(Received 12th Apr 2017; accepted 12th Aug 2017)

Abstract. Water saving was and remains an acute problem in places with water scarcity and inaccessibility. In order to solve this problem, drip irrigation started to be used in many countries, and for the first time, in Kazakhstan, there were used cultures that consume water sufficiently in large quantities such as rice and soybean. Ways of irrigation have significant effect on elements of structure of a rice and soybean crop. Drip irrigation with a two-row tape way of crops forms essentially distinct structure of a rice crop in comparison with usual technology of cultivation of rice and soybean. Rice (*Oryza sativa* L.) and soybean (*Glycine Max* L. Merr.) crops were grown in 2013-2016 to determine effect of drip irrigation in the different variants water levels on growth and productivity under conditions of the south-east of Kazakhstan. In result of three years of researches on studying of rice and soybean drip irrigation efficiency were made the following conclusions: Drip irrigation (Di) with application of the mulching film promotes emergence of early and amicable shoots of rice and soybean, intensive growth and development of plants, productivity increase. Drip irrigation with use of the mulching film at 8-10 times reduces a contamination of crops of rice that allows to exclude application of manual use, mechanical and chemical processing of crops. Use of the mulching film under rice drip irrigation promotes creation of the favorable nitric mode of the soil with big accumulation of ammoniac and nitrate nitrogen and mobilization of motile phosphorus. The best way of rice crops under drip irrigation is 2-row tape crops with distance between tapes of 70 cm and a row-spacing in a tape of 30 cm. At the same time the drip tape keeps within row-spacings in a tape. Comparison of the productivity of soybean varieties showed that productivity in variants with mulch far exceeded variants without mulching.

Introduction

Irrigated agriculture, the major contributor of agricultural production, faces the challenge of improving irrigation water use efficiency and meanwhile ensuring food security (Li et al., 2016a). The global water consumption for irrigation has been steadily growing over the last 50 years and today it makes 70% of all water consumption (Tian et al., 2016). The great challenge of the agricultural sector is to produce more food from less water, which can be achieved by increasing Crop Water Productivity (CWP) (Zwart, 2004). Deficiency of fresh water increases in high places around the world.

According to forecasts of FAO and IFPRI global demand for water resources according to the scenario of usual development by 2030 will increase twice. The Water Resources Committee of the Ministry of Agriculture deals with the management and allocation of water resources and water use. This situation often makes it difficult to conduct complex, integrated scientific research. State and private land ownership is recognised and equally protected. However, it is difficult to deal with the maintenance of the irrigation systems for small peasant farmers. Government support is required. Public-private partnership should be considered to introduce the most advanced water-saving technologies (FAO).

Especially critical situation with water supply is predicted in the countries of Central Asia because of the growing intake of water, thawing of glaciers and droughts, the processes of degradation of lands and desertification. For Kazakhstan with strong dependence on climate change and cross-border water currents, the scenario of usual development in principle does not allow to solve problems of water supply of economy and the population in the near future.

The main consumer of water resources in Kazakhstan, as well as in other countries of the Central Asian region, is the irrigation whose share is over 70% of all potential of a superficial drain. Practically in all territory of the Republic the intense water management situation is caused by a lack of water resources and pollution of water sources is present (Paramonov, 2009; Kwan et al., 2011). Annual deficiency of water in Kazakhstan makes 2-3 km^3. The problem of water dependence can be dangerous to national security of Kazakhstan because of emergence of the interstate and regional conflicts (the cross-border rivers) (Water resources of Kazakhstan in the New Millennium: 2004). Alternative irrigation layouts and water management approaches could contribute to reduced water use and increased irrigation efficiency (Beecher et al., 2006).

The greatest consumer of irrigation water per unit area is rice. Rice (paddy) is the second most important commodity worldwide, and rice cropping fields significantly contribute to climate change since they are a considerable source of methane (Coltro et. al., 2016). Rice paddy agricultural methods require a large quantity of water (Kang et al., 2007). Statistics indicate that the water consumption of rice accounts for approximately 54% of the total water consumption (He et al., 2014); and more than 50% of reserves of irrigation water is spent on cultivation of this culture in Kazakhstan. In Kazakhstan, as well as in the countries of Central Asia, the way of cultivation of rice based on continuous flooding of crops is accepted. Under production conditions the irrigating norm of rice with continuous flooding and pro-accuracy changes ranging from 25 to 35 thousand m^3/hectare. Under this method of an irrigation a consumption of irrigation water on rice cultivation greatly exceeds biological need of plants for water which considerable part is lost on evaporation, filtration and feeding of ground waters. That is why rice irrigation by method of flooding is one of methods of melioration of highly salinized lands and way of fight against weeds weed control. Cultivation of rice with an expense of a huge amount of irrigation water within more than 50 years has brought to an environmental problem of Aral and in recent years of Balkhash, too. Long-term cultivation of rice with flooding of checks has led to sharp decrease in efficiency of use of the irrigated lands with considerable reduction of the areas and efficiency of other irrigated cultures. Now rice in Kazakhstan is cultivated on the area of about 100 thousand hectares. For cultivation of rice on such square about 3 billion m^3 of irrigation water are annually spent.

In this regard, undoubted relevance is acquired by the researches directed to the development of systems of agriculture and technologies providing effective use of natural and water resources, increase of efficiency of the irrigated arable land and have a strategic importance, as in national, and international scale. There is a need for an agriculture intensification, use of new breakthrough high technologies for crop cultivation. The developed nature protection technology of cultivation of rice is suitable for distribution on the irrigated lands of a zone of paddy culture in Uzbekistan, Tadzhikstan, Turkmenistan, introduction of which will provide improvements of an ecological situation in the region of the Aral-Syrdaryinsky basin and in general Central Asia.

Many water-saving technologies are currently used in rice production, including alternate wetting and drying irrigation, the rice intensification system, aerobic rice and the ground cover rice production systems (GCRPSs) (He et al., 2016). But the numerous researches, conducted mainly abroad, show that the most effective way of rational use of irrigation water is, without any doubts, the drip irrigation. Drip-irrigation is the slow and frequent application of small amounts of water (Zhu et al., 2013). Drip irrigation is the most effective way to supply water and nutrients to the plant and not only saves water but also increases yield of fruits and vegetable crops (Tiwari et. al., 2003), it also stabilizes the daily range of soil temperatures (Xing et al., 2012), which can benefit crop growth (Li et al., 2016b). Drip irrigation is a way of watering at which water is pumped in the small portions evenly to plant roots throughout all vegetative period and irrigational moisture goes only to plants, but is not spent for row-spacings. Because of it, many researchers have reported higher application efficiency of drip irrigation system over the conventional irrigation methods (Tiwari et al., 1998). Drip irrigation also has been used extensively to reclaim the salt-affected soils for crop productivity in recent years (Zhang et al., 2014). Efficiency of use of the mulching films under drip irrigation in preservation of moisture and control of weeds is proved (Raina, 1998; Seyfi, 2007). With the invention of new technologies and the equipment for drip irrigation, in foreign literature there is mentioned this method's efficiency in rice cultivation. In the separate experiments made in the USA, India, Australia, nowadays it is reported about efficiency of a combination of drip irrigation ways with zero processing of the soil or with use of the mulching films (Enciso-Medina et. al., 2001).

The use of plastic mulch in agriculture has increased dramatically in the last 10 years throughout the world (Kasirajan, 2012). Introduction mulched drip irrigation (MDI) has been widely employed in arid and semiarid regions for crop cultivation to accurately supply water and fertilizer in the soil in conjunction with soil evaporation reduction (Zhou et al., 2017). Mulched drip irrigation is a combination of the drip irrigation and the mulch technique (Liu et al., 2012). When soil temperature is insufficient, plastic mulch enhances tuber yield and water use efficiency (WUE) (Wang et al., 2011). Conventionally, mulches increase the yield and water use efficiency (WUE) to a great extent by augmenting the water status in the root zone profile (Mukherjee et al., 2010). Different types of materials like wheat straw, rice straw, plastic film, grass, wood, sand etc. are used as mulches. They moderate soil temperature and increase water infiltration during intensive rain (Yaghi et al., 2013). Drip irrigation with plastic film mulch (DI-PFM) can maintain high rice yields with significant water savings. Both plastic mulch and drip irrigation profoundly influence soil environment, especially through spatiotemporal changes in soil water (Zhang et al., 2017). However, rice seedlings often develop chlorosis when grown

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_15811603

with DI-PFM on calcareous soil. Chlorosis in drip-irrigated seedlings occurs not because Fe availability is low but because the Fe uptake capacity of roots is weak at low temperatures (Zhang et. al., 2016). Rice plants are more sensitive to the HCO_3^- concentration of irrigation water under FI than under DI-PFM (Zhang et al., 2015). Water application systems under wells extracting groundwater are one of the major factors influencing climate change in the agricultural sector. In the context of growing demand for adaption of pressurized irrigation with electric pumps in south central India, the present study was undertaken to assess the carbon dioxide emission (CO_2) for different irrigation systems. It was observed that among all the irrigation systems, the drip system gave the lowest CO_2 indicating the maximum climate change mitigation potential in the irrigation sector of selected region under wells (Reddy et al., 2015). While straw mulch usually reduces soil evaporation and stabilizes soil temperature, hence increasing yield, this effect may depend on the irrigation water input conditions. Two experiments in lowland rice paddies in lao pm tested the effect of rice straw mulch under various water input-standard farmer condition to reduced input condition by using either drip irrigation or lower furrow irrigation water input by increasing the furrow irrigation interval before flowering- on growth and yield of sweet corn. The time course of water balance components was determined to elucidate the mechanisms of mulch and water input interaction for row planted maize after rice harvesting (Vial et al., 2015). The method involves performing seed preparation, soil preparation by preventing and treating a weed, seeding, seedling management, irrigation management, fertilizer management and pest control, where seedling density is 33.3 to 36 thousand holes per mu in seeding or the seedling density is 30.5 to 32.6 thousand holes per mu in seeding. Target yield and fertilization weight are determined. Nonflooded irrigation is an important water-saving rice cultivation technology, but little is known on its photosynthetic mechanism. The aims of this work were to investigate photosynthetic characteristics of rice during grain filling stage under three nonflooded irrigation treatments: furrow irrigation with plastic mulching, furrow irrigation with nonmulching, and drip irrigation with plastic mulching. Compared with the conventional flooding treatment, those grown in the nonflooded irrigation treatments showed lower net photosynthetic rate, lower maximum quantum yield, and lower effective quantum yield of psii photochemistry (He et al., 2014).

The grain yield ranged from 3.35x10(3) kg ha(-1) to 6.86x10(3) kg ha(-1) under plastic mulching drip irrigation, which was 19.3-60.31% lower than that under flooding irrigation. Correlation analysis showed that the roots at the a1 and b1 sites were positively significantly correlated with yield components and aboveground agronomic traits. Therefore, improving root development at the a1 and b1 sites at flowering stage could be a key factor to obtain higher grain yield and good agronomic performance under plastic mulching drip irrigation (He et al., 2013). The experiment demonstrates that the di treatment has greater water saving capacity and lower yield and economic benefit gaps than the fim and fin treatments compared with the cf treatment, and would therefore be a better water-saving technology in areas of water scarcity (He et al., 2015). Under non-flooded irrigation, root length was significantly reduced with more roots distributed in deep soil layers compared with the conventional flooding treatment; the drip irrigation treatment had more roots in the topsoil layer than the fim and fin treatments (Chen et al., 2015). The weeding method involves spraying the fencers and harrowing with soil sealing agent before seedling in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_15811603

rice drip irrigation planting. The rice is planted by process of the drip irrigation under the film after spraying the fencers with soil sealing agent for 5-7 days. The fencers are sprayed with herbicide after seeding in rice drip irrigation planting under a film when a rice seedling has 3-4 leaves.

In order to enhance the productivity of aerobic rice from present yield level, a production technology which has proved beneficial in increasing the productivities of both grain and water. Disclosed is combined effect of scheduling irrigation at 125% pan evaporation, application of 100% recommended doses of nitrogen, phosphorus and potassium (npk) fertilizers, azophosmet and humic acid through drip system. It is proved that drip fertigation technology is beneficial in boosting grain yield coupled with the increased values for water productivity besides improving the fertilizer use efficiency (Arulmozhiselvan, 2009). Drip irrigation is the future of irrigated agriculture, which needs to be strengthened by optimizing the technology for different crops (Sharda et al., 2016).

(Irmak, S. et al.,2014) evaluated the relative evaporative losses and water balance components in two soybean (*Glycine max* (L.) Merr.) fields under subsurface drip irrigation and center pivot irrigation systems in south-central Nebraska. Evaporation losses were estimated as the difference between measured evapotranspiration and estimated transpiration . Average soil water content in the crop root zone and effective rainfall were estimated using the water balance method.

Soybean (Glycine max) is one of the most important legume crops which fix atmospheric nitrogen in symbiotic association with bacteria through nodules. A study was conducted to investigate the effect of molybdenum and preinoculation of Rhizobium on biological nitrogen fixation and yield of soybean under drip irrigation system (Kanaan et al., 2013).

The growth and yield potential of soybean and the effects of mulching on desert sand were evaluated in relation to N accumulation in nodules. It was concluded that nitrogen fertilization improves the nutraceutical properties of soybean, although its effect depends on the activity of the isoflavone biosynthetic pathway and the concurrent extent of seed bulging (Vamerali et al., 2012).

A field experiment conducted during 2009 and 2010 at the research farm of the Indian Agricultural Research Institute, New Delhi to study the performance of soybean as influenced by the intercropping of cereals, viz. maize (*Zea mays* L.), sorghum (*Sorghum bicolor* (L.) Moench.) and pearl millet (*Pennisetum glaucum* L.) with 0, 50, 75 and 100% of their respective recommended dose of N (RDN) levels. The highest gross returns, net returns, B: C ratio and soybean equivalent yield (SEY) were observed under soybean+maize intercropping system along with 100% RDN to intercropped maize in both the years of experimentation (Layek et al., 2015). Soybean grown under soybean-wheat-mungbean system had significantly higher total uptake N and K over soybean-wheat-fallow system (Prajapa et al., 2015). Impact of short-term zero tillage is short lived for favourable soil health and root parameters when skipping with conventional tillage (Rajkumar et l., 2015).

The water requirement of soybean and wheat estimated by Penmann-Monteith method was in close agreement (-2.58% and 9.26% deviation) with the measured average water requirement (401.6 and 352.2 mm) respectively followed by Hargreaves method for Bhopal district (Singh et al., 2015). Sharma et al. (2015) IP of resident AM fungi in soybean rotation involving maize in conservation tillage was found to be highly correlated (r=0.96 to 0.99) with grain yield of soybean and maintaining higher

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_15811603

organic carbon which indicates the functioning of resident AM fungi in enhancing the soybean yield.

Rice (*Oryza sativa* L.) and soybean (*Glycine Max* (L.) Merr.) crops were grown in 2013-2016 to determine effect of drip irrigation in the different variants water levels on growth and productivity under conditions of the south-east of Kazakhstan.

Material and Methods

To solve objective solutions were carried out one-factorial and multiple-factoral field experiments on a demonstration site of the Center of distribution "Ushkonyr" of the Kazakh scientific research institute of agriculture and plant growing (*Figure 1*, *Tables 1-4*).

The minimum areas of soil lots are connected with system of drip irrigation in experiments, high cost of materials and equipment.

Technique of carrying out accounts and supervision

- Phenological supervision over growth and development of plants in the main phases by a technique of State commission on a gradetesting;
- Studying of water and physical and meliorative properties of the soil. The accounting of field viability of seeds by calculation on 4 fixed platforms on 0.25 sq.m on all soil lots at full shoots. The accounting of density of plants standing plants by calculation of quantity of plants with 1 sq.m of a soil lot at the beginning and the end of vegetation of the studied cultures in two-staged replication.
- The accounting of dynamics of accumulation of biomass of plants of the studied cultures in the main phases of their development by selection of plants with 1 sq.m of each soil lot in two-staged replication with measurement of crude and dry weight.
- Water consumption of rice plants was defined by a balance method.
- The accounting of a contamination of crops, disease vulnerability and damageability by pests is carried out by the standard technique (Methodical instructions on monitoring of number of weed plants, pests and developments of diseases, Astana, 2004);
- Sampling for studying of maintenance of nutritious elements in the soil and plants will be carried out on the main growth phases and rice developments.
- Before harvesting from three replications of the experiment sheave samples with 1 sq.m were selected. Basic elements of structure of a rice harvest (quantity of plants, quantity of the general and productive stalks, mass of a sheaf, amount of grains in a whisk, the mass of 1000 grains) are determined by a technique of State commission on a gradetesting (Balashev, 1968);
- The accounting of a harvest is carried out seperately by the SAMPO-250 combine;
- Processing of harvest data according to Dospekhov's technique, 1985;
- Quality of grain by the technique stated in the reference book "Assessment of Quality of Grain", M. V.O "Agropromizdat", 1987;
- Studying of agrochemical properties of the soil by a technique of agrochemical researches. Calculation of economic efficiency is made on the actual costs of unit of the made production from area hectare according to the actual monetary and power costs of cultivation of the studied cultures.

Statistical processing of morphometric indicators was done via standard methods Lakin, 1990. The average number of M ± m was calculated by the Student method. The statistical processing of the data was carried out using Student's t-test for P> 0.05.

The system of drip irrigation includes: Irrigation water tank on 36 m^3 near the river Kaskelenka (*Figure 2*). The water pump Pedrollo F 32/200B with a productivity of 50 m^3/hour. A settler on 25 m^3 at the height of lower level of 5 m. Sandy strainer (*Figure 3*). Intake strainer; an injector for additional fertilizing; main pipes; distributive pipes; irrigation tapes with drippers for a surface drip irrigation.

DOI: http://dx.doi.org/10.15666/aeer/1504_15811603

Figure 2. *Water intake system for drip irrigation*

Figure 3. *Water cleaning and additional fertilizing system*

For preparation of the soil under drip irrigation the general agrotechnology consisted in the following:

- Fall plowing on depth of 25-27 cm.
- Current planning.
- Early-spring braking.
- Introduction of phosphoric fertilizers for creation of grounds.
- Cultivation on depth of 12-15 cm.
- Preseeding processing on depth of crops of seeds.
- Crops of rice and soybean are made by a seeder 2BMJ-4 (People's Republic of China) which carries out simultaneous laying of a drip tape, a tension of the mulching film, seal of seeds over a film and a packing with filling of the soil (*Figures 4-5*).
- Norm of seeding- 15-30 kg/hectare depending on ways of crops.
- Additional fertilizing was made by ammonium nitrate with irrigation water of drip irrigation, schemes of the experiments: the first – at the beginning of tillering, the second - in a phase of a full tillering, the third – in a booting phase, the fourth – in an ear emergence phase, the fifth – in a phase of dairy grain ripeness.

Agrophysical nature of the soil

Drip irrigation has positively influenced the maintenance of water-stable aggregate (>0,25 mm) in the above-mentioned soils under the studied cultures. So, their quantity from before drip irrigation and after that has increased in an arable layer of earth by 0.8-3.3%, at maximum increase under crops of soy without lamina with plowing on the 22-25 cm – by 3.3% and at minimum - under crops of oats with plowing on the 22-25th – by 0.8% and in subarable by 0.6-3.8% at the greatest under crops of also soy without lamina with plowing on the 22-25th – by 3.8% and the smallest - under crops of sugarbeet under lamina with disking on the 8-10th – by 0.6% (*Table 5*).

Definition and assessment of density of the light brown irrigated soils in May of reporting year demonstrates that the volume mass of 0-40 cm of a layer under various cultures before drip irrigation which can be accepted as initial fluctuated in the range of 1.22-1.29 g/cm^3. Indicators of volume mass of the specified layer of earth after carrying out a series of drip waterings have raised in September under the studied cultures up to 1.29-1.45 g/cm^3 (*Table 6*).

Results and Discussions

Ways of irrigation have significant effect on elements of structure of a rice crop. Drip irrigation with a two-row tape way of crops forms essentially distinct structure of a rice crop in comparison with usual technology of cultivation of rice. As it can be seen from data of *Table 1*, indicators of the general, and a productive tilling capacity of plants

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_15811603

raises on 15.17-16.36 units or 7-8 times. At the same time the greatest productive tilling capacity (16.36) is reached under subsurface drip irrigation of rice (*Table 8*).

Table 8. *Structure of a rice harvest depending on ways of irrigation (average for 2013-2014)*

Ways of irrigation	Number of plants, piece/sq.m	Tilling capacity		Number of grains in a whisk,piece	Mass of 1000 grains, g	Proportion grain/ straw
		general	productive			
Flooding irrigation	106	2.11	1.86	39.1	32.5	0.24
Surface drip irrigation with mulching film	18	16.73	15.17	63.9	35.3	0.38
Subsurface drip irrigation with mulching film	17	18.89	16.36	62.0	34.7	0.38

There is a noticeable Influence of drip irrigation on formation of a bigger whisk grains/ear and mass of 1000 grains of rice, that eventually increased in a share of the productive part of a harvest expressed in the ratio 0.38 to 0.24 in control option.

Under drip irrigation depending on ways of crops formation of structural elements of a rice harvest was controversial (*Table 9*).

The greatest productive tilling capacity and mass of 1000 grains were formed by grades Bakanassky and Yantar, and whisk set of seed by Aru and KAZNIIR 5.

Table 9. *Structure of a harvest of rice grades depending on ways of crops under drip irrigation, 2013*

Grades	Ways of seeding	Number of plants, piece/sq. m	Tilling capacity		Number of grains in a whisk,piece	Mass of 1000 grains, g	Proportion grain/ straw
			general	productive			
Bakanassky	2-row	19	9.95	7.37	101	36.7	0.67
	4-row	32	4.94	3.06	84	35.1	0.52
Aru	2-row	18	10.4	6.61	108	33.9	0.68
	4-row	34	4.64	4.12	71	34.6	0.53
KAZNIIR 5	2-row	16	11.12	4.38	141	32.3	0.56
	4-row	32	5.94	2.66	94	30.8	0.35
Yantar	2-row	16	10.44	7.19	100	34.2	0.67
	4-row	30	4.26	3.22	85	35.4	0.42

Increase in irrigating norm of drip irrigation exerts positive impact on formation of rice tilling capacity and mass of 1000 grains (*Table 10*).

The irrigating norm of drip irrigation of 4000-6000 m3/hectare was the most rational norm of watering for formation of the largest sizes of structure of a rice harvest. In these conditions the productive tilling capacity has reached 11.75 pieces, and amount of grains in a whisk of 78 pieces.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_15811603

At the same time the best time of implementation of drip irrigation showed watering in the afternoon and in the evening. Positive impact of afternoon and evening terms of drip irrigation on an indicator of the general and productive tilling capacity is noted (*Table 11*).

Table 10. *Structure of a rice harvest depending on the mode of drip irrigation (average for 2013-2014)*

At night	17	14.12	11.95	71.8	35.6	0.39

Significant effect on formation of structure of a harvest renders conditions of mineral food of rice. As it can be seen from *Table 12*, without fertilizers the productive tilling capacity of plants of rice under drip irrigation did not exceed 9 units.

Use of nitrogen fertilizers in additional fertilizing with irrigation water promotes sharp increase of coefficient of rice tillering, the indicator of the tilling capacity in option with four and five nitric additional fertilizing on ground P90 reaches size of 18.2-18.7 and a productive tilling capacity of 15.7-17.0 units.

Results of the accounting of a harvest of the first year of researches (*Table 13*) show that in option with a usual way of an irrigation with flooding with introduction of average doses of fertilizers the harvest of rice of 29.1 c/hectare are received. In options on studying of drip irrigation ways without the mulching film crops of rice were unaccountable, have grown with weeds and at a booting phase growth of plants has stopped. Mechanical and chemical ways of control of weeds in these options are not effective. Therefore, in the next years options of drip irrigation without the mulching film are excluded from experience.

Table 13. *Crop yield of rice depending on ways of irrigation, c/hectare*

Ways of irrigation	2012	2013	2014	Average
Flooding irrigation	29.1	17.4	32.2	26.2
Surface drip irrigation	0	-	-	-
Surface irrigation with film	48.5	49.3	59.4	52.4
Subsurface drip irrigation	0	-	-	-
Subsurface drip irrigation with film	20.3	58.6	50.8	43.2
P=4.3%	3.6	4.5	4.9	
HCP 0.95=5.1 centners per a hectare	2.9	5.6	7.0	

Efficiency of drip irrigation ways by years of researches was ambiguous. In 2012 and 2013 there was an efficiency of surface way of drip irrigation, and in 2013 - subsurface drip irrigation with mulching film. In general, in three years at a usual way of cultivation of rice by flooding 26.2 c/hectare had been received, and at ways of drip irrigation with a film 43.2-52.4 c/hectare of a grain yield of rice are received. The greatest and most stable grain yields of rice by years have been received under surface drip irrigation with use of the mulching film.

In 2013 there were formed experiment options with 4-row tape way of seeding. Results of the experiment show that the new way of seeding had no advantage comparing with 2-row tape seeding. As it is seen from data of *Table 14*, the new way of seeding was effective only under drip irrigation of an early ripe grade Aru. From the studied grades the greatest productivity in Almaty region showed the grade Bakanassky under drip irrigation with 2-row tape seeding.

Yantar	33.5	35.5	26,8
P= 4.9%	3.4	6.4	
HCP 0.95=4.0, centners per a hectare	2.6	5.4	

Studying of the mode of rice drip irrigation shows that relatively big crops of rice are received when watering by irrigation norm 4000-6000 m3/hectare (*Table 15*) in the afternoon and in the evening.

Relatively low productivity of rice at the morning term of drip irrigation can be explained by low temperature of irrigation water. Whereas at the afternoon term of watering, water significantly heats up when passing through a drip tape, at evening watering irrigation water heats up in the tank.

Table 15. *Productivity of rice depending on the mode of drip irrigation, c/hectare*

Irrigating norm, m^3/ha	Irrigation time			
	morning	afternoon	evening	night
2013				
2000	39.2	39.9	42.6	46.8

Studying of efficiency of nitric additional fertilizing under drip irrigation on three phosphoric food (*Table 16*) shows that without introduction of phosphoric fertilizers of an increase of a harvest from nitric additional fertilizing makes 6.6-13.1 c/hectare. On this background two additional fertilizing by drip irrigation on 30 kg on hectare are rational and the harvest reaches 46.2 c/hectare.

Efficiency of nitrogen fertilizers was most accurately shown in 2014, when additional fertilizing from nitric have made 16.6-36.9 c/hectare depending on a phosphoric ground and number of nitric additional fertilizing. At the same time nitrogen share factor in formation of a harvest has made 70%, to 4% of phosphorus share.

In the experience it has been shown that mulch has excellent impact on the growth and development of plants and has a negative impact on the nodule bacteria, that in the early phases provide favorable conditions for growth and development of soybean. In the variant without mulch, which are actively developing nodule bacteria in the initial phase inhibit the growth and development of soybeans, in connection can be noted in the early phases of nodule bacteria are parasitic.

In the literature, there are studies that confirm our data, but we note that in the version with a modern film developing nodule bacteria, but then their parasitism is not particularly stands out since, by the time the plant is well adapted in a supportive environment.

The observation showed that good loosening and sheeting occurs during branching, especially in the film version, the early spring foil retains not only moisture, but also allows heat in the field sites to clearly demonstrate good growth in the embodiment with the film, this proves a favorable film. The effect at drip irrigation, drip irrigation affects high productivity in comparison with traditional irrigation, since in experimental plots where the furrow is traditionally watered, soybean does not receive Due to the fact that water is not fully used in the direction, and here to save water. It is worth mentioning the procedure that should be implemented in all regions where there is a shortage of water, thus ensuring maximum productivity, not just soybean, And in many cultures.

In terms of the fact that water saving is due to the films also need to emphasize that the film under the water does not evaporate into the air and vaporized water is supplied to the reverse order of the plant. This not only saves water, but also keeps the heat under the film, which in the cold season supports the plants. In the Almaty region in the south-east of Kazakhstan the climate is not homogeneous, as the weather is variable, in this regard, the film is a necessity. In the *Figure 8* soybean were grown without mulch by drip irrigation. In the *Figures 9-10* soybean were grown with mulch under drip irrigation.

Figure 8. *Soybean grown without mulch under drip irrigation*

Figure 9. *Soybean grown with mulch under drip irrigation*

Figure 10. *Growth and development of soybean under mulch*

Intensive growth and development of soybean plants during vegetation with formation of bigger biomass of plants, a leaf surface and basic elements of harvest structure eventually led to formation of more crops. It should be noted that the bigger soybean harvest was in option with surface drip irrigation on 3.6-9.2 c/hectare. Despite the bad weather conditions for growth and development of soy in the southeast of Kazakhstan, we have got a big crop (42.2 c/hectare) in option with use of the mulching

film. At the same time the most effective way of drip irrigation was the surface one (Abdukadirova et al., 2016). As a result of research, there has been revealed the most acceptable option of cultivation and irrigation for the Kazakhstan soy gradessurface drip irrigation with the mulching film (*Table 17)*, and also the grades Lastochka and Dikovit showed the highest results in harvest in three years.

Table 17. *Structure of the harvest of soy grades under drip irrigation, 2013-2015*

Three-year studies have been shown that the use of mulching film in rice and soybean cultures primarily contributes to the economic use of resources, as a result of which the growth of weeds is suspended. Since water helps stop the growth of weeds in rice and soybean, the use water saving technologies and mulching film when growing rice and soybean for increase productivity of rice and soybean in Kazakhstan.

For rice in southeastern Kazakhstan under drip irrigation there are 2-row ribbon cultures with a distance between the bands of 70 cm and rows in the tape of 30 cm. At the same time, the drop band is held within the slots in the belt. According to these results, it is recommended to increase the yield of rice to growth under the drip irrigation of mulch. Comparison of the productivity of soybean varieties showed that productivity in variants with mulch far exceeded variants without mulching.

Conclusions

Results of three years of researches on studying of rice and soybean drip irrigation efficiency let us make the following conclusions:

- Drip irrigation with application of the mulching film promotes emergence of early and amicable shoots of rice, intensive growth and development of plants, productivity increase.
- Drip irrigation with use of the mulching film at 8-10 times reduces a contamination of crops of rice that allows to exclude application of manual use, mechanical and chemical processing of crops.
- Use of the mulching film under rice drip irrigation promotes creation of the favorable nitric mode of the soil with big accumulation of ammoniac and nitrate nitrogen and mobilization of motile phosphorus.
- The best way of rice crops under drip irrigation is 2-row tape crops with distance between tapes of 70 cm and a row-spacing in a tape of 30 cm. At the same time the drip tape keeps within row-spacings in a tape.
- Most optimum mode for efficiency of rice was under rice drip irrigation in the evening and night period by irrigating norm of 4-6 thousand m^3/hectare. The consumption of irrigation water on cultivation of rice is reduced by 5-10 times.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_15811603

- Optimum conditions of mineral food of rice under drip irrigation of rice is reached by introduction of phosphoric fertilizers under preseeding cultivation by a dose of 45 kg on 1 hectare and 4-5 triple nitric additional fertilizing under drip irrigation to a phase of dairy ripeness of rice grain a dose of 30 kg of on 1 hectare. Efficiency of the introduced fertilizers significantly increases under drip irrigation.
- Drip irrigation with or without mulch was adopted for the experimental plots. The most effective way to combat weeds in soybean crops proved to drip irrigation under mulch film, where the number of weeds in the early growing season did not exceed 36-44 units / m^2.
- Despite the prevailing adverse weather conditions for the growth and development of soybean in the south-east of Kazakhstan, we have received a fairly high yield (42.2 tonnes / ha) on a variant using a mulching film.
- The results indicated that use mulch under drip irrigation significantly increase plant growth and production soybean. This increase is due to benefits such as increase in soil temperature, reduced weed pressure, moisture conservation, reduction of certain insect pests, higher crop yields, and more efficient use of soil nutrients.

Abstract. This research investigated the effects of exogenous sodium nitroprusside (SNP) supplementation as nitric oxide (NO) on alleviating Pb-induced oxidative damage in lemon balm (*Melissa officinalis* L.) plants. Pb (100, 300 and 500 µM) alone and in combination with SNP (100 and 200 µM) were given to hydroponically grown *Melissa officinalis* L. plants. The findings suggested that in Pb-treated plants, height, total dry weight, and chlorophyll content of leaves markedly decreased while application of 100 µM SNP alleviated the inhibitory effect of Pb on plant growth and chlorophyll content. Pb exposure caused oxidative stress by elevating lipid hydroperoxide contents of the seedlings. Application of 100 µM SNP counteracted Pb toxicity by reducing lipid hydroperoxide contents of Pb-treated seedlings. Furthermore, it was found that the activities of antioxidant enzymes such as polyphenol oxidase, catalase, guaiacol peroxidase, and ascorbate peroxidase were increased in Pb-treated plants. The use of NO especially at low concentrations reversed Pb-induced negative effects whereas high concentrations of NO had no obvious alleviating effect on Pb toxicity in *Melissa officinalis* L. On the other hand, application of 100 µM SNP could function as a defense mechanism of the plant against Pb toxicity and mitigate Pb stress.
Keywords: *medicinal plant, oxidative sterss, lead pollution, antioxidant response, sodium nitroprusside*

Introduction

Heavy metal pollution has become a prominent environmental problem around the world. Among heavy metals, lead (Pb) is one of the most dangerous pollutants of the environment and Pb pollution in the air, water, and agricultural soil is an ecological concern due to its impact on human health and the environment. Although it is not an essential nutrient for plants, a great portion of Pb is easily taken up by plants from the soil and accumulated in roots while only a small fraction is translocated upward to the aerial parts of plant (Bai et al., 2015). Pb exposure affects growth and physiological parameters and leads to decreases in germination percent, length, and dry mass of roots and shoots, disturbing mineral nutrition and reducing cell division (Singh et al., 2011). In most studies, Pb has been known to induce oxidative stress through overproduction of reactive oxygen species (ROS) and hydrogen peroxide (H_2O_2), which in turn act on the unsaturated lipids in the cell membranes, ultimately leading to lipid peroxidation and damages in cell membranes (Kumar et al., 2013).

Plants are exposed to a wide range of pollutants, particularly heavy metals. However, they are different in their responses to heavy metal pollution. For instance, while some are sensitive to Pb, others show tolerance for this heavy metal and are able to take in considerable amounts of Pb (Nemati et al., 2013). In fact, plants have adopted

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_16051621

specific ways to deal with pollution. Blocking the heavy metals' entrance into the cell via exclusion or binding them to cell wall is the first major mechanism of detoxification and this is an important mechanism for Pb pollution (Antosiewicz and Wierzbicka, 1999). Also, some plants have improved an anti-oxidative system, including anti-oxidative enzymes such as guaiacol peroxidase (GPOX), catalase (CAT), and ascorbate peroxidase (APX) (Cakmak and Horst, 1991).

Nitric oxide (NO), a free radical in living organisms, is considered a key signaling molecule and a phytohormone which has important roles in various physiological processes of plants such as germination, growth, senescence, photosynthesis, and response mechanisms to specific environmental stresses (Del Rio et al., 2004). It is reported to protect the plants against toxicity of reactive oxygen species (ROS), enhance their tolerance to abiotic stress, and improve their defense response (Besson-Bard et al., 2008; Neill et al., 2008). The application of a NO donor, SNP, confers tolerance to various abiotic stresses in plants by enhancing their antioxidant defense system under stress conditions (Xu et al., 2010). Nitroprusside plays its role through the production of compounds involved in detoxification of H_2O_2 and antioxidant enzymes such as catalase (CAT), peroxidase (POD), ascorbate peroxidase (AXP), and guaiacol peroxidase (GPOX) (Tewari et al., 2006). NO has been found to reduce Pb uptake in Arabidopsis thaliana, thereby reducing toxicity symptoms (Phang et al., 2011). It also influences gene expression in response to oxidative stress in *Zea mays* leaves (Hermes et al., 2011). Nitroprusside decreased absorption of cadmium in *Melia azedarach* cuttings and improved some growth parameters under cadmium stress treatment (Arany et al., 2015). It was recently reported that exogenous application of SNP (as a NO donor) alleviated the hostile effects of abiotic stresses induced by heavy metals such as As (Hasanuzzaman and Fujita, 2013), Br and Al (Aftab et al., 2012) and Cu (Zhang et al., 2009). Pretreatment of cowpea seeds with SNP as NO donor before exposure to Pb had a protective effect against Pb toxicity conducing to an improvement of the chlorophyll value, RWC, and net photosynthetic rate by increasing antioxidant enzyme activities (Sadeghipour, 2015). *Melissa officinalis* L contains some phenolic and flavonoid compounds such as rosmarinic acid. Phenolic contents in plants have some antioxidant properties (Chen et al., 2001). This plant is widely used around the world because of its medicinal properties. In the *Melissa officinalis* L. plants treated with sodium nitroprusside, increase in concentrations of sodium nitroprusside led to an increase in oxidative stress molecules and malondialdehyde (Esmaeilzadeh et al., 2015).

Lemon balm (*Melissa officinalis* L.) is a member of the Lamiaceae family, which spreads widely from the western part of Europe (Ulbricht et al., 2005) to western and central parts of Iran. This plant is widely used around the world because of its medicinal properties. However, there is a paucity of data regarding the role of NO in alleviating Pb-induced toxicity. With that background in mind, we hypothesized that NO may ameliorate Pb-induced toxic effects in *Melissa officinalis* L. The present work aimed at investigating the role of exogenously supplied SNP (NO donor) in alleviating Pb stress in *Melissa officinalis* L.

Materials and Methods

Plant material and culture conditions

Melissa Officinalis L. seeds were cultured in perlite puts 2 centimeters deep at equal distances before they were sterilized with 5% sodium hypochlorite for 15 min and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_16051621

washed thoroughly with distilled water. The pots were irrigated by distilled water for 10 days. After germination, the seeds were nourished with Hoagland feeding solution for 15 days. Irrigation was continued during 3-leave stage with Hoagland solutions containing different concentrations of Pb $(NO_3)_2$ (0,100, 300, and 500 μM) and sodium nitroprusside (0,100, and 200 μM) alone and in combination for two weeks. Our experiment was performed under regulated conditions, daily temperature of 25/17° C and 60 ± 5% relative humidity. For the assessment of plant dry matter content, the plants were dried at 80° C for 48 h, to produce a constant weight. This research was conducted under the standard conditions at Sari Agricultural Research Center in Iran.

Determination of Photosynthetic pigments

The leaves were chopped into small pieces that were extracted with 80% acetone. The absorbance was measured at 645 nm and 663 nm for chlorophyll a and b, respectively. Then photosynthetic pigments (chlorophyll a and b) were assayed as per the method of Litehtenhaler and Wellburn (1983) formulae:

$$\text{Chl a (mg g}^{-1}\text{ leaf fresh weight)} = [12.7\ (OD663) - 2.69\ (OD645)] \times V/1000 \times W$$

$$\text{Chl b (mg g}^{-1}\text{ leaf fresh weight)} = [22.9\ (OD645) - 4.68\ (OD\ 663)] \times V/1000 \times W$$

$$\text{Total Chl (mg g}^{-1}\text{ leaf fresh weight)} = [20.2\ (OD645) - 8.02\ (OD\ 663)] \times V/1000 \times W$$

where:
OD= Optical Density
V = Volume of Sample
W = Weight of Sample

Determination of lipid peroxidation

Lipid peroxidation was determined by measuring MDA, a major thiobarbituric acid reactive species (TBARS), and product of lipid peroxidation (Heath and Packer, 1968). Samples (0.2 g) were ground in 3 mL of trichloroacetic acid (0.1%, w/v). The homogenate was centrifuged at 10,000 g for 10 min and 1 mL of the supernatant fraction was mixed with 4 mL of 0.5% thiobarbituric acid (TBA) in 20% trichloroacetic acid (TCA). The mixture was heated at 95° C for 30 min, chilled on ice, and then centrifuged at 10,000 g for 5 min. The absorbance of the supernatant was measured at 532 nm. The value for non-specific absorption at 600 nm was subtracted. The amount of MDA was calculated using the extinction coefficient of 155 mM^{-1} cm^{-1} and expressed as nM g^{-1} FW.

Determination of antioxidant enzymes

For extraction of antioxidative enzymes, shoots and roots were homogenized with 50 mM Na_2HPO_4-NaH_2PO_4 buffer (pH 7.8) including 0.2 mM ethylene diamine tetra acetic acid (EDTA) and 2% insoluble polyvinyl pyrrolidone in a chilled pestle and mortar. The homogenate was centrifuged at 12,000 g for 20 min and the resulting supernatant was used for determining enzyme activities. The whole extraction procedure was carried out at 4 °C.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_16051621

PPO activity was determined by measuring the increase in the absorbance at 420 nm for catechol and 4-methylcatechol substrates and at 320 nm for pyrogallol substrate (Dogan et al., 2007). CAT activity was measured as the decrease in the absorbance at 240 nm due to the decline of extinguishment of H_2O_2 by the procedure of Patra et al. (1978). APX activity was measured by the decline in the absorbance at 290 nm, as ascorbate was oxidized (Nakano and Asada, 1981). GPX activity was calculated by using the extinction coefficient of 26.6 M^{-1} cm^{-1} for H_2O_2 at 436 nm and was expressed as nKat/mg^{-1} of protein. The 10 % gel was stained by the procedure of Hamill and Brewbaker (1969).

Statistical analysis

All data presented here are the mean values of three independent experiments with three replicates. All results were analyzed statistically by two-way ANOVA with SAS 9.1.3 software and means were compared with the LSD test ($P < 0.05$).

Results

Growth, malondialdehyde content and photosynthetic pigments

Total dry weight of Pb-treated plant was reduced significantly compared with control (*Table 1*). Different concentrations of Pb (0, 100, 300 and 500 µM) and interaction with sodium nitroprusside (100 and 200 µM) on plant growth, expressed that dry weight was increased in SNP100,however,200 µM SNP into Pb-treated solution was not diminished and dry weight of plant was decline significantly.

Effects of different concentrations of Pb (0, 100, 300 and 500 µM) and their interaction with sodium nitroprusside (100 and 200 µM) on plant growth expressed as height are shown in *Table 1*. Pb exposure inhibited the growth of *Melissa officinalis* significantly compared with control (Pb 0 Snp 0); however, this inhibition was moderated by the additions of 100 µM SNP. On the other hand, after application of 200 µM SNP into Pb-treated solution, Pb-induced inhibition on plant growth was not diminished and height of Pb-treated plant was reduced significantly (*Table 1*).

According to *Table 1*, the rate of MDA in shoots and roots increased in Pb-treated plants in comparison with the control group, significantly ($P<0.05$). Increasing MDA content resulted in increased lipid peroxidation in the metal-exposed plants. Under Pb stress, application of low SNP concentrations (SNP 100 µM) decreased MDA content, but increasing SNP concentrations (SNP200 µM) to Pb treatments did not alleviate the effects of Pb stress on lipid peroxidation (*Table 1*).

The rise in shoot chlorophyll a and b contents of *Melissa officinalis* plants exposed to Pb stress was statistically significant compared with control group; however, application of 100 µM SNP alleviated Pb toxicity in the photosynthetic system. High concentration of SNP (200 µM) had no mitigating effects on decreasing chlorophyll contents and both chlorophyll a and b contents were reduced, meaning fully compared to others (*Table 1*).

Enzymes activity

Under Pb stress condition, CAT enzyme activity in shoots and roots of *Melissa officinalis* increased significantly (P≤0.05). In SNP-treated plant, both concentrations of nitroprusside increased catalase activity significantly (P≤ 0.05) and the increase was more pronounced at SNP100 concentration. Interaction between Pb and SNP ed that CAT enzyme activity increased significantly in Pb+SNP100 µM but there was a significant decrease at Pb+SNP200 µM. It seems that low concentration of NO enhances negative effects of Pb stress (*Figs. 1 and 2*).

With an increase in Pb concentrations, leaf APX enzyme activity decreased significantly (P≤0.05). Also, with increase in SNP concentrations, APX enzyme activity decreased. Under different concentrations of Pb and SNP, the maximum and minimum APX enzyme activities were recorded in Pb+SNP100 and Pb+SNP200, respectively (*Fig. 3*).

In roots, under Pb stress APX enzyme activity increased significantly (P≤0.05). In addition, in both roots and leaves, with increase in SNP concentrations, APX enzyme activity decreased. Also, APX enzyme activity significantly decreased (P≤0.05) in Pb+SNP200 treatment while there was a significant increase in the activity of this enzyme in the treatment containing Pb+SNP100 (*Fig. 4*).

In leaves of *Melissa officinalis* under Pb stress, guaiacol enzyme activity did not change with an increase in lead concentration but under SNP treatment, enzyme activity decreased significantly (P<0.05) with increasing SNP concentrations and in fact, SNP 100 µM showed the greatest increase in enzyme activity. The highest level of guaiacol activity was seen in the treatment containing Pb 300 µM + SNP100 µM.

In roost, under SNP concentration, enzyme activity was unaltered with increasing SNP. Also, with increasing concentrations of lead, enzyme activity increased in roots and the increase was particularly remarkable at Pb 300 µM. By application of SNP to Pb-treated plants, the highest level of guaiacol enzyme activity was seen at Pb (100 µM and 300 µM) + SNP100 µM while the lowest activity was seen at Pb 500 µM + SNP 200 µM (*Figs. 5 and 6*).

Discussion

Pb is a toxic heavy metal that exerts adverse effects on morphology and growth of plants causing inhibition of enzyme activities. It has been suggested that exogenous application of the NO donor, sodium nitroprusside (SNP), enhances plant tolerance to heavy metals (Kumari et al., 2010) and oxidative stress (Esim and Atici, 2013). In the present study, the probable effects of exogenous NO was investigated on reducing lead toxicity in *Melissa officinalis*. Different concentrations of NO were applied in the Pb-treated plants and the physiological parameters of *Melissa officinalis* under Pb Stress were investigated under different NO concentrations.

Plant biomass is a good indicator for characterizing the growth performance of plants in the presence of heavy metals. Results indicated that application of Pb (100, 300, and 500 µM) especially concentration of 500 µM decreased the dry weight of *Melissa officinalis*. However, simultaneous application of low concentration of NO (100 µM) increased the dry weight and height of *Melissa officinalis*. Pb-induced growth inhibition in this study was reflected by total dry weight. Similar response to lead treatment was previously reported in various plants (Brunet et al., 2009). Decrease in growth parameters (dry weight and height) in *Melissa officinalis* plants might be the result of changes in metabolic processes, e.g. oxidative damage, nutrient uptake, and photosynthesis or it might be associated with the inhibition of mitotic index observed under Pb heavy metal treatment (Sheldon and Menzies, 2005). Previous studies on the mechanism of Pb toxicity suggested that Pb binds to nucleic acids and causes aggregation and condensation of chromatin, inhibiting the process of replication and transcription and ultimately affecting cell division and plant growth (Johnson, 1998). In our study, Pb-induced inhibition was significantly reduced by the lower concentration of NO. The mitigation effect of lower concentration of NO might be because NO improved photosynthesis by increasing chlorophyll content and counteracted oxidative damage by decreasing the generation of ROS. When the higher NO concentration was applied in *Melissa officinalis* plants, the mitigation effect was not obvious.

In the present study, the chlorophyll content significantly decreased with the increasing concentrations of externally supplied Pb in *Melissa officinalis*. This reduction

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_16051621

in chlorophyll content can be regarded as a specific response of the plants to metal stress, which resulted in chlorophyll degradation and inhibition of photosynthesis (Gajewska et al., 2006). Chlorophyll content showed maximum range at Pb (100 μM) and it was decreased beyond that concentration. Heavy metals inhibit chlorophyll and other pigments biosynthesis. Lead may impair the uptake of essential elements, such as Mg and Fe, for chlorophyll biosynthesis, substitute divalent cations, prevent enzyme activity like aminolevulinic acid dehydratase and increase chlorophyll biodegradation by enhancing chlorophyllase activity (Nareshkumar et al., 2014; John et al., 2009; Prasad and Prasad, 1987). Therefore, reducing the amount of chlorophyll can be due to several factors, namely, inhibition of enzymes associated with chlorophyll biosynthesis (John et al., 2009), inhibition of Calvin cycle enzyme activity (Sharma and Dubey, 2005), obstruction of electron transportation (Pourrut et al., 2011), and stomatal closure and distortion of chloroplast ultrastructure (Bharwana et al., 2014; Bai et al., 2015). Also, it may be the result of interaction of Pb with SH group of enzymes of chlorophyll biosynthesis as well as lipid peroxidation-mediated degradation as indicated by Singh et al. (2006). Similar cause was suggested by Tanyolac et al. (2007) in maize (*Zea mays* L.) under Cu stress.

Similarly, reduction in the chlorophyll content has been reported in many plant species exposed to Pb (Bharwana et al., 2014; Malar et al., 2014). Our results indicated that NO-mediated improvement of chlorophyll contents played a role in the enhancement of photosynthesis. In this experiment, exogenous NO at lower concentration (100 μM) increased the chlorophyll content under Pb toxicity but high concentration (200 μM) of NO had no positive effect and chlorophyll content significantly decreased at Pb (500 μM) ($P<0.05$). A high NO-induced accumulation of chlorophyll was also observed under Cd stress in Rapeseed and tomato (Jhanji et al., 2012) and wheat under As-induced oxidative stress (Hasanuzzaman and Fujita, 2013).

It was found that NO raised the antioxidant enzyme activity and consequently reduced chlorophyll desolation induced by ROS. On the other hand, NO also protected chlorophyll by increasing the uptake of Fe and Mg under Pb stress (Bai et al., 2015). In this way, NO protects chlorophyll by improving its biosynthesis and reducing its destruction under Pb stress conditions.

In our study, the MDA level was significantly increased by Pb treatment. Increase in the concentration of lead was observed to increase the level of malondialdehyde production. MDA is the final product of peroxidation of membrane lipids and accumulates when the plants are subjected to oxidative stress. Therefore, MDA level is routinely used as an index of lipid peroxidation under stress conditions. A high level of MDA is demonstrative of an increased formation of ROS and oxidative damage. Actually, ROS reject hydrogen from unsaturated fatty acids and produce lipid radicals and reactive aldehydes, which deform the lipid bilayer (Kumar et al., 2013). Pb is known to induce oxidative stress in plants due to the elevated manufacture of ROS (Singh et al., 2011). In this work, increasing MDA levels showed that oxidative stress and lipid peroxidation of membranes were induced by Pb stress in *Melissa officinalis* plants. This is supported by many studies, e.g., Pb toxicity caused oxidative damage and elevated MDA content in mung bean (Hassan and Mansoor, 2014), *elsholtzia argyi* (Islam et al., 2007), and cotton (Bharwana et al., 2014).

It was also observed in the present study that application of SNP 100 μM under Pb stress conditions inverted the Pb toxicity effect and decreased the MDA content compared to Pb treatment alone. However, the use of high concentrations of NO did not

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_16051621

mitigate the oxidative effects of lead. NO moderated Pb stress in *Melissa officinalis* plants by averting oxidative damage via the enhancement of antioxidant enzyme activity. This suggests that NO acts as an efficient ROS scavenger and/or membrane stabilizer in *Melissa officinalis* plants subjected to Pb stress. The reaction of NO with ROS could prevent the damage to the membranes. It has been demonstrated that the reaction of NO with lipid alcoxyl (LO) and peroxyl (LOO-) radicals is quick (Beligni and Lamattina, 1999). Nitric oxide has also been reported to inhibit ion drip from plant tissue and protect plants against membrane damage due to lipid peroxidation under various stress conditions. This role of NO has been observed in heavy metal stress induced by Cd (Kumari et al., 2010), Br (Esim and Atici, 2013), and Al (Wang and Yang, 2005).

Under normal conditions, ROS are produced at a low concentration and there is a balance between the generation and alleviation of ROS. This balance may be disturbed by many environmental stresses. In order to protect themselves against oxidative stress, plants have developed a compound antioxidative protection system for scavenging ROS (Sharma et al., 2012). In order to scavenge ROS and to escape oxidative injury, plants possess an antioxidative system including antioxidative enzymes. Antioxidant system plays an important role in the plants' tolerance to stress conditions, which is based on the fact that the activity of one or more of these enzymes or antioxidant substances in general increases in plants exposed to stressful condition and this enhancement is related to increased stress tolerance (Fecht-Christoffers et al., 2003) and is considered as an efficient system for detoxification and cleaning up of the toxic oxygen species through an adaptive mechanism involving upregulation of anti-oxidative enzymes like SOD, CAT, PPO, APX, and GPX (Foyer et al., 1994).

Our results show that activities of enzymes had various effects on *Melissa officinalis* under Pb-stress. APX enzyme activity decreased with increasing Pb concentrations but CAT and PPO enzyme activities increased while GPX enzyme activity was unchanged compared to the controls. However, application of exogenous NO, particularly 100 μM improved antioxidant enzyme activity. Modification in the activity of antioxidative enzymes with Cd stress has been reported by a number of researchers (Mishra et al., 2008; Laspina et al., 2005).

Our results show that the maximum activity of CAT was found at Pb 500 μM and we found that with increasing concentration of the lead, activity of CAT increased. CAT is a generally present oxidoreductase that disintegrates H_2O_2 to water and molecular oxygen, and it is one of the key enzymes involved in the ejection of toxic peroxides. Increase in CAT activity can be illustrated by an increase in its substrate, to support the level of H_2O_2 as an adaptive mechanism of the plants (Reddy et al., 2005). Therefore, reduction in the activities of CAT might be due to the formation of a protein complex with metals that results in the structural integrity of proteins (Mohan et al., 1997). At higher concentration of Pb the activity of protein-based enzyme might be reduced due to the effect of ROS through reduced enzyme synthesis or change in assembly of its subunits (Verma and Dubey, 2003). CAT enzyme can play a role in controlling H_2O_2 level in cells. In subcellular compartments of pea root cells increased catalase activity was observed when plants were grown in nutrient $Pb(NO_3)_2$. However, a decline in the activity of catalase with an increased heavy metal concentration has also been observed in *Lemna gibba* (Parlak and Yilmaz, 2013) and in *Becopa monnera* (Mishra et al., 2006). Laspina et al. (2005) reported a decline in CAT activity under Cd stress. Thus, it

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_16051621

seems that the differences in activities of antioxidant enzymes in heavy metal treated plants are highly dependent on species and experimental model.

Our results indicate an enhancement in the activity of GPX and PPO by the low concentration of Pb, suggesting that this enzymes work as an essential defense tool to resist Pb-induced oxidative damage in plants. GPX is located in cytosol, cell wall, vacuole, and in extracellular spaces. Increased peroxidase activity in Pb-stressed plants might be possibly due to increased release of peroxidases localized in the cell walls. Under sub lethal salinity and metal toxicity conditions, level of peroxidase activity has been used as potential biomarker to evaluate the intensity of stress. Similar to our findings, the activity of guaiacol peroxidase (GPX) increased in *S. Roxburghiana* plants exposed to Pb and in *Lemna minor* (Paczkowsk et al., 2007).

In the present study, APX activity was different in shoots and roots of *Melissa officinalis* under Pb stress. It was enhanced at low concentration of pb in roots, but, decreased in shoots. APX is generally attributed to an adaptive mechanism against increase levels of ROS content produced by Pb metal ions. Enzymes of ascorbate are localized mainly in chloroplasts and in other cellular organelles and cytoplasm, where they play an important role in combating oxidative stress. The positive correlation between APX activity and excess ROS may be attributed to effective scavenging of H_2O_2 content to protect stressed plants against oxidative damage induced under lead stress. Similar to the results observed in the present study, an increase in APX activity in plants following exposure of heavy metals was reported by Malar et al. (2014) in *water hyacinth*. In *Phaseolusvulgaris* and *Pisumsativum* (Rodriguuez-Serrano et al. 2006) and *Ceratophyllum demersum* (Mishra et al., 2008) APX reduced under Cd stress, but a decline in APX activity under Cd stress was reported by Gomes-Júnior et al. (2006).

Our results showed that Polyphenol Oxidase activity increased by the low concentration of Pb. Similar our study, Chinmayee et al. (2014) demonstrated that, PPO activity in *Jatropha curcas* L. increased in all plant parts under chromium, cadmium and lead stress. Also, Saffar et al. (2009) reported that in *Arabidopsis thaliana*, PPO activity might be the result of extended heavy metal stress. PPO catalyzes the formation of highly active Quinone that reacts with amino or sulfhydryl groups in proteins or enzymes. As a result, these reactions lead to changes in physical, chemical, or nutritional characteristics of proteins and, in many cases, to inactivation of enzymes including PPO (Mayer and Harel, 1979).

All the antioxidant enzymes studied in this work had maximum activity in shoots compared to roots. This might be due to moving of Pb in all parts as a micronutrient and this enhances the concentration of antioxidant enzymes in shoots compared to roots. In our study SNP (100 μM) was effective in improving all measured traits in the plants under lead stress but it had no positive effect in high concentration of Pb and this might be due to the fact that NO is itself a ROS and its dual behavior (protective or toxic) depends on the conditions (Beligni and Lamattina, 1999). The protective role is based on its capacity to regulate the level and toxicity of ROS. In many studies, the alleviation of oxidative damage by NO was attributed to the induction of activity of various ROS-scavenging enzymes (Esim and Atici, 2013). The present observation is in agreement with the previous findings on rice roots treated with As (Rodríguez-Serrano et al., 2006), and *Cassia tora* roots treated with Al (Kumari et al., 2010).

Two mechanisms have been reported which may explain NO protective action against oxidative damage. One possibility is that NO might activate antioxidant systems

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_16051621

to scavenge ROS. Beside the role of NO in the activation of antioxidant enzymes that scavenge ROS, it can also react with $O_2 \bullet^-$ and generate peroxynitrite ($ONOO^-$). $ONOO^-$ is unstable and may be protonated and disintegrated to a nitrate anion and a proton, or it can react with H_2O_2 to produce a nitrite anion and oxygen (Fan et al., 2014). Second, it is now accepted that NO acts as a second messenger in plants. The cytoprotective role of NO is mainly based on its ability to maintain the cellular redox homeostasis and to regulate the level and toxicity of ROS (Hayat et al., 2010). Present results indicate that SNP plays a protective role in APX, PPO, CAT, and GPX activity in *Melissa officinalis*. In the present study, the application of high concentration of NO did not reduce Pb-induced ROS damage. In fact it even produced more toxic effects in *Melissa officinalis.* One of the most intriguing behaviors in NO biology is its dual function as a potent oxidant and effective antioxidant. This dual role of NO might depend on its concentration as well as on the environmental conditions.

Conclusion

The present study demonstrated that Pb stress caused oxidative damage and membrane lipid peroxidation, leading to a significant decrease in chlorophyll content and shoot and root growth in *Melissa officinalis* plants. On the other hand, application of SNP as NO donor in *Melissa officinalis* under Pb stress had a protective effect against Pb toxicity by increasing antioxidant enzyme (PPO, CAT, APX, and GPX) activities leading to an improvement of the chlorophyll content and dry weight. Thus, exogenous NO can be used to alleviate Pb toxicity in Melissa. In fact, the lower concentration of NO (100 µM) had a higher protective effect on Pb toxicity, while high concentration of NO (200 µM) did not alleviate Pb toxicity considerably. NO may help plants to survive stressful conditions through its function as a signaling molecule in the activation of antioxidative enzymes or its direct reaction with active oxygen, nitrogen, and lipid radicals. While supplementation of SNP resulted in growth enhancement, as well as increase in the contents and activities of all investigated biochemical components. Thus, our results indicate that SNP application might alleviate Pb toxicities and regulate plant growth and development of *Melissa officinalis* and that Pb tolerance of *Melissa officinalis* cultivated in Pb-mediated nutrient solution increased at low concentrations of NO. This indicates that NO acts as an efficient ROS scavenger and membrane stabilizer in *Melissa officinalis* plants exposed to Pb stress.

(Received 12th Jun 2017; accepted 20th Sep 2017)

Abstract. This study investigated the correlation between mandibular length versus the age and body mass of European roe deer. Mandibular length was measured in 7560 roe deer (3888 females and 3672 fawns younger than 1 year) that were hunter-harvested in the Czech Republic in 2007-2012. The body mass and age of every animal were determined. Average mandibular length was determined at less than 130 mm in fawns and more than 153 mm in adult females. The greatest increase in mandibular length and body mass of 24.8 mm and 5.3 kg, respectively, was observed in animals aged up to 4 years. In older roe deer, mandibular length increased at a slower rate and remained fairly constant. Mandibular length increased with body mass, and the cross-correlation coefficient was determined at 0.8255. The results of this study indicate that mandibular length is a useful metric for describing the quality of roe deer populations and individuals.
Keywords: *craniometry, game management, individual development, morphometry, population*

Introduction

The European roe deer (*Capreolus capreolus*) is a species with high levels of morphological variation. Twenty-six subspecies of roe deer have been identified based on phenotypic and geographic variations in roe deer populations (Mayr, 1942; Sempéré et al., 1996). Differences in cranial measurements are significant determinants of inter-population variability in the species (Kulak and Wajdzik, 2009) and other wild cervids (Markov, 2014). Cranial dimensions are influenced by primary production which is responsible for the isolation of local populations and differences in cranial morphology. According to Stubbe and Passarge (1979) and Zedja and Koubek (1988), the body mass of animals is directly linked with habitat productivity which is influenced by soil type, vegetation, population density and ecotone length. Animals that forage on woody plants have shorter and wider crania than animals that feed mainly on herbaceous plants (Aragon et al., 1998). The mandible is one of the first bones in the body to ossify (Hewison et al., 1996), and mandibular length in adult animals is determined mainly by environmental conditions in early life.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_16231632

In wild animals, including game, the mandible constitutes interesting research material because it does not have any economic value. Analyses of mandibular measurements support the search for new parameters to describe variations in local populations and the quality of their habitats (Sheremetyeva and Sheremetyev, 2008; Hanzal et al., 2012; Mendoza et al., 2002).

The aim of this study was to investigate the relationship between mandibular length versus the age and body mass of roe deer.

Materials and Methods

The study was performed on mandibles of the European roe deer *Capreolus capreolus* that were hunter-harvested in the Žďár nad Sázavou District of the Czech Republic in 2007-2012. Mandibular length was measured in 7560 roe deer, including 3888 females (does) and 3672 individuals aged up to 1 year (fawns).

Roe deer were hunter harvested in the Žďár nad Sázavou District, Jihlava county of the Vysočina Region (Czech Republic) at the altitude of around 500 m above sea level. The district has an area of 1 579 km^2 (Misar et al., 1983). Water bodies occupy 2.9% of the district's area. Agricultural land and forests (where the animals were harvested) have a similar share of the district's area at around 49% and 41%, respectively (Czech Statistical Office, 2014).

Mandibular length (mm) was measured between the zygomatic arch and incisor root to the nearest 0.1 mm. The animals' body mass (kg) was determined to the nearest 0.1 mm, immediately after harvesting (in the hunting site) and before evisceration. Potential blood loss associated with hunter harvesting was not subtracted from body mass measurements.

The animals' age was estimated based on physiological features and the wear of mandibular teeth (Lochman, 1987; Vach, 1993). Due to the extensive experimental material (7560 mandibles), the age of the analyzed roe deer could not be determined with the use of laboratory methods for organizational reasons.

The following variables were processed statistically:

- body mass,
- mandibular length,
- age,
- harvest date.

The data were expressed as means ± standard error of the mean (SEM). The results were analyzed statistically by one-way ANOVA, and the significance of differences between groups was determined with Duncan's multiple range test at a significance level of $P \leq 0.05$. All calculations were carried out in the Statistica 10.0 program (StatSoft, 2011).

Results

Average mandibular length was determined at less than 130 mm in fawns and at more than 153 mm in adult females (*Table 1*).

The greatest increase in mandibular length and body mass of 24.8 mm and 5.3 kg, respectively, was observed in animals aged up to 4 years. In older animals, mandibular length increased at a slower rate and remained fairly constant (*Fig. 1*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_16231632

***Table 1.** Average body mass (kg) and mandibular length (mm) in fawns and does*

Trait	Fawns (n=3672)	Does (n=3 888)
Average body mass	7.96	13.03
Average mandibular length	129.30	153.44

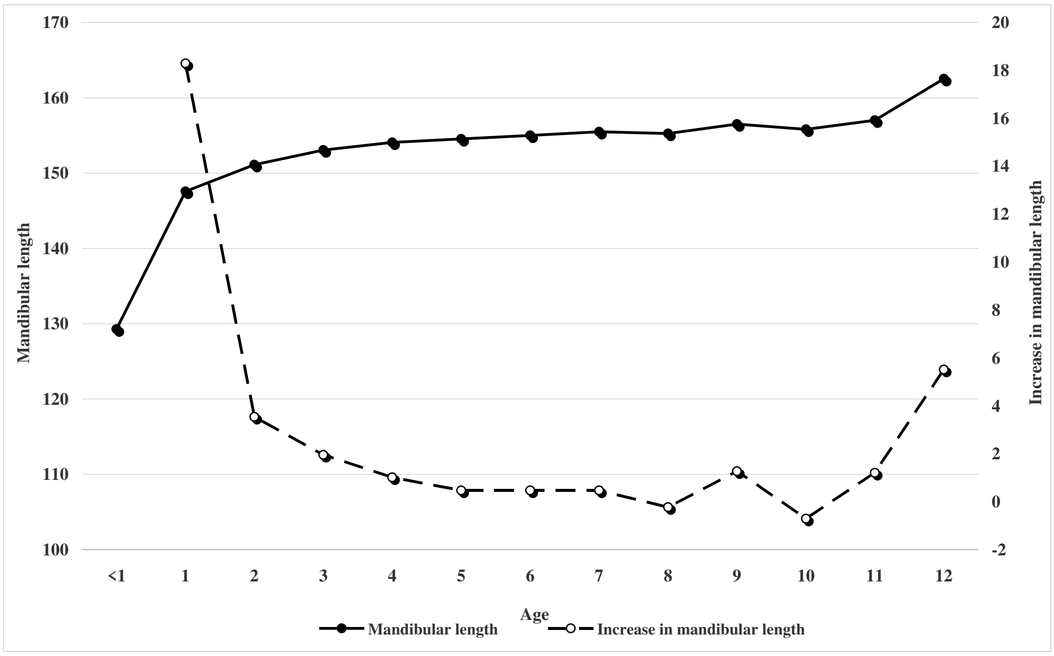

***Figure 1.** Average mandibular length [mm] and increase in mandibular length [mm] in roe deer aged to 12 years*

The greatest difference in mandibular length was observed between 2-year-old individuals and fawns, and it reached 18.28 mm on average (*Fig. 1*). The noted difference accounted for around 60% of the total increase in mandibular length in the analyzed period of life. The observed difference was highly significant (*Table 2*).

According to estimates, the youngest animals were approximately 5 months old, and the oldest individual was 12 years old in September of the first experimental year, which suggests that the overall increase in mandibular length in the examined period of life was approximately 30.4 mm.

Mandibular length increased with body mass (*Table 2*, *Fig. 1*), and the value of the cross-correlation coefficient reached 0.8255. It should be noted that body mass was characterized by greater variations than mandibular length across the examined age groups (*Table 2*).

In females, average mandibular length was determined at 153.44 mm, and this value was noted in hypothetical animals with average body mass of 13.03 kg, and average age of 4.4 years (*Table 1*). In fawns, average mandibular length reached 129.3 mm, and it was observed in hypothetical animals with average body mass of 7.96 kg, and average age of 5-7 months.

The average mandibular length of fawns harvested in each year of the study was analyzed (*Table 2, Fig. 2*). The measured parameter was higher in 2008, 2009 and 2012 than in the remaining years of the experiment.

Individuals that were harvested later in the year (December) and were, therefore, older, were characterized by longer mandibles than fawns harvested in earlier months. Mandibular length was approximately 10.6 mm higher in roe deer harvested in December than in individuals harvested in September, and it was determined at 133.6 mm and 123.0 mm, respectively (*Table 3, Fig. 2*).

No significant differences in mandibular length were noted across the experimental years.

Discussion

In animals, selected elements of the skeletal system are often used as retrospective indices to describe bodily dimensions, physiological development and resistance to seasonal changes in food availability (Zanneśe et al., 2006b). Slow bone growth observed under unfavorable environmental conditions can be compensated for in periods when food is more abundant (Bailey, 1984). Animal density, habitat quality, genetic structure and climate are significant predictors of body size in ungulates. Mandibular length can be an important indicator of physiological status in many cervid species. Animals living in more supportive environments are characterized by more developed maxillary and mandibular bones (Høye and Forchhammer, 2006).

Wustinger et al. (2005) analyzed 29 mandibles of female roe deer from the Polish region of Wielkopolska. Mandibular length was determined at around 132 mm in fawns and 156 mm in adult individuals. In our study, the examined mandibles were shorter at 129.3 mm in fawns and 153.4 mm in adult females. The results reported by Wustinger et al. (2005) could indicate that habitat conditions in the examined region were more favorable for roe deer.

In our study, average mandibular length in female roe deer from Czech lowland regions was more than 2 cm lower than that noted in does inhabiting the Prokletije mountain range in Serbia, where this parameter was determined at 156.55 mm (Labus et al., 2010). No significant differences in mandibular length were observed between males and females. The average mandibular length of roe deer in Bosnia and Herzegovina (not adjusted for gender or age) was also determined at 156 mm (Avdić et al., 2013), which suggests that the above value is typical of *Capreolus capreolus* inhabiting the Balkan region.

According to Zanneśe et al. (2006a) and Dvorak et al. (2002), the highest rate of mandibular growth is observed in the first 5 years of life. Similar observations were made in our study of roe deer from the Czech Republic. Mandibular length increases most dynamically in the first year of life, after which, this parameter increases annually by around 1 cm on average until the age of 4 years. Similar results were reported by Vach (1993) who observed the highest rate of mandibular growth in roe deer in the first 2 years of life.

An analysis of an increase in mandibular length in all examined individuals (aged 1 to 12 years) yielded similar results to those reported by Anděra & Horácék (1982) in whose study, the evaluated parameter increased from 142 mm to 164 mm. In our study, average mandibular length in all roe deer was determined at 151.71 mm, and it increased from 129.27 mm in fawns to 147.56 mm in one-year-olds to 162.51 mm in 12-year-olds. According to Hrabe and Koubek (1991), the greatest increase in cranial length is observed between 11 and 39 months of age.

In does, mandibular growth is completed at 4 years of age. In cervids, this parameter is correlated with other, apparently unrelated physiological functions, such as fertility. Animals with better nutritional status and higher body mass reach puberty earlier, and the probability of ovulation in does exceeds 0.95 when mandibular length reaches 130 mm. The population of one-year-old females that had calved was higher in habitats where food was more available. In does aged 1 to 7 years, age, body mass and mandibular length were significantly correlated with fertility. Fertility was most highly correlated with mandibular length (Górecki et al., 2014; Bertouille and Cromburugghe, 2002).

A study investigating the influence of environmental factors on the mandibular length of roe deer in the Italian region of Belluno produced highly interesting results. Differences in mandibular length were determined in animals inhabiting northern and southern parts of the region. The studied locations are marked by considerable differences in altitude (167 m above sea level in the north, and 3327 m above sea level in the south) which influence the local climate and flora. In fawns (younger than 1 year) inhabiting the southern part of Belluno, average mandibular length was determined at 128.8 mm in 1990-1995 and 127.7 mm in 1996-2001. In the northern part of the examined region, the value of this parameter reached 123.6 mm and 123.9 mm, respectively. The average mandibular length in one-year-old males was determined at 153.3 mm in the south and 150.00 mm in the north. The analyzed parameter in 2-year-old bucks reached 157.4 mm in the south and 154.0 mm in the north, and in 2-year-old does – 156.1 mm in the south and 153.0 mm in the north. The above results indicate that the southern part of the Belluno region is characterized by a more supportive environment for roe deer. The observed variations in mandibular length were cross-referenced with the density of roe deer populations in the studied areas. Animal density was higher in the north (0.44 animals per km^2), and it decreased towards the south (0.33 animals per km^2). These results indicate that the density of animal populations also influences mandibular length (Zanneṡe et al., 2006b).

In the present study, the average mandibular length of fawns (up to 1 year of age) from the Czech Republic was determined at 129.2 mm, and was higher than that observed in Italian fawns. In older animals, the rate of mandibular growth was slower in Czech than in Italian roe deer. One- and 2-year-old individuals from the Czech Republic had shorter mandibles than Italian roe deer living in less favorable environmental conditions (145.7 mm and 151.1 mm on average, respectively). Our findings point to limited availability of food, high population density, a different genetic pool as well as differences in ecotype.

The results of our study and literature data can be used to develop a new strategy for monitoring the quality of local populations of European roe deer. Seasonal variations in bone size within one subpopulation are correlated mainly with environmental factors. Bone growth is most highly correlated with climate and population density. The body mass of fawns in winter, mandibular length in adult roe deer and foot length are most highly correlated with population density. In cervids, foot bones begin to grow rapidly immediately after birth, and their growth is completed relatively early, which is why this parameter is sensitive to environmental conditions. The length of hind feet varied across regions and was lower in areas characterized by lower availability of food, less supportive habitats and higher population density, regardless of gender (Zanneṡe et al., 2006a).

Conclusions

The results of this study indicate that mandibular length can be a reliable and easy to measure indicator of the quality of individual roe deer and, indirectly, roe deer subpopulations. The mandibular length and body mass of roe deer can also be robust bioindicators of habitat quality. Both parameters can be used in practice by wildlife specialists and practitioners responsible for managing free-living deer populations. Further, detailed research should be extended to include other species of game and protected mammals.

Abstract. One the effects of climate change on populations has been the alteration in the geographical limits and spatial mobility of plants, which generates changes with associated species, such as honeybees which could produce changes in beekeeping. The aim of this study was to determine the spatio-temporal mobility of beekeeping, in the short, medium and long term, in the main honey-producing area in the Gulf of Mexico`s beekeeping region due to changes in temperature resulting from climate change using a regional assembly model with scenario A2. The productive potential of eight indicator melliferous species was determined: *C. sinensis, C. paradisi, B. simaruba, C. arabica, A. germinans, R. mangle, B. nigra* and *S. mombin*. The development potential for *A. mellifera* was determined based on combining bee thermal comfort and melliferous species' information, forming four categories for apicultural development. Based on the type of flowering, beekeeping will be confronted by a loss of suitable area for citrus species and an increase in area for the rest of the indicator species, which demonstrated different changes according to each species from the short to the long term. Therefore, beekeeping will have a varied spatio-temporal mobility according to the availability of botanical resources and the thermal comfort of the honeybee.
Keywords: *apiarian mobility, melliferous flora, beekeeping and climate change, Apis mellifera, honey*

Introduction

Global temperature increases forecasted by the Intergovernmental Panel on Climate Change are estimated to range from 1.4 to 3.1 °C over the next 100 years (IPCC, 2014). This will affect individuals, populations and species, as well as ecosystems, resulting in changes in the geographical limits and spatial and elevational mobility of plant communities. This will generate changes in space and time in ecosystem relationships with associated species (Bravo et al., 2011, Zhou et al., 2016).

Among the ecological relationships, the one which exists between plants and bees is one of the most valued since 35% of global food production comes from crops pollinated by bees (Saturni, 2016), and also because beekeeping is an economic activity seen as a tool for the development of the primary sector in different countries (Huerta, 2008).

In beekeeping, the honey yields that determine the sector's profitability are related to the weather conditions that directly and indirectly affect honeybee (*Apis mellifera* L.) dynamics (Delgado et al., 2012, Mendizabal, 2005) and plant phenology (Hegland et al.,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_163175

2009). Therefore, phenological processes related to thermo-pluvial variations are one of the main factors influencing ecosystems (Hildrew et al., 2017), as a result of climate change (Gomez-Diaz et al., 2007). Such variations affect bloom times due to increases in temperature, generating imbalances with pollinators associated with the vegetation (Tam and McDaniels, 2013).

Variation in vegetation phenology is an indicator in climate change ecosystems (Zhou et al., 2016). At regional scales, this impact has been underestimated for honey production (Delgado et al., 2012), which depends on the comfort state provided by the balance between the physiology of an organism and the environment that surrounds it, for optimum food transformation (Ruiz et al., 2011).

Therefore, the presence of tropical storms, hurricanes with destructive force and droughts as a result of climate change have an impact on bee production (Guemes et al., 2003), as well as its profitability (Magaña et al., 2016). In Mexico, honey production has maintained a downward trend (SIAP, 2015), which is attributed to, among other factors, the presence of erratic storms, early frosts and droughts that are not conducive to optimum flowering development (Contreras-Escareño et al., 2013). In 2005 and 2007, a 11.1% reduction in honey production coincided with the presence of Hurricanes Wilma and Dean on the Yucatan Peninsula. However, in 2009 and 2010 a combination of the ENSO neutral and negative (La Niña) phases contributed to a 6.1% drop in domestic honey production (CONAGUA, 2011, SIAP, 2015).

Therefore, an alteration in the climatic system can define a new spatial distribution of bees intervening in the foraging relationships between species and races, as well as in the development of associated parasites and pathogens. This will force beekeepers to change their production methods in the coming decades (Le Conte and Navajas, 2008).

In countries such as Puerto Rico, the trend in terms of areas for honey production has been evaluated with climate projection models, based on future climate change scenarios. This is where a risk is foreseen in the form of a predicted reduction in the spatial areas suitable for apicultural development (Delgado et al., 2012).

The study of changes in beekeeping through future scenarios that allow projecting possible changes induced by climate change, based on the plant-insect relationship in tropical regions, would enable exploring the availability of suitable areas for apiculture in space and time, for the development of use and adaptation strategies.

In this regard, the aim of this research was to determine the spatio-temporal mobility of beekeeping in the central region of the state of Veracruz along the Gulf Coast in the short (2021-2030), medium (2041-2050) and long term (2051-2060), due to changes in temperature and precipitation resulting from climate change predicted by the SICC regional assembly projection model under scenario A2 conditions (IPCC, 2007). The information thus generated is intended to provide a comprehensive overview of the impacts that this phenomenon will have on beekeeping in this important apiarian region, considering the spatial area available for the development of melliferous species.

Materials and Methods

The study area was the main production area in the beekeeping region of the Gulf of Mexico (Villegas et al., 2003), located between 97° 27' 0'' and 95° 26' 41.9'' WL and 18°31' WL. This region comprises 20 municipalities in the state of Veracruz, namely: Altotonga, Alvarado, Atzalan, Boca del Rio, Coatepec, Comapa, Córdoba, Cosautlán de

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_163175

Carvajal, Emiliano Zapata, Ixhuacán de los Reyes. Jalacingo, Martínez de la Torre, San Rafael, Soledad de doblado, Teocelo, Tlapacoyan, Veracruz, Xalapa, Xico and Zentla.

The indicator melliferous species that account for the bulk of honey production and that have a high weighting in terms of the number of individuals per hectare were identified. This information was based on the records of the transhumance routes in the region (PRONATURA-Veracruz, 2010), as well as information provided by n= 88 beekeepers on the main blooms on each of the routes.

It was taken as a sample beekeepers population who issued record levels of infestation by *Varroa destructor* Anderson and Trueman (2000), as issued by the national governing body in the state delegation of SAGARPA. To estimate the sample size from a population of N=247, a simple random sampling technique was used (Scheaffer et al., 1987), where:

$$n = \frac{N\sigma^2}{(N-1)D + \sigma^2}$$

N = Number of hives
n = Sample size
σ = Standard deviation
D = Error disposition

Sample size (n = 88) was obtained by replacing the following values in the formula: N = 247, the standard deviation of the number of hives (σ) = 200.6 and B = 34.4, with α = 0.95.

We used the Mexican productive crop potential method (Diaz et al., 2012) and geographic information system tools (scale 1:50,000), along with Series III climate (precipitation and temperature) data from the National Institute of Statistics and Geography (INEGI) and edaphoclimatic requirements of indicator species such as temperature, precipitation, elevation, soil type, depth and texture, and the salinity variable for the species that required it. Vector images were developed at the INIFAP Teocelo Experimental Site's Digital Agromap Laboratory; the images were reclassified at two levels: the high (1) and medium (2) development area based on the edaphoclimatic requirements of the species (Ruiz et al., 2011).

In parallel, the response in *A. mellifera* L. development to the environmental temperature was defined to predict the potential geographical distribution amplitude of the species, using the cartographic process employed for the productive potential of the melliferous plants.

In the final stage, an intersect of the resulting vector models between plants and bees was made to determine the spatial distribution for the beekeeping activity in the desired time period. The INIFAP National Environmental Information System (SIA for its acronym in Spanish) was used, with historical normal values for the period 1961-2003 (Ruiz et al., 2003), which was worked in raster format, adding algebraically the estimated future anomalies by Magaña and Caetano (2007) in their model SICC. The simulation of climate changes due to climate change in the short (2021-2030), medium (2041-2050) and long term (2051-2060) was based on the SICC assembly model proposed by Magaña and Caetano (2007) with weighted climate values from 10 General Circulation Models (mpi_echam5, miub_echo_g, csiro_mk3_0, csiro_mk3_5, cccma_cgcm3_1, giss_model_e_r, ncar_ccsm3_0, miroc3_2_hires, mri_cgcm2_3_2a,

DOI: http://dx.doi.org/10.15666/aeer/1504_163175

ukmo_hadcm3), with a resolution of 90 m x 90 m. This assembly presented changes according to scenario A2 contained in the AR4 published by the IPCC (2007).

With the SICC and SIA we calculated deviations of the study variables between the 1961-2003 climatology and the decades of short (2021-2030), medium (2041-2050) and long term (2051-2060) showing that the temperature will have an increase of 1.8 to 2 °C, from tropical regions and high valleys such as the apicultural region of the study área.

The indicator melliferous species used for the present study were: *Citrus sinensis* (L.) Osbeck (lemon), *Citrus paradisi* Macf. (grapefruit), *Bursera simaruba* (L.) Sarg. (gumbo-limbo), *Coffe arabica* L. (coffee), *Avicennia germinans* L. (black mangrove), *Rizophora mangle* L. (red mangrove), *Brassica nigra* (L.) Koch (black mustard) and *Spondias mombin* L. (jobo) (*Figure 1*).

In the mapping process, waterbodies and urban areas were excluded because they included wild plants that did not correspond to specific crop areas. In addition, due to the similarity in edaphoclimatic requirements, the two citrus (*C. sinensis* and *C. paradisi*) and mangrove forest (*A. germinans* and *R. mangle*) species were grouped into two flowerings: citruses and mangrove. The changes in the area with productive potential for melliferous species were presented in units of hectares to quantify the changes in the spatial and temporal dimension based on the projection model.

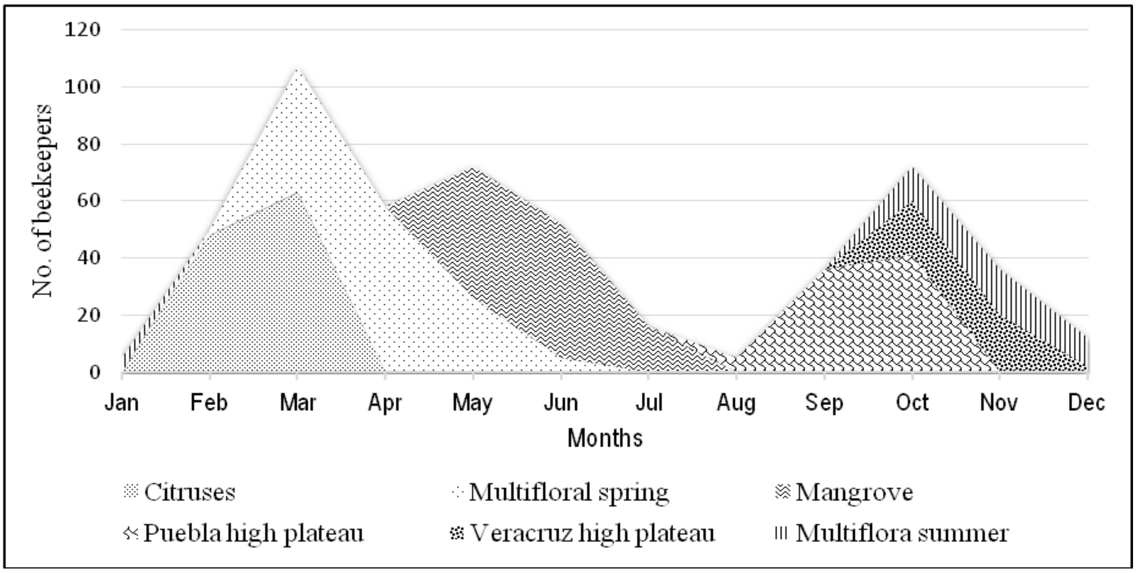

Figure 1. *Temporality of blooms available in the beekeeping region of the Gulf of Mexico, based on the percentage of beekeepers*

Results and Discussion

Mobility of the melliferous flora

Based on the projection model, it was found that the cultivated citrus species (*C. sinensis* and *C. paradisi*) showed a reduced area with high potential in the short (57.6%), medium (70.1%) and long term (75.2%). The replacement of the area with high potential, by areas with characteristics of medium potential, reflected that the predictions of the simulation model for these species are negative. However, by being

DOI: http://dx.doi.org/10.15666/aeer/1504_163175

cultivated species, the impacts could be cushioned by human actions rather than by any response mechanisms they may have (*Table 1*).

Table 1. *Percentage change in the melliferous flora area at temporal scale*

		Level of change			
Period	**Indicator species**	**High**	**Trend**	**Medium**	**Trend**
Short term	Citruses	-57.6	↓	56.6	↑
(2021-2030)	*B. simaruba*	4.7	↑	-8.2	↓
	C. arabica	2.1	↑	8.3	↑
	Mangrove	0.0	=	0.0	
	B. nigra	-4.1	↓	0.9	↑
	S. mombin	12.0	↑	-12.4	↓
Medium term	Citruses	-70.6	↓	69.4	↑
(2041-2050)	*B. simaruba*	5.1	↑	-7.9	↓
	C. arabica		↑	-4.1	↓
	Mangrove	0.0	=	0.0	
	B. nigra	-3.3	↓	0.7	↑
	S. mombin	13.6	↑	-14.1	↓
Long term	Citruses	-75.2	↓	73.9	↑
(2051-2060	*B. simaruba*	5.0	↑	-8.0	↓
	C. arabica	-1.9	↓	-11.6	↓
	Mangrove	0.0	=	0.0	
	B. nigra	-3.0	↓	0.6	↑
	S. mombin	4.0	↑	-4.2	↓

The sign (-) indicates reduction in area percentage value.

The citrus species involved in transhumant beekeeping are cash crops where production depends on characteristics such as technical handling, input and management, technological efficiency, soil, pests and diseases, productivity per tree and per hectare, management requirements, shipping costs and logistics (Neves et al., 2012).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_163175

Thus, impacts caused by climatic variations that jeopardize production are only determined by the geographical and temporal location of these crops (Rosenzweig et al., 1996), so that climate change will exacerbate their spatial distribution problems (Fitchett et al., 2014).

For its part, *C. arabica* (coffee) is another cultivated indicator melliferous species that improves its production yields due to the presence of bees (Saturni et al., 2016). In this regard it was observed that in the short and medium term, the development area with high potential showed an increase of only 2.1 and 2.0%, respectively, compared to the current potential area, but in the long term it had a reduction of 1.9% with respect to the current area values. Therefore, the variation between one period and another did not allow demarcating a positive or negative spatial trend (*Table 1*).

Although *C. arabica* showed a lower reduction percentage in the area with high productive potential, it coincides with reports from the Southern Sudan in Africa, where the loss of optimum area for coffee cultivation, under the A2A scenario, is up to 68%. However, in contrast to the results of the model used in this study, the area of intermediate potential is reduced by 11.6%, whereas in Africa this area increases by 95% until the 2080s (Davis et al., 2012).

While the change in projected areas is greater in that reported by Davis et al. (2012), the reduction in the area with optimum conditions for coffee cultivation is confirmed in this study and the percentage difference between the two can be attributed to geographic factors and the structure and approach of the type of climatic modeling used (Zhang et al., 2015).

For the species *B. nigra*, the projection model showed a negative impact for the area with high development potential, with a 3% reduction in relation to the current area from the short to the long term (*Table 1*).

For their part, the mangrove species (*A. germinans* and *R. mangle*) showed no spatial changes in areas with high productive potential, so based on the A2 scenario these plant communities will not undergo changes (*Table 1*). However, the IPCC predicts that coastal systems will experience adverse impacts from inundation, flooding and coastal erosion, which can lead to a loss of area suitable for the development of these species (IPCC, 2014). Because they are bio-complex systems that involve changes in the relative increase in sea level, temperature and soil chemical conditions, mangrove ecosystems require a comprehensive approach to ecosystem management to understand their operation and the effects that climate change entails (Yañez-Arancibia et al., 2014, Day et al., 2008).

One hypothesis is that these ecosystems could benefit by undergoing a spatial and temporal expansion due to the effects of climate change, based on a possible tropicalization of the Gulf of Mexico (Yañez-Arancibia et al., 2014) excluding the impacts mentioned, as well as those generated by demographic, economic and urban growth that put the structure, composition, function and distribution of these ecosystems at risk (IPCC, 2014, Yañez-Arancibia et al., 2014).

The species that expanded their development areas were those that make up part of the wild vegetation, *B. simaruba* and *S. mombin*, as part of the spring and autumn flowering. In both species the climate projection model predicts a positive impact in the short, medium and long term, increasing the development area with high potential by 5% for *B. simaruba* and 4% for *S. mombin*, with respect to the current area.

The amplitude of intervals in the edaphoclimatic development characteristics of the species gave them greater tolerance to the changes that the model projects, which is why

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_163175

an increase in the development area in comparison with the cultivated species is predicted. However, according to the fifth IPCC report (2014), tree mortality and forest decline due to rising temperatures will increase in different regions, jeopardizing carbon storage, biodiversity, timber production, water quality and aesthetic value.

Therefore, whether there is an increase or reduction in the development area of the indicator species as a consequence of global warming will be subject to the dispersion ability of each species, based on its edaphoclimatic characteristics, tolerance intervals and associated fauna. As a result, spatial mobility will be different for each type of species or set of plant populations (Yañez-Arancibia et al., 2014).

Thermal comfort of A. mellifera

It was found that the space projected with optimum comfort conditions for bee (*A. mellifera*) development increased. Based on the thermal factor, the high potential development area showed an expansion in spatial distribution of 19% in the short term, 23.40% in the medium term and 25.4% in the long term, while the medium potential area decreased by 32.6% in the short term, 40.9% in the medium term and 45% in the long term, which indicates an increase in the geographical distribution, as a consequence of the variations in temperature that climate change entails in the A2 scenario**.**

These results confirm that temperature is one of the main determinants of the ecological role played by species (Hildrew et al., 2017) and biogeographical distribution (Jeffree and Jeffree, 1994, Bravo et al., 2011). Therefore, the amplitude of the geographical space for the bee (*A. mellifera*) predicts that it will favor the expansion in the current limits of areas with thermal comfort. As has been reported for other insects, bees will have a clear spatial mobility (Regniere, 2009; Kiritani, 2013). However, landscape modification and extensive agriculture are constant risk factors that promote the fragmentation of suitable habitats for beekeeping (Burkle et al., 2013) (*Table 2*).

Table 2. *Percentage change in thermal comfort area for A. mellifera from short to long term*

Potential/period	Short	Trend	Medium	Trend	Long	Trend
High	19.0	↑	23.4	↑	25.4	↑
Medium	-32.6	↓	-40.9	↓	-45.0	↓

The sign (-) indicates reduction in area percentage value.

Spatio-temporal mobility of beekeeping areas

With the intersects, the area with optimum thermal comfort for bees and optimum development potential for melliferous plants in each type of flowering was projected.

In the citrus species (*C. sinesis* and *C. paradisi*), negative changes were observed due to a 57.6% loss of spatial distribution in the optimum area for beekeeping development from the short (2021-2030) to the long term (2051-2060), as well as in the species *S. mombin*, which showed a 12% reduction in distribution for the same period (*Table 3*) (*Figure 2*).

	B. simaruba	12.3	↑	-100.0	↓	16.0	↑	-57.6	↓
	C. arabica	683.2	↑	-70.9	↓	37.6	↑	-16.1	↓
	Mangrove	1.0	=	--------	--	--------	--	--------	--
	B. nigra	9266.0	↑	41.4	↑	18514.0	↑	-16.9	↓
	S. mombin	-12.0	↓	--------	--	51.0	↑	-52.0	↓

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_163175

Medium term	Citruses	-70.6	↓	--------	--	163.5	↑	-91.9	↓
	B. simaruba	13.0	↑	-99.6	↓	21.9	↑	-68.1	↓
	C. arabica	835.3	↑	-87.3	↓	29.3	↑	-31.9	↓
	Mangrove	1.0	=	--------	--	--------	--	--------	--
	B. nigra	9332.9	↑	42.5	↑	28946.0	↑	-29.7	↓
	S. mombin	14.0	↑	--------	--	66.0	↑	-65.0	↓
Long term	Citruses	-75.2	↓	--------	--	-172.8	↓	-95.7	↓
	B. simaruba	13.0	↑	-99.4	↓	-24.2	↓	-72.6	↓
	C. arabica	850.2	↑	-93.3	↓	24.3	↑	-41.4	↓
	Mangrove	-2.0	↓	--------	--	--------	--	--------	--
	B. nigra	9430.1	↑	42.5	↑	35056.0	↑	-37.1	↓
	S. mombin	4.0	↑	--------	--	101.0	↑	-70.0	↓

By contrast, the projections for the species that are expected to broaden their spatial distribution due to an increase in the optimum development area for beekeeping from the short to the long term were the association of the bee with *B. simaruba*, *B. nigra*, and *C. arabica*, showing an expansion in area of the region suitable for bee development (*Table 3*) (*Figure 2*).

For their part, mangrove species (*A. germinans* and *R. mangle*) showed no changes in development area, maintaining the current area in the apicultural zones of the region in the three projected time periods. Therefore, the model does not foresee significant changes in beekeeping in these ecosystems due to the climatic variants (*Figure 2*).

Beekeeping is an activity that is established on the basis of available flowering, which is considered as one of the main elements in the industry (Khabbach et al., 2013, Al-Ghamdi et al., 2016). In this research it was observed that the distribution of apicultural zones with high potential for the insect and melliferous plants was not defined by any specific characteristic. However, the negative trend in citrus areas entailed by an average 1.9 °C temperature increase up to the long term (2051-2060) is a result of the effect of climate change.

This confirms what has been found in other studies (Delgado et al., 2012, Davis et al., 2012, Le Conte and Navajas, 2008, Redi et al., 2012, Lehébel-Péron et al., 2016) where it has been stated that increases in temperature, precipitation and relative humidity will affect the areas suitable for apicultural development, from phenological time-shifts to landscape modification, influencing the volume of production.

Because *A. mellifera* is generalist, it is believed that it may modify its foraging behavior in relation to the type of vegetation present (Gaines-Day and Gratton, 2016), since the intensity of visits is varied among the heterogenous blooms of the natural habitat, compared to crop blooms (Saturni et al., 2016).

The results of reclassifying the sites allowed confirming that there may be geographical expansion in areas with thermal comfort conditions for bees, congruent with the antecedents that foresee the territorial expansion of insect populations mainly due to the effect of temperature (Musolin and Saulich, 2012, Regniere, 2009, Le Conte and Navajas, 2008, Kiritani, 2013). Therefore, the thermal variations predicted in the A2 climatic scenario, of 1.9 °C up to the 2051-2060 decade in the area (Ruiz et al., 2011), could represent an advantage for the development of bees in the beekeeping

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_163175

region of the Gulf of Mexico and contribute to a greater number of areas that offer comfortable thermal development conditions for the bee.

It is thus expected that the transhumance routes, used by 91% of the beekeepers (Castellanos-Potenciano et al., 2015) in this apicultural region, will have a spatial and temporal mobility as a consequence of the changes in potential development areas, since climate fluctuations influence the availability of botanical resources (Medina-Cuéllar et al., 2014); however, the background of landscape modification, extensive agriculture and fragmented and deteriorated ecosystems where beekeeping is currently established (Burkle et al., 2013, Lehébel-Péron et al., 2016, Redi et al., 2012) continue to put this activity at risk.

Conclusion

In the short (2021-2030) medium (2041-2050) and long term (2051-2060), the indicator melliferous flora of the center of the state of Veracruz along the Gulf of Mexico will have a different spatio-temporal mobility, due to changes in temperature and precipitation as a result of climate change.

On the other hand, the current thermal comfort zone of *A. mellifera* L. in the region will have an expanded territory and the spatio-temporal mobility will be positive in the short, medium and long term as a result of temperature change due to the effect of climate change, which will manifest itself in optimum honeybee development.

Based on the intersects, it was concluded that apiculture will have a varied spatio-temporal mobility in the short, medium and long term according to the availability of botanical resources and the thermal comfort of the bees, since according to the characteristics of each species, there will be a reduced territory for citrus species, linked to a negative impact on the high potential development area. On the other hand, the other six species will have an expanded territory that will result in a positive impact for the apicultural development of the region, as a function of the climatic characteristics.

Under the future scenario of beekeeping in this area, there will be an increase in the optimum area for honey production, due to the effect of climate change (temperature and precipitation) on spatio-temporal scales. It is therefore recommended that future research include new IPCC climate projection scenarios, the variation in floral phenology, the genetic adaptation potential of *A. mellifera* races and historical honey production volumes, as well as consider other climatic variables such as radiation and the chemical composition of the atmosphere.

(Received 4th Jul 2017; accepted 26th Sep 2017)

Abstract. In Brazil, a high number of woody species have been used for forest restoration plantings. However, this action is widely questionable due to the no re-establishment of a considered “normal” successional trajectory. In this study, we analyzed subtropical rainforest natural regeneration at abandoned pastures and we showed that vegetation is characterized, predominantly, by few high dominant native woody species, highlighting especially *Vernonanthura discolor* (Asteraceae), *Myrsine coriacea* (Primulaceae), and *Piptocarpha regnellii* (Asteraceae). Our results also indicate that these high dominance species favor the lowest diversity of natural regeneration. In this regard, we suggest implementing actions that provide improvements and facilitate natural processes of ecological succession by planting dominant native woody species. This takes into consideration the re-establishment of a considered “normal” successional trajectory.
Keywords: *forest regeneration; “normal” successional trajectory; dominant species; species diversity; CSR ecological strategies*

Introduction

The subtropical forests are exposed to a continuous degradation process, due to anthropic landscapes changes (Ribeiro et al., 2009; Vibrans et al., 2013a). These landscapes are mainly pastures mosaics, crops and urban areas fringed by small forest patches (Tabarelli et al., 2010). The forests conversion into cattle raising pastures is known for reducing biological diversity, interrupting the ecological processes (Tinoco-Ojanguren et al., 2013), and also reducing water infiltration into the soil due to soil compaction by animals trampling, what increases superficial runoff and soil erosion (Kunz et al., 2013). In these areas, natural regeneration of native species is limited by a variety of processes coming from the conversion forest–pasture, including land degradation (Holl and Aide, 2011), unfavorable microclimate (Pröll et al., 2015), lower seed dispersion (Reid et al., 2015) and competition from invasive exotic species (Mantoani and Torezan, 2016).

There are ~177.282,00 km² of potential areas for forest restoration in Brazil (Rodrigues et al., 2011). These areas are generally situated in highly fragmented forest regions and present low agricultural potential due to massive livestock farming (Rodrigues et al., 2009). Such as in other Brazilian regions, Santa Catarina Atlantic

DOI: http://dx.doi.org/10.15666/aeer/1504_16331676

Forest is composed of secondary forest physiognomy with different regeneration stages, being rare the remaining with primary forests (Reis et al., 1992). The whole area has suffered destructive extractivism and disorderly soil occupation for agriculture and livestock expansion (Vibrans et al., 2013b). Although, secondary forests are important for global biological diversity conservation (Gibson et al., 2011), in Southern Brazil there are few studies on species diversity of natural regeneration at the secondary succession process of subtropical forests (Meyer et al., 2013; Fiorentin et al., 2015).

If we understand the secondary succession process of abandoned pastures and priority areas indicated for restoration in Brazil (see Rodrigues et al., 2011; Brasil, 2012; 2017), we can show potential species to be used in the forest regeneration projects (Martins, 2013; Maçaneiro et al., 2016a; Mota et al., 2017; Turchetto et al., 2017). For example, species that colonize abandoned pastures are typical from disturbed environments, once they frequently occur in open areas (such as clearings) or, on the edge of forests, where environmental conditions are unfavorable for most of the demanding plants (Chazdon and Guariguata, 2016). Besides this, those species are adapted to local environmental conditions, characterizing native regeneration vegetation in the initial stages and, therefore, being recommended for use on subtropical forests restoration (Kageyama and Reis, 1993; Meli et al., 2014; Mota et al., 2017).

Heliophytic and light demanding plants are among the species prepared to take place at abandoned pastures (Chazdon, 2008; Cheung et al., 2009). They are highly adapted to unfavorable microclimate conditions (higher light levels) and degraded soil (compacted and low in nutrients) (Holl and Aide, 2011). These species are also often described as single-dominants or monodominants (see Connell and Lowman, 1989; Hart et al., 1989), since they occur in large numbers, have relative density or relative dominance between 50-100%, and dominate the forest canopy. Some studies were developed in Santa Catarina with the purpose to understand both the natural regeneration composition and structure of the Atlantic Forest (see Schorn and Galvão, 2009; Siminski, 2009; Meyer et al., 2013; Fiorentin et al., 2015; Higuchi et al., 2015; Maçaneiro et al., 2016a). Those studies verified that successional trajectories vary in function of the land use and the anthropic history. Although its descriptive content focus, those researches contribute to meta-analysis studies and also serves as basis for forest restoration projects in similar areas (Mota et al., 2017; Turchetto et al., 2017). However, none of these studies emphasized the relationship between natural regeneration dominant species and diversity in abandoned pastures.

The use of a large number of woody species in plantations for forest regeneration purpose is a widely questionable action, although it is a traditional practice in Brazil (Naeem, 2006; Wright et al., 2009; Durigan et al., 2010; Durigan and Engel, 2015). For instance, a degraded ecosystem is a highly organizaded system opened to matter and energy flows, with dissipative structure, presenting internal (among the system components) and external interactions (with the landscape) (Aumond and Maçaneiro, 2014). In this context, the answer for how many species would be necessary in order to have a stable community and a functional ecosystem must take into account how a considered "normal" successional trajectory re-establishment happens (see Suding and Gross, 2006; Naeem, 2006; Durigan and Engel, 2015). Furthermore, there are few woody species that seems to dominate at the beginning of forest succession of the subtropical forests (see Klein, 1980; Schorn and Galvão, 2009; Siminski, 2009; Meyer et al., 2013). In this regard, the aim of this study was to analyze natural regeneration woody species composition, structure, diversity, and abundance at abandoned pastures

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_16331676

in order to respond tree key issues: (1) How many and which are the species growing at a four-year abandoned pasture? The pasture mentioned was used by cattle raising for more than a half century. (2) Do distribution abundance patterns of the natural regeneration woody species present important implications to the choice of new species for forest restoration projects?

Material and Methods

Study area

The study area is inserted in Faxinal do Bepe locality, Serra do Itajaí National Park, state of Santa Catarina, Southern Brazil. The area is within the limits of Itajaí river watershed, being the river Warnow a sub-watershed. Faxinal do Bepe has a total area of ~250 ha, altitude which varies of 700 to 1,039 m s.n.m. and is located between 27°05' - 27°07' S e 49°11' - 49º13' W (*Figure 1*).

The climate is Cfa - humid subtropical climate, without dry season and with hot summer (Alvares et al., 2014). The average annual temperature range between 16-18 °C, with temperature average monthly varying between 12-14 °C in the coldest month (July) and 20-23 ºC in the warmer months (January and February). The annual relative humidity varies between 82-84% and the total annual rainfall is between 1,500-1,700 mm well distributed during the year (Pandolfo et al., 2002).

The predominant vegetation is Subtropical Upper Hills Broadleaved Evergreen Rainforest (*sensu* Oliveira-Filho, 2015), hereafter referred to as Subtropical Rainforest, inserted at Atlantic Forest Domain. Regarding the natural resources historical use, after the year 1953, it has initiated the colonization and occupation process at Faxinal do Bepe, that lasted until 2004. At that period, large part of the forests were submitted to selective logging and posterior conversion to vast pasture areas that, currently, are found abandoned and at an initial regeneration stage.

Data collection

We selected three four-year abandoned pastures which were at an initial regeneration stage (*Figures 1 and 2*). Each area was constituted by a slope with the same historical use. We used plots arranged in transects (Soares et al., 2012), to represent the possible greatest variation throughout the three areas with abandoned pastures. At each area we distributed, systematically, 15 sample plots of 10 x 20 m (200 m²), corresponding to 3,000 m² sampling area and making up 20% of the total studied. We disposed these sample plots in three transects, all of them starting at the base of the slope and ending at the top of the slope. We distanced these sample plots approximately 25 m each other and 35 m from the transects. At each sample plot we sampled the upper layer, characterized by live individuals with diameter at breast height (DBH) ≥ 5 cm. Inside each sample plot we inserted a 10 x 10 m (100 m²) subplot, to sample lower layer, characterized by individuals with height ≥ 50 cm and DBH < 5 cm.

We identified botanical material collected by comparison with exsiccates deposited at the Dr. Roberto Miguel Klein Herbarium of Fundação Universidade Regional de Blumenau (FURB) and, also, through taxonomic literature and FURB experts consultation. We used the species classification system proposed by APG IV (2016) and PPG I (2016).

Data analysis

We calculated, for upper layer, Mueller-Dombois and Ellenberg (2002) structural parameters, in other words, density, dominance and frequency absolute and relative, and importance value for each species. For lower layer, besides the parameter described above, we calculated absolute and relative height classes and the natural regeneration importance value for each species (Hosokawa et al.,

APPLIED ECOLOGY AND ENVIRONMENTAL RESEARCH 15(4):1633-1676.
http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_16331676

2008). Afterward, we classified these species by CRS ecological strategy (see Grime et al., 1997), adopting the methodology suggested by Pierce et al. (2013) into the following categories: C – competitor specie with high potential growth rate and rapidly biomass expanding; S – stress-tolerant specie and slow-growing; R – ruderal specie with premature reproduction for prolonged period.

We verified species abundance distribution patterns (PDSA) of the natural regeneration by Whittaker diagram (Magurran, 2004). Similarities or differences between PDSA layers analyzed were verified by Kolmogorov-Smirnov test for two sample plots, at the significance level $\alpha = 0.01$ (Sokal and Rohlf, 2011). The Whittaker diagram is considered a useful tool to analyze species PSDA into plant communities, once contrasting patterns between species richness and vegetation uniformity can be clearly observed (Krebs, 2014; Maçaneiro et al., 2016b).

We estimated the vegetation heterogeneity (Krebs, 2014) by Shannon index (*H*', Napier's logarithms) and Simpson index (1-*D*). Afterwards, we converted these indexes to the effective number of species – ENS (see Jost, 2006) by the following expressions: Shannon index = exp(*H*') and Simpson index = 1/(1-(1-*D*)). Indexes *H*' and 1-*D* conversion into real diversity (effective number of species) giving it a set of common behaviors and properties, easily interpretable. After this conversion, the diversity is always measured as species number, regardless of the index used (Jost, 2010). Additionally, we used Pearson correlation coefficient and scatterplots to verify the relationship between the diversity and abundance of dominant woody species at the layers. First, we correlated relative density (*DR%*) of the specie with the greatest individual number of each sample plot with its respective *H*' e 1-*D* converted into ENS. Next, we investigated the statistical significance ($\alpha = 0.01$) of the correlations through *t* test for correlation existence (Zar, 2010). Finally, we constructed dispersion graphics between diversity evidences (axis y) and *DR%* (axis x), and inserted a linear trend line for the relation between *H*' and *DR%*, and 1-*D* and *DR%* , both converted into ENS.

Results

We sampled 1,079 individuals belonging to 45 woody species *(Table 1)* in both layers. The natural regeneration presented 497.8 ind.ha^{-1} and monodominance of *Vernonanthura discolor* (*DR* > 50%), in the upper layer. Besides *Vernonanthura discolor*, *Piptocarpha regnellii*, *Piptocarpha axillaris*, *Myrsine coriacea* and *Piptocarpha angustifolia* (*VI* = 266.2%) also characterize the upper layer.

In the lower layer, we found density of 1,402.2 ind.ha^{-1} and the mains species that characterized the vegetation structure were *Vernonanthura discolor*, *Myrsine coriacea*, *Clethra scabra*, *Piptocarpha regnellii* and *Piptocarpha axillaris* (*RNR* = 186.2%). Similar to what was found on the upper layer, *Vernonanthura discolor*, *Myrsine coriacea*, *Piptocarpha regnellii* and *Piptocarpha axillaris* also were the main species at the lower layer (*Table 1*).

We observed that woody species presented different ecological regeneration strategies (*Table 1*). However, competitors and stress tolerant plants (S/SC) were predominant at the analyzed layers (upper layer = 64.4%; lower layer = 70.5%).

Differences between vegetation layers are particularly visible at the community structure (*Figure 3*). We verified PDSA significantly different throughout the analyzed layers (Kolmogorov-Smirnov, D = 0.68; p < 0.01). However, Whittaker diagram showed that natural regeneration is characterized by few high dominant woody species, highlighting *Vernonanthura discolor*, *Myrsine coriacea* and *Piptocarpha regnellii*.

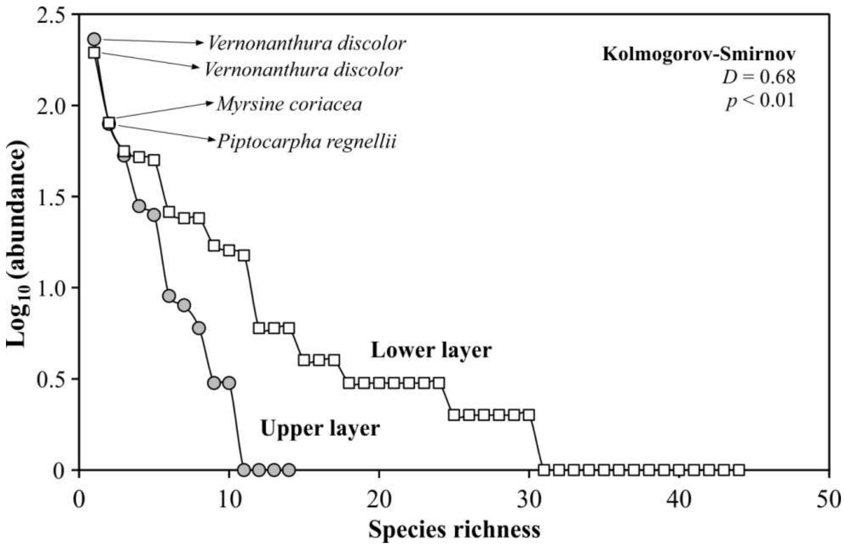

***Figure 3**. Whittaker diagram for two layers of natural regeneration of a Subtropical Rainforest in Southern Brazil.*

We found highly significant correlations (Pearson, r > -0.79; p < 0.01) between diversity index (Shannon and Simpson) and relative density of the mostly abundant woody species at the sample plots analyzed (*Table 2, Figure 4*).

***Table 2**. Pearson coefficient correlation (r) between diversity indexes and relative density of the most abundant woody specie at the sample plots in two layers of natural regeneration of a Subtropical Rainforest in Southern Brazil.*

Diversity index	ENS	R^2	r	p
Upper layer				
Shannon	4.78	0.62	-0.79	<0.0001
Simpson	3.16	0.79	-0.89	<0.0001
Lower layer				
Shannon	13.00	0.68	-0.82	<0.0001
Simpson	7.21	0.78	-0.88	<0.0001

ENS = effective number of species.

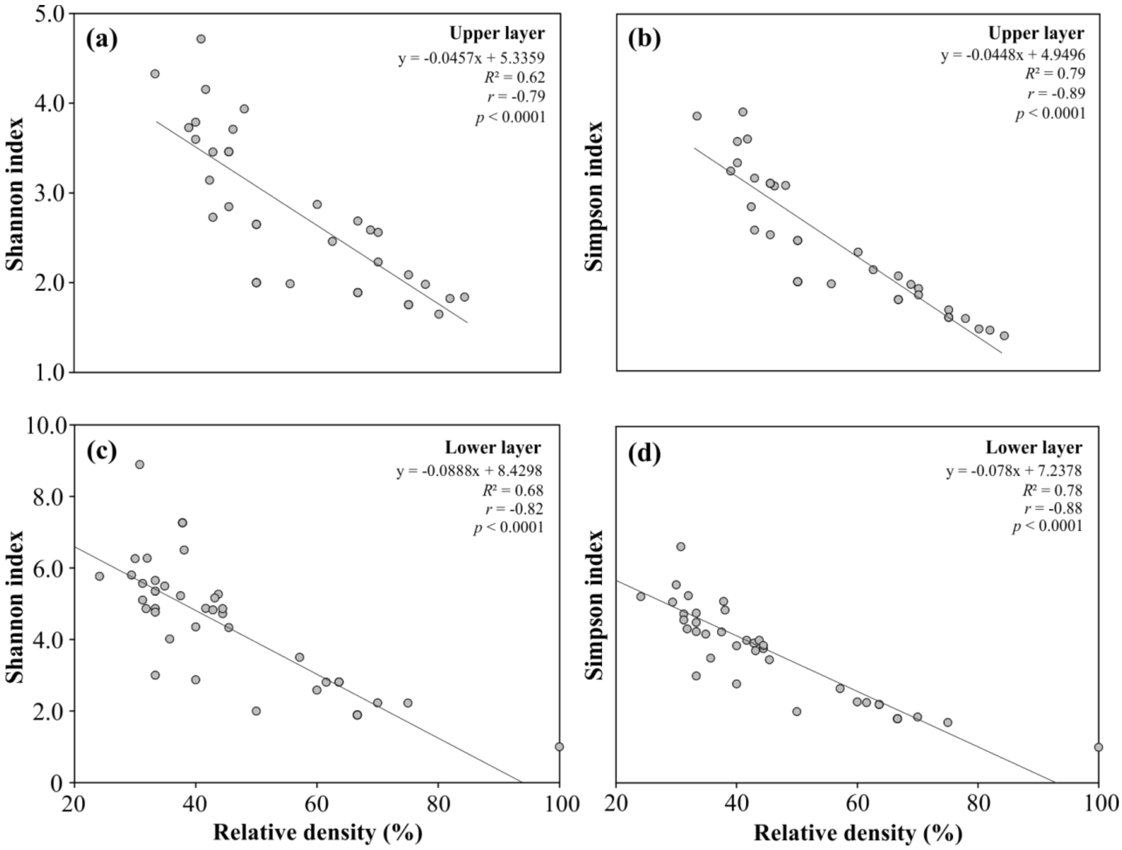

***Figure 4**. Relation between diversity indexes and relative density of the most abundant woody species on upper layer (a, b) and lower (c, d). Each point represents one of 45 sample plots of the natural regeneration of a Subtropical Rainforest in Southern Brazil.*

Discussion

Our study revealed that natural regeneration of Subtropical Rainforest at abandoned pastures is characterized by few highly dominant woody species. These species have specific ecological strategies as stress physiological tolerance and competitive capacity for resources. The ecological strategies of native species are closely related to the successional process (Munoz et al., 2016), where the temporal changes of colonizers and locally persistent and more demanding species are observed at the forest ecosystem affected by a disruption (for example, clearings). In this context, ecological succession

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_16331676

benefit species with physiological tolerance to stress or with competitive capacity (Caccianiga et al., 2006). Furthermore, the environmental type where the plants are subjected (for example, plains and slopes) can also influence changes at ecological strategies that species have among forest succession. For example, Navas et al. (2010) verified changes between ruderal plants to competitor plants at not stressful ambient and where vital resources are unlimited, whereas at stressful environments and with limited resources ruderal plants tend to be replaced by stress tolerant plants. At the present study, components connected to geomorphology (relief, slope, elevation) and pedology (soil types, water availability) might possibly be acting as environmental filters, as at an environmental gradient relief and soil conditions vary among the slope, enabling influence plants ecological strategies (Thuiller, 2013; Maçaneiro et al., 2016c; Munoz et al., 2016).

Dominant native woody species are common in stressful environments (Peh et al., 2011; Nascimento et al., 2015), like initial successional stage in tropical (Morais et al., 2013) and subtropical rainforests (Klein, 1980; Schorn and Galvão, 2009; Siminski, 2009; Meyer et al., 2013). For example, Steege et al. (2013) determined that Amazon watershed is represented by 16,000 woody species, but that only 227 (1.4%) represent half of all registered woody species. In secondary forests in the initial succession stage, dominant woody species generally are the first plants to grow due to its rapid growth and strong adaptation to local conditions, may formatting dense groupings that characterize young forests canopy (Klein, 1980; 1984; Kageyama and Reis, 1993; Chazdon, 2008; Schorn and Galvão, 2009; Chazdon, 2014; Chazdon and Guariguata, 2016). The establishment of these species during the forest regeneration also contributes to ecosystem resiliency, since they bring mutualist species that generate greater heterogeneity and diversity (Howe, 2016; McAlpine et al., 2016). These species form small patches that provides favorable microclimate for more demanding species grow (Scervino and Torezan, 2015) and attracts seeds dispersing agents, which provides improvement on soil conditions and facilitate forest regeneration (Bechara et al., 2016). Therefore, dominant native woody species generally occur in the initial succession stage of subtropical rainforest and are beneficial for forest regeneration, as observed on this study.

We verified that highly dominant woody species generate lowest natural regeneration diversity, especially on upper layer. In subtropical rainforests, the species located on the upper layer act as environmental filters for those species in lower layer species (see Carvalho et al., 2016; Boukili and Chazdon, 2017). These studies showed that some regenerating woody species are favored by mature species and that the future forest structure is related to the environmental filters. Beyond species, several biotic and abiotic factors act as environmental filters (for example, seeds dispersal, seedlings competition with exotic grasses, predation and germination seedlings, soil chemical and physical characteristics, decaying tree trunks, luminous intensity, herbivory etc), which selected or exclude determined woody species at biological communities (Holl, 2000; Christie and Armesto, 2003; Lortie et al., 2004; Chazdon, 2014; Reid et al., 2015; Chazdon and Guariguata, 2016). However, these environmental filters can help to understand what processes maintain biological diversity and explaining species distribution among environmental gradients (Elith and Leathwick, 2009; Lewis et al., 2014; Maçaneiro et al., 2016c).

Besides that, convert the natural regeneration in a true diversity (effective number of species) will depend on the uniformity vegetation level or on the diversity index

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_16331676

applied. Considering the characteristics of diversity index in relation to rare species (Magurran, 2004; Jost, 2006; Melo, 2008; Buckland et al., 2011), our study presented that Shannon and Simpson's index are strongly influenced by dominant species. This issue is important when considering the woody species selection for subtropical rainforests regeneration projects, once at the present Brazil suffers with lack environmental legislation and also technical/scientific consistent criteria for species recommendation, leading many projects to use high diversity of species in the forest restoration plantings, what is widely questionable (Naeem, 2006; Wright et al., 2009; Durigan et al., 2010). Our results show that few species can establish themselves in an explored environment by more than half century of intensive use. In this context, implementing actions that provide improvements and facilitate the ecological natural succession processes through dominant native woody species with high density of seedlings are important for the initial stages of subtropical rainforests restauration, since it considers basic principles of "normal" ecological succession (see Suding and Gross, 2006; Naeem, 2006; Durigan and Engel, 2015), besides being an initiative much more affordable, enabling smallholder farmers to restore degraded pastures.

In Neotropical forest restorations, multiple techniques have been used for ecosystem reconstruction with the maximum biodiversity possible, especially planting a high diversity woody species (Rodrigues et al., 2009; Martins, 2013; Bechara et al., 2016; Chazdon and Guariguata, 2016). However, generally the diversity of native species available in tree seedlings nurseries is limited and determined by availability of regional fruits and seeds (Palma and Laurence, 2015; Turchetto et al., 2017). In this study, we observed that some of the most important species are common in all vegetation layers, presenting potential for restoration plantings, especially on open areas as new abandoned pastures, since the are species tolerant to stress and competitors for resources (for example, *Vernonanthura discolor*, *Myrsine coriacea*, *Piptocarpha regnellii*, *Piptocarpha axillaris*, *Piptocarpha angustifolia*, *Clethra scabra* and *Symphyopappus itatiayensis*). Another combination of species that we observed occurs only on low layer, presenting potential for restoration plantings in order to enrichment, at abandoned pasture areas in succession advanced stages (for example, *Ficus luschnathiana*, *Campomanesia guaviroba*, *Inga vera* subsp. *affinis*, *Myrcia splendens*, *Syagrus romanzoffiana*, *Miconia cabucu* and *Alchornea triplinervia*, among several others). Thus, due to structure importance and ecological strategies that these species have in Southern Brazil Subtropical Rainforest natural regeneration, we recommend preferentially this species (or this kind of species) for restoration plantings at abandoned pastures.

In this study, we indicate evidences about how the high dominance of some species (for example, *Vernonanthura discolor*, *Piptocarpha regnellii* and *Myrsine coriacea*) favor the lowest diversity of natural regeneration. However, this standard must be seen as facilitator of forest restoration, once these species presents huge adaptation to local conditions and provide the biggest soil cover and improvement in environmental conditions for more exigent new woody species colonization. These results encourage a further analysis about how these species contribute ecologically for abandoned pastures restorations. Therefore, we suggest the addition of species functional attributes in new vegetation studies, since additional information about ecological strategies of dominant woody species may indicate standards that accelerates the ecological successional process of subtropical rainforests.

APPENDIX

Appendix 1. *Basic field data 1: species found in upper layer*

Sample plot	Individual	Species	DBH (cm)	Height (m)
PO1	1	Piptocarpha axillaris (Less.) Baker	6,05	2,5
PO1	2	Vernonanthura discolor (Spreng.) H.Rob.	4,93	2,5
PO1	3	Vernonanthura discolor (Spreng.) H.Rob.	4,97	3
PO1	3	Vernonanthura discolor (Spreng.) H.Rob.	5,54	3
PO1	3	Vernonanthura discolor (Spreng.) H.Rob.	5,41	3
PO2	1	Piptocarpha regnellii (Sch.Bip.) Cabrera	5,41	3
PO2	1	Piptocarpha regnellii (Sch.Bip.) Cabrera	4,77	3
PO2	2	Vernonanthura discolor (Spreng.) H.Rob.	6,68	4
PO2	2	Vernonanthura discolor (Spreng.) H.Rob.	4,62	4
PO2	3	Vernonanthura discolor (Spreng.) H.Rob.	9,45	5
PO2	3	Vernonanthura discolor (Spreng.) H.Rob.	7,86	5
PO2	4	Vernonanthura discolor (Spreng.) H.Rob.	6,24	2,5
PO3	1	Piptocarpha regnellii (Sch.Bip.) Cabrera	5,25	2,5
PO3	2	Vernonanthura discolor (Spreng.) H.Rob.	5,25	3
PO4	1	Piptocarpha regnellii (Sch.Bip.) Cabrera	5,57	3
PO4	2	Piptocarpha axillaris (Less.) Baker	5,09	3
PO4	3	Vernonanthura discolor (Spreng.) H.Rob.	5,41	3
PO4	4	Vernonanthura discolor (Spreng.) H.Rob.	4,77	3,5
PO4	5	Piptocarpha angustifolia Dusén ex Malme	5,09	2,5
PO5	1	Piptocarpha angustifolia Dusén ex Malme	8,05	3
PO5	2	Piptocarpha axillaris (Less.) Baker	5,89	3
PO5	3	Piptocarpha axillaris (Less.) Baker	6,53	3,5
PO5	4	Vernonanthura discolor (Spreng.) H.Rob.	4,93	3
PO5	5	Vernonanthura discolor (Spreng.) H.Rob.	4,93	3
PO5	6	Piptocarpha regnellii (Sch.Bip.) Cabrera	4,93	3
PO5	7	Piptocarpha angustifolia Dusén ex Malme	5,73	3
PO5	8	Piptocarpha angustifolia Dusén ex Malme	5,19	2,5
PO5	9	Piptocarpha angustifolia Dusén ex Malme	5,19	3
PO5	10	Piptocarpha angustifolia Dusén ex Malme	5,09	3
PO5	11	Vernonanthura discolor (Spreng.) H.Rob.	6,05	3,5
PO5	11	Vernonanthura discolor (Spreng.) H.Rob.	5,25	3,5
PO5	11	Vernonanthura discolor (Spreng.) H.Rob.	5,57	3,5
PO6	1	Vernonanthura discolor (Spreng.) H.Rob.	4,77	2,5
PO6	2	Vernonanthura discolor (Spreng.) H.Rob.	5,89	3,5
PO6	3	Piptocarpha axillaris (Less.) Baker	4,77	3
PO6	4	Piptocarpha angustifolia Dusén ex Malme	6,53	3,5
PO6	4	Piptocarpha angustifolia Dusén ex Malme	4,93	3
PO6	5	Piptocarpha axillaris (Less.) Baker	4,77	3
PO6	6	Piptocarpha angustifolia Dusén ex Malme	4,93	3
PO6	7	Vernonanthura discolor (Spreng.) H.Rob.	4,93	3
PO6	8	Vernonanthura discolor (Spreng.) H.Rob.	5,51	3,5
PO6	9	Piptocarpha axillaris (Less.) Baker	4,90	3
PO6	10	Piptocarpha axillaris (Less.) Baker	4,77	3
PO6	11	Piptocarpha angustifolia Dusén ex Malme	7,54	4,5
PO6	12	Vernonanthura discolor (Spreng.) H.Rob.	7,96	4,5

Abstract. Resolution of plant diversity goals with the agricultural demands placed on grasslands may result in conflict between farmers and conservationists. To investigate options for reconciling these important issues implementable in the short-term within agro-environmental schemes, we analysed the impact of four years' management with grazing replaced by mowing on coordination of agricultural objectives, i.e. herbage yield, plant functional groups, nutrient contents and removal, forage value and plant diversity, i.e. species richness, Shannon-Wiener index, Ellenberg N indicator value. The study was carried out in three hillslope highland pasture sites (S1-S3) in the Šumava Mountains, Czech Republic, differing in soil properties and animal stocking rates, which were 0.92 in S1, 0.34 in S2, combined with mowing in some years and 0.73 in S3 LU ha^{-1}. Some sections of each pasture site were twice yearly mowed. Our findings related to grazing combined or replaced with mowing were relevant to farmers' priorities acceptable for dairy cattle nutrition. Across sites, the herbage dry matter yield, herbage P, K and Mg contents and removal, proportion of graminoids and Ellenberg N values decreased with mowing, but forage value and herbage Ca removal remained identical under both managements. Species richness, Shannon-Wiener index and herbage Ca content increased with mowing via spread of forbs and/or legumes. However, to achieve a merit, short-term grazing exclusion with mowing has to take into account site-specific soil nutrient conditions. Very high soil P availability prevented from the increase in species richness with mowing (S3). Contrarily, in sites with lower soil P availability, but different availability of other nutrients (S1, S2), mowing fostered number and/or proportions of forbs and/or legumes.
Keywords: *grazing, mowing, grassland, available soil nutrients, biodiversity, above-ground biomass*

Introduction

Resolution of plant diversity goals with the agricultural demands placed on grasslands is an important issue of agri-environmental policies (Isselstein et al., 2005). Improvement in plant diversity (species richness and species evenness) is linked with extensive grassland management, which is often accompanied by a decline in agricultural production (Plantureux et al., 2005; Blüthgen et al., 2012). Hence, plant species diversity, forage quality, and biomass production may not correlate, resulting in conflict between farmers and conservationists (Pavlů et al., 2006). To resolve these issues, an effective agro-environment subsidy policy is needed to compensate for production losses. In addition, positive effects of vegetation diversity on production

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_16771695

stability, efficient nutrient and water use, and forage quality may encourage farmers to cooperate (Sanderson et al., 2004; Wrage et al., 2011).

The plant diversity-productivity relationship varies strongly along with site conditions and is integrated in herbage nutrient contents, which reflect plant growth, plant functional composition, land use, and management practices (Klaus et al., 2013a).

Extensive grazing, the predominant farming system in upland and marginal areas, can deliver both economic benefits and increase in grassland biodiversity, reducing the environmental impact of animal production (Marriott et al., 2005; Rose et al., 2012). Plant relations in pastures influence biodiversity responses through both positive (e.g., facilitation, N_2 fixation, hydraulic lift) and negative interactions (e.g., competitive exclusion, allelopathy) (Sanderson et al., 2004). Grazing at a stocking rate (SR) of fewer than 1.5 livestock units (LU) ha^{-1} has the potential to facilitate restoration of sward heterogeneity and thus floral and faunal diversity, by selective defoliation through grazing, treading, nutrient cycling, and propagule dispersal (Zhang et al., 2013; Dubeux et al., 2014; Quan et al., 2015). A variety of vegetation structures can develop regardless soil conditions under the influence of grazing animals and their foraging strategy resulting to structural patterns of short- and high-growing vegetation patches (Gilhaus et al., 2014). Short-growing species with higher fodder values are preferably grazed and, hence, the likelihood of their endozoochorous dispersion is supposed (Gilhaus et al., 2017).

To restore plant diversity in soils with intermediate nutrient content, mowing of grazed pastures has been demonstrated to reduce nutrient availability, especially phosphorus (Isselstein et al., 2005; Blüthgen et al., 2012). Alternating mowing and grazing should promote coexistence of multiple forbs and grasses and balance nutrient limitation (Mládková et al., 2015). Plantureux et al. (2005) considered the combination of an early cut and late grazing as a compromise between quality forage production and biodiversity maintenance for the conditions of Central Europe. A combination of grazing and mowing can also enhance the opportunity for regeneration of seedlings, if a closed canopy exists in grazed plant communities (Plantureux et al., 2005).

