRMR-IJ31) to 22.55 % (NRCDR-2) over control (N0).
Keywords: *total phenol, ascorbic acid, total soluble sugars, crude fiber, seed storage protein*

Introduction

Indian mustard is a winter oilseed crop largely grown in semi-arid regions of northern India. It is considered healthy and ideal for cooking because of low saturated fatty acid (SFA), high monounsaturated fatty acid (MUFA), moderate polyunsaturated fatty acid (PUFA) content, ideal ω6/ω3 ratio, low acid value, low saponification value and high smoke point. Besides high quality oil, the seed meal has high protein content which is ideal for animal feed or even fit for human consumption (Wanasundara, 2011). The high protein content also implies a high absorption of nitrogen from the soil which makes nitrogen fertilizers very important for this crop.

Plants take up nitrogen in the form of nitrate, as well as ammonium, this in turn can modulate the uptake of other anions and cations causing a change in the primary and secondary metabolic process and consequently the quality of oil and meal. Optimization of nitrogen application is important for the synthesis of C-based phytochemicals, including natural antioxidants such as phenolic groups (Björkman et al., 2011). Some

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_14271445

reports have shown decrease in phenol content under higher doses of nitrogen fertilizers (Li et al., 2008; Giorgi et al., 2009; Zaghdoud et al., 2016) while Tavarini et al. (2015) have observed increase in phenolic content up to a certain level of nitrogen dose. Likewise, ascorbic acid content is found to vary with nitrogen treatments in different Brassica crops like cabbage (Roni et al., 2015) and cauliflower (Lisiewska and Kmiecik, 1996). Ascorbic acid being an essential vitamin which needs to be obtained through diet is very important as an antioxidant and for synthesis of collagens L-carnitine and conversion of dopamine to norepinephrine.

There is one report of soluble sugars such as stachyose, raffinose and sucrose in diet causing flatulence in animals and digestive problems in poultry (Hartwig et al., 1997). Since seed meal from mustard has been suggested as a protein source for livestock, aquaculture and also for human consumption (Wanasundara, 2011), it is also necessary to look for potential anti nutritional factors in it. Also more emphasis should be given to soluble proteins than total proteins as they add more value to the seed meal. For example it is important to know the amount of storage proteins like albumin and globulin as they can be used for fortification of food products. Low fiber meal is preferred for animal feed because it increases the digestibility and palatability of the feed. The low metabolizable energy of mustard seed meal (2000 kcal/kg) compared to that of soybean (2230 kcal/kg) is one of the reasons for considering mustard seed meal as inferior (Suprianto, 2014).

Increasing population and dwindling natural resources have promoted the excess use of fertilizers. High yielding varieties of crops also demand heavy use of fertilizers which results in irreversible degradation of soil and natural resources. Excessive use of fertilizers also contributes to global warming. There have been numerous studies that relate fertilizer use and its effect on yield and oil content of oilseed Brassica (Joshi et al., 1998; Parmar and Parmar, 2012). However, little is known about the effect of fertilizer application on chemical composition of oil and seed meal.

Keeping this in view, in this study we have tried to see the effect of nitrogen fertilizer on the nutritional quality of oil and seed meal. In many of the mustard growing regions in India, use of 80 kg N/ha has been recommended to enhance the productivity of mustard (Shekhawat et al., 2012). No data to our knowledge are available on the study of nutritional composition of oil and meal in relation with nitrogen fertilizer application in Indian mustard. Such studies can open new avenues for future research and proper documentation pertaining to Indian mustard.

Materials and methods

Experimental site

The experiment was conducted at ICAR-Directorate of Rapeseed Mustard Research (DRMR) Bharatpur (27°11’N Lat. and 77°27’E Long.); India, during 2013-15. The climate of the region is predominantly semi-arid with long hot summers, intermittent short rainy period due to south-west monsoon and almost 5 month long winter when average temperature drops to below 22.5°C. The winter season often coincides with one or two rains due to western disturbances. The soils of the region are mainly coarse to fine loamy, deep, well drained Inceptisols and fallow-mustard is the predominant cropping system of the region. In general, the soils of the experimental site was alkaline (pH 8.1), low in exchangeable salts (EC 0.6 dS/m), organic carbon content (2.6 g/kg), available N (95.4 kg N/ha $KMnO_4$ oxidisable) and available P (5.4 kg P/ha 0.5N-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_14271445

$NaHCO_3$ extractable); and high in available K (267 kg 1N-NH_4OAC exchangeable K_20/ha). Initially, the field was put under exhaustive pearl millet (*Pennisetum glaucum*) – Indian mustard without any external fertilizer inputs for continuous three pre-experimentation years. *Pennisetum glaucum* was sown in the first week of July every year followed by Indian mustard var. Rohini.

Experimental design

During 2013-14, a replicated trial in split plot design keeping two nitrogen environments (0 and 80 kg N/ha) in main plot and 108 oilseed Brassica (OSB) genotypes in sub-plot was conducted to screen out low nitrogen requiring germplasms. Based on field and yield attributes, 24 genotypes were found promising. These selected 24 genotypes were further evaluated for detailed growth, yield and biochemical studies during 2014-15 under two distinct N environments. The genotypes were sown at 5 cm depth in 30 cm row spacing with the help of manual plough in subplots (4.5 m x 5.0 m) during second fortnight of October 2014. The plant to plant distance was maintained at 10-15 cm by thinning at 20-25 days after sowing (DAS). As per the treatment, half dose of nitrogen as urea, full recommended dose of phosphorus in the form of single super phosphate were applied at the time of sowing, and the remaining nitrogen in the form of urea was top dressed after the first irrigation. At maturity, 5 plants were randomly selected from the second and third row from the left side of the plot for recording growth and yield attributes. Harvesting was done by avoiding boarder area and observation lines manually by cutting at surface level using sickles to estimate biological and economic yields. Further, three samples from each plots were collected for all biochemical analysis. Each biochemical parameters for accuracy of data were done in three technical replicates.

Total nitrogen

The total nitrogen was estimated by miro-kjeldahl (Pro-Nitro A Model of JP Selecta, Spain) method as procedure suggested by AOAC (1955).

Fatty acid profiling

Fatty acid profiling was carried out as described by Paquot and Hautfenne, (1987) with little modification. A Nucon model 5765 gas chromatograph with SP-2300 (2%) + SP-2310 (3%) packed silica column was used. The programme was set at N_2 flow rate: 30 ml/min, H_2 flow rate: 30 ml/min, Zero air flow rate: 300 ml/min, Injector temp: 240 ^oC and Detector (FID) temp: 250 ^oC. Individual fatty acids were compared to the retention time of standard methyl esters of fatty acids.

Stability index of oils

Stability index of oils were calculated empirically by the ratio of MUFA: PUFA (Chauhan et al., 2010).

Defattening of seed meal

Oil was extracted from ground seeds after homogenizing with n-hexane using pestle and mortar at room temperature. This was repeated for three to four times to ensure

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_14271445

complete extraction of oil. The seed meal was dried till hexane is completely removed and stored at 4 ^{o}C.

Total phenols and crude fiber

Total phenols and crude fiber were estimated by non destructive method using FTNIR-Bruker (model Matrix-1) as described by Bala and Singh (2013).

Vitamin C (Ascorbic Acid)

Ascorbic acid was estimated using the titrimetric method described by Ranganna (1986). 0.1g of the defatted seed meal was homogenized with 3% HPO_3 and final volume made to 10 ml. The supernatant was collected into glass vials after centrifugation for 10 min at 5000 rpm. Aliquot of the extract was taken in a 25-50 ml conical flask and titrated against the standardized dye (2,6 -dichlorophenol indophenol) till persistent pink color was detected that lasted for 5s. Vitamin C was calculated using the following formula.

$$\text{mg of ascorbic acid}/100\text{ g} = \frac{\text{Titre } x \text{ Dye Factor } x \text{ Final volume made up}}{\text{Aliquot of extract taken } x \text{ Weight of sample taken}}$$

Total antioxidant capacity

Total antioxidant capacity (TAC) was determined as per Prieto et al. (1999). 100 mg of defatted seed meal was dissolved in 80 % methanol overnight. The supernatant was collected after centrifuging at 4000 rpm for 10 min and final volume was raised to 2 ml. Reduction of Mo(VI) to Mo (V) and the subsequent formation of green colour complex was measured by spectrophotometer (Labomed UV-VIS Double beam UVD-3500) at 695 nm and is expressed as ascorbic acid equivalent (AAE).

Total soluble sugars

Total soluble sugars were estimated as per protocol of Hansen and Møller (1975). 100 mg of defatted seed meal was homogenized with 100% acetone by vortexing. After centrifugation the residue was washed with hot ethanol (80%). This was repeated twice. Supernatant was collected and final volume was raised to 2 ml with 80% ethanol. This extract was used for the estimation of total soluble sugar by Anthrone method whose absorbance was taken at 620 nm.

Total soluble protein

Soluble protein content in the defatted seeds was estimated by the method of Lowry et al. (1951) after precipitation with trichloroacetic acid. Soluble protein was resuspended in laemmili lysis buffer denatured at 95^{0}C for 4 min.

Gel electrophoresis

SDS-PAGE of seed storage protein was carried out in a 12 % Polyacrylamide gel in a discontinuous buffer system. 15 µl (20 µg/ µl) was loaded in each well of the stacking gel. Wide range prestained protein ladder was run as reference. The gel was stained with solution containing of 2 % Coomassie Brilliant Blue, followed by destaining after 1 h with mixture of methanol, acetic acid and water (5:1:4).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_14271445

Statistical analysis

The data obtained under different treatments with respect to various parameters were subjected to Analysis of Variance (ANOVA) using SAS 9.3 software package.

Pair-wise comparisons on the least squares mean (LSMEANS) were performed using the Tukey's honest significant difference (HSD) test.

Results and discussion

Application of nitrogen influences the nutritional quality of meal

Total nitrogen content in seed

Studies on the effect of nitrogen on quality traits have been carried out in leaves of *B. juncea* and *B. rapa* (Fallovo et al., 2011), cabbage (Leja et al., 2007), curly kale (Groenbaek et al., 2016) and broccoli (Zaghdoud et al., 2016), but not many reports on effect of applied nitrogen on quality of seed and oil are available. In our study, total seed nitrogen content ranged from 2.86 % (Maya and RL-1359) to 3.95 % (EC399300) at zero nitrogen (N0) application and 3.1% (RL-1359) to 4.3 % (IC212031) at 80 kg N/ha (N80) (*Table 1*). About 63 % of the genotypes showed increase in total seed nitrogen by 3 % (DRMR-IJ-31) to 34.0 % (NRCDR-2) over N0.The increase in total seed N content was proportional to the increase in total soluble protein which varied from 1% (Maya) to 34 % (NRCDR-2), with a confirmation of a positive correlation (r=0.33, p0.019) (*Table 2.a*). Though, exceptions in some genotypes showed reduction in soluble protein by 4 % (78-1-1-1) to 16% (NATP-124 and RGN-55) (*Table 1*). The decrease in soluble protein, even when there is increase in nitrogen intake, could be due to the partition of nitrogen towards the synthesis of other carbon containing compounds in TCA cycle as it shares common substrates. This is substantiated, by increase in ascorbic acid (14. 29 % to 50 %) and phenol (1.14 % to 14 %) content (*Table 1*). However, rest of the 37 % genotypes showed decrease in seed N content at N80 by 5.6 % (HB9916) to 20.2 % (EC399300) over N0. These are the genotypes that also showed a reduction in soluble proteins from 5 % (78-1-1-1, NRCHB-101, HB9916) to 16 % (RGN-55) and could be less responsive to nitrogen uptake. According to Chopin et al. (2007) in *Arabidopsis* there are high and low affinity nitrate transporters that regulate the uptake of nitrogen into plants. Our study also found genotypes such as EC399294 (5%), EC399307 (14%) and GM-2 (7%) that showed an increase in soluble proteins in spite of low content nitrogen. This interplay of nitrogen fertilization × genotype × quality trait needs more in-depth investigation.

Total phenol content

Natural antioxidants and their use as food additives or supplements has been a hot topic in recent years. Members of Brassica family are known to possess health promoting phytochemicals, especially those with antioxidant properties. Among the phytochemicals, phenolic compounds are very important due to their antioxidant properties (Björkman et al., 2011).

The total phenol content in our study ranged from 1.35 % (RL-1359) to 2.26 % (Rohini) under N0 and from 1.46 % (HB-9902) to 2.18 % (DRMR-IJ-31) under N80 (*Table1*). There are reports of decrease in phenol content under higher doses of nitrogen fertilizer (Li et al., 2008, Giorgi et al., 2009; Zaghdoud et al., 2016) which was also

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_14271445

observed in our study as the phenol content reduced by 0.83 % (QM-16) to 21.83 % (Rohini) in about 33% of genotypes (*Table 1*). This reduction in phenol content as reported by Ibrahim et al. (2011) could be due to inhibition of phenylalanine ammonia lyase (PAL) at higher levels of nitrogen or may be due to diversion of metabolites in the direction of protein synthesis. As expected, 63 % of our genotypes increased in phenol content by 1.14 % (GM-2) to 14.01 % (RL-1359) over N0 application (Table1). Our studies is in tune with work by Groenbaek et al. (2016) in traditional kale. Surprisingly, 4 % of our genotype showed no change in phenol content after N80 application. It is interesting to note within the same species the effect of nitrogen can have varied effects on the phenol content.

This discrepancy between different reports could be due to the differences in the form of nitrogen fertilizers (nitrate or ammoniacal) applied. Fallovo et al. (2011) reported increase in phenol content in the leaves of *B. juncea* and *B. rapa* due to forms of N fertilizer. Leja et al. (2007) observed decrease in concentration of phenolic compounds in cabbage head which were fertilized using calcium nitrate, ammonium sulphate, ammonium nitrate and urea by broadcasting. However, Smolen and Sady (2009) observed rise in phenolic concentration in carrots irrespective of the type and mode of nitrogen application. Sousa et al. (2008) have reported the profile of phenolic compounds to have varied even within the plant organ of the same Brassica species.

Our study suggests that variation in total phenol content is due to genetic variability that determines the optimization of nitrogen uptake and in turn alters the biochemical composition. According to Nguyen and Niemeyer (2008) in basil (*Ocimum basillicum* L.) phenolic content is a genotype dependent property. In this study more number of cultivars were analysed unlike the works reported previously in one or two cultivars.

Vitamin C (Ascorbic acid)

Another important natural antioxidant studied was ascorbic acid, an essential nutrient usually obtained from fruits and vegetables. The biological functions of ascorbic acid include radical scavenging, electron transport in plasma membrane and as cofactor in biosynthesis of collagen and conversion of dopamine to norepinephrine. It can scavenge superoxide and hydroxyl radicals besides regenerating α-tocopherol.

Our study on Indian mustard genotypes, showed significant variation in ascorbic acid content from 43mg/100g to 172 mg/100g seed meal (*Table 1*). However, about 58 % of the genotypes showed ascorbic acid content to increase by 14.29% (HB9916) to 50% (EC399307, NATP-124, NRCDR-2, BEC-16), about 21 % genotypes showed decrease in ascorbic acid content by 20 % (QM-16) to 100 % (HB-9902) and the rest 21 % of the genotypes did not show any change. Increase in ascorbic acid content upon nitrogen treatment has also been reported in cabbage (De and Shankar, 1987). Decrease in ascorbic acid in cabbage (Freyman et al., 1991) and cauliflower (lisiewska and Kmiecik, 1996) have also been reported. The variation in ascorbic acid content could be due to their sensitivity to the enzyme GDP-Mannose pyrophosphorylase, an enzyme essential for the synthesis of metabolite GDP-Mannose, a precursor of ascorbic acid which has been confirmed in model plant to be hypersensitive to NH_4^+ and is a genetic determinant for NH_4^+ sensitivity (Qin et al., 2008). As we have also observed not all genotypes studied had the same levels of nitrogen in seed. This could be the reason for differences in ascorbic acid among the different genotypes. Our study is the first of its kind done in Indian mustard and more enquiries are needed to prove whether there is any dose dependent effect of nitrogen application on ascorbic acid content in seed meal.

Total antioxidant capacity

Phenolic compounds and ascorbic acid are known for its antioxidant properties which are highly desirable for improving the keeping quality of meal as well as for providing health benefits. Seed meal extracts of 24 genotypes of Indian mustard showed TAC to range between 20 mg/g AAE (HB-9916) to 48 mg/g AAE (Rohini) under N0 and between 21.83 mg/g AAE (HB9912) to 54 mg/g AAE (EC399307) under N80 application (*Table 1*). We observed, 58 % of genotypes showed TAC to increase and 42 % of genotypes showed reduction in TAC over N0. It may be noted that the genotypes in which the TAC was lowered also showed concomitant reduction in ascorbic acid. According to Nguyen and Niemeyer (2008) reduction in TAC upon treatment with NO_3^- correlated with phenol content. Aires et al. (2011) examined the potential antioxidant activities of ascorbic acid, total flavanoid and total phenol in Brassica vegetables and concluded that among the naturally occurring antioxidants, ascorbic acid contributed the maximum towards antioxidant capacity. Our findings are in agreement with this. Ochoa-Velaso et al. (2016) have reported that TAC was strongly influenced by ascorbic acid and phenolic content in tomatoes. The correlation between TAC with that of phenols and ascorbic acid observed in our study (r=0.316, p=0.028) is comparatively less but statistically significant (*Table 2a*).

Soluble sugars

Seed meal of *B. juncea* is comprised of about 30% carbohydrates which includes many beneficial as well as harmful components. One report showed soluble sugars such as stachyose and raffinose are harmful as it causes flatulence in animals and digestive problems in poultry (Hartwig et al., 1997). In this study, we evaluated the effect of N80 treatment on soluble sugar content. The total soluble sugar ranged between 74.44 mg/g (EC399300) to 546.71 mg/g (DHR-991) under N0. Under, N80 application it ranged from 60 mg/g (EC399307, HB9902) to 404 mg/g (DHR-991). All genotypes reported reduction in total soluble sugar level ranging from 8 % (Maya) to 80% (HB-9912). Similar observations were made by Smolen and Sady (2009) in carrots (*Daucus carota* L.). Further, Krober and Cartter (1962) had shown reduction in soluble sugar content in four cultivars of soybean at higher nitrogen input with a concomitant increase in protein content. Higher nitrogen levels may divert the biosynthetic process as towards the amino acids and proteins consequently reducing the production of soluble carbohydrates. This may be true in 63% genotypes having inverse relationship between soluble sugars and seed nitrogen content. But, contrasting results was observed in 37 % of genotypes where they experienced reduction in both parameters after N80 treatment.

Cruder fiber

Fiber is primarily derived from cell walls and is made up of cellulose, hemicelluloses and lignin. High fiber in animal's diet is undesirable as it would dilute the availability of energy, proteins and minerals such as Mn and Zn (Suprianto, 2014). As an animal feed, the seed meal should be preferably rich in protein and energy rich carbohydrates rather than crude fiber that only add to the bulk and cause digestive disorders. The crude fiber content in the genotypes under N0 ranged between 7.03 % (Rohini) and 12.02 % (RL-1359 and NRCDR-2) whereas; it ranged from 5.69 % (DRMR-IJ-31) to 11.33% (NDRE-7) at N80 application (*Table 1*). 88 % of the genotypes showed reduction in crude fiber content by 1.10 % (GM-2) to 35 % (DRMR-IJ-31) over N0. One report is in agreement with decrease of crude fiber content in fodder beet but it is also dependent on the type of nitrogen fertilizer (Khogali et al., 2011). Within the same experiment they observed no significant effects in maize. Similarly, in forage kale no effect on fiber content was observed (Chakwizira et al., 2015). It is quite evident that response to nitrogen application is not the same in all crops. In the present experiments about 12 % of genotypes showed increase in crude fiber content by 7 % (Rohini, HB-207) to 17.9 % (EC399294). This suggests that variations in seed nitrogen upon N80 application leads to variation in crude fiber and is genotype dependent.

Total soluble protein and seed storage protein

The two major seed storage proteins of oilseed *Brassica* are the 2S albumin called napin and the 11S or cruciferin a legume type globulin having heteromeric structure. Cruciferin, rich in nitrogen containing amino acids have role in modulating nitric oxide signaling which is potential regulator of nutrient metabolism (Wanasundara, 2011), while albumin rich in sulphur containing amino acids have been annotated with several allergic responses such as celiac disease and Baker's asthma (Wanasundara, 2011). However, not all 2S

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_14271445

albumin causes allergy and it affects only a minority of the population (Wanasundara, 2011). None the less, both storage proteins have found its place in industry as they are highly surface active in monolayers and emulsion formation (Wanasundara, 2011).

Profiling of seed storage proteins with respect to nitrogen treatment has never been done in Indian mustard. We have profiled the seed storage proteins in 24 genotypes of *B. juncea* using SDS–PAGE to see the effect of nitrogen application on the protein profile (*Fig. 1*). Molecular weights of the proteins were compared to previous reports (Wanasundara, 2011, Wanasundara et al., 2012). Our results showed genotypes DRMR-IJ-31, HB-207, HB-9902, NATP-124, RGN-55, NRCHB-506 had low expression of 2S albumin in case of nitrogen treatment (*Fig. 1*). According to Wanasundara et al. (2012) molecular weight of cruciferin ranged between 18.1 kDa and 31.2 kDa in *B.juncea* and that of napin between 6.5 and 12 kDa in reducing environment. But we found the corresponding band between 15 and 16 kDa for napin. This difference in molecular weight may be due to the slight modification in the protocol as we had given heat treatment only for 4 min instead of 15 min as reported earlier. We found genotypic variability in the banding patterns of α and β chains of cruceferin (*Fig 1*). According to Yu (2008) this determines the digestibility of proteins in *B. rapa* and *B. napus.* Since this is the first report in *B. juncea*, it will lead to better ideas on manipulating the meal composition for quality improvement by managing nitrogen fertilization.

Application of nitrogen influences the nutritional quality of oil

Nutritional composition of oil

There are reports on the effect of nitrogen fertilizer on improvement of oil yield and quality (Joshi et al., 1998; Paramar and Paramar, 2012) but, there are no sufficient data to support the role of nitrogen fertilizers in modifying the nutritional composition of oil in *B. juncea* genotypes. Fatty acid profiling in 24 genotypes was done under treated and controlled conditions (*Table 3*). Our results showed, SFA (Palmitic +Stearic acid) content to be within 1.37 % (RGN-55) to 5.76 % (HB-9902) at N0 and between 1.96% (HB-9916) to 4.32 % (NDRE-7) under N80 (*Table 3*). About 50 % of genotypes showed decrease in SFA and 50 % showed increase compared to control, but the rise in SFA levels were still within the permissible limit (< 7%) of healthy edible oil. Paramar and Paramar (2012) have also found a significant decrease in SFA at 50 kg/ha. Reduction in SFA is desirable as it is associated with cardiovascular diseases. Even though, SFA content of Indian mustard is within the optimum range it is possible to manipulate its level by optimizing the nitrogen application as evident from our study.

The level of MUFA (Oleic + Eicosenoic + Erucic) ranged from 50.79% (HB-9902) to 63.51% (NDRE-7) under N0 and from 54.16 % (NDRE-7) to 61.65 % (NATP-124) under N80. The levels of MUFA were found to have increased in about 58 % of genotypes by 1.02% (EC39900) to 20.46 % (HB-9902) over N0, while in the rest 42% of genotypes it decreases by 0.27 % (78-1-1-1) to 14.72 % (NDRE-7) over control.

Mustard oil contains moderate levels of PUFA that includes linoleic acid and linolenic acid (15-20 %) which is ideal range for healthy oil. They are essential fatty acids and are required for the biosynthesis of eicosapentanoic acid and docosahexanoic acid, which are beneficial to human beings. In this study, linoleic acid (ω6) ranged from 13.47 % (DHR-991) to 22.94 % (HB-9002) under N0 and 15.20% (NRCHB-506) to 22.38 % (QM-16) for N80. Since, almost all genotypes analyzed in this study are having >15% ω6 content, they can be used as potential source for extraction (Zambiazi et al., 2007). It is to be noted, about 42 % of the genotypes showed increase in ω6 by 1.23% (NRCHB-101) to 29.32 % (DHR-991) over N0. Whereas, 58 % of the genotypes showed reduction in ω6 by 0.89 % (EC399300) to 18.20 % (HB-9916) over N0 application.

T comparison lines for least Squares means of genotypes*nitrogen
LS- means with same letters are not significantly different

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_14271445

The ω3 levels were found to range between 13.62 % (DHR-991) and 22.61 % (RGN-55) under N0 while, under N80 it ranged between 13.31 % (HB-9916) to 20.49 % (IC212031). These levels are high enough (>12%) to be considered as a source for commercial extraction of ω3 according to Zambiazi et al. (2007) who reported the bench mark to be 12 %. It has been reported earlier that a dose of 60 kg/ha nitrogen fertilizer was optimum to enhance ω3 in Indian mustard (Joshi et al., 1998) but it is contradictory to our findings where we found a variation within the same species at N80. 29 % of the genotypes showed an increase in ω3 by 4.09 % (DRMR-IJ-31) to 27.77 % (DHR-991) over N0 and 71 % of the genotypes reported reduction by 0.06 % (Maya) to 29.54 % (RGN-55) over N0. Previous works have reported the effect of nitrogen only in one genotype and comparative studies have not been explored.

Generally *B. juncea* is known for having all the fatty acids in the ideal range for e.g. high levels of MUFA, low SFA, moderate PUFA, ω6:ω3 ratio of 1.2:1 (Chauhan et al., 2010). Under N0, the ω6:ω3 ranged from 0.91 (NDRE-7) to 1.23 (QM-16) and under N80, it ranged from 0.88 (DRMR-IJ31) to 1.37 (GM-2) (*Table 3*). According to various medical researchers (Simopoulos, 2012) there is so no ideal ω6:ω3 ratio that would prevent chronological diseases. The optimal ratios vary with the disease under consideration and according to their documentation, ratio beyond 10:1 was observed to have deleterious effects on health (Simopoulos, 2012). However, a low level ω6:ω3 is preferable. It was observed that under N80, 50 % of genotypes had increased the ratio by 0.88 % (HB-9912) to 57.28 % (NDRE-7) over N0. While, 50 % genotypes showed reduction in the ratio by 0.33 % (NRCDR-2) to 11.04 % (Maya) over N0.

The MUFA: PUFA ratio depicting oil stability index (OSI) ranged from 1.23 (HB-9902) to 2.20 (DHR-991) under N0 and from 1.27 (QM-16) to 2.07 (HB-9916) in N80 (*Table 3*). Most of the genotypes (96%) failed to reach the ideal range of 2 (Chauhan et al., 2010). However, under N80 about 63 % of genotypes improved in OSI by 1.81 % (GM-2) to 39.54 % (HB9902) while, the rest 37 % of the genotypes showed reduction by 0.78 % (DRMR-IJ-31) to 20.90 % (DHR-991) over N0 application.

Nutritionally undesirable erucic acid was found to exceed the recommended percentage of 2% at both N0 and N80 application (*Table 3)*. Erucic acid, under N80 observed an increase in 63 % of genotypes by 0.9 % (DHR-991) to 38.31% (HB9902) and 37 % of genotypes showed decrease by 1.14 % (DRMR-IJ 31) to 22.5 % (NRCDR-2) over N0. The variations in nitrogen levels hence contribute to the variation in oil quality as seen in case of composition of individual fatty acids.

Conclusion

This study showed N application can bring about changes in oil and seed meal quality. 63 % of the genotypes showed increase in total N content in seeds by 3 % (DRMR-IJ-31) to 34.0 % (NRCDR-2) and rest 37 % genotypes showed reduction in seed N content by 5.6 % (HB9916) to 20.2 % (EC399300) over control. These genotypes also have positive correlation to the total soluble protein content. However, some genotypes showed an inverse relationship between N and soluble protein which could be due to the flux in N to biosynthesis of other carbon compounds as observed by an increase in the case of ascorbic

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_14271445

acid content and phenol content. Ascorbic acid and total phenolic content showed a positive correlation with TAC (r=0.316, p0.028). Crude fiber and total soluble sugars were observed to decrease under N80. These reductions are desirable for increasing the digestibility and palatability of meal. Seed storage protein profiled under N80 revealed differences in the banding patterns especially in α and β chain of the cruciferin which determines the digestibility and quality of seed meal. Fatty acid profiling showed reduction of SFA and ω6:ω3 in 50 % of genotypes and 50 % of genotypes showed increase in their ratios after N treatment. 63% of genotypes showed improvement in OSI after N80 treatment. N80 application caused 63 % of the Indian mustard genotypes to increase in erucic acid. Our findings showed application of nitrogen even with recommended dose can influence biochemical changes within same species. All in all our observations suggest that nitrogen fertilizers can play a role in enhancing nutritive status of oilseed Brassica when applied in appropriate doses. Information on the effect of nitrogen application on nutritional status of oil and meal will be quite useful in quality improvement programmes.

Acknowledgements. The authors are grateful to Indian Council of Agricultural Research for providing all the necessary facilities and funding (DRMR-B7) to carry out this work. The authors are grateful to plant breeders for sharing their materials used in this study.

Conflict of interest statement. The authors do not have any conflict of interest.

Abstract. Climate change is a global concern and part of it is due to agricultural activities. Therefore, optimizing the agricultural operation is seen as a strategy to alleviate climate change effects. The purpose of this research was energy and carbon dioxide emission assessment in wheat production. To do so, first, six conventional wheat planting fields were identified in the counties of Jouybar, Ghaemshahr and Sari in Iran, in 2015. Then, through improved planting methods (based on growing low-input wheat, designed by researchers) they were compared. The identification of the field was done in a way that covered all main production methods in each county. After that, the improved and conventional methods of planting in the three counties were investigated as four scenarios. The results showed that the average input energy in four scenarios was 11811.61 MJ ha^{-1} where the least input energy in the improved scenario was 11169.72 MJ ha^{-1}. The highest portion of input energy in the four scenarios was of nitrogen fertilizer with average of 4492.14 MJ ha^{-1} and 38.03 per cent of it had the highest rate of CO_2 emission and global warming potential (GWP). Fuel, phosphorus fertilizer, and seed held the next rank of CO_2 emission. The average GWP of wheat production in the four scenarios was 894.07 kg CO_2 per ha^{-1}. The lowest and highest amount of GWP were 710.2 and 933.59 kg CO_2 per ha^{-1} in scenarios I and II, respectively. Moreover, the amount of GWP per energy input unit was the maximum in scenario II and minimum in scenario IV. Furthermore, the improved scenario had the lowest GWP per energy output unit and scenario I achieved the first rank. In general, the amount of GWP has a direct relationship with the method of field management and input consumption.
Keywords: *climate change, cropping system, environment, food security, global warming potential*

Introduction

Taking a look at the statistics and information about the gap between energy consumption in Iran and developed countries, we can see the deficiencies in energy consumption in Iran more clearly. The most important reasons for this are inefficient energy conversion technologies and improper culture of energy consumption. Agricultural production in the 21st century has to go along and result in increased food security and it has to be less dependent on fairly rare resources such as agricultural lands, water, fossil fuel and non-renewable energies (Uphoff, 2012). While modern methods in this area have not been understood completely and are transitioning, their agricultural and scientific justification is being slowly understood. Many achievements have been recorded by making changes and managing plant's growth environment, soil, water and nutrients, and there is a need for more attention from researchers, policymakers and authorities especially for decreasing climate change consequences (Uphoff, 2012). In producing agricultural crops, such as wheat and to do agricultural

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_143161

operations such as ploughing, applying fertilizers, pesticides, planting, irrigation, harvesting, processing and transformation, there is need for some forms of energy (Chauhan et al., 2006). Efficient use of energy in agriculture is an important factor for the development of sustainable agriculture because it brings economic saving, preservation of fossil fuel and reduction in air pollution (Pervanchon et al., 2002). Concerns about preserving fossil fuels, and greenhouse gases emission have led to an increase in studies about energy efficiency in crop production systems (Koga, 2008). Global warming, due to greenhouse gases emission, is one of the most important global environmental challenges. It is endangering the future life on earth (IPCC, 2007a). Agriculture has a considerable role in greenhouse gases emission and, consequently, global warming (Robertson et al., 2000). Reducing the fossil energy consumption in agricultural systems can decrease the consumption of the limited energy resources and contribute to reduction of greenhouse gases emissions (Dalgaard et al., 2001).

In a study to investigate the energy input in wheat production in Gorgan region, Iran, it was observed that among all the direct energy inputs, fuel consumed in agricultural operation had the highest place with an average of 3390 MJ ha^{-1} and the second slot was for supplying electricity with an average of 309 MJ ha^{-1} (Soltani et al., 2013). Tipi et al. (2009), by investigating energy consumption in 97 fields in Marmara state in Turkey, show that wheat production consumes 20653.5 MJ.ha^{-1} among which the fuel energy input has the highest portion of total energy consumption with 45.15 per cent, and after that comes the chemical fertilizer with 34.21 per cent (especially nitrogen fertilizer with 31.77 per cent). By analyzing the energy efficiency in the Mediterranean agriculture systems in a research, it was reported that energy consumption of low input systems had significantly decreased to 30 per cent. The most important input resources in canola production were chemical fertilizers (64.66 per cent), diesel fuel (24.45 per cent) and pesticides 4.14 per cent (Nassi et al., 2011). Furthermore, in a study done by Ghorbani et al. (2011), the amounts of energy input in the low input and high input planting system for wheat were 9354.2 and 45367.6 MJ ha^{-1}, respectively. Koocheki et al. (2011), while investigating the total energy needed in the fields of bean *(Phaseolus vulgaris* L.*)*, lentil *(Lens culiparis* L.*)* and pea *(Cicer arietinum* L.*)* states that the energy inputs in bean and lentil fields were 23666.8 and 14114.79 MJ ha^{-1}, respectively. Also, in the irrigated and rain-fed cultivation of pea, energy input was reported to be 15756.21 MJ ha^{-1} and 2630.12 MJ ha^{-1}, respectively. In studying 13 scenarios of sugar beet production in England, the average of the total GWP was obtained to be 1.25 t eq-CO_2 ha^{-1}. Also the average GWP for production was estimated to be 0.024 t eq-CO_2 t^{-1} which was 0.0062 t eq-CO_2 GJ^{-1} per unit energy output. According to various production conditions in each of the scenarios, it was said that the amount of GWP had a direct relationship with the amount of energy input in sugar beet production (Tzilivakis et al., 2005a). The development of agricultural systems with less input and more efficiency can contribute to reducing CO_2 emission in agricultural section. Agriculture, especially growing wheat, is considered a noticeable factor in the release of greenhouse gases. It is necessary to investigate the wheat production cycle to determine the amount of energy consumed in order to reduce greenhouse gas emission and global warming. Therefore, the aim of this research was to investigate the energy consumption and global warming potential in wheat production fields in the central parts of Mazandaran province in Iran.

Materials and methods

Description of the site

Mazandaran province is located in the north of Iran. The experimental region is geographically situated at 35°, 47' till 36°, 35' N latitude and 50°, 34' till 54°, 10' E longitude. Based on temperature, rain, and topography of the region, this province is divided into two climates of Caspian mild weather and mountain weather. This research was done in the Caspian mild weather comprising the central portion of the province to the northern foothills. As a result of being close to the Caspian Sea on one side and the Alborz mountain range on the other and due to the short distance between the sea and the mountain, this region enjoys a mild temperature which leads to considerable rain. The mean annual rain in the coastal area of the province is 977 mm. The maximum rainfall occurs in fall and the minimum in spring. Hot and humid summers and mild and humid winters are the main characteristics of this type of weather. Therefore, the weather in some parts of this area is similar to that of the Mediterranean. Also, soil properties in each wheat production scenarios in different counties in depth of 0-30 cm are detailed in *Table 1*.

Description of regions and counties under study

The area this research covers includes three central counties of Mazandaran province (Jouybar, Sari, and Ghaemshahr counties), and based on the research method, we tried to investigate the target population through statistics and scientific methods. To do the research, first, 6 fields for conventional planting of wheat for each county were identified in 2015. Then, they were compared to the improved planting method (according to the growing low input wheat developed by the researchers). Identification of the fields was done in a way that covered all main production methods in every county. After that, the improved and conventional methods of planting in the three counties were investigated as four scenarios. The features of the fields and their complementary information are presented in *Table 2*.

DOI: http://dx.doi.org/10.15666/aeer/1504_143161

All the managerial practices of the chosen fields were being observed by agriculture engineers. In order to collect information from the fields, first, all agricultural practices were divided into eight parts of providing field, planting, fertilizing, preserving the plants, controlling the weeds, irrigating, harvesting, and transportation. Then, with the beginning of every operation, according to temperature fluctuations, information on various production methods and different amounts of input use by farmers of the region was collected. Typical information of agricultural operations such as the commencement date of every operation and the amount of inputs in every stage of work (from planting to harvesting) was collected and recorded by the observers who went to the fields and observed. Moreover, in the improved planting method, the researchers were seeking reduction of input use, environmental damage and also increase in efficiency and its comparison with common methods of planting wheat in the region. The variables investigated in the improved planting method were as follows:

Improved planting method: The operation of field preparation was done only once by the disc with Massey Ferguson 2850 tractor. The planting operation was done by using 200 kg seed ha^{-1} only by the second disc. The varieties of wheat seeds Milan and Morvarid were planted for dry land farming. According to soil analysis, chemical fertilizers N, P and K (92 kg N h^{-1}, 50 kg P_2O_5 h^{-1} and 50 kg K_2O h^{-1}) were applied to the basal. Moreover, 33.33% N was used in basal, 33.33 % N was used in tillering stage and 33.33 % top dressing of N fertilizer was applied in flowering stage. To control the weeds, herbicide Tapic was applied at 1 litre per hectare once on narrow leaf weeds and simultaneously herbicide Granestar at 25 gram per hectare was applied on wide leaf weeds. Protection operation for fighting pests and diseases was done according to recommendations of the region.

Data collection

All the managerial operation in this is research from the primary plowing and preparing soil to harvesting were recorded through field studies. In these investigations, the method of each managerial operation in the fields was determined in each of the phases of preparing soil, planting, cultivating and harvesting. All data about agricultural management including soil preparation (time and number of plowing, disc, etc.), planting time, fertilizer (amount and time of the applied fertilizer), pests, diseases and weeds control, irrigation (number and time of irrigation) and issues about harvesting (harvest time and yield) were collected. At the end of the growing season, the amount of real harvested yield was recorded. To estimate energy consumption and CO_2 emission, the fields under study in each county with improved planting method were taken as scenarios and totally four scenarios were investigated. To estimate the energy of the inputs and agronomic practices, expressed in MJ ha^{-1}. The energy equivalents in *Table 3* were utilized.

All the information about CO_2 emissions due to direct and indirect energy consumption was recorded and collected. After calculating the amount of energy consumed in the experiment, the result got generalized to an area of one hectare. To estimate energy consumption, the amounts of inputs and outputs were determined. To assess the energy input (consumed), all inputs at the time of practicing the agricultural operations changed into their equivalent by using the relationships of energy equivalence (conversion coefficients) extracted from various sources of every agricultural operation. Then, the input energy for each input and operation was calculated (Singh et al., 2007; Soltani et al., 2013). To determine the energy output

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_143161

(produced) obtained from grain and straw, they were changed to their equivalents by using energy equivalence (conversion coefficients) extracted from wheat grain and straw. After that, the total amounts of their input and output energies were calculated separately (Singh et al., 2007; Soltani et al., 2013). With calculation of the total input and output energies, different forms of energy consumption were identified. Direct energy includes fuel and labor. Indirect energy includes seed, fertilizer, pesticides, water and machinery. Moreover, renewable energy includes labor, seed and water used in irrigation. Non-renewable energy includes fuel, fertilizer, pesticides and machinery (Hatirli et al., 2006; Jarvis, 2000; Mandal et al., 2002; Mirin et al., 2001).

Energy assessment indices including energy ratio, energy productivity, specific energy, and net energy yield were calculated for each planting method (Soltani et al., 2013). It has to be mentioned that the described indices have been determined in order to assess the relationship between the total input and output energies which vary according to the type of product, type of soil, the nature of plowing operation for preparing soil, type and amount of chemical fertilizers and manure, cultivation operation, harvest and finally the yield levels (Soltani et al., 2013). The equations of energy indices are:

$$ER=EO/EI \quad \text{(Eq.1)}$$

where:
ER is the energy ratio and is a number without a unit, EO is the total energy output from the field (MJ ha^{-1}), and EI the total energy input to the field.

$$EP=GY/EI \quad \text{(Eq.2)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_143161

where:
EP is the energy productivity (kg MJ^{-1}), GY is grain yield (kg ha^{-1}) and EI the total energy input to the field (MJ ha^{-1}).

$$SE=EI/GY \quad \text{(Eq.3)}$$

where:
SE is the special energy (MJ kg), EI is the total energy input to the field (MJ ha^{-1}), and GY the grain yield (kg ha^{-1}).

$$NEY=EO-EI \quad \text{(Eq.4)}$$

where:
NEY is the net energy yield (MJ ha^{-1}), EO is the total energy output from the field (MJ ha^{-1}), and EI is the total energy input to the field (MJ ha^{-1}).

In order to calculate the global warming potential, first, the fuel for consumption in the factory and the energy consumed for production and transportation of inputs including chemical fertilizers, pesticide, machinery and fuel consumption for agricultural operations were determined (Green, 1987; IPCC, 2007b, 2007c; Tzilivakis et al., 2005a, 2005b). Then, CO_2 emission for every section was calculated. To calculate carbon dioxide emission from winnowing, disinfection and transportation of the grains, the factor was determined according to the type of agricultural management and grain quality (IPCC, 2007a, 2007d). After calculating the total GWP, estimation of CO_2 emission per unit area (kg eq-CO_2 ha^{-1}), per unit weight (kg eq-CO_2 t^{-1}), per unit of energy input (kg eq-CO_2 GJ^{-1}) and per unit of energy output (kg eq-CO_2 GJ^{-1}) were done (Soltani et al., 2013).

Results

Analysis of energy input and energy output

The mean for total energy input in the four scenarios was 11811.61 MJ ha^{-1}. The lowest energy input was obtained in the improved planting method at 11169.72 MJ ha^{-1}, and scenarios II and III got the next rank with little difference (11261.26 and 11262.21 MJ ha^{-1}, respectively). Scenario I, which is the conventional planting method in Jouybar county, bagged the first place with significant and noticeable difference with 13553.25 MJ ha^{-1} *(Table 4).*

By comparing different types of inputs in the four scenario, we see that the percentage of total energy consumed (nitrogen input) with total mean of 4492.14 MJ ha^{-1} (38.03 per cent) is on the top of the chart. The highest amount is for the improved scenario with 49.91 per cent (5572.2 MJ ha^{-1}). Scenario I bags second place with 39.50 per cent (5358.2 MJ ha^{-1}). Other ranks were of scenario II and III with nitrogen inputs of 31.63 and 30.84 per cent (3561.87 and 3473.29 MJ ha^{-1}, respectively). After the energy input of nitrogen, energy input of the fuel (3069.56 MJ ha^{-1} and 25.99 per cent) and seed (3045.75 MJ ha^{-1} and 25.79 per cent) had the highest amount. About the energy of the consumed fuel, scenario III got the first rank with 34.97 per cent of the total input and scenario IV bagged the last rank with 17.82 per cent of the total input. Scenarios I and II with 28.77 and 28.86 per cent of the consumed fuel, got the second and third place. By comparing the four scenarios about the seed consumed, it was seen that the fields of scenario I had the lowest amount with 2820.6 MJ energy (21.81 per cent); scenario III with 2862.58 MJ was placed before it. Scenarios II and IV with the consumption of 3359.8 and 3140 MJ ha^{-1} (29.84 and 28.11 per cent respectively) showed the highest amount of input energy for the seed *(Table 4)*. Findings show that in the region's farming culture, the energy input belonged to the nitrogen chemical fertilizer, fuel and seed. The main reason for this is that wheat production method in the region is traditional. To strong then the field, farmers used great amounts of chemical fertilizers, which utilized in the wrong way without paying attention to organic materials and biological resources.

Other inputs in the fields under study didn't show noticeable measures in different scenarios. The lowest inputs belonged to consuming pesticides. In most fields under study in the four scenarios, farmers did not use insecticides or fungicide. Also, little herbicide was used. The energy input for labor was little considering conversion coefficient. The energy input of machinery with the mean of 511.25 MJ ha^{-1} and 4.33 per cent of the total, got the fourth rank which was higher in scenarios I and III compared to scenarios II and IV. Moreover, the energy input of potassium (K_2O) and phosphorus (P_2O_5) with the means of 462.12 and 165.09 MJ ha^{-1} had 3.91 and 1.4 per cent of the total energy input, respectively *(Table 4)*.

An average of the total production energy in the four scenarios was 172041.8 MJ ha^{-1} and 35.63 per cent of it belonged to grain production energy (61301.78 MJ ha^{-1}) while 64.37 per cent of it belonged to straw energy (110740 MJ ha^{-1}). The highest energy production was obtained in the improved planting methods 187081.3 MJ ha^{-1} and 36.34 per cent of it belonged to grain energy (67987.5 MJ ha^{-1}) while 63.66 per cent of it belonged to straw energy (119093.75 MJ ha^{-1}). Scenario I with 180820 MJ ha^{-1} energy output got the second rank which consisted of 39.68 per cent grains (71747.1 MJ ha^{-1}) and 60.32 per cent straw (109072.9 MJ ha^{-1}). The next fields with scenarios II and III got the next places with 150921.3 and 169344.6 MJ ha^{-1}, respectively *(Table 4)*. The main reason for the observed differences between the amount of input energy and output energy in the four scenarios under study is the difference in the ways to manage things and amounts of input consumption.

The highest energy input coming from fuel in the four production scenarios is about land preparation operation where scenario III showed the highest amount of fuel consumption (1649.77 MJ ha^{-1}) and scenarios I and II with the consumption of 1557.6 and 1428.8 MJ ha^{-1} bagged the second and third places, respectively. By managing the field in the improved scenario, energy of the consumed fuel (452.2 MJ ha^{-1}) decreased significantly. After land preparation operation, the harvest operation had the highest

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_143161

amount of fuel input, where scenario III and I (1595.11 and 1313.09 MJ ha^{-1}) were significantly higher than scenarios II and IV (1192.75 and 1187.5 MJ ha^{-1}). Planting operation got the third place with regard to fuel input. It was significantly lower in the improved method than in the other three scenarios. In all four scenarios, the operations of weed control, plant protection, nutrition and transportation got the next places, respectively. Considering that all fields in all four scenarios were dry land planting, no energy input was recorded for irrigation (*Figure 1*).

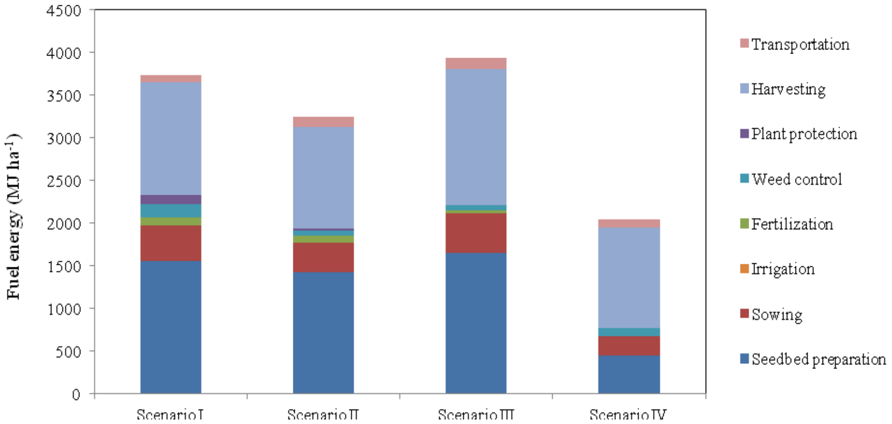

Figure 1. *Energy consumption in fuel in each production operation in each scenario of wheat production. Note that scales are different for the panels*

The energy input of the machinery in different stages of wheat production shows that the biggest part of it in the four scenarios was land preparation which was 284.87, 236.8 and 281.73 MJ ha^{-1} for scenarios I, II and III, respectively. In scenario IV, it was 99.69 MJ ha^{-1}. The operations of planting and harvesting got the next places which were different in different scenarios. Weed control and transportation of the machinery were placed lower. Energy consumption of the machinery for nutrition and protection was little: it was considered zero in the improved scenario. Moreover, because there was no irrigation in the four scenarios, this section did not have an energy input (*Figure 2*).

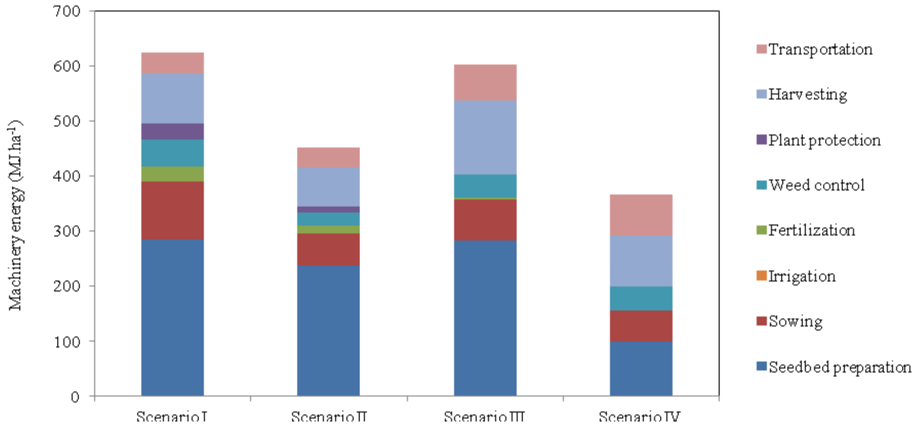

Figure 2. *Energy consumption in machinery in each production operation in each scenario of wheat production. Note that scales are different for the panels*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_143161

Most energy for labor was in the scenarios number I to III for land preparation with 8.9, 7.4 and 8.8 MJ ha^{-1}, respectively. But in the improved scenario, the highest amount of labor energy was nutrition and planting (7.78 and 7.58 MJ ha^{-1}, respectively), and land preparation operation (3.12 MJ ha^{-1}) stood in the next place. Labor energy input was not observed in this scenario for protection. Irrigation in scenarios I and II nutrition bagged the second place and planting operation got the third rank. But in scenario III harvesting and planting operation got the next places (*Figure 3*).

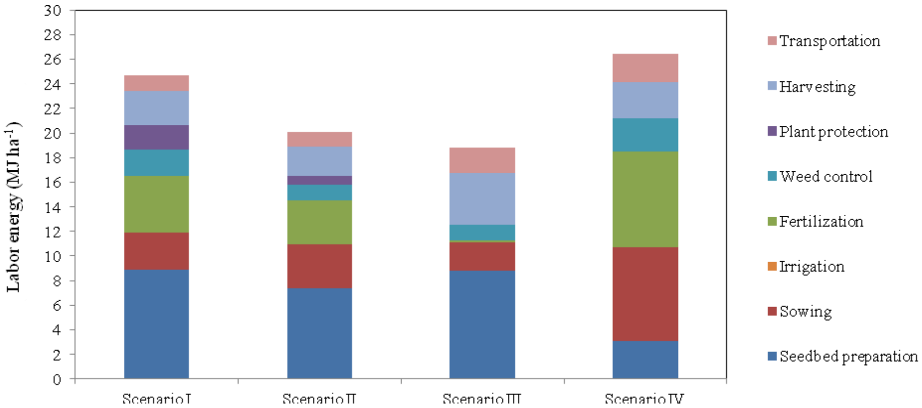

Figure 3. *Energy consumption in labour in each production operation in each scenario of wheat production. Note that scales are different for the panels*

Portions of energy input in wheat production

About different forms of energy, the findings in *Table 5* show that the means for direct and indirect total energy input in the four scenarios were 3295.09 and 8516.52 MJ ha^{-1}, respectively. The highest amount of directly consumed energy was for scenarios III and I with 3968.91 and 3924.35 MJ ha^{-1}. Scenario II with the input of 3270.23 MJ ha^{-1} bagged the third spot and scenario IV with 2016.86 MJ ha^{-1} was at the bottom of the list. Also, the two scenarios I and IV had the highest amounts of indirect energy inputs (9628.9 and 9152.86 MJ ha^{-1}), respectively. The amounts of indirect energy input for scenarios II and III were 7991.03 and 7293.3 MJ ha^{-1}, respectively (*Table 5*). According to the findings in *Table 5*, the means for renewable and non-renewable energy inputs in the four scenarios were 3071.28 and 8740.33 MJ ha^{-1}, respectively. In a group comparison between the two types of renewable and non-renewable energies, it was observed that renewable input energy in scenarios II and IV (3379.89 and 3166.42 MJ ha^{-1}) was more than in scenarios I and III (2845.25 and 2893.55 MJ ha^{-1} of the total consumed energy), respectively.

The lowest non-renewable input energy (7881.37 MJ ha^{-1}) belonged to scenario II and the highest non-renewable input energy (10708 MJ ha^{-1}) belonged to scenario I. Non-renewable energy in scenarios III and IV were 8368.66 and 8003.3 MJ ha^{-1} (*Table 5*).

Analysis of energy indices in wheat production

As shown in *Table 5,* energy ratio was 14.57. The highest energy ratio (16.75) was of the improved scenario and the lowest amounts (13.34 and 13.3) were in case of scenarios I and II. The reason for the low energy ratio can be attributed to their heavy dependence on inputs and use of more energy for production; these inputs are used without considering environmental issues. About the index of energy productivity, research findings showed that the mean for this index in the four scenarios was 0.37 kg MJ^{-1}, the highest amount of which was obtained in scenarios I and IV as 0.43 and 0.41 kg MJ^{-1}, respectively. As for scenarios II and III, the amounts were 0.28 and 0.35 kg MJ^{-1}, respectively (*Table 5*), which were lower than the results of Khan et al. (2010) in Australia. This is probably because of high energy input in Iranian production systems and the region's farming culture. The mean of the specific energy in the four scenarios was 2.68 MJ kg, where scenario II had the highest amount (3.51 MJ kg). The lowest specific energy belonged to scenario I (2.34 kg MJ^{-1}), and for scenarios III and IV it was 2.84 and 2.42 kg MJ^{-1}, respectively *(Table 5)*. Specific energy is the opposite of energy productivity, so its lower mounts show that less energy has been used for production per every unit of yield *(Table 5)*. About productivity and yield of the four scenarios as a system of energy conversion, research findings showed that the mean for net energy index was 160230.19 MJ per hectare. The highest net energy belonged to the improved scenario (175911.58 MJ per hectare) and scenario I (167266.75 MJ per hectare) got the second rank and scenario II (139660.04 MJ per hectare) stood last. Correct management method in the improved scenario and high amounts of inputs led to this result *(Table 5).*

CO_2 emission and global warming potential

According to the findings in *Table 6*, the mean for the 4 scenarios is 894.07 kg eq-CO_2 ha^{-1}. The lowest amount of global warming potential was for scenario I (710.2 kg eq-CO_2 ha^{-1}) and the highest amount of it was in case of scenario I (equal to 933.59 kg eq-CO_2 ha^{-1}). GWP in scenarios III and IV were 748.66 and 765.78 kg eq-CO_2 ha^{-1}, respectively.

Among different activities, nitrogen energy input got the first place in CO_2 emission and global warming in all scenarios with the average of 327.04 kg eq-CO_2 ha^{-1}, equal to 41.42 per cent. It showed a considerable difference compared to other inputs where the improved scenario stood first with 405.88 kg eq-CO_2 ha^{-1} and scenario I stood second rank with 390.15 kg eq-CO_2 ha^{-1}. Scenarios II and III were in next places with 259.27 and 252.86 kg eq-CO_2 ha^{-1}.

After nitrogen fertilizer, the consumed fuel had the highest CO_2 emission the mean of which in the four scenarios was 254.03 kg eq-CO_2 ha^{-1}, equal to 32.17 per cent, where the improved scenario stood last with 155.25 kg eq-CO_2 ha^{-1}. Scenario III and I got first and second places with 307.17 and 304.17 kg eq-CO_2 ha^{-1} *(Table 6)*. Machinery with average of 63.98 and seed with average of 87.83 kg eq-CO_2 ha^{-1} comprise 8.10 and 11.12 per cent of the total CO_2 emission in the four scenarios. Moreover, global warming potential coming from the use of herbicide had the average of 2.57 kg eq-CO_2 ha^{-1} and 0.33 per cent of the total CO_2 emissions. The portion of other activities in production and transportation of the agricultural inputs was not significant *(Table 6).* The mean for the global warming potential of all scenarios in the unit of area was 894.07 kg eq-CO_2 ha^{-1} which was minimum in scenario II, III and IV (710.2, 748.66 and 765.78 kg eq-CO_2 ha^{-1}) and maximum in scenarios I (933.59 kg eq-CO_2 ha^{-1}). In the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_143161

same respect, the total amounts of global warming potential in the unit of area for potato, canola, barley and peas were 3, 1.7, 1.2, 0.7 and 0.7 t eq-CO_2 ha^{-1} (Tzilivakis et al., 2005 b). Also, global warming potential in the unit of energy input had mean of 66.75 kg eq-CO_2 GJ^{-1} in the four scenarios which was minimum in scenario IV (68.56 kg eq-CO_2 GJ^{-1}) and was maximum in scenario II (63.07 kg eq-CO_2 GJ^{-1}). The mean of global warming potential in the unit of energy output was 4.94 kg eq-CO_2 GJ^{-1} in the four scenarios. The improved scenario had the least global warming potential in unit of energy output width 4.35 kg eq-CO_2 GJ^{-1} and scenario III stood second with 4.73 kg eq-CO_2 GJ^{-1}. Scenarios I and II had the highest global warming potential in the unit of energy output with 5.58 and 5.08 kg eq-CO_2 GJ^{-1} *(Table 7).* Mean of the global warming potential in the unit of grains' weight in the four scenarios was 184.2 kg eq-CO_2 t^{-1}. The lowest global warming potential in the unit of grains' weight was observed in scenarios I and IV where 161.05 and 165.57 kg eq-CO_2 t^{-1} were obtained. The highest global warming potential was in scenario II which was 221.64 kg eq-CO_2 t^{-1}. Less global warming potential was seen in the units of area and weight in scenarios I and II compared to other two scenarios. This can be attributed to less consumption of energy input and also higher production rate in this planting scenario *(Table 7).* The comparison between energy input and the resulting CO_2 emission in this research showed that there was a direct relationship between energy input and global warming potential in wheat production scenarios *(Figure 4)*, in a way that for every MJ increase in energy input in the four scenarios, CO_2 emission increased 75.1 kg per hectare. Since fossil fuel is important factors in GHG emissions, especially CO_2, appropriate agricultural operations have to be used.

Discussion

The results showed that non-renewable energies have little portion in the region. This issue is ecologically important because the source of non-renewable energy is generally fossil fuel, and relying on this recourse can bring danger in the future. Research findings show that agriculture in Iran heavily depends on non-renewable energy (Beheshti et al., 2010). High consumption of non-renewable energy decreases the energy productivity of production systems because producing chemicals and using machinery as the main indices of current systems requires the consumption of a lot of energy. In this research the portion of indirect energy is bigger than that of direct energy and the portion of non-renewable energy is higher than that of renewable energy. According to Moore (2010), in order to reach a sustainable production system, we have to increase the energy productivity and portion of renewable energy in the ecosystems. However, nowadays supplying food to the growing population of the world without non-renewable energy seems difficult or perhaps impossible. Therefore, considering the consequences of using chemicals and fossil fuel, agriculture experts will have no other options than think about increasing the sustainability in agriculture and the portion of renewable energy in production systems.

Agriculture is the system of energy conversion; it converts some commercial and non-commercial energy sources into products containing energy which is usable by humans (Kizilaslan, 2009), yield and productivity of this conversion are accessed through indices such as energy ratio, energy productivity and net energy. Energy ratio in Australian and Indian rice planting systems appears to be similar (Khan et al., 2010). According to the results obtained, we can increase energy productivity by decreasing fuel consumption, mechanization and machinery. Moreover, energy consumption decreases when energy resources are used more effectively through optimization of different types of the inputs by choosing the right type, amount, method and time of using the inputs such as chemical pesticides and fertilizers. A research study investigated energy consumption in 97 wheat fields in Marma state, Turkey, and it was observed that wheat production consumed 20653.5 MJ per hectare of energy, where the biggest portion was fuel energy inputs with 45.15 per cent of the total consumed energy and the next was chemical fertilizers with 34.21 per cent (specially nitrogen filled with 31.737 per cent) (Tipi et al., 2009). Other researches also showed that energy ratios in Australian and Indian rice planting systems were similar (Iqbal, 2007; Khan et al., 2010). In another research, the highest amount of fuel consumption and energy input was land preparation operation (Canakci et al., 2005). On the other hand, researches showed that fuel comprises the biggest portion of energy input compared to other direct inputs (Strapatsa et al., 2006). Fuel consumption per unit of field area is affected by factors such as tractor's steam horsepower, depth of plowing, soil type, etc (Kaltsas et al., 2007). Therefore, by analyzing energy input in growing wheat, we realize the use of all energy forms.

The comparison between energy input and global warming potential resulting from them showed that there was a significant relationship between the two. In this regard, Wood and Cowie (2004) stated that CO_2 emission during various agricultural activities either happened directly through consuming fossil fuel or indirectly at the time of production or transportation of the field's needed inputs (herbicides, pesticides and chemical fertilizers). Pathak and Vassmann (2007) stated that agricultural and non-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_143161

agricultural operations (production and transportation of fertilizers and pesticides) in production of rice, made 80-90 and 16-91 kg eq-CO_2 ha^{-1} in global warming potential, respectively. Furthermore, the results of similar researches in olive and sugar beet have shown that consumption of chemical fertilizers, especially nitrogen fertilizer and fossil fuel has had the biggest effect in GHG emission and global warming potential (Kaltsas et al., 2007; Tzilivakis et al., 2005a). In this respect, Soltani et al. (2013) stated that the highest and lowest global warming potentials in the unit of weight were 271.5 and 103.8 kg eq-CO_2 t^{-1}, respectively, and the unit of energy input were 44.6 and 34.8 kg eq-CO_2 GJ^{-1} and in the unit of energy output were 11.7 and 4.5 kg eq-CO_2 GJ^{-1}. In the other research results showed average reduction levels of up to 20% and 25% per material input for spring and summer systems, leading to impact reductions which ranged from 8% to 11% for spring farms and 19% to 25% for summer farms depending on the chosen impact category (Mohammadi et al., 2014). The energy use efficiency was improved about 25% by converting present farms to target units. Furthermore, the GHG emission of each input was investigated for present and optimum units. The results indicated that the total GHG emission of present and optimum farms was calculated as 1847.26 and 1483.52 kgCO_2eq. ha^{-1}, respectively. Moreover, the effect of energy optimization in reduction of GHG emission was found to be as 363.74 kgCO_2eq. ha^{-1} (Nabavi Pelesaraei et al., 2014). Kaltas et al. (2007) investigated the two planting methods organic and conventional in Greece and decided that global warming potential was less in the organic method than in the conventional method. Dayer and Desjardins (2003) investigated the effective management of farm machinery in GHG emission in Canada’s agriculture. They showed that decrease in consumption of fossil fuel reduced GHG emission. The issue of using fossil fuel energy in agriculture is very important because of the preservation of natural resources and also because of the release of greenhouse gases into the atmosphere. Furthermore, developing agricultural systems with the least energy input can help reduce GHG emission in agriculture.

(Received 28th May 2017; accepted 2nd Aug 2017)

Abstract. Aromatic rice has a high market value due to its special fragrance and the most important compound in the grains of aromatic rice is 2-acetyl-1-pyrroline (2-AP). In an effort to improve the 2-AP content and the yield of aromatic rice, two known rice cultivars, *Yungao* and *Yundi,* were cultivated across two seasons, and two irrigation and nitrogen management practices were investigated. The results showed that the treatment management practice (TNW) treatment improved panicle number per hill, seed setting rate, and 1000 grain weight and grain yield for both cultivars in early and late season. Significant improvement in grain yield was only observed in *Yundi* in both seasons. Moreover, the 2-AP content in grains was increased for both cultivars in both seasons during grain filling period. Significant increase in 2-AP in grains was observed for *Yungao* at maturity in both seasons, at 7 d AH in early season and at 14 d AH in late season whilst for *Yundi* at 7 d AH, 14 d AH and 21 d AH in early season, and at 14 d AH in late season. Furthermore, 2-AP content in leaves and grains was decrease during grain filling period while proline content in grains was enhanced during grain filling period. Significant relationships were also observed between 2-AP and proline contents in the leaves/grains of both rice cultivars.
Keywords: *aromatic rice; 2-acetyl-1-pyrroline; proline; nitrogen; irrigation*

Introduction

Rice is one of the most important cereal crops and feeds billions of people around the world. Aromatic rice, such as Basmati and Jasmine, has a characteristic fragrance and good grain quality (Ashraf et al., 2017; Ashraf and Tang, 2017). The aromatic rice grains valued at a higher market price than non-aromatic rice varieties (Zhang et al., 2008). Since the 1980s, numerous studies have investigated hundreds of fragrant compounds in scented rice grains and identified the 2-acetyl-1-pyrroline (2-AP) as the key fragrant

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_14471460

compound of aromatic rice (Yajima et al., 1979; Buttery et al., 1982; Widjaja et al., 1996; Champagne, 2008).

The 2-AP accumulation in aromatic rice is affected by many environmental factors during aromatic rice growth. For example, high night temperature reduced grain quality remarkably (Mohammed and Tarpley, 2010; Nagarajan et al., 2010). During grain filling period, shading treatments significantly improved the 2-AP content and γ-aminobutyric acid (GABA) content in aromatic rice grains (Mo et al., 2015). With salt stress treatment, the popular aromatic rice (*Khao Dawk Mali 105*) cells accumulated Na^+ and proline (Summart et al., 2010) whilst the reduction of fragrant rice yield was related to the fragrance in rice (Fitzgerald et al., 2010). Moreover, some studies reported that salt stress can increase 2-AP content in grains (Gay et al., 2010; Poonlaphdecha et al., 2012). Some minor elements were also found to be associated with 2-AP accumulation in aromatic rice (Lei et al., 2017). Manganese (Mn) application had a positive effect on rice yield, quality and 2-AP content (Li et al. 2016). 2-AP content and proline dehydrogenase (ProDH) activity were increased by moderate concentration of zinc (Zn) and lanthanum (La) treatment (Mo et al., 2016). Furthermore, silicon fertilization also modulates 2-acetyl-1-pyrroline content n fragrant rice (Mo et al., 2017).

Many previous studies have reported that nitrogen and water as important aspects for aromatic rice growth and development. The nitrogen utilization efficiency is associated to the rice genotypes and locations (Djaman et al., 2016). Sikdar et al. (2008) found that N level at 80 kg/hm^2 improved grain quality and soil fertility. However, high nitrogen can lead to lodging in rice (Mahajan et al., 2010). In Asia, rice production is limited due to water shortage (Arora et al., 2006), thus, irrigation patterns directly influence rice production. Alternating wetitnng and drying could regulate rice yield (Zhang et al., 2012), whilst moderate irrigation control can also have a positive impact on 2-AP content and grain yield of aromatic rice (Yoshihashi et al., 2002; Tian et al., 2014). Hakoomat et al. (2014) found the N and Zn interactions had the most significant improvement on yield and yield related traits when the N level was 12kg/hm^2 and Zn level was 14kg/hm^2. Moreover, moderate irrigation at tillering, booting, and grain filling stage could increase the 2-AP content in grains (Tian et al., 2010; Wang et al., 2013a, b). Yang et al. (2012) reported high aroma content in grains was associated to high total nitrogen in soil. Zhong and Tang (2014) found that 2-AP content in grains was increased with increasing nitrogen application. Li et al. (2014) found the 2-AP content in brown rice was highest when the N supply was 60kg/hm^2 and the irrigation potential was -20 kPa at tillering stage.

In our previous studies, we have investigated the interaction effect of water and nitrogen at tillering stage (Li et al., 2014), booting stage and grain filling stage on grain yield and 2-AP accumulation in grains (data unpublished), then, we selected the best water and nitrogen treatment of the three stages and combined the treatments together for investigating the additive effect of the nitrogen and water management treatment on aromatic rice yield and 2-AP accumulation. In this study, we aimed to identify the affects of the combinations of water and nitrogen applications implemented at tillering stage, booting stage, and grain filling stage on 2-AP accumulation and grain yield.

Materials and Methods

Plant materials and growing condition

Two popular aromatic rice cultivars, *Yungao* and *Yundi*, having 115 -120 days of growth period were planted in early season and late season in 2015 at the College of Agriculture, South China Agricultural University, Guangzhou, China (23°20’ N, 113°30’ E and 11 m above the sea level. The experimental site has a subtropical-monsoon type climate with mean annual air temperatures of 22.4 ºC and mean annual precipitation of 2638.3 mm (Fig. 1). The seeds were soaked in water for 24 h, germinated in manual climatic box for the next 24h, and raised at the Research Farm of the College Agriculture. 30-day-old seedlings were transplanted to the field at the recommended planting distance (30 cm × 12 cm). The experimetal soil was sandy loam with of 25.65% organic matter content, 1.362% total N, 0.958% total P, and 17.520% total K.