Our study was conducted in three highland pasture sites to investigate options for reconciling plant diversity and agronomy targets implementable in the short-term within agro-environmental schemes. We evaluated the effects of four years' mowing as opposed to grazing on agronomic factors and plant diversity parameters. Prior to our research, we hypothesized that i) short-term mowing could improve plant diversity parameters (species richness, Shannon-Wiener index, and Ellenberg N indicator), but ii) eventually deteriorate agronomic objectives (herbage dry matter yield, plant functional groups, herbage nutrient content and removal, tetany ratio, and forage value). However, a complex of site nutrient conditions allow specific adaptations to management changes (Gilhaus and Hölzel, 2016). Hence, we also took into account the applicability of short-term grazing exclusion with mowing to plant diversity improvement related to different soil site conditions and grazing types.

Materials and methods

Study site

The study took place 2011-2014 in Pasečná (48°36'18.0"N; 14°07'12.0"E), an upland, geomorphologically heterogeneous, plateau near the Czech-Austrian border, in the foothills of the Šumava Mountains (*Fig. 1*). Mean altitude of the study site is 822.6 m a.s.l. with range from 781.4 to 882.4 m a.s.l. The region is cool with mean air

temperatures annually and in the growing season of 5.5 °C and 11.2 °C, respectively, and average annual and growing season precipitation of 910 mm and 510 mm, respectively. Parent rock in Pasečná is granite. The soils are predominantly acidic, Haplic to Gleyed Cambisols, and Gleysols with distinct stand-conditioned dissimilarities in soil texture, soil depth, and soil water regime. In 1993, the study area changed from intensive cultivation to pasture. Until 2011, the land was under a rotational pasturing with mean SR of 0.7 LU ha^{-1}, with the lowest SR in S2 due to the combination with occasional mowing.

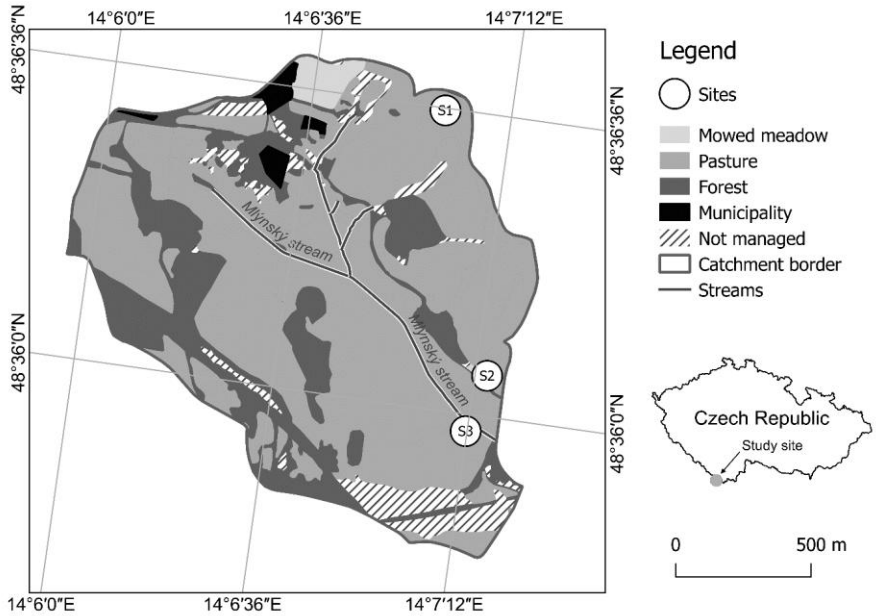

Figure 1. *The catchment in Pasečná; experimental sites S1-S3*

Three experimental sites differing in soil properties and SR (*Table 1*) were selected randomly in hillslope geomorphological zones (recharge – S1, transport – S2, discharge – S3). Site S3 consisted of tile-drained soil.

SR – stocking rate, LU ha^{-1}; TM – twice yearly mowed; SM – spring mowing; AG – autumn grazing; TRG – twice yearly rotational grazing; CG – continuous grazing; N – number of species; G – grasses; L – legumes; F – forbs

Stand-typical plant community was not described for the sites until 2011, but some dominant plants were already obvious (*Table 1*).

The effects of grazing (combined with mowing in S2) and mowing were observed in separate sections of each site from 2011-2014 (*Fig. 1*). Grazing regimes differed among the experimental sites and, in S2 and S3, from year to year (*Table 1*). Mean SR was generally low (0.66 LU ha^{-1}), although in S1, which had the highest SR (0.92 LU ha^{-1}) and the content of available plant nutrients, a heavy cattle load for about three weeks each year considerably damaged the plant cover. Site S2, where grazing was combined with mowing in 2011 and 2014 and replaced with mowing in 2013, had the lowest mean SR at 0.34 LU ha^{-1}. Grazing in S3 was carried out throughout the season with a mean SR of 0.73 LU ha^{-1}.

Mowed areas of 60 m^2 (6x10 m) enclosed by wooden fences were established randomly in each site in spring 2011 to be representative of plant community. Within this area, four 1 m^2 plots were delineated to assess herbage dry matter (DM) yield, weight proportions of functional plant groups, and herbage nutrient content by probability sampling. In addition, a permanent 16 m^2 (4x4 m) plot was delineated for phytosociological monitoring.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_16771695

For monitoring DM yield and herbage properties associated with grazing in S1 and S3 and with the combination of grazing and mowing in S2, four moveable 1 m^3 wire cages were placed randomly on each site in spring prior to the grazing season. Twice yearly, in accordance with mowed areas, the cages were moved several metres and the biomass under the cage was cut. Prior to the cage shift, the above-ground biomass at the new placement area was cut to a similar height of the grazed area. A permanent 16 m^2 plot was also established in grazed areas.

Soil single samples were taken in accordance with herbage samples each year 2012-2014 from soil layers of grazed and mowed sections at 4-8 cm and 10-14 cm depth to analyse pH (KCl), available plant nutrients, and organic matter content (*Table 2*). Available plant nutrient levels extracted using Mehlich III solution were categorized according to Sáňka and Materna (2004) in S1 as good/satisfactory (Ca, Mg), very high/high (K), and good (P). In S2, nutrient levels were satisfactory/low (Ca), low (Mg), low/satisfactory (K), and good/satisfactory (P); and in S3 satisfactory (Ca, Mg), satisfactory/low (K), and very high (P). The organic matter content ranged from good to very high (3.81 % ± s.d. 1.79).

Table 2. *Mean soil pH, available soil nutrient content (P, K, Mg, Ca, N_{min}), organic carbon (C_{org}), and total nitrogen (N_{tot}) content in experimental sites under grazing and mowing from 2012-2014 (sampled simply twice per year at 4-8 and 10-14 cm)*

Herbage biomass sampling

The 1 m^2 plots in both management areas were cut in early June and late September to 5 cm above the soil surface. Herbage was weighed, and proportions (% by weight) of graminoids (*Poaceae, Cyperaceae*, and *Juncaceae* families), legumes, and other forbs, considered functional plant groups, were determined. Herbage was desiccated and dry matter (DM) content determined. Dry matter herbage yield in tons ha^{-1} was calculated for each cut and combined for an annual DM herbage yield. Dried herbage from all 1 m^2 plots was crushed, and 100 g samples were weighed for determination of N, P, K, Ca, and Mg content in g kg^{-1}. Herbage N content was determined by the Kjeldahl method (ISO 11261, 1995). To determine P, K, Ca, and Mg content, samples were digested by nitric and perchloric acid in an open system, and concentrations of the elements in solution were determined spectrophotometrically by continuous flow analyser (P) and atomic absorption spectrometer (K, Ca, and Mg). The tetany ratio [K:(Ca+Mg)] was determined from values of K, Ca, and Mg content converted into milliequivalents per kilogram (Kayser and Isselstein, 2005). Annual N, P, K, Ca, and Mg removal in kg ha^{-1} by harvested biomass was calculated by multiplying DM herbage yield by the content of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_16771695

each nutrient for each cut. Values obtained for both cuts were combined. To estimate the limitation of grassland growth by nutrients nutrient ratios (N:P, N:K, K:P) were calculated according to Koerselman and Mueleman (1996), Olde Ventering et al. (2003) and Güssewell (2004). N limitation was designated as N:P ≤ 10 and N:K < 2.1, NP co-limitation as N:P >10 and < 16 and K:P > 3.4, K (co-)limitation as N:K > 2.1 and K:P < 3.4 and P limitation as N:P > 16.

Phytocenological assessment

The percent cover of vascular plant species (nomenclature following Kubát et al., 2002) was estimated visually in May, July, and late September/early October in 2011-2014 in the permanent 4x4 m plots. The first phytocenological assessment was conducted prior to grazing. The number of vascular plant species, Shannon-Wiener index (SW index), forage value (FV), and the Ellenberg nutrient indicator values (EIV-N) were calculated. Classification of species followed Regal (1980) and Veselá et al. (2009). The Ellenberg N indicator value (Ellenberg et al., 1992) was calculated as the mean of indicator values weighted by extent of cover of each species.

Statistical analysis

To evaluate the effects of management, site characteristics, and management/site (M-S) interaction on agronomic factors and plant diversity, the within-subject ANOVA model (R package nlme; Pinheiro et al., 2016) was used. To take into account the effect of repetition (pseudo-replication), the random factor (sampling date) was nested in site and in experimental year (temporal change) within the ANOVA model. Backward selection based on marginality rules was used for exclusion of non-significant effects from the ANOVA models. Reduced models were compared to the previous models using the Akaike Information Criterion. Post hoc comparison of the differences among tested groups was based on pairwise t-tests with *p*-values adjusted by the Holm correction (Pinheiro et al., 2016). Normality of the data was tested by the Shapiro–Wilk test. Data with non-normal distribution were transformed either by logarithmic transformation or by rank transformation in which the function *rntransform* from R package GenABEL (GenABEL project developers, 2013) was used. Relationships among measured variables were assessed by Pearson's correlation coefficient. All statistical analyses were processed using R (Pinheiro et al., 2016).

Results

Herbage biomass parameters

Herbage DM yield in 2011-2014 was significantly affected by management (*Fig. 2, Table 3*). Mean herbage DM yield decreased by 1.31 tons ha^{-1} with mowing (*Table 4*). The highest mean herbage DM yield was found in S1 (6.97 tons ha^{-1}), associated with satisfactory to very high available soil nutrient content (*Table 2*), which produced similar herbage DM yields under both managements in 2011-2013 (mowed 7.02, grazed 6.98 tons ha^{-1}). However, in 2014, the herbage DM yield in S1 dropped significantly in mowed plots (4.90 tons ha^{-1}) compared to grazed (8.89 tons ha^{-1}). In S2 and S3, mowing decreased mean herbage DM yield from 5.68 to 4.32 tons ha^{-1} and from 7.41 to 5.88 tons ha^{-1}, respectively.

*Values from 2012-2014, +values from 2011-2014

Proportion of functional groups was significantly affected by management for graminoids and forbs and by site and M-S interaction for all groups (*Fig. 3*, *Table 3*). With mowing, the proportion of graminoids decreased in S1 and S2 accompanied by increase in forbs (in both sites) and legumes (in S2), while legumes decreased in S1 and S3 (*Table 4*). The increase of high Ca demanding forbs was significantly correlated to decreased soil Ca availability in S1 (r = -0.62, p < 0.05, F= 6.36, df = 11). The increase of legumes in S2 was positively correlated with soil K availability (r = 0.72, p < 0.05, F = 6.49, df = 7). The decrease in legumes (*Trifolium repens*) in S1 and S3 was connected with soil Mg depletion (r = 0.42, p < 0.05, F = 4.78, df = 23).

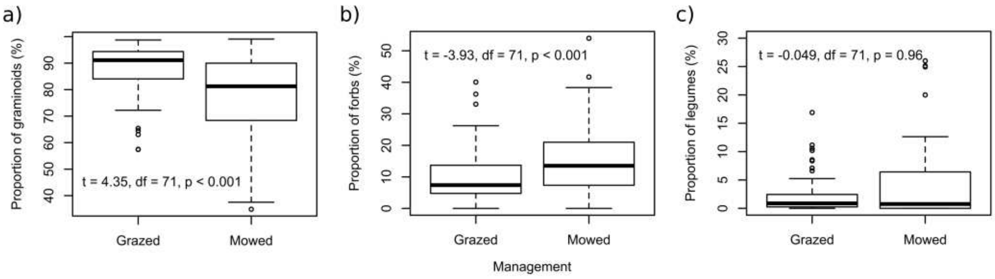

Figure 3. *Proportions of graminoids (a), forbs (b), and legumes (c) associated with management*

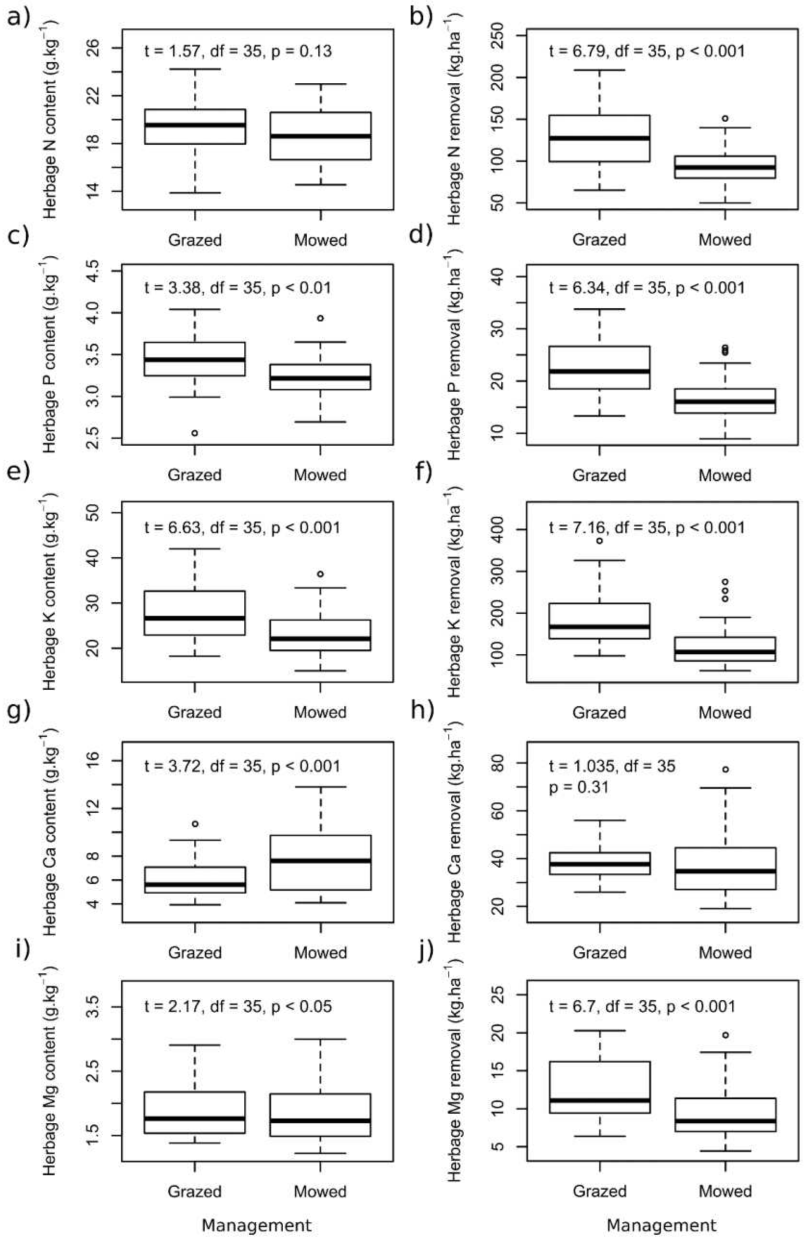

Figure 4. *The herbage N (a, b), P (c, d), K (e, f), Ca (g, h), and Mg (i, j) content and removal associated with management*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_16771695

Herbage nutrient content was significantly affected by management (P, K, Mg, and Ca), site (all nutrients), and M-S interaction (Ca) (*Fig. 4*, *Table 3*). Mowing depleting available soil nutrients by herbage removal decreased herbage P, K, and Mg content (*Table 4*) and altered the pattern of functional plant groups' occurrence. Across all sites, the reduction in herbage K content with mowing correlated strongly with depletion of soil K availability ($r = 0.60$, $p < 0.001$, $F = 16.87$, $df = 31$). Conversely, the herbage Ca content increased with mowing, which was significantly correlated with decrease in herbage DM yield (*Fig. 5*) and the proportion of graminoids (r = -0.78, $p < 0.001$, $F = 214.4$, $df = 143$) and with increase in forbs in S1 and S2 ($r = 0.61$, $p < 0.001$, $F = 27.12$, $df = 47$ and $r = 0.44$, $p < 0.01$, $F = 11.09$, $df = 47$) and legumes in S2 (r = 0.65, $p < 0.001$, $F = 34.11$, $df = 47$).

Herbage N, P, K, Mg, and Ca removal, which reflected the combined effect of herbage DM yield and nutrient content, was significantly affected by management (N, P, K, Mg), site (K, Mg, Ca), and M-S interaction (Ca) (*Fig. 4*). With mowing, the herbage N, P, K and Mg removal decreased (*Table 4*), while the herbage Ca removal increased markedly in S1, due to the increase in forbs proportion.

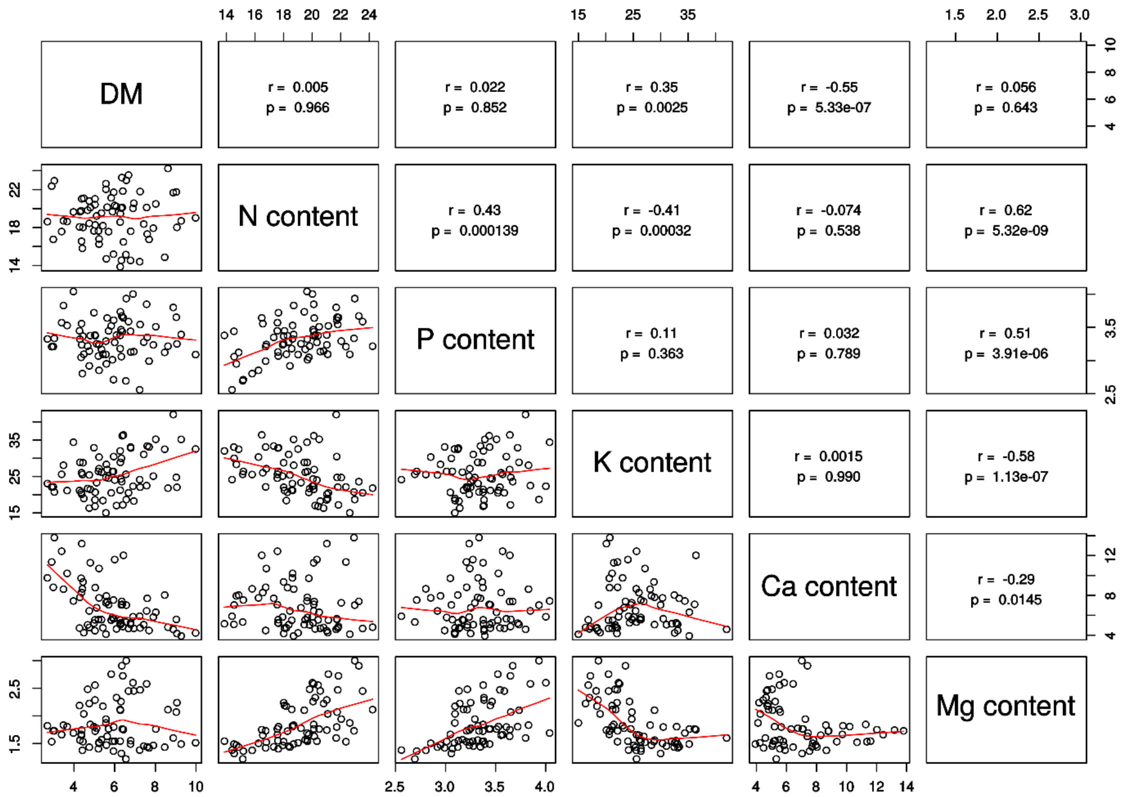

Figure 5. *Scatter plots of herbage dry matter yield (DM, tons ha^{-1}) and herbage nutrient content (g kg^{-1}) with correlation among variables. r is Pearson correlation coefficient, p is significance level. Data were fitted by spline model in the scatter plots*

Figure 5 shows significant relationships among herbage nutrients. The negative relationship between K and Mg content reflected the herbage K/Mg antagonistic relationship. The relationship between herbage N and K content in S2 was explained by significant spread of legumes with mowing, which increased the herbage N content but

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_16771695

decreased the herbage K content. The mean herbage N content of < 20-22 g kg^{-1} in all sites was considered deficient for herbage production. The lowest herbage N content, seen in S1 under both managements, was negatively correlated with the herbage DM yield (r = -0.53, p < 0.001, F = 18.20, df = 47) induced by the dilution effect, i.e., a decrease in herbage nutrient content with the progressive accumulation of above-ground biomass. Similarly, nutrient ratios showed plant growth N limitation indicated by N:P ≤ 10 and N:K < 2.1 in all sites and both managements. Other type of nutrient limitations did not occur.

Forage value was significantly affected by site. The highest FV was observed in nutrient rich S1. Mowing in all sites was associated with a steady FV decline throughout the study period by approximately 10 points.

The tetany ratio was significantly affected by management, site, and M-S interaction (*Fig. 6, Table 3*). The tetany ratio was significantly declined with mowing (*Fig. 6, Table 4*). The highest tetany ratio in S1 (in grazed parts > 2.2) was caused primarily by high herbage K content. Lower tetany ratio, observed in S2 and S3, resulted from a mixed effect of lower herbage K content and higher herbage Ca content (S2) or Mg content (S3). The increase of tetany ratio coincided positively with herbage dry matter yield (r = 0.63, p < 0.001, F = 91.09, df = 143).

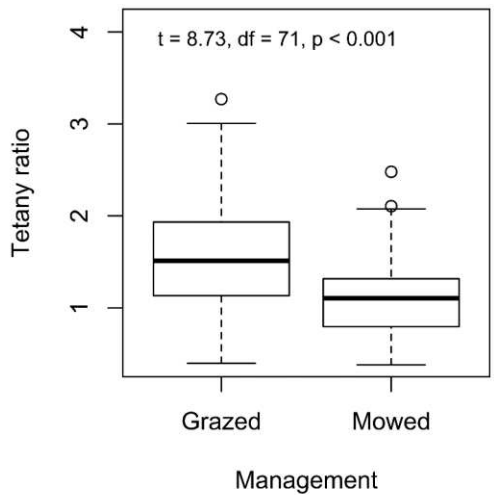

Figure 6. *Tetany ratio associated with management*

Species richness, Shannon-Wiener index, and Ellenberg N indicator values

Over years and across sites, mowing increased species richness and SW index compared to grazing (*Tables 3, 4, Fig. 7*). Both species richness and the SW index were substantially higher in S2 compared to S1 and S3 (mean of both managements), which may be attributed to lower cattle SR and available soil nutrients, combined with mowing in S2. In S1 and S2, mowing was associated with significantly higher species richness compared to the mowed section in S3.

The significant effect of management and site on EIV-N was revealed (*Fig. 8*). Nutrient removal by mowing reduced EIV-N (*Table 4*, *Fig. 8*). The highest EIV-N, seen in S1, were probably linked with the highest SR and soil nutrient levels. Nitrophilous species proliferated considerably in S1 (*Lolium perenne, Anthriscus sylvestris, Heracleum sphondylium*) compared to the more valuable forage species (*Lathyrus*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_16771695

pratensis, Vicia sativa, Lotus corniculatus, Tragopogon pratensis) found in S2. Conversely, the lowest EIV-N, showing the steepest decline throughout the trial, was recorded in S2 with medium nutrient availability and low SR combined with mowing. The Ellenberg N values were correlated negatively with species richness ($r = -0.49$, $p < 0.000$, $F = 22.13$, $df = 71$).

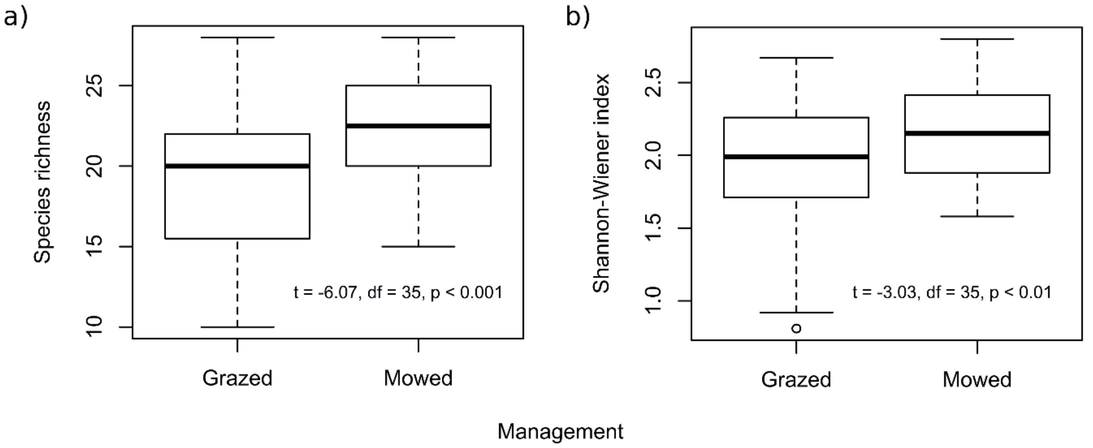

Figure 7. *Species richness per 16 m^2 (a) and Shannon-Wiener index (b) associated with management*

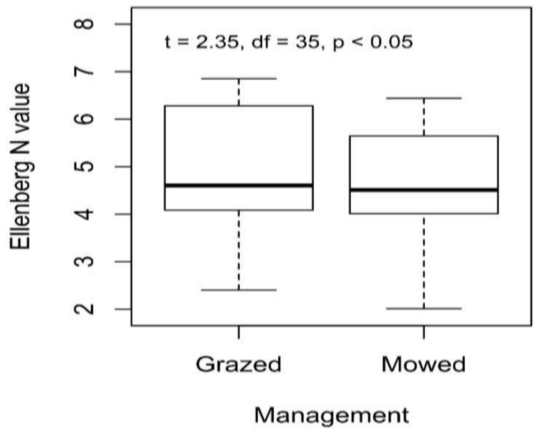

Figure 8. *Ellenberg N values associated with management*

Parameters obtained from the first phytocenological assessment (species richness, SW index, FV, EIV-N) were correlated with plant functional composition, herbage DM yields and nutrient contents of the first biomass sampling. Proportion of graminoids correlated negatively with species richness (r= -0.55**, *df* = 17) and S-W index (-0.72***, *df* = 17). Similarly, herbage DM yield was linked negatively with species richness (-0.54*, *df* = 23). Conversely, both species richness and SW index correlated positively with herbage Ca content (0.58**, *df* = 17 and 0.66**, *df* = 17, respectively) and S-W index reflected the increase in proportion of legumes (0.81***, *df* = 17). Forage value increased along with herbage DM yield (0.63***, *df* = 23), but declined due to increase in herbage Ca content (-0.60**, *df* = 17).

Discussion

Our results summarize that short-term grazing exclusion with mowing can increase biodiversity parameters together with maintenance of agronomic demands in sites with different soil nutrient availability (including nutrient rich S1) and grazing types (twice yearly rotational grazing in S1 and mixed grazing types combined with mowing in S2). The only restriction, which prevented from biodiversity improvement via mowing, was high soil P availability supporting markedly spreading of competitive graminoids (S3). The increase of species richness linked with mowing was induced by changes in plant functional composition (i.e. by a decrease in cover of graminoids and an increase in cover of legumes and forbs) accompanied by acceptable herbage productivity and forage values.

Parameters of agronomic demands

High soil available P in S3 was responsible for grass species spreading in both mowed and grazed sections at the expense of forbs and legumes (Marriott et al., 2005; Hejcman et al., 2007). In contrast, in S1, and especially in S2, reduced P availability supported the decrease of graminoids related to mowing, which enabled forbs to regenerate to a greater extent than seen with grazing (Hejcman et al., 2007; Blüthgen et al., 2012). Cover of legumes were suppressed by mowing in high yielding S1 and S3, not only by decline in Mg availability, but likely – except climbing *L. pratensis* – by lack of light and defoliation (Marriot et al., 2009). The substantial increase of legumes in the exclusively mowed section of S2 correlating with soil K availability could be favoured by better light conditions (Kayser and Isselstein, 2005; Gilhaus et al., 2014).

Despite soil nutrient removal by mowing, water and nutrient availability was sufficient to keep herbage DM yields above 4 tons ha^{-1}; hence, the grassland types observed in the experiment could be considered highly productive (Hrevušová et al., 2015). Grazing provided higher herbage DM yields, even though lower yields of pastures than of meadows are usually reported due to livestock trampling and more frequent defoliation leading to photosynthesis restriction (Whitehead, 2000; Mládková et al., 2015). Even if 60-99% of nutrients ingested by livestock are returned to pasture in urine and manure (Jones and Tracy, 2014), distinct ratio of nutrients in excreta (P removal in animal body) than in forage decreases their effective utilization. Our opposite results could be related to quite low SR not leading to frequent trampling and defoliation and also to the type of methodology.

The highest yield, in grazed S1, was related to high nutrient availability (con N), maintaining almost the same herbage DM yields during the first three years after grazing was replaced by mowing. In S2 and S3, in which available nutrient levels were lower due to lower SR, herbage DM yield reduction with mowing was more pronounced. The observed inter-annual variability in herbage production is a common feature of all grassland types in Central Europe, primarily related to water supply (Pavlů et al., 2011).

Not only mowing, which decreased the proportion of graminoids, but also the type of grazing management affected the abundance of grasses. Tall grasses sensitive to frequent defoliation were in accordance with Pavlů et al. (2003) more abundant in rotationally grazed S1 compared to S3, where short grasses prevailed under continuous grazing.

No significant differences in the herbage N content were observed between managements. This could be explained by the substantial increase of legumes in the mowed section of S2, which increased herbage N content due to N_2-fixing bacteria (Rose et al., 2012; Klaus et al., 2013b), while the herbage N content decreased with mowing in S1 and S3 with negligible proportion of legumes (Jones and Tracy, 2014). Nitrogen limitation of herbage production was indicated not only by the herbage N content, but also by the N:P (3.8-7.5) and N:K ratios (0.37-1.51) (Koerselman and Mueleman, 1996; Güssewell, 2004). In addition, in half the samples, mainly from S1 and S2, N was below the optimal range for dairy cattle of 19.2-25.6 g kg^{-1} (Whitehead, 2000). Nitrogen deficiency is common in pasture biomass (Mackay et al., 1995; Klaus et al., 2013a) and regulates other nutrient acquisition and translocation, such as P (Duru and Ducrocq, 1996). Hence, the positive relationship between the herbage N and P content may be explained by N deficiency.

Herbage P, K, and Mg contents significantly decreased with mowing, but P and K contents remained relatively high without any herbage P and K limitations. The herbage P content was considered optimal for dairy cattle, being 2.3-3.7 g kg^{-1} (Whitehead, 2000). In S3, herbage P content did not respond to extremely high soil P availability, further evidence of P uptake limited by N deficiency (Mengel and Kirkby, 1987).

Potassium uptake by plants under high K availability tends to exceed the threshold of physiological need of 28.0 g kg^{-1} (Hejduk, 2011) as shown in both managements of S1. High K availability supported by urine and manure deposition could result in inadequate uptake of Ca and Mg, impaired forage quality, and animal health problems related to grass tetany, the incidence of which is related to high plant growth rate (Kayser and Isselstein, 2005; Schonewille, 2013; Jones and Tracy, 2014). The risk of grass tetany (tetany ratio > 2.2) was almost completely eliminated in our study; only grazed parts in S1 with very high soil K availability revealed tetany ratio slightly over threshold value (2.21).

Herbage Ca content increased with mowing via forbs and legumes spreading (Reid, 1983). Contrarily, low herbage Ca content was linked with a predominance of grasses that are generally Ca and Mg poor in comparison to forbs and legumes (Daccord et al., 2001). Grass magnesium absorption is also affected by species. Powell et al. (1978) reported significantly greater Mg absorption in *Dactylis glomerata* than in *L. perenne*.

Along with the decrease in herbage nutrient contents and DM yields seen with mowing, herbage N, P, K, and Mg removal was reduced significantly (Kayser and Isselstein, 2005). Herbage Ca removal increase slightly with mowing in S1 and S2, due to the herbage Ca content increase (Reid, 1983).

Forage values ranged from 50 to 75 and were considered good (Grozavu et al., 2010), maintained by the grasses *Agrostis capillaris, D. glomerata*, *Poa pratensis,* and *L. perenne* in both managements and *Festuca rubra* in mowed areas, as well as the forbs *Taraxacum* sect. *Ruderalia* in grazed areas and *Plantago lanceolata, Achillea millefolium,* and *Pimpinella major* in mowed areas, along with legumes *T. repens* in grazed areas and *V. sativa* and *T. pratense* in mowed areas, all of which are attractive to animals due to medicinal and aromatic characteristics (Mládek et al., 2006). Legumes also are characterized by high protein and mineral contents. Similar to results of Hakrová et al. (2015), FV was found to decrease with increase in forbs. On the other hand, forbs improve livestock health, immunity, and forage consumption via aromatic substances (Mládek et al., 2006).

Plant diversity

In agreement with Blüthgen et al. (2012) and Klaus et al. (2013a), land use and management were recognized as the major drivers of changes in plant diversity. Management regime is closely associated with herbage productivity, which is largely negatively related to plant species richness, often inter-correlated with herbage nutrient contents. In agreement with that, we recognized that plant species richness increased via suppressed competitive ability of grasses and spread of less productive forbs in mowed parts in S1 and S2, which was associated with the herbage Ca content increase (Duffková and Libichová, 2013; Duffková et al., 2015).

Due to more intense nutrient supply by pasturing before the study, species richness and SW index in mowed plots of S1 and S3 had lower values than grazed area of S2 with lower nutrient supply and occasional mowing (Marriot et al., 2009).

In addition, there are other important factors such as soil site properties (pH and available nutrients), which determine plant species richness. High soil P availability was designated as an important factor relating negatively to species richness (Hejcman et al., 2010; Merunková and Chytrý, 2012). Hence, the lack of increase in species numbers, along with the high proportion of graminoids under mowing in S3 may be explained by the extremely high P availability, which allowed highly productive species to dominate (Hejcman et al., 2007). Phosphorus persists in the soil unaffected for decades and thus, it is not worth trying short-term mowing as a tool for plant diversity improvement in such sites (Semelová et al., 2008).

High soil K availability in S1 provided sufficient K supply for forbs increase together with decreased productivity and better light conditions in mowed plots (Elberse et al., 1983).

In accordance with Briemle et al. (2002), the adaptation to more intensive grazing in S1 and S3 was pronounced for cover of low-growing rosette legume *T. repens,* which decreased in mowed parts under lower soil Mg content. Spread of nitrophilous species in S1 was observed as a consequence of soil nutrient supply by cattle excrements (Plantureux et al., 2005).

The highest EIV-N (S1) were associated with broad nutrient supply (Blüthgen et al., 2012) and endozoochorous dispersal (Albert et al., 2015). Conversely, the lowest EIV-N (S2) in the exclusively mowed section reflected previously low SR.

Conclusions

A four-year experiment conducted in upland pasture found herbage DM yield, herbage nutrient contents (K, P) and nutrient removal (N, P, K, Mg) to be decreased by mowing twice a year replacing low intensity cattle grazing, but these agronomic factors remained acceptable for dairy cattle nutrition. Although our set of data was limited, such clear benefits as wider plant diversity related to legume and forb spreading and the elimination of the risk of grass tetany (i.e. tetany ratio < 2.2) with mowing were associated with a herbage K decrease and increase in herbage Ca content. To reconcile biodiversity and agricultural targets on pastures, a compromise between maintaining grassland species richness and herbage properties according to site-specific conditions may be required. Our findings on short-term grassland management changes are relevant to farmers' priorities when they operate within sustainable agro-environmental schemes.

Abstract. To understand the functioning of montane forests, this study was conducted in the highlands of the Kahuzi-Biega National Park in the Democratic Republic of the Congo. The relationship between the altitude and the floristic stability of woody layers and regeneration capability of canopy species after many years of disturbance was studied. Ten 1-ha plots were established from 1935m to 2760m a.s.l. In each plot we inventoried the trees ≥10cm of diameter at breast height (DBH), separating a canopy layer (10% of the tallest trees) and an understorey layer (all the other trees). In each plot, we nested a 0.1 ha subplot to inventory the saplings between 1 and 10 cm DBH. We found that the Jaccard index of dissimilarity between the understorey layer and the canopy layer decreases with the altitude. The proportion of species which are well represented in the three layers increases with the altitude. The number of pioneer species decreases with the altitude while that of non-pioneer and shade tolerant species increases. These findings suggest that altitude influences the stability of highland forests, higher altitude being more stable than lower ones in the case of this study.
Keywords: *highland forests, regeneration capability, woody layers, Jaccard index of dissimilarity, non-pioneer species*

Introduction

Montane forests are biodiversity-hotspots and are among the most species-rich ecosystems worldwide (Bussmann, 2001a, 2001b). They are also particularly rich in uncommon and endemic species (Plumptre et al., 2006; Skarbek, 2008). Their high diversity is due to a great variety of environmental conditions (Clinebell et al., 1995; Richter et al., 2009) as well as persistence of favorable climatic conditions during past geological times, which has allowed the survival of numerous plant species (Dimitrov et al., 2012). They are nevertheless one of the most fragile ecosystems (Sharma et al., 2009) and one of the most vulnerable to global change (Lenoir, 2009). Their

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_16971713

vulnerability is due to the fact that they cover rather small areas at the Earth's scale and that they are governed by specific environmental conditions (geomorphological factors, soil, cloudiness, humidity, temperature,…) which may rapidly change under climate warming and human pressure (Fjeldså and Lovett, 1997; Körner, 2009; Skarbek, 2008; Nzigidahera, 2012).

In tropical forests, numerous studies on montane forests have focused on the relationship between altitude and structure, or between altitude and floristic composition (Hedberg, 1951; Jamir et al., 2006; Hemp, 2006). Several studies have shown that lower altitudes are home to taller trees than higher altitudes (Ashton and Hall, 1992; Siebert, 2005; Richter et al., 2009), even in small elevation gradients (Gonmadje et al., 2017). In the same way the lower altitude forests differ from the higher ones in their floristic composition (Schmitt et al., 2010; Gonmadje, 2012; Admassu et al., 2016; Imani et al., 2016), with a decrease of species diversity with increasing altitude (Doumenge, 1998; Lomolino, 2001; Tassin et al., 2004; Hemp, 2006; Mangambu et al., 2013; Mwanga Mwanga et al., 2014; Admassu et al., 2016; Imani et al., 2016), even if not systematically (Siebert, 2005; Delnatte, 2010; McCain and Grytnes, 2010; Salas-Morales and Meave, 2012).

Some studies in the montane forests focused on their dynamic patterns through space and time (Fine et al., 2005; Zhang and Zhang, 2007; Njunge and Mugo, 2011). However, the study of vegetation dynamics requires observations through relatively long time scales. When such observations are unavailable, a comparison of the floristic composition between forest layers – canopy, understorey, sapling layers - can lead to some interesting results on the possible dynamics between these layers (Kalacska et al., 2004; Schulze et al., 2005; Behera and Misra, 2006). This approach is simple when it is used for forests dominated by one species and becomes more complex in forests with many species and a diversified canopy (Woods and Whittaker, 1981). Taking into account both the abundance and the occurrence of species in the considered forest layers can spread some light on the vegetation dynamics (Hall and Swaine, 1976; McEwan et al., 2005; Amani and Lejoly, 2014). Such studies were performed in various lowland forests (Letouzey, 1957; Woods and Whittaker, 1981; Swaine and Hall, 1988; Connell and Lowman, 1989) but in a limited number of highland forests (Njunge and Mugo, 2011; Shiels and Walker, 2013).

Based on the abundance patterns of species within different layers, Pivellon and Coutinho (1996) distinguished "stationary" stable forests and "transient" unstable forests or changing forests. Stable forests are those in which floristic composition of the canopy layer does not differ significantly from that of the lower forest layers. Connell and Lowman (1989) also defined stable forests as those characterized by one or more similar dominant species in the canopy and lower layers (meaning that these species will likely dominate the canopy in next generations) whereas unstable forests are considered to be characterized by one or more species which are currently dominant in the canopy but become scarce in lower layers. From a floristic dynamics point of view, it is expected that tree species characterizing the current canopy will die and eventually be replaced by the species found in the current sapling and understorey layers which are able to reach the canopy (Hallé et al., 1978; Woods and Whittaker, 1981; Nicotra et al., 1999).

It is generally agreed that young forests tend to have more canopy species with few – if any – regeneration in the sapling and understorey layers while old growth and stable forests are mainly dominated by canopy species with abundant regeneration in the sapling and understorey layers. In other words, forests which have experienced some disturbance

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_16971713

are expected to incorporate in their canopy a higher proportion of poorly regenerating pioneer species than old growth forests (Connell and Lowman, 1989; Pivellon and Coutinho, 1996; Vandermeer and Granzow de la Cerda, 2004; Yang et al., 2008).

In a case of non-disturbance or equal disturbance between lower and higher altitudes, lower altitudes develop more stable forests than higher ones. Due to the sensibility of higher altitudes to global change, they are liable for instability (Pierlot, 1966; Njunge and Mugo, 2011). These forests thus tend to be dominated by many pioneer species (e.g. forests at higher altitudes in general, Pierlot, 1966) and could be more instable (Wood and Whittaker, 1981) compared to forests at lower altitudes, but this general trend is reversed in a case of unequal disturbance history between lower and higher altitudes (Runge, 2007).

The forest ecosystems in the highlands of the Kahuzi Biega National Park (KBNP) are spanning from 1800 to 3315 m of altitude. Some of them have been severely disturbed as a consequence of recurrent political turmoil (and its subsequent wars and various armed conflicts) in the Democratic Republic of the Congo (DRC) and neighboring countries (World Heritage, 2005; Jepson et al., 2015). Though some studies reported the consequences of these anthropogenic pressures on the vegetation of the KBNP (Masumbuko, 2011; Kabonyi et al., 2011), very few is known regarding the regeneration and restoration capabilities of its forest ecosystems, more particularly in its highland areas. The role of altitude in the restoration processes has also been poorly studied (Gonzalez et al., 2013; Njunge and Mugo, 2011) while the lack of such information for the KBNP highland's forests is detrimental to the evaluation of their sensitivity to global change and the development of a sustainable management strategy (Dupuy, 1998; Dupuy et al., 1998). In the KBNP, it can be assumed that these political conflicts disturbed more the lower altitudes than higher altitudes as it is easier to make camping or logging activities in lower altitudes than going far at mountain's summits in higher altitudes (Magrath et al., 2007)

Here we investigated the stability state of these highlands forests with respect to disturbance history and in relation with the altitude. We evaluated the dynamic trends of these montane forests by testing if 1) the dissimilarity between the canopy layer and understorey layer decreases with the altitude; 2) the most abundant canopy species remain abundant in lower layers at higher altitudes; 3) the proportion of pioneer species decreases with the altitude and that of non-pioneer species increases with the altitude in the three layers.

Material and methods

Study area

The study was conducted in the Kahuzi Biega National Park (KBNP) which is located in the eastern part of the DRC, between 28.45°E - 28.85°E of longitude and 2.66°S - 2.09°S of latitude. The KBNP harbours three main vegetation types according to the altitude, including lowland forests (stretching from 700 m to 1250 m a.s.l), submontane forests (from 1250 m to 1800 m) and highland forests from 1800 m to 3315 m a.s.l (Fischer, 1993; Mangambu, 2013). This study covers only the highland forests (*Fig. 1*).

The KBNP is established in two main climatic zones. The lowland areas undergoes an equatorial climate where it rains almost throughout the year. Precipitations are high and can reach more than 2 600 mm; temperature varies between 15 and 25°C. In the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_16971713

highland areas and submontane forests, the climate is characterized by 3 to 4 months of dry season and lower rainfall (mean: 1 900 mm; Fischer, 1993). The highlands are dominated by hills and marshes. They are located in the Albertine rift, a biodiversity hotspot (Plumptre et al., 2006, Poulsen et al., 2005). In terms of phytogeography, the highlands are part of the afromontane center of endemism but the lowlands belong to the guineo-congolese center of endemism (White, 1983).

The highlands of the KBNP are dominated by a vegetation which is structured in 3 main strata including arborescent strata, understorey strata and herbaceous strata. This forest has many epiphytes especially lichens, ferns and many *Orchidaceae* species. The arborescent strata is characterized by species such as *Albizia adianthifolia, Neoboutonia macrocalyx, Dombeya torrida, Macaranga capensis, Polyscias fulva, Alangium chinense, Shirakiopsis elliptica, Pleiocarpa pycnantha, Syzygium guineense, Symphonia globulifera, Tabernaemontana stapfiana, Carapa grandiflora, Nuxia floribunda, Lachnopylis thomensis, Agauria salicifolia, Morella salicifolia, Podocarpus milanjianus, Afrocarpus usambarensis*… The understorey strata is constituted by *Hagenia abyssinica, Maesa lanceolata, Galiniera saxifraga, Psychotria mahonnii, Rapanea melanophloeos, Cyathea manniana, Erica arborea, Alchornea hirtella, Chassalia subbochreata...* In the herbaceous strata we can see species like *Sinarundinaria alpina, Lobelia gibberoa, Salacia sp, Urera hypselodendron, Pilea sp, Ipomoea involucrata, Scadoxus multiflorus, Hypoestes trifolia, Sericostachys scandens, Centella asiatica, Ageratum conyzoides, Aspilia kotschyii, Helichrysum spp, Microglossa pyrifolia, Mikania spp, Senecio spp, Vernonia spp, Impatiens spp, Begonia spp, Cuscuta kilimanjari...* and many ferns.

Data collection

A total of 10 1-ha (200 m x 50 m) nested plots (displaying the canopy layer, the understorey layer and the sapling layer) were established between 1935 and 2760 m a.s.l. As there are many conflicting statements on the minimum height of canopy species in montane forests (Lebrun and Gilbert, 1954; De Barcellos Falkenberg et al., 1995), we arbitrary considered the 10 % tallest trees of the stand as belonging to the canopy layer, the remaining trees belonging to the understorey layer. Trees of the canopy and the understorey layers and reaching at least 10 cm of diameter at breast height (DBH), were inventoried within (1 ha) plots. For this category of trees, height and diameter were measured, respectively by a Laser Ace and a DBH-meter. The height varied from 2 to 28 m while the diameter varied from 10 to 155 cm. Inside each 1-ha plot, the sapling layer (comprising all woody species between 1 cm and 10 cm of DBH) was inventoried within 0.1 ha (200 m x 5 m) subplots. The altitude was recorded using an altimeter SUUNTO Vector (± 5 m) while the geographic coordinates were recorded with a Garmin GPS (± 3 m of precision).

Species identification

Most species were directly determined in the field. The remaining species were later identified at the Herbarium of the Lwiro research center, by comparing collected plant samples and using existing floras (Troupin and Bridson, 1982; Fischer and Killmann, 2008) and to the online flouring plant database of Geneva (African Plant Database, Lebrun and Stork, 1991-2015). We identified 87.6 % of all species till to the level of species, 9.3 % to the level of genera and 3.1 % of all species were not identified. We used the nomenclature proposed by the Angiosperm Phylogeny Group (APG IV) in 2016 (Chase et al., 2016).

Data analysis

Species richness and diversity indices

In each plot and for the canopy and understorey layers, species richness was estimated using the rarefaction index (r) while diversity was calculated by the Fisher alpha index (α). The rarefaction index (*Eq. 1*) for species richness estimations represents the expected number of species in a sample of n individuals selected at random from a collection containing N individuals, S species and N_i individuals in the i^{th} species (Hurlbert, 1971). If a random sample of n individuals is taken from each community, the number of species recorded increases with the number of individuals sampled (Bell, 2000), that is why it is better to analyse the species richness with standardized number of individuals within plots. This index is:

$$r = E(S_n) = \sum_1 \left[1 - \frac{\binom{N-N_1}{n}}{\binom{N}{n}} \right] \quad \text{(Eq. 1)}$$

The Fisher alpha index was calculated from the formula proposed by Fisher et al. (1943). This index is mostly influenced by rarer species (Magurran, 2004) and estimates the number S of species with N observed individuals (Fisher et al., 1943; Magurran, 2004), it is frequently used in forest related studies (Gonmadje et al., 2011, Gourlet-Fleury et al., 2013). We used this index as it considers the whole individuals sampled in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_16971713

each plot without any standardization of individuals as it is in the previous index, it calculates the diversity.

Variation of woody layers floristic dissimilarity along the altitudinal gradient

We compared the floristic compositions of the two layers (canopy and understorey) within the established 10 plots. The Jaccard index of dissimilarity was calculated between each pair of plots situated at the same altitude one belonging to the understorey and another to the canopy. This allowed to quantify the variation in floristic composition of communities at each altitude (Jaccard, 1908; Legendre et al., 2005; Tuomisto and Ruokolainen, 2006). We then made the correlation between this dissimilarity index and the altitude to assess the way the altitude and related factors can influence the floristic stability in this area).

Correlation between "well represented species" and the altitude

The distribution of canopy species into the canopy layer, understorey layer and sapling layer were performed. We calculated the relative abundance of each species in the three layers plot by plot and compared those three values using a Chi² test to test if those relative abundances show any statistical difference or not. If the difference is significant, the distribution of the considered species is not equilibrated in the three layers. If the difference is not significant, it means that the relative abundance of the species in the canopy is not different statistically from its relative abundance in the understorey and sapling. These species are considered as well represented species in the three layers. We then made a correlation of the proportion of well represented species and the altitude to test if higher altitudes have more "well represented species" than lower altitudes.

Light requirement of species in the three layers

The light requirement (LR) of species informs on the degree of disturbance in a forest (Hawthorne, 1996; Van Gemerden et al., 2003a). The LR of each species was found in the literature especially in Lebrun and Gilbert (1954), Pierlot (1966), Lovett et al. (2006) and in the database developed by Bénédet et al. (2016). Three categories were considered: Pioneer species, Non-Pioneer Light Demanding species and Shade tolerant species. Species for which we didn't find their LR were categorized as "Unclassified". In each layer we calculated the proportion (*Eq. 2*) of individuals belonging to each LR category:

$$PX_A = \frac{\text{Individuals of } X_A}{N_A} \times 100 \qquad \text{(Eq. 2)}$$

Where PX_A is the proportion of individuals belonging to X light requirement category present in the plot A and N_A the total number of individuals in the plot A. The number of individuals belonging to each LR were correlated with the altitude layer by layer.

For correlations, the Pearson method were used as our data required a parametric option. For regressions, we used linear models. All statistical analyses were performed with R software (R Development Core Team, 2015) using the vegan (Oksanen, 2017) and ecodist package (Goslee and Urban, 2007).

Results

Richness, diversity, and their relationship with altitude

General characteristics of the stands

We inventoried a total of 7590 individuals: 1940 in the sapling layer (194 ± 58.6 per 0.1 ha subplot), 5087 in the understorey layer (508.7 ± 176.8 per 1 ha plot) and 563 in the canopy layer (56.3 ± 19.8 per 1 ha plot). A total of 62 species (17.6 ± 3.75 per 0.1 ha subplot) belonging to 34 families were collected in the sapling layer, 82 species (22.7 ± 9.04 per 1 ha plot) belonging to 37 families in the understorey layer whereas in the canopy layer 45 species (10.8 ± 2 per 1 ha plot) belonging to 29 families were collected.

In term of number of individuals, the most abundant families are the *Rubiaceae* followed by the *Monimiaceae* in the sapling layer, the *Euphorbiaceae* followed by the *Rubiaceae* in the understorey layer and the *Euphorbiaceae* followed by the *Myrsinaceae* in the canopy layer. The richest families are the *Rubiaceae* (10 and 16 species) in the sapling and understorey layers and the *Euphorbiaceae* (5 species) in the canopy layer. One of the 62 species of the sapling layer was only identified at the family level (*Rubiaceae*) and was represented by 3 individuals at 2355 m a.s.l. Three of the 82 species of the understorey were only determined at the family level (*Rubiaceae*). The three species were represented by only one individual and were collected at 1935 m a.s.l.

The relationship between numbers of individuals, numbers of species, Fisher-Alpha index of diversity, rarefaction index of richness and altitude are represented below (*Fig. 2* and *Table 1*).

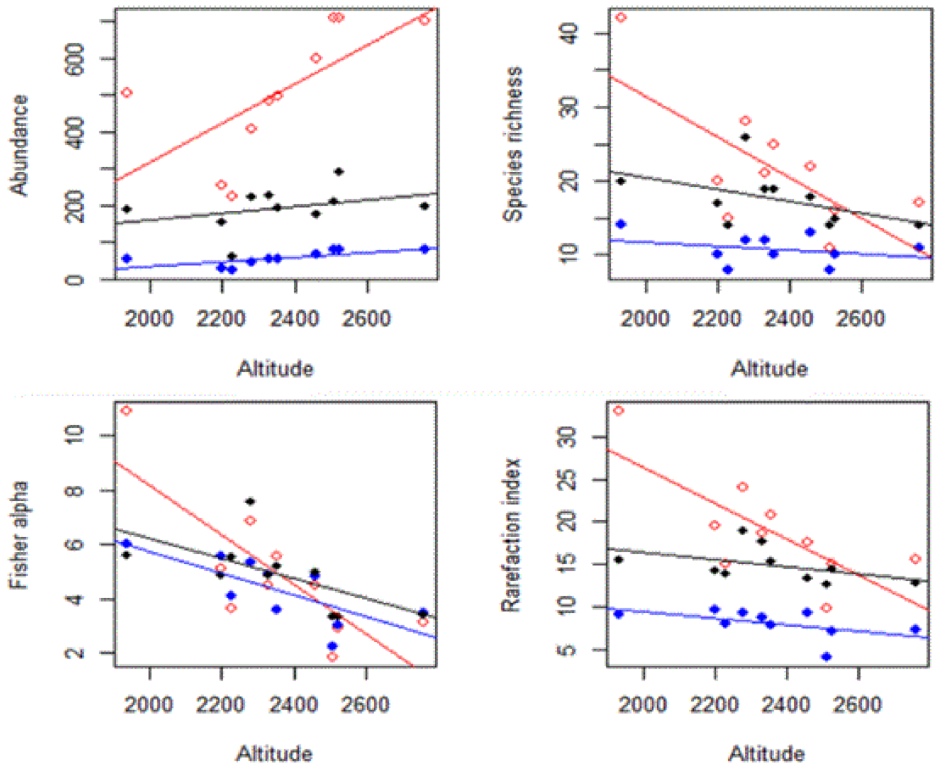

Figure 2. *Relationship between number of individuals, species richness, Fisher-Alpha index, Rarefaction index and altitude in the three layers. The sapling layer is represented by the black line, the understorey by the red line and the canopy by the blue line.*

DOI: http://dx.doi.org/10.15666/aeer/1504_16971713

Within the three layers, the number of individuals increases with altitude, significantly for the understorey and the canopy (*Fig. 2*) while the species richness, the Fisher-Alpha index and the rarefaction index decrease with the altitude, but not significantly in most cases.

Table 1. *Correlations between number of individuals, number of species, index of rarefaction, index of Fisher-Alpha and altitude in the three layers. "r" is the coefficient of correlation of Pearson, R^2 the coefficient of determination and bold p-values show significant correlations at α = 0.05. The sapling layer was inventoried in 0.1 ha plots.*

Layer	Variables	r	R^2	p-value
UNDERSTOREY	Individuals/Altitude	0.67	0.45	**0.034**
	Species/Altitude	-0.71	0.5	**0.022**
	Rarefaction/Altitude	-0.75	0.56	**0.012**
	Fisher-Alpha/Altitude	-0.78	0.64	**0.006**
CANOPY	Individuals/Altitude	0.67	0.44	**0.035**
	Species/Altitude	-0.31	0.1	0.38
	Rarefaction/Altitude	-0.52	0.27	0.12
	Fisher-Alpha/Altitude	-0.73	0.53	**0.02**
SAPLING	Individuals/Altitude	0.34	0.11	0.34
	Species/Altitude	-0.47	0.22	0.17
	Rarefaction/Altitude	-0.45	0.2	0.19
	Fisher-Alpha/Altitude	-0.64	0.41	**0.048**

Relationship between floristic dissimilarity and altitude

The dissimilarity between the understorey and the canopy layer of each plot were calculated according to the altitude (*Fig. 3*), to study whether the floristic stability of this ecosystem is correlated to the altitude.

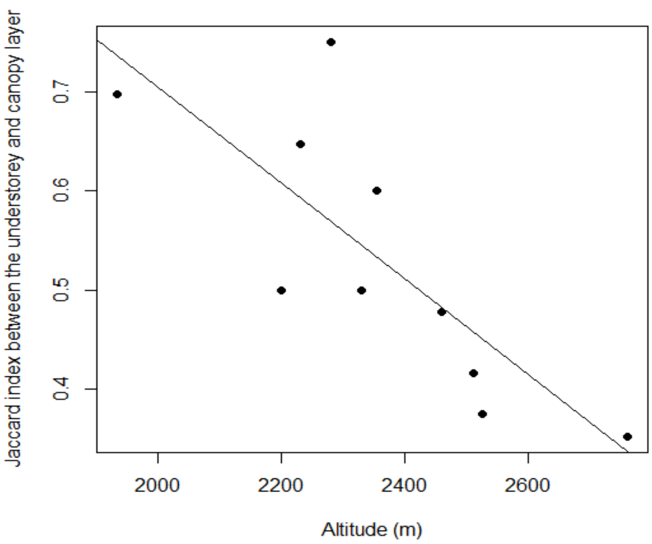

Figure 3. *Correlation between the floristic dissimilarity (Jaccard index) between the understorey and the canopy layers and the altitude.*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_16971713

The Jaccard index of dissimilarity significantly decreases with altitude (r = - 0.79, p = 0.006). This decrease confirms a more homogeneous floristic composition between the understorey and canopy layers when the altitude increases. Homogeneous floristic composition between the understorey and the canopy layer is a sign of floristic stability as this means that the species which are present in the canopy layer at higher altitude are also well represented in the understorey layer.

Floristic and functional composition of the three layers and their relationship with altitude

Distribution of the canopy species into the three layers

In the *Figure 4*, the percent of canopy species for which the proportion of their relative abundance (RA) in the three layers do not differ statically are presented. The relative abundances of canopy species in the canopy, the understorey and the sapling layers were computed and compared through a Chi² test (see appendix for more details).

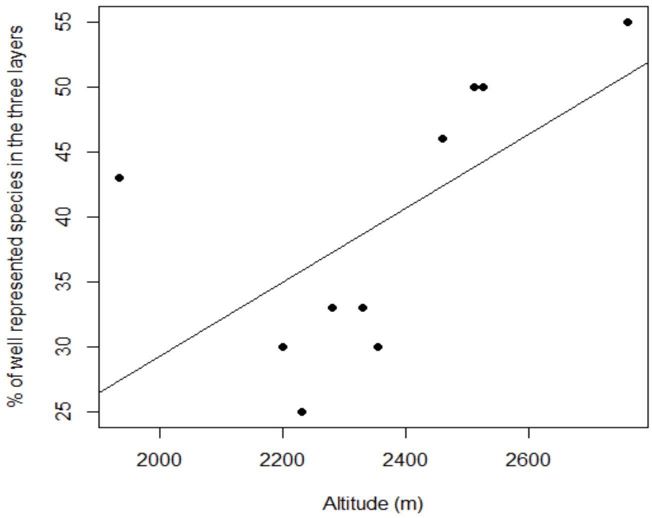

Figure 4. *Correlation between the percent of well represented species and the altitude. Well represented species are those for which their relative abundance in the three layers do not differ significantly.*

As shown in the *Figure 4*, the percent of well represented species in the three layers tends to increase with the altitude (r = 0.61, p-value = 0.06). This suggests that most abundant species in the canopy still in more cases abundant in lower layers particularly at higher altitude plots. The species which do not follow this trend are those which are abundant in the canopy but become scarce in lower layers or they are abundant in lower layers and become scarce in the canopy (see species with p-values ≤ 0.05 in the appendix).

Correlation between light requirement and altitude in the three layers

The variation of the light requirement (pioneer species, non-pioneer light demanding species: "NPLD" and shade tolerant species) is presented in the *Table 2* to test if they are correlated to the altitude in the three layers. The aim in this computation is to assess if the number of pioneer species is negatively correlated to the altitude and the number of non-pioneer light demanding and shade tolerant species are positively correlated to the altitude.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_16971713

Table 2. *Correlation between the number of individuals belonging to each light requirement (LR) category within the three layers and the altitude. Bold p-values represent significant correlations at α = 0.05. The proportion of each LR category is represented in the % column.*

	Sapling layer			Understorey layer			Canopy layer		
Light requirement	*%*	*r*	*p*	*%*	*r*	*p*	*%*	*r*	*p*
Pioneer species	6.3	-0.72	**0.02**	16.3	-0.7	**0.03**	21.8	-0.67	**0.03**
Non-pioneer light demanding species	26.0	0.65	**0.04**	43.9	0.61	0.06	64.0	0.85	**0.002**
Shade tolerant species	41.4	0.63	0.05	33.6	0.35	0.32	13.3	0.03	0.93
Unclassified species	26.3	-0.1	0.78	6.2	0.17	0.64	0.9	0.03	0.93

In terms of individuals, non-pioneer light demanding species are more represented in the whole studied area (40.8 %) followed by shade tolerant species (34.1 %), pioneer species (14.1 %) and unclassified species (11 %), the Chi squared test showed a significant difference ($\chi^2 = 25.59$, df = 3, $p < 0.0001$). The number of pioneer species generally decreases with the altitude this pattern being significant in the three layers. On contrary, the number of non-pioneer light demanding species and the number of shade tolerant species tend to increase with the altitude. This correlation is significant for the non-pioneer light demanding species in the sapling and the canopy layer.

Discussion

The species richness and diversity of woody layers decrease with altitude

In some montane forests, the species richness and diversity of woody plants begins to decrease above 1500 m a.s.l (Gentry, 1988). This decrease is due to multitude factors which vary with the altitude including the geomorphological factors, soil, humidity, cloudiness, temperature… (Delnatte, 2010; Malhi and Phillips, 2005). This pattern is also observed for non woody plants (Raman et al., 2005; Richter et al., 2009) even if the opposite trend (increasing species richness and diversity with altitude) can be observed, for example, in rattan communities in Indonesia (Siebert, 2005) and for the *Melastomataceae* family in French Guiana (Delnatte, 2010).

In the highland areas in the KBNP, species richness of plants and their diversity decreases with altitude for the *Rubiaceae* family (Mwanga Mwanga et al., 2014) and for ferns (Mangambu et al., 2013). We obtained the same result for the total woody floristic composition in the sapling, understorey and canopy layers. This confirms the findings of Imani et al. (2016) who found the same trend in a study conducted in the same ecosystem and in the surroundings of the Park in which they only considered tree species ≥10cm DBH. The higher altitudes are characterized by a lower number of species and a lower diversity. Nevertheless, the number of individuals increases with the altitude, the same pattern was found by Gonmadje et al. (2011) in Cameroonian montane forests and Imani et al. (2016) in the KBNP and its surroundings.

Forest stability in the Kahuzi-Biega National Park's highlands

The dissimilarity between the canopy and understorey layer decreases with altitude

The canopy layer plots at higher altitudes are more similar to their understorey layer compared to the lower altitudes plots. The Jaccard index of dissimilarity decreases when

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_16971713

the altitude increases. This encounters the statements of Bell (2000) for whom the composition of a community will be highly correlated with that of its immediate successor. Environmental-limitation conditions (lower temperatures, humidity, cloudiness…) created by the altitude act as ecological filtering and inhibit the installation of some species at higher altitudes (Salas-Morales and Meave, 2012). Only some plant species succeed to live in such conditions. This is the reason why the floristic difference between layers diminishes with increasing altitude as many species present in the canopy layer are encountered also in the understorey layers at those altitudes. McEwan et al. (2005) found in the case of their study in an old-growth forest of Kentucky in the USA that layers similarity increases with altitude. Wu et al. (2007) found the same results in the Mount Fuji in Japan.

Variation of the relative abundance of canopy species

After past disturbances in the highlands of the KBNP (Masumbuko, 2011; Kabonyi et al., 2011), the regeneration capabilities of canopy species were less known. The results from this study showed that the most represented species in the canopy are also well represented in the lower layers at higher altitudes (see *Figure 4*). Gonzalez et al. 2010 found that the relative abundance of a given species in two compared layers can highlight some insights on its dynamics and the forest stability.

Successive layers such as sapling/understorey and understorey/canopy are not independent because each one is largely built from survivors and offspring of previous ones (Hall and Swaine, 1976; Bell, 2000). This represents the main interest of studying sapling and or understorey layers which are made of species which may constitute the canopy layer in next generations (Gonzalez et al., 2010). In a dry tropical forest of Costa Rica, Kalacska et al. (2004) found that there are some species which are present only in the early stage of development and are absent in the late stage. Some species can be present in all stages of development but with varying abundances. It has been argued that the appearance or disappearance of species in a given layer (or stage of development) is a great signal in its dynamic trend (McGill et al., 2007), either it is replacing or it is being replaced (McEwan et al., 2005; Zhang et al., 2009; Njunge and Mugo, 2011). Canopy species with high relative abundance in lower layers could maintain their presence in the canopy layer even in next generations (Hall and Swaine, 1976).

Does the light requirement confirm the floristic stability of higher altitudes?

The light requirement of species can be informative of the level of stability of a forest (Pierlot, 1966; Lovett et al., 2006). In the sylvigenetic cycle, early stage of development of a forest is dominated by trees which will be replaced by others, these trees are generally pioneer species (Hallé et al., 1978; Gourlet-Fleury et al., 2005). In the absence of high disturbance, pioneer species characterized by a short life span form a first canopy which constituent will be replaced by non-pioneer light demanding species and/or shade tolerant species which grow beneath this canopy (Whitmore, 1989; Van Gemerden et al., 2003b). When the forest tends to be stable it becomes more dominated by non-pioneer light demanding and shade tolerant species (Hall and Swaine, 1976; Whitmore, 1989; Van Gemerden et al., 2003b; Lovett et al., 2006). This affects the understorey and sapling's composition because of the lack of sunlight causing difficult germination and growth conditions to pioneer species (Harper 1977 in Reed and Foster, 1984). In the case of this study, we find that the number of pioneer species is lower than that of shade tolerant species and non-pioneer light demanding species.

The *Table 2* showed that in all layers the number of pioneer species which are proof of large and recent disturbance (Van Gemerden et al., 2003b) are negatively correlated to the altitude and that non-pioneer light demanding species and shade tolerant species are positively correlated to the altitude. Plots situated at lower altitude are more disturbed than those at higher altitude suggesting that higher altitudes are more stable than lower. As said above, this could be a consequence of past and recurrent political turmoil which affected severely lower altitudes than higher ones.

Conclusion

Like herbaceous species and other organisms, woody plant species richness and diversity decrease with increasing altitude. Both sapling, understorey and canopy species showed this trend. Higher altitudes have low number of species and high number of individuals in the three layers. Plots situated at higher altitudes are more stable than those at lower altitudes. This was confirmed by the result from the Jaccard index of dissimilarity, the comparison of relative abundances and the variation of pioneer and non-pioneer species with the altitude. From the comparison of canopy and understorey or sapling abundances we can predict that the well represented canopy species in the understorey or in the sapling could form the future canopy as long as an equilibrium rate of mortality, regeneration and growth is maintained. Furthermore, we observed that pioneer species which are more abundant in unstable forests are more represented at lower altitudes than they are at higher and that non-pioneer and shade tolerant species increase with the altitude supporting the statements that high altitudes are more floristically stable than lower altitudes. In spite of these conclusions, we suggest that other studies can be conducted to clarify the role of other factors than altitude (geomorphological factors, soil, temperature, cloudiness, humidity, seed dispersal…) in the stability of montane forests.

Acknowledgements. This paper is one of findings of a PhD thesis research being conducted in the Kahuzi-Biega National Park (KBNP) thanks to financial supports from the European Union (EU) through the Center for International Forestry Research (CIFOR). We thank the University of Kisangani staff for their support and accompaniment. Thanks to our field guides and all researchers who helped us during data collection campaigns and analysis.

Abstract. Using eleven treatments, the present study aimed at investigating the influence that organic and inorganic fertilizers exert upon the germination percentage, the length and weight (i.e. dry and fresh) of the shoot and root, and number of leaves which are considered the morphological characteristics associated prominently with the burdock that is technically entitled *Arctium lappa*. Significant differences were observed between such treatments as urea, vermicompost, vermicompost combined with Nitroxin, 15% manure in comparison with the control treatment in terms of the germination percentage. Another salient feature of urea and vermicompost treatments was that they led to a decrease in the rate of germination. Vermicompost treatments were proven to be significantly different in terms of number of the plant leaves. Shoot and root length was shown to be significantly influenced by the vermicompost treatments utilized both individually and in combination with Nitroxin. Compared with the control treatment, the experimental treatments were more significant as far as the weight of the fresh root and shoot was concerned. Another source of significant difference in terms of dry root weight was identified to be correlated with the 15% and 30% vermicompost individually used as well as the 15% vermicompost and manure employed in combination with Nitroxin. As for the dry shoot weight, no significant difference was witnessed between Nitroxin and 30% manure treatments.
Keywords: *Arctium lappa, growth parameters, inorganic fertilizer, Nitroxin, vermicompost*

Introduction

Arctium lappa Linne, popularly known as burdock or bardana, is a member of the *Asteraceae* (*Compositae*) family and can be found worldwide (da Silva et al., 2013). This genus is native to Eurasia (Duistermaat, 1997). In Flora Iranica, three studied species are reported in Gilan, Golestan, Mazandaran, Tehran, Khorasan, Kerman, Lorestan and Azerbaijan provinces (Henry, 2002; Karimi et al., 2001). The morphological characteristics of this plant include the straight and branched stems covered with fluff, heart-shaped leaves, and same-genus heaps and the cluster inflorescences or pistil and almost spherical involucres, bracteoles in several bayonet and narrow rows, akene with cut and slightly compressed tip (Ghahreman, 1994). In addition, the root of burdock is long and fleshy, gray-brown outside and whitish inside, with a somewhat thick bark and soft wood tissue with a radiate structure. It has a sweet taste and crisp texture. Burdock (*Arctium lappa* L.) has long been cultivated and commonly consumed as a very popular vegetable in Asia (Imahori et al., 2010). The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_17151731

nutrients contained in *A. lappa* include inulin, polyphenols, chlorogenic acid, proteins, carbohydrates, vitamins, amino acids, minerals, and unsaturated fatty acids (Chang et al., 2009). Moreover, in folk medicine, *A. lappa* had been used to treat throat pain, arthritis, rashes, and various skin problems, and also as a diuretic, depurative, and digestive stimulant (Chan et al., 2011). The burdock beneficial effects observed are related to hypertension, gout, arteriosclerosis, hepatitis and other inflammatory disorders (Lieber, 1994; Tamayo, 2000). The several investigators have been demonstrated that *A. lappa* displayed hepatoprotective (Lin et al., 2002); antibacterial properties against gram-positive and gram-negative bacteria (Gentil et al., 2006; Pereira et al., 2005) and anti-inflammatory effects (Zhao et al., 2009), which might be due to its free radicalscavenging activity (Leonard et al., 2006). Many of the biological properties attributed to burdock, including antimutagenicity, anticarcinogenicity, and antiaging, may originate from the antioxidant ability of its component (Mclarty, 1997; Niki et al., 1997; Yang et al., 2001).

Roots from *A. lappa* are popular in the Asian cuisine being widely consumed, whereas the leaves are used as infusions or, externally, as a poultice (Jeelani and Khuroo, 2012). Although the leaves are rich in phenolic compounds (Lou et al., 2010), to which many health benefits are associated (Tamayo et al., 2000; Sun et al., 2011; da Silva et al., 2013), there is a prevalence of investigations on the roots and seeds. Extracts from roots containing several monocaffeoylquinic acids (MCQA) and dicaffeoylquinic acids (DCQA), including several isomers, were reported to have gastroprotective activity (da Silva et al., 2013; Santos et al., 2008). Other compounds were also found in *A. lappa*, including arctiin and arctigenin, caffeicacid, chlorogenicacid, cynarin, rutin, quercitrin, quercetin, luteolin, benzoic and p-coumaricacid (Lou et al., 2010; Liu et al., 2005). They are associated to the medicinal properties of *A. lappa*, such as the lignin arctigenin that exhibited antitumor and antidiabetic activities (Awale et al., 2006), these squilignans isolappaol C, lappaol (C,D,F) and diarctigenin, which have anti-inflammatory activity (Park et al., 2007). Therefore, improving the productivity and quality of *A. lappa* is an ultimate goal.

Biofertilizers are the formulation of living microorganisms which are able to make atmospheric nitrogen available for the plants (Subba Rao, 1993) and which contain microorganisms capable of transforming the nutritive elements from a non-usable form to a usable one through biological processes (Tien et al., 1979). Several bacteria that are associated with the roots of the crop plants can induce beneficial effects on their hosts and often are collectively referred to as PGPR standing for plant growth promoting rhizobacteria (Azarpour et al., 2011). Nitroxin is a biologic nitrogen fertilizer that contains *Azotobacter* and *Azospirillum* (Arun, 2007). *Azotobacter* and *Azospirillum* are the two most important non-symbiotic nitrogen-fixing bacteria in non-leguminous crops. Under appropriate conditions, *Azotobacter* and *Azospirillum* can enhance plant development and promote the yield of several agriculturally important crops in different soils (Okon and Labendera-Gonzalez, 1994). These beneficial effects of *Azotobacter* and *Azospirillum* on plants are attributed mainly to an improvement in root development, an increase in the rate of water and mineral uptake achieved by roots, a displacement of fungi and plant pathogenic bacteria and, to a lesser extent, biological nitrogen fixation (Okon and Itzigshohn, 1995). Furthermore, vermicompost is a product of biodegradation and stabilization of organic materials made by an interaction between earthworms and microorganisms. It contains microbial activities (Edwards, 1998). Vermicompost contains plant-growth regulating materials such as humic acids (Senesi

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_17151731

et al., 1992; Masciandaro et al., 1997; Atiyeh et al., 2002) and plant growth regulators like auxins, gibberellins, and cytokinins (Krishnamoorthy and Vajrabhiah, 1986; Grappelli et al., 1987; Tomati et al., 1988), which are responsible for the increased plant growth and yield of many crops (Atiyeh et al., 2002).

Therefore, in reference to the mentioned issues, the growth characteristics including the percentage and rate of germination, the number of leaves, roots and shoot height, root and shoot fresh and dry weight of the burdock constituted the focal points of the current study. The effects of Nitroxin (mixed with *Azospirillium* and *Azotobacter*), vermicompost and cow manure bio-fertilizers; chemical fertilizers (i.e. urea) at two levels (15 and 30%) on the morphological characteristics were also examined.

Methods

Context and Materials of the Study

The design of the current study was completely randomized, and it was based on some experiments conducted throughout the study using 11 treatments and 4 replications in a greenhouse located in Isfahan (Khorasgan Branch), Islamic Azad University, Isfahan in Iran in 2013-2014. To achieve the main goal of the study, such fertilizers as vermicompost, Nitroxin (*Azotobacter* and *Azospirillium brasilense*), cow manure and urea as a chemical fertilizer were utilized along with some pots (16*19 cm) containing approximately 2 kg of soil and sand extracted from some farms near the university context mentioned above. The burdock is a biennial (lives 2 years), the most development of leaves and root occurs in second year. However, measurement of vegetative growth of seeds can be determining the deferent fertilizer treatments potential in first year in regard with the potted planting of burdock. In the bottom of pots the holes with a diameter of 1.5 cm is considered, it is to measure the roots that grow larger than the size of the pot. Moreover the pots embedded in an 80 cm height of ground surface (*Fig. 1*).

Figure 1. *Arrangement of pots in the greenhouses*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_17151731

Treatments

The pots 1-4, 5-8, 9-12, 13-16, 17-20, 21-24, 25-28, 29-32, 33-36, 37-40, and 41-44 were comprised of some soil and sand as the control sample of the study (i.e. 15% vermicompost and 85% soil, 15% vermicompost and Nitroxin and 85% soil, 30% vermicompost and 70% soil, 30% vermicompost and Nitroxin and 70% soil, Nitroxin and soil, 15% cow manure and 85% soil, 15% cow manure and Nitroxin and 75% soil, 30% cow manure and 70% soil, 30% cow manure and Nitroxin and 70% soil, urea and soil, respectively). After 25 burdock seeds were planted in each pot, and the seeds were covered with one centimeter soil, the pots were once irrigated every two days.

Measurement

The seedlings were counted once a week. On the fourth day, the germinated seeds were counted for 32 days. Finally, after 110 days, the shoot and root length was measured using a transparent ruler, and the normal seedlings were counted again. The leaves of each plant were counted as well. Afterwards, the roots and stems were washed, and the fresh weight was determined. To determine the root and shoot dry weight, the samples were dried in an oven for 48 hours at 72 °C. The dry weight was determined using a digital scale (accuracy level=one ten thousandth of a gram). The germination percentage was calculated using equation (1) below:

$$PG = \frac{Ni}{N} \times 100 \qquad \text{(Eq.1)}$$

Where PG is the germination percentage, Ni indicates the number of the germinated seeds per N day, and N shows the number of seeds planted.

Statistical Analysis

All the experiments were repeated four times. The measured data (Tables of the Appendix 1) were analyzed using the analysis of variance (ANOVA), and the mean values of the treatments were compared using Duncan's Multiple Range Test (DMRT) at P≤0.05. The 19th version of the SPSS was used to analyze the whole data.

Results and Discussion

The results gained from the ANOVA for the vegetative characteristics such as the number of leaves, root and shoot length, fresh and dry weight of root and stem and the germination percentage are shown in *Table 1* below.

Table 1. *Effect of the treatments on the vegetative characteristics of the medicinal burdock plant*

Germination Percentage

According to the statistical analysis of the experimental data gained from the studied treatments shown in *Table 1* above, urea made the most significant difference among all the treatments tends by inhibiting the germination process. Urea has many advantages and is widely used as a nitrogen fertilizer throughout the world of agriculture; however, there are problems related to its use (Engelstad and Hauck, 1974). Some of these problems have adverse effects on germination, seed and early plant growth in soil (Gasser, 1964; Goyal and Huffaker, 1984). The adverse effect of urea on germination is due to the presence of impurities such as biuret (Wilkinson and Ohlrogge, 1960), due to cyanate formed by the isomerization of urea in aqueous solution, PH or high concentrations of ammonium ions due to hydrolysis of urea by soil urease (Widdowson et al., 1960; Court et al., 1964), Ammonia production from urea hydrolysis (Court et al., 1964), or nitrite production by nitrification and urea nitrogen by soil microorganisms (Court et al., 1964). Bremner and Krogmeier (1989) reported that the effect of urea fertilizer on seed germination of wheat, rye, barley and maize showed that the adverse effects of urea on seed germination in soil is due to ammonia formed by urease hydrolysis which is not related to urea. Impurities in urea as biuret or nitrite resulted from the nitrification of urea nitrogen. The studies compared the effects of germination on soils made by pure urea, urea and impure urea. Also, the compounds formed as a result of changes in soil microbial and enzymatic urea showed that ammonia volatilization from soils treated with urea completely inhibit the germination process.

Both the vermicompost and the vermicompost combined with Nitroxin showed significant differences in comparison with the control treatment. Also, the two treatments 30% vermicompost combined with Nitroxin and Nitroxin indicated significant differences, but the germination was less than half in the combined treatment. Other treatments including the vermicompost treated both individually and in combination with Nitroxin were not observed to be significantly different from the control treatment. The 15% vermicompost treatment did not reduce the germination level. Once combined, the 15% vermicompost treatment turned out to exert a greater effect on the germination process. It is so likely that in the early stages the plants are susceptible to the negative effects of the vermicompost. The studies showed that the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_17151731

application of the vermicompost inhibits the germination and seedling growth so that when the concentration of the vermicompost increases, the growth decreases linearly (Ievinsh, 2011). Buckerfield et al. (1999) reported that radish seed germination decreases gradually once the concentration of the vermicompost increases, but a tenfold increase is observed in the 100% vermicompost as compared with its 10% counterpart.

In the early stages of growth, the plants were susceptible to the negative effects of vermicompost. Moreover, the stability and maturity are essential for successful application (Wang et al., 2004), Stability is related to microbial activity (Lasaridi and Stentiford, 1998). Puberty refers to the degree of decomposition of organic matter during composting and is produced in the absence of pathogens and weed seeds (Wu et al., 2000). Unstable compost leads to the creation of a competition for oxygen uptake between the biomass and the root or seed. The roots and seeds are deprived from oxygen; the H_2S and NO_2 reduce (Mathur et al., 1993). According to Nadi et al. (2011), the germination of pistachio in vermicompost cow manure treatments, compared with the control treatments, showed a significant increase owing to the growth of fungi and the disease in seeds in pots treated by the premature vermicompost. Bachman and Metzger (2008) stated that vermicompost were used to improve the growth and a lack of increase in the percentage or rate of germination caused by new seeds and the effect of vermicompost. Joshi and Vig (2010) reported that the highest germination percentage at 15% vermicompost treatments was observed to be up to 86%, and an increase in the concentrations of the 30 and 45% treatments that were gradually reduced to 60 and 55% owing to the presence of excessive nitrogen that inhibited the germination.

As Saleem et al. (2007) mentioned, Plant Growth Promoting Bacteria (PGPR) including the enzymes of amino cyclopropane and dideaminase carboxylic acid (ACC) facilitates the growth of the plant indirectly by reducing plant pathogens, but directly by facilitating the absorption of nutrients through production phytohormone such as auxins, cytokines and gibberellins and enzymes reducing the level of ethylene. They added that PGPR totally breaks the ACC ethylene precursor to utyrate and reduces ammonia and ethylene levels in growing plants. Throughout their study, Gallardo et al. (1994) demostrated that although a large amount of ethylene was not required for the germination of pea seeds, a certain amount was necessary. A comparison made between the cow manure and control treatments indicated that the 15% cow manure was significantly different from the control treatment, though no difference was found between other sorts of the cow manure treatment and the control treatment. However, the combination of the cow manure treatment and Nitroxin was found to be apt for germination in that the highest germination level was observed to be attributed to the %30 cow manure treatment combined with Nitroxin. Germination increased when the concentrations of the %15 to %30 cow manure treatments increased.

It should be mentioned here that the components of the manure treatment can enhance or hinder the germination process. Studies demonstrate that access to a higher level of nitrogen stimulates the germination of some species (Luna and Moreno, 2009). Using different doses of manure with the purpose of influencing the germination process, Carlos et al. (2013) argued for a threshold level above which cow manure could not be influential in the germination process.

Number of Leaves

In terms of the number of the leaves, no significant difference was found between 30% vermicompost treatment combined with Nitroxin, the 15% vermicompost and the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_17151731

15% manure treatments combined with Nitroxin. As indicated by *Table 1*, no significant difference was witnessed between the 15% and 30% cow manure treatments. Through the application of vermicompost for the growth of strawberries, Singh et al. (2008) showed that the vermicompost highly influenced such growth parameters as the leaf width and dry weight. This effect was due to the availability of plant growth regulation and humic acid, which is produced by increasing the activity of microbes in vermicompost (Arancon et al., 2004). Microbes such as fungi, bacteria, yeasts and actinomycetes that produce hormones like auxin and gibberellin make a significant amount of vermicompost (Brown, 1995; Arancon et al., 2004).

Stem Length

The results gained from a statistical analysis of the stem length presented in *Table 1* indicate a significant difference made by the vermicompost and the composition of vermicompost and Nitroxin. The 30% vermicompost treatment which turned out to exert the most significant influence on the stem length exhibited no significant difference from the vermicompost composition, though a significant difference was observed as far as the 15% vermicompost treatment combined with other treatments was concerned. The greatest impact on the stem elongation was found to be related to the 15% and 30% vermicomposts combined with Nitroxin and the 30% vermicompost treatment. The 15% vermicompost was more effective once combined with Nitroxin. Joshi and Vig (2010) demonstrated that the application of 15%, 30% and 45% vermicompost treatments increased the height of tomato more significantly than their control treatments. Gutiérrez-Miceli et al. (2007) contended that a significant increase in the average stem diameter and plant height was caused by the use of different doses of sheep manure vermicompost. High microbial activities in the vermicompost are due to fungi, bacteria and autonomists (Tomati et al., 1988). Microorganisms such as bacteria, fungi, yeasts, algae and actionists cause the production of plant growth regulators such as auxin, gibberellins, cytokinin and ethylene (Frankenberger and Arshad, 1995) and vermicompost showed a positive effect on the growth of *Begonias* and *Coleus* (Tomati et al., 1988).

Nitroxin treatment, as indicated by *Table 1* above, was not significantly different from the control treatments, but it significantly reduced the stem length. The average nitrogen rate of soil or nitrogen by nitrogen fixation is not a barrier to nitrogen fixing but its high levels reduce nitrogen fixing (Marschner, 1995).

The cow manure and its combination with Nitroxin were not observed to be significantly different. This composition had a greater impact on the stem length than the individual application of the cow manure treatment. The differences between the 15 % and 30% cow manure and control treatments were not significant.

Shoot Fresh Weight

As for the fresh weight of the shoots, the vermicompost treatments (i.e. the vermicompost itself and its combined form) were shown to be significantly influential. Specifically, the 30% vermicompost was found to play the most critical role in the weight than other treatments of the study. According to other studies (Peyvast et al., 2008), the greatest impact on the plant growth and yield was demonstrated to be made by low ratios of vermicompost (20 to 40 %). A reduction in shoot fresh weight was observed in the Nitroxin treatment, but there was no significant difference between this

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_17151731

treatment and the control one. The cow manure treatments were found not to be significantly different in this respect. They had not been different from the control treatment neither. However; the stem was much more significantly affected by this treatment than the control treatment of the study.

Shoot Dry Weight

As for the shoot dry weight, a significant difference between the vermicompost itself and its combined form was found. In addition, the 30% vermicompost was more significantly influential than other treatments. The Nitroxin treatment decreased the shoot dry weight in comparison with the control treatment, yet the difference was not significant. This treatment was significantly different from other treatments, but the difference existing between the 30% cow manure treatments applied individually and the one utilized in combination with Nitroxin was not significant. The greatest impact on stem dry weight was found to be correlated with the combination of the 15% cow manure and Nitroxin.

Root Length

According to *Table 1*, significant differences between the experimental and control treatments were observed. The root length increased due to the 15 and 30% vermicompost treatments. The plants respond differently to different doses of vermicompost due to the production of growth enhancing materials in lower doses than higher doses (Arancon et al., 2004). No significant difference was found between the 15% vermicompost and 15% vermicompost combined with Nitroxin, as well as between the 30% vermicompost treated solely and the one combined with Nitroxin. A root length reduction was observed in 15% and 30% vermicompost treatments combined with Nitroxin. Nitroxin treatments were demonstrated not to be significantly different from the 15% and 30% vermicompost treatments combined with Nitroxin, but the difference was significant between the Nitroxin and other treatments. Also, a significant reduction in the root length occurred due to the experimental treatments in comparison with the control one. Vessey (2003) opined that an increase in gibberellins can increase cell elongation influenced by biological fertilizers. He asserts that rhizosphere bacteria are likely to cause the synthesis and release of auxin as a matter of secondary metabolites in roots.

Cow manure treatments applied individually or in combination with Nitroxin didn’t exert a significant influence on the root length in comparison with the control treatments. Verlinden et al. (2010) conducted a study on the effect of biofertilizers on increasing pasture vegetative organs. The availability of food increased the population and colonization of bacteria in the root of the organic fertilizers combined with *Azotobacter* and *Azospirillium* (Siddiqui, 2004).

Root Fresh Weight

As presented by *Table 1*, the vermicompost treatment applied both individually and in combination with Nitroxin made a significant influence upon the fresh weight of the roots in comparison with the control treatment. The 30% vermicompost was the most significantly influential in the root fresh weight among all the treatments of the current study. This significance can lie in the increasing amount of available nutrients, the number of beneficial microorganisms, enzyme activities and plant growth promoters

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_17151731

such as gibberellin, cytokinin and auxin. Kadam and Pathade (2014) showed that using the proper proportions of vermicompost, root fresh weight increased more significantly in the experimental treatment than its control counterpart. In their study, the Nitroxin treatment showed no significant differences, but it led to a higher reduction in the root fresh weight in comparison with the control treatment. The cow manure treatments were greatly but insignificantly effective in the fresh weight as compared with the control treatments.

Root Dry Weight

Regarding the root dry weight, the vermicompost treatments, especially the 30% form, had a more significant influence than the control treatment. Bachman and Metzger (2008) examined the effect of 10% and 20% vermicompost treatments on marigold, revealing that the latter brought about a greater increase in shoot and root dry weight than the former. In their study, the Nitroxin treatment showed no significant differences as compared to the control treatment. The cow manure treatments, especially the 15% form, and their combination with Nitroxin were more significant than other treatments in this respect.

Conclusions

The results gained from the current study showed different effects of application of vermicompost, biological, cow manure and urea fertilizers on the germination process. The germination percentage of the vermicompost and Nitroxin decreased in comparison with the control treatment. The cow manure treatment and its combination with Nitroxin increased the germination percentage. Furthermore, a higher dose of the vermicompost treatment was found to be more influential in the number of the leaves. Both levels of the cow manure treatment turned out to be negatively influencial in the number of the leaves. A negative effect was found to be made by the Nitroxin treatment on the shoot fresh weight. Regarding the shoot dry weight, all the study treatments had a great effect except for Nitroxin. In terms of the root length, all treatments were significantly different in comparison with the control treatment. The 15% vermicompost applied individually, the 15% vermicompost used in combination with Nitroxin, and the 30% cow manure were witnessed to be the most significantly influential, but the Nitroxin was found to have a negative influence. Of all the treatments included in the present research study, the 30% vermicompost treatment had the highest effect on the root fresh weight which was differently influenced by the experimental treatments (i.e. vermicomposts) and the control treatment. The root dry weight was shown to be positively significantly influenced by the 15% and 30% vermicomposts, and the 15% cow manure treatment combined with Nitroxin. More importantly, the vermicompost treatments applied individually and in combination with Nitroxin had the greatest effect among all the treatments. The 30% vermicompost was observed to be the highest in this respect. The organic manures and their combination with biofertilizers played a crucial role in the growth of burdock. As for the number of the leaves, stem length, fresh and dry weights of the roots and shoots, the higher doses of the vermicompost 30% were more influential than the 15% vermicompost treatment. Regarding the characteristics such as the germination percentage, the number of the leaves, and the length of the roots, the 15% vermicompost assumed the most significant role, whereas the combined version of the vermicompost treatment was most influential in other parameters.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_17151731

The individual and non-individual application of the 15% vermicompost treatment had a negative effect, so this level was proved to be far from optimal as far as the morphological characteristics were concerned. The negative impact of Nitroxin treatment (containing *Azotobacter* and *Azospirillium*) was probably due to the negative interplay between two bacteria. The 15% cow manure applied both individually and non-individually was significantly influential in all parameters except for the root length, but the 30% counterpart had the highest impact on all the features of the plant. Consequently, it is suggested that a lower dose of the animal manure be applied in order to enhance the growth of burdock. However, as for the germination percentage, and the shoot and root dry weight, the combined form is highly recommended. A lower dose of other treatments combined with Nitroxin is suggested once other parameters are intended to be taken into consideration.

Abstract. Results of estimating geosystems'sustainability in conditions of anthropogenic impacts are presented in this work. The method for assessing the potential sustainability of geosystems in conditions of anthropogenic impact was improved and adapted. Integral assessment of the sustainability of geosystems of Sarysu Basin, Kazakhstan with regard to human impact by identifying landscape factors, allowed the differentiation of geosystems into 5 classes, requiring different approaches to the development of optimal environmental management structures.
Keywords: *basin, landscape, sustainability, anthropogenic impact, geographic information systems*

Introduction

The question of geosystem sustainability is becoming increasingly important in the case of increasing anthropogenic influence on the environment. Geosystems need to be researched, and to predict their conditions as a result of external factors to increase further production growth. The selection and implementation of the proper forecast methodology is only possible in static equilibrium systems. The development of the system in geosystems which are in a condition of crisis and in which an unstable equilibrium is emerging, can take an unpredictable path and lead to catastrophic consequences.

The concept of sustainability in physical geography has no clear definition. The definition depends on the purpose of assessment of natural or human-modified geosystems, which is given by different authors. All interpretations of this concept can be summarized in the following components: limits of natural functionality, ability to resist external influences (natural and anthropogenic), and ability to relax after load reduction (Chorley et al., 1971; Ryumin, 1990; Bastian et al., 2002). According to Sochava (1971), all the dynamic changes which take place within a single invariant (qualitatively unchanged) are an example of geosystem sustainability, because this represents the ability to restore to a previous condition or position. According to Ryumin (1990), a proper functioning of the system is linked with the phenomena of seasonal dynamics and has second importance in the definition of the sustainability. On the other hand, Isachenko (1980) emphasizes the role of dynamics in geosystems' sustainability.

The research into geosystem sustainability in the face of anthropogenic pollution and the self-purification ability of technogenic materials plays an important role in landscape geochemistry (Solntseva, 1982; Glazovskaya, 1983; Volkova et al., 1987; Turner et al., 2001; Fu et al.,2013; Wu, 2013; Michaeli_et al., 2014). The stability of geosystems with regard to technogenesis is described by Glazovskaya (1997), via the self-purification ability. This ability is conditioned by the speed of transformation of man-made substances and their removal beyond geosystems (Glazovskaya, 1983). In many ways, this ability is possible owing to the compatibility of natural and man-made substance flows (Solntseva, 1982; Shadrina et al., 2014; Yermolaev et al., 2014; Michaeliet al., 2015).

Research into the sustainability of geosystems of the Sarysu Basin focuses on the increasing human impact on its environment. In this regard, the aim of the study of selected areas is determined by the necessity to obtain new landscape environmental information demanded for the future creation of the Sarysu Basin nature management strategy.

Methods

There is potential and real sustainability of the landscape. The first concept refers to the natural (undisturbed) condition; the second to a modern condition, absorbed by all layers that have accumulated in the history of human impact (Benson et al., 2007). However, it should be noted that the starting point for assessing the current sustainability of geosystems for forecasting development and work should be the initial variant, as the object of the basic landscape classification on the basis of its sustainability.

We analyse the geosystem's sustainability as the ability to maintain its structure and function under external impact. We used the principles of assessing the sustainability of the soil and the landscape, created by Glazovskaya (1997), Bashkin and Evstafieva (1993), and Orlova (2002; 2006) (*Table 1*), to assess the sustainability of geosystems with regard to human impacts. These principles of assessment are based on normalizing methods of individual indicators, and their subsequent summation on a point system. They take into account the complex for an integrated assessment of sustainability of the whole group and geosystems, in terms of their overall sustainability (*Table 1*). The authors are fully aware that the proposed method of assessment of geosystem sustainability is only one of several possible practical approaches, which realization demands a lot to go through.

Table 1. *The scale of mark estimation potential of landscape sustainability in conditions of anthropogenic impacts (compiled from materials of Glazovskaya (1997) Bashkin, Evstafieva (1993), Orlova 2002; 2006)*

Indicators	**Scores Of Sustainability**				
	1 score	**2 score**	**3 score**	**4 score**	**5 score**
Radiation balance, kcal/cm^2 per year	5–10	11–20	21-30	31–50	more than 50
Radiation index of dryness	less than 0.45 and more than 3	-	1.01. or 3.00	-	0.45–1.00
Wind conditions (amounts of days with strong wind)	more than 51	-	21–50	-	0.45–1.00

Wind conditions (amounts of days with strong wind)	more than 51	-	21–50	-	less than 20
Nature of the landform	hilly	hilly steeply sloping terrain	gently hilly terrain	plateau and slightly wavy terrain	plain
Downhill gradient, degree	more than 20	5.1–20	3.1–5	1.1–3	0–1
Geochemical location	accumulative	-	Transit	-	eluvial
The rate of natural drainage	>0.0005very poorly drained	a little bit poorly drained 0,0005-0,001	poorly drained 0.001–0.008	drained	intensive drained
Level of hydromorphic soil	hydromorphic	-	semi-hydromorphic	-	automorphic
Texture of soil	sand	clay sand	light loam	medium loam	heavy loam
Humus horizon power, cm	less than 3	3–10	10.1–25	25.1–80	more than 80
Humus content in horizon 0–20 cm, %	less 2	2.0–4.0	4.1–6.0	6.1–9.0	more than9.0
Acidity status of the soil (pH)	very acid soil (4.5 and less) or very alkaline soil (8.5 and more)	acid (4.5–5.0) or alkaline (7.5–8.5)	slightly acid soil (5.0–5.5) or slightly alkaline soil (7.0–7.5)	near to neutral (5.5–6.0)	neutral (6.0–7.0)
Salinity (the amount of salt in the upper layer of horizons, %)	highly saline and very saline (0.6)	moderately saline (0.3–0.6)	slightly saline(0.2–0.3)	very slightly saline(0.15–0.2)	non-saline (less than 0.15)
Cation exchange capacity, mg.ekv /100 gr. soil	less than 10	10–20	21–30	31–40	more than 40
Type of water regime	desuctive-exudational regime	exudational regime	non-leaching regime	periodically leaching regime	leaching regime
Square canopy %	Lesst han 20	20–40	41–60	61–90	more than 90

We have to pay attention among climatic factors to some important factors determining energy flow in geosystems, such as radiation balance, irrigation adequacy, and wind conditions.

Radiation balance is determined by the relationship between the amount of energy reaching an object (or a portion of it) and the amount leaving it. The value of the radiation balance depends on many factors: latitude, surface properties and surface moistening, which have a direct impact on albedo and effective terrestrial radiation. The energy of the main biogenic and abiogenic processes in geosystemsis determined by radiation balance. According to Glazovskaya (1983), the speed and direction of chemical transformations of technological products is determined by radiation balance as well. Moreover, large parameters of radiation balance coincide with the maximum geosystem sustainability (under *ceteris paribus*) (Bashkin et al., 1993).

DOI: http://dx.doi.org/10.15666/aeer/1504_17331744

The radiation index of the dryness value of dryness index characterizes the lack of moisture and is considered the lowest rate of sustainability (less than excessive moisture). From moisturizing performance, very informative radiation dryness index (K), the proposed M.I. Budyko (1984), which is the ratio between the radiation balance of the territory and the annual amount of precipitation, expressed in calories latent heat of vaporization, the equation (*Eq. 1*):

$$K = R/LQ \qquad \text{(Eq. 1)}$$

R - radioactive balance per year, kilocalorie/cm^{2}per year;
L - latent energy of vaporization, kilocalorie/cm^{2}per year;
Q - annual amount of precipitation, mm.

With K=1 the possibility of vaporization is approximately around the amount of fallen humidity. This is relevant to conditions of maximum geosystem sustainability. With R/LQ less than 0.45 to 1 climate is called a damp climate, with K from 1 to 3 it is temperate climate , with K more than 3 it is an arid climate. Radiation index of dryness reflects water and humidity conservation with radiation conditions (Reymers, 1990).

The wind regime, on the one hand, is the factor of dispersion of artificially produced elements in the air, but on the other hand, it is also the factor of lateral (eolian) processes, and determines the adaptation features of biota. The number of days with strong wind per year are used as quality indicators to estimate the sustainability of geosystems.

The features of relief are used as an indicator which represents age and stage of development of the geosystem and compliance with endogenous and exogenous processes. Flat, uniform, slightly wavy and sleepy, sloping terrains have the highest degree of sustainability, whereas hilly terrains have the lowest one.

A steep slope plays an important role concerning geosystem sustainability, because an increase in steepness leads to more intense surface run-off, which increases the risk of the mechanical demolition of solid substances. Therefore this leads to the development of soil erosion. In addition, the speed of the real steep slope influences the speed of the real growth of the humus soil horizon, and the speed of the geosystem's recovery on slopes depends on thesteep slope. The angle of repose, the angle between the ground surface after land subsidence and floor sliding and the horizon are used to characterize the steep slope (Glazovskaya, 1997).

The important factor to determine the sustainability of geosystems from human impact is the determination of its geochemical position, which characterizes the nature and intensity of migration flows. Glazovskaya (1983, 1997) highlights three main types of gradation and two transition types, based on the classification of landscape types. Eluvial (watershed) landscapes are the most highly located, and are geochemically autonomous. They obtain their flow of material from the atmosphere. Transit landscapes are located on the lower stage of the cascade and geochemically are subordinates of elementary landscapes. This landscape obtains its flow of substitutes from the atmosphere and water release from surface and ground waters located higher than some stages of cascade. Accumulative landscapes are usually located on the flat areas near slopes, close to water bodies and floodplains, where there is an accumulation of substances. The accumulative landscapes located in the zone of storage of all incoming substances are the least stable.

The level of natural drainage of geosystems leads to the process of accumulation or leaching out of chemicals. We used a method of evaluation of morphometric parameters of the basin created by Uglanov (1981), to calculate the natural drainage of geosystems (*Eq. 2*):

$$\mathrm{P} = i\frac{H}{F}, i = \frac{h_1 - h_2}{l} \qquad \text{(Eq. 2)}$$

P - natural drainage;
H - the total length of all the elementary streams that are the basis of erosion (including their length) km;
F - area of the basin, km^2; *i*- main angle of site;
h_1–h_2- height difference of elementary watercourse from its source to its mouth (depth oferosional dissection);
l - watercourse length, km.

The natural drainage classification, including the existing one but with some changes, was created by the authors during the analysis of the literature dedicated to drainage. Thus, geosystems are evaluated according the geosystems' sustainability to drainage: P 0.01–0.2 is very poorly drained; P 0.2–1 is poorly drained; P 1–3 is moderately drained; P 3–10 is well-drained; P 10 and higher is intensively drained.

Soil has a junction place, and forms a natural part of the ground cover's natural components. Indetermining the sustainability of the soil, we proceeded from the fact that it is formed by a buffer capacity (the ability to 'take on' neutralizing this effect, and due to external factors' ability to 'throw off' the load on to other ecosystems, due to the situation in catena, due to climate features) (Vasilevskaya et al., 1997). Next we used soil-geochemical indicators to assessthe sustainability of natural systems to human impact: the rate of hydromorphic soils, texture of soil, depth of humus horizons, the rate of soil acidity, and cation exchange capacity.

Next were groups of soil, depending on the location in the relief and the nature of hydration, called the rows of humidification: automorphic soil formed on flat surfaces and slopes in conditions of free surface water flow, with a deep water table (below 6 m); semi-hydromorphic soil formed by the brief stagnation of surface water or groundwater occurring at a depth of 3–6 m (capillary fringe can reach the roots of plants); hydromorphic soils formed under conditions of prolonged stagnation of surface water or groundwater occurring at a depth of less than 3 m (capillary fringe may reach the soil surface). Rows of humidification of geosystems characterize the geochemical sustainability, which largely determines the intensity of the migration of chemical substances.

The texture of the soil is important for the soil's porosity, air and water permeability, hygroscopicity, absorption capacity, soil temperature, and others (Dobrovol'skiy, 1989). Loam and heavy loam have the best aforementioned indicators than sand and sandy loam.

The rate of soil sustainability to a variety of physical and mechanical stresses, and erosive and deflationary processes is determined by the depth of the humus horizons of the soil (Snakin et al., 1993). The content of humus in the soil largely determines the absorptive capacity of the soil and affects the formation of the structure of the upper soil layers and their physical features. Soils with high humus content can largely resist external impacts.

DOI: http://dx.doi.org/10.15666/aeer/1504_17331744

The level of soil acidity (the reaction of medium, pH) characterizes many genetic and industrial types of soil. Soils can react differently to pollution products depending on their acidic properties. The mobility of chemical elements and their chemical compounds can be changed in different environments.

The cation exchange capacity (CEC) (the amount of absorbed bases and hydrogen ions) is a crucial characteristic of the soil. It consists of the absorptive capacity of human substances, mineral soil particles, as well as the microorganisms that it includes. The value of soil CEC is correlated with the content of humus in it, the granulometric and mineralogical composition and the level of pH. Soil has a buffering capacity depending on the amount of soil ionic exchange. Hence it has different resistance to external effects (Bashkin et al., 1993).

The type of water regime characterizes the geochemical sustainability of the soil, which is largely determined by the intensity of the removal of substances outside this landscape, the rate of scattering these to the surface, as well as underground drainage and air flow. Based on the classification of types of water regime, Vysotsky and Rode (1965) is necessary to allocate: leaching type and periodical leaching regime (as an intermediate form), non-leaching, and exudative and desuctive-exudational (or stagnation). Leaching type leads to the removal of pollution products; exudative, desuctive-exudational regimes lead to an accumulation of pollution products in the soil profile.

The canopy also helps to reduce soil degradation from erosion. Geosystems covered with a large area of canopy are more resistant to external impact than areas without canopy.

Integral assessment of the sustainability of geosystems to human impacts was obtained by summing the ratings analysed parameters within the operating units of study, which in our work is the landscape. It is based on previously made contact medium-scale landscape map (1:5000 of the Sarysu Basin (*Figure 1*; *Table 2*), which allocated 58 individual landscapes as a result of its typological groups, and also based on the result of the following structural-genetic classification, where groups are arranged in a hierarchical taxonomy: class (plain and mountain landscapes), types (semi-desert and desert landscapes), subtypes (north-desert and south-desert landscapes).

The maximum possible score that characterizes the highest relative sustainability for the area was set at 100%; all other points are expressed as a percentage, which was carried out by recalculating the total points according to the equation presented in Orlova (2002). See equation (*Eq. 3*):

$$C = \frac{100 \sum_{g=1}^{n} Cg}{Q} \quad \text{(Eq. 3)}$$

C - Assessment of potential sustainability of geosystems to anthropogenic influences, %;
Cg - score for each indicator;
Q - maximum possible amount of points;
g - serial number indicator;
n - number of indicators.

DOI: http://dx.doi.org/10.15666/aeer/1504_17331744

As a result, the following were identified as a Geosystems Group, where grading was based on the total points (%): relatively sustainability geosystems, 100–90; average sustainability, 90– 80; weak sustainability, 80–70; low sustainability. less than 70.

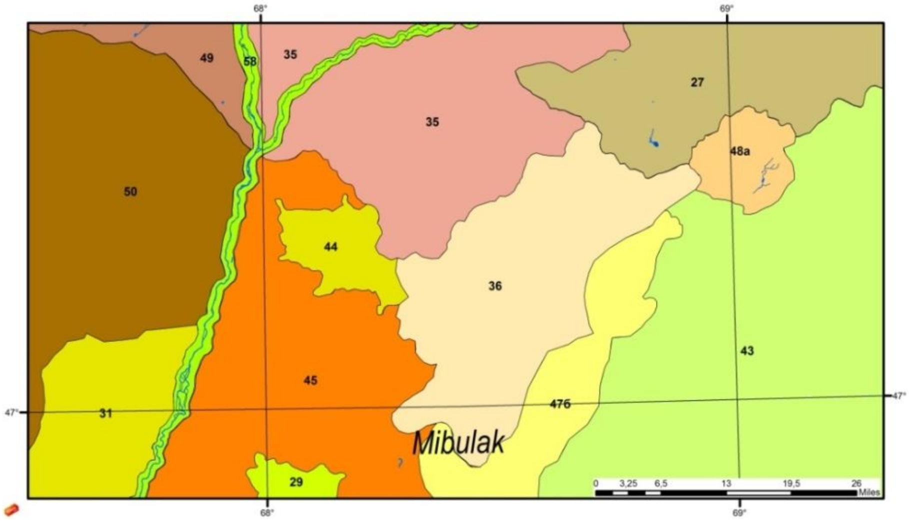

Figure 1. *Landscape map of Sarysu Basin, Kazakhstan (fragment)*

Results

According to the integral estimation of geosystem sustainability we could define that geosystems with the relatively degree of sustainability (landscapes 12, 14, 25, 26, 27, 33, 35, 57) spread over 19.69% of the basin. Geochemical landscapes have an eluvial position with two rather different major landforms: hilly terrain with different slopes (especially 2–6°); and geosystems characterized by relatively favourable thermal and hydrothermal conditions. Dominated by medium and heavy loam automorphic soils, characterized by a non-leaching water regime, non-saline and with neutral or close to neutral the reaction of the soil solution. The humus content inthe layer of 0–20 cm is on average 2.3%, humus horizon is around 12–38 cm. The Cation Exchange capacity is around 16–17 mg.ekv /100 gr. soil. The canopy area is around 70–75% (*Table 3*; *Figure 2*).

Geosystems which have an average degree of sustainability occupied 35.68% of the basin (landscapes 1, 2, 3, 4, 7, 10, 13, 15, 16, 18, 19, 21, 29, 31, 45, 49, 55, 55b, v). Mostly they are hilly and uplands-ridged-sloping plains with low mountain terrain. The geochemical geosystems have an eluvial position with different surface slopes (mostly 0–5°) and low mountain (4 –21°) dominated by medium and light loam automorphic soils, characterized by a leaching water regime, slightly saline, and with neutral or slightly acidic and slightly alkaline reaction of the soil solution. The humus content in the layer of 0–20 cm is around 2.1%, humus horizon is around 15–20 cm. The cation exchange capacity is around 15–16 mg.-ekv / 100gr soil. Hollow sleepy sloping plain is almost completely ploughed up, and uplands-ridged low mountains have an average degree of canopy.

Geosystems which have a weak degree of sustainability occupied 41.26% of the basin (landscapes 5, 8, 9, 11, 17, 24, 28, 30, 32, 34, 36, 42, 43, 50, 51). The geochemical geosystems has a transit and accumulative position mainly with flat terrain and slopes of surface of around 2°, dominated by hydromorphic loamy and sandy loam soils, characterized by an exudative water regime, moderately saline, and with an alkaline reaction of the soil solution. Depending on the type of soil humus content can change in the layer of 0–20 cm in the scope of values reaches 10.5 and is 1.5–12%, humus horizon is around 10–11 cm. The cation exchange capacity is around 15 mg.-ekv./100 gr. soil. The canopy area is around 55–65%.

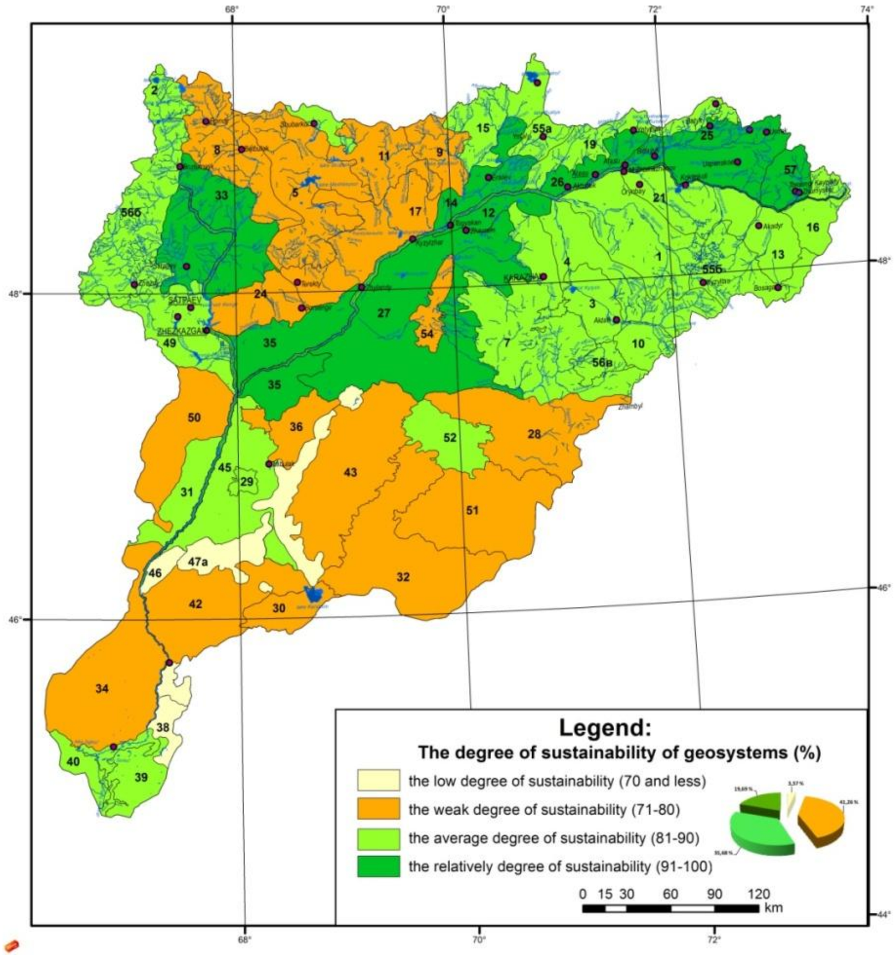

***Figure 2.** Map of landscape sustainability of Saursu Basin, Kazakhstan in conditions of human impact*

The last group of geosystems (landscapes 46–48) was determined like those with a low to anthropogenic impact. They are hilly-ridged Aeolian plains with wheatgrass, artemisia terrae-albae-ceratoides vegetation on the sand, and floodplain meadow soils. The geosystems mainly have an accumulative position with flat relief and slopes around 0–2°. Sandy hydromorphic soils have a desuctive-exudational water regime, moderately saline, and an alkaline reaction of the soil solution. The humus content in the layer of 0–20 cm is around 0.3–0.4%, humus horizon is around 5–7 cm. The cation exchange capacity is around 16–17 mg.-ekv/100 gr. soil. The canopy area is around 25–30%.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_17331744

In general, geosystems with a low degree of sustainability (41.26%) and an average degree of sustainability (35.68) dominate the study area. In the future, information about geosystems, obtained via the assessment of sustainability will be interpreted from the standpoint of commercial geography, to develop the optimum environmental management structure. This structure includes information about the status of the potential sustainability of geosystems with regard to human impact, and the level of anthropogenic load on geosystems. Sustainability is regarded as a special natural resource because it an environmental assimilation capacity environment concerning the emission of substances and energy. Moreover, it can be used as an indicator to determine environmental policy during human impacts. It is assumed that the optimum environmental management structure does not lead to negative consequences, and does not reduce geosystems' features of resource and environmental forming. On the other hand, imperfect environmental management formed without the landscape features of the territory leads to disruption and degradation.

Conclusions

The Sarysu Basin region is a closed drainage basin with poor biodiversity eroded by aquatic, but also the strength of intensive and direct air links. The Basin is located mainly within desert and semi-desert landscape zones. The Basin's geosystems have a combination of natural factors, which strengthen the pollution of geosystems. Hence it cuts down the centralization, streamlining, self-organization and sustainability of the landscape.

The integral evaluation of the level of sustainability of natural complexes to anthropogenic impacts by identifying landscape factors of the geosystems allows the identification of landscapes with different levels of sustainability potential (from relatively stable to weakly stable). It demands different approaches in the development of environmental management structures. The research identified geosystems with sustainability relative to human impact located at the Sarysu flow in the upper steam. The upper steam geosystems are eluvial and have favourable thermal and hydrothermal conditions, whereas geosystems located at the flow subsidence are accumulative, with low resilience.

Abstract. This paper evaluates the quality of the groundwater in and around a coconut husk retting area. The area selected for the study is Mondaikadu of Kanyakumari district, Tamil Nadu, India, which is very near to the coast of the Indian Ocean. Groundwater samples were collected during summer, winter and pre-monsoon season and analyzed using analytical instruments. It was observed that the groundwater quality is significantly affected by coconut husk retting process. The pH level in the groundwater was found to be unacceptable because it was below the permissible limit of 6.5 to 9.2 as per the World Health Organization (WHO) and Bureau of Indian Standards (BIS). All other parameters such as Total Dissolved Solids (TDS), Electrical conductivity (EC), Hardness, Calcium (Ca), Magnesium (Mg), Sodium (Na), Potassium (K), Ferrous (Fe), Manganese (Mn), Nitrate (NH_3), Chloride (Cl), Fluoride (F), Sulphate (SO_4) are within the limits. Low pH water was neutralized using addition of Sodium Hydroxide methods (NaoH), addition of soda ash and aeration process. Using correlation analysis, the dependent and independent variables were selected and regression analysis was conducted for these variables and the best fit regression model was created.

Keywords: *correlation, regression, pH, electrical conductivity, neutralizer*

Introduction

Water is one of the most common and most precious resources of our earth. About 80% of the earth's surface is covered with water. It cannot be made electronically or hydrologically or by any other means (Brindha and Elango, 2011). It may be classified as groundwater and surface water. Groundwater is the main source for drinking purpose. Groundwater contains less pollution as compared to surface water and does not have suspended solid particles also having less turbidity (Gajendran et al., 2013). The most important environmental issue is groundwater contamination (Oyelami et al., 2013). About 70 % of India's groundwater resource has been contaminated by organic, inorganic and biological pollution (Anitha and Sugirtha, 2013). Most of the contamination occurs on account of mining, land clearance, agriculture, acid precipitation, domestic and industrial waste (Appelo and Dieke, 2005). Population growth and rapid urbanization are one of the reasons for qualitative degradation of groundwater (Abd El-Salam and Abu-Zuid, 2015). The soil influence on the water quality of an area is very important and it can be described as the process controlling the exchange of chemicals between the soil and water (Hesterberg, 1998). The groundwater quality is constantly changing with respect to season and climate. As per WHO, about

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_17451756

80 % of all the diseases in human beings is caused by impure water. Recent results indicated that many groundwater quality analyses have been conducted in different areas, such as landfill leachate, limestone aquifer, municipal land fill lagoons, rural settlement, municipal solid waste site etc. (Abd El-Salam and Abu-Zuid, 2015; Jamshidzadeh and Mirbagheri, 2011; Longe and Balogun, 2010; Adekunle et al., 2007; Kurakalva et al., 2016). It is important to identify the source of pollution to avoid future degradation of groundwater quality (Dieng et al., 2017). This is the first study to conduct the groundwater quality analysis near the coconut husk retting area.

In the process of retting of a coconut husk lot of solid waste is produced. This gets mixed up with solids and gradually decomposes. This merges with the soils and the aquifer and pollutes the groundwater system. The effluent generated from the coir industry is acidic, also contains phenolic compounds and other toxic substances (Simple Lotus, 2012). The heavy pollution caused by the retting yards is found to have serious environmental degradation and ecosystem damage. Many researchers analysed the physic- chemical characters of the retting water and finally they found that it will affect the retting water and land. It causes serious health impacts to the people (Najee and Philipose, 2013; Manoj, 2014). Due to the contamination of surface water the soil may get contaminated (MaryHelen et al., 2011). This leads to groundwater contamination. In order to assess the quality of water continuously, prediction is needed. The prediction can be used for resource planning and management if it is of acceptable accuracy (Seyyed et al., 2013). Recently, mathematical, statistical, computational and spatial analysis is used to simulate and assess many aquifer water quality parameters. Spatial analysis of pollution is used to identify the source of the pollution in a particular study area (Ang et al., 2016).

Regression analysis was the linear modelling tool used for prediction. It is a form of predictive modelling technique which investigates the relationship between a dependent and independent variable**.** This technique was used for forecasting, time series modelling and finding the causal effect relationship between the variables. The curve must be fitted to the data points, in such a manner that the differences between the distances of data points from the curve or line was minimized. In this study it was used to predict one dependent variable by using other independent variables.

The main aim of this study is to assess the groundwater contamination in the area specified, to compare the water quality parameters with drinking water quality standards, suggestions were given to treat the contaminated water and the groundwater quality modelling is created. Regression analysis is used to create the groundwater models. The parameters selected for analysis were based on the correlation matrices.

Kanyakumari District is mostly covered by costal area. The geographical extent of Kanyakumari District is 1,672 km^2. The soil type is mostly red loam and laterite with coastal alluvium in the south. The district has a warm and humid climate with a maximum day temperature ranging between 24 °C and 34 °C throughout the year and an annual rainfall of 146 cm. The main occupations of the coastal area are coir making and fishing (ENVIS Centre, Tamil Nadu). In the coir production process, the coconut husk is soaked in a retting pond for a period of 6 months to one year. During this period, it may produce a lot of organic, inorganic and biological components. This process is highly affecting the quality of water in the retting pond. It produces a bad smell around the surrounding places.

The area taken for this study is Mondaikadu at Kanyakumari District. Mondaikadu lies between 8°9’47” latitude and 77°16’48.09” longitude. It is a Panchayat town of

DOI: http://dx.doi.org/10.15666/aeer/1504_17451756

Kanyakumari District, Tamil Nadu. Here, the coconut husk retting operation is carried out near the AVM canal. That canal water is used for the coconut husk retting process.

Material and methods

The water sampling process was done during winter, summer and monsoon seasons for the period of three years from December 2012 to November 2015. There were 10 groundwater samples collected from different bore wells near the retting site. The specifications of the different bore wells are mentioned in *Table 1*. Samples were collected in one 1itre polythene bottles, which were pre cleaned with concentrated hydrochloric acid and distilled water. pH was measured on the site with a digital pH meter (Ahamefula et al., 2013). This was done to avoid unpredictable changes in characteristics as per the standard procedure (APHA, 1998). All the collected samples were preserved in the refrigerator and the analysis such as TDS, EC, Hardness, Ca, Mg, Na, K, Fe, Mn, NH3, Cl, F, SO_4 were completed in the Environmental engineering laboratory within two days.

Results and discussion

Statistical analysis

Physical and chemical properties of the groundwater in all the three seasons are evaluated. Each season has different range of parameters. In general, the winter season has higher values compared to the other two seasons. As compared to WHO (1993) and BIS (2009) standards all parameters are within the permissible limit, except pH. *Table 2* shows the comparison of BIS, WHO standards and minimum, maximum range of each parameter.

pH value

The pH range of groundwater for all the three seasons is below the permissible level of WHO and BIS, which means the water is acidic and corrosive in nature. *Figure. 1* shows the spatial variation of the pH in various sampling sites for three seasons. The map was interpolated by using kriging method. Kriging is a linear interpolation procedure that provides linear unbiased estimation for quantities, which vary in space and it is an advanced geostatistical procedure for interpolation (Gunarathna, 2016).

The main reason for low pH is a low concentration of ions present in the groundwater. The effluent from the retting site is acidic, this may be the reason for low pH in the study area. As per WHO, if the pH range is less than 6.5 or greater than 9.2 it affects the portability of the drinking water. But it has no direct impact on human health (Jasem et al., 2010). U.S. environmental protection agency says that low pH in water can damage the metal pipe and give the sour taste (EPA, 2003). It may be treated by adding neutralizer to the water. Neutralizer prevents the water from reacting with the metal pipe.

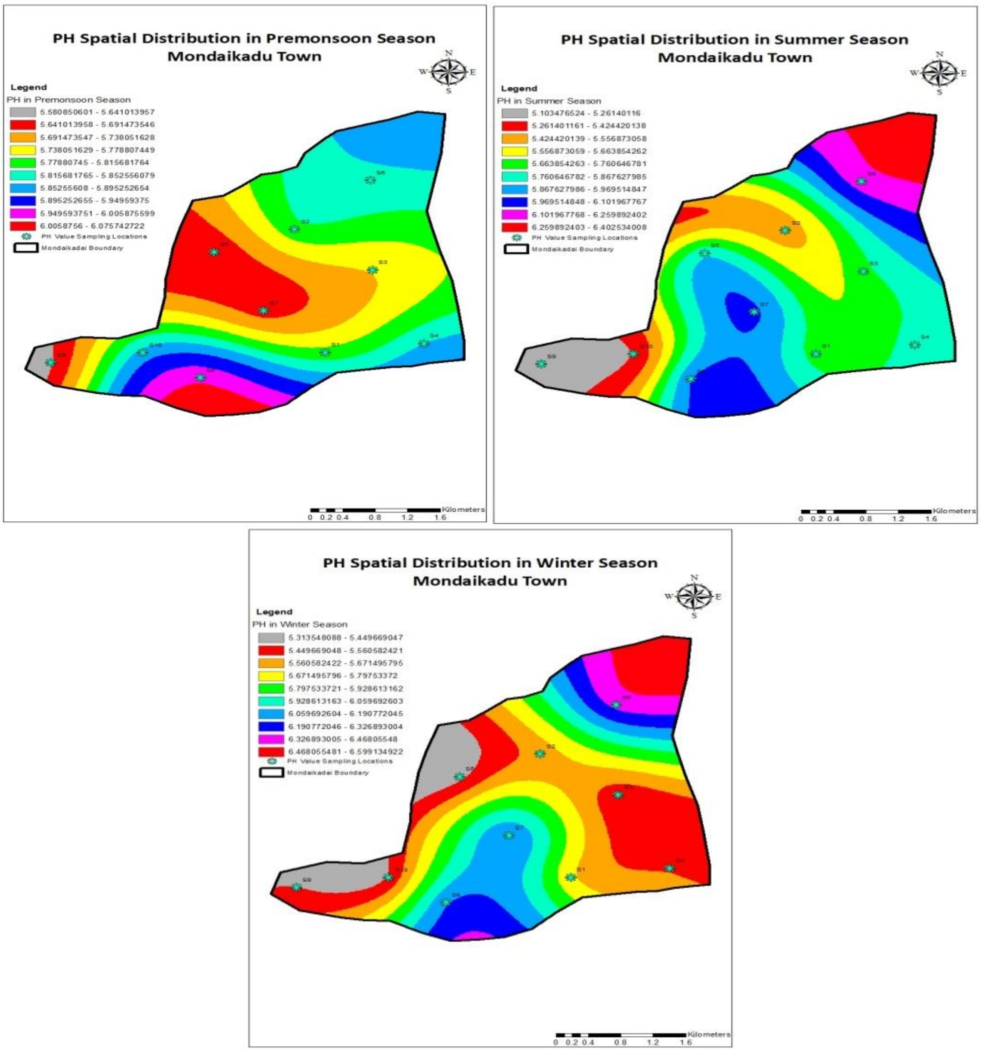

Figure 1. *Spatial variation of pH for three seasons*

Neutralize the low pH water

1. Addition of sodium hydroxide (NaOH)

This is the one of the best methods to increase the pH level in water. Titration method is used to determine the amount of NaOH needed to raise the pH of the water. NaOH solution is prepared by adding 4 g of NaOH pellets to 100 ml of distilled water. Then the NaOH solution obtained is taken as the burette solution and titrated against 20 ml of water sample. Phenolphthalein ($C_{20}H_{14}O_4$) is added as the indicator and the end point is colourless to pink. The burette reading gives the amount of NaOH used for 20 ml of the water sample. If sodium hydroxide is added manually, good ventilation should be maintained to avoid breathing vapours and wear protective gloves, goggles to avoid skin and eye contact (Wagenet et al., 1995).

The amount of NaOH added to the water is calculated using the below formula:

$$\text{NaOH needed} = \frac{(\text{NaOH used per litre of Sample} \times \text{Normality of NaOH} \times \text{Equivalent weight of 1 litre of 1 N NaOH})}{1000}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_17451756

The calculated quantity of NaOH added to the water (H_2O) and mixed thoroughly suddenly pH level is increased by the following reaction:

$$H_2O + NaOH \rightarrow \text{aqueous solution containing NaOH}$$

Water reacts with NaOH to form an aqueous solution containing NaOH.

2. Addition of soda ash

120 g of soda ash is added to 1 L of water (Glenda and Jennings, 1996). The sample is stirred well, so that the soda ash gets completely dissolved in water. Now the pH of the water sample is measured. The reaction is taking place as follows:

$$2H_2O + Na_2CO_3 \rightarrow 2NaOH + H_2CO_3$$
$$H_2CO_3 \rightarrow H_2O + CO_2 \uparrow$$

Water reacts with sodium carbonate (Na_2CO_3)to form NaOH and carbonic acid. Carbonic acid decomposes to water and carbon dioxide.

3. Aeration process

The process by which air is circulated through, mixed with or dissolved in a liquid is called aeration. In this method, water is taken in a vessel and air is supplied to the water using an aerator. Immediately air bubbles will be produced and the pH gets increased. Water displacement from the expulsion of bubbles can cause a mixing action to occur and the contact between water and the bubble will result in oxygen transfer. 3.78 L of water are aerated for 2 s to increase the pH of water to a permissible level (Kirby et al., 2007).

Table 3 shows the amount of pH present in the water before and after the neutralizing process. It seems that all methods of a neutralizer are very effective one.

Table 3. *pH before and after neutralizing*

Sample no.	Neutralizing method			
	Initial	NaOH	Soda ash	Aeration
1	5.98	7.95	7.69	8.14
2	5.81	6.83	8.05	7.86
3	4.67	8.07	7.70	7.74
4	5.26	7.66	6.99	7.17
5	5.32	7.48	8.22	8.32
6	4.74	7.52	8.12	7.58
7	4.33	6.98	6.89	7.71
8	4.60	7.31	6.91	7.35
9	4.4	7.1	6.7	7.12

Correlation analysis

Correlation analysis is used to check the relation between the variables. It is the one of the methods of multivariate statistical study. Many statistical analysis were conducted to determine the temporal variations of the study area. Many statistical analysis were conducted in various research (Özdemir, 2016; Asfandyar et al., 2016; Tokatli, 2015). Correlation analysis is the easiest one among all.

All variables are used to check the correlation. The correlation coefficients are computed using the following equation (*Eq.1*):

$$r = \frac{\sum xy}{\sqrt{(\sum x^2 \mathrm{X} \sum y^2)}} \qquad \text{(Eq. 1)}$$

where $x = X - \bar{X}$; $x = \frac{\sum x}{n}$; $y = Y - \bar{Y}$; $y = \frac{\sum Y}{n}$; n = no of samples.

SPSS 20 software was used to conduct the correlation analysis. There were 50 samples used to find out the correlation between the variables. If the correlation coefficient (R) between the parameters are closer to 1 then the parameters are more positively correlated.

Table 4 shows the correlation matrix for the different variables. It shows that the correlation between fluoride (F) and Cl is having lower R value, that is 0.001.