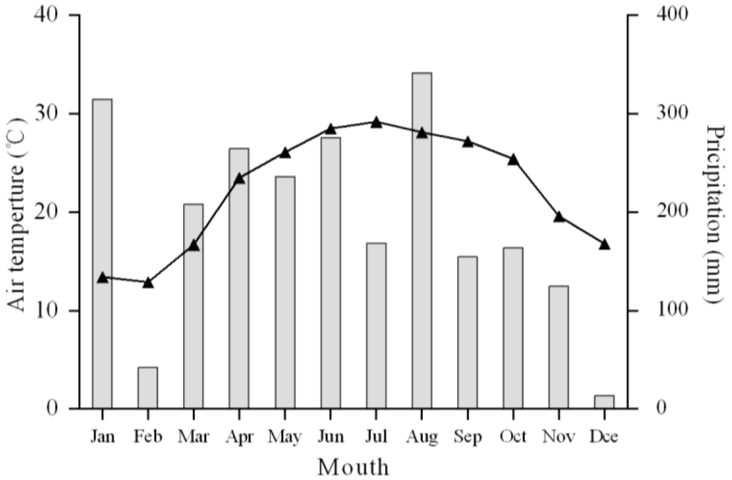

Figure 1. *Mean monthly temperature and precipitation in 2016 of the experimental site*

Treatments and plant sampling

The experiment was conducted in early season and repeated in late season. Experimental treatments are as follows: (i) The conventional management practice (CK) involves applying nitrogen (30 kg/hm^2) at tillering stage, booting stage, and grain filling stage; the water flow at these three stages was 0 kPa in both early and late season rice. (ii) The treatment management practice involved applying nitrogen (60 kg/hm^2) at tillering stage with heavy drought conditions (water potential of - (25±5) kPa), applying 60 kg/hm^2 nitrogen at the booting stage with feebly arid conditions (water potential of - (15±5) kPa), and applying no nitrogen at the grain filling stage with shallow-watered irrigation (water flow of 0 kPa) (TNW). P_2O_5 (90 kg/hm^2), K_2O (195 kg/hm^2) were applied as basic fertilizer. The fresh leaves and grains were sampled from the rice at the end of tillering stage; after 7, 14, and 21 d heading stage; and at maturity. Samples were immediately stored at -20°C for 2-AP analysis.

DOI: http://dx.doi.org/10.15666/aeer/1504_14471460

Yield and yield related traits

At maturity, the grains were harvested from one unit sampling area (8.1 m^2) in each plot and threshed by machine. The harvested grains were sundried, and the dry weight was used to estimate the grain yield. Thirty hills of rice plants from different locations in each plot were sampled for calculating the average effective panicles number per hill. Then, three hills representative plants were taken for determination of the yield related traits.

Proline estimation

The proline content in leaves and grains were measured according to the method established by Bates et al. (1973). Leaves or grains in which the weight was almost 0.3 g, were homogenized in a 4 ml solution of 3% sulfosalicylic acid and cooled after bringing to a boil for 10 min. Samples were filtered and 2 ml of the filtrate was mixed with 3 mL ninhydrin reagent (2.5 g ninhydrin in 60 mL glacial acetic acid and 40 mL 6 M phosphoric acid) and 2 mL glacial acetic acid. For the extraction of proline, the mixture was boiled for 30 min and 4 mL toluene was added to the cooled liquid. The extract was centrifuged at 4000rpm for 5 min, and proline absorbance was detected at 520 nm. The proline concentration, expressed as $\mu g \cdot g^{-1}$, was assayed by using standard curve to calibrate.

2-AP estimation

The 2-AP content was estimated using the method described by Huang et al. (2012), Prior to analysis, leaves were cut into sections and grains were ground by mortar and pestle. Approximately 5 g leaves or 10 g grains were mixed homogeneously with 150 mL purified water into a 500 mL round-bottom flask attached to a continuous steam distillation extraction head. The mixture was boiled at 150°C in an oil pot. A 30 mL aliquot of dichloromethane was used as the extraction solvent and was added to a 500 mL round-bottom flask attached the other head of the continuous steam distillation apparatus, and this flask was boiled in a water pot at 53°C. The continuous steam distillation extraction was linked with a cold water circulation machine in order to keep temperature at 10°C. After approximately 35 min, the extraction was complete. Anhydrous sodium sulfite was added to the extract to absorb the water. The dried extract was filtered by organic needle filter and analyzed for 2-AP content by GCMS-QP 2010 Plus. High purity helium gas was used as the carrier gas at flow rate of 2 mL/min. The temperature gradient of the GC oven was as follows: 40°C (1 min), increased at $2°C \cdot min^{-1}$ to 65°C and held at 65°C for 1 min, and then increased to 220°C at $10°C \cdot min^{-1}$, and held at 220°C for 10 min. The retention time of 2-AP was confirmed at 7.5 min. Each sample had three replicates, and 2-AP was expressed as $\mu g \cdot kg^{-1}$.

Treatment design and statistical analysis

This study was arranged as a randomized complete block design (RCBD) with three replicates (n=3). Data were analyzed by SPSS 16.0 software (SPSS Inc., Chicago, USA), and the probability level was set at 5% ($P < 0.05$).

Results

Grain yield and yield related traits

As shown in *Table 1*, the panicle number per hill, seed-setting rate, and 1000-grain weight and yield were higher in TNW treatment than in CK for *Yungao* and *Yundi* in both seasons. The seed setting rate was significantly improved by 11.75% in TNW treatment for *Yundi* in late season. The grain yield was dramatically increased by 12.13% and 21.00% for *Yundi* in early and late season, respectively. CK treatment had higher grain number per panicle than TNW treatment in *Yungao* and *Yundi* in both seasons.

Table 1. *Effects of irrigation and nitrogen management practices on yield and yield related traits in aromatic rice*

Season	Cultivar	Treatment	Panicle number per hill	Grains number per panicle	Seed-setting rate (%)	1000-grain weight (g)	Yield (t hm^{-2})
Early season	Yungao	CK	14.03±0.62a	82.52±2.07a	87.24±0.81a	25.13±0.08a	5.16±0.45a
		TNW	15.48±0.71a	74.92±1.50a	88.58±2.37a	26.20±0.51a	5.74±0.38a
	Yundi	CK	13.05±0.48a	108.80±8.96a	88.60±1.70a	24.68±0.12a	5.36±0.20b
		TNW	13.30±0.55a	93.68±4.00a	90.25±0.96a	24.85±0.30a	6.01±0.07a
Late season	Yungao	CK	12.76±0.49a	111.00±5.41a	81.98±4.72a	25.88±0.22a	4.59±0.27a
		TNW	13.00±0.57a	108.49±4.12a	86.10±0.78a	26.50±0.44a	4.73±0.14a
	Yundi	CK	12.69±0.47a	114.82±3.40a	79.97±2.33b	24.03±0.13a	4.81±0.08b

Means in the same column followed by different lower case letters for the same variety differ significantly at $P < 0.05$ by T-test. CK (control); TNW (60 kg/hm^2 nitrogen and water potential of - (25±5) kPa) were applied at the tilling stage, 60 kg/hm^2 nitrogen and water potential of - (15±5) kPa were applied at the booting stage, no nitrogen and water flow of 0 kPa were applied at the grain filling stage)

2-AP content in grains

We observed higher 2-AP content in grains in TNW treatment than CK for both cultivars at all the sampling stages in the early and late season. For *Yungao*, the 2-AP content in grains were significantly increased by 61.88% and 31.10% at 7 d AH and maturity in early season, respectively; significant increase in 2-AP content in grains by

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_14471460

79.02% and 13.88% were observed at 14 d AH and maturity in late season, respectively. For *Yundi*, the 2-AP content in grains in TNW treatment were remarkably higher than CK at 7 d AH, 14 d AH and 21 d AH in early season; significant improved in 2-AP content in grains by 12.07% was found at 14 d AH in late season.

Table 2. *Effects of irrigation and nitrogen management practices on 2-AP content of grains at different stages (μg·kg^{-1})*

Season	Cultivar	Treatment	7 d AH	14 d AH	21 d AH	Maturity

2-AP content in leaves

Table 3 shows that TNW treatment decrease 2-AP content in leaves at all the sampling stages. In early season, 2-AP content in leaves were significantly decreased except for 21 d AH and 14 d AH for *Yungao* and *Yundi*, respectively. The 2-AP content in leaves in TNW treatment decreased for both rice cultivars at 14 d AH, and for *Yungao* at the maturity.

Proline content in grains

The proline content in grains increased at all the sampling stages during grain filling in the early and late season. For *Yungao*, the proline content significantly enhanced at 21 d AH and maturity in early season and remarkably increased at 7 d AH, 14 d AH and 21 d AH in the late season. For *Yundi*, TNW treatment significantly increased proline content in grains at 7 d AH in early season, significantly improved proline content in grains at 7 d AH and 14 d AH in late season was observed (*Table 4*).

Proline content in leaves

We observed a decrease in proline content in leaves at all the sampling stages in the early and late season. For *Yungao*, significant decreased in proline in leaves was found at the 7 d AH and maturity in the early season; a significant decrease in proline in leaves was detected at 7 d AH, 14 d AH and 21 d AH in late season. For *Yundi*, TNW treatment showed significantly lower in proline content in leaves than CK at 7 d AH, 21 d AH and Maturity in early season, and at 7 d AH and 14 d AH in late season (*Table 5*).

Discussion

The biosynthesis and accumulation of 2-AP in aromatic rice is an important phenomenon that is affected by several factors (Mo et al., 2016). Precious studies have reported some precursors in the pathways of 2-AP biosynthesis, for example, Seitz et al. (1993) and Huang et al. (2012) found proline was the most important precursor and directly involved in 2-AP formation, then, ornithine and glutamic acid were found to have relevant relationship with the fragrance constitution (Yoshihashi, 2002). The fragrance of aromatic rice is affected by environmental factors, in particular, the irrigation model and nitrogen application. For water irrigation, Wang et al. (2013b) found that moderate soil water potential (- (25±5) kPa) at the tillering stage significantly enhanced in 2-AP accumulation in grain by 22.70%-29.76%. Similar findings were also observed when the soil water potential was - (25±5) kPa at the booting stage, the 2-AP content in grain was significantly increased by 35.88%-47.02% (Wang et al., 2013a). Moreover, when the shallow-water irrigation method was applied at grain filling stage, the 2-AP content in grains was markedly increased by 54.80%-322.90% (Tian et al., 2010). The enhancement in 2-AP content in grains was associated to the improvement in proline content in grains (Tian et al., 2010; Wang et al., 2013a,b). Moreover, nitrogen application also has positive influence on the accumulation of proline and 2-AP. Yang et al. (2012) reported higher proline was found in aromatic rice grains which was planted in paddy filed contains higher total nitrogen, and higher proline content contributed to the accumulation of higher aroma.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_14471460

Li et al. (2014) found that 2-AP content in grains increased significantly by 10.33%-23.50% when 60 kg/hm^2 nitrogen fertilizer was applied at the tillering stage. Zhong and Tang (2014) also found that the grains 2-AP content was increased, because of the proline concentrations in leaves and grains were improved with the increasing nitrogen application. Meanwhile, the effects of water deficit and nitrogen interaction on proline content have been reported in some previous studies. Lalelou and Fateh (2014) reported that under severe water conditions (60% field capacity loss) and 80 kg/hm^2 nitrogen, the proline content in flag leaf of wheat was increased (15.76-20.39 fold). All the previous indicated the single water or nitrogen treatment could improve the gain 2-AP content. According our previous studies (data unpublished), we have found the water-nitrogen treatment improved the grain 2-AP content at tillering stage, booting stage, and grain filling stage. In this study, we have further found that 2-AP content in grains was increased by TNW (The treatment management practice involved applying nitrogen (60 kg/hm^2) at tillering stage with heavy drought conditions (water potential of - (25±5) kPa), applying 60 kg/hm^2 nitrogen at the booting stage with feebly arid conditions (water potential of - (15±5) kPa), and applying no nitrogen at the grain filling stage with shallow-watered irrigation (water flow of 0 kPa)) (*Table 2*). Similarly, the proline concentration in grains at the four sampling stages was increased in early and later seasons (*Table 3*). Moreover, the 2-AP content in grains at maturity was significantly positive correlated to the 2-AP content in grains at 21 d AH, the 2-AP content in grains at 14 d AH, and positive correlation between 2-AP in grain at maturity and proline content in grain at 7 d AH was also observed (*Fig. 2 a-c, e*). This indicated that the TNW treatment can increase 2-AP content in grains at maturity due to the improvement of 2-AP content in grains at 14 d AH and 21 d AH and the proline content in grains at 7 d AH.

Interestingly, we observed that the proline content and 2-AP content in leaves at the four sampling stages was decreased (*Table 4, 5*). Correlation analysis indicated that the 2-AP content in grains at maturity showed significant negative correlation with the proline content in leaves at 14 d AH and the proline content in leaves at 21 d AH (*Fig. 2d*). Further, the 2-AP content in leaves at 21 d AH showed significant positive correlation with the proline content in leaves leaf at 14 d AH and 21 d AH (*Fig. 3 a-b*). This suggested that proline or 2-AP may possibly transport from leaves to grains (Buttery et al., 1983; Maraval et al., 2010; Mo et al., 2016).

The water and nitrogen effects on crop yield have been investigated by many researchers (Wang et al., 2003; Cai et al., 2006; Yang et al., 2016). Wang et al. (2016) found that 200 kg/hm^2 nitrogen fertilizer application and alternate wetting and moderate drying regime increased grain yield due to more panicle and more spikelet number of per panicle; 300 kg/hm^2 nitrogen fertilizer application and alternate wetting and serve drying regime treatment increased the number of panicle, spikelet number per panicle and the percentage of filled grains and produced high yield. Li et al. (2014) found that the yield aromatic rice varieties were increased under the interaction of 60 kg/hm^2 nitrogen fertilizer application and water flow of - 10 kPa because of higher seed-setting rate, 1000-grains weight or number of panicles. Our results also confirmed that water and nitrogen applications have a positive effect on the yield of two fragrant rice cultivars. The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_14471460

improvement in grain yield is associated to the higher panicle number per hill, seed-setting rate, and 1000 grain weight. Moreover, we found significant positive correlation between grain yield and seed-setting rate (r=0.8402, P <0.01) (*Table 1, 6*).

Conclusion

In conclusion, the TNW treatment increased grain yield, and some yield parameters, 2-AP and proline in grains, and led to improve the grain aroma. For revealing the mechanism of 2-AP transportation by irrigation and nitrogen management practice treatment, much work should be done at molecular and physiological level.

(Received 15th Jun 2017; accepted 20th Sep 2017)

Abstract. The suitability of clay modified with sodium carboxymethyl cellulose was tested for the removal of Pb^{2+} from aqueous solutions. The effect of pH on the adsorption process was investigated in the pH range from 1 to 9. Tests were conducted at different temperatures: 20 °C, 30 °C, 40 °C, 50 °C and 60 °C. The effect of initial concentration of adsorbate on lead removal was analysed using solutions with lead concentrations from 50-150 mg L^{-1}. Also, the amount of adsorbent in the process of removing lead was determined. The efficiency of lead removal was observed to be 86.19 % from solution with the initial concentration 100 mg L^{-1}. Obtained Freundlich adsorption isotherms show extremely high correlation coefficient R^2, i.e. processes of equilibria on the investigated clays can be described using this equation. The series of conducted experiments shows that the clay modified with carboxymethyl cellulose is suitable for the removal of lead from waste waters. Further researches should be focused on modifying clay with other long chain molecules which can improve adsorption properties.
Keywords: *adsorption, ICP-OES, scanning electron microscopy, FTIR spectral analysis, waste waters*

Introduction and literature review

Heavy metals are very toxic and that their discharges from industrial plants into waste waters cause harmful effects on human health and the environment is well known. Due to the lead production and its widespread use, it can contaminate air, soil, and via them enter the food chain through food of plant and animal origin. Main sources of lead in the environment are petrol to whom tetraethyl lead is added as a detonator (in many countries lead is fallen into disuse with this purpose (WHO, 2011) metal industry, industrial waste, paint colours, lead water pipes in old buildings etc) (Mirić and Šorbajić, 2002). According to the data of World Health Organization (2011), concentration of lead in water should be below 10 μg L^{-1}.

DOI: http://dx.doi.org/10.15666/aeer/1504_14611472

Lead is one of the oldest known toxicants. Around 10 % of lead is getting absorbed from digestive tract. According to IARC (International Agency for Research on Cancer), lead is belonging to group 2 of the potential human carcinogen agent (Mirić and Šorbajić, 2002). Exposure to lead during pregnancy affects the DNA methylation status of the fetal germ cells, which leads to altered DNA methylation in grandchildren's neonatal dried blood spots (Sen et al., 2015). Long exposure to low doses mainly harms nervous system (these changes occur at concentrations in blood from 100-150 μg L^{-1}). Mechanism of its toxicity on nervous system can be one of the following: direct neurotoxicity (apoptosis excitotoxicity, influences on neurotransmitter storage and release process), calcium replacement (lead has ability of passing through blood-brain barrier; back-transport of lead via the Ca-ATPase pump) (Lidsky and Schneider, 2003). Toxic effects of lead are manifested as renal failure, hypertension, fertility problems and spontaneous miscarriage, and even fatal outcome due to problems with cardiovascular system (WHO, 2011). Toxic effects are consequences of the inactivation of particular enzyme systems, binding to SH groups of proteins, replacements of essential elements (Mirić and Šorbajić, 2002). Some techniques for removing lead from water are: removing by coffee grounds as vegetable biomass (Tokimoto et al., 2004); adsorption onto calcined phosphate (Aklil et al., 2004); adsorption onto zeolites (Scott et al., 2002; Panayotova and Velikov, 2002), adsorption onto clays (Celis et al., 2000; Cooper et al., 2002). Addition of polymers on the physico-chemical properties of bentonite was tested for cleaning water solutions (Stojiljkovic et al., 2014). All mentioned techniques are relatively cheap. Therefore, it is an imperative to find suitable and cheap technique for the removal of toxic metal from the environment.

Generally, techniques developed for the removal of toxic metals from water solutions include precipitation, ion exchange, adsorption, filtration, electrodeposition, reversed osmosis (Rao et al., 2010). Clay is finely granulated soil, which includes combination of one or more clay minerals and metal oxides or organic substances contained in trace amounts (Guggenheim and Martin, 1995). Adsorption of heavy metals was investigated in several works using the clay as the adsorbent: lead on the bentonite (Zhu et al., 2008), lead on the clay activated with acid (Resmi et al., 2012), chromium on the modified clay (Arfaouia et al., 2008), and Inglezakisa et al. (2007) achieved the efficiency of 100 % in the removal of Pb^{2+} from water solutions using clinoptilolite and bentonite as adsorbents. The influence of different factors affecting the adsorption was investigated, such as pH, agitation time, temperature, quantity of adsorbents, concentration of adsorbate, kinetics of adsorption (Resmi et al., 2012). Maximal adsorption capacity of natural clays for Pb^{2+} ion is 104.28 mg g^{-1} (Zhu et al., 2008). The efficiency of the removal of lead ions using acid activated clay is equal to 92.4 % at the initial concentration 100 mg L^{-1} at pH=6 and 30 ^{0}C (Resmi et al., 2012). Bentonite is used in food industry as an anticaking agent, helping prevent food particles from sticking together (E 558). There are no data in the literature that anyone performed the removal of lead from aqueous solutions using the bentonite modified with sodium carboxymethyl cellulose (NaCMC), a food additive labeled as E 466 (Mirić and Šorbajić, 2002).

In this paper it was investigated the efficacy of the clay modified with NaCMC for the removal of lead from aqueous solution by adsorption and monitoring of the influence of pH value, temperature, dose of the adsorbent and the concentration of adsorbate was performed. The aim of this work was to create a new adsorption material,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_14611472

clay modified with long chain molecule (in this case carboxymethil cellulose), with improved properties for heavy metal ions adsorption (Zhu et al., 2008). New adsorption material provides simple and cheap technique for removing Pb(II) ions from waste waters.

Material and methods

Reagents

NaCMC was purchased from Weifang Lude Chemical Co., Shandong China. For the acid activation of clay (bentonite-Riznica prirode, Serbia) concentrated HCl (p.a. Zorka Pharma, Serbia) was used. Lead nitrate (p.a. Alkaloid Skopje) was used for the preparation of adsorbate solution. Multistandard-UltraScientific Analytical Solutions (USA) were used for the quantitative determination of lead. Deionized water was used for the preparation of all solutions.

Apparatus

The following apparatus were used: ICP-OES iCAP 6000 (Thermo Scientific, United Kingdom), FTIR spectrometer Bomem MB-100 (Hartmann & Brown, Canada) with standard DTGS/KBr detector, scanning electronic microscope JSM-5300 (JEOL, Japan), the device for the preparation of samples for electron microscopy JFC-1100E ION SPUTTER (Jeol Co., Japan), digital pH meter (HANNA, USA), and hothouse (Trade Raura, Spain).

Adsorbent

Acid activated clay was prepared by the treatment of crude clay with concentrated HCl. 15 g bentonite clay was suspended in the beaker with 300 mL deionized water. Afterwards NACMC was added in the quantity of 1 % of clay mass (0.15 g) (modified clay GI), 3 % (GII) and 5 % (GIII) and then heated at 90 °C and mixed on rotary mixer (1-2 h). 5 mL of conc HCl was added dropwise. The probe was left overnight, and then filtered through Buchner funnel on vacuum pump and rinsed with plenty of deionized water until negative reaction on chlorides. Modified clay was dried in the oven at 110 °C to constant weight, left overnight and then smashed in the mortar. Before the addition of NaCMC pH was 9.2±0.1, while pH after the addition of NaCMC and HCl was 1.35±0.1.

FTIR spectral analysis

Samples of carboxymethyl cellulose, modified clays (GI, GII, GIII) and unmodified clay (G0) were recorded on FTIR spectrometer. Scanning was performed in the range of wavelengths from 4000-400 cm^{-1} with the resolution 4 cm^{-1}.

SEM analysis

SEM analysis of surface samples was performed by scanning electron microscope JEOL JSM-5300, which is operated at a working potential of 30 kV, and the depth of penetration of electron beam was 10 pm. Characteristics of surface samples are observed at different magnifications (1000×, 2000×, 5000×). SEM-EDS analysis was performed using the same scanning microscope, but with the detector (probe) Linx Analytical QX 2000b.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_14611472

Adsorbate

The stock solution of Pb^{2+}ions (1000 mg L^{-1}) were prepared by weighing exactly known mass of $Pb(NO_3)_2$ and dissolving in deionized water in volumetric flask. Thus solution was used for further investigations by diluting to required concentrations.

Adsorption study

Particular mass of adsorbent was added into the beaker with 50 mL of lead nitrate solution of particular concentration. Solutions were mixed for 20 min on the rotary mixer (speed 150 rpm) at particular temperature, and filtered through filter paper (Whatman Grade 589). Concentration of the lead in the filtrate was determined using optical emission spectrometry with inductively coupled plasma (ICP-OES) (Yi et al., 2011). The influence of the temperature was investigated by heating on the water bath, and the influence of pH by the addition of HCl and NaOH solutions to solution of Pb^{2+} ions (Adhikari and Singh, 2003).

Adsorption capacity can be calculated according to the equation (Eq. 1):

$$q_e = (C_o - C)\frac{V}{m} \qquad \text{(Eq. 1)}$$

where c_0 is the initial concentration of Pb^{2+} ions, c remaining concentration of Pb^{2+} in the state of equilibrium, V volume of the solution and m mass of the adsorbent (Yasemin and Zeki, 2007).

Results and discussion

Characterization of adsorbents

Scanning electron microscopy

According to the producer specification, bentonite clay contains minerals: montmorillonite, kaolinite, illite and hydromuscovite. Chemical composition of the initial sample is presented in *Table 1*.

Table 1. *Chemical composition of the initial bentonite sample*

	Bentonite						
Chemical composition	SiO_2	Al_2O_3	K_2O	Fe_2O_3	TiO_2	MgO	CaO
Content, %	67.81	24.73	3.25	1.89	1.06	0.93	0.33

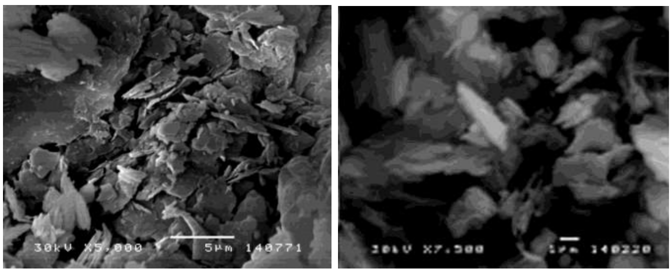

Figure 1. *SEM of unmodified clay*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_14611472

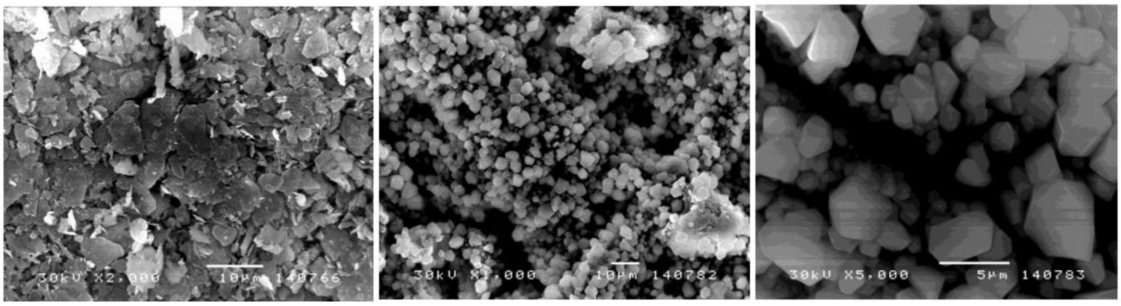

Figure 2. *SEM of clay modified with sodium carboxymethyl cellulose*

SEM analysis of unmodified clay (5000× magnification) shows characteristic morphology of clay minerals, i.e. platelet particles of different sizes (*Fig. 1*). SEM analysis of GI sample indicates lamellar particles with dominant fraction of 5-10 µm in diameter. Microphotographs of GII sample show polyhedral crystals, which are more evident on SEM analysis of GIII sample. Having on mind that there are no published publications of clay modification with NaCMC, we assumed these crystals originated from NaCl were formed in the reactions of HCl and sodium from NaCMC (*Fig. 2*).

SEM-EDS analysis shows that predominant elements in unmodified clay are: Fe, Al, Si, and O. In sample of GI, GII and GIII aluminum is the most dominant, due to leaching of Fe during the synthesis of composite material.

FTIR spectral analysis

FTIR spectra of modified clays (GI, GII, GIII) (*Fig. 3*) show OH band at 3430.65 cm^{-1}, 3433.42 cm^{-1}, 3433.87 cm^{-1} succesively characteristic for clay minerals (montmorillonite, illite, hydromuscovite and kaolinite).

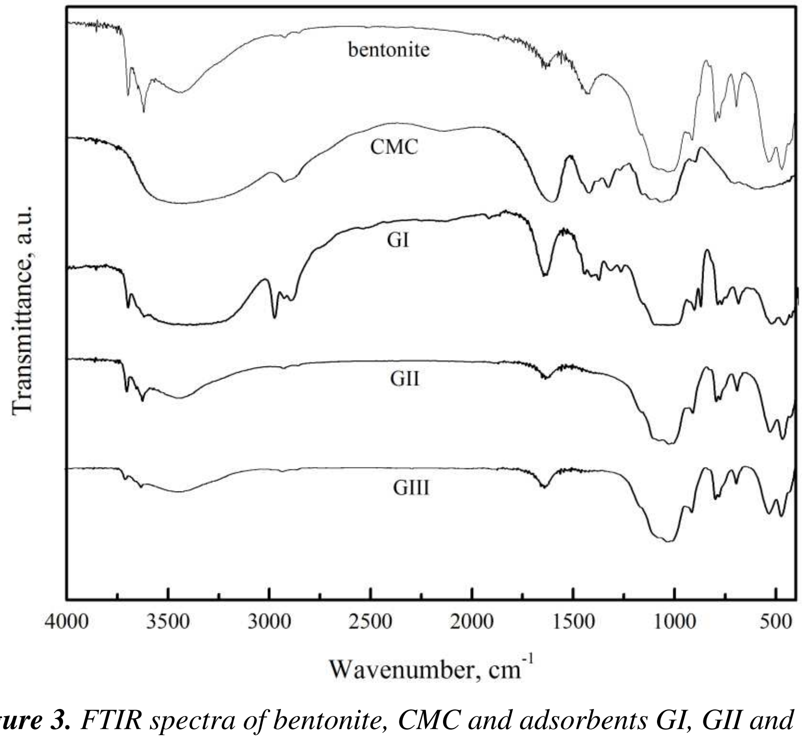

Figure 3. *FTIR spectra of bentonite, CMC and adsorbents GI, GII and GIII*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_14611472

Also, in spectra (G0, GI, GII, GIII) it is clearly visible the intensive band coming from deformational vibration of Si-O bond, with maximums at 1033.27 cm^{-1}, 1028.52 cm^{-1}, 1037.13 cm^{-1} and 1019.46 cm^{-1} (characteristic for alumosilicates present in the clay). At the spectrum of modified clay GI, peaks at 2926.41 and 2854.77 cm^{-1} come from C-H vibrations and they are results of the presence of carboxymethyl cellulose. In spectra of GII and GIII, these bands are less pronounced, which means that sample GI contains mostly unmodified carboxymethyl cellulose, although in the process of the preparation the least quantity of this organic compound as a modifier of the surface and adsorption characteristics of clay was used.

Adsorption experiments

Influence of pH on the adsorption

Lead adsorption (50 mL of the Pb^{2+} solution, concentration 100 mg L^{-1}) on modified clay (1.00 g) was investigated at pH values 1, 3, 5, 7 and 9. At *Figure 4,* it was given the dependence onadsorption capacity of adsorbent for Pb^{2+} ions (mg g^{-1}) as a function of pH of the environment. It is obvious that the adsorption increases with the increase of pH value. In strong acidic environment, the number of H_3O^+ ions is higher that the number of Pb^{2+} ions in the solution, so at low pH values the active places for the adsorption are occupied with H_3O^+ ions which unable the adsorption of Pb^{2+} ions (Bhattacharyya and Gupta, 2007). Qiu et al. (2008) noticed the existence of lead in different forms at different pH, such as Pb^{2+}, $Pb(OH)^+$, $Pb(OH)_2$, $Pb(OH)^{3-}$, $Pb(OH)_4^{2-}$, etc. At pH=6.7, the precipitation of lead in the form of hardly soluble $Pb(OH)_2$ occurred, so the decrease of the concentration in this pH range can not be attributed to adsorption (Qiu et al., 2008). In any case, it is evident the increase of the percentage of removed lead by adsorption at pH values up to 7. Similar results were obtained by Bhattacharya and Gupta (2007).

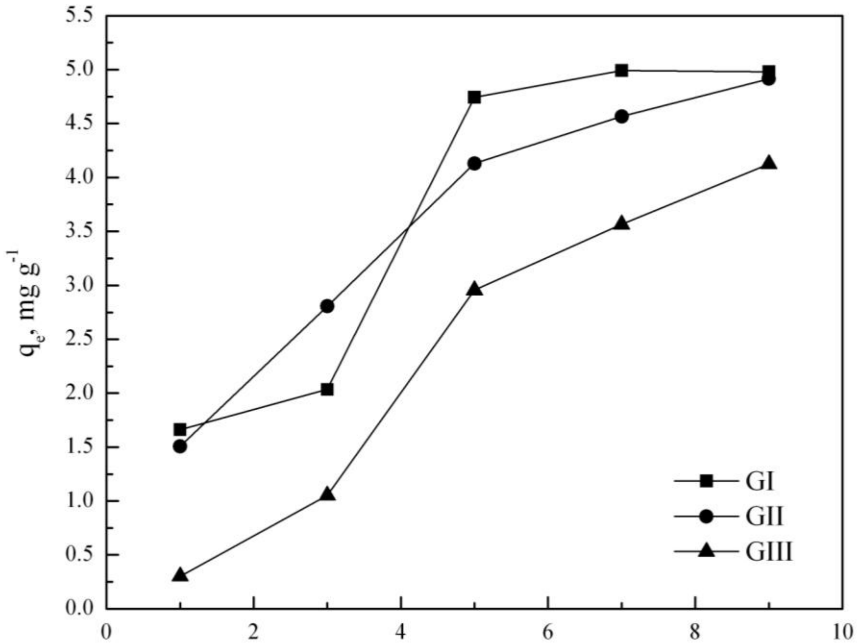

Figure 4. *The influence of pH on the adsorption of Pb^{2+} ions*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_14611472

Modified clay GI is the most sensitive to pH change which increases the possibility of its application.

The influence of temperature on the adsorption

The influence of the temperature on the adsorption of lead (50 mL of Pb^{2+} solution, c=100 mg L^{-1}) on modified clay (1.00 g) was investigated at five different temperatures (20 ^{0}C, 30 ^{0}C, 40 ^{0}C, 50 ^{0}C and 60 ^{0}C). From *Figure 5*, it is obvious that the increase of temperature causes the increase of Pb^{2+} adsorption from the solution, indicating that the adsorption of lead on the investigated adsorbents is an endothermic process. This increase is the most pronounced in case of sample GI.

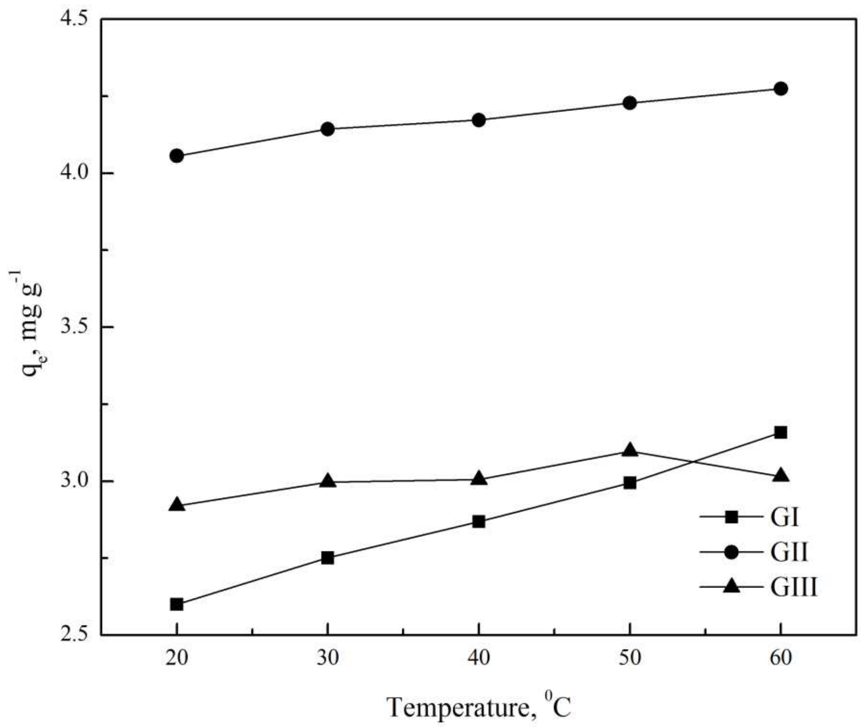

Figure 5. *The influence of the temperature on the adsorption of Pb^{2+} ions*

The influence of the mass of the adsorbent

The influence of the mass of the adsorbent on the adsorption of Pb^{2+} ions (50 mL of Pb^{2+} solution, c=100 mg L^{-1}) was investigated with the following weights of modified clay: 0.25, 0.50, 1.00, 1.50 and 2.00 g. Results are shown in *Figure 6*. It is obvious that increasing of mass of the adsorbent causes the increase of the percentage of adsorbed lead since the adsorption is carried out on the available surface, so for the solution of fixed concentration, the increase of the quantity of adsorbent gives the higher area i.e. more places for the adsorption (Chaari et al., 2008).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_14611472

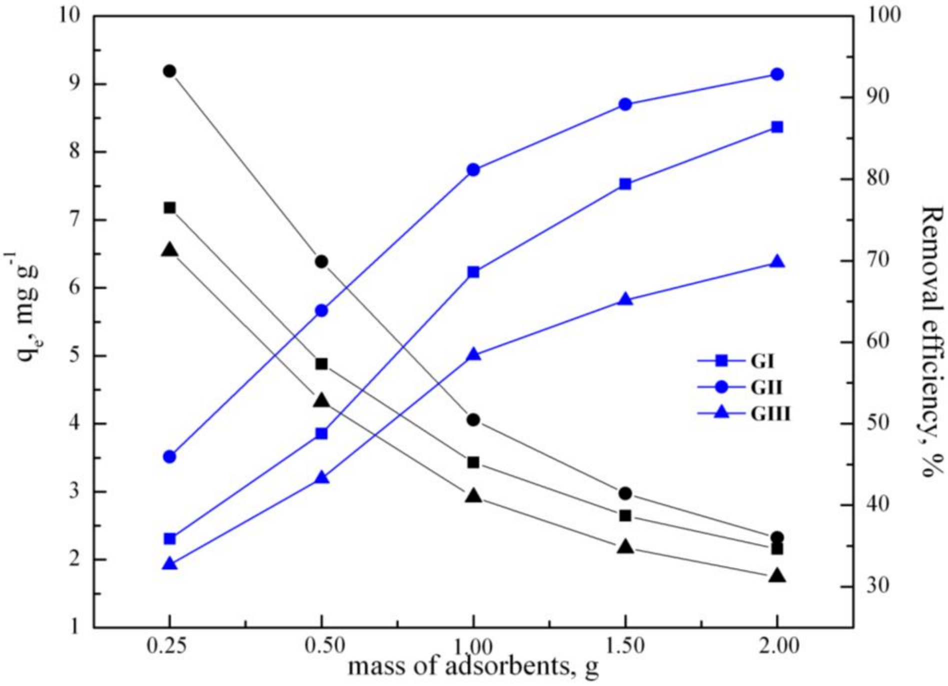

Figure 6. *The influence of the mass of the clay on the adsorption of Pb^{2+} ions*

The highest effect of the removal of Pb^{2+} ions was shown by the modified clay GII.

50 mL of the solution of different initial concentrations Pb^{2+} was added to 1 g of the modified clay. pH of solution was 5.0, and experiments were performed at 20 ºC (*Fig. 7*).

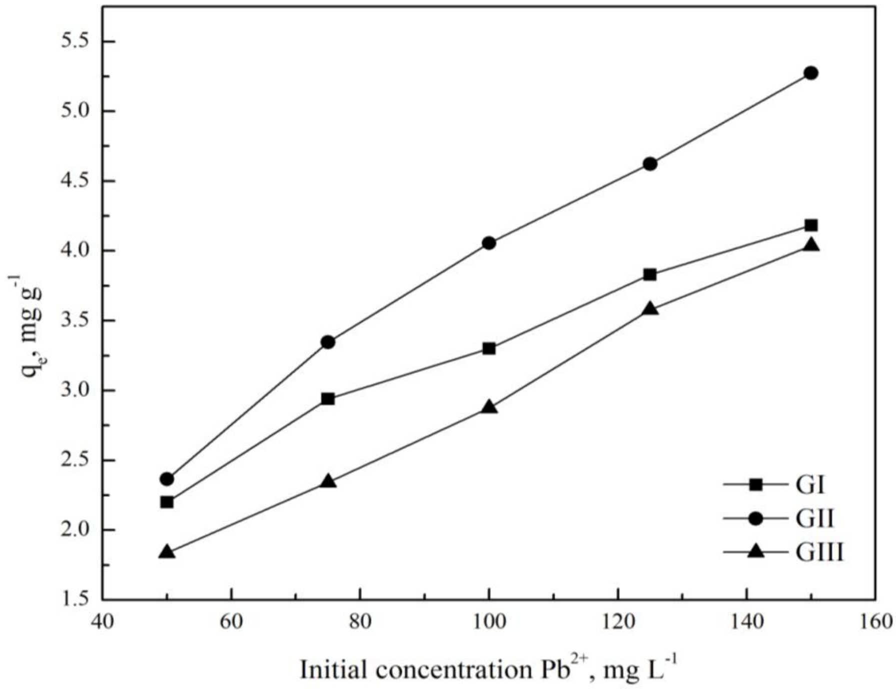

Figure 7. *The influence of the initial concentration of adsorbate on the adsorption of Pb^{2+} ions*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_14611472

Adsorption capacity of clay (adsorbate) GII is the highest and increases with increasing of initial concentration of Pb^{2+}, while the smallest is for clay (adsorbate) GIII. The highest percentage of added NaCMC (5%) is the reason of minimum adsorption capacity. The results show that under the same experimental conditions, adsorbate with 3% of NaCMC is the most efficient (with highest adsorption capacity). This can be explained by the formation of the most suitable structure with the addition of NaCMC in concentration of 3%. The addition of polymer onto clay and improving the adsorption properties is also reported other authors (Stojiljkovic et al., 2014).

Adsorption isotherms

Based on the obtained results, Langmuir and Freundlich adsorption isotherms were applied for the investigation of modified clay.The Langmuir model assumes that the uptake of metal ions occurs on a homogeneous surface by monolayer adsorption without any interaction between adsorbed ions (Langmuir, 1918). The Langmuir parameters can be determined from a linearized form, by plotting Ce/qe vs. Ce (*Fig. 8, Eq. 2*):

$$\frac{c_e}{q_e} = \frac{1}{K_{Lq\max}} + \frac{1}{q_{\max}} c_e \quad \text{(Eq. 2)}$$

where C_e is the equilibrium concentration of adsorbate (mg dm^{-3}), q_{max} is the Langmuir equilibrium constant related to maximum monolayer coverage capacity (mg g^{-1}), and K_L is the Langmuir constant which is related to the enthalpy of adsorption (dm^{-3} mg^{-1}).

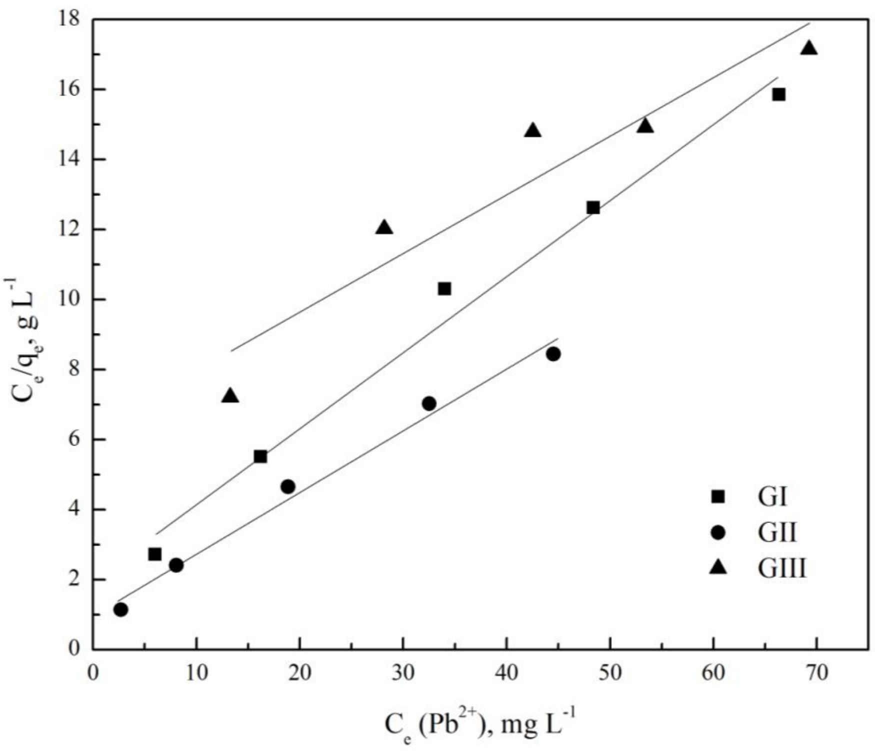

Figure 8. *Langmuir adsorption isotherms for the adsorbents GI, GII and GIII*

Based on logarithmic form of Freundlich equation (*Eq. 3*):

$$\log q_e = \log K_f + \frac{1}{n}\log c_e \qquad \text{(Eq. 3)}$$

where q_e is the adsorption capacity (mg/g), K_f Freundlich constant, 1/n Freundlich exponent and c_e concentration of Pb^{2+} ions in the equilibrium (mg dm^{-3}), the plot of the log q_e against log c_e is presented (*Fig. 9*).

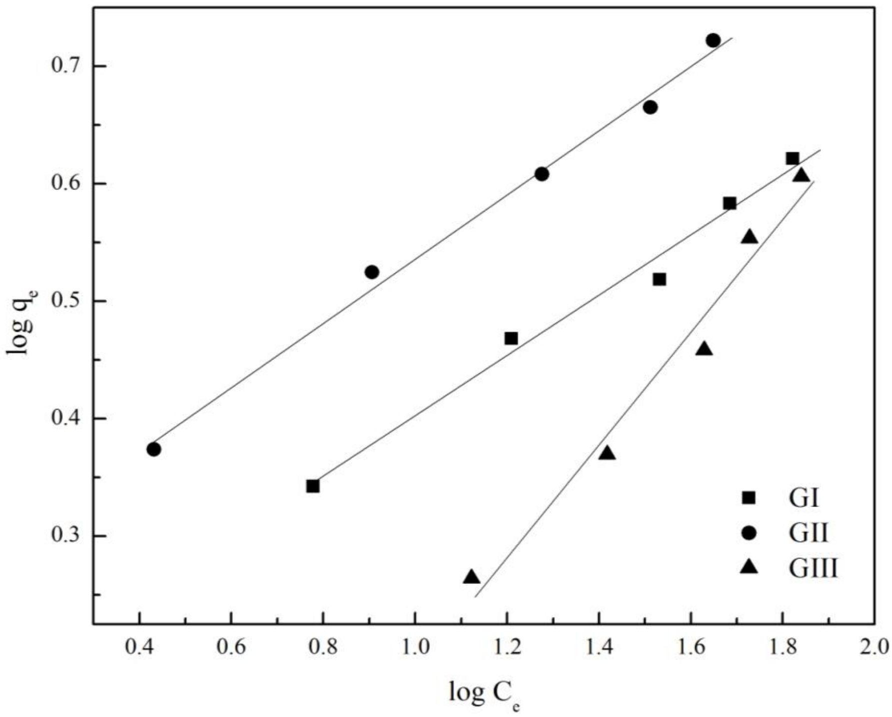

Figure 9. *Freundlich adsorption isotherms for the adsorbents GI, GII and GIII*

In *Table 2* parameters of Langmuir and Freundlich adsorption isotherms were given for the investigated adsorbents.

Table 2. *Parameters of Langmuir and Freundlich adsorption isotherms for the investigated adsorbents*

Adsorbents	Freundlich			Langmuir		
	K_f	n	R^2	K_L	Q_{max}	R^2
GI	1.3890	3.8585	0.98159	0.1099	4.6024	0.98232
GII	1.8256	3.6387	0.99181	0.1789	5.6860	0.98325
GIII	0.5108	2.0849	0.96289	0.0266	5.9687	0.87946

Results obtained by this study are similar with results for clay modification with polymers (Stojiljkovic et al., 2014). This is not surprising because both NaCMC and polymers, which are used to modify clay, are long chain molecules that are expected to increase adsorption process.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_14611472

Conclusions

Suitability of the clay modified with NaCMC for the removal of toxic heavy metal (lead) from the aqueous solution was tested in adsorption studies. The effect of various factors, such as the effect of pH of the solution, temperature, quantity of the adsorbent, concentration of the adsorbate was determined in a series of the experiments. It was found that the adsorption, i.e. the percentage of removed lead increases with the increase of these parameters. Obtained Freundlich adsorption isotherms show extremely high correlation coefficient R, i.e. processes of equilibria on the investigated clays can be described using this equation. The series of conducted experiments shows that the clay modified with carboxymethyl cellulose is suitable for the removal of lead from waste waters. Removing metal ions from aqueous solutions by adsorption onto bentonite and its modifications is efficient and cheap technique. Further researches should be aimed to test adsorption properties of the clay modified with other long chain molecules, and to test its efficiency in removing heavy metal ions from water solutions in different conditions.

(Received 27th Jun 2017; accepted 2nd Oct 2017)

Abstract.A field experiment was carried out in two crop seasons in the lateritic sandy loam soils of Kharagpur, West Bengal, India, to investigate the response of banana (*Musa acuminata* L.) cv. Grand Naine at different levels of nitrogen, phosphorous and potassium nutrients applications through drip fertigation and plastic mulch. A randomized complete block design was used with four fertigation levels in conjunction with mulch and without mulch. Fertigation levels caused a significant increase in fruit yield and determined the response to N, P and K fertilizers. The results of recommended dose of fertilizers application through drip either alone or in conjunction with black plastic mulch conditions were compared with other fertigation treatments in terms of growth and crop of yield. Both the main and ratoon crops performed best for 80 per cent of the recommended fertigation dose (160 N: 48 P: 240 kg plant^{-1} year^{-1}) covered with plastic mulch in respect of (a) growth parameters; maximum plant height, stem girth, functional leaves, yield parameters and shortened total crop duration for 34 days and for (b) quality parameters; higher levels of TSS, reducing sugar and non-reducing sugar, pulp:peel ratio and lower content of acidity. Hence, fertigation with 80 per cent of the recommended dose coupled with plastic mulch was found to be optimum and economical for banana cultivation.
Keywords: *crop coefficient; nitrogen; potassium; nutrient conversion efficiency; B-C ratio*

Introduction

Banana is a fast growing plant that requires high and continuous nutrient and water supplies to sustain a yearlong cycle and ensure economically high yield. These nutrients may be partly supplied by the soil, but fertilizer application is generally needed to satisfy the needs of theplant and to obtain profitable production. In almost all thefertigation studies, researchers suggested high nutrition (nitrogen, phosphorous, potassium) requirement of banana crop (Lahav, 1995). According to Lahav (1995), a banana crop yielding 50 t ha^{-1} requires about 390 of N, 50 of P and 1440 of K (kg ha^{-1}).

The increasing fertilizer costs and the demand have emphasized the need for full exploitation of sources of nutrientson a global scale. So in today's perspective, it is essential, especially in crops like banana which are the heavy feeder of nutrients it is desired to use efficien tmethod of fertilizer application and splitting the dose to get maximum fertilizer use efficiency (FUE) and net profit. Under sub-tropical conditions, soil nutrients will be leached rapidly due to various factors and therefore it should be applied in small doses at shorter intervals. In recent years, liquid fertilizers are used as astrong alternative to solid fertilizers. The major advantage of liquid fertilizers is that, they are completely soluble in water and can be applied through drip system with an ease, without any harm and in number of splits. The second strong point goes in favour of liquid fertilizeris that they contain major essential nutrients in readily available form. In the fertigation process predissolved soluble fertilizers are injected into the feeder line

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_14731488

of drip irrigation system. Fertigation increases the nutrient use efficiency by 30-40%, prevents soil degradation, reduced the cost of fertilizer application and minimizes the pollution of groundwater, also preventing losses through runoff and leaching. It ultimately increases the FUE by increasing the nutrient uptake and minimizing the losses. It also improves the productivity andquality of the produce (Srinivas, 1999; Mahalakshmi et al., 2001; Pandey et al., 2001).

Mulches also contribute to the crop productivity by way of influencing moisture content, soil productivity, weed control etc. (Sweeney et al. 1987). Use of different types of soil covers ormulches like straw, leaves, husk, crop residues and black plastics have been found to conserve moisture, nutrients, control weeds, moderate soil temperature and increase in yield ofdifferent vegetables. It is observed from studies that beneficial response of plants to mulch includes earlier production (Call and Courter, 1989), greater total yield and reduced insect and disease problems (Greenough et al., 1990). The yield response of plastic mulch in vegetable and fruit crops is reported to be greater than organic mulches (Tiwari et. al., 1998a,b; Tiwari et. al., 2014). The combined effect of fertigation and mulch on banana crop yield has not been studied for sub humid climatic and lateritic soil condition.

The objective of the present study is to investigate the response of different levels of fertigation through drip and black plastic mulch on yield and nutrient use efficiency of banana crop. It is alsoproposed to investigate the effects of cropping on chemical properties of soil.

Materials and Methods

Experiment was conducted at the Experimental Farm area of Precision Farming Development Centre Project, Agricultural and Food Engineering Department, Indian Institute of Technology, Kharagpur, India. The experimental site is located at flat land with latitude of 22°18.5' N, longitude of 87°19' E and an altitude of 48 m above mean sea level. The local climate is sub-humid subtropical with an average annual rainfall of 1390 mm, of which about 80% is received during June to October. The mean monthly minimum temperature is 6 ^{0}C in January, whereas the mean monthly maximum temperature is 43.5 ^{0}C in May. The mean monthly relative humidity varies from 35% in February to 96% during July-August. The soil of the experimental area is lateritic with sandy loam texture.

The experiments were laid out with tissue cultured banana cv. Grand Naine as a test crop in randomized block design (RBD) with eight treatments and three replications (*Figure 1a*). Each treatment had a net area of 2 m × 15 m with 15 plants in each treatment. Banana was planted on raised bed and four treatments (12 rows) of crop bed. The bed was covered with black plastic mulch of 50 micron thickness of 1 m wide and 10 m long for each row (*Figure 1b*). The details of the treatments are furnished below.

T_1 (1.2 RDF + M):	120% of fertilizer requirement application through drip and plastic mulch
T_2 (1.2 RDF):	120% of fertilizer requirement application through drip and without mulch
T_3 (RDF + M):	100% of fertilizer requirement application through drip and plastic mulch
T_4 (RDF):	100% of fertilizer requirement application through drip and without mulch
T_5 (0.8 RDF + M):	80% of fertilizer requirement application through drip and plastic mulch
T_6 (0.8 RDF):	80% of fertilizer requirement application through drip and without mulch
T_7 (0.6 RDF + M):	60 % of fertilizer requirement application through drip and plastic mulch
T_8 (0.6 RDF):	60 % of fertilizer requirement application through drip and without mulch

Estimation of crop water requirement and irrigation water supply

Reference crop evapotranspiration (ET_O) was estimated using the FAO-56 modified Penmanmethod using weather data collected from Weather Station, 0.5 km away from the field site. The values of crop coefficient (Kc) suggested by Allen et al. (1998) were considered and appropriately adjusted. Soil surface evaporation component in crop evapotranspiration is considered negligible as it was covered with the black plastic mulch. The actual evapotranspiration was estimated by multiplying reference evapotranspiration with crop coefficient for different months based on crop growth stages. The daily irrigation water requirement for the banana crop was estimated using the following relationship:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_14731488

$$IR = ET_0 \times K_c - R_e \quad \text{(Eq. 1)}$$

where:
IR Net depth of irrigation (mm day^{-1})
ET_o Reference evapotranspiration (mm day-^{1})
K_c Crop coefficient
R_e Effective rainfall (mm day^{-1})

The net volume of water required by the plant can be calculated by the relationship

$$V = IR \times A \quad \text{(Eq. 2)}$$

where:
V Net volume of water required by a plant (L day^{-1} $plant^{-1}$)
A Area under each plant (i.e. spacing between rows, m x spacingbetween plants, m)

The reference evapotranspiration was estimated using FAO 56 method. The crop coefficient K_c was estimated considering the local soil condition. The effective rainfall is the part of the rainfall that forms the part of the consumptiveuse. The irrigation water was supplied after subtracting the effective rainfall from the total irrigation requirement (*Eq. 1*).The water requirement was estimated for the main and ratoon crop of banana using *Eq. 2*. The irrigation water was applied for the entire crop season as per the crop growth stages using drip irrigation (*Figure 2a*).

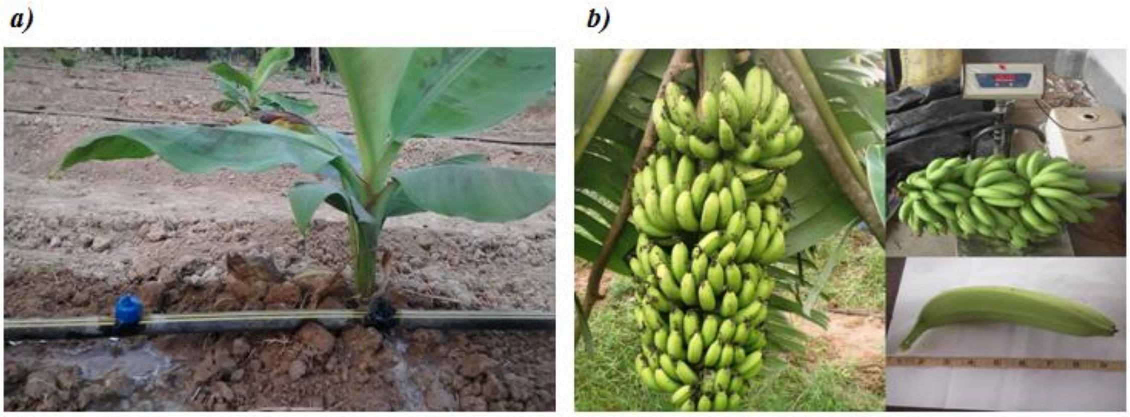

Figure 2a*. Application of fertilizer for banana crop using micro irrigation*
Figure 2b*. Weighing banana bunch and measuring length of banana fruit*

Fertigation schedule application

The dose of fertilizer for Grand Naine was considered as 200:60:300 N:P_2O_5:K_2O $kgha^{-1}$as recommended by Mahalakshmi et al. (2001) and Nalina et al. (2000). This recommendation is for manual application. Using this recommended values weekly schedule was estimated considering the nutrients requirement at different growth stages of plant as given in *Table 1*. Water soluble fertilizers were applied twice in a week through drip irrigation system.

DOI: http://dx.doi.org/10.15666/aeer/1504_14731488

Monitoring the growth parameters

Growth parameters monitoring under each treatment included seasonal increase in plant height (5 cm from the base of thepsuedostem to the point of interaction of the petioles ofthe two youngest leaves), plant girth (5 cmabove the ground levels), the number of green leaves, and leaf area (Murray, 1960). Mature bunches were harvested when they reached full three quarter shape. Yield and yield components were recorded under each treatment (*Figure 2b*). The second hand of freshly harvested bunch was used to measure the fruit quality analysis (Pulp:peel ratio, TSS, Total sugar, Acidity) as suggested by Dadzie & Orchard (1997).

Table 1. *Fertilizer recommendation for banana crop*

Crop stage (No. of weeks after transplantation)	Quantity (N:P:K), g/plant	Schedule ((N:P:K), g/plant/fertigation*
Basal Dose	1 kg Neem Cake,+ 20 FYM	While Transplanting
Initial stage (1 to 8)	58:30:30	3.6: 1.9: 1.9
Developmental stage (9 to 16)	90:30:90	5.6: 1.9: 5.6
Fruiting stage (17 to 24)	32:00:100	2: 0: 6.3
Harvesting stage (25 to 40)	20:00:80	0.7: 0 : 2.7

*fertigation is scheduled twice in a week

Monitoring the plant chemical parameters

Third leaf laminas were sampled (after the first hand of male flowers could be seen onthe inflorescence) as recommended by Martin-Prével (1992); samples from bunch stalkand fruits were also taken and their nutrient concentrations were determined. The plant parts were dried at 80°C for 48 hours and the concentrations of N (Kjeldahl method), P (Spectro colorimeter) and K (flame photometer) were measured. The amountof nutrient in each organ was calculated from dry weight and nutrient concentration.

Statistical analysis was performed using SPSS software package to test the significance of different treatments individually as well as in combinations experimental ANOVA was performed by the method described by Gomez and Gomez (1984). In order to the comparisons between the treatment means and variance were tested at 5% significance level. Duncan multiple range test was conducted to know the significance level between the treatments and groups of treatments.

Results and Discussion

Estimated water requirement for banana crop

Reference crop evapotranspiration (ET_o) was estimated using the FAO-56 modified Penman method using weather data. The actual evapotranspiration was estimated by multiplying reference evapotranspiration with crop coefficient based on crop growth stage. In present study the value for daily crop coefficient (Kc) was estimated using dual crop coefficient method. Summation of both Kcb and Ke curve makes crop coefficient (Kc) curve on daily basis for banana crop. The soil evaporation coefficient (Ke) was considered zero when soil is covered with plastic mulch. Therefore the value of Kcb is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_14731488

considered as Kc for calculation of crop evapotranspiration under mulch cover. The ground cover reduction factor for banana crop under drip irrigation started from 0.1 and maximum ground cover estimated is about 0.96 at the developmental stage. The daily irrigation water requirement for the banana crop was estimated by subtracting the effective rainfall from the calculated evapotranspiration. The estimated quantity of water applied to banana plants for main and ratoon crop was 1236, 612 mm for without mulch and 1115 mm, 520 mm for plastic mulch treatment respectively. *Figure 3* shows the month wise distribution of banana crop water requirement for the tissue cultured banana plantlets transplanted in October month. The total crop duration was 11-12 months for main crop and 10-11 months for ratoon crop. The crop water requirement of banana varies from 1.59 to 19.6 L day^{-1} $plant^{-1}$ from early stage to peak demand period without mulch and 0.66 to 17.71 L day^{-1} $plant^{-1}$ for plastic mulch covered condition (*Fig. 3*). The total quantities of water applied to banana plants were 3.43 m^3through drip irrigation system without plastic mulch coverand to 2.59 m^3 for drip with plastic mulch covered condition.

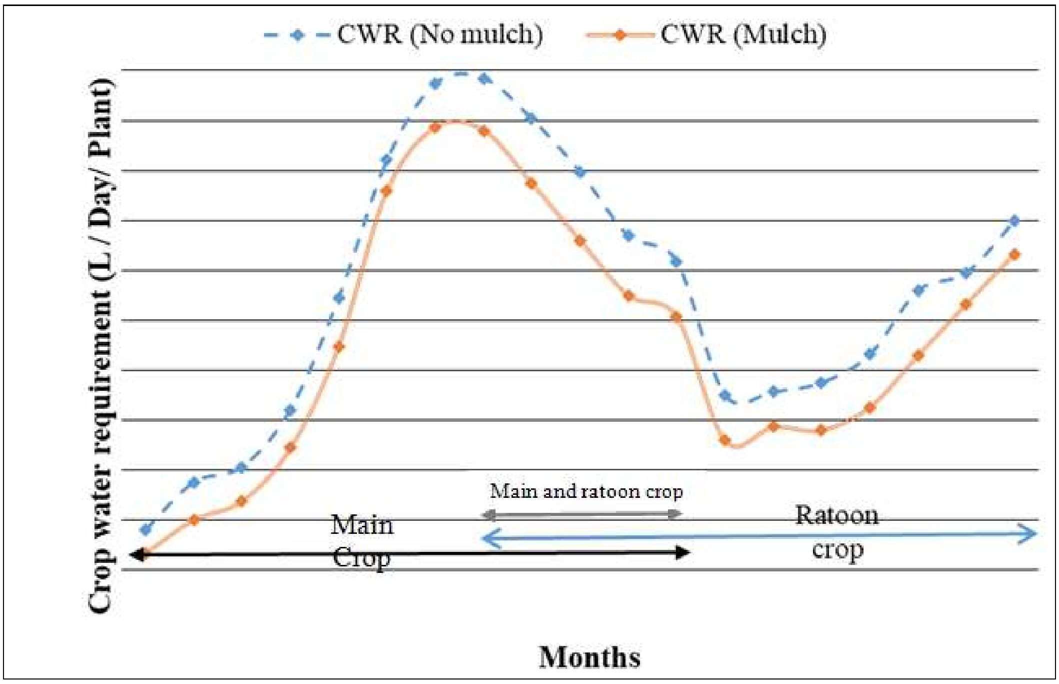

Figure 3. *Estimated crop water requirement of banana in open and plastic mulch conditions*

Effect of fertigation levels on biometric properties of banana crop

Treatment wise biometric observations of the crop were recorded and after analysis of data these are given in *Table 2*. Pooled data over two crop season indicates that vegetative growth parameters were significantly influenced by different level of fertigation treatments. *Table 2.* shows the values of biometric attributes (plant height, stem girth, no. of functional leaves and leaf area) under different treatments. The results showed that thetreatments differences were very highly significant forplant height, no. of functional leaves & significant for leaf area of the main plant and ratoon crop of banana cv. Grand Nain. The best growth parameters were obtained at 80% of RDF covered with plastic mulch (T_5) followed by 100% RDF covered with plastic mulch (T_3).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_14731488

The result indicated that there was a significant difference among fertigation treatments in pseudo stem height and stem circumference or girth. The stem height in all the treatments showed steady increase throughout the growt hcycle of the first and ratoon banana plants. The treatment T_5 recorded the maximum plant height (207.1&183.8) in comparison to other treatments, which was statistically at par with treatment T_3 80% of recommended dose of NPK through drip irrigation and soil covered with plastic mulch, which registered a plant height of (201.6 & 178.3) in first and ratoon crop respectively. While the treatment T_8 had the lowest stem height (171.0&153.4) in first and ratoon crop respectively. Growth response of banana to NPK fertilization through drip irrigation (fertigation) indicated that the T_5 (80% RDF + mulch) treatment responded best performance in terms of growth in main crop under study. These results are almost similar with the data reported by Belalcazar and Espinosa (2000). Increased uptake of nutrients particularly nitrogen under fertigation system could be attributed to enlarge of stem height. The absorbed nitrogen ultimately might have been utilized by the plants in the formation of complex substances like protein and amino acids which in turn help to build up new tissues (Childers, 1966). These results are in accordance with the findings of Martinsson et al. (2006) who obtained maximum plant height in starw berry for optimum dose of fertilizer application through drip.

* Any two means having a common letter are not significantly different at the 5% level of significance

Pooled mean values of two crop season showed that fertigation with 80 per cent RDF through drip irrigation and plastic mulch (T_5) recorded highest stem girth (60.6 and 52.2 cm) in main and ratoon crop respectively. It was followed by the treatment T_3 (57 & 48.7 cm) and the lowest value was recorded in T_8 (53.8 & 43.2 cm) in main and ratoon crop respectively. Effect of fertigation level on stem girth in main crop was not statistically significant. However, effect of treatment was significant in ratoon crop. This may be due to plastic mulch which influences the emergence and growth of suckers. Hegde and Srinivas (1991) also had similar observations as in the present study which indicated that increasein amount of nitrogenand potassium fertilization had no significant effect on stem girth effect. This is perhaps due to sufficient amounts of soil NPK 80% RDF maintained adequate vegetative growth in this study.

A banana crop should produce sufficient number of leaves to harness thelight energy and synthesize adequate photosynthates for biomass production. The role of leaf parameters such as number of leaves produced and number of functional leaves retained at shooting is crucial in determining the yield potential.The fertilizer treatment had little effect in producing number of leaves. The leaf number increased slightly in response to the fertigation treatments. At the time of flowering, all the treatments produced the same number of leaves (ranged from 10-14 leaf/plant). This exceeded the lowest number of leaves (eight leaves) required at flowering to obtain high yield (Martinez, 1984). The application of 80% NPK per plant and plastic mulch (T_5) significantly enhanced the number of leaves at all stages of growth both in plant and ratoon crops which indicated that the application of NPK at optimum rate promoted faster rate of leaf production.

Apart from the number of leaves, leaf area at any growth stage is very critical for banana crop as it has a close bearing on photosynthetic efficiency reflecting on biomass production. An increase in leaf area results in better utilization of solar energy. For individual leaf, treatment T_5 had the largest leaf area followed by T_3 which is at par with treatment T_5.

The increased height, girth, number of leaves and leaf area in mulched treatments corresponding with same fertigation level was recorded. This may be attributed to sufficient soil moisture near root zone and minimized leaching of nutrients due to mulching. Similar findings have also been obtained by Ansary and Roy (2005) in water melon, Al-Majali and Kasrawi (1995) in muskmelon, Hallidri (2001) in cucumber.

The maximum number of suckers were recorded in the treatment T_3 (100 % RDF with plastic mulch) as 10.7 in the main crop and 4.3 in the ratoon crop. Treatment T_5 (80% RDF covered with plastic mulch) took 336& 305.7 days to harvest main and ratoon crop respectively which was lesser than other treatments (*Table 3.*). Crop duration or is an important factor to be considered in banana cultivation especially under fertigation through drip. The crop duration can be divided into two phases viz., days taken from planting to shooting in main crop or sucker setting to shooting of ratoon crop and days taken from shooting to harvest. In the present experiment, it was revealed that optimum dose of fertigation through drip with plastic mulch caused reduction in crop duration of main and ratoon (*Table 3*). From these experimental results, it appears that the main crop grown under treatment T_5 shooting flower nine days earlierthan treatment T_4 (100 % RDF with no mulch), while in the ratoon crop eight days early flower emerges from the treatment T_5 compare to the treatment T_4. The early shooting under the treatment (T_5) could be attributed to the rapid production of leaves, which would have elaborated more photosynthates and increased flowering stimulus.

Normally, higher fertigation and irrigation levels cause excess vegetative growth that may delay in flowering period. The delay in shooting and harvest in the treatments T_1 and T_2 may be due to increased nitrogen status which might have been causedby the supra optimal level of nutrients leading to poor development of root system which also reflected in lesser number of roots. When the root number is less, it may notbe adequate to meet the nutrients required by the aerial parts. This is in agreement with Nalina et al. (2000) whofound that the crop supplied with optimum dose of fertigation needs less number of days to shooting (226 days) and total crop duration (338 days). Mahalakshmi (2001) also noted early shooting, early bunch development including total crop duration under low levels of nutrients and water. This can be explained due to the better source sink relationship in treatment T_5 which recorded more leaf area with more photosynthetic activity, translocating the carbohydrate efficiently to the development of bunch.

* Any two means having a common letter are not significantly different at the 5% level of significance

Yield and yield component are the most important economic traits, which are very highly influenced by fertigation treatments. Yield in banana is a function of bunch weight and number of plants perhectare. In the present study, the most important economic trait, namely bunchweight was significantly influenced by the various fertilizer treatments (*Table 4*). The maximum yield and bunch weight was obtained T_5. The number of hands andfingers per bunch with treatmentsT_5, T_3, T_6 and T_4 were significantly greater than others fertigation treatments of the first and ratoon crop (*Table 4*). The bunch weight decreased when level of N, P and K fertilizer doses decreased T_7 and T_8 also increased doses at T_1, T_2, T_3 and T_4. The results also showed thatthe higher dose of fertilizer application (as in T_1& T_2) mayresult in small bunch weight. This was also observed by Bolanos et al. (2003) where excessive potassium applications reduced banana yield.

The increase in yield (bunch weight) was attributed toincrease in the total fruit weight. Highest yield was recorded in treatment T_5 and yield of treatment T_3 is at par with the yield T_5 treatment (64.49 & 50.07 t ha^{-1}) in both main and ratoon crop. Remaining treatments show significant difference in yield. Similar findings were observed by Srinivas (1999), while studying the effect of N, P and K fertilizers on banana cv. Basrai. Kohli et al. (1976) reported that the nitrogen application significantlyinfluenced the fruit yield in both the crops (plantcrop, first ratoon and second ratoon).