Table 4. *Correlation matrix between the variables*

Parameter	Turbidity	TDS	EC	pH	Alkalinity	Hardness	Ca	Mg	Na	K	Cl
Turbidity	1										
DS	0.482	1									
EC	0.47	0.984	1								
pH	0.085	-0.321	-0.277	1							
Alkalinity	0.355	0.7	0.708	-0.253	1						
Hardness	0.501	0.926	0.951	-0.184	0.633	1					
Ca	0.291	0.734	0.706	-0.14	0.618	0.665	1				
Mg	0.464	0.882	0.909	-0.33	0.605	0.932	0.519	1			
Na	0.382	0.951	0.937	-0.319	0.715	0.817	0.779	0.772	1		
K	0.24	0.699	0.637	-0.344	0.612	0.447	0.665	0.422	0.803	1	
Cl	0.469	0.97	0.946	-0.28	0.557	0.923	0.667	0.861	0.889	0.607	1

The reason for the low correlation is due to the ionic alteration by anthropogenic activities (Bodrud-Doza et. al., 2016). EC is highly correlated with TDS, hardness, Mg, Na, Cl, and the values of correlation coefficient (R) are given in the *Table 5*. The reason

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_17451756

for the high correlation was that the parameters are related to each other. If the EC was highly correlated parameter it means it depends on TDS, hardness, Mg, Na, Cl. If, these values increase it means EC also increases and if these values reduce that means EC value reduces. Therefore EC was called a dependent variable and other parameters are independent variables. These independent variables are not dependent on EC. These highly correlated variables were used as data for regression analysis.

Table 5. *Correlation coefficient (R) value of most correlated parameters*

Parameters	R value
EC-TDS	0.984
EC-Hardness	0.951
EC-Mg	0.909
EC-Na	0.937
EC- Cl	0.946

Regression model

The aim of the regression analysis is to determine the relation between the dependent variable and independent variable. The dependent variable is EC and the independent variables are TDS, Hardness, Mg, Na, and Cl are selected from the correlation analysis. Since the number of independent variables is more therefore multiple linear equation is created. *Eq. 2* shows the multiple linear equation of the variable:

$$y = a_1x_1 + a_2x_2 + a_3x_3 + a_4x_4 + a_5x_5 + c \quad \text{(Eq. 2)}$$

where y represents the EC content and, x_1, x_2, x_3, x_4, x_5, represent the TDS, Hardness, Mg, Na, Cl respectively; a_1, a_2, a_3, a_4, a_5 are the corresponding coefficient of the independent variables, c is the constant of the regression equation. The best fit model is found based on the coefficient of determination (R^2). If it is nearer to 1, there is a good relationship between the dependent and independent variables.

Multiple linear regression analysis were conducted in the Matlab programming for the regression model. The constants are calculated and the model is developed as *Eq. 3*:

$$y = 0.0129x_1 - 0.141x_2 + 0.112x_3 + 6.46x_4 + 1.64x_5 + 131.66 \quad \text{(Eq. 3)}$$

Figure 2 shows the regression plot for the target and predicted EC content. The R value of the regression model is 0.95995. It shows that there is a good relationship between the target and the output of the model. *Figure 3* shows the linear relationship between the observed and regression predicted EC. The coefficient of determination, R^2 value is 0.9215; this value shows that the predicted EC has a good coefficient of determination with observed EC.

DOI: http://dx.doi.org/10.15666/aeer/1504_17451756

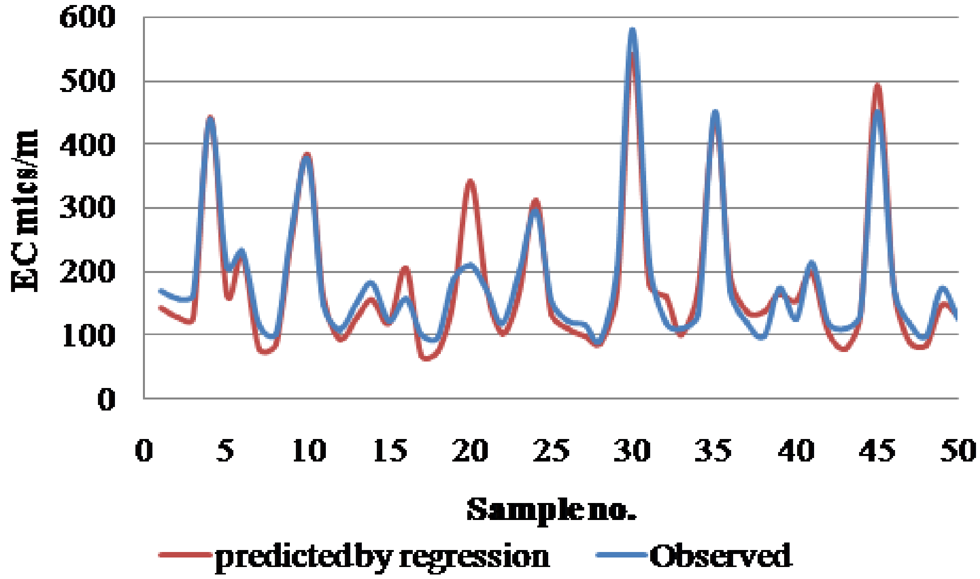

Figure 4. *Comparison of observed and predicted EC*

Conclusions

The result of study indicates that the borewell water in the coconut husk retting area are suitable for domestic purpose. The experimental analysis reveals that the parameters such as TDS, EC, Hardness, Ca, Mg, Na, K, Fe, Mn, NH_3, Cl, F and SO_4 of all 50 samples are within the prescribed limit of WHO and BIS, except for pH. The water can be used for drinking after neutralising by addition of NaOH, addition of soda ash and aeration methods.

The results of correlation analysis shows that EC was highly correlated with other parameters. The regression analysis shows the coefficient of determination for the observed and predicted EC was 0.9215, which was close to one, therefore regression model was a good prediction tool for this problem.

Abstract. The purpose of this study was to evaluate the general profile of wildlife in Turkey in terms of injured wild animals, their treatment and re-introduction to the nature. It was analysed the records regarding the Treatment and Rehabilitation of wild animal, collected from 2012 to 2015 and determined the number of wild animals injured in nature and treated, the number reintroduced to nature, the amount settled in zoos and having died during this process. Of 11,110 treated animals, 50.18 % were reintroduced into nature, 24.95 % were settled into zoos and the remaining 24.87 % died. However, the evaluation in this study also showed that the number of both harmed and dead animals in nature has been gradually increasing by years ($p < 0.05$). This study covered a general evaluation of the damage on the wild animals in Turkey; therefore there is a need for detailed exploration of these damages, including the causes, consequences and proposals for solutions in the future. In this context, it is also important to increase opportunities for cooperation between Ministry of Forestry and Water Affairs, other countries, universities and relevant NGOs.
Keywords: *recording system, conservation, rehabilitation, wildlife damage*

Introduction

Turkey is a rich country in terms of the variety of species within its three bio-geographical zones, Europe-Siberia, Mediterranean and Iran-Turanian (Demirsoy, 2002; Eken et al., 2006; Atalay and Efe, 2015). As in other countries, however, industrialization and technological development, population growth, unplanned urbanization, thoughtless use of agricultural chemicals, environmental pollution and drying out of water sources, continues to cause serious habitat loss that threatens Turkey's wildlife (Hadidian et al., 2006; Ogurlu, 2008; Aslan et al., 2011; Akkuzu et al., 2015). Diseases, injuries and death in wild animals are mostly due to human activity and unnatural causes (Vitouse et al., 1997; Sanderson et al., 2002; Manfredo and Dayer, 2004; Thompson et al., 2010; Burton and Doblar, 2004). In many developing countries, with widespread poverty and weak institutionalization, intense pressures to hunt, and the conversion and fragmentation of wildlife territories cause conflicts between humans and wildlife (Bulte and Rondeau, 2007; Gore et al., 2008; Chynoweth et al., 2016; Ambarlı et al., 2016). Yet, wildlife is not only critical to maintaining the integrity of the earth's ecosystem but wild animals are also biological indicators of environmental conditions in urban and rural areas. Although public interest in wildlife has increased nowadays, wildlife species and habitats are more threatened than ever before. In

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_17571763

response, the rehabilitation of wildlife has been highlighted in recent years, with studies being conducted with official rehabilitation centers on how to mitigate human impact on wildlife (Burton and Doblar, 2004). The determination of morbidity and mortality rates in wildlife is important for both wildlife conservation projects and resettlement or relocation projects (Gilmartin et al., 1993). As well as its importance for ecosystems, wildlife is also a significant risk element in the emergence of new zoonoses (Cabello and Cabello, 2008; Thompson et al., 2010; Rout et al., 2016). Approximately 75 % of emerging diseases during the past few decades have included zoonoses originating from wildlife (Bengis et al., 2004; Jones et al., 2008).

Responsibility for the protection, development and sustainable management of wildlife resources and biodiversity in Turkey lies with the Ministry of Forestry and Water Affairs. In Turkey, various laws have been enacted to protect, support and maintain wildlife for future generations, with various organizations for the conservation of nature being established and Turkey becoming a party to international conventions. Although new regulations prepared with a view to these conventions make an important contribution protecting wildlife, it is essential that Turkey continues to increase such efforts, and that the value of biological assets and their relevant rights are disseminated comprehensively (Aslım et al., 2012). The General Directorate, which is responsible for protecting wildlife resources and biological diversity, supporting them and preserving them for future generations, carries out its duties through 15 regional directorates under the General Directorate. Game and Wildlife Units within the regional directorates co-operate with Wildlife Rescue and Rehabilitation Centers established by the ministry, veterinary faculties and zoos, in accordance with protocols governing the protection, treatment and release of wild animals (www.ormansu.gov.tr).

This study is the first research to reveal the suppression on wildlife in Turkey and to draw attention to the damage in wild animals. Despite being a rich country in terms of wildlife, there is a big deficiency in Turkey in terms of the studies in this area. The sustainability of wildlife depends on the existence and continuity of such investigations. In this respect, the purpose of this study was to evaluate the general profile of wildlife in Turkey in terms of injured wild animals, their treatment and re-introduction to the nature and make recommendations.

Materials and Methods

The data used as the material of this study which covers the period between 2012 and 2015 was collected from the Department Directorate of Game and Wildlife of the Ministry of Forestry and Water Affairs (DKMPGM) in Turkey.

The research material comprises information forwarded to DKMPGM from the 15 regional directorates since 2012 while data for 2015 includes records to October. The records contain information regarding the number of animals seized for violation of Law 4915 (Official Gazette, Date: 11/7/2003, Number: 25,165) and the CITES convention (Convention on International Trade in Endangered Species of Wild Fauna and Flora – Accession: 23/09/1996, Entry: 22/12/1996), the number of animals harmed in nature and treated, the number of treated and released animals, and the number of animals placed into rescue centers or zoos. The number of dead animals was calculated from inventory records. Data regarding seized animals for violating Law 4915 and the CITES convention were eliminated. Data were analyzed by using SPSS 20.0 computer software package program. General analysis of data

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_17571763

was carried out using frequency counts and percentages. Comparisons between the annual records of wild animals was performed by ANOVA and significance was tested by Duncan test.

Results and Discussion

The relevant inventory figures for wild animals registered by the DKMPGM between 2012 and 2015 is given in *Table 1* and shows the number of animals recorded yearly.

Table 1. *Numbers of suffering wild animals registered 2012-2015*

Year	Animals treated and released into nature[A]	Animals treated and placed in the rescue centers/zoos[B]	Dead animals[C]	Total animals harmed in nature and treated[A+B+C]
2012	821	408	451	1680
2013	1211	643	535	2389
2014	1763	830	734	3327
2015	1780	891	1043	3714
TOTAL	5575	2772	2763	11110

[A+B+C]Total animals harmed in nature and treated

The total number of animals registered over the four years categorized by registration criteria is given in *Figure 1* of 11,110 wild animals harmed in nature and treated within this four year period, 50.18 % were released back into nature, 24.95 % were placed in zoos and the remaining 24.87 % died. The proportion of animals treated and released in Turkey was 50.18 %, which is consistent with a study of RIAS in, Portugal, a wildlife rehabilitation center. In 2015, this centre received 1,335 wild animals including reptiles, birds and mammals. Of these 52.3 % was released in to nature after treatment and rehabilitation while 22 % deaths were determined (http://www.aldeia.org/portal/user/documentos/relatorio_RIAS_2015.pdf.).

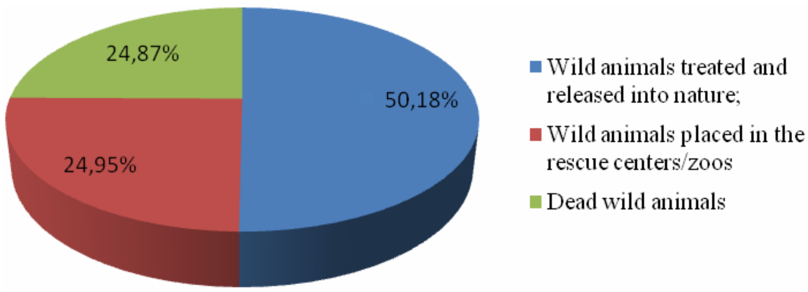

Figure 1. *The total distribution of wild animals registered during 2012-2015 (4 years)*

The distribution of recorded wildlife by taxonomic group shows that almost 85 % of registered species were birds and mammals (*Figure 2*). As *Figure 2* shows, according to the number of animals registered, the most frequently injured and/or diseased species in Turkey are birds. However, because there were no data about the causes of injury

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_17571763

and/or disease, the researcher could not compare and/or analyse these issues in the study. Records are also available, in fewer numbers than for birds or mammals, for invertebrates, fish, amphibians and reptiles. Due to the seasonal changes concomitant with its geographical location, many species use Turkey as a feeding area or overwintering and breeding area (Baran, 2005; Kiziroğlu, 2008). Furthermore, Anatolia is also a transit zone during spring and autumn bird migrations, with many species migrating across Turkey between Europe, Africa and Asia (Hagemeijer and Mundkur, 2006; Üner et al., 2010; Şekercioğlu et al., 2011).

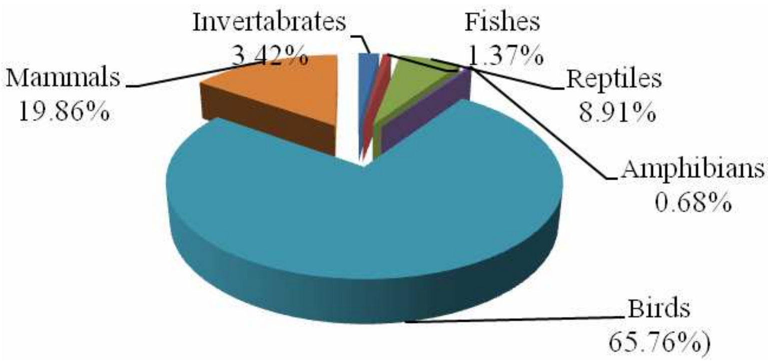

Figure 2. *The taxonomic distribution of recorded wild animals*

The categorization of the recorded wild animals by loss and compensation status is evaluated in *Table 2*. It clearly shows that number of wild animals that were harmed and died in nature. However, the number of wild animals released or placed into zoos has not changed.

Table 2. *Changes in recorded damaged wild animals by year*

$^{A+B+C}$Total animals harmed in nature and treated
*Means in the columns followed by different letters indicate statistically significant differences ($P < 0.05$)

According to *Table 2* while this study found no difference in the data between numbers of animals released into nature or placed into zoos while there were significant ($p < 0.05$) increases in both total animals harmed in nature and treated and both failed to respond to treatment and subsequently dead animals. The reason for this statistical increase in the number of animals dying by years may be related to the increase in the number of animals damaged in the nature by years. The increase in the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_17571763

number of animals damaged in the nature may be due to human activity and unnatural causes by years (Ogurlu, 2008; Aslan et al., 2011; Akkuzu et al., 2015).

The reason for the increase in the number of dead wild animals in recent years may be resulted from both the education and implementation studies on the treatment and rehabilitation of wild animals in Turkey have started relatively recently compared with many countries and the numbers of wildlife rescue and rehabilitation centers and the numbers of veterinarians and wildlife experts are inadequate. Although it seems ironically, the recent increase in the number of harmed and deaths in wild animal might have been due to the increase of the result of conservation and monitoring activities, scientific projects, social awareness and training activities of DKMPGM in cooperation with universities and NGOs; by this way it may be easier to access and record than in the past.

Conclusion

Consequently, in this research it was found that the damage of wild animals was increasing from by years. This situation shows that wild animals are under some threats in Turkey. These threats on wildlife should be identified and produced solutions. The decisions taken by DKMPGM to establish a Wildlife Rescue and Rehabilitation Center in each region promises hope for the future of Turkey wildlife. Additionally, increasing the number of wildlife rescue and rehabilitation centers, providing opportunities for the training of wildlife veterinarians and rehabilitators, supporting wildlife researches, dissemination conservation and awareness-raising activities are important for sustainable wildlife in Turkey. In this context, it is also important to increase opportunities for cooperation among the government ministry, other countries, universities and relevant NGOs. This study is the first research about the Turkey wildlife damage. Following this first study, which investigates the suppression of wild animals in Turkey, there is a need for studies that include causes, consequences and suggestions for solutions of casualties on wild animals in Turkey. These studies are important not only for the wildlife of Turkey, but also for the sustainability of the wild life which is the common ecological heritage of the whole world.

Acknowledgemens. This study was supported by Afyon Kocatepe (BAPK Project No: 15.HIZ.DES.133). We thank the Ministry for Forestry and Water Affairs, the General Directorate of Nature Protection and National Parks and the Department Directorate of Game and Wildlife for providing the raw data for our analysis.

Abstract. *Prangos ferulacea* is one of the species of essential oil plants, which is appreciated because of its value in medicine, perfumery, and forage industries. In order to gain the optimum oil yield of *P. ferulacea*, the essential oils of fertile and infertile individuals were isolated from the aerial parts by steam distillation and hydrodistillation methods at three maturity stages of pre-flowering, flowering, and seeding. The oils were analyzed by capillary GC (Gas Chromatography) and GC/MS (Gas Chromatography/Mass Spectroscopy). The extraction yields from the aerial parts of *P. ferulacea* were found to be 0.17% and 0.24-0.29% for steam distillation and hydrodistillation, respectively. The highest oil yield was obtained at the flowering stage in infertile individuals (0.29% w/w) for hydrodistillation. Thirty-four components, comprising 99.98% of the total oil, were identified at the flowering stage of infertile individuals, in which (E)-caryophyllene (48.21%), α-humulene (10.28%), spathulenol (9.36%), linalool (3.46%), and δ-3-carene (3.37%) were recognized as the major components. Based on our findings, essential oil yields vary considerably from stage-to-stage and are also influenced by extraction methods. As well as, we found that infertile individual at the flowering stage can strongly enhance the quality of commercial oils in *P. ferulacea*.
Keywords: *Prangos ferulacea, steam distillation, hydrodistillation, (E)-Caryophyllene, α-Humulene, δ-3-Carene*

Introduction

The genus *Prangos* consists of 30 species, 15 of which grow wild in many regions of Iran, and five are endemic (Mozaffarian, 1996). *Prangos ferulacea* (L.) Lindl. is found in the Balkans, Italy, Sicily, W. Syria, Caucasia, Turkey, and semi-arid regions of Iran (Rechinger, 1987; Ghahreman, 1997). This species is well-known for its economic importance in the form of various essential oils and for its high forage quality (Ayres et al., 1994; Sefidkon et al., 1998; Razavi, 2012).

The storage of essential oils in *P. ferulacea* is not restricted to specific parts of the plant. In fact, essential oils occur in roots, stems, leaves, flowers and seeds, or in the plant as a whole. Various compounds have been already identified in the oil of *P. ferulacea*. The number of components in the aerial parts and the seed is more than 30

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_17651776

components according to Sefidkon and her colleagues (1998) and Razavi (2012). Moreover, 39 and 33 components were reported in the fruits (Massumi et al., 2007) and the roots (Sajjadi et al., 2011), respectively. Besides the applications in cosmetics, perfumes, and flavors, essential oils have been studied with regard to their antimicrobial properties (Eshbakova et al., 2006; Massumi et al., 2007), antioxidant properties (Razavi, 2012), hypoglycemic activities (Soltani band et al., 2011; Mohammadi and Zare, 2013), and antihyperlipidemic effects (Ramesh and Pugalendi, 2005).

Previous phytochemical studies on *P. ferulacea* (L.) Lindl. have indicated the presence of coumarin, alkaloid, flavonoid, and terpenoid derivatives. The performed investigations have reported the principal components in the leaves as follows: α-pinene (28.2%), δ-3-carene (15.3%), limonene (8.1%), and myrcene (6.7%); and in the fruit oil: α-pinene (25.4%), 3-n-butylphthalide (13.8%), limonene (10.6%), δ-3-carene (9.1%), and sabinene (8.1%); and in the roots, δ-3-carene (22.5%), β-phellandrene (11.8%), α-pinene (8.6%), terpinolene (7.2%), p-cymene (6.3%), α-phellandrene (6.2%), and myrcene (4.5%).

Not only the ontogenesis, but also the intraspecific variation in particular (i.e., the differences between the individuals of an identical species), must be taken into account for the appropriate treatment of the plant samples, in order to determine the quality and variability of essential oil with regard to their composition. In general, *P. ferulacea* individuals annually seed 5 to 15 percent (Gheitori et al., 1997), and the biological properties of *P. ferulacea* show that it is polycarpic perennial (polycarpic plants flower and fruit more than once in their lifetimes) (Reuther, 2013). Thus, this species has both fertile and infertile individuals at different ranges.

It is worth stating that even though essential oils may be produced from an endemic population, but physiological and environmental factors as well as extraction methods may play an important role in the essential oil quality, purity, and origin, and also the composition of aromatic plants (Hay, 1993; Hay and Svoboda, 1993; Jordán et al., 2013; Sellami et al., 2012). The economic importance of *P. ferulacea* organic compounds in perfumery, food, medicine, and pharmaceutical industries, depends on the extract of the oil during the plant growth stages, which can consequently lead to increase the yield, quality, and purity of components (Ayres et al., 1994; Sefidkon et al., 1998; Coskun et al., 2004; Razavi, 2012).

Hydrodistillation and steam distillation methods can obtain essential oils from the plant material and induce thermal degradation, hydrolysis, and water solubilization of some fragrance constituents or solvent residues (Faborode, 1996). As a part of the biochemical studies at the Plant Biocentre, both techniques have been simultaneously utilized in the volatile analysis of essential oils in order to develop appropriate methods for different purposes.

The aim of the present work is the investigation of the effects of different maturity stages and types of individuals on the essential oil content and the chemical composition of *Prangos ferulacea* (L.) Lindl. For comparison purposes, the essential oils obtained by hydrodistillation and steam distillation were used. To the best of the authors' knowledge, no report has yet been accomplished on the comparison of the essential oil contents and the chemical components of fertile and infertile plants in *P. ferulacea.*

Materials and methods

Study Area

This study was conducted in the Bistoon mountains of Kermanshah province in Iran (north-eastern slope at 34°27′ N and 46°55′ E). The average annual temperature and annual rainfall are 11.88 ºc and 650 mm respectively that more precipitation is snow. At altitudes from 2200 to 2900 m. the plant grows. The site soil is classified as a Regosolic. In the upper 5 cm of the site soil below the litter layer, total soil nitrogen, total soil phosphorus and potassium per unit soil volume are 0.46 (%), 37.6 (p.p.m) and 610 (p.p.m) respectively.

Plant materials

During the annual growth, fertile and infertile plants grow together. First, at the pre-flowering stage, the aerial parts of fertile and infertile plants were cut on April, 12^{th} (stage 1). Then, at the flowering stage, the flowers appeared 42 days after leaf emergence on May, 6^{th} (stage 2). Finally, at the seeding stage, the seeds appeared 62 days after leaf emergence on June, 1^{st} (stage 3). They were cut regularly during May and June 2014 in a sample area of 50 m^2 and randomly replicated three times. At each maturity stage, 36 plant samples were harvested at 10 cm above the ground level. The samples were then dried without conditioning and grounded in a laboratory mill, until they passed through a 1-mm-pore-size screen for chemical analysis.

Hydrodistillation (HD) and steam distillation (SD)

The dried plant materials (including fertile and infertile individuals) were submitted by hydrodistillation and using a Clevenger-type apparatus at each stage of the plant growth (i.e., the pre-flowering, flowering, and seeding stages). Distillation was performed by using approximately 100 g of each plant sample for 2 hours. In order to determine the composition of the oil and the contents at the flowering stage for infertile individuals, the aerial parts of the plant were subjected to hydrodistillation and steam distillation methods. The volatile distillates were collected over anhydrous sodium sulphate and stored in the refrigerator at 4 °C before the analysis. The oil yield was calculated as v/w of the dried plant material. Overall, three oil samples (3 replicates) were prepared from each type of plant, as described above.

GC and GC/MS analyses

GC analyses were performed using a Shimadzu GC- 9A gas chromatograph equipped with a FID and a DB-1 fused silica column (60 m· 0.25 mm i.d., film thickness 0.25 lm). Oven temperature was programmed to 50 C for 5 min, and then increased to 250 C at a rate of 4 C/ min. Injector and detector temperatures were 250 and 265 C, respectively. The carrier gas, helium, was adjusted to a linear velocity of 30 cm/s. The SFE samples (1 ll) were injected into the GC (without any further dilution) using the split mode with a split ratio of 1/60. Hydrodistilled extracts were diluted 30 times and 1 ll of diluted solution was injected into the GC with the same split ratio. The GC/MS analysis was carried out on a Varian 3400 equipped with a DB-1 column with the same characteristics as the one used in GC. The transfer line temperature was 260 C. The ionization energy was 70 eV with a scan time of 1 s and mass range of 40–300 amu. The percentages of compounds were calculated by the area normalization method,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_17651776

without considering response factors. The components of oil were identified by comparison of their mass spectra with those assembled via a Wiley 5 mass spectra computer library or with authentic compounds. Data obtained were confirmed by comparison of their retention indices, either with those of authentic compounds or with the data published in the literature (Adams, 2007).

Statistical analysis

The data on the composition of oils were calculated by analysis of variance (ANOVA) using SPSS software (version 19) (1993).

Results and discussion

Essential oils normally contain a complex mixture of organic compounds. They are largely composed of a range of saturated or partly unsaturated cyclic and linear molecules of relatively low molecular mass and within this range, a variety of hydrocarbons and oxygenated compounds occur. Various parameters, such as environmental and experimental conditions, physiological and ecological responses, growth rates, and productivity, potentially influence on the content and composition of oils. In this study, the main focus has been on the potential of extraction methods, the type of individuals, and the stage of maturity.

In total, thirty-four components were identified in the essential oil of *P. ferulacea* at the flowering stage for infertile individuals, representing 99.98% of the oil. The main components were (E)-caryophyllene (48.21%), α-humulene (10.28%), spathulenol (6.73%), α-bisabolol (4.25%), and δ-3-Carene (3.37%) (*Table 1*).

Table 2 lists the yields, the growth stages, the fertility and infertility states, the compounds, and the chemical composition of the essential oil from the aerial parts of *P. ferulacea*, extracted by hydrodistillation. The highest oil yield was obtained at the flowering stage in the infertile individuals (0.29% w/w) by hydrodistillation.

In some essential oil compounds, significant differences were observed in the growth stage and in the type of individual treatments. Duncan's test was carried out to determine the composition parameters and means ± standard error and also, to test the impact of the growth stage and the type of individual treatments on oil compounds (*Tables 2* and *3*). Furthermore, *Figure 1* compared the percentage of the major components of *P. ferulacea* oils, extracted at different growth stages.

As can be seen in *Table 2*, some oil compositions of *P. ferulacea* were significantly affected ($p < 0.01$) by the type of individuals at the flowering and seeding stages. At the flowering stage, a significant difference was observed between fertile and infertile plants for octen-3-yl acetate, myrcenol, 3-octanol acetate, 1-terpineol, cis-pinocarvyl acetate, and β-eudesmol; and also, at the seeding stage, for α-thujene, myrcene, limonene, δ-3-carene, γ-terpinene, italicene, (E)-caryophyllene, (E)-β-farnesene, and caryophyllene oxide (*Table 2*). This difference may have been resulted from the existence of flowers and seeds in fertile plants. Akhgar et al. (2011) showed that the essential oil content and the chemical composition of *P. ferulacea* leaves is higher than fruits.

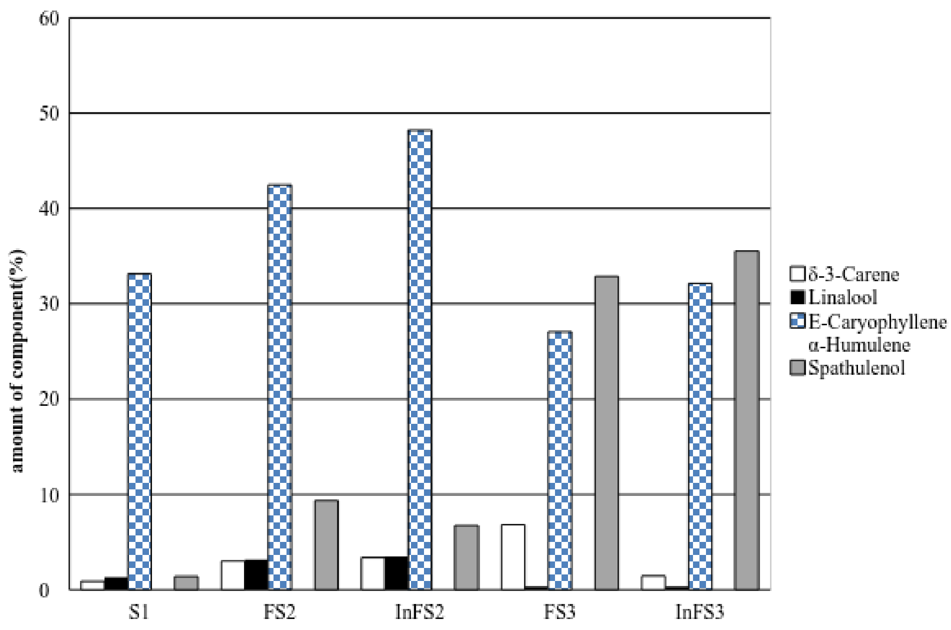

Figure 1. *Comparison between amounts of the major components (%) of P. ferulacea oils extracted at different growth stages. S1: before flowering (stage 1), FS2: the fertile plant in stage 2 or flowering, FS3: the fertile plant in stage 2 or seeding, InFS2: the infertile plant in stage 1, InFS2: the infertile plant in stage 2.*

Table 3 revealed that in 26 components of fertile and 23 compounds of infertile individuals at two growth stages (flowering and seeding), significant differences have been observed. This finding indicates that the phenology factor can play an important role in determining the composition of oils.

Optimization of hydrodistillation and steam distillation methods for the other plant species has been previously studied. *Table 4* exhibits the summary of the number and concentrations of the components present in the volatile fractions, obtained by the HD and SD. There are evident differences between the percentage and the number of components, as follows: HD: 99.98% and 30, and SD: 94.87% and 23. The yield of volatile components of *P. ferulacea* obtained by use of the HD (0.29%) was higher than the SD (0.17%). This result is consistent with the findings of Kiran et al. (2005) and Sefidkon *et al.* (2007). The main components of these extractions were (E)-caryophyllene (48.21-52.26%), α-humulene (3.97-10.28%), spathulenol (6.73-10.37%), linalool (0.51-3.18%), and δ-3-carene (1.31-3.37%), among which the amounts of α-humulene and spathulenol were higher in the SD method than the HD method.

Conclusions

According to the performed study, it can be concluded that based on the certain analyses of phenology and physiology, extending the extraction method can definitely increase the quality and quantity of the extracted essential oil of *P. ferulacea*.

On the basis of the findings, it can be suggested that the infertile individual at the flowering stage is a good sample for a comprehensive analysis of volatile compounds in *P. ferulacea* and can strongly enhance the quality of commercial oils. Moreover, while the SD and HD methods are relatively proper techniques for the quantitative analysis of volatile components, but it should be declared that extensive works are still required in order to adopt them for qualitative analysis.

Abstract. Earlier publications about the main directions of the environmental movement have been incomplete. Some papers discussed the relationships between nature conservation and animal advocacy, but they either disregarded environmentalism, or treated it as a synonym of nature conservation. This latter is a conceptual error since it does not take into account the different primary objectives, distinct historical roots and dissimilar ethical standards of nature conservation and environmentalism. Although a few publications did recognise the difference between nature conservation and environmentalism, these papers failed to include animal advocacy into their analyses. Consequently, a comprehensive overview of all three directions of the environmental movement is still lacking. In this article we argue that the environmental movement has three main directions: (1) nature conservation, (2) environmentalism and (3) animal advocacy. We analyse their main objectives, historical roots and ethical standards, and we scrutinise their relationships to one another. Distinguishing the three main directions will ease the use of clear ethical arguments supporting specific decisions. By clarifying the relationships among the main branches, our conceptual scheme will help to find allies and solve conflicts in applied conservation, animal advocacy and environmentalism. If the three directions join forces, there will be some reason for optimism.
Keywords: *nature conservation, environmentalism, animal advocacy, environmental history, environmental ethics*

Introduction

It is a commonplace that, in an environmental sense, we are at a critical point in history (e.g. Vitousek et al., 1997; Williams and Crutzen, 2013). Given the various types of destructions we face and the enormous diversity of people who want to be part of the solution, it is no wonder that considerable differences exist among the different groups of the environmental movement. Differences range from minor variances in emphasis to desperate combats. A total harmony may be unrealistic and undesirable, but

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_177194

a clear and accurate definition of the main directions may contribute to the identification of powerful ethical arguments, reveal the causes of conflicts and help solve them, and result in a better co-operation.

As public environmental awareness has been rapidly increasing since the middle of the twentieth century, the environmental movement has also become more and more diverse. At the same time, it has become increasingly obvious that the environmental movement is not a solid block, but it consists of considerably different branches. However, there have been relatively few attempts to analyse the main directions and their characteristics, let alone their relationships.

As disagreements between conservation biologists and animal advocates came to light (with a debate occasionally resulting in strong exaggerations and misinterpretations on both sides; e.g. Callicott, 1980; Regan, 1983; Sagoff, 1984), considerable attention was paid to define these two directions. (We see that there is a fundamental difference within animal advocacy, namely between animal welfare and animal rights, but for the purposes of the present article, there is no need to treat them separately.) As a result, scientists and philosophers have regularly restricted their attention to only two branches of the environmental movement: animal advocacy and nature conservation (e.g. Callicott, 1988; Ehrenfeld, 1991; Midgley, 1992; Jamieson, 1998; Perry and Perry, 2008; Paquet and Darimont, 2010; Keulartz, 2015). The first problem with the above distinction is that it does not give the full picture: environmentalism is either totally disregarded, or it is merged with nature conservation. The lack of distinction between nature conservation and environmentalism is a general phenomenon (e.g. Western, 1989; Norton, 2000; Switzer, 2003; DesJardins, 2006; McShane, 2007; O'Neill et al., 2008), the cause of which probably lies in the fact that the words 'nature' and 'environment' are used as synonyms. Fusing nature conservation and environmentalism is a conceptual error, which does not take into account their different primary objectives, distinct historical roots and dissimilar ethical standards. The second problem is that the conclusions concerning the relationships between conservation and animal advocacy were highly variable, from total irreconcilability (e.g. Saggoff, 1984) (*Fig. 1a*) to compatibility (e.g. Jamieson, 1998) (*Fig. 1b*).

There are extremely few publications that distinguish between nature conservation and environmentalism, recognising their different primary purposes (Margóczi, 1998; Heiland, 1999; Foreman, 2006; Gallé, 2013), or the different purposes plus the distinct historical traditions (Noss, 1999; Hunter and Gibbs, 2007). Unfortunately, the relationships between the two directions have never been explored in detail, although some publications noted that they are overlapping (e.g. Margóczi, 1998). In addition, none of the above publications regard animal advocacy as belonging to the environmental movement (*Fig. 1c*), which is unfortunate, to say the least.

Although Foreman (1991) clearly differentiated among the three main directions (i.e. nature conservation, environmentalism, animal advocacy), this was only in a brief footnote, without further considerations or analyses. The idea has not gotten much scientific attention nor has it been elucidated in detail.

In sum, a careful examination of the main aims, ethical principles and historical roots of the three directions within the environmental movement is still lacking. Also, their complex relationships have never been examined thoroughly, which may have far-reaching theoretical and practical consequences.

In this article we argue that it is convenient and useful to distinguish between nature conservation and environmentalism, for several reasons. First, environmentalism is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_177194

usually concerned about human welfare and human environment, which does not apply to conservation (Noss, 1999; Foreman, 2006; Hunter and Gibbs, 2007). Second, as a consequence of the above distinction, the ethical foundations differ considerably, environmentalism having a more human-centered focus, while conservation being non-anthropocentric (Margóczi, 1998). Third, the two branches have a rather different history: nature conservation has its roots in the nineteenth century activity of distinguished American writers and naturalists such as Ralph Waldo Emerson, Henry David Thoreau and John Muir, whereas environmentalism emerged in the second half of the twentieth century, marked by notable figures such as Rachel Carson, Barry Commoner and Denis Hayes (cf. Strong, 1988; Switzer, 2003; Hunter and Gibbs, 2007).

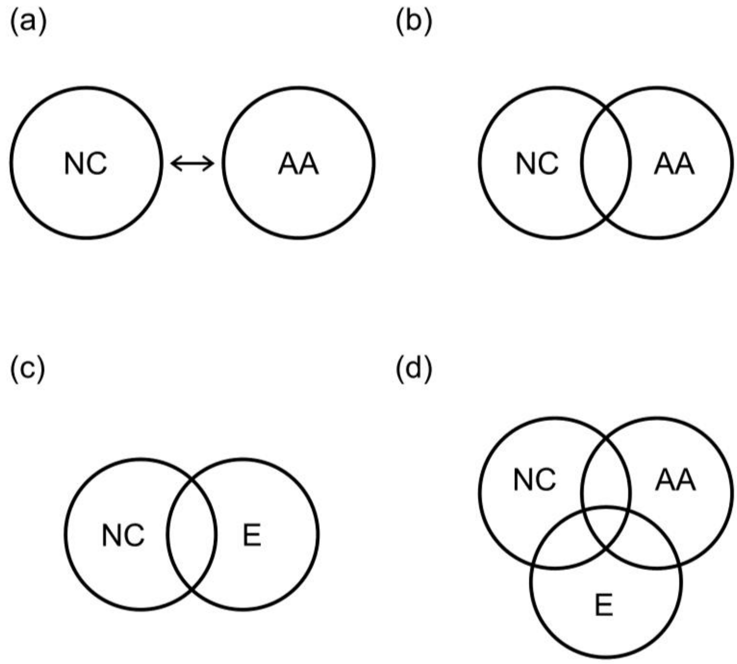

Figure 1. *Relationships among the main directions of the environmental movement. (a) Concepts exploring nature conservation and animal advocacy, regarding them as irreconcilable, (b) Concepts exploring nature conservation and animal advocacy, realising their compatible and overlapping character, (c) Concepts exploring nature conservation and environmentalism, regarding them as overlapping, (d) Our conceptual scheme exploring all three directions with considerable overlaps. NC: nature conservation, AA: animal advocacy (animal rights/welfare activism), E: environmentalism.*

The conceptual scheme to be described in the present paper was built on the embryonic outlines of the three-way solution of Foreman (1991). Thus, unlike the overwhelming majority of the earlier publications, we suggest that three main directions should be recognised within the environmental movement: (1) nature conservation, (2) environmentalism, and (3) animal advocacy. We make an attempt to identify the primary aims of the three branches. We also give a basic insight into how different their historical backgrounds are. In addition, we try to identify the ethical principles underlying the three main directions. Our further goal is to clarify their relationships to one another. In doing so, we give some examples how a better co-operation of the three directions may be possible.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_177194

We think that our clarification and the resulting conceptual scheme have the potential to contribute to a better usage of well-founded ethical arguments in applied nature conservation, environmentalism, and animal advocacy. Furthermore, areas of overlaps (where the aims of two or three directions converge) can be identified, which can help to find allies for particular environmental measures or actions. In other cases, our scheme may reveal the reasons underlying specific conflicts, and may help solve them. We hope our present work will contribute to an increased efficiency of the environmental movement.

The main directions and their historical roots

Nature conservation is often defined as an activity that aims to conserve species, natural communities, ecosystems and ecological processes (e.g. Soulé and Wilcox, 1980; Ehrlich and Ehrlich, 1981; Soulé, 1985, 1986; Primack, 1993, 2004; Begon et al., 1996; Gaston, 1998; Mascia et al., 2003; Borgerhoff Mulder and Coppolillo, 2005; Meffe et al., 2006). The primary focus of nature conservation is biodiversity; it intends to prevent or minimise unwanted loss in the diversity of life at several levels (e.g. genetic diversity of populations, species diversity, habitat diversity). It is important to emphasise that nature conservation does not necessarily intend to reach the highest possible biodiversity (it would be nonsense to plant invasive species into a species-poor habitat to increase its diversity). Instead, it seeks to maintain an appropriate level of diversity. In sum, nature conservation focuses on species, communities, and it does not engage in the welfare of individuals (Soulé, 1985).

The focus of nature conservation on natural and near-natural habitats, processes and diversity is understandable if one considers the beginnings of modern conservation. Till the nineteenth century, at least in the Western world, nature (or wilderness) was considered worthless, hostile and undesirable, something that had to be destroyed, tamed and exploited (Cronon, 1996; Herrmann, 2007). Among the first ones who recognised the aesthetic and spiritual values of nature was Emerson (1836). His followers, most notably Thoreau (1854) and Muir (1912) were fascinated by the wilderness, and took every opportunity to observe its beauties. For them, wilderness areas were sacred places. Their influence culminated in the work of Leopold (1949), who is rightly considered the father of nature conservation.

As for environmentalism, first we have to determine whose environment we want to protect. It has been recognised that there is no such thing as a common environment, which would be the same for every living being. Instead, there are at least as many environments as there are organisms (Juhász-Nagy, 1984, 1986; Bartholomew, 1987; Heiland, 1999; O'Neill et al., 2008). It seems clear that the primary aim of environmentalism is to optimise the environmental parameters of the human species (Margóczi, 1998; Heiland, 1999; Noss, 1999). The primary interest of environmentalism is not wilderness, nor ecosystems, nor diversity, but human environment. Preventing smog formation, reducing soil contamination, providing safe drinking water, protecting the ozone layer, lessening soil erosion, and so on, are all human-centered actions (although they are clearly beneficial for a variety of other organisms as well). Even combatting global climate change, one of today's main focal points in environmentalism, is mainly interested in the future of the human species, although we do not deny that concerns do exist for other species and natural communities as well.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_177194

Environmentalism is considerably younger than nature conservation. The start of modern environmentalism is marked by the now legendary book of Carson (1962). Even though the horrible effects of pesticides on birds and other living creatures were a central issue, considerable attention was paid to the negative influences on human health and human environment. Other classics during this initial period of environmentalism also focused primarily on energy issues, air pollution, soil contamination, human overpopulation and climate change, while biodiversity was discussed as a marginal topic, or was not discussed at all (e.g. Boulding, 1966; Hardin, 1968; Meadows et al., 1972; Schumacher, 1973; Hayes, 1977; Gore, 1992). Thus, the focus clearly differs from that of the nineteenth century conservation (see also Wildes, 1995).

Animal advocacy is interested in the rights and/or well-being of individual animals. It does not focus on species but on individual organisms who have interests, welfare or a quality of life (Ehrenfeld, 1991). It aims to cease or lessen animal mortality and suffering evoked by humans.

Of the three directions discussed in this paper, animal advocacy has the longest tradition, dating back to at least the eighteenth century, with one of the most prominent forerunners being utilitarian philosopher Jeremy Bentham (Guither, 1998; Beers, 2006). In the nineteenth century the movement spread primarily in the UK and the US (Guither, 1998), and it gained new momentum in the twentieth century, with the publication of three landmark books in animal advocacy (Ryder, 1975; Singer, 1975; Regan, 1983).

Ethical foundations

If the three main directions of the environmental movement are recognised, the corresponding ethical bases should also be identified.

As noted by Soulé (1985), conservation biology tends to be holistic. It seems clear that so does conservation activity. Thus, nature conservation focuses on biological levels above individuals. In an ideal case, nature conservation is not human-centered (Soulé, 1985; Barry and Oelschlaeger, 1996). Correspondingly, the underlying ethical principle must be holistic and non-anthropocentric. The statement of Leopold (1949) may serve as a useful guiding principle: ‘A thing is right when it tends to preserve the integrity, stability, and beauty of the biotic community. It is wrong when it tends otherwise.’ This is an ecocentric ethic, as it focuses neither on humans nor on the welfare of individual organisms, but on whole ecological systems. Although other targets of nature conservation (species, processes, etc.) are not mentioned in this short normative claim, it is obvious that these are necessary for the integrity, stability and beauty of a community. Similar arguments emphasizing the non-instrumental (intrinsic) value of nature had appeared earlier (e.g. Muir, 1912), but Leopold’s (1949) effect on current conservation ethics proved to be the greatest. In fact, according to Callicott (1990), a correct interpretation of Leopold’s (1949) famous maxim is able to guide our current conservation activities.

One may argue that nature conservation is, to some extent, anthropocentric. In fact, some researchers differentiate between ‘resource conservation’ and ‘preservation’ (e.g. Callicott, 1990; Hunter and Gibbs, 2007). The distinction is rooted in the nineteenth century history of the movement, when ‘resource conservation’ placed an emphasis on an optimal use of natural resources for the benefit of present and future human

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_177194

generations, while ‘preservation’ favoured setting aside large natural areas where any major human activity should be prevented (Wildes, 1995; Wellock, 2007). Nowadays, both subfields are placed under the umbrella of conservation (Noss, 1999), but it is easy to recognise the human-centered view of the first approach. However, as pointed out by Madhusudan and Shankar Raman (2003) and Kareiva (2014), the two concepts are additive rather than mutually exclusive. Even though some conservation stakeholders place more emphasis on anthropocentric reasons for protecting nature, research has shown that most if not all of them share some fundamental ecocentric values (Berry et al., 2016). Scientists and practitioners have recognised that to gain public support for conservation efforts, we have to emphasise nature’s goods and services for humans (e.g. Norton, 1991; Odenbaugh, 2003; see also Reyers et al., 2010; Lele et al., 2013). Nevertheless, the primary and most important reason to protect nature, at least for most conservationists, is nature itself (cf. Ehrenfeld, 1976; Ehrlich and Ehrlich, 1981; Soulé, 1985; Barry and Oelschlaeger, 1996; Foreman, 2006; McShane, 2007). Even conservationists who usually emphasise instrumental values may well prove ecocentric. Consider, for example, the statement of Kareiva (2014): ‘I would prefer a world in which everyone believes that saving nature for nature’s sake is simply the right thing to do and a moral imperative.’ This is clearly an ecocentric view, even though he is regarded as rather anthropocentric (Hunter et al., 2014). The recognition of the benefits of nature for humans does not annul conservationists’ thinking about the non-instrumental value of nature (Ehrenfeld, 1976). In addition, anthropocentric reasons for conservation efforts may have serious limits, while ecocentrism may be a more robust ethical foundation for nature conservation (Ehrenfeld, 1976; Callicott, 2002; Deliège and Neuteleers, 2015). Strongly related to this topic is the debate concerning the ecosystem services approach, especially the economic valuation of ecosystem services (e.g. Ridder, 2008; Norgaard, 2010; Gómez-Baggethun and Ruiz-Pérez, 2011; Salles, 2011; Costanza et al., 2014). In sum, we firmly believe that, at heart, nature conservation should be ecocentric. In contrast, disciplines and management activities with an exclusively anthropocentric base, focusing solely on the sustainable human use of resources (such as wildlife management or forestry) may be termed resource management or resourcism, but they should not be confused with nature conservation (Noss, 1999; Foreman, 2006).

As discussed above, environmentalism is primarily focused on humans. Therefore, it is reasonable to think that the underlying ethical principle is human-centered, i.e. anthropocentric. However, it is important to emphasise that this anthropocentrism is not equal to the conventionally accepted meaning of anthropocentrism. Anthropocentrism usually states that only humans have intrinsic value (or at least they have the largest intrinsic value), or that only humans are morally considerable (cf. Callicott, 2006; DesJardins, 2006; Nolt, 2015). We think that most environmentalists would strongly object to such a statement. Instead, environmentalism focuses on one species, ours, by protecting the environment we live in, without claiming that other organisms or ecological entities are less valuable. This concept may be termed ‘environmental anthropocentrism’. Moreover, it is also clear that numerous other species also benefit from protecting the human environment.

At the base of animal advocacy (including both animal rights and animal welfare activism), there are individualistic ethics. Among individualistic ethics, sentiocentrism and biocentrism have to be evaluated. Both the utilitarian arguments of Singer (1975) and the rights-based theory of Regan (1983) pay major attention to the ability of feeling

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_177194

pain and pleasure. Therefore, both views can be regarded as sentiocentric (Callicott, 2006) or pathocentric (Wolf, 1996; Krebs, 1997). Biocentrism appears if our moral horizon is further expanded to include all living beings, as was done, for instance, by Schweitzer (1923), Goodpaster (1978) and Taylor (1981). Both sentiocentric and biocentric ethics are potential candidates for the ethical base of animal advocacy, since both concentrate on individuals. Nevertheless, sentiocentrism, focusing on sentient animals (and disregarding individual plants), seems to be more closely connected to current animal advocacy issues. It has to be noted that since Darwin (1859, 1871), sentiocentrism has a firm scientific basis, while traditional anthropocentric views are undermined and out-dated (see also Rachels, 1990; Erdős, 2015; Puryear et al., 2017).

It is doubtful whether one single ethical theory is capable of guiding our decisions in all of the difficult environmental situations (Norton, 2000). Instead, a value pluralism may be a better choice (Norton, 2000; Minteer and Collins, 2005; DesJardins, 2006; Carter, 2011; also see Wenz, 1993). Minteer and Collins (2005) argued that in many cases, nature-centered (i.e. ecocentric), human-centered (i.e. anthropocentric) and individual-centered (i.e. sentiocentric or biocentric) arguments should be considered simultaneously. For example, during ecological studies or conservation actions focusing on habitats or ecosystems, not only the holistic viewpoint (ecocentrism), but also animal welfare issues (sentiocentrism) and the effects on humans (anthropocentrism) should be taken into account.

Thus none of the above three ethical bases suggested for nature conservation, animal advocacy and environmentalism (ecocentrism, sentiocentrism and environmental anthropocentrism, respectively) should be considered universally valid. A careful examination and balance of these principles is needed, especially in the most difficult and complex cases.

Areas of conflict and co-operation

Although the three main directions of the environmental movement are separable, in the followings, we will demonstrate that they overlap considerably (*Fig. 1d*). If, for example, a tropical rainforest is set aside as a reserve, this may be considered an action that belongs to nature conservation, since the primary aim was probably the preservation of habitats and species. At the same time, however, large amounts of carbon are sequestrated in the biomass, which would contribute to global warming if the forest was destroyed. Thus, the designation of the reserve fits the goals of environmentalism. Finally, it also fits animal advocacy viewpoints, for it is quite obvious that no wild animal has a chance to a decent life without a natural habitat (cf. Taylor, 1981; Jamieson, 1998; Paquet and Darimont, 2010).

We do not deny that conflicts arise, but the above example shows that a co-operation of the three branches is possible and desirable. To give an exhaustive analysis of conflicts and solutions is not the aim of the present paper. In the following sections, we only want to give a basic insight into areas where conflicts may emerge, and fields where there are great potentials for co-operation. We will focus on the relationship between nature conservation and animal advocacy, but the other two pairs of the triangle will also be discussed briefly.

Nature conservation versus animal advocacy

Confrontation, as already noted in the Introduction, is well-known between nature conservationists and animal advocates. The cause is simple: animal advocates care for individuals, while nature conservation is interested in species, habitats, etc. However, the common points should not be neglected either. For example, both branches are put under the umbrella of 'green issues' by the public (Perry and Perry, 2008). Most conservationists do care for individual's welfare, and most animal advocates value natural communities (Perry and Perry, 2008). In addition, the membership of animal advocacy and conservation groups overlaps considerably (Ehrenfeld, 1991; Jamieson, 1998). Finally, they form a common platform, since both directions reject anthropocentric views common and dominant in western societies (Callicott, 1988; Paquet and Darimont, 2010). It has been shown that open and rational dialogues between the two groups may reveal that, despite some differences, they do agree concerning several issues (Thompson and Lapointe, 1995). As Aitken (1997) noted, concerns for individual animals do not necessarily contradict conservation goals.

Conservation of a habitat or a species very often requires the elimination of a non-native animal species, and the killing of the unwanted individuals may seem a plausible solution, which, quite naturally, is not welcome by animal advocates. However, even in this seemingly inextricable case, the co-operation has proven possible and mutually beneficial (Perry and Perry, 2008). First of all, preventing the establishment of potential invasive species corresponds to the ethical principles of both directions. Second, if the invasive species has already arrived, alternative measures such as live-trapping and subsequent neutering or translocation (instead of killing) should be discussed between animal advocates and conservationists as early as possible. Perry and Perry (2008) concluded that the two groups should make every effort to find a common ground, and this could result in conservation actions that are acceptable for both parties. Killing invasive species all too often occurs routinely and easily, and killing is usually carried out in the name of conservation even if it serves other goals (van Dooren, 2011). We think conservationists and animal advocates agree that similar practices should be abandoned.

Feral and unowned cats may cause considerable damage to native fauna (Longcore et al., 2009) (although some argue that they only have a limited and short-term effect on native bird and mammal populations; Jarvis, 1990). As a possible solution to reduce the negative impacts on wildlife, the killing of the cats is usually proposed, which is unacceptable for most animal advocates. As a compromise, trap-neuter-release (TNR) programs have been introduced as non-lethal alternatives, during which cats are sterilised and put back where they were trapped. Although animal advocates claim that the method is efficient (e.g. Levy et al., 2003), conservationists have serious doubts and state that cat colony sizes do not decrease fast enough (e.g. Longcore et al., 2009). Irreconcilable as the debate may seem, the common ground is easily reached when we consider that the long-term reduction in the number of stray animals is the goal for both sides. For this, neither lethal methods, nor TNR-programs will be satisfactory; rather, the source of the problem has to be treated. The propagation of responsible animal keeping is necessary, to prevent steady new supplies to free-roaming cat populations. Encouraging citizens to neuter their cats would contribute to a significant decrease in unwanted reproduction, lessening the damage to natural values and at the same time avoiding unnecessary animal suffering (Jarvis, 1990). For a fruitful co-operation, animal advocates have to accept the concern of conservationists for wildlife, and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_177194

conservationists should appreciate cat-lovers' enormous efforts in neutering and adopting unowned cats, often without any funding. It should also be kept in mind that TNR-schemes combined with adopting of at least some of the cats can bring relatively fast successes in the reduction of unowned cat population sizes (Levy et al., 2003).

One of the most promising areas of co-operation between nature conservation and animal advocacy groups is, somewhat surprisingly, meat production. Tens of billions of animals are confined to extremely small areas in 'factory farms' worldwide, living under terrible conditions (Nierenberg, 2006; Halweil and Nierenberg, 2008). At the same time, at least in many European and Asian temperate landscapes, grazing is considered an efficient conservation management, yet several valuable grasslands are undergrazed or not grazed at all (Zahn et al., 2007; Peeters, 2009; Erdős et al., 2011; Kiss et al., 2011; Házi et al., 2012; Saláta et al., 2012; Wichmann et al., 2013; Mardari and Tănase, 2016). Market trends clearly show that consumers prefer animal products that have been produced according to stronger animal welfare standards (i.e. products that originate from free-ranging animals) (e.g. Phan-Huy and Fawaz, 2003; Halweil and Nierenberg, 2008; Ventura et al., 2015). It is not difficult to recognise the common ground of conservationists and animal welfarists, although it has to be noted that those who hold the animal rights position would not join this platform, since they refuse any kind of animal exploitation, irrespective of how the animals are kept (e.g. Regan, 1983; Francione, 2008). However, even they admit that free-ranging animals have a better life than those living in confinement.

Another promising area of co-operation is the action against the overharvest of animal populations, which is a serious conservation threat, and at the same time it has obvious effects on the animals' welfare. Whaling, for example, is in the crosshairs of both animal advocates and conservationists. In addition, the (mainly illegal) trade of other animals and animal products should also be considered in this regard. Baker et al. (2013) suggested that an efficient collaboration between animal advocates and conservationists would be most welcome in issues like this.

Not only do some animal welfare issues have a practical conservation relevance, but they may be of scientific importance as well. For example, toe clipping of amphibians in mark-recapture surveys (the removing of a combination of their digits) has been a wide-spread tool. Animal advocates' arguments against the unethical practice may have been automatically rejected and declared 'unscientific' once, but as we now know, the method in fact distorts scientific results and has conservation effects due to reduced survival of marked individuals (May, 2004).

Nature conservation versus environmentalism

A conflict has recently come to light between the use of renewable energy and the conservation of natural values, as certain disadvantages of alternative energy sources have been revealed. For example, the large-scale application of solar energy facilities in natural habitats (e.g. deserts) has various direct and indirect detrimental influences on native species (Lovich and Ennen, 2011). Wind turbines also proved to have serious adverse effects on wildlife (Kuvlesky et al., 2007; Lin 2017). Although negative impacts may not be completely eliminated, they can be minimised through careful planning (e.g. Stewart et al., 2007; Lin 2017). As the need for renewable energy increases, the co-operation of environmental engineers and conservation biologists is desperately needed.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_177194

Strongly related to this issue are the adverse effects of biomass production for providing 'green' energy, which usually needs huge areas of land. Needless to say, biomass monocultures of fast-growing plants totally disrupt native communities (e.g. Abbasi and Abbasi, 2010; Gomiero et al., 2010) and are often objected by conservationists. However, the conflict is not as serious as it may seem at first glance. For example, biomass production that results in deforestation is not only unwanted from a conservation perspective, but it is questionable from an environmentalist's point of view, since its net effect is likely to exacerbate global warming (Field et al., 2007). A compromise may be possible in some cases, if, for example, traditional agroforestry practices using biomass energy are re-established (Plieninger and Bens, 2008), or used cooking oil is converted to biofuel.

Animal advocacy versus environmentalism

Conflicts between animal advocate groups and environmentalists have probably not been as apparent as in the previous two cases. Nonetheless, it should be mentioned that environmentalists sometimes refer to the fact that keeping companion animals is environmentally destructive, mainly because of the meat-based diet of the pets (Rushforth and Moreau, 2013). However, negative impacts can be reduced with conscious selection of the pet food type. Moreover, it should be kept in mind that one of the main goals of the animal advocacy groups is the reduction in the number of companion animals, through the propagation of neutering and responsible animal keeping. Moreover, some animal advocates strongly oppose the breeding of pets, claiming that no more animals should be brought into existence just to be abused or exploited later by cruel or indifferent humans (Francione, 2008). (Of course, animal advocates insist that we must care for animals who are already alive.) In fact, what seems to be a conflict can turn into a common ground by close inspection: Action against careless or profit-oriented breeding reduces environmental harm and avoids unnecessary animal suffering.

It is well-known that, besides being responsible for incredible animal suffering, intensive animal farms also have highly destructive effects on the environment by producing greenhouse gases and causing water pollution (Koneswaran and Nierenberg, 2008; Ilea, 2009; Rossi and Garner, 2014; Waldau, 2011). Several solutions may be possible, ranging from a reduction in meat consumption (e.g. Halweil and Nierenberg, 2008) to the avoidance of products from 'factory farms' (e.g. Appleby, 2005) to becoming vegetarian or vegan (e.g. Hill, 1996), all of which benefit animals and the environment at the same time (e.g. Goodland, 1997; Jamieson, 1998; Halweil and Nierenberg, 2008; Jankielsohn, 2015). In some or most of the above cases, there is much room for animal advocates and environmentalists to co-operate.

Conclusions

To efficiently combat today's various environmental challenges, we have to see where we have come from, and what our ultimate goal is. In this paper, expanding the ideas of Margóczi (1998), Noss (1999) and Hunter and Gibbs (2007), we differentiated between environmentalism and nature conservation. As a result, building on the proposal of Foreman (1991), we identified and defined the three main directions of the environmental movement: nature conservation, environmentalism and animal advocacy. We are aware that the three areas overlap considerably. We also

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_177194

see that they may further be subdivided. Nevertheless, we think that the use of the three basic categories is justified by their different emphases, distinct ethical principles and different historical roots.

Although conflicts do exist among the three directions, we think that they can be overcome if we understand the underlying reasons. Members of the three directions should try to understand each other's views. As we demonstrated with some examples, the areas for co-operation are huge and promising (*Fig. 1d*). Not only are the three directions reconcilable in most cases, they have much in common.

Earlier works either focused on nature conservation and animal advocacy, and disregarded environmentalism, or examined nature conservation and environmentalism, but did not consider animal advocacy. As a result, the complex inter-relationships among the three directions remained unexplored. In contrast, our conceptual scheme takes into account all three directions. One advantage of this is that it may help reveal ethical or historical reasons behind specific conflicts. On the other hand, it may ease the identification of convergences, which could support finding allies for particular measures or actions. All directions of the environmental movement typically have serious budgetary, staff and time constraints. Thus, both the rapid solution of conflicts and joining forces in converging situations may be essential if we are to increase the effectiveness of the environmental movement. We hope our conceptual scheme is one step in that direction.

As it was suggested in the previous sections, challenging humankind's present meat production and consumption practices is a focal point where overlaps exist among the different directions. First, it seems clear that a shift from an animal-based towards a plant-based diet in Western countries could be a win-win-win situation for nature conservation, environmentalism and animal advocacy. Nature conservationists may consider that 'the livestock sector may well be the leading player in the reduction of biodiversity' (Steinfeld et al., 2006). Environmentalists can be concerned about livestock's resource intensity (requiring a lot of agricultural land, water and energy) and its high levels of pollution (emissions of greenhouse gases, acidifying gases, reactive nitrogen compounds, veterinary medicines and pesticides). Animal advocates care about the immense suffering of farm animals. Thus, cutting down meat consumption could be one of the great challenges of the twenty-first century (Rösch, 2002, Stoll-Kleemann, 2014). It must be emphasized that, as high meat consumption has negative social and health effects, producing less meat could mean a win situation for other fields beyond the environmental movement as well (e.g. Hill, 1996; Stoll-Kleemann, 2014, Westhoek et al., 2014).

Second, animal-friendly and environmentally friendly methods should be supported. According to Appleby (2005), improved animal welfare in farms promotes environmental sustainability and vice versa, because both approaches regard agriculture mainly as a biological rather than a mere technological process. At the very least, meat and other animal products from cropland and resource intensive low-nature-value farming systems, including 'factory farms', should be avoided. Unfortunately, even small-scale farms are environmentally harmful and animals have in some cases as miserable lives as in intensive farming. It is clear that we should make every effort to avoid animal products from each of these deeply unethical sources. It is important to point out here that, according to Curry (2011), organic and animal-friendly farming would be able to feed the whole human population on Earth, provided that global meat consumption is limited.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_177194

Third, adopting a vegetarian or vegan lifestyle will have the greatest positive effect on animals, nature, and the environment. Pluhar (2009) concluded that a vegetarian diet (and possibly in-vitro meat production) may be the best alternative to factory farming, while Deckers (2009) claims that veganism is even better and more consistent both from an environmentalist's and an animal advocate's point of view.

The above examples clearly show that challenging intensive and cruel animal farms is a key point where animal advocates, conservationists, and environmentalists can agree and work together (Regan, 1983; DeGrazia, 2002; Halweil and Nierenberg, 2008; Gjerris et al., 2011; Gjerris, 2015; Hayes and Hayes, 2015). However, it sometimes appears that a strong collaboration between the nature conservation, environmental and animal advocacy movements is hindered by an obstacle, a psychological bias. When there is too much justification, such as in a win-win situation, motivation can be undermined. Regarding a shift in diet away from animal products, some environmentalists seem scared to talk about animal suffering. Meanwhile, some animal rights activists invest a lot of time and energy criticising other people who eat vegan or want to become vegan due to health or environmental reasons. Animal advocates think that the health and environmental vegans have the wrong objectives and some even believe that advocating veganism for health and environmental reasons is counterproductive. They believe that one should always and only refer to the animal rights objective when promoting veganism. This phenomenon is also at work in other areas, such as family planning (access to contraceptives to prevent unwanted pregnancies): women rights activists who campaign for family planning as a reproductive right often criticize environmentalists who propose family planning as an effective means to limit the environmental impact from human overpopulation. According to those feminist advocates, environmental concerns should not be a valid objective for promoting family planning. Reversely, many environmentalists and conservationists are reluctant to talk about family planning as a means to decrease population growth. We can call this pyschological phenomenon the 'single objective bias', which can be strong enough to generate mutual hostility between the movements. When this single objective bias can be overcome, all three movements will gain strong benefits in an effective collaboration.

We are facing great challenges, and there is no doubt that solutions will be easier with co-operation. Probably the best-known example for synergism among the main directions of the environmental movement is provided by Jane Goodall, who is a dedicated conservationist, an animal advocate and an environmentalist at the same time (see for example: Goodall and Berman, 1999; Goodall and Bekoff, 2002; Goodall et al., 2005).

Besides being a role-model for millions, Jane Goodall has also been a lifelong optimist. If conservationists, environmentalists and animal advocates join forces, perhaps there will be some reason for optimism.

Abstract. Coal has provided a great proportion of energy supply for the country. However, coal mining has caused lots of ecological and environmental problems. In this study, a field investigation experiment was conducted in subsided area of Zhaogu coal mine of Jiaozuo Coal Group, Henan Province, China, to explore effect of surface cracks caused by coal mining on the soil characteristics and crop growth. The results showed that during the jointing stage of wheat, the ranges within which the larger crack (C-1) and smaller crack (C-2) caused the effects on both soil water content and soil respiration were 0-60 cm and 0-30 cm from the cracks, respectively. C-1 significantly reduced the activities of soil urease and invertase within 0-60 cm from the crack but C-2 did not cause significant inhibition on soil enzymes. During the flowing stage of wheat, C-1 and C-2 significantly reduced soil water content, available nitrogen content and soil respiration within 0-60 cm and 0-30 cm from the cracks, respectively. The range within which C-1 caused inhibition on urease activity was 0-60 cm while such range for C-2 was 0-30 cm from the crack. The ranges within which both C-1 and C-2 caused significant inhibition on invertase activity were 0-60 cm from the cracks. C-1 and C-2 caused significant inhibition on photosynthesis of wheat within 0-60 cm and 0-30cm from the cracks, respectively. C-1 and C2 significantly reduced spike number and grain yield within 0-90 and 0-60 cm from the cracks, respectively. In conclusion, surface cracks resulted in loss of water and nutrients and reduction in crop yield, which is more serious with lager cracks. Therefore, further studies are needed to address this problem and to find effective measures to resolve it.
Keywords: *coal mining subsidence; coal mine; characteristics of soil microorganisms; soil water; fertilizer*

Introduction

Coal is the major energy source in China. Coal mining industry in Henan province is ranked the second place in China and its coal output accounts for nearly 10% of the country's total (Hu et al., 2014a). While the coal mining areas in Henan have provided substantial proportion of energy supply for the country, some ecological and environmental problems have been caused by coal mining, especially underground coal mining, which have become increasingly serious. Underground coal mining leads to large-scale surface settlement, increases the original geomorphological slope and generates a large number of cracks (gaps), causing substantial damage to the ecological environment in the mining areas (Kuang and Deng, 2007; Tripathi et al., 2009). Under the comprehensive interactions of the subsidence disturbance, rain and wind, the loss of water and fertilizer and soil erosion can easily take place in the farmland in the subsided areas, leading to the degeneration of soil quality (Hu et al., 2014b). Furthermore, due to the uneven surface and the distribution of cracks/gaps all over the subsided areas, the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_17771790

soil evaporation area and evaporation intensity are not only increased, the farmlands also loss irrigation capacity. Their drought-resisting capabilities are greatly weakened, which, in turn, seriously affects the farmland productivity. Additionally, coal mining also destroys the structure of the water-holding layer of soil and causes a series of problems such as the declined phreatic table, drought well and the death of vegetation etc (Kuang and Deng, 2007). Therefore, to investigate the effects of cracks caused by coal mining on soil characteristics and crop production is of practical significance and theoretical value for reclamation and management of the farmland in coal mining areas.

In the recent years, a large number of studies have been conducted on the damaged farmland in coal mining areas. However, these studies mainly focused on such aspects as the effects of mining subsidence on physicochemical characteristics of soil (Li et al., 2010; Chen et al., 1999; Sadhu et al., 2012), the surface vegetation (Zhou et al., 2009; Quan et al., 2006; Moreno-de las Heras et al., 2008; Brom et al., 2013), quality of farmland (Meng et al., 2009; Martinez et al., 2013; Hossain et al., 2015) and restoration technologies of the damaged farmland (Cheng et al., 2014) etc. While a few studies have been conducted on the mechanisms underlying the formation of cracks/gaps (Wu et al., 2009) and the effects of cracks on soil water (Zou et al., 2013; Wei et al., 2006; Zhang et al., 2007), very few reports about the temporal and spatial changes in the characteristics of the soil surrounding the cracks/gaps and the effects of cracks on plant growth and development have been available. In the subsided areas, the newly formed micro-geomorphic features such as subsided hole, subsided cave, and cracks (gap) etc. caused by mining subsidence also bring about corresponding changes in the spatial structures of soil. The changes in the spatial factors that affect the soil characteristics certainly cause the spatial changes in the physicochemical properties of the surrounding soil (Zhao et al., 2010). The cracks (gaps) in the soil lead to the increase in the evaporation area and evaporation intensity of soil in subsided areas. The disturbance of cracks on soil water affects not only soil physicochemical properties but also the characteristics of soil microorganisms (Li et al., 2014) and ultimately affects the growth of plants. Thus, strengthening the studies in this aspect will be beneficial for complete understanding and evaluating the effects of coal mining on the regional environment.

In this study, by choosing the farmland located in the subsided area of Zhaogu Second Coal Mine of Jiaozuo Coal Group, Henan Province, China, as the research object, a field investigation and laboratory analysis experiment was conducted to explore effect of surface cracks caused by coal mining on the soil characteristics and crop growth in different locations surrounding the cracks, which may provide the theoretical basis for reclamation/management of farmland and for improvement of the productivity of farmland in coal mining subsidence area.

Materials and methods

Site description

In this experiment, the subsided area of the Zhaogu Second Coal Mine of Jiaozuo Coal Group, Henan province, China, was selected as the studied area (*Fig. 1*). The mean annual atmosphere temperature was 14^{o}C, the mean annual precipitation was 603-713 mm and the mean water evaporation intensity was 2039 mm. The air temperature and precipitation during the wheat growing season are shown in *Table 1* and *Figure 2*, respectively. During the recent years, the large-scale coal mining has caused serious damage to the local farmland. Approximately 40 hm^2 subsided area have been formed,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_17771790

among which, approximately 30 hm^2 was the stable subsided region and 10 hm^2 was the dynamically subsided region (Xu et al., 2015). There are many cracks (gaps) caused by surface subsidence in the dynamically subsided region, which led to the serious loss of soil water and nutrients. This seriously affected not only the quality of soil environment but also the regional agricultural production.

Sampling methods

This experiment was conducted in the subsided farmland in Zhaogu Second Coal Mine from February to June, 2014. The soil was silty clay loam. For studying the effects of subsided cracks on the crop growth, two vertical, obviously well-developed cracks in this subsided area were selected as the studied objects. Among which, the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_17771790

length, width and depth of larger crack named Crack 1(C-1) were 45 m, 5-10 cm and 200 cm, respectively. The length, width and depth of smaller crack named Crack 2 (C-2) were approximately 25 m, 1-3 cm and 100 cm, respectively. These cracks had been formed for about 30 days. Soil and plants sample in the locations with 30, 60, 90 and 120 cm from the edges of the cracks were collected. The physicochemical properties of soil and physiological and ecological characteristics of wheat were examined. The soil and plant samples in the locations with different distances from the edge of cracks collected three times at each side of the cracks with the total of 6 times of collecting these samples.

The experimental crop was winter wheat (Bainong Aikang 58) with the mean planting density of 1.8×10^6 plants /hm^2. At both the jointing and the flowering stages, soil samples at 0-30 cm and 30-60 cm layers were collected were collected by using auger boring at each sampling point. These soil samples were immediately put into the aluminum box and sealed completely, and then brought back to laboratory for subsequent analysis.

The measurement parameters and methods

The measurements of soil water content, soil available nitrogen content and soil respiration rate: the soil water content was measured with the method of weighting after being dried. The soil available nitrogen content was measured with alkaline hydrolysis diffusion method. Soil respiration rate was measured with EGM-4 portable soil respirator (PP Systems, Amesbury, MA, USA) at each sampling point. Samples at each distance point were collected three times.

Measurement of the activities of soil enzymes: the soil samples within the 0-30 cm layer were collected at the locations of 30, 60, 90 and 120 cm from the edges of the cracks, respectively. The collected samples were fully blended and then put into the ice bottle, immediately brought back to laboratory and stored at -20^{o}C freezer. These soil samples were used for subsequent analysis of the activities of soil enzymes. The urease activity was assayed with sodium phenate colorimetry. The invertase activity was assayed with 3, 5-dinitrosalicylic acid colorimetry. A total of 6 replicate soil samples were measured at each location (Yao et al., 2006).

Measurements of photosynthesis rate and chlorophyll content: the net photosynthesis rate of wheat leaves was measured with LI-6400 Portable Photosynthesis System (LI-COR, Lincoln, NE, USA) in 9:00-11:00 AM in the morning. Chlorophyll content of the leaves of the same plants was measured with SPAD-502 chlorophyll meter (Minolta Co., Ltd, Osaka, Japan). A total of 6 replicate plant samples were measured at each location.

Measurements of Grain Yield and Yield Trials: At the mature stage of wheat, at each sampling point, the grain yield of wheat at two lines with the length of 1 m were randomly selected to assess the yield capacity. The assessment was repeated three times. At the same time, at each sampling point, a total of 30 wheat plants were selected randomly and used to measure the plant height, weight per stem, number of grain, number of fertile spikelet, the number of infertile spikelet and the 1000-grain weight.

Data were statistically analyzed using Microsoft Excel 2000. The differences in the effects between treatment groups were compared by t-test with $P < 0.05$ being regarded statistically significant.

Results

Effects of the surface cracks on characteristics of soil water and fertility

The surface cracks caused by mining subsidence not only destroyed soil structure but also led to the loss of soil water and soil fertilizers. During the jointing stage of winter wheat (20 days after the formation of the cracks), the cracks had no significant effects on the available nitrogen content of soil but significantly affected soil water content in the soil surrounding cracks. Cracks with different widths caused the different effects on soil water content. Within 0-30 cm soil layer, C-1 significantly affected the soil water content within 0-60cm from the cracks. When the distance from the cracks was over 60 cm, the cracks had no significant effects on soil water content. The range of soil water content affected by C-2 was only 0-30 cm. Within the soil layer of 30-60 cm, C-2 had no effects on soil water content. C-1 had significant effects on soil water content only within 0-30 cm from the cracks. During the flowering stage, within the soil layer of 0-30 cm, C-1 and C-2 both significantly reduced soil water content and available nitrogen content in the surrounding soil within 0-60 cm and 0-30 cm from the cracks, respectively (*Figs. 3 and 4*). Within the soil layer of 30-60cm, both C-1 and C-2 significantly reduced soil water content and available nitrogen content in the surrounding soil within 0-30 cm from the cracks. When the distance from the cracks was over 30 cm, the cracks had no significant effects on soil water content and available nitrogen content.

Effects of subsided cracks on characteristics of soil microorganisms

The characteristics (such as the activities of soil enzymes and soil respiration rate) of soil microorganisms are very sensitive to the changes in soil environment. Soil respiration rate reflects, in a large extend, the metabolic intensity of soil organic matters and the transformation/supply capacity of soil nutrients. During the jointing and flowering stages, the surface cracks inhibited the respiration rate of the surrounding soil, the closer the soil from the cracks was, the lower the soil respiration rate was. For C-1, the range within which it inhibited soil respiration rate was 0-60 cm. When the distance from the cracks was over 60 cm, its inhibition on soil respiration rate was not significant. The range within which C-2 inhibited soil respiration rate was 0-30 cm. When the distance from the cracks was over 30 cm, its inhibition was no longer significant (*Fig. 5*)

The subsided cracks had significant effects on the activities of both urease and invertase (*Fig. 6*). Within the distance of 0-30 cm from cracks, the cracks caused maximal inhibition on the activities of soil enzymes. With increasing the distance from crack, this inhibition was gradually reduced. However, during different stages, different soil enzymes performed differently. During the jointing stage of winter wheat, C-2 had no significant inhibition on the activities of both urease and invertases. The range within which C-1 caused inhibition on the activities of two enzymes was 0-60 cm. When the distance from the cracks was over 60 cm, its inhibitory effects were no longer significant. During the flowering stage, the ranges within which C-1 and C-2 caused

DOI: http://dx.doi.org/10.15666/aeer/1504_17771790

inhibition on the activity of inverase were both 0-60 cm. When the distance from the cracks was over 60 cm, their inhibitory effects on invertase were no longer significant. The range within which C-1 caused inhibition on the activity of urease was 0-60 cm while such range for C-2 was 0-30 cm.

Effects of subsided cracks on chlorophyll content of wheat leaves and photosynthetic characteristics

Surface cracks affect physiological characteristics of plant via disturbing the physicochemical properties and microbial characteristics of soil. The chlorophyll content of plant leaves and photosynthetic characteristics are the two important physiological characteristics. During jointing and flowering stages, within 30 cm from the crack, the chlorophyll content of wheat leaves was lowest. When the distance from the crack was over 30 cm, the differences in the chlorophyll content of wheat leaves were no longer significant (*Fig. 7*). The photosynthetic rates of wheat leaves were different during different stages. During the jointing stage, both C-1 and C-2 caused significant inhibition on photosynthetic rates within 0-30cm from the crack. When the distance from the crack was over 30 cm, cracks had no significant effects of photosynthetic rate of wheat. During the flowering stage, C-1 caused significant inhibition on photosynthetic rate of wheat within the distance of 0-60 cm from the crack while C-2 caused significant inhibition on photosynthetic rate of wheat leaves within the distance of 0-30 cm from the crack (*Fig. 7*).

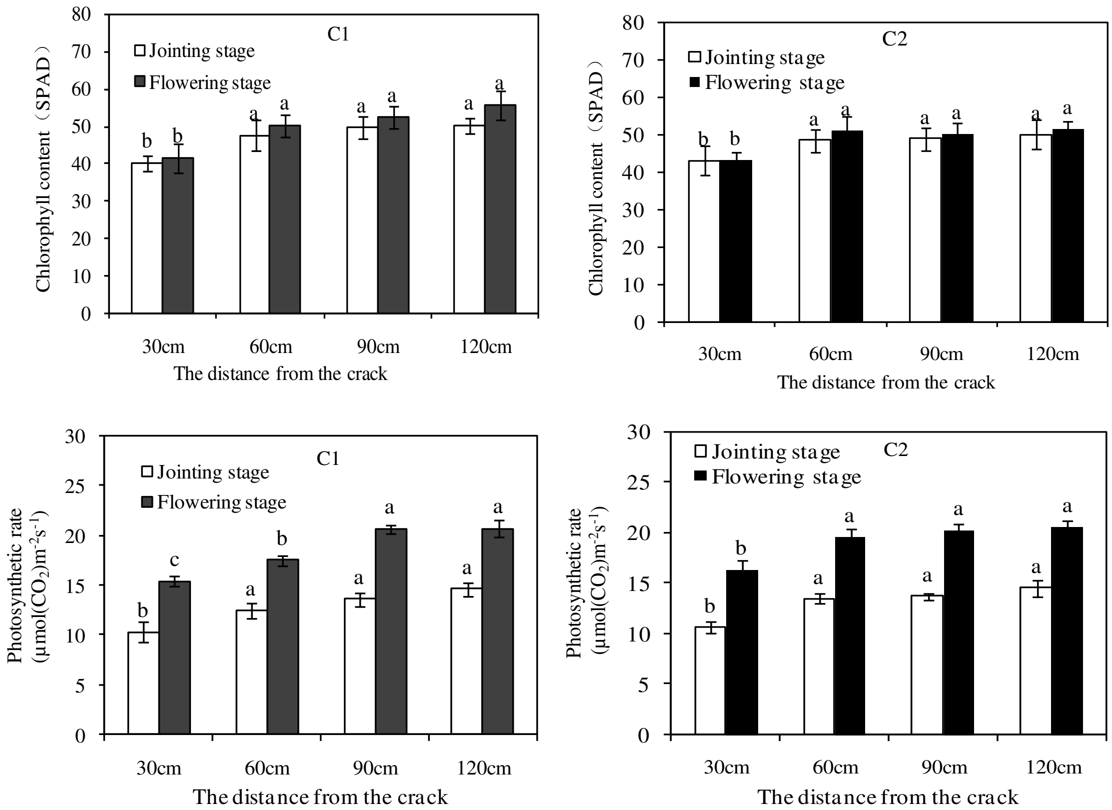

Figure 7. *Effects of the surface cracks on chlorophyll content and photosynthetic rate of wheat in coal mining subsided area. C-1: larger crack with a 45 m in length, 5-10 cm in width and 200 cm in depth; C-2: smaller crack with a 25 m in length, 2-5 cm in width and 100 cm in depth. Vertical bars represent SE of the mean. For a given growth stage, mean values followed by the same letter did not differ significantly (p<0.05).*

Effects of surface cracks on the yield trail of wheat

It can be seen from *Table 2* that surface cracks had different effects on various yield traits of wheat. Both C-1 and C-2 lowered plant height, weight per stem, and grain number but increased the number of infertile spikelet of wheat within 0-60 cm from cracks. When the distance from the crack was over 90 cm, both C-1 and C-2 had no effects on plant height, weight of single stem, the number of infertile spikelet and the grain number. Both C-1 and C-2 had no significant effects on 1000-grain weight. However, C-1 significantly reduced the number of fertile spikelet and grain yield of wheat within the distance of 0-90 cm from the crack. C-2 significantly reduced the number of fertile spikelet and grain yield of wheat within the distance of 0-60 cm from the crack. Compared with the grain yield of wheat at the distance of 120 cm from cracks, C-1 and C-2 reduced grain yield of wheat at 30 cm from the cracks by 53.3% and 34.8 %, respectively.

Discussions

Effects of surface cracks on the characteristics of soil water and fertilizers

Soil cracks cause extremely important effects on the transport process of water and solutes in soil. Coal mining subsidence leads to the formation of cracks (gaps) with different widths on the ground surface, which makes the rainfall to more easily penetrate into underground and thus, reduces the water supply to soil. During the non-raining periods, the crack increases the contact area between soil and external environment and accelerates the lateral evaporation of soil water and exacerbates the loss of water from the soil. Both the reduced water supply and the increased evaporation rate certainly lead to the reduction in soil water content. Furthermore, the vertical cracks (gaps) also weaken the total water-holding capacity of soil. The combined actions of these factors reduce soil water content to different extends (Li et al., 2011). In this study, the result of the investigation on water contents in soil in different spatial

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_17771790

locations in the subsided area indicates that the cracks significant reduce soil water content in soil surrounding the cracks but the affecting ranges of cracks with different sizes on soil water content varied. The affecting range of the larger crack was larger than that of smaller crack.

The changes in soil nutrients are closely related to the migration of soil water. In the coal mining subsided area, due to the formation of many cracks (gaps) on the ground surface, many nutritional elements in the soil can more easily leak with the direct runoff along cracks during raining, which, in turn, cause the deficiency of soil nutrients, degrade soil environmental quality and seriously affect crop growth (Zhao et al., 2010). In this study, we measured the available nitrogen contents in soils with different distances from the cracks. The results indicated that in the early stage of the crack formation (at the jointing stage of wheat), because of the lack of raining, the available nitrogen content in soil was not changed largely. During the flowering stage, the cracks significantly reduced available nitrogen content in the soil surrounding the cracks. The closer the distance from the crack was, the lower the available nitrogen content in soil was. The effects of the larger cracks on the available nitrogen content in soil were larger than those of the smaller cracks.

Effects of surface cracks on of soil microorganisms

The characteristics of soil microorganisms, including microbial quantity, activities of soil enzymes and soil respiration etc, are very sensitive to the changes in soil ecological quality and are generally used to evaluate the supply capacity of soil nutrients and soil quality (Zhou and Ding, 2007). Du et al. (2013) reported that surface cracks caused by coal mining obviously reduced microbial quantities and activities of soil enzymes, and also altered the compositions and structure of microbial community in the rhizosphere of Artemisia ordosias. Among different indicators reflecting the characteristics of soil microorganisms, soil respiration rate is the most sensitive one to respond the status of soil water and soil nutrients (Singh et al., 1977; Zheng et al., 2014). In this study, subsided cracks reduced the contents of water and available nitrogen in the soils surrounding the cracks and, at the same time, also significantly reduced soil respiration rate.

All the biochemical processes taking place in the soil are carried out and accomplished by soil enzymes (Zhou and Ding, 2007). Soil enzymes are very sensitive to the changes caused by environmental factors and exhibited quite well the characteristics of timeliness. Most of soil enzymes are mainly derived from soil microorganisms. Soil structures and the status of soil water and nutrients all cause important effects on soil microorganisms. The changes in soil physicochemical properties and in the quantitation of soil microorganisms certainly lead to the directional changes in the activities of the soil enzymes (Noah et al., 2003). For instance, the study by Liu et al (2006) indicated that the activities of both soil invertase and urease were highly and positively correlated with the available nitrogen. In this study, the results of the investigation on the activities of invertase and urease in the soils surrounding the cracks also confirmed the above-mentioned results, i.e. the cracks significantly reduced soil available nitrogen content, which, in turn, affected the activities of soil enzymes. Thus, the activities of both invertase and urease in soil were also significantly reduced.

Effects of surface cracks on physiological characteristics and grain yield trials of wheat

Cultivation of crops requires the high soil quality and the proper landform of farmland. The destroying soil environment will affect the cycling processes of water and nutrients in soil and finally cause serious loss of crop yield (Ma et al., 2014). It has been reported that mine subsidence in Illinois, USA, caused a significantly lower corn yield in subsidence areas (Darmody et al., 1989, 1992, 2014). Surface subsidence and cracks caused by coal mining destroyed the stability and integrality of soil structure. Water and fertilizers easily leak and loss along with the cracks, resulting in increasing degeneration of soil quality. Furthermore, due to the lack of scientific management, proper application of fertilizers and irrigation measures in the subsided area, the poor soil quality is further exaggerated. The contents of water and nutrients in soil are the key factors affecting plant growth. Their levels will directly affect the physiological and ecological characteristics and the yield of crops (Cao et al., 2009). Among which, chlorophyll content of leaves somehow reflects the nitrogen level of plants, which is positively correlated with the soil nitrogen content (Guan et al., 2000). The present study also indicated that changes in chlorophyll content of leaves was consistent with the changes in available nitrogen content in soil, i.e. when the soil was closer to the cracks, the content of the available nitrogen in soil was more significantly reduced and, at the same time, chlorophyll content of wheat leaves was also significantly reduced. These results are the same as those of Xu et al. (2015). Photosynthesis is one of important physiological characteristics of plant and is limited by both the internal factors and external environmental conditions. Soil water and nitrogen are two important environmental factors frequently limiting for plant growth. Water and nitrogen stresses will inhibit photosynthesis and the growth of plant (He et al., 2010). Increasing soil nitrogen content can not only significantly increase chlorophyll content of plant leaves but can also improve the photosynthetic characteristics of crops and increase the grain number and grain weight of wheat (Zhang et al., 2005). In this study, subsided cracks significantly affected the contents of water and available nitrogen in soil and also affected plant’s uptake of trients and water. Thus, plant photosynthesis was also significantly affected. The growth and yield of plant are closely related to the accumulation of photosynthates. The closer to cracks were, the greater the effect on photosynthesis of wheat was. Thus, the plant height, grain number and weight per stem were all significantly reduced. The deficiency in photosynthetic capability finally led to the reduction in grain yield of crop. A recent study by Hu et al.indicated that in the eastern plains of China, the overlapping of coal resources and cropland occupied a total area of 1.33×10^5 km^2, accounting for 31.93% of the total cropland area. It is estimated that by 2020, the accumulative total area of cropland destroyed by continuing coal mining in that area may reach as high as 3.83×10^3 km^2, leading to the reduction of grain yield by 9.63×10^8 kg and an increase in number of landless farmers up to 1.91×10^6 (Hu et al., 2014a). Similar situation may also happen in coal mining areas in Henan province. Therefore, further studies are needed to address this problem and to find effective measures to resolve it.

Conclusions

The effect of surface cracks caused by coal mining on the soil characteristics and crop growth was studied in subsided area of Zhaogu coal mine of Jiaozuo Coal Group, China. The results show that surface cracks affected significantly soil characteristics in the soil surrounding the cracks. The larger crack (C-1) had larger effect ranges on both soil water content and the characteristics of soil microorganisms compared to smaller crack (C-2). Surface cracks lowered significantly chlorophyll content and photosynthetic rate of plant via affecting soil characteristics. During jointing and flowing stage, both C-1 and C-2 caused significant inhibition on photosynthesis of wheat within 0-60 cm and 0-30cm from the cracks, respectively. Surface cracks promoted loss of water and nutrients in the soil surrounding the cracks, which finally led to significant reduction in crop yield. The large crack had stronger effects on grain yield compared to small crack. Therefore, further studies are needed to address this problem and to find effective measures to resolve it.

(Received 13th Jun 2017; accepted 5th Oct 2017)

Abstract. In this study, the effect of Super-AB-A-200 polymer on salt and drought resistance of *Eucalyptus globulus* Labill. was evaluated. The treatments were: (1) Control, Control + polymer; (2) NaCl, NaCl+ polymer; (3) Drought, Drought + polymer; (4) Drought + NaCl, Drought + NaCl + polymer. The results showed that Super-AB-A-200 in root medium helped *E. globulus* cuttings to resist the salinity and drought stresses, because of the following reasons: (1) *E. globulus* roots absorbed the held water from Super-AB-A-200 polymer in soil water-deficit conditions; (2) in saline conditions, Super-AB-A-200 retained Cl^- and Na^+ in the soil solution because of their high water-holding capability, moreover, the exchangeable K^+ included in Super-AB-A-200 resulted in an amended K^+/Na^+ balance in salinized plants; (3) Super-AB-A-200 helped *E. globulus* cuttings to resist interactive effects of salinity and drought stresses, which was essentially justified by their salt- and water-holding capabilities.
Keywords: *acrylate polymers, gas-exchange, salinity stress, water-saving agriculture, water use efficiency*

Introduction

A lot of countries have not sufficient water resources to confront their actual environmental, urban and agricultural requirements. With increasing water deficiency, population and water claims are increasing simultaneously (Bouwer, 2002). Superabsorbent polymer (SAP) perform as a soil reformer to decrease soil water loss and increase crop yield. SAP is a hydrophilic polymer that can store and take up 1000 times more water or aquatic solutions than its first weight and size (Sojka and Entry, 2000). Therefore, SAP can increase soil water-holding capacity and nutrient use efficiency (Lentz et al., 1998) and decrease water loss (Al-Omran and Al-Harbi, 1997). SAP is applied in the soil to make a water supply, near the rhizosphere zone and advantage agriculture (Han et al., 2010). Because of the water resource crisis, water-saving agriculture is necessary for the sustainable development. Moreover, droughts are anticipated to be increasingly crucial because of climate change (Gornall et al., 2010). Hydrophilic polymers are usually cross-linked 3-D hydrophilic nets that are able to take up and keep noteworthy values of aquatic liquids even in certain pressure or temperature. SAPs are able to perform in several fields like agriculture (Puoci et al., 2008), sanitary productions (Kosemund et al., 2009), waste water refining (Kasgoz and Durmus, 2008; Kasgoz et al., 2008; Wang et al., 2008a). SAPs are in three types containing natural, semi-artificial and artificial (Mikkelsen, 1999). Unnatural polymers applied more than natural ones because they have more endurance against environmental collapse (Peterson, 2002). Superabsorbent minimizes micronutrients from washing out to the water table and causes more water use efficiency, a decline in costs of irrigation and intervals by 50 percent water stress and damages to transplant during transferring (Abedi Koupai and Mesforoush, 2009). Teimouri and Sharifan (2013) assessed the effect of KCl and NaCl in varied concentrations on dehydration and hydration of some SAPs. According to the results, Super-AB-A-200 and Colophony had

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_17911802

the most hydration and dehydration respectively. Fazeli-Rostampoor et al. (2011) showed that drought stress and applying Super-AB-A-200 had a significant effect on increasing corn grain yield and water use efficiency. Li et al. (2014) reported that the addition of SAPs significantly increased the soil water content and soil maximum hygroscopic moisture in the booting and filling stages but had no effects on the soil available water-holding capacity compared with the control in the filling stage. Yadollahi et al. (2012) assessed the impact of Super-AB-A-200 and organic matters in soil water retention and construction of almond orchards in rainfed conditions. The results showed that Super-AB-A-200 and organic matters could increase soil water retention significantly. Besides, this conditions could increase growth indices of almond seedlings. *Eucalyptus globulus* is a woodland tree and native to Australia, however, it has been planted in Iran and is under evaluation. In spite of ecological importance, Eucalyptus has important medicinal and horticultural worth and several species are applied for forest landscape and street planting. The *E. globulus* trees are used in the south of Iran as park landscape and street planting. Besides, salinity and drought stresses are essential restrictions for their survival. SAPs may help them to tolerate these harmful stresses. The aim of this study was to evaluate the effects of Super-AB-A-200 polymer on salt and drought resistance in *Eucalyptus globulus* Labill.

Materials and Methods

Hydrophilic polymer

The hydrophilic polymer Super-AB-A-200, produced by Rahab Resin Co. with product license holding of Iran Polymer and Petrochemical Institute (Rahab Resin Co, 2016), was used in this study (*Table 1*). This hydrophilic polymer is a granular-type tripolymer of acrylamide, acrylic acid, and acrylate potassium.

Table 1. *The characteristics of Super-AB-A-200 polymer*

Characteristics	Super-AB-A-200 polymer
Shape	Granular
Density	1.4-1.5 (gr.cm^{-3})
Size of particles	50-150 (µm)
Maximum stability in soil	7 (year)
Practical capacity of water uptake	220 (g.g^{-1})

Experimental treatments

One-year-old cuttings of *Eucalyptus globulus* (48 plants) were obtained from a nursery under natural conditions near Shush, Iran. The cuttings were planted separately in 6-L pots filled with sandy soil. Prior to treatment, the plants were grown in a greenhouse and well-irrigated with 1000 mL of Hoagland's nutrient solution every 15 days. Uniform plants with a height of about 90 cm were collected for this study. The plants were transferred to 15-L pots randomly filled with either saline soil (sandy soil pretreated with 2000 mL of 300 mM NaCl) or a control soil without the NaCl with the polymer or without it (0.5% of dry weight). The four treatment groups were classified as follows: (1) Control + Super-AB-A-200, Control; (2) NaCl + Super-AB-A-200, NaCl;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_17911802

(3) Drought + Super-AB-A-200, Drought; (4) NaCl + Drought + Super-AB-A-200, NaCl + Drought. The drought treatment was applied after the start of water-deficit stress by withholding irrigation, but the control plants were well-irrigated.

Plant harvesting

The experimental plants were harvested (three replicate plants for each treatment) after 40 days of exposure to drought and salinity treatments. Plant roots were thoroughly washed with deionized water to remove soil. The fresh weights of the leaves, roots, and stems were assessed and the tissues were dried in an oven at 65°C for 5–7 days to determine the dry weight. Dried samples were ground into powder and stored for analysis.

Plant water usage capacity

Each pot containing one plant was covered by a plastic case and protected at the stem base to stop rainfall and soil evaporation. The water usage was measured as the daily weight loss of the pot and the plant together over a 12-h period (08:00–20:00) on days 4, 8, 12, 16, and 20 and the mean value of each plant was recorded. Three individual replicates were examined for each treatment.

Gas-exchange of leaves

The gas-exchange of the 5th through 7th leaves of the *E. globulus* shoots was determined on days 17, 28, 34, 36, and 38 and the mean value of each plant was recorded (the radiation of natural light was greater than 600 µmol m^{-2} s^{-1}). Stomatal conductivity (Gs), net photosynthetic rates (Pn), and leaf transpiration rates (TRN) were recorded between 9:00–10:30 a.m. with a CIRAS-3 Portable Photosynthesis System (PP Systems, Amesbury, MA, USA) where the photosynthetically active radiation (PAR) was approximately 1300 µmol m^{-2} s^{-1}. If the PAR was very low, the light was supplemented by halogen lamps (Shi et al., 2010). Leaf temperatures were 30 to 35°C during the measurements.

Ion analysis of roots and leaves

Ion analysis was conducted according to Storey (1995). Dried samples (1 g) of roots and leaves were extracted with 2 $NHNO_3$. K^+ and Na^+ were measured by an atomic absorption spectrometer (AAS) (PerkinElmer 2380). PerkinElmer 2380 is a double-beam, optical system and high-dispersion monochromator with a wavelength range of 190 to 870 nm. Cl^- was measured by an adjusted method of silver titration. A solution of $AgNO_3$ (0.027 N) was applied to the sediment the Cl^- of aquatic extracts and surplus, Ag^+ was evaluated by NH_4SCN (0.01 N) titration. $NH_4Fe(SO_4)_2$ was applied as a color indicator for ionic spot assignment. Concentrations of Cl^- were determined by the equation (1) as follows (Shi et al., 2010):

$$Cl^- \, (\text{mmol g}^{-1}\text{ DW}) = \frac{N_{AgNO_3} V_1 - N_{NH_4SCN} V_2}{DW} \quad \text{(Eq.1)}$$

where
DW: dry weight (g)
V_1: total volume of the $AgNO_3$ solution in chloride extracts (mL),
V_2: volume of the NH_4SCN solution, applied for surplus Ag^+ sediment (mL).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_17911802

Soil ion analysis

The soil was sampled at harvest and the soil water content was tested. The soil sample extracts (dried soil:deionized water = 1:5, w/v) were used to measure Cl^-, K^+, and Na^+ contents. K^+ and Na^+ were measured by AAS (PerkinElmer 2380) at 771 and 594 nm, respectively; and Cl^- was measured by silver titration.

The analysis of data

ANOVA was used to compare the data and significant differences between mean values were measured by Duncan's multiple range test. Differences between means were designated as statistically significant when $p < 0.05$.

Results

Salinity and drought stress-induced leaf damages

Leaf damage gradually increased as the soil water deficit increased and about 40% of *E. globulus* leaves were withered after 40 days of drought treatment (*Figure 1*).

Figure 1. *The withered leaves of E. globulus*

Dry weight of plant

The dry weights of the *E. globulus* stems, roots, leaves, and whole plants were significantly reduced under salinity and/or drought stresses compared to the control. However, the NaCl + Drought treatment did not decrease dry weight more than the salt and drought stresses alone (*Table 2*). The plants treated with the Super-AB-A-200 polymer had higher dry weights compared to the plants without the polymer in all treatments (*Table 2*). The stem, leaf, and whole plant dry weights in the NaCl + Drought + polymer treatment were not significantly different from the control. This indicated that the Super-AB-A-200 polymer improved growth under salinity stress, especially in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_17911802

drought conditions. In addition, the Super-AB-A-200 polymer significantly improved the dry weights of the *E. globulus* stems, roots, leaves, and whole plants in the NaCl, drought, and NaCl + Drought treatments (*Table 2*).

Table 2. *The effect of Super-AB-A-200 polymer on dry weight of stems, roots, leaves and whole plants of Eucalyptus globulus under NaCl and/or drought stresses*

Dry weight (g)	Treatment	- Polymer	+ Super-AB-A-200
Root	Control	15.23a^{A}	15.78a^{A}
	NaCl	10.42b^{B}	12.71a^{B}
	Drought	10.63b^{B}	12.48a^{B}
	NaCl + Drought	10.21b^{B}	12.41a^{B}
Leaf	Control	16.25a^{A}	16.51a^{A}
	NaCl	11.48b^{B}	13.69a^{B}
	Drought	11.68b^{B}	12.67a^{B}
	NaCl + Drought	11.31b^{B}	14.98a^{B}
Stem	Control	16.49a^{A}	16.41a^{A}
	NaCl	11.45b^{B}	13.21a^{B}
	Drought	11.74b^{B}	12.88a^{B}
	NaCl + Drought	11.39b^{B}	14.17a^{B}
Plant	Control	52.56a^{A}	53.88a^{A}
	NaCl	39.61b^{B}	45.56a^{B}
	Drought	40.43b^{B}	44.14a^{B}
	NaCl + Drought	39.12b^{B}	47.68a^{B}

Every value is the average of three separate plants. Values pursued by varied letters in the similar column (A, B) or the similar row (a, b) are significantly varied at $p<0.05$.

Plant water use efficiency

The daily water use of the *E. globulus* cuttings was reduced under salinity or drought stress in the presence of the polymer, and this decline was further evident in the NaCl + Drought treatment (*Table 3*).

Table 3. *The effect of Super-AB-A-200 polymer on plant water use (gH_2Oday^{-1}) in Eucalyptus globulus plants under NaCl and/or drought stresses*

Treatment	- Polymer	+ Super-AB-A-200
Control	164.5a^{A}	168.6a^{AB}
NaCl	141.8b^{B}	165.9a^{AB}
Drought	129.4b^{B}	153.1a^{B}
NaCl + Drought	95.7b^{C}	177.6a^{A}

Every value is the average of three separate plants. Values pursued by varied letters in the similar column (A, B, C) or the similar row (a, b) are significantly varied at $p<0.05$.

Gas-exchange of leaves

The transpiration rates (TRN), net photosynthetic rates (Pn), and leaf stomatal conductivity (Gs) of the *E. globulus* cuttings was reduced over time in the salinity or drought stress treatments (*Table 4*). In the NaCl + Drought treatment the TRN, Pn, and Gs was reduced by 30%, 48%, and 55%, respectively (*Table 4*). The addition of Super-AB-A-200 increased the gas-exchange in the NaCl-, Drought-, and NaCl + Drought-treated plants (*Table 4*). The effect of the Super-AB-A-200 on the gas-exchange in the drought-stressed plants was significantly higher than the NaCl-treated plants (*Table 4*).

Table 4. *The effect of Super-AB-A-200 polymer on transpiration rates (TRN), net photosynthetic rates (Pn) and leaf stomatal conductivity (Gs) in Eucalyptus globulus plants under NaCl and/or drought stresses*

Gas-exchange	Treatment	- Polymer	+ Super-AB-A-200
Gs (mmol m^{-2} s^{-1})	Control	138.56a^{A}	144.32a^{A}
	NaCl	95.22b^{B}	113.76a^{B}

Ion concentrations in roots and leaves

The concentrations of Cl^- and Na^+ in the leaves and roots of *E. globulus* significantly increased after 40 days of NaCl treatment compared to the control and the drought stress aggravated the increased ion concentrations in salinized plants, particularly Cl^- (*Table 5*). Application of Super-AB-A-200 polymer decreased the accumulation of Cl^- and Na^+ in leaves and roots in the presence or absence of drought stress and could confine Cl^- and Na^+ in NaCl + Drought-treated plant organs (*Table 5*). The Super-AB-A-200 polymer did not significantly affect the concentrations of Cl^- and Na^+ in the leaves and roots under drought stress conditions, with some exceptions (*Table 5*). The NaCl treatment decreased the concentration of K^+ in the roots irrespective of drought treatment, but this did not occur in the leaves (*Table 5*). Moreover, the addition of Super-AB-A-200 altered K^+ in leaves and roots of drought-stressed plants (*Table 5*).

Ion concentrations in soils

As expected, the concentrations of Cl^- and Na^+ increased significantly in the NaCl-treated soils compared to the control soils, and drought stress increased the soil salinity (*Table 6*). However, addition of the Super-AB-A-200 polymer reduced the Cl^- and Na^+ levels in the saline soil in both the NaCl and the NaCl + Drought treatments (*Table 6*). The Super-AB-A-200 treatments increased the K^+ concentration in the NaCl-treated soil (*Table 6*). The K^+ concentration in the drought-treated soil was reduced by application of Super-AB-A-200; however, application of Super-AB-A-200 did not decrease the K^+ level in NaCl + Drought-treated soil (*Table 6*).

Discussion

The effect of Super-AB-A-200 polymer on drought tolerance

The Super-AB-A-200 polymer improved the growth in the *E. globulus* cuttings (*Table 2*) and reduced the occurrence of leaf damage caused by the drought treatments. These results are similar to other studies, in which the application of SAPs improved the growth of *Citrus* (Arbona et al., 2005), *Eucalyptus* (Viero and Little, 2006) and *Populus popularis* (Shi et al., 2010) in water-deficit conditions. Shi et al. (2010) reported that the application of SAPs improved the growth of *P. popularis* cuttings. The effects of SAPs result from the excess water retained by the SAP granules (Bouranis et al., 1995). Super-AB-A-200 polymer is a tripolymer of acrylamide, acrylic acid, and acrylate potassium. This hydrophilic polymer has tridimensional hydrophilic networks that can absorb and hold a large volume of water equal to hundreds of times its own weight (Abedi-Koupai and Asad-Kazemi, 2006; Marandi et al., 2009). Consequently, *E. globulus* roots absorb water held by the polymer. According to our results, *E. globulus* roots accumulated around the Super-AB-A-200 granules, rather than growing inside them. This result is consistent with the observation that drought-treated plants had fewer leaves, reduced gas-exchange and decreased plant water use without the polymer (*Tables 4 and 3*). Thus, the Super-AB-A-200 polymer lengthened the period of water supply for the plant.

The effect of Super-AB-A-200 polymer on salt tolerance

E. globulus is a semi-salt-tolerant species with a medium capacity for salt exclusion (Osareh and Shariat, 2009). Accumulation of salts in plant cells can cause toxicity and oxidative injury (Wang et al., 2007, 2008b). In this study, the increase of plant growth

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_17911802

and leaf gas-exchange in the polymer-treated *E. globulus* plants is likely due to its increased capability for salt exclusion. When amended with the Super-AB-A-200 polymer, the Cl^- and Na^+ concentrations were reduced in the leaves and roots of the plants under NaCl stress (*Table 5*). Application of Super-AB-A-200 polymer also reduced the concentration of salt in the soil water solution because of its salt-holding capability. Thus, minimal amounts of salts were taken up by the roots (*Table 5*). Furthermore, the concentrations of the Cl^- and Na^+ in the Super-AB-A-200 polymer were diluted because of the water volume held in the polymer. The concentration of Na^+ was 0.005 mM and the concentration of Cl^- was 0.004 mM in Super-AB-A-200. Thus, root accumulation in or around the polymer resulted in less salt taken up by the plant roots, resulting in improved plant growth and gas-exchange under salinity stress (*Tables 2–4*). Moreover, the Super-AB-A-200 decreased the Na^+ concentration in the roots and leaves of the plants under NaCl stress (*Table 5*) due to the increased exchangeable K^+ level in the Super-AB-A-200 polymer (*Table 6*), thereby improving salt exclusion capability of the plants. This result was in accordance with Shi et al. (2010) in which K^+ levels in *P. popularis* roots and leaves were increased by amendment with SAPs of Stockosorb and Luquasorb on saline soil. Additionally, the Super-AB-A-200 polymer provided a K^+ source, consequently, uptake of K^+ increased in the plants treated with the polymer. K^+ enrichment led to a K^+ balance in the plants under salt stress, resulting in enhanced salt resistance, since the balance of K^+/Na^+ is pivotal for tolerance to toxicity from ions (Munns and Tester, 2008; Sun et al., 2009a,b; Shabala and Cuin, 2008; Shi et al., 2010). Our results showed that the addition of Super-AB-A-200 polymer can improve access to quality water and a source of K^+ while decreasing contact with Cl^- and Na^+, thereby promoting resistance to salt stress.

The effect of Super-AB-A-200 polymer on salt and drought tolerance

The water consumption of NaCl + Drought-treated plants was reduced by 42%, which was significantly greater than the plants under drought or salt stress alone, 21–14% (*Table 3*). Leaf gas-exchange showed a similar trend (*Table 4*). This was the consequence of an interaction of salinity and drought stresses. As the soil dried, the water availability decreased and the concentration of salt ions in the soil increased (*Table 6*). The roots could not absorb enough water to compensate for the water lost through the shoots, resulting in leaf damage. The impact of the co-existing drought and salinity stresses on dry weight was not as apparent as effect on short-term factors such as daily plant transpiration and leaf gas-exchange (*Tables 2–4*). There are three possible explanations as to why the Super-AB-A-200 polymer improved plant performance under drought and salinity stress in this study: (1) the water-filled Super-AB-A-200 polymer granules increased the access to water (*Tables 4 and 3*), (2) the exchangeable K^+ in this polymer promoted K^+/Na^+ balance (*Table 5*), and (3) the polymer granules retained the salt ions, maintaining a lower concentration in the drying soil (*Table 6*). It is important to note that the effects of Super-AB-A-200 on plant dry weight and leaf gas-exchange were considerable (*Tables 2–4*). The addition of Super-AB-A-200 lengthened the duration of water supply to the plants and consequently decreased the damage caused by high soil Cl^- and Na^+ in drought and salinity conditions (*Table 6*). As a result, the absorption of salts by roots and transportation of salt from the root to shoot were both effectively limited, resulting in improved plant growth and survival during an extended period of drought and salinity stress.

Conclusion

According to the results, Super-AB-A-200 polymer could store water and nutrients in the sandy soil and release them under drought stress conditions. Besides, it could improve sandy soils and increase water-holding capacity. In addition, in saline conditions, Super-AB-A-200 retained Cl^- and Na^+ in the soil solution because of their high water-holding capability and the exchangeable K^+ included in Super-AB-A-200 resulted in an amended K^+/Na^+ balance in salinized plants. Furthermore, Super-AB-A-200 helped *E. globulus* cuttings to resist interactive effects of salinity and drought stresses, which was essentially justified by their salt- and water-holding capabilities. Finally, it is recommended to use other types of hydrophilic polymers for the cultivation of other plants because of their effects on the other ions (heavy metals, calcium and etc). In addition, it is recommended to use Super-AB-A-200 polymer for the cultivation of other plants especially in arid and semi-arid regions with sandy soil. Because this polymer significantly improved the dry weights of the *E. globulus* stems, roots, leaves, and whole plants in the NaCl, drought, and NaCl + Drought treatments, decreased the accumulation of Cl^- and Na^+ in leaves and roots in the presence or absence of drought stress and could confine Cl^- and Na^+ in NaCl + Drought-treated plant organs, reduced the Cl^- and Na^+ levels in the saline soil in both the NaCl and the NaCl + Drought treatments and increased the K^+ concentration in the NaCl-treated soil. Therefore, by using this polymer, lower quality and amount of water could be used for cultivation and the cultivated lands could be extended by storing water in reservoirs.

(Received 13th Jun 2017; accepted 26th Sep 2017)

Abstract. The aim of the study was to evaluate variation in PM10 concentrations in the city of Sosnowiec, Poland in relation to the type of atmospheric circulation. Data on the average daily concentration of PM10 during the heating season in the years 2013-2015 were obtained from the Sosnowiec monitoring station on Lubelska Street, belonging to the Air Quality Monitoring System run by the Voivodeship Inspectorate for Environmental Protection in Katowice. PM10 concentrations were found to be higher in anticyclonic conditions, on average 55 $\mu g/m^3$, as compared to 45 $\mu g/m^3$ in cyclonic conditions. The highest risk of exceeding the permissible PM10 concentration is observed in Ka, Sa, SWa and Ca conditions. The results of this study may be used to predict high PM10 concentrations and exceedances of permissible levels based on synoptic forecasts.
Keywords: *air quality, particulate matter, heating seasons, air masses advection, baric system*

Introduction

Air pollution is one of the most important environmental issues. Poland has exceptionally poor air quality, which is largely due to excessive PM10 particulate matter concentrations. According to the European Environment Agency, Poland ranks second in Europe in terms of the daily concentration of PM10 in the air (European Environment Agency, 2016). Analysis of spatial variations in pollutant concentrations within Poland indicates that they are higher in the southern part of the country, especially in the Silesia and in Małopolska regions. Particularly high air pollution occurs in the Upper Silesian Agglomeration, which is linked to the industrial character of this area, dating back many years, as well as its high population density (WIOŚ Katowice, 2016). Air pollution negatively affects human health. Particulates in the air can increase the incidence of respiratory and cardiovascular diseases and the risk of cancer, and affects life expectancy. Periods with high concentrations of pollutants, known as smog, are particularly dangerous. The level of pollutants in the air is affected not only by current emissions associated with the municipal and housing sector, transport, and industry, but also by local and regional meteorological conditions, such as air temperature, precipitation, wind velocity, and the type of atmospheric circulation (Majewski, 2005; Czarnecka and Kalbarczyk, 2008; Leśniok and Caputa, 2009, Leśniok et al. 2010). The focus of the present work was the concentration of PM10 particulate matter in the city of Sosnowiec, located within the Zagłębie Dąbrowskie (coal basin), which is part of the Silesian Voivodship (region). In terms of the number of inhabitants, Sosnowiec is the third largest city in Silesia and fifteenth largest in the whole country. The aim of the present study was to assess the variability of PM10 concentrations in the area of Sosnowiec, depending on the type of atmospheric circulation.

DOI: http://dx.doi.org/10.15666/aeer/1504_18031813

Materials and methods

The basis for the study consisted in the data on average daily concentrations of PM10 particulate matter in the months of the heating seasons, within the period of 2013-2015. Exceedances of the permissible concentrations of PM10 in the air (Official Journal of Laws 2012 item 1031) are closely linked to the combustion of fossil fuels of poor quality in home furnaces and fireplaces (WIOŚ Katowice 2014). Air pollution is characterized by seasonality (Majewski, 2007; Czarnecka and Nidzgorska-Lencewicz, 2010). The concentrations analysed were recorded at the monitoring station in Sosnowiec on Lubelska street (*Fig. 1*), belonging to the Air Quality Monitoring System run by the Regional Inspectorate for Environmental Protection in Katowice.

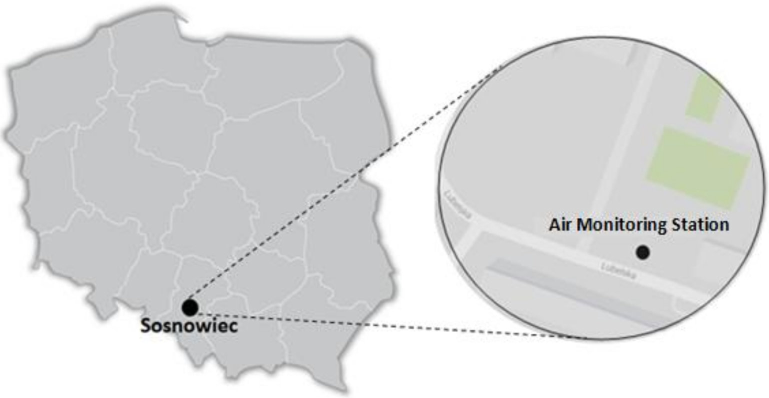

Figure 1. Location of the air quality monitoring station

The calendar of circulation types developed by Niedźwiedź (Niedźwiedź, 1981) was used to analyse the concentrations of PM10 particulate matter depending on the type of atmospheric circulation. For each of the 21 types of atmospheric circulation, the incidence and the mean, maximum and minimum concentrations of PM10 were recorded during the heating season months, i.e. January, February, March, April, October, November and December in the period of 2013-2015, for a total number of 636 days. The overall incidence of each atmospheric circulation type and their frequency of occurrence on days with excessive PM10 levels have been presented.

Research results

Using the data from the measurement station belonging to the Regional Inspectorate for Environmental Protection in Katowice, the average daily concentration of PM10 particulate matter was computed and assigned to each day of the heating season. The arithmetic mean of the PM10 concentration reached 50.9 µg/m^3, the standard deviation was 29.6 µg/m^3, and the variation coefficient was 58.0%, which means that the PM10 concentration varied considerably during the study period. The analysis showed that the permissible levels were exceeded 252 times, which represents 40.0% of the total period under consideration (*Fig. 2*).

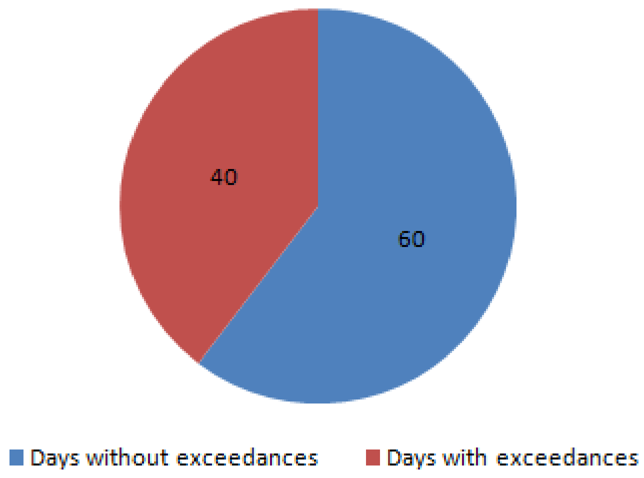

Figure 2. *Percentage share of days with exceedances of permissible concentrations of PM10, as well as days without exceedances throughout the study period*

It should be noted that, as required by law, the permissible annual number of days with exceeded permissible levels of airborne particulate matter is 35 (Official Journal of Laws 2012 item 1031), while in Sosnowiec only during the heating seasons in the years 2013, 2014, and 2015, the number of days exceeding the air quality standards was 106, 77 and 66, respectively, and thus far in excess of the permissible value of pollution (*Fig. 3*).

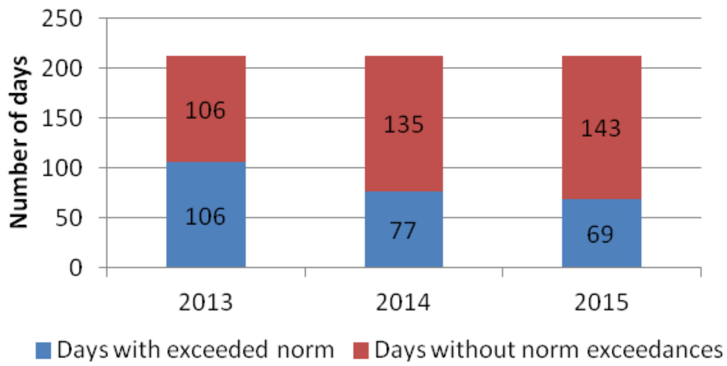

Figure 3. *Number of days on which the permissible air quality norms were exceeded during the heating seasons between 2013-2015 in Sosnowiec*

The concentration of airborne particulate matter in the city varies according to the type of atmospheric circulation (Knozová, 2012). The characteristics of the latter are often determined on the basis of the calendar of circulation types developed by Niedźwiedź, which distinguishes ten cyclonic situations, ten anticyclonic situations and one unidentified situation (Niedźwiedź, 1981).

In general, it can be concluded that higher concentrations are associated with anticyclonic situations (Leśniok et al., 2010, Bokwa, 2012). For the city of Sosnowiec, the mean concentration of PM10 particulate matter during anticyclonic conditions was

55 µg/m^3, whereas the mean concentration of this pollutant in the case of cyclonic conditions was 45 µg/m^3 within the heating seasons of 2013-2015 (*Table 1*).

Explanations: N - north air advection; NE - north-east air advection; E- east air advection; SE - south-east air advection; S – south air advection; SW - south-west air advection; W – west air advection; NW – north-west air advection; Cc - central cyclonic conditions; Ca - central anticyclonic conditions; Ka – anticyclonic wedge; Bc – cyclonic trough; X - unidentified situation; A - anticyclonic conditions; C - cyclonic conditions

The highest concentrations of PM10 particulate matter in Sosnowiec during the heating season in the years 2013-2015 occurred during an anticyclonic wedge, on average amounting to 71 µg/m^3. The minimum concentration for this type of anticyclonic situation was 26 µg/m^3. The maximum concentration at the anticyclonic wedge was 235 µg/m^3, which is a significant exceedance of 200 µg/m^3. Above this level, there is a considerable risk to human health among particularly vulnerable groups of the population resulting from even a short-term exposure to pollution (Official Journal of Laws 2012 item 1031). In the case of anticyclonic advection from the south

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18031813

mean concentration was not much lower, at 69 μg/m^3. In this case, the minimum concentration was 39 μg/m^3, while the maximum was 148 μg/m^3. A high mean concentration also occurred in the anticyclonic south-west air advection, amounting to 66 μg/m^3. The minimum concentration for this type of situation was 25 μg/m^3. The maximum concentration was higher than that of the anticyclonic advection from the south, as it amounted to 174 μg/m^3. The occurrence of central anticyclonic conditions was associated with an average concentration of 63 μg/m^3, which is also significantly over the permissible limit. The minimum concentration was 17 μg/m^3, while the maximum reached 123 μg/m^3. In this case, the minimum concentration was lower than the permissible PM10 level in the air. Although the mean concentration for the anticyclonic advection of air from the east was 56 μg/m^3, which was significantly lower than the highest of the mean concentrations (71 μg/m^3), the maximum concentration was as high as 225 μg/m^3 reaching the highest level of all the situations. Anticyclonic conditions, such as north-east air advection, south-east air advection, west advection and north-west advection, shared very similar mean concentrations of 48-49 μg/m^3, not exceeding the permissible level of PM10 concentrations. The maximum concentrations were in the range of 85-152 μg/m^3. The lowest mean concentration of PM10 was noted during the anticyclonic advection of air from the north, at a level of 33 μg/m^3. In this case the minimum concentration was 16 μg/m^3, while the maximum was 76 μg/m^3.

In the case of cyclonic conditions, the highest mean concentration of PM10 particulate matter in Sosnowiec during the heating seasons in the years 2013-2015 occurred during cyclonic advection from the north-east and amounted to 63 μg/m^3. The minimum concentration was 16 μg/m^3, i.e. not exceeding the permissible level, while the maximum concentration was 177 μg/m^3. It should be noted that central cyclonic conditions occurred only once during the entire study period, so the relatively high concentration of 56 μg/m^3 for this type of circulation cannot be taken into account in the analysis. The high value could have been accidental, which cannot be determined without more data. Other than the central cyclonic situation, advection from the south was associated with the second highest mean PM10 concentration of 53 μg/m^3. The minimum concentration reached 23 μg/m^3 and therefore it did not exceed the permissible level. The maximum concentration was 88 μg/m^3. A slightly lower mean concentration of 52 μg/m^3 was associated with cyclonic south-west air advection. The minimum concentration did not exceed the permissible level and was 14 μg/m^3, while the maximum concentration was 127 μg/m^3. A mean concentration just below the permissible level of 49 μg/m^3 can be attributed to the cyclonic trough. It should be noted that the lowest of all the minimum concentrations of 10 μg/m^3 was noted for this type of situation, reaching the same level only with the cyclonic north-west air advection. The maximum concentration was 134 μg/m^3. Similar concentrations in the range of 43-44 μg/m^3 were associated with cyclonic advection of air from the east and south-east. The minimum concentrations were in the range of 14-17 μg/m^3, while the maximum concentrations were 81-95 μg/m^3. The mean concentrations during cyclonic advection from the north and cyclonic advection from the west ranged from 32 to 35 μg/m^3. Minimum concentrations were 10-12 μg/m^3, while maximum concentrations showed a greater variation, with values ranging between 73-136 μg/m^3. The lowest mean concentration in cyclonic conditions occurred with the north-west air advection, amounting to only 24 μg/m^3. This was at the same time the lowest average concentration among all types of cyclonic and anticyclonic conditions. The minimum concentration in this case was 10 μg/m^3, which, as mentioned above, is also the lowest

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18031813

minimum concentration occurring during a cyclonic trough. The maximum concentration was 60 µg/m^3 and was the lowest of all maxima, with the exception of the central cyclonic situation.

Unidentified situations were characterized by a mean PM10 concentration, remaining at a level of 57 µg/m^3. The minimum concentration did not exceed the permissible level, reaching a value of 28 µg/m^3. The highest recorded concentration for unidentified situations was 93 µg/m^3.

It can be observed that higher concentrations of PM10 particulate matter in Sosnowiec are associated with anticyclonic conditions. The worst air quality with respect to PM10 particulate matter throughout the heating seasons of the 2013-2015 period occurred during anticyclonic conditions. Also, higher concentrations of pollutants are correlated with air inflow from the south, irrespective of the anticyclonic or cyclonic nature of the conditions. The mean concentration for advection from the south is approximately 55 µg/m^3, compared to 41 µg/m^3 for north advection. The mean particulate matter concentration for east advection is 51 µg/m^3, while the mean concentration associated with advection from the west is 46 µg/m^3. The average concentration of PM10 for the north-east advection is 46 µg/m^3, while for the north-west advection it is 37 µg/m^3. The mean concentration of PM10 in the south-east air advection is 53 µg/m^3, and in the case of south-west advection, it is 54 µg/m^3.

Another important issue in addition to the concentration occurring for a particular type of atmospheric circulation is the frequency of this situation. During the period considered, the prevalence of anticyclonic events was 54.72%, while 43.24% of cases were cyclonic. Unidentified situations accounted for merely 2.04% of cases. During the days with exceeded permissible PM10 levels, the incidence rate was 66.51% for anticyclonic systems and 30.72% for cyclonic systems. The frequency of various atmospheric circulation types overall and during PM10 exceedances in the 2013-2015 heating seasons in Sosnowiec are presented in *Table 2* below.

In the case of anticyclonic conditions, the most common type of atmospheric circulation in the heating 2013-2015 seasons in Sosnowiec was the west air advection, which averaged 11.32%, while during the period of exceeded permissible levels of PM10 particulate matter, the incidence of this type of situation amounted to 12.39%. It is worth noting that the anticyclonic advection from the west was the most common of all situations. The second most common in terms of the prevalence of anticyclonic conditions was the south-west advection, amounting to 8.65% of all situations. In the case of days with exceeded permissible PM10 levels, this situation reached a frequency of 13.75%. Despite the fact that anticyclonic advection from the south-west is less frequent than advection from the west, its appearance is more frequently associated with exceeded permissible levels of PM10 in Sosnowiec. The third most frequently occurring type of anticyclonic conditions was the advection of air from the south-east, occurring in 8.33% and 7.70% of cases during days with excessive particulate matter pollution levels. The anticyclonic wedge associated with the highest mean concentrations of PM10 occurred only in 5.97% of cases, but for days with PM10 levels above the permissible level, the frequency of the anticyclonic wedge was at a level of 10.86%. In spite of the moderate incidence of this situation, its occurrence is in many cases associated with the exceedance of permissible levels of particulate matter PM10. The lowest prevalence among anticyclonic conditions was observed in the case of north advection, occurring in 2.04% of cases. During days with PM10 levels exceeding the permissible limit, north advection was only 0.63%.

In cyclonic conditions, the cyclonic trough proved to dominate, at 8.49% and 8.11% on average observed during the days when PM10 particulate matter levels were exceeded in the city. The second most common type of cyclonic conditions was the advection of south-west air, which averaged 6.92% and 7.61% on days with exceeded permissible PM10 levels. Equally frequently, cyclonic advection of air from the west amounted to 6.92%, but during days with exceeded permissible levels of PM10 this situation occurred in only 1.71% of cases. Except for the central cyclonic situation, which occurred only once in the analysed period, the cyclonic north advection was least

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18031813

frequent at 1.42%, and only 0.43% on days when permissible levels were exceeded. It should be noted that cyclonic advection from the north was the least common type of atmospheric circulation.

Unidentified situations accounted for only 2.04% of the total, and 2.78% of the days when permissible levels of PM10 in Sosnowiec were exceeded.

Interesting conclusions can be drawn from the analysis of the mutual relationship between mean concentrations and the frequency of incidence. For example, a high mean concentration of 69 μg/m^3 is linked to anticyclonic advection from the south, but this situation occurs with a frequency of 3.30%, which is not high. It could be interesting to attempt to assign particular types of atmospheric circulation to groups of hazards (Ziernicka-Wojtaszek, 2012). Permissible levels of PM10 concentrations of 50 μg/m^3 and a median of the overall prevalence of 5.66% were chosen as parameters separating individual groups of hazards (*Fig. 4*).

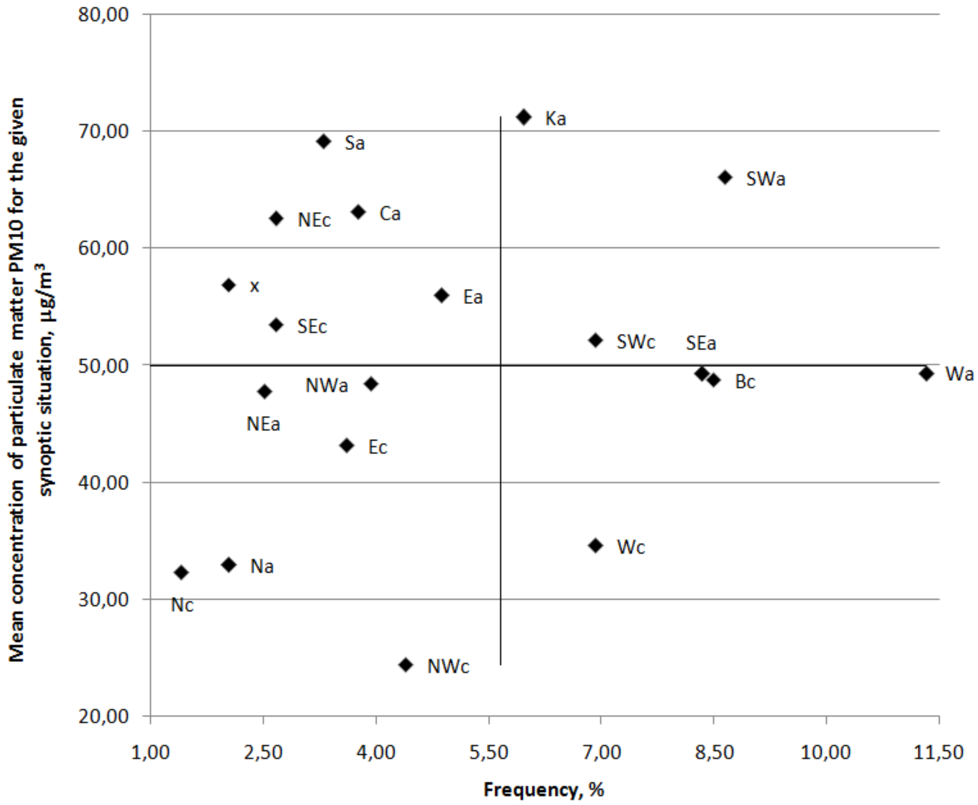

Figure 4. *Circulation conditions for the mean concentrations of PM10 in the 2013-2015 heating seasons in Sosnowiec*

These parameters can be divided into four groups. The first group, representing the greatest hazard, includes situations such as the anticyclonic wedge, the anticyclonic advection from the south-west and the cyclonic advection from the south-west. These situations are characterized by an average PM10 particulate matter concentration higher than the permissible level, and prevalence higher than 5.66%. The second group, representing a high level of hazard, concerns situations with a mean concentration of more than 50 μg/m^3 and a prevalence of less than 5.5%. This includes unidentified situations, anticyclonic advections from the south, anticyclonic advections from the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18031813

east, central anticyclonic situation, cyclonic advection from the south-east, and cyclonic advection from the north-east. The third group, representing a minor hazard, includes situations such as cyclonic and anticyclonic advection from the south-east, anticyclonic advection from the west and cyclonic advection from the west. These situations are characterized by a mean concentration of PM10 below the permissible level, and a prevalence of over 5.66%. The above-mentioned situations comprise the fourth, low hazard group, characterized by an average concentration of PM10 below 50 μg/m^3 and the lowest frequency.