The banana yield with drip fertigation in the presence of black plastic mulch (T_1, T_3, T_5, T_7) were significantly higher than that obtained without mulch (T_2, T_4, T_6, T_8) with respective same amount of fertilizer application. The results of the present study agreed with the finding of Igbal et al. (2009), Wang et al. (2009), and Parmar et al. (2013) who indicated that plants under polyethylene mulch produce larger fruit and have higher fruit yield per plant because of the better plant growth due to favorable hydro thermal regime of soil and complete weed free environment. Furthermore, they mentioned that the extended retention of moisture and availability of moisture also lead to a higher uptake of nutrient for proper growth and development of plants.

There was significant difference in yield with the treatment T_5 in comparison with the Treatment T_2 (120% RDF with plastic mulch). Though banana crop is known for an

DOI: http://dx.doi.org/10.15666/aeer/1504_14731488

exhaustive crop amount of nutrients requiring crop at various stages of growth and development, perhaps availability of nutrientsbeyond its requirement might probably have cause its negative effect. This is also evident from the present study, where in, application of nutrients above 100 per cent did not correspondingly increased bunch weight in both plant and ratoon crops. Similar study by Bolanos et al. (2003) has shown that appropriate amount of addition of nutrients in the soil is important in obtaining higher total fruit weight.

Effect of fertigation levels on leaf and fruit nutrient concentration

Leaf nutrient concentration in banana plant provides information on the nutrient status of the plant. In banana crop cultivation practices, especially with nutrient management the optimum leaf concentration of major nutrients provides proper growth and development of banana plant. Nutrient analysis of leaf is an important diagnostic tool to verify if the crop suffers due to nutrient deficits or inadequate in amount if thecrop health status is good. Nutritional status must be in optimal concentration especially at flower initiation stage to achieve good growth and yield the leaf analysis should be done at this stage.

The nutrient content in the leaf of the present investigation both in plant and ratoon crops revealed thatthe treatmentT5 recorded higher of N,P and Kcontents over theother treatments, which indicated that the critical level of NPK was maintained (*Fig. 4*). Based on an average N content, one would getthe impression that nitrogen nutrition of banana is well above the critical level of 2.6% N in treatments T3, T4, T5 & T6 as proposed by Lahav and Turner (1983). Different researchers have proposed different

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_14731488

critical levels of N (in the 3rdleaf of banana)which ranged from 1.81 to 4.0% and an average of 3.03% (Angeles et al., 1993). Detailed examination of the data, however, revealed that N content was less than 3.03 % in all the treatments except treatment T3 and T5, below this critical value photosynthesis will be affected and results in lesser yield. Theleaf P content were analyzed and compared with the critical level of 0.2% as proposed by Lahav and Turner (1983). Based on this criterion, Phosphorous content is in optimum level (>0.14%) in all the treatments. Potassium content of leaves shows optimum (4.0-5%) as given by Lahav and Turner (1983) except in Treatment T7 & T8. This signifies the need for additional application of K fertilizers for improving nutrition and high yield of banana. It is well established fact that K improves the quality of banana, in addition to its role in increasing banana production.

Removal of plant nutrients in the harvested banana fruit is one of the major considerations informulating fertilizer recommendations. *Figure 5* shows the higher nutrient content accumulated in 80% RDF covered with plastic mulch (T_5) followed by 100% RDF covered with plastic mulch (T_3).

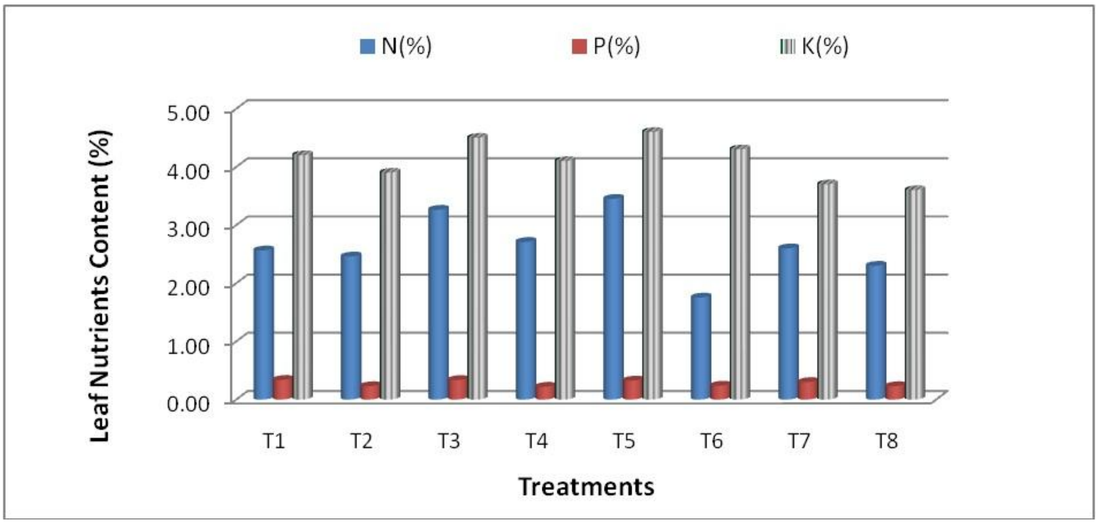

Figure 4. *NPK content of banana leaf samples in different treatments*

Effect of fertigation levels on qualitative parameters of banana

In any production systems, the primary objective is to obtain maximum fruit yield per unit area without affecting the fruit quality. The fruit quality in banana is mainly judged by the sugar content and acidity in the pulp. A marked effect on fruit quality was observed with the application of adequate amount of nutrients. Higher levels of TSS, reducing and non-reducingbut a lower acidity were recorded in fruits in T_5 or T_3 (*Table 5*). Higher fruit quality especially sugar content can be explained due to the better role of nutrients particularly potassium which is involved in carbohydrate synthesis, breakdown and translocation of starch, synthesis of protein and neutralization ofphysiologically important organic acids. Further, the fruit quality parameters namely TSS and sugarswere significantly influenced by the fertigation treatments.

Table 5 shows that T_5 recorded the highest pulp: peel ratio of 2.27:1 indicating thin skin. The minimum ratio was noticed in T_8. Among the treatments evaluated, $T_5$was sweetest (24.10 ^{0}Brix) followed by T_1 (23.4 ^{0}Brix) and T_4 (23.3^{0}Brix), banana fruit analysis revealed that the treatment T_8 resulted in highest titrable acidity of 0.275%. The study reveals that N content influences TSS, sugar and acidity of banana fruit (Nalina et al., 2000). Similarly Dinesh and Pandey (2008) recorded statistically significant values of TSS, total sugars and reducing sugars with application of 75 % RDF. Hence the increased values of total sugars in banana might be due to higher uptake of nitrogen and potassium bythe plant.

61.22 t kg^{-1}(ton of fruit yield to per kg of applied nitrogen), Phosphorous conversion efficiency of 537.42 t kg^{-1}, Potassium conversion efficiency of 107.48 t $kg^{-1}$and total nutrient efficiency of 57.58 t kg^{-1}were registered under water soluble fertigation through drip fertigationat 80% NPK dose with plastic mulch cover treatment (T_5) and followed by water solublefertilizers application through drip at 100% NPK dose under plastic mulch cover (T_3). The increased nutrient conversion efficiency recorded under treatment $T_5$was mainly due to better crop growth and increased yield by effectiveutilization of available nutrients that were supplied at optimum level throughout the cropperiod to meet the crop demand (Bangar and Chaudhari, 2004).

Table 6. *Nutrients conversion efficiency*

Economic analysis

The gross cost of production, net return and benefit cost ratio for different fertigation levels are presented in *Table 7.* The net returns were computed by multiplying average market rate of banana during the crop harvesting period with the yield obtained and subtracting the gross cost incurred in crop cultivation for different treatments. Maximum net profit of US $. 7199.22 per hectare and B:C ratio of 5.2 were obtained for the treatment T_5 whereas the treatment T_8 resulted in lowest net profit of US $ 3277.77 with B:C ratio of 2.7. Increase in fertigation levels causes increase in the cost of production significantly due to high cost of water soluble fertilizers as the water soluble fertilizers are generally imported in India and sold at high prices compared to straight fertilizers. Higher amount of water soluble fertilizer application in treatments T_1 and T_2 and less yield obtained compared to other treatments (T_5, T_3, T_6 and T_4) were the reason for least B:C ratio in treatments T_1 and T_2. The fertilizer levels also had significant effect on B-C ratio. The results obtained for different fertigation levels in *Table 7* are in similar trends with results reported by (Rajaraman and Pugalendhi, 2013). The mulched treatments T_1, T_3, T_5 & T_7 resulted in greater net return per ha ranging between 4% and 23% and higher B:C ratio than their corresponding treatments without mulch with drip fertigation.

Conclusions

At the current fertilizer input and farm gate banana prices, fertilizers can probably only be recommended to farmers when coupled with practices that increase soil moisture availability, such as micro irrigation and plastic mulch. Results of the present study showed that both main and ratoon crops, 80 per cent of the recommended fertigation dose (160 N: 48 P: 240 kg plant^{-1} year^{-1}) covered with plastic mulch (T_5) performed well in respect of growth parameters; maximum plant height, stem girth, functional leaves, yield parameters and shortened the total crop duration. Higher levels of TSS (24.1 ^{0}brix), reducing (13.53%) and non-reducing sugar (1.76%), pulp: peel ratio (2.34:1) but a lower acidity (0.25 %) were recorded in fruits in treatment T_5. The highest nutrient conversion efficiency (57.58 t/kg nutrient) was obtained with treatment T_5 and the lowest was (20.91 t/kg nutrient) with 120 % RDF without mulch cover (T_2). Hence, fertigation with 80 per cent of the recommended dose with plastic mulch was found to be optimum and economical.

Fertigation schedule comprises of optimum dose of nutrients and suitable frequency of nutrient applications. The present study determined the optimum dose of nutrients for banana crop in sandy loam soils and nutrient conversion efficiency under fertigation and plastic mulch. More research will be needed to know the suitable frequency of nutrients application based on climatic conditions and phenological stages of the crop. Comprehensive study required for better understanding of the effect of types of fertilizers, soil physical properties, soil chemical properties and moisture stress onnutrient uptake by banana plants, its yield and physical and chemical properties of banana fruits.

Abstract. In studying the hydro-ecological conditions in northwestern Sichuan of southwestern China, an area at the edge of the Qinghai-Tibet Plateau, stream waters were extensively sampled and analyzed for the stable hydrogen and oxygen isotope ratios (δ^2H and $\delta^{18}O$) which are often excellent indicators for a water body genesis and evolvement. The heavy isotopes of hydrogen and oxygen were found to be, in general, gradually depleted from east to west in the region; the phenomenon is attributed mainly to continentality based on the assumption that the isotopic signatures in the precipitations were preserved in the stream waters. The δ^2H and $\delta^{18}O$ data from the Yangtze River basin were found to fall well on the global meteoric water line (GMWL), indicative of the fact that the runoff waters in this basin were primarily of meteoric origin with a regional weak evaporation prevailing during our sampling time. However, the isotopic data from a relatively small part of the area in the north belonging to the Yellow River basin are characterized by the appreciably flatter slope of the local water isotope line and lower d-excess values, suggesting that the steam waters had undergone significant evaporation due to kinetic fractionations of isotopes in a more arid climate. The stable isotope data were also applied in calculating water mixing for some selected rivers. This study represents a snapshot study of the area's hydro-ecology; more systematic studies are required in better understanding the seasonal hydrological variations.

Keywords: *meteoric water, hydro-ecology, δ^2H and $\delta^{18}O$, three-river headwaters (TRH), southwestern China*

Introduction

The hydro-ecological conditions of the Qinghai-Tibet Plateau are of critical importance to several Asian countries including a large part of China. The three-river headwaters (TRH) region, located in southern Qinghai province (31°39′–36°16′N, 89°24′–102°23′E), is known as China's water tower where China's three largest rivers (among the world's largest ones) originate. The Big Three, i.e., the Yangtze River, the Yellow River and the Lancang River, obtain, respectively, 25%, 50% and 15% of their water from the TRH region (Zhao et al., 2010). Because of the fragile primordial ecosystem and due to the increased anthropogenic activities during the past several decades, the eco-environmental problems in the region such as grassland degradation, wetland shrinkage and soil erosion started to accelerate since the 1980's and presently serious and immediate attentions are called for (Li et al., 2012; Gao et al., 2013). Li et al. (2012) found that the water loss due to evapotranspiration in the TRH region

DOI: http://dx.doi.org/10.15666/aeer/1504_14891510

increased 11.6 mm annually between 1980 and 2000, meanwhile exhibiting an accelerating trend. It is therefore important to understand the hydro-ecological system of the region in order to conserve and restore its environmental conditions. However, this vast area is generally not easily accessible due to high altitude, harsh climate, extreme remoteness and lack of roads.

The northwestern Sichuan area studied in this work, with gradually decreasing elevations southeasterly, forms the easternmost part of the Qinghai-Tibet Plateau. This area can be divided into two sub-regions: the Northwestern Sichuan Plateau and the Southwestern Sichuan Mountainous Terrain (*Figure 1*). The former is characterized by vast and hummocky plateaus with high elevations (3,500 to 4,000 m or higher); the latter consists of numerous high mountain ranges separated by deep valleys with elevation differentials as much as 3,000 m, known generically as the Hengduan Mountains. The river systems and wetlands in the region are intrinsically connected with those in the upper part of the TRH region. These wetlands provide many important ecological services such as lessening the greenhouse effect by taking up and storing carbon, and are invaluable environmental and ecologic resources (Avis et al., 2011). The hydro-ecological condition of this region is an important integral part of the TRH regional ecology; a thorough understanding of this region may hold the key for the entire TRH region. These wetlands have experienced significant degradation over the past 4 decades and have shrunk by some 29%, and the wetland ecosystems are increasingly fragmented at an accelerated pace (Li et al., 2012; Qi and Li, 2007; Wang et al., 2007) mainly due to the increased anthropogenic activities in the region (Li et al., 2012). In order to stabilize and possibly reverse the ecological conditions of the region, the regional hydrology including the sources of the precipitations, the general water cycle processes of the drainage basins must be understood.

The stable isotopes of oxygen (^{18}O) and hydrogen (^{2}H) can be accurately determined (usually as isotope ratios) with modern technologies (Richelle et al., 2004; Bowen et al., 2005a; Paul et al., 2007), and have become some of the most widely used tracers in drainage basin hydrological studies (Clark and Fritz, 1997; Kendall and McDonnell, 1998; Buttle and McDonnell, 2004). In particular, stable isotope fractionation during precipitation processes are well understood, both ^{18}O and ^{2}H in precipitations vary spatially and temporally depending on the moisture sources and the environmental conditions (e.g., relative humidity and temperature) during cloud formation and rainfall. The isotope ratios in precipitations, their seasonal variations at a given location, and their distribution over a region often reflect the relevant meteorological and geographical conditions such as local temperature and temperature variation, distance from the coast (continentality), latitude and altitude, amount of precipitation and duration (Clark and Fritz, 1997).

Due to their spatial and temporal variability in meteoric waters, these isotope ratios ($\delta^{2}H$ and $\delta^{18}O$ values) have been used to identify sources of water such as atmospheric moisture (Liu et al., 2010; Sjostrom and Welker, 2009; Vachon et al., 2010; Welker, 2000), groundwater recharge (Abbott et al., 2000; Blasch and Bryson, 2007; Adomako

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_14891510

et al., 2010), and plant water uptake (Brooks et al., 2010). In this work, the surface stream waters in the northwestern Sichuan region, an area covering part of both the Yangtze River and the Yellow River drainage basins (divided by the Chazhengliangzi Mountain in Hongyuan, Sichuan) were extensively sampled and analyzed for δ^2H and δ^{18}O. Most rivers in the region including the Minjiang, Jialing, Fuhe and Dadu flow from north to south or from west to east to the Yangtze River (Yangtze River drainage basin), whereas the Heihe and Baihe rivers from south to north to the Yellow River (Yellow River drainage basin). The main objective of this study is to enhance our understanding of the regional hydrology of the study area through characterizing the isotopic variation patterns of the runoff waters and identifying the main influential factors including the geographical and meteorological parameters. As the TRH region is difficult to access and its hydrology study is still at a relatively early stage, the current work may help fill some of the gaps in the study of the hydrological-ecological conditions of the entire TRH region.

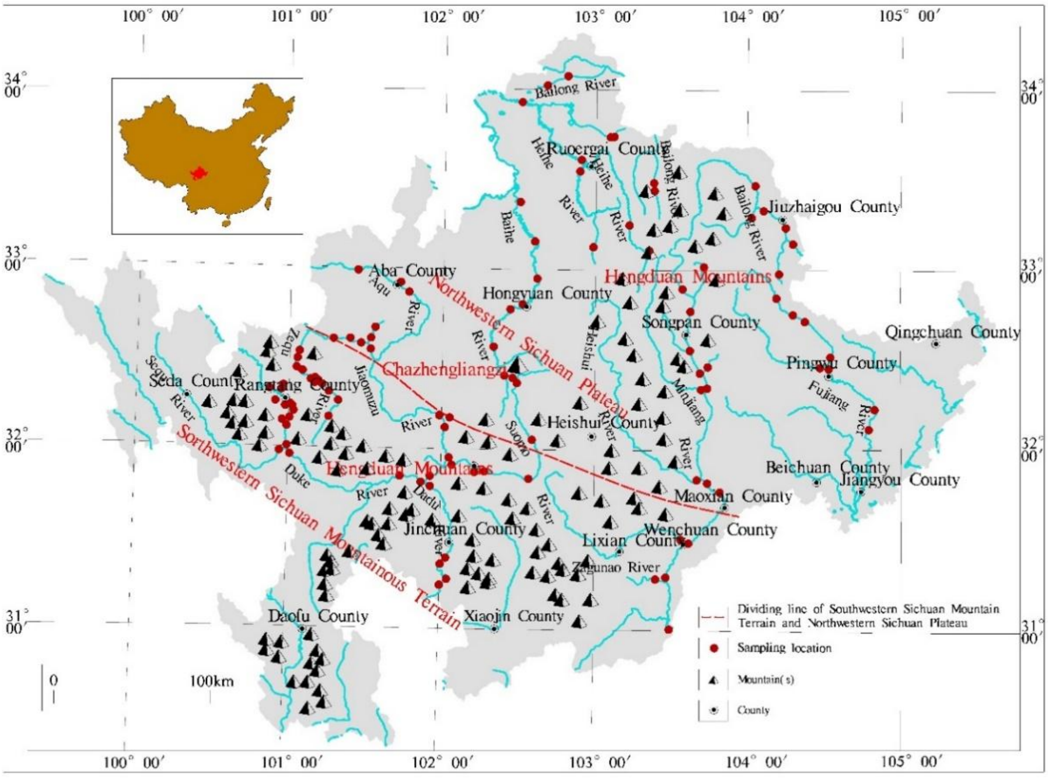

Figure 1. *Map of the main rivers in the study area with sample locations*

Materials and methods

Study area

The study area is at the edge of the Qinghai-Tibet Plateau and is generally known as the Northwestern Sichuan Plateau. Water samples were taken from locations in 28 counties: 13 alpine counties including Rangtang, Aba, Songpan, Ruoergai and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_14891510

Hongyuan in Aba Prefecture, and 18 mountainous counties including Seda in Ganzi Prefecture, Wangcang in Guangyuan City, Hanyuan in Ya'an City, and Pingwu in Mianyang City, covering a total area of 149,000 km^2. In total 86 stream water samples were collected for δ^2H and $\delta^{18}O$ analysis from 7 river systems (*Table 1*). Owning to logistic difficulties, the sample campaign had to be conducted in two consecutive summers of 2010 and 2011. Approximately half of the samples were taken in July of 2010 and half in July and August of 2011. The climatic conditions of the sampling area from June to August are summarized and compared in *Table 2* for 2010 and 2011 (data were downloaded from Tutiempo Network website, http://en.tutiempo.net/). From *Table 2,* it is clear that the climatic conditions of the area were closely similar between 2010 and 2011 during the sampling months. It is noted that August 2011 appeared to be drier than August 2010; however, this difference would not impact our discussions because the dry season essentially occurred after our sampling campaign.

Methods

The sampling locations are listed in *Table 3* and shown on the map in *Figure 1*. We have exercised rigorous and systematic quality assurance measures in the field at various levels to ensure the samples were taken and labeled appropriately. We conducted the sample taking following strictly the procedures set out in the Quality Assurance Manual for Environmental Water Monitoring (Zhang, 1994). The water samples were taken at a depth of a few centimeters below the water surface to ensure that the river water was fully mixed to avoid any potential surface isotope fractionation effect due to evaporation. When sampling from a water body where two streams met, samples were taken only in the fully mixed zone, 200 m or further downstream from the meeting point. During sampling, observations of water quality, river flow rate, vegetation on both banks, rock composition and geological features were also made. More details on sampling was described elsewhere (Shi et al., 2016).

Notes：Catch. - Catchment; Elev - Elevation; Temp - Temperature

Hydrogen and oxygen isotopes (δ^2H and $\delta^{18}O$ values) were determined by the Sichuan Provincial Key Isotope Laboratory at the Chengdu University of Technology, using high temperature conversion elemental analysis – isotopic ratio mass spectrometry (TC/EA-IRMS) with the instruments supplied by Thermo Fisher (TM Flash 2000 coupled with a mass spectrometer, MAT-253). The accuracy of the isotopic ratio analysis relative to the Vienna-Standard Mean Ocean Water (VSMOW) was determined to be ±0.2‰ and ±2.0‰ for $\delta^{18}O$ and δ^2H, respectively. Water samples were analyzed without pre-treatment. For more details about the analytical procedure used, the reader is referred to Burgoyne and Hayes (1998), Hoefs (2009), and Richelle et al. (2004).

Results and discussion

$\delta^{18}O$, δ^2H, d-excess and local meteoric water line (LMWL)

The measured stable hydrogen and oxygen isotope δ-values are presented in *Table 3* together with the associated information of sample locations and the relevant river catchments/drainage basins. Because altitude and temperature are two of the most important parameters governing isotopic fractionations in precipitation (see discussions below), these two parameters were therefore also measured and are included in *Table 3*. Since the climatic conditions in 2010 and 2011 were very similar during the sampling times (*Table 2*), the measured isotopic data were analyzed and discussed without distinction of the sampling year. The parameter d-excess can convey additional information about the water bodies studied, therefore the derived d-values are also tabulated in *Table 3*.

The measured $\delta^{18}O$ and δ^2H values range from, respectively, -14.87‰ to -9.68‰ and -107.5‰ to -64.7‰ for the water samples taken from the various river systems in the study area. When the data are plotted in a δ^2H–$\delta^{18}O$ diagram as shown in *Figure 2,* the data points align well with the GMWL as defined by Craig (1961), suggesting that the area's stream water was likely of meteoric origin primarily. Recently, Liu et al. (2014) studied and reported the isotopic compositions of precipitations in China based on the data collected from 29 stations including two within the present study area: 1. Maoxian (MX), elevation 1,826 m, located near the southeast border of the study area, and 2. Gonggashan (GG), elevation 2,950 m, located at the southwest border of the study area.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_14891510

The reported δ^2H values are from -83.3 to 8.5 with a mean of -49.5 for MX, from -147.8 to 1.4 with a mean of -76.5 for GG; and $\delta^{18}O$ from -11.98 to 0.31 with a mean of -7.77 for MX, from -19.50 to -2.35 with a mean of -10.82 for GG. These data compare very well with our data of samples from the same general areas (see *Figure 2* and *Table 2* for data from Fujiang River and Duke River, respectively) considering that the data by Liu et al. (2014) are monthly precipitation-weighted averages while our data are one-time values. Therefore, it is assumed in this work that the samples taken from the streams represent the local precipitations in terms of isotopic compositions. Our data span relatively narrow ranges when compared to the China national data of $\delta^{18}O$ (-29.47 to -2.75 ‰) and δ^2H (-229.6 to 45.4 ‰) (Liu et al., 2014). This is, perhaps, expected due to the fact that the area is located in the Asian monsoon region and our sampling times coincided with the monsoon prime times (Liu et al., 2014). The area was receiving rainfalls almost daily during our sampling times with the total precipitations of 100-200 mm/month. As the sampling was conducted during the warmest time of a year, the melting of alpine snow and ice was also expected at the peak time. There is usually no isotopic fractionation during snowfalls as the solid phase does not exchange isotopes with the atmospheric moisture; and snowpacks tend to conserve the isotopic composition of the cloud moisture with an elevated d-excess value (Gat et al., 2001). The value of d-excess varies locally and was shown to correlate with the physical conditions such as relative humidity, air temperature and sea surface temperature of the oceanic source area of the precipitation moisture (Merlivat and Jouzel, 1979). Thus the waters would be expected to to be more enriched with heavy isotopes and with an elevated d-excess if the streams were heavily recharged by meltwaters, and this is not the case in this work with Aqu River as possibly an exception (*Table 3*). Because of the heavy and frequent rainfalls, the ground water contribution to the streams is also considered to be insignificant. The “catchment isotope effect” (Rozanski et al., 2001) in the region during the sampling times was such that the isotopes of the steam waters may be considered having essentially the same composition as those in the precipitation waters.

As noted earlier that the isotopic ratios (δ^2H and $\delta^{18}O$ values) are distributed quite evenly along the GMWL in *Figure 2* (when the data from the Yellow River basin are excluded, see below for details). This may indicate that, as the stream waters were primarily of meteoric origin, the rain moisture may originate primarily from a single remote location and rainfalls formed along the way with different distances of moisture transport. Recently, Wang et al. (2016) used the entropy analysis method of stable isotopes in precipitation to study the monsoon systems in China, found that in southern China, the water vapor is mainly supplied by the Indian monsoon. “one stream of the Indian monsoon (I1) passes eastward from the southwestern border of China and then turns to the northeast of the south central China before reaching eastern China, where its intensity weakens after producing heavy rainfalls.” However, the authors also recognized the impeding effect of the Himalayas that impedes the movement of the Indian monsoon from the south to north and the movement of the winter monsoon from the north to south (Wang et al., 2016).

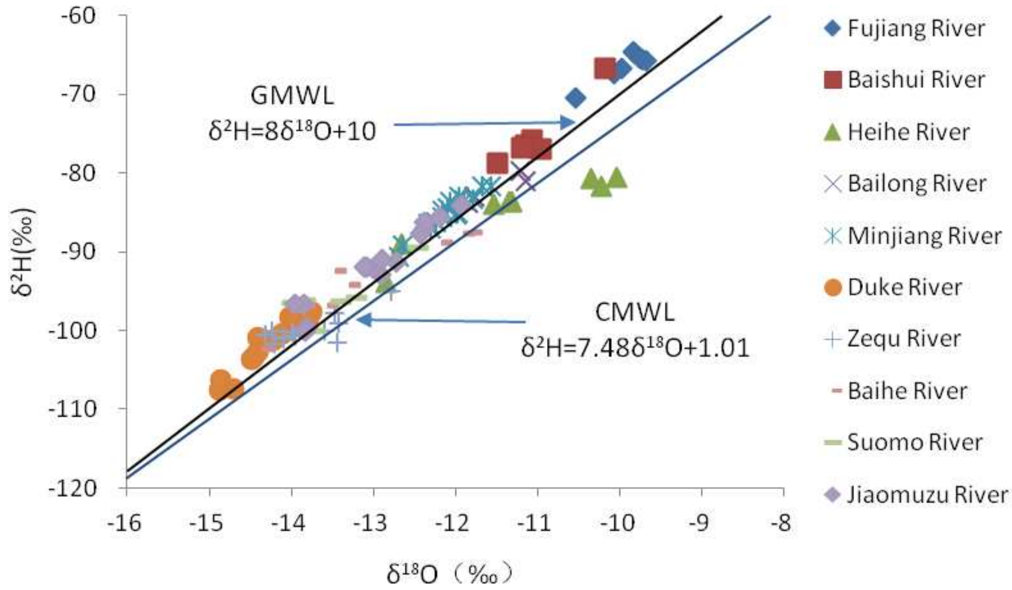

Figure 2. *Diagram of hydrogen and oxygen isotopic ratios (δ^2H vs. $\delta^{18}O$) for all water samples analyzed in this study. Note that the upper line represents the global meteoric water line (GMWL), and the lower line represents the China meteoric water line (CMWL)*

These observations are also supported by the d-excess data. In the study area the d-values span a relatively large range from -0.25 to 15.33 with a mean of 11.30 (*Table 3*), which is close to the global average (Rozanski et al., 1993). In examining the d-values, no apparent anomalies nor any reasonable patterns (e.g. decreasing values when further away from alpine glaciers) could be found, suggesting a predominantly well-mixed, relatively homogeneous source for the river waters, and contributions from the melting of alpine snow and ice were likely insignificant. Lower d-values relative to the surrounding areas were found in the Heishui County region (*Figure 3*); this may be attributed to high evaporation in the region where abundant sunshine is available throughout the year and the landscape is characterized by interweaved high mountain ranges and deep valleys (elevation differential as much as 1,000–2,000 m). This unique combination of climatic and geographic conditions gave result to widely uneven precipitations and large temperature swings between day and night in the Heishui region. However, the rather low d-values may not be fully counted for by the evaporation effect; it is suspected that some water component previously affected by evaporation and stored in the riparian zone might have been pushed into the streams by the newly fallen precipitation through infiltration and hyporheic flow (National Research Council, 2002). The lower d-values found in the Heihe River and Beihe River area will be further discussed in a later section.

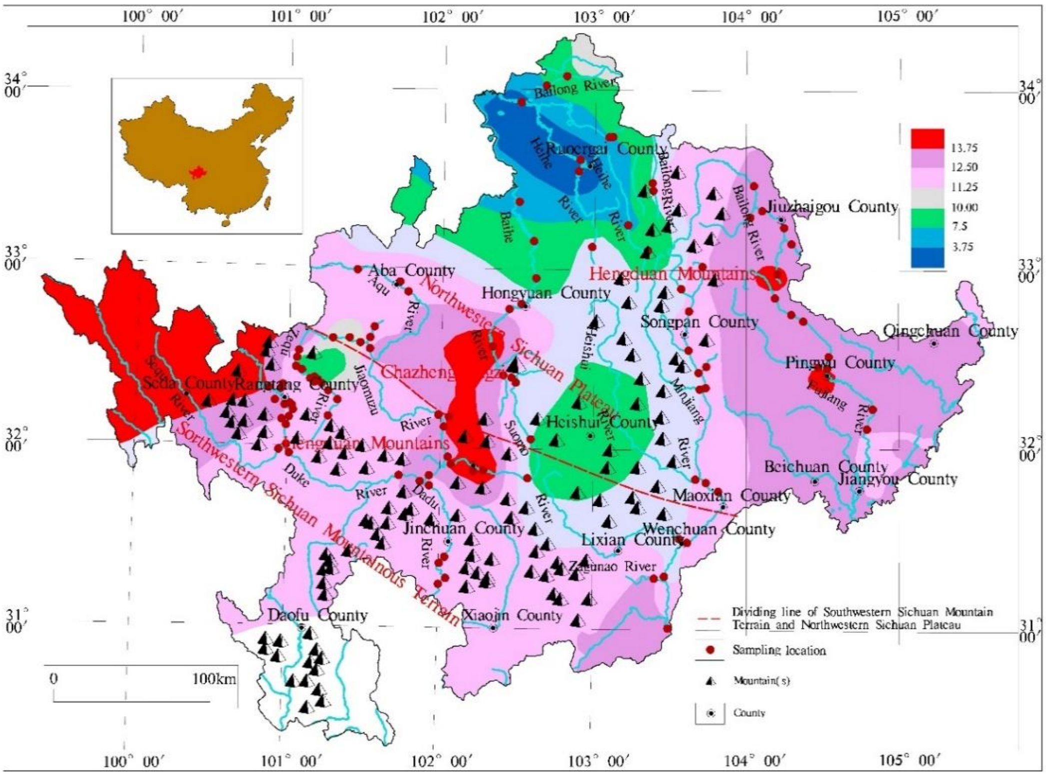

__Figure 3.__ Spatial distribution of d-excess in the study area

Effects of temperature, altitude and continentality

The stable isotope ratios δ^2H and $\delta^{18}O$ are shown in *Figures 4* and *5* as mapped contours through interpolation. In examining the contours in both figures, it is noted that there is a general trend: both ^2H and ^{18}O become progressively more depleted from east to west across the region. The study area is located inland at the west margin of the south China (SC) region and near the Tibet (TP) and north China (NC) regions according to Liu et al. (2014). The precipitation moisture of this area has a complex origin and is composed of components from the South China Sea, the Pacific and Indian Oceans, and local evaporation and circulation. This complex situation may be visually appreciated by the back-trajectories of the air masses on June 30 and July 4, 2010 and 2011 from two selected locations near the center of the studied area depicted in *Figure 6,* produced using the HYSPLIT transport and dispersion model (Stein et al., 2015; Rolph, 2016). In this region, the air mass has a general trend of undergoing progressive rainout of heavy isotopes during the pole-ward (latitude effect) and westward (continental effect) atmospheric transport (Liu et al., 2014). However, the southwesterly monsoon from the Indian Ocean may be effectively obstructed from reaching here by the Qinghai-Tibet Plateau, this is supported by studies such as Liu et al. (2007, 2014). It is postulated that the moisture for precipitation in this region originated primarily from the Pacific Ocean and the South China Sea during a period shortly prior to the sample campaigns. That is, the moisture air masses traveled mainly from east to west, isotopically enriched rain

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_14891510

formed and fell from diminishing moisture mass and the residual moisture became progressively depleted in heavy isotopes with respect to earlier rains from the same cloud. This westerly continental effect explains well the observed isotope ratio contours seen in *Figures 4* and *5,* where no apparent pole-ward isotopic fractionation pattern is observed which is perhaps due to the ineffectiveness of the southwesterly monsoon in penetrating the Qinghai-Tibet Plateau (Liu et al., 2007, 2012).

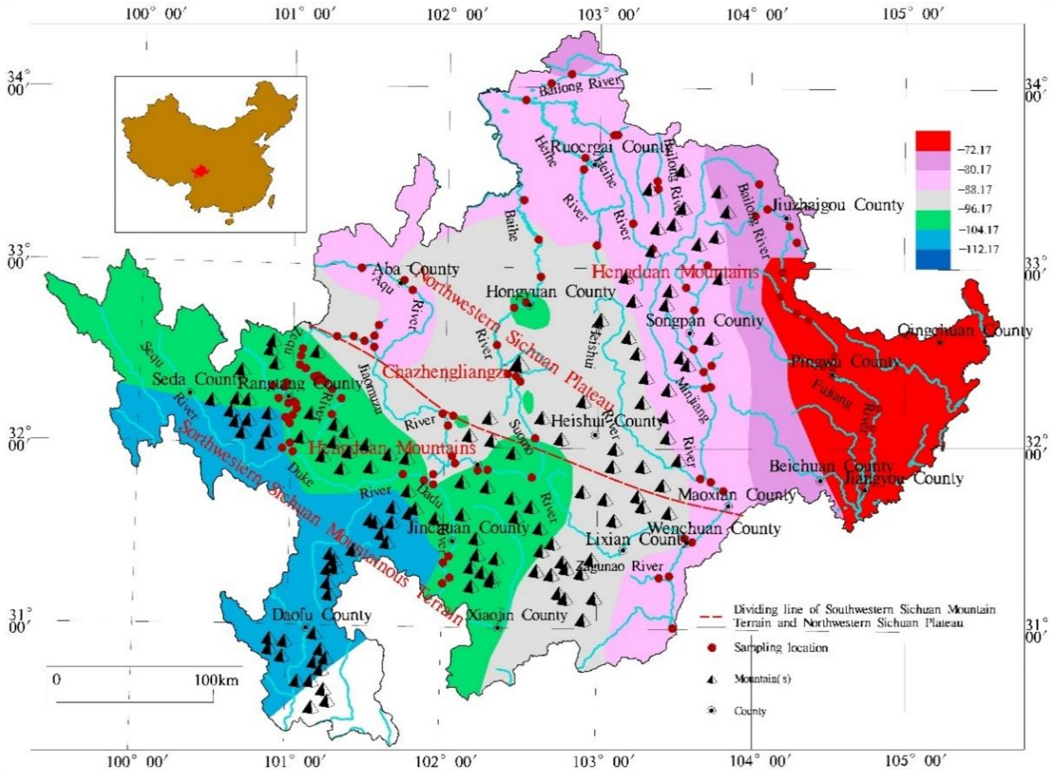

Figure 4. *Spatial zonation of δ²H in the study area*

This noted general trend of isotopic composition change from east to west due to continental effect is fundamentally governed by temperature change. With decreasing temperature, rainfalls becomes more depleted in the heavier isotopes, ^{2}H and ^{18}O (^{2}H and ^{18}O are linearly correlated). Similar effects have been shown with increasing elevation and increased distance from the equator, both of which correspond to lower temperatures (Bowen et al., 2005b; Terzer et al., 2013). Our statistical analysis shows that both $\delta^{2}H$ and $\delta^{18}O$ are positively correlated with temperature, the Pearson product-moment correlation coefficients 0.492 and 0.517 for $\delta^{2}H$-temperature and $\delta^{18}O$-temperature, respectively, were obtained. Some early work (e.g., Zhang and Wu, 2007) suggests that the correlation between isotopic fractionation and temperature tends to be stronger when the temperature is lower.

Though the general zonation of $\delta^{2}H$ and $\delta^{18}O$ in the region (*Figures 4* and *5*) is believed to be governed by continentality, with increasing altitude the elevation and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_14891510

other effects (e.g. amount effect) are superimposed on the continental effect and might become predominant resulting in a local enrichment of the heavier isotopes. This may be observed in *Figure 5* where both ^{2}H and ^{18}O are noticeably more depleted near Hongyuan presumably due to high altitude. Notwithstanding the altitude effect, the other factors including the amount effect (Dansgaard, 1964) and anthropogenic effect may also have played a role that should be fully investigated. For example, the east part of the study area is more densely populated and economically more developed; the increased anthropogenic activities including large amount of agricultural consumption of surface waters might have cut down the water runoff volumes and augmented natural evaporation and transpiration in the area, resulting in a more arid-like climate which in turn resulted in heavier isotopes relatively enriched (*Figures 4* and *5*).

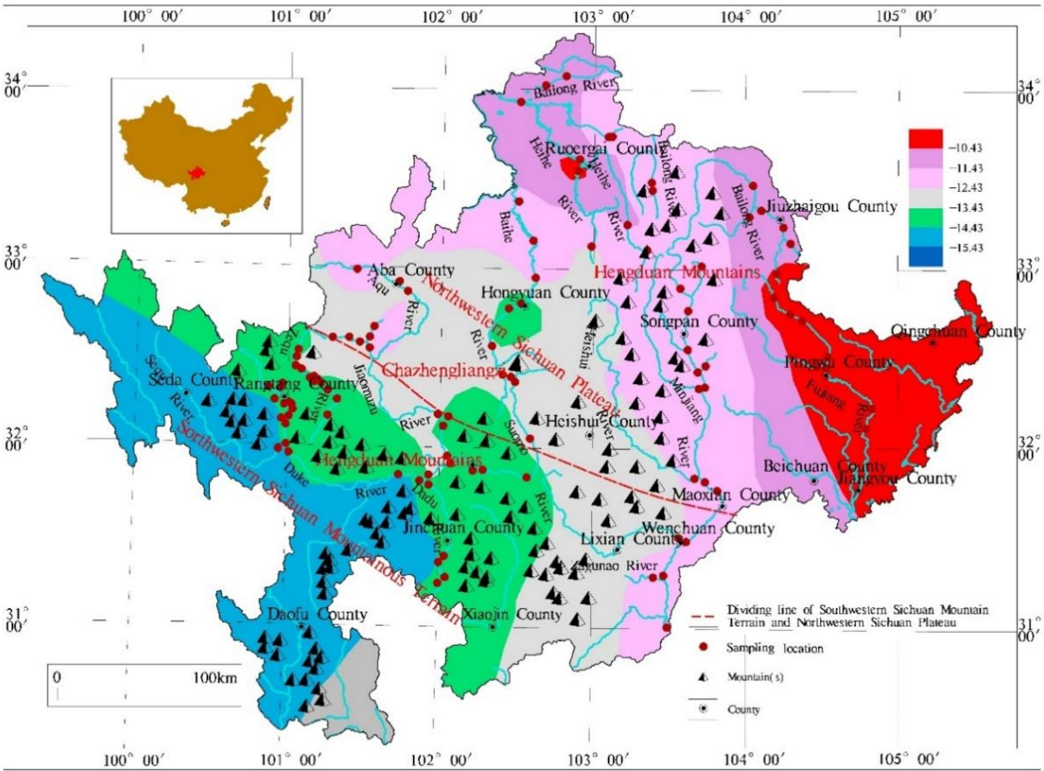

Figure 5. *Spatial zonation of* $\delta^{18}O$ *in the study area*

Long-term data sets are necessary to fully understand the processes of water cycles because seasonal and climate changes can be significant (Stumpp et al., 2014). For this reason, the results reported in this work may be regarded as a snapshot of the area's water cycle processes at the wettest time of a year and much of the discussion should be taken in this context. As seasonal variations are expected to be greater for rivers that are mainly recharged by surface runoff from recent precipitations (Rozanski et al., 2001) such as the rivers in this study, more systematic sampling and investigations are necessary to fully understand the area's runoff isotope hydrology.

Isotope distinction between the drainage basins of Yangtze River and Yellow River

The meteoric water line specific to a certain location is controlled by local climatic factors including the oceanic moisture source and secondary processes affecting the isotopic composition of water vapor such as evaporation and re-circulation of moisture from large water bodies (Clark and Fritz, 1997). These factors together define a particular local meteoric water line (LMWL). A closer examination of *Figure 2* reveals that some data points deviate appreciably from the GMWL which otherwise represents the stable hydrogen and oxygen isotope ratio data quite well. However, when only the data from the Yangtze River basin are plotted in *Figure 7,* a single LMWL is obtained: $\delta^2H=8.06\delta^{18}O+12.69$ with $R^2 = 0.98$, which is almost identical to the GMWL as revised by Rozanski et al. (1993): $\delta^2H=8.17\delta^{18}O+10.35$, or by Gat et al. (2001): $\delta^2H=7.8973^{18}O+9.0133$. This is indicative of the fact that heavy and frequent rainfalls prior to our sampling in the region had rendered the stream waters resemble the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_14891510

rainwaters so closely, and the streams in the Yangtze River drainage basin were recharged and maintained mainly by the rainfalls and the surface runoff. The lower the relative humidity is, the faster the evaporation rate would be and the greater the kinetic fractionation becomes. Humidity affects hydrogen and oxygen fractionations differently such that the slope of the evaporation line would vary due to changes in relative humidity. At very low relative humidity (< 25%), the slope of the evaporation line would be close to 4; for moderate relative humidity (25% to 75%) the slope would be between 4 and 5; only for relative humidity above 95% would the slope approach 8, i.e., the slope of the meteoric water line (Clark and Fritz, 1997). Therefore, from *Figure 7* it is inferred that humid conditions likely prevailed with relative humidity above 95% much of the time in the region. For a comparison, Liu et al. (2014), based on 928 groups of precipitation data, reported a Chinese Meteoric Water Line (CMWL) as $\delta^2H=7.48\delta^{18}O+1.01$, as also shown in *Figure 7*. It appears that there is a fair amount of difference between our local water line (i.e., LMWL) and the CMWL; however, considering our data range is relatively very narrow when compared to the data used for deriving the CMWL (Liu et al., 2014), the difference is not that significant. Nevertheless, it is noted that our data are systematically located above the CMWL, which is reflected by the relatively big difference in the d-values (12.69 vs. 1.01) indicating that the source of vapor for the area's precipitation was likely unique, i.e., sufficiently different from the bulk from that the CMWL was derived.

As noted earlier, the rivers belonging to the Yangtze River basin have rather different characteristics of stable hydrogen and oxygen isotopes from west to east across the area (*Table 3*). In the west of the Northwestern Sichuan Plateau the rivers including the Duke River, the Zequ River, the Suomo River, and the Jiaomuzu River are relatively enriched in the light isotopes; an exception is the Aqu River, a tributary of the Jiaomuzu River, which is relatively enriched in heavy isotopes and its d-values are lower than the other rivers. In comparison, the rivers in the east of the Northwestern Sichuan Plateau including the Fujiang River, the Minjiang River, and the Baishui River are relatively enriched in heavy isotopes. As discussed above, the isotope ratios change from east to west likely due to the continental effect, whereas the Aqu River was probably also appreciably recharged by alpine lake waters which were collection of glacier meltwater. However, the hydrogen and oxygen isotope ratios of the Fujiang River and the Minjiang River also have a trend of increasing from north to south possibly due to the altitude effect as the elevations increase appreciably (by as much as 2,000 m) from north to south along the two rivers. Besides, these two rivers have been more significantly affected by anthropogenic activities that may have added additional impact to the hydrogen and oxygen isotope ratios. For example, the water samples taken from the lower reach of the Minjiang River are slightly enriched in heavy isotopes with δ^2H /$\delta^{18}O$ as -70.4/-10.54 and -81.7/-11.69 respectively from two locations (500 m downstream of the Yilixiang Hua'neng Hydro Station, and downstream after the Heishui River enters the Minjiang River), compared to the values of -90.6/-12.69 in its upper reach (upstream of the Zagu'nao River Hydro Station).

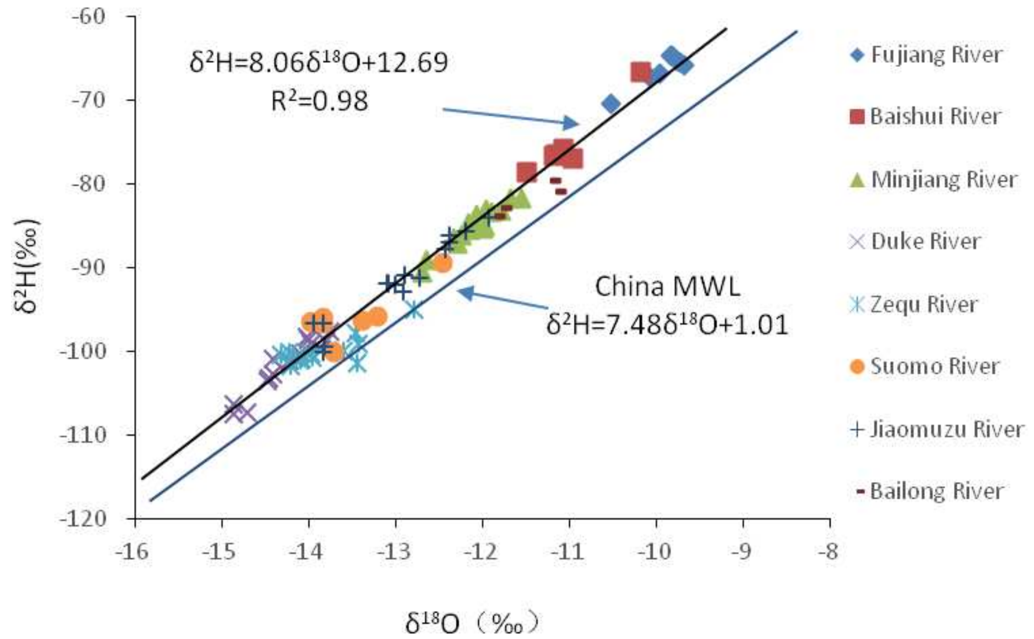

Figure 7. *δ^2H vs. $\delta^{18}O$ diagram for stream water samples collected from the Yangtze River basin*

The relatively small area in the northern part of the study area (*Figure 1*) including the Heihe River and the Baihe River catchments belongs to the Yellow River drainage basin. When the stable hydrogen and oxygen isotope ratios from this area only (i.e., the data points that deviate from the GMWL in *Figure 2*) were plotted as shown in *Figure 8*, a local evaporation line (LEL) was obtained: $\delta^2H=4.77\delta^{18}O–30.99$ with $R^2=0.93$, which differs appreciably from the GMWL (Rozanski et al., 1993; Hoefs, 2009), the CMWL (Liu et al., 2014), and the LMWL of the Yangtze River basin (*Figure 7*). The much smaller slope (4.77) is usually an indication of a more arid climate (i.e., lower relative humidity) (Gat, 1996).

The δ^2H and $\delta^{18}O$ values of water samples from the Yellow River basin range from -100.1 to -79.7 and from -13.98 to -10.03, respectively, varying over wider ranges (particularly the Heihe River) in comparison with those from the Yangtze River basin. In particular, the Heihe River and the Baihe River extend hundreds of kilometers from south to north before eventually flowing into the Yellow River, and their hydrogen and oxygen isotope compositions exhibit a general trend of increasingly more depleted in heavy isotopes. The d-excess data are presented as contoured lines in *Figure 3;* the d-values of water samples from this area are noticeably lower with a minimum of -0.25, also exhibiting a trend of decreasing from the upper reach to the lower reach of the rivers (i.e. form south to north). According to Gat (1996), in more arid areas evaporation from the falling rain droplets beneath the cloud base or from surface waters can result in the enrichment of the heavy isotopes in the remnant raindrops along the evaporation line, the resulting precipitation would show a smaller d-value

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_14891510

than at the cloud base. Therefore, even though both this small area belonging to the Yellow River basin and the east part of the study area display some isotopic features in common (e.g., relatively less depleted in heavy isotopes and smaller d-values), the underlying governing factors are different. This area is at or near the north China (NC) region where $\delta^{18}O$ was shown to be closely related to the wind directions, relative humidity and vapor pressure; this is distinctively different from the case of the SC region where $\delta^{18}O$ was shown to depend on the remaining fraction of the vapor phase in an isothermal condensation process (Liu et al., 2014).

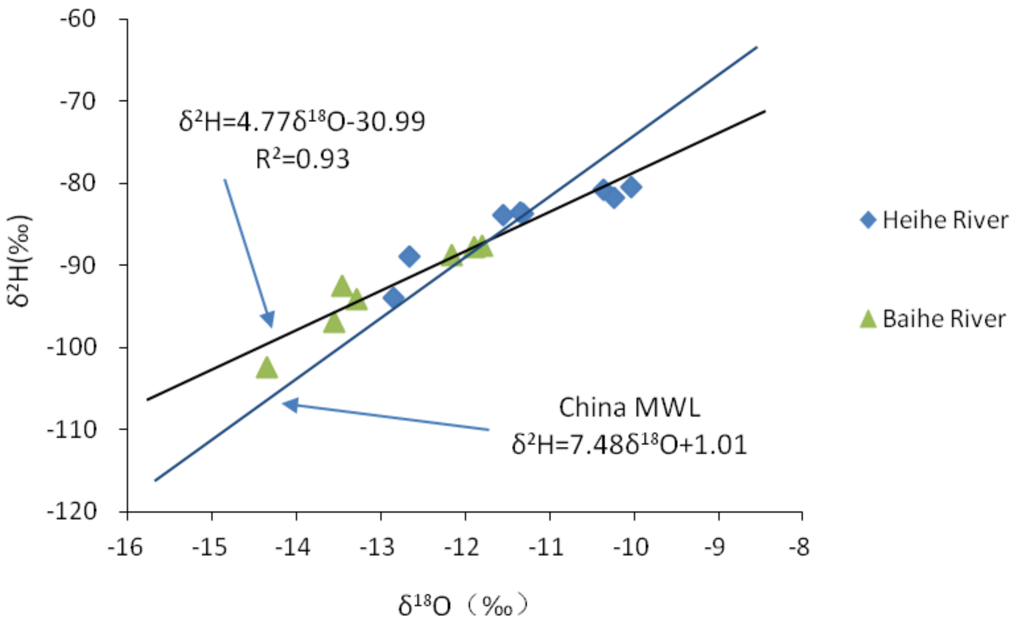

Figure 8. *δ^2H vs. $\delta^{18}O$ diagram for water samples collected from the Yellow River basin*

Mixing of some major rivers

When two or more tributaries merge to form a mainstream, the mixing ratio from each can be quantitatively calculated based on the isotopic mass balance principle. The fundamental equation (*Eq. 1*) can be written as:

$$r_T m_T = r_1 m_1 + r_2 m_2 + \cdots + r_n m_n \quad \text{(Eq. 1)}$$

where *r* is the fractional abundance of a stable isotope, *m* the molar quantity of the stable isotope, and the subscripts *T* and *n* denote, respectively, the merged mainstream and a tributary. When 2 tributaries merge to form a mainstream, the mass balance equation (*Eq. 2*) for ^{18}O can be written as:

$$r_{^{18}O} m_{^{18}O} = r_{^{18}O_1} m_{^{18}O_1} + r_{^{18}O_2} m_{^{18}O_2} \quad \text{(Eq. 2)}$$

APPLIED ECOLOGY AND ENVIRONMENTAL RESEARCH 15(4):1489-1510.
http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_14891510

where (*Eq. 3*):

$$r_{^{18}O}=\frac{m_{^{18}O}}{m_{^{18}O}+m_{^{16}O}} \quad \text{(Eq. 3)}$$

For all practical purposes, r_{18_O} may be substituted by $\delta^{18}O$ and *Eq. 2* becomes (*Eq. 4*):

$$\delta^{18}Om_{^{18}O} = \delta^{18}O_1 m_{^{18}O1} + \delta^{18}O_2 m_{^{18}O2} \quad \text{(Eq. 4)}$$

Eq. 4 is not exact because of the approximation of the δ values for *r* values. The errors due to this approximation have been carefully evaluated and proven negligible for all practical applications (Fry, 2003). *Eq. 4* can be rearranged (note that $m_{^{18}O} = m_{^{18}O1} + m_{^{18}O2}$) to read as (*Eq. 5*):

$$\frac{m_{^{18}O1}}{m_{^{18}O}} = \frac{\delta^{18}O-\delta^{18}O_2}{\delta^{18}O_1-\delta^{18}O_2} \quad \text{(Eq. 5)}$$

where $\frac{m_{^{18}O1}}{m_{^{18}O}}$ is the fraction contribution of tributary 1 to the mainstream.

The Dadu River is the most important tributary of the Minjiang River that in turn is a major tributary of the Yangtze River. The Dadu River has three sources: the east source Suomo River, the west source Duke River, and the main source Zumuzu River. At the confluence where the Sequ River merges into the Duke River, samples were taken and analyzed, and the following $\delta^{18}O$ values were obtained: -14.9‰, -14.0‰ and -14.2‰, respectively, from Sequ River, upstream of Duke River, and downstream of Duke River. Using *Eq. 5* it is calculated that $\frac{m_{^{18}O1}}{m_{^{18}O}}$ equals 0.28, i.e. the component from the Sequ River to the Duke River was 28% at the time of sampling.

Further upstream of the Sequ River, the Angkegou Stream in Rangtang is another tributary of the Duke River, but is much smaller than the Sequ River. The following $\delta^{18}O$ values were obtained around the point where the Angkegou Stream enters the Duke River: -14.9‰, -13.8‰ and -13.8‰, from the Angkegou Stream, upstream and downstream of the Duke River, respectively. Apparently, given the precision of our isotope analysis, it is not feasible to calculate the contribution of the Angkegou Stream to the Duke River using the oxygen isotope ratios with any confidence.

The Suomo River and the Duke River merge at Baiwan and then flow into the Dadu River. Near the joint, the $\delta^{18}O$ values were obtained as -13.1‰, -14.4‰ and -13.8‰, respectively, for the water samples from the Suomo River, Duke River and the Dadu River. The contribution of the Duke River to the Dadu River was calculated to be 55% and Suomo River to the Dadu River to be 45%.

The calculations based on mass balance are valid only when the tributary waters are fully mixed in the mainstream. Using the same method, the contribution of Ake River to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_14891510

Ma'erqu (a secondary tributary of the Yangtze River, upper reach of the Jiaomuzhu River) was calculated to be 75%; but it was noted during field work that the Ake River flow was too small and its contribution to the Ma'erqu River could not possibly be that high. This apparent error was likely due to the fact that the sample taken from downstream Ma'erqu River with $\delta^{18}O$ = -12.4 was most likely not representative of the well-mixed water body due to physical difficulty in sampling: a steep cliff prevented the sample from being taken near the center of the Ma'erqu River. Instead, the sample was taken near the cliff where the water was suspected to be predominantly from the Ake River ($\delta^{18}O$ = -12.2), and a thorough mixing with the Ma'erqu River water had not yet achieved. Note that these river mixing calculations are approximate, as the uncertainties in the δ-values (±0.2‰ and ±2.0‰ for $\delta^{18}O$ and $\delta^{2}H$, respectively) are not evaluated.

Conclusions

In general, the stable oxygen and hydrogen isotope ratios are correlated with the distance to the east coast of China, in agreement with a continentality model. That is, the stream waters were gradually depleted in heavy isotopes from east to west in the area studied. This phenomenon is attributed to the successive rainfalls from the same moisture cloud and the preservation of isotopic signature in the runoff from the precipitations. Local deviations from this general trend may be explained by the elevation effect and some anthropogenic factors.

The $\delta^{2}H$ and $\delta^{18}O$ data of the samples from the Yangtze River basin, which covers the majority of the study area, align well with the CMWL and particularly with the GMWL, suggesting that the stream waters in this area were primarily of meteoric origin (including ice and snow melting) with a regional weak evaporation effect prevailing. However, the data from a relatively small area belonging to the Yellow River basin are characterized by an appreciably flatter slope of the isotope water line, suggesting that the waters had undergone significant evaporation due to kinetic fractionations of isotopes in a more arid climate. These observations are also supported by the d-excess values.

Since the samples were taken during summer time, this study provides a snapshot of the region's river hydrology during the rainy season. As the stable isotope ratios can vary greatly both over time and space, for a more complete understanding of the local river hydrology more systematic sampling and analysis over time will be necessary. Precipitation samples should be collected and analyzed together with the stream water samples so that a direct correlation between the runoff waters and precipitations could be more firmly established. Nevertheless, the stream isotope data presented in this work should be valuable to those who are concerned with the TRH eco-system or, more broadly, the eco-environment of the Qinghai-Tibet Plateau.

(Received 19th Feb 2017; accepted 30th Aug 2017)

Abstract. The role of environmental factors in the formation of zooplankton in tributaries of Lake Ladoga is still poorly investigated. The authors aimed at exploring composition and quantitative patterns of zooplankton development in the major tributaries of Ladoga and assessing the impact of environmental factors and features of river catchment basins on the parameters of zooplankton development. A total of 137 taxa ranking below genus were identified (56 species and subspecies of *Rotifera*, 57 of *Cladocera*, 24 of *Copepoda*). Species composition and patterns of quantitative development cannot be explained by any environmental factors or their combination. It is impossible to determine groups of rivers with similar patterns of zooplankton development basing on the composition and abundances of individual zooplankton species. River clustering based on hydrochemical and hydrological parameters and features of catchment basins provides an opportunity to distinguish groups of similar rivers. Total abundances of copepoda, cladocera, and rotifera in the rivers are closely associated with certain combinations of studied physiographic parameters. Physiographic factors, namely, the catchment basin area, water discharge, and lake percentage on the territory of the catchment basin, are the most important in the level of quantitative development of *Copepoda*, *Rotifera*, and *Cladocera* in tributaries of Lake Ladoga.
Keywords: *Copepoda, Cladocera, Rotifera, rivers, species composition, physiographic factors*

Introduction

Tributaries of Lake Ladoga greatly influence its water balance, hydrochemical water composition, biocenoses, and general ecological condition. River discharge counts for almost 85% of water balance input and more than 95% of chemical balance of the lake (Alekin, 1953). In river ecosystems, zooplankton community is an important structural and functional unit, for exampe, zooplankton organisms are a primary food source for larval and some adult fish (Thorp and Casper, 2003).

Zooplankton of lake tributaries have seldom been studied in comparison with zooplankton of lakes and reservoirs (Thorp and Mantovani, 2005; Turschak et al., 2011). Development of zooplankton in rivers is controlled by a still poorly understood mixture of abiotic and biotic factors varying seasonally and correlated to chemical and physical features of the rivers and physiographic conditions of their drainage basins (Thorp and Casper, 2002; Zhao et al., 2017).

DOI: http://dx.doi.org/10.15666/aeer/1504_15111540

Planktonic crustaceans and rotifers play a big part in the process of transformation and circulation of organic matter and so participate in river self-purification (Krylov, 2002a; Ejsmont-Karabin et al., 2004).

Contrary to thoroughly studied zooplankton of Lake Ladoga (Andronikova, 1996; Kurashov et al., 1996; Telesh, 1996; Korovchinsky, 2000), the zooplankton of its tributaries has not been properly studied.

Literature contains limited data on zooplankton communities of some rivers of the Northern Ladoga area (Ryzhkov, 1999; Kulikova, 2012; Ryabinkina et al., 2012) and main tributaries (Makartseva, 2004; Kulikova, 2012; Aleshina et al., 2014). These data have been collected with the help of different methods at various times, therefore, the results cannot be properly compared, making it impossible to assess the influence of environmental factors on the communities of crustaceans and rotifers. It is vital to determine the patterns of this influence to provide a better understanding of the processes taking place in river ecosystems and opportunity to model and predict the zooplankton reaction to environmental changes, including those connected with current climate changes (Vadadi-Fülöp et al., 2009).

Previous studies of the Lake Ladoga tributaries have shown that the development of phytoplankton in rivers depends on the supply with nutrients, first of all, phosphorus, and on factors such as the productivity in the source of the river, character and rate of river flow, presence or absence of lakes or widened stretches with retarded water exchange in the course of the river (Trifonova and Pavlova, 2004). The role of environmental factors in the formation of zooplankton in tributaries of Lake Ladoga is still poorly investigated.

In this study, we aimed to explore qualitative composition and quantitative patterns of development of zooplankton in the major tributaries of Lake Ladoga, and to assess the impact of environmental factors and features of river catchment basins on the parameters of zooplankton development.

In the face of constantly increasing anthropogenic load on the Lake Ladoga catchment basin (Kondratyev and Trumbull, 2012), it is important to reveal interactions between environmental factors and the state of biota. In this connection, the results of the current study can be used to develop the strategy for management and preservation of water resources of the Ladoga area rivers.

Materials and Methods

Study area

Three major tributaries can be determined within the catchment basin of Lake Ladoga: the Svir, the Volkhov, and the Vuoksa system of lakes and rivers, entering Lake Ladoga in two branches – the northern one, Vuoksa River, and the southern one, Burnaya River. Second-order tributaries are the Pasha, the Oyat, the Syas, and the Olonka rivers. Although the Pasha and the Oyat are tributaries of the Svir, they are considered to be independent lake tributaries, as they enter the Svir near its mouth. There are 20 major water courses entering Ladoga (*Table 1*), including the Burnaya and the Vuoksa, which actually belong to the same Vuoksa system of lakes and rivers. For our study in 2011–2014 we chose the stations at the lower course of these rivers and at the Neva River head (*Fig. 1*).

Material and data analysis

Our study included 9 periods: May, August, and October 2011, July and October 2012, June and September 2013, May and July 2014. Hydrochemical data were obtained with the help of YSI 6600D multiparameter automatic sonde (YSI Incorporated, USA) directly during the zooplankton sampling within the surface layers or assessed with routine methods at the laboratory (Semenov (ed.), 1977). The following parameters were measured and used for the statistical analyses (abbreviations are given for the variables that were later included in the regression equations): content of aluminium (Al, µg/l), copper (Cu, µg/l), iron (Fe, µg/l), lead (Pb, µg/l), zinc (Zn, µg/l), sodium and potassium (Na+K, µg/l), manganese (Mn, µg/l), ions of calcium (Ca^{2+}, µg/l) and magnesium (Mg^{2+}, µg/l), ammonium (NH_4^+, mg/l), chlorides (Cl^-, mg/l), nitrates (NO_3^-, mg/l), sulphates (SO_4^{2-}, mg/l), carbonates (HCO_3^-, mg/l), total nitrogen (N_{tot}, mg/l) and phosphorus (P_{tot}, mg/l), inorganic phosphorus (P_{min}, mg/l), total carbon (TOC, mgC/l), biological oxygen demand in 5 days (BOD_5, mgO_2/l), chemical oxygen demand (COD, mgO_2/l), hardness of water, content of hydrocarbons (Carb, mg/l), content of oxygen (percent saturation and mg/l), content of total suspended matter, water colour (W_{col}, degrees), turbidity (NTU), acidity (pH), specific conductance (Cond, mS/cm), total dissolved solids (TDS, g/l), temperature, content of chlorophyll (Chl, µg/l) and cyanobacteria abundance (BGA, cells/ml).

* – data for a single river-lake system Vuoksa.

The following parameters of catchment basins of Lake Ladoga major tributaries were used: river length (L, km), areas of wetlands (Sh_{wetl}, %), lake percentage on the territory of the catchment basin (Sh_{lakes}, %), catchment area (S_{cat}, km^2), river flow rate (W_{fl}, m^3/s) (*Table 1*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_15111540

Zooplankton samples were collected from the shore at open areas lacking macrophytes by pouring 100 L of water through the Apstein cone-shaped net (mesh size is 75 μm) and fixed in 40% formalin (diluted to 4.0%). Species composition and qualitative development patterns of rotifers of the tributaries zooplankton were assessed after processing the sediment samples. The material was processed according to the routine protocols described by Abakumov (1992). Biomass of the organisms (raw formalin weight) was calculated using the formulas for the dependence between body length and weight of planktonic crustaceans (Ruttner-Kolisko, 1977; Balushkina and Vinberg, 1979). Species composition was determined with the help of identification manuals (Rylov, 1963; Kutikova, 1970; Alekseev and Tsalolikhin (eds.), 2010).

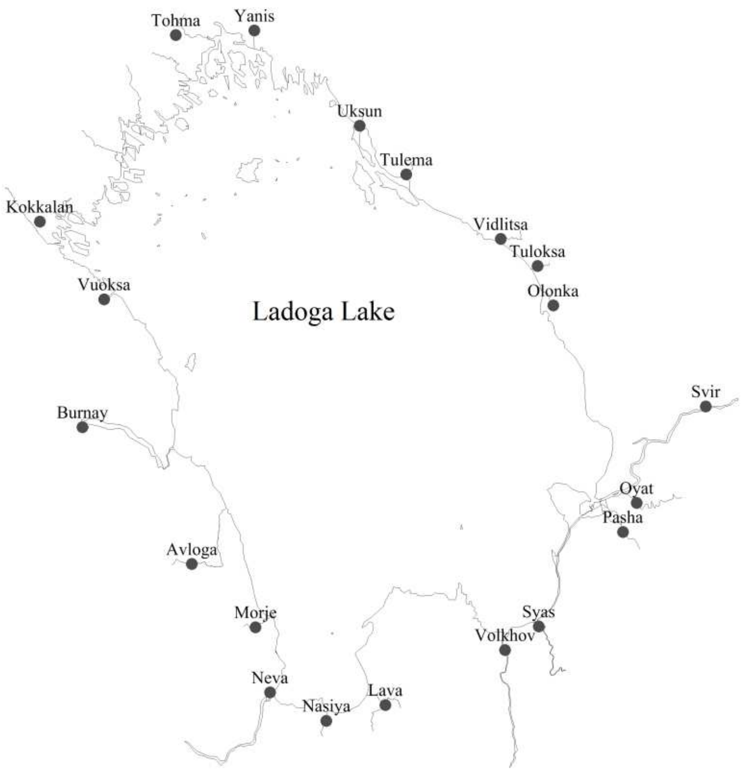

Figure 1. *Scheme of sampling stations on the tributaries of Lake Ladoga and Neva River*

The following parameters were used to characterize the zooplankton community: number of species (n), abundance (N, ind./m^3), biomass (B, mg/m^3), the Shannon diversity index (Shannon, 1948) estimated for both abundance (H_N, bit/ind.) and biomass (B_N, bit/mg). To separate groups of rivers, similar in zooplankton, the numbers of individual species of Copepoda, Cladocera, and Rotifera, and members of Copepoda, Cladocera, and Rotifera groups that have not been identified to species (Copepodits of Calanoida, Copepodits of Cyclopoida, Nauplii of Calanoida, Nauplii of Cyclopoida, Cyclopoida spp.) (86 variables in total), as well as total numbers of Copepoda, Cladocera, and Rotifera were used.

Statistical analysis of the variables was performed for each time period. Cluster analysis, correlation analysis and regression analysis (stepwise multiple regression) included in Statistica 6.0 software package (StatSoft Inc.) were used to reveal

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_15111540

interrelationships between the studied parameters. The authors used the modification of cluster analysis, where the variables correlation measure was Euclidean distance or Pearson correlation coefficient; individual rivers were included into clusters according to the complete linkage method or Ward method (Pesenko, 1982).

Results

Chemical composition

Chemical composition of water in tributaries of Lake Ladoga is typical for the area under study, its common features result from similar climate conditions, and the differences are caused by peculiarities of geomorphologic characteristics, the composition of the rocks (*Appendix A*).

The waters of tributaries of Lake Ladoga fall into the hydrocarbonate class of calcium group. Calcium ions prevail in the cationic composition of water of all rivers – 1.6 to 52.63 µg/L, the content of magnesium ions varies from 0.7 to 16.2 µg/L, the content of sodium and potassium ions – from 0.08 to 19.95 µg/L. The content of sulphates varies from 1.82 mg/L (the Uksun River) to 17.00 mg/L (the Kokkolan River), the content of chlorides – from 1.03 mg/L (the Uksun River) to 19.14 mg/L (the Volkhov River), the content of carbonates – from 0.73 mg/L (the Uksun River) to 185.93 mg/L (the Lava River). During the period of studies, the water temperature was above 3.5ºC and below 22.5ºC.