Discussion

This paper analyses the effect of the type of circulation on the PM10 particulate matter concentration in the air in the city of Sosnowiec. The impact of meteorological conditions such as air temperature, wind force, or precipitation values, which also affect airborne concentrations of pollutants, has not been analysed (Czarnecka and Nidzgorska-Lencewicz, 2008). Exceeded permissible levels of pollution with PM10 particulate matter in Sosnowiec pose a serious environmental hazard. Permissible levels of airborne particulate matter were exceeded pollution on about 40% of days in the heating seasons between 2013 and 2015. In this area anticyclonic conditions dominate, representing 54.72% of all days in the studied period. This result is confirmed by scientific studies addressing the issue of air quality (Demuzere et al., 2009), whose authors concluded that anticyclonic conditions predominate over Europe, and thus also in Poland. In cities, air quality is associated with anticyclonic conditions, which is consistent with the results of this research (Bielec-Bąkowska et al., 2011). The most unfavourable group of situations includes the anticyclonic wedge, the anticyclonic advection from the south-west, and the cyclonic advection from the south-west. The maximum concentration of PM10, at a level of 235 μg/m^3 occurred during the anticyclonic wedge. Anticyclonic advection from the north-west, anticyclonic advection from the north-east, anticyclonic advection from the north, cyclonic advection from the east, cyclonic advection from the north, and cyclonic advection from the north-west belong to the group associated with the lowest risk of PM10 exceeding the permissible level. Frequent exceedances of permissible levels are correlated with inflow of air from the south. A similar dependency occurs in other Polish cities (Leśniok and Caputa, 2009; Bokwa, 2012; Czarnecka and Nidzgorska-Lencewicz, 2015; Leśniok et al., 2010).

In the city of Sosnowiec and the Upper Silesia region, several studies have been conducted on the impact of synoptic conditions on PM10 concentrations from various periods in the past. Although the air quality in Sosnowiec and Upper Silesia is not satisfactory, there are positive trends in the reduction of pollutants due to excessive PM10 concentrations. Comparison of the results from 1994-2004 averaged from nine monitoring stations in Upper Silesia (Leśniok et al., 2010) with the results of this study for Sosnowiec from 2013-2015 shows that the mean PM10 concentrations are currently lower by 18 μg/m^3 for anticyclonic conditions and by 9 μg/m^3 for cyclonic conditions. For conditions where the concentrations are highest, i.e. SWa, the values are on average as much as 23 μg/m^3 lower. The downward trend of PM10 concentration in the air in the Katowice region is illustrated by the results presented in the graphs for the 1994-2004 period (Leśniok and Caputa, 2009). The positive trend of reduction of air pollution by PM10 in Sosnowiec is confirmed by the results for the number of days when permissible levels were exceeded in the 2013-2015 heating seasons in Sosnowiec,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18031813

presented in this paper. These values in successive years were 106, 77 and 69 days. For 2009 the number was 108 days (Bielec-Bąkowska et al., 2011). It is also worth noting that in previous research of this type concerning the dependence of PM10 concentrations on synoptic conditions, only the mean concentrations for various synoptic conditions were given. What is new in the present study is the simultaneous presentation of both the mean PM10 concentration for each synoptic situation and the frequency of these situations. Despite the downward trend in particulate air pollution due to air protection programmes, the variability of PM10 concentrations in different synoptic conditions is very high. Conditions generating high and excessive concentrations are particularly interesting. The results of this study and future research may be used to predict high concentrations and exceedances of permissible PM10 levels on the basis of forecasts of synoptic conditions.

Conclusions

The following conclusions can be drawn from the research:

1. Daily PM10 concentrations in the heating season vary a great deal depending on frequently changing synoptic conditions. Higher PM10 concentrations are associated with anticyclonic conditions, during which the PM10 concentration was 55 $\mu g/m^3$, a compared to 45 $\mu g/m^3$ for cyclonic conditions. During the heating seasons in Sosnowiec, anticyclonic conditions predominate, accounting for 54.7%, and 66.5% on days when permissible PM10 levels were exceeded in the air.
2. The highest risk of exceeding the permissible levels of PM10 particulate matter in the city of Sosnowiec occurs in the anticyclonic wedge, but other hazardous situations include anticyclonic and cyclonic advection from the south-west. These situations are characterized by an average PM10concentration above the permissible level and a frequency of 5.66%.
3. There is a downward trend in the PM10 concentration both during the research period and in comparison to periods in the years preceding it, studied by other authors.
4. The relationships observed can be used to predict high concentrations of PM10 and exceedances of permissible levels on the basis of forecasts of synoptic conditions.

Acknowledgments. The research was carried out under Project no. DS-3337/KEKiOP/2017 financed from a research grant allocated by the Ministry of Science and Higher Education.

(Received 16th Jun 2017; accepted 3rd Oct 2017)

Abstract. This study aims to develop an approach which integrates the concept of climate-sensitive design with housing community design for the design of better residential buildings fitting into local wind environment. Employing research methods involving field investigation and computational fluid dynamics (CFD) simulation, the ventilation environment of four typical community atrium spaces were examined and compared in this study. Through a combination of CFD simulation and scenario-based design studies, the research results reveal that the typical long-shape building blocks with high-density housing development lead to poor natural ventilation in atrium open spaces. The research also indicates that if the openings of building masses and atrium can match the prevailing wind direction, the ventilation in community atrium open spaces will be significantly improved, but the overall effects are also affected by several design factors such as the distance between buildings, the size and shape of urban blocks, organization of building masses, and whether or not the wind corridor effect is effectively utilized. It is suggested for further research that more detailed issued-based CFD simulations (e.g., various land use controls or user preferences) of the relationship between wind environment and various design strategies should be conducted in the early stage of the entire design process to obtain the improvement in ventilation environments.
Keywords: *computation fluid dynamic (CFD); housing design; ventilation; wind environment; thermal environment*

Introduction

Given the impacts of global climate change and the urban heat island effect, sustainable design methods by which to create a community environment that better fits into the local microclimate characteristics has become an important research issue in both urban design and community design (Mirzaei and Haghighat, 2010; Jan et al., 2013; Hsieh et al., 2016; Yang et al., 2017). Climate change and the negative effects of urbanization on the living environment, such as high temperatures, increases in PM 2.5, and increases in the heat island effect, make the aerodynamic properties of urban areas increasingly important in architectural and urban design, especially in hot and high density urban areas (Chao and Ng, 2014; Yim et al., 2014). Wind passing from rural areas into a city provides cleaner and cooler air into urban canopy layers in summers and good ventilation has been noted as one of the possible mitigation solutions to improve urban air environments and mitigate the impact of heat island effect (Hang, 2013; Hsieh and Wu, 2012). Good ventilation not only helps eliminate pollutants, it also improves outdoor human comfort by accelerating heat exchange, as well as enhances the natural ventilation capacity of interior spaces (Givoni, 1998; Ishida et al., 2005; Xie et al., 2006).

Urban wind corridors can result from roads, open spaces, and passages through which air reaches the interiors of urbanized areas (Suder and Szymanowski, 2014). Over the years, urban wind research has investigated turbulent flow conditions in different street canyon models (Shi et al., 2015; Allegrini et al., 2015). Building blocks with limited open spaces between them, uniform building heights, and large podium structures have led to lower permeability for urban air ventilation at the pedestrian level (Ng, 2009; Yuan and Ng, 2012). High density housing development patterns and improper building layout in many dense urban areas have affected the ventilation of residential buildings as well as the comfort of residents (Walton et al., 2007; Du et al., 2017). These kinds of studies have shown that there are significant impacts of site planning and building layouts on the resulting wind environment around buildings. Therefore, it has become a great challenge for both urban designers and architects to determine how to better utilize the wind environment and natural ventilation to improve the outdoor wind environment as well as to enhance air quality in urban areas (Hsieh and Huang, 2016; Peng et al., 2017).

Previous studies have also revealed the importance of carrying out an environmental assessment of the available alternatives in the design stage of urban and building projects (Asfour, 2010). However, in spite of the fact that some research effort has been made, the lack of good interaction between urban wind environment researchers and urban space designers, together with a shortage of easy-to-use and easy-to-understand simulation tools for evaluating design alternatives in the design process has limited the practical application of related research. In terms of methodology and analytical tools, the effects of the urban building arrangement on the wind environment have been investigated through wind tunnel experiments or numerical simulations, such as Computational Fluid Dynamics (CFD). CFD has become a commonly used numerical simulation method and analytical tool for studying the wind environment (Takahashi et al., 2004; Mochida and Lun, 2008; Hu and Ryuichiro, 2013). It has some important advantages over wind tunnel testing. For example, wind tunnel measurements are generally performed at a few selected points under similar requirements in urban models. CFD, on the other hand, is conducted at full scale and provides whole-flow field data and information on the relevant parameters at all points of the computational domain (Blocken et al., 2012; Mirzaei and Caemeliet, 2013) Moreover, CFD is being increasingly used to assess pedestrian-level wind conditions in urban areas (Wu et al., 2013). Because of these advantages, CFD is being increasingly used to study a wide range of wind-related environmental problems in urban areas, such as urban air pollution and natural ventilation of community building design (Gromke et al., 2015; Mora-Pérez et al., 2015; Wang and Li, 2016).

It is also worth mentioning that, thanks to the development of numerical simulations, a more efficient design approach and design project evaluation has been made possible. Generally speaking, the entire design process normally includes three stages: a pre-design stage, a design stage, and various post-design stages. In an age when digital simulation tools have not been widely applied in design practice, many conceptual design ideas have been difficult to put into practice because they could not be validated before being mass produced. Also, in a design age that is heavily reliant on drawing tools such as pens and papers, it is quite often the case that many design products have

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18151831

been manufactured without pre-design evaluations. Although sometimes post-design evaluations or post occupancy evaluations (POEs) have been conducted to help identify some design mistakes, it is often too late to make any adjustment because the products or buildings have already been manufactured.

Similar cases in community housing design, systematic considerations of the topic are limited and normally not included in decision-making at the pre-design and design stage in community planning and design. In spite of these effects being noticed by researchers, relatively few efforts have been made by urban designers and architects to integrate the effects of natural ventilation into block-level community housing design. In high density Asian cities for example, in order to allocate the maximum number of housing units or maximum Floor Area Ratio (FAR), natural ventilation is normally not seen as a key consideration in organizing housing layout and building masses. Moreover, local building codes in many Asian cities also have failed to take the effect of the wind corridor into consideration in arranging building setback and design guidelines for community open spaces.

Unlike the past approach, current applications of digital simulation tools such as CFD, enable design problems to be identified in the pre-design stage or sketch design stage. Moreover, with the help of computer simulations, an integrated product evaluation process that links the design stages, simulations, and assessments can be established before products are actually manufactured. For example, the development of CFD has resulted in the widespread use of this technique not only as an environmental research tool but also as an architectural design tool. In view of this dilemma, this research is an attempt to address the issues indicated above by using four prototype building layouts in Tainan City, Taiwan as case settings. The practical applications of wind engineering (CFD modeling) on architectural design and community open space design are discussed to together with considerations of housing market requirement. This study is aimed toward changing traditional experience-based design methods toward more scientific wind environmentally-sensitive architectural design an community design, in order to ensure that the surrounding wind environment of the proposed residential buildings is adequately considered. Employing research methods involving field investigation and CFD simulation, this study is an attempt to explore two research issues: (1) how to systematically analyze the influence of community building layouts and atrium designs on the ventilation of community outdoor spaces and (2) how to suggest suitable building layouts and open space design principles that strengthen the coordination between the local wind environment and the design of community open spaces. Based on our empirical approach, the effect of building arrangements on average ventilation efficiency is numerically evaluated in selected residential areas at the pedestrian level, and practical design suggestions are proposed to serve as a guide for better urban ventilation design.

Materials and methods

Study area

Tainan City (23°0’16’’N, 120°13’10’’E) is located in a tropical climate zone, considerably close to the Tropic of Cancer which divides the subtropical zone and tropical zone. Known as the fourth most populated city in Taiwan, Tainan City is also highly urbanized. The heat island intensity, defined as the maximum air temperature

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18151831

difference between the urban and rural areas of Tainan City during the nighttime and daytime, is 3.4 °C and 3.2 °C, respectively (Lin et al., 2005; Lu, 2008).

According to data from years 2001-2016, the average temperature from June to September was more than 28.5 °C. Among them, the temperature in July was the highest, recorded as 29.6 °C during the summer season (Hsieh et al., 2016). Furthermore, Tainan City is close to the sea and therefore having high humidity in summer. The wind environmentally-sensitive architectural design which consider how the natural ventilation can be utilized becomes an crucial step to improve the outdoor wind environment. The above weather characteristics, make Tainan City a good candidate for wind environment analysis, one of the main objectives of this study. It is a common issue in the southern part of China and also the Southeast Asia areas, especially for those places with the similar weather characteristics of high air temperature and humid in summer (Feriadi and Wong, 2004; Nguyen and Reiter, 2014; Priyadarsini et al., 2014; Sharmin et al., 2017).

Field measurement design

To achieve the purposes of this research, a representative residential neighborhood next to Barclay Park in Tainan City, Taiwan (a subtropical climate zone) was selected as the empirical case setting. The residential neighborhood includes four types of housing communities with different building masses and building layouts. Each of them is a complete block development, and the buildings are typical housing types in Taiwan. Given that there are four prototypes of residential building layouts appearing in the same microclimate environment, this residential neighborhood provides an excellent case for addressing the relationship between the outdoor wind environment and building layouts as well as the effects of atrium design. The location and current situation of study area is shown in *Fig. 1*.

Figure 1. *Location map of study area*

The famous Barclay Ecological Park is located on the east side of the study area, and a large agricultural experimental farm was located on the south, which has been just rezoned by the Tainan City Planning Commission as a new urban development site, but new land development has not occurred yet. To the north is a 40-M main road, and to the west are a large parking lot and some low-rise houses. Given that the prevailing wind direction in summer of the study region is mostly southerly, it can be assumed that the impact of the surrounding buildings on the local wind environment is small.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18151831

The selected residential neighborhood (the study area) contains four different types of atrium housing communities (*Figs. 2* and *3*). Type A Community contains one 63 m high-rise elevator building complex (three sets of connected 20-story apartment buildings), which has a small-scale unilateral open atrium facing the south. Type B Community contains two blocks; each has several connected 7-story apartment buildings, with a height of 24 m and a narrowed atrium with two unilateral openings. Type C Community is a townhouse residential community shaped by 4 unit building complexes with a building height of 16 m. It contains two residential blocks; each has a ribbon-shaped atrium open space with three openings. Type D Community is a row house residential community shaped by connected 5-story buildings (16 m), with the opposite side opening into a ribbon-shaped atrium in each block. All the blocks are densely developed in order to obtain the maximum number of housing units, and this is a common situation in land development practice in Taiwan in order to increase economic profit.

(c) Community: belt atrium community with opening on two sides. (d) Community: belt atrium community with opening on the edge*

Figure 3. *Measurement equipment*

The measurement time of our survey was between July 5th and July 28th of 2014. This three weeks period in Taiwan is when the weather is the hottest, and the impact of the urban heat island is the strongest. Therefore, a study on how to enhance the ventilation of atriums in such communities is critical in order to create a comfortable environment for outdoor activities. The microclimate measurement was conducted on

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18151831

selected spots, at selected time periods in the mornings and afternoons during the three weeks (9:00-11:00 in the morning and 2:30-4:30 in the afternoon) when the weather conditions were typically torrid without obvious strong wind. The major factors examined in the survey were wind speed, temperature, humidity, and the perceived comfort of users of each atrium space. The measurement equipment included Cambridge Accusense UAS 1500 anemometers (*Fig. 3*), AM-4214SD anemographs, and HT3007SD hydro-thermal meters. The Cambridge Accusense UAS 1500 anemometer, whose accuracy can reach 0.10~20 m/s ± 5 %, was assembled on a tripod 1.5 m above the ground (the range of wind often affects pedestrian comfort). With regard to the arrangement of the measurement points (*Fig. 4*), the points were carefully selected to reflect the critical points that influencing atrium wind fields and user comfort, including points in the main nodes of outside activity spots and wind paths, and in the opening of the atriums. Effort was also made to keep the survey points equally and spatially distributed. Because the Type A Community is the highest building in the study area, a measurement point was set on the floor of the attic to measure the surrounding wind speed, which was imported into the CFD analysis later as a baseline parameter.

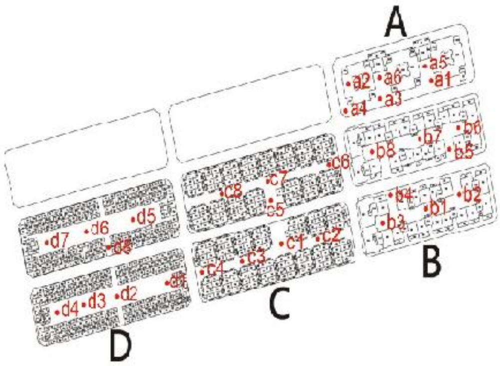

Figure 4. *Map of measurement points*

CFD simulation

Computation fluid dynamics (CFD) numerical simulations were employed to analyze the surrounding wind environment of the buildings. In regard to the setting of boundary conditions for the CFD simulation, the velocity inlet was set to be the gradient wind, where the vertical wind speed distribution was represented by the power law profile (*Eq. 1*). The land surface was set to be a no-slip condition.

$$\frac{U_{(z)}}{U_0} = \left(\frac{z}{\delta}\right)^{\alpha} \qquad \text{(Eq.1)}$$

where

U_0: wind speed (m/s) outside of boundary layer (also known as the gradient velocity)

$U_{(Z)}$: the wind speed at the height of Z(m/s)

Z: the reference height (m) (set to be the height of Building A = 60 m in this case)

δ: the height of gradient (m)

α: power law value (index)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18151831

In accordance with relevant research practices, the height and the power law value of the boundary layer was determined depending on ground conditions. The simulation area was dominated by middle-story buildings, so the power law value was set at 0.25, and the gradient height was set at 400 m. The remaining parameter settings are shown in *Table 1*.

Table 1. *Parameters of boundary condition settings*

Items	Setting
Wind direction	S
Wind velocity (m/s)	3.40
CFD scheme	Central difference scheme
Governing equations	Navier-Stokes equations
Boundary volume (X×Y×Z)	1500 m(N-S)×1500 m(E-W)×450 m
Total mesh number	7,957,000 meshes
Reference height (δ)	60 m
Power law value (α)	0.25

In the case under study, the simulation area is surrounded mainly by a park, a large area of agricultural land and a large parking lot. Because there are no buildings of significant mass in the major wind directions of the study area, the influence of surrounding buildings on the wind environment was considered to be negligible in the model calibration. When calculating the flow field using a CFD model simulation, the setting up of a reasonable grid system and selection of suitable boundary conditions are key requirements for efficient computer calculation. Based on the experiences discussed in previous relevant studies, the boundary condition for the simulation was set to be 10 times of the height of the main buildings, and the height of the calculation area was set to be 5 times of the height of the main buildings. A structural grid was used in order to enhance the simulation accuracy. Due to the fact that the fluid variation around the buildings is much larger than that around other areas, a more refined grid system was developed around the buildings in order to get more accurate simulation results. WindPerfectDX was the software employed in this research. Its advantages include the capacity to develop a very fine grid system for a simulation as well as the ability to import the Sketch up 3D files easily and directly. Also, it has a strong visualization capacity for simulation results, which makes communication with developers and architects much easier.

Results

In order to validate whether the simulation results could be used for reference to community planning and design, a simulation model based on the current situation was first calibrated, and then the CFD simulation results were compared with the results of our microclimate survey conducted on the site. The model validation process involves making sure the CFD simulation model is reasonable and that the results are accurate and could be used for the evaluation of design plan. After the model validation process,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18151831

the proposed alternative plans were then analyzed and compared. The model validation was conducted using the measured wind speed and prevailing wind direction, which is southerly. The wind speed measured at point a2 on the roof of the Type A 20-story building was used as the initial inflow wind speed.

The simulation results were compared with the actual measured results for the measurement points to examine the accuracy of the simulation model. Part of the results are shown in *Fig. 5*, which is a simulation based on southerly wind at an average speed of 1.3 m/s. The results indicate that the simulation values at points a6, b1, b5, c1, c8, d5 were all very close to the measured values, indicating that the model was reasonable. The simulation results of measurement points a1 and d2 were slightly different from the measured values, but the differences were both within an acceptable level (less than 0.09 m/s). In addition, a correlation analysis between the simulation values and measured values was conducted for all 30 measurement points, and the results showed a correlation coefficient r = 0.86, which indicates that the simulation results were close to the measured results. This further confirmed that the CFD simulation model could be used in the subsequent scheme assessment and analysis.

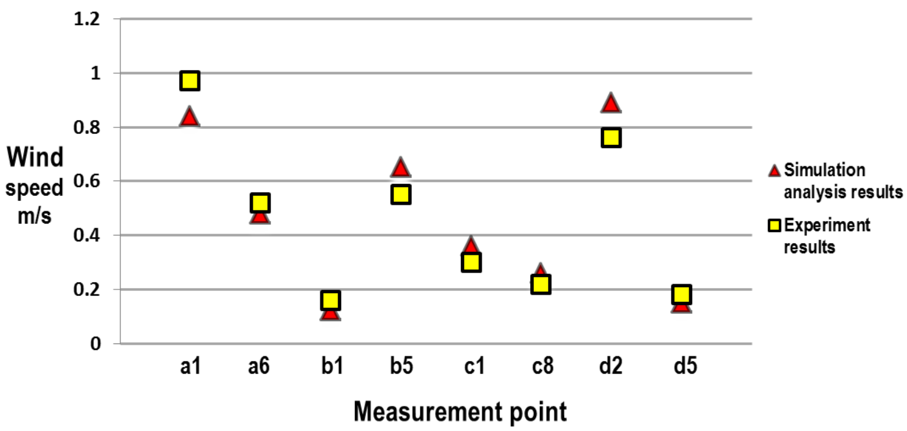

Figure 5. *Measurement point comparison between simulation analysis results and experiment results*

Evaluation of simulation results for community development plan on different blocks

After confirming the reliability of the proposed simulation model, a CFD simulation was conducted to evaluate the atrium ventilation performance of the four types of housing communities. The main process of the analysis involves calculating the spatial distribution of wind speed at pedestrian height in the outdoor space of the four communities. The CFD simulation was conducted using the prevailing wind direction in the summer. According to a field survey and the information obtained from a local weather station, southerly wind was used as the prevailing wind direction. The simulation results are shown in *Fig. 6*. The results reveal that “the position in which buildings face the wind field” and “the form and position of the openings in the community atrium in relation to the wind field” are two key factors influencing the ventilation condition in the community atrium situation. For the assessment of human comfort from viewpoint of landscape architects and urban planners, the high wind speed ($u \geq 1.0$ m/s) and low wind speed ($u < 1.0$ m/s) areas were defined (Hsieh et al., 2016). Moreover, pedestrian-level natural ventilation in the street canyon was assigned as the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18151831

stagnant (u < 0.3 m/s), poor (0.3 m/s ≤ u < 0.6 m/s), low (0.6 m/s ≤ u < 1.0 m/s), satisfactory (1.0 m/s ≤ u < 1.3 m/s), and good (u ≥ 1.3 m/s) in Hong Kong (Yuan and Ng, 2012). According to previous studies and the results of our interviews with community residents, a wind speed of pedestrian field between 1.0 m/s and 2.5 m/s is a more comfort wind range for community atrium open space design, and the atrium open spaces of the four selected housing communities in urban blocks were examined subsequently.

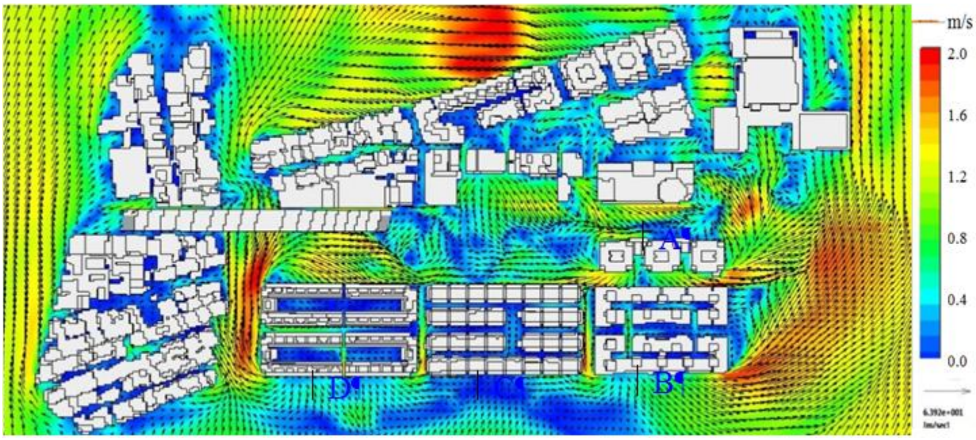

Figure 6. *CFD results of residential community environment (regional scale)*

The atriums, directly facing the direction of the summer prevailing wind, should have a better ventilation conditions compared to those of housing community type A. However, our analysis results show that the type A residential buildings in the back of building blocks perform better in terms of outdoor atrium ventilation. A possible explanation for this phenomenon is that the building blocks facing the windward side (building blocks on the outside of south facade) in type B and type C housing communities did not provide a corresponding opening on the windward side, so the airflow has to get in from the side entrances and the atrium entrance on the back side of the buildings, which leads to poor atrium ventilation. As for housing community type D, although these have openings on the windward side, the size of the opining is relatively small, and the atrium is too narrow and long, so the wind corridor effect can not expand to the entire atrium, which therefore leads to poor ventilation of the entire outside open space.

The research results also reveal that if there are sufficient openings provided in linear atrium communities (housing community type C), or if the position of the atrium opening is helpful for enhancing the airflow convection of the atrium (housing community type B), the outside ventilation condition will be significantly improved in areas that can be affected by air convection. In addition, our empirical results also indicate that “the relationship between the axial building layout and the wind corridor” and “the separation distance between buildings” both have obvious influences on community outdoor ventilation. For example, the arrangement of the long axis in housing community type C caused failure to match the prevailing wind direction and thus contributed to a weak effect of the wind guiding function. Similarly, housing community type D has only a narrow opening facing the windward side, which also limits the wind guiding effect of the passing wind corridor.

DOI: http://dx.doi.org/10.15666/aeer/1504_18151831

Discussions

After exploring the possible reasons leading to poor atrium ventilation in the study cases, two alternative community design plans were proposed, and a CFD simulation was used to evaluate the effects of each plan. By considering consumer demand, housing development and local housing market trends (the demand for maximization of total floor area and the total number of housing units in order to make significant profit) as well as the principles of community ventilation design, two refined alternative plans were provided: one is a minor adjustment plan, and the other is a complete block redesign plan. Together with the plan of "business as usual" (the current one), there were a total of three plans to be simulated and compared. The architectural perspectives and selected elevation views of these plans are shown in *Figs. 7* to *9*.

The two alternative plans have different planning goals and considerations. The minor adjustment plan (community residential building plan 2, *Fig. 8*) adds ventilation openings and vents in selected buildings, while trying not to reduce the total floor area and total housing units in order to meet the expectations of developers who are seeking profit.

(a)

(b)

Figure 9. *Community residential building plan 3 (climate-sensitive adjustment situation). (a) Perspective view. (b) The south elevation view*

The design methods of the plan included adding one opening on the south side of the buildings of Community Type B, and then transferring the decreased floor area resulting from the new opening to the top floor of the buildings on both sides of the community entrance. This creates double effects: it maintains the total floor area on the one hand, while creating an enhanced image of the community entrance. A similar approach was used in Community Type C, where several air vents were added to the three connected building units in the middle building complex facing south, while the decreased floor area was added to the top floor of the buildings near the community entrance to create enhanced visual effects. As for Community Type D on the left, air vents were placed at the junctions of the building units on the four corners, and the decreased floor area was added to the top floor of the buildings next to the community entrance to enhance the entrance image.

The above-mentioned minor adjustments were made on the basis of a planning goal to add ventilation openings and vents to existing building forms and building masses, while trying not to decrease the total floor area and the number of housing units. Based on our interviews with the local land developers, this approach was highly accepted by them. The actual effect of the improvement atrium ventilation in this approach, however, will need to be examined based on the results of the simulation analysis.

As for the second alternative plan (community residential building plan 3, *Fig. 9*), it involves a large adjustment in which building blocks and building type mix are redesigned based on the concept of climate-sensitive design and the consideration that without significantly reducing the allowed floor area ratio of land development. The original two long narrow shaped blocks in Community Type B, Community Type C and Community Type D are combined into one block for each community. The size of the new block is about 80 m ×100 m, which is a block size good for human walkability and a better arrangement for building layout. The building types and arrangement of the building masses are also redesigned, and the scale of atriums, the building configuration, and the distances between buildings are all reconsidered so as to try to obtain the optimal atrium ventilation. Moreover, what is worth mentioning is that a combination of town houses and mid-rise apartment buildings are adopted in the building forms of Community Type C and Community Type D. The combination of different housing types and sizes reflects different housing prices and market demand,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18151831

which is helpful to introduce households with various socio-economic backgrounds, and therefore contributes to the diversity of the population in these communities.

The simulation results for the three plans using CFD software are shown in *Fig. 10*. *Fig. 10* shows an enlarged image of the four communities. These results reveal that the two refined schemes, to various degrees, enhanced the natural ventilation of the atrium open spaces.

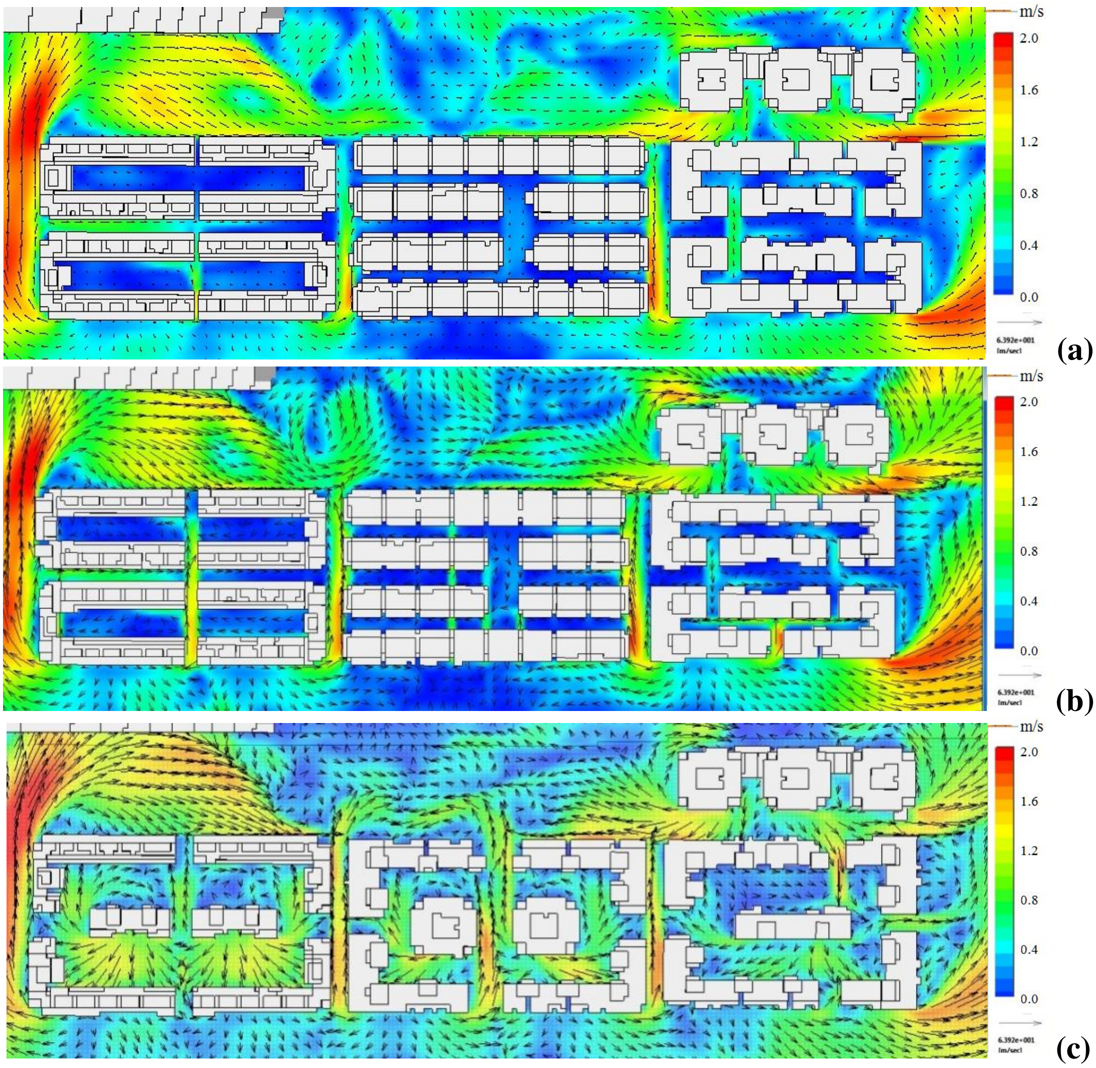

Figure 10. *The CFD analysis result comparisons among three community building setting plans (partially enlarged drawing) (a) Current Plan. (b) Slightly-adjusted plan. (c) Climate-sensitive adjustment plan*

For the minor adjustment plan (Plan 2), improvement of outdoor natural ventilation can be found in the areas close to the added ventilation openings or vents, such as those areas in housing Type B. However, for the community Type C, because the distance between the buildings is too short, and the linear atrium is too narrow and long, the effect of the three newly added ventilation vents was found to be very limited, and the effect of wind guiding and natural ventilation resulting from the vents was not able to expand to the full scope of the atrium. Similar situation occurred in Community Type

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18151831

D, where the newly added ventilation vents in the four corners partially improved the natural ventilation of the nearby areas on the windward side. However, given that the community has a very closed narrow-shape atrium with only two small openings to the outside wind corridor, the effect of the newly added vents on the improvement of natural ventilation in the atrium were also found to be very limited.

In terms of the complete adjustment plan (climate-sensitive adjustment plan) (Plan 3), which redesigns the building blocks, housing types, building layout, and atrium openings based on the characteristics of the local wind corridor and the design principles of outdoor natural ventilation, the results of the CFD simulation met our expectations. As indicated in *Fig. 10*, for all the Housing Types B, C, and D communities, the CFD simulation results the natural ventilation of their atrium open space to be significantly improved, both for the entire atrium and for partial areas in the atrium. For the case of climate-sensitive adjustment plans, it was showed from the simulation results that the wind speed areas in the stagnant and poor wind speed classes were largely decreased. This indicates that in order to obtain the optimal effect of natural ventilation for a community open space, it requires a comprehensive consideration of the size of the building block, organization of building types, building masses, building layout, and the community atrium openings. Also, a careful study of the relationships between these design factors and the local wind corridor is indispensable.

Similar with the climate characteristics of high hot and humid in South-East Asia, this study area also has similar climate, and therefore the design issue of ventilation are needed to be considered. In Vietnam, natural ventilation was found a better choice for passive cooling due to its hot and humid climate (Nguyen and Reiter, 2014). In Jogjakarta, people seemed to prefer higher wind speed and showed a tendency of creating higher air movement to modify the hot and humid living environment (Feriadi and Wong, 2004).

Recent studies have shown that the geometry and aspect ratio of urban canyons play a crucial role in moderating the microclimate at the street level (Xie et al., 2006; Asfour, 2010; Du et al., 2017). Heights and layouts of building group were found to influence ventilation, and step up configuration can distribute the wind evenly and allow the wind to reach the leeward side of each building. It was shown very effective in improving the overall natural ventilation and thermal comfort at pedestrian level (Rajagopalan et al., 2014). Another research in Dhaka used H/W ratios as an index originally to represent uniform and diverse geometric character of different sites (Sharmin et al., 2017). In our study, we also found the building arrangement, building layout and atrium openings were important design issues for a good ventilation. However, only few openings facing the windward side was found limited for ventilation improvement. The different height of buildings in an urban block such as the combination of town houses and mid-rise buildings shown in this study were one of the better design criterion to create a better wind environment.

Besides hot and humid environmental analysis considered in this study, the other aspects that most of the above papers were not discussed is that we took land development, urban planning and residential type preferences into consideration. It was shown even under the premise of housing preferences and economic profits of land development, it is still possible to enhance ventilation environment of the external space of communities. All the above findings can be applied to other tropical cities.

Conclusion

In order to provide a useful methodology and a suitable operational tool to integrate housing community design with climate-sensitive urban design, this study demonstrated a research approach which improves the natural ventilation of community atrium open spaces on an urban block scale with the help of a CFD simulation. Based on a review of related theories and literature as well as the analyses of current situation and suggested design alternatives, the study results show that this methodology has practical value in assisting community housing planning and design and is particularly useful for developing draft evaluations of strategic planning and design in determining building layouts and masses on site planning, where the simulation outcomes from this method could be used to modify design concepts and strategies. Moreover, by utilizing the proposed CFD simulation to analyze suggested scenario-based design alternatives to the natural ventilation of blocks and residential buildings as well as comparing the simulation results of the proposed improvements, this research shows that the method may enhance the scientific base of the traditional urban design approach because it can diagnose planning and design problems in the early stage of the design process and therefore guide the modification of design schemes on a timely and cost-efficient way.

Referring to practical community planning and design, the study analyzed and compared four typical types of housing community design and their atrium ventilation conditions. After a review of relevant literature, the CFD simulation parameters in our modeling approach were verified through on-site field survey of the microclimate situation. Subsequently, the atrium ventilation performance of four different housing communities in the selected four adjacent blocks was examined and compared through CFD simulations. This provides an operational method to integrate the consideration of climate-sensitive design approach into community design process.

Under the simulation condition with a prevailing wind from the south (long axis of the buildings facing prevailing wind), the research results indicated that the typical long-shape urban blocks with high density in southern Taiwan have poor natural ventilation in their atrium open spaces. The research also shows that if the openings of building masses and atrium could be arranged according to the prevailing wind direction, the community atrium ventilation could be improved greatly. It was also found from a comparison of the results of various design schemes that the natural ventilation in community atrium open spaces can be significantly optimized by properly controlling design factors including: the size and shape of urban blocks, the distances between buildings, organization of building masses, and the coordination of the openings of buildings and atrium open space with the direction of wind corridors. Furthermore, the results show that if a consideration of wind environment can be conducted in the early stage of community planning and design process, together with a proper CFD wind simulation approach, improvement in community external ventilation environments can be obtained without significantly reducing the expectation of developers who often attempt to meet the requirements of taking full use of all allowed Floor Area Ratio (FAR) and build more housing units to generate economic benefits in land development. In fact, this study reminds us that a good ventilation environment in community atrium open spaces will lead to a comfortable residential environment. If this concept can be accepted by developers and home buyers as well as be capitalized into property values, and subsequently lead to some adjustments in housing design preferences which take the concept of wind-sensitive design into consideration, more

DOI: http://dx.doi.org/10.15666/aeer/1504_18151831

and more residential communities will be built with good ventilation environments, and therefore the goal of climate-sensitive urban design will be realized sooner than later.

Finally, it is worth mentioning that this paper provides a methodology and operational approach to integrate the concept of wind-sensitive design with community outdoor space design within the requirement local housing market practice and the expectation of land developers. But there are still many issues and limitations needed to be addressed in local housing market environment as well as in zoning, urban design, and building code regulations. It is suggested that more detailed and issued-based simulations of the relationship between wind environment and various design strategies and alternatives which meet local context and content should be conducted before setting up real design guidelines in conducting urban design control.

(Received 16th Jun 2017; accepted 3rd Oct 2017)

Abstract. For over a decade now, decomposition analysis has become popular in energy and environment studies. This paper therefore identifies the factors that have influenced changes in CO_2 emissions in Iran for the period 1990–2010. The Refined Laspeyres Index method has been utilized in order to decompose the CO_2 emissions while four main factors of the observed changes have been identified: economic activity, energy intensity (energy use per unit of economic output), carbon intensity (CO_2 emission per unit of energy use), and population effect. The study period has been divided into two decades, the first one encompassing the period from 1990 to 2000 and the second one from 2000 to 2010. Our empirical findings have revealed that the main factor which is accelerating CO_2 emissions in Iran is the economic activity for the entire study period. Also within the first decade of the study, economic activity has been followed by energy intensity while in the second decade; it has been followed by population effect. Furthermore, the carbon intensity has made minor contributions to CO_2 emissions in Iran throughout the study period. Given that Iran is an energy intensive and largely oil dependent country; we therefore suggest it would be better off in terms of reduced CO_2 emissions by pushing down current energy intensity as its main environmental and economic policy objective. For the future studies, a sectoral CO_2 emissions analysis could be conducted for Iran in order to examine the carbon emissions increasing and decreasing factors and provide some sectoral policy implications.
Keywords: *environment, energy, sustainability, pollution, intensity, carbon, population*

Introduction

Environmental problems, especially climate change and global warming, have been on the world's agenda over the past several decades (Halder et al., 2013; Kuo and Perng, 2016; Lin, 2017). These problems have also raised the concern of energy analysts and policymakers about environmental sustainability. Many scientists argue that the increasing amount of CO_2 concentration in the atmosphere may create the greenhouse effect and this may cause global warming (IPCC, 2007). As Lotfalipour et al. (2010) states the main source of increasing CO_2 emissions in the atmosphere is fossil fuel combustion. The main factors that are raising fossil fuel consumption can be linked to economic development, technological changes, demographic changes, institutional frameworks, lifestyle, and international trade (Hatzigeorgiou et al., 2008).

Most of the Asian countries achieved a spectacular economic growth performance in recent decades (Zhang, 2008). As the Energy Information Administration (EIA) states, amongst these countries Iran is an energy superpower since it accounts for the world's second largest natural gas reserves and fourth largest oil reserves in 2015. Ninety eight % of Iran's overall energy demand is generated from natural gas and oil. On the other hand, Iran has the 7th rank in World Bank's CO_2 emissions ranking. Besides its one dimensional structure (depends mostly on oil revenues) Iran's economy expanded by

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18331846

139 % in real terms between 1990 and 2010 while the country's CO_2 emissions increased by 170.7 % in the same period (World Bank, 2015). Since the acceleration in Iran's CO_2 emissions is faster than its GDP increase this could be evidence that Iran's economic development is not environmentally sustainable. For instance, in China (which has experienced the most spectacular economic growth in Asia) the real GDP increased by 630 % while its CO_2 emissions increased by 236 % between 1990 and 2010 (World Bank, 2015).

In recent decades, there is an ongoing debate about the environmental impacts of high energy consumption among countries (Kumbaraoglu, 2011). Parallel to this, social and environmental aspects of energy sector projects gained importance in Iran. Accordingly, it is possible to state that there is an increasing awareness about energy production, conversion and utilization in Iranian government, industry and public.

In Iran electricity and heat production are the major activities which create CO_2 emissions. They constitute 32 % of overall Iranian emissions in 2010 (World Bank, 2015). In Iran energy prices are low and winter months are cold, therefore electricity consumption is increasing during the winter. Since 95 % of electricity supply is generated using oil and natural gas then this yield to an increase in CO_2 emissions (World Bank, 2015). The second major CO_2 emitting activities are manufacturing and construction. As the World Bank data indicates 25.8 % of overall CO_2 emissions arise from manufacturing and construction. As Moshiri (2012) states, Iran's industrial sector uses old technologies which are inefficient in terms of energy conversion. Transportation is another sector which increases Iran's CO_2 emissions. Transportation technologies are old in Iran and there exist high subsidies on gasoline (Moshiri, 2012). Therefore CO_2 emissions due to the transportation are increasing. Residential buildings and commercial & public services are also contributing to Iranian CO_2 emissions. This is probably due to the insulation deficiencies of the residential and commercial buildings and the use of high energy consuming home appliances. To sum up, it is possible to state that in Iran almost the whole of the economic activities are energy intensive and such high energy intensity increases the CO_2 emissions.

Together with the increasing awareness about CO_2 emissions reduction among the world countries, analyzing and understanding the factors that cause emissions increase has gained importance. Iran's CO_2 emissions exceeded 571 thousand KT in 2010 and this value is higher than those of some other countries that have similar GDP and population. Turkey can be given as an example to these countries. For instance Iran's CO_2 emissions are 1.9 times greater than Turkey's overall CO_2 emissions, where Turkey has almost the same population and higher GDP as compared with Iran (World Bank, 2015). Accordingly, analyzing the factors that accelerate or decelerate CO_2 emissions in Iran has gained great importance over the years. Identifying the components that are changing the CO_2 emissions is an important input to the policy makers and energy analysts who are developing some economically and environmentally sustainable projects. In addition, due to the geographic location Iran has the potential to diversify its energy sources. The identification of the sources of CO_2 emissions in Iran has not been widely studied. Published studies are mostly for developed countries and some developing countries, such as, China, India, Turkey, and Korea.

What are the factors that change the CO_2 emissions? This question can be answered by identifying the most important factors contributing to the overall changes in CO_2 emissions. One possible way for analyzing the CO_2emission changing factors is through econometric regressions. For instance, in his work Halicioglu (2009) proved that there

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18331846

exist a long run relationship between CO_2 emissions and income, energy consumption and foreign trade. Another possible way for analyzing the factors changing CO_2 emissions is the decomposition analysis (Kumbaroğlu, 2011). The method adopted in this paper is the decomposition analysis. The paper contributes to the literature by decomposing the CO_2 emissions in Iran, in a detailed way.

The aim of this study is to identify the factors that have been changing Iran's CO_2 emissions for the period 1990–2010. The Refined Laspeyres Index (RLI) method which was developed by Sun (1998) has been applied to the data set. The data set is gathered from the World Bank database. The impacts of the four main factors, namely economic activity, energy intensity, carbon intensity, and population, have been considered in the analysis.

The structure of the paper is as follows. In the next section, a brief literature review about the country based decomposition analysis studies is provided. In the third section the decomposition analysis methodology and basically the Refined Laspeyres Index method are discussed. This section is followed by the overview of Iran's economic, demographic, energy, and environmental conditions. The empirical results are presented in section 5. The last section contains the conclusions of the paper.

Literature Review

Various methodologies have been developed to analyze the variations in energy and environmental factors. Decomposition Analysis (DA) techniques are among these methodologies used to identify the components changing the energy demand and related CO_2 emissions. A remarkable literature exists about the country-based decomposition studies. For instance, Paul and Bhattacharya's (2004) country-based study, analyzes the factors that increase and decrease the CO_2 emissions from the energy use of India between 1980 and 1996. Their empirical results indicate that economic activity has the greatest increasing effect on CO_2 emissions in India. Fankhauser and Cornillie (2004) studied the decomposition of energy data to identify the determining factors for energy intensity improvement in Eastern Europe and former Soviet Union countries. The researchers proved that energy prices and progress in enterprise restructuring are the two major contributors of efficient energy use. Furthermore, Wang et al. (2005) has also studied on decomposition of the energy-related CO_2 emissions for China between 1957 and 2000. Their empirical findings have shown that China achieved a remarkable decline in its CO_2 emissions due to improvements in its energy intensity. Kawase et al. (2006) have also worked on the decomposition of CO_2 emissions in Japan, for the period between 1985 and 1995, and they evaluated the long-term climate stabilization scenarios. On the other hand, Ma and Stern (2008) have also focused on Chinese CO_2 emissions between 1980 and 2003, and their results revealed that technological improvements reduced energy intensity, and this led to a reduction in overall CO_2 emissions. Moreover, Akbostanci et al. (2009) has studied the decomposition of CO_2 emissions for Turkey between 1970 and 2006 and their study showed that economic activity and energy intensity are the two major factors for evaluation of CO_2 emissions. Difurio (2010) has also focused the decomposition of CO_2 emissions in the US for the period 1990–2004 and their study showed that efficient energy use and reduction of fossil fuels in overall energy consumption offset the accelerating contributions of GDP per capita and population growth in the entire research period. Kumbaroglu's (2011) work has focused on the decomposition of CO_2 emissions for Turkey between the years

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18331846

1990 and 2007 by main economic activities, including agriculture, manufacturing, electricity, residential buildings, and transportation. His findings reveal that energy intensity and economic activity are the two major determinants of increasing CO_2 emissions in Turkey. On the other hand, carbon intensity and composition make only minor contributions to CO_2 emissions. Lei and Fan (2015) analyzed the CO_2 emissions in Beijing that are emitted from transportation over 1995 – 2012. By using the Generalized Fisher Index (GFI) method, the authors concluded that the economic growth, energy intensity, and population size have raised carbon emissions in the city during the study period. On the other hand they reported that transportation intensity and energy structure are the two factors that reduced the speed of transportation emissions in Beijing. Rüstemoğlu (2016) has provided a comparative decomposition analysis for Turkey's and Iran's carbon dioxide emissions from 1990 to 2011. By utilizing the Logarithmic Mean Divisia Index (LMDI) technique the researcher concluded that economic activity and population are the two major carbon emissions accelerating factors in Turkey and Iran. In addition, the researcher stated that Turkey has better achievements in terms of energy efficiency. *Table 1* summarizes these selected decomposition analysis studies in the literature.

Table 1. *Selected studies that provide an overview of country based decomposition analysis*

Study	Methodology	Empirical Findings
Paul and Bhattacharya, 2004. CO_2 emissions from energy use in India: A decomposition analysis	• Refined Laspeyres Index Method	• Economic Activity is the major factor which is increasing the CO_2 emissions.
Fankhauser and Cornillie, 2004. The energy intensity of transition countries	• Laspeyres Index Method • Paasche Index • Average Divisia Index Method • Adaptive Divisia Weighting Method	• For efficient energy use, they concluded that energy prices and progress in enterprise restructuring are the two main factors.
Wang et al, 2005. Decomposition of energy – related CO_2 emissions in China: 1957 – 2000.	• Logarithmic Mean Divisia Index Method	• China achieved a success to reduce the speed of CO_2 emissions by energy efficiency.
Kawase et al, 2006. Decomposition analysis of CO_2 emissions in long – term climate stabilization scenarios.	• Extended Kaya Identity • Scenario Analysis	• They evaluated the long term climate stabilization scenarios for Japan.
Ma and Stern, 2008. China's changing energy intensity trend: A decomposition analysis.	• Logarithmic Mean Divisia Index Method	• A decrease is observed in energy intensity due to the technological improvements.
Akbostanci et al, 2009. A decomposition analysis of CO_2 emissions from energy use: Turkish case.	• Logarithmic Mean Divisia Index Method	• Economic activity and energy intensity are the two major contributing factors to Turkish CO_2 emissions.

Decomposition Analysis Methods

Introduction to Decomposition Analysis

Decomposition analysis techniques can be considered mainly in two groups, Index Decomposition Analysis (IDA) and Structural Decomposition Analysis (SDA). SDA uses the input–output model in quantitative economics; however, IDA uses the index number concept under various methods linked to different index computations (Kumbaroğlu, 2011).

Both SDA and IDA methodologies are utilized in energy and CO_2 decomposition analysis, however, the use of IDA studies regarding CO_2 emissions is much larger. Ang and Zhang (2000) produced a survey of IDA related to the energy and environmental studies. In addition, Hokestra and Van Den Bergh (2003) made a comparison between SDA and IDA techniques and they stated that SDA is more efficient for the decomposition of economic and technological effects and IDA is more efficient for more detailed time and country studies. According to Ma and Stern (2008), the main advantage of IDA is it can be applied to any available data at any level of application. Like any other methods decomposition analysis also have some shortcomings. For instance, the analysis does not include the biomass use, since the comparable international data is not available. Therefore non - CO_2 greenhouse gas emissions are not included. In addition, CO_2 emissions only from fossil fuel combustion are

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18331846

considered. The other activities (forestry, land use changes) which also emit CO_2 emissions are not analyzed, again since the comprehensive data for them is not available. However, since it identifies the major contributing factors of CO_2 emissions generally a decomposition analysis is employed in the paper.

Refined Laspeyres Index Method

Different methods have been developed and utilized under the IDA methodology. As Kumbaroglu (2011) states, the Laspeyres Index isolates the impact of a variable by letting that specific variable change between two years while holding other variables as a constant at the base year values. The Laspeyres Index method contains a residual term; therefore, a refinement process is suggested by Sun (1998) to eliminate it. Sun's refinement process distributes the residual term to each variable. This approach is referred to as the Refined Laspeyres Index method and according to Ang and Zhang (2000) it passes all tests, namely time reversal, factor reversal, and zero value robustness. We chose to use the Refined Laspeyres Index method because it is easy for both calculation and understanding and does not leave any residual terms.

The Refined Laspeyres Index method is an extension of the Kaya Identity. The Kaya Identity is used to investigate the role of different factors that change CO_2 emissions (Kumbaroğlu, 2011). It describes the CO_2 emissions as a multiplication of four factors: population (POP), carbon intensity of energy use (CO_2/ENG), energy intensity of production (ENG/GDP), and production per capita (GDP/P). That is:

$$CO_2 = POP * \frac{CO_2}{ENG} * \frac{ENG}{GDP} * \frac{GDP}{POP} \quad \text{(Eq. 1)}$$

For this study, our aim is to show the overall impacts of the main components on CO_2 emissions. Therefore, we calculate the cumulative contributions of the four main components, as follows:

$$\begin{aligned} CO2(i) &= \textstyle\sum_j CO2(j), \\ POP(i) &= \textstyle\sum_j POP(j), \\ ENG(i) &= \textstyle\sum_j ENG(j), \\ GDP(i) &= \textstyle\sum_j GDP(j). \end{aligned}$$

Then the first equation can be written as,

$$CO_2(i) = \textstyle\sum_j POP(j) * \frac{CO2(j)}{ENG(j)} * \frac{ENG(j)}{GDP(j)} * \frac{GDP(j)}{POP(j)} \quad \text{(Eq. 2)}$$

It is possible to denote the carbon intensity by CI, the energy intensity by EI, and economic activity by EA. Then the previous equation can be written as:

$$CO_2(i) = \textstyle\sum_j POP(j) * CI(j) * EI(j) * EA(j) \quad \text{(Eq. 3)}$$

The effect of changes in production activity is referred to as the economic activity effect (EA_i^t), and it can be calculated as:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18331846

Economic Activity Effect

$$(EA_i^t) = \sum_j \Delta EA(j) * \left\{POP(j) * EI(j) * CI(j) + \frac{1}{2} * (\Delta POP(j) * EI(j) * CI(j) + POP(j) * \Delta EI(j) * CI(j) + POP(j) * EI(j) * \Delta CI(j))\right\} + \sum_j \Delta EA(j) * \{\frac{1}{3} * \left(\Delta POP(j) * \Delta EI(j) * CI(j) + \Delta POP(j) * EI(j) * \Delta CI(j) + POP(j) * \Delta EI(j) * \Delta CI(j)\right) + \frac{1}{4} * (\Delta POP(j) * \Delta EI(j) * \Delta CI(j))\} \quad \text{(Eq. 4)}$$

The economic activity effect (EA_i^t) shows the change in CO_2 emissions results from changing activity levels. According to the economic activity effect, an increase in activity levels increases the amount of CO_2 emissions, and a decrease in activity levels decreases the amount of CO_2 emissions.

Population Effect

$$(POP_i^t) = \sum_j \Delta POP(j) * \{EA(j) * EI(j) * CI(j) + \frac{1}{2} * (\Delta EA(j) * EI(j) * CI(j) + EA(j) * \Delta EI(j) * CI(j) + EA(j) * EI(j) * \Delta CI(j))\} + \sum_j \Delta POP(j) * \{\frac{1}{3} * \left(\Delta EA(j) * \Delta EI(j) * CI(j) + \Delta EA(j) * EI(j) * \Delta CI(j) + EA(j) * \Delta EI(j) * \Delta CI(j)\right) + \frac{1}{4} * (\Delta EA(j) * \Delta EI(j) * \Delta CI(j))\} \quad \text{(Eq. 5)}$$

The population effect (POP_i^t) shows the change in CO_2 emissions results from changes in the population. An increase in population increases CO_2 emissions and a decrease in population decreases CO_2 emissions.

Energy Intensity Effect

$$(EI_i^t) = \sum_j \Delta EI(j) * \left\{EA(j) * POP(j) * CI(j) + \frac{1}{2} * \left(\Delta EA(j) * POP(j) * CI(j) + EA(j) * \Delta POP(j) * CI(j) + EA(j) * POP(j) * \Delta CI(j)\right)\right\} + \sum_j \Delta EI(j) * \{\frac{1}{3} * (\Delta EA(j) * \Delta POP(j) * CI(j) + \Delta EA(j) * POP(j) * \Delta CI(j) + EA(j) * \Delta POP(j) * \Delta CI(j)) + 1/4 * (\Delta EA(j) * \Delta POP(j) * \Delta CI(j))\} \quad \text{(Eq. 6)}$$

The energy intensity effect (EI_i^t)suggests an indication of efficiency in the energy process, conversion technologies, and energy conservation. Energy-saving activities, reducing the use of fossil fuels and the use of renewable technologies increase energy efficiency. As a result, energy efficiency reduces the amount of CO_2 emissions.

Carbon Intensity Effect

$$(CI_i^t) = \sum_j \Delta CI(j) * \left\{EA(j) * POP(j) * EI(j) + \frac{1}{2} * \left(\Delta EA(j) * POP(j) * EI(j) + EA(j) * \Delta POP(j) * EI(j) + EA(j) * POP(j) * \Delta EI(j)\right)\right\} + \sum_j \Delta CI(j) * \{\frac{1}{3} * (\Delta EA(j) * \Delta POP(j) * EI(j) + \Delta EA(j) * POP(j) * \Delta EI(j) + EA(j) * \Delta POP(j) * \Delta EI(j)) + 1/4 * (\Delta EA(j) * \Delta POP(j) * \Delta EI(j))\} \quad \text{(Eq. 7)}$$

The carbon intensity effect (CI_i^t) is used to show the impact of fuel substitution on CO_2 emissions. For instance, if the share of renewable sources increases or if people use natural gas instead of coal, there will be a decline in overall CO_2 emissions.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18331846

The change of CO_2 emissions between two years is the sum of these four effects:

$$\Delta CO_2(i) = Economic\ Activity(i) + Population(i) + Energy\ Intensity\ (i) + Carbon\ Intensity(i) \quad \text{(Eq. 8)}$$

For a detailed analysis regarding the RLI method, Ang and Zhang's (2001) work could be followed.

Analysis of Data

The decomposition analysis covers the period 1990–2010, and the energy, CO_2, economic activity, and population data sets employed in this study are taken from the World Bank database. An overview of the economic and demographic developments, energy market, and emission growth trajectories is presented below. [1]

Economic and Demographic Developments in Iran

During 1990–2010, real GDP grew at an annual average rate of 4.5 %. However, Iran's economy was faced by recession in the years 1993 and 1994 and the real GDP declined by 1.6 % and 0.4 % (World Bank, 2015). Recently, economic sanctions, which are targeting the oil and natural gas sectors, hampered Iran's economy profoundly (EIA, 2015). Starting from 2008 the economic growth of Iran slowed down and in 2012, real GDP declined by 1.9 %. Real GDP per capita also increased from $1801 to $3259 during the research period (World Bank, 2015).

Iran's population has increased from 56.3 million (in 1990) to 74.4 million (in 2010). The average population growth rate of Iran is 1.4 % and this value is very similar to the world's population growth rate (World Bank, 2015). The share of the urban population also increased from 56.3 % (in 1990) to 68.9 % (in 2010) (World Bank, 2015).

Energy Market in Iran

Iran is the 12th largest energy consumer in the world and during the study period its energy consumption has increased from 69.3 thousand kt to 210.6 thousand kt (World Bank, 2015). Similarly, the energy production of Iran has increased rapidly from 187.8 thousand kt to 350.1 thousand kt between 1990 and 2010. According to EIA (2015), Iran is the fourth largest oil producer and second largest natural gas producer in the world and 98 % of overall energy demand is generated from these sources. The electricity production and electricity consumption of the country is 3.9 times and 3.7 times greater in 2010 if we compare with the 1990 level. As the World Bank data indicates, 95.8 % of overall electricity demand was generated by nonrenewable energy sources in 2010 (World Bank, 2015). In 2011, Iran's first nuclear energy power plant became operational.

CO_2 Emissions in Iran

Iran's overall CO_2 emissions increased from 211 thousand kt (in 1990) to 571 thousand kt (in 2010) and the country follows the most developed countries such as the US, Germany, Japan, and the UK and the rapidly developing populous countries such as

[1] The data set is available for the interested researchers through the authors' e-mail.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18331846

China and India in the emission rankings (World Bank, 2015). Similarly, per capita emissions of the country have increased from 3.7 tons (in 1990) to 7.7 tons (in 2010). In 2010, shares of the liquid and gaseous fuels in CO_2 emissions are equivalent to 43.2 % and 51.4 % respectively (World Bank, 2015).

Results and Discussion

Before proceeding to the results of the RLI method, we discussed the general structure of Iran's economy, energy market, and CO_2 emissions between 1990 and 2010. The impacts of all identified factors on CO_2 emissions during 1990–2010 can be followed in *Figure 1*.

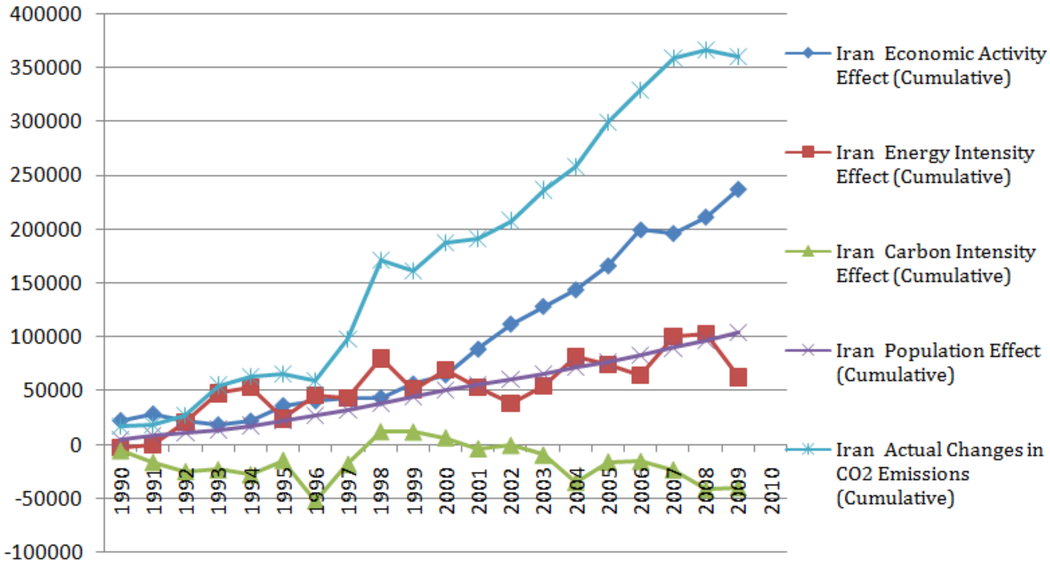

***Figure 1.** Decomposition of CO_2 emissions in Iran between 1990 and 2010*

Figure 1 indicates that the major determinant of Iran's CO_2 emissions is the economic activity. The economic activity is followed by the energy intensity and population. Finally, the carbon intensity has some minor reducing effects on CO_2 emissions in Iran. The detailed analysis about the impacts of the identified factors on CO_2 emissions is presented below.

Economic Activity Effect

As Kumbaroglu (2011) states, the economic activity effect represents the changes in CO_2 emissions resulting from changing economic activities. Except for the years 1993 and 1994, real GDP in Iran has increased. During the period 1990–2010, Iran's GDP and GDP per capita have experienced 139.1 % and 80.9 % increases respectively (World Bank, 2015). As a result of the spectacular economic growth, the economic activity played a dominant role in the decomposition of CO_2 emissions. In the first decade, we observed that the share of economic activity is 34.5 % in overall CO_2 emissions. Moreover, in the second decade, the contribution of economic activity in CO_2 emissions became more visible. The share of the economic activity in CO_2

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18331846

emissions has increased to 65.6 % between the years 2000 and 2010. *Figure 2* represents the contribution of economic activity regarding CO_2 emissions.

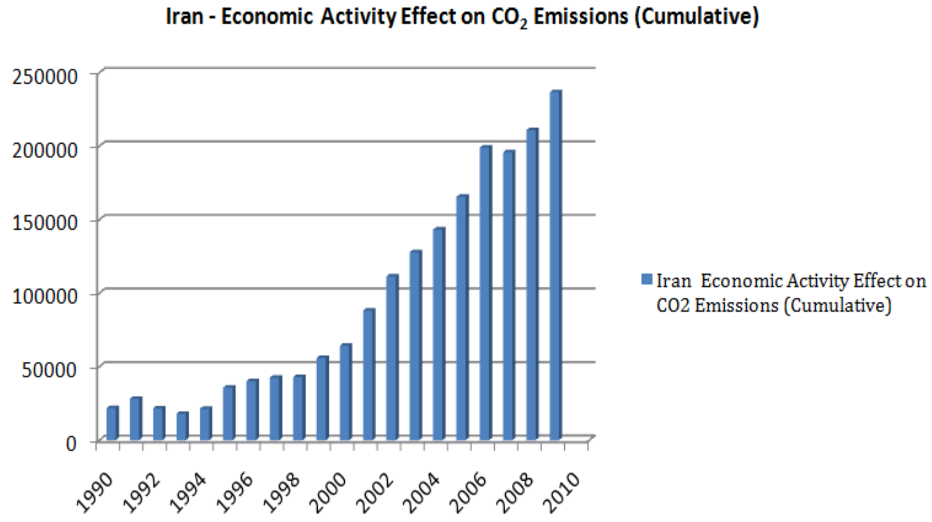

Figure 2. *Contribution of the economic activity to CO_2 emissions in Iran over 199–2010*

Energy Intensity Effect

According to Kumbaroglu (2011), the energy intensity effect provides an indication of the efficiency in energy processes, conversion technologies, and energy conservation. Increasing energy efficiency decreases the CO_2 emissions and vice versa. An energy efficiency goal can be obtained either by using renewable energy sources or reducing the use of fossil fuels by implementing the appropriate energy-saving policies. The energy intensity is the second determining factor on CO_2 emissions in the first decade. The share of the energy intensity is calculated as 31.3 % in overall CO_2 emissions. However, the energy intensity followed a negative trend in the years 1991, 1996, 1998, and 2000. In the second decade the contribution of the energy intensity in CO_2 emissions started to decrease. The share of energy intensity is calculated as 17.1 % in CO_2 emissions between 2000 and 2010. In addition, the energy intensity followed a negative trend in the years 2002, 2003, 2006, 2007, and 2010. The decomposition analysis results indicate that Iran achieved a success in reducing the energy intensity especially in the second decade, however, this success cannot be considered as remarkable since the cumulative contribution of the effect is still positive on CO_2 emissions. The energy intensity effect offsets the accelerating impact of other components when its cumulative impact on CO_2emissions turns to negative. *Figure 3* shows the contribution of the energy intensity effect in CO_2 emissions.

Population Effect

The population effect describes the changes in CO_2 emissions due to the increases or decreases that are observed in the population. Iran's population accelerated to 74.4 million from 56.3 million in 20 years, which corresponds to a 32.1 % increase (World Bank, 2015). As a result of its remarkable growth, population increased CO_2 emissions constantly in the entire research period. Between 1990 and 2000, population

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18331846

is the third major determining factor of CO_2 emissions and its share is calculated as 26.9 %. However, during the second decade, the population effect became the second major determining factor on CO_2 emissions and its share has increased to 28.3 %. Since the population of Iran is increasing, then accelerating CO_2 emissions due to the population effect is an expected and a consistent result. *Figure 4* indicates the impact of population effect in Iran's carbon emissions from 1990 to 2010.

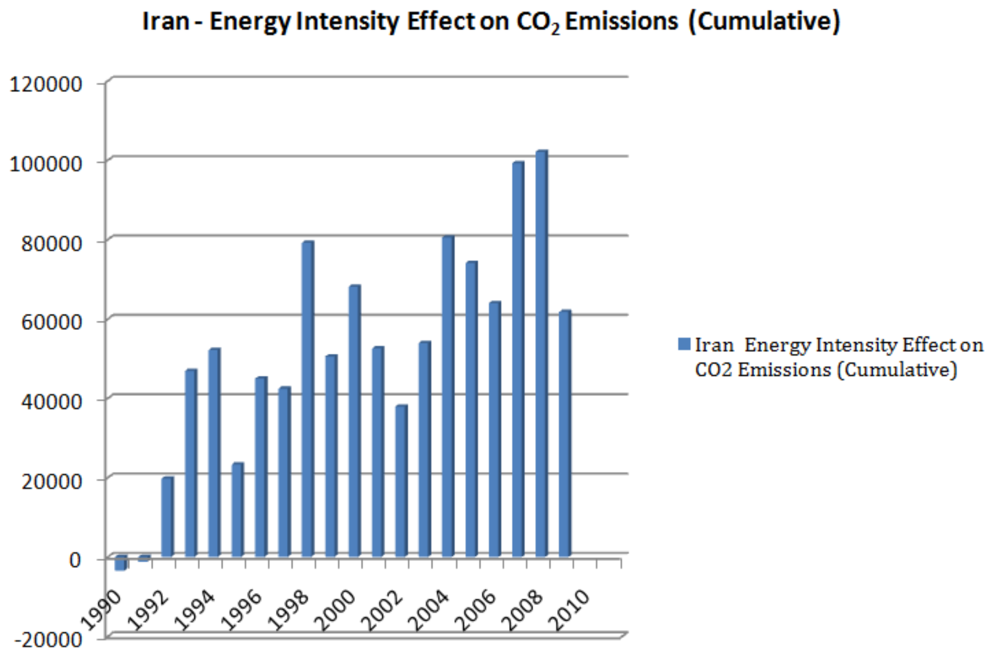

Figure 3. *Contribution of the energy intensity on CO_2 emissions in Iran over 1990–2010*

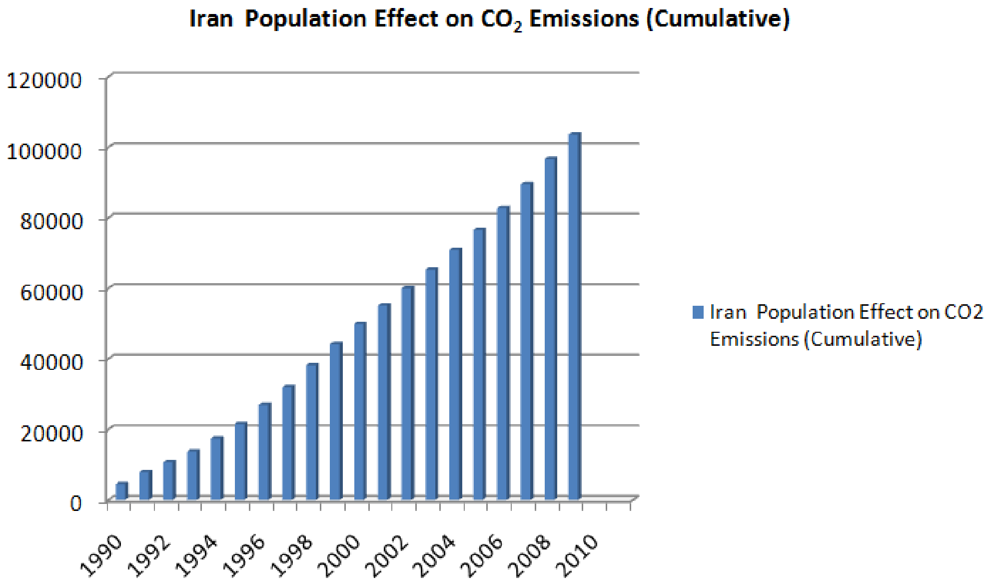

Figure 4. *Contribution of population on CO_2 emissions in Iran over 1990–2010*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18331846

Carbon Intensity Effect

The carbon intensity effect has been used to estimate the impact of fuel substitution in CO_2 emissions. If the energy mix becomes less carbon intensive or renewable sources are implemented instead of nonrenewable sources, then emission reduction can be obtained (Kumbaroğlu, 2011). The share of the carbon intensity in overall CO_2 emissions was 7.2 % during the first decade. Additionally, in the years 1991, 1992, 1993, 1995, 1997, and 2000 the carbon intensity followed a decreasing trend. Furthermore, between 2000 and 2010, the overall contribution of the carbon intensity on CO_2 emissions turned to negative. The share of the carbon intensity is estimated at -11 %, which is a desirable result for a reduction of the emissions. In the second decade, the carbon intensity decreased during the years 2001, 2002, 2004, 2005, 2008, and 2009. This remarkable decline is probably the result of a decreasing share of oil and increasing share of natural gas in overall energy consumption. For instance, in electricity production, the share of oil declined from 37.1 % to 19.8 % and the share of natural gas increased from 52.5 % to 75.9 % for the entire period (World Bank, 2015). The pollution coefficient of natural gas is relatively smaller than the pollution coefficient of oil. The carbon intensity is the only factor that offsets a small amount of the negative contributions of the income effect, the energy intensity effect, and the population effect for Iran's CO_2 emissions. *Figure 5* indicates the declining trend of carbon intensity in CO_2 emissions.

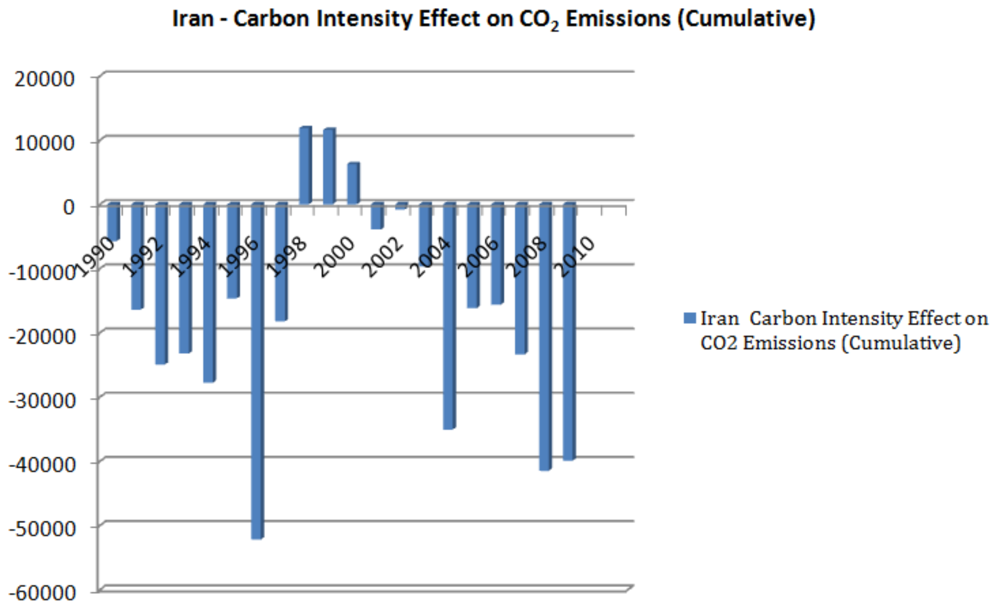

***Figure 5.** Contribution of carbon intensity on CO_2 emissions in Iran over 1990–2010*

Conclusion

In this paper, a decomposition analysis is used to identify the factors that influence the changes in Iran's CO_2 emissions for the period 1990 – 2010. The factors that lead to changes in CO_2 emissions are economic activity, energy intensity, population, and carbon intensity. A particular decomposition technique – the Refined Laspeyres Index method – is used to evaluate the relative contribution of these components that account for changes in CO_2 emissions.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18331846

Our empirical results have shown that in Iran economic activity was the most important component of CO_2 emissions change during 1990–2010. Energy intensity also increases CO_2 emissions; however, its contribution in the second decade was relatively smaller than in the first decade. Population is also a dominant factor on Iran's CO_2 emissions changes; it constantly increased the amount of CO_2 emissions during the study period. Especially in the second decade the contribution of population on CO_2 emissions became more visible. The carbon intensity made minor increasing contributions to CO_2 emissions between 1990 and 2000. However, in the second decade its impact on CO_2 emissions turned to negative, which is a desirable result for emissions reduction. The decrease in the carbon intensity is probably an outcome of the fuel switching. In Iran, during the period 1990–2010 the share of natural gas consumption gradually increased while the share of oil gradually decreased. Since the pollution coefficient of natural gas is relatively smaller than the coefficient of oil, then this led to a reduction in emissions due to the carbon intensity.

Regarding decomposition analysis, Iran is not a widely studied country. Therefore, in this respect, our study contributes to the literature by analyzing Iran. In the future, GDP and population of the country are expected to increase and, therefore, economic activity and population will raise the CO_2 emissions. However, the emission reduction goal can be accomplished by reducing the contributions of energy intensity and carbon intensity. This study creates an opportunity for policy makers to develop economically and environmentally sustainable projects.

Given that Iran is indeed an upper-middle income country which is dependent on oil revenues, volatility in oil prices would create a distortionary and direct impact on the economy. Our policy suggestions include a massive diversifications of the economy to other equally productive sectors; particularly agriculture and industry. Also a very robust and consistent policy framework should be directed towards energy conservation principles in every economic sector. This can be achieved through a high-tech mechanization including the use of fuel efficient equipments in the agricultural sector, use of heat insulators and double layer glasses, and sealing doors and windows in homes and the provision of small loans to households will encourage them to purchase a more energy efficient appliances. In the transportation sector policies should equally be directed not only towards a reduction in gasoline subsidies to bring down CO_2 emissions; but also setting appropriate policies that adheres to energy efficient manufacturing standard vehicles.

Finally since Iran has a remarkable high solar, wind and hydro energy potential due to its geographic location, a policy that is directed towards energy principles will lead to a richer Iran in the near future.

This study made a decomposition analysis to identify the factors that contributed the most to CO_2 emissions in Iran. A further research would be to employ an econometric analysis as of Halicioglu (2009) to include the effect of foreign trade in the determining factors.

Abstract. Metrodesis, a deltamethrin containing commercial formulation has been extensively used in Turkey, in the framework of integral pest management thanks to its target-specific toxicity. So as to assess the potential impacts of Metrodesis (EC; active ingredient 25 g/L of deltamethrin) on thyroid hormone (TH) homeostasis of rainbow trout (*Oncorhynchus mykiss*); mRNA levels of thyroid hormone receptors (*TR*s), *TRα* and *TRβ*, were determined by RT-PCR soon after sublethal administration in a static bio-assay system. The sublethal dose of 4.15 µg/L (¼ of LC_{50} value) led to induction of relative expression levels of *TRα* and *TRβ* genes both in muscle and liver tissues, provided that *TRα* expression quantities were considerably higher than *TRβ*, although the differences were found statistically insignificant (P>0.05). Results of this study revealed an endocrine interaction between deltamethrin-based formulation and TH homeostasis corroborating previous researches that approved deltamethrin as an endocrine disrupting compound.
Keywords: *fish, bioassay, synthetic pyrethroid, gene expression, mRNA*

Introduction

A great deal of chemical substances dumped to the aquatic environment disrupt endocrine homeostasis in organisms by interfering with developmental processes and endocrine systems (Mortensen et al., 2006). Endocrine disrupting chemicals (EDCs) are endocrine active compounds causing specific effects on endocrine systems at several levels without relevant toxic actions (Kloas, 2002; Kloas and Lutz, 2006). In respect to the European Union (EU) list of potential EDCs, pyrethroids are candidate substances as compiled in category 1 (Danish EPA, 2016).Pyrethroids are synthetic analogs of pyrethrins, which are toxic components contained in the flowers of *Chrysanthemum cinerariaefolium* (De Assis et al., 2009). Deltamethrin [(S)-α-cyano-3-phenoxybenzyl, (1R)-cis-3-(2,2-)-2,2 dimethycyclopropane carboxylate], the active ingredient of the commercial formulation Metrodesis, is a non-composite synthetic pyrethroid, which is used in control of ectoparasites for animals, as an insecticide in agricultural production and to manufacture long-lasting insecticidal mosquito nets for controlling malaria vectors (Siwicki et al., 2010; Sayeed et al., 2003).

Considering its high efficiency of counteracting the insects, as well as non-cumulative characteristic, selective toxicity and rapid photodegradation (Benli et al., 2009), as in other pyrethroids, it has wide acceptability (Erdoğan et al., 2011; Haverinen and Vornanen, 2014; Haverinen and Vornanen, 2016). It is commercially available as

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18471857

emulsifiable concentrate for water emulsion and extensively used in Turkey for pest management. In fish, an ectothermic vertebrate, deltamethrin emanated extremely high toxicity (Haya, 1989; Bradbury and Coats, 1989; Viran et al., 2003; Mikata et al., 2011; Srivastav et al., 2010). This is comparatively associated with lower metabolic rate of fish and ineffective metabolic degradation of this neurotoxic agent by fish tissues (Haverinen and Vornanen, 2014; Haverinen and Vornanen, 2016) due to the lack of carboxylesterases (Haya, 1989) that catalyze hydrolysis of pyrethroids in the liver (Srivastav et al., 1997). Furthermore, the lipophilic structure of deltamethrin entails the high rate of gill absorption which is an another remarkable factor to elucidating the high sensivity of fish to toxicity (Viran et al., 2003; Mikata et al., 2011; Srivastav et al., 2010).Some critical toxic effects of deltamethrin on fish can be varied with respect to species, age of the fish and duration of the exposure and elaborated as cardiotoxicity (Haverinen and Vornanen, 2014), disturbance of the calcium and phosphate homeostasis (Srivastav et al., 1997), changes in liver, gill and gut histopathology (Cengiz and Unlu, 2006), inducing hyperglycemia (Aziz et al., 2009) and significant alterations in blood chemistry and kidney function (Aziz et al., 2009; Kumar et al., 1999). It is also noteworthy that, deltamethrin acts as a oxidative stressor and causes inhibition of activity in various proteins including antioxidant enzymes (Erdoğan et al., 2011) and inducing the expression of *HSP70* (Ceyhun et al., 2010b), *CYP 1A*, *MT-A, MT-B* (Erdoğan et al., 2011) and reducing *IGF*s and *GH* in rainbow trout (Aksakal et al., 2010). Although some studies has been done on the impacts of deltamethrin-based formulations (Decis) on avians and fish (Marques et al., 2014; Bhaskar et al., 2016), nevertheless, there are limited researches related to the endocrine disrupting potential of this chemical on fish (Brander et al., 2016; Tu et al., 2016) when we consider the extensive use of this commercial formulations for the pest management.

The thyroid hormones (THs; T_4, T_3) regulate a wide range of cellular functions, including growth, development, differentation, metabolism and maintenance of homeostasis, in almost every tissue of teleost (Brent, 1996; Marchand et al., 2001; Filby and Tyler, 2007). Regulation of gene expression by TH is mediated by nuclear thyroid hormone receptors (*TR*s) (Wu and Koenig, 2000) which has two forms (*TRα* and *TRβ*) encoded by distinct genes (Filby and Tyler, 2007). As presented in Kloas and Lutz (2006), thyroid system of fish is affected direct or indirectly via accumulation via exposure or the food chain by endocrine disrupters and a detailed understanding of hypothalamus-pituarity-thyroid (HPT) axis regulation in teleosts is necessary to whole evaluation of thyroid-disrupting impacts of environmental compounds.

Therefore, the present paper aims to reveal the endocrine disruption potential of commercially available insecticide of deltamethrin (Metrodesis) in a well-known teleost, *Oncorhynchus mykiss*, centering upon the TH mechanism regarding to *TR*s as a response to sublethal exposure.

Materials and Methods

Insecticide

The commercial formulation tested, Metrodesis, is manufactured by Özbaşkent Kimya, Ankara, Turkey. It is an emulsifiable concentrate formulation containing 25 g deltamethrin/L in light aromatic solvent naptha (petroleum>25%).

Experimental design

Rainbow trout (*Oncorhynchus mykiss*) (mixed sex) with a mean body weight of 83.36±7.73 g (Mean±S.D., *n*=252) were obtained from Cifteler Sakaryabasi Aquaculture and Research Station of Ankara University in Eskişehir, Turkey where the experiments were conducted. Prior to experiments for acclimatization, fish were kept in 200 L tank, aerated consistently, for two weeks and fed daily with commercial trout feed (45% crude protein) ad libitum. Fish were deprived of feed for 48 h before and during the experiment. To eliminate the fish faeces and excess feed, the water in the tanks were changed (10%) by siphoning and replaced with fresh water in the acclimatization period. All tanks were shielded with netting material to prevent fish from escape and minimize stress during the trials. The maintenance of the animals and the experiments were performed under approved protocols in accordance with the principles of Ankara University Animal Ethics Committee (Date/No: 16.02.2011/2011-105-384). In exposure system, providing triplicates per each concentration (fish per tank; preliminary, main and control: 4 / sublethal and control: 10), dosing solutions of deltamethrin were prepared from Metrodesis and the calculation of dosing solutions was done according to the active ingredient of insecticide. The dosing volumes never exceeded 0.2 ml.

Water analysis

The water quality was evaluated (APHA, 1995) and the measurements of physicochemical parameters of water during the preliminary (range finding), main (LC_{50}) and sublethal toxicity tests were presented in *Table 1*.

Table 1. *The physicochemical parameters of water during the preliminary (P), main (M) and sublethal (S) toxicity tests (Mean values±S.D.) (n=3).*

Acute toxicity (LC_{50} –Median lethal concentration)

Acute toxicity tests were carried out in compliance with the standardized methods (OECD, 1992) at two stages in unrenewable static experimental conditions for 96 h with a total number of 192 fish. In stage I, a range finding (preliminary) test was performed

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18471857

to determine the concentrations of the main acute test by using wide ranges (Schäperclaus, 1979) as follows, 0.5, 1, 5, 10, 50, 100, 200, 300 µg/L of dosing concentrations. In stage II, with regard to the preliminary test results, six concentrations (4, 8, 10, 16, 32 and 50 µg/L) that comprised 0% and 100% death were chosen as the main acute toxicity concentrations. Meanwhile, control groups (non-exposure) were maintained for both preliminary and main exposure tests in triplicates.In the course of exposure tests, dead individuals were removed immediately from the tanks and behavioral changes and mortalities were monitored closely and noted down every 24 h. The Probit regression, a dose-response, analysis was used to compute the median lethal concentration (LC_{50}) of deltamethrin, with confidence limit of 95%, for 96 h exposure (Unsal, 1996).

Sublethal toxicity

For the assessment of sublethal effects of Metrodesis (25 g deltamethrin/L), ¼ of 96 h LC_{50} value as computed in acute toxicity test, was considered and exposed as a sublethal concentration. The sublethal exposure tests were conducted in triplicates for both treatment and control groups with total number of 60 fish in static system likewise in acute toxicity tests.

Sampling of fish tissues

At the end of the sublethal exposure of deltamethrin, the tissue samples (liver and white muscle) of rainbow trout were collected from all individiuals of both exposure and control groups. The dissection of liver and muscle tissues was performed on crushed ice and the samples were flash-frozen in liquid nitrogen and preserved at -80°C for further procedures.

RNA isolation and reverse transcription into cDNA

Total RNA was isolated from the frozen tissues using High Pure RNA Tissue Kit (Roche Diagnostics) according to the manufacturer's instructions. The purity of isolated RNA was quantified by spectrophotometric absorbance (A_{260}/A_{280} ratio) using a Nanodrop ND-1000 spectrophotometer (Thermo Fisher Scientific, Schwerte, Germany) and the integrity of RNA samples was verified by agarose gel electrophoresis on agarose gel that comprised ethidium bromide (EB).The complementary DNA (cDNA) was synthesized by reverse transcribing from total RNA using the transcriptor first strand cDNA Synthesis Kit (Roche Diagnostics) following the protocol of the manufacturer. Random hexamer primer was chosen in reverse transcribing of cDNA due to the use of *18S* rRNA as a housekeeping gene. The cDNAs were stored at -20°C until used for real-time PCR (RT-PCR).Gene-specific primer pairs and probes were provided from Universal ProbeLibrary (UPL) system (Roche Diagnostics) which constituted a web-based software (ProbeFinder software). UPL probes are hydrolysis probes substituted with Locked Nucleic Acids (LNA) and they are labeled at the 5′ end with FAM (Fluorescein amidite) and at the 3′ end with a dark quencher dye. The sequences of primer pairs and probes were presented in *Table 2*.

*UPL; Universal ProbeLibrary Probe

RT-PCR procedure

The amplification was performed with a LightCycler 480 RT-PCR system (Roche, Switzerland) using LightCycler 480 Probes Master Kit (Roche Diagnostics). The thermal cycling conditions consisted of an initial pre-incubation for 10 min at 95°C, followed by 45 cycles of denaturation of the target DNA at 95°C for amplification of the target DNA with for 10 s, primer annealing at 60°C for 30 s, extension at 72°C for 1 s and 1 cycle of cooling for 30 s at 40°C.A standart curve was constituted for target and housekeeping gene seperately and efficiency of each reaction (1.8-2.0) was determined. PCR samples were run in duplicates for standarts, samples and negative controls. Negative control samples (nuclease-free water instead of cDNA) were used in each run to test the target specifity of the cDNA amplification.

Data normalization

The housekeeping gene *18S* was used as an endogenous standart and expressions of target genes of *TRα* and *TRβ* were normalized to the corresponding level of *18S* mRNA relatively to the untreated control by using comparative Ct ($2^{-\Delta\Delta C_T}$) method (Livak and Schmittgen, 2001).

Statistics

All data were expressed here as means±standart error of the mean (SEM) unless indicated otherwise. A total of ten fish were used from exposure and control groups and two technical replicates per fish and treatment were made. Paired Samples T-test, a confidence level of 95%, was applied using statistical software IBM SPSS Statistics 23.0 to determine the presence of significant differences among the groups.

Results

Median lethal concentration (LC_{50})

The calculated 96-h acute LC_{50} value of Metrodesis (25 g deltamethrin/L) in a static bioassay system for rainbow trout was 16.582 µg/L (χ^2=0.500) with 95% confidence limits of 13.525-22.156 using Probit regression analysis. The sublethal concentration was 4.15 µg/L and determined as ¼ of 96-h LC_{50} value. The behavioral responses of the individuals during the acute exposure were observed and recorded every 24-h. In the highest concentration (50 µg/L), within an hour, test fish were demonstrated reactions including movements as trembling and fasciculation, poising at upright, tendency to swim to the water surface and gulping for air. At all concentrations, excessive mucus secretion was detected and below 50 µg/L, fish were quite motionless and mostly gathered at the edge of the tanks with high respiration frequency. Control test groups were comparatively calm and no significant behavioral changes were monitored.

Expression of TRs in white muscle and liver

The relative expression levels of *TRα* and *TRβ* genes in white muscle and liver tissue of rainbow trout after exposed to sublethal treatment of deltamethrin (4.15 µg/L) were presented in *Table 3*. Sublethal exposure of deltamethrin did not emerge a statistical difference (P>0.05) in expression of *TRα* gene between white muscle and liver tissue, however a slight but insignificant up-regulation was observed in liver tissue compare to white muscle. Similarly, no significant mRNA alteration (P>0.05) was detected for *TRβ* of white muscle and liver tissue with respect to the toxic treatment. Unlikely from *TRα* expression pattern, the white muscle tissue was slightly up-regulated for *TRβ* gene, though the difference was nominal. However, when we compare the results in a gene-specific manner, for *TRα* gene, an apparent increase of mRNA in the white muscle, which was about 5 fold, was recorded compare to liver tissue, whereas the liver tissue was 6 fold higher than white muscle. In general, the relative expression quantity of *TRα* gene was found considerably high in comparison to *TRβ* for both white muscle and liver tissue due to the 96-h sublethal exposure of deltamethrin. Nonetheless, no statistical differences were noted (P>0.05) according to Paired samples T-Test, although a remarkable effect was observed corresponding to deltamethrin treatment

Table 3.*mRNA expression levels of TRα and TRβ genes in white muscle and liver tissue of rainbow trout that are expressed relative to control values and normalized to 18S with their respective standard errors in response to 4.15µg/L of deltamethrin.*

Gene	**Fish Tissue**	
	White muscle	**Liver**
TRα	3.036±1.57$^{N.S.*}$	3.129±1.63
TRβ	0.679±0.16	0.578±0.19

*N.S. (Non-significant); Means (Means±S.E.M) (n=5) in the same row and column were found in-significant according to Paired Samples T-test (P>0.05).

Discussion

Deltamethrin, a synthetic pyrethyroid, is well-known with its rapid knock down action in insects, low persistence in the environment and low mammalian toxicity (Erdoğan et al., 2011). Despite these aspects and wide spread on a global scale, it has become the most controversial environmental compound due to the potential of high toxicity to aquatic organisms notably to fish. Here, the 96 h acute LC_{50} value of commercial formulation of deltamethrin, Metrodesis, in rainbow trout was found 16.582 µg/L. In quite a few research have been reported the LC_{50} of deltamethrin in a variety of fish and their findings, which are consistent with the present study result, revealed the potential of high toxicity of this substance to fish. Ural and Sağlam (2005) stated that incremental concentrations of deltamethrin exposure, duration of 96 h, led to increase the number of death fry fish in rainbow trout, that the estimated LC_{50} value was 0.6961 µg/L. Similar observations were notified for common carp by Koprucu and Aydın (2004) after 48 h exposure and the LC_{50}values were 0.213 and 0.074 µg/L for embryos and larvae, respectively. The toxicity takes effect in a time, dose, specie and the size manner as so in young mirror carp that the LC_{50} values were found 9.41, 4.47, 2.37 and 1.65 µg/L in the time of 24, 48, 72 and 96 h of exposure in a static bioassay system (Calta and Ural, 2004). In the same work, the toxicity studies for deltamethrin compiled in a table for *Poecilia reticulata* (5.13 µg/L for 48 h), *Clarias gariepinu*s (40.01 µg/L for 96 h), *Esox lucius* (23.0 µg/L for 96 h) and *Ctenopharyngodon idella* (91.0 µg/L for 96 h). The other LC_{50} studies in *Oreochromis niloticus* as reported by Golow and Godzi (1994) and Boateng et al. (2006) resulted with values of 14.5 and 15.47 µg/L, these results were comparable with the present data even in the case of different species. The exposure with deltamethrin revealed behavioral changes in the treatment groups, in congruent of the present study, Ural and Saglam (2005) also monitored some responses in *O. mykiss* as loss of equilibrium, hanging vertically, erratic swimming, air gulping from the water surface, staying motionless and color darkening in the concentrations of 1, 2, 4, 6, 8, 10, 12, 25 and 50 µg/L, and no changes in the control group. Similar changes were detected in *P.reticulata*(Viran et al., 2003),*Cyprinus carpio*(Koprucu and Aydın, 2004) and *O. niloticus*(Golow and Godzi, 1994).

The previous reports of deltamethrin toxification posed the critical influences on fish physiology. The hypocalcemia, observed in *Heteropneustes fossilis*, a freshwater catfish, after the exposure of deltamethrin for 96 h with a LC_{50} value of 1.86 µg/L, could be the response of impairment of electrolyte influx at the gill (Srivastav et al., 1997). In the long-term exposure of deltamethrin (0.37 µg/L for 28 days), prolactin cells of *H. fossilis* exhibited hyperactivity which is inferred by degranulation and accreted nuclear volume to cope with the hypocalcemia (Srivastav et al., 2010). Further, Srivastav et al. (1997) also stated that the exposure elicited hypophosphatemia due to the redistribution of electrolytes between the intracellular or the extracellular compartments of renal function. In furtherance, it has been represented that the erythropoiesis have been accelerated to avoid from anaemic state tending to increase the production of erythrocytes in a research by Kumar et al. (1999), they pointed to the alterations in morphological and functional structure of renal tubules and liver cells, which the LC_{50} value is recorded as 0.52 µg/L for the same specie, *H. fossilis*, as indicated above. Excess of melano macrophage centers, congestion, odema and lymphocytic infiltrations were observed for liver tissue, whereas hemorrhages in several sites of kidney associated with renal tubule damage in *Clarias lazera* were noticed after acute exposure of 0.5 µg/L for one week (Aziz et al., 2009). Moreover, gill activity and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18471857

heart NA^+ K^+-ATPase were inhibited by deltamethrin exposure whereas the liver total CYP450 and EROD activity were induced in *Ancistrus multispinis* as reported by De Assis et al. (2009). Besides its neurotoxic characteristic, Haverinen and Vornanen (2014; 2016) asserted that deltamethrin is also cardiotoxic to fish and this response could be interpreted with the high affinity of fish Na^+ channels to deltamethrin as in other pyrethroids.The immunosuppressive and oxidative stress inducing potencial of deltamethrin were evidenced in various researches including different fish species and should not be underestimated. The dose of 2 and 4 μg/L of deltamethrin conduced cell-mediated and humoral-mediated immunosupression in rainbow trout which left the fish vulnerable to viral and bacterial disease (Siwicki et al., 2010). Due to the primary sites of deltamethrin absorption, gills are the most susceptible tissues to exposure and it is not puzzling that the reducing levels of oxidative stress indicators in terms of catalase, GST and GPx were obtained from the gills of *Channa punctatus* after 0.75 μg/L of deltamethrin treatment (Sayeed et al., 2003) and this coincided to a series of researches in rainbow trout as performed by Ceyhun et al. (2010a,b).

THs participates in several metabolic functions in terms of development, growth and metamorphosis in fish (Nelson and Habibi, 2009) and presented their activity by binding to *TR*s (genomic pathway) or through a rapid non-genomic signaling pathway (Manchado et al., 2009), nonetheless the action mechanism for fish is not fully understood.*TR*s are members of a large superfamily of nuclear receptors (NR), along with steroid hormones, retinoids and vitamin D (Mortensen et al., 2006). *TR*s have a core role in the genomic regulation of THs (Power et al., 2001), particularly they appear in the early development and metamorphosis in fish (Manchado et al., 2009; Filby et al., 2006) and serve different functions and demonstrate tissue-specific and developmental state-specific expression (Chen et al., 2002; Tu et al., 2016). EDCs, which deltamethrin is regarded as acting a member of this extensive compound group (Mnif et al., 2011)induce to changes, particularly inhibitory ones, in formation and synthesis of THs, affect their bioavailability by binding deiodinases which is responsible for activation or inactivation of THs in peripheral tissues (Kloas and Lutz, 2006). In the present study, *TRα* was up-regulated in comparison to *TRβ* for both liver and white muscle tissue after sublethal exposure of deltamethrin-based formulation, despite the differences were found statistically insignificant. The increased mRNA levels of *TRα* was totally associated with *TR*s subtypes (*TRα* and *TRβ*) as mentioned by Filby et al. (2006). Tu et al. (2016)reported that bifenthrin and λ-cyhalothrin, two synthetic pyrethroid, exposure conduced to remarkably higher mRNA levels of *TRα*gene in zebrafish which is consistent with this study results. Considering these results, exposure of pyrethroids comparatively can be responsible for the disruption of motor activity associated with the alterations of TH levels (Brander et al., 2016) and concurrent increase in calcium values (Kaul et al., 1996).

Conclusion

Overall results of this study, suggest that sublethal exposure of deltamethrin-based insecticide Metrodesis, led to alteration in expression of *TR*s subtypes, specifically *TRα*, independent from tissue-manner, emanating wider potential impacts on the physiological function of fish. Considering the extensive use of this chemical and its high toxicity to aquatic organisms, the specification of risk assessment, particulary endpoints and molecular mechanisms regarding toxicity is a dictate of environmental

DOI: http://dx.doi.org/10.15666/aeer/1504_18471857

sustainability. Further studies are needed to understand the dose-response relationship between deltamethrin and deltamethrin based formulations and endocrine disruption centering upon non-target organisms as fish.

Abstract. The aim of the study is to be able to create a solid catalyst that would be sourced from cheap materials, inexpensive to produce, and can comparatively produce high FAME yields in transesterification reactions involving microalgae as lipid source. The impregnation method was used to synthesize the catalysts Li-pumice, K-pumice, and Na-pumice. The synthesis parameters were varied at different solution concentrations to determine which created the best performing catalyst in the transesterification process. Catalyst characterization was evaluated using Hammett indicators, Scanning Electron Microscopy (SEM), Energy-dispersive X-ray Spectroscopy (EDS), and Infrared Spectroscopy (IR). The catalyst was easily separated by filtration and further investigation proved that it can be reused multiple times in transesterification processes. The best performing catalyst was observed to be K-pumice and the optimum concentration of the contact solution in the synthesis was 1.0 N. The transesterification reaction was able to generate an optimum of 77% Fatty Acid Methyl Ester (FAME) yield when process parameters were: reaction temperature = 60 ºC; methanol to oil ratio = 18:1; catalyst load = 10%; and reaction time = 2 hours. The results were able to prove that effective catalyst for biodiesel production can be sourced from cheap materials such as pumice and that the preparation of such can be done in a fast and cost effective manner. It is encouraged that more cheap materials should be investigated for catalyst synthesis that would become ideal for biodiesel production.
Keywords: *bioenergy, pumice, synthesis, transesterification, yield*

Introduction

The spike in the demand of fuel globally and the realization that fossil fuels will be depleted in the near future had caused scientists and opportunists to look for an alternative. For years, researchers have gone back investigating biofuels as the alternative in the exhaustion of fossil fuels (Meher et al., 2006). Not only can biofuels replace the impending loss of fossil fuels, it also has environmental benefits such as a lesser greenhouse gas emissions when compared to fossil fuels. The cultivation of plants as a result of biofuel production also sequestrates carbon dioxide in the atmosphere (Slade and Bauen, 2013).

Biodiesel, a biofuel, is produced by transesterification process were oil is mixed with alcohol in the presence of a catalyst. The oil could be from canola, peanut, corn, animal fat, rapeseed, palm, soybean and waste cooking oil (Singh et al., 2014). Other raw materials that gained importance as potential feedstock for biodiesel production are karanja, rubber plant, tobacco, jatropha, mahua, rice bran, animal fats and more

recently, microalgae (Borugadda and Goud, 2012). Microalgae is currently considered to be the most feasible alternative since it has a higher photosynthetic yield (3-8%) compared to other plants (less than 1%) that makes them grow faster (1-3 doublings per day) (Slade and Bauen, 2013) (Alam et al., 2012), sequestrate carbon dioxide much better, and accumulate lipid yield of up to 50% (Spolaore et al., 2006). Moreover, microalgae can grow in arid lands, swamps, and saline or fresh water which makes them a non-competitor in land utilization against others crops whether for fuel or food production (Alam et al., 2012). Also, microalgae are a tough species that makes them tolerant severe environmental conditions where losses due to calamities such as floods and storms are negligible when compared to other terrestrial plants (Najafi et al., 2011).

The downside of biodiesel production from microalgae are the cost associated with microalgae cultivation, lipid extraction and oil purification (Raslavičius et al., 2014). To minimize costs associated with algal biodiesel production, certain processes and catalyst were evaluated. The usual catalyst for biodiesel production are homogenous alkali catalyst like NaOH or KOH (Lam et al., 2010). However, there is cost associated with its separation from the final product and full recovery are always a challenge. A few studies have recommended the use of synthesized catalyst but they are either expensive or underperforming (Sharma et al., 2011; Díaz and Borges, 2012). Synthesized catalysts had been made by using metal oxides such as calcium oxide and magnesium oxide (Zabeti et al., 2009), metal complexes (Tariq et al., 2012), and metal hydroxides (Wang et al., 2013). The ease of separation and more cost efficient downstream processes were highlighted in these studies. However, the formation of the three phase system proved to be a huge factor in leading to low FAME yields (Zabeti et al., 2009). This study presents the synthesis of a catalyst that promises to be cheap, easier to prepare and can deliver biodiesel with acceptable methyl ester yields.

Materials and Methods

Materials

Pumice powder was purchased from Sigma Aldrich Chemical Corporation, USA. The microalgae was provided by the Food Protein Research and Development Center (FPRDC) of Texas A & M University (TAMU). The microalgae was in dried colletized form and are labelled to be 95% *Chlorella vulgaris* with 8-10% moisture. Other chemicals and reagents used in the oil extraction, transesterification and analysis of biodiesel were purchased from Sigma Aldrich Chemical Corporation, USA and VWR Chemical Corporation, USA.

Preparation of Catalyst

Pumice powder was used in this study as the support for the synthesis of metal-pumice catalyst. Pumice was initially dried in an oven at 120 ºC for 3 hours after which it was ion exchanged by impregnation method with an alkali solution for 24 hours. The alkali solution varied in terms of concentration and kind. There were three kinds of alkali aqueous solutions used in this study namely KOH, NaOH and LiOH. Concentrations of the solutions also varied from 0.5N to 4.0N. After ionic exchange, the pumice was recovered and dried again in an oven at 120 ºC for another 3 hours. The subsequent product was then kept in a tightly sealed jar ready for evaluation and transesterifcation processes.

Catalyst Characterization

Pumice and metal-loaded pumice (K-pumice, Li-pumice, and Na-pumice) were characterized using Hammett indicators, X-ray Diffraction (XRD), Scanning Electron Microscopy (SEM) and Infrared Spectroscopy (IR).

The Hammett Indicators measured base strength of the catalysts and its base total amount. The base strength is measured with pH of aqueous solution saturated with catalyst (20g / 50 ml). Base total amount was measured by titrating 0.1N Benzoic Acid in Benzene to the mixture of 1g catalyst sample in 20ml Benzene with 1 ml indicator solution (phenolphthalein in ethyl alcohol).

The SEM and EDS analysis was done with the JEOL JSM-7500F, an ultra-high resolution field emission scanning electron microscope (FE-SEM) equipped with a high brightness conical FE gun and a low aberration conical objective lens. The catalysts samples were loaded into the equipment in one batch. The samples were labelled each prior loading into the equipment. For each analysed sample, at least three areas for were chosen purposely with images taken thereafter ranging from 1 µm to 100 nm. The best image taken from each sample was presented in these paper. The EDS analysis were then done right after the images were taken. Sites in the surface of the samples that were evaluated by the EDS were also purposely chosen.

The IR measurements were performed with the Shimadzu IR Affinity-1 equipment. The KBr pellet technique was used in determining IR spectra of the samples at room temperature. The range was adjusted at 600-4500 cm^{-1}, with 300 scans and 4 cm^{-1} resolution.

Transesterification Reaction

The transesterification experimental runs started with the oil extraction from the milled microalgae. The extraction was done via Soxhlet facility whereby 500g of microalgae was loaded per batch and the extracting solvent was 250ml of n-hexane. The whole extracting procedure was done after about 20 passes which took 6 hours. After the distillate was cooled to room temperature, it was transferred to the rotary evaporator to separate the algal oil from n-hexane. The algal oil was then further purified using the methods described by Tyagi et al. (2012).

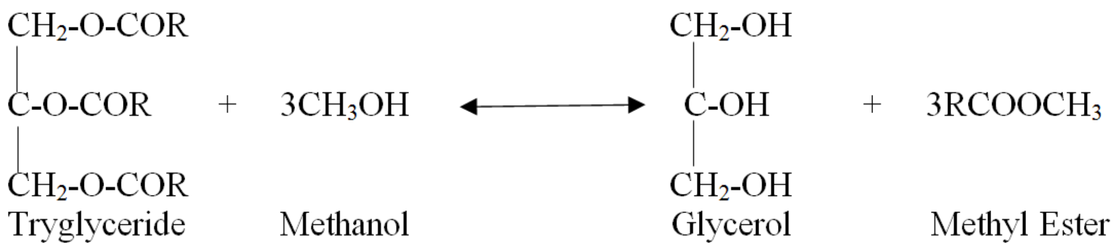

***Figure 1.** The transesterification reaction*

The transesterification reactions (as described in *Figure 1*) were carried out in a 125 ml three-neck glass flask equipped with a stirrer, a water cooling condenser and an electric jacket with thermocouple. Five grams of initially extracted and purified algal oil was placed into the flask and was heated in the range 40-60 ºC while stirring. After the oil has reached the desired temperature, methanol and the catalyst where carefully added to the system. The kind of catalyst (Li-pumice, K-pumice, Na-pumice), amount

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18591870

of methanol (methanol to oil ratio 6:1-22:1) and catalyst loading varied in each transesterification procedure (5-20% by weight of algal oil). The reaction time for each transesterification process was also varied from 30 minutes to four hours. After transesterification, the mixture was filtered to separate the catalyst from the liquid. The liquid mixture was then subjected to the rotary evaporator to remove methanol. It was then placed in a separatory funnel and laid to rest for six hours before removing the glycerine that settled at the bottom of the funnel. The remaining liquid, which is presumed to be mostly biodiesel, is washed with hot water (60-80 ºC) to dissolve and separate soap formed during the reaction. The water is removed using again the separatory funnel. The washed biodiesel was then weighed and a sample was collected and loaded to the Shimadzu GC-2010 with Zebron ZB-5MS column for qualitative analysis. Meanwhile, the separated catalyst from the transesterification reaction was washed with methanol, dried and calcined for 12 hours in a temperature of 300 ºC. It was again regenerated by ion exchanging in a 1.0 N alkali aqueous solution and placed in a 120 ºC for 3 hours. The regenerated catalyst was then left to cool in a desiccant where it was later transferred in a cool dry jar for storage.

Analysis

The fatty acid methyl ester (FAME) yield of biodiesel was calculated by its weight in the crude biodiesel in relation to the weight of oil extracted from the algal biomass. The composition of FAME contained in the washed biodiesel was analysed by GC-MS. The biodiesel samples collected were dissolved in dichloromethane in the ratio 1:4 and loaded into the GC trey. The carrier gas used was helium and the injection volume of the sample was set at 1.0 µl at an injection temperature of 180 ºC. The temperature program of the GC-MS was initially set at 50 ºC held for 5 min, increased to 250 ºC at 5 ºC /min, and held at 250 ºC for 10 min. The relative weight composition of the sample was determined using methyl stearate as the standard. Data gathered from all experiments were carefully recorded and were done in triplicate.

Results and Discussion

Catalyst Characterization

The results of Hammett Basicity Test (*Table 1*) suggested that considerable difference in base total amount can be observed in between catalyst that were impregnated in 0.5N solutions and 1.0N solutions. As concentration of contact solution increases, so is the base total amount but of negligible margins for solutions with concentrations more than 1.0 N. Base strength is almost unanimously the same for contact solutions 1.0N and above. K-pumice generally is more basic and has higher number of basic sites while Li-pumice has the least.

Table 1*. Base Strength and Base Total Amount of Synthesized Catalysts*

Catalyst	Contact Solution (N)	Base Strength	Base total amount (m mol /g)
Li- pumice	4.0	12.1	50
	2.0	12.1	47
	1.0	11.7	33
	0.5	11.3	2

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18591870

Na-pumice	4.0	12.4	56
	2.0	12.4	55
	1.0	12.2	47
	0.5	11.9	7
K-pumice	4.0	12.6	62
	2.0	12.6	60
	1.0	12.5	55
	0.5	12.1	12

The EDS values (*Table 2*) are relative weight percentages of the elements found in the surface of the catalysts evaluated. The catalysts presented in the table are Na-pumice and K-pumice contacted with a 1.0N solution. The Li-pumice was not included upon EDS evaluation since the equipment could not detect spectra of elements lighter than carbon which included lithium. It was also assumed that the same values will transpire for catalysts that were contacted with solutions greater than 1.0N since their base strength and base total amount are relatively similar to those catalysts contacted with 1.0N solution. In retrospect, the value of base total amount indicates the quantity of metal impregnated in the catalyst support (Galadima and Muraza, 2014).

Table 2. *Relative weight percent composition of pumice and metal impregnated pumice*

Element	Blank	Na	K
C	15	14.5	14.5
O	59	58	58
Si	4	4	4
Al	18	17.5	17.5
K	1.5	1.5	3.5
Na	1	3	1
Others	1.5	1.5	1.5
Total	100	100	100

As noted in *Table 2*, the blank pumice is predominantly composed of silicon, aluminum, carbon and oxygen being it a volcanic rock that is mostly silica and alumina. It initially has 1% sodium and 1.5% potassium. By impregnating it with a metal hydroxide solution, the relative weight percentage of the element is increased by 2%, thus the increase in the basic sites of the synthesized catalyst. On this presumption, the Li-pumice (with 1.0N or above contact solution) may likely also to have 2% lithium in its over-all weight composition. The elements that listed as others are magnesium, calcium, palladium, iron, nickel and nitrogen.

The FTIR readings (*Figure 2*) of the selected catalysts displayed there absorbance from 600 to 4000 cm^{-1}. The catalysts that were evaluated was limited to 6 since the objective is to demonstrate the difference in the infrared spectrum of absorbance in pure pumice, pumice impregnated with different metals, and pumice impregnated with different concentrations of alkali aqueous solution.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18591870

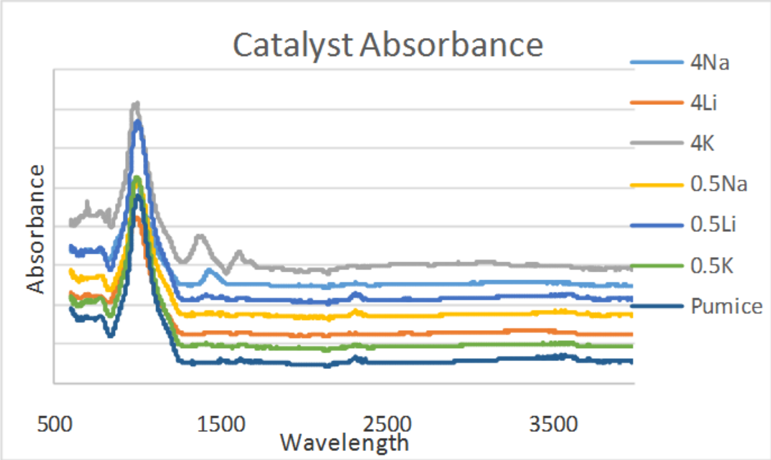

***Figure 2.** Catalyst absorbance of pumice and selected synthesized catalysts*

The peaks at 600 and 800 cm−1 in the FTIR spectrum of the pumice and metal loaded pumice may have resulted from the Si–O bending strength vibrations of the amorphous quartz which constituted the structure while the strong peak around 1000 cm^{-1} may have resulted from Si–O stretching vibrations (Selli and Forni, 1999). Pumice is predominantly composed of SiO_2 (70%) and Al_2O_3 (15%). The noticeable difference on the FTIR spectrum in the strongest reactive catalyst (K-pumice contacted with 1.0N KOH solution) and the weaker ones are the peaks detected between 1300 and 1600 cm^{-1}. According to E. Selli et al. (Selli and Forni, 1999), the peak can be attributed to the Metal–O bond structure vibration that was formed in the surface of the pumice during the activation of the catalyst. Such peaks may not have been present in pumice that had been contacted in lower concentration solutions since the metals (K, Li, Na) may have been embedded in the pores and not enough ions was able to have been adsorbed in the surface. The peaks are also noticeable but not as quite pronounced in the Na-loaded pumice (with 4.0N as contact solution). The peak that could be observed around 2400 cm^{-1} for all the catalyst sampled pointed out the -OH stretching vibrations of the water (moisture) which was adsorbed by the sample from the outside environment (Selli and Forni, 1999).

The SEM images (*Figure 3*) were taken out of the selected three kinds of catalyst and the blank pumice. All images were taken to almost the same resolution and magnification for efficient and proper comparison (see scale = 1μm). It can be noted that the pure pumice has mostly rough surfaces and orifices which are ideal for metal catalyst impregnation.

Shown also in an isolated case is a smooth surface with the absence of anything attached to it. For pumice impregnated with metals, the surfaces clearly has some particles that can be observed. The images though would be a bit imprecise to judge the differences on the appearance of the particles attached on the surfaces of pumice support with different metal impregnations. The images that were taken were just plainly made to observe what is in the surface of the impregnated pumice and to see how it is synchronized. Eminent in the images taken are the wavy-like material on the surface of K-pumice and the long and crystalline in shape (resembling fine broken glasses) in the surface of Na-pumice.

Transesterification Process

The process parameter that was firstly investigated was the concentration of the contact solution. With the other variables fixed at 20% catalyst load, 18:1 methanol oil ratio, reaction temperature at 60 ºC, and reaction time equal to 2 hours, it was observed that K-pumice and Na-pumice with contact solutions 1.0N to 4.0N gave the best FAME yields (see *Figure 4a*). K-pumice had peaked at 77% FAME yield when the concentration of contact solution is 1.0N and the same yield have been recovered when the concentration of contact solution had been increased up to 4.0N. Na-pumice also had about 75% FAME yield at the same process conditions and just slightly increased to 76% when contact solution is increased up to 4.0N. Li-pumice had about 5% lower FAME yield as compared to the other two catalysts ion exchanged in the same concentration of contact solution.

During shorter reaction times, it is observed that K-pumice had a better FAME yield than Na-pumice and that the FAME yield gap between K-pumice and Li-pumice becomes larger. This phenomena maybe attributed to the difference in solubility of the three metals in methyl alcohol, with potassium to be the most soluble and lithium to be the least (Gryglewicz, 2000). Nevertheless, it is observed that the optimum contact solution for all catalyst is 1.0N. It is thru this concentration where the possible highest FAME yield was achieved for K-pumice and the curves plotted in *Figure 4* for the other catalysts suggested it to be the most optimum.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18591870

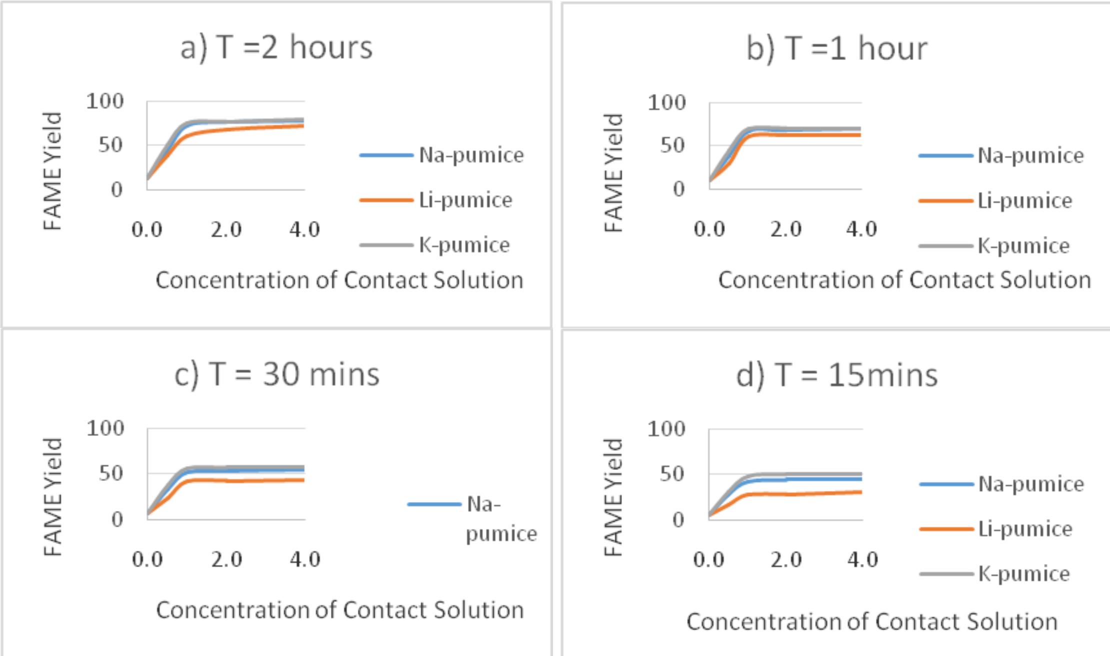

Figure 4. *Process performance in terms of FAME yield of catalysts impregnated with different concentrations of contact solution at different reaction temperatures.*

When the investigation was focused upon the optimum reaction time (*Figure 5*), the other process parameters were fixed at methanol to oil ratio at 18:1, reaction temperature equal to 60 ºC, catalyst load at 20% and the catalysts used were those contacted with 1.0N solution. Both Na-pumice and K-pumice achieved the optimum FAME yield (75-77%) after 2 hours of transesterification while Li-pumice still has an improved FAME yield after 4 hours. The best yield however that was acquired in the setup was that of K-pumice just after 2 hours of transesterification.

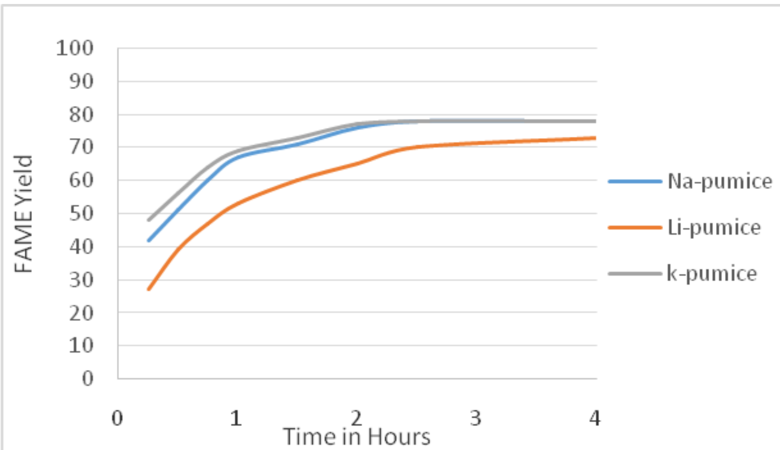

Figure 5. *Influence of reaction time on the FAME yield using different types of catalysts*

In the investigation of the optimum catalyst load (*Figure 6*), methanol to oil ratio (*Figure 7*), and reaction temperature (*Figure 8*), the catalysts used were limited to that

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18591870

contacted with 1.0N solution. The other synthesized catalysts were not used in these experiments since it was proven earlier that the optimum concentration of contact solution is 1.0N. Also, the reaction time in these investigations were set at 2 hours.

The optimum catalyst load that was observed during these transesterification reactions was 10% for all the kinds of catalyst (see *Figure 6*). As with the data presented earlier, it had been noted that Li-pumice performed the least while K-pumice slightly fared better than Na-pumice. The methanol to oil ratio and reaction temperatures on these catalyst load optimization were set at 18:1 and 60 ºC, respectively.

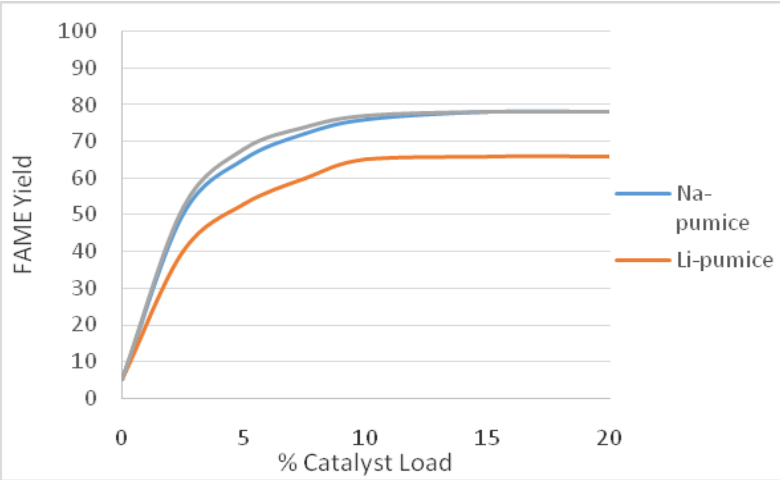

Figure 6. *Influence of catalyst loading on the FAME yield using different types of catalyst*

As far as the analysis on the methanol to oil ratio was concerned, the experiments showed that the optimum value is 18:1 (see *Figure 7*). Increasing the amount of methanol beyond that does not seem to increase the FAME yield of the reaction. Even though the optimum ratio in transesterification experiments is 6:1 when the catalyst is homogenous and alkali in nature, the same ratio using the catalyst being used in these experiments can only give a maximum of 35% FAME yield. It is most likely because of the three-phase system in the reaction that more alcohol should be introduced in order to hasten the reaction forward.

Finally, the investigation on the optimum reaction temperature only settled the long standing observation that the best reaction temperature of a transesterification process is the temperature just slightly below the boiling point of the reacting alcohol (Bharathiraja et al., 2014). Since methyl alcohol was used in these transesterification proceedings with a boiling point around 64.7ºC at atmospheric conditions, the optimum reaction temperature obtained in these experiments were 60ºC (see *Figure 8*). Having the reaction temperature above the boiling point of the alcohol can make it to evaporate, lessening the interaction of oil and alcohol for them to produce biodiesel.

The reuse of the synthesized catalyst in this study was also scrutinized. It is very important that the catalyst should be able to prove itself for reuse in order to justify its use economically. The experiments reused the catalyst that were earlier used in prior transesterification experiments. The investigation covered the reuse of the catalysts that were regenerated and those that were not. Regeneration is the term used in this study whereby the catalyst is being washed by methanol, dried, calcined and impregnated

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18591870

again in 1.0N contact solution (NaOH, KOH, or LiOH). Those that were not regenerated was just dried, calcined and used again on the next transesterification process. The process conditions in the reusability transesterification processes were the optimum as based on the earlier experiments.

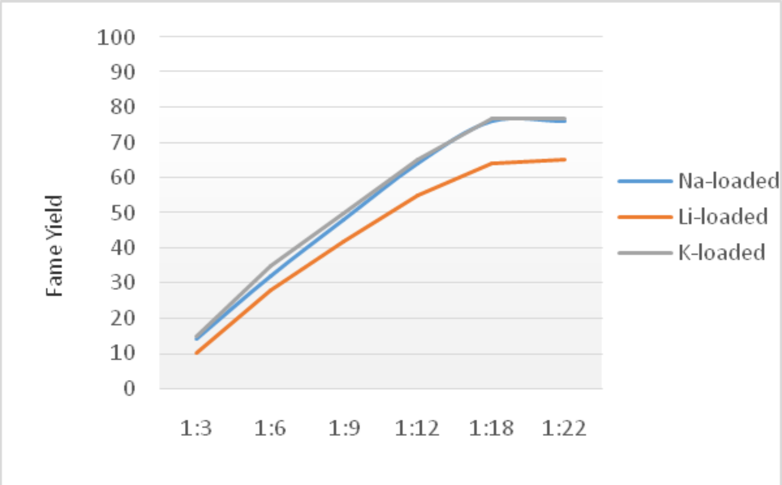

Figure 7. *Influence of methanol to oil ratio on the FAME yield using different types of catalysts*

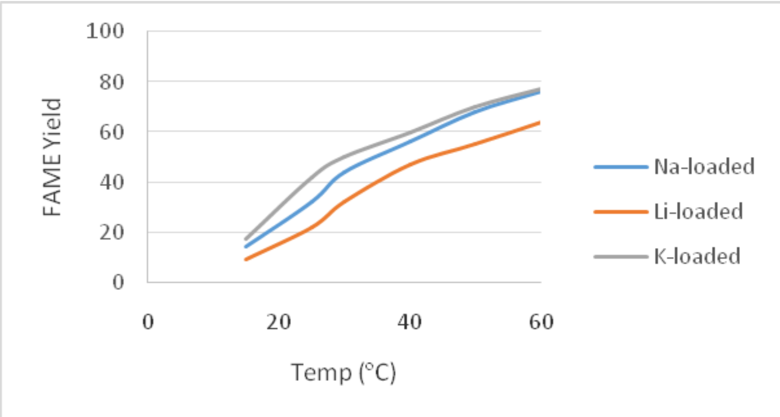

Figure 8. *Influence of reaction temperature on the FAME yield using different types of catalysts*

The reusability experiments discovered that without regeneration, the most effective number of reuse that the synthesized catalysts could do is just up to three uses (see *Figure 9a*). If it would be regenerated, the catalyst can be reused multiple times over without affecting its prior performance (*Figure 9b*). It is worth noting that blank pumice can be able to produce biodiesel even at a lower yield. It is most probable that the surface of the material has catalytic properties that can support transesterification reactions even if it was not impregnated at all by an alkali solution. Also, the data in *Figure 8b* showed the resemblance of the curves by the three kinds of catalyst even when they are at different levels. It could indicate that the reusability can particularly be associated with the physical nature of the catalyst support which in this case is pumice.