Community composition and quantitative patterns of zooplankton development

In the investigated rivers, a total of 137 zooplankton taxa ranking below genus were identified in the lower course of the Lake Ladoga tributaries and the Neva River head. Rotifera group accounted for 56 species and subspecies (40.9%), Cladocera – 57 (41.6%), Copepoda – 24 (17.5%), including 6 members of Calanoida (4.4%), 18 – Cyclopoida (13.1%). The greatest number of species was found in large rivers: the Vuoksa (57), the Burnaya (51), the Volkhov (49), the Svir (45), the Neva (45), the lowest number – in the Kokkolan River (26) (*Appendix B*).

Species composition considerably varied between different rivers. *A. harpae*, *B. (E.) coregoni*, *C. sphaericus* were the only crustaceans found in all rivers. Almost every tributary was inhabited by following zooplankters: *A. priodonta* (except for the Naziya River), *E. lyra* (except for the Pasha River), *B. (B.) longirostris* (except for the Vidlitsa River), *M. leuckarti* (except for the Tokhma River and the Vidlitsa River). Such members of lower crustaceans as *B. (E.) coregoni* (frequency of occurrence, F = 11.5%), *C. sphaericus* (F = 11.5%), *B. (B.) longirostris* (F = 9.6%), *A. harpae* (F = 9.3%), *P. pediculus* (F = 9.3%), *D. cristata* Sars (F = 7.6%), and such rotifers as *Synchaeta spp.* (F = 12.4%), *A. priodonta* (F = 10.4%), *C. unicornis* (F = 7.6%), *K. longispina* (F = 7.1%), *Bdelloida spp.* (F = 5.4%), *B. hudsoni* (F = 4.3%), *E. incisa* (F = 3.8%), *K. quadrata* (F = 3.2%), *A. herricki* (F = 2.7%) were the most abundant in the zooplankton samples.

As a rule, several species simultaneously prevailed in the rivers. Among Cladocera *B. (E.) coregoni* was dominant more often than any other zooplankters (*Table 3*). The members of the lake complex – *A. priodonta*, *K. longispina*, *C. unicornis, D. (D.) cristata, E. gracilis*, *T. oithonoides*, as well as the crustaceans of the littoral macrophyte complex – *A. harpae*, *A. quadrangularis*, *C. sphaericus* prevailed in most tributaries.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_15111540

Plankton community was formed by 53 cosmopolitan species (43.8%), 32 holarctic species (25.4%), 31 palaearctic species (25.6%), 5 boreal species (4.1%).

The highest numbers of zooplankton within the Lake Ladoga tributaries were observed in the Avloga River in May 2011 (9580 ind. /m^3), in the Tuloksa River and the Burnaya River in June 2014 (9190 ind./m^3 each). The highest levels of biomass development were observed in the zooplankton communities of the Vuoksa River in May 2015 (266.2 mg/m^3), in the Tuloksa River in June 2014 (256.5 mg/m^3). The lowest levels of population and biomass (30 ind./m^3 and 0.17 mg/m^3 respectively) were observed in small rivers (the Tokhma River, the Uksun River). The mean levels of population in the tributaries during the study period of 2011–2014 varied from high – 2870 ± 670 ind./m^3 in the Vuoksa River – to low – 210 ± 50 ind./m^3 in the Lava River, the levels of biomass – from 191.77 ± 125.22 mg/m^3 in the Vuoksa River to 1.84 ± 0.55 mg/m^3 in the Kokkolan River (*Table 2*).

Table 2. *Mean abundance (N_{tot}, ind/m^3); biomass (B_{tot}, mg/m^3) and the values of the Shannon index, calculated on the number (H_N, bit/ind.) and biomass (H_B, bit/mg) of zooplankton species in the tributaries of Lake Ladoga and the Neva river in 2011–2014.*

Note: above the line – the arithmetic mean ± standard error of the mean, below the line – the coefficient of variation of the characteristics.

The highest numbers of population and biomass at the station of the Neva River head were observed in August 2011 (29360 ind./m^3 and 468.3 mg/m^3 respectively), whereas the lowest ones – in May 2015 (480 ind./m^3 and 4.65 mg/m^3 respectively). Mean value of zooplankton abundance was 6910 ± 3320 ind./m^3, mean biomass – 123.87 ± 53.97 mg/m^3 (*Table 2*).

The values of the Shannon index for zooplankton abundance (H_N) varied from 0.29 bit/ind. (the Pasha River) to 3.07 bit/ind. (the Vuoksa River) and from 0.18 bit/mg (the Yanis River) to 2.89 bit/mg (the Vuoksa River) for zooplankton biomass (B_N).

Mean values of Rotifera abundance were higher than those of the crustaceans in the Tuloksa and the Morje rivers, mean biomass – in the Burnaya, the Tuloksa, the Morje, the Kokkolan rivers. The Copepoda crustaceans prevailed in both number and biomass in the zooplankton communities of the Neva head and the Volkhov mouth. Mean values of number and biomass of Cladocera were higher than total values of other zooplankton groups in the rest of the rivers (*Figs. 2, 3*).

Statistical analysis

Cluster analysis of the variables was performed for 9 time periods: May, August, and October 2011, July and October 2012, June and September 2013, May and July 2014.

When clustering rivers according to the species composition and species abundance, no similar clusters could be formed both in different seasons of the same year and in different years (*Figs. 4–7*).

River groups of the Vidlitsa-Pasha-Tulema and the Tokhma-Kokkolan-Volkhov showed similar trends of clustering in spring and summer 2011; the Lava-Kokkolan and the Syas-Olonka – in summer and autumn; the Pasha-Tulema – in spring and autumn (*Fig. 4*).

In 2012, the rivers did not form similar clusters for different time periods, when the analysis was based on the numbers of individual zooplankton species (*Fig. 5*).

In 2013, similar trends of clustering were observed in case of the Kokkolan-Volkhov rivers in summer and autumn (*Fig. 6*).

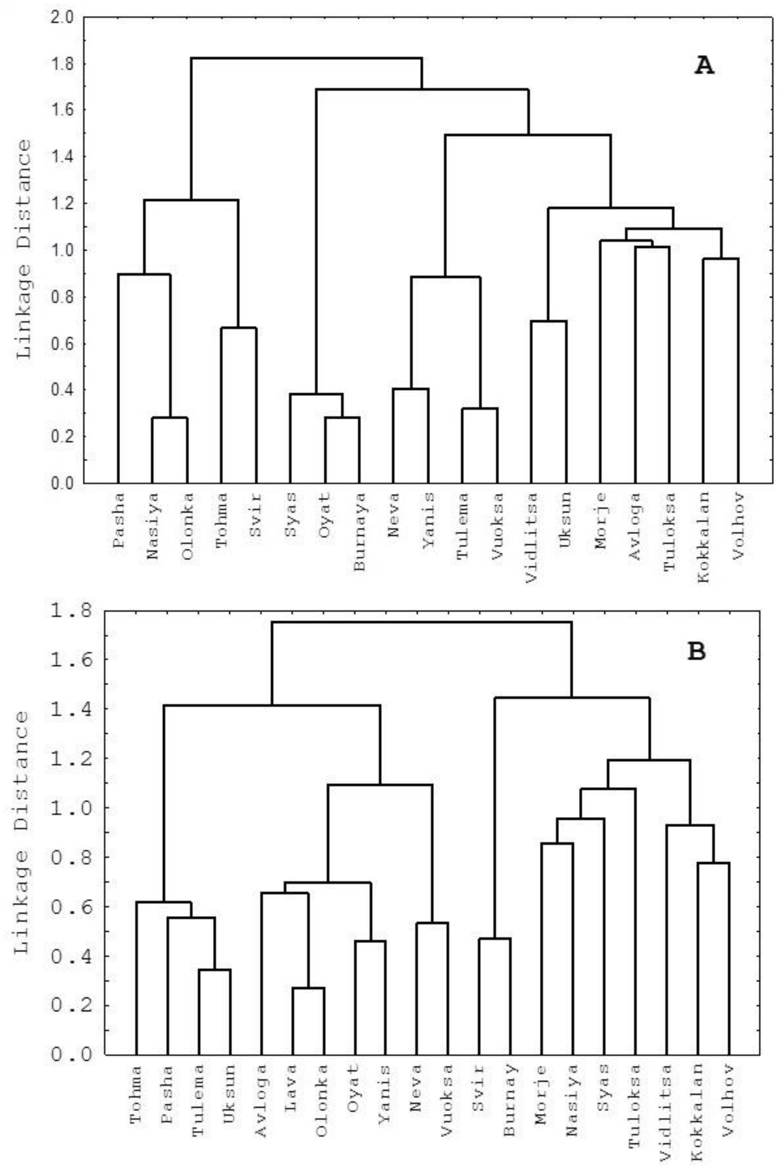

Figure 6. *Diagram of similarities of tributaries of Lake Ladoga in 2013, based on the analysis of the composition and abundance of zooplankton species (joining by the Ward's method, distance measure – Pearson correlation coefficient). A – June, B – September.*

In 2014, similar trends of clustering were only observed in case of the Lava-Pasha rivers and the Oyat-Naziya-Volkhov rivers in spring and summer (*Fig. 7*).

The examples of river clustering based on the hydrochemical, hydrological parameters and the catchment basin features (4 periods of 9) are shown in *Fig. 8*.

In general, the clusters of rivers similar in zooplankton communities did not coincide with the clusters of rivers that considered all the hydrochemical, hydrological parameters and the catchment basin features, in any year of studies (*Fig. 8*).

Generally, the clustering based on the hydrochemical, hydrological parameters and the catchment basin features was consistent in different years and seasons. Similar rivers were grouped according to their physiographic position (*Fig. 8*).

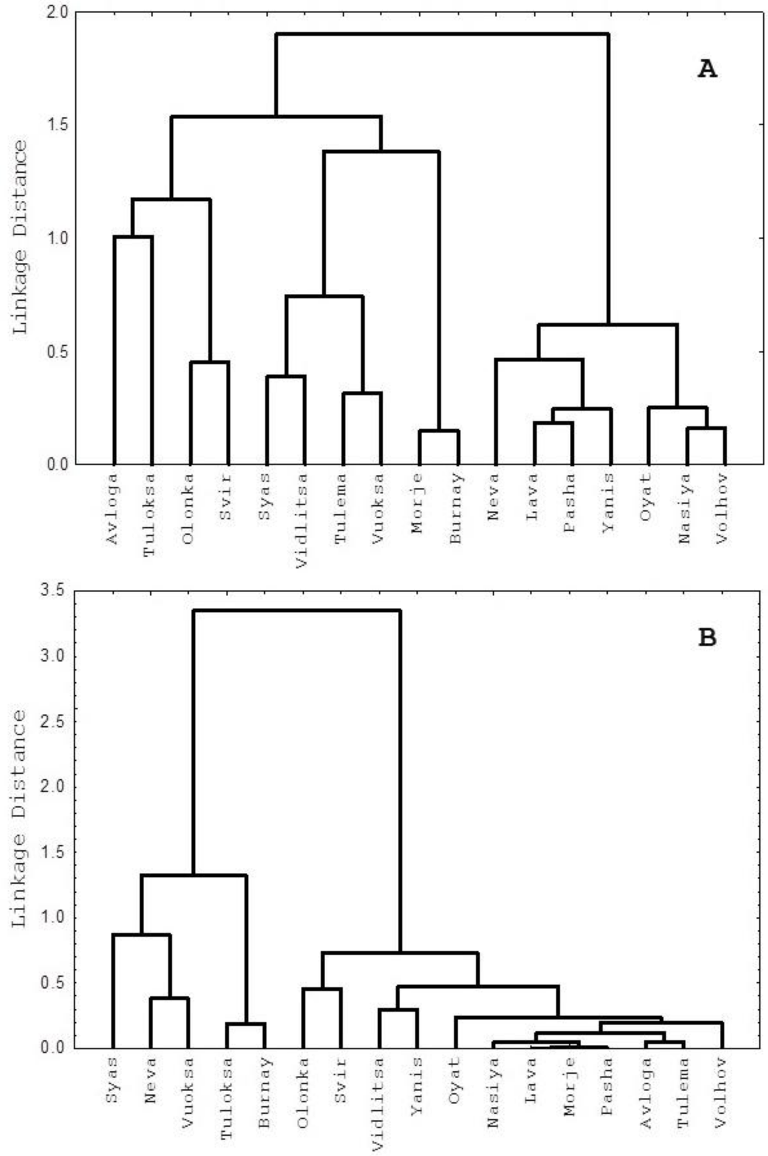

Figure 7. *Diagram of similarities of tributaries of Lake Ladoga in 2014, based on the analysis of the composition and abundance of zooplankton species (joining by the Ward's method, distance measure – Pearson correlation coefficient). A – May, B – July.*

The results of regression and correlation analysis did not show significant ($p<0.05$) relationship between the parameters of the development of individual zooplankton species and the assessed parameters of water of the Lake Ladoga tributaries.

Unlike the regression analysis that failed to show connection between the development of zooplankton species and the environmental factors, and to provide significant ($p<0.05$) equations of regression, the analysis of total numbers of Copepoda, Cladocera, and Rotifera resulted in highly significant correlations. 8 of 9 possible significant regression equations describing the group size as a function of a certain set of variables were obtained for Copepoda, 7 – for Rotifera, 6 – for Cladocera (*Table 3*).

Table 4 shows the most common predictors of 9 regression equations for each of the groups of *Copepoda*, *Rotifera*, and *Cladocera*. The most common predictors of the regression equation for the *Rotifera* number were the catchment basin area, the lake percentage of the catchment basin (6 cases each), the content of sulphates, chlorides, and lead (5 cases each). The following predictors were considered significant ($p < 0.05$): the catchment basin area (6 cases), the lake percentage of the catchment basin, the sulphates content (5 cases). Common and significant ($p < 0.05$) predictors for the numbers of *Cladocera* zooplankters included the catchment basin area (5 cases) and the river discharge (4 cases). The content of chlorides and copper were included in the regression equations at the rate of 4. The numbers of *Copepoda* crustaceans were determined by such parameters of the regression equations as water discharge and the catchment basin area, found at the rate of 6. They were significant ($p < 0.05$) in 6 and 5 cases respectively. The regression equations included such variables as the area of wetlands within the catchment basin, the length of the river and some chemical parameters: content of metals (aluminium, copper and iron), pH, total dissolved solids, content of certain ions (Na+K, NH_4^+, Mg^{2+}), total carbon and total phosphorus, such physical parameters as turbidity and water colour (*Table 4*).

Discussion

The study performed in 2011–2014 showed that taxonomic composition of the zooplankton community of the rivers of Lake Ladoga local catchment basin and the Neva River was common to the fauna of water bodies of the European North (Kulikova, 2012; Ryabinkina et al., 2012) and was mostly cosmopolitan. The total list of species composition of the zooplankton communities of the studied watercourses, as well as the species richness of most rivers were formed by Cladocera. Rotifers predominated only in two rivers – the Kokkolan and the Burnaya. Virtually all species (99%) were found in Lake Ladoga (Rodionova, 2011). The dominant complex of the river zooplankton communities was formed by the members of lake and littoral macrophyte complexe, due to high lake percentage within the areas of the catchment basins of the studied rivers (up to 14%). Biogeographic analysis shows that it is eurythermic and moderately warm-water species that prevailed in the integrated zooplankton complex of the lake tributaries.

Despite the fact that quantitative parameters of the Ladoga tributaries considerably varied between the stations during the study period, major trends of the zooplankton community development in different seasons can be described. In spring, the number and biomass of zooplankton of large rivers (Svir, Vuoksa, Burnaya, Volkhov, Syas) were essentially formed by the members of Rotifera, while in other tributaries – by copepods, mostly juvenile. In summer, the number of zooplankton in most communities consisted of Copepoda (Cyclopoida) and Cladocera crustaceans, and the biomass – of Copepoda (Cyclopoida and Calanoida) only. In autumn, all the groups of zooplanktons prevailed in numbers in different rivers and in different proportions, but the biomass was essentially determined by the members of Cladocera. The major trends in seasonal changes of the community of crustaceans and rotifers observed at the stations of study were common for lotic communities (Czerniawski et al., 2013; Gromova et al., 2013).

Quantitative parameters of the zooplankton development considerably varied between different stations and different seasons, but the mean values over the period were low, which is typical for the watercourses of the region. The highest values of number and biomass were observed at the station at the Neva River head. *Figures 2* and *3* show that in most rivers mean values of number and biomass of Cladocera crustaceans were higher than mean quantitative parameters of the development of Rotifera and Copepoda zooplanktons. A regular pattern of decrease in quantitative parameters of the zooplankton development in the rivers with smaller catchment basin areas can also be noted (*Figs. 2, 3*). The only exception were low number and biomass at the lower course of a large tributary – the Volkhov River. The zooplankton community of the river mouth can probably be depressed by the Volkhov hydroelectric plant.

The results of the statistical analysis of the data we have performed show that, in case of river clustering based on the species composition and abundance, similar clusters in different seasons of the same year or in different years are almost never formed.

Virtually absent regular patterns in river clustering based on the number of individual zooplankton species and discrepancy in the obtained river clusters and the clusters of similar rivers, based on the physic-chemical parameters and the catchment basins features, indicate high variance and unpredictability of the development of individual species within the Lake Ladoga tributaries.

The results of regression and correlation analyses did not show significant ($p<0.05$) relationship between the parameters of the development of individual zooplankton species and the assessed parameters of water of the Lake Ladoga tributaries.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_15111540

Such results prove that abiotic factors and physiographic characteristics of the rivers catchment basins certainly influence the zooplankton in the general way, but apparently the actual structure of community and the populations of individual zooplankton species of the Lake Ladoga tributaries are to a greater extent determined by other factors that were not considered in current study.

Perhaps, these factors include such hydrological parameters as the current speed, the width and depth of rivers, which, according to the concept of river continuum, have great impact on the species composition, the trophic structure, and the distribution of hydrobiont communities (Vannote et al., 1980). The possible influence of the trophic state of the lakes that give rise to rivers and biotic interactions in the water courses on the development of zooplankton communities, should not be excluded, too (Krylov et al., 2007; Czerniawski and Domagała, 2010; Krylov et al., 2011; Chaparro et al., 2015).

Similar results were obtained in case of 54 small water bodies of Wisconsin (USA), showing that the number of species and distribution of spring zooplankton communities were not correlated with physiographic features, pH, electric conductivity, total phosphorus, nitrogen, ions of calcium, sulphates, nitrates, chlorides and silicates (Schell et al., 2001).

In our study, we considered both individual factors that directly influence biota and such integrated variables as catchment basin area, area of wetlands, lake percentage of the catchment basin, etc. These integrated factors virtually determine the parameters considered in our study and the environmental factors that have not been defined and measured. It gives reason to the fact that these integral variables turned out to be the most significant ones and most commonly included in the regression models we obtained (*Table 4*). We did not manage to discover consistent correlations with any of studied parameters of water of the Lake Ladoga tributaries for individual zooplankton species. At the next stage we tried to reveal any possible association between the parameters of the environment and total abundances of Copepoda, Cladocera, and Rotifera groups. We performed multiple forward stepwise regression analysis involving 37 above-listed abiotic parameters at the first stage. The data shown in *Table 4* prove that the integral factors (catchment basin area, water discharge, and lake percentage) are the most significant ones and most often included in the regression equations of the number of Copepoda, Rotifera, and Cladocera.

In earlier studies of the phytoplankton inhabiting the Lake Ladoga tributaries, the dependence of quantitative patterns of the community development on the lake percentage within the rivers catchment basins has also been revealed (Trifonova (ed.), 2006).

The dependence of the structure of plankton communities on the integrated parameters rather than on individual physic-chemical parameters has been shown for different types of aquatic ecosystems. The study of the impact of environmental factors on the zooplankton of lowland rivers of Central Russia has shown that the results of man-induced and zoogenic environmental influence are manifested in different ways, depending on many natural factors, especially hydrological ones (Krylov, 2002a, 2002b). Mechanism of effect of hydrological factors on zooplankton structure and quantitative parameters as element of the lotic ecosystems was shown in (Gromova et al., 2013). The abundance of potamoplankton in the Vistula River (Poland) is also determined by hydrological conditions (Napiórkowski and Napiórkowska, 2013). The variation of water level and the flow pattern are the most important factors of structure and life of alluvial river ecosystems (Junk et al., 1989; Neiff, 1990; Tockner et al., 2000a, 2000b; Bozelli et al., 2015).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_15111540

The results of the study of planktonic crustaceans in the reservoir cascade in Brazil indicate that the water residence time (WRT) and such morphometric features of reservoirs as their size, depth, and shape, have a considerable impact on the structure and functioning of zooplankton communities (Bini et al., 2008; Perbiche-Neves and Nogueira, 2010, 2013).

The analysis of the data on the community of crustaceans and rotifers in the regulated Oder River revealed that the most important factor that determines the condition of zooplankton and the physic-chemical properties is WRT (Czerniawski et al., 2013). The influence of hydrochemical factors on the zooplankton of the Novosibirsk reservoir is also connected to the peculiarities of hydrological regime in the parts of the water body (Dvurechenskaya and Yermolaeva, 2014). Zooplankton of 20 lakes of Kejimkujik National Park (Canada) was strongly correlated with such factor as elevation, but not with the studied hydrochemical parameters (Bowman et al., 2014). Only the differences in hydrological and geomorphological conditions led to structural and functional differences in the planktonic communities of the semiarid Macquarie Marshes (Australia) (Kobayashi et al., 2015).

Content of Mg^{2+}, Na^{+} + K^{+} ions and such metals as Pb, Fe, Cu, Al were included in the regression equations less frequently (*Table 4*). It is well-known that depending on chemical and physical speciation, metals can enter the zooplankters in different ways; for instance, dissolved metals can come directly from water, while the particles of associated metals can be consumed with food (Sofyan et al., 2006). Thus, they have different impact on the short-term and long-term changes in structure and composition of the zooplankton community (De Paiva Magalhães et al., 2015). Unfortunately, we have no data on the form of metals present in the water of the tributaries and on their bioavailability for the organisms during the period of our study.

Total phosphorus content was often (up to 4 cases out of 9) included in our multiple regression equations describing total numbers of Copepoda and Rotifera (*Table 4*). Considering low natural concentrations of biogenic elements, especially phosphorus, in the catchment basin of Lake Ladoga (*Appendix A*), one might assume that the concentration of biogenic elements in rivers is the limiting factor for zooplankton, influencing the primary production of phytoplankton. Similar results were obtained for the rivers in Shanghai (China), where population figures and structure of the zooplankton community depended on the content of another biogenic element – total nitrogen, whose concentrations were 20 times lower than those of total phosphorus (Na et al., 2014).

It is interesting that there are many studies describing positive correlation between qualitative patterns of the zooplankton development and water temperature (for instance, in such large rivers as the Danube (Hungary), the Oder (NW Poland)) (Vadadi-Fülöp et al., 2009; Czerniawski et al., 2013), or between it and electric conductivity. However, according to the results of our study, these variables were not included in the equations linking the abundance of zooplankton groups in the Lake Ladoga tributaries and in the Neva River to the environmental factors.

Conclusions

A total of 137 zooplankton taxa ranking below genus were identified in 19 tributaries of Lake Ladoga and the Neva River head in 2011–2014, including 56 species and subspecies of Rotifera (40.9%), 57 – of Cladocera (41.6%), 24 – of Copepoda (17.5%). Quantitative parameters of zooplankton varied in different rivers, still mean values of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_15111540

numbers (30–9580 ind./m^3) and biomass (0.17–266.2 mg/m^3) were low. The members of Copepoda and Rotifera were dominant in the lake tributaries in spring, Cladocera – in summer, Cladocera and Copepoda – in autumn.

The development patterns of individual zooplankton species of Copepoda, Cladocera, Rotifera in tributaries of Lake Ladoga was proven to be stochastic. Species composition and patterns of qualitative development cannot be linked to any environmental factors or their combination. It is impossible to identify groups of tributaries of Lake Ladoga with similar patterns of zooplankton development basing on the composition and numbers of individual zooplankton species.

River clustering based on hydrochemical, hydrological parameters and catchment basins' features provides an opportunity to distinguish groups of similar rivers that were consistently formed during different years and seasons. Groups of similar rivers were isolated according to their physiographic position. The cases of belonging of some rivers to different clusters in different time periods turned out to be rare.

Total abundances of Copepoda, Cladocera, and Rotifera in the tributaries of Lake Ladoga are consistently linked with certain combinations of studied physiographic parameters and features of the aquatic habitat, which was proved by the possibility to develop highly significant regression models, describing the number of zooplankton groups as a function of a certain set of variables. Integrated physiographic factors, like the catchment basin area, water discharge, and lake percentage of the catchment basin, are the most important in the level of qualitative development of Copepoda, Rotifera, and Cladocera in tributaries of Lake Ladoga.

Acknowledgements. The authors are thankful to M. O. Dudakov and I. A. Sotnikov for assistance in sampling. We are grateful to N. V. Rodionova, N. V. Polyakova, A. A. Kotov, and A. Y. Sinev for their help in the taxonomic analysis of zooplankton. We are grateful to the Environmental Safety Observatory Resource Centre of St. Petersburg State University for the technical support for this study as well.

(Received 24th Mar 2017; accepted 1st Aug 2017)

Abstract. Former excavation remnants can play a significant role in increasing the species richness and local biodiversity on heavily altered, post-industrial sites. In this article we examined 30 plots – mounds and areas surrounding mounds to evaluate the influence of different key factors on floristic composition, including selected edaphic parameters (pH, EC, organic matter, $CaCO_3$ and content of metals: Pb, Cd, Zn, Fe). We also tested the species-area correlations. Additionally, we assessed basic characteristics of plant species, which inhabit those plots, measuring species richness and biodiversity with Shannon-Weiner index (H′) and also estimating the similarities in species composition between mounds and the surrounding areas, using Sörensen's index (S_o). In result, we noted 92 vascular plant species, with mostly native origin (98%). Based on the performed analysis, mounds which were studied had slightly higher values of mean species richness and species diversity compared to the surrounding area. Contribution of socio-ecological groups showed, that, mounds were inhabited predominantly by forest species from *Querco-Fagetea* and *Vaccinio-Piceetea* classes. Analyses of collected soil samples indicated strong influence of pH and content of metals (mostly zinc, lead and iron) in relation to the floristic composition on the examined plots. Unique characteristics of soil samples taken from the studied plots can explain the distinct preferences of some plant species which grow on them. This allowed to classify those structures as a refuge area, considering their positive contribution to the increase of species richness and biodiversity. Nowadays the old remnants can be also treated as a crucial part of historical and cultural heritage.
Keywords: *habitat islands, species richness, human disturbance, local biodiversity, abiotic characteristics*

Introduction

A variety of landscape modifications, which relate to anthropological use and particularly, human destruction of natural habitats, can influence and increase the process of habitat fragmentation, directly threatening the natural state of balance in local diversity (Andrén, 1997). Despite that,, many forms of remnants such as excavations, pits or tailings positively influence species composition during the long term process of reclamation, which occur on them. Man-made sites can also become local shelters for many endangered plant species (Rehounková and Prach, 2006; Rostański, 2005, 2006; Bzdon, 2008; Czylok and Szymczyk, 2009). Due to their distinctive characteristics and role in the process of landscape fragmentation, these structures can be treated as small habitat islands, which corresponds with the main concept of biogeographical theory proposed by MacArthur and Wilson (1967). The state of equilibrium, according to this theory, can be achieved, depending on few basic factors, such as the immigration and extinction rate of plant species, size of studied "island" and level of its isolation from similar structures. In the case of remnants of past activities, we have to consider

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_15411563

numerous amount of human-based disturbances in form of mining and excavating among the crucial factors, which characterize those differences. In this article we attempt to make a detailed studies on the remnants of mid forest iron ore excavations as a refuge area for local diversity of vascular plant flora, emphasizing the influence of heavily modified abiotic and biotic parameters. We would also like to verify whether other factors (such as the size of the mounds studied) can affect the state of local biodiversity, in accordance with the biogeographical theory of habitat islands.

Materials and methods

Study area

The fieldwork area is located in the Forest District of Koszęcin (Boronów Forestry – Katowice directorate: 118g, 118c, 118a, 117h, 117i, 117g, 117d, 98c and 98i). Fifteen mounds (remnants of iron ore excavation) were investigated during this project. Records were made of vascular plant species composition on those structures, as well as on their surrounding area *(Fig. 1)*, located in the vicinity of two settlements Boronów and Zumpy (Silesian voivodeship). Most of them were already buried and covered by surface layer of soil. Some of the shafts investigated were flooded and then transformed into small artificial reservoirs of rainwater (*Fig. 2*). Every mound was thoroughly measured and their basic parameters were taken, including: length, width, area, height (max and min), the diameter of internal shafts, located on top of the mounds, type of forest habitat and also the GPS coordinates (*Tab. 1*)

Table 1. *Characteristics of the mounds (based on own data)*

Figure 2. *Sample picture illustrating mound and surrounding area (photo A. Rostański)*

Climate and geological conditions

The area of our studies corresponds with the climatic region of western part of the Lesser Poland voivodship, according to the division proposed by Woś (1999). This

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_15411563

region is characterized by considerably high amount of annual rainwater, due to its specific features, which are typical on the upland site. The mean values of annual temperature set at around 7-8 ° C (the peak is around 14° C in July and the lowest value is -4° C in January). The monthly mean values of rainfall water hover at around 80 mm/m^2 in July and drop to the 40 mm/m^2 in the following months (*Fig. 3*). The winds are mainly western with relatively low speed.

Land relief has slightly sinuous profile with small elevations reaching up to the several meters above ground. In terms of soil conditions, there are mainly 2 types of soils distinguished in this area: proper fallow soils (mostly occurring in the directorates 117 and 118 g) and the proper pseudogley soils (occurring in the directorates 118 c, a and 98 c) (Operat siedliskowy, 2003).

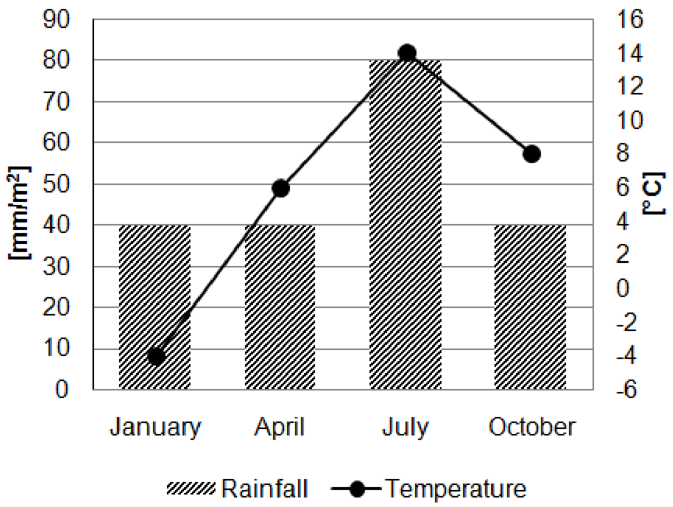

Figure 3. *Climate diagram of area studied with the temperature and rainfall mean values in selected months (source: Kruczała, 2000, modified)*

Methods of fieldwork sampling

For the investigation we established 30 assessment plots, which were differentiated into the excavation mounds themselves (M) and the strip of land around each mound (15 metre in diameter), which was referred to as the surrounding area (S). We used the standard Braun-Blanquet method (1928) to assess cover and constancy for each individual species in the relevés with modified scale (*Tab. 2*). Within those plots, 30 soil samples from depth of 10-15 cm (root zone) were taken (bulk samples from each mound and surrounding area) and prepared for the laboratory analysis.

Table 2. *Constancy scale for species noted*

Degree	% constancy
V	100-80
IV	80-60,1
III	60-40,1
II	40-20,1
I	20-1

DOI: http://dx.doi.org/10.15666/aeer/1504_15411563

Methods of biotic analyses

The nomenclature for plant species was taken from Mirek et al. (2002). Their origin (including apophytes – native species occurring on synanthropic habitats and kenophytes – species permanently established in Poland after the year of 1500) was based on classifications from Tokarska-Guzik (2005) and Mirek et al. (2002). Affinity to socio-ecological groups of designated plant communities was assigned, based on classification of Matuszkiewicz (2007) with distinction of 6 classes, which had the highest contribution: *Querco-Fagetea* and *Vaccinio-Piceetea* (forest communities), *Molinio-Arrhenatheretea* and *Epilobietea angustifolii* (wet meadows and nitrophilous communities), *Nardo-Callunetea* (turfs and moors communities) and *Artemisietea vulgaris* (ruderal communities of perennials). Relevant species traits, including life strategies were estimated, based on Grime (1979, 2002) and Klotz et al. (2002) classifications, which allowed primary strategies (C – competitors, R – ruderals, S – stress tolerators) to be distinguished, as well as some of the mixed strategies (CR – composition/ruderal, CS – competitors/stress tolerators, SR – stress tolerators/ruderals and CSR – competitors/stress tolerators/ruderals).

Vegetation diversity and similarity indices

The level of overall biodiversity within plots was measured using the Shannon-Wiener index of diversity (H'), based on the species cover values noted (Whittaker 1972), according to this formula:

$$H' = -\sum_{i=1}^{n} Pi \ln Pi \quad \text{(Eq. 1)}$$

Pi – number of individuals of i-th species
n – total number of species

In order to measure the similarity level in species composition between mounds and surrounding area plots, Sörensen index of similarity (S_o) was applied (Trojan, 1980), as the necessary calculations were made according to this formula:

$$So = \frac{2c}{a+b} \times 100\% \quad \text{(Eq. 2)}$$

where **a** represents the number of species on the mounds, **b** represents the number of species in the surrounding area and **c** represents the number of species which are common for both facilities. This index shows the resemblance on the percentage scale, where 0% means lack of any common species between specific mound and its surrounding area and 100% means that, species composition in both cases is identical.

Methods of soil sample analysis

The soil samples collected from the plots were dried at 105 °C and sieved through 2mm mesh. Active pH (in H_2O) and electric conductivity (EC) were measured using a pH/conductivity/TDS meter. The content of organic matter (% OM), was measured, based on the loss of ignition analysis of dried samples. Percentage equivalent of the calcium carbonate (% Eq$CaCO_3$), was estimated using Scheibler's method. Metal

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_15411563

concentrations (lead, cadmium, zinc and iron) in the soil samples were analyzed using the flame atomic absorption spectrometry (AAS).

Statistical methods and correlations

All of the listed parameters, which refer to the vegetation (diversity index and number of species noted) and soil (pH, electric conductivity, % Eq$CaCO_3$, content of organic matter, content of metals) properties have been also measured, to identify statistical differences in pairs of plots (mound-surrounding area) using standard U-Mann Whitney test. For the correlation in species diversity-area model we transformed data using semi-log scale and used linear regression method and also testing the statistical significance. We applied the canonical correspondence analysis (CCA) to estimate the species-environmental relations and we also used the cluster analysis (Ward method with Euclidean distance) to indicate whether the physico-chemical variables are distinctive for each group of plots. The following software was used to perform the statistical calculations and visual interpratations: CANOCO 4.5 (Ter Braak and Šmilauer, 2002; Lepš and Šmilauer, 2003) Statistica 12 (StatSoft 2011) and RStudio 1.01 (2015).

Results

Vegetation diversity and similarity measurements

There were 92 vascular plant species noted together on the mounds and their surrounding area (*Appendix 1*). Based on the mean values of the species diversity indices we observed that, the mounds had slightly higher species richness compared with the area which surrounded them (23 ± 2.21 on mounds and 19 ± 2,13 in the surrounding area), following the slightly higher values of species biodiversity noted (4.31 ± 0.15 on mounds and 4.01 ± 0,15 in the surrounding area), although that, difference between those groups was estimated as not statistically significant according to the results of conducted U-Mann Whitney test (*Tab. 3*).

Table 3. *Mean values (with standard error) for biotic parameters and results of the U-Mann Whitney test (* – significance at p<0.001)*

Parameters	Mounds	Sur. area	Z	p
Number of species	23 ± 2.21	19 ± 2,13	1.267339	0.205035
Diversity index (H′)	4.31 ± 0.15	4.01 ± 0,15	1.244342	0.213375

Native species (98%) were almost exclusively building the composition of the flora investigated, which is a commonly observed phenomenon on abandoned areas with post industrial origin. Only 2% of the total composition was represented by alien species (kenophytes), such as: *Impatiens parviflora* (mainly concentrated in the surrounding area) and *Quercus rubra*, (recorded on one of the studied mounds).

There were 13 different socio-ecological classes distinguished in the plots sampled, although some of them were represented only by single species. Most of the mid-forest mounds consisted of typical forest and scrub species (representing the classes: *Querco-Fagetea* and *Vaccinio-Piceetea*). Together they exceeded a contribution of 38%. The second and also influential group, consisted of fresh meadows species (representing the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_15411563

class: *Molinio-Arrhenatheretea*) (*Fig. 4*), with a contribution level of 18%. If the results are compared the in three different groups of species, representing those which occurred only on mounds (M), those which occurred on mounds and in the surrounding area (M/S) and those which occurred only in the surrounding area (S), we observed a higher contribution of species from *Querco-Fagetea* and *Artemisietea vulgaris* classes, which were present only on mounds, compared with those species, which exclusively inhabit the surrounding area (*Fig. 5*).

DOI: http://dx.doi.org/10.15666/aeer/1504_15411563

CSR (competitors/stress tolerators/ruderals) strategy (30) (*Fig. 6*). The contribution of species, representing C and CS strategies was higher on mounds, although surrounding areas had slightly higher contribution of species with CSR type of life strategy.

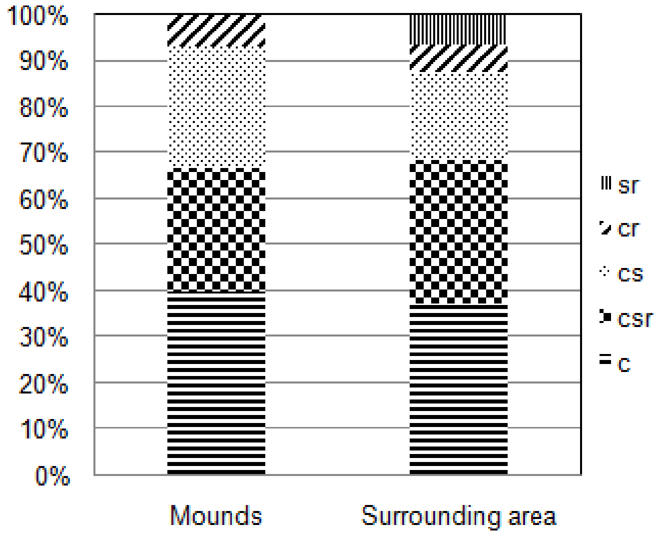

Figure 6. *Contribution of life strategies in both groups of plots*

Most of the species noted belong to constancy class I both on the mounds (12) and in the surrounding area (14), which corresponds with a low amount of individual species and a relatively high contribution of common ones, although a few species were present only on mounds and had substantially high level of constancy there (IV, III and II classes of constancy). In addition, some plant species were present only in the areas around the mounds (II and III classes of constancy) (*Fig. 7* and *Tab. 4*). Rare and valuable plant species, like: *Daphne mezereum* (IV class), *Luzula multiflora* (II class), *Galium schultesii* (II class) represented the general group, whose occurrence was exclusively limited to the mounds. At the opposite extreme, common woody species, such as: *Acer platanoides* (II class) and *Hieracium murorum* (III class) had relatively high frequency level in the surrounding area.

The comparison between mounds and their surrounding areas in regard to their level of similarity highlighted some noticeable discrepancy between studied groups of plots. The highest values of Sörensen coefficient were noted on mounds 14 (S_o= 61.54%) and 15 (S_o= 60%) with 8 and 6 common species. In the contrary, one of the lowest levels of similarity were noted in the plots 9 (S_o= 38.89%) and 13 (S_o= 41.38%) with 7 and 6 common species respectively (*Fig. 8* and *Tab. 5*). Furthermore, one of the biggest mounds (with number 9 and 13) had the lowest value of commonly shared species which indicates their substantial distinctiveness compared to the smaller ones. This also proves the theory, that, those habitats which correspond with the large islands are less prone to the extinction threat with their optimized species pool.

The relationship between species diversity and area of mounds

We also wanted to examine the linear correlation in the commonly used species-area model, although we put more focus on the investigation of species diversity of local plant communities, which better emphasizes the essentials of our studies. In case of our mounds which have been divided into three separate size categories (*Tab. 6*), the correlation between those variables was determined as positive, although not statistically significant ($r^2 = 0.2923$, $P = 0.021$). According to the previously mentioned theory, relatively small mounds, due to the size limitations, tend to have less diverse species pool, comparing to the bigger ones which, but at the same time, can support more heterogeneous habitats. Moreover, the biggest mound reached its threshold which resulted in much lower species diversity compared to the other structures (*Fig. 9*).

Table 5. *Number of species (mean ± SE) which are present on the plots (commonly, only on the mounds, only in the surrounding area)*

Correlation between soil parameters and composition of vascular plant flora

We determined that, there is a difference between soil samples taken from mounds and surrounding areas, specifically related to the variables: pH ($Z = 4.21$; $p = 0.000025$), content of zinc (Zn) ($Z = 4.64$; $p = 0000003$) and iron (Fe) ($Z = 4.64$; $p = 0000003$) with the significance level confirmed by the results of the U-Mann Whitney test (*Tab. 7*). The values of these variables also indicate the main components in the canonical correspondence analysis. The respective scores of canonical correspondence analysis showed, that, the first and second axis describe 13.1% of total variation in the floristic composition (*Tab. 8*).One of the analyzed edaphic factors (content of calcium carbonate (Eq% $CaCO_3$)) was omitted due to its ambiguous correlation to both axes, which caused slight distortion. The right side of the graph (*Fig. 10*) presents a group of correlated variables (pH, Fe and Zn), which corresponds with the first axis positively and also explains the external differentiation between mounds (M) and surrounding area (S). The second, quite substantial group (related to organic matter, electric conductivity and content of Cd and Pb) is correlated with the second axis, which is more likely responsible for the process of internal differentiation within each group of plots (mounds and surrounding areas respectively).

The cluster analysis (Ward method with the Euclidean distance) also highlighted the fact, that, the environmental conditions of studied sites (mounds and surrounding areas) are definitely unique, which manifested in occurance of two major groups of variables and one additional group on the graph (*Fig. 11*). The first group (on the right side) of surrounding area plots (S) is considered less homogenous with two subgroups representing greater distance between them. In contrary, in the second group (in the middle) there was only single plot (13) separating from the main two subgroups, although the distance between those two major subgroups is considerably smaller. The appearcence of mixed group (with surrounding area and mound plots) explains the fact, that, some of the plots were located in the same linear transect.

Table 7. *Mean values (with standard error) for the soil parameters (* – significance measured by the U-Mann Whitney test at p <0.001)*

Parameters	Mounds	Sur. area	Z	p

Discussion

Based on the obtained results of analyses, which included all of previously listed biotic and abiotic variables, the mid-forest mounds are clearly distinguished, from the areas which surrounds them. Further studies showed, that, the floristic composition of plots consisted mainly of native species (apophytes), with a marginal contribution of alien species (kenophytes). Forest communities (from classes: *Querco-Fagetea* and *Vaccinio-Piceetea*) dominated in the composition of the flora in both types of plots studied (mounds and surrounding area), with a slightly higher contribution of species from *Querco-Fagetea* class on the mounds (35 %), than in the surrounding area (22%). The higher values of contribution of species from *Artemisietea-vulgaris* class was noted on the mounds studied. The results of research conducted on the similar structures in the Gielniowski Hump (Małopolska Upland) also confirmed that, mesophilous forest communities, which consist of predominantly native species, can colonize these habitats more frequently. The studies also suggest that, throughout the extensive mining activities, the influence in local habitats could potentially increase the overall species richness (particularly by species from *Querco-Fagetea* class), as well as local diversity (Podgórska, 2010, 2016). During the studies we determined, that, some of the plant species were more commonly distributed on mounds, with their relatively high level of contribution, like *Lathyrus pratensis* or partially protected in Poland species *Daphne mezereum*. Other species like *Acer platanoides* or *Hieracium murorum* had relatively higher constancy in the surrounding area plots. Based on analyses of species distribution in each group of life strategies, the investigated plots were characterized by a high contribution of species representing the C (competitors) and CSR (competitors/stress

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_15411563

tolerators/ruderals) strategies. It has been shown that, moderate disturbance and stress are factors which can potentially limit the process of competition between plant species on various anthropological habitats. Substantial contribution of plant species with C (competitors) strategy is also expected in places, where both human and natural stress factors (related to mining activities, fires or floods) have ceased to exist for a long time (Nowak, 2009). Sörensen's index of similarity showed that, the majority of mounds have a vast amount of common species, which can also occur in the surrounding area. Although, one of the biggest mound (number 9) had the lowest similarity index which contribute to the assumption that, large habitat islands have their own unique species pool. The results of diversity-area studies, based on the linear regression method, showed positive correlation between species diversity and size of inhabited mound (island), indicating strong relationship between those variables. Species richness is mostly related to the amount of different habitats created on the island. Typically, more spacious islands contain more types of habitats, which directly translates into increase in species richness (Kohn and Walsh, 1994; Rickless and Lovette, 1999). Also, due to the fact that, small islands consist of rather small species pools, different environmental modifications and human related disturbances, even at a relatively low level, can have a strong impact on the composition of the vascular plant flora which occupies them (Panitsa et al., 2006). However, in some individual cases, we can observe the "small island effect", where species diversity is actually independent from the size parameter (Triantis et al., 2006). According to the results of the canonical correlation analysis, the soil variables measured: pH, content of Fe and Zn, were considered as valid, key factors which explain the differences between observed groups (mounds and surrounding areas). Further division between plots have been shown to be influenced by other parameters, including organic matter (OM), electric conductivity (EC) and content of the heavy metals Cd and Pb. High content of heavy metals, alongside other detrimental soil characteristics have been considered as one of the possible factors influencing the rate of colonization process by plant species on iron ore tailings Ma On Shan in the Hong Kong area (Wong and Tam, 1977). A variety of iron tailings and remnants are also characterized by significantly high amount of other heavy metals (including Pb, Zn, Ni and Cu) (Zhang et al., 2006). Some studies also prove that, low pH values can have a strong impact on the composition of plants, representing typical woody communities (Podgórska, 2015; Peet et al., 2003). Some authors also claim that, values of pH between 5-6 are preferable for many plant species, although, when soil become more acidic or alkaline, the number of tolerant species decreases and more specialists start to occur (Schuster and Diekmann, 2003). In contrast, others suggest that, higher concentration of calcium (Ca), which is often correlated with increased values of pH, can possibly have more impact in the process of reclamation on a variety of mine tailings, than the higher uptake of heavy metals (Hossner and Hons, 1992).

Conclusions

The remnants of iron ore excavations undoubtedly play a significant role influencing the state of local diversity which was confirmed by increasing number of species (with native origin), representing typical woody communities. In result of long inactivity of mining process we observed strong contribution of species with C (competitors) life strategies, although species with CSR (competitors/stress tolerators/ruderals) were also significantly present in the composition of the vascular plant flora. During our studies

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_15411563

we presented strong correlation between modified soil properties and species composition on the mounds investigated. The excavating process, which involves mining lower layers of soil and depositing the material on the surface resulted in completely altered soil parameters on the mounds, which promoted some of plant species to inhabit them, which led to some relevant differences in species composition, compared with the surrounding areas. The composition of vascular plant flora of former excavating sites indicates the process of their gradual naturalization, which manifests through the domination of native species and occurrence of some valuable species. Apart from the natural values of mounds studied, they can be also treated as a part of historical and cultural heritage.

Despite the negative affection of human disturbances on the mounds studied in this project, their appearance significantly improved the level of species richness and local biodiversity of typical forest habitats around Boronów district.

(Received 7th Apr 2017; accepted 5th Jul 2017)

Abstract. Parishan International Wetland, an Iranian Ramsar Site in Fars Province, is one of the two demonstration sites for the UNDP/GEF Conservation of Iranian Wetlands Project. The aim of this study was to examine the factors influencing water bird abundance, density, the number of species, and species richness in Parishan wetland from 1991 to 2010. We used remote sensing techniques to study some environmental factors affecting waterbirds community. Spearman's Correlation Coefficient and linear regression were also used to examine the impact of environmental factors on the community of waterbirds. The results showed that only the nearest wetland area was significantly correlated with abundance and density of species ($p < 0.01$). Also, the vegetation cover surface of wetland ($P < 0.01$); the deepest depth of wetland ($P < 0.01$); and the areas shallower than 1m ($P < 0.05$) were significantly correlated with the number and richness of species (Margalef Index). The Resulting models of the backward multiple regression test also indicated that the nearest wetland area was a good predictor of abundance (P value < 0.01) and density of waterbirds (P value < 0.05). Furthermore, the vegetation cover surface of wetland, was a good predictor of the number of species (P value<0.01) and of the richness species based on Margalef Index (P value<0.01). The area of the Parishan wetland has fallen very low in 2010 and reducing the area of the wetland has led to a sharp decrease in the number of birds in the wetland.
Keywords: *species richness, remote sensing, Fars province, wetland, bird abundance*

Introduction

Conservation of wetlands has become a frequent topic among wildlife managers (Kumar et al., 2007). Wetlands are important conservation sites due to their rich biodiversity; they are among the most productive ecosystems in the world and they harbor many globally threatened species (Casado and Montes, 1995; Green, 1996;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_15651579

Petrie, 1998; Getzner, 2002; Kumar et al., 2007). Wetlands have one of the highest biodiversity and biological productivity in the world (Whittaker and Likens, 1973; Gibbs, 1993; Casado and Montes, 1995; Paracuellos and Tellería, 2004). One of the most important functions of wetlands is to protect biodiversity. In fact, biodiversity envelops all forms of life on the planet and includes all genes, ecosystems, species, and ecological processes in the world (Balton et al., 2002; Collwell and Dodd, 1995; Behrouzi-Rad, 1996). Preserving the genetic diversity of species and ecosystems guarantees continuity of the environment. So, for the continuation of the health of the environment, identification of species, their habitats, and also the study of their population dynamics based on scientific methods are required (Mori et al., 2001; Mehrjoo, 1992). The importance of aquatic habitats for dependent organisms as irreplaceable ecosystems and preservation of biodiversity of valuable plant and animal species, has attracted the attention of protective agencies to these areas (Balton et al., 2002; Collwell and Dodd, 1995). Aquatic birds are considered as the most significant animal species to detect ecological changes in the aquatic environment and mangroves (Bambang, 2008; Bayly and Gomez, 2008). Waterbirds are important biological indicators that play an important role for the determination of the health of the wetlands (Amat and Green, 2010; Hoyer and Canfield, 1994; Sonal et al., 2010). Therefore, studying changes in the populations of Waterbirds and the factors involved in these changes is essential for the management of wetlands. Understanding factors that determine population size is central to ecology, population genetics, and conservation biology (Backwell et al., 1998; Frankham et al., 2002; Taft et al., 2002). Water bird community dynamics are complex and influenced by many natural and anthropogenic factors (Mundava et al., 2012). Natural dynamics of water bird populations is mainly affected by rain or by having access to water (Paillisson et al., 2002). Other factors affecting the community composition and abundance of birds include migration, breeding, and moulting of birds along with human factors (hunting, Water Harvesting and Agricultural activities) (Caziani et al., 2001; van Niekerk, 2010; Mundava et al., 2012). The aim of this study is to assess the changes in waterbirds community and the factors affecting these changes in Parishan wetland in Fars province in Iran.

Materials and methods

Study area

Lake Parishan, an Iranian Ramsar Site in Fars Province, is one of the two sites nominated for the UNDP/GEF Conservation of Iranian Wetlands Project. As a part of Arjan Parishan Protected Area, Parishan Lake was registered by UNESCO as a Biosphere Reserve (Department of Environment of Fars, 2010). This wetland is located in the eastern part of Kazeroun City surrounded by Parishan protected area (29° 34' 48" N and 51° 54' 36" E) with an area of about 60000 hectares in southwest Iran (*Fig. 1*). Parishan wetland with an arid and desert cold climate at an average elevation of 820 m above sea level receives an annual rainfall of about 430 mm (Department of Environment of Fars, 2010). The evaporation capacity in the area is high (2470 mm/yr on average) ranging between 1600-3350 mm/yr. The surface area of the water body changes

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_15651579

seasonally according to the hydrological condition and generally varies from more than 2500 to almost 5000 ha. The Lake does not have a natural outflow and its main source of water loss is through evaporation and consumption by vegetation cover. However, a large number of deep wells (more than 800) have been dug around the Lake exploiting significant volume of groundwater for agricultural uses resulting in wetland discharge (Fars DOE, 2010). The wetland is almost surrounded by agricultural farms in all directions; however, further on the northern elevations, there exists a semi-dry type of forest cover consisting mainly of scattered oak trees. The water body of the Lake as well as different patterns of vegetation cover around and inside the lake provides diverse habitats which supports the rich biodiversity of the wetland. The Lake hosts significant number of migratory waterbirds specially wintering population which breed there. At least, five globally threatened species such *as Pelecanus crispus, Marmaronetta angustirostris, Aythya nyroca, Oxyura leucocephala* and *Aquila heliaca* (Fars DOE, 2010) are usually present on the lake, occasionally in large population.

Figure 1. *Study area: Geographical location of Parishan Wetland in Fars Province, Iran (Fars DOE, 2010)*

Waterbird surveys

The avian characteristics monitored for each year are presented in *Table 1*. The Environmental Protection Agency of Iran is doing the mid-winter count of waterbirds in Parishan wetland every year. Information about the counting of waterbirds over the past years was obtained from the Environmental Protection Agency of Iran and Waterbird surveys were conducted from 1990 to 2015. To calculate the species richness the index of Margalef was used (*Table 1*).

S = the number of Species, N= Total size of population, Pi= Relative abundance of species i, ni= Number of species i

Environmental characteristics

All environmental factors monitored are shown in *Table 2*. Landsat satellite images were used to calculate the area of the wetland, shoreline length, the deepest depth of the wetland, coverage of water surface by vegetation and the area of the nearest wetland (Arjan wetland) in each year. Firstly, radiometric and geometric corrections were applied to all images using ENVI 5.1 Software. Then, the layers of the coverage of water surface by vegetation and water area were prepared using supervised classification method.

Table 2. *Environmental and human factor descriptions and abbreviations*

Factors	Abbreviation	Measuring unit
Wetland area	Wa	hectare
Open water area	OWa	hectare
Vegetation cover	Vc	hectare
Shoreline length	Sl	m
Area shalower than 1 meter	As	hectare
The nearest wetland area	Nw	hectare
Average temperatures	At	C0.
Shoreline Development Index	SDI	
Most depth	Md	m

To calculate the water areas with a depth of less than 1 m and the deepest depth of the wetland in each year, the bathymetric maps of the wetland in different years were obtained from the Environmental Protection Agency of Fars province and on the basis of bathymetry maps of the wetland, the DEM layers of the wetland area was prepared by the ARC gis 10.2 Software. Then, the DEM layers of the wetland were cropped for each year according to the water surface area of the wetland. Finally, these layers were entered into the ARC gis Software and the water areas with a depth of less than 1 m and the deepest depth of the wetland were calculated for each year.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_15651579

Temperature data were obtained from the weather station of the Parishan wetland and average temperatures for the winter months (when counting birds) were calculated.

Shoreline development was calculated based on the following equation for each year (Margalef, 1983):

$$SDI = \frac{Sl}{2\sqrt{OWa \times \pi}} \quad \text{(Eq. 1)}$$

where SDI stands for Shoreline Development Index; Sl stand for Shoreline Length; and OWa stands for Open Water Area

Data analysis

Abundance data were first transformed into densities (number of birds per ha) to allow comparison of the wetland with different sizes in different years. Square-rooted densities were numerically transformed to down weight dominant species that could have given erratic counts over the replicated samples (Niu et al., 2013).

The Shapiro-Wilk test was used to test for normality on all variables analysed (SPSS 18.0); and if non-normal variables transformed logarithmically or trigonometrically (Jobson, 1992; Atmar and Patterson, 1993; Sokal and Rohlf, 1994). But transformations did not stabilize variance of some independent variables.

Therefore the Spearman's Correlation Coefficient (r) was used for simple relation analyses with the variables. Then, a backward multiple regression test was employed for modeling the relation between the number of species, the species density, total number of birds, and Margalef species Richness Index as the dependent variables and the characteristics of the wetland as the independent variables.

In this method, all variables are first entered into the model and then, the least important variable is removed according to removal criteria; this process continues until all the less important variables are gradually removed. Finally, the final model will be calculated based on the main variables. Therefore, all the remaining variables have an acceptable and significant correlation with each other. Models obtained by backward method are superior than those made by Enter and Stepwise methods in terms of the number of variables. That is to say, the number of variables is not as many as that in the Enter models and not as few as that in the Stepwise models. Also in these models, higher correlation between the calculated performance and actual performance is observed compared to the Stepwise model. Logistic regression is used for modeling the relation between binary dependent variable and one or more environmental predictor variables. In other words, logistic regression can be used to predict the dependent variable based on the predictor variables. Formula of Backward Model is given in *Equation 2*.

$$Yi = \beta 0i + \beta 1iX1i + \beta 2iX2i + \beta 3iX3i + \beta 4iX4i + \ldots + \beta(p-1)i\, X\,(p-1)i \quad \text{(Eq. 2)}$$

Yi= the linear predictor

β0i= Constant coefficient

β1i - β4i= the coefficients of the variables

X1i - X4i= Variable values

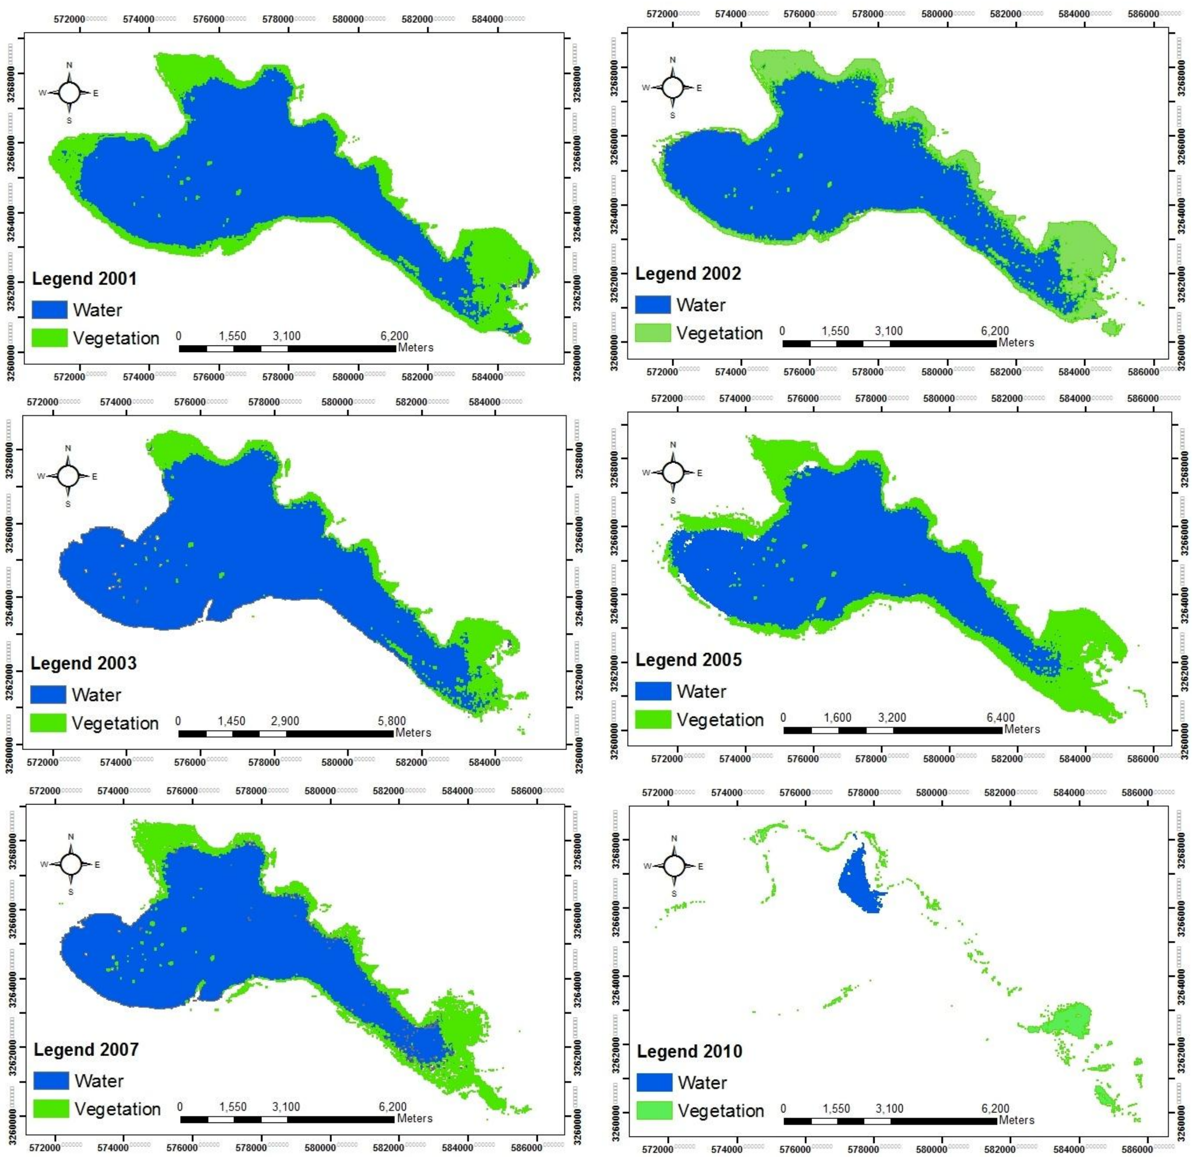

Figure 3. *Classes of water and vegetation of Parishan wetland during the different years*

Only one environmental variable was significantly correlated with the total members of species and the density (the number of waterbirds per ha) ($P < 0.01$) (*Table 5*). The correlation between these variables was negative. They were entered into backward multiple regression tests for modeling to predict the frequency and density of the waterbirds (*Table 6* and *7*).

Also, three environmental variables (vegetation cover surface of the wetland ($P < 0.01$); the deepest depth of the wetland ($P < 0.01$); and the areas shallower than 1m ($P < 0.05$)) were significantly correlated with the number of species (*Table 5*). They were entered into backward multiple regression tests for modeling to predict the number of species (*Table 8*).

Also, three environmental variables (vegetation cover surface of the wetland (P < 0.01); the deepest depth of the wetland (P < 0.01); and the areas shallower than 1m (P < 0.05)) were significantly correlated with the Margalef species Richness index. (*Table 5*). They were entered into backward multiple regression tests for modeling to predict the Margalef species Richness index (*Table 10*).

Discussion

Our results showed the importance of the nearest wetland area in explaining the frequency and density of waterfowl in Parishan wetland. Our results showed that when the nearest wetland area attracted an abundant number of birds, the Parishan wetland area decreased. It means there is no rise in competition, i.e. the birds occupy both wetlands to prevent increased competition for food, shelter, nesting, etc. But, when a wetland area decreased they migrated to nearby wetlands to satisfy their biological needs. Many studies were conducted on the effect of isolation (distance to the nearest wetland) as a variable affecting the abundance of waterbirds (Brown and Dinsmore, 1986; Craig and Beal, 1992; Andrén, 1994; Rosenberg et al., 1997; Tellería and Santos, 2001), but we did not find any report on the impact of the nearest wetland area on the frequency and density of waterfowl.

At the beginning of our study, we assumed that the area of wetland had a significant impact on the abundance of birds, but the results showed that wetland size had no significant effect on the bird abundance. The results of this study performed on the effect of wetland area on the abundance of birds were consistent with those obtained by Sulaiman et al. in 2015. But, other studies showed a significant relation between an increase in the number of birds and that in the size of wetlands (He and Legendre, 1996).

The models obtained by the backward multiple regression test indicated that the nearest wetland area was a good predictor of frequency (P value < 0.01) and density of waterbirds (P value < 0.05).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_15651579

The results also showed that three environmental factors (area of vegetation cover of the wetland; the deepest depth of the wetland; and the areas with depths less than one meter) had significant relation with the number of species. Number of bird species may increase as a result of an increase in habitat heterogeneity (He and Legendre, 1996; Elmberg et al., 1994; Sulaiman et al., 2015). A more heterogeneous range of habitats allows the co-occurrence of more species because they meet the habitat requirements of more species (Sulaiman et al., 2015). Also, more species may occur in areas of more diverse habitat because of spatial segregation that reduces competition (Sulaiman et al., 2015) and these three factors can increase heterogeneity of the wetlands. Other studies conducted in wetland ecosystems have demonstrated the importance of habitat heterogeneity (Svingen and Anderson 1998; Fairbairn and Dinsmore 2001; Riffel et al. 2001; Gonzalea-Gajardo et al., 2009).

Furthermore, the results of this study showed a significant relation between the Margalef species richness index and three environmental factors (area of vegetation cover of the wetland; the deepest depth of the wetland; and the areas with depths less than one meter). Increasing the richness species index as well as increasing the number of species may increase as a result of an increase in habitat heterogeneity; these three factors can increase heterogeneity of the wetlands.

Other studies have shown a significant relation between the size of habitats, the number of species, and richness species (Sillén and Solbreck 1977; Brown and Dinsmore 1986; Opdam 1991; Andrén 1994; Turner 1996; Tellería and Santos 2001), but this study found that the wetland size had no significant effect on the number of species and richness species index.

The models obtained by the backward multiple regression test indicated that among these three variables, the vegetation cover surface of the wetlandwas a good predictor of the number of species (P value<0.01) and the richness species index of Margalef (P value<0.01).

Conclusion

The result showed that abundance was fundamentally affected by the nearest wetland area which required integrated management of adjacent wetlands.

Also, the results showed that the number of species had a significant relation with the vegetation cover surface of the wetland, the deepest depth of the wetland, and the areas shallower than 1m. These 3 factors play a major role in habitat heterogeneity. So, to increase biodiversity, habitat heterogeneity should be managed at an appropriate level.

Wetlands provide ecological functions such as protective nursery habitat for fish and shellfish, erosion prevention, flood protection, and water filtration (Dahl, 2005; Behrouzi-Rad, 2014). They also provide vital feeding, resting, and breeding habitat for resident and migrating birds. Seabirds and colonial waterbirds face threats to their habitats and sites on which they depend (Behrouzi-Rad, 2014); conservation of seabirds and colonial waterbirds is a local matter. Nesting and roosting seabirds and colonial waterbirds are particularly affected by local conditions (Behrouzi-Rad, 2014). Parishan wetland is one of the two demonstration sites for the UNDP/GEF Conservation of Iranian Wetlands Project. The water body of the Lake as well as different patterns of vegetation cover around and inside the lake provides diverse habitats which supports the rich biodiversity of the wetland. The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_15651579

Lake hosts significant number of migratory waterbirds which use it for wintering, feeding, breeding, and stationing. The higher records of waterbirds population in the Lake exceed 120,000 (1970s and 1980s). (DOI, 2010). In 7 out of 17 years of accessible records since 1990, the annual counts of waterbirds in Lake Parishan have exceeded the 20,000 Ramsar threshold for internationally important wetlands. Also, *Podiceps cristatus*, Great Crested Grebe, *Phalacrocorax pygmaeus* Pygmy Cormorant, *Anser anser*, Greylag Goose, *Oxyura leucocephala* White headed Duck, *Larus ridibundus* Black Headed Gull, and *Tadorna ferruginea* Ruddy Shelduck have been recorded in numbers exceeding %1 of their bio-geographical population. At least, five threatened species are usually present in the lake and occasionally in noticeable population. These are *Pelecanus crispus*, *Marmaronetta angustirostris, Aythya nyroca, Oxyura leucocephala*, and *Aquila heliaca* (DOI, 2010). Unfortunately, the Parishan wetland has completely dried up since 2011.

The wetland is almost surrounded by agricultural farms in all directions. Water for irrigation is supplied from groundwater wells. Now, there are more than 940 water wells around the wetland and the water extracted from these wells is used in agriculture (DOI, 2015). Excess exploitation of water wells has brought about a drop in underground water level by 15.11 meters between 1990 and 2015 (WAOI, 2015). As long as the resources of underground water are not restored, there is no chance of restoring the wetland because all the water entering the wetland, penetrates into the ground.

Agricultural sector imposes agreat pressure on the wetland due to excessive withdrawals of water from the wells, digging water wells, and excess use of fertilizers and pesticides to increase productivity. Therefore, until rigorous and scientific management is not practiced in agricultural land around the wetland, it is not possible to manage the wetland and protect its ecological benefits.

Therefore, drying up of springs, reduction of the level of underground water, an increase in organic and inorganic contaminants, and finally drying up of the wetland are all resulted from uncertain effects of land use changes along with climate changes.

As shown in *Figure 3*, the area of the Parishan wetland has fallen very low in 2010 and reducing the area of the wetland has led to a sharp decrease in the number of birds in the wetland.

Parishan wetland has completely dried up from 2011 onwards. Along with the increased discharge of water from wells surrounding wetlands, the underground water level and the volume wetland water also have declined and the wetland has completely dried up in 2011. Most of wetland water is supplied through precipitation and spring water and a portion is supplied through groundwater flow; this is while the amount of annual precipitation in the region is very small compared to the rate of evaporation from free surface of the wetland. The average evaporation in the study area during the studied period has been equal to 2731.8 mm; and considering the coefficient of evaporation pan (0.7) (Zamin Ara Consulting Engineers of Fars, 2011), evaporation from the wetland surface has been equal to 1912.26 mm. Now, given that the average area of wetland during the studied period was 24 square kilometers, it follows that the average annual evaporation from the wetland surface has been equal to 38.245 million cubic meters, while the average rainfall has been equal to 8.892 million cubic meters. On the other hand, the water of springs around the wetlands is consumed by farmlands before reaching the wetland; and in recent years, most springs have dried up due to drought and low levels of underground water. Meanwhile,

digging a large number of wells around the wetlands and depletion of groundwater have caused the groundwater level go down 13.68 meters; and now, there is no possibility of providing water of wetland by underground water flows (Jahanbakhsh Ganjeh et al, 2017).