DOI: http://dx.doi.org/10.15666/aeer/1504_18591870

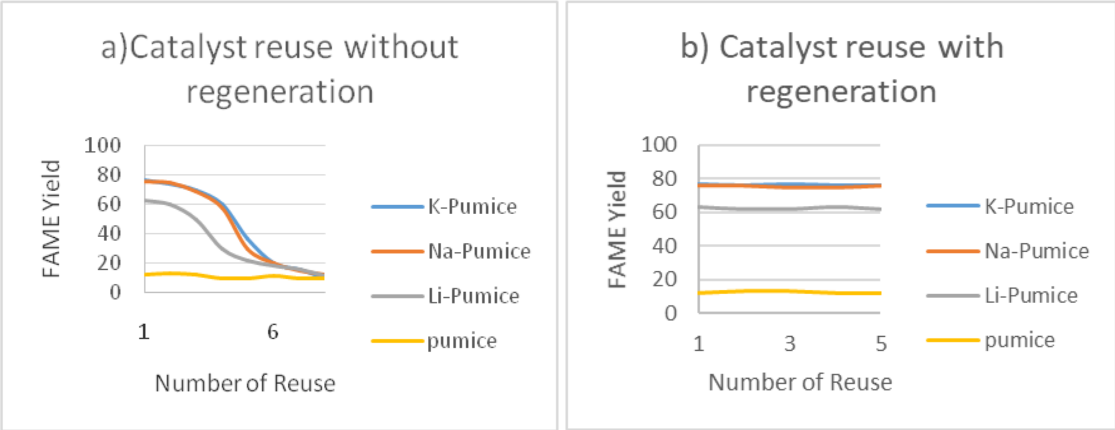

Figure 9. *Reusability of the catalysts*

Conclusion

The synthesized catalyst that was made by ion exchanging an alkali solution with pumice powder proved to be one of the better alternatives to the pre-existing catalysts in the production of biodiesel. The cheap cost of the catalyst support which is pumice, and the ease of preparation of the catalyst make it viable in transesterification processes. It was easily separated by filtration and was proven to be effective in reuse with regeneration. The best performing catalyst as far as FAME yield is concerned was K-pumice, followed by Na-pumice and then Li-pumice. The optimum contact solution in the synthesis of the catalysts were 1.0N. The K-pumice catalyst was able to generate FAME yield of 77% from microalgae. The optimum process conditions to guarantee maximum FAME yield when using K-pumice as the catalyst are: reaction time = 2 hours; reaction temperature = 60; methanol to oil ratio = 18:1 and catalyst load = 10%. The current FAME yield could still be improved by tapping to current technologies that are being used in transesterification reactions. It is strongly recommended that ultrasound and microwave technologies be incorporated to the current set-up since it may affect positively the yield of the resulting biodiesel. Also, it would be interesting if the synthesized catalyst in this study be tried for biodiesel production using other lipid source such as animal fat, waste vegetable oil, or others sources that are considered to be waste. Further investigation in catalyst synthesis using cheap materials not yet tried for biodiesel production will be encouraged.

Acknowledgement. The authors would like to thank the assistance of the three departments of TAMU, namely; Food Protein Research and Development Center (FPRDC), for their supply of microalgae that was given without a fee; the Materials Characterization Facility (MCF), for the assistance and use of the JEOL JSM-7500F responsible for the EDS and SEM analysis; and the Bioenergy Testing and Analysis Laboratory (BETA), for the use of the facility during the course of this research. Also, this project is indebted to the USAID STRIDE Program for funding the needs from all the materials consumed to the lease of various equipment that made this research possible.

Abstract. Extensive management of tobacco curing facilities can lead to fuel waste and environmental pollution. In this study, a new integrated equipment controlled by a microcomputer is proposed and built, including a flat panel solar-collector heating system located on the unoccupied flat rooftops of a bulk curing barn, a heat-pump heating system, and a heat-pump-type dehumidification system. Test results show that from 10:00 am to 3:00 pm, under sunny or partly cloudy weather during tobacco season, the air temperature in the flat-panel solar collector exceeds 68 °C, which is higher than the highest dry-bulb temperature required for tobacco curing. Compared with an existing air-source heat pump heating system in the barn, a curing cost saving of 21% per kilogram of dry tobacco leaves is achieved. Because of waste-heat recovery for recycling and solar energy heating, the operating time of the new device heating compressor is approximately 70.6 h during a curing time of 142 h, which is less than the control compressor, i.e., 115.8 h. The heat pump dehumidification system controls the difference between the actual wet-bulb temperature and target wet-bulb temperature of the barn to be within 0.5 °C.
Keywords: *hot air drying, dehumidifier, precision control, dry-bulb and wet-bulb temperature, bulk curing barn*

Introduction

Flue-cured tobacco is dried by fire in a process generated inside a furnace and the heat is transferred through the flue pipes laid in a strategic position inside an airtight barn where the leaves are hung (Truong et al., 2016). The large-scale use of coal fuel for tobacco curing can result in environmental degradation (Li et al., 2017; Wang et al., 2015). In recent years, with serious haze weather conditions occurring frequently in North China and more than 30% (2.3 million ton) of flue-cured tobacco leaves produced in China, air pollution caused by coal burning and heating used for conventional tobacco curing has received significant attention (Liu et al., 2016; Mana and Fatt, 2017). The government attaches considerable importance to the use of clean energy for tobacco curing and emission reduction (Xiao et al., 2015).

Literature Review

Solar energy is an abundant, renewable, and sustainable energy source that has attracted several eminent researchers globally to work in the field of solar energy applications for flue-cured tobacco leaves (Kumar et al., 2016; Patil and Gawande,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18711882

2016). From 1974 to 1986, Huang and Bowers Jr. (1986) developed two types of solar greenhouse designs namely the load supporting wall type and the shell type for tobacco curing. Janjai et al. (1986) investigated the technical feasibility of using solar energy for flue curing of tobacco in a bulk barn. Subsequently, Indian tobacco operators built a solar barn in Lajiawang, Delhi, which could save 43%–45% fuel (Subramaniam et al., 1998; Randrianarison and Ashraf, 2017). China is one of the first countries to use solar energy for tobacco curing. With the extensive application of bulk curing barns since 2008, a few researchers built a solar heating system on the unoccupied roof of a barn that was used only in the tobacco yellowing period (Lu et al., 2011). Limited by monolithic computer technology, the early solar energy system used for flue curing of tobacco was relatively simple and could not be controlled accurately.

Heat pump technology was first introduced in Germany in 1930, and it was rapidly applied and promoted in all fields (Carl, 1933). Owing to its significant advantages, such as energy-saving and reduced emissions, heat pump drying became widely used in the industry (Bao and Wang, 2016). Gong and Pan (2003) were the first to use the heat pump technology to provide independent heat for tobacco curing, and they built numerous barns that were heated using a heat pump in a few tobacco planting areas in China. Heat pump dehumidification led to recovery of waste heat for recycling (Ahn et al., 2016; Chantoiseau et al., 2016). A heat-pump dehumidifier was used by Maw et al. (2004) in 1999 for the first time for tobacco curing, which was only applied during the lamina and stem drying phases (Wu et al., 2017).

Based on the above literature, a device that combined a waste-heat-recovery heat pump with an auxiliary solar-energy heat supply priority for tobacco curing was developed for use in a single bulk curing barn. Through precise control of curing process parameters, the objective was using the adequate solar energy during the season of tobacco plant harvest and the recycling of heat from the high temperature moist air during the tobacco curing process to cure tobacco leaves.

Materials and methods

Equipment structure

The integrated energy-heating equipment consists of a heating structure with a distinct appearance (*Figure 1*), which includes a solar air heating system, a heat pump heating system, a heat pump dehumidification system, a microcomputer, and other components. The equipment power supply is 380 V. In China, the basic structure and specifications of a bulk curing barn were established by the State Tobacco Monopoly Administration on April 18, 2009 (hereinafter referred to as barn no. 418) (TSBCN, 2009). The overall size of the barn was 11440 × 2700 × 3500 mm (length × width × height).

The solar air heating system is located on the unoccupied flat rooftops of a bulk curing barn, which is comprised of a flat-panel solar collector (1), a solar hot air chamber (SHAC) (2), an outlet duct for lower temperature air (3), an intake duct for higher temperature air (4), a centrifugal fan (11), etc. Air is the energy carrier medium in the solar air heating system. The centrifugal fan interactively drives airflow between SHAC (2) and the heating chamber to utilize solar energy. It is hermetically connected to the end of the outlet duct for lower temperature air (3). The flat-panel solar arrays are installed facing south and oriented at an angle of 6° to the horizontal. Each barn consists of eight flat-panel solar-collector arrays with dimensions of 3200 × 1200 × 60 mm (length × width × height), which are connected in series through an insulation board and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18711882

airflow pipeline. As a result, one barn with eight arrays forms a solar energy collecting area of 28.8 m^2. Special heat insulation is provided on the roof of the SHAC (2) using a double-glazed organic transparent glass with a thickness of 4 mm and a black multilayer absorbing metal net (23) that is suspended below the glass layer. On the outlet duct for lower temperature air (3), air outlets (22) for different sections have circular holes with different diameters depending on the wind pressure generated by the centrifugal fan (11). Each SHAC is connected in series through the outlet duct for lower temperature air (3) and the intake duct for higher temperature air (4) (*Figure 2*).

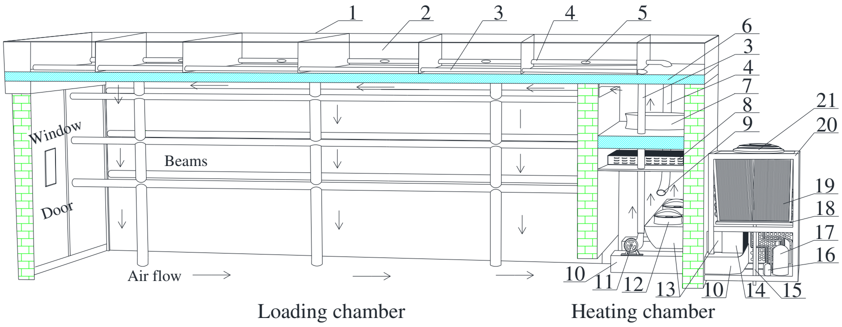

Figure 1. *Structure of the integrated energy-heating equipment.*

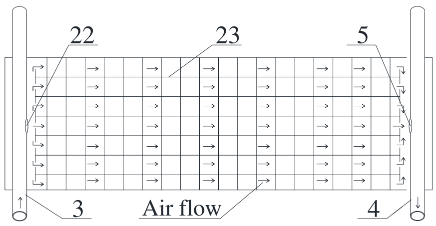

Figure 2. *Internal structure of SHAC.*

Note: 22. Air outlet, 23. Black multilayer absorbing metal net.

In the reflux condenser (8), there are two sub-condensers for heat pump heating and heat pump dehumidification drying, which share a heat pipe fin and the structural frame of the equipment. However, the condensate pipes of the sub-condensers are separated. The reflux condenser (8), compressor I for dehumidification (16), evaporator I for dehumidification (14), two cabinets for moist air entry from the loading chamber (10), two cabinets for dry air outlet after dehumidification (13), and two fans I with spring caps (12) constitute the waste heat recovery recycling system of the heat pump dehumidification system. The dehumidification system is operated in a closed loop, in which the air inside the barn is dehumidified and re-circulated. During dehumidification, heat is generated and accumulated in the barn. In this manner, higher internal

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18711882

temperature and lower relative humidity are achieved, as compared to the case in which fresh ambient air is used and higher temperature air with higher relative humidity is discharged. Evaporator I for dehumidification (14) is the connection point between the two cabinets for dry air outlet after dehumidification (13) and the two fans I with spring caps (12). Compressor I for dehumidification (16) is composed of two single 2.94-kW·h compressors (Emerson Climate Technologies, the same as below). When tobacco leaves in the barn require dehumidification during the curing process, the two fans I with spring caps (12), which are controlled by the microcomputer, start working. Moreover, the caps of the fans open under wind pressure and cause moist air, which is flowing from the loading chamber to the heating chamber, to flow into two cabinets for moist air entry from the loading chamber (10). Moist air is dehumidified by evaporator I for dehumidification (14), and it returns to the heating chamber through the cabinet for dry air outlet after dehumidification (13). Subsequently, the microcomputer stops the two fans I with spring caps (12), and their caps fall down under gravity.

The heat pump heating system is composed of a reflux condenser (8), a pipeline for directing flowing water outside (15), compressor II for heating (17), a channel for flowing water (18), evaporator II for heating (19), fan II (21), etc. Compressor II for heating (17) is composed of two single 2.94-kW·h compressors and two single 4.42-kW·h compressors.

To facilitate the operation of the integrated energy-heating equipment and precisely control tobacco curing, the microcomputer is designed based on curing requirements. The electronic control valve for throttling service is adopted to realize efficient heating and dehumidification of the heat pump.

Working principle

The working principle of the integrated energy-heating equipment is shown in *Figure 3*. The equipment has three independent and coordinated systems for providing heat. Solar energy provides auxiliary heating energy to preferentially assist the heating for tobacco curing. Moreover, energy from the ambient atmosphere, which is independent of the heat pump, primarily provides heat for tobacco curing. The heat pump dehumidifies moist air and recovers waste heat for tobacco curing. The conversion of energy in the three heating cycles is accomplished using the microcomputer operated by a tobacco curing technician.

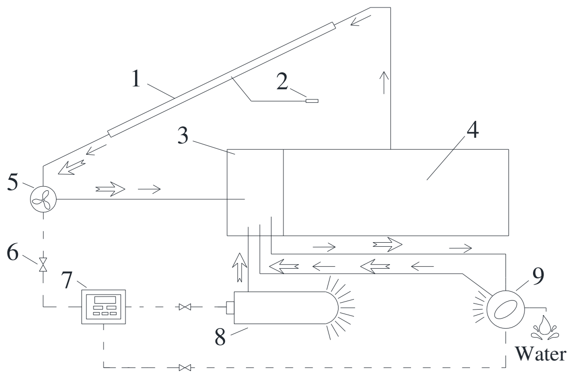

Figure 3. *Schematic of the system's operating principle.*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18711882

The heat supply mode is controlled by the microcomputer as follows: 1) The difference between the actual dry-bulb temperature in the curing barn and the target dry-bulb temperature set by the microcomputer is -0.5–0.5 °C. In this case, if the air temperature in the SHAC is more than 10 °C higher than the target dry-bulb temperature, hot air heated through solar heating is driven preferentially by the centrifugal fan through wind pressure to the heating chamber. Then, it is transported by the circulating fan to the loading chamber. Moreover, if the temperature of the SHAC is not more than 10 °C higher than the target temperature, the solar air heating system stops providing heat to the heating chamber, and the heat pump heating system starts working and absorbs heat for tobacco curing from the ambient atmosphere. 2) The actual dry-bulb temperature in the curing barn is lower than the target dry-bulb temperature set by the microcomputer by 0.5 °C. In this case, if the air temperature in the SHAC is more than 10 °C higher than the target dry-bulb temperature, the solar hot air system and heat pump heating system provide heat for tobacco curing. Furthermore, if the air temperature in the SHAC is not more than 10 °C above the target dry-bulb temperature, only the heat pump heating system works. 3) The actual dry-bulb temperature in the curing barn is higher than the target dry-bulb temperature set by the microcomputer by 0.5 °C. In this case, the solar hot air system and the heat pump heating system stop working simultaneously.

According to the requirements of tobacco curing, the heat pump dehumidification system, i.e., evaporator I, converts the excessive water in the high humidity air of the barn into liquid water, while the heat in moist air is recovered for recycling through the reflux condenser in the heating chamber.

To maintain the high efficiency of the heat pump dehumidification system, the speed of fan I is controlled by a variable frequency power, and it is changed at the wet-bulb temperature points from 38–68 °C. The variable speed of fan I can control the ventilation flow between the cabinets for the entry of moist air from the loading chamber and the cabinets for dry air outlet after dehumidification, which could reduce the frost on evaporator I for dehumidification and condense a significant amount of water in the liquid state.

System operation test

The experiment was conducted in the experimental field of the Xuchang branch campus of Henan Agricultural University in 2015 and 2016 (N34°09，E113°49). The curing season typically lasts for 7–9 months, and it is primarily sunny with few rainy days.

Experimental treatment

Three single bulk curing barns (no. 418) with air descent were employed. Barn A was installed with the integrated energy-heating equipment. To facilitate experimental comparison, the equipment in barn B was a conventional heat pump that provided independent heating, and that in barn C was a coal burning furnace, which is widely used locally. Only the heating equipment was different between barns B and C, which had a conventional ventilation-based dehumidifying pattern in which fresh ambient air enters and high temperature moist air is discharged. The mature upper leaves of flue-cured tobacco of cultivar Zhongyan 100, with a uniform quality, were picked simultaneously and hung using the same type of clips used to hang tobacco. The error in the weight of the loaded green tobacco in barns A, B, and C was controlled to be ±50 kg.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18711882

The tobacco curing technology was in accordance with the curing process used in local bulk curing barns.

Basic performance test

When the three single barns started to cure tobacco simultaneously, the target dry-bulb temperature and target wet-bulb temperature (both set by the microcomputer), the air temperature in the SHAC, and the actual wet-bulb temperature in the loading chamber of barn A, were recorded at 1 h intervals from 6:00 am to 8:00 pm.

Working characteristics of system components

Intelligent electric parameter test instruments (Zurui, EPM6600-T) were employed to detect the electric energy consumption and operating time of the circulating fan, compressor I for dehumidification, compressor II for heating, centrifugal fan, fan I with a spring cap, and fan II for external heat exchange. The curing time was recorded, and the moisture lost from tobacco after curing was calculated by measuring the weights of green tobacco and dried tobacco after curing.

Grades and grade indices of cured tobacco

Fifty representative clips of cured tobacco were selected per batch per barn from the same position. Grades were assigned to the selected samples of tobacco by the graders of Tobacco Henan Industrial Company Limited. Grading was performed based on the indices of quality of appearance, which include proportions of superior tobacco, orange tobacco, and lemon tobacco, and whether tobacco leaves are green or black (GB2635-92, 1992).

Results

Heating coincidence degree between the solar energy provided and the tobacco curing required

Figure 4 shows the difference between the heat provided by solar energy and that required for tobacco curing in terms of the target dry-bulb and SHAC temperatures.

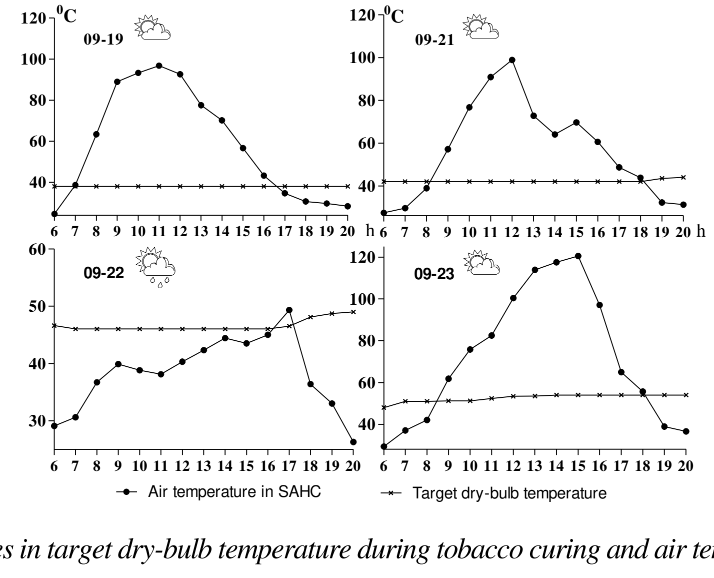

Figure 4. *Changes in target dry-bulb temperature during tobacco curing and air temperature in SHAC.*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18711882

The flat-panel solar collector receives solar energy radiation, and the air temperature in the SHAC rises and fluctuates between ambient temperatures and 120.5 °C. Except in the case of rainy and cloudy weather on 22 September, the air temperature in the SHAC is higher than the target dry-bulb temperature set by the microcomputer from 9:00 am to 5:00 pm, which shows that solar energy could provide heat for tobacco curing. From 10:00 am to 3:00 pm, solar radiation is the most abundant, and the air temperature in the SHAC is considerably higher than the highest temperature (68 °C is the highest dry-bulb temperature required for tobacco curing), which could provide heat during the entire tobacco curing process.

Effect of heat pump controlled dehumidification on tobacco curing

Figure 5 shows effect of heat pump controlled dehumidification on tobacco curing. According to the requirements of tobacco curing, when the wet-bulb temperature is required to remain constant, the actual wet-bulb temperature fluctuates consistently around the target wet-bulb temperature at regular intervals, such as on September 21 and 22. When the wet-bulb temperature is required to rise in the loading chamber, the actual wet-bulb temperature increases, remaining close to the target wet-bulb temperature, such as on September 23. Thus, based on the requirements of tobacco curing, the actual wet-bulb temperature could be controlled by the heat pump dehumidification system to be within ± 0.5 °C of the target wet-bulb temperature.

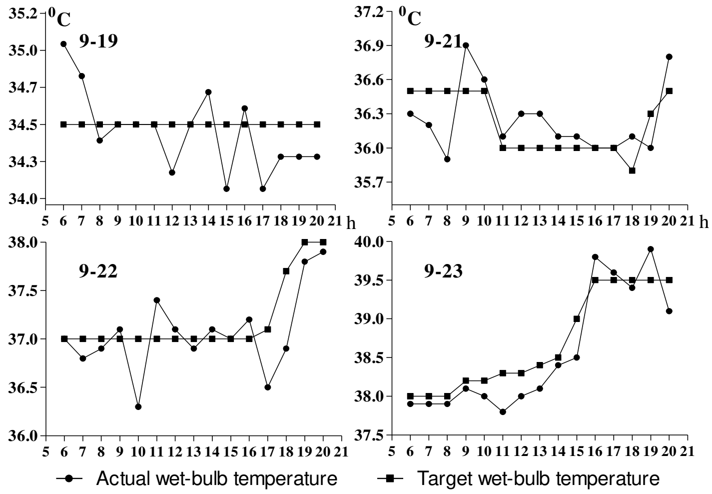

Figure 5. *Change in actual wet-bulb temperature and target wet-bulb temperature.*

Operating characteristics of equipment components

The test results (*Table 1* and *Table 2*) show that the operating time of the heat pump heating system (70.6 h) in barn A is considerably lower than that of the compressor for heating in barn B (115.8 h). The total operating times for barns A and B are 142 h and 141 h, respectively. The heat pump dehumidification system in barn A consumes 347.4 kW power to remove 3815 kg moisture from the tobacco leaves after curing, which is equivalent to 1 kW power for dehumidifying 10.98 kg water from moist air. The curing costs per barn for barns B and C are close to each other; however, they are higher than that for barn A. For the same heat pump heating for tobacco curing, barn A saves 21%

more curing cost than barn B. This suggests that a large amount of heat is lost from barns B and C during the curing process through discharge of hot moist air. With the closed loop operation of the heat pump dehumidification system in barn A, the air from the barn was dehumidified and recirculated, thus attaining a higher internal air temperature and lower relative humidity than is possible by taking in fresh air. Combined with solar energy assisted heating, this could reduce the cost of tobacco curing.

Discussion

New device technology and precision control tobacco curing

The new device, which is a mature electrical industrial product integrated with solar collector, heat pump heating and heat pump dehumidification technology, used in this study can accurately and steadily control the dry-bulb and wet-bulb temperature of air according to curing process parameters, which is particularly advantageous for the synthesis and degradation of inner substances in tobacco leaves. Empirical addition of fuels and fuels combustion characteristics can adversely affect tobacco curing in production (Frey et al., 2003). Typically, heat for tobacco curing is provided by burning of fuels, such as coal or firewood, through manual labor and automatic fuel combustion under natural conditions (Truong et al., 2016; Tippayawong et al., 2006), which bring the large difference between the actual dry and wet-bulb temperature and target dry and wet-bulb temperature of the barn during tobacco curing process. This result is also consistent with the observation of Gong and Pan (2003) using a precise control equipment to cure tobacco.

Utilization prospect of solar energy resources in China

Solar irradiation and collecting area are the two main factors effecting solar-energy collection efficiency (Chow, 2010). *Figure 6* shows the distribution of solar radiation and the tobacco growing regions in China. From July–September, the daily total radiation at the experimental station in Xuchang was 18.55–23.33 MJ/m^2, which belongs to a general resources region. In certain provinces, such as Yunnan and Liaoning, solar energy resources are more abundant, and the design and installation of solar energy collectors at the top of barns should be considered for tobacco curing. Solar collection efficiencies above 94 % have recently been achieved (Sabiha et al., 2015; Verma et al., 2015) and many policies that encourage use of green energy have been issued by the government (Wang et al., 2015; Xiao et al., 2015). These have great significance for fossil-fuel energy savings in the tobacco curing industry in the near future.

Conclusion

This study proposed an integrated energy-heating equipment that could accomplish preferential solar energy assisted tobacco heating, which primarily consisted of heat pump heating and utilization of heat recycled from heat pump dehumidification. The equipment has the advantages of compact combination, precise control, and it is suitable for the popularization of a few tobacco planting areas. The experimental results show that in general resource regions with sunny days or partly cloudy days, solar energy could be efficiently used to provide heat for tobacco curing during the entire curing process. Heat pump dehumidification technology can discharge excess water in barns and recycle the heat from high temperature moist air. Using the equipment to cure tobacco can improve the appearance quality of the tobacco leaves and reduce the curing cost per kg of dry tobacco by 21% when contrasted to coal-fired curing. Thus, this device that can remove about 3500 kg of water in 142 h from this study may be suitable to use for drying other agricultural products after transformed.

PROTEIN BAITS, VOLATILE COMPOUNDS AND IRRADIATION INFLUENCE THE EXPRESSION PROFILES OF ODORANT-BINDING PROTEIN GENES IN *BACTROCERA DORSALIS* (DIPTERA: TEPHRITIDAE)

(Received 4th Jul 2017; accepted 18th Oct 2017)

Abstract. Chemical communication in insects is based on odorant-binding proteins (OBPs), but the molecular mechanisms by which these OBPs allow the perception of volatiles and host chemicals remain unclear. *Bactrocera dorsalis* (Hendel) is one of the most economically important pests of fruits and vegetables. In this study, the OBPs of *B. dorsalis* (BdorOBPs) were evaluated in response to different attractive protein baits, brewer's yeast volatile compounds and irradiation. The expression of 10 genes encoding OBPs in the antennae of *B. dorsalis* during three adult physiological life stages (pre-mating, post-mating and post-oviposition) were analysed. All selected BdorOBP genes were found to contain one conserved pheromone-binding protein/general-odorant-binding protein domain (PBP-GOBP), except OBP8, which contained two of these conserved domains. An unrooted phylogenetic tree was constructed to show the relationships among these 10 BdorOBPs and the OBPs belonging to the same OBP family in other insects. We found significantly different transcript expression profiles in each OBP gene at each stage in response to different treatments; these results revealed that OBP2 expression was significantly increased in response to baits at each adult physiological stage, while OBP2, OBP5 and OBP1 were highly expressed in response to combined-volatiles treatment at all tested physiological stages. OBP3, OBP5 and OBP10 showed high expression in response to irradiation at all tested physiological stages. Thus, we infer that protein baits, brewer's yeast volatiles and irradiation significantly influence the transcript levels of OBP genes, which may act in olfactory perception.
Keywords: *transcript analysis, irradiation, brewer's yeast volatiles, oriental fruit fly, insect olfaction*

Introduction

Bactrocera dorsalis is the most devastating pest in several Asian countries including China. This fruit fly was reported for the first time in Taiwan in 1912 (Hardy, 1973). *B. dorsalis* is a serious quarantine pest throughout the world, resulting in severe financial damage to multiple crops that are among its 270 host plant species (Clarke et al., 2005; Chen et al., 2008; Leblanc et al., 2013; Vargas et al., 2015). The extensive damage caused by this particular pest worldwide raises serious concerns about crop yields due to the high resistance of this pest to chemical insecticides (Hu et al., 2014). A variety of methods such as the sterile insect technique, mass trapping, protein bait spraying and male annihilation have been developed to suppress or eradicate *B. dorsalis* and related species throughout Asia and the Pacific regions (Jessup et al., 2007; Mau et al., 2007; Piñero et al., 2009a; Piñero et al., 2009b; Vargas et al., 2015).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18831899

Chemoreception is an important characteristic in the selection of host plants by phytophagous insects. Odorant-binding proteins (OBPs) present in the olfactory system play an essential role in sensitivity to odorants, such as pheromones and host chemicals (Zheng et al., 2013). The olfactory system in insects consists of three central types of proteins: OBPs, odorant receptors (ORs) and odorant-degrading esterases (ODEs) (Justice et al., 2003). Among these proteins, OBPs frequently function in the first step of odour perception. The process of chemical communication in both insects and vertebrates is performed by OBPs (Tegoni et al., 2004; Dahanukar et al., 2005; de Bruyne and Baker, 2008). Insects possess a notably complex and cosmopolitan olfactory system, through which they are potentially able to detect a variety of external volatile compounds including plant volatiles and gender-specific mating pheromones (Hsu et al., 2012; Zheng et al., 2012b; Papadopoulos et al., 2013; Zheng et al., 2013; Liu et al., 2015). Insect OBPs may represent an important molecular target in the application of eco-friendly pest management approaches, as they are proposed to be involved in olfactory cue discrimination due to their intense expression in antennal sensillum lymph (Qiao et al., 2009; He et al., 2011; Sun et al., 2013a, 2014; Pelosi et al., 2014). Insects usually use their antennae as olfactory organs in order to detect the odours of plants, fruits and chemicals in the outside environment (Sun et al., 2016a).

Conversely, many studies have shown that the expression of OBPs is not limited to the olfactory organs; thus, their physiological functions may be broader and more difficult to understand than expected (Park et al., 2000; Foret and Maleszka, 2006; Li et al., 2015; Sun et al., 2012; Yuan et al., 2015). To determine whether the OBPs in the antennae of *Bactrocera* species respond to volatiles, the present study focuses on the expression patterns of 10 OBPs in the antennae of *B. dorsalis* (BdorOBPs) in response to protein baits, volatiles and irradiation. Insect OBPs, which are specifically or primarily expressed in the antennae, have been proposed to play roles in olfactory function in response to different kinds of attractive host plant volatiles (Zhou, 2010; Leal, 2013)**.** Previously, an electroantennogram (EAG) was employed to record the electrophysiological responses of the antennae of *B. dorsalis* to spent brewer's yeast volatiles, alcohols, aldehyde alcohols and aldehydes to determine the olfactory response of the antennae towards chemical odours. The results of that study revealed that volatiles could potentially evoke higher relative EAG values in the antennae of *B. dorsalis* during three adult physiological stages (Jang and Light, 1991; Du et al., 2015). A total of 20 BdorOBP genes have been identified from the *B. dorsalis* transcriptome; however, only 10 BdorOBP*s* have been characterized (Zheng et al., 2012b, 2013).

B. dorsalis transcriptomes and expression analysis in different tissues have been analysed, but the study of the molecular basis of olfaction in response to different stimuli is still in its initial stages (Shen et al., 2011a; Geib et al., 2014). In the studies mentioned above, scientists have reported the EAG response of *B. dorsalis* to different chemical odours and identified OBP genes that are responsible for the first step in the perception of chemical odours. However, few studies have evaluated the expression profiles of the different OBP genes of an insect pest in response to different volatiles, particularly different baits, spent brewer's yeast volatiles and irradiation. Hence, there is a pressing need to study the influence of different kind of volatiles on the expression levels of OBP genes in the antennae of *B. dorsalis.*

Therefore, the current study was based on the hypothesis that different protein baits, spent brewer's yeast volatiles and irradiation would influence the expression levels of OBP genes at three adult physiological stages in the antennae of *B. dorsalis.* The objective of the study was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18831899

to evaluate the effects of different protein baits, spent brewer's yeast volatiles and the application of radiation on the transcript levels of the 10 previously identified BdorOBP genes in the antennae of *B. dorsalis* during the pre-mating, post-mating and post-oviposition stages. The findings of the present study may provide knowledge of the molecular mechanisms of action of the variety of OBPs present in the antennae of *B. dorsalis* and potentially suggest novel tactics for the suppression of *B. dorsalis*. A greater understanding of the mechanisms underlying OBP function may allow the invention of novel control methods to disrupt these internal physical mechanisms, perhaps by influencing the gene expression profiles of OBP genes and thus support novel strategies for long-term effective management of tephritid fruit fly species.

Material and Methods

Insect rearing

The insects were reared at the Institute of Beneficial Insects, Fujian Agriculture and Forestry University, Fuzhou, Fujian Province, China, under controlled conditions (26±1°C; 60-70% RH; 12 hr light/12 hr dark photoperiod) for approximately 60 generations. The eggs of *B. dorsalis* were collected using a homemade ovipositional bottle including artificial juice and then were placed on a single layer of wet tissue paper in a larval diet tray. The adult flies were reared on artificial diet prepared with yeast extract and sugar in accordance with the procedures described by (Spencer and Fujita, 1998).

Experimental materials

Proteins were prepared at the Institute of Beneficial Insects at Fujian Agriculture and Forestry University, Fuzhou, Fujian Province, China, while torula yeast was obtained from Baifude Biotechnology, Wuxi, Jiangsu. Spent brewer's yeast volatile compounds phenyl acetate, ethyl caprylate, and octyl acetate (analytical reagents) were purchased from Solarbio Pvt. Ltd., Shanghai, while paraffin oil (100%) was obtained from Acros Organics (Geel, Belgium).

Experimental methods

Protein baits and volatile regulation for female and irradiation application method for male B. dorsalis

This experiment was planned to evaluate the effects of protein baits and torula yeast on the transcript expression of 10 previously identified full-length cDNAs of OBP genes in the antennae of *B. dorsalis* at different adult life stages: pre-mating (2-3 days), post-mating (7-9 days) and post-oviposition (11-13 days). A total of one hundred (100) mature females were released in a 33 cm × 33 cm × 33 cm cage and starved for 12 hrs overnight prior to feeding using protein bait and torula yeast. The insects were treated with two different protein baits (1:10 dilution with paraffin oil), whereas the control group was treated with an equal volume of normal protein diet (Zheng et al., 2012b). Three spent brewer's yeast volatile compounds and their blend mixtures were prepared: 15% paraffin oil (Control, Ck), 15% (75 µl phenyl acetate + 425 µl paraffin oil), 25% (125 µl ethyl caprylate + 375 µl paraffin oil), 15% (75 µl octyl acetate + 425 µl paraffin oil) and a mixture of all compounds (15% phenyl acetate + 25% ethyl caprylate + 15% octyl acetate) (MIX). Treatments were denoted by Ck: control, PA: phenyl acetate, EC: ethyl caprylate, OA: octyl acetate, MIX: mixture of three volatile compounds (PA + EC

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18831899

+ OA). *B. dorsalis* was irradiated with ^{137}Cs at 100 Gy for 1, 2 and 3 days at the pupal stage, and kept at 25 ± 1 °C, RH 65% ± 5%, and L:D = 12:12 after adult emergence for 1 day, 6 days and 8 days. Afterwards, 100 infertile males were collected on each day, and their antennae were dissected.

RNA isolation and qRT-PCR analysis

Adult tissue samples were dissected from 500 individuals. The total RNA for each group was extracted from the antennae of *B. dorsalis* at 2-3 days (pre-mating stage), 7-9 days (post-mating stage) and 11-13 days (post-oviposition stage) by using a Tiangen RNeasy Kit. Two micrograms of total RNA was reverse-transcribed by the PrimeScript 1st strand cDNA Synthesis Kit (TaKaRa, Japan) using the oligo dT primer. qRT-PCR was conducted to detect the expression of genes encoding OBPs by using gene-specific primers (*Table 1*), Top Green qPCR Super Mix (Transgen, China) and a real-time thermocycler (Bio-Rad, Hercules, CA, USA) following the manufacturer's instructions. For internal standardization, β-*Actin* was amplified. Prior to starting the gene expression analysis, the PCR efficiency of the genes was validated. The qRT-PCR was performed in a volume of 20 µl containing 10 µl of 2× TransStart® Top Green qPCR Super Mix, 2 µl cDNA (1:100 diluted), 0.8 µl of each (forward and reverse) primer and 6.4 µl nuclease-free H_2O. The qRT-PCR programme was: 94°C for 30 s followed by 40 cycles at 94°C for 15 s, 60°C for 30 s, and 72°C for 10 s. The melting curve was analysed for the PCR products to confirm the presence of a single amplified fragment at the end of each PCR. The β-actin gene was used as a housekeeping gene to standardize the qRT-PCR results. A relative quantitative computing method ($2^{-\Delta\Delta Ct}$ method) was used to compute gene expression (Livak and Schmittgen, 2001). Three biological replicates were performed.

Statistical analysis

Statistical analysis was performed using the SPSS 17.0 software package (IBM Corporation, Somers, NY, USA) to calculate *Dunnett's test* for comparing control with other treatments (SPSS for Windows, Version 16.0, 2007).

Results

Identification of PBP-GOBP domains in BdorOBP genes

All 10 BdorOBP genes were found to contain one conserved PBP-GOBP domain, except for OBP8, which, remarkably, contained two such conserved domains. In the OBP family, the amino acid sequence residues of each BdorOBP gene were green when compared with the hidden Markov model (HMM), which indicates a very high-quality hit. BdorOBP conserved domains are presented in (*Figure 1*), while the BdorOBP genes along with their accession numbers are presented in (*Table 2*). The PBP-GOBP conserved domain was identified by using the Pfam database (version 31.0) (Finn et al., 2016).

Phylogenetic analysis of insect OBPs

A phylogenetic tree was generated by obtaining the amino acid sequences of the ten putative OBPs of *B. dorsalis* from the work of (Zheng et al., 2013). The phylogenetic tree was built to demonstrate the relationships of the 10 BdorOBPs to 140 OBP sequences from 7 different orders and families of insects that possess the same OBP family, including 20 OBP sequences from *Apis mellifera* (Hymenoptera: Apidae), 7 OBP sequences from *Bombyx mori* (Lepidoptera: Bombycidae), 30 OBP sequences

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18831899

from *Drosophila pseudoobscura* (Diptera: Drosophilidae), 29 OBP sequences from *Halyomorpha halys* (Hemiptera: Pentatomidae), 15 OBP sequences from *Spodoptera litura* (Lepidoptera: Noctuidae), 10 OBP sequences from *Tenebrio molitor* (Coleoptera: Tenebrionidae) and 44 OBP sequences from *Tribolium castaneum* (Coleoptera: Tenebrionidae), as shown in (*Figure 2*). This phylogenetic tree clarified the connections between *B. dorsalis* and other insects in the groups listed above. Amino acid sequences were used to build an unrooted phylogenetic tree using MEGA 7.0 with the pairwise deletion option under the JTT empirical amino acid substitution model (Kumar et al., 2016). Branch support was assessed by bootstrap analysis with 1000 replicates.

Figure 2. *Unrooted phylogenetic tree of candidate OBPs from Bdor (B. dorsalis) and seven additional insect species with available amino acid sequences (Amel: Apis mellifera, Bmor: Bombyx mori, Dpse: Drosophila pseudoobscura, Hhal: Halyomorpha halys, Slitura: Spodoptera litura, Tmor: Tenebrio molitor and Tcas: Tribolium castaneum). The highly divergent signal peptides in the N-terminal region were removed, and a neighbour-joining tree was constructed by using MEGA 7 with the pairwise deletion option under the JTT empirical amino acid substitution model. Only bootstrap values above 50% are shown. The black diamonds indicate the 10 B. dorsalis OBP genes.*

Effects of bait and torula yeast on BdorOBP transcript levels in females

The qRT-PCR results revealed that all BdorOBPs showed significant changes in expression in response to protein bait and torula yeast except OBP4, OBP8 and OBP9, as shown in (*Figure 3a*). However, BdorOBP3 showed no significant expression in response to starvation (*Figure 3a*).

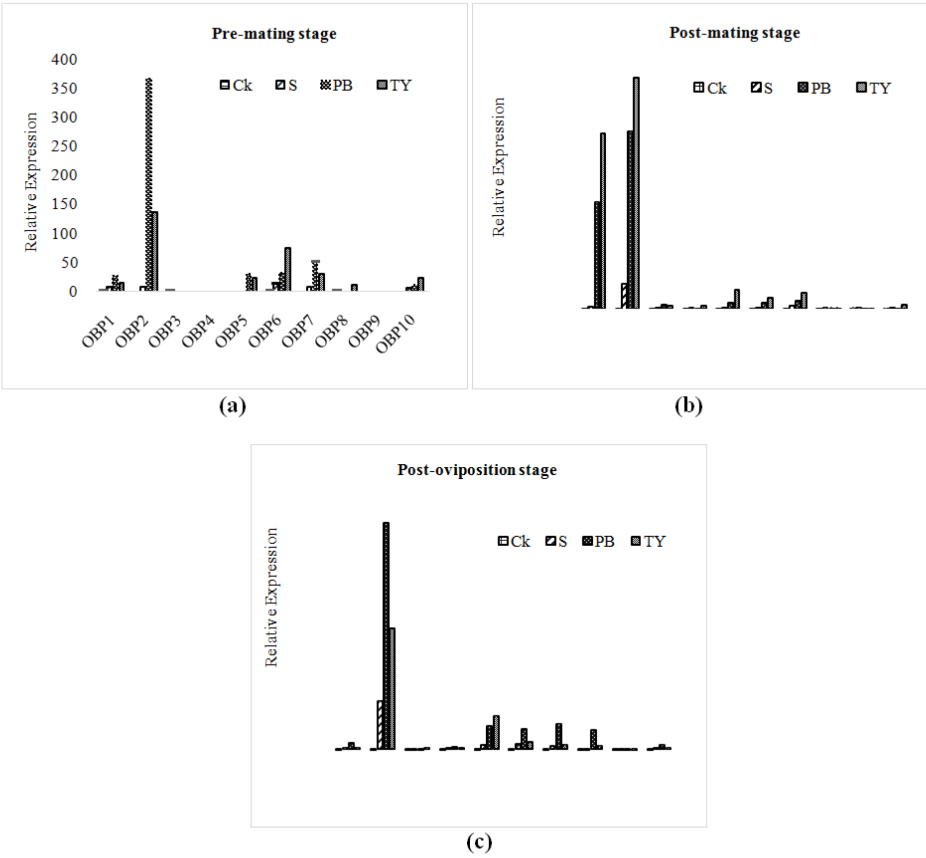

Figure 3. *Transcript expression analysis by qRT-PCR of the ten BdorOBP genes in the antennal tissues of mature adult females in response to protein bait and torula yeast. (a) Pre-mating stage; (b) post-mating stage; (c) post-oviposition stage. Treatments were denoted by Ck: control, S: starvation, PB: protein bait, TY: torula yeast. Analysis of variance (ANOVA) indicated a significant difference in the expression levels of OBPs at p < 0.05. However, OBP3 was expressed weakly under starvation treatment, and hence, ANOVA indicated that this difference was not significant (Figure 3a). The ANOVA indicated a significant difference among the expression levels of all BdorOBPs (p < 0.05, Figure 3b), except those of OBP9 and OBP10. However, OBP6 in response to starvation and OBP8 to starvation and protein bait were not highly expressed (Figure 4b). The ANOVA indicated a significant difference (p < 0.05) among the expression levels of all BdorOBPs (Figure 3b), while OBP1 in response to starvation and torula yeast; OBP4, OBP8, OBP9 to starvation; and OBP10 to starvation and torula yeast were not expressed significantly (Figure 3c).*

The expression levels of OBP1, OBP2, OBP5, OBP6 and OBP7 were higher in insects given protein bait and torula yeast than those of OBP3 (*Figure 3b*). OBP6 and OBP8 exhibited no significant expression in response to starvation and protein bait treatments, respectively ($p > 0.05$, *Dunnett's test*) (*Figure 3b*). However, the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aer/1504_18831899

transcript levels of OBP4, OBP9 and OBP10 were not altered significantly (p > 0.05) in response to any of the treatments (*Figure 3b*). Protein bait and torula yeast increased the transcript level of OBP6, while all of the remaining OBPs showed no response to protein bait and torula yeast, as shown in (*Figure 3b*). The expression levels of OBP1 and OBP10 were significantly increased in the antennae of *B. dorsalis* in response to starvation and torula yeast, while those of OBP8 and OBP9 showed no response to starvation. OBP4 showed no change in expression in response to the baits at any of the tested stages (*Figure 3c*). These results suggest that different baits may significantly alter the transcript profiles of some BdorOBPs, which may play an important role in altering the mechanism of insect olfaction.

Effects of volatiles on BdorOBP transcript levels in females

The analysis of the volatile treatments indicated relatively low expression levels in OBP5, OBP8, OBP9 and OBP10, while the remaining BdorOBPs showed significantly higher expression in all treatments, as shown in (*Figure 4a*).

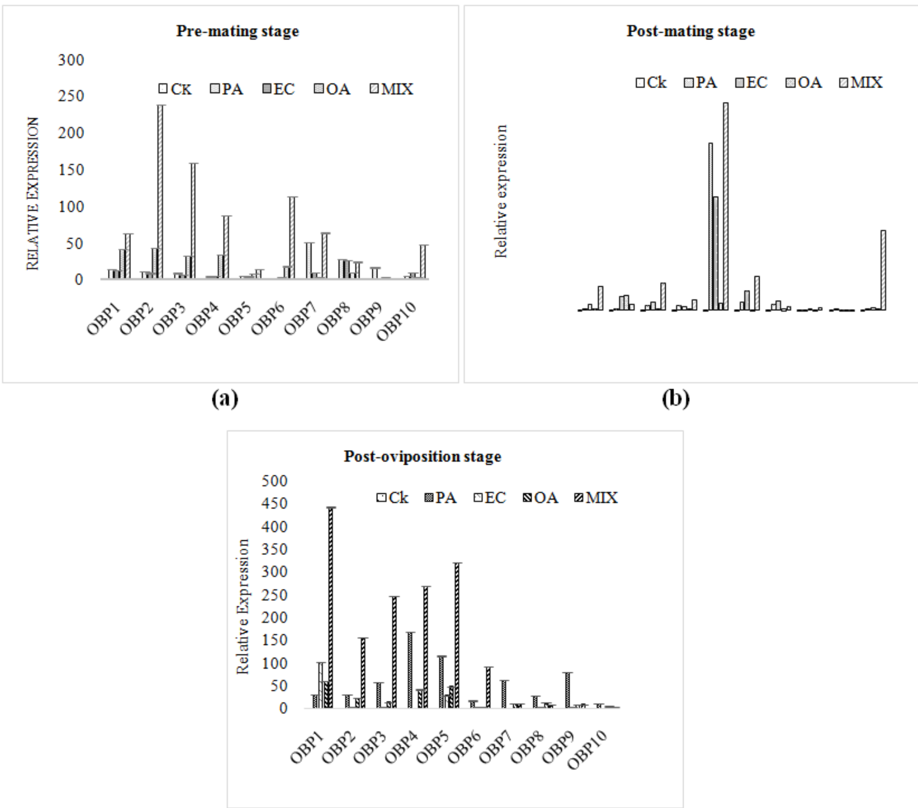

Figure 4. *Transcript analysis of the ten BdorOBP genes in the antennal tissues of mature adult females in the (a) pre-mating stage; (b) post-mating stage; and (c) post-oviposition stage. Treatments were denoted by Ck: control, PA: phenyl acetate, EC: ethyl caprylate, OA: octyl acetate, MIX: mixture of three volatile components (PA + EC + OA). Relative transcript levels were calculated using β-actin as the standard. A significant difference in the expression levels of BdorOBP genes was found by Dunnett's test ($p < 0.05$). OBP6 in response to starvation (Figure 4a), OBP8 to PA and EC (Figure 4b), OBP6 to OA, and OBP10 to PA and EC were not expressed significantly (Figure 4c).*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18831899

Interestingly, higher expression levels were observed in response to MIX and OA at all tested stages, as shown in (*Figure 4a, 4b* and *4c*). Only OBP*5* exhibited a significant expression change in response to all treatments, as shown in (*Figure 4b*). In contrast to the lower expression levels observed in the last five BdorOBPs (OBP6-OBP10), the first five BdorOBPs (OBP1-OBP5) showed significantly increased expression in response to all treatments, particularly MIX and PA, as shown in (*Figure 4b*). OBP6 showed no change in expression level in response to PA and OA, as shown in (*Figure 4a, 4b*), while OBP8 and OBP10 also showed no change in response to PA and EC, as shown in (*Figure 4b, 4c*).

Effects of irradiation on BdorOBP transcript levels in males

The qRT-PCR results showed that the transcript levels of the BdorOBPs changed significantly at all tested stages with a ^{137}Cs irradiation dose of 100 Gy. The expression levels of the BdorOBPs were altered significantly in response to irradiation, except those of OBP3, OBP4 and OBP7. The expression levels of OBP2, OBP5, OBP7 and OBP9 were significantly increased, as shown in (*Figure 5a*).

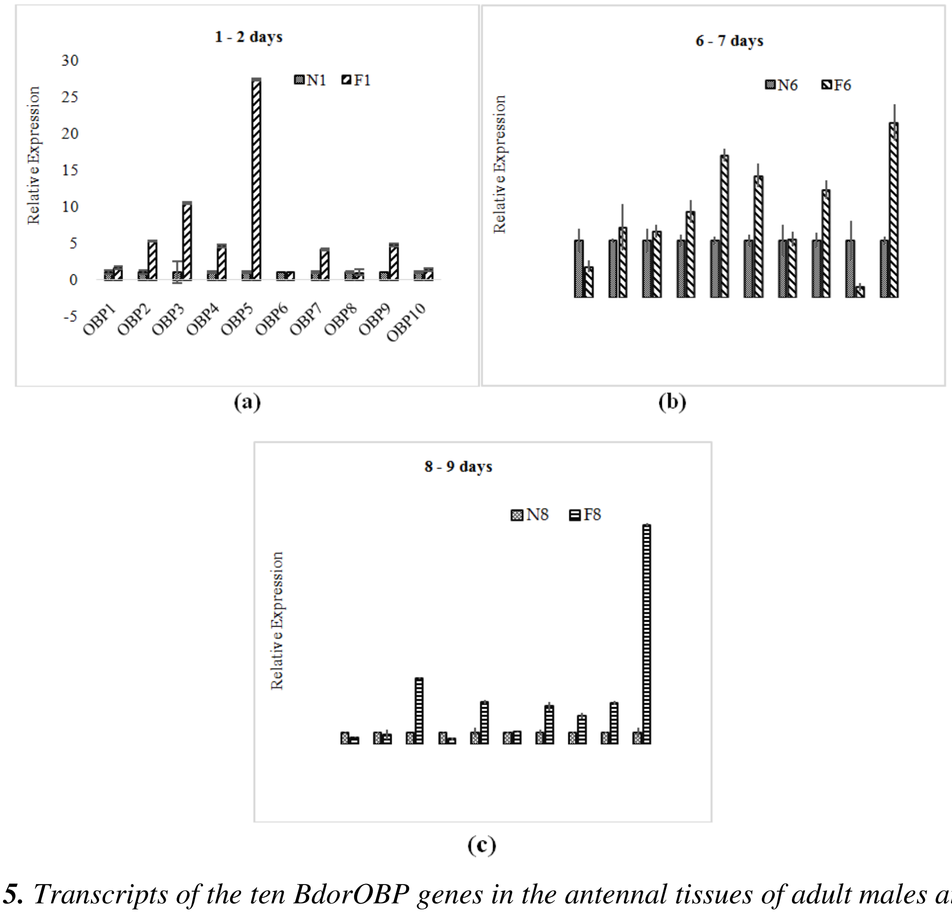

Figure 5. *Transcripts of the ten BdorOBP genes in the antennal tissues of adult males at (a) 1-2 days; (b) 6-7 days; (c) 8-9 days. The treatments were denoted by N: normal male and F: irradiated (infertile) male. Relative transcript levels were calculated using β-actin as the standard. A significant difference among the expression levels of all BdorOBP genes was found at p <0.05. Low expression levels were observed in OBP3, OBP4, and OBP7 (Figure 5a), while OBP1 did not show significant expression (p > 0.05, Figure 5b, 5c).*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18831899

However, each OBP was significantly differentially expressed, except OBP1, which showed no change. OBP4, OBP5, OBP6, OBP8, and OBP10 exhibited particularly high expression in response to irradiation, as shown in (*Figure 5b*). OBP3, OBP5, OBP7, OBP8, OBP9 and OBP10 showed exceptionally abundant expression in contrast to the other OBPs, as shown in (*Figure 5c*). However, OBP1 showed no response to irradiation, as shown in (*Figure 5b*, *5c*).

Discussion

Insects essentially depend on the antennae to distinguish plant volatiles or sex pheromones in the environment (Steinbrecht, 1997); hence, we selected *B. dorsalis* antennae to evaluate the expression profiles of 10 BdorOBP genes in response to protein baits, brewer's yeast volatiles and irradiation. Previously published papers have reported functional studies of insect OBPs in chemoreception since their discovery in 1981, but the exact functions of insect OBPs in response to different stimuli present in the environment are still unknown (Zhou, 2010; Leal, 2013). Highly developed olfactory systems are present in phytophagous insects, allowing them to use numerous chemical stimuli to identify plant hosts (Pelosi et al., 2006). The OBPs in the olfactory signal reception pathway play an essential role in the transportation of specific odorants to ORs to stimulate insect behaviours (Pelosi et al., 2006). Hence, OBPs are thought to be directly essential for odorant perception and represent potential targets for pest control via insect attraction.

B. dorsalis antennae have a strong EAG response to spent brewer's yeast volatiles (Du et al., 2015), and the results of the present study revealed that OBP2, OBP5 and OBP1, which are present in the antennae of *B. dorsalis*, were highly expressed in response to spent brewer's yeast volatiles at all tested stages. OBPs show significant attraction responses to different volatiles (Cornelius et al., 2000; Hu et al., 2007; Liu et al., 2010; Shen et al., 2011b). Another author has reported that some volatile compounds, such as benzaldehyde, showed very weak attraction effects in all adult physiological stages of female *B. dorsalis* (Ling, 2013), and the results of our study also showed that some OBPs were down-regulated, perhaps due to the weak affinity of volatiles to some OBPs. A similar phenomenon was observed in the case of ester alcohols, the major constituents of aromatic odour in most fruits, which plays an essential role in the attraction behaviour of *B. dorsalis* (Zhang et al., 2007). Tephritidae have shown significant differences in their responses to other esters, such as beer waste yeast, hydrolysates, and volatile compounds of the other 3 kinds of esters (Du et al., 2012).

Previously, thirty-four compounds were selected to investigate the interaction of OBPs with rice plant volatiles (Lou et al., 2005; Sun et al., 2013b). *Cnaphalocrocis medinalis* OBP2 (CmedOBP2) showed a significant response to host volatiles, whereas CmedOBP3 showed relatively little response to these volatiles (Sun et al., 2016b); our study found that all BdorOBP genes showed low or no response to combined volatile treatments at all tested physiological stages, except the OBP2, OBP5 and OBP1 genes, which were highly expressed. Because all insects have different OBP sequences and each OBP family might perform a different function, different OBPs can display different mechanisms in response to different kinds of volatiles present in plants and fruits (Sun et al., 2016b).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18831899

A previous report indicated that synthetic volatile compounds targeted OBP3 or OBP7, which were confirmed to be accountable for (*E*)-ß-farnesene sensitivity, and provoked significant behavioural responses in aphids (Sun et al., 2012), while the results of our studies revealed that the first five BdorOBP genes (OBP1-OBP5) were significantly expressed in response to all treatments, specifically to MIX and PA, and weak expression was observed in the last five BdorOBP genes (OBP6-OBP10) in response to volatiles.

The prerequisite for the illumination of the molecular mechanism of olfaction is the documentation of the genes accountable for volatile discrimination. Candidate olfaction genes have been recognized in numerous other species through annotation and antennal transcriptome analysis. Although *B. dorsalis* olfaction research has previously lacked transcriptome data for the classical olfactory organs, specifically the antennae, several studies of the *B. dorsalis* transcriptome have recently been conducted (Shen et al., 2011b; Zheng et al., 2012a; Geib et al., 2014). However, limited studies have investigated the effects of the volatile compounds reported for control of *B. dorsalis* on OBP gene expression profiles in *B. dorsalis* and other insect pests. In light of the present findings, the fact that *B. dorsalis* males and females were captured in greater numbers in torula yeast bait traps than in protein bait traps likely reflects a lower availability of proteinaceous food in the habitats sampled by (Siderhurst and Jang, 2010; Royer et al., 2014).

Insect OBPs are responsible for the detection of host plant attractants. A single OBP may participate in the recognition of several chemical odours (Vogt et al., 1991; Pelosi et al., 2014); however, our results reported that only OBP2 was significantly expressed in response to baits at each adult physiological stage among these 10 OBP genes. On the other hand, specific compounds might be recognized by more than one OBP gene, as the results of our study revealed that few OBP genes showed significant responses to spent brewer’s yeast volatiles, while others showed no response. To the best of our knowledge, our data exhibit the relationship of these ten OBP genes to spent brewer’s yeast volatiles, protein bait and irradiation for the first time.

The combination of different OBPs in insects may form a molecular basis for the ability to identify and distinguish relevant olfactory cues amid the vast spectrum of odorants emitted from fruits or plants (Takken and Knols, 1999; Zwiebel and Takken, 2004). In our study, some OBPs showed the same response to MIX treatment and were highly expressed at all physiological stages. This result further supports the view that OBPs are not just simple, general solubilizers that act as transporters for odorants but also play a vital role in the perception of different kinds of chemicals in the environment (Pelosi et al., 2006; Swarup et al., 2011). An OBP in *Hylamorpha elegans* showed a high binding affinity to β-ionone (Venthur et al., 2016), a volatile compound derived from plant carotenoids (Simkin et al., 2004).

Most of the OBP genes showed significant responses to MIX treatment at all adult life stages (*Figure 4a, 4b* and *4c*). Irradiation has been reported to significantly destabilize fly fitness by damaging tissues and interior organs to some degree, inducing metabolic disorders (Lauzon and Potter, 2012; Yao et al., 2017), and our results showed that irradiation significantly altered the transcript levels of OBP genes at all adult life stages (*Figure 5a, 5b* and *5c*), with especially abundant expression in the second and third stages (*Figure 5b, 5c*). These significant observations suggest that the effects of applied treatments on the transcript levels of BdorOBP genes may play an essential role in understanding the insect olfaction mechanism in response to different kinds of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_18831899

protein baits, volatiles released by different kinds of plants in the environment and irradiation applied to insects at the pupal stage.

Our results provide a direct BdorOBP transcript analysis that represents new evidence for the role of olfactory proteins in the reception of protein baits and volatiles. We believe that these findings establish a foundation for understanding the molecular mechanisms by which OBPs contribute to olfactory recognition and have applications for integrated pest management techniques. However, an urgent need exists to identi characterize the remaining ten OBP genes of *B. dorsalis* in order to understand the transcriptional regulation of all OBPs in response to protein baits, volatiles and irradiation. The functional study of antennae-specific or antennae-enriched OBPs can assist us to better understand the involvement of OBPs in the mechanisms of insect olfaction with respect to different environmental stimuli and to design an odorant-based insect control strategy for the management of *B. dorsalis*.

Conclusions

Since its arrival in mainland China, *B. dorsalis* has become one of most destructive pests in orchards. Furthermore, this pest is presently spreading to more suitable areas of North China. The use of chemical insecticides remains the foremost way to control *B. dorsalis* in most developed countries, especially in China. In previous decades, various approaches have been established to monitor its detection and dispersal in order to minimize damage, and many studies have been carried out to interpret different aspects of its invasion mechanism. Further studies are still needed to understand its adaptation to new environments, resistance to chemicals, and high procreative ability. For the first time, we have evaluated the effects of different kinds of attractive baits, brewer's yeast volatiles and irradiation on the transcript expression levels of 10 OBP genes in the antennae of *B. dorsalis* during three adult physiological stages. Some BdorOBP genes are significantly up-regulated in response to the applied treatments, and others may play a vital role in mediating the response of males to irradiation, while OBP genes in females showed high transcript levels in response to different baits and brewer's yeast volatiles.

Acknowledgements. We express our appreciation to Ms Shumei Wang for rearing the *B. dorsalis*. This work was supported by the Institute of Beneficial Insects Laboratory, Fujian Agriculture and Forestry University, Fuzhou, Fujian Province, China. We sincerely thank Prof Lai Zhongxiong and Prof Zonghua Wang (Fujian Agriculture and Forestry University) for their kind help in allowing us to perform qRT-PCR experiments in their Laboratory.

(Received 6th Jul 2017; accepted 2nd Oct 2017)

Abstract. Banazi Black grape which is almost never consumed freshly is a very important, seed bearing, local type which is directly dried in the sun with its cluster without any processing. Ungrafted (5 years old and over 40 years old) and grafted (41B, 99R, 1103P and 110R) Banazi Black grape varieties which were 5 years old were used in the study conducted in Turkey, Malatya, Yesilyurt district, Konak town. The grapevines in the farmer vineyards, grown in dry conditions, were established in the form of blocks, serpene cultivation was applied on the stocks, and cane training was made. The photochemical characteristics of the dried grape belonging to the rootstocks used in 5 year-old Banazi Black grape which were ungrafted (5 and 40 years old ungrafted) and grafted with 41B, 99R, 1103P, 110R rootstocks were investigated in this study. It was determined from the analyzed phenolic compounds that gallic acid was 4.10-14.43 mg/kg; catechin was 146.87-306.87 mg/kg, rutin was 38.96-78.15 mg/kg, naringin was 22.54-50.97 mg/kg, phloridzin was 40.03-107.72 mg/kg, and quercetin was 0.47-1.67 mg/kg. Total antioxidant capacity in total phenolic substance rootstocks was determined to be 0.19-0.22 mg trolox equivalent/g; gallic acid/g was 7.51-21.66 mg. The amount of resveratrol was between 0.19-1.30 mg/kg among the rootstocks. The differences between the rootstocks were statistically significant in terms of phenolic compounds. 40 year-old ungrafted vinestock took a higher value when compared to the other rootstocks in terms of phenolic compounds.
Keywords: *dried grape, grafted-ungrafted, antioxidant content, phenolic content, Malatya*

Introduction

Turkey is an important vine cultivation center in the world. According to the data of TÜİK [Turkish Statistical Institute] (2016), 4,000,000 tones grapes, including 1,990,604 tones table, 1,536,269 tones dried, and 472,534 tones wine grapes, were grown totally in the 4,352,269 da. area in Turkey (Anonymous, 2017).

The farming of cultivated grapevine (*Vitis vinifera* L.) has been conducted in Turkey since 6000-5000 B.C. (Doğer, 2004). Grapevine is an important cultivated plant in Turkey as it is economical in terms of grape yield and a genetic material with its abundant varieties. (Celik, 1998; Celik et al., 1998). This abundance of the grapevine gene potential creates an important source for both the rehabilitation works and the production of the local types that have economic importance.

Grapevine has always kept its value among the agricultural products with its richness in terms of gene potential, its economic importance, and its significance in human nutrition and health. Generally, there are water, sugars, organic acids, phenol

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_19011915

compounds, pectic substances, aroma substances, nitrogenous substances, enzymes, vitamins and minerals in the compound of grapes (Fidan and Yavas, 1986; Canbas, 2003; Jackson, 2003).

The species and varieties of grapevines are the foremost plant species that are rich in phenolic compounds (Lohachoompol et al., 2004). These compounds are synthesized structurally in all organs of the grapevine and their proportions in fruit and seeds are affected by environmental conditions (Ough and Amerine, 1988).

Phenolic components which are defined as the secondary metabolism products of the plants are the primary natural compounds standing out with their antioxidant characteristics in terms of human health. According to scientific studies, phenolic compounds have antiallergic, antiinflammatory, antidiabetic, antimicrobial, antipathogenic, antiviral and antithrombotic effect (Knekt et al.,1996; Le Marchand et al., 2000; MacDougall, 2002; Aras, 2006; Kafkas et al., 2006).

One of the distinguishing characters of the colorful (red, black) grapes is phenolic compounds. It has been determined in the researches that colorful types are richer than white types in terms of phenolic substances (Cemeroğlu, 2004).

Just as each grape variety has a different tendency in terms of soil and climate, their response to the American grape-vine rootstock on which they are grafted may be different. For this reason, the most appropriate chemical component a grape type can reach is directly related to the soil structure and climate of the territory it is cultivated in and the rootstock on which it is grafted (Amerine et al., 1972; Jackson, 2000; Ribéreau-Gayon, et al., 2000; Canbas, 2006; Kelebek, 2009; Rolle et al., 2010).

There are some studies on the influence of the local grape varieties in Turkey, the vineyards that they are cultivated in, and the climatic conditions on the phenolic compounds of the grapes, yet these studies are not enough. However, vine cultivation activities are distributed in different geographical regions in our country which have different climatic characteristics. The fact that these regions have different characteristics in terms of climatic and soil conditions will make a difference in terms of phenolic compounds which directly affect the quality factor of our local grape varieties. For this reason, new studies which will deal with our local grape varieties the regions in which they are cultivated are needed.

Banazi Black grape is cultivated throughout Malatya, but it has specifically adapted to Konak town (Banazi), Yesilyurt and Akcadağ districts which are located in 1000-1300 m above sea-level (Koc et al., 2015).

People prefer ungrafted cultivation, since they think grapes have a specific taste, flavor, and color. However, the fact that the vineyards in the region are limy and waterless led people to use rootstocks resistant to lime and aridness. The use of rootstocks is important because it provides earliness in Banazi Black grape (Koc et al., 2015).

It was determined in the studies that phenolic compound concentration varies by grape variety, the environment it is cultivated and environmental factors. This study aims to determine some photochemical characteristics of Banazi Black grape, which has adapted to Malatya Yesilyurt ecology and is cultivated with or without grafting, within the scope of the significance of rootstock-variety relationship in vine cultivation.

Materials and methods

Material

Our study, the analyses of which were carried out in Malatya Apricot Research Institute research and application laboratories, was conducted in 2014 (38°16′53.31” N - 38°17′13.38” E, at 1290 m altitude) (*Figure 1*).

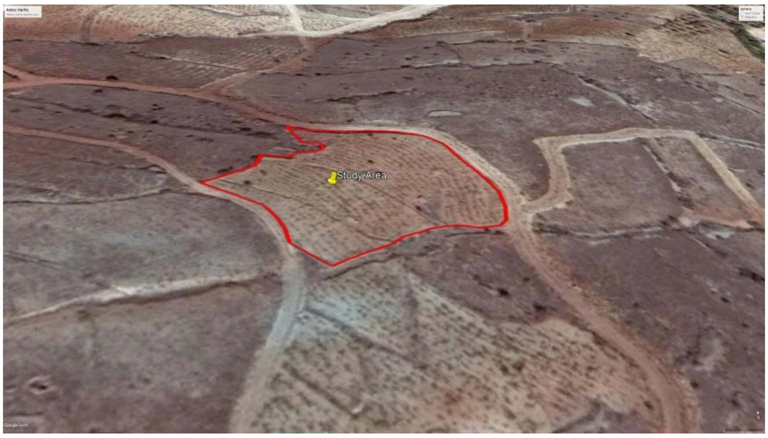

Figure 1. *The research center where the experiments were conducted*

The materials of the study are ungrafted 5 and 40-year old Banazi Black grape and 5 year-old Banazi Black grape variety grafted on 41B, 99R, 1103P, 110R American grape-vine rootstocks.

The study was conducted in the farmer vineyard, where serpene cultivation was applied on the stocks shaped like blocks in dry conditions with 2×2 distances and cane training was made, in the control of Malatya Apricot Research Institute personnel in Malatya Konak (Upper Banazi) area which is 1290 m above sea-level.

Banazi Black grape which ripens between September 10th and 20th is a seed bearing, local variety which is dried in clusters and put on market naturally. Grapes are blue-black, globular and moderate-sized. The fact that it is dried with its cluster provides a perceptual superiority for the consumer. The clusters are conical, medium (250 g-350 g) and dense (*Figure 2*).

Figure 2. *Fresh and dried Banazi Black grape fruit*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_19011915

It is not subjected to any chemical process during drying process. Harvest starts when the first withering appears on the grapes of the cluster on the stock. The clusters that are harvested are subjected to drying process either directly on the soil or on the cloths laid on the soil (*Figure 1*) Drying process lasts between 5-9 days (Koc et al., 2015).

Geographic position of the research location

Yesilyurt, which is one of the two central districts of Malatya with its surface area of 1013 km², is surrounded by Battalgazi on the east, Akcadağ and Doğansehir on the west, Celikhan and Adıyaman on the south, Yazıhan on the north. Yesilyurt district where the vineyard used in the test is located is on a transit area between Southeastern Anatolia Region terrestrial precipitation and Mediterranean Region marine precipitation, and between Eastern Anatolia Region terrestrial precipitation and Central Anatolia Region precipitation (Anonymous, 2015).

Soil characteristics of the research location

Earth sample taken from 0-30 cm depth in the vineyard was analyzed in Malatya Apricot Research Analysis Laboratory (*Table 1*).

Table 1. *Soil analysis values of the test field*

Saturation (%)	**pH**	**Total salt (%)**	**Lime (%)**	**Organic matter (%)**	**EC (µS/cm)**	**P (kg/da)**	**K (kg/da)**
51.70	7.75	0.0228	37.90	1.33	0.69	8.48	77.89

It can be seen on *Table 1* that since saturation value is 51.70, vineyard where the research was conducted has “Clay-Loam” soil. It can be seen that the test field is saltless with a value of 0.02%, is very limy with 37.90% lime ratio, has low organic substance with 1.33% ratio, and has an adequate structure with 8.48 kd/da phosphor and 77.89 kg/da potassium. It was determined that it had loose-alkali structure with 7.75 pH and its electrical conductivity EC (mS/cm) value was 0.690. As a consequence of the soil analysis 300-400 g sulfur and 15-20 kg burnt farm manure were applied on each stock during the early spring.

Climatic characteristics of the research location

Some important meteorological data belonging to Malatya-Yesilyurt district ecology where the research was conducted are given on *Table 2* and *Table 3* (Anonymous, 2015).

The ripening of the clusters belonging to the stocks coincided with September in which the average temperature was 22.7 °C during the time when the research was conducted in 2014. During the harvest season in this year total precipitation was 53.8 mm for September, monthly average relative humidity was 32.6%, and minimum temperature was 8.3 °C for September, 2014 (*Table 3*).

Method

The test was planned to be in three repetitions with 6 stocks for each one in the vineyard where the research was conducted, which was shaped like blocks.

Sampling

Sample grape clusters for each stock and each of the three repetitions were taken when the first withering started on the clusters of the stocks (Koc et al., 2015), the color and taste specific to the variety formed and the dry matter amount reached to 23-24 Brix value, and these samples were left for drying on cloth shelves.

The grapes on the dried clusters belonging to the stock in each repetition were plucked and ground in blenders. These samples were put into glass jars to be analyzed later and kept in -20 °C.

Extraction of the phenolic components

2.5 g was taken from the Banazi Black grape sample which was dried, ground, and homogenized, and it was put into a falcon tube of 50 ml. 15 ml of methanol:water:HCI (70:29, 9:0.1) solvent mixture which was prepared previously was added on the sample and it was homogenized. The samples which were kept in dark for 12 h were centrifuged at 9000 rpm and transferred to a new supernatant falcon tube. 15 ml solvent mixture was added on the residue and it was mixed and centrifuged again. The supernate was added to the previous one. Extraction process was repeated for the third time. After about 45 ml of extract was obtained, the same extract was evaporated in a vacuum evaporator in inert environment until dryness. Rhe residue was dissolved with 3 ml methanol:water (50:50), syringed, filtered through 0.45 µm cellulosic filter, and the final filtrate was used in the determination of phenolic components, total phenolic substance amount and total antioxidant capacity (Milan et al., 2011).

Determination of phenolic components with HPLC

First, RT (retention time) in HPLC system and wavelength were determined for each of the 17 different phenolic standard compounds (*Table 4*). Then, mixture standard including all phenolic compounds was prepared and its calibration chart was drawn. Two different solvent mixtures were used as the mobile phase.

Mobile Phase A: Water: Acetic Acid (95.5%: 4.5%), Mobile Phase B: Acetonitrile

Table 4. *Gradient program applied on HPLC system*

Determination of total phenolic substance amount

The content of total phenolic compound was determined according to Folin-Cicalteu spectrophotometric method developed by Slinkard and Singleton (1977) in the study. “Folin & Ciocaltue” method was used to determine total phenolic substance amount and total phenolic substance values were measured in terms of gallic acid. After 50 µl was taken from the extracts and 950 µl water was added on it, 1 ml of Folin-Ciocaltue solution was added and it was kept waiting for 3 min. After this period, 1 mL was made 3 mL with 2% Na_2CO_3 solution, it was kept waiting for 10 min, and reaction was balanced. Absorbances of the colored solutions were measured to be 760 nm in terms of wavelength.

Determination of total antioxidant capacity

Two tests, DPPH Radical Scavenging Power Test and TEAC (Trolox Equivalent Antioxidant Capacity) were carried out.

DPPH radical scavenging power test

Radical scavenging power (RSP) measurement was carried out according to formula 1 suggested by Yen et al. (2000). The samples which were prepared in 1.10-4 M DPPH ethanol were left for incubation at ambient temperature with extracts obtained from grape samples in 0.1 ml of different concentrations and 2.9 ml of DPPH solution that were put into in spectrophotometer tubs. During the control, ethanol was put instead of the sample. The absorbance of the tubes was read against 517 nm after 30 min of incubation. RSG values were calculated according to the following formula (*Eq. 1*).

$$RSG = [1 - \frac{A_{Ö:30}}{A_{K:30}}] \times 100 \quad (1)$$

$A_{Ö:30}$: For example, absorbance in the 30^{th} min of $A_{K:30}$: Control

TEAC (Trolox Equivalent Antioxidant Capacity) test

7 mM ABTS (2,2-Azinobis 3-ethylbenzothiazoline 6-sulfonic acid) was mixed with 2.45 mM potassium bisulfate and it was kept waiting in a dark environment for about 12-16 h. This solution was purified with 0.700±0.01 absorbance in 734 nm wavelength with sodium acetate (pH 4.5) buffer in spectrophotometer, 2.98 mL of the solution was blended in 20 µL fruit extract, and the absorbance was measured in 734 nm wavelength in spectrophotometer ten minutes later. The obtained absorbance values were calculated with Trolox (10-100 µmol/L) standard slope chart and it was stated as µmol Trolox equivalent/g fruit (Özgen et al. 2006).

Statistical analysis

SPSS packaged software was used in determining the influence of rootstocks on photochemical characteristics and the differences between the averages were stated with Duncan multiple comparison test. 3 repetitions and the averages of 10 clusters taken from 6 vinestocks in each repetition were used for the characteristics measured in the study. Statistical materiality level was considered as $P < 0.05$.

Results

Findings concerning the change of phenolic components

Quercetin, catechin, gallic acid, rutin, naringin and phloridzin dehydrate in Banazi black were found to be in identifiable levels. As can be seen in *Table 5,* the examined phenolic compounds were statistically significant in comparison with the rootstocks. Average gallic acid was determined to be at the lowest amount in 99R rootstock (4.10 mg/kg) and at the highest amount in 40-year old ungrafted vinestock (14.43 mg/kg). Catechin was at the lowest amount in 110R rootstock (146.87 mg/kg) and at the highest amount in 40 year-old ungrafted vinestock (306.87 mg/kg). Rutin was at the lowest amount in 99R rootstock and at the highest amount in 40-year old ungrafted vinestock (38.96-78.15 mg/kg). Naringin was determined in ungrafted young and 40 year-old vinestocks with 22.54-50.97 mg/kg, Phloridzin was in 99R and 40 year-old ungrafted vinestocks with 40.03-107.72 mg/kg, and Quercetin was in 110R and 40 year-old ungrafted vinestocks with 0.47-1.67 mg/kg.

Table 5. *Some phenolic compounds in detectable levels in the study*

Rootstocks	Gallic acid mg/kg dry	Cateşin mg/kg dry	Rutin mg/kg dry	Naringin mg/kg dry	Phloridzin mg/kg dry	Quercetin mg/kg dry
Ungrafted (young)	5.164bc	212.60b	75.44ab	22.54b	50.22c	0.65c

*$P < 0.05$ level of significance. Different letters show that the difference between the averages is significant according to Duncan test

Taking the average values into consideration, 99R and 110R rootstocks, known to be late season variety, were at lower levels when compared to the other rootstocks in terms of the determined phenolic compounds. The values of the clusters obtained from 40 year-old ungrafted vinestocks were recorded to be higher than the other rootstocks' values.

Total antioxidant capacity (TAC)

There was no statistically important difference among the rootstocks in terms of free radical (DPPH) removal activity in determining total antioxidant capacity (TAC) in the study. TAC values were determined to be 0.19-0.22 mg /g between the rootstocks (*Table 6*).

It can be seen from *Table 6* that there were statistically significant between the rootstocks in determining TEAC (trolox equivalent antioxidant capacity). While the lowest average value was obtained from 99R rootstock, the highest value was determined to be in the clusters obtained from 40 year-old ungrafted vinestocks (0.17-0.70 mg/g). The values in other rootstocks were young ungrafted vinestock 0.18 mg/g, 1103P 0.59 mg/g, 110R 0.49 mg/g, 41B 0.50 mg/g.

*$P < 0.05$ level of significance. Different letters show that the difference between the averages is significant according to Duncan test

Bozan et al. (2008) revealed in their study, in which they investigated the antiradical effects of different grape varieties growing in our country, that different grape varieties removed DPPH radical in different proportions with the effect of their different phenolic contents.

Total phenolic substance amount (TPSA)

Average total phenolic substance amount (TPSA) in dried Banazi Black grape variety changed between 7.51-21.66 mg gallic acid/g. The differences between the rootstocks in terms of TPSA were considered statistically significant in our study. The lowest value was obtained from 99R rootstock and the highest value was obtained from 41B rootstock and 40 year-old ungrafted vinestocks (21.66-21.37 mg gallic acid/g). TPSA in the clusters obtained from the other rootstocks was 110R 17.08 mg/g, 1103P 14.73 mg gallic acid/g and TPSA in ungrafted young vinestock was 11.60 mg gallic acid/g.

Özden and Vardin (2009) determined in their study that Chardonnay (3170 mg/kg) variety had high phenolic substance amount, followed by 2376 mg/kg Merlot 9 variety, and total phenolic contents of Cabernet sauvignon and Syrah varieties were 1968 and 1805 mg/kg, respectively.

Alphonse Lavallèe and Horoz Black grape varieties were determined to be the ones with the highest production of total phenolic substances, 3.084 and 2.832 mg/g, respectively (Cetin, 2012).

In the study on ripe grapes belonging to 12 wine grape varieties, Singleton (1966) determined that total phenolic compound amount in terms of gallic acid was 3770 mg/kg as an average value (when it is converted into the unit in our study, the result is 3.77 mg/g). The researcher also determined that phenolic compound amounts were different according to species and varieties.

Resveratrol

It was determined as a result of the analyses that Banazi Black grape contained the phenolic compound named in many studies as resveratrol, which has antioxidant, antimutagenic, antiinflammatory, anticarcinogenetic and chemoprotective effects.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_19011915

Resveratrol amount changed in 0.19-1.30 mg/kg between the rootstocks. The lowest average value was determined in the grapes obtained from 41B rootstock and the highest value was determined in the grapes obtained from young ungrafted vinestocks. For 40 year-old ungrafted ones, it was determined to be 0.32 mg/kg, 1103P 0.49 mg/kg, 110R 0.71 mg/kg and 99R 0.49 mg/kg (*Table 6*).

The flavonoid contents of 500 µl fruit extract of Banazi Black are 1523.07 µg catechin, 591.79 µg rutin and 1.6661 µg resveratrol (Özşahin, 2010).

Discussion

In this study, the changes of young-old and rootstock-variety performances in the levels of phenolic compounds, total antioxidant capacity (TAC), total phenolic substance amount (TPSA) and resveratrol after Banazi Black grape variety, which has an important position in Malatya as seed-bearing grape for drying with its gene potential, was grown on different rootstocks in its original ecology were investigated within the scope of the importance of rootstock-variety relationship in vine cultivation practices.

Because common and interconverted units are not used to evaluate phenolic compound results in literature studies, the comparison and discussion of the results have become a problem. For this reason, the obtained values were compared to the studies using similar or interconvertible units (mg/kg, mg/100g, mg/g, g/kg etc.).

The differences among the rootstocks in terms of TPMS amount were considered statistically significant in our study. According to the averages, the lowest value was obtained from Banazi Black grape grafted on 99R rootstock, the highest value was obtained from Banazi Black grape grafted on 41B rootstock and 40 year-old ungrafted vinestock (21.66-21.37 mg gallic acid/g). Taking the worldwide known wine grape varieties such as Cabernet sauvignon (1968 mg/kg), Merlot (2376 mgkg), Syrah (1805 mg/kg) and edible variety Alphonse Lavallée (3466 mg/kg) into consideration (Singleton, 1966; Núñez et al., 2004; Özden and Vardin, 2009; Kelebek, 2009) 7.51-21.66 mg gallic acid/g values (when the units were converted, Cabernet sauvignon 1.968 mg/g, Merlot 2.376 mg/g, Syrah 1.805 mg/g, Alphonse Lavallée 3.466 mg/g) obtained in our study were over these limits.

Aras (2006) determined that TPSA content changed between 2.88-3.42 mg/g for red grapes and 1.87-2.22 mg/g for white varieties. Karakaya et al. (2001) reported that total phenolic substance amount was 3.99 mg/g for dried grapes and 2.21 mg/g for red grapes. When these data are compared to the ones in our study, we can say that Banazi Black grape contains a very high amount of TPSA.

According to studies, while TPSA concentrations of black grapes are 1800 mg/kg on average, this value is 405 mg/kg for white varieties (Frankel et al., 1995; Shahidi and Naczk, 1995).

Cultivation conditions, rootstocks that are used, grape variety, and extraction and analytical methods that are used are considered to have an effect on the values found by the researchers.

Free radical (DPPH) removal activity was determined to be 0.19-0.22 mg/g (41B and 99R) in determining total antioxidant capacity (TAC) in the study. There was no statistically important difference among the rootstocks.

The differences among the rootstocks were considered statistically significant in determining TEAC (trolox equivalent antioxidant capacity). In terms of the averages,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_19011915

the lowest value was obtained from Banazi Black grape grafted on 99R rootstock and the highest value was in ungrafted old vinestock (0.17-0.70 mg/g).

Banazi group in the samples of 25µl concentrations had radical cleaning effect in a very significant proportion when compared to the other samples in a study comparing free radical cleaning activities of the grape extracts (Özsahin, 2010).

When Bozan et al. (2008) investigated the antiradical effects of different grape varieties cultivated in our country, they revealed that different grape varieties removed DPPH radical in different proportions because of their different phenolic contents.

According to a study, while CAT (catalase antioxidant enzyme) activities of Sultani seedless grape variety grafted on 1103P, 110R and 41B rootstocks in low salt concentration increased, CAT activities of Sultani seedless grape variety grafted on 1616C and 1103P rootstocks in high salt concentration increased. SOD (super oxide dismutase) activities of Sultani seedless grape variety grafted on 1103P, 110R and 99R rootstocks in high salt application increased. On the contrary, SOD activities of Sultani seedless grape variety grafted on 140Ru and 41 B rootstocks decreased. In low salt application SOD activity on 1616C 140Ru, 110R and 41B rootstocks decreased. According to the control, AP (ascorbate peroxidase) activities of Sultani seedless grape variety grafted on 110R, 99R and 41B rootstocks in low salt application increased while AP activities of 1616C and 140Ru rootstocks decreased. AP activity of Sultani seedless grape variety grafted on 110R rootstock in high salt application increased (Sahin, 2009).

This study on Sultani seedless grape grafted on different rootstocks show that the effect of rootstocks on antioxidative enzyme activities is significant. According to our study, the statistical differences in TEAC determination on six rootstocks belonging to a single variety resulted from the rootstocks.

Quercetin, catechin, gallic acid, rutin, naringin and phloridzin dihydrate were found in detectable levels in the extracts of dried Banazi Black grape in our study. Gallic acid was determined to be at the lowest amount in Banazi Black grape grafted on 99R rootstock (4.10 mg/kg) and at the highest amount in ungrafted old vinestock (14.43 mg/kg). Catechin was at the lowest amount in Banazi Black grape grafted on 110R rootstock (146.87 mg/kg) and at the highest amount in ungrafted old vinestock (306.87 mg/kg). Rutin was at the lowest amount in Banazi Black grape grafted on 99R rootstock and at the highest amount in ungrafted old vinestock (38.96-78.15 mg/kg). Naringin was determined in ungrafted young and old vinestocks with 22.54-50.97 mg/kg, Phloridzin was in Banazi Black grape grafted on 99R and ungrafted old vinetocks with 40.03-107.72 mg/kg, and Quercetin was in Banazi Black grape grafted on 110R and ungrafted old vinestocks with 0.47-1.67 mg/kg. According to a study, the amount of total phenols increase with the ripening of leaves; old leaves on the same vinestock contain more phenolic compounds than young leaves (Medeghini et al., 1992). According to our study, the phenolic compound amount obtained from ungrafted old vinestocks is higher than the phenolic compound amount obtained from Banazi Black vinestocks produced as young grafted and ungrafted vinestocks.

The differences among the detected phenolic compounds were considered statistically significant in the rootstocks. Taking these values into consideration, it is considered that the rootstocks used in our study are effective on phenolic compound amount.

In another study done by Aydınlık (2012), phenolic substance analyses of the grape molasses (pekmez) samples produced in Niğde were conducted with the method of HPLC. It was found out that grape molasses (pekmez) samples contained gallic acid,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_19011915

catechin, caffeic acid, epicatechin, p-coumaric acid and ferulic acid and their concentrations were 47.94±2.58, 148.69±11.17, 20.7±2.08, 101.25±5.8, 12.24±1.65 and 18.26±2.58 mg/kg, respectively.

Resveratrol amount changed between grafted and ungrafted rootstocks in 0.19-1.30 mg/kg. the lowest value was obtained from Banazi Black grape grafted on 41B rootstock and the highest value was obtained from the young vinestock without rootstocks.

Flavonoid and resveratrol contents of Banazi Black grape extracts were determined to be 1980.00±2.88 mg/g for catechin, 769.33±2.33 mg/g for rutin, 2.16±0.16 mg/g for resveratrol (Özsahin, 2010). These values show that Banazi Black grape has a rich phenolic substance source in harmony with our study.

Bartolomeo (1996) and Zhao (1999) reported that the fundamental phenolic content of the grape consisted of resveratrol, catechin ve epicatechin. In addition, the studies showed that grape was a rich phenolic compound source and 46-69% of these phenolic compounds was in the seed, 12-50% was in the skin, 8% or less was in the pulp.

Phenolic substance amount of the grapes change depending on the variety, ripeness, environmental conditions such as climate and soil and applied cultural processes (Ribéreau-Gayon et al., 2000). However, the quality and quantity of phenolic compounds of grapes depend on grape variety. While the existence of certain phenolic substances and the proportions of their amounts to each other depend on the characteristics of species and varieties genetically controlled, total phenolic substance amount or the sort of phenols in the compound depend on environmental factors (Singleton and Esau, 1969).

The content of phenolic compounds changes based on the soil conditions in which the vinestock is cultivated and cultural applications. The soils with high sodium content and pH reduce phenolic substance amount in the seed, peel and stem (Quintana and Gomez, 1989), and irrigation applications increase total phenol amount in leaves and offshoots (Madero et al., 1978). Besides, the form of cultivation, rootstock and herbicide applications affect the content of phenolic substances in the vinestock and grape (Bezhanishvili et al., 1982; Smart and Smith, 1988). In line with our study, these studies conducted by other researchers show that rootstocks are effective in terms of phenolic compound contents.

In addition to the reasons reported in the previous studies, the difference in the values of our study may result from the fact that dried Banazi Black grape is ground and analyzed with its peel, pulp and seed and from the rootstocks that are used. As a matter of fact, according to a study, the 38% of the total phenol content of red and white grape varieties is seeds, 36% is peel, 20% is stem and 6% is pulp (Flanzy et al., 1972).

The researchers who determined that pure and hybrid rootstocks used in modern vine cultivation has different effects based on the content of grape juice, wine quality and coloration (Ruhl, 1991; Bisson, 1992; Kaserer and Schofll, 1994) reported that sugars, amino acids, pH and K level in the content of anthocyanin, acidity and grape peel color changed with grafting, and acidity increased excessively with the increase in productivity and affected wine quality.

Conclusion

One of the oldest forms of conserving fruits and vegetables is drying, its importance still continues. Drying grapes for preserving is the easiest and most economical way of conservation that has been implemented for years (Dokuzoğuz, 1972).

Because both edible grapes and various products produced from them are rich in phenolic compounds and they have bioactive characteristics for human health, grape, especially black grape, is a food product that must be a part of our nutrition.

When the data in this study is taken into consideration, the fact that grafting is effective on Banazi Black grape type produced with or without grafting, with regard to Resveratrol, Total Phenolic Substance amount, Total Antioxidant Capacity and some Phenolic Compounds, becomes more important. The obtained results are expected to provide an insight into the studies that will be conducted in future, since the current study is the first study conducted on dried grape of "Banazı".

(Received 13th Jul 2017; accepted 5th Oct 2017)

Abstract. The aim of this paper is to determine the effect of soil conditioners and one mineral fertilizer on turf, as well as their interaction with meteorological conditions in maintaining of lawn compactness. The field experiment was conducted in the experimental facility between 2013 and 2015. The following grass species were used in the experiment: *Lolium perenne*, *Festuca rubra*, and *Poa pratensis*. Another experimental factor tested in the research was soil conditioners. Between 2013 and 2015 an assessment of grass compactness based on the methods described by Domański (1998) was carried out. This assessment was conducted in three seasons: spring, summer, and autumn. Grass species tested in the experiment formed turf of different compactness, varying throughout seasons of the year and responding strongly to weather conditions. In drier periods red fescue had better turf, contrary to smooth meadow grass and perennial ryegrass, both of which had better turf in more humid conditions. Out of all the types of fertilizer Humus Active Papka affected turf compactness in the most favourable way although the response of individual grass species was not the same. From a practical point of view out of the grass species tested in the experiment *Poa pratensis* treated with Eko-Użyźniacz responded the most favourably.
Keywords: *compactness, turf quality, red fescue, smooth meadow, grass perennial ryegrass*

Introduction

Architects dealing with spatial planning pay more and more attention to green areas, with lawns, relatively inexpensive to set up, being their important element. Lawns have multiple functions, from environmental, through sanitary-hygienic, to recreational and aesthetic (Czeluściński et al., 2017).

The increase in the standard of living in Poland and other countries is accompanied by the awareness of the importance of green areas and the need for an attractive and healthy environment (Watsson et al., 1992). Lawns are common in parks, gardens, streets, squares, and recreational areas (Ignatieva et al., 2015; Bertoncini et al., 2012; Stewart at al., 2009). Dense and uniform turf is the most important element of lawn functional value (Domański 1998; Grabowski et al., 1999; Harkot and Czarnecki, 2001; Harkot et al., 2006; Jankowski et al., 2010, 2011a; Prończuk et al., 1997). According to Jankowski et al. (2011d, 2012a) as well as Rutkowska and Pawluśkiewicz (1996) turf quality largely depends on its treatment and maintenance, on habitat conditions, but also on the proper selection of grass species and varieties used to set up a lawn (Wheeler et al., 2017).

Grass is commonly used for lawns, regardless of their type. Some 160 grass species can be found in Poland (Prończuk and Żurek, 2008). Yet, with such a huge number only 16 species are suitable for lawns. *Festuca rubra* (red fescue), *Poa pratensis* (smooth

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_19171928

meadow grass), and *Lolium perenne* (perennial ryegrass) are grass species most common on lawns used extensively (Jankowski et al., 2012b).

To a large extent lawn quality depends on frequent watering, which in turn affects maintenance costs (Jankowski et al., 2011a; Jankowski et al., 2011b; Jankowski et al., 2011c; Jankowski et al., 2011d; Jankowski et al., 2011e). The use of modern watering systems is not always a good solution. Usually those systems are too expensive and not every owner can afford such an investment (Jankowski et al., 2012a).

With the growing interest in the use of environmentally friendly products, numerous soil conditioners have been approved for the use in green areas, fulfilling the role of fertilizer, or chemicals used in plant protection. Continuous progress in the studies on soil conditioners shows their competitiveness in relation to conventional solutions.

The aim of this paper is to determine the effect of soil conditioners and one mineral fertilizer on turf, as well as their interaction with meteorological conditions in maintaining of lawn compactness. The study deals with practical aspects of the impact of soil conditioners on the compactness value of individual species of lawn grass. In addition, the research aims at getting information about the extent to which soil conditioners can replace mineral fertilizer without degrading functional value of the lawn.

Material and methods

Set up in 2012 the field experiment was conducted in the experimental facility of the University of Natural Sciences and Humanities in Siedlce (52°12'N, 22°28'E) between 2013 and 2015. The research was carried out as a mini-plot experiment, in the split plot design with three replications and the plot area of 1 m^2. The following grass species were used in the experiment (factor B): *Lolium perenne* -variety Info, *Festuca rubra* -variety Nil, and *Poa pratensis* -variety Alicja. They were sown on their own, each of them at the rate of 28 g/m^2. Another experimental factor tested in the research was soil conditioners (factor A)

Soil conditioners used in the experiment improve soil properties, according to the Institute of Soil Science and Plant Cultivation (IUNG) in Puławy. The composition of the soil conditioners used in the research is presented in *Table 1*.

The UGmax soil conditioner is an extract from compost, containing macronutrients (N, P, K, Mg, Na) and micronutrients (Mn). It also contains lactic acid bacteria, photosynthetic bacteria, *Azotobacter*, *Pseudomonas*, yeast, and *Actinomycetes*. The micro-organisms in the conditioner have a capacity of processing organic and natural fertilizers into compost and humus. These processes are conducive not only to the production of humus but also to improving soil structure, which in turn has a positive effect on water balance in the soil. In addition, the UGmax soil conditioner increases disease resistance, keeping plants healthy, but it also stimulates the development of the root system and supports the biological reduction of molecular nitrogen.

Humus Active Papka contains macronutrients (N, P, K, Ca, Mg), trace elements (Mn, Fe, Zn, Cu), and active humus with useful microorganisms. According to the manufacturer Humus Active, among other beneficial effects, positively affects plant health as well as soil structure, and releases nutrients not readily available to plants.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_19171928

Table 1. *Composition of soil conditioners applied in the experiment.*

Soil conditioner	Macronutrients ($g \cdot kg^{-1}$)					Micronutrients ($mg \cdot kg^{-1}$)						Microorganism and others
	N	**P**	**K**	**Ca**	**Mg**	**Na**	**Mn**	**Fe**	**Zn**	**Cu**	**Mo**	
Substral (S)	220	21.8	83		12.06		12	50	12.5	12.5	1	-
Humus Astive Papka (HAP)	0.2	1.3	4.6	3.0	0.5	-	15	500	3	1	-	Active humus with useful microorganisms
Eko-Użyźniacz (EU)	0.6	0.3	0.7	-	-	-	-	-	-	-	-	Endo micorhizza, fungi, bacteria, enzymes of earthworms
UGmax (UG)	1.2	0.2	2.9	-	0.1	0.2	0.3	-	-	-	-	lactic acid bacteria, photosynthetic bacteria, Azotobacter, Pseudomonas, yeast, Actinomycetes

Eko-Użyźniacz is extracted from bovine vermicompost and contains the main macronutrients (N, P, K), micro-organisms, and enzymes related to metabolism of earthworms. This soil conditioner stimulates biological life in soil degraded chemically, mechanically, or biologically, and increases plant resistance to different stress factors.

Soil conditioners were applied annually in spring (mid May) in the following doses: UGmax – 25 ml $\cdot$ m^{-2} (0.6 l in 250 l of water), Eko-Użyźniacz - 100 ml $\cdot$ m^{-2} (10 l in 100 l of water), and Humus Active Papka - 250 ml $\cdot$ m^{-2} (0.2 l for 10 l of water). In turn, Substral, a slow release fertilizer used on lawns, was used in the quantity of 20 g $\cdot$ m^{-2}.

At the end of each growing season between 2013 and 2015 an assessment of grass based on the methods described by Domański (1998) was carried out. Among other things its compactness was assessed in accordance with the methodology by Prończuk and Żurek (2008), using a 9-point rating scale in which 1 stands for no aesthetic value; 3 for unattractive appearance; 5 for average; 7 for attractive; 9 for very attractive. This assessment was conducted in three seasons: spring, summer, and autumn. In each year of the research spring assessment was made around May 20, summer assessment around 20 August, and autumn assessment around October 10.

The experiment was set up on the soil developed from loamy sand, belonging to anthropogenic soils of the culture-earth order, and of the type of hortisole (Systematics of Polish Soils). Chemical analysis showed that the soil was alkaline, with high content of magnesium and phosphorus, and low potassium content. The test results were evaluated statistically with the analysis of variance. Tukey's test ($P \leq 0.5$) was used to find significantly different means of the effects of experimental factors and their

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_19171928

interaction. Based on lawn appearance ratings, standard deviation and coefficient of variation were calculated for separate seasons, years, and soil conditioners.

Weather conditions

Meteorological data between 2013 and 2015 were obtained from the Hydrological and Meteorological Station in Siedlce. The average air temperature during the experiment was very similar to the long-term average temperature *(Table 2)*. In each year of the research the highest temperature was in July (19.3 on average) and August (19.0), while the lowest temperature, taking into account only the growing season, was in April (an average of 8.5) and October (an average of 8.2).

Table 2. *Average air temperature (°C) and precipitation (mm) in individual months of the growing seasons.*

Year	Month							
	Apr.	**May**	**June**	**July**	**Aug.**	**Sept.**	**Oct.**	**Means**
Temperature (°C)								
2013	7.5	15.3	17.7	18.8	18.3	11.4	9.6	14.1
2014	9.7	13.7	15.1	20.5	17.8	13.7	8.4	14.1
2015	8.2	12.3	16.5	18.7	21.0	14.5	6.5	14.0
Means	8.5	13.8	16.4	19.3	19.0	13.2	8.2	14.1
Long-term means	8.5	14.0	17.4	19.8	18.9	13.2	7.9	14.2
Rainfall (mm)								
2013	57.6	145.8	111.9	49.1	44.1	86.6	18.0	73.3
2014	39.5	79.5	74.2	37.5	105.7	26.3	3.0	52.2
2015	30.0	100.2	43.3	62.6	11.9	77.1	39.0	52.0
Means	42.4	108.5	76.5	49.7	53.9	63.3	20.0	59.2
Long-term means	33.0	52.0	52.0	65.0	56.0	48.0	28.0	47.7

A meteorological element with major temporal fluctuations is rainfall (Skowera and Puła, 2004). By analyzing its amount in different months of the experiment it was found that the lowest average monthly precipitation was in 2015 (52.0 mm), but still it was higher by 2.3 mm than the long-term average. In the growing season of 2013 the average monthly precipitation of 73.3 mm was the highest. May 2013 was a month in which rainfall was the highest of all months during the experiment (145.8 mm). The lowest rainfall was recorded in October 2014 (3.0 mm) and August 2015 (11.9 mm).

In order to determine the temporal variation of meteorological elements and their effects on vegetation, Sielianinov's hydrothermal coefficient (Bac et al., 1993) was calculated on the basis of monthly rainfall (P) and the monthly total air temperature (Σt), using the formula: $K = P/0.1\ \Sigma t$ (Skowera and Puła, 2004).

In assessing temperature and moisture conditions ten-scale classification of Sielianinov's hydrothermal coefficient (K) was used, which, according to Skowera and Puła (2004), has the following ranges:

$K \leq 0.4$ extremely dry (ss);
$0.4 < K \leq 0.7$ very dry (bs);
$0.7 < K \leq 1.0$ dry (s);

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_19171928

$1.0 < K \le 1.3$ quite dry (ds);
$1.3 < K \le 1.6$ optimal (o);
$1.6 < K \le 2.0$ quite wet (dw);
$2.0 < K \le 2.5$ wet (in);
$2.5 < K \le 3.0$ very wet (bw);
$K > 3.0$ extremely wet (sw).

The values of Sielianinov’s hydrothermal coefficient for individual months of the experiment are shown in *Table 3*. It was assumed that the conditions were extreme when coefficient values were below 0.7 and above 2.5 (Skowera and Puła, 2004).

Table 3. *Sielianinov’s hydrothermal coefficient (K) during the growing season.*

Years	Month						
	Apr.	**May**	**June**	**July**	**Aug.**	**Sept.**	**Oct.**
2013	2.56 (bw)	3.07 (sw)	2.11 (w)	0.84 (s)	0.78 (s)	2.53 (bw)	0.60 (bs)
2014	1.36 (o)	1.87 (dw)	1.64 (dw)	0.59 (bs)	1.92 (dw)	0.64 (bs)	0.12 (ss)
2015	1.22 (ds)	2.63 (bw)	0.87 (s)	1.08 (ds)	0.18 (ss)	1.46 (o)	1.94 (dw)

Optimal temperature and moisture conditions were only in April 2014 and in September 2015. In the remaining months of all the growing seasons the weather conditions were not as favourable, varying from extremely dry in August 2015 to extremely wet in May 2013. Throughout the experiment the best conditions occurred at the beginning of each growing season. It can be concluded that the most difficult period for plants was in 2015, when, apart from May and the end of the growing season, the weather conditions ranged from quite dry to extremely dry.

Results and discussion

According to different authors (Prończuk et al., 1997; Harkot and Czarnecki, 2001; Jankowski et al., 2011a), dense and uniform turf has a big impact on the functional value of a lawn. Lawn appearance is one of the most important features determining its compactness. Rutkowska and Pawluśkiewicz (1996) point out that turf compactness is influenced by many factors, such as environmental conditions, the kind and frequency of maintenance treatment, the appropriate selection of grass species and varieties, and the way in which the lawn is used.

Table 4. *Assessment of turf compactness (9-point scale) in the spring from 2013 to 2015.*

Year (C)	Species (B)	Fertilizers (A)				$\bar{x}$
		(S)	**(EU)**	**(HAP)**	**(UG)**

$LSD_{0.05:}$ A=NS; B=NS; C=NS; A/B=NS; B/A=NS; A/C=1.04; C/A=0.93; B/C=0.81.; C/B=0.81.

Turfs of the lawns studied in this experiment were diverse both in terms of the species tested and the fertilizer applied. Their compactness changed throughout years and seasons of research. Assessment of the lawn turfs showed that their quality in the spring (*Table 4*) varied throughout the experiment, and it was different for different species of grass. In the spring of the first and third year red fescue had the best turf (8.9^{o}) in comparison with the other species. In turn, in the second year (2014) the compactness of this grass was the worst of all of them (7.3°). These differences were statistically significant.

Changes in the compactness of red fescue turf were related to the weather. Red fescue is one of those species that reach optimum development in habitats with variable water conditions and often even in dry places. Therefore, in 2013 and 2015, in which years there were a lot of dry periods (*Tables 2 and 3),* this grass formed a good quality turf. Similarly, in the studies of Grabowski et al. (1999) and Jankowski et al. (2011c) seeding mixtures with a high proportion of red fescue formed the best turf. According to Golińska (2002) high turf-forming potential of red fescue is a specific and important feature.

Throughout the research in the spring seasons (*Table 4)* both smooth meadow grass and red fescue had the best turf, both at the level of 8.4°, as the average of three years between 2013 and 2015. According to Martyniak and Prończuk (2003), chewings fescue has rhizomes of varying length underground, and they form very strong and dense turf. Therefore, it is an excellent grass with good compactness turf on grassland, lawns, and other areas. Additionally, comparing different species with different types of fertilizer applied, it was found that the best turf in the spring was on the plot with red fescue treated with UGmax (8.9°). The worst lawn (7.8°) was on the plot with perennial ryegrass, also treated with UGmax. In the case of smooth meadow grass lawn compactness did not vary much (from 8.4 to 8.5°), no matter what type of fertilizer was used. In the studies of Kitczak et al. (2000) smooth meadow grass had a better turf than a mixture with perennial ryegrass.

Assessing the effect of fertilisers in the spring it was found that for all of the grass species turf compactness was similar, no matter whether Substral, Humus Active Papka, or UGmax was applied, being at the same level of 8.4°. Eko-Użyźniacz was an exception causing slightly weaker lawn compactness (8.1°)

Assessing the effect of different forms of fertilizer in different spring seasons, turf of the best compactness was in the spring of 2015 (from 8.3 to 8.7°). That year the best

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_19171928

grass was on the plots with Humus Active Papka (8.7°) and Eko-Użyźniacz (8.6°). Similarly, in 2013 these forms of fertilizer ensured the best lawns (8.6 and 8.3°, respectively). In 2014, which was the wettest year (*Tables 2* and *3*), turf on plots treated with Humus Active Papka and Eko-Użyźniacz was the worst (7.2 and 7.5°, respectively), but it was best of all as a result of UGmax (8.8°) and Substral (8.6°) application. Statistical analysis showed a significant interaction between the year of the research and the form of fertilizer in their impacts on turf compactness.

Table 5. *Assessment of turf compactness (9-point scale) in the summer from 2013 to 2015.*

Year (C)	Species (B)	Fertilizers (A)				$\bar{x}$
		(S)	(EU)	(HAP)	(UG)	
2013	Smooth meadow grass	8.8	7.9	9	9	8.7
	Perennial ryegrass	8.9	7.6	7.5	9	8.3
	Red fescue	3.3	7.9	8.4	3.8	5.9
2014	Smooth meadow grass	9	9	8.9	8.8	8.9
	Perennial ryegrass	8.7	9	8.8	8.9	8.9
	Red fescue	9	8.8	8.9	8.9	8.9
2015	Smooth meadow grass	5.9	8.2	6.1	7.3	6.9

$LSD_{0.05:}$ A=NS; B=1.44.; C=1.44; A/B=NS; B/A=NS; A/C=NS; C/A=NS; B/C=2.25; C/B=2.25.

In the summer *(Table 5)* turf compactness was slightly worse than in the spring time, and to a greater extent it was dependent on weather conditions (*Tables 2 and 3*). The best possible degree of turf compactness for each species of grasses was in 2014 (on average 8.9° for each species). The spring that year was rainy (*Table 3*), with hydrothermal coefficient indicating optimal conditions in April, but quite wet in May and June. Similarly, during the summer that year weather conditions were much more favourable for grass than in the other two years of the research. For all the grass species the highest average compactness rating (8.9°) was also in 2014, when, on average, lawns treated with different types of fertilizer had the same turf compactness. Comparing all the species throughout the experiment, in summer seasons perennial ryegrass formed the best lawn (on average 8.3°), and with references to the forms of fertilizer, Substral was the most effective (8. 9°). Red fescue had the worst lawn in summer (an average of 6.1°), and with regard to fertilizer types, plots with Substral (5°) and UGmax (5.5°) had turf of the lowest compactness. Statistical analysis revealed significant differences in the degree of turf compactness between red fescue and the other two species of grasses. The interaction between the form of fertilizer and grass

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_19171928

species in their effect on the turf compactness turned out to be statistically significant. Comparing the effect of the forms of fertilizer on all grass species during summer in all experimental years, the application of Humus Active Papka (7.7°) resulted in the best turf, while the effect of Substral (7.3°) was the worst. Differences between the impacts of both of them were not statistically significant.

Table 6. *Assessment of turf compactness (using 9-point scale) in the autumn from 2013 to 2015.*

The turfs in autumn seasons *(Table 6*) were to a large extent a reflection of meteorological conditions (*Tables 2* and *3).* During this period the most adverse weather conditions for grass development were in 2014 (*Table 3*), when September was very dry and October extremely dry. In effect, turf compactness was the worst (an average of 7.8°) although red fescue that year was in good condition (on average 8.9°), while much worse lawns were those with perennial ryegrass (on average 6.3°). Those differences were statistically significant. In the other two years (2013 and 2015), when water conditions were by far better, turf was at its best (from 8 to 9°). The experiment showed significant differences in turf compactness between grass species and between autumn seasons. As an average for all grass species, the best turf was in 2013 and 2015. In addition, the best turf was obtained as a result of the application of Eko-Użyźniacz (9.0 in 2013 and 8.8° in 2015) and Humus Active Papka (8.9° in both years). In autumn seasons red fescue had the best turf (from 8.8 to 9.0°), and with regard to the type of fertilizer, in the same seasons both Eko-Użyźniacz (9 in 2013 and 8.8 in 2015) and Humus Active Papka (8.9° in 2013 and 2015) application resulted in a very good lawn.

Out of the grass species in the autumn perennial ryegrass had the worst turf (on average 8.0°). Statistical analysis showed that the interaction between the grass species

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_19171928

and the year of research in their effect on lawn compactness was statistically significant. In assessing the effects of fertilizer types on all grass species in each year, it was found that in the autumn Eko-Użyźniacz and Humus Active Papka increased turf compactness in autumn seasons the most (8.6°).

Table 7. *Fertilizer effect on turf compactness (9-point scale). Means within species, years, and season.*

Species (B)	Fertilizers (A)				$\bar{x}$
	(S)	(EU)	(HAP)	(UG)	
Smooth meadow grass	8.3	8.4	8.3	8.3	8.3
Perennial ryegrass	8.3	7.9	8.2	8.1	8.1
Red fescue	7.5	8	7.9	7.8	7.8
Fertilizer effect - means					
	8	8.1	8.2	8.1	8.1
Year (C)	**Average annual assessment**				
2013	8	8.4	8.6	8.1	8.3
2014	8.3	8.1	8	8.4	8.2
2015	7.7	7.8	7.8	7.7	7.7
Average assessment in seasons (D)					
spring	8.4	8.1	8.4	8.4	8.3
summer	7.3	7.6	7.7	7.5	7.5
autumn	8.3	8.6	8.6	8.4	8.5

$LSD_{0.05}$: A=NS; B=0.41; C=0.49; D=0.33

By comparing average grass species ratings in the experiment as a whole *(Table 7)* it turned out that smooth meadow grass had the best turf (8.3°) and red fescue the worst (7.8°). Differences in the degree of turf compactness between grass species were statistically significant, especially between smooth meadow grass and red fescue. Grabowski et al. (1999) pointed out that the advantage of smooth meadow grass is its durability and high turf-making potential. In Poland in this regard this species easily competes with perennial ryegrass. Out of the types of fertilizer Humus Active Papka application resulted in the best turf (8.2°) in the experiment, although differences in its compactness on plots with different forms of fertilizer were small and not statistically significant. With regard to the seasons it was found that generally the best turf was in the autumn (8.5°) and spring (8.3°) and the worst in the summer (7.5°). Differences in the degree of its compactness between the summer, the spring, and the autumn were not statistically significant. Whatever the time of the year, in subsequent years of research the average assessment rating systematically deteriorated from 8.3° in 2013 to 7.7° in 2015, and these differences were statistically significant.

Table 8. *Standard deviation and coefficient of variation in assessing of turf compactness*

Species	*Min. rating*	Max. rating	Means values	Standard deviation	Coefficient of variation
Smooth meadow grass	*5.9*	9	8.33	0.737	8.84
Perennial ryegrass	*5.6*	9	8.10	1.052	12.98
Red fescue	*2.8*	9	2.06	2.062	26.48

Coefficient of variation: 0-20% - small variability, 20 – 40% - medium variability, 40-60% - large variability, > 60% - very large variability

By analyzing the durability of compactness ratings in relation to particular grass species *(Table 8)* it turned out that coefficient of variation for smooth meadow grass and perennial ryegrass was the most favourable, indicating moderate variability. For red fescue the coefficient of variation of compactness rating was above 20%, indicating medium variability. Therefore, to install a lawn, smooth meadow grass both on its own and in mixtures, should be recommended first of all.

Conclusions

1. Grass species tested in the experiment formed turf of different compactness, varying throughout seasons of the year and responding strongly to weather conditions. In drier periods red fescue had better turf, contrary to smooth meadow grass and perennial ryegrass, both of which had better turf in more humid conditions.
2. Out of all the types of fertilizer Humus Active Papka affected turf compactness in the most favourable way although the response of individual grass species was not the same.
3. Out of all the grass species smooth meadow grass and red fescue had the best turf on plots where Humus Active Papka was applied, and perennial ryegrass had the best turf on plots with Substral. In the subsequent years of research there was a deterioration of lawn compactness, with a weakening effect of all types of fertilizer, in particular in the case of Eko-Użyźniacz and Humus Active Papka.
4. From a practical point of view out of the grass species tested in the experiment P*oa pratensis* treated with Eko-Użyźniacz responded the most favourably.

(Received 19th Aug 2017; accepted 27th Oct 2017)

Abstract. The volatile component composition of leaves and flowers for *Ballota nigra* subsp. *anatolica* P.H. Davis that were collected between 2015 and 2016 from Çamlıca provice of Kütahya city during three different vegetation periods as pre-bloom, bloom and post flowering were determined by gas chromatography mass spectroscopy (GC-MS) after solid phase micro extraction (SPME). 59 different volatile oil components were determined of *Ballota nigra* subsp. *anatolica*. As main components, Hexenal (17.60%), germacrene D (6.70%) and β-caryophyllene (8.80%) were found during pre-blooming period, also Hexenal (21.16%), germacrene D (7.77%) and β-caryophyllene (10.03%) in blooming period and Hexenal (15.88%), germacrene D (7.60%) and β-caryophyllene (9.48%) in post-flowering period.
Keywords: *SPME, black horehound, volatile component, Lamiaceae*

Introduction

The research on the essential oil content of medicinal plants is quite important both in scientific and economic aspects. The increase in microorganism resistance against all known antibiotics has made it necessary to investigate plant sources and their effects on cells. There are also essences, most of which constitute essential oils in medicines as well as some substances such as cellulose, pectin, sugar and it is known that these substances have an important pharmacological effect (Kilic, 2005)

Lamiaceae family, one of the greatest families that can be grown almost anywhere without discrimination of habitat type and height, is the most spread especially in the Mediterranean Basin (Watson and Dallwitz, 1978). This family has 200 genus and approximately 3200 species and family members represented with 45 genus and more than 546 species in Turkey are important in pharmacology and perfumery industry because they contain essential and aromatic oil (Davis, 1982, Baytop, 1991). Lamiaceae has a rate of endemism of 44.2% in Turkey (Baser, 1993).

The genus *Ballota* L., which is a member of the Lamiaceae family that constitutes the material of this study, has about 35 taxa around the world (Patzak, 1958). It is represented with 12 species and 8 subspecies in Turkey (Guner, 2012). *Ballota* L. is a well-known genus in Europe due to its spasmolytic and sedative effects (Garnier et al., 1961). It is used in folk medicine for cough, asthma, headache, nausea, hemorrhoids, wound and burn treatment (Baytop, 1984).

The Black horehound (*Ballota nigra*) bearing only simple hairs. Stems erect, 50-100 cm, simple or branched above. Cauline leaves ovate-orbicular to ovate, 25-70 x 20-50 mm, acute, crenate dentate, truncate or rounded at base, distinctly petiolate. Inflorescence long, lax below. Floral leaves 1-2 x dense verticillasters. Bracteoles subulate, usually shorter than calyx tube. Calyx 7-10 mm, tubular obconical, dilated above into usually 5, very short to attenuate teeth that are porrect to patent or recurved,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_19291933

mucronate or aristate. Corolla purple or pink, 9-14 mm; upper lip concave, emarginate or erose (Davis, 1982; Anonymous, 2016).

In this study, volatile components of leaf and flower of *Ballota nigra* subsp. *anatolica* P.H. Davis, that belong to three different vegetation periods including prebloom, bloom and post-flowering were determined by SPME (solid-based microextraction method).

Materials and Methods

The materials of this study which was conducted in 2015 and 2016 are leaves and flower samples of *Ballota nigra* subsp. *anatolica* P.H. Davis that were collected in 3 different periods as pre-flowering term, flowering term and post-flowering from Çamlıca province (39° 43′ N, 29° 91′ E) of Kütahya city which is situated in the inner part of western Turkey.

The leaves and flower samples that were collected were put into paper packages and transferred to the laboratory in the same day without kept waited and exposed to sunlight. After the plant materials collected were dried at room temperature (25°C), flower and leaf samples were subjected to solid phase microextraction (SPME). 2 g of samples were placed into a 10 mL vial. After incubation for 30 min at 60°C, SPME fibre was pushed through the headspace of a sample vial to adsorbed the volatiles, and then inserted directly into the injection port of the GC-MS (Shimadzu 2010 Plus GC-MS with the capillary column, Restek Rxi®-5Sil MS 30 m x 0.25 mm, 0.25 µm) at a temperature of 250°C for desorption (5 min) of the adsorbed volatile compounds for analysis. Identification of constituents was carried out with the help of retention times of standard substances by composition of mass spectra with the data given in the Wiley, NIST Tutor, FFNSC libraries.

Results

59 different volatile components were specified by gas chromatography mass spectroscopy (GC-MS) after solid phase micro extraction (SPME) for *Ballota nigra* subsp. *anatolica*. The results are given in *Table 1*. Hexenal, germacrene D and β-caryophyllene were specified as the main components of *Ballota nigra* subsp. *anatolica*. Hexenal (17.60%), germacrene D (6.70%), and β-caryophyllene (8.80%) in the prebloom period; Hexenal (21.16%), germacrene D (7.77%) and β-caryophyllene (10.03%) in the bloom period, Hexenal (15.88%), germacrene D (7.60%), β-caryophyllene (9.48%) in post flowering period were identified (*Table 1*). It was observed that there was an increase in the proportion of volatile components during the bloom period.

Table 1. *Volatile components of Ballota nigra subsp. anatolica P.H. Davis according to different vegetation periods*

	Retention Time	Components	Pre-bloom (%)	Bloom (%)	Post-flowering (%)
1	1.401	Isobutanal	0.17	0.70	-

Discussion and Conclusions

Bader et al. (2003) studied the volatile oil components of *Ballota nigra* ssp. *foetida*, *B. undulata* and *B. saxatilis*. β-caryophyllene (25.1%) and germacrene D (24.2%) were identified as the main components of *Ballota nigra* ssp. *foetida*. Morteza-Semnani et al. (2007) determined 42 components, specifying caryophyllene oxide (7.9%), epi-α-muurolol (6.6%), δ-cadinene (6.5%), and α-cadinol (6.3%) as the main components. The main components differ according to our study. Kazemizadeh et al. (2009) found the germacrene D (18.1%), nerolidol epoxyacetate (15.4%), sclareol oxide (12.1%), linalyl acetate (11.5%), and β-caryophyllene (10.5%) as the main components in *B. nigra* subsp. *anatolica*. Vukovic et al. (2009) determined 115 components in *Ballota nigra* in Serbia. They reported that β-caryophyllene, germacrene D, and α–humulene in the leaves and stalks, p-vinylguiacol (9.24%), borneol (7.51%), myrtenol (7.13%), trans-pinocarveol (5.22%), pinocarvone (4.37%), 2-methyl-3-phenylpropanal (4.32%), and p-cymen-8-ol (4.30%) in the roots as the main components.

Fraternale et al. (2009) identified 37 components in *Ballota nigra*. They found β-caryophyllene (20.0%), germacrene D (18.0%), and caryophyllene oxide (15.0%) as the main components. Fraternale and Ricci (2014) have specified β-caryophyllene (22.6% and 21.8%), caryophyllene oxide (18.0% and 20.5%) and germacrene D (16.5 and 13.1%) as the main components in *Ballota nigra* L. ssp. *foetida*. In our study, germacrene D (7.77%) and β-Caryophyllene were determined as the main components, sharing similarities to other works. Unlike other studies, hexenal component were identified.

Jamzad et al. (2013) reported 12 different components including β-pinene (39.0%) and α-pinene (34.5%). However, 59 different components were found, specifying Hexenal (21.1%), germacrene D (7.77%) and β-caryophyllene (10.03%) as the main components. The main components in our work differ from those of Jamzad et al. (2013).

As conclusion; *Ballota* taxa are consumed in South Anatolian regions against cough, asthma, headache, nausea and hemorrhoids, and they are used externally in wound and burn treatment. Studies should be increased for people to consume and use consciously. It is considered that local people will be informed, random collection of plants and economic losses to be incurred due to false information will be prevented, and collection of plants will be performed more consciously. Further studies related to volatile components and possibilities of their usage within the scope of antibacterial, antimicrobial and deterrent etc. should be investigated.

Abstract. The springs are unique ecotones that integrate ecological characteristics and human impacts associated with both underground and surface water as well as terrestrial ecosystems. A clear definition of the management of springs is a precursor to their effective protection and restoration. Species diversity of springs areas in the eastern part of the Krkonoše Mts. was investigated in eight various localities. By a cover-abundance scale species richness (plants and mosses) and habitat type (phytocenological survey) were evaluated. Statistical analyses were used to compare springs by main gradients with respect to environment determinants (Principal component analysis with environmental supplementary variables, Simpson's dominance index and Shannon's diversity index). A total of 59 vascular plants, 9 mosses and 4 communities were found, including 8 endangered taxa of them. The springs of Modry brook and Renner brook had the highest species diversity and the largest number of vascular plants were observed on the headwater area of Upa River. The fewest endangered species were determined on the springs of Suchy brook and Javori brook. The resulting species richness is a function of the combination of altitude and exposure, where the highest species richness values were recorded in the highest located subalpine headwater areas.
Keywords: *wetland vegetation; Montia fontana; plant communities; altitude; subalpine spring*

Introduction

Springs are ecosystems in which groundwater reaches the Earth's surface either at or near the land-atmosphere or land-water interface. At their sources (orifices, points of emergence), the physical geomorphic template allows some springs to support numerous microhabitats and large arrays of aquatic, wetland, and terrestrial plant and animal species. Yet, springs ecosystems, however, differ significantly from other aquatic, wetlands and riparian ecosystems (Stevens et al., 2005). They fundamentally contribute to the circulation of nutrients, soil formation, climate regulation, carbon accumulation, nutrient and water retention (Sorooshian and Whitaker, 2003). As wetland habitats are one of the most threatened in all of Europe, detailed knowledge of relationships between springs vegetation and environmental conditions is, among others, highly important for applications in nature conservation. This study is intended to fill a large gap in the knowledge of the springs vegetation diversity in Krkonoše high-mountain regions and its ecological determinants.

The Krkonoše was proclaimed as a government-protected area for water accumulation because of its significance as a headwater area. The collecting area of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_19351945

underground waters is shallow and has a relatively low springs discharge. The springs water maintains a year-around temperature between 4 - 6 °C, so the headwater areas do not freeze (Stursa et al., 2012). Thanks to various geologic and ecologic conditions, headwater areas include a wide range of locations (Danks and Williams, 1991).

Twelve springs types are recognized, not including paleo-springs (Springer and Stevens, 2009). In a recent study biology of springs widely used simple division into three basic types (according to the method of seepage of ground water and the intensity of its velocity: Limnocrene; Helocrene; Rheocrene), as aptly describes the nature of springs (Cantonati et al., 2006). This differentiation of communities is primarily conditioned by the ground water mode; water chemical composition, temperature, nutrition content, springs discharge, water flow rate and slope angle. The most significant species diversity is influenced by mineral richness and the reaction of springs water (Tahvanainen et al., 2002; Nekola, 2004; Novakova, 2007).

Earlier vegetation studies carried out by Czech and Poland researchers were mostly performed using the dominance approach (see Chumanova-Vavrova et al., 2015; Vacek et al., 2017). Moreover, springs have been investigated only marginally in these studies. Studies of springs vegetation that focus on the overall species composition of the vegetation are very rare in Czech Republic. A vegetation study from Czechoslovakia (Hadac, 1983) and the syntaxonomic evaluation of spring communities with *Montia fontana* (Hadac and Vana, 1971) represent the exceptions. In the present study, we describe the diversity of Krkonoše high-mountain springs with respect to major environmental factors measured directly in the field.

Vegetation of springs is widespread throughout Europe, and is more frequent at higher altitudes with humid climates. Spring represent azonal habitat, sometimes referred to as hydrological sub-climax (Hinterlang, 1992). The *Montio-Cardaminetea* class comprises vegetation developing in springs with cold and well oxygenated water. Cold water with low nutrient content reduces vascular plant productivity, while leading to increasing bryophyte cover. Enhanced input of nutrients can therefore quickly change the structure of springs vegetation to the benefit of vascular plants (Hajkova et al., 2006). Variability of this class is relatively large and therefore may occur in the springs ecologically distinct from foothills to alpine levels in deciduous and coniferous woods and on open sites (Zechmeister and Mucina, 1994). With increasing distance from a springs, flow rates and oxygenation decrease and springs vegetation is replaced by other communities, typically mire and fen vegetation of the class *Scheuchzerio palustris-Caricetea nigrae* (Økland et al., 2001).

By describing vegetation diversity, we examine the major ecological determinants of vegetation variation springs in a biogeographical context. Another objective is to evaluate the floristic elements in ecologically diverse springs vegetation types in the Krkonoše Mountains National Park, Czech Republic.

Materials and methods

Study area

A field survey was conducted at the The Krkonoše Mountains National Park (Czech Republic, official abbreviations KRNAP – KPN). Krkonoše is home to the highest mountains in the Czech Republic, but that is also true throughout Central Europe to the north of the Alps. In fact, the mountains form the northernmost montane border of Central Europe, stretching in length just over 50° of northern latitude, whilst their slopes

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_19351945

protrude above the alpine tree line. Consequently, the Krkonoše Mountains represent a mighty and natural barrier on the perimeter of large open plains in Germany and Poland. They measure approximately 35 km in length, with their main ridges and valleys arranged in a direction from northwest to southeast. This significantly affects all the geographical, climatic and biological features of these European medium-sized mountains and their surroundings. Therefore, Krkonoše Mountains are a truly important area for geobiodiversity in Central Europe.

Vegetation samples were taken from representative springs, which we found in Krkonoše Mountains during our extensive research in vegetation seasons 2015 –2016. Eight springs were chosen:

L1 – Zeleny brook 50°42′42.704′′N 15°40′26.351′′E | L2 – Modry brook 50°43'21.799"N 15°41'23.273"E | L3 – Javori brook 50°39′30.148′′N 15°44′27.238′′E | L4 – Weber brook 50°40′33.614′′N 15°44′19.803′′E | L5 – Renner brook 50°43′45.719′′N 15°49′29.460′′E | L6 – Max brook 50°39′26.506′′N 15°50′58.014′′E | L7 – Suchy brook 50°39′45.649′′N 15°51′26.606′′E | L8 – Upa River (so called ′Deliquescent Rock′) 50°40′1.685′′N 15°47′321.445′′E – for more characteristics, see *Table 1* and *Fig. 1*.

Table 1. *Summary of different springs at different sites of the The Krkonoše Mountains National Park (Czech Republic)*

	Exposure	Soil	Altitude (m a.s.l.)	Slope (°)	Coverage E_1 (%)	Coverage E_0 (%)	Springs type
L1	East	Podsol	1 375	12	70	40	Limnocrene
L2	South	Podsol	1 350	39	70	50	Helocrene
L3	North	Podsol	1 220	14	15	90	Helocrene
L4	Northwest	Podsol	1 110	9,5	60	50	Helocrene
L5	West	Podsol	1 080	11,3	70	50	Helocrene
L6	West	Cambisol	965	54	90	15	Rheocrene
L7	West	Cambisol	940	10,5	60	20	Helocrene
L8	East	Podsol	625	69	80	5	Rheocrene

The phyto-sociological part was worked out with the help of the Zürich Montpellier School of Phytosociology and included analysis, synthesis and identifying vegetation. Sixteen phyto-sociological relevés were taken (Rosenthal, 2003). The vegetation plot size was delimited in such a way as to represent full floristic composition of the phyto-coenosis. It varied from 3.75 to 12 m^2 depending on plant density and the homogeneity of vegetation cover (Chytry and Otypkova, 2003).

Cover of vascular plants and bryophytes was estimated using the seven-grade Braun-Blanquet scale (van der Maarel, 1979). Vegetation and environmental data were simultaneously collected in submontane and lowland springs and from subalpine tall-form vegetation. The slope of the sample plot was subjectively estimated. Altitude and coordinates were measured by GPS Garmin Oregon 400t (WGS 84 system) with altimeter calibrated by current atmospheric pressure. Other environmental factors (soil types, aspect) were noted for each relevé.

The nomenclature of vascular plants follows Danihelka et al. (2012) and the bryophytes nomenclature follows Kucera et al. (2012). The vascular plant species were classified into five groups according to their threat status by Grulich (2012).

Data analysis and statistical methods

The springs type was determined by analysing its groundwater environment. Simpson's dominance index and Shannon's diversity index was calculated for each individual location, using the PAST software (Hammer et al. 2001). A TWINSPAN analysis (Hill and Smilauer, 2005) was used to perform the preliminary classification of communities (cluster analysis). Principal component analysis (PCA) of species composition (relevé diversity is expressed as Shannon-Wiener index) with forward selection of environmental factors was analysed by CANOCO 5 software package (Smilauer and Leps, 2014).

Results and discussion

On selected springs, a total of 59 vascular plants and 9 mosses were determined, including 8 endangered taxa among them (*Table 2, Appendix I*). The highest occurrence of endangered species is represented by the springs L2, characterized by the continuous plant cover of *Cardamine amara* subsp. *opicii* (*Fig. 4*) with almost equal coverage of herbaceous and mosses layer. It is a newly discovered locality with this taxon, which is extremely rare and critically endangered. This subspecies is extended, among other things, in the highest mountains of the Western Carpathians (Marhold, 1995). It is a natural habitat without the necessary regular management; question is the occurrence of forest animals. There is also *Montia fontana*, which, according Grabherr and Mucina (1993), due to the overall eutrophication of the landscape and increased productivity of stands from the whole of Europe is receding.

Table 2. *Summary of threatened taxa determined at different springs*

	Statutes by Red List (Grulich 2012)	**Springs**	**Cover-abundance scale**
Cardamine amara subsp. *opicii*	C1 b - Critically threatened taxa	L2	3
Delphinium elatum	C2 r - Endangered taxa	L6	2
Epilobium alsinifolium	C3 - Vulnerable taxa	L2, L4, L8	2, +, 1
Epilobium palustre	C4 a - Lower risk – near threatened	L5	1
Chrysosplenium oppositifolium	C4 a - Lower risk – near threatened	L8	1
Montia fontana subsp. *fontana*	C1 b - Critically threatened taxa	L2	1
Swertia perennis	C2 r - Endangered taxa	L2	+
Viola biflora	C4 a - Lower risk – near threatened	L2, L3, L5	+, r, r

Cover-abundance 7-degree scale follows Braun-Blanquet | L1 – L8 see Materials and methods

Species richness

Fig. 2 (left side) shows highest species richness on L5 and L3 (with 19 vascular plants and 4 mosses, respectively 18 and 3). It is probably connected with this that the index is heavily dependent on the most numerous species and less sensitive to rare species. On the other hand, the lowest diversity was observed on L7 and L4 (5 vascular plants and 2 mosses) – which are closely similar. On right side of *Fig. 2* is a clear cluster with L1 and L2 (subalpine altitude) that also shows in other clusters, as well as springs. First cluster covers L6-L8, localities with lowest altitude (submontane zone).

DOI: http://dx.doi.org/10.15666/aeer/1504_19351945

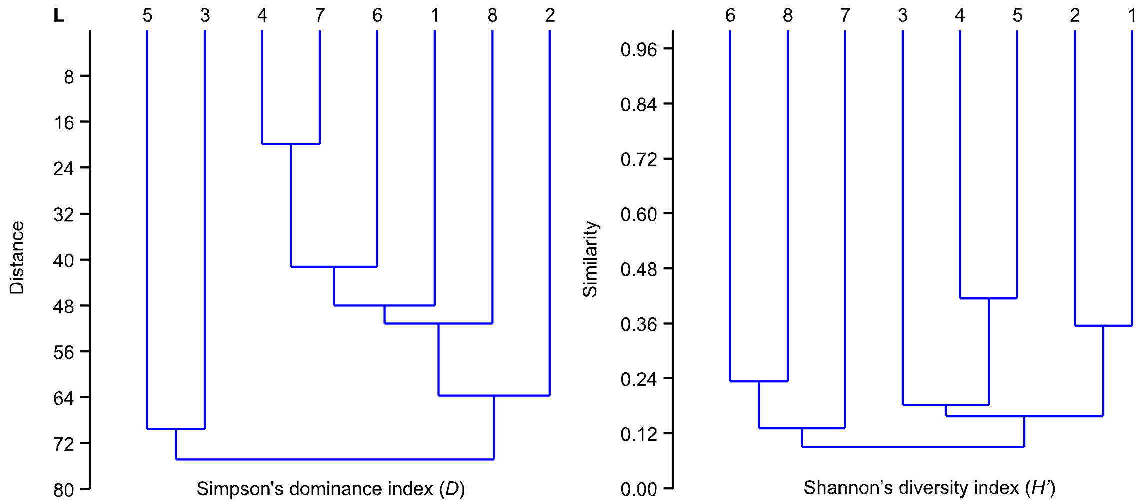

Figure 2. *Cluster analysis of species richness of different springs indicated by Simpson´s dominance index (D) and by Shannon's diversity index (H') - complete linkage (Euclidean distance) | L1 – L8 see Materials and methods*

The results of species diversity and phytocenological relevés show diverse types of communities in the springs. These are communities of the alliance *Swertio perennis-Dichodontion palustris* Hadač 1983 (L1-L4) and associations *Caricetum remotae* Kästner 1941 (L5, L6), *Cardamino-Chrysosplenietum alternifolii* Maas 1959 (L7) and *Pellio epiphyllae-Chrysosplenietum oppositifolii* Maas 1959 (L8).

According to Hajkova et al. (2006) the major species turnover in springs follows the variation in water pH and mineral content in water but altitude remains an important factor in all cases. Our results indicated that springs preserved in managed forests constitute biodiversity hotspots in the landscape because they provide habitat for many species of plants, including protected and endangered (Spalek and Prockow, 2011).

The first and second axis in PCA are explained in 24.62 and 23.72, respectively. *Fig. 3* shows both species abundance and richness by various springs in relation to their environmental gradient. First axis represents the effects of elevation and slope while the second illustrates aspect. The resulting species richness is a function of the combination of altitude and exposure, where the highest species richness values were recorded in the highest located subalpine headwater areas with southern exposures.

This contradicts the conclusions of some studies (Hajkova et al., 2006); that the plant species richness decreases significantly with increasing altitude. On the contrary, Krkonoše Mountains are specific due to rarity of calcareous bedrock. In such conditions, vegetation of the high-mountain springs (*Montio-Cardaminetea* class) is not diversified according to the gradient of mineral richness. Species composition is more influenced by the variation in altitude and also by succession advancing due to *Sphagnum* sp. expansion and peat accumulation (Hajek et al., 2005). As a general conclusion, our results show that subalpine springs vegetation should be analysed separately while searching for vegetation-environment relation.

Management of springs

In terms of the overall approach to management of habitats, springs are distinguished by two basic groups. The first involves the natural habitat (forest and subalpine springs as L1, L2 and L3; bogs and some types of transitional bogs), which should generally leave the spontaneous development with possible one-off interventions aimed primarily at restoring the natural water regime. This corresponds with Barquin and Scarsbrook (2008). The second group consists of semi-natural habitats – mainly springs L4 and L6.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_19351945

The existence of these semi-natural habitats is conditioned especially by human activities, including deforestation and subsequent traditional management in the past of non-forest springs, calcareous and non-calcareous moss springs and some types of transitional bogs. These habitats require more or less steady, albeit extensive management to replace the former traditional agricultural practices.

Conclusions

The springs are unique ecotones that integrate ecological characteristics and human impacts associated with both underground and surface water and terrestrial ecosystems. Spring vegetation occurs across a broad altitudinal range from lowlands to the subalpine belt, both in open places and under forest canopies. A clear definition of the management of springs, with the help of vegetation and environmental factors surveys, is a precursor to their effective protection and restoration. Our results suggest that subalpine springs vegetation should be analysed separately with respect to vegetation-environment correlations. Separate analysis of springs below and above timberline is quite appropriate.

Figure 4. *The critically threatened plant Cardamine amara subsp. opicii (large bitter-cress) on subalpine springs Modry brook (L2 | 18. 9. 2015) with protection (fleece) against grazing forest animals*

Abstract. The aim of this study was to examine the effect of different planting regimes on anatomical traits of floret and root effective on productivity and seed hollowness as well as grain yield of 12 aerobic rice genotypes in subplots under the influence of four different irrigation regimes (irrigation intervals of 1, 3, 5 and 7 days) in the main plots by split-plot based on randomized complete block with three replications for two years (2014 and 2015) in Khuzestan. Results of combined analysis showed that there were significant differences in all parameters between genotypes, irrigation regimes and the interaction of the two factors except for the stigma length and the central cylindrical area of roots. Reduction of the amount of irrigation had decreased central cylindrical area and xylem of root in order to increase efficiency and maintain the water potential in plants. The highest length of anthers and stigmas was observed in the 5-day irrigation regime and maximum width of anthers, style length and pollen area was observed in the 3-day irrigation regime and the genotypes had the highest grain yield (5094.31 kg/ha) due to the ideal conditions. Therefore, it can be concluded that by focusing revision goals on reducing the central cylinder and xylem areas in order to increase the efficiency of irrigation water in terms of reduced irrigation and controlling lengths of florets parts we can hope to increase connection between pollen and flower and finally fertility to increase production under different irrigations.
Keywords: *rice, irrigation regimes, anatomy, cluster, floret*

Introduction

Rice is one of the oldest cultivation plants (Ghosh and Chakma, 2015) and is the main food of more than half the world's population (Park et al., 2014). Drought is a serious risk for the successful production of major crops in the world, especially rice, which can occur at any time during the growing season. Hence, one of the main challenges in agriculture Is to produce more food with less water (Tuyen and Prasad, 2008). Seventy percent of world's fresh water is consumed in agriculture, which 25 to 30 percent of this amount is devoted to rice cultivation (Sedaghat et al., 2015). Rice has the greatest amount of water consumption among agricultural products and about 80% of Asia's fresh water is used for this (Sedaghat et al., 2015). Almost 75% of world's rice is obtained from irrigated rice paddies (Carmelita et al., 2011). Irrigation with few days interval provides enough oxygen for the plant root system, which this would accelerate the mineralization of organic matter and soil nitrogen-fixing. All of these improve

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_19471970

increasing in the plant nutrients and thus increase its growth (Dong et al., 2012). Lack of moisture is one of the most important growth limiting factors (Mosavy et al., 2016). Intermittent irrigation management can provide plant needs in crisis situations (Shanmugasundaram, 2015). The main advantage of intermittent irrigation with intervals of few days is savings in water consumption (Uphoff et al., 2013). Limuchi et al. (2014) reported the reduction of growth period length in order to decrease the un-structured carbohydrates to the main tank, i.e. grain, as an important factor in reduced yield (Limuchi et al., 2014).

Anatomical changes in plants under environmental stress can reduce the vascular bundles area such as Xylem area, which the result of these changes can protect cells from death and dieback (Mostajeran et al., 2008).

There was a difference in terms of pollen germination at times after anthers' opening. Variety Minyhui 63 had the highest germination rate (85%) at time 0 or immediately after anthers' opening; But variety Rufipogon with lower germination rate (60%), 50% of pollens were alive after 12 min (longer). The lowest germination rate (34%) was observed in hybrid varieties with an average longevity that more than 50% were alive after 10 min even after 40 min (Song et al., 2001). Uniformity between opening of florets and anthers causes high self-pollination in rice, but stressful situations at the time of flowering can postpone the turgidity and growth of pollens (Matsui et al., 2000). Matsui and Hisashi (2003) showed that there were positive correlation between the number of pollen on stigma and morphological characteristics.

Many researches were carried out on the root structure and its effect on yield in drought conditions and the structural changes and root anatomy were studied in irrigation conditions and the best cross-section due to irrigation conditions for example, increasing and decreasing cross-section in order to increase water absorption and increase efficiency in drought conditions and selection should be done from genotypes with small cross-section in order to increase water use efficiency in root (Lopes and Reynolds, 2010; Hamadanzadah et al., 2015). It should be stated the management practices of different irrigation should be overcome to increase the volume and finally cross-section of root (Sadranasab et al., 2014). In terms of root characteristics it can be stated that the desirable root characteristics change with different irrigation conditions and modification to increase cross-section, central cylinder and xylem of root to absorb more water in favorable irrigation conditions (Zhou et al., 2007; Moshafaghi et al., 2014). The root is the only organ in direct contact with the surrounding soil, so having an efficient xylem bundles and central cylinder appropriate to the circumstances and anatomical changes in order to organs adaption according to previous statements can have an effective role in dealing with decreased water or watering more than plants need in line with the absorption of nutrients and minerals and finally can fill the main plant reservoir, i.e. grains (Sadat Jamali et al., 2014; Shelden et al., 2013). To increase their survival under conditions of drought and temperatures, plants change anatomically such as reduced vascular bundles area for better compatibility with the environment (Ghorbani et al., 2011).

Increased drought to maintain the water potential in plant causes a reduction in diameter of Xylem vascular bundles (Majd et al., 2009). Xylem vascular bundles area decreases in different conditions leading to water stress in order to improve irrigation efficiency and to maintain plant water potential (Limouchi and Farahvash, 2014). Stresses can decrease vascular bundles area and diameter to improve water use efficiency and to reduce transpiration, while these traits are positively and significantly

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_19471970

correlated to grain yield (Limouchi, et al., 2013). Water shortage for rice leads to a reduction in the value of anatomical traits effective in water retention and movement such as vascular bundles to maintain the amount of water in rice (Daxylem, 2016).

This study aimed to identify the tolerance and sensitivity mechanisms to drought in different irrigation intervals in order to increase florets fertility and reduce hollowness as well as to study changes in anatomical characteristics of roots.

Materials and methods

This study aimed to reduce and optimize water consumption and increase irrigation efficiency in split-plots by two factors and 3 replications in a randomized complete block design by upland rice method (3 × 4 m plots) for two years (2014 and 2015) in Shavoor Agricultural Research Station of Agriculture and Natural Resources Research Center of Iran in Khuzestan province at 70 km north of Ahvaz between the rivers of Karkhe and Karun (31° 50′ latitude and 48° 28′ longitude, 33 m above sea level). Farm soil texture was loamy-clay with pH = 7-7.5 and electrical conductivity of 2.5 mmhos/cm, and amounts of nitrogen, phosphorus, potassium and zinc were 0.09%, 10-12, 120 and 2.5 ppm, respectively. Four irrigation regimes include intermittences of one-day or control (common in the region) (I1), 3 (I2), five (I3) and seven days (I4) as main factor levels and 12 rice genotypes were places in subplots (*Table 1*).

The numbers from 1 to 9 have the highest and lowest drought tolerance, respectively.

After soil preparation, dry seeds of each genotype were sown in 20 cm rows by a Hamadani farmer and then irrigation regimes were applied since the mid-tillering. Plots were irrigated to a height of 5 cm with water supplied by a pump and then irrigation stopped. This trend was applied for whole growing season and all four treatments. To prevent water infiltration into adjacent plots, all stacks to a depth of 1 m into the soil and irrigation streams' walls were covered by a plastic. Irrigation regimes were selected according to the conditions and potential of water and the amount of water entering the plots was determined according to the water height and plots' size during irrigation, which was about 7 h, as well as regarding the water discharge. Some meteorological

parameters are shown in *Table 2*. To provide nutrients; nitrogen of urea source was used by 200 and 300 kg/ha as 25% baseline (20-25 days after emergence) and the remaining 75% in three times (25%) as first to third first input respectively in the first bud cluster formation (35 to 40 days after using baseline fertilizer), The seed formation (30-35 days after the first first input) and 50% in time of the emergence of clusters 50 kg of phosphorus fertilizer per ha from triple superphosphate source, 100 kg of potash fertilizer and 40 kg zinc per ha from sulfate source were used in the soil. Integrated weed control including weeding and using 2,4-D pesticide (1.5-2 L/ha; 35 to 40 days after emergence) was applied. The following traits were studied.

Matsui and Omasa method (Matsui and Omasa, 2002) was used to determine the length and width of anthers as well as length of stigma and style. One day before the opening of florets, 1/3 of florets from the tip of first cluster branch (18 anthers from three florets) were collected for each variety. Measurements were done under a microscope after stabilizing in F.A.A mix (Formalin-acetic acid-alcohol). Anther length from longer side of anther sac and anther width from average of two sides, one parallel to anther wall that opens after maturity (W1) and the other perpendicular to it (W2), were taken. Measuring length of stigma and style and counting pollen on the stigma were performed after staining 15 florets with Cotton blue for 15 min. Then stained samples were placed on a lamel to prepare images and traits were measured with a light microscope with a magnification of 40. Length of stigma and style were measured from the tip of stigma to the junction with style and from base of stigma to the junction with ovary, respectively. Viability, diameter and area of pollens were determined by using the Erie classification system based on their shape and staining with potassium iodide (Anonymous, 1982).

For the measurement of anatomical traits, roots were taken out of the soil at the time heading and then 2-3 cm slices in middle parts were prepared. F.A.A solution was used to store samples. Cross- section and thin slices were manually prepared using Styrofoam and to stain cross- sections of roots in order to observe and measure the central cylindrical area and xylem, samples were washed with distilled water and placed in bleach for 15 min and then in Carmen Zaji for 20 min and finally in green methyl for 10-15 s and they were washed thoroughly with distilled water between each stage. Then stained samples were placed on a lamel to prepare images and traits were measured with a light microscope with a magnification of 40 (Limouchi, 2013).

DOI: http://dx.doi.org/10.15666/aeer/1504_19471970

Measurement of the grain yield at 14% moisture (the moisture after harvest) was done after reaching 85% grain in harvest cluster in an area of 1.5 m^2 in the middle of each plot and removing borders.

Dry matter per ha (after placement of samples without base for 72 h in an oven), fertility rate (the ratio of filled florets to total florets) and the weight of one thousand seeds by randomly picking 30 main clusters from each replication were measured.

All data obtained from the study after ensuring normality were analyzed using analysis of variance (combined) and correlation in SAS and SPSS and Duncan test was used for mean comparison of data at 5% level.

Results and discussion

Anther length

In this study, it was found that there were significant differences between years, irrigation regimes and genotypes and the interaction of irrigation regimes and genotypes at 1% level and also between the interaction of years and genotypes and interaction of years, irrigation regimes and genotypes at 5% level; but other factors were not significantly different (*Table 3*).

According to mean comparison, the highest and lowest anther lengths were related to the third (5-day interval) and the first (1-day interval) irrigation regimes, respectively (*Table 4*). The interaction between the two factors is shown in *Figure 1* (*a* and *b*), which genotypes reaction was entirely dependent on irrigation regimes so that genotype IR 78908-193-B-3-B with high tolerance to drought had the longest anther in all irrigation regimes due to the genetic reasons, and the lowest length (1448.271 µm) was seen in the second irrigation regime. In other irrigation regimes, anther length of this genotype was in one statistic class. The lowest length of anther (930.056 µm) was seen in Tarom in the first irrigation regime (1-day interval), which had the least drought tolerance among the studied genotypes. It seems that based on genotypes resistance to drought, reduced anther length with increased contact with pollen and prevention of wasting pollen fertility could increase fertility and grain yield. Thus, increasing performance of genotype IR 78908-193-B-3-B in 3- day interval irrigation and Tarom in 1- day interval irrigation can be due to the reduced length of anthers, increased fertility efficiency and trapping pollens (*Table 5*).

I1, I2, I3 and I4 include irrigation regimes of 1, 3, 5 and 7 days, respectively

Due to the fact that starch degradation and the availability of non-structural carbohydrates are essential for formation of anther wall and elongation together with the generative (producing pollen), it seems that depending on the irrigation regime the relative contribution of these carbohydrates is different in formation of anther parts. The results did not correspond to Suzuki (1981) on larger anthers had more pollens that can compensate the reduction of number of germinated pollen and thereby increase the tolerance to thermal stress, because in addition to pollen number, their size and the water potential of each pollen to create pressure for anther opening and pollen releasing are also factors for increasing fertility.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_19471970

Correlation coefficients results showed that length negatively correlated with yield (-0.012), which can be due to the longer length of anther for transferring pollen from the anther to the stigma and this corresponded to other studies (Arvin and Vafabakhsh, 2016; Akbari et al., 2016) on high effect of increased fertility on grain yield (*Table 6*).

6-pollen area						1

* and **: Significant at 5% and 1% probability levels, respectively

Anther width

Results of combined analysis showed that differences between factors except for interaction between year and irrigation regimes (*Table 3*). According to mean comparison, anther width was in one level for three irrigation regimes (1-, 3- and 5-day interval) shown in *Figure 1* (*a* and *b*), but significant decrease in anthers width was seen in the fourth irrigation regime (7 day interval) due to the reduced nutrients transportation and lack of growth and this could be one of the reasons of grain yield reduction due to decreased diameter suitable for the pollen passage. Genotype IR 80508-B-194-3-B had the widest anther in all irrigation regimes, which the highest width (493.116 μm) was seen in the first irrigation regime (1-day interval) and the lowest width was seen in the fourth irrigation regime (7-day interval) and the lowest width in this irrigation regime belonged to Tarom (145.523 μm) (*Fig. 1, Tables 4* and *5*). Comparison of changes trends in fertility and anther width showed it was a slightly different trend or in other words, having the widest anther does not lead to higher fertility. Although it seems that wider and longer anthers have more potential for more pollens. The above results corresponded to those of Mamnan et al. (2009).

Stigma length

In this study it was found that the effect of years, genotypes and the interaction of years and genotypes were significant at 1% level and the effect of irrigation regimes and the interaction of years, irrigation regimes and genotypes were significant at 5% level but no significant difference was observed for other effects (*Table 3*). Mean comparisons showed that increasing irrigation interval had increased stigma length, so that the longest stigma (991.428 μm) was observed in the fourth irrigation regime (7-day interval) (*Table 4*). Due to the interaction of two factors, the maximum length of stigma was related to genotype IR 78875-176-B-1-B, which was in one statistical level in all irrigation regimes. The minimum length of stigma was related to Tarom, which reduction in irrigation intervals affected stigma length. The results indicated the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_19471970

presence of genetic differentiation between them and it can be concluded this difference was due to the plant internal and genetic factors that requires more attention to breeding and improvement of rice genotypes in order to optimize the length of stigma with anther length to enhance pollen contact and fertility and finally raising grain yield (*Table 5*). Comparing length of anther and stigma the fourth irrigation regime (7-day interval) suggested an almost same trend and other reasons were reduced nutrients absorption and as a result reduced anther growth. Irrigation regimes with longed anthers had longer stigmas. But the process was quite different among the genotypes and genotypes with longer anthers had shorter stigmas. The results regardless of water conditions can be due to stigmas' morphological differences in receiving and holding pollens. On the other hand, irrigation regimes with larger anthers and longer stigmas had more pollen, which was consistent with Suzuki (1981) on the correlations between the length of stigmas and pollen number. Relative comparison of anthers and stigmas in the fourth irrigation regime suggested a same trend between them and irrigation regimes with longer stigmas had longer anthers. However, this trend was not constant among genotypes and it seems this result is due to the difference between genotypes in terms of stigma morphological characteristics. The above results were consistent with Oyiga et al. (2010) (*Figure 1*).

Stigma length was positively correlated with grain yield (0.139*). It seems that increased length had caused less distance between stigma and anther and hence receiving more pollen, fertility and grain yield, which corresponded to (Oyiga et al., 2010) (*Table 6*).

Style length

The results showed that all factors were significantly different at 1% level (*Table 3*). The second irrigation regime (3-day interval) and the fourth irrigation regime (7-day interval) had the longest and shortest styles, respectively (*Table 4*). The interaction between genotype and irrigation regimes the differences were very diverse and resistance genotypes had longer styles. Unlike genotypes with less resistance, genotype IR 78908-193-B-3-B, which had the longest style in all irrigation regimes, had the longest style (868 μm) in the fourth irrigation regime (7-day interval) and the shortest styles were seen in genotypes with lower resistance. Increasing the planting space affected the style length, so that genotype IR 80508-B-194-3-B had the shortest styles (150.409 μm) in the fourth irrigation regime (7-day interval) (*Table 5*). Given that the time required for pollen tube to reach embryo sac is affected by the irrigation amount, the relative comparison of the length of style and stigma (Takeoka et al., 1992) showed that the style length in the fourth irrigation regime (7-day interval) was slightly higher than other irrigation regimes. The length of pollen tube was very short despite the fact that the lengths of anthers and stigma were high. With improving irrigation conditions in 3-day interval regime at the time of pollination and fertilization, the style length increased. Genotype IR 80508-B-194-3-B with shortest style had a good fertility rate. According to the results, it seems that in addition to anthers' size, the release of pollen and stigmas power to hold pollens, the role of style after the process of pollination is very important for fertilization and seed production. The results corresponded to (Oyiga et al., 2010) on increased length of style in favorable conditions (*Figure 1*).

Correlation coefficients showed this trait had a significant correlation with anthers length (0.462**), stigmas length (0.0404**) and pollen area (-0.204**), which shows the positive and negative effects on these traits because of the increased length of these

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_19471970

traits together led to perfect adjustment of female organs to get the pollen from the male organ. However, increased pollen area because of inverse relationship with increases style diameter can decline the transferring or accelerating of pollen transport to the ovary, and finally fertility and increased grain yield. Recent comments are consistent with others (Arvin and Vafabakhsh, 2016; Akbari et al., 2016) (*Table 6*).

Pollen area

Results of combined analysis showed that the effect of year, irrigation regimes and genotypes were significant at 1% level and the interaction of irrigation regimes and genotypes, year and irrigation regimes and genotypes were significant at 5% level, but in other cases the differences were not observed (*Table 3*). The mean comparisons revealed that the highest and lowest pollen areas were seen in the second irrigation regime (986.675 μm) and in the fourth irrigation regime (869.657 μm), respectively (*Table 4*). The interaction between the two factors, genotype IR 80508-B-194-4-B with low resistance to drought had the highest pollen area in all irrigation regimes that decreased with increasing irrigation like other genotypes with low resistance, while increased pollen area was seen in genotypes with higher resistance in 3-day irrigation regime, which can be one of the main reasons for increasing grain yield due to having more nutrients energy in larger pollens and more strength to reach the ovary and pollen fertility (*Table 5*). Comparing the size and number of pollens in different planting regimes confirms that the second irrigation regime (3-day interval) had led to larger but less pollens. The pollen fertility can be showed based on the interaction between the amount of starch in pollen and iodide compound, which the pollen staining rate was very high in the second and third irrigation regimes and pollen were mainly globular with dark color. However, the pollen staining rate was low in the fourth irrigation regime (7-day interval) and a lot of damaged pollens with abnormal shape were observed. Recent results consistent with Sing et al. (2005). In addition, these results consistent with Erie classification system (Anonymous, 1982) that showed pollens were globular with dark color.

According to *Table 6,* the pollen area had a positive and significant correlation with male organ in terms of the same influence on all male organs in one direction and also with the style length that had to travel a long distance to reach the ovary as well as the reduction of large pollens entry to the longer styles with reduced diameter are the reasons for lack of entry and thus fertility and grain yield, a significant negative correlation was seen (-0.204**). The results consistent with other studies (Arvin and Vafabakhsh, 2016; Akbari et al., 2016).

Central cylindrical area of roots

In terms of the characteristics associated with root, it can be stated that the desirable characteristics of a root system can change with different soil and climatic conditions (Moshafaghi et al., 2014). In this study it was found that the effect of year, genotypes and irrigation regimes and interaction between year and genotypes were significant at 1% and the simultaneous effect of three year, irrigation regimes and genotypes was significantly different at 5% (*Table 7*). Increasing irrigation intervals resulted from increasing drought had reduced the central cylindrical area due to loss of vascular bundles area inside it due to better water conservation and efficiency (*Table 8*).

Further investigation on the interaction of irrigation regimes and genotype (*Table 9*) showed that genotype IR 81025-B-347-3 could achieve the highest central cylindrical area in all irrigation regimes due to genetic reasons; while, Tarom had the lowest central cylinder area in all irrigation regimes and like the previous genotype was in one statistical level in all irrigation regimes. So, in addition to environmental conditions, it can be concluded that the reason of differences between genotypes can be related to internal factors and genetics of studied rice genotypes, which did not correspond to other studies (Akbari et al., 2010; Sadat-jamali et al., 2014) reported that genotypes with less resistance had the lowest central cylindrical area and genotypes with greater resistance had the highest one. Because in the current study, the genotype with least

DOI: http://dx.doi.org/10.15666/aeer/1504_19471970

resistance had the lowest central cylinder area but another genotype (IR 81025-B-347-3) with low resistance had the highest pollen area (58351.239 μm^2).

Means in each column, followed by at least one similar letter(s) are not significantly different at 5% probability level using Duncan's Multiple Range Test
I1, I2, I3 and I4 include irrigation regimes of 1, 3, 5 and 7 days, respectively

However, the results corresponded to other studies (Lopes and Reynolds, 2010; Daxylem, 2016) on the reduction of traits size related to root anatomy such as central cylinder, which can reduce vascular bundles area by reducing the interior space in order to increase the efficiency of water (*Table 5*). Positive and significant correlation between central cylindrical area and xylem (0.667**) also showed increased likelihood of positive and negative impacts of these two traits in a line (*Table 10*).

Xylem area (posterior) of root

The results of combine analysis showed that there was a statistically significant difference between the year, irrigation regimes and genotypes and interaction of irrigation regimes and genotypes at 1% level and was no significant difference with other factors (*Table 7*). Increasing irrigation intervals had negative effects on the xylem area (*Table 8*). Mean comparison of the interaction of two factors showed that genotypes IR 79971-B-202-2-4 and IR 78908-193-B-3-B had the highest and the lowest xylem areas in all irrigation regimes, respectively due to genetic reasons; like other genotypes, it decreased with increasing irrigation intervals (*Table 9*). Due to the task and nature of xylem vessels in transferring water and nutrients, it seems that more water was maintained in genotype IR 78908-193-B-3-B with high resistance. On the other hand, in the first irrigation regime (1-day interval) with relatively larger vessels (985.616 μm^2), water transfer and drain was faster, which is considered a positive factor in warm conditions of rice growing environment. Given that the movement of water in Xylem vessels is affected by water uptake (xylem vessels wall) or adhesive force in addition to cohesive force; therefore, capillary rise of water in xylem vessels depends on the angle of the liquid contacting the wall, xylem vessels' radius and surface tension of liquids as well as gravity force, because the capillary rise in vessels is inversely proportional with its radius as a result capillary force retaining water is higher with smaller xylem area, and more pressure is needed to move water in vessels, which can be the main cause of compatibility of genotypes with high resistance to drought conditions due to reduced xylem area and hence improving the photosynthetic efficiency and water consumption (Daxylem, 2016; Hamadanzadah et al., 2015). By this reason, water is maintained with more force in genotype IR 78908-193-B-3-B with smaller xylem area (425.653 μm^2). In this system, transpiration is a physical phenomenon to produce movement force for water and inorganic elements (McKenzie et al., 2009; Daxylem, 2016). Given the importance of this route, changes in the xylem area at the time of planting and according to different environmental conditions and the amount of irrigation can disrupt the absorption and transportation processes of water and nutrients to photosynthetic parts (*Figure 2*). Results correspond to Limouchi et al. (2013) about reduced xylem area with increased stresses, drought stress in this study (compared to favorable conditions at heading stage).

DOI: http://dx.doi.org/10.15666/aeer/1504_19471970

Number of xylem vessels in root

According to *Figures 2* and *3*, number of xylem vessels in root was not affected by irrigation regimes and had a stable trend in all irrigation regimes and differences were due to internal factors and genetic reasons of investigated genotypes. Genotype IR 81025-B-347-3 had the highest number with 8 xylem vessels in cross-section of root. It seems that this genotype could have a consistency to absorb and maintain more water with increased number and decreased area due to lower central cylinder area. The results corresponded to (Daxylem, 2016) that number of xylem vessels depends on internal factors of plants and would not be affected by surrounding environment such as irrigation.

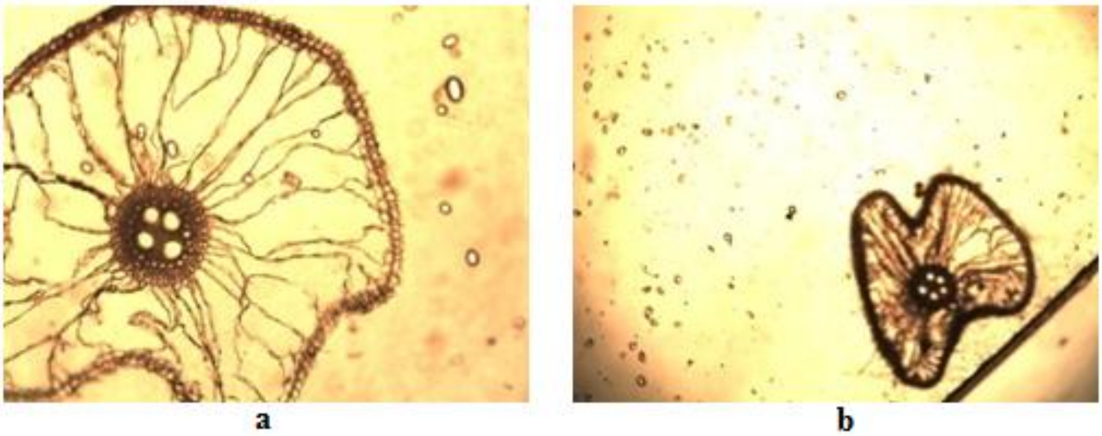

Figure 2. *Root anatomy; a and b: cross-section of the root with a magnification of 40 and 10, respectively*

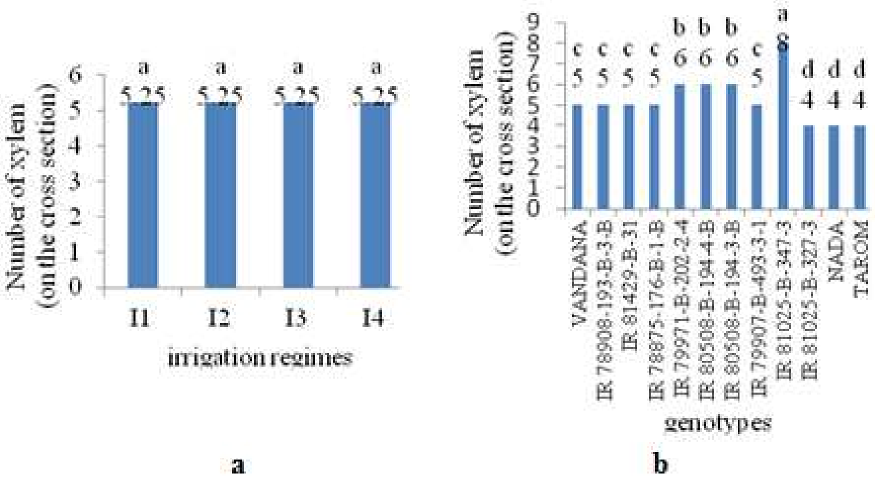

Figure 3. *Number of posterior xylem bundles; a and b: number of vascular bundles in the different irrigation regimes and aerobic rice genotypes, respectively. I1, I2, I3 and I4 include irrigation regimes of 1, 3, 5 and 7 days, respectively*

The weight of one thousand seeds

The results of combined analysis showed that except for the interaction of year and irrigation regimes, other factors and the interaction between them had significant

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_19471970

differences at 1% (*Table 7*). The highest and lowest weights of one thousand seeds were seen in the second irrigation regime (3-day interval) (20.394 g) and the fourth irrigation regime (7-day interval) (19.369 g), respectively (*Table 8*). As it can be seen, genotypes in 7-day interval irrigation regime had less weight of one thousand seeds in addition to reduced grain yield. The highest and lowest weights of one thousand seeds were achieved for Neda (21.788 g) in the second irrigation regime and genotype IR 81025-B-347-3 (19.033 g), respectively. Increased capacity of active reservoir and more strength to provide assimilates to seed in particular by providing favorable conditions in 3-day interval irrigation regime for genotype Neda contrary to other genotypes can be the reasons for reaching this conclusion. The results corresponded to other researchers (Arvin and Vafabakhsh, 2016) about the relationship between source and reservoir in increased weights of one thousand seeds and increased strength in ideal irrigation to fill the reservoir (*Table 9*).

Fertility rate

The results of this study showed that there was significant difference between years, irrigation regimes and genotype at 5% level and between the interaction of two factors at 1% level, but no difference was observed in other cases (*Table 7*). Mean comparisons represented the different reactions of genotypes to different irrigation regimes; despite the decline in fertility rate from the first to fourth irrigation regimes that actually represented the negative impact of increased drought on this trait. The highest and lowest fertility rate were seen in genotype IR 78875-176-B-1-B (98.029%) in the third irrigation regime (5-day interval) and genotype IR 79907-B-493-3-1 (23.443%) in the fourth irrigation regime (7-day interval), respectively. The result could be due to different responses of genotypes in the processes of production and accumulation of nonstructural carbohydrate soluble in vegetative parts of plants as well as panicle structure and its role in providing photosynthesis material in reproductive and vegetative parts and finally the harvest index. Soluble nonstructural carbohydrate plays an important role in the production of viable pollens, respiration rate and filling rate. It was found that by changing the irrigation regime and increasing fertility rate, the amount of soluble carbohydrates in vegetative parts at the time of physiological maturity had significantly declined (*Tables 8* and *9*). The results corresponded to others (Arvin and Vafabakhsh, 2016; Shanmugasundaram, 2015) about increased sterility due to high drought, the release and fertility of pollen role in fertility rate and the negative effects of high drought during maturity.

Dry matter yield per hectare

The results of this study showed that except for effects of years and genotypes as well as years, genotypes and irrigation regimes, other factors had significant differences. The interaction between years and irrigation regimes had significant differences at 5% level and other factors were significantly different at 1% level (*Table 7*). Relative superiority of dry matter of studied genotypes in the 3-day, 5- day and 7-day interval irrigation regimes and also genotypes with high resistance showed that changes in this trait fit perfectly with the grain yield (*Table 8*). Given that the highest grain yield was obtained in this irrigation regime and genotypes, it can be a result of increased leaf area index and net photosynthesis in order to transfer to the main reservoir (seeds). The highest (19291.015 kg/ha) and lowest (9562.587 kg/ha) dry

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_19471970

matter per hectare was seen in genotype IR 81429-B-31 with high resistance in the 3-day interval irrigation regime (*Table 2*) and genotype IR 78875-176-B-1-B in the 7-day interval irrigation regime, respectively (*Table 9*). In addition to grain yield, the results can be explained by genetic differences and their different responses to different irrigation regimes. Although the results are not consistent with (Ghasemi-Nasr et al., 2016), which stated flood irrigation increased dry matter, but corresponded to (Abdola and Zarea, 2015) about the reduction of dry matter in 1- day irrigation regime flooding) due to increased nutrients washing and making them unavailable for plants. The results are consistent with (Durand et al., 2016) on the reduction of nutrients accumulation to increase dry matter due to reduced plant growth period In terms of increased drought according to what happened in the fourth irrigation regime (7-day interval).

Grain yield

According to combined analysis results between years, irrigation regimes, their interactions as well as between genotypes and interaction of genotypes and irrigation regimes were significant at 1% level. However, there were no significant differences for the interaction of genotypes and year and the simultaneous effect of three factors and this indicates that grain yield was affected by genetic features, different irrigation regimes and their positive integration (*Table 7*). Mean comparisons showed that the highest grain yield (5094.31 kg/ha) was related to the 3-day interval irrigation regime, which had increased the production compared to flooding irrigation regimes (probably due to the incompatibility and waste of resistance energy such as the energy for creating aerenchyma) and also 5- and 7-day interval irrigation regimes (could be due to the unavailability to nutrients and assimilate accumulation at the base of plants) with rates of 19.50, 10.72 and 34.21%, respectively or 993.52, 546.05 and 1742. 79 kg/ha, respectively (Durand et al., 2016; Mohd Zain and Razi Ismail, 2016). Recent results according to others (Tarlera et al., 2015) indicated that the second irrigation regime and in the absence of water, 5-day interval irrigation regime might be appropriate to increase irrigation efficiency and reducing environmental pollutants such as methane. Besides, in addition to being compatible with most of the studied genotypes, permanent flooding conditions can wash nutrients and make them unavailable for plants. According to the reducing trend from first to fourth irrigation regimes, it seems that different reaction during different developmental stages due to the limited assimilates and shorter filling and grain growth periods are one of the reasons for reaching this conclusion (*Table 8*). Genotypes IR 81025-B-327-3 was superior to the other rice genotypes that the highest value (6555.10 kg/ha) was belonged to the second irrigation regime (3-day interval). Escaping from the water stress by reducing plant height to 10-20 cm, especially in the maturity period, as well as the allocation of more carbohydrates to the main reservoir are the reasons for compatibility and superiority of this genotypes. The interaction of two factors showed that according to other studies (Tavala et al., 2015) genotypes responses to different irrigation regimes regarding their tolerance threshold thus traits related to genotypes was different. Hence, all genotypes in the fourth irrigation regime due to the short growing season and thus Allocation of less carbohydrates and minerals transferred to the main tank and ultimately Reduction of the tank activity and dry matter accumulation capacity (capacity × number of seed), grains had the lowest yield (*Table 9*). The results are consistent with other studies (Durand et al., 2016) on the reduction of grain yield in terms of increased tension, higher than plant tolerance due to the growth disturbance during reproductive stage and lack of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_19471970

transferring and allocation of carbohydrates and sugars to the grain as well as other studies (Abdola and Zarea, 2015) based on yield loss in flooded conditions; however, it is not in accordance with study of Ghasemi-Nasr et al. (2016), which stated increasing available water for roots in flooded irrigation had increased rice yield.

The results of regression analysis of grain yield and traits showed that the lengths of stigma and style and xylem area are factors affecting grain yield; so that, 0.016% of the changes associated with 0.01% more than the style length was related to the stigma length, which in turn represents the role and importance of this trait compared to the traits in rice production. According to recent results, in order to achieve an optimum value for this index, creating a perfect reservoir can provide a base for transferring dry matter to the reservoir and the formation of economic performance in line with increased production (*Table 11*). The results corresponded to (Oyiga et al., 2010) about the effect of the stigma on grain yield due to its high influence on receiving pollen and fertilization.

Conclusion

The results of the present study indicated that the size of anatomical characteristics of florets was more dependent on internal properties of the plant; so that, genotypes with larger and smaller sizes of these traits maintained their preference to other genotypes while under the influence of different irrigation regimes. In general, increasing irrigation intervals from the second (3-day interval) to the fourth (7-day interval) irrigation regimes and thus increased drought around plants reduced pollen area and as a result nutrients reservation was also reduced that can reduce its transfer to ovaries and plants fertility rate. The first irrigation regime with one day rotation also in flood The IR 80508-B-194-4-B genotype had the highest grain pollen area in all irrigation regimes due to genetic reasons. Increasing the irrigation interval had a negative effect on the pollen grain surface due to reduced food and energy needed to reach ovaries that ultimately led to lack of fertility and reduced grain yield conditions, due to the aerobic nature of genotypes, reduced pollen grains due to more energy to expand the adaptive mechanisms such as arranchym. From the highest to the shortest anther length, the irrigation regimes were observed in intervals of five, seven, three and one days, respectively. The IR 78908-193-B-3-B genotype also had the highest anther length among all irrigation regimes, except for a significant decrease in the second irrigation regimen with a three-day rotation that could be a major factor in increasing fertility and grain yield was due to the proximity to the stigma and hence more effective grain

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_19471970

transfer, but no significant difference was observed in other irrigation regimes. In the fourth irrigation regimen with a seven-day irrigation interval, we observed a decrease in anther width, but in other irrigation regimes there was no difference in width. The IR 80508-B-194-3-B genotype had the highest anther width in all studied irrigation regimes, which increased the irrigation intervals and, as a result, drought reduced. The highest length of the stigma was for IR 78875-176-B-1-B genotype in all irrigation regimes, which, like other genotypes, increased with increasing length of irrigation intervals. The length of the style in the fourth irrigation regimen with a seven-day interval decreased, and there was no significant difference in other irrigation regimes. The IR 78908-193-B-3-B genotype also had the highest length of style in all irrigation regimes, which increased the length of style by increasing irrigation intervals, so that it had the maximum length of style in the fourth irrigation regimen with irrigation interval of seven on the contrary to genotypes with less resistance and therefore more favorable compatibility with these conditions. Due to having a good-sized stigma, style, anther and anther width, the second irrigation regime was able to get and keep more pollen and thus increased fertility rate and grain yield. While in other irrigation regimes such as the fourth irrigation regime (7-day interval) with increased anthers and reduced style length, the distance between male and female organs increased and thus receiving pollen decreased. The results also showed water shortage in 5- and 7-day irrigation regimes caused a reduction in central cylindrical area and xylem area, which could be a mechanism to increase water use efficiency and reduce the transpiration. The results showed that the IR 81025-B-347-3 and IR 79971-B-202-2-4 genotypes had the highest values for all the irrigation regimes in the central cylindrical and xylem area crests, respectively. By increasing the irrigation intervals and thus the drought around the plant to adapt to the conditions and increase the efficiency of use, the potential and the transfer of water from the surface were reduced. As a result, the dryness around the plant was reduced to adapt to the conditions and to increase the efficiency of use, the potential and the transfer of water from their surface. Of course, it could lead to a reduction of material transferring and ultimately grain yield such as that obtained for the fourth irrigation regime (7-day interval). Among the traits dependent on yield and grain yield components, weight of a thousand seeds dry matter and seed yield were highest to the lowest in irrigation regimes of three, five, one and four days, respectively. Fertility also increased the irrigation intervals due to reduced pollen grains and lack of energy to reach the ovary and to inoculate. NADA genotype had the highest weight of a thousand seeds in irrigation regimes of one and three days and the IR 79971-B-202-2-4 genotype had the highest amount in irrigation regimes of five and seven days. Increasing the weight of a thousand seeds in low-resistance genotypes in conditions of increasing irrigation intervals over the previous discussion could result in a reduction in the number of florets and more infertility, thereby reducing competition and increasing the space in the paniculum. The IR 78908-193-B-3-B genotype had the highest fertility rates in first and fourth irrigation regimes, with one and four-day irrigation intervals, NADA and IR 78875-176-B-1-B genotypes also had the highest fertility rates, respectively in the second and third irrigation regimes with irrigation intervals of three and five days according to the previous descriptions. Due to the large canopy structure, large leaves and thick stems, IR 81429-B-31 genotype with the highest dry resistance had the highest dry matter yield in all irrigation regimes. The TAROM, IR 81025-B-327-3, IR 81025-B-347-3 and IR 81429-B-31 genotypes have the highest grain yield in irrigation regimes of one, three, five and seven days, respectively. Resistant genotypes

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_19471970

with improved resistance to irrigation intervals maintained their grain yield better than less resistant genotypes. However, under daily irrigation conditions due to increased energy, resistance to other genotypes had lower grain yield, which could be used depending on the different moisture conditions. The results of this study indicated that the second irrigation regimen with three-day irrigation interval was able to adapt the aerobic rice genotypes with the highest positive and significant correlation with grain yield and decrease the negative correlation traits. Finally, the relative yield of genotypes was increased. The IR 81025-B-327-3 genotype with an average of 10.6555 kg/h in the second irrigation regimen had the highest grain yield and could be recommended as the superior genotype for cultivation in similar conditions.

Therefore, it can be suggestions for further studies that by focusing main goals on reducing the central cylinder area and xylem of root to increase water use efficiency in dry condition and controlling lengths of florets parts we can hop to increase connection between pollen and flower and finally fertility to increase production under different irrigations.

Abstract. Drought is a major limiting factor of plant production in arid and semi-arid regions including Iran. The use of arbuscular mycorrhizal fungi and plant growth promoting rhizobacteria (PGPR) may constitute a biological alternative to increase crop yield and plant resistance in water stress conditions. In order to evaluate the synergistic effect of four strains of *Pseudomonas* and arbuscular mycorrhizal fungi (AMF) on nitrogen and phosphorus uptake and yield components of Iranian barley cultivars (Dasht and Sahra) under rain-fed conditions, a two-year experiment was conducted in factorial randomized complete block design. The results demonstrated that in most of the characteristics, the interaction effect of *Pseudomonas* × AMF on cultivars in both years was significant. While *Pseudomonas* strains exhibited different reactions to cultivar and AMF use, in most of the traits measured, they were superior when compared to control. In both cultivars, the maximum yield parameters studied was obtained from co-inoculation of AMF + S4 strain. The Sahra has more production sustainability in comparison to Dasht (seed yield of Dasht 1293 and 1912 kg/ha; Sahra 1752 and 1939 kg/ha in first and second year, respectively). Moreover, in both years and in both cultivars, the co-inoculation increased P and N concentration and uptake significantly. It increased seed yield, while the yield increase was more evident in the Sahra. According to the results obtained, to achieve the maximum seed yield in rain-fed conditions of Iran, cultivation of Sahra alongside co-inoculation of AMF + *Pseudomonas putida* S4 strain is recommended.
Keywords: *Glamus intraradices; N concentration; P concentration; seed yield*

Introduction

Drought is one of the most serious problems in the Middle East, especially in arid and semiarid countries (Kheiri et al., 2017). Considering population growth rates and limited global water resources, it is anticipated that food security will become a serious challenge in the coming decades (Sheffield et al., 2012). The agricultural sector in Iran is one of the most important economic sectors of the country, and water is the most limiting factor for production (Schoppach et al., 2017). Whereas around 92% of agro products depend on water, less than one-third of the cultivated area is irrigated; the rest is devoted to dry farming (FAO, 2014). In these areas, barley (*Hordeum vulgare* L.) is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_195216

grown mainly under rainfed conditions and could fall victim to drought at any stage of growth (Dijkman et al., 2017; Schoppach et al., 2017).

Extensive research is being carried out throughout the world to develop strategies to cope with drought stress by developing drought tolerant cultivars (Oukarroum et al., 2009), shifting crop calendars (Lu et al., 2017), and optimizing fertilizer use (Cetin and Akinci, 2015), agronomic practices (Mupangwa et al., 2012) and resource management practices (Parry et al., 2005; Habiba et al., 2012). Most of these technologies are cost-intensive. Non-normative and long-term use of chemical fertilizers gradually decreases soil quality, reduces the quality of the product, causes imbalances in the natural ecosystems and extends environmental pollution (Ali et al., 2005; Vurukonda et al., 2016).

As a relatively simple and low-cost alternative strategy, the use of free-living plant growth-promoting rhizobacteria (PGPR) is a promising broad-spectrum means of improving plant growth (Yang et al., 2009). The use of microorganisms, especially for intensive culture and in nutrient-poor soil, is essential to preserving the quality of the soil in Iran (Arzanesh et al., 2011). Recent studies in Iran indicate that microorganisms can also help plants to cope with drought stress (Tabatabaei et al., 2016; Khalilzadeh et al., 2016; Delshadi et al., 2017). These bacteria contribute to plant growth by fixing free-living nitrogen, producing growth metabolites such as plant hormones, increasing the solubility of insoluble compounds such as P and K by producing mineral and organic acids and by siderophore production. This increases the supply of micronutrients, especially iron, and reduces the negative effects of stress ethylene and the production of amino cyclopropane-1-carboxylate (ACC) (Arshad et al., 2008). A large number of PGPRs hydrolyze ACC to ammonia, ethylene and alpha ketobutyrate to prevent overproduction of stress ethylene in plants and reduce root growth by producing ACC deaminase enzyme (Glick, 2014).

Pseudomonas fluorescent has been investigated because of its catabolic versatility, excellent colonization ability at the root surface and the ability to produce a wide range of enzymes and metabolites that may be useful in a variety of biotic and abiotic stresses (Mayak et al., 2004). *Pseudomonas* is an important ACC deaminase enzyme-producing bacteria (Glick, 2014). In many arid regions of the world and in Iran, it reduces the negative effects caused by stress tests. Arshad et al. (2008) demonstrated that inoculation of wheat (*Triticum aestivum*) with *Pseudomonas putida* under drought stress improved water status and an additional elastic adjustment that increased grain yield and mineral quality (Mg, K, and Ca). Frohlich et al. (2012) carried out greenhouse and field experiments and reported that *Pseudomonas* sp. DSMZ 13134-treated barley showed increased yield and straw weight under nutrient deprivation. Plants treated with exopolysaccharide (EPS) producing bacteria displayed increased resistance to water stress (Bensalim et al., 1998).

The EPS-producing strain of *Pseudomonas putida* GAP-P45 formed a biofilm on the root surface of sunflower seedlings and imparted tolerance to plants against drought stress (Sandhya et al., 2009). The inoculated seedlings showed improved soil aggregation and root-adhering soil and higher relative water content (RWC) in the leaves. Inoculation of two different crops (tomatoes and peppers) with PGPR *Pseudomonas putida* KT2440 augmented the antioxidant catalase under severe drought conditions, suggesting that trehalose produced by these microorganisms correlates with their ability to protect plants against drought (Vílchez et al., 2016).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_195216

Arbuscular mycorrhiza fungi (AMF) form beneficial symbiotic associations with most plants and play a vital role in plant growth under various conditions by modifying the root system and enhancing the mobilization and uptake of several essential elements. They have also been reported to stimulate plant stress tolerance by enhancing enzymatic as well as non-enzymatic antioxidant defense systems (Wu et al., 2014; Ahmad et al., 2014), lipid peroxidation (Abd_Allah et al., 2015), and phytohormone synthesis (Navarro et al., 2013).

Researchers have stated that some *Pseudomonas* strains can have stimulatory effects on AM growth under drought stress (Meyer and Linderman, 1986). One study found that severe colonization of barley roots by AMF increases plant growth and dry matter production (Chaurasia and Khare, 2005). AMF helper bacteria colonization such as *Pseudomonas* stick to root surfaces and reform the symbiotic relationship between AMF and the plant to provide many benefits to the host plant (Schalamuk et al., 2006). AMF helper bacteria offer mechanisms that affect the deployment and performance of AMF symbiosis and stimulates spore germination, fungal contact with roots or prompt AMF root production (Frey-Klett et al., 2007; Parmar and Dufresne, 2011; Nadeem et al., 2014).

These findings indicate that the co-inoculation of AM and *Pseudomonas* can enhance the activity of AM during symbiosis with the host plant (Artursson et al. 2006). Barea et al. (2005) concluded that the cooperation of *Pseudomonas* and AM in nutrient uptake by plants is probably due to specific attributes of the microorganisms and there is a growing interest in improving understanding of their involvement in nutrient cycling and non-nutritional physiological values that make the plant more tolerant of drought stress.

There have been no investigations thus far into the synergistic effect of root colonization of fluorescent Pseudomonads and AMF on barley under dry land farming conditions in Iran. In many crops, root colonization by fluorescent Pseudomonads and AMF changes a plant's nutrient uptake, growth and drought resistance. The present study focused on the agronomic effects of native *Pseudomonas* strains and AMF on N and P uptake and yield in barley. The hypothesis tested was that the co-inoculation of *Pseudomonas* strains and AMF would increase the nutrient uptake and yield of barley cultivars and would induce resistance against water deficit.

Materials and methods

The study site

A field experiment was carried out in Research Center of Ardebil Islamic Azad University with a height of 1460 meters above sea level, longitude 48˚20' and latitude of 38˚19' under rain-fed conditions during both 2014-2015 and 2015-2016 growing seasons. Climatic condition of Ardebil province is characterized by a semi-arid climate (humid winters and dry summers). Rainfall distribution is fluctuate in Ardebil province and most of precipitation occurs between October and May, and precipitation of long term is 424 mm. Annual rainfall were 348 and 407 mm during 2014-2015 and 2015-2016 growing seasons respectively in Ardebil. Mean monthly rainfall (*Figure 1*) and monthly temperature (*Figure 2*) during plant growth for both years have been presented. Soil samples were collected from the surface (0-30 and 30-60 cm depth) before sowing. Samples were air dried and powdered with wooden mortar and pestle and passed through a 2 mm stainless steel sieve. Soil experiment results are presented in *Table 1*.

Treatments and experimental design

Experiment was conducted in a factorial randomized complete block design with three replications. Experimental factors include AMF species *Glamus intraradices* strain of BEG11 (inoculated (M1) and non-inoculated (M0)), strains of *Pseudomonas* (four strains of *Pseudomonas* bacteria, including S153, S169, S4, S8 and a control (without inoculation) and barley cultivars (Dasht and Sahra cultivars).

Preparation and characterization of Pseudomonas strains

These *Pseudomonas* strains were isolated from soil samples collected from fields in Ardebil province, Iran. The strains were evaluated for their siderophores, P-solubilizing capability, acid and alkaline pH, and produces the phytohormone indole-3-acetic acid (IAA) (Alishahi et al., 2013). *Pseudomonas* strains was characterized as described below:

Siderophore production by *Pseudomonas* strains were tested on universal Chrome Azurol S (CAS) agar (Schwyn and Neilands, 1987). The bacterial strain was inoculated at the center of the plate and incubated at 28 °C for 3 days. Siderophores production were detected by a halo of color change from blue to orange on the CAS medium and measured in triplicate as the ratio between the two diameters of the halo and the two colony diameters.

Phosphate solubilization by *Pseudomonas* strains were assayed according to Goldstein (1986), using two different media, one containing dicalcium phosphate (DCP) (NH_4Cl 4.25 g l^{-1}, NaCl 0.85 g l^{-1}, glucose 8.5 g l^{-1}, $MgSO_4$ $7H_2O$ 0.85 g l^{-1}, K_2HPO_4 2 g l^{-1}, $CaCl_2$ $2H_2O$ 4 g l^{-1}, agar 17 g l^{-1}) and one containing tricalcium phosphate (TCP) (NH_4Cl 5 g l^{-1}, NaCl 1 g l^{-1}, $MgSO_4$ $7H_2O$ 1 g l^{-1}, glucose 10 g l^{-1}, $Ca_3(PO_4)_2$ 40 g l^{-1}, agar 20 g l^{-1}). The strains were inoculated at the center of the plate and incubated at 28 °C for 15 days. DCP solubilization was indicated by a clarification halo around the colony; TCP solubilization was identified by a colony growth on the media.

Indole-3-acetic acid (IAA) production by *Pseudomonas* strains were quantified according to De Brito Alvarez et al. (1995). The bacterial strain was inoculated onto a nitrocellulose disk placed on trypticase soy agar (TSA) with 10 % added to L-tryptophan (5mM) and incubated at 28 °C for 3 days. The membrane was then stained with the Salkowskys reagent ($FeCl_3$ 2 % in percloric acid 35 %), the presence of a red/pink halo around the colony indicated a positive reaction.

The 1-aminocyclopropane-1-carboxylate (ACC) deaminase enzyme activity was assayed based on Penrose and Glick (2001) method which measures the amount of α-ketobutyrate produced when the enzyme ACC deaminase cleaves ACC. The µmole quantity of α-ketobutyrate produced by this reaction was determined by comparing the absorbance of a sample to a standard curve of α-ketobutyrate ranging between 0.1 and 1.0 nmol at 540 nm. A stock solution of α- ketobutyrate was prepared in 0.1 M Tris-HCl (pH 8.5) and stored at 4o °C. In order to measure the specific activity of the cultures, protein estimation was carried out according to Lowry et al. (1951). *Pseudomonas* strains characterized are presented in *Table 2*.

Table 2. *Characteristics of Pseudomonads strains*

Pseudomonas Strains	Phosphorus solubilizing activity	ACC-deaminase activity µmoles mg^{-1} h^{-1}	IAA production (mg L^{-1})	Siderophore production (halo diameter/colony diameter)
P. fluorescens strain 153	+	4.61	3.1	1.6
P. fluorescens strain 169	+	4.45	2.8	1.5
P. putida strain 4	+	8.17	6.6	1.7
P. putida strain 8	+	7.34	5.9	1.6

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_195216

The bacterial strains were kept in nutrient broth with 15% glycerol at –80 °C for long-term storage. For this experiment, a single colony was transferred to 500 mL flasks containing NBRIP and grown aerobically on a rotating shaker for 48 h at 27 °C and 150 rpm. The bacterial suspension was then diluted in sterile distilled water to a final concentration of 10^8 colony forming units (CFU) mL^{-1}, and the resulting suspensions were used for the experiment.

Experimental plots, seed inoculation and sowing

Before sowing, barley seeds were soaked by Arabic gum and active bacteria were added to seeds. After inoculation, seeds were dried on a surface sterilized plastic sheet in laminar flow.

The AMF inoculum contained colonized root fragments, sand, AMF hyphae and spores. The inoculum was blended with an inert material for solution and homogenizing the distribution in the soil. A 50-g portion of inoculum was added to each plot at sowing time just below the seeds (Vazquez et al., 2002). The AMF was obtained from the culture collection of the Soil and Water Research Institute (SWRI), Iran.

The first effective rainfall was in November 23 and cultivation operation began after it. In the fall and before planting, plowing operation and disc were conducted and after land leveling, the seeds were planted with density of 400 seeds per m^2. Plots were 6 rows, 5 meters long, and spaced 20 cm. Hand weeding was operated after planting. Farm management was conducted conforming to organic farming principles with no application of chemical materials.

Sampling of mycorrhizal colonization and plant height, yield components, seed yield, and biological yield

The mycorrhizal colonization was enumerated using the method of Philips and Hayman (1970). The roots were examined under a microscope and the percent of root colonization was determined by dividing the number of colonized roots by the number of total roots examined.

In physiological maturity stage, sampling of middle lines of each plot was conducted with respect to the sidelines and among competing bushes. To calculate the plant height, number of fertile tiller per plant, seeds per spike and thousand kernel weight (weight of 1000 seeds), samples taken from 10 plants were randomly selected and counted in each of 10 plants. Then, their mean was calculated in each plant. Seed yield was measured from middle rows of each experiment plot with 1 m^2 area. For measuring biological yield, the samples were dried for 72 h at 70 °C in an oven. Harvest index was calculated by following formula:

$$\text{Harvest index (\%)} = \frac{\text{Seed yield (kg/ha)}}{\text{Biologicalyield (kg/ha)}} \times 100 \qquad \text{(Eq.1)}$$

Nutrient analysis

The seed nitrogen (N) content was determined following the semi-micro Kjedahl procedure using a nitrogen analyzer (Kjedahl, 2300; FOSS, Hoganas, Sweden). The phosphorus (P) content was estimated using the vanadomolybdo-phosphoric colorimetric method (Jackson, 1962). Uptake of seed elements was calculated by following formula:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_195216

$$\text{Element uptake (kg/ha)} = \frac{\text{Seed yield (kg/ha)} \times \text{Element concentration (\%)}}{100} \qquad \text{(Eq.2)}$$

Statistical analysis

Experimental data were analyzed statistically using ANOVA. Significance of the effect of treatment was determined by the magnitude of the F-value ($P \leq 0.05$). When a significant F-test was obtained for the treatments, separation of means were done using the LSMEANS procedure with LSD adjustment at $P = 0.05$. Statistical analysis of the results was performed using general linear model (GLM) in SAS software version 9.2.

Results and Discussion

Plant height

The results demonstrated that the interaction effect of *Pseudomonas* × AMF × cultivars × year had significant on plant height was significant (P<0.05) (*Table 3*). Mean comparison showed that in the first year in the Sahra cultivar at the AMF inoculation levels, there was no significant difference between the *Pseudomonas* strains. Nevertheless, in the Sahra at the AMF non-use conditions, control (76.96 cm) exhibited the greatest height.

In the second year, in both cultivars, S4 strain in comparison to other *Pseudomonas* strains produced more height (0.7-29.5% and 1.1-16.5% under AMF use and non-use conditions, respectively), although there was no significant difference between some strains and control (*Table 4*). Increasing the plant height plays an important role in the remobilization of photosynthetic materials to seeds during seed filling period (Sharma et al., 2014). Vazquez et al. (2000) on their investigation on wheat also reported that AMF and cultivar had significant effect on plant height, but the effect of bacteria on plant height was not statistically significant.

The useful impact of AMF in uptake of water and elements required by plant through root and root development and increased uptake of elements in the soil to be used by plant, which caused increased in height. Roesti et al. (2006) reported that PGPR strains and AMF can synergistically improve the height of wheat without negatively affecting AMF growth. We also found that the impact of *Pseudomonas* strains on plant height was stronger in AMF-treated plants than untreated plants. This result was in line with the result of the study performed by Chaurasia and Khare (2005).

The number of tiller and number of seed per spike

The interaction effect of *Pseudomonas* × AMF × cultivars × year on number of tiller was significant (P<0.05) (*Table 3*). Mean comparison of the number of tillers showed that in the first year in the Dasht cultivar, though *Pseudomonas* strains were superior compared to control, significant differences were not found between strains. Nevertheless, in Sahra cultivar, both in conditions of consumption and non-AMF conditions, strains of bacteria were superior to the control (10-54% and 5-46% under AMF use and non-use conditions, respectively), while this superiority in some strains was not significant and strain S4 had significant superiority compared to other strains (5.5-32% and 12-28% under AMF use and non-use conditions, respectively).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_195216

In the second year, in both cultivars, in the presence and absence of AMF, *Pseudomonas* strains compared to control had significant superiority (16.1-55.2% and 3.3-46% under AMF use and non-use conditions, respectively) and strain S4 compared to other strains had significant superiority (7.0-13.3% and 5.1-29.6% under AMF use and non-use conditions, respectively) (*Table 4*). In total, in both cultivars, application of AMF led to increased influence of *Pseudomonas* strains and the number of tillers in plant.

The interaction effect of *Pseudomonas* × AMF × cultivars × year on seed per spike was significant ($P<0.05$) (*Table 3*). Comparison of the mean interaction effect of AMF and *Pseudomonas* strains inoculation with barley cultivars on seed number in the spike also revealed that in the first year in the Sahra cultivar in AMF non-use conditions, there was no significant difference between *Pseudomonas* strains and control, and at the AMF use conditions, only strain S4 had superiority compared to control (25.7%). In the Sahra cultivar in AMF non-use conditions, with the exception of strain S4, other strains did not demonstrate any significant difference compared to control. Nevertheless, the use of AMF in plants inoculated with *Pseudomonas* strains increased the number of seeds per spike significantly compared to control (29.0-41.9%). In the second year, in the Dasht cultivar, *Pseudomonas* strains showed significant superiority compared to control (8.9-31.3% and 15.2-23.6% under AMF use and non-use conditions, respectively), however in the AMF non-use conditions, there was no significant difference between the strains of *Pseudomonas*. In the Sahra cultivar, similar trend was observed, while in the AMF use conditions, significant difference was not seen between the S169 strain and control. In total, in both years and cultivars, the maximum number of seeds per spike was obtained from S4 strain under the use of AMF (*Table 4*). Given that tillers are determined earlier than flowering stage, inoculation of seeds with growth stimulating bacteria increased the number of fertile tiller.

**, ** Significant at P < 0.05 and P < 0.01, respectively. CV: Coefficient of Variation*

In both years, some *Pseudomonas* strains enhanced grain number under AMF use through producing more tillers. In this respect, Shaharoona et al (2008) reported an increase in the number of tillers per plant inoculated with growth promoting bacteria.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_195216

Bacteria used in this experiment can produce ACC deaminase enzyme and this increase in number of tiller can be attributed to this enzyme.

Results of this experiment are in line with results of Nadeem et al. (2007) that reported increased number of tillers in rainfed conditions by growth promoting bacteria. Bacteria mediated changes in the elasticity of the root cell membranes is one of the first steps towards enhanced tolerance to water deficiency (Dimkpa et al., 2009). PGPR improves the stability of plant cell membranes by activating the antioxidant defense system, enhancing drought tolerance in plants (Gusain et al., 2015).

Wagar et al. (2004) reported the effect of AMF in increasing the efficiency of *pseudomonas* bacteria. Therefore, depending on the strain combination, microbial interactions within AMF had positive effects on inoculant establishment in roots and resulted in enhanced tillers and number of seeds as compared to single inoculation.

Means within a column followed by the same letter are not significantly (P < 0.05) different according to LSD test. (Y1 = 2014-2015; Y2 = 2015-2016) (M0 = AMF non-use; M1 = AMF use)

Thousand kernel weight

Results of analysis of variance revealed that the main effect of AMF and interaction effect of bacteria × year on seed weight was significant ($P<0.01$) (*Table 3*). Mean comparisons of AMF impact on thousand kernel weight revealed that use of AMF increased thousand kernel weight by 11.2% compared to non-use of AMF (*Figure 3*). AMF provided more water to plant by increasing uptake level, thus during the seed filling, it can help the plant and increase the weight of seeds (Estrada-Campuzano et al., 2012). A comparison of the mean interaction effect of bacteria × year also revealed that in both years, the control in comparison to *Pseudomonas* strains was superior (*Figure*

DOI: http://dx.doi.org/10.15666/aeer/1504_195216

4). Thousand kernel low weight in rainfed conditions is due to competition of seeds in obtaining food and reduced carbohydrate stored by plant such that number of cells produced decreases and thousand kernel weight decreases, while AMF played a significant role in increasing weight of wheat seeds (Arshad et al., 2008). Allahverdiyev et al. (2015) reported that in other crops such as wheat, inverse relationship was observed between yield elements, such that with changes in yield elements, the production amount cannot be increased from the final range. It seems that increasing adequate water supply from the beginning of plant growth leads to increased tillering and number of leaf. Generally, it leads to increased yield elements and thus seed yield.

Biological yield

The interaction effect of *Pseudomonas* × AMF × cultivars × year on biological yield was significant ($P<0.05$) (*Table 3*). The comparison of mean showed that in the first year in the Dasht cultivar, the use of AMF increased the biological yield such that S4 strain (which showed the highest biological yield) in the conditions of AMF usage, caused increased biological yield of 22.73% in comparison to control. However, at the conditions of AMF non-use, biological yield increased by 14.66%. In the Sahra cultivar, S4 strain in both AMF using and non-using conditions had superiority in comparison to other strains of *Pseudomonas* (24.2% and 27.8% under AMF use and non-use conditions, respectively, in comparison to control), while significant difference was not found between some strains and control.

In the second year in the Dasht cultivar, the AMF use led to significant superiority of *Pseudomonas* strains compared to the control (10.2-18.3%), such that even in the control, the use of AMF increased biological yield by 5.47% in comparison to AMF non-use condition. In the Sahra cultivar in conditions of using AMF, only S4 strain had significant superiority compared to control (33.8%) and there was no significant difference between other strains of *Pseudomonas* and control (*Table 5*).

The increase in biological yield by soil and seed inoculation of *Pseudomonas* strains and AMF at different conditions has been reported by many researchers (Germida and Walley, 1996, Shaharuna et al., 2008). Khan et al. (2003) in the review of research conducted on growth stimulating bacteria reported the significant effect of inoculation with *P. fluorescent* on dry weight of aerial part of barley. Growth stimulating microorganisms such as *Pseudomonas* and AMF can provide optimum conditions to increase biomass by creating positive variations on soil physical and chemical properties around the root, and the timely provision of required elements during the growing season (Esfahani et al., 2009). Messele and Pant (2012) observed improved biological yield and P uptake in chickpea (*Cicer arietinum* L.) by phosphate-solubilizing *Pseudomonas*. An increase in P availability to plants through the action of phosphate-solubilizing bacteria (PSB) has also been reported for wheat (Panhwar et al., 2011). Application of plant growth stimulating bacteria that can also produce the enzyme ACC deaminase and alongside AMF can provide the elements needed by plant and lead to increased plant growth (Lingua et al., 2003). Their synergistic interaction increased N, P and K uptake by plants under water deficit conditions (Malfanov et al., 2011). Strains appear to have some plant growth-promoting activities, such as IAA production and solubilization of phosphate, which together or alone might explain the capacity of *Pseudomonas* strains to improve plant growth and nutrient acquisition.

Seed yield

The interaction effect of *Pseudomonas* × AMF × cultivars × year on seed yield was significant ($P<0.01$) (*Table 3*). A comparison of the mean interaction effect of *Pseudomonas* and the AMF on seed yield of barley cultivars revealed that in the first year at Dasht cultivar using AMF conditions, significant differences were not observed between *Pseudomonas* strains. However, the use of AMF led to increased seed yield in all strains and even in control and S4 strain with yield of 1293 kg/ha which increased seed yield by 17.63% compared to control. In the Sahra cultivar, *Pseudomonas* strains increased seed yield at both levels of AMF.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_195216

In the second year at Dasht cultivar in both levels of AMF, strains of *Pseudomonas* when compared with control showed significant superiority and at the level of AMF non-use conditions, strain S8 with mean of 1529 kg/ha and at the AMF use conditions, strain S4 with mean of 1912 kg/ha (had no significant difference with S169) exhibited the highest seed yield. In the Sahra cultivar, *Pseudomonas* strains increased seed yield in comparison to control, and S4 increased seed yield by 13.33% at AMF non-use conditions and 18.66% at AMF use conditions (*Table 5*). The effect of microorganisms on plant depends on many factors such as soil organic matter, the amount of existing elements in the soil, soil texture, soil moisture, strain type, and plant cultivar (Vessey, 2003). The relationship between plant cultivars and strains have been reported in the studies of Kader et al. (2002) and Dijkman et al. (2017). Nonetheless, with increased seed yield in AMF non-use conditions, *Pseudomonas* strains compared to control caused increase in seed yield in Sahra cultivar, but the increase in seed yield is increased by adding AMF, and in the Dasht cultivar, its efficiency of bacterial inoculation is increased. The effect of AMF on the increased efficiency of bacterial inoculation has been reported by Sexena and Jha (2014). However, increase in seed yield can be attributed to the role of AMF and *P. Putida* in increasing uptake of elements such as Fe and P (Vessey, 2003). However, partial increase in barley seed yield can be attributed to the secretion of plant hormones secreted such as Auxin- by microorganisms. Secretion of IAA and other plant growth hormones in canola, wheat, and tomatoes inoculated with *P. Putida* has been reported by Mayak et al. (2004). In addition, plant growth stimulating microorganisms affect the root morphology and size and thus affect the root ability in accessing larger volume of soil. Consequently, they increase uptake of water and plants yield (Arshad et al., 2008).

Harvest index

The interaction effect of *Pseudomonas* × AMF × cultivars × year on harvest index was significant ($P<0.01$) (*Table 3*). The mean comparison revealed that in the Dasht cultivar at the AMF use condition, there was no significant difference between strains, but at AMF non-use condition, *Pseudomonas* strains had significant superiority when compared to control and S4 showed the highest harvest index. In Sahra cultivar, at the AMF use conditions, strains S8, and at the AMF non-use conditions, S153 had the highest harvest index. In the second year, only the Dasht cultivar and at the AMF use conditions, strain S4 demonstrated maximum harvest index, but at the AMF use conditions in the Dasht cultivar and in Sahra cultivar at both AMF use and non-use conditions, control exhibited the greatest harvest index (*Table 5*).

N uptake and N concentration of seed

The interaction effect of bacteria × cultivar on seed N concentration was significant ($P<0.01$) (*Table 6*). A comparison of the mean interaction effect of bacteria × cultivar on seed N concentration showed that in the Dasht cultivar, only strain S8 had significant superiority compared to control (14.2%) and other strains demonstrated no significant superiority. Nevertheless, in the Sahra cultivar, strain S8 showed no significant superiority when compared to control, while other strains showed superiority when compared to control and the highest seed N concentration was obtained by S4 strain (28.7%) (*Figure 5*).

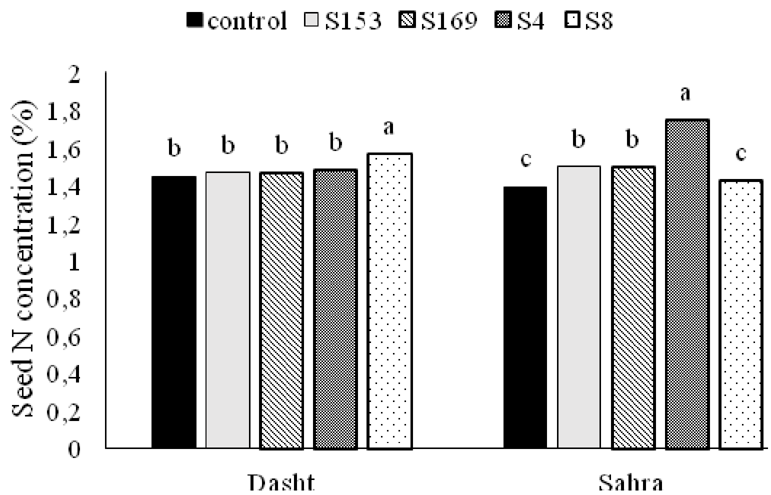

Figure 5. *Interaction effect of barley cultivars × Pseudomonas strains on seed N concentration. Means in each column followed by at least one similar letter are not significantly different at 5% probability level, using LSD test*

The results of the analysis of variance showed that the interaction effect of *Pseudomonas* × AMF × barley cultivars × year on seed N uptake was significant ($P<0.05$) (*Table 6*). A comparison of the mean interaction effect of *Pseudomonas* × AMF × barley cultivars × year on seed nitrogen uptake showed that in the first year in the Dasht cultivar at the AMF non-use conditions, strains of *Pseudomonas* exhibited significant superiority compared to control and S4 strain (20.19 kg/ha) demonstrated the

DOI: http://dx.doi.org/10.15666/aeer/1504_195216

highest nitrogen uptake, but in AMF use conditions, there was no significant difference between *Pseudomonas* strains. In the Sahra cultivar, in both AMF use and non-use conditions, strains of *Pseudomonas* exhibited significant superiority compared to control (8-49% and 2-40% under AMF use and non-use conditions, respectively, in comparison to control) and S4 strain (32.01 and 27.17 kg/ha under AMF use and non-use conditions, respectively) showed maximum nitrogen uptake (*Table 7*).

In the second year at Dasht cultivar in both AMF use and non-use conditions, strains of *Pseudomonas* exhibited significant superiority compared to control (22-65% and 16-69% under AMF use and non-use conditions, respectively, in comparison to control). In the Sahra cultivar, at the AMF non-use conditions, S4 strain (29.43 kg/ha) and in AMF use conditions, S8 strain (27.65 kg/ha) exhibited the maximum seed nitrogen uptake. In total, the highest nitrogen uptake in both years was seen in Sahra cultivar and in strain S4, while in the first year, it was obtained in the AMF use conditions and in the second year, it was found in AMF non-use conditions (*Table 7*).

Given that this experiment was conducted at rainfed and water shortage conditions, it could be stated that the growth period has been increasingly reduced and plant has been faced with fewer opportunities for the accumulation of starch in the seed. Consequently, seed protein content is increased. In addition, according to many researchers, through participation in the building of RNA polymerase, zinc caused increase in amino acids and the synthesis of proteins (Koutroubas et al., 2016). As a result, it increased protein content as suggested by the high content of zinc in inoculated treatments in this experiment.

The seed nitrogen uptake that depends on seed nitrogen concentration and seed yield was more in most of co-inoculated treatments of AMF + *Pseudomonas* compared to plants merely inoculated with AMF or *Pseudomonas*. It seems that in stress conditions, AMF played an important role in the formation and stability of soil aggregate. Consequently, its improved soil hydrolytic conductivity led to the development of root system and improved water and nutrients uptake (Estrada-Campuzano et al., 2012).

In evaluating the interaction between *Pseudomonas*, *Azotobacter* and AMF on uptake of elements in sorghum, Sultana et al. (2016) stated that AMF inoculation alongside *Pseudomonas* increased the concentration of iron, zinc, copper, and protein, but increase in manganese content was not significant. They believed that the increased uptake of iron, zinc, copper, and protein was due to impact of the seed co-inoculation *Pseudomonas* + AMF in increasing cell division and elongation in roots and thus lateral root development in co-inoculation treatments of *Pseudomonas* + AMF. However, Haling et al. (2010) studied the root of millets in food and water shortage conditions. They reported that in poor and alkaline soils, when the ability of root in the production of organic acids in the root environment is higher and guides the rhizosphere toward acidification, it could lead to uptake of elements such as N and P thereby leading to increased plant growth. Therefore, microorganisms used in this study have the potential to produce organic acids and they could increase uptake of nutrients by reducing the pH of the soil. However, Nogueira et al. (2007) assessed the impact of AMF and some PGPRs on nutrient uptake in soybean and reported the role of AMF in N uptake as result of indirect symbiosis of AMF and plant. They believed that AMF increased the uptake of elements such as P, Fe and Mn and it increased the uptake of nutrients by increasing the level of hyphae at the root surface, and this increase was independent from N uptake. In this experiment, the effect of inoculation in increasing the seed N in response to barley cultivar and year was different.

P uptake and P concentration of seed

The results of the analysis of variance showed that the interaction effect of *Pseudomonas* × AMF × barley cultivars × year on P concentration was significant ($P<0.01$) (*Table 6*). By comparing the mean interaction effect of *Pseudomonas* × AMF × cultivars × year on P concentration, it was found that in both years and in both cultivars, *pseudomonas* strains were significantly superior to control. In both years, S4 strain in most treatment combinations of AMF × cultivar had significant superiority compared to other strains. The important point is the impact of AMF on increasing the concentrations of seed P so that in most *Pseudomonas* treatments, using AMF increased seed P concentrations significantly (*Table 7*).

**, ** Significant at $P < 0.05$ and $P < 0.01$, respectively. CV: Coefficient of Variation*

The results of the analysis of variance showed that the interaction effect of *Pseudomonas* × AMF × barley cultivars × year on P uptake by seed was significant ($P<0.01$) (*Table 6*). Comparing the interaction effect of *Pseudomonas* × AMF × cultivars × year on P uptake revealed that in both years and in each of the cultivars, *pseudomonas* treatments increased P uptake significantly in comparison to control. In the Dasht cultivar, in AMF use conditions, there was no significant difference between strains in the first year, but in the second year, this difference was significant and strain S8 showed the highest P uptake. AMF use in Dasht cultivar increased the difference between strains in both years so that in both cultivars, strain S8 had significant superiority when compared to other strains. In the Sahra cultivar, the process of phosphorus uptake was similar to Dasht cultivar, while in AMF non-use conditions in the second year, strain S4 showed the highest P uptake compared to other strains (*Table 7*).

Means within a column followed by the same letter are not significantly (P < 0.05) different according to LSD test. (*Y1 = 2014-2015; Y2 = 2015-2016*) (*M0 = AMF non-use; M1 = AMF use*)

Initial experiments on the strains of the bacterium used in this experiment show that *Pseudomonas* strains is able to dissolve the insoluble mineral P via the reduction of pH and it is able to produce and secrete acid and alkaline phosphatase enzymes and obtaining P from organic sources. Furthermore, efficiency of strain S4 in comparison with three other strains is higher in these characteristics. Therefore, it is obvious that the amount of P uptake and transport in strain S4 is higher and treatments inoculated had higher P content compared to control. Some believe that this increase in ionic content is related to the development of root systems and a general increase in the level of absorption of ions and is not associated with a specific mechanism (Guadarika et al., 2003). However, Kader et al. (2002) showed that bacterial inoculation affects ATPase and electrogenic pump in root cell membranes and by increasing leakage of protons from the root, it provides the driving force necessary to attract other ions for plant.

These microorganisms that have the ability to dissolve P mineral, and by secreting organic acids such as oxalic acid and citric acid, lead to the release of P into the soluble soil through chelating and the formation of stable complexes with iron, aluminum and calcium cations. In addition, 2-ketooxalic acid and glucuronic acid reduce the environment pH and soil insoluble phosphate solubilization by releasing protein (Salimpour et al., 2011). As a result of release of phosphorus in the soil, the root access to this element increases and the efficiency of P uptake in leaf increases. However, the type and amount of organic acids in any environment is related to the type of microorganisms producing the organic acid (Ghaderi et al., 2008). These results are in line with the results of the research conducted by Naseri et al. (2013). Saxena and Jha (2014) reported the greatest amount of P of wheat plant in relation to the co-inoculation of AMF + endophytic bacteria. The researchers reported the

DOI: http://dx.doi.org/10.15666/aeer/1504_195216

increased uptake of P by plants symbiosis with P solubilizing microorganisms due to the production of carbon by these microorganisms and its impact on increased ability in P uptake (Khan et al., 2013). Shaharoona et al. (2008) reported that *P. fluorescents* strain F increased absorption of N, P and K compared to non-inoculated plants while reforming the growth elements of the wheat.

The findings of this study showed that phosphate-solubilizing microorganisms could increase growth and phosphorus uptake in the atmosphere, leading to increased crop tolerance under water deficit stress. In this experiment, increased phosphorus in aerial organs led to an increased seed phosphorous content such that maximum phosphorous was observed in the same strain. Therefore, we can say that any factor that increases phosphorous of aerial organs transports more phosphorus to seed, leading to an increased level of phosphorous content.

Conclusion

Given that this experiment was conducted in rainfed conditions, rainfall is the factor of change in seed yield and other physiological and biochemical reactions. In this experiment conducted in two consecutive years under rainfed conditions in Ardebil on barley cultivars under interaction between AMF and *Pseudomonas* strains, seed yield in both cultivars in the second year was higher due to more rainfall and effective dispersion (in terms of growth to plant barley). For this reason, reaction of cultivars inoculated treatments compared to first year was different. In both cultivars, maximum seed yield in both years was obtained from co-inoculation treatment of AMF + strain S4, while Sahra cultivar had more production sustainability compared to Dasht cultivar. While maximum seed yield in both cultivars was obtained from the same treatment, Sahra cultivar exhibited the better reaction to inoculation. The high seed yield in Sahra cultivar compared to Dasht cultivar can be attributed to reasons such as increased number of fertile tillers and number of seed per spike. Increase in the number of seed per spike and increase in fertile tiller can be due to proper nutrition and providing nutrients by AMF and *Pseudomonas*, since co-inoculation increased concentration of N and P significantly. However, the capability of AMF fungi in increasing uptake level that increases the uptake and retention of water in the rhizosphere plant should not be ignored. In addition, strains used in this experiment were associated with the production of the enzyme ACC deaminase and reduced levels of ethylene production (in rainfed conditions in which the plant is faced with water shortage and ethylene produced in the incidence of stress). Although in most of the characteristics measured, inoculated treatments were superior compared to control, the use of AMF also increased bacterial inoculation efficiency and by increasing the uptake of nutrients and increasing tolerance to water shortage conditions, it increased the seed yield, while this increase was more evident in the Sahra cultivar. Therefore, to plant barley in the rainfed conditions of Iran, Sahra cultivar alongside co-inoculation AMF and *P. putida* strain S4 is recommended. The development of drought-tolerant crop varieties through genetic engineering and plant breeding is essential but it is a long drawn process, whereas PGPR inoculation to alleviate drought stresses in plants opens a new chapter in the application of microorganisms in dry land agriculture. Taking the current leads available, concerted future research is needed in terms of identification of the right kind of microbes and barley cultivars and addressing the issue of delivery systems and field evaluation of potential organisms at diverse agro-ecological conditions under N and P fertilization.

Abstract. The aim of this study was to determine the accuracy estimation of actual evapotranspiration by using Surface Energy Balance Algorithm for Land (SEBAL) in comparison with FAO-Penman-Monteith method in Landsat and MODIS images in Malayer County of Iran. In this study, Landsat 8 and MODIS images of 2013 were used. Result showed that there are not many differences between SEBAL and FAO-Penman-Monteith methods in estimation of evapotranspiration. According to the aim of the study, result showed that MODIS sensor with high accuracy have calculated evapotranspiration more accurately than Landsat 8 by RMSE = 1.004 and MBE = 0.0033 respectively in surface temperature estimation which has great effect on estimation of the net radiation flux, soil heat flux and the sensible heat flux. On the other hand, according to low spatial resolution of MODIS sensor, we can conclude that this sensor has less value for zoning of evapotranspiration than Landsat 8 image according to the area topography and heterogeneous land uses.
Keywords: *evapotranspiration, remote sensing, SEBAL, Malayer city, MODIS, Landsat 8*

Introduction

Evapotranspiration (ET) is an important component of water balance in arid and semi-arid areas and accurate estimation of ET is significantly important for optimum management of water resources (Sepaskhah, 1982). Hasheminia (1999) reported, 70 % of precipitation returns to the atmosphere through ET. He also cited in arid areas it is about 90 %. According to his output, water shortage problem has been widespread in many parts of the world which has brought about conflict over water in the near future. It seems that limitation of water resources and uneconomical uses of water are the main factors that limit the development of agriculture and increase food production in Iran (Akbari, 2004). On the other hand, ET plays significant role in the world's climate through hydrologic cycle. ET estimation has an important utilization on runoff prediction, product performance prediction, land use design, design of irrigation channels, water distribution constructions and it is also effective on natural disasters like drought (Ogawa et al., 1999; Bastiaanssen, 2000; Norman et al., 1995). Many methods have been developed for calculating ET in different geographical and climatic conditions by using meteorological data. These methods often use point (data) measurement for ET estimation, so they are appropriate for local area and they are not expendable to large basins because of dynamic nature and regional changes of

DOI: http://dx.doi.org/10.15666/aeer/1504_19711982

ET (Li and Lyons, 1999; 2002). Development of remote sensing technology provides possibility of actual ET and potential ET estimation in a wide scale. In many researches satellite images were used to estimate actual ET and temporal and spatial distribution. Remote sensing is able to estimate ET also it can examine spatial distribution, because it can extract parameters such as surface temperature, albedo coefficient and vegetation index which is compatible with the environment and it is economically affordable (Norman et al., 1995). This distribution is important for management at the macro level. In the irrigation conference which was held by Food and Agriculture Organization (FAO) and International Commission on Irrigation and Drainage (ICID) and World Meteorological Organization (WMO) in cooperation in 1990 for investigating FAO methods and presenting an accurate method, FAO-Penman-Monteith method proposed as a standard method for ET estimation (Allen et al., 1998). ICID and FAO proposed FAO-Penman-Monteith method as a standard method for ET calculation via climate data (Hargreaves, 1994). Heretofore, the multiple algorithms have been provided to estimate ET using remote sensing data. Thereby, the methods based on energy balance are divided into single-source and two-source models. Single-source models consider soil and plant as one source named “Big-Leaf” and they only use an aerodynamic resistance in water-heat transition process (Nishida et al., 2003). In these models, it is assumed that the entire affected surface receives the same temperature and humidity. Unlike single-source models, two-source models by separation of soil and plants in all modeling process use several distinct aerodynamic resistances for soil and plant (Huntingford et al., 2000). Among the popular models in single-source base, we can mention Surface Energy Balance for Land (SEBAL), Mapping Evapotranspiration at High Resolution with Internalized Calibration (METRIC) and Surface Energy Balance System (SEBS) (Bastiaanssen et al., 1998; Su, 2002; Allen et al., 2007; Ogawa et al., 1999). The models such as TSEB and STSEB are two-source models (Norman et al., 1995; Sánchez et al., 2008).

Review of literature

The SEBAL algorithm was used with different sensor images in multiple parts of the world and it provided acceptable results. The old SEBAL model with METRIC in Idaho and their output results were compared which had a good agreement with lysimeter data (Tasumi et al., 2005). In another study daily ET amounts with lysimeter data by using Landsat images and METRIC model were compared and error less than 28 % was reported (Chavez et al., 2007). Estimation of ET by using Landsat images and energy balance METRIC model in Brazil had highlighted the model performance of water consumption estimation and improved water management in semi-arid and irrigated area in northeast of Brazil (Folhes et al., 2009). Evapotranspiration by using SEBAL algorithm and water balance model was calculated and results were compared, correlation by 70 % was reported (Mutiga et al., 2010). Useful results were reported about using Landsat images and SEBAL algorithm for actual ET estimation in multiple land uses of Nansi Lake basin, China (Sun et al., 2011). Surface temperature, net radiation, soil heat flux and hourly ET amounts were calculated by using SEBAL algorithm and 16 TM images were used in Texas plain. Output results were compared with measured values of 4 lysimeters which in cotton planted in two modes: irrigated and under water stress. Results

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_19711982

showed high accuracy of output results (Colaizzi et al., 2011). Different methods of ET estimation based on remote sensing data were investigated and results indicated that remote sensing methods have average accuracy for ET estimation (Raghuveer et al., 2011). Variable ET on the agriculture land, water body, forests and grasslands, are justifiable with different amount of ET (Yuting et al., 2012). Measured ET and other SEBAL components with measured field data through 4 accurate weighty lysimeters in two areas wet and dry farming were compared and acceptable results by using SEBAL were emphasized (Paul et al., 2013). Actual ET of pistachio in Ardakan, Yazd, by using 12 MODIS images and SEBAL algorithm were calculated. Results showed that average actual ET of pistachio is 1123 mm in desired year during a complete grow season which is much less than the amount of water consumption (Dasturani et al., 2012). Estimation and comparison of ET by using SEBAL algorithm, MODIS and Landsat 7 images were done and it was concluded that TM sensor image accuracy was about two and a half times more than MODIS (Simaie et al., 2013).

Although a huge number of studies have used different algorithms including SEBAL and multiple satellite images such as MODIS and Landsat. Over two decades studies were done about this issue, it is necessary to study different climate and weather for an accurate evaluation of ET based on these models and satellite images. Whereas, these models are experimental and they use a set of methods and experimental equations, they have to be calibrated for regional conditions. In the present study, actual ET have been estimated in Malayer city which has heterogeneous land uses such as range, residential, agricultural land (wet and dry), water bodies and so on. It should be mentioned that there is no record of any study using MODIS, Landsat or even other remote sensing images such as SEBAL or other models about ET estimation in the study area. However, most previous studies considered ET estimation in agricultural areas, either in an area with different land uses or new Landsat 8 satellite image, but the present study with an emphasis on performance of SEBAL, MODIS and Landsat 8 sensors have been investigated in a heterogeneous area.

Material and methods

Malayer city in Iran has an area of 3208 km^2 which includes 16.9 % of Hamadan province (*Fig. 1*). Elevation changes between 1617 and 3345 m (*Fig. 1,* digital elevation model is shown). The average amount of annual precipitation ranges is between 250 and 327 mm based on elevation gradient and extracted precipitation from whole city stations and neighborhood stations (Nahavand, Toiserkan, Hamadan Airport, Nouzhe, Arak, Kangavar and Borojerd) in a 17 years period (1995 to 2012). The amount of 24 hourly potential ET has been recorded by 7.58 mm averagely in Malayer station in May. Lysimeter data is usually used in different remote sensing studies for ET estimation. According to lack of lysimeter station in Malayer, synoptic station which records temperature, precipitation and evaporation are used as observed station to control output results (*Fig. 1*). Hourly data of 13 May 2012 at the same time with time recording of MODIS and Landsat 8 images were used by FAO-Penman-Montieth. Since the amount of precipitation and agriculture lands have been affected by water scarcity, thereby water consumption can be managed through ET estimation to reach a high efficiency.

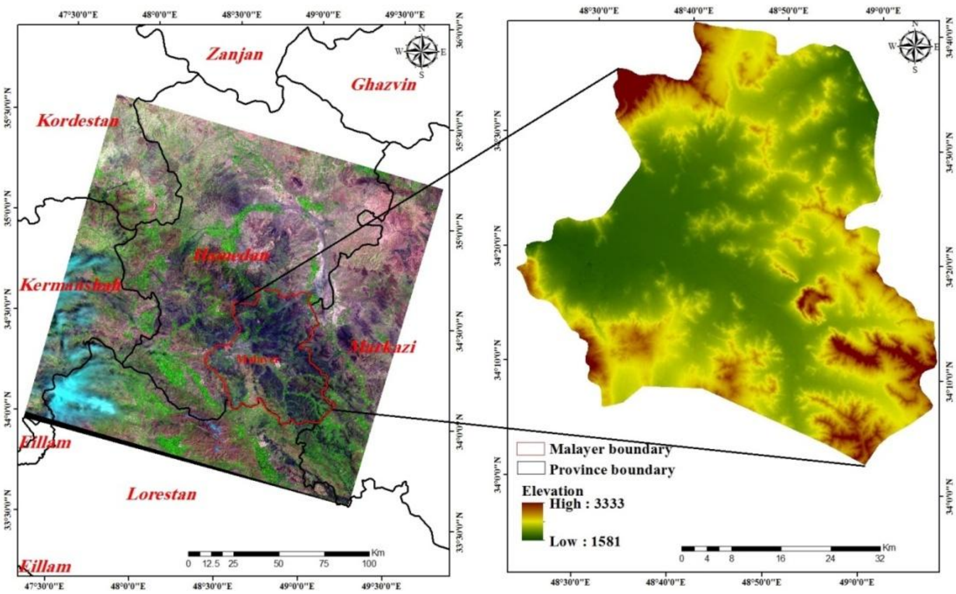

Figure 1. *Geographical location of study area in Hamadan province*

Image selection, preparation and preprocessing

One of the suitable images that are used around the world is free MODIS image. New free Landsat 8 images (OLI sensor) are one of the new feature in this case. Another point that should be mentioned is calibration of different images especially cheap images to local condition. Although MODIS image had been used in around of the world and also Iran, but these images and different algorithm including SEBAL are in the stage of development. Furthermore, significant research does not fulfillment in the field of use or calibration of different images including MODIS and Landsat 8 (OLI) images in Hamadan province which has distinct vegetation and climatic condition. In the present study images which have been selected are MODIS and Landsat 8 images for comparing factors including temporal condition (spring), desirable quality and lack of cloud cover spots. Although, the selected images were Level-II and they do not need geometric correction, but they were controlled with 10 ground control point (GCP) of GPS before using. Images did not need atmospheric correction because there was no atmospheric turbulence and they were one-temporal interpretation (Song et al., 2001). *Table 1* presents used images properties.

Table 1. *Properties of selected OLI image (Official Landsat 8 Site, 2013) and MODIS image*

MODIS	Landsat OLI	Image
05/14/2013	05/14/2013	Data catch
64-95	125.471-128.2050	Sun azimuth angle

250, 500 & 1000	15 & 30	Spatial resolution

Surface energy balance on land (SEBAL) algorithm

Theoretical basics of ET calculation using SEBAL method are provided in different references detailed. In this model, actual ET is calculated by using satellite images

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_19711982

based on balance energy equation. Selected satellite images can only provide information about past time, so mentioned models are allowed possibility of estimating instantaneous latent heat flux in time imagery (Allen et al., 2007). Latent heat flux was calculated by using *Equation 1* for each pixel of image.

$$\lambda ET = R_n - H - G \quad \text{(Eq. 1)}$$

where λET is latent heat flux (W/m^2), R_n is net radiation flux on land surface (W/m^2), G is soil heat flux (W/m^2) and H is sensible heat flux (W/m^2). SEBAL method was presented first time in order to estimate ET in agricultural and plain areas. But it is corrected in new version (Allen et al., 2007) which is presented for application in rugged and mountainous areas. In the present study new version of SEBAL were used because of Malayer condition which has heterogeneous land use. Accuracy of latent heat flux estimation depends on calculation process and accuracy of H, G and Rn estimation. The value of net radiation that is the first calculation to solve surface energy balance equation was calculated using *Equation 2* and incoming and outgoing radiation fluxes (Allen et al., 2007).

$$R_n = (1-\alpha)R_{S\downarrow} + R_{L\downarrow} - R_{L\uparrow} - (1-\varepsilon_0)R_{L\downarrow} \quad \text{(Eq. 2)}$$

where $R_{S\downarrow}$ is incoming short wave radiation (W/m^2), $R_{L\downarrow}$ is incoming long wave radiation (w/m^2), $R_{L\uparrow}$ is outgoing long wave radiation (W/m^2), α is surface albedo and ε_0 is surface radiation power of 31^{th} and 32^{th} MODIS bands and 10^{th} and 11^{th} Landsat 8 bands. Soil heat flux (G) is the amount of heat transfer in soil and vegetation via molecular conduction. Since it is difficult to calculate the amount of soil heat flux using satellite image directly, so first G/R_n ratio calculated in middle of the day using experimental equation (Bastiaanssen et al., 1998) (*Eq. 3*).

$$\frac{G}{R_n} = \frac{T_s}{\alpha}(0.0038\alpha + 0.0074\alpha^2)(1 - 0.98NDVI^4) \quad \text{(Eq. 3)}$$

where T_s is surface temperature (°C) and α is surface albedo. The G value was obtained by multiplying the above ratio in Rn. If NDVI value is less than 0, then the area considered as water and G/R_n ratio considered equal to 0.5. The area having T_s less than 4 °C and α more than 0.45 considered as snowy area and G/R_n ratio was applied equal to 0.5. Sensible heat flux (H) (the loss of heat to the air via molecular convection and conduction) is because of temperature difference which calculated using *Equation 4* (Allen et al., 2007).

$$H = \frac{\rho . Cp . dT}{r_{ah}} \quad \text{(Eq. 4)}$$

where ρ is the air density (kg/m^3), C_p is the specific heat of air (1004 J/Kg/K), dT is temperature difference (°K) between two elevation (Z_1-Z_2) and r_{ah} is aerodynamic resistance against heat transmission (s/m). Sensible heat flux is a function of the temperature gradient, surface roughness and wind speed. Solving the above equation is difficult because of existence of two unknown parameters including r_{ah} and dT and therefore we used two cold and hot pixels of the study area (which reliable values are predictable for H and so present estimation of dT) and wind speed in the certain height.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_19711982

Regarding that r_{ah} was a function of sensible heat flux, *Equation 4* did not have explicit solution and it was solved based on cyclic method. In order to correct atmospheric stability Monin-Obukhov length was used. The cold pixel selected from an area covered with complete vegetation and irrigated completely based on mentioned instructions which it is assumed surface temperature equal to near surface temperature. As the same way, the hot pixel selected from an arid area without any vegetation which it is assumed ET is 0. In selection of these pixels, some factors such as surface temperature, albedo and vegetation indices were used. That the cold pixel had low temperature, albedo of about 0.22 to 0.24 in accordance with alfalfa land and high NDVI, while hot pixel had high temperature, high albedo similar to other dry lands and without vegetation and low NDVI. In selection of hot/cold pixels, it considered to avoid very low or very high temperature selection. After correction of the sensible heat flux amount based on atmospheric condition, the instantaneous amount of latent heat flux calculated for each pixel of both images using *Equation 1*. Since the outcome amounts of net radiation flux (R_n), sensible heat flux (H) and soil heat flux (G) were instantaneous amounts and for satellite pass time, the amount of latent heat flux (λET) calculated instantaneous too. Therefore, ET amount was obtained from numerical calculation of λ and by dividing the number of per-pixel. The amount of ET was obtained using instantaneous latent heat flux and *Equation 5*.

Latent heat flux and instantaneous ET

Latent heat flux is the amount of heat loss from surface due to ET process which was obtained using *Equation 3*. Since the amounts of net radiation flux (R_n), sensible heat flux (H) and soil heat flux (G) are instantaneous amounts then the amount of latent heat flux (λET) is momentary too. λET is the amount obtaining from satellite image. Therefore, we should calculate λ numerical amount so the amount of ET is obtained by dividing the number of per-pixel.

The amount of ET is obtained using instantaneous latent heat flux as:

$$ET_{inst} = 3600\frac{\lambda ET}{\lambda} \qquad \text{(Eq. 5)}$$

where ET_{inst} is the amount of instantaneous ET (mm/hr), λ is evaporation latenet heat (J/Kg) and 3600 number convert the time from seconds to hours. The amount of λ is obtained using *Equation 6*.

$$\lambda = [2.501 - 0.00236(T_S - 273.15)] \times 10^6 \qquad \text{(Eq. 6)}$$

Ratio of reference ET

Ratio of reference ET is defined as ratio of instantaneous ET (ETinst) of each pixel (mm/hr) to reference ET (ETr) obtained from meteorological data for image time (mm/hr) (*Eq. 7*).

$$ET_rF = \frac{ET_{inst}}{ET_r} \qquad \text{(Eq. 7)}$$

ET_rF is similar to vegetation coefficient (Kc) and used to extrapolate of ET from image time to 24 h period or much longer. The amount of ET_rF usually ranges between

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_19711982

0 and 1, so in a completely dry ET = 0 and $ET_rF = 0$, but in case of the cold pixel in an alfalfa or corn, ET is a few more than ET_r and so $ET_rF > 1$ (1.1 likely). The negative amount for ET_rF is because of systematic errors which enter to SEBAL via various assumptions.

Various equations are developed to calculate ET_r, out of which, Penman-Montieth equation is proposed by FAO to most countries, such as Iran, having arid and semiarid climate. Penman-Montieth method has various versions; many of the researchers use FAO-Penman-Montieth version as one of the most reliable method for ET estimation (Alizade, 2002). Therefore, FAO-Penman-Montieth version 56 was used in REF-ET software for ET_r calculation.

24 hourly ET

The daily amount of ET (ET_{24}) usually has more application than the instantaneous amount. SEBAL calculate ET_{24} amount assuming instantaneous ET_rF is similar to average ET_rF during 24 h. The amount of ET_rF (mm/day) is calculated as (*Eq. 8;* Allen et al., 2007):

$$ET_{24} = ET_rF \times ET_{r\_24} \quad \text{(Eq. 8)}$$

where ET_{r_24} is sum of ET_r during 24 h for the same day image recorded which is obtained by adding up the values of the hourly ET_r together on the satellite pass day.

Accuracy assessment

Hourly and 24 h values of ETr obtained via FAO-Penman-Montieth method using hourly data of Malayer meteorological station was used to validate SEBAL model. Root Means Square Error and Mean Bias Error were used for statistical assessment of the models accuracy. The value of RMSE presents the amount of model error (Dashtaki et al., 2010). MBE index shows trend to overestimation or underestimation. Mathematical descriptions of these statistics are as follows (*Eqs. 9* and *10*):

$$\text{RMSE} = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(Yest,i - Yobs,i)^2} \quad \text{(Eq. 9)}$$

$$MBE = \frac{1}{n}\sum_{i=1}^{n}(Yest,i - Yobs,i) \quad \text{(Eq. 10)}$$

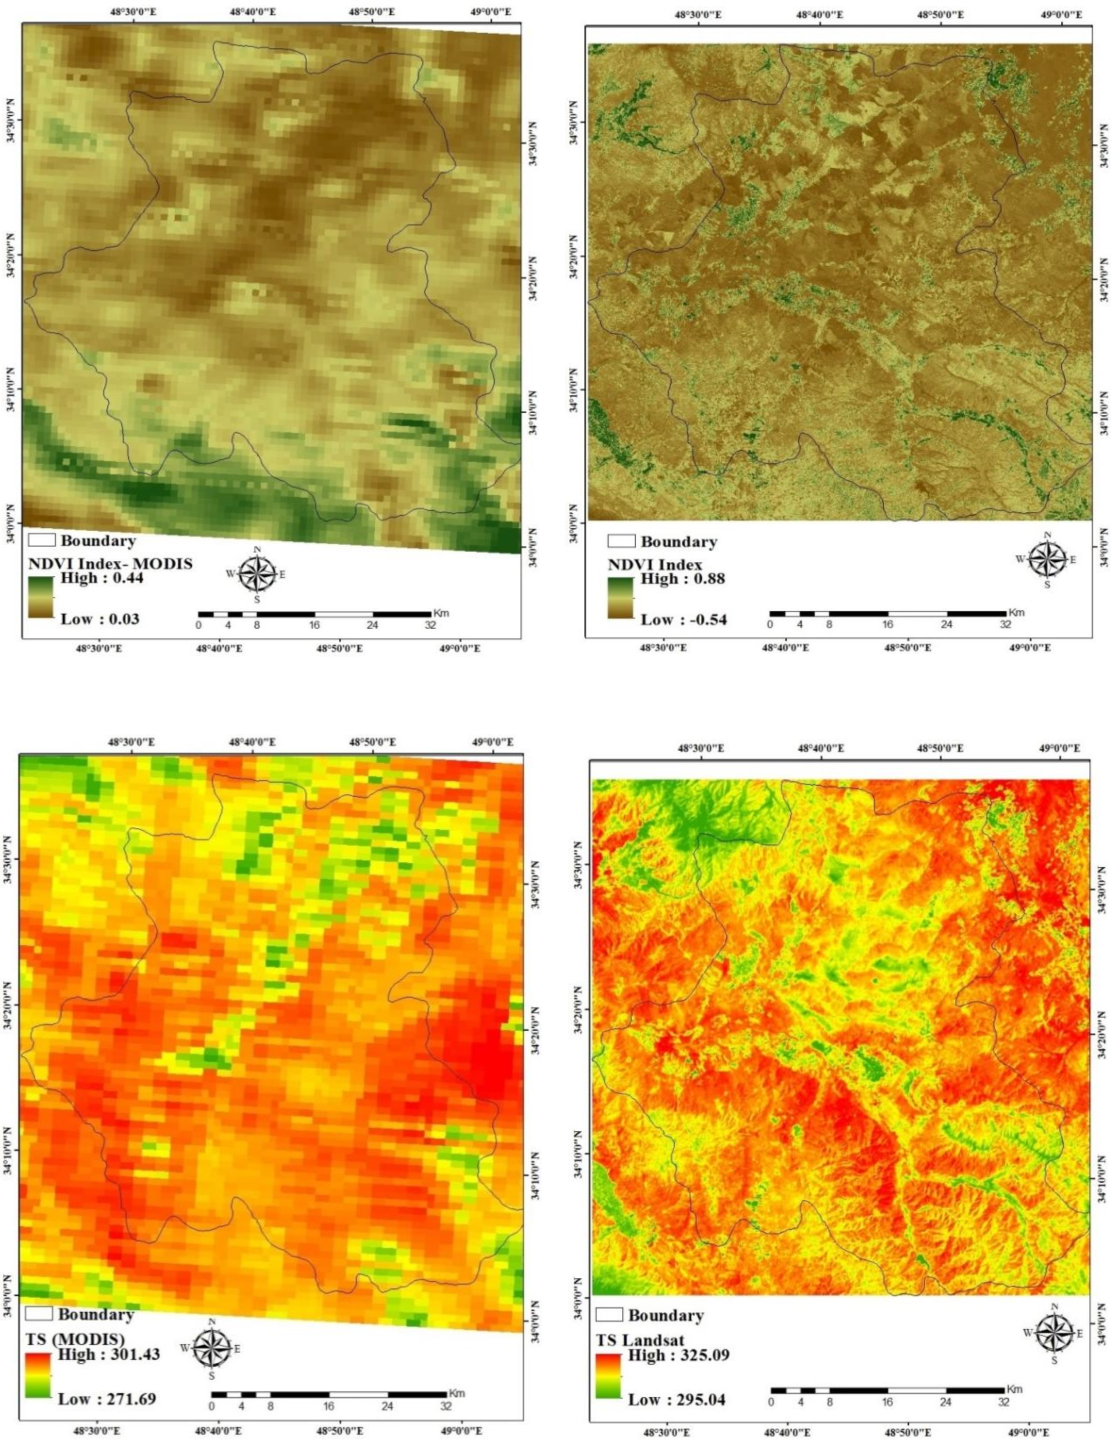
where Yest is the projected amount, Yobs is the measurement amount and n is the number of data.

Results

The maps of surface temperature distribution, vegetation index and daily ET are shown in *Figure 2*. Surface temperature and vegetation index are two important incomes to SEBAL model. These two indices, which are also applied to select hot/cold pixels, have a strong inverse correlation in case of accessing sufficient nutrient (Ruhoff et al., 2012). As shown in *Figure 2*, daily ET distribution shows a wide range of values regarding heterogeneous lands. Also, results show that an area which has high

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_19711982

vegetation index (VI) and low temperature has more ET and vice versa. Based on the maps, there is an inverse correlation between surface temperature distribution and vegetation index.



http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_19711982

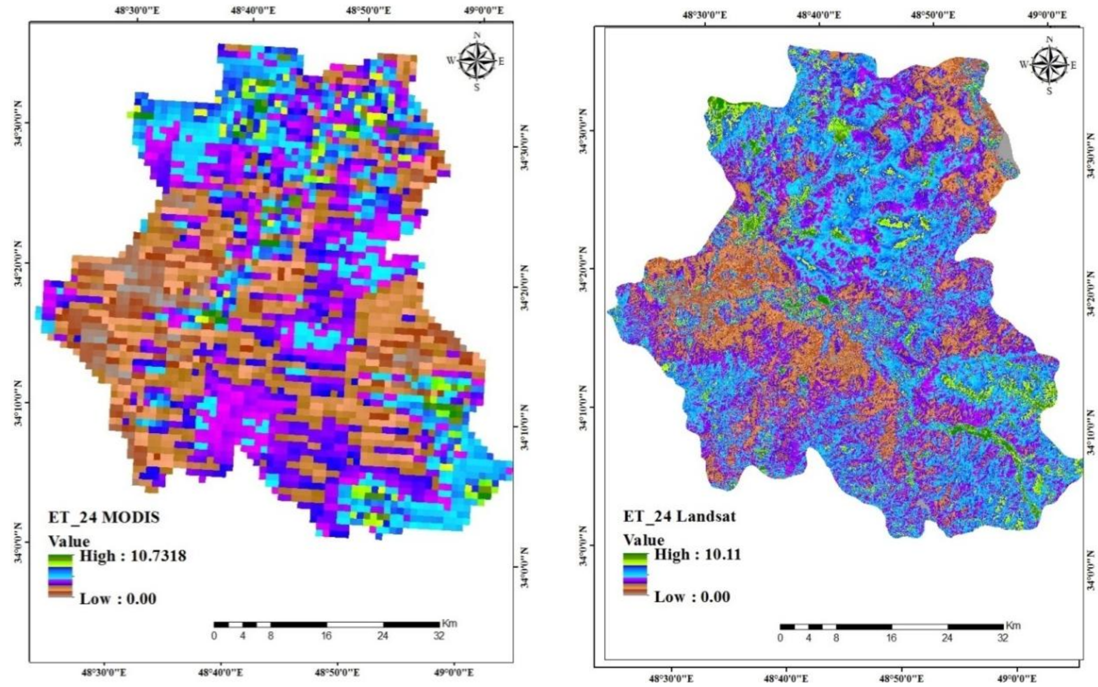


Figure 2. *Top to bottom and left to right are: MODIS surface temperature, Landsat surface temperature, NDVI of MODIS, NDVI of Landsat, 24 hourly ET of MODIS, 24 hourly ET of Landsat respectively*

Actual ET estimation

After calculating the net radiation flux (Rn), sensible radiation flux (H), soil heat flux (G) and latent heat flux of instantaneous evaporation, the amount of actual instantaneous ET (ETinst) was estimated.

The crop type and culture date were determined in desirable parts by using agriculture calendar. Then, the observed ET value of cultivated plants was estimated by using FAO-Penman-Montieth method and compared with results of SEBAL. The results of statistical comparison of SEBAL and FAO-Penman-Montieth are presented in *Table 2* and *Figure 3*.

Table 2. *Statistical comparison of SEBAL with FAO-Penman-Montieth (daily and hourly)*

Image	ET instant	ET ref instant	ET 24	ET ref 24
MODIS	0.7533	0.75	6.89	6.86
Landsat	0.7888	0.75	7.23	6.86

The ET amount measured by Landsat showed more differences with observed values. According to hourly ET measured through ETr software and calculated instantaneous values via satellite images showed MODIS accuracy is higher than Landsat with RMSE and MBE by 1.004 and 0.0033 respectively in comparison with Landsat with RMSE and ME by 1.05 and 2.88, respectively. But regarding images type and spatial resolution, it can be seen that accuracy of Landsat is much higher than MODIS image and it can interpolate the values of ET much better and clearer because

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_19711982

of its smaller pixels. Ogawa et al. (1999) investigated performance of MODIS sensor in ET estimation in Savanah, West Africa. In that study, SEBAL method, MODIS and ASTER images were used. Their results showed both sensors have good capability to estimate ET in large heterogeneous areas and according to their results the present study has logical results in comparison with observed method. Sun et al. (2011) used SEBAL algorithm and Landsat image to estimate actual ET in various land uses in Nansi Lake Basin, China. These researchers reported positive results, similar to the present study which has emphasized on SEBAL capability in Malayer city.

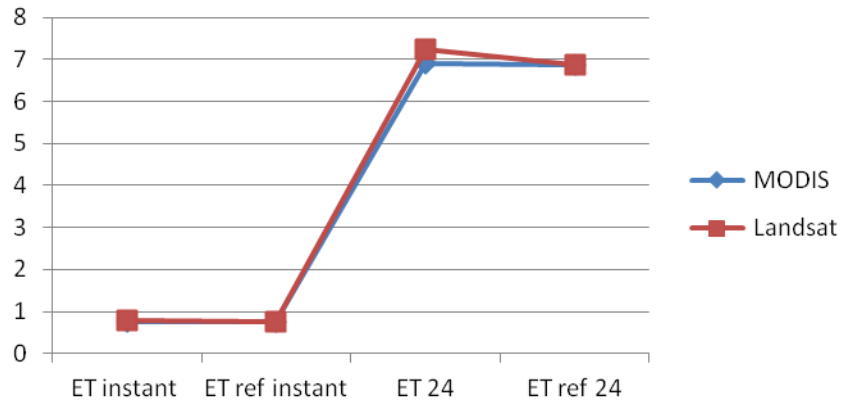

Figure 3. *Plotting comparison of SEBAL with observed method (FAO-Penamn-Montieth)*

According to assumption of SEBAL model based on *Equation 8*, daily ET was estimated. On the other hand, after correction of Kc based on proposed in FAO 56 leaflet for the study area and multiplied by observed ET of alfalfa which is obtained from meteorological data, daily actual ET values were estimated for desirable pixels. As shown in *Table 2*.

Conclusion

The greatest difference between SEBAL estimation and observed method is related to Landsat image. Based on daily ET obtained from ETr software, daily values that are calculated through satellite images and their statistical comparison, it is concluded that MODIS is more accurate than Landsat image and has less difference to observed ET. However, according to *Figure 2* which shows daily ET and high spatial resolution of Landsat, precision of this image is much higher than MODIS image and it can show ET clearer and more suitably. According to SEBAL estimations despite the error which caused deviation and due to lack of needed equipment and image errors, it can be said that data obtained from this algorithm are acceptable.

The aim of this study was to estimate ET of vegetation by MODIS and Landsat 8 images. For this purpose, SEBAL algorithm was used. Besides, Malayer city does not have any lysimeter station so FAO-Penman-Montieth’s results were used for accuracy assessment. Results showed SEBAL algorithm can estimate parameters such as surface albedo, surface temperature and vegetation index as well. Daily and hourly actual ET values were estimated in the study area by using mentioned parameters. Comparison of results from SEBAL algorithm and observed method (FAO-Penman-Montieth) did not show significant difference in either hourly or daily cases. It means hourly ET can be

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_19711982

estimated with acceptable precision in comparison with observed ET in the study area. According to spatial resolution and free MODIS and Landsat images, it seems that the use of these images can be satisfactory and practical in order to estimate daily water requirement and plan for irrigation especially in wide lands.

The results of this study showed hourly estimations of ET through SEBAL algorithm have higher precision than daily estimations that is because of constant hourly ETref with daily ETref in model. Furthermore, comparison of estimating ET by two images which have different resolution made it clear that ET in MODIS image was estimated with higher accuracy for two anchor pixels (hot and cold pixels) than Landsat image. Nevertheless, according to observed ET, Landsat images had more accuracy due to higher spatial resolution and various heterogeneous land uses with low extent of study area.

Abstract. The aim of this study is to assess the soil texture and nutrient components across three seasons at three different mangroves habitat according to the land used types; Kelantan (human settlement area); Johor (protected Ramsar's site) and Selangor (agricultural). The soils were sampled one-meter deep and divided into five segments for analysis. The pH of surface water for Selangor and Kelantan were slightly acidic ranging from 6.4 to 6.9. In Johor, the water was basic with value ranging from 8.3 to 8.7 across all seasons. Salinity in Selangor (26 ppm) was higher than in Johor (16 ppm) and in Kelantan (11 ppm). Johor and Selangor soils were dominated by silty loam, while Kelantan was dominated by sandy loam. Carbon, nitrogen, phosphorus and potassium analysis showed that they were significantly different in all locations but not between seasons. Except for phosphorus in Johor, consecutive depth did not influence the nutrient availability in mangrove soil. The results for carbon and nitrogen were following this order; Johor > Kelantan > Selangor, phosphorus; Selangor > Johor > Kelantan, potassium; Johor>Selangor>Kelantan. The protected mangroves habitat in Johor has siltier and clayey component and can retain more nutrients for the plant growth. Therefore, the conservation and preservation of mangroves habitat is crucial for the stable coastal ecosystems.
Keywords: *soil texture, carbon, nitrogen, phosphorus, potassium*

Introduction

Mangroves are a diverse group of predominantly trees, shrubs, palms and grounds ferns, which have adapted to the extreme saline conditions between the tides (Duke et al., 2002). They are one of the most productive and unique ecosystems, growing on sheltered shores and in estuaries in the tropical and subtropical area (Hogarth, 2015). Although the number of species diversity is low as compared to terrestrial ecosystems, it is the various adaptation abilities to survive the harsh environment (e.g. strong wind, high salinity and muddy substrate) that makes this ecosystem so critical and crucial for conservation. The largest mangroves areas are located in Asia, extending over 6.8 million ha and representing about 34-42 % of the world's total (Giri et al., 2011). Furthermore, many mangroves species were located at the equatorial area or country such as Indonesia, Malaysia and Philippines (Spalding et al., 2010). This forest is high in values, serves multiple ecological roles and important for socio-economic and microbes continuity (Walters et al., 2008). For instance, the high demand of charcoal and firewood had resulted in high production of mangrove woods in southern region of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_19831998

ASEAN, estimated around 10 to 17 tonnes/ha/year (Bosire et al., 2008). In Peninsular Malaysia, fish landing alone has been reported as much as 0.86 million tonnes in 2003 and this number increased every year (Chong, 2007).

Therefore, over the past decades, mangrove ecosystem became a subject to a high pressure of anthropogenic activities and natural phenomenon (Giri et al., 2011; Jusoff, 2013). Reclamation of mangroves area for development purposes; i.e. industrial area, human settlement, port and agriculture has been increasing and such acts have caused irreversible damage in coastal area. Erosion and accretion of the coastline regions are changing the sediment properties, physical and/or chemical ones (Kamaruzzaman et al., 2008). The mangrove forest clearance activities through unsustainability logging decreased the nutrients concentration in soil (Ngole-Jeme et al., 2016). This is due to the lack of litter production in mangroves ecosystems (Hemati et al., 2015). In addition, the climate change has contributed to sea level rise which directly causes the coastline changes and alter the mangrove coverage worldwide. This will change the coastline landscape and mangroves area that could change the soil physical and chemical properties (Tajul Baharuddin et al., 2013).

A good establishment of mangrove stands relies on the soil properties and this has been reported by several authors (e.g. Li et al., 2008; Kamali and Hashim, 2011; Salmo et al., 2013). Soil provides a good source of nutrient for growth and strong physical structure for anchorage and stability being in the soft sediments (Ashman and Puri, 2002). In mangroves, the sediment or soil texture, salinity and pH are important physical elements in determining the condition of the study area. The ability of soils to retain C, water and nutrient ions are strongly influenced by the soil texture (Havlin et al., 2014). Basically, soil texture is determined through the particle size percentage of clay, silt and sand (Ashman and Puri, 2002). The mixture of the results in actual mangrove sedimentation is classified as sand, loamy sand, sandy loam, loam, silt loam, silt, silty clay, silty clay loam, clay loam, sandy clay loam, sandy clay and clay. Most of the mangrove soils are known as mud, which is the mixture of silt and clay (Spalding et al., 2010).

The study on soil texture is important as mangrove plants may grow in different types of soil, hence determining the mangroves zonation pattern (Vilarrubia, 2000; Sherman et al., 2003; Twilley and Day, 2012). The soil pores are different for clay, silt and sand. For clay, the soil pores are the smallest when compared to silt and sand. Hence, this type of soil has a higher ability to retain water and nutrients (Ashman and Puri, 2002). Sasternegara (2004) reported that the silty clay is mostly found at the mangroves area, either logged or undisturbed mangroves area. But some species may favor other types of soil. *Avicennia* sp. can be found at the seaward zone with sandy soil type (Lewis, 2005; Ibrahim and Hussain, 2012). While for other species like *Rhizophora* spp. and *Bruguiera* spp. are mostly found in silty clay area (Robertson and Alongi, 1992; Ibrahim and Hussain, 2012).

Apart from soil texture, pH and salinity also play an important role in mangrove distribution. Several studies of mangrove forests worldwide had found that mangrove soil may be either acidic or alkaline (Wakushima et al., 1994; Salmo et al., 2014; Hemati et al., 2015). In the Sibuti Wildlife Santuary Miri, Sarawak, the pH was acidic with average 3.34 in the area dominated with *Rhizophora apiculata* (Rambok et al., 2010). In Sundarban forests, the pH values were slightly alkaline ranging from 7.4 to 8.2 with various mangroves species (Das et al., 2012). For the salinity, there are a few species known as halophilic or salt tolerant (Nandy et al., 2007). Salinity may affect the structure of mangrove forests through the distribution of dominant species in Gazi Bay

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_19831998

(Matthijs et al., 1999). Mangroves species that face tidal inundation daily or twice a month may tolerate extreme pH and high salinity (Nandy et al., 2007). But, Wakushima et al. (1994) stated clearly that the pH and salinity were highly affecting the zonal distribution of mangroves. *Kandelia candel* is the species that can grow well in low pH and salinity, while *Avicennia* sp., *Rhizophora* sp. and *Sonneratia* sp. can tolerate extreme pH and high salinity (Wakushima et al., 1994).

In term of soil chemical or nutrient properties, mangroves areas are also subjected to the changes of chemical concentrations, either in soil or water. Yet, the study about this matter is limited. Mangals are finely balanced, highly effective nutrient sinks with net imports of dissolved nitrogen, phosphorus and silicon. Nutrient fluxes in these environments are closely tied to particle size, pH and salinity, water input, plant assimilation and microbial mineralization (Alongi et al., 2013). Varying nutrient concentrations can also change competitive balances and affect species distributions (Chen and Twilley, 1999; Twilley and Chen, 1998). The carbon (C) in soil is determined by organic carbon and the production of C is depending majorly from litter such as leaf, propagule, seed, trunk and root (Alongi, 2014). The nitrogen (N) is highly present in soil through biological fixation, transformation and leaching (Nandy et al., 2007). Like C, N concentration in soil is also originated from the decomposition process of litter and the lack of this element in soil will cause soil infertility (Ashman and Puri, 2002). Phosphorus (P) element in soil is present as phosphate ion and it is required by the plant in large amount for growth (Greger, 2004). Potassium (K – known as Kalium) is another element that present in soil in form of cationic (Ashman and Puri, 2002). K is more abundant in silty or clayey soil compared to sand (Reef et al., 2010).

In mangrove forest, the nutrients are supplied by the litter fall from trees and suspended materials from surface runoff above ground, fauna activities and microorganisms' decomposition mechanism (Cannicci et al., 2008). The litter fall or surface materials were utilized by macro invertebrates such as *Scylla serrata* and that is broken down into smaller sizes. Then, the process was taken over by microorganisms until all the materials deposit into the soil permanently.

Soil physical and chemical properties of mangrove forest can indicate the current status and can determine the characteristics of tested soil (Furukawa and Wolanski, 1996; Havlin et al., 2014). Data obtained may represent the soil status of mangroves area thus to plan a proper action for enhancement of soil quality and governing ideal ecosystem. As medium of growth, soil should supply enough nutrients and have good characteristic to ensure better tree performance and establish greater forest ecosystem for wildlife conservation, economic value and most important to balancing environmental condition (Hopkins and Huner, 2004). According to Gruber and Galloway (2008), changes in land use patterns, coupled with climate issue and rising of global population have given a serious impact on nutrient release into the environment. Soil nutrient status has the most direct controls on the mangrove ecosystems (Alongi et al., 2003). Concentrations of nutrients and organic matter in mangrove soil can also be subjected to anthropogenic activities nearby such as sewage discharge either from and waste dumping (An et al., 2007).

As a result, nutrient availability could threaten ecological balance in mangrove ecosystems. Yet, the study about the effect of soil characteristics is still lacking in mangroves area. Many authors focused on the crop study as the intention to develop agricultural activities is the main concern for many countries (Ashman and Puri, 2002; Havlin et al., 2014). In this paper, we ask this question: to what extent the changes in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_19831998

land use pattern can alter the physical and chemical properties in mangrove soil? Hence, we attempt to examine seasonal and depth variation and variability of soil nutrient concentration in three different mangrove forests in Peninsular Malaysia, based on different anthropogenic activities.

Material and methods

Study site

In this study, three sites within Peninsular Malaysia were selected based on mangroves forest status and the activities at the surrounding area. The sites chosen are shown in *Figure 1*. The study was conducted within the Mangrove Forest Reserve (MFR) under the surveillance of Department of Forestry Peninsular Malaysia (DFPM). Generally, three criteria were selected; 1) mangroves at human settlement area (villages) at Kelantan (east coast), 2) mangroves at Ramsar's Site at Johor (southern-west coast) and 3) mangroves at agriculture area at Selangor (west coast).

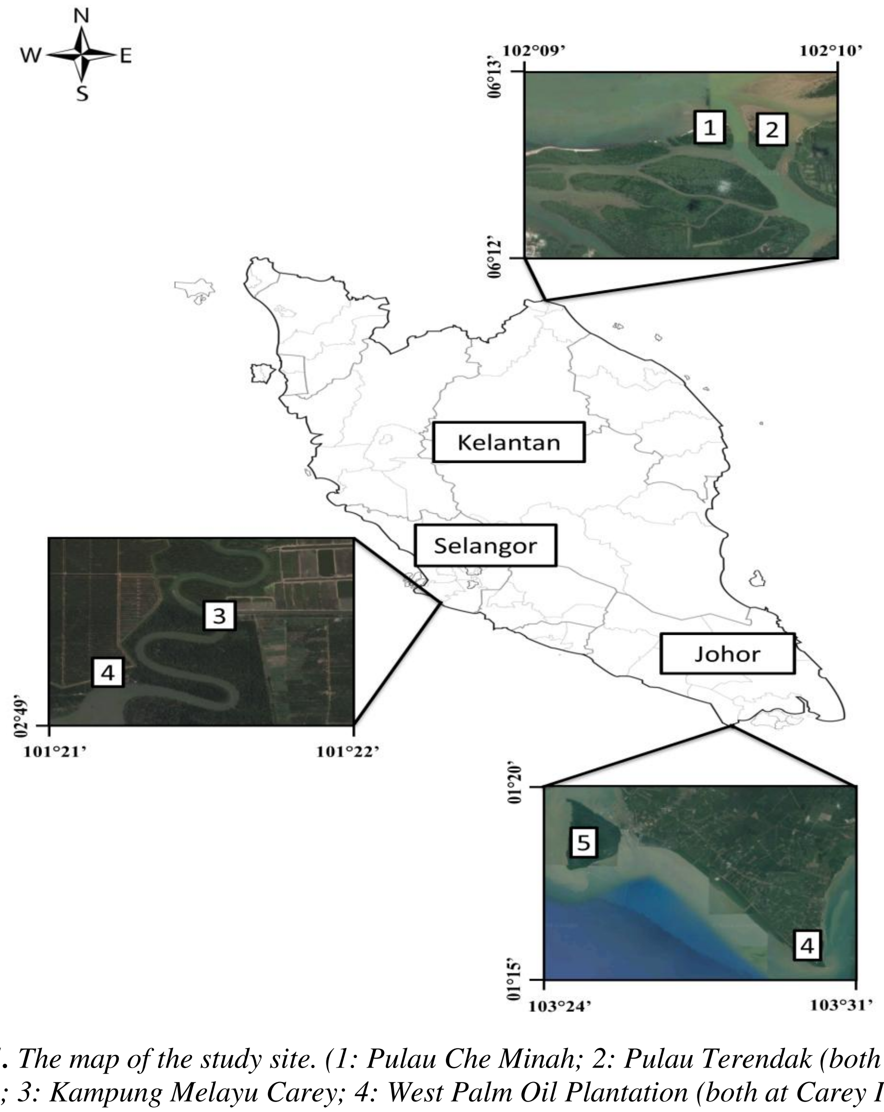

Figure 1. *The map of the study site. (1: Pulau Che Minah; 2: Pulau Terendak (both at Delta Kelantan); 3: Kampung Melayu Carey; 4: West Palm Oil Plantation (both at Carey Island); 5: Pulau Kukup; 6: Tanjung Piai (both at Ramsar's Site, Johor)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_19831998

Delta Kelantan

The main river running through the delta is the Kelantan River, which meets the South China Sea at the east of the study area. A large delta has been developed by the river with sand spits and sand bars common at, and close to the outlets of larger river mouth. There are almost seventeen islands surrounding Delta Kelantan where area was covered with mangrove forests around 1200 ha. In this case study, Pulau Terendak (6º12'47.23" N 102º10'13.07" E) and Pulau Che Minah (6º12'44.38" N 102º09'53.84" E) were chosen and both locations were located in the western part of Kelantan Delta, Tumpat. Kelantan state’s climate regime is influenced by the northeast and southeast monsoons that blow from late November to March and from June to September respectively. The estimated total amount of rainfall was 2700 mm per annum with heavy rainfall during the Northeast monsoon (November to March). The temperature ranged from 22.7 °C to 32.9 °C with and estimated mean of 26.8 °C. The humidity of the region was estimated to be about 83.7 % (Malaysian Meteorology Department (MMD), 2010a; 2010b). There were few species can be found at Delta Kelantan. But the most common species were *Sonneratia caseolaris, Nypa fruticans, Avicennia alba, Rhizophora mucronata and Bruguiera gymnorrhiza* (Satyanarayana et al., 2010).

Ramsar sites, Johor

Johor is the southern states in peninsular Malaysia where also the home of three Ramsar Sites (wetland of Pulau Kukup, Tanjung Piai and Sungai Pulai Forest Reserves). Johor was estimated to hold 28.7 % (27,733 ha) of mangrove forests in Peninsular Malaysia (Wetlands International Malaysia, 2009). In Johor, Pulau Kukup (1°18'60.00" N 103°26'59.99" E), Tanjung Piai (01°16'1.177"N 103°30'37.766"E) and Sungai Pulai (1º23'39.01" N 103º32'33.3" E) besides being Ramsar Sites are also designated as State National Parks. Pulau Kukup, Tanjung Piai and Sungai Pulai covered about 10,299 ha of mangroves in Johor. Pulau Kukup is a mangrove island while Tanjung Piai and Sungai Pulai are coastal mangrove. In this study, only two from three Ramsar sites were chosen which are Tanjung Piai and Pulau Kukup. According to Tan et al. (2012), Pulau Kukup has the higher number of species with 11 species compared to Tanjung Piai with only 9 species. Pulau Kukup are typical examples of a *Rhizophora-Bruguiera* dominated coastal forest. It is dominated by *Rhizophora apiculata* as the most common species, followed by *Bruguiera cylindrica* and *Ceriops tagal*, while *Rhizophora mucronata* is found along channels. The total amount of rainfall in this area was about 2104.1 mm. The highest and the lowest rainfall were in July (302.9 mm) and April (84.4 mm), respectively. The air temperature was highly recorded in May with 29.5 °C and the lowest was in January 2011 of 26.0 °C (Nordatul Akmar and Wan Juliana, 2012).

Carey Island, Selangor

Carey Island, Selangor is located approximately 70 km south from Kuala Lumpur. Carey Island is one of the 8 islets within Klang Isles facing the Straits of Malacca and separated from mainland by Langat River. The total area of Carey Island is 16,187.45 ha comprising of 65 % of palm oil plantation while the rest are divided into forest reserves (1,876.85 ha) and settlements. The study was conducted at Kampung Melayu Carey (02°49'2.2376"N 101°21'16.236"E) and West Palm Oil Plantation (02°49'24.2904"N 101°21'34.65"E). The total annual rainfall is 2,100.5 mm with the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_19831998

maximum and minimum monthly rainfalls were 496.0 mm and 28.3 mm in December 2012 and March 2013, respectively. The tide at this area is irregular and semi-diurnal, with two high tides and low tides in one day. An extensive survey in 2008 revealed that there were 43 mangrove species including associate species fringing around Carey Island (Rozainah and Irfan, 2017). Furthermore, Saraswathy et al. (2009) recorded that *Avicennia alba, A. officinalis* and *Rhizophora mucronata* are the dominant species here. The zonation patterns of the mangrove trees are obviously dominated by *Avicennia* sp. and *Rhizophora* sp. majorly at 5 m to 20 m seaward zone.

Soil sampling

Soil samples at one-meter depth were taken during low tide using a soil sampler (Eijkelkamp multi-sampler) at each location with three replicates. Then, the soil was divided into five segments according to vertical depth (0-20, 20-40, 40-60, 60-80 and 80-100 cm). The soil samples were taken during three different seasons; wet season (October-December), dry season (June-September) and inter-monsoon period (March-May) from November 2012 until July 2014 (Malaysian Meteorology Department (MMD), 2010a, 2010b). The soil was kept in sealed plastic bag at 4 °C and brought back immediately to the laboratory for further analysis. In laboratory, the soil samples were air-dried in room temperature for five days. Then, the soils were sieved through 2-mm screen to remove visible roots, litters and large elements such as shell.

Soil physical (texture) and chemical analysis

The soil surface water was taken for *in-situ* salinity test using a refractometer (Master-S10M, Atago Co. Ltd., Tokyo, Japan) and the pH was tested using a pH meter (IQ 170, Spectrum Technologies Inc., San Diego, USA). A total of 270 soil samples were sieved into less than 2 mm and further tested using a Beckman Coulter (LS 13, 320) to determine the soil texture (silt, clay and sand). The results were then calculated by percentage while the soil triangle (USDA, 1951) was used to determine the soil type.

The soil chemical studies were conducted using four nutrient parameters. The organic carbon (C) content was analysed using the Walkley and Black analysis (De Vos et al., 2007) and the results were reported in percentage (%). The total nitrogen (N) analysis was done using Kjedahl method and results for the determination of total nitrogen by distillation process were reported in percentage (%) (Nelson and Sommers, 1980). Phosphorus (P) analysis was done by determining the available P in soil using the Deniege method and the results were reported in part per million (ppm) (Binkley and Fisher, 2012). The potassium (K) analysis was done using the determination of exchangeable K by distillation method and the results were reported in cmol/kg (Ross, 1995).

Statistical analysis

All the results from 2 sampling locations in each site were pooled together to represent only one site. Analysis of variance (ANOVA) was performed to compare differences in soil physical and chemical properties between study sites, seasons and vertical depth. Analyses were performed using SPSS (version 20.0), including the assumption tests. Means were compared using the Tukey honest significant difference (HSD) test to evaluate variations in physical and chemical properties with sites and seasons and with sites and depth.

Results

Soil physical analysis

In terms of pH, Selangor and Kelantan showed that the surface water were slightly acidic in wet and intermediate season ranging from 6.4 to 6.9, while slightly basic in dry season with value >7. On the other hand, sites in Johor indicated that the water was in basic condition with value ranging from 8.3 to 8.7 across all seasons. The salinity results were difference for each site, where Selangor study site showed the highest value ranging from 20 ppm to 26 ppm, followed by Johor with value of 14 ppm to 16 ppm. The salinity at Kelantan was the lowest with the average of 11 ppm.

In this study, the soil textures were different for each location. The results showed significant difference amongst sites for all parameters. The composition of clay and silt were recorded high in Johor site while sand composition was highest at Kelantan. But in term of season, there were no significant difference for all locations. At Johor and Selangor study site, the soils were dominated by silty loam type. Whereas, in Kelantan, the soil type was sandy loam type (*Table 1*).

Table 1. *Soil texture at different seasons and locations (mean ± SD)*

Location	Season	Clay (%)	Silt (%)	Sand (%)	Soil type
Johor	Dry	9.24±0.65	75.34±3.46	15.40±3.69	Silt loam

^{x,y,z}Different letter denotes significant difference amongst locations

The detail results of the soil texture based on consecutive depth showed that different location had different trend. For example, in Selangor, the composition of clay increased going to the deeper segment. The result also showed that the clay in 60-80 cm significantly higher than 0-20 cm. In Johor, the results for silt and sand showed significantly difference between 0-20 cm and 60-80 cm. However, in Delta Kelantan, the soil texture showed no significant difference amongst depth (*Figure 2*). The soil types were identified at the end of the study. At Johor study site, the soil textures were silt loam for all depth. On the other hand, at Selangor study site, the soil types were different between 0-40 cm and 40-100 cm, sandy loam and silt loam, respectively. At Kelantan, the soil textures were identified as sandy loam except for 60-80 cm (*Table 2*).

Soil chemical analysis

The results showed that there were significantly different in terms of carbon, nitrogen phosphorus and potassium for all locations. The results for carbon and nitrogen were following this order; Johor>Kelantan>Selangor. The result also showed that Selangor has the highest concentration of phosphorus, followed by Johor and Kelantan. For potassium, the result showed a different trend. The potassium concentration in Johor was significantly higher to the other locations. The following order is Johor>Selangor>Kelantan (*Table 3*). With exception for phosphorus in Johor study site (*Table 4*), all chemical properties according to consecutive depth were found to be not significant different.

Discussion

The mangrove soil or sediment condition and properties are very important in maintaining the integrity of mangrove ecosystem so that it can fully functioning while providing services to mankind and environment. A sound physical and chemical qualities would ensure that mangrove forest can thrive well despite of worldwide's physically challenging pressure on mangrove land. Malaysia is blessed with 60 % of forested mangroves which includes some areas that have been gazette as Permanent Reserve Forest (PRFs) and declared as Ramsar sites (Jusoff, 2013; Wong, 2004).

The pH value in Selangor and Kelantan was slightly acidic compared to Johor site. But those values which range from 6.5 to 9.0 are still within the suitable range for marine ecosystem (Robertson and Alongi, 1992). Similarly, the salinity values were within the range for mangrove to grow in healthy condition (Kathiresan and Bingham, 2001). Although the salinity level in Selangor was the highest compared to Kelantan and Johor site. According to Nandy et al. (2007), mangrove species that face tidal inundation daily or twice a month may tolerate extreme pH and high salinity. The site on Carey Island recorded high salinity 20-26 ppm. Carey Island experience daily tide range varies from 1.5 to 2.5 m and spring tides and neap tides occur twice a month. The site is exposed to high energy wind and currents, and shipping activities at the nearby Port Klang, whereby the current flow can go up to 70cm/s (Rizal et al., 2010; Sakmani et al., 2013). These winds generate waves with heights of 0.1 to 1.5m on the coasts of Carey Island with wave periods of 2~8 s (Muzathik et al., 2011). Kelantan showed very low salinity value, 11 ppm due to its deltaic settings. Johor site also recorded a low value with 14-16 ppm. Its location within a small and narrow Straits of Johor might impending a high salinity influence from the seawater.

Determination of the physical characteristics of the soil texture is important to further explain its ability to retain soil nutrients in the targeted area. Silt and clay particles are finer than sand and have a higher ability to trap nutrients (Ashman and Puri 2002; Kamaruzzaman et al., 2004; Nguyen et al., 2013). In our study, Johor study site recorded a finer soil particle compared to Kelantan and Selangor, with higher percentage of silt and clay compared and therefore, it is expected to retain more nutrients.

The sedimentation refers to the deposition of inorganic or organic matter onto the soil surface in two condition; allochthonous and autochthonous. Kristensen et al. (2008) explained allochthonous is the material derived from outside the mangrove area. For example, Sundarbans mangrove area received over billions of tonnes of sediment from Ganges-Brahmaputra River. Autochthonous refers to the material derived within the mangroves area such as leaf litter, dead trunks and branches, and roots (Cahoon et al., 2003; McKee, 2011). Delta Kelantan receive sediment from few large tributaries rivers that running down to the delta. Carey Island and Johor mainly receive sediment from within its mangrove forest.

Furthermore, soil physical characteristics also influence primary soil nutrients such as carbon (C), nitrogen (N), phosphorus (P), and potassium (K) (Havlin et al., 2014). Many mangrove sediments have extremely low nutrient availability and high salinity, although they can vary greatly among and within mangrove forests (Reef et al., 2010). In contrast to most terrestrial soils, the flooded soils greatly restrain nitrification, the microbial formation of $NO3^-$, which would result in a low nutrient bioavailability in the intertidal sediments (Li et al., 2008). N deficiency (Feller et al., 2002, b; Reef et al., 2010) and salinity (Wakushima et al., 1994) have repeatedly been found to be important factors limiting mangrove productivity. Cheng et al. (2012) discovered that a moderate salinity could delay the entry of metals into the roots and thereby contributed to a higher metal tolerance.

The soil nutrients at Johor study site showed the highest concentration; i.e. CNK. But, for P, the value was lower than in Selangor. The soil results also showed a high concentration of nutrients in the bottom soil. This is followed what Havlin et al. (2014) discovered that more nutrients were concentrated in deep soil as a result of plants with extensive roots system, where the roots act as conduits for nutrients from the surface. Without any vegetation, nutrients were concentrated near the surface as a result of natural phenomena like weathering and atmospheric pressure (Jobbagy and Jackson 2001). A high concentration of nutrients, especially in the bottom soil, is very important so that they can be absorbed effectively by higher plants that have extensive root systems (Reef et al., 2010).

Mangroves also known as carbon-rich ecosystems that provide dumping pools for carbon from the atmosphere, allocthonous riverine, ocean elements and authochthonous organisms mechanism (Steven et al., 2004). C concentration was highest in the Johor and Kelantan sites, where those areas were not really affected by agriculture activities, unlike in Carey Island. According to Havlin et al. (2014), C is a fundamental element in mangroves as it promotes biological and physical health and protects from harmful elements. C concentration in the soil is largely determined by the volume of organic carbon as it is required in large amounts and can be obtained predominantly from the atmosphere. Soil organic carbon (SOC) is affected by both biotic and abiotic activities (Hopkins and Huner, 2004).

In this study, N also was highly concentrated at Johor and Kelantan. This is important because deficiency in N could result in soil infertility (Havlin et al., 2014). In soil, the ranges of N are about average of 0.05 % and the concentrations decrease with soil depth (Havlin et al., 2014). In our study, the N concentration at Selangor had the minimal effect to the mangroves growth. Some mangrove plants can accumulate the N through atmospheric nitrogen fixation or symbiotic bacteria present on or in the plants (Reef et al., 2010). The ammonium concentration is higher in muddy areas with high clay and silt composition compared to sandy soil (Alongi et al., 2013). Ashman and Puri (2002) described that the small particles such as silt have the stronger ability to retain N compared to sandy soil.

The P concentration was recorded high at Pulau Carey, Selangor. This is might be due to a small river running within Carey Island and receives sediments from the existing oil palm plantation activities as well as rainfall. The standard amount of P in soil must be within the range of 30-50 ppm (Havlin et al., 2014). For Johor and Kelantan, the values were below the minimum range. Potassium has also been used in fertilizer to increase soil fertility and acts as an indicator of healthy plants (Ashman and Puri, 2002; Havlin et al., 2014). The lack of K value in soil could lead to unhealthy plant growth. K is usually more abundant in silt or clay soil (Reef et al., 2010).

The current study found the amount of K was highly at Johor, followed by Selangor and Kelantan. At Kelantan study site, the value of K was within the range from very low to high concentration. The maximum values for K in soil should not less than 0.41 cmol/kg (Havlin et al., 2014).

Johor is expected to retain higher nutrient since this area was not really disturbed from anthropogenic activities, being gazetted under the Ramsar Site Treaty. This action is a very sound and exemplary of retaining mangrove forest so that little or none disturbance can be expected towards this site. And in turn, the mangroves forest at Tanjung Piai and Pulau Kukup were declared as Johor's State Park and proven that conservation status could well retain the quality and quantity of mangrove forest (Jusoff and Taha, 2008). Mangrove species differ in their growth-response to salinity. Our study sites recorded a reasonable value of salinity, as Patel et al. (2010) suggested that in extreme saline habitats N, P, K, Ca and Mg can be limiting factors for the growth of *A. marina.*

Conclusion

The soil in Johor and Selangor are dominated by silty loam while Kelantan soil is dominated by sandy loam. Nevertheless, the soil texture in these three study sites indicate stability in soil physical properties since there are no changes across seasons. In term of soil nutrient properties, the protected mangrove area in Johor has higher carbon, nitrogen and potassium compared to other sites. On the other hand, phosphorus concentration in Selangor soil is the highest which might be due to the run-off from oil palm agriculture site. Generally, there are no changes of nutrient concentrations across seasons except for carbon which is much higher in dry season in Selangor and Kelantan, while phosphorus level in Selangor is higher in wet season. Based on the depth, the nutrients are stable since there are no changes for all parameters except for phosphorus in Johor where it was found that the phosphorus was significantly higher in deeper soil.

The finding of this study indicates that the different mangrove habitats according to the land use types yielded different results in soil texture and nutrient composition. The protected mangrove habitat in Johor has siltier and clayey component which in turn can retain more nutrients for the plant growth. This finding proved that conservation and protection of mangrove habitats are needed to maintain the ecosystem services and functions for the well-being of mankind.

Acknowledgements. The authors wish to express their gratitude for the financial support provided by University of Malaya under the grant RP019D-16SUS. We acknowledged the support from the Institute of Biological Sciences, Institute of Ocean and Earth Sciences and Sime Darby Plantations. Permission and assistance from Kelantan Forestry Department and Johor Parks Corporation in conducting the study is greatly appreciated.

Abstract. The number of forest fires in Serbia caused by climate change has been continuously growing in recent decades, thus making the rehabilitation of the burned area increasingly important. In the period from 2003 to 2015, the total burned area (42.2%) was in beech forests. Cost-Benefit Analysis (the dynamic and the static approaches) was used as an approach to estimating the effects that restitution of beech forests can have on the environment, with the aim of finding the best solutions and making the best decisions about the desirability of the project. The dynamic approach (the analysis of tangible benefits and costs) led us to the conclusion that the investment in the restitution of beech forests destroyed by fires could be profitable only if it was based on wood production. Wood production may, depending on the site class, bear slightly higher interest rates (to better site classes) compared to previous estimates which ranged mainly around 3%. At lower discount rates (on poor quality sites), it takes more time to reach the break-even point, while the period of time needed to reach the break-even point shortens with higher discount rates. According to the static approach (the analysis of intangible benefits and costs) the benefits outweigh the costs, which makes the restitution of beech forests destroyed by fires acceptable.
Keywords: *forest fire, beech forests, restitution, financial analysis, economic analysis*

Introduction

Forests have always been considered as national treasures of a country. In addition to their ecological role in the preservation of important life cycles, they have other relevant economic and social (tourism, recreation, health) functions. Most of forest functions and their ecosystem services are not fully "captured" in comercial market (Costanza et al., 1997). This situation produce lack of valuation of ecoystem services what directy influence in sustainability of humans in the biosphere. There are many reasons for quoetionable in sustainability but one of most citet tiday can be found in processes of climate change. Forests are particularly vulnerable to climate change because they are not easily adapted to new environmental conditions.

The effects of modern civilization on climate change are becoming increasingly apparent. There has been an obvious trend of global temperature rise of 0.8°C since 1900 (Hansen et al., 2010). According to the European climate change scenario for 2100, the temperature is likely to rise by 2.8°C in Ireland and the UK, by 3.8°C in Central Europe and 4-5°C in Southern Europe (Christensen et al., 2007).

DOI: http://dx.doi.org/10.15666/aeer/1504_19992010

The number of forest fires caused by climate change has been continuously growing in recent decades, thus making the rehabilitation of the burned area increasingly important. This number ranges between 50,000 and 70,000 fires a year in Europe. They affect 3,000 to 5,000 km^2 and cause millions of euro worth damage. Forest fires cause significant environmental, economic and social issues in many European countries, with possible long-term effects on the natural environment and the economy.

Climate change increases the risk of forest fire occurrence and spread (Allen et al., 2010; Ertuğrul and Varol, 2016). There are a large number of models and official reports that predict that the risk of forest fires will be increasing in the future (Flannigan et al., 2009; Aleksić et al., 2009; Sekulić et al., 2012). The climate, with the doubled amount of carbon dioxide in nature, will extend the fire season and increase the frequency and intensity of forest fires (Lindler et al., 2010). These predictions are so serious that they call for urgent changes in the forest fire management and the establishment of modern fire protection organization.

The total area of forests in Serbia amounts to 2,252,400 ha, or 29.1% of its territory (Banković et al., 2009). The state-owned forests account for 53.0% and privately-owned for 47.0% of the forested area. High intensity and frequency of fires may affect the sustainable management of forests to a certain extent. There is a general concern that the territory of Serbia has been affected by an increasing number of forest fires and this trend can cause substantial losses to forestry. Serbia has already recorded an increase in the frequency, intensity and duration of droughts. This trend will in the near future be particularly expressed in the southeast and east of Serbia.

The vulnerability of forest ecosystems depends on the ability of natural ecosystems to resist adverse influences (Schröter et al., 2005). Forest fires affect the forest ecosystem, and often seriously hinder its functioning over a longer period before it is restored to the state before the fire (González-Cabán, 2013). Proces of revitalization forest ecosistems is a matter of making the right choises, espoecialy from the aspect of income effect (Broberg, 2007).

Since revitalization of forest ecosystems requires significant financial funds, these sites are often left to natural regeneration. On the other hand, it is questionable whether the investment into the establishment of forest stands with the species that used to grow at these locations is reasonable at all.

In Serbia, in the period from 2003 to 2015, the total burned area (42.2%) was in beech forests. In this situation, the restitution of these forests after they have been damaged by forest fires is of huge economic importance. The process of forest restitution raises the issue of financing and assessing the profitability of the investment.

This problem can be viewed from many different aspects, but the main questions to be answered are:

- What will be produced and how much of it, i.e. which products will carry the greatest burden of repaying the financial liabilities?
- What discount rates should be applied in the assessment of profitability?

The main goal was to make an economic and financial analysis in order to examine the feasibility of the restitution of beech coppice forests, with the maximum considersation of ecological site characteristics.

It should be noted there has been no research related to the evaluation of the economic effeciency of investments in the artificial restitution of fire-damaged forest complexes (i.e. in the establishment of plantation). Previous analyses were mainly focused on the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_19992010

assessment of the cost-effectiveness of the establishment and exploitation of commercial plantations (artificially-established forest plantations) of certain genera of deciduous trees or on the evaluation of the investments in forest fire prevention.

For instance, Keča et al. (2009) applied some of the basic methods of dynamic assessment of the economic effeciency of investments (simple rates of yields, payback period, internal rate of return, net present value of the investment and cost-revenue ratio) in order to evaluate the investment in the establishment of an artificially-established plantation of one of the poplar clones in Serbia, with the subsequent commercialization of wood mass (tree cutting) 29 years after the establishment. They concluded that in the current financing conditions (at a fairly high cost of borrowing in the financial market) such an investment would not be commercially viable for any of the applied parameters. The same authors came to a similar conclusion in the case of the establishment of a commercial poplar plantation with a 25-year rotation period, with the recommendation that profitability would be achieved by lowering the capital costs to below 10%, i.e. by reducing the rotation period to 20 years (Keča et al., 2008). Similar results, for high interest rate conditions, were obtained in the economic assessment of the plantation establishment in Latvia (Greğe-Staltmane and Tuherm, 2010).

On the other hand, the evaluations of the economic effeciency of investments in forest fire prevention measures, regardless of the method used, showed a certain level of economic viability (Mokhtari et al., 2017). Moreover, recent years have seen the development of risk assessment models and economic assessment of the management of forest fire risk which are of particular interest in the regions that are highly endangered by forest fires (Rodriguez y Silva and Gonzalez Caba, 2010; Gould et al., 2013; Calkin et al., 2014).

Materials and Methods

Given that the investment goal should be the highest possible level of the obtained economic effects per unit of the invested financial funds, the level of the effects depends on the quantity and quality of both the expenditures and the revenues. The economic effeciency of the investment is calculated as the ratio of the obtained effects to the realized investments, or as a ratio of the realized investments to the obtained effects (Cicea et al., 2008), according to the equation (1):

$$e = \frac{E}{\varepsilon} \rightarrow maximum \text{ or } e' = \frac{\varepsilon}{E} \rightarrow minimum \quad \text{(Eq. 1)}$$

where e and e' represent economic effeciency; E is the obtained effect (the achieved result), while ε represents the realized investment (spent resources).

In the first case, the formula expresses the economic effect that is obtained per unit of the realized investment and it should have the maximum value. In the second case, the formula presents the investments realized per unit of the obtained economic effects and it should be minimum.

Cost-Benefit Analysis (with the Dynamic and the Static Approaches) was used to assess the economic effeciency of the realized investments. The value of production was calculated without taking into account exploitation costs because they would quite complicate the analysis (over longer periods of time they can significantly change with the changes in technology). Besides, there is a trend to separate forest exploitation from silviculture. The value of wood was calculated using the stumpage price list of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_19992010

Public Enterprise “Srbijašume” (2012). Another reason for excluding the exploitation costs is the fact that the money invested in the exploitation cannot greatly change the amount and profitability of the invested funds because it remains tied up in the production for a relatively short time (Pudar, 1985).

The analysis included the following costs: coating stumps to prevent regrowth (purchase costs - 40,000 RSD per hectare) and cutting the shoots in the third year after the restitution had been conducted and the new stands established (22,400 RSD per hectare).

The subsidy granted by the state was treated as profit (for the organizations that perform the restitution). It amounted to 150,000 RSD per hectare and covered the costs of soil preparation, the value of seedlings, planting costs, the costs of ploughing and weeding with the aim of establishing high forests.

The cost of buying forest land was not taken into account since the restitution of beech forests was planned to be carried out on the areas with well-defined ownership status.

The profit was analyzed through the value of wood assortments at certain ages. The data on wood yield and the relevant prices of wood assortments were used to make tables showing the value of wood of the studied tree species growing on the sites of different quality classes. The obtained values were discounted at the discount rate ranging from 2 to 10%, which produced several different “current values”, depending on the applied discount rate. The value of wood production was calculated for different lengths of the production cycle (from 20 to 140 years). All the calculated values are expressed per unit area (1 ha).

The value of wood assortments that were taken into account when calculating the value of the wood production was determined using the stumpage prices of sawlogs class I (5,783 RSD) sawlogs class II (4,728 RSD) sawlogs class III (3,917 RSD) mine timber (4,852 RSD), cordwood (3,595 RSD), pulpwood (2,655 RSD) and forest residue (2,175 RSD)[1].

Apart from the tangible costs and benefits, the Cost-Benefit Analysis included a separate presentation of the intangible costs and benefits. Unlike the first approach (the dynamic approach), the second one (the static approach) was focused on the impact of beech forests on biodiversity (including species, ecosystem and genetic diversity), on environment, on the community and on the economy. For this reason, the dynamic method of assessing the profitability of the investments (net present value[2] and internal rate of return[3]) was supplemented with the static method of determining the intangible costs and benefits (i.e. the ordinal scale of Cost-Benefit Analysis and the quantitative data processing were used).

Results and Discussion

Tangible benefits and costs

We analyzed the value of wood production for the observed tree species on sites of different quality classes (I to V), with different lengths of the production cycle (20-140 years) and at discount rates of 2, 3, 4, 5, 6, 8 and 10%, since it was found that wood

---

[1] 1 EURO = 124.00 RSD

[2] Net present value represents the difference between the cash flows expected to be generated from the investment and the cash outflows needed for its acquisition and use in the initial stage of using the investment (moment $n = 0$) (Subić, 2010). An investment is considered to be economically justified if its net present value is not negative (NPV> 0), *i.e.* if the ratio between the inflows and outflows discounted at the initial moment of its use (n = 0) is greater than 0.

[3] The internal rate of return can be defined as the interest rate, where the amount of monetary income from investments discounted at a given calculation moment is equal to the outflow needed for the purchase and use of the investment, discounted at the same calculation moment (Subić, 2010). The investment is economically viable when the internal rate of return is greater (or at least equal) than the assumed calculative interest rate (discount rate) (ISR ≥ i).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_19992010

production in forest cultures can be cost-effective only at discount rates lower than 10% (Brumelle et al., 1991).

In order to get a better insight into the flow of the current value of wood and the costs over time, we constructed graphs (*Figs. 1, 2, 3*) which show the curves of change in the current value of the wood of the given species at different site classes, depending on the length of the production cycle, for the six discount rates. The analysis of the data for all site classes shows that the investment in some site classes can be profitable even at slightly higher discount rates provided that the production cycle is short.

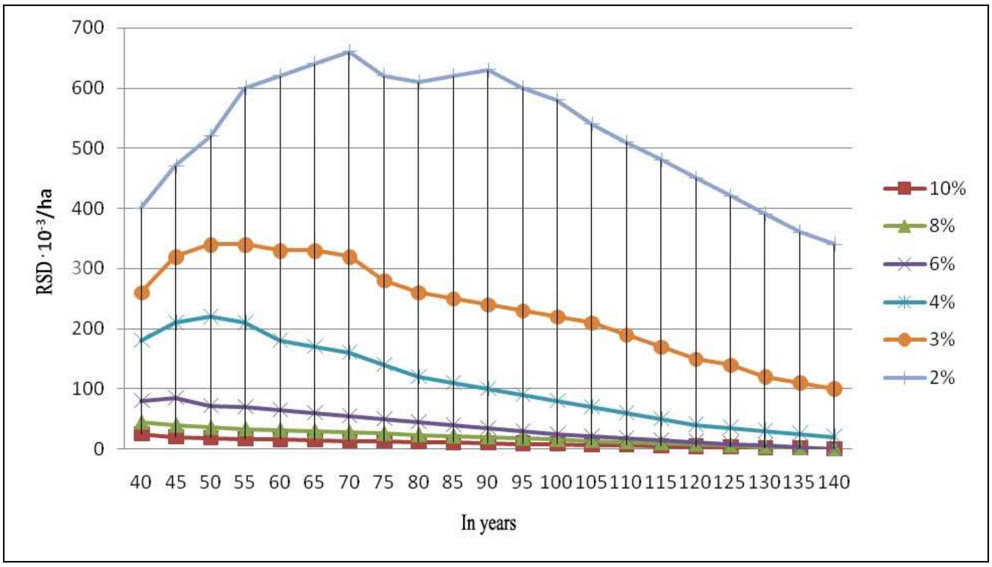

Figure 1. *Changes in the current value of wood with the age at different discount rates (Beech Site class I).*

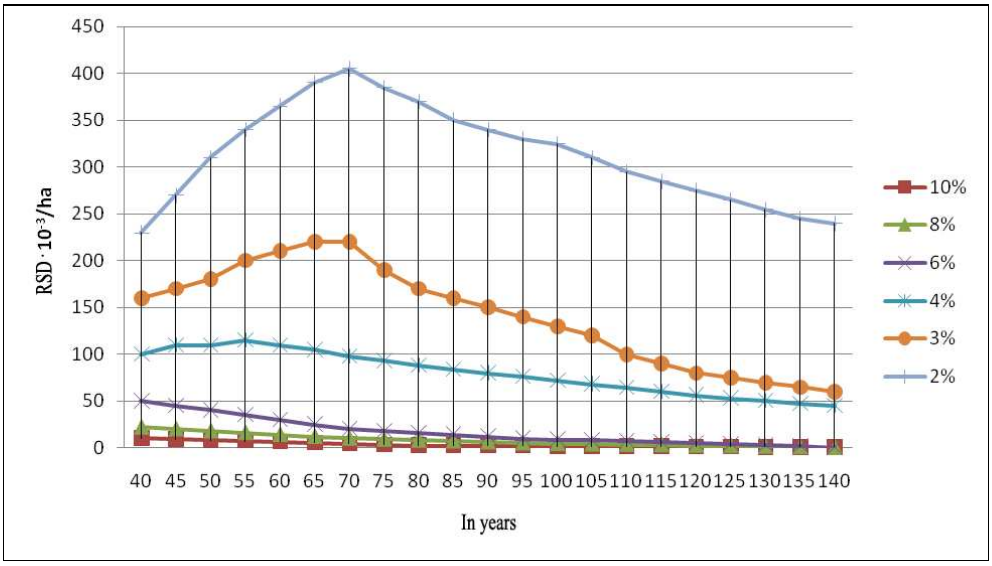

Figure 2. *Changes in the current value of wood with the age at different discount rates (Beech Site class III).*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_19992010

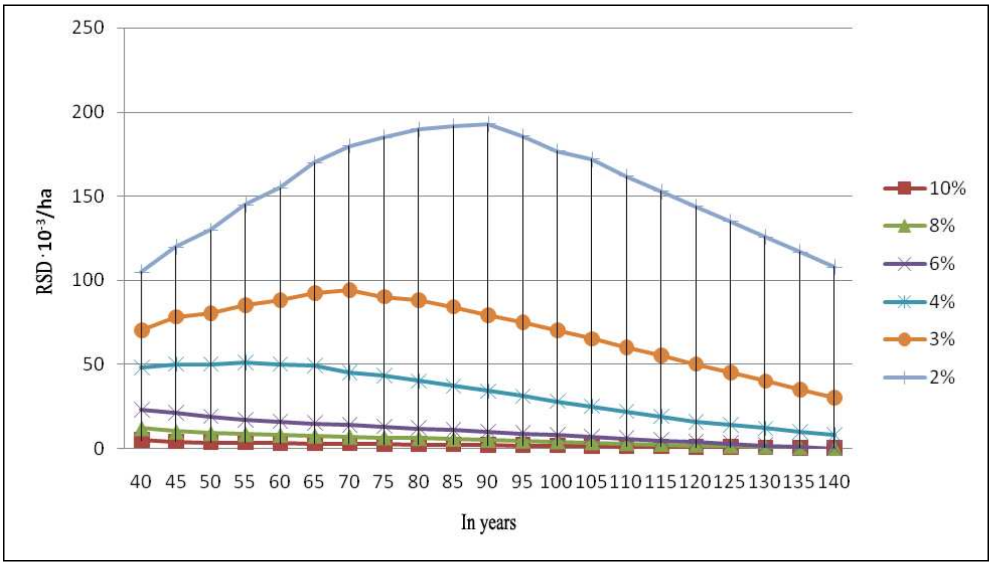

Figure 3. *Changes in the current value of wood with the age at different discount rates (Beech Site class V).*

Having in mind the equality of benefits and costs, we determined the highest discount rate and the maximum length of the production cycle at which the project could be expected to break even (*Table 1*). The table clearly shows that the discount rates at which the investment profitability is achieved are pretty lower than usual for similar projects (e.g. in agriculture). This indicates that wood production cannot bear regular interest rates. This fact should be taken into consideration when choosing the most appropriate interest rate.

Table 1. *The maximum discount rates and the break-even point by site classes.*

Site class	Discount rate (%)	Break-even point (in years)
I	5.66	45
II	5.19	50
III	4.28	55
IV	3.74	55
V	2.83	70

Source: Original

It can be concluded that if wood production is selected as the main production objective, the profitability of the investment can be achieved at different discount rates depending on the site class and the length of the production cycle (*Table 2*).

The obtained maximum discount rates are related to the length of rotation. In most cases, an increase in the discount rate shortens the length of rotation. This means that if long rotations must be selected from the aspect of the goal that is to be attained, the profitability can be achieved only at a discount (interest) rate below the maximum value.

This points to the complexity of the problem. There are no easy solutions and each particular case requires a thorough analysis to decide on the best option which would meet both financial and economic objectives.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_19992010

In some cases (site class and rotation), the profitability of investment can be achieved at higher discount rates (4%). This, to some extent, changes the current standing that investments in forestry can generally be profitable only at interest rates equal to or lower than 3%. Higher interest rates can mainly be applied only to better site classes (I and II), while the interest rate for poorer site classes (III-V) ranges around the values of 3% or even less than that (*Table 2*).

Table 2. *Break-even point of the production of wood in beech forests at different discount rates (per age).*

Discount rate (%)	Site class I	Site class II	Site class III	Site class IV	Site class V
2	Over 140	Over 140	Over 140	Over 140	140
3	135-140	120-125	110	95-100	-
4	85-95	75-80	70-75	-	-
6	-	-	-	-	-
8	-	-	-	-	-
10	-	-	-	-	-

Source: Original

It follows that the appropriate discount rate should be calculated for each particular case. The rate should correspond to the given tree species, site class and the length of the production cycle. The obtained value can be used to assess the profitability of the investments into the restitution of fire-affected beech forests.

”The duration of the production cycle” is in this case difficult to determine because the restitution of beech forests involves natural regeneration and production of wood and other forest benefits which can continue in perpetuity without any new investments. This is the fundamental difference between the forestry and standard industrial or agricultural projects, which in most cases have clearly defined duration, after which new investments are required.

Intagible benefits and costs

Apart from the dynamic method of determining the tangible benefits and costs, the static method of non-angible costs and benefits was also used. This method aims at determining the benefits that the restitution of beech forests brings to the wider community, but which cannot be expressed in monetary terms. To assess the intangible costs and benefits we used the ordinal scale of Cost-Benefit Analysis and the quantification (arithmetic operations) was done using the transformations that allow such procedures (Hastie et al., 2013). The results quantified on the basis of scoring the intensity of individual effects were used to perform the transformation (Ratknić and Braunović, 2013). The intensity of the effects and scoring are shown in *Table 3*.

Table 3. *Assessment of intangible effects on the environment.*

Effect	Intensity	Score
Positive or negative	Very weak	0-2
	Moderate	3-5
	Significant	6-8
	Very strong	9 – and over

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_19992010

The process of restitution of beech forests is in the analysis divided into two periods: a period up to 20 years of age of new stands and a period between 21 and 120 years of age, when the rotation of beech high forests is completed. We selected 33 intangible effects (benefits and costs) that make relevant factors in the restitution of beech forests destroyed by forest fires (*Table 3*). The data are presented collectively by type of activity in *Table 4*.

The estimate of intangible benefits and costs is based on the assumption that they will be actually achieved (although it may not always be a realistic option). The analysis of intangible benefits and costs shows that in the first 20 years after the restitution has been performed, the costs are much higher than the benefits (*Table 5*). The reason is that the initial phase of the restitution is carried out on the sites that have been completely destroyed by forest fires and before the normal functioning of the new ecosystem is established, the costs are higher than the benefits.

In the period from 21 to 120 years of age, when the rotation of beech high forests ends, the benefits exceed the costs, which means that restitution is justified (*Table 5*). Of course, it should be noted that in each case (micro-location) an analysis should be conducted to determine whether intangible costs exceed benefits.

Table 5. *Quantification of the value of the estimate of intangible benefits and costs.*

Conclusions

Forests and their resources belong to the resources of the future because they are renewable, and with the help of science and technology, they can replace some exhausted natural resources which are certain to disappear from the Earth. The establishment of new and the improvement of existing forests would enhance other forest functions (benefits to climate, conservation, erosion control, ambient aesthetics, tourism and recreation). It would further increase the yield of other forest resources - wild berries, mushrooms, medicinal and aromatic plants, or improve hunting opportunities. All in all, the cumulative effect on the level of society would be significant.

The presented results lead us to the following conclusions:

- The investment in the restitution of beech forests destroyed by forest fires can be profitable only if it is based on wood production and different discount rates can be applied depending on the site class.
- Wood production may, depending on the site class, bear slightly higher interest rates compared to previous estimates which ranged mainly around 3%. This primarily refers to better site classes, while on poor quality sites it may fall below the limit of 3%.
- The interest rate and the assessment of investment profitability are also closely related to the length of the production cycle because the break-even point varies with the discount rate. At lower discount rates, it takes more time to reach the break-even point, while the period of time needed to reach the break-even point shortens with higher discount rates. The length of production cycle plays an important role in determining the investment profitability, especially regarding the relation between the length of the production cycle and production targets (type and quality of wood assortments produced).
- Based on the analysis of intangible benefits and costs it can be concluded that the benefits outweigh the costs (generally speaking), which makes the restitution of beech forests destroyed by forest fires acceptable.

Abstract. Recently there has been a renewed interest in the optimization and development of legume cultivation technologies in many European Countries. By choosing the species which fit well the local soil and weather conditions might be an excellent solution to obtain a high fodder and grain yield. Field trials with faba bean (*Vicia faba* L.) and faba bean spring wheat (*Triticum aestivum* L.) mixture were conducted to evaluate the effect of seed inoculation with *Rhizobium* strain on the productivity of faba bean and its mixture with spring wheat. The study was conducted at two sites, Joniškėlis Experimental Station (site I) and Vėžaičiai Branch (site II) of the Lithuanian Research Centre for Agriculture and Forestry. The findings obtained in site I revealed that the dry matter (DM) yield of crops at the pod development stage averaged 7575 kg ha^{-1} and the grain yield averaged 6067 kg ha^{-1}; the corresponding values for site II were 5684 kg ha^{-1} and 4937 kg ha^{-1}, respectively. In most cases, the content of nutrients - crude proteins, crude fat, crude fibre, neutral detergent fibre, and crude ash in the biomass was higher in site I. The faba bean – spring wheat mixture produced a higher grain yield and a higher metabolizable energy content in grains compared with the faba bean grown as a sole crop; other measured parameters did not reveal the superiority of the mixture over the sole faba bean. *Rhizobium spp.* application had a positive impact by increasing the above-ground biomass DM yield and grain yield in a sole crop as well as in a mixture with wheat.
Keywords: *legume, mixture, dry matter production, seed quality, grain yield, Rhizobium spp.*

Introduction

Due to the increasing production area of cereals and oil crops in many European Countries, as well as the introduction of modern plant protection means, the area under legume crops and their role in crop rotation systems significantly decreased (Pascual and Perrings, 2007). According to the statistics, the area under legumes in the EU countries has declined from 5.8 million ha (in 1960) to 1.7 million ha (in 2013). Soybean (*Glycine max* (L.) Merr.) is a dominant legume crop, representing 50 % of the global legume crop area and 68% of global production (Herridge et al., 2008). Meanwhile in Europe, common pea (*Pisum sativum* L.) and faba bean (*Vicia faba* L.) are the predominant legumes. However, in order to diminish the dependence on import material (particularly soya bean meal) from America Continent and increase

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_20112021

biodiversity according to the "greening" programme, some legume species have good prospects in the coming decades. Accordingly, the legume species have a huge potential worldwide (Jensen et al., 2015). Legume cultivation and economic profit depend on numerous factors, including economic, political, climatic, and social ones in each region and country (Pilorge and Muel, 2016). Grain-legumes have many functional and nutritional properties both as feed and food (Voisin et al., 2014; Magrini et al., 2016).

Recently in Lithuania, as well as in other countries of temperate climate, the area under faba bean has been steadily increasing (Siddique et al., 2012). Despite the fact that faba bean is more sensitive to biotic and abiotic factors than other legumes, it has a higher capacity for N fixation, higher photosynthetic activity, thus forming higher above-ground biomass (Jensen et al., 2010). In Lithuania, faba bean is an important protein source for both food and feed (Jensen et al., 2010). To improve feed quality, legumes are often grown in a mixture with barley, oats and other cereals (Strydhorst et al., 2008). Such mixtures could sustain more stable yields, improve nutrient cycling in the soil, perform better in terms of resource use efficiency, provide better protection against weeds, diseases and pests, and increase biodiversity (McKenzie, 1999; Strydhorst et al., 2008; Šarūnaitė et al., 2013).

Legumes are not only a source of protein, they also play a significant role in the nitrogen cycle in the biosphere due to their most important ecological process - atmospheric nitrogen fixation (Bloemberg and Lugtenberg, 2001). The cultivation of faba bean and other legumes has an important economic benefit in sustainable cropping systems, which allows reduction of of mineral N fertilizer use, whose manufacturing requires fossil materials (Nemecek et al., 2008; Bedoussac et al., 2015). Each year, in agricultural systems, annual crops capture up to 50-70 Tg of atmospheric nitrogen (Herridge et al., 2008). The inoculation of faba bean seeds with *Rhizobium* strains has a positive effect on the symbiotic N fixation rate, above-ground biomass of crops as well as seed productivity (Lapinskas, 2006; Elkoca et al., 2007). *Rhizobium* bacterial activity is the most efficient in the soils that had been intensively managed, including heavy input of chemicals, for many years and no bacterial agents had been used for more than 10 years.

Inoculation of faba bean seeds is an efficient tool to increase crops productivity in a crop rotation and enhance economic profitability. Although the positive role of faba bean has been known for a long time, the growing technology needs to be refined and optimized. It has been well documented that inoculation of legume grains by bacterial strains is an efficient way of introducing effective *Rhizobia* to the soil and the rhizosphere of legumes. Threrefore, much work has still to be done in order to realize the full productivity potential of faba bean (Deaker et al., 2004).

The aim of the current study work was to get a better understanding and evaluate the efficiency of *Rhizobium* application on faba bean and faba bean – wheat mixture and their productivity in the two locations, differing in precipitation regime and soil type.

Materials and methods

Field experiments were carried out in two locations differing in the agroclimatic contitions: Joniškėlis Experimental Station (site I) and Vėžaičiai Branch (site II) of the Lithuanian Research Centre for Agriculture and Forestry. Joniškėlis Experimental Station is situated in the northern part of Central Lithuania's lowland (56°12′ N, 24° 20′ E). The soil of this experimental site is *Endocalcaric Endogleyic Cambisol (Siltic, Drainic)* (clay (<0.002 mm) – 27.0 %) with pH_{KCl} 6.5-7.0, P_2O_5 and K_2O - 198 mg kg^{-1}

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_20112021

and 273 mg kg^{-1}, respectively, humus - 2.8-3.0 %. The annual amount of precipitation is 500-600 mm, and most precipitation falls in the spring – summer period. Vėžaičiai branch is located in the seaside lowland eastern edge (Western Lithuania, 55°43′ N, 21° 27′ E). The soil of this experimental site is naturally acid, moraine loamy *Bathygleyic Dystric Glossic Retisol* (WRB, 2014), (clay (<0.002 mm) – 15.0 %), pH_{KCl} 5.2-5.5, P_2O_5 and K_2O - 200 mg kg^{-1} and humus 2.2-2.3 %. The annual amount of precipitation is 700-900 mm and most of it occurs in the autumn and early winter period.

Experimental designs and details

The experimental site was divided into two strips (factor – crops) – faba bean as sole crop and faba bean – spring wheat mixture. Further, each strip was randomly split into two smaller strips (factor – *Rhizobium* application) - without *Rhizobium* application and with *Rhizobium* application. The plots were sowin at the rates of 0.65 million ha^{-1} (65 faba bean plants m^{-2}) of viable faba bean seeds (in sole crop) and 0.40 million ha^{-1} of viable faba bean seeds + 2.5 mlillion ha^{-1} viable spring wheat seeds (40 faba bean plants m^{-2} and 250 wheat plants m^{-2}). Faba bean seeds (cv. Bioro) were inoculated with microbial fertilizer *Rhizobium leguminosarum bv. fabae* just before the sowing. The rate of phosphorus (single superhosphate) was equal for all treatment – 60 kg ha^{-1} P_2O_5. other fertilizers have not been used. Fertilizers were incorporated into the soil with a combined seed drill together with seeds.

Plant analyses

The dry matter yield was assessed at a pod development stage on July 18 and July 16 in site I and site II, respectively and at a full maturity stage (grain yield adjusted to 14% moisture) on August 20 and August 11 in site I and site II respectively.

The following chemical parameters were analysed: crude proteins (CP) (after Kjeldahl), crude fat (CF) (Soxhlet extraction method), water-soluble carbohydrates (WSC), crude fibre (Cfib) (by Henneberg and Stohman method), neutral detergent fibre (NDF) (by Van Soest method) and crude ash (CA) (gravimetrically). All analyses were done at the Chemical Laboratory of the Lithuanian Research Centre for Agriculture and Forestry.

The data of all studied parameters and their interactions were statistically processed using analysis of variance (*ANOVA*) as a three factorial randomized block variant to determine significant differences between means (*P< 0.05 and **P< 0.01), LSD_{05} and LSD_{01} (at 95 % and 99 % probability levels) (Tarakanovas and Raudonius, 2003).

Results and discussion

According to the data of Fisher's criterion, at pod development stage, location/site (L) had an essential effect on all studied parameters: dry matter yield (DM kg ha^{-1}), crude proteins (CP), crude fat (CF), crude fibre (CFib), crude ash (CA), water soluble carbohydrates (WSC), neutral detergent fibre (NDF) contents (mg kg^{-1}) and energy value (MJ kg^{-1}) (EV) (at p< 0.01) (*Table 1*). There were no significant differences in DM yield between the both crops (Cr) (growing faba bean as a sole crop and in mixture with spring wheat). However, there were significant differences (at p< 0.01) in all the studied chemical parameters as well as energy value beteween the both crops. Bacterial application (Rh) caused the differences between crops' DM yields (at p< 0.05), CF, CFib, NDF contents as well as ME (p< 0.01). There were significant differences

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_20112021

between location and crop (LxCr) interaction in the following parameters: CF, CFib, CA and ME (at p< 0.01). The effect of location (L) and bacterial (Rh) interactions on the studied parameters (except insignificant effect on CA content) was similar. CrxRh interaction caused the differences in CF, Cfib (at p< 0.01) and CA (at p< 0.05) contents. With regard to the three factors' interaction between LxCrxRh, it gave a significant impact on CP, CF and CA contents in the above-ground biomass (at p< 0.01).

Table 1. *F statistics values for the studied parameters at pod development stage*

Note: DM - dry mater, CP - crude proteins, CF - crude fat, WSC - water soluble carbohydrates, CFib - crude fibre, NDF - neutral detergent fibre, CA - crude ash.

At a full maturity stage, the location/site (L) as a factor had an essential effect on the grain yield (GY) and grain chemical parameters: CP, CF, CFib, CA, WSC and ME (at p< 0.01) (*Table 2*). There was no difference between crops (Cr) SY; however, grain quality parameters as well as EV differed significantly (at p< 0.01). Bacterial application (Rh) had an impact on SY (p< 0.05) and the following parameters: CF, CFib, WSC, NDF and ME (at p< 0.01).

Note: DM - dry mater, CP - crude proteins, CF - crude fat, WSC - water soluble carbohydrates, CFib - crude fibre, NDF - neutral detergent fibre, CA - crude ash.

Concerning the interactions among the different factors, LxCr was the most distinctive and strongest for the studied parameters: GY, CP, NDF and ME (at p<0.01) as well as for CF, CA and ME (at p< 0.05). The effect of the other two pairs of interaction was less noticeable. In this respect, LxRh interaction had a significant variation for CFib, WSC (at p< 0.01) and CA, ME (at p< 0.05); meanwhile CrxRh

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_20112021

interaction significantly influenced CFib and NDF (at $p< 0.05$). The three-fold factorial interaction (LxCrxRh) had a significant impact for CFib and CA (at $p< 0.01$) only.

The data of the above-ground biomass dry matter (DM) yield at pod development stage are presented in *Figures 1* and *2*.

The results evidently showed that the location/site (growing under different soil and temperature regime) had an essential effect on DM yield. The average DM yield at site I (Joniškėlis) surpassed DM yield at site II (Vėžaičiai) by 33.27 % (at 99 % probability level). In both locations, when growing faba bean in mixture with spring wheat, DM yield was higher than that in sole crop; however, the increase of biomass was not statistically significant (at 95 % level).

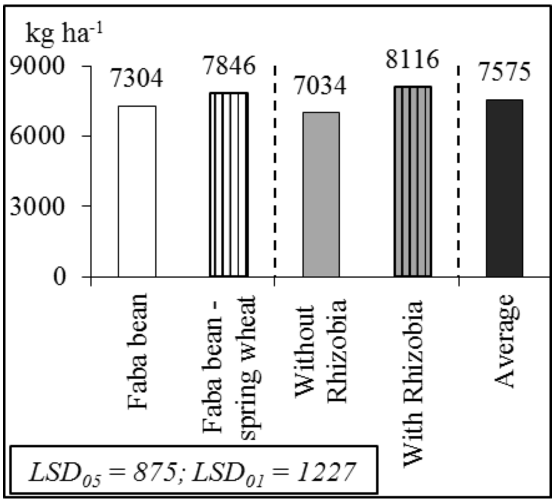

Figure 1. Faba bean and faba bean - spring wheat mixture (kg ha^{-1}) dry matter (DM) at pod development stage as affected by crop and *Rhizobium* application at site I

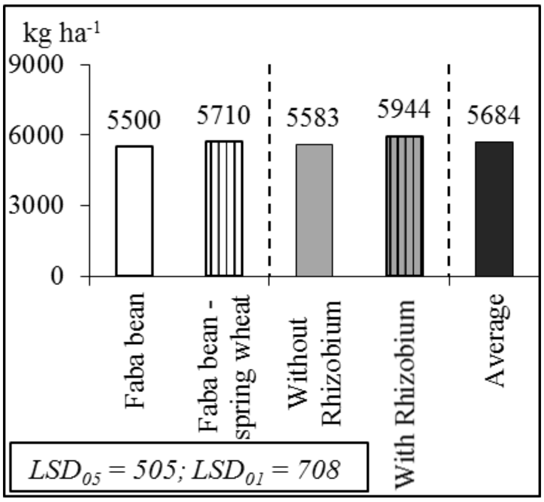

Figure 2. Faba bean and faba bean - spring wheat mixture (kg ha^{-1}) dry matter (DM) at pod development stage as affected by crop and *Rhizobium* application at site II

The inoculation of seeds with of *Rhizobium* had a significant and positive effect on biomass productivity. DM yield increased from 7034 kg ha^{-1} to 8116 kg ha^{-1} (by 15.38 %) (in site I) and from 5583 kg ha^{-1} to 5944 kg ha^{-1} (in site II) (both at 95 % probability level).

The highest grain productivity was obtained at site I where the yield averaged 6067 kg ha^{-1} and was by 22.89 % higher than in site II) (*Figs. 3* and *4*).

The grain yield in the faba bean – spring wheat mixture amounted to 6268 kg ha^{-1}, which was by 6.87 % higher than of sole bean crop (site I) (at 99 % probability level). However, the opposite situation was observed at site II, where sole crop produced higher yield averaging 5353 kg ha^{-1}. As mentioned before, the sowing rate of faba bean to be grown in a mixture with cereals was lower compared to that of a sole crop. Further, the spring wheat plants were shorter than faba beans ("Bioro") (biometrical data are not presented), therefore beans shaded them, which resulted in a relatively smaller share of wheat plants in the mixture.

The application of *Rhizobium* resulted in a grain yield increase from 5817 kg ha^{-1} (without inoculation) to 6316 kg ha^{-1} (by 8.58 %) at site I and from 4617 kg ha^{-1} to 5257 kg ha^{-1} (by 13.86 %) at site II (both at 99 % probability level).

DOI: http://dx.doi.org/10.15666/aeer/1504_20112021

In most cases, (except for WSC), the average values of quality parameters,(CP, CF, CFib, NDF and CA) were higher at site I (Joniškėlis).

At site I, the contents of CP, WSC, CFib and CA in sole faba bean biomass were significantly higher than those in faba bean – spring wheat mixture by 6.98 %, 24.68 %, 4.68 %, 2.90 % and 2.28 %, respectively; altogether, CF content in the biomass mixture was higher by 8.49 %. At site II, the higher contents of nutrient parameters were in sole faba bean biomass as well, where CP content was by 20.34 %, CF by 3.69 %, WSC by 1.18 %, CFib by 9.59 %, CA by 19.10 % higher than in the faba bean – wheat mixture. Only the content of NDF was higher in the mixture by 10.85 %.

In many cases, the role of *Rhizobium* on the studied parameters was unambiguous; however, the application of bacterial application had no positive effect on the measured quality parameters.

As regards the amount of metabolizable energy, there were no significant differences between either the two sites or *Rhizobia* application. However, the share of the energy was higher in the faba bean sole crop than in the faba bean – wheat mixture.

Faba bean and faba bean – spring wheat chemical parameters in grains at full maturity stage was somewhat different from that at pod development stage (*Table 4*).

Note: CP - crude proteins, CF - crude fat, WSC - water soluble carbohydrates, CFib - crude fibre, NDF - neutral detergent fibre, CA - crude ash, ME - metabolizable energy.

In general, the values of different grain nutrient parameters were higher at site I. However, these differences were less apparent than those in biomass at pod development stage. Overall, the content of nutritional elements in sole faba bean grain

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_20112021

was by 2.65 – 18.38 % higher compared with faba bean – wheat mixture grains in site I and by 20.94 – 37.26 % higher in site II. Except for CF, *Rhizobium* application did not increase the content of the studied parameters. It is known that a clear inverse relationship exists between protein and fat content in grains of many crops; that is with decreasing CP content, the CF content increases.

Despite the lower nutritional elements content, the higher amount of metabolizable energy was estimated in the grain from site II. As well, higher amount of the energy, averaging 13.21 MJ kg^{-1} was estimated in sole faba bean grains in site I and 13.16 in site II, There is an inverse relationship between CFib and metabolizable energy. *Rhizobia* application tended to decrease metabolizable energy amount in grains.

Discussion

Up to now, the development of legume growing technologies has been lagging behind that of cereal crops (Siddique, 2012). Consequently, an increase in the productivity of legumes has also been falling behind so far. Since legume – cereal mixtures are important components in animal husbandry, we intended to compare a sole faba bean sward with a faba bean – spring wheat mixture. At pod development stage, the DM yield of the biomass of mixture tended to be higher than that of faba bean sole crop. However, the grain yield results are unambiguous. Contrary to our expectations, grain yield of the faba bean – wheat mixture was lower than that of sole faba bean (site II, Vėžaičiai). Yet, some authors suggest that depending on the crop mixture, competition for water and nutrients, the yields in some cases might decrease (Yadav and Yadav, 2001; Olowe and Adeyemo, 2009). Our research findings do not always agree with those reported by other authors. Some research evidence suggests that cultivation of two or more crops in a mixture has the potential to achieve higher grain yields than do sole crop systems by improving efficient use of water, light, and nutrients (Zhang et al., 2010; Arlauskienė et al., 2011). However, other authors argue that faba bean - cereal mixtures do not necessarily increase faba bean sward grain yield or biomass productivity (Scalise et al., 2015).

One of the most important factors, which limit crop productivity, is the N fixation efficiency. It has been documented that inoculated plants activate nitrogen fixation, increase the rate of photosynthesis and respiratory enzymes; therefore, plants produce higher yields (Lapinskas, 2008). Legume bacteria sensitively react to a wide range of environmental conditions, including moisture, aeration, temperature and lighting variations (Köpke and Nemecek, 2010). Among other legumes, faba bean yield highly depends on N fixation efficiency (Jensen et al., 2010). N fixation efficiency as well as faba bean yields highly vary (Jensen et al., 2010; Foyer et al., 2016). In dry vegetation periods, the limiting biotic factor in the upper layer of *Cambisols* is high amount of clay particles, which leads to low aeration and crust formation. Still, clay soils are characterized by a weaker microbial activity and less favourable conditions of soil fauna (Janušauskaitė et al., 2008). In turn, *Albeluvisols* are traditionally acid soils, in which mobile aluminium and its toxic effect on plant roots are important limiting factors for many traditional crops. In both cases, taking into account these yield limiting factors, faba bean productivity might be increased by the application of the following practices: seed inoculation with bacterial products, optimization of the basic soil tillage, crop rotation diversification of basic and catch crops (Verhulst et al., 2010). These

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_20112021

experiments confirmed the positive effect of *Rhizobia* bacteria on DM increment as well as grain yield at both experimental sites.

Another issue we addressed in our research was chemical parameters of the biomass. In particular, faba bean plants are valued as protein feed (Voisin et al., 2014), which is required for weight gain of ruminants, milk production, maintenance of vital and reproductive functions (Butkutė, 2011) and are also suitable for monogastric animals (Jezierny et al., 2010) and laying hens (Koivunen et al., 2014). We found that there are few published data on how well the bacterial fertilizer affects different nutritional parameters of legumes. We expected to emphasize the role of *Rhizobium* to nutrient composition. Although there were significant differences in the parameters between the both study sites, the direct effect of *Rhizobia* application on nutrient parameters in the biomass as well as in grains was less explicit. Ascertainment of the role of bacterial agents for chemical parameters of the biomass warrants more precise experiments. Moreover, further studies on the current topic are required to validate the positive role of legumes, particularly faba bean in agricultural systems and to more comprehensively elucidate the effects of *Rhizobium* (or other bacterial strains) on plants and their nutritional quality.

Acknowledgements. The study was conducted in compliance with the long-term program "Plant biopotential and quality for multifunctional practice".

Abstract. Soil acidity and aluminum presence may reduce plant growth worldwide. In several cases, these two parameters, either alone or associated, can lead to plant constraints, which is barely known in natural ecosystems. In order to address these constraints, current model of study is *Qualea cordata*, an endemic species of Brazilian impoverished soil of rupestrian fields. Plants were grown, both in very acidic soil and in little deacidificated soil. After 6 months of growth in two acidic soil conditions and aluminum presence, the accumulation and dry biomass partitioning and content of nitrogen, calcium, magnesium, phosphorus, aluminum and chloroplastic pigments were evaluated and also chlorophyll fluorescence was obtained in intact plants. The soil deacidification induced an increase of mineral element contents in the leaves, however, lower total plant biomass and aluminum accumulation, also induced differential biomass partitioning and greater carotenoid levels. Regardless of the soil acidity, the levels of chlorophyll were not altered even in photosynthetic parameters. The results highlighted the resilience of this species to natural and very acidic soil conditions, indicating the need and the beneficial effect of aluminum accumulation in this specie.
Keywords: *aluminum resilience, metal accumulator, soil pH, Vochysiaceae*

Introduction

Acidic soil with aluminum (Al) availability is one of the environmental factors which compromises plant growth in many parts of the world, because in such soil the increase of this metal availability reduces plant development in most cases (Poschenrieder et al., 2008; Kochian et al., 2015). In general, the Brazilian savanna soil, including the rupestrian fields, is acidic, oligotrophic and containing high Al concentrations (Oliveira et al., 2015). However, throughout the world, some plants not only tolerate Al, but also accumulate significant quantities in the shoots and are therefore identified as Al accumulators (Jansen et al., 2002a), for example, *Camellia sinensis* (Theaceae) leaves are used for tea and may accumulate up to 30,000 mg Al kg^{-1} of dry mass (Matsumoto et al., 1976). Many of these Al accumulating plants are found in the Brazilian flora, especially species of the Melastomataceae, Vochysiaceae and Rubiaceae families (Souza et al., 2015), and very little is known about the ecological adaptation traits of these species.

Arboreal species or bushes frequently found in rupestrian fields such as those represented by the Vochysiaceae family, including *Qualea grandiflora*, *Q. parviflora*,

Vochysia thyrsoidea, *V. haenkeana*, as well as Melastomataceae (*Miconia* spp) and Rubiaceae (*Palicourea rigida*) families, are known to be Al accumulators (Jansen et al., 2002b; Olivares et al., 2010). Some of these species have notable behaviors in terms of adaptation to soluble Al in the soil. For example, contrary to expectations, high Al concentrations in leaves are not associated with low essential nutrient content. While some Al accumulating plants are restricted to oligotrophic soil, others are indifferent to soil fertility (Haridasan, 2000).

The elevated Al content found in shoots of the Al accumulators suggests that these plants have an Al uptake and translocation system which cannot be found in non-accumulating plants (Ma and Hiradate, 2000). Considering the arboreal native species from rupestrian fields, a small number of studies have been conducted. Most of them evaluate the quantitative plant Al accumulation obtained *in situ* and are rarely related to ecological adaptations and to controlled alterations of abiotic factors. Some authors argue that the capacity of Al accumulation is a determining evolving trait in these species to the point that some of them cannot survive without this metal present in the soil (Jansen et al., 2002a). Floristic studies have shown that the Vochysiaceae family has many endemic species in this ecosystem (Shimizu and Yamamoto, 2012) and that in its majority; it has an accumulating trait of more than 1000 mg Al Kg^{-1} in the shoots (Jansen et al., 2002a). These species are spread out in the Espinhaço Mountains in Brazil, and in other areas of the South American region (Shimizu and Yamamoto, 2012). In terms of growth, in general, plants respond positively to soil deacidification, including some native plants of different ecosystems (Haridasan, 2000). Thus, the hypothesis in this study was that minor alterations in soil acidity may interfere in the mineral nutrient and Al accumulation as well as plant development of *Qualea cordata* (Vochysiaceae). The relationship between changes of the acidic soil conditions and its related nutrients and Al levels were verified for the growth of this plant of the Brazilian Cerrado and rupestrian field.

Materials and Methods

Plant material and acidic soil conditions

Qualea cordata plants are an arboreal species, seed propagated, that grow in mesotrophic soil rich in Al and also occur in dystrophic and very acid soils (Haridasan, 2008; França, 2015). The species is found in South America, from Brazil to Bolivia, in savannahs, the Atlantic and cost rainforest (Correa, 1926). The plants grew in a greenhouse from the botanic department of the Federal University of Minas Gerais, Brazil. Seeds and soil used in the experiments were collected in rupestrian fields of the Serra do Cipó National Park, Santana do Riacho, Minas Gerais. The harvested fruits were left in the open at room temperature for 30 days for drying and opened to allow seed removal. After this period, they were kept in the freezer until use.

The soil was collected at 25 cm of depth, in the site of occurrence of this species using a shovel, and the vegetation and organic remains were removed. The soil fertility was analyzed according to Claessen et al. (1997) using the EMBRAPA method in the soil fertility laboratory at the Federal Rural University of Rio de Janeiro.

Seeds were sterilized in 5% hypochlorite for 5 min and then washed 3 times in deionized water. Germination was conducted in plastic gerbox plates covered with 2 germination papers moistened with deionized water, conditioned in germination chamber for 7 days at 30°C and for a 12h photoperiod. After germination, well-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_20232034

developed seedlings of the same size were selected for experiments. For growth assays, the seedlings were transplanted to 2 L pots containing the respective soil with or without liming treatment and no fertilizers. The slight variation in soil deacidification was performed by liming ($CaCO_3$), aiming at increasing the soil acidity in one unit only from 4 to 5, which reduces the Al availability by 50%.

Growth evaluation and leaf mineral element content

Plants (n=10) were grown in two different soil acid conditions in the greenhouse for 6 months and irrigated on alternate days with distilled water up to water saturation of the soil. After this period, plants were carefully withdrawn from the pots and the shoot and root lengths were measured. After this, the plants from both soil treatments were separated into stalk, roots and leaves, and then taken to a forced air oven at 60°C until constant mass, to obtain the corresponding dry mass of parts and total biomass. The relation of roots to shoots (R:S) was calculated starting from these values.

The leaf content of the elements iron (Fe), aluminum (Al), magnesium (Mg), calcium (Ca), nitrogen (N) and phosphorus (P) was obtained after dry mass digestion in sulfuric acid and hydrogen peroxide. The P content was determined colorimetrically at 410 nm using ammonium vanadomolybdate and N content, according to the Kjeldahl procedure (Allen, 1989). The Al, Ca and Mg content was obtained through flame atomic absorption spectrometry (FAAS) using Varian, model AA240FS (Mulgrave, Australia).

Chloroplastic pigments and photosynthetic evaluation

For photosynthetic pigment contents, three leaf discs with 1 cm diameter were withdrawn from a totally expanded leaf of five individuals of two soil treatments and submerged in 5 mL of 80% acetone for 48 h at 4°C. These tissues were macerated, centrifuged and the supernatant was used for spectrophotometric determination of chlorophyll *a*, chlorophyll *b* and carotenoids in the following wave-lengths 470, 646 and 663 nm, respectively. The chloroplastic pigment levels were determined as proposed by Lichtethaler and Wellburn (1983).

The photosynthetic parameters were evaluated on a typical day through chlorophyll fluorescence, measured with a modulated fluorescence meter (MINI-PAN, Walz-Germany), and the potential quantic yield values (Fv/Fm) and the effective quantum yield ($\Delta F/Fm'$) was obtained in plants from the acid and less acidic soil. The Fv/Fm from the photosystem II was evaluated in the early morning and the leaves were adapted in the dark for 30 min, being that $Fv/Fm = (Fm - F_0)/Fm$ in which Fm refers to the maximum fluorescence and F_0 to the basal fluorescence. Concerning the $\Delta F/Fm'$ values, these were determined being that $\Delta F/Fm' = (Fm'-F)/Fm'$, in which F is the chlorophyll fluorescence of the sample adapted to the light and Fm' to the maximum fluorescence of samples with saturating pulse.

Statistical analysis

Variance analysis (ANOVA) was carried out to analyze obtained data in the assays. The software used was JMP 5 SAS (Statistical Analysis System 1980, U.S.) and the Tukey test at 5% of probability was employed to compare the obtained means.

Results

Acidic soil and nutrient levels and plant growth evaluation

The results of fertility soil analysis from the site of occurrence of *Q. cordat*a revealed soil pH values extremely acid with high aluminum content. Also, the nutrient content is low, characterizing the soil as impoverished and dystrophic (*Table 1*).

Table 1. *Fertility analysis of soil collected from the site of occurrence of Qualea cordata Spreng. H2O = pH in water, Ca, Mg and P = calcium, magnesium and phosphorus exchangeable, OM = organic matter, V = base saturation, m = aluminum saturation. Data from 3 composite samples.*

pH	**cmol$_c$ dm^{-3}**		**mg dm^{-3}**	**dag kg^{-1}**	**%**	
H_2O	Ca	Mg	P	OM	V	m
4.0	0.29	0.06	4.91	1.89	6.2	86

The less acidic soil affected negatively and significantly the *Q. cordata* plant growth. The plants grown in more acidic soil presented greater increase in root, leaf and shoot dry weight as well as the total dry weight in comparison to those grown in less acid soil. However, there was no variation in dry weight of the stem or in the root and shoot ratio (R:S) (*Figure 1*). After 180 days of growth, the increment of dry biomass of root, shoot and total biomass of plants from more acidic soil was significantly higher compared to the same values of plants from less acidic soil. However, the R:S ratio was not significant.

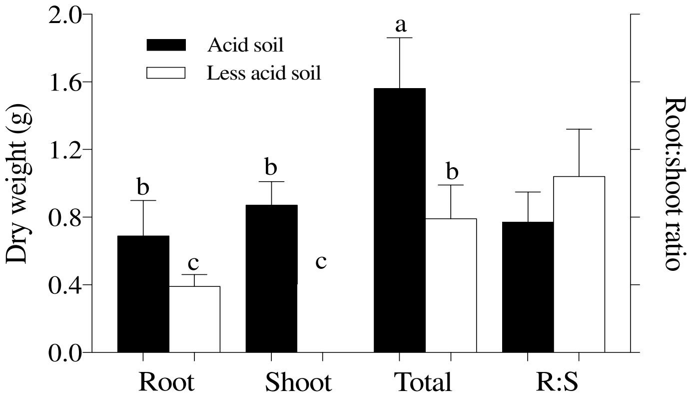

Figure 1. *Root, shoot and total dry weight (g) and root: shoot ratio of Qualea cordata plants after 6 months of growing in more acidic soil and also in less acidic soil. Means followed by the same lowercase letter in the column did not differ significantly by Tukey test at P ≤ 0.05. Means followed by standard deviation with n = 10.*

Regarding the total plant height (*Table 2*), those grown in more acidic soil presented an average apex root length of 43.9cm, while those obtained in the less acidic soil presented 45.0cm. However, the greatest length of roots was found in plants in the less acid soil, and there was a difference in the shoot height of plants in this soil in contrast to those obtained after growth from less acidic soil.

Table 2. *Root, shoot and total length (cm) of the Qualea cordata plants after 6 months of growing in more acidic soil and also in less acidic soil. Means followed by the same lowercase letter in the column did not differ significantly by Tukey test at $P \leq 0.05$. Means followed by standard deviation with $n = 10$.*

	Root	**Shoot**	**Total**
Acid soil	27.27 ± 1.72 b	16.61 ± 2.95 b	43.89 ± 2.09 b
Less acid soil	32.20 ± 2.89 a	12.79 ± 1.94 c	44.99 ± 3.48 b

Leaf mineral element analysis

In terms of the mineral element content in leaves, the greatest values of N, P, Ca and Mg were found on leaves of plants grown in less acidic soil (*Figure 2*). Contrastingly, the Al leaf content was greater in plants grown in more acidic soil.

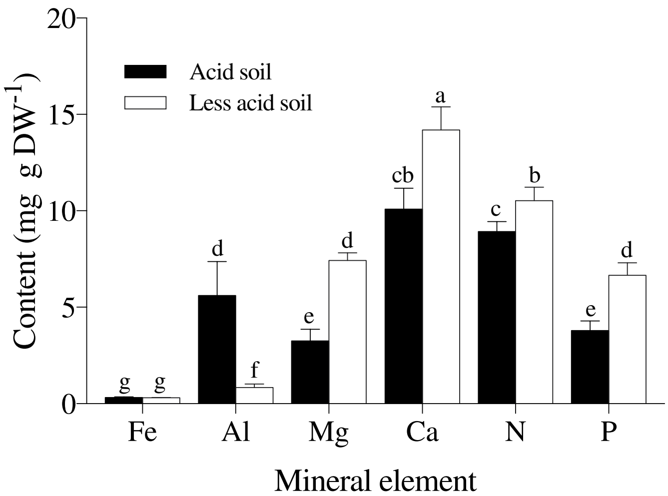

Figure 2. *Content of elements iron (Fe), aluminum (Al), magnesium (Mg), calcium (Ca), nitrogen (N) and phosphorus (P) in the leaves of Qualea cordata after 6 months of growing in more acidic soil and also in less acidic soil. Means and standard deviation with $n = 3$.*

Chloroplastic pigments and photosynthetic evaluation

The total chlorophyll content, distributed among *a* and *b*, was not altered in plants from less acidic soil (*Table 3*), but the carotenoid content and the chlorophyll: carotenoid ratio changed, where the carotenoid content was two times greater in those plants grown in this deacidification soil.

The analysis of fluorescence of chlorophyll *a* (*Figure 3*) indicated discrete lower values of effective quantum yield (ΔF/F'm) and potential (Fv/Fm) quantum yield in the early morning hours in plants from more acidic soil. The Fv/Fm values remained below 0.8 and reduced progressively in the evaluated time between 7 am and 1 pm. However, the ΔF/F'm values diminished drastically at 9 am, raising at 10 am and decreasing again and keeping constant from as of 12 pm. At the same time, the plants cultivated in more

DOI: http://dx.doi.org/10.15666/aeer/1504_20232034

acidic soil presented values lower that 0.77 for both parameters. The ΔF/F'm values decreased at 9 am and remained below 0.46 during measurements. The variations of these parameters were similar regardless of the soil treatments, but there was a less significant decrease of ΔF/F'm in plants grown in more acidic soil, without statistical differences between soil treatments.

Discussion

Soil nutrient levels and plant growth evaluation

The soil nutrient analysis at the occurrence site of *Q. cordata* revealed very low values of the base saturation such as the content of P, Ca and Mg, and organic matter as it has been highlighted for rupestrian field soils (Baligar et al., 1995; Oliveira et al., 2015). Contrastingly, elevated values of Al saturation were found, making the ion Al the most predominant cation (Benites et al., 2003). However, the acidity and elevated Al saturation found on site were above those generally found in the Brazilian Cerrado (Baligar et al., 1995). Despite the elevated acidity, excessive Al content and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_20232034

impoverished soil that were found, the greatest total biomass accumulation was evident in plants that were grown in this soil, and the shoot was larger in comparison to the roots, that is, a greater investment in structural carbon took place in the shoot. Contrastingly, plants from less acidic soil, there was an equitable partition between shoot and roots. Considering the present chemical soil conditions, the results suggest that the photoassimilated drain in the roots was as strong as of that in the shoots. For *Miconia albicans*, Haridasan (2008) showed that when plants grow in acidic and fertile soil, there was a greater increase in height and biomass, compared to those from acidic and oligotrophic soil, and in alkaline soil, plant growth was significantly less than in those from acidic and impoverished soil. In the present study, there were no nutrients added to the soil, but deacidification was enough to modify the carbon partition. The results also showed a larger carbon displacement for biochemical purposes due to the smaller biomass incorporation of plants in less acidic soil.

There was no difference in the root: shoot (R:S) mass ratio obtained in plants that were grown in less acidic soil, but in relation to the plant length, this condition favored an increase in root size but not in the shoot. In the more acidic soil, a larger mass and a shorter root were indicators of a greater root diameter, and the inversion of these parameters in the less acidic soil suggests thinner roots. The greatest root system length in less acidic soil can be related to alterations in soil nutrient to improve the root uptake system, however, it is also considered that even an Al tolerant plant develops symptoms associated with metal toxicity, such as the thickening and shortening of roots (Silva et al., 2014).

Soil and leaves mineral content

It is known that soil deacidification promotes Al and Fe precipitation which is exchangeable, and reduces P precipitation, increasing labile P fraction (Souza et al., 2007). This was confirmed through the greatest P content found in leaves. A large N content was also observed in plant leaves from less acidic soil; however, the greatest presence of these elements did not induce the greatest growth of shoots or biomass accumulation. The N and P contents found in *Q. cordata* leaves, after growth in both acidic soil conditions, were similar to those found in *Q. grandiflora* and *Q. parviflora* (Nardoto et al., 2006) and other arboreal species in natural field conditions (Delitti et al., 2006). The Ca and Mg contents in leaves from less acidic soil increased significantly, mainly the Mg content with values nearly twice as high and this response had already been previously reported in other native and cultivated plant species of this ecosystem (Furtini Neto, 1999). In *Plantago almogravensis*, Al hyperaccumulator plant, the concentrations of Ca and Mg in the shoot were maintained along the Al gradient (Serrano et al., 2011). In *Q. cordata* the greatest content of N, Ca, Mg and P in leaves, despite not having induced the greatest biomass accumulation in plants, is closely related to the greatest uptake of these nutrients due to soil deacidification, and to the root system length which was approximately 20% higher.

According to Jansen et al. (2002b) the Al content found in leaves of *Q. cordata* (5.6 ± 1.77 mg g^{-1}) from more acidic soil allows this species to be included into the group of Al accumulating plants. However, in plant leaves from the less acidic soil the Al content found was significantly reduced, different than what was found by Haridasan (2000), who said that the increase of oligotrophic soil pH and the higher Ca content in mesotrophic soil did not reduce the Al accumulation in Al accumulating plants. The reduction of Al and biomass accumulation in plants from less acidic soil indicates a

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_20232034

relation of this metal to the growth of *Q. cordata*. Although these observations refer to the involvement of Al in the cell physiology, there is still no definition of its role in the plant metabolism, even though some authors consider the actions of Al in plants to be beneficial (Haridasan, 2000; Pilon-Smits et al., 2009; Hajiboland et al., 2013). Recently, in *Camellia sinensis*, a hyper Al accumulating plant, the toxic fluorine effect was relieved in the presence of Al (Yang et al., 2016). In rice, it was also found that Al relieves Mn toxicity (Wang et al., 2015). Watanabe et al. (2005) evaluated the beneficial effects of Al in the growth of *Melastoma malabathricum* and when its roots were exposed to 0.5mM of Al, an increase in root growth and Al accumulation in leaves were observed. This only took place in plants grown in complete nutrient solution, evidencing that without nutrients there was no stimulatory effect of Al. Contrastingly, it is expected that soil deacidification may reduce the availability of some micronutrients (Buni, 2014), which can constrain plant growth. In natural acidic soil conditions with higher Al content, Olivares et al. (2010) highlights the positive correlation between Al, Fe and Zn leaf content in 19 Melastomataceae species, some being Al accumulators.

Chloroplastic pigments and photosynthetic evaluation

No changes were observed in the chloroplastic pigment of plants from less acidic soil, except the carotenoid content. Although an increase was expected, the chlorophyll content remained unchanged, since there is a positive correlation to the N content (Verhoeven et al., 1997). Interestingly, despite the less acidic soil plants having accumulated more N, it was not converted to more chlorophyll synthesis that could enhance the photosynthetic capacity. It is probable that the N was conducted for enzyme synthesis for the metabolism of other nutrients and perhaps if the soil organic matter content were higher, the greatest N availability/uptake could have enhanced photosynthetic activity. Haridasan (2008), cultivated *Miconia albicans* and *Vochysia thyrsoidea* in calcareous soil and observed leaf chlorosis. This symptom disappeared in these plants removed to acidic soil whereas in *Q. cordata*, leaf chlorosis was not observed. Also, in *Q. grandiflora*, Al enters the chloroplasts without apparent damage to this organelle (Andrade et al., 2011). In relation to the carotenoid content, Franco et al., (2007) suggested that zeaxanthin plays an important role in the dissipation of non-photochemical energy in trees at moments of higher irradiance. Thus, the highest carotenoid content found in plants from less acidic soil suggests that the change in soil acidity generated the need for more photoprotective capacity, evidenced by the increase in *Chl*:Cx ratio.

Chlorophyll fluorescence data indicated chronic photoinhibition in *Q. cordata* leaves in the evaluated time period. The performance of the photosynthetic apparatus observed by Fv/Fm and ΔF/F'm did not change in plants from less acidic soil, indicating that lower carbon incorporation would result in greater damage to photosystem II, as often reported in plants under stress due to the lack or excess of boron (Pinho et al., 2010), nitrogen (Tripodi and Sievering, 2010) or copper (Padua et al., 2010). The slight photoinhibition observed since dawn (Fv/Fm < 0.8) became more pronounced with the increase of irradiance. Franco et al. (2007), demonstrated similar behavior in *Schefflera macrocarpa* and *Ouratea hexasperma* and suggested that increased vulnerability to photoinhibition in the morning was reversed by the cycle activity of the xanthophylls, leading to an improvement in the photochemical process. Thus, in this plant growth stage, the results pointed to the failure of adaptation to higher photosynthetic rates, as constitutive levels of chlorophyll are maintained, and there was greater biomass

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_20232034

incorporation even with an increased nutrient uptake. However, the increase of carotenoid level indicated the need for photoprotection and without this mechanism the photoinhibition could be more severe in plants from less acidic soil conditions.

Conclusions

Our data support the ecological adaptation of *Q. cordata* growth in impoverished rupestrian field soils and can also explain the distribution pattern of the species in extremely acidic soil with high Al content. This research revealed that such species is an Al accumulating plant. The slight variation of soil deacidification in the occurrence areas of this species, and other plants with similar ecological chemical soil adaptations, can induce a constraint in the reintroduction process, once it leads to reduced initial growth and its possible plant establishment. Despite the results obtained in controlled conditions, the resilience of this species and also other Al accumulator plants should be revealed in field conditions, like other environmental constraints that compromise the growth of native plants.

Abstract. In the present study, eight apple genotypes were analyzed using internal cpDNA trnL intron sequence. Furthermore, these genotypes species were evaluated for their antioxidant activity, total phenolic and flavonoid contents. Genotypes in question show quite a variation in biochemical characteristics and molecular systematic analysis. One of the genotypes “Helesan” was the best graded genotype based on the high content of the total phenolic (12,21±1,25) and total flavonoid (7,98±0,26) content. As a result of the molecular analysis, which is one of the main aims of the study, genotypes are comprised of three main clades with robust bootstrap (95) value. It was concluded that these genotypes could be useful to improve genetic diversity among genotypes for breeding.
Keywords: *antioxidant; Malus sp.; cpDNA trnL; molecular systematic*

Introduction

Hundreds of clinical trials and epidemiological studies have been carried out to investigate the effect of diet on health. Although not all studies show a link between vegetable and fruit and health, in a major part of them, positive correlation is observed between vegetable, fruit consumption and health and reduced risk of some chronic diseases such as cancer, cardiovascular diseases (Arts and Hollman, 2005; Boyer and Liu, 2003; Lampe, 1999). This association partially may be due to the antioxidant compounds present in fruits showing protective effect on the cell against oxidative effect caused by reactive oxygen species (ROS) and reactive N species (RNS) (Arts and Hollman, 2005; Henríquez et al., 2010; Scalbert et al., 2005). Therefore, it is very important to consume foods rich in antioxidants. These compounds may reduce oxidative stress through a number of mechanisms (Kalinowska et al., 2014). The total antioxidant capacity of fruit extracts was measured by using spectrophotometric approaches with DPPH (2,2-diphenyl-1-picrylhydrazyl) (Rivero-Pérez et al., 2007). DPPH method is based on the electron transfer from an antioxidant to a free radical (Duarte-Almeida et al., 2006).

Apple (Malus × domestica Borkh.) is among the commonly consumed fruits. In Turkey, apple production has reached to 2.57 million ton/year (Bugem). Apple makes up a significant part of human diet as they have sugars, acids and a number of biologically active compounds such as phenolic and flavonoid compound (Boyer and Liu, 2003; Lampe, 1999; Wu et al., 2007). There is a strong link between phenolic content of apple and antioxidant activity. The main phenolics acid found in apple is chlorogenic acid and this compound has the ability to scavenge free radicals (Panzella et al., 2013). The concentration of these phytochemicals including phenolics and flavonoids compounds greatly depends on the apple genotype and the maturity stage of the apples and is closely related to their nutritional and sensory properties (Wu et al., 2007).

Though there are over 7,000 apple genotypes known across the globe, nowadays the world's production is based on a limited number of genotypes (Hokanson et al., 2001; Patzak et al., 2012). Therefore, A genetic characterization of the apple genotypes plays a key role in breeding programs, patent protection and nursery control (Goulão and Oliveira, 2001; Smolik et al., 2004). The recent advances in DNA technology have provided several methods which may be employed for the characterization of apple germplasm collections (Patzak et al., 2012). The trnL-F region, consisted of the trnL intron and trnL-F spacer, has been among the commonly used chloroplast markers for phylogenetic analyses in plants. The trnL-F region has been found to be useful in molecular phylogenetic studies of a broad range of plant groups (Pirie et al., 2007; Quandt et al., 2004).

Therefore, the aim of this study is: (a) to determine the total phenolic and flavonoid contents and the antioxidant activity of the eight native apple genotypes, (b) to assess the phylogenetic relationship between genotypes by alignments of DNA sequences from *cpDNA trnL-F* region.

Material and methods

Apple genotypes

Eight apple genotypes (Benekli, Helesan, Hese, Ovacin, Seva Zer, Sıvi Şirin, Sıvi Tırş, Sohrık) from *Malus domestica* otor were analyzed in this study. The name of the apple genotypes is given in *Table 1*.

Table 1. *Total phenolic and total flavonoid contents of peel for different apple genotypes*

Apple genotypes	TPC (mg GAE/g)	TFC (mg RE/g)
1. Benekli	3,75±1,64[cd]	4,49±0,13[e]
2. Helesan	12,21±1,25[a]	7,98±0,26[a]
3. Hese	5,22±0,83[bc]	5,21±0,22[bc]
4. Ovacin	4,23±0,56[bc]	4,79±0,16[de]
5. Seva Zer	2,57±0,41[d]	4,02±0,11[f]
6. Sıvi Şirin	4,67±0,21[bc]	5,01±0,38[cd]
7. Sıvi Tırş	4,87±0,20[bc]	5,37±0,19[bc]
8. Sohrık	5,78±0,31[b]	5,47±0,17[b]

TPC – total phenolic content; TFC – total flavonoid content; GAE – gallic acid equivalents; RE – rutin equivalent. The results were expressed as mean ± standard deviation. Means sharing the same letter in a column are not significantly different by Duncan's multiple range test at P ≤ 0.01

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_20352044

All genotypes were identified by specimen. The apples were collected during harvest seasons (June-August, 2013-2015). Fresh peel was manually separated from the pulp and seeds with the help of pens and forceps and then was dried until reaching a constant weight. The fresh peel was powdered with mortar and pestle by methanol (80 %) and was shaken at dark for a night. The extracts were evaporated by the rotary evaporator and solutions of 1 mg/ml concentration were prepared. For phylogenetic analysis, the leaves belonging to each apple genotypes were protected in silica gel and the samples were homogenized with liquid nitrogen and stored at -20°C.

Preparation of apple genotypes

The powdered peels from eight apple genotypes were weighted (1.0 gr) and mixed with methanol (80 %). The samples were homogenized with the homogenizer for 2 minutes and subjected to the ultrasound for five minutes. The extracts were shaken on an orbital shaker at midnight and evaporated to dryness. The concentration of all crude extracts was adjusted to the same value through addition of 80 % methanol.

Total phenol contents

Total phenolic contents (TPC) of powdered apple peels were performed by methods involving Folin–Ciocalteu reagent and gallic acid as standard (Slinkard and Singleton, 1977). Extract solution (0.1 ml) containing 1,000 mg extract was taken in a tube, and 1 ml Folin–Ciocalteu reagent was added and the flask was shaken thoroughly. After 3 min, 1 ml of solution of 6 % Na_2CO_3 was added and the mixture was allowed to stand for 1 h with intermittent shaking. Absorbance was measured at 760 nm with a Shimadzu UV mini 1240 spectrophotometer (Japan). The same procedure was repeated to all standard gallic acid solutions.

Total flavonoid content

The total flavonoid content was estimated using aluminum chloride colorimetric assay (Zhishen et al., 1999; Zou et al., 2004). The 0.5 ml of test samples solution in methanol were mixed with 2 ml of distilled water and 150 µl of 5 % sodium nitrate. After 6 min, 150 µl of 10 % aluminum chloride and 2ml of 1 M sodium hydroxide were added and left at room temperature for 15 min. The absorbance of mixtures was measured at 510 nm. Rutin was used as a standard to determine flavonoid contents of the grape seed extracts.

DPPH assay

DPPH (2,2-diphenyl-1-picrylhydrazyl) assay was performed in accordance with (Villano et al., 2006). Concentrations were adjusted to 1, 5 and 10 mg/ml respectively. Briefly, 1 ml of sample was added to the freshly prepared 4 ml of 0.01 mM DPPH solution (dissolved in methanol), incubated for 15 min in dark conditions and measured at 517 nm (*Eq. 1*).

$$\text{DPPH activity}\ (\%\ \text{incubation}) = \left(A_C - A_1\right) / A_C \times 100 \qquad \text{(Eq. 1)}$$

(A_C: Control Absorbance, A_1: Sample Absorbance)

DOI: http://dx.doi.org/10.15666/aeer/1504_20352044

Statistical analysis

Results obtained were reported as mean ± SD of triplicate measurements. Significance differences for multiple comparisons were determined by one way analysis of variance (ANOVA) followed by Duncan test with $\alpha = 0.01$ using SPSS (version 20).

DNA isolation, PCR condition and phylogenetic analysis

DNA was extracted from leaf tissues of genotypes according to CTAB (cetyl trimethylammonium bromide) method (Doyle, 1987). DNA quality was checked on 1 % agarose gel and then quantification was measured by using the Nanodrop (Thermo). To achieve the amplification of trnL-F region of chloroplast (cp) genome, PCR was performed in 25 µl volume. That volume was occurred from 3 µl (100 ng) DNA template 2,5 µl 10X taq buffer, 3 µl $MgCI_2$, 1 µl forward, reverse primers and 10 mM dNTP mix, 0,25 µl Taq polymerase and finally 13 µl ddH_2O. PCR products were separated by gel electrophoresis on 1.5 % agarose gels, containing ethidium bromide, and photographed under UV light in a gel doc system. PCR products of trnL-F region were sequenced by Iontek Company, Istanbul, Turkey.

Alignment and phylogenetic analysis

The sequences obtained were blasted (basic local alignment search tool) in NCBI (National Center for Biotechnology Information) database and percentage homology scores were assessed to identify apple genotypes. Phylogenetic trees were done with MEGA version 6 using a neighbor-joining algorithm with bootstrap analyses for 1,000 replicates.

Results and discussion

Antioxidant properties

Total phenolics and flavonoids

The total phenolic content (TPC) and the total flavonoid content of the apple peel of all genotypes, quantified as gallic acid equivalent and rutin respectively, are shown in *Table 1*. The TPC varied considerably depending on the genotype. Of all the apple genotypes, the highest TPC was observed in Helesan, whereas Seva Zer had the lowest TPC. In addition, the highest total phenolic content (TFC) was found in Helesan followed by Sohrık. As regards total flavonoid contents, they changed between 4,02 and 7,98. There was a significant difference at $p < 0.01$ between all samples for the total phenolic and flavonoid contents.

These results are incongruent with (Vieira et al., 2009; Manzoor et al., 2012) but in line with the results of (Wolfe et al., 2003; Faramarzi et al., 2014; Leahu and Ropciuc, 2013).

According to the results of previous studies (Awad and de Jager, 2000; Duda-Chodak et al., 2011; Escarpa and Gonzalez, 1998; Łata et al., 2009), it can be noted that some apple genotypes have higher TPC than others (Kalinowska et al., 2014). For example, the peel of ‘Red Rome’, ‘Idared’, ‘Fiesta’, ‘Fuji’, ‘Gloster’, ‘McIntosh’ and ‘Pilot’ contains higher amount of chlorogenic acid in comparison to other varieties, whereas ‘Elan’, ‘Elstar’ and ‘Jonamac’ show the lowest content of chlorogenic acid. ‘Red

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_20352044

Rome', 'Prima', 'Pilot' and 'Elstar' possess high amount of catechin and epicatechin in peel. 'Starking Delicious', 'Gloster', 'Golden Delicious', 'Granny Smith', 'Idared' and 'Monroe' possess high content of phloridzin. While the peel of 'McIntosh' and 'Reineta' are abundant in procyanidin B1, 'Elstar' and 'Idared' in procyanidin B2, 'Gloster', 'Idared', 'Lobo' and 'Elstar' are rich in procyanidin C1. The composition of the peel dependent on apple genotype differs significantly. However, most of the phloridzin, procyanidines B2 and C1, catechin and epicatechins are present in apple fruit (Carbone et al., 2011). The differences among TPCs can be attributed to the presence of the mixture of different cyanidin glycosides (Tsao et al., 2005; Wolfe et al., 2003) or to the biosynthesis pathway of phenolic compounds (Treutter, 2001; Wang et al., 2013). Fruit maturation also plays an important role on the concentration of the phenolic compounds in apple peel (Treutter, 2001). Moreover, since all eight apple genotypes tested in the present study were grown in the same region with similar ecological conditions, the variation in total phenolics and flavonoids demonstrates that the genetic variability may have given rise to the differences in the biosynthesis of phenolic secondary metabolites.

DPPH radical scavenging activity

The DPPH free radical is a constant free radical which has been utilized as a tool for determination of free radical scavenging activity of antioxidants (Acharya et al., 2012; Fenglin et al., 2004; Oyaizu, 1986). The results are presented in *Table 2*. According to DPPH scavenging activity assay results, the highest scavenging capacity was found in Hese extract followed by Sıvi Şirin of 5 mg/ml concentration with a clear difference, and for all the genotypes studied these values ranged between 79,62 % and 77,43 %.

Table 2. *Free radical scavenging activity (Percentage) of 8 different apple genotypes in the concentrations of 5 mg/ml by DPPH reduction*

Genotypes	Inhibition (%)
Benekli	77,43
Helesan	74,92
Hese	79,62
Ovacin	75,86
Seva Zer	77,74
Sıvi Şirin	78,06
Sıvi Tırş	77,43
Sohrık	77,74

Our findings are in disagreement with some research results (Jelodarian et al., 2012; Yoshizawa et al., 2005), but consistent with some others (Manzoor et al., 2012; Sownthariya and Shanthi, 2015).

It has been noted that free radical scavenging activity of the plant based food (fruits and vegetables) extracts principally arise from phenolic compounds, which are largely distributed in the epidermal tissue (Cheng et al., 2006; D'Abrosca et al., 2007). Furthermore, the method used for determination of antioxidant activity has

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_20352044

various effects on results. It should be mentioned that antioxidant activity can be affected by the solvent type. As different extraction solvents differ greatly in terms of polarity, their extracting abilities for different compounds are different (Kong et al., 2012; Li et al., 2014; Liu et al., 2009; Razali et al., 2012). For example, Li et al. (2014) reported that DPPH values of 10 crab apples (Malus wild species) ethanol extracts were found 6 times higher than ethyl acetate extracts on average. Apart from the solvent type used, the extraction method used is another important parameter. He et al. (2015) used three different extractions methods (microwave-assisted extraction, ultrasound-assisted extraction and water bath extraction) for the extraction of apple polyphenols and concluded that microwave-assisted extraction was much better than the other two methods.

Molecular phylogeny of apple genotypes using the chloroplast trnL-F DNA sequences

Chloroplast DNA (cpDNA) is a robust tool for inferring the interspecific relationship between the plant taxon. To study the genetic relationship of the interspecific genotypes between trnL (UAA) 3'exon and trnF (GAA) gene is known quite informative (Ashworth, 2017; Taberlet et al., 1991). In this study, a molecular phylogenetic analysis of eight apple genotypes commonly consumed in Turkey was performed by using trnL-F cpDNA sequences.

trnL-F cpDNA sequences are usually used for molecular classification plant cultivars, genotypes, species and interspecies analyses (Ashworth, 2017). In our study, ML and NJ phylogenetic analysis of trnL-F sequences showed almost the same profile but only NJ tree with *Mespilus germenica* out group is presented here (*Figure 1*).

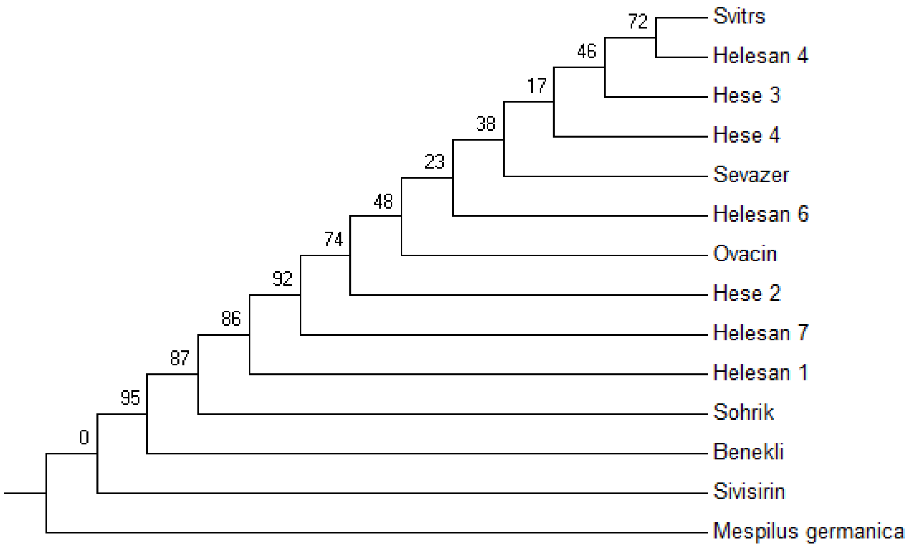

Figure 1. *Phylogenetic analysis of apple genotypes based on trnL-F chloroplast region with Neighbour-Joining method (numbers on branches show the bootstrap value)*

Based on the NJ tree, genotypes are comprised of three main clades with a robust bootstrap (95) value. The widest of these three clades comprised the Sivitırs, Helesan 4, Hese 3, Hese 4, Sevazer, Helesan 6, Ovacin, Hese 2, Helesan 7, Helesan 1 and Sohrik genotypes. The second clade comprised only Benekli genotype and Sivisirin constituted the obviously separated clade (*Figure 1*). In the first clade, it was found that all replicate

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_20352044

genotypes fell within the same group. Thus, genetic relationships of the apple genotypes based on trnL-F region were estimated to be quite effective. There are many phylogenetic studies that found that trnL-F cpDNA region was quite effective for separating plant genotypes (Ashworth, 2017; Zhang et al., 2014; Zhang et al., 2016). In the present study, polymorphism of trnL-F analysis was found to be more informative. It produced fairly clear dendrogram that explains all apple genotypes according to morphological character and aromatic properties. To support this point in our analysis, Sivisirin apple genotype, which has different aromatic feature (it is known so sweet), comprised an evidently separated clade (*Figure 1*). Furthermore, this genotype has the highest inhibition rate (78 %) in DPPH analysis (*Table 2*). Sivisirin also showed a different value according to other genotypes in TPC and TFC analysis (*Table 1*).

Conclusion

This study was carried out to determine the biochemical and molecular relationships of eight apple genotypes that were collected from different regions of Turkey. The relevant genotypes show quite variation in biochemical characteristics and molecular systematic analysis. "Helesan", one of the genotypes, was the best graded genotype based on the high content of the total phenolic (12,21±1,25) and total flavonoid (7,98±0,26) content. As a result of the molecular analysis, which is granted as one of the main points of the study, genotypes are comprised of three main clades with a robust bootstrap (95) value. The widest of these three clades comprised the Sivitırs, Helesan 4, Hese 3, Hese 4, Sevazer, Helesan 6, Ovacin, Hese 2, Helesan 7, Helesan 1 and Sohrik genotypes. The second clade comprised only the Benekli genotype and Sivisirin comprised the obviously separated clade. Consequently, it is expected that this study will be a useful step for the molecular biotechnology breeding in horticulture agriculture. These local apple genotypes can also be assessed as a quite important source of genes for apple breeding program and for the production of value added apple genotypes. Hence, further studies are recommended on local and ancient genotypes to identify their biological potentials.

Abstract. The widespread use of nanomaterials in recent years has caused rising pollution in surface and waste waters. It may be seriously affecting aquatic life such as cyanobacteria and thus, there is a compelling need to evaluate the potential effects of these substances in aquatic ecosystems. Copper oxide is one of the most common nanoparticles (CuO-NPs) used today. In this study, the responses of *Anabaena sp.* to CuO-NPs, salt stress and their combined effects (CuO-NPs+NaCl) were investigated. After 72 h exposure, MDA (malondialdehyde), proline, protein content, soluble sugar, total phenols and the activities of antioxidative enzymes such as peroxidase (POD), catalase (CAT), ascorbate peroxidase (APX), and polyphenol oxidase (PPO) were measured using spectrophotometry. Scanning electron microscopy (SEM) was used to image the results of exposure of cyanobacterial cells to nanoparticles. The effective concentrations (EC10, EC50, EC90), no observed effect concentration (NOEC) and percent inhibition (I %) was also calculated after 24, 48 and 72 hours. EC and NOEC data for CuO-NPs treatments were considerably higher than were those for NaCl treatments. CuO-NPs had a significant impact on the shape and morphology of *Anabaena sp.* cells and resulted in their swelling and enlargement. Modulations in enzymatic and non-enzymatic antioxidants were clearly evident in *Anabaena sp.* exposed to salt and CuO-NPs stress. Lipid peroxidation, measured in terms of MDA levels, increased with CuO-NPs and CuO-NPs+NaCl stress. Flavonoid and proline contents were also increased by CuO-NPs stress. Similarly, increases in POD and CAT activities were more pronounced in the CuO-NPs+NaCl treatments. On the other hand, APX activity enhancement was strongest in *Anabaena sp.* exposed to CuO-NPs.
Keywords: *antioxidant activity, aquatic ecosystems pollution, cyanobacteria, CuO-NPs, salinity, two combinational stress*

Introduction

Nanomaterials, products of nanotechnology, are an important part of numerous industrial and medical products and their use has increased dramatically in the past decade (Peralta-Videa et al., 2011). Being so widely used, it is likely that they will increasingly contaminate aquatic ecosystems (Klaine et al., 2008). Despite this obvious eventuality, the toxic ecological effects of nanomaterials have nevertheless not been easily evaluable; the mechanisms of toxicity of nanoparticles are not understood (Dhawan et al., 2009). The key physicochemical features of nanomaterials associated with toxicity which have been identified by toxicological researchers to date include factors such as aggregation, solubility, size, shape, elemental

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_20452059

composition, contact area, porosity, surface ionic charge, and hydrodynamic diameter (Griffitt et al., 2008; Johnston et al., 2010, Peralta-Videa et al., 2011).

Biological responses of organisms are very much dependent on the physicochemical properties of nanoparticles. For example, nanoparticles are highly mobile in water and thus they can easily pollute aquatic ecosystems (Oukarroum et al., 2012). Nanotoxicity, as one of the most important aspects of nanotechnology, is induced by nanomaterials whose safety and toxicity characteristics are not clearly defined; and therefore must be determined to ensure public safety. In addition, high concentrations of salts, especially sodium chloride, are among the most important abiotic factors which can affect the survival of living organisms, including aquatic organisms such as cyanobacteria (Denizet al., 2011). The presence of toxic ions, mainly Na^+, creates distress due to osmotic potential and their effect on the uptake of inorganic nutrients (Deniz et al., 2011). This leads directly to inhibitory effects on growth, oxidative stress and finally death. It has been shown that high salinity inhibits photosynthesis, resulting in a decrease in the carbon pool of freshwater cyanobacteria (Srivastava et al., 2008) and lowering of the synthesis of compatible solutes (Ferjani et al., 2003). Furthermore, although nano metals and metal-oxides (Haulik et al., 2014) and salinity have harmful effects on cyanobacteria and plants individually, their effect cannot be directly extrapolated when two or more combinational stresses are induced (Suzuki et al., 2014). Algal cells, in contrast to human and animal cells, possess a cellulose cell wall, which acts as a barrier to particle uptake, prohibiting uptake of nanoparticles larger than 20 nm in size. Nevertheless, nanoparticles are capable of inducing pore formation, which may result in uptake of larger-sized particles (Navarro et al., 2008). Cyanobacteria are major organisms in aquatic productivity and significantly contribute to the availability of nitrogen in agriculture (Singh, 1961) and the evolution of oxygen-dependent respiration. *Anabaena*, as one of the significant cyanobacteria, is not only widely distributed across a wide range of salinities (Srivastava et al., 2011), able to cope with high osmotic potential by enhanced osmolyte synthesis (Hagemann, 2011), but also a preferred candidate for dinitrogen fixation (Singh, 1961). On the other hand, phytoplanktons are used as an early and direct warning signal because of their rapid response to stresses (Del Arco et al., 2014). However, not many studies have previouslybeen conducted on the combined effect of salt and CuO-NPs in cyanobacteria in general and *Anabaena* in particular, although their exposition to many kinds of stresses, individually, has been reported previously (Rai et al., 2013).

In the present study, the impacts of combined effect of CuO-NPs and salt stress were investigated on antioxidant activity and growth inhibition of *Anabaena sp.* collected from Guilan wetlands.

Materials and methods

Nanoparticles

CuO-NPs produced by US Research Nanomaterials Company, were used. The size of used CuO nanoparticles was 40 nm. A 2000 mg/l stock solution was used for preparing appropriate concentrations (*Table 1* and *Fig. 1*).

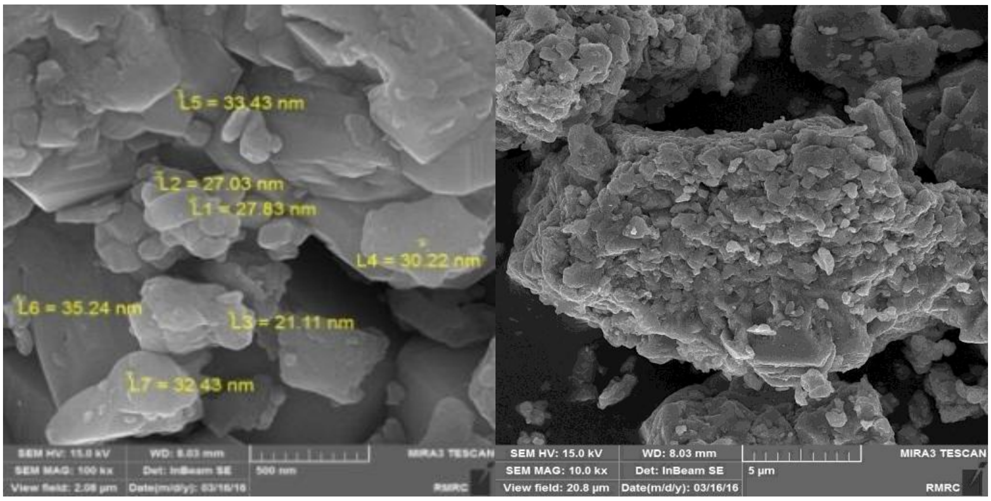

Figure 1. *SEM of CuO-NPs*

Release of Cu^{2+} From CuO-NPs

Stocks of nanoparticles at concentrations of 5, 10, 20 and 25 ppm were prepared with distilled water and the particles dispersed by sonication (Misonix Sonicator 3000, Iran) for 60 minutes. The pH was adjusted to 8.5 using NaOH. After 24 hours, 10 mL of the shaken up solution was taken from each flask, centrifuged 20 minutes at 4500 rpm and filtered through a 150 nm filter membrane. The content of Cu^{2+} was measured by atomic absorption flame spectrometer (Varian Spectra AA 220FS Varian Spectra Co. Australia).

Isolation of Anabaena sp. and preparation of culture medium

Cyanobacteria *Anabaena sp.* were collected from Guilan wetlands and isolated by repeated plating on solid Zander culture medium (Miller, et al., 1978). The pH of the culture medium was adjusted to 6.8, and the culture temperature was maintained at 24 ± 2 ˚C with aphoto period of 12 hours light/12 hours darkness. Light intensity was 60 μmol photon $m^{-2}S^{-1}$. Culture medium was sterilized by autoclaving at 121°C for 15 min and then refrigerated at 6°C.

Preparation of main treatments

The main stock of nanoparticles was prepared by 60 minutes ultrasonic treatment. Six treatments and one control with three replicates for each treatment and control were

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_20452059

prepared. The concentrations of nanoparticles used in the experiments were 0, 5, 10, 15, 20 and 25 mg/l. 4×10^4 cells from the main stock of *Anabaena sp.* were added to 40 ml of the treatments by dilution of primary algal stock. This step was performed under completely sterile conditions. The test tubes were then stored at 24±2°C which was adjusted by a thermostat. All samples were maintained at constant light periodic condition (12 hours darkness and 12 hours light) for the 72 hours of the experiment.

Determination of growth rates in cyanobacteria

Growth inhibitory effects were studied according to the OECD201 method (Handy et al., 2012). At 24, 48 and 72 hours after the start of the experiment, aliquots of the solution were removed from the test tubes using Pasteur pipettes and the cells present were counted in a Neubauer chamber under an optical microscope. After counting and recording the data, the average number of cells in the top and bottom squares was calculated and then the number of cells was calculated using the following formula:

$$\text{Cell density per ml} = \text{average cells counted in the large square} \times 10^4 \times \text{dilution factor}$$

In each experiment, percent inhibition values were calculated using spectrophotometric data compared with the growth in control systems. EC values were calculated using linear regression analysis of transformed chemical concentration as natural logarithm data versus percent inhibition.

Experimental design and stress application

The EC_{30}doses of single and combined salt and CuO-NPs treatments were determined using the plate colony count method (Rai and Raizada., 1985). A 0.052 M solution of NaCl was used for salt treatment. In addition, 12.58 mg/L of CuO-NPs was used. For the NaCl+CuO-NPs study, the two doses were applied simultaneously. Biochemical evaluations were determined similarly 72 h after treatment. All experiments were done in triplicate.

Antioxidant assays

Assay for total phenolics

Measurement of total phenol was performed by method of Gao et al. (2000), using Folin- Ciocalteu reagent and a standard of gallic acid. For this purpose, 100 µl of extract (2 mg/ ml) was poured into a glass tube. Then, 200 µl Folin solvent and 2 ml of distilled water were added to the extract. 1 ml of sodium carbonate (21%) was added after 9 minutes to the glass tube in darkness. Finally, the samples were stored at room temperature in the dark for an hour. Blanks were prepared with 100 ml of solvent, instead of the extract. Absorptions were read at 765 nm. The total phenolic content was determined as gallic acid equivalents (mg GAE/g extract).

Assay for total flavonoids

Total flavonoid content was determined using a spectrophotometer according to Arvouet-Grand *et al*. (1994). 1 ml of extract solution with 2 mg/ml concentration was mixed with 1 ml of 2% aluminum trichloride ($AlCl_3$) methanolic solution. Absorbance of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_20452059

the reaction mixtures were measured at 415 nm against a blank after 10 min. Quercetin (QE) was employed as a standard reference and the total flavonoids content of the extracts was expressed as µg quercetin equivalents per gram of extract (µg QE/g extract).

Extraction and measurement of proline

Proline content in the samples was measured using the method of Bates et al. (1973). For this purpose, 1 g fresh biomass of Cyanobacteria was harvested and their cell walls were broken using 4 ml of 3% sulfosalicylic acid and sonication for 10 minutes (5 pulse seconds and 5 seconds rest). The resulting solution was centrifuged for 20 minutes at a speed of 13,000 rpm and immediately transferred to an ice bath. Finally, 4 ml of toluene was added to the reaction solution and absorbance was measured at 520 nm. Proline content in micrograms per gram fresh weight was calculated.

Total soluble protein

The measurement of total protein was conducted using 2 mg/ml extracts and Coomassie Brilliant Blue G-250 staining solution - in 95% ethanol and 85% ortho phosphoric acid (Bradford, 1976) using bovine serum albumin as a standard.

Lipid peroxidation content assay

Lipid peroxidation was measured in terms of the total content of 2-thiobarbituric acid (TBA)-reactive substances and expressed as equivalent of MDA (malondialdehyde), extinction coefficient 155 mM^{-1}, using the method of Heath and Packer (1968).

Estimation of enzymatic antioxidants

Measuring the activity of catalase (CAT)

The method of Aebi (1984) was used for investigation of catalase activities. For this purpose, 2.5 ml of 0.05 M phosphate buffer was mixed with 0.2 ml of 3% hydrogen peroxide and 0.2 ml enzyme extract. Absorbance was read at 240 nm for 2 minutes. The enzymatic activity of the enzyme was reported as units/mg of protein.

Measuring the activity of ascorbate peroxidase (APX)

APX activity was determined at an absorbance of 290 nm (extinction coefficient 2.8 mM^{-1} cm^{-1}) for 1 min in 1 ml reaction mixture containing 50 mM potassium phosphate buffer (pH 7.0), 0.5 mM ascorbic acid, 0.1 mM H_2O_2, and 200 µl of enzyme extract (Nakano and Asada., 1981)

Measuring the activity of polyphenol oxidase (PPO)

Activity of polyphenol oxidase was assayed according to the method of Grigori (1993). 3 ml reaction solutions containing 2.5 ml phosphate buffer 50 mM (pH =7.2), 0.2 ml Pyrogallol 0.02 M and 300 Micro liters of enzyme extract were used. Changes in absorption were read at 430 nm for 2 minutes. The enzyme activity was calculated based on units of enzyme in 1 gram of fresh weight with extinction coefficient of 0.001 mM^{-1}/cm^{-1}.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_20452059

Measuring the activity of Guaiacol peroxidase (POD)

Kinetic activity of Guaiacol peroxidase was determined according to Kalir et al. (1984). First, 1 ml of the reaction solution containing 475 µl Guaiacol 45 mM, 475 µl hydrogen peroxide 100 mM and 50 µl enzyme supernatant was prepared. Changes in absorption due to Guaiacol oxidation were read by spectrophotometer at 470 nm for 2 minutes. An extinction coefficient of 26.6 mM^{-1}/cm^{-1} was used in the calculation of the enzyme activity. Peroxidase enzyme activity was calculated in Unit/gr FW. Each enzymatic unit is the amount of enzyme which increases 0.01% of the absorption at 470 nm per minute.

Electronic images

Scanning electron microscopy (SE-SEM, MIRA3 TESCAN) was used to investigate the effects of nanoparticles on the shape and size of cells in microscopic tissues of *Anabaena sp.* and to image the surfaces. Imaging of the surfaces of control and NP-treated cells was performed on cells exposed to the 10.93 mg/L NP concentration, which had affected 30% of the cells (EC_{30} = 10.93 mg/L).

Statistical analysis

Each treatment was replicated three times; the results were reported as the average of three parallel determinations of the mixture of three replicated samples. All statistical analyses were carried out using SPSS 16.0. One Way ANOVA with Duncan's test was used to determine significant changes in the results ($p < 0.05$).

Results

Release of Cu^{2+}

Suspensions of 0, 5, 10, 20 and 25 mg/l Cu^{2+} nanoparticles caused the release of 0, 0.017, 0.116, 0.249 and 0.310 mg/l of Cu^{2+} respectively, as assayed by atomic absorption flame spectrometry. After 24 hours, less than 0.31 mg/l Cu^{2+} was detected in our experiments (*Fig. 2*).

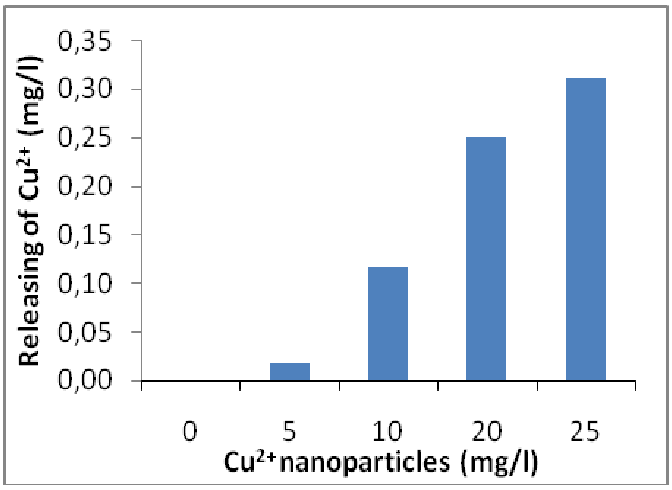

Figure 2. *Cu^{2+} release from N- CuO*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_20452059

Effects on growth rates

Anabaena growth in the presence of various concentrations of copper nanoparticles and salt is shown in *Figure 3*. The results indicate that cyanobacterial growth decreased by increasing the concentration of salt particles as compared with the control. The highest reduction occurred at 0.32 M NaCl and 25 mg/l CuO-NPs (*Fig. 3*). This was visually apparent, as seen by yellowing and fragmentation of filaments.

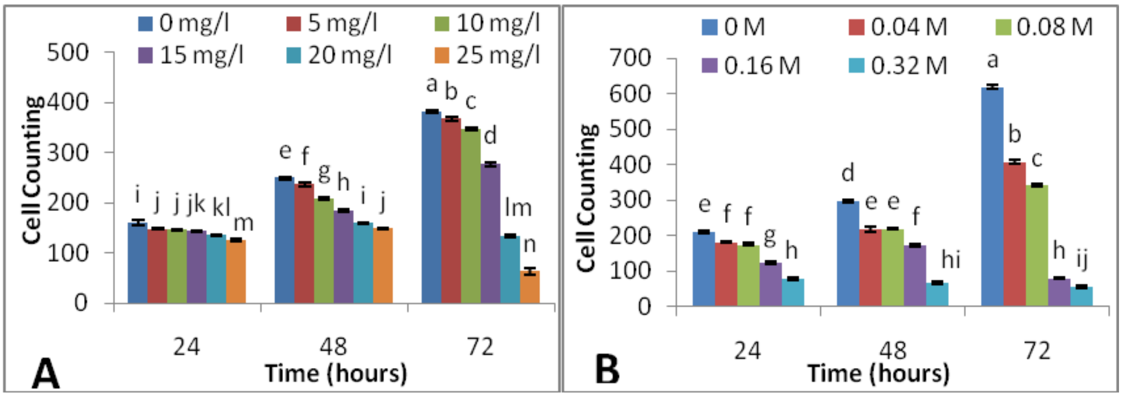

Figure 3. *Growth rate of Anabaena sp. after exposure to different concentrations of CuO-NPs (A) and NaCl (B).The data represents the average of three replicates ± standard error (SE). Different letters indicate significant differences among treatments according to Duncan's test with p<0.05.*

The results of 72-hour toxicity tests, the 24, 48 and 72-hour levels of EC_{10}, EC_{30}, EC_{50} and EC_{90} for CuO-NPs and NaCl toxicity are summarized in *Tables 2* and *3*. The range of EC_{30} values varied from 177.82 mg L^{-1} (24 h) to 12.58 mg L^{-1} (72 h) for CuO-NPs tests and from 0.114 M (24 h) to 0.052 M (72 h) for NaCl.

The effect on malondialdehyde

Lipid peroxidation was assayed by measuring malondialdehyde (Zhanga et al., 2013). Changes of malondialdehyde in cyanobacteria *Anabaena sp.* under stress from copper nanoparticles, salinity and both stresses at the same time is shown in *Table 4*. Malondialdehyde content significantly increased under CuO-NPs and CuO-NPs+NaCl compared to control.

Proline content

Proline content in treatments with NaCl and NaCl+CuO-NPs showed no significant changes. However, in the CuO-NPs treatment, proline content increased 64.1 % at the 10.93 mg/l level of CuO-NPs (*Table 4*).

Total phenols and total flavonoids

Phenolic content did not differ significantly between the three types of treatment compared and with the control group. Flavonoid content significantly increased 63.1% in CuO treatment compared to the control, while there was no significant difference between control, NaCl and NaCl+CuO treatments.

The effect on enzymatic antioxidants

In this study, the enzyme activity of POD in treatment with CuO-NPs and NaCl was found to be significantly increased. In contrast, polyphenol oxidase (PPO), another enzyme that is involved in neutralizing ROS compounds and assayed in this study, was significantly reduced in all treatments compared to control. CAT activity showed a different behavior, with a significant increase compared to control (~600 %, $p < 0.05$) in treatment with NaCl+CuO as well as (~400 %, $p < 0.05$) in treatment with CuO, while it remained unchanged in NaCl treatments; and finally, the other peroxide scavenging enzyme, APX, was also found to be induced under CuO-NPs stress (*Table 5*).

Electron microscopy

CuO-NPs attached to the surface of the cyanobacterial cells in direct contact with them is demonstrated clearly by SEM images in *Figure 4*. Generally, electron microscopic images showed that the nanoparticles bound to each other and, more relevantly, to the surface of the cyanobacterial cells, altering the appearance of cells through disruption of direct physical interactions between the cells and increasing the number of lysed cells (*Fig. 4*, *A-E*).

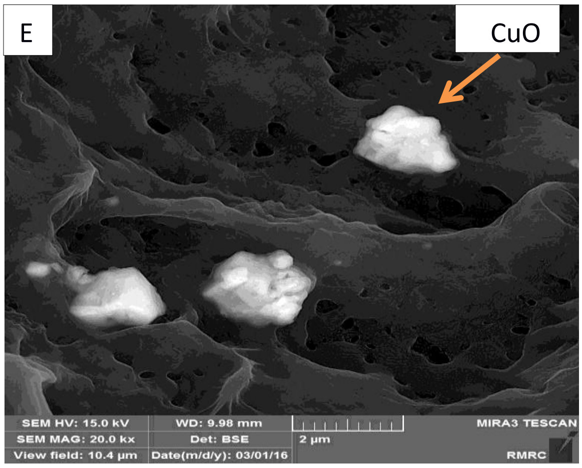

Figure 4. *SEM images of Anabaena sp. after 72 hours exposure to CuO-NPs at concentration of 10.93mg/l. Figures of A and C show control samples and figures B, D and E show Anabaena cells which treated with CuO-NPs.*

Discussion

As illustrated in *Figure 2*, small amounts of Cu^{2+}were released. This can be attributed to the aggregation of CuO-NPs and the slightly alkaline pH environment of the suspension (Wang et al., 2013). Cells cannot exclude Cu^{2+} and accumulate it in high quantity. Cu^{2+} becomes powerfully toxic for phytoplankton communities at concentrations between 0.1 and 1.0 mg/l (Deniz et al., 2011). The release of Cu^{2+} which is seen in our experiment is in this range too. Although algal cells are able to encase and detoxify Cu^{2+} but this can occur in restricted ranges (Toncheva et al., 2006). The decrease in the rate of cell division caused by metals has been primarily attributed to their binding to sulfhydryl groups which are important for regulating plant cell division (Visviki and Rachlin., 1991). Furthermore, The difference between effective concentrations ($EC_{10,30,50}$) in two treatments indicated that the degree of nanoparticle toxicity is also likely to depend on their nano structures and high surface to mass ratio as well as the nature of their constitutive element (Hernández Battez et al., 2010).This varies between algal species (Pendashte et al., 2013).The results of Shi (2011) have also indicated that CuO-NPs toxicity is three to four times higher than that of ionic Cu, because of the larger uptake of NPs-released Cu. Therefore, as it is shown in *Figure 2*, cell counting decreased during CuO-NPs treatment, compared to NaCl treatment.

As is shown in *Table 4*, percentages of proteins decreased in treated samples relative to control samples meaningfully. Rahman et al. (2011) observed similar findings in cyanobacteria under metal stress; Cu^{2+} treatment also resulted in reduction of protein content extensively. This decline may be due to production of ROS, which is known to damage protein, and therefore disturbs the cellular homeostasis. Similar observations were made, also, in *A. doliolum* exposed to cadmium and UV-B stressed (Bhargava et al., 2007). In contrast, adaptation to salt stress in cyanobacteria is generally accomplished by excretion of inorganic ions from the cells to balance osmotic potential; cells can also prevent denaturation of macromolecules via accumulation of some osmolytes, such as sucrose, trehalose, glucosylglycerol, glycine betaine, proline and/or glutamate (Allakhverdiev et al., 2005).

Lipid peroxidation is linked to the production of O_2^-. The presence of high amounts of transitional metals such as Cu (II) favors the enhanced generation of OH° from O_2^-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_20452059

through the Fenton reaction (Luna et al., 1994). Thus, the increased levels of MDA suggest that Cu (II) ions stimulated free radical formation in *Anabaena sp*.

Increases in proline concentration under heavy metal and salt stresses have been reported in some higher plants and in the cyanobacteria *Spirulina*, *Anabaena* and *Cylindrospermum* (Rahnama and Ebrahimzadeh., 2004; Chris et al., 2006; Choudhary et al., 2007). It seems that an adaptive mechanism via increase in proline is activated for neutralization of accumulated CuO-NPs and the acidity. Proline's chelating ability to bind metal ions can also be a defense mechanism for survival (Deniz et al., 2011).

It has been recently shown that accumulation of secondary metabolites, such as phenylpropanoids, including flavonoids, which has scarcely been reported in cyanobacteria, could be one of the strategies for cyanobacterial organisms to protect against cellular damage (Singh et al., 2014). Flavonoids, phenolic acids, and tannins, as well as some derivatives of flavonoids, are also compounds which have many different biological activities including antioxidant activity under stress conditions (Agati et al., 2011), in addition to some medicinal activities (Fresco et al., 2006). Although only scarce reports are available on total phenols and total flavonoid content under salt and nano particle stress tolerance responses in cyanobacteria, positive correlations with the accumulation of polyphenolics, enhanced antioxidant activity and tolerance to stresses have been reported in plant species (Korkina, 2007). As a result, there is no additive response of non-enzymatic antioxidant factors in NaCl+CuO-NPs combination treatment compared to their responses to single stresses. This may be due to their antagonistic effects (Rai et al., 2013).

During oxidative stress, POD is a very important enzyme able to remove the dangerous radical products of superoxide and hydrogen peroxide (Beier et al., 1991). The greater activity of POD in treated compared to control plants can be attributed to stress caused by the treatments (Cosio and Dunand, 2010). These results suggest that NaCl and CuO-NPs individually as well as NaCl+CuO-NPs can be very important stressors impacting plant physiology. Reduction of PPO in both NaCl and CuO-NPs-treated cells was more than other treatments. In our study, CAT activity significantly increased compared to control in all treatments of CuO-NPs. Free Cu^{2+} can catalyze the formation of highly toxic ROS such as hydroxyl radicals ($OH^{\bullet}$) from superoxide anions ($O2^{\bullet-}$) or hydrogen peroxide (H_2O_2) (Melegaria et al., 2013). Therefore, increase in CAT activity of treated samples compared to control very probably is a response to substantial ROS production. APX induction may be attributed to the *apx* operon induction by H_2O_2 production (Vranova et al., 2002). Therefore, it seems that H_2O_2 can be detoxified by a combined effort of POD, CAT and APX in *Anabaena sp*. That enhanced levels of most antioxidant enzymes, CAT, POD and APX, were observed for *Anabaena sp.* in this study indicates the protective role of these enzymes against copper-induced oxidative stress (*Table 5*). Finally, it can be noted that, except for CAT, which shows more activity in NaCl+CuO-NPs treatments compared to NaCl and CuO-NPs treatments, there were no additive activities in other enzymatic antioxidants.

CuO-NPs often increased cell aggregation by forming bridges between the cells in the areas where the nanoparticles had accumulated. The Cuo-NPs attached to the surface of the cyanobacterial cells and the direct contact is demonstrated clearly by the SEM images in *Figure 4*. Their external surfaces had begun to fracture compared with the surfaces of cells that were not in contact with these particles. The structure of the cell wall was probably affected by the metal ions (*Fig. 4E*). Similarly, others have found cellular ultrastructural changes in *Microcystis aeruginosa* which were exposed to Ag-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_20452059

NPs (1 mg l^{-1}) (Duong et al., 2016). After 48 h exposure with Ag-NPs the structure of *Microcystis* was changed; the cells were shrunken and distorted. Other studies on the impact of nanoparticles on other species have yielded similar results (Ayatallahzadeh Shirazi et al., 2015).

Conclusion

The outcomes of this study suggest that single stresses of NaCl and CuO-NPs can have inhibitory effects on *Anabeana sp.* in the used ranges, inducing severe damages in high concentrations. However, stress induced by these factors in combination did not result in elevated inhibitory effects, more than those observed in single stresses. This may be related to interactions between released ions from NaCl and CuO-NPs.

(Received 8th Aug 2017; accepted 27th Oct 2017)

Abstract. The effects of elemental sulphur and farmyard manure on agronomic biofortification within the parameters of N, P, S and N:S ratio were evaluated in green bean (*Phaselous vulgaris* L.). Sulphur 0 (S_0), 50 (S_1), 100 (S_2), 150 (S_3), 200 (S_4), 400 (S_5) mg kg^{-1} and farmyard manure 0 (FYM_0), 3 (FYM_1) tonnes da^{-1} were applied to a calcareous sandy loam soil with low organic matter and sulphur deficient. Three weeks after the applications, bean seeds were sown in pot soils and after eight weeks of growing period the shoots were harvested. The soil pH was decreased while EC was increased by the applications of S and FYM. The P concentration of shoot was increased by S with FYM. While the dry weight and S concentration of shoot were increased, N concentration was slightly decreased by S, alone. The N:S ratio decreased from 23.76 in S_0FYM_0 to 15.93 in S_5FYM_1. All results indicate that sulphur applications in S_1 and S_2 levels with farmyard manure can be sufficient for growing bean in the soil.
Keywords: *malnutrition, chemical fertilizer, organic manure, nitrogen, phosphorus*

Introduction

Two thirds of the world population faces with one or more essential mineral deficiencies in their nutrition. Solutions to this problem are being investigated by means of dietary diversification, mineral adding, food supplements or increasing bioavailability and concentrations of mineral elements during crop production. Especially there have been recent studies on plants which have an essential importance in human nutrition with agronomic and genetic biofortification. Agronomic biofortification tries to ensure the optimization of mineral fertilizer applications and improving of mineral element mobility and solubility in soil. The optimization of chemical fertilizer and organic manure applications or the applications of essential elements with enriched fertilizer (especially NPK fertilizers) throughout soil, leaf or seed during cultivation should not only provide a quick solution in human and animal nutrition but also will be a complementary approach for ongoing plant breeding programme.

Sulphur is one of the essential elements in plant growth. Plants need sulphur for protein synthesis, chlorophyll, oil and vitamin formation. Sulphur deficiency has a negative effect on both yield and quality of crops which are grown for human and animal consumption (Tiwari et al., 1997). The specific aim of most biofortification studies is to reduce mineral, vitamin and protein deficiencies in edible parts of plants. Sulphur takes role in synthesis of some compounds such as cysteine, cystine and methionine for protein formation in plants. Low sulphur content in proteins is a nutritionally adverse situation and the methionine which is the main source of protein

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_20612069

and can be synthesized in the presence of sulphur is a basic amino acid for human nutrition.

Sulphate absorbed by the roots is the most important source of sulphur. Despite the sulphur's distribution on all parts of soil profile, it has at its highest concentration on surface soil which is rich in organic matter. Sandy or low organic content soils are the ones which are encountered with sulphur deficiency. On the situations of high efficiency on crop yield, especially on sandy soils and soils that are poor in organic matter which has abundant watering, the sulphur content is not in sufficient quantity for the needs of plants (Anonymous, 1982). The sulphur deficiency in plants can also occur on coarse textured soils having a high pH and when there is insufficient moisture on their root zone (Tiwari, 1995). And also the sulphur deficiency usually occurs on cultivation areas where chemical fertilizers are used and of the plants that are in highly need of sulphur due to their high yield capacity. Therefore, in addition to nutrients such as N, P_2O_5 and K_2O, S which is also named as the fourth basic macro nutrient should also be considered while doing fertilization programmes.

Bean is not only a product of high nutritional value, but also is an important vegetable protein source for humans. It has been widely consumed in Turkey and in Asian, African, European, North, South and Central American countries. For this reason, it is essential that it takes an important role among plants which are to be studied for increase yield and nutritive value. In this study, the effect of sulphur and farmyard manure applications on calcareous sandy loam soil having a low-sulphur and organic matter content for agronomic biofortification in bean is being examined using parameters of N, P, S and N:S.

Material and methods

Experimental setup

Soil was air dried and passed through a 4 mm sieve. A total of 9 kg of sieved soil was placed in pots with holes at the bottom. Sulphur (S_0:0, S_1:50, S_2:100, S_3:150, S_4:200, S_5:400 mg kg^{-1}) without farmyard manure (FYM_0: 0 tonnes da^{-1}) and with farmyard manure (FYM_1: 3 tonnes da^{-1}) was applied to soil according to completely randomized design factorial with 4 replicates. At the time of the application materials were mixed to soil, soil samples were taken at 1st sampling period. Then, basal fertilization (as 8 kg N da^{-1}, 8 kg P_2O_5 da^{-1} and 8 kg K_2O da^{-1}) using 15.15.15 fertilizer was made to each pot soil. Each pot was equally watered and incubated for 3 weeks. The green bean 'Öz Ayşe' was used as an experimental plant. At the end of the 3 weeks, 2nd period soil samples were taken and four green bean seeds were sown in each pot soil. After the seeds germination, one bean plant was left in per pot and the plants were grown for 8 weeks. During the vegetation period, N 8.5 kg da^{-1} (NH_4NO_3, 33% N), P_2O_5 3.7 kg da^{-1} (MAP), K_2O 10 kg da^{-1} (KNO_3), MgO 0.62 kg da^{-1} ($MgNO_3$) and 1.73 kg microelement fertilizer da^{-1} (Hortrilon, 5% Fe, 2.5% Mn, 0.5% Zn, 2.5% Cu) were applied to each pot as fertilizer solution. At the end of the experiment, the shoots were harvested and 3rd period soil samples were taken from each pot.

Plant analysis

The shoots were washed with deionized water and then dried 65 $^{\circ}$C for 72 h to determine dry weight. The dried shoots were ground in a stainless steel mill which

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_20612069

enabled them to be passed through a 20 mesh screen. The samples of 0.5 g each were digested with 10 mL HNO_3 and $HClO_4$ (4:1) acid mixture on a hot plate and filtered and then, diluted to 100 mL using distilled water. Total S was conducted by the turbidimetric method with $BaCl_2{\cdot}2H_2O$ and the readings were taken using a spectrophotometer at 430 nm (Kacar and Inal, 2008). Total P was measured by a modified colorimetric molybdo-vanado-phosphate method using a spectrophotometer at 430 nm (Kacar and Inal, 2008). Total N was determined by a modified Kjeldahl procedure (Kacar and Inal, 2008).

Soil analysis

The soil samples were air-dried and passed through a 2 mm sieve. The pH was measured in H_2O (1:2.5 soil:deionized water) and the electrical conductivity (EC) value was determined directly on the saturation paste. The soil particle size analysis was done by using the hydrometer method (Bouyoucos, 1955) and the $CaCO_3$ content was determined by using a Scheibler calcimeter. Organic matter was determined by using modified Walkley-Black procedure (Black, 1965). The total nitrogen was done by using modified Kjeldahl procedure (Kacar, 2009). Available P was extracted by $NaHCO_3$ and determined by a molybdate colorimetric method (Olsen and Sommers, 1982). Soil samples were extracted for SO_4-S by using 500 mg kg^{-1} P as KH_2PO_4 which contents of Fox et al. (1964). Analyses were conducted by the turbidimetric method with $BaCl_2{\cdot}2H_2O$ and the readings were taken using a spectrophotometer at 430 nm (Kacar, 2009). Some of the physical and chemical properties of experiment soil were given in *Table 1*.

Table 1. *Physical and chemical properties of soil used*

Parameter	Soil
Sand (%)	63.52
Clay (%)	18.48
Silt (%)	18
Texture	Sandy loam
pH	7.80
$CaCO_3$ (%)	18.92
EC (dS m^{-1})	2.07
Organic matter (%)	2.27
Total N (%)	0.049
Available-P (mg kg^{-1})	34.57
Extractable-SO_4-S (mg kg^{-1})	2.40

Statistical analysis

The data were analyzed by standard ANOVA procedures and their significances were always based on the $P<0.05$ level using the LSD tests.

Results and discussion

Effects of sulphur and farmyard manure on soil pH and EC

In the 1st soil sampling period, the farmyard manure caused an important but little increase of 0.03 units on soil pH. In the 2nd and 3rd soil sampling periods, the effects of interactions of sulphur and farmyard manure on soil pH were found significant. In the 2nd sampling period, the highest decrease on soil pH was respectively obtained as 7.65 and 7.64 in applications of S_5FYM_0 ve S_5FYM_1. When the sulphur applications whether with or without farmyard manure compared, the applications of S_0FYM_0 and S_0FYM_1, S_2FYM_0 and S_2FYM_1, S_4FYM_0 and S_4FYM_1 differed from each other and in these applications, soil pH was determined to be a little bit lower when sulphur is applied with farmyard manure. And in the 3rd soil sampling periods, the highest decrease on soil pH was respectively obtained as 7.70 and 7.76 in applications of S_5FYM_0 and S_5FYM_1. When the sulphur applications with or without farmyard manure compared, S_2FYM_0 and S_2FYM_1, S_5FYM_0 and S_5FYM_1 differed from each other and in these applications, a little increase in soil pH was obtained when sulphur is applied with farmyard manure. In an overall evaluation, especially in the 2nd sampling period (after three weeks from applications) depending on irrigation, the pH of control soil (S_0FYM_0) rose from 7.81 up to 8.01, whereas no increase in sulphur with farmyard manure applications was observed. Almost similar effects of the applications were determined in the 3rd sampling period (*Table 2*). Kaplan and Orman (1998) reported that the sulphur applied to high calcareous soil decreased pH in units of 0.07-0.35 and the pH started to rise again depending on time.

In the 1st soil sampling period, the effects of sulphur on soil EC was not significant whereas the farmyard manure effect was important. While the soil EC was highly affected from the sulphur and farmyard manure in the 2nd and 3rd sampling periods, the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_20612069

interaction between these two applications was not significant in each three sampling periods. The farmyard manure caused an increase about 0.29, 0.37 and 0.29 units in soil EC, respectively in the 1st, 2nd and 3rd sampling periods. The sulphur yet caused an increase on soil EC only in the 2nd and 3rd sampling periods and the highest increase of EC was observed in S_4 and S_5 (*Table 3*). The sulphur applications are reported to cause an increase in soil salinity in several studies (Modaish et al., 1989; Kaplan and Orman, 1998; Orman and Kaplan, 2011; Orman and Ok, 2012). And also in this study, it has been indicated that especially the sulphur applications increases the soil salinity significantly. It is thought that this is because of the SO_4^{-2} having been formed in soil after the sulphur applications and also because of irrigation and fertilization during the growing period. Thus, a significantly positive correlation between EC values and SO_4^{-2}-S concentrations of greenhouse soils where tomato cultivation is made in West Mediterranean Region has been reported by Orman and Kaplan (2009).

Effects of sulphur and farmyard manure on bean plant

The effects of applications on total nitrogen, sulphur, and phosphorus concentrations, N:S ratio and dry weight in the shoots of bean were given in *Table 4*.

The sulphur alone is found important to have a significant effect on nitrogen concentration in shoots an especially in higher doses of 100 mg S kg^{-1}, there has been a reduction in nitrogen concentration. Schung (1990) specified that the increase of S content in plant tissues with suitable sulphur fertilization in vegetables had been effective in decrease of NO_3 content in tissues. It was reported that sulphur applied to soil has no significant effect on nitrogen concentration in tomato plant, but the N concentration is observed to be lower than the control (Orman and Kaplan, 2011). Gaines and Phatak (1982) reported that with the increase of the sulphur ratio applied to soybean grown in hydroponic culture, the N concentration decreased in a significant

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_20612069

rate. In our study, the decrease in nitrogen concentrations of bean shoots by the sulphur applications can either be related with sulphur and nitrogen relationships, or just arise due to the dilution effect of nitrogen in result of dry weight increase by sulphur.

The sulphur, farmyard manure and sulphur with farmyard manure interaction had a great impact on shoot phosphorus concentration. The shoot phosphorus concentration is determined as 0.28% in S_0FYM_0 whereas it is seen as 0.35% in S_5FYM_0. Having been evaluated with or without farmyard manure, the applications of S_0FYM_0 and S_0FYM_1, S_2FYM_0 and S_2FYM_1 differed from each other statistically and in these applications, applying sulphur with farmyard manure caused an increase in shoot phosphorus concentration. Also, it is thought that shoot phosphorus concentration increases due to the decrease in soil pH because of consequent sulphur applications. Brahim et al. (2017) indicated that the combined application of rock phosphate and elemental sulphur was the potential to improve the P nutrition of soybean.

The applications of sulphur alone significantly affected on shoot sulphur concentration. There has been an increase between 5.9% and 15.79% in shoot sulphur concentration according to the S_0. This impact is especially determined in 100 mg S kg^{-1} level. Even though the shoot sulphur concentration has an increase about 5.56% by farmyard manure application, this impact is not found important statistically. Tiecher et al. (2012) observed that the amount of S accumulated in the shoots of sunflower, bean, soybean and castor bean and the level of available S increased due to S fertilization.

Reuther and Robinson (1998) notified that bean plant in early stage has a sufficient S content of 0.16%-0.64% in shoots. The sulphur concentrations of shoots in our study range from 0.14% to 0.20%. According to the limit values, it is significantly output that

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_20612069

there has been an improvement in sulphur nutrition level of bean, especially as a result of sulphur applications.

The sulphur alone and sulphur with farmyard manure applications were significantly affected on total N: total S ratio of shoot. The N:S ratio in shoot is assigned as 23.76 in S_0FYM_0 and 18.72 in S_0FYM_1 and it showed statistically significant differences. The other applications of sulphur with or without farmyard manure were statistically included in the same group. The highest ratio of N:S was determined in S_0FYM_0 application and the lowest of that was in S_5FYM_1 application. The shoot N:S ratio showed a significant reduction especially as a result of sulphur alone applications. Barczak and Nowak (2015) reported that the potato plants fertilised with sulphur, in comparison with the control, N:S ratio was narrowed due to a higher increase in the content of sulphur rather than nitrogen in potato tubers.

Although it has been obtained that the effects of sulphur with farmyard manure has a great role on the shoots N:S ratio, it is thought that the determining factor in the decline of this ratio is the sulphur applications. Total N: Total S ratio of the leguminous for protein synthesis is reported to be 17 (Kacar and Katkat 2007). It is pointed out by Stewart and Porter (1969) that the sulphur deficiency may be limiting in protein formation in case of the total N:total S ratio's being over 16 and it is just a severe sulphur deficiency in case of the ratio's being over 20 or more. The soil SO_4^{-2}-S concentration below 10 mg kg^{-1} is considered to be deficient (Radish et al., 1995). According to this limit value, the extractable SO_4^{-2}-S (2.40 mg kg^{-1}) concentration of our experiment soil appears to be deficient. In this case, N:S ratio designated as 23.76 in S_0FYM_0 application is the indicator of the plant's facing with a deficiency in its sulphur nutrition and this will obviously cause negative effects in protein synthesis. However, by the increase of the sulphur applications, the imbalance of plant's N:S ratios disappeared and it seems to have a balance between nitrogen and sulphur elements which are highly important in protein synthesis. The uptake of sulphur, yield, quality and optimizing the N:S ratio in plants were improved by sulphur fertilization (Skwierawska et al., 2016). But also while trying to maintain this balance, the risk of sulphur's increasing soil salinity should be kept in mind and it should be taken into consideration while doing sulphur fertilization especially on saline soils. A greenhouse survey study in Antalya/Turkey, it appears that there are imbalance for N:S ratio, even if a sulphur deficiency is not determined in tomato leaves (Orman and Kaplan, 2009)

The effect of sulphur alone is found to be important on shoot dry weight. The dry weight was 22.28 g pot^{-1} in S_0 application whereas there became an increase about 17-22% by sulphur applications. The increase occurred was not due to the increase of sulphur level, the sulphur application doses statistically took place in the same group. Crusicol et al. (2006) indicated that sulphur fertilization has not considered by bean (*Phaseolus vulgaris* L.) growers. Whereas, the increase of grain yield can be limited by low levels of sulphur fertilization in common bean crops with high-input technology. Researchers reported that leaf S content, dry weight and grain yield of common bean is increased by sulphur fertilization. Kaplan and Orman (1998) reported an increase in dry weight of sorghum with sulphur applications.

Conclusion

The sulphur is an advisable material in order to decrease the soil pH on calcareous sandy loam and high pH soils and also to increase the uptake of the phosphorus element

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_20612069

by plants of which the solubility in soil is significantly depending on pH. But the risk of the sulphur's creating salinity in soil should be taken into consideration and this negative effect should be well managed especially on the agricultural lands under the risk of salinity. Also, Gulmezoglu et al. (2016) reported that salt application generally reduced the fresh and dry weights of green bean genotypes.

On the sulphur deficient soils, the sulphur or other sulphur fertilizers absolutely should be included on fertilization programmes to obtain sulphur for the plants that are in need of sulphur requirement such as bean. Because it has been determined that if the necessary sulphur applications are not done on such soils, a significant imbalance may emerge in N:S ratio of the plant and the balance may be damaged against sulphur. When considering not only nitrogen but also sulphur as well is effective in protein formation in plants, this situation might have negative repercussions on high protein content plant's protein synthesis and quality such as bean.

According to the data obtained from this study, the applications of sulphur in 50 mg kg^{-1} and 100 mg kg^{-1} levels to bean growing on a calcareous sandy loam soils which are deficient in organic matter and SO_4^{-2} are thought to be sufficient in terms of yield and quality. Consequently, the further studies are needed to optimize amount of sulphur addition for other soil types and plant species.

(Received 22nd Aug 2017; accepted 8th Nov 2017)

Abstract. The present study was conducted to investigate the effects of maturity stages on the chemical composition, in vitro gas and methane production, metabolic energy and organic matter digestibility for eleven *Astragalus* species widely encountered over the rangelands and intensely grazed by ruminants. *Astragalus* samples were collected from the rangelands at three different stages namely as before flowering, flowering and bear fruit stages. Dried samples were then subjected to various chemical analysis. Effects of *Astragalus* species and maturity stages on chemical composition, in vitro gas and methane production, metabolic energy and organic matter digestibility were found to be quite significant ($P < 0.001$). Acid detergent fiber (ADF) and neutral detergent fiber (NDF) ratios increased, while the crude protein, crude ash, crude oil, condensed tannin contents, gas and methane production levels decreased with the progress of maturity stage. It can be suggested that grazing was more favorable at before flowering or flowering stages of *Astragalus* species because of high crude protein and metabolic energy content of plant at these stages. Also, although all *Astragalus* species were considered as a quality feed source for ruminants, endemic *Astragalus oocephalus* and *Astragalus longifolius* species were prominent with their superior nutritive properties.
Keywords. *chemical composition; in vitro gas production; metabolic energy; digestibility; condensed tannin content; grazing*

Introduction

Astragalus with about 2000 species is a member of legumes family and commonly composed of herbaceous and small shrubs. They are used in animal feeds, medicines and pharmaceuticals, in erosion prevention, bee pastures, dye and textile industries (Gruenwald et al., 1998). *Astragalus* species are widespread in steppes with low precipitation levels and Alpines with low temperatures and commonly grazed by

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_20712080

ruminants. There is limited information about the nutritional properties and grazing periods of *Astragalus* species.

Harvest or grazing periods greatly influence nutritive values of feeds. Studies about harvest or grazing periods of these species are of great significant for yield and quality of feed and also for sustainable use of natural resources. Despite these kinds of investigations on several species, there are still a lot of different plant species to be researched (Kamalak and Canbolat, 2010; Kaplan et al., 2014a).

Chemical composition, metabolic energy and digestible nutrients are the significant quality indicators for animal feeds (Canbolat, 2012). For this purpose, in vitro gas production technique developed by Menke et al. (1979) is widely used in recent years to determine nutritional values of feeds under in vitro conditions since the technique is a fast, easy and cheap method (Kaplan et al., 2014b). The gas production technique is also used to determine the methane reduction potential of feeds affecting global warming (Lin et al., 2013). The present study was conducted to investigate the effects of maturity stages on chemical composition, in vitro gas and methane production of different *Astragalus* species.

Materials and methods

Plant materials

Eleven different *Astragalus* species widespread in Bingol province of Turkey and commonly grazed by ruminants were harvested from the rangelands and natural areas at three different maturity stages (before-flowering, full-flowering, fruit-set). *Astragalus gummifer* Labill, *Astragalus cinereus* Willd, *Astragalus compactus* Lam, *Astragalus lineatus* Lam. var. *longidens, Astragalus oocephalus* Boiss subsp. *stachyophorus, Astragalus amblolepis, Astragalus declinatus* Wild, *Astragalus lineatus* Lam. var. *lineatus, Astragalus longifolius* Lam., *Astragalus aureus* Willd and *Astragalus onobrychis* species were used as the plant materials of the study. From these species *Astragalus oocephalus* Boiss subsp. *stachyophorus* and *Astragalus longifolius* Lam. are endemic species.

Climate data

Climate data for Bingol province were received from the nearest meteorological station of Directorate of Meteorology. According the meteorological data of research area, the long-term (2000-2015) monthly average temperature is 12.3 °C, total precipitation is 917.8 mm and relative humidity is 56.6%. Average temperature, precipitation and relative humidity of the research period (August 2015-August 2016) were quite close to long-term averages (13.9 °C, 923.7 mm and 53.4%, respectively). Soil structure of the Bingol province is clay-loam and loamy (Ates and Turan, 2015).

Chemical analysis

The *Astragalus* species were harvested at before flowering, flowering and bear fruit stages. Samples were dried at 70 °C for 48 h, ground and sieved through 1 mm sieve. Crude ash content of samples was determined by ashing the samples at 550 °C for 8 h in an ash oven. Soxhlet extracting system was used to determine the crude oil content of the samples by ether extraction method (AOAC, 1990). Kjeldahl method was used to determine nitrogen (N) content of the *Astragalus* species and crude protein level was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_20712080

calculated by multiplying N content by 6.25 constant (AOAC, 1990). NDF (Van Soest and Wine, 1967) and ADF (Van Soest, 1963) analysis were performed by using ANKOM 200 Fiber Analyzer (ANKOM Technology Corp. Fairport, NY, USA). Condensed tannin content analysis of the samples was performed by using Butanol-HCl technique (Makkar et al., 1995).

The in vitro total gas and methane production

In vitro gas production technique developed by Menke et al. (1979) was used to determine in vitro gas and methane production of the samples. The rumen liquid was collected from three fistula installed hogget fed with a mixture 60% alfalfa and 40% barley. Liking blocks and clean water was supplied ad-libutum to the hogget. The rumen liquid was collected before feeding in the morning, filtrated through 6-layer cheesecloth to remove solid particles and mixed with twice as much synthetic saliva solution. Approximately 200 mg ground samples were placed in 100 ml glass syringes. The samples were weighed in triplicates. The sample syringes were then supplemented with 30 ml buffered rumen liquid. Three syringes including only buffered rumen liquid as control group and the syringes including samples and buffered rumen liquid were placed into a water bath set at 39 °C. The net gas production was calculated by subtracting gas production of control group from the gas production of sample group. Total gas production was determined as mL after incubation of *Astragalus* samples at 39 °C for 24 h. The methane ratio of the gas was obtained by using an Infrared methane analyzer (Sensor Europe GmbH, Erkrath, Germany) and the following equation (*Eq. 1*) was used to calculate methane production levels (Goel et al., 2008):

$$\text{Methane production}\ (\text{mL}) = \text{Total gas}\ (\text{mL}) \times \text{Methane ratio}\ (\%) \quad \text{(Eq. 1)}$$

Metabolic energy (ME) and organic matter digestibility (OMD)

Metabolic energy content of *Astragalus* samples was calculated in accordance with the following equation (*Eq. 2*) using some parameters related to 24 h gas production and chemical composition of samples (Menke and Steingass, 1988). Organic matter digestibility (%) of the samples was determined by using *Eq. 3* as suggested by Menke et al. (1979):

$$\text{ME}\ (\text{MJ kg}^{-1}\text{DM}) = 2.20 + 0.136\ \text{GP} + 0.057\ \text{CP} + 0.002859\ \text{CP}^2 \quad \text{(Eq. 2)}$$

$$\text{OMD}\ (\%) = 14.88 + 0.889\ \text{GP} + 0.45\ \text{CP} + 0.0651\ \text{CA} \quad \text{(Eq. 3)}$$

In these equations; DM: Dry matter, GP: Net gas production after 24 h (mL), CP: Crude protein ratio (%), CO: Crude oil ratio (%), CA: Crude ash ratio (%) and OMD: Organic matter digestibility (%).

Statistical analysis

The experimental design was completely randomized design with 3 replications. Variance and correlation analysis were performed by using Jump SAS (2009) statistical software. Tukey test was used to determine the difference between the means. As a complement of ANOVA procedure, Biplot Analysis was performed using nutritive

DOI: http://dx.doi.org/10.15666/aeer/1504_20712080

value and gas production parameters as variables and *Astragalus* species as classification criterion (Yan and Kang, 2003).

Results

Chemical composition

The effects of harvest time on nutritional characteristics of different *Astragalus* species were investigated in this study. Chemical composition of *Astragalus* samples is provided in *Table 1*. The effects of *Astragalus* species, harvest time and *Astragalus* x harvest time interaction on chemical composition were found to be highly significant ($P \leq 0.01$). ADF and NDF ratios increased and crude protein, crude ash, crude oil and condensed tannin contents decreased with the progress of harvest time. Crude protein ratios varied between 11.65-32.79%, ADF ratios between 16.22-48.54%, NDF ratios between 35.62-66.08%, crude oil contents between 0.40-3.43%, crude ash contents between 3.14-11.54% and condensed tannin contents between 0.32-1.00%.

Gas and methane production, metabolic energy and organic matter digestibility

Average gas production, methane production, metabolic energy and organic matter digestibility of *Astragalus* species harvested at different vegetation stages are provided in *Table 2*. The effects of *Astragalus* species, harvest times and *Astragalus* x harvest time interaction on gas and methane production, ME and OMD levels were found to be highly significant ($P \leq 0.01$). Gas and methane production, ME and OMD decreased with the progress of harvest time. Gas production values varied between 31.50-50.00 ml, methane productions between 3.31-6.54 ml, metabolic energy contents between 7.19-10.43 MJ kg^{-1} DM and organic matter digestibility levels between 50.47-69.52%.

Biplot analysis

Biplot analysis revealed that two principle components were able to explain 73.10% of total variation (41.80% by PC1 and 31.30% by PC2). As can be seen in *Figure 1*; crude ash, crude protein and condensed tannin parameters constituted one group; ME and OMD constituted one group and GP, methane and ADF constituted another group. Crude oil and NDF alone separately constituted different groups. *Astragalus longifolius* was prominent with ME and OMD, *Astragalus amblolepis* with NDF, *Astragalus oocephalus* with crude protein, *Astragalus compactus* with ADF and *Astragalus aureus* was prominent with methane production *(Table1, Table 2, Figure 1).*

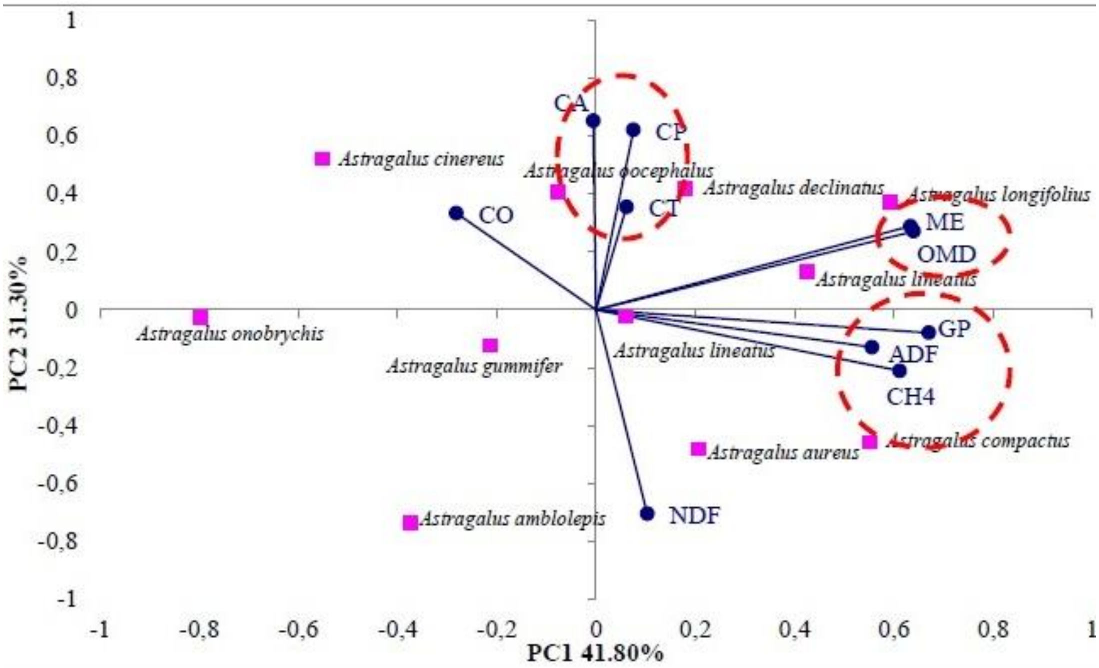

Figure 1. *The biplot for nutritive values of Astragalus species*

Discussion

Crude protein content is a significant indicator of feed quality (Assefa and Ledin, 2001). It was reported that differences in crude protein contents of different varieties can be resulted from genetics of the plants and such values can also vary depending on leaf, spike and stem ratios, ripening periods, fertilization, climate and soil conditions (Ball et al., 2011). Number of leaves and thus leaf/stalk ratios decrease with the progress of ripening. Ripening reduces number of leaves rich in crude protein and reduces crude protein ratios of the plants (Buxton, 1996). In present study, crude protein ratios of *Astragalus* species decrease with the progress of ripening and quite significant differences were observed among the species. The crude protein contents of the present study ranged within the values reported by Davis (1982) for 33 different *Astragalus* species. However, crude protein content (32.79%) of endemic *Astragalus oocephalus* at before flowering period was higher than those reported values.

The differences in stem and leaf ratios in plants result in differences also in crude protein contents, ADF and NDF ratios. ADF and NDF levels, which are the cell wall components, increased with the progress of ripening. It was reported for several plant

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_20712080

species that increased ADF and NDF ratios reduced crude protein, crude oil and carbohydrate levels of the plants with the progress of vegetation period (Canbolat, 2012; Kaplan et al., 2014a, 2014b).

It was reported that low condensed tannin levels (2-3%) had beneficial effects because they prevent extreme decomposition of proteins in rumen (Barry, 1987). Kumar and Singh (1984) reported that high condensed tannin levels had harmful effects because they decrease protein digestibility. In the current study, condensed tannin levels (0.32-1.00%) were lower than those specified ones and thus such levels had beneficial effects. Crude ash is the residual unburnt portion after ashing dry matter in an as oven (Genctan, 1998). Since it cannot be synthesized by animal organisms, they should be taken externally.

Gas production of *Astragalus* species were different because of the differences in crude protein, crude oil, ADF and NDF ratios resulted from differences in their stem and leaf ratios. The increased crude oil and crude protein levels caused an increase in the metabolic energy. In vitro gas productions through fermentation in feeds are directly related to the fermentable carbohydrate content. The differences in ME and OMD levels of *Astragalus* species were mainly resulted from differences in their gas production, crude protein, crude ash and crude oil contents as well as harvest period-induced reductions in these parameters. Decreased fermentable carbohydrate contents with the progress of ripening and differences in stem and leaf ratios also decreased in vitro gas production levels (Blummel and Orskov, 1993). The gas production and thus carbohydrate levels decrease with the progress of ripening.

The feeds are classified according to the methane content after fermentation as low anti-methanogenic (> 11% and ≤ 14%), medium anti-methanogenic (> 6% and < 11%) and high anti-methanogenic (> 0% and < 6%) (Lopez et al., 2010). Accordingly, *Astragalus* species of the present study were classified as high anti-methanogenic.

Conclusion

It was concluded based on present findings that nutritive values of *Astragalus* species were quite different from each other and the progress of growing stages affected the nutritive profile of *Astragalus* samples significantly. Just because of high protein and ME contents, it was recommended that *Astragalus* species should be grazed in before flowering or full flowering stages. Among 11 *Astragalus* species investigated in this study, the endemic *Astragalus oocephalus* and *Astragalus longifolius* were found to be prominent with their high crude protein content and ME levels and low ADF and NDF ratios. It was observed that *Astragalus* species had superior properties for the animals. Further research is recommended on nutritive values of different *Astragalus* species with new in vivo and in vitro studies and also on the effects of *Astragalus* species on animal health.

(Received 21st Jul 2017; accepted 27th Oct 2017)

Abstract. The Gezhouba Dam was the first and lowermost dam on the major stem of the Yangtze River. Up to now, the dam has been operating for more than 35 years. The time period was a fast economic development stage in the Yangtze basin. Therefore, the entire Yangtze aquatic ecosystem has been highly affected by various anthropogenic activities. Especially, the fish population and distribution in the Yangtze River have been largely altered. This study reviews the ecological effects of the Gezhouba Dam to the Yangtze aquatic biodiversity for the past 60 years based on literatures. It was concluded that the pre-assessment of the Gezhouba Dam on Yangtze fishes in 1970s was appropriate. Blocking the migration of migratory fishes, such as Chinese sturgeon *Acipenser sinensis*, and the four major Chinese carps, was a critical adverse effect. Currently, the Yangtze aquatic biodiversity is facing further problems not only the existence of the Gezhouba Dam but also anthropogenic activities. Effective and practical protected measures are recommended and should be conducted urgently to rescue the Yangtze aquatic biodiversity.
Keywords: *ecological impact assessment, anadromous fish, movement and migration, Gezhouba Dam, Yangtze River*

Introduction

The Yangtze River originates from the Qinghai-Tibet Plateau and connects to the west Pacific. It is the third largest river in the world with more than 6,300 km in total length and 180 km^2 basin area which corresponds approximately one fifth of China mainland size (Yu and Lu, 2005). It has 437 tributaries with larger than 1,000 km^2 of sub-basin area and 22 of them larger than 10,000 km^2. The total area of freshwater lakes is larger than 22,000 km^2. The annual run off is 960×10^9 m^3/s. Due to the huge size, the river holds high aquatic biodiversity including about 2,000 aquatic species, thereinto there are approximate 400 fish species (Yang et al., 2007). In the world, it is the only river which holds Acipenseriformes (Chinese sturgeon *Acipenser sinensis*, Yangtze (Dabry's) sturgeon *A. dabryanus*, and Chinese paddlefish *Psephurus gladius*) and Cetacea (Yangtze River dolphin *Lipotes vexillifer*, Finless porpoise *Neophocaena phoconoides*).

Due to high elevation variations and abundant runoff, the Yangtze River contains rich water energy. The theoretical reserve of hydraulic resources is 2.78×10^8 kW, and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_20812097

the annual power generation is 2.43×10^{13} kWh (Yang et al., 2007). No hydropower dam on the Yangtze main stem was built until late 1960s. In 1970, the Gezhouba Dam was begun to construct and it blocked the river stream in 1981. It was the first and up to now the lowermost dam in the Yangtze main stem. It should be mentioned that at that time, as the economic difficulties and thought that a fish passage might not have worked effectively, a fish passage was decided not to be built in the end after countrywide discussions and disputes (Chang et al., 1998).

For 35 years, the Gezhouba Dam has been operating and affecting Yangtze aquatic organisms in various aspects. It is speculated that the ecological effects of the dam should have already emerged. Therefore, it should be the right time to review all relevant studies on the first and lowermost dam on the Yangtze main stream. More precisely, a comprehensive review on ecological impacts on the Yangtze aquatic biodiversity on the basis of the existence of the Gezhouba Dam is needed. In this study, we review the ecological impacts of the Gezhouba Dam and the relevant Yangtze aquatic biodiversity for the past 60 years mainly based on literature studies. Furthermore, this study is to re-evaluate whether the original decisions of the Gezhouba Dam's effects on Yangtze aquatic organisms are appropriate, and to examine how the mitigated protection measures recommended were performed. In addition, the future conservation strategies and measures are proposed and discussed on the basis of the current status of Yangtze aquatic biodiversity and threatening factors.

The Yangtze aquatic biodiversity

In accordance with the first systematic investigation on Yangtze fishes conducted about 60 years ago, approximately 2,000 aquatic species have been reported in the Yangtze Basin (*Table 1*) (Yang et al., 2007). According to the China Red Book of Endangered Animals, the number of threatened fishes was 69 species (occupied 18.25% of the entire Chinese endangered fishes), amphibian was 69 species (47.59%), and reptile was 54 species (32.53%). All had the highest threatened ratio among the China inland water areas. In addition, 162 fish species are regarded as endemic species. Many of them are listed as important protected species both inside and outside China (*Table 2*).

The Gezhouba Dam and reservoir

The Gezhouba Dam was located about 1,678 river km from the Yangtze estuary (river km 0 was at the estuary, *Fig. 1*). The Gezhouba Dam was constructed from 1970 for 20 years, blocked in 1981, and completely finished in 1990 (Anonymous, 1993;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_20812097

CWRC, 2002). It was the largest dam since the P. R. China constructed in 1949. The dam was 2606.5 m in length, 53.8 m in height, and 70 m in elevation. The annual flow discharge at the dam was 14,300 m^3/s, and sediment content was 1.19 kg/m^3. The reservoir capacity was 1.58×10^{10} m^3, and adjustable capacity was 0.8×10^9 m^3. The total installed capacity of the power plant was 2,715 MW. The normal water level of the reservoir was 66 m. In flooded season, the length of backwater was approximately 110 km (to Badong, Hubei Province), and in dry season, the length can be up to 180 km (to Fengjie, Chongqing Municipality). Additionally, the design of the Gezhouba Dam helped in building the Three Gorges Dam, which is the biggest dam in the world, as an anti-regulated shipping cascaded dam in 1994.

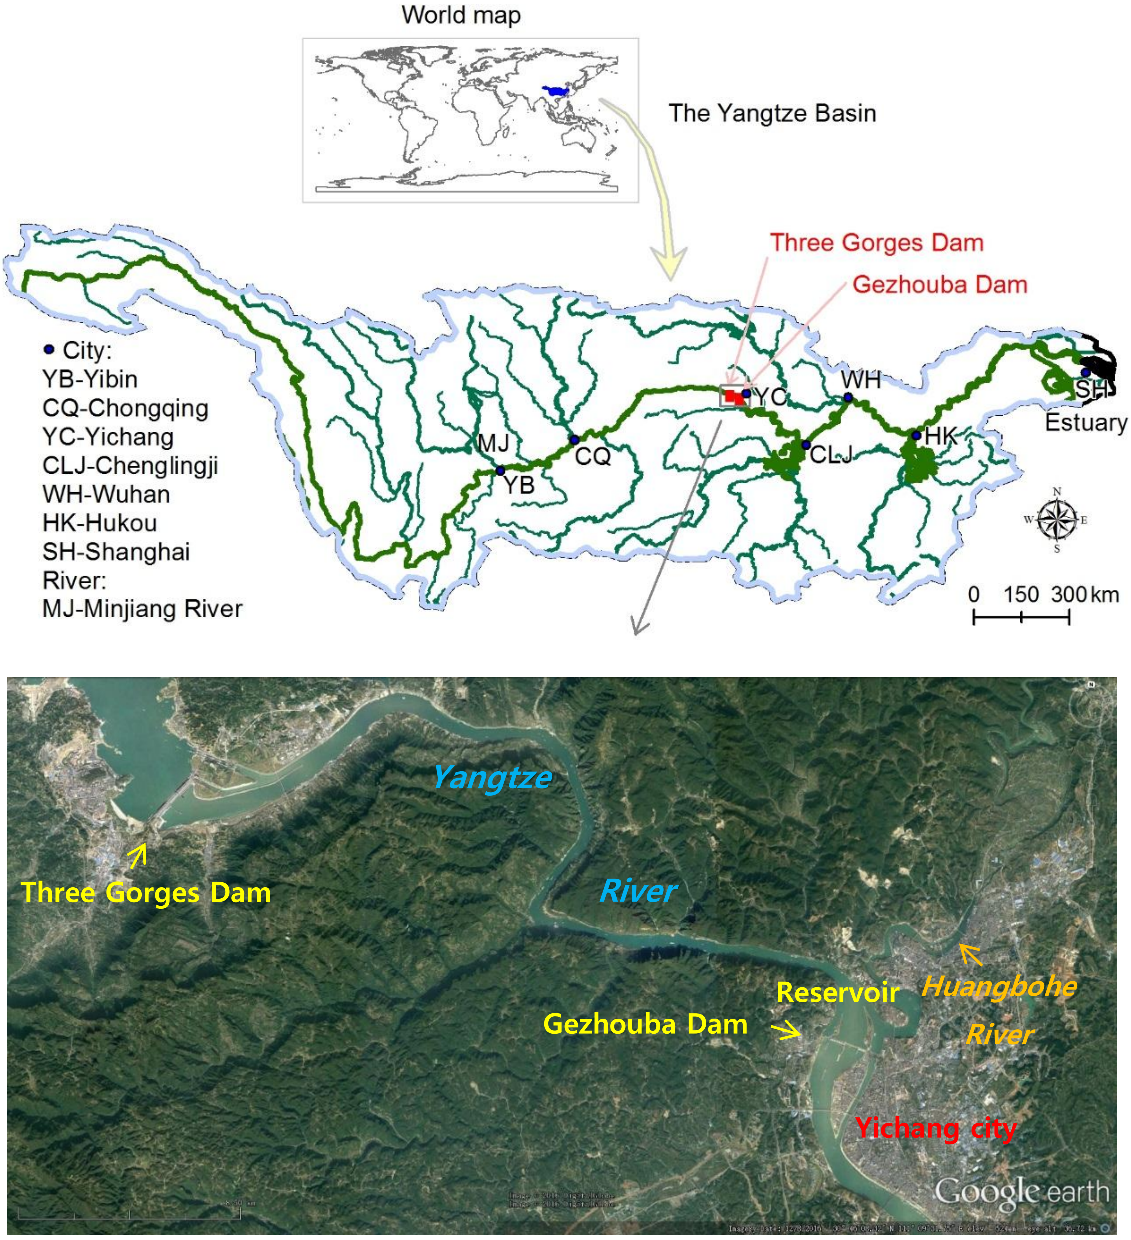

Figure 1. *The Gezhouba Dam and reservoir in the Yangtze River Basin*

Impact assessment before the dam construction

Before the dam was constructed, a series of special studies on fishes and fisheries in the Yangtze Basin had been conducted (FLIHHP, 1976; YARSG, 1988; Yi et al., 1988; Chen et al., 1997). The studies can be summarized into three categories: field surveys, laboratory studies, and theoretical studies. The field surveys included survey on spawning areas of the four major Chinese carps, ecological survey of Chinese sturgeon, and survey on the aquatic organisms in the upper Yangtze main stem. The laboratory studies included fishes, for example Chinese sturgeon, swimming ability for designing a fish passage, and artificial propagation of Chinese sturgeon. The theoretical studies included reviews on fish passages all over the world and plans on fish rescue measures.

These studies concluded that Yichang reach had more than 100 fish species, which was equivalent to approximately one third of the entire Yangtze River fish species. As the Gezhouba Dam was a low-head runoff hydropower station, it might not have changed the hydrological regime and river fluvial habitat significantly. However, blocking the migration route of migratory fishes was the major adverse effect. On the issue on building a fish passage for free migration, national-wide and long-term disputes were aroused. This dispute finally terminated in 1982, when the spawning activity of Chinese sturgeon was confirmed below the Gezhouba Dam (Yu et al., 1985; Chang et al., 1998). Before the dam was closed in 1981, the major conclusions and recommended protection measures on migratory fishes were as follows:

1) The Chinese sturgeon: a fish passage might not have functioned properly for this species, because the species is huge (250−400 cm in length). Even though the species could swim up to the upstream by passing through the passage, a way how they could swim downstream was problematic. On the other hand, if the species might have the ability to adapt to the new environment below the dam, they probably could spawn in the new site. In addition, artificial propagation and releasing could be good methods to increase the population of the species.

2) The four major Chinese carps: as their spawning areas were widely distributed in the entire Yangtze main stem, the dam construction could only destruct the spawning areas near the dam. Blocked population would have spawning in above or below the dam respectively. Therefore, the dam would have had a little adverse effects on them and no further protection was needed.

3) Other freshwater migratory fishes: white bream *Parabramis pekinensis*, black bream *Megalobrama skolkovii*, bronze gudgeon *Coreius heterodon*, and *Rhinogobio typus* and other species would have migrated among river main stream, tributaries or lakes. Thus, they should have adapted to the new dammed river environment like the four major Chinese carps.

4) Other river-sea migratory fishes: most of Reeves shad *Macrura reevesii* and Japanese eel *Anguilla japonica* could not have swum upstream to the dam location, it was speculated that the dam would not have affected obvious adverse effects on them.

Co-effect of other anthropogenic activities

The Yangtze Basin was one of the most developing zones in China, and it produced approximately 40% of country’s Gross Domestic Product (Yang et al., 2007). Before and after the Gezhouba Dam was constructed, anthropogenic activities imposed various adverse effects on the aquatic ecosystem. The anthropogenic activities included water conservancy projects (other dams), fishing, water pollution, disconnection of river and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_20812097

lakes, sand and gravel excavation, navigation, port construction, channelization, bank protection projects, invasion of exotic species (Yang et al., 2007). Fish capture production shows that the overfishing have been occurred since early 1950s (*Fig. 2*) (SGFRYR, 1990). *Fig. 3* shows that the ship cargo volume increased by double in 1980s since the Gezhouba was constructed (Yin et al., 2002; CTGC, 2015). The increase of ship cargo volume implied the increase of ship number, ship size as well as heavy human activities on the water. These were potential threats to Yangtze aquatic biodiversity besides the Gezhouba Dam.

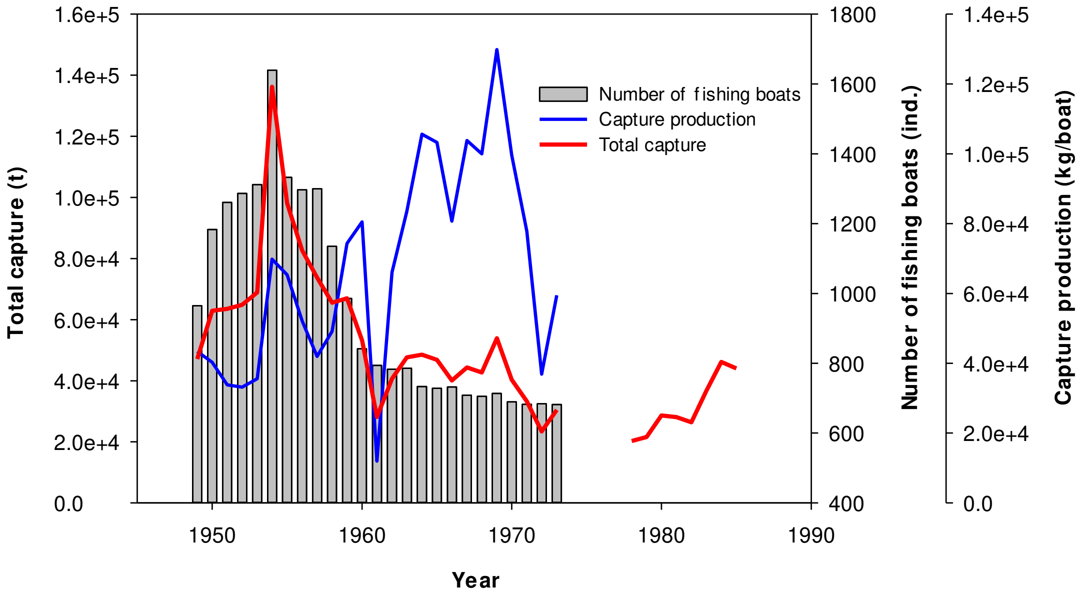

Figure 2. *Fish capture production in Hubei Province (from Yichang to Hukou) before and after the construction of the Gezhouba Dam (SGFRYR, 1990)*

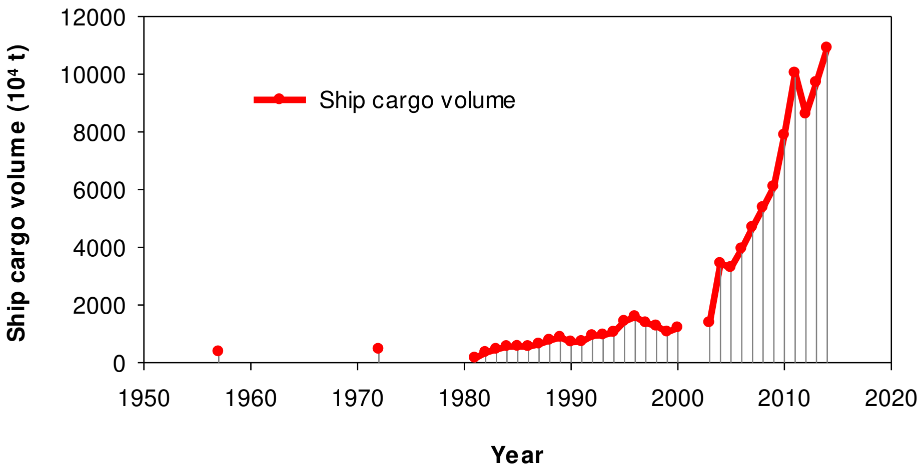

Figure 3. *The ship cargo volume before and after the construction of the Gezhouba Dam. Few data were obtained before 1980, but it was known the data in 1957 and 1972 were historical peaks because of political reasons (Yin et al., 2002; CTGC, 2015)*

Main ecological effects of the Gezhouba Dam

Influence pathways

The main ecological effects of the Gezhouba Dam contain two aspects: 1) blocking the movement and migration of aquatic organisms directly, and 2) reservoir operation altered the river environment and then affected the aquatic organisms indirectly. *Fig. 4* presents the detailed influence pathways of the Gezhouba Dam on aquatic organisms.

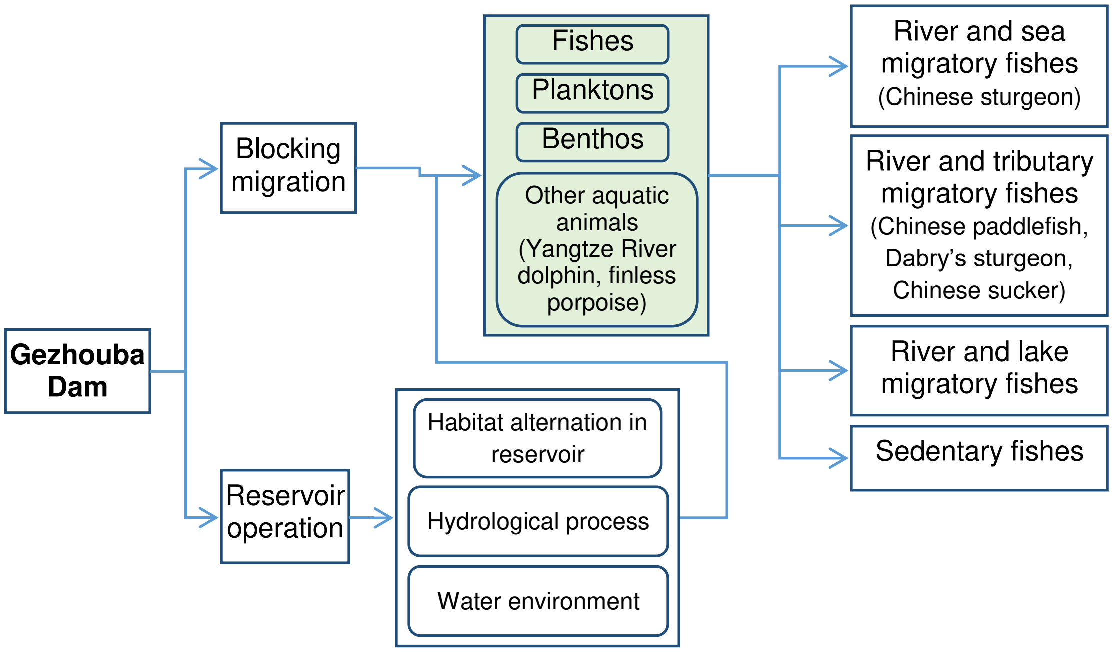

Figure 4. *Ecological influence pathways of the Gezhouba Dam on Yangtze aquatic organisms (representative endangered species are showed in the brackets)*

Effects on fishes

Effects on fishery composition

In both time periods between before and after the dam was constructed, the compositions of the fish fauna around the Yichang River section (above and below the Gezhouba Dam) were dominated by riverine and plain fish species. Hundred fish species were found before the dam closed while 94 species were observed after that closed on the basis of the investigations (WCPBHB, 1975; Wu et al., 1988). In the time after the dam was built, the proportion of fluvial fish in the reservoir area was slightly reduced, six fluvial fish species, for instance *folifer brevifilis,* were not found in the later investigation (Wu et al., 1988). As the river environment below the dam had little change compared with that before the dam was constructed, the main commercial fishery species had not fundamentally changed. The majority of fish family such as Cyprinidae and Bagridae has been observed before the dam was built, and later the dam was constructed, Siluridae was founded (Wu et al., 1988). As a result of the dam's blocking, the number of migratory fishes increased below the dam, such as the Chinese sucker. The proportion of the major economic fishes in the catch composition varied slightly, more precisely nine species such as *leiocassis longirostris* were increased.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_20812097

However, the fishery resources in the Yangtze River occurred decline trend at that time. Overall, the dam had no obvious effects on the harvest of fish production in the Yichang section (Wu et al., 1988).

Effects on river and sea migratory fishes

Three typical fish species belong to this category: the Chinese sturgeon and Reeves shad are anadromous, and the Japanese eel is diadromous. The Chinese sturgeon has been greatly affected by the Gezhouba Dam (Wei et al., 1997). Firstly, its migration route was completely blocked, approximate 1,100 km of migration route in the upper Yangtze River was not accessible. Accordingly, the spawning areas originally in that reach could not function at all. Although new spawning activities have been documented below the dam since 1982 (Chang et al., 1998), the number of spawning areas and spawning scale were significantly decreased compared with those before constructing the dam. More than 16 spawning areas had been reported in the 600 km historical spawning reach but only 2−3 new spawning areas were reported in the 30 km reach below the dam (Zhang et al., 2009). Moreover, the spawning scale was greatly decreased. Secondly, blocking made many Chinese sturgeon aggregated below the dam and over exploited by fishing. In 1981−1982, fishing on the species was not prohibited, and approximately 1,805 adults were captured which made the natural population of the species incurred a great loss (Wei et al., 1997). Thirdly, the adult population below the dam was significantly deteriorated due to the altered inhabiting environments. For instance, the sex ratio (female to male) was used to be 1:1 before constructing the dam, however it gradually became 5.86:1 in 2003−2004, which probably caused a very low spawning success rate (Wei et al., 2005). Moreover, approximately 40% adults appeared difficulties in gonadal development (Wei et al., 1997; Xiao et al., 2006). Clearly, the breeding population was ageing and the number of recruitment adult individuals became very small (Wei, 2003; Wei et al., 2005). Fourthly, as the migration route of the adults was greatly shortened, that is approximately 1,100 km, correspondingly, the living area for the filial generation of the species was considerably reduced by about 40% (Zhang et al., 2012).

On the other hand, historically, only a few of Reeves shad and Japanese eel had been found above Yichang. It was speculated that only a few of them would have migrated into the reach above the dam site. Based on the variations of capture on the two species since 1980s, the two were more affected by other anthropogenic activities such as overfishing and destruction of spawning areas. Hence, it was concluded that the Gezhouba Dam had little adverse effects on these two species (FLIHHP, 1976; SGFRYR, 1990).

Effects on river and tributary migratory fishes

The typical species which belong to this category include Chinese paddlefish, Dabry's sturgeon, Chinese sucker, brass gudgeon *Coreius heterokon*, and largemouth bronze gudgeon *C. guichenoti*. In fact, the life history of Chinese paddlefish and Dabry's sturgeon had not been fully understood (YARSG, 1988; Zhang et al., 2009, 2011). In general, they were regarded to be migrated to the Yangtze main stream (from upstream to estuary) and the tributaries. Their spawning areas were speculated to be located in the upstream near Yibin. After blocking the Gezhouba Dam in 1981, the two species were captured below the dam (Wei et al., 1997). In earlier 1980s, approximate

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_20812097

10−30 paddlefish in every year were caught according to the capture records. However, the catch record decreased less than 10 individuals in earlier 1990s. Since 1995, no capture record was found. The capture record on Dabry' sturgeon showed the similar to that of the paddlefish (Wei et al., 1997). It was concluded that the number of two species has been extremely affected by the Gezhouba Dam.

The Minjiang River, a tributary in the upper Yangtze reach, was well-known as the spawning area of Chinese sucker. The construction of the Gezhouba Dam blocked its migration. Five new spawning areas for the Chinese sucker were reported below the dam in 1980s (Liu et al., 1992). However, since the 1990s, the natural spawning activity of the species was not documented in the entire Yangtze Basin. On the basis of the incidental capture records of adults, the natural population of the fish was notably declined. The Gezhouba Dam was considered to be one of the most important factors for the decline of this species.

The external morphology and migration behavior between Brass gudgeon and largemouth bronze gudgeon are very close. However, the spawning area of Brass gudgeon was widely distributed in the entire Yangtze main stream, while that of large mouth bronze gudgeon was only in the lower Jinsha River. The spawning area of Brass gudgeon was not largely changed although the Gezhouba Dam blocked its migration route (Liu et al., 1990). However, the only spawning area of largemouth bronze gudgeon was found in the upper Yangtze reach, the breeding population of this species was largely blocked at below the dam. It can be assumed that the spawning activities of this fish had been greatly affected by the dam.

Effects on river and lake migratory fishes

The typical species for this category are four major Chinese carps, as well as some other economically important fish species. Taking the four carps for instance, the number of spawning area and the estimation of spawning scale were remarkably decreased since the Gezhouba Dam was closed in 1981 (*Table 3*).

Table 3. *Spawning variations of the four major Chinese carps before and after the closure of the Gezhouba Dam in the Yangtze River on January 4th 1981*

Survey time	Survey reach	Number of spawning areas (ind.)	Number of estimated eggs and larvae ($\times 10^9$)	References
1964−1965	Chongqing−Pengze (1695 km)	36	1183.7	Yi et al., 1988
1981	Chongqing−Wuxue (1520 km)	24	173	SGSAYFMCC, 1982
1986	Chongqing−Tianjiazhen (1460 km)	30	175.5	Yu et al., 1988
2015	Jingkou−Huangshi	15	11.4	YRFA, 2016

The number of spawning area decreased by 20.0−33.3%, while the spawning scale decreased approximately 16.0% (from 1964−1965 to 1981 and 1986). In consideration with the entire Yangtze River, the spawning locations were not largely alternated. However, the spawning areas around the dam were destroyed, and the spawning areas were divided above and below the dam (SGSAYFMCC, 1982; Yi et al., 1988; Yu et al., 1988). Furthermore, hereafter the Three Gorges Dam started to be operated in 2002, the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_20812097

spawning scale decreased further to 11.4 billion in 2015 (YRFA, 2016). It was concluded that the original assessment on the effects of the dam for four carps was appropriate. However, the decline of the fish natural population was far beyond the previous judgements since various and fast developing anthropogenic activities threatened the species. An example of anthropogenic activities was that some lakes turned into farming fields. Other examples could be fishing and water pollution (SGFRYR, 1990).

Effects on sedentary fishes

Except for the reservoir area, the environmental conditions of other river sections were not changed. Thus, the distribution of the species in the river sections were not largely altered. The environmental alternations of the reservoir increased lentic fishes, yet reduced lotic fishes. However, there was only little effect on all resources of the settlement fishes (Huang, 2002), such as the common carp *Cyprinus carpio* and crucian carp *Carassius auratus*.

Effects on phytoplankton

In either above or below the dam, the species composition and biomass of phytoplankton were analogous to before and after the dam was constructed. The dominated species were Bacillariophyta, Chlorophyta, and Cyanophyta. Only in the Huangbohe Reservoir, the biomass of phytoplankton was higher than that in the original natural river (Huang, 2002).

Effects on zooplankton

The protozoan was dominant species in terms of species number, however, the copepod was the most abundant species which means it had the highest biomass. The distribution and biomass of the zooplankton were similar before and after the dam was constructed, the dominant species seemed to be nearly same (Huang, 2002).

Effects on benthos

The species and biomass of benthic organisms were very related with the river ecological environments such as water depth, substrate, water flow, water quality and food supply (plankton). As the Gezhouba Dam was a low-head run-off hydropower plant, it did not greatly change the river flowing environment. This reach was in the gorges with step riversides so that there were a few riparian areas. Hence, the benthic organisms have not been extremely influenced. Only in the Reservoir, the dominated species of benthic organisms was changed into Oligochaeta (Huang, 2002).

Effects on aquatic vascular plant

The aquatic vascular plants near the dam were relatively poor conditions either before or after the dam construction since this reach was in the gorges and had a few riparian areas as well as high fluctuation of water level and high sediment content. Therefore, it was concluded that the dam had little influence on the aquatic vascular plant.

DOI: http://dx.doi.org/10.15666/aeer/1504_20812097

Effects on other aquatic animals

Other aquatic animals affected by the dam could be Yangtze River dolphin, finless porpoise, and Chinese giant salamander. Their life history could be influenced by the dam. The Yangtze River dolphin was reported to be distributed from Huanglingmiao (a site at Yichang reach, approximately 30 km upstream the dam) to the Yangtze estuary, that is approximate 1800 km in river length (Chen et al., 1997). The finless porpoise was distributed in the river reach below Yichang to Yangtze estuary which is approximately 1700 km in river length (Chen et al., 1997). The Gezhouba Dam was almost at the top of the upstream living area for the Yangtze River dolphin and finless propose. Accordingly it should not have considerable adverse effects on the two aquatic animals. The Chinese giant salamander is mainly distributed in the mountainous tributaries and stream. The Gezhouba Dam was a low-head run-off hydro power plant located in the main stem, and the reservoir was relatively small, the backwater did not greatly affect the tributaries. Therefore the dam did not have significant influence on the Chinese giant salamander.

Conservation measures

Because of the construction of the Gezhouba Dam, many protective measures have been adopted to reduce the adverse effects on Yangtze fishes. The main mitigated measures included catching and moving the Chinese sturgeon to the upstream, building a Chinese sturgeon hatchery, and conducting artificial propagation and releasing. In addition, in view of increasingly adverse impacts of various anthropogenic activities on the Yangtze aquatic biodiversity, other protective measures such as natural population protection, habitat protection, fishing ban policy, and special rescue plan for flagship species have also been adopted.

Catching the sturgeons below the dam and moving them above the dam

After the closure of the dam in 1981, many Chinese sturgeons were concentrated in the 20-km reach below the dam. To help the species to distribute above the dam, a number of the species were captured and moved to the upstream area by boats or trucks (Liu and Xiao, 1993). The fixed or drifting gill nets and setlines were used to capture the species. Fishing was highly affected by water level, discharge, and water temperature. In summer, it was difficult to catch due to high water level and vast flow discharge. In winter, the species moved less than other seasons because of low temperature, thus it was not easy to catch them. The good fishing seasons were spring and autumn, especially in autumn, the sturgeons were tended to be aggregated. When the river flow reduced to 8,000−20,000 m^3/s, it was the best time for fishing operations. In the catch, the mature individuals (gonad for stage IV) were used for artificial propagation, and immature individuals (gonad for stage III) were transported to upper area from the dam or kept for culturing them. The transportation of the sturgeons was carried out for four years (Liu and Xiao, 1993). The captured brood stock was placed in a temporary canvas basket with water, and then transported by a boat or truck to the upper reservoir area. During 1982−1985, a total of 40 individuals, with male and female ratio of 1: 1.2, were transported for trial purpose. It was concluded that transporting a number of the species over the dam to "save the species" had little significance. In fact the transported population was very small which was not enough to form spawning

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_20812097

activities. To enable to form a breeding population in the upstream, a large amount of fishing was required. At that time, it was perceived that a great number of catching and transporting the species required very high costs and heavy workloads. Finally, the transportation of the species was stopped since 1986 when the spawning activity of Chinese sturgeon was documented below the dam in 1982.

Hatchery construction and artificial releasing program

In 1982, the state authorities set up the Chinese sturgeon Institute in Yichang, which charged specially for the controlled reproduction and release of this endangered species (Liu and Xiao, 1993). This was another mitigated measure to compensate for the negative effects of the Gezhouba Dam which imposed on natural reproduction of the sturgeon. In addition, sturgeons were released in both protect areas located in the Yichang and Shanghai regions by relevant enterprises and research institutes (MOA, 2015). Up to now, over six million Chinese sturgeons of different sizes (mostly less than 35 cm) have been released by the relevant units. The released sites were mainly in the middle reaches of the Yangtze River, the Yangtze River Estuary, the Pearl River, and the Minjiang River as well as other waters to support the remaining population by restocking. However, although the artificial releasing has been conducted for more than 30 years, results have not been thoroughly evaluated. A reason can be the difficulty of monitoring them in a vast spatiotemporal range. In early 21 century, only a few research indicated that more than 90% of the juveniles in Yangtze estuary was originated from natural reproduction (Zhu et al., 2002; Wei, 2003; Yang et al., 2005). Both mark-recapture and molecular genetic methods showed the similar results to the above one. That means the artificial enhanced program was of limited significance and needed further improvements.

The optimistic aspect was that many Chinese sturgeons in different ages have been stored for the controlled propagation and releasing practices. Among them, a certain number of specimens have reached sexual maturity (8 years old). The mechanism of rescuing individuals suffered from accidental by-catch or injury was clearly understood. The mechanism was used to conduct artificial reproduction. Moreover, the artificial propagation technique of Chinese sturgeon was succeed since 2009 (Guo et al., 2011; Wei et al., 2013), which allows to sustain the species in complete artificial environments. It built a good foundation for natural population enhancement, as the artificial propagation and releasing can independent of natural mature individuals, which means natural population can purely and largely be supported by artificial population.

Prohibition of fishing and listed as protected animals

As a large number of Chinese sturgeon was captured after the Gezhouba Dam blocked its migration route in 1981 and 1982, a total ban on commercial fishing of the species was implemented since 1983 (MOA, 2015). In 1989, the species was listed as one of the top-level protected animals in China. In 1996, the species was registered as an Endangered (EN) species on the Red List of the International Union for Conservation of Nature (IUCN). Later in 2010, the species was upgraded as a Critical Endangered (CR) species in the Red List. In 1998, the species was also included in the Appendix II of the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES). Prohibition of fishing and listed as an important protected species protected this species directly and remarkably.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_20812097

Critical habitat protection and protected area constructions

To protect the only known spawning area, that is below the Gezhouba Dam, and to breed cohorts of Chinese sturgeon, the "Yangtze Provincial Nature Reserve for Chinese Sturgeon" was established in 1996 in Yichang, Hubei Province (MOA, 2015). To protect the sturgeon juveniles and their feeding grounds along the Yangtze River estuary, the "Yangtze Estuary Nature Reserve for Chinese Sturgeon in Shanghai" was established in 2002. Some other protected areas were also set along the middle and lower reaches of the Yangtze River. For example, the "National Nature Reserve for Baiji in Xinluo Section of the Yangtze River in Hubei" played a positive role in the protection of this species and its habitats.

Fishing ban policy

Since 2003, the fishing ban policy was executed in the Yangtze Basin. In the Yangtze main stream from Deqin County, Yunnan Province to the Gezhouba Dam and some tributaries such as Min River, Jialing River, Wu River, and Chishui River (*Fig. 1*), fishing was forbidden from 12 o'clock of February 1 to 12 o'clock of April 30 every year. In the Yangtze main stem from the Gezhouba Dam to Yangtze River estuary, and Hanjiang River, as well as Dongting lake and Poyang lake, fishing was prohibited from 12 o'clock of April 1 to 12 o'clock of June 30 in each year. In December 23, 2015, the Ministry of Agriculture announced to enforce the fishing ban policy. The fishing ban area in the Yangtze main stem was extended into a longer stretch from Qumalai County, Qinghai Province to the estuary. Tributaries for example Tuo River, Dadu River, and Huai River were included. Moreover, the fishing period in the whole Yangtze Basin was unified into a four-month period from 0 o'clock of March 1 to 24 o'clock of June 30 every year. The fishing ban area and time period cover nearly all spawning areas and time periods of major fish species in the Yangtze River. Hence, it protected the breeding populations and their spawning activities very effectively. Below the Gezhouba Dam, the spring spawning species and their spawning activities could be well protected. However, the autumn spawning species, such as the Chinese sturgeon, was outside the fishing ban period.

Flagship species protection

In consideration with the fact that few rare and endemic species are on the verge of extinction, the Chinese government has exclusively designed protection measures on these species, such as Chinese sturgeon and Yangtze finless porpoise. Some decree documents issued to upgrade the Finless porpoise as a Class I protected animal. The central government also designed a very long period rescue plan for them, such as "The Action Plan for Conservation of the Chinese Sturgeon (2015−2030)" (MOA, 2015) and "The Action Plan for Conservation of the Yangtze finless porpoise (2016−2025)". Take the action plan for Chinese sturgeon as an example, it includes *in-situ* and *ex-situ* conservation actions, conservation action for genetic resources and supporting actions. The action plans will be used as guidelines and will play a very important role for future conservation of the two species.

Conclusions and conservation recommendations

In summary, the original judgement regarding the ecological effects of the Gezhouba Dam on Yangtze aquatic organisms was appropriate. However, after the construction of Gezhouba Dam, the economic and social environments of the Yangtze River Basin have been undergone in great developments. The adverse effects of various anthropogenic activities on the Yangtze aquatic ecosystem have become more intensive and extensive (Zhang et al., 2016). Although some protective measures have been taken, the current aquatic biodiversity and fishery resources of the Yangtze River are still declining rapidly (Yang et al., 2007). Currently, the impacts of the Gezhouba Dam on aquatic biodiversity in the Yangtze River would be of little significance because the anthropogenic activities and ecological environment of the Yangtze Basin have been undergone in great changes. Overall, to protect the Yangtze aquatic biodiversity, it is recommended to focus on the following five aspects of work.

1) To further enhance the fishing ban or even to prohibit fishing in the entire Yangtze Basin gradually. The four-month fishing prohibition period at present is not enough to protect the fish biodiversity. It is recommended to extend the prohibition period, or to have a very long prohibition period for example ten years, in that period, most of the fishes can reproduce for 2−3 generations. The prohibition area can be extended gradually, the nature protected area and aquatic resource protected area could be the first priority, then moved to the main stem and tributaries. Lastly the lakes, such as Dongting Lake and Poyang Lake, where fishing is still important for a great number of fishermen to earn their livings. It is believed that the enhanced fishing ban below the Gezhouba Dam (80 km reach below the dam is a nature protected area in province level) will be of great importance to protect the migratory fish populations and their spawning activities.

2) To further strengthen habitat conservation and rehabilitation, the following action can be considered: the construction and management of protected areas, optimizing dam ecological dispatch, rehabilitating critical habitats and reconnecting of migratory channels.

3) To further enhance the protection of flagship species such as Chinese sturgeon and finless porpoise. The protection measures in the two action plans should be well performed in the future. It should be mentioned that with the emphasis on protection of these flagship species with extensive living space and long life-span, actually it can protect the whole Yangtze aquatic biodiversity.

4) To further strengthen the policy guidance to make artificial propagation and releasing more effectively, to control the alien species strictly to prevent biological invasion, and to revise the list of protected species.

5) Last yet not least, a watershed collaborative management mechanism is urgently needed. To enhance communication and cooperation between national and local administrative organizations along the Yangtze River, achievable and comprehensive improvement-oriented management for the basin environment should be accomplished.

Abstract. Although the ecological attributes of many weed species are well-known, their eco-physiological relations – particularly at stand level – are scarcely researched. Based on this the main objectives of our examination are to measure the stand level CO_2 flux (NEE) for 5 weed species generally widespread in Central Europe as well as to explore the dependence of NEE on air temperature, radiation and stand level evapotranspiration. The selected weed species represent archaeophyte and neophyte plants as well as different functional groups (C_3, C_4, therophytes and cryptophytes). The research covering an entire vegetation cycle of the weed species has been implemented *ex situ* in 15 patches of the Szent István University's Botanical Garden. Stands of the involved species showed really significant CO_2 uptake for months. This value is the multiple of what is indicated in literature regarding Central European herbaceous vegetation (e.g. grasslands) – this fact can be one of the key factors leading to the success of this plant group. By comparing the average CO_2 fluxes of these five weed species in the entire vegetation period it can be concluded that the values of the two endemic species are almost completely identical exceeding the average values of non-endemic C_4 weed species. Furthermore, significant linear regression ($P<0.05$) has been observed between the net ecosystem CO_2 gas exchange of *Ambrosia artemisiifolia* and *Chenopodium album* and the values of stand level evapotranspiration.
Keywords: *canopy chambers; weeds; net ecosystem; carbondioxide exchange; dependence*

Abbrevations: *Ama ret – Amaranthus retroflexus*; *Amb art – Ambrosia artemisiifolia*; *Art vul – Artemisia vulgaris*; *Che alb – Chenopodium album*; ET – evapotranspiration; LAI – leaf area index; NEE – net ecosystem CO_2 exchange; PPFD – photosynthetically active photon flux density; *Sor hal – Sorghum halepense*; T_{air} – air temperature

Introduction

One of the main objectives of recent international ecosystem researches is to measure the cycles of important greenhouse gases (including carbon dioxide) in different habitats (e.g. Yamuki et al., 1997; MacDonald et al., 1998; Dong et al., 2000; Papen et al., 2001; Hefting et al., 2003; Horváth et al., 2006). Such European projects have examined ecosystems of grasslands, shrubs, waters, watersides and forests together with their plant communities/stands. However it is surprising that stand level research regarding greenhouse gas fluxes of weed stands has not yet been conducted although they can have fundamental influence on the carbon balance of certain areas due to their wide range and constant expansion. Ecological characteristics of several weed species are well-explored (e.g. Holzner and Numata, 2013; Čekić and Kovačević, 2015; Kleunen et al., 2015) but their stand level ecophysiological relations are hardly examined.

Examinations implemented so far on greenhouse gases in relation with weeds mainly focused on the impacts of increased CO_2 concentration on the growth and production of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_217226

weed species instead of their CO_2 fluxes. Based on the responses given by different C_3 and C_4 weed species on increased CO_2 concentration in the air the highest growth rate among the involved taxa belonged to the C_4 *Amaranthus retroflexus*. In case of *Ambrosia* growth was more intensive under increased CO_2 concentration in the first half of the examination period while in the second half current atmospheric conditions (i.e. 350 ppm) resulted higher growth (Garbutt et al., 1990). The amount of reproductive biomass was increased in case of *Amaranthus retroflexus*, *Chenopodium album* and *Ambrosia artemisiifolia* when atmospheric CO_2 concentration was higher. Strong correlation can be observed between the change of leaf surface and accumulation of biomass in case of *Abutilon theophrasti* and *Amaranthus retroflexus* (Akerly et al., 1992). Development of leaves has been accelerated for these species by increasing either the air temperature or the CO_2 concentration.

Other researchers examined the impacts of not only increased but also decreased carbon dioxide concentration on – among others – C_3 and C_4 weed species (Dipperey et al., 1994.). Regarding C_4 taxa CO_2 concentration had no effect on either growth rate or total biomass within the first 35 days following germination. In case of C_3 taxa biomass showed positive correlation with higher atmospheric CO_2 concentration.

The effect of aridity was different in the involved functional groups (Ward et al., 1999). Photosynthetic rate of plants with good availability rate has increased when atmospheric CO_2 concentration was higher but their leaf surface and biomass has not changed. As opposed to that both leaf level CO_2 uptake and biomass of C_3 taxa increased under the concentration of 700 ppm. Due to the aridity leaf surface of C_3 plants reduced significantly; as a consequence of that water potential value of remaining leaves became relatively high. The LAI of C_4 plants decreased in smaller extent. Lower water potential value was measured in their leaves. Under non-limiting nutrient provision whole individuals of C_3 taxa developed significantly as a result of increased CO_2 concentration while more moderate growth has been examined in case of C_4 plants (Bernacchi et al., 2000). In limiting environment neither types showed significant development. Shoot-root rate remained unchained or decreased in the observed taxa as a result of higher CO_2 concentration.

Considerable competition can occur among weeds in mixed communities as a result of which the amount of biomass – both above and below soil surface – change as well as the habit of the plants (e.g. Bazzaz et al., 1989). Interference of different species can be observed not only in competition for resources. For instance, *Artemisia vulgaris* has allelopathic characteristics among the examined weed species (Barney et al., 2005). In mixed vegetation species can influence not only negatively the development of other taxa. Weeds growing under higher plants can utilise absorbed and photosynthetically active radiation with higher efficiency (Gramig et al., 2006). Selected parameters can be examined in a taxon specific way (Borjigidai et al., 2008) in monodominant stands of the selected weed species.

By examining archaeophyte and neophyte weed species representing different physiognomy and functional groups the CO_2 balance of these stands and plant communities can be explored. Photosynthetic capacity of invasive plants is usually higher (Nielsen et al., 1993; Patterson et al., 1998) but their mass invasion is not a primary consequence of this feature (Brodersen et al., 2008).

Measurement of carbon dioxide fluxes in the weed stands can also provide a basis in the future for monitoring alterations occurring as a result of global climate change regarding these stands and plant communities dominated by these species. Due to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_217226

climate change extreme weather conditions become more frequent (Brodersen et al., 2008) to which taxa give different answers. Examining the success of adaptation to extreme precipitation conditions may help when establishing a prognosis in relation to the future range of certain weed species since different types of photosynthesis influence the water utilisation efficiency of plants (Niu et al., 2005; Sharkawy, 2009).

The main objective of our research is to implement comparative measurement of carbon dioxide fluxes at stand level in case of five weed species generally widespread in Central Europe (Lososová et al., 2006): *Amaranthus retroflexus, Ambrosia artemisiifolia, Artemisia vulgaris, Chenopodium album* and *Sorghum halepense*. Dependence of NEE on air temperature, radiation and stand level evapotranspiration has also been examined.

When selecting the species it has been taken into consideration that archaeophyte (*Artemisia vulgaris, Chenopodium album*) and neophyte (*Amaranthus retroflexus, Ambrosia artemisiifolia*, *Sorghum halepense*) plants as well as members of different functional groups /C_3 (*Ambrosia artemisiifolia, Artemisia vulgaris, Chenopodium album*), C_4 (*Amaranthus retroflexus, Sorghum halepense*); therophyte (*Amaranthus retroflexus, Ambrosia artemisiifolia, Artemisia vulgaris, Chenopodium album*), cryptophyte (*Sorghum halepense*)/ species and angiosperms (3 families and 5 genera) are all to be represented.

Materials and Methods

Site description

Examination covering the entire vegetation cycle of weed species have been implemented in the Experimental Site of Szent István Egyetem Botanical Garden (Gödöllő 19°14’E, 47°25’N, 250 m elevation) (Szirmai et al., 2014). Mean annual temperature is 10.5 °C; average amount of precipitation is 500 mm. The soil of the site is loose and moderately calcareous sand (Szente et al., 1993b). 15 homogenous stand patches have been created within the selected area. The size of the patches was 1 by 1 metre, with 3 repetitions by species and by examinations. Proper isolation distances have been kept among the stands. Parcels were established following random block pattern in order to avoid spot effect.

Stand level measurements

Measurements were conducted in the 2008 vegetation period by using CIRAS-2 infrared gas analyser (PP Systems, Hitchin, UK) and the so-called “open chamber” method. Measurements have been taken weekly or in every two weeks with the help of transparent, water-clear plexi chambers adjusted to the actual height of stands. The chamber used initially consisted of a cylinder wall with 60 cm diameter and a half-sphere shaped transparent part installed at the top airtight (in details see Czóbel et al., 2004). In order to harmonise the tools with the actual height of stands 70 cm and 200 cm high chambers were used. External fans ensured the consistent mixing of air within the chambers as well as air exchange. The same measurement technique has been applied regardless the size of the chambers. Measurements were taken between 11 am and 3 pm under cloudless and clean sky. Data recording took at least 30 minutes for each weed species and treatment. The equipment measured the difference in stand level CO_2 flux (in the incoming and outgoing tubes of the chamber) by taking 10 samples per

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_217226

minute. It also recorded the photosynthetically active radiation (PPFD), air temperature (T_{air}) and evapotranspiration (ET) in the stand covered by chamber. Average temperatures of the given stand have been used for CO_2 flux calculations. The following differential equation has been applied when calculating CO_2 flux:

$$F=\Delta c* Q/A$$

where 'F' is the stand level flux /CO_2 uptake of the plant stand, vegetation and soil respiration in case of CO_2 flux; the resultant of the evaporation regarding soil surface covered by vegetation in case of evapotranspiration/ (mol m^{-2} s^{-1}), 'Δc' represents the difference in incoming and outgoing concentration /CO_2 or H_2O/ (mol m^{-3}), 'Q' stands for flowrate (m^{-3} s^{-1}) and 'A' is the soil surface covered by the chamber (m^2).

Following quality control raw data have been manually filtered where negative evapotranspiration values as well as outliers recorded at the initiating and final phases of the measurement (due to human respiration) have not been taken into account.

Parallel to CO_2 flux measurements ET, PPFD and T_{air} have been recorded by patches with a portable infrared gas analyser /CIRAS-2 (PP Systems, Hitchin, UK)/

Statistics

Only significant correlations have been represented in the figures indicating the strength of the correlation. The strongest significant correlation has been fitted to the data in all cases. Values of regression have been calculated by SigmaPlot 8.0 software. In case of time series t-tests were implemented to check the level of significance regarding correlation values, impacts of manipulation experiments and the differences among the involved taxa. Standard deviance (SD) values are indicated in the figures.

Figures have been created by using SigmaPlot 8.0 software.

Results and Discussion

Net ecosystem CO_2 exchange (NEE) examinations

All five species reached considerable CO_2 exchange values until the time of cutting (*Fig. 1*). Significant values of standard deviance is connected to high CO_2 fluxes regardless of the species. Stands of *Ambrosia artemisiifolia* and *Sorghum halepense* reached the maximum of CO_2 uptake relatively late. Maximal value of CO_2 fixation, in case of both species, can be the multiple compared to that of either a fully developed loess grassland (Frank et al., 2002; Hunt et al., 2002; Czóbel, 2007; Czóbel et al., 2008) or a stand of spring forest geophytes (BARCZA et al. 2011). Different functional groups cannot be significantly separate based on their NEE values. During spring both early germinating C_3 species (*Che alb*: -9.20; *Art vulg*: -6.28) produced remarkably high NEE values even from May while stands of C_4 weeds showed lower CO_2 uptake (*Ama ret*: -4.06; *Sor hal*: -2.53) in this period. Average net ecosystem exchange increased in a great extent (*Ama ret*: -8.29; *Sor hal*: -8.44) during summer. Stands of *Amb art* reached the highest value of the summer period (-15.95) by showing great increase in biomass and NEE. In this season average NEE value of *Art vul* also increased (-9.98) while in stands of white goosefoot it has been reduced (-7.66). Order of CO_2 fixation among the species has not reflected the amount of biomass. Following cutting CO_2 exchange of the weed species significantly decreased as a result of both losing the majority of foliage

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_217226

and the poor regeneration due to aridity stress, therefore differences among taxa have been levelled off. During the autumn period *Ambrosia artemisiifolia* and *Sorghum halepense* showed the highest (-2.85) and the lowest (-0.85) average NEE value, respectively.

In case of *Amaranthus retroflexus* until uptake irrigated stand and no-precipitation stand showed the most intensive and lowest CO_2 uptake, respectively.

NEE averages of the examined weeds remarkably exceeded values measured in temperate grasslands (e.g. Frank et al., 2002; Hunt et al., 2002; Soussana et al., 2007). Compared to grasslands the examined weed species were characterised by high CO_2 fixation even in the arid summer period (Valentini et al., 1995; Suyker et al., 2003; Li et al., 2005; Pintér et al., 2008).

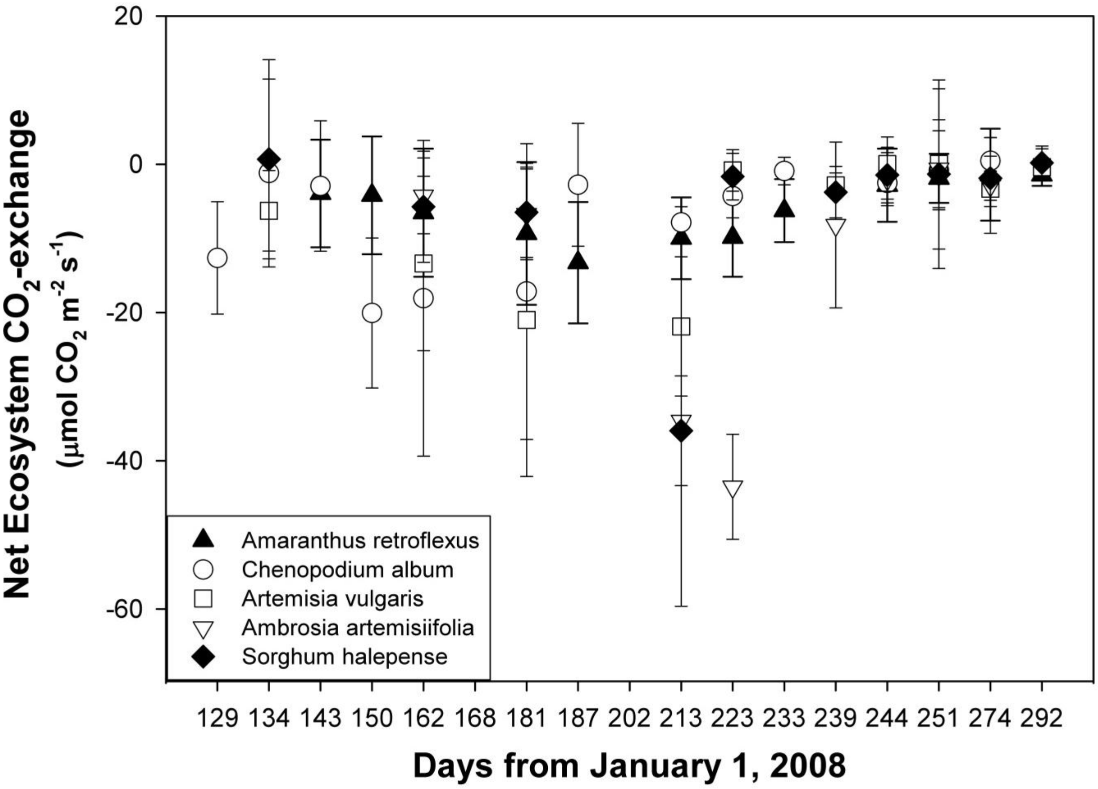

Figure 1. *Seasonal dynamics of net ecosystem CO_2 exchange (NEE) regarding the examined weed species during an entire vegetation period*

Dependence of NEE on light, temperature and evapotranspiration

As regards of NEE light dependence no significant difference could be observed among neither the 5 examined weed species nor C_3 and C_4 taxa (*Fig. 2*). Positive correlation was found between CO_2 uptake value of the stands and PPFD. In stands of *Chenopodium album* this relation was significant when using exponential fit ($P<0.05$). The most intensive CO_2 fixation was measured when PPFD value ranged between 1400 and 1600.

CO_2 fixation of the stands showed Gaussian curve when their dependence on air temperature has been examined (*Fig. 3*). No clear difference could be observed between C_4 and C_3 species. Correlation between the two parameters was significant in stands of *Chenopodium album* ($P<0.05$).

DOI: http://dx.doi.org/10.15666/aeer/1504_217226

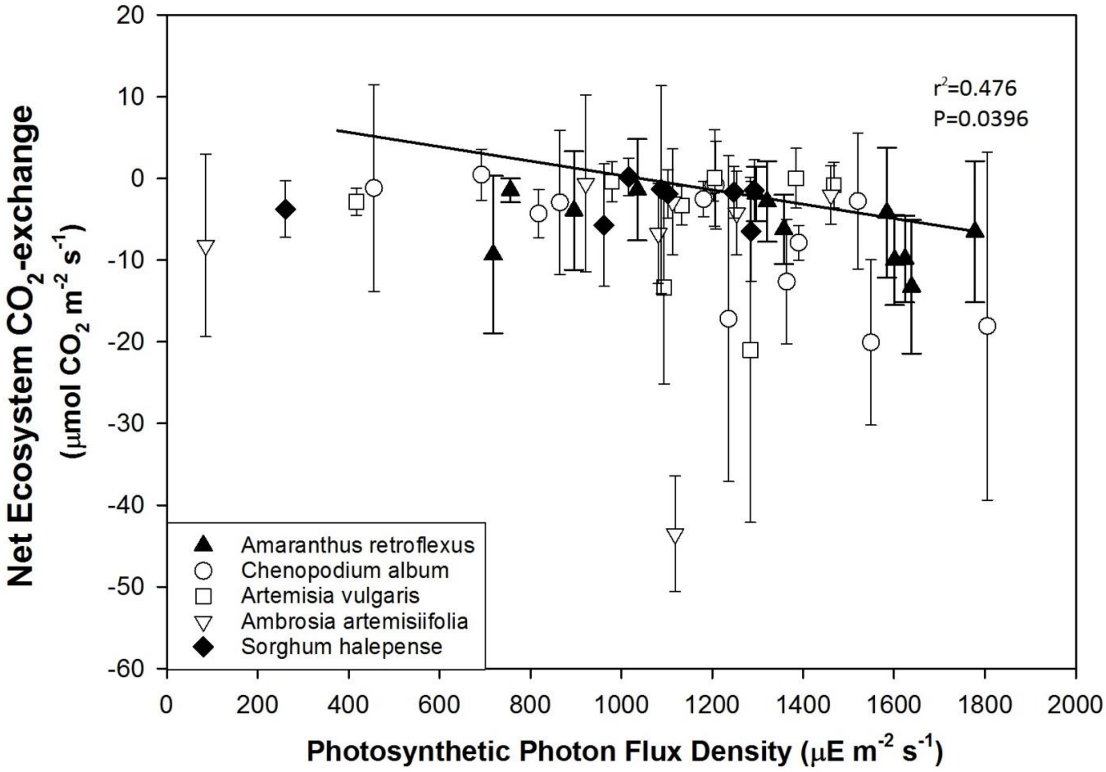

Figure 2. *Dependence of net ecosystem CO_2 exchange (NEE) regarding the examined weed species on photosynthetically active radiation (PPFD)*

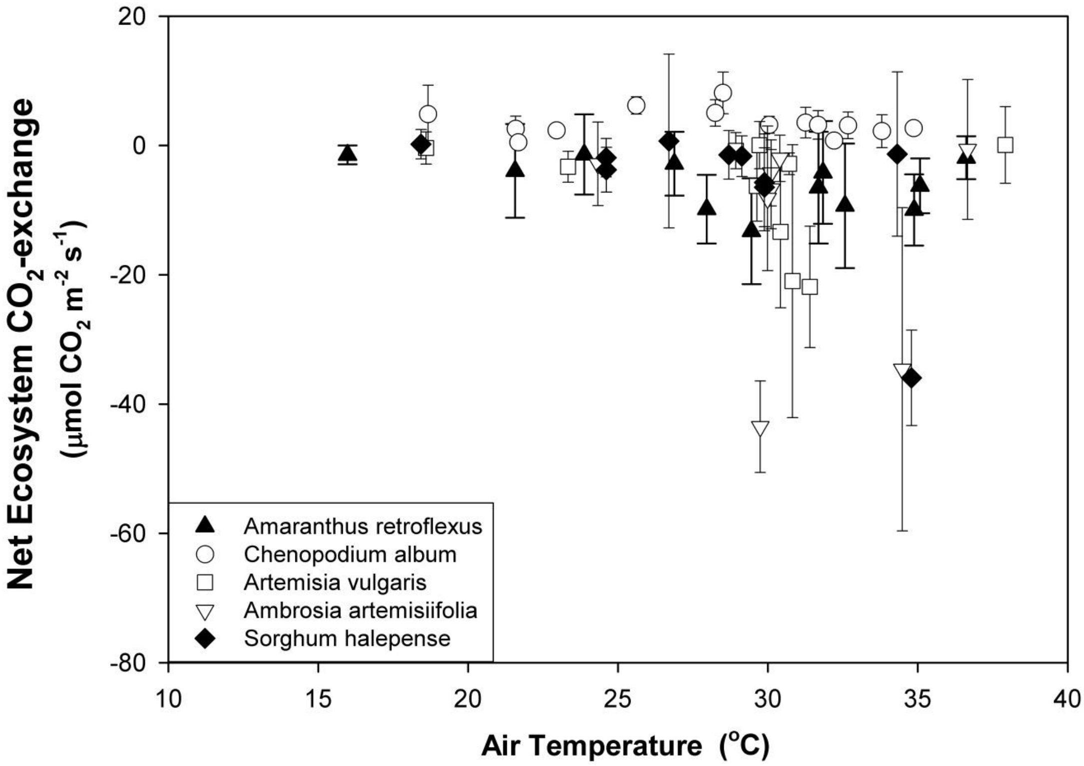

Figure 3. *Dependence of net ecosystem CO_2 exchange (NEE) regarding the examined weed species on air temperature (T_{air})*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_217226

Considering CO_2 fixation optimum heat ranged between 28 and 35 °C for all five species. Gas exchange intensity continuously increased up to 30 °C in case of each taxon while considerable retrogression was observed over 35 °C. Latter phenomenon was experienced for C_4 type weeds also, thus presumably not only stomatal closure (C_3) but also lover level of soil humidity contributed in its development.

Positive correlation could be noticed between CO_2 uptake and ET within the examined stands (*Fig. 4*). ET dependence of NEE did not show significant distinction regarding the plant species and functional groups. However, significant linear regression ($P<0.05$) could be observed between net ecosystem CO_2 exchange and stand level evapotranspiration in case of *Ambrosia artemisiifolia* and *Chenopodium album*. When conducting the measures increased ET was usually coupled with slightly higher CO_2 uptake.

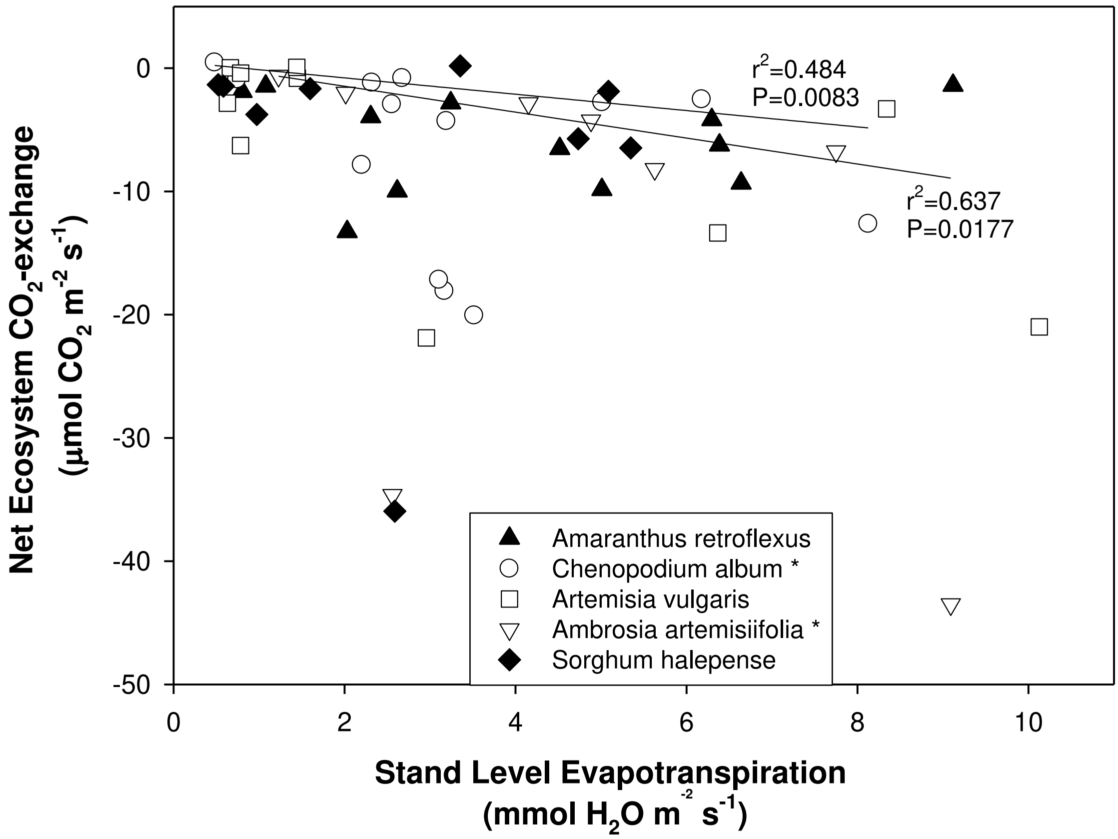

Figure 4. *Dependence of net ecosystem CO_2 exchange (NEE) regarding the examined weed species on evapotranspiration (ET)*

Conclusions

The examined species all reached remarkable production that is the multiple of values presented in literature regarding herbaceous vegetation (e.g. grasslands) in the Carpathian Basin. Despite the species represented different functional groups and characterised by different stem count and biomass they all showed very similar dynamics. This can be explained by the above-average precipitation of the examination year and by the high level of CO_2 fixation maintained for months. This latter feature can prove as one key feature leading to the success of this plant group.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_217226

By examining the stand level CO_2 fluxes of the five involved weed species regarding the entire vegetation period it can be concluded that values of two species endemic in Central Europe (*Chenopodium album* and *Arthemisia vulgaris*) are nearly identical while exceeding the average values of non-endemic C_4 weed species (*Amaranthus retroflexus*, *Sorghum halepense*). The latter two plants, despite their different morphological features, can be characterised by almost the same average regarding CO_2 uptake. The average CO_2 fixation of the neophyte ragweed significantly exceeded that of all other plants involved. As for C_3 weeds endemic species initiated more intensive CO_2 uptake compared to the also C_3 but invasive *Ambrosia arthemisiifolia*. C_4 taxa reached higher NEE values later, similar to *Ambrosia*.

Further study is needed to define and measure the effects of intraspecific and interspecific competitions.

Abstract. There is a lack of knowledge on germination capabilities of native species and their relation to field establishment that could help optimize ecological restoration efforts. We studied laboratory germination and second year field establishment of 12 native vascular dry grassland plant species in the frame of a restoration project in NE Hungary. Our questions are:1) For which species is cold-stratification necessary to break dormancy of seeds? 2) Is there a positive correlation between germination and second year establishment? Laboratory germination was studied with and without cold-stratification and the impact of cold-stratification was tested by linear model. Relationships between germination and field establishment were tested by generalized linear models. Cold-stratification decreased significantly the germination of four grass species, and was important to break dormancy for one dicot. Field establishment is positively connected with germination under both germination treatment. We conclude that, laboratory germination has a high predictive value on the establishment success of seeded species.
Keywords: *cold-stratification, field plant cover, germination percentage, Hungary, sandy grassland*

Nomenclature: Scientific plant names follow the nomenclature of Király (2009).

Introduction

The unprecedented loss of biodiversity and the degradation of habitats justifies the need for ecosystem restoration, which is currently acknowledged at the policy level (Aronson and Alexander, 2013; Suding et al., 2015) and as a result, large-scale restoration efforts are planned (Aichi Target 15, SCBD, 2011). To support this volume of restoration need, the use of seeds of native species has to be scaled up and survival success has to be increased (Merritt and Dixon, 2011). Difficulty in achieving scaling up lies partly in the lack of sufficient amount of seeds and wasting by seeding more than necessary in the hope of restoration success (Williams et al., 2002; Hedberg and Kotowski, 2010; Merritt and Dixon, 2011). The other limitation of restoration is that seeding often fails to reach restoration target (Pyke et al., 2013) due to scattered knowledge on requirements of early life stages of reintroduced plant species (Larson et al., 2015). The early stages of plant recruitment are essential in the reestablishment of wild species at restoration areas as high mortality occurs during this period (James et al., 2013; Carrington, 2014). Advancements in the science of seed ecology and early life stage characteristics of plants is needed to

DOI: http://dx.doi.org/10.15666/aeer/1504_227239

underpin restoration success (Commander et al., 2009; Larson et al., 2015) and help to assess seed amount in future restoration planning.

Spontaneous succession is often hindered by the lack of seeds that originates from the depletion of soil seed bank and limited seed dispersal (Kiehl et al., 2014). Seed introduction methods to overcome this limitation include among others direct seeding, diaspore transfer with substrate, hay or brush harvesting, slot seeding, plug planting (Hedberg and Kotowski, 2010) or, under extreme conditions, e.g. in Mediterranean areas hydroseeding (Sheldon and Bradshaw, 1977; Oliveira et al., 2012). Direct seeding is the most widely used restoration method (Kiehl et al., 2010; Török et al., 2011). The composition of a seed mixture is dependent on the condition of the restoration site, the availability of seeds of target species (Török et al., 2011) or their dominance in the target vegetation (Hedberg and Kotowski, 2010). Commercial seed mixtures can be purchased easily and in large quantity. However adverse climatic and soil conditions can hinder their establishment or if established, highly competitive, fast-growing species can constrain further vegetation development (García-Palacios et al., 2010). In contrast, difficulty in using native seeds lies in the lack of seed market or scarce information on seed biology (Commander et al., 2009).

Germination is a critical transition influencing survival after seeding (Larson et al., 2015; Gallagher and Wagenius, 2016). Without knowledge on germination characteristics, the necessary amount of seeds for restoration cannot be properly estimated. Germination is generally studied under laboratory or greenhouse conditions by testing germination percentage (Grime et al., 1981; Haslgrübler et al., 2013; Larson et al., 2015; Gallagher and Wagenius, 2016). Knowledge gained during these experiments can be exploited in restoration to estimate the necessary amount of seeds; to identify best seeding time for different species based on cold-stratification requirements (Jones and Kaye, 2014), or optimal pre-treatment of seeds (Krock et al., 2016). Seed dormancy, a key attribute in the diversification of seed plants is another critical determinant of establishment success (Willis et al., 2014), and thus influences species distribution (Donohue et al., 2010). In order to enhance restoration success, breaking dormancy is a key issue. Physiological seed dormancy is the most common type of dormancy (Baskin and Baskin, 2004). Non-deep physiological seed dormancy might be broken by cold-stratification treatments (Baskin and Baskin, 2004; Krock et al., 2016), with an optimal dormancy breaking time between 2 to 12 weeks (Jones and Kaye, 2015; Kaur et al., 2016). Krock et al. (2016) investigated ten prairie species and discovered the optimal cold-stratification time below the standard protocol guidelines at eight species, they suggest 15 to 60 days of treatment. In the seed germination database of Hungary, eight of the twelve species involved in our study were pre-treated by cold-stratification of 1 week (Peti et al., 2017). There is a lack of knowledge concerning the relationship of germination ability and establishment of herbaceous plants that are most widely used in vegetation restoration (Carrington, 2014). Species must first be able to germinate to establish (Willis et al., 2014) thus producing seedlings that are prone to further mortality losses. Larson et al. (2015) have disentangled the relative importance of physiological and morphological traits that influence germination and early recruitment success for several species, but the time span of their experiment has not expanded over three weeks. Oliveira et al. (2012) found that the germination ability of single species cannot predict the behaviour in multispecies situations as co-seeding of species with various traits can have adverse results. The early seedling stage is critical under field conditions, given the stochastic nature of early recruitment events and high

DOI: http://dx.doi.org/10.15666/aeer/1504_227239

mortality in the first summer (De Steven, 1991; Oliveira et al., 2012), establishment by the end of the first growing season is an important milestone to predict restoration success (Clarke and Davison, 2004; Kiehl et al., 2014; John et al., 2016). However, little is known on later stages of seeded species. Only few studies have compared early life stage transition and second year field establishment in grassland restoration projects (Kotorová and Lepš, 1999; Clarke and Davison, 2004).

In this study, we attempt to link germination ability to second year field establishment. We analyse twelve grassland species native to the Pannonian ecoregion that are used, among others in a restoration project at a factory site in NE Hungary. The following questions are addressed: 1) For which species is cold-stratification necessary to break dormancy of seeds? 2) Is there a positive correlation between germination and second year establishment?

Materials and methods

Study area

The restoration experiment is located in NE Hungary, in the acidic inland sand dune region of Nyírség (lat 47° 57' N; long 21° 39' E). Annual average temperature is 9.8 ºC, average precipitation is 550-600 mm. The natural vegetation has been mostly transformed by human use, resulting in the loss of natural habitats and the expansion of invasive species (e.g. *Asclepias syriaca, Robinia pseudo-acacia,* Botta-Dukát (2008)). The construction of a new factory enabled us to carry out an experiment with the aim to restore native vegetation at the factory area (approx. 7 ha). Target communities are open (*Festuco vaginatae – Corynephoretum* Aszód (1935), priority habitat: 6260 Pannonic sand steppes (Romão, 1996)) and closed sandy grasslands (*Pulsatillo hungaricae - Festucetum rupicolae* Borhidi (1996)*, Potentillo arenariae – Festucetum pseudovinae* Soó (1940), priority habitat: 6260 Pannonic sand steppes (Romão, 1996)). The site was used as agricultural field, mostly apple orchard prior to the construction. The closest semi-natural dry grassland is 2.5 km far from the factory at a kurgan.

Grassland reintroduction started in 2014 in the form of seeding (with the application of mulch) or hay transfer. Two fescue species were seeded in larger quantities (*Festuca rupicola, F. pseudovina*) as matrix species. Altogether 45 native plant species were introduced in September 2014 as seed in different amount. Seeds originated from different sources including cultivated and wild forms (details in *Table 1*). Here we report on the seedings in two restoration parcels: NW1 seeded by purchased cultivated species and S seeded by collected species. The collected seeds included the self-collected and purchased collected seeds in this study. For the map of restoration area see *Figure 1.*

Studied species

Measurements of all seeded species were not feasible because of the limited amount of seed lots. Therefore, seed mass and germination of twelve native species were investigated in the present study under laboratory conditions and compared with establishment in the field. Principle for species selection was that the sample should represent all three seed origin types (seeds purchased from cultivators, self-collected and purchased collected seeds), grasses and forbs. For further details on the species, please see *Table 1.*

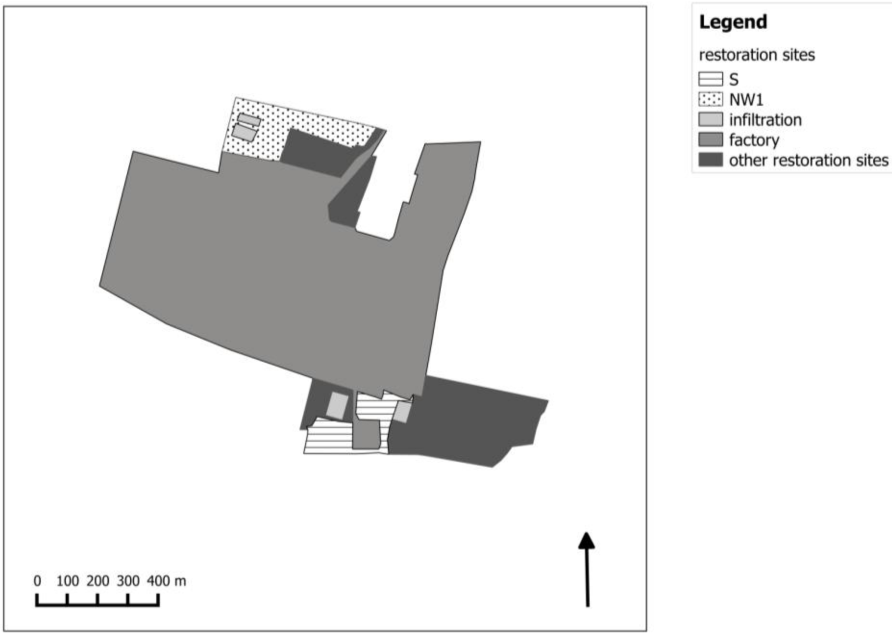

Figure 1. *Map of restoration parcels and treatments within the factory. Establishment of species was estimated in two restoration parcels (named by NW1, S) seeded with 1) cultivated plants (NW1); and 2) collected seeds (S). The collected seeds included the self-collected and purchased collected seeds in this study. In the latter case the amount of hand-collected seeds was not enough to seed the whole parcel, therefore only seven smaller patches were seeded, marked by yellow line. Species list and seeding rates are listed in Table 1.*

Laboratory study

All seeds were harvested in the summer and autumn of 2013 or 2014. Seeds were cleaned and stored at dry conditions (temperature: 25±3 °C, humidity: 38±4%) until the beginning of the germination experiment. All species involved in the study have orthodox seeds, so their long-term viability can be conserved under dry and cool circumstances (Hong and Ellis, 1996). Laboratory tests were carried out on samples from thoroughly mixed, dry seeds. Visibly fertile seed samples of 8 x 100 seeds of each species were counted in January 2015. The dry weight of 100 seeds was measured with 0.0001 g accuracy using an analytical balance. The values of seed mass were calculated as the average of 8 sample results. Laboratory germination of 100 seeds with four replicates per species was tested with and without cold-stratification (Hendry and Grime, 1993; ISTA, 2015). Samples of 100 seeds / Petri-dishes were placed on sterile, wet filter paper. The surface of seeds was not sterilised. Seeds under cold-stratification were placed in refrigerator at 4 °C for a month (Grime et al., 1981; Hendry and Grime, 1993; ISTA, 2015). Seeds without cold-stratification and after cold-stratification were kept under room condition (temperature: 25±3 °C, humidity: 38±4%, light: 3051±939 Lux). The germination experiment started in February 2015 (without cold-stratification), and in March 2015 (with cold-stratification). Seeds were watered by 1-2 ml distilled water every 1-2 days. Germination was defined as emergence of the radicle. The germinated seeds were counted weekly for four months and removed from Petri-dishes.

Field study

Second year field establishment was estimated in June 2016 in the two restoration parcels (*Figure 1*). Five randomly placed 2 m x 2 m coenological plots per parcel were surveyed by visual estimation of cover (%) by species. In case of species sown into patches, establishment estimation was made by population cover estimation within whole patches. As sowing densities (seed/m^2, *Table 1*) differed between species, according to the availability of seeds, field establishment was calculated as the second-year cover weighted by sowing densities.

Table 1. *List of studied species with origin of seed samples and sowing densities. Seeds were collected in 2013 or 2014 and seeded in September 2014. Origin of seeds: P- seeds purchased from cultivators; CP – purchased collected seeds; CS- self-collected seeds.*

Species	Family names	Origin of seeds	Sowing densities in the field (seed/m2)
Achillea collina Becker ex Rchb.	Asteraceae	CS	2534
Corynephorus canescens (L.) P.Beauv.	Poaceae	CS	123
Festuca pseudovina Hack.	Poaceae	P	7631
Festuca rupicola Heuff.	Poaceae	CP	19496
Festuca vaginata Waldst. et Kit. ex Willd.	Poaceae	CS	28
Galium verum L.	Rubiaceae	P	147
Jasione montana L.	Campanulaceae	CS	323
Poa angustifolia L.	Poaceae	CS	4
Salvia nemorosa L.	Lamiaceae	P	175
Salvia pratensis L.	Lamiaceae	P	63
Securigera varia (L.) Lassen	Fabaceae	P	18
Silene vulgaris (Moench) Garcke	Caryophyllaceae	P	122

Data analysis

Linear model was used to assess the effect of species and cold treatment (explanatory variables) on germination percentage (response variable). Germination percentage was estimated based on four replicates of 100 seeds. This data fulfilled the assumptions of normality. Model residuals showed heterogeneity of variances, therefore generalized least squares (GLS) linear model (Zuur et al., 2009) was used by using the *nlme* package (Pinheiro et al., 2016) with varIdent variance structure that allowed for different residual spread for each level of the species variable. Finally, *contrast* package based on Wald test was used as post hoc test to prove for cold-stratification the significant differences within species (Kuhn et al., 2013).

The impact of seed germination with or without cold-stratification (explanatory variables) on field establishment (response variable) was analysed by two separate generalized linear models (GLMs) with Gaussian distribution and identity link function (Zuur et al., 2009). Average values of germination percentage per species were used. Field establishment was square root transformed before analyses to fulfil the assumptions of normality and homoscedasticity. All analyses were carried out in the R 3.3.1 statistical environment (R Core Team, 2016).

Results

Seed mass was very different among species. From the studied forbs *Jasione montana* had the lowest (0.0155 g), and *Securigera varia (*4.0269 g) had the highest seed mass. As for the grasses, *Corynephorus canescens* had the smallest (0.0544 g) and *Festuca vaginata* had the largest seeds (0.5546 g) (*Table 2*).

Table 2. *Seed mass, laboratory germination of studied species with or without cold-stratification based on 4x100 seeds and field coverage in 2016 (% of total cover in the sampled plots and patches). Mean seed mass is expressed as thousand seed weight in g (based on 8x100 seeds).*

Species	Seed mass (mean ±SE, g)	Germination with cold-stratification mean±SE (%)	Germination without cold-stratification mean±SE (%)	Field coverage (%)
Achillea collina	0.0727±0.0024	71±2	70±4	1
Corynephorus canescens	0.0544±0.0035	18±2	41±2	0
Festuca pseudovina	0.3931±0.0039	91±1	95±1	47
Festuca rupicola	0.1539±0.0027	40±1	63±4	29
Festuca vaginata	0.5546±0.0102	64±2	78±3	0.02
Galium verum	0.2991±0.0070	6±1	9±2	0
Jasione montana	0.0155±0.0003	79±1	75±8	0.03
Poa angustifolia	0.1939±0.0094	35±3	30±3	0.01
Salvia nemorosa	0.6277±0.0098	1±0	1±1	0.01
Salvia pratensis	1.7581±0.0741	25±5	16±1	0
Securigera varia	4.0269±0.0615	49±3	48±4	0.01
Silene vulgaris	0.5966±0.0200	94±1	89±1	0.51

All species germinated under laboratory conditions, but germination greatly differed (*Table 2*). The highest germination percentages (exceeding 90%) were found for *F. pseudovina* and *Silene vulgaris* both with and without cold-stratification. *Salvia nemorosa* and *Galium verum* germinated in very low numbers (1-9%) under both conditions. Significant interaction was detected between cold stratification and species ($F=13.04$, $df=11$, $p < 0.05$) (*Table 3*).

Table 3. *Effect of cold-stratification and species on germination percentage. Df, F and p values are the result of GLS model. Significant differences are given at p<0.05.*

Explanatory variables	df	F-value	p-value
Cold-stratification	1	7.54	<0.05
Species	11	1869.76	<0.05
Cold-stratification x species	11	13.04	<0.05

The results of post hoc test showed significant response to cold-stratification for five species. Cold-stratification decreased the germination success of four grass species significantly: *Corynephorus canescens, Festuca pseudovina, F. rupicola* and *F. vaginata*. Only one forb species, *Silene vulgaris* germinated better after the cold-stratification (*Table 4*).

Table 4. *Effect of cold-stratification within species. Df, F and p values are the results of post hoc test, based on Wald test. Significant differences are given at p<0.05, not significant results are marked by n.s.*

Species	t-value	df	p-value
Achillea collina	0.31	72	n.s.
Corynephorus canescens	-8.91	72	<0.05
Festuca pseudovina	-2.39	72	<0.05
Festuca rupicola	-5.45	72	<0.05
Festuca vaginata	-4.06	72	<0.05
Galium verum	-1.30	72	n.s.
Jasione montana	0.48	72	n.s.
Poa angustifolia	1.21	72	n.s.
Salvia nemorosa	-0.31	72	n.s.
Salvia pratensis	1.55	72	n.s.
Securigera varia	0.25	72	n.s.
Silene vulgaris	3.69	72	<0.05

Only nine species of twelve established in the restoration sites by the second year (*Table 2*). The highest plant cover was found for *Festuca pseudovina* (47 %) and *F. rupicola* (29 %). *Corynephorus canescens, Galium verum* and *Salvia pratensis* were not established in the restoration sites. Significant positive relationship was detected between field establishment and both laboratory germination (F=8.52, df=1, p<0.05 and F=7.74, df=1, p<0.05) with and without cold-stratification *(Figure 2*).

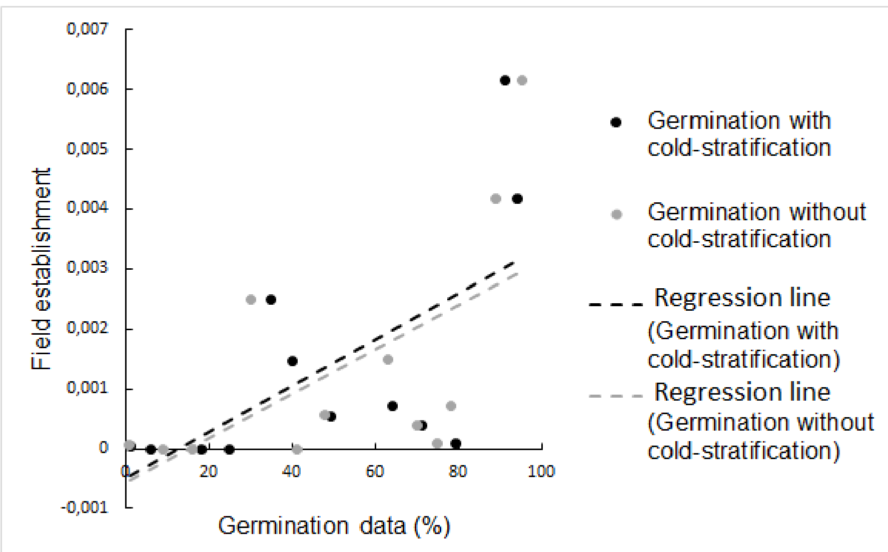

Figure 2. *Relationship between second year field establishment and laboratory germination with / without cold-stratification. Germination was based on 4x100 seeds, field establishment was defined by species cover (%) weighted by seeding rate. Establishment and laboratory germination with cold-stratification (marked by black) and laboratory germination without cold-stratification (marked by gray).*

Discussion

Importance of cold-stratification for germination

The most broadly used and simplest technique for breaking physiological seed dormancy for native species is pre-chilling, or cold-stratification (Baskin and Baskin, 2004; Russell, 2011; Haslgrübler et al., 2013; Jones and Kaye, 2015). Cold-stratification increased germination potential for only one of twelve studied species in this study. The results are in accordance with literature results concerning grasses that do not require cold-stratification for germination (Partzsch, 2010; Russell, 2011; Hardegree et al., 2013, 2016) since they emerge in autumn (Stampfli and Zeiter, 2008). We found even lower germination percentages with cold-stratification than without cold-stratification for four studied grass species. Forbs respond more variably and may require cold-stratification (Jones and Kaye, 2015; Wang et al., 2016). However, in our study, out of seven forb species we found only one (*Silene vulgaris*) germinating better after cold-stratification. *Silene vulgaris* generally does not require cold-stratification (Liu et al., 2008; Partzsch, 2011), only HUSEED wild database (Peti et al., 2017) supported our contrasting results. The reason might be the different behaviour of different seed samples, as found for *Eriophyllum lanatum* by Russell (2011). In summary, we identified one forb species that need cold-stratification, but most of the studied species did not positively react to this treatment. Other dormancy breaking methods (e.g. mechanical or chemical scarification) should be tested for species with very low germination percentage, like *Galium verum* or *Salvia nemorosa* (Liu et al., 2008; Peti et al., 2017). *G. verum* showed higher germination percentage measured by the Pannon Seed Bank (66% avg. compared to 6-9 % in this study, Peti et al. (2017)), 11 % of *S. nemorosa* seeds germinated compared to 1% in our case, both species after one week of cold treatment. The difference in one order of magnitude can originate from regional differences in population variability. *Salvia* species often require gibberellic acid to break dormancy (Liu et al., 2008).

Germination and second year field establishment

As in previous studies (Clarke and Davidson, 2004; Oliveira et al., 2012; Gallagher and Wagenius, 2016), germination was higher under controlled laboratory conditions than under field conditions. This seems self-explanatory, as field conditions imply further constraints that jeopardize establishment ability. Germinated seeds in the field are challenged by abiotic (drought, inappropriate soil conditions (Leishman, 1999; Clarke and Davidson, 2004; Stampfli and Zeiter, 2008; Carrington, 2014) and biotic (competition with existing species (Leishman, 1999; Clarke and Davidson, 2004; Carrington, 2014; Oliveira et al., 2014), allelopathy or the lack of mycorrhizae (Maltz and Treseder, 2015; Koziol and Bever, 2016) factors to develop further and establish.

Laboratory germination with and without cold-stratification was found to be positively connected with second year field plant establishment in this study. This means that the capacity of seeds to germinate has a long-lasting effect on species establishment. Germination success is dependent among others, on seed age, origin, moisture content, and storage conditions (Mondoni et al., 2013), whereas survival in the field can depend on sowing density, timing and seedling characteristics of co-seeded species (Oliveira et al., 2014). Although seeds were sown in the field prior to winter, when moisture and low temperature conditions are most favourable for germination (Commander et al., 2009),

DOI: http://dx.doi.org/10.15666/aeer/1504_227239

only four species were well established (field coverage > 0.5 %), contrary to laboratory results with seven species over 40% of germination success. Studied species, sown in high density were more successful, than others. *Festuca pseudovina* germinated and survived best in the study. This species is a matrix forming grass of closed sand steppe adapted to grazing, and the seeds used for restoration originated from cultivation. Perennial grasses were found to establish better also in other studies compared to forbs (Clarke and Davison, 2004). However, the other tested fescue species (*F. rupicola, F. vaginata*) performed much worse than *F. pseudovina,* and the grey hair-grass (*Corynephorus canescens*) was not even detected in the field. This suggests that other constrains emerged that might be related to e.g. seed origin, collection time, soil requirements or competition. Based on this the choice of dominant grass species for restoration purposes is a major challenge (Gallagher and Wagenius, 2016).

Only three species out of twelve failed to establish or survive till the second year of restoration and five species reached higher cover than 0.5 %. In high diversity mixtures Oliveira and co-workers (2014) found single species being more successful to germinate, establish and grow in the field compared to species mixtures. The performance of target species included in seed mixtures was usually drastically impaired. The unsatisfactory establishment in case of *Galium verum, Salvia nemorosa, S. pratensis* and *Securigera varia,* can be explained in part by the special requirements of seeds for breaking dormancy as explained earlier. On the other hand, traits enabling for fast-growing and competitive advantage of dominant species can supress slow growing species and hinder long-term diversity (García-Palacios et al., 2010). Therefore, we suggest using a matrix of grass species (in this case *Festuca pseudovina* and *F. rupicola*) for the restoration of dry grasslands diversified with a number of non-competitive forbs.

Conclusions and recommendations

Germination performance is usually higher in the laboratory than under field conditions (Oliveira et al., 2012), where environmental conditions (both abiotic and biotic) result in lower germination and establishment. Despite environmental limitation, germination percentage in the laboratory and establishment in the field was found to be correlated in this study. This supports the view that laboratory tests of germination or existing germination databases have the potential to help predict establishment success of selected species.

This study provides results to help unfold the relative importance of germination capabilities of species in determining restoration success, as suggested by Larson et al. (2015), but stepping further by measuring second year establishment in the field. Laboratory germination trials are important to understand and predict the processes in the field (Commander et al., 2009). Germination tests can also help estimate the required seed input. During restoration projects seed introduction of several species occur, but the time and available seed quantities represent constrains for testing the germination capability of all sown species. We suggest carrying out quick laboratory germination tests of dominant species to help identify seeding intensity in restoration programmes. Performance of species with low germination result in the laboratory is very hard to predict in the field. In such cases, we can only remain with the general approach to seed higher amounts in the hope of success, unless further knowledge on dormancy is gained to support decision making in order to cope with future needs (Broadhurst et al., 2016).

LOW ABUNDANCE OF THE WHISKERED BAT *MYOTIS MYSTACINUS* (KUHL, 1817) IN POLAND – CONSEQUENCE OF COMPETITION WITH PIPISTRELLE BATS?

Abstract. Interspecific competition is an important factor influencing the distribution of animals, including bats. In this study we tested if the presence of pipistrelles *Pipistrellus* sp. affects the distribution of the whiskered bat *Myotis mystacinus* using information about the species structure of bat communities obtained by capturing with mist nets in whole Poland. Abundance of the whiskered bat is low (on average 3.1%), and it only occurs frequently in the western part of the Carpathian Mountains (24.5%). The negative correlation between the abundance of the whiskered bat and pipistrelles (especially *P. nathusii* and *P. pipistrellus*) in bat communities across Poland seems to support the hypothesis that its occurrence is shaped by competitive interactions.
Keywords: *bat distribution, species range, mountains, sympatric bats, species coexistence*

Introduction

The whiskered bat *Myotis mystacinus* (Kuhl, 1817) has an extensive range in Europe that covers almost the entire continent (Dietz et al., 2009; Benda et al., 2016; Sachanowicz et al., 2016). However, there is no certainty about the eastern boundary of its occurrence due to the difficulty in distinguishing it from the steppe whiskered bat *Myotis aurascens* Kuzyakin, 1935 (Hutson et al., 2008). In Poland, the whiskered bat is widespread throughout the country (Sachanowicz et al., 2006). However its abudance seems to be unequal, with some areas lacking the species (Sachanowicz et al., 2006a) and other regions dominated by them (Piksa, 2011).

Presence of the whiskered bat can be affected by interspecific competition with pipistrelles *Pipistrellus* sp. (Baagøe, 1973). Such processes are key factors shaping the distribution patterns of organisms, as ecologically analogous species sharing a niche cannot occur in the same area (Gause, 1934). This results in the exclusion of one of the competing species (Hardin, 1960), which influences the structure of communities. Interspecific competition is an important factor influencing the distribution of mammals (Ylönen, 1990; Letchter et al., 1994; Eccard and Ylönen, 2003; Bonesi et al., 2006); however it has rarely been considered during the assessment of bat ranges (Arlettaz et al., 2000; Delaval et al., 2005; Santos et al., 2014; Zeus et al., 2017).

In this paper, we attempted to validate the predictions of Baagøe (1973) by comparing the distribution of the whiskered bat with that of pipistrelle species in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_241248

Poland. Our null hypothesis was that the whiskered bat is more abundant in areas where pipistrells are rare or absent.

Material and Methods

To assess the current occurrence of the whiskered bat in Poland we used information on the species structure of bat communities obtained by capturing with mist nets. We analysed both data published since 1997 and our unpublished data from studies conducted since 2000. Initially, we obtained data from 42 locations distributed across the whole of Poland (*Table 1*), and for further analysis we divided these locations into three groups: locations where (1) whiskered bats were not caught, (2) the total contribution of the species accounted for less than 10%, and (3) locations where the whiskered bat accounted for over 10% of all caught individuals. Statistical analyses were performed in R (R Development Core Team, 2009).

Results

The whiskered bat was the most abundant bat species found in southern Poland, and it was most common in the western part of the Carpathian Mountains (*Fig. 1*, *Table 1*) where its average share in bat communities was 24.5% (SE±7.0). In the remaining areas it was rather rare (Welch t-test, t=−3.0315, df=5.059, p<0.05), with its average share in bat communities only 3.1% (SE±0.5).

The abundance of the whiskered bat in Poland was negatively correlated with abudance of pipistrelle species, especially *P. nathusii* and *P. pipistrellus* (*Table 2*).

Table 2. *Spearman's correlation coefficient (Rho) for the percentage of whiskered bats (Myotis mystacinus) in combination with pipistrelles (considered collectively by each species or group of species) in the cohorts of trapped bats in Poland. The table shows the value of the test statistic (S), statistically significant correlation (p-value), and sample size (N).*

Myotis mystacinus in combination with:	Rho	S	p-value	N
Pipistrellus sp.	− 0.589	14519.28	p<0.001	38
P. nathusii	− 0.551	12055.46	p<0.001	36
P. pipistrellus s.l.	− 0.396	9135.34	p<0.05	34
P. pipistrellus s.s.	−0.408	4613.76	p<0.05	27
P. pygmaeus	−0.263	3694.32	ns	26

Disccussion

The observed pattern of whiskered bat abundances in Poland could be explained by their selection for mountainous habitats or intraspecific competition. A factor that may limit the occurrence of the whiskered bat in Poland is the wintering ecology of the species. Whiskered bats hibernate in a fairly broad spectrum of caves; however, they prefers caves located between 1,000 and 1,930 m above sea level (Piksa et al., 2013). Thus, the main wintering grounds of this species can be found at higher altitudes on mountains, where in a study by Piksa et al. (2013), bats from *M. mystacinus* complex group (species are usually impossible to distinguish during winter counts, although the community is probably dominated by the whiskered bat) accounted for 88.5%. The whiskered bat is a species that does not migrate and only undertakes relatively short flights up to a distance of 165 km (Hutterer et al., 2005). Thus, limited abilities for long-distance migration may also limit the distribution and abundance of the species to around the most suitable hibernaculas.

Nethertheless, the presence of mountains alone does not seem to be the most important factor shaping their distribution. Reproducing females were recorded in the lowlands, and the species roosts mainly in anthropogenic shelters and utilizes feeding grounds located primarily in woodlands scattered across agricultural lands (Buckley et al., 2012; Kurek, 2014), which are common in the lowlands. Furthermore, the wide range of the whiskered bat in Europe, which reaches the northern edges of the continent (Hutson et al., 2008), shows that this is a not thermophilic species restricted to the southern and central, i.e. warmer, parts of the continent.

Antagonistic interactions between species most likely explain the observed pattern of whiskered bat distribution in Poland. Gerell (1987), by analysing the density of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_241248

distribution of Brandt's and whiskered bats in northern Europe, suggested that the distribution of these two species is the result of competitive interactions with the common pipistrelle *Pipistrellus pipistrellus* (Schreber, 1774). Our analyses confirmed the constraining effects of at least two pipistrelle species (Nathusius's and common pipistrelle) on whiskered bats. In areas where whiskered bats were captured in large numbers, pipistrelles were not observed at all or were scarce. In addition, pipistrelles were found in these regions beyond the reproductive period (Piksa et al., 2011; Kurek, 2014), which suggests that they were migrating individuals. In other areas, pipistrelle bats are a stable part of the bat fauna (Sachanowicz et al., 2006). Both the whiskered bat and pipistrelles show a preference for similar foraging areas and shelters of anthropogenic origin (Dietz et al., 2009; Buckley et al., 2012; Kurek, 2014), and competition for such resources could be a major factor for the push-out of a significant part of the whiskered bat population to more hostile mountainous areas.

We are aware that the analysis of bat communities based solely on the results of mist-netting could be biased due to a number of factors, including the size and placement of nets, and the frequency at which investigators check the nets (Kunz et al., 2009). Nonetheless, we believe that the potential bias was minimized by using data from numerous studies conducted across the whole country, which includes the repeated sampling of targeted regions, utilization of a variety of netting sites, and use of variable net-sets as suggested by Larsen et al. (2007). Another source of bias may be the use of data obtained during swarming. Places where this phenomenon occurs are called 'hot spots', and during mist-netting researchers capture bats that are not necessarily resident in that given area (Fenton, 1969; Kerth et al., 2003; Bogdanowicz et al., 2012). However, taking into account only catches made in potential feeding grounds, the share of whiskered bats in the southern regions of the country is still estimated to be over 10% (*Table 1*), which supports our findings that the western Carpathians are the main area in Poland where whiskered bats occur.

(Received 31st Mar 2017; accepted 19th May 2017)

Abstract. This study aimed to evaluate the impact of surfactant on herbicide efficiency in *Medicago sativa* L. fields. To this end, a randomized complete block design with 10 treatments and 4 replications was used in three and four-year alfalfa fields, infested with different weeds. The treatments included the standard dose and a 20% reduced dose, a combined treatment and a control sample (weeding and no weed control). Combination of the treatments was applied along with cytogate, and included mixtures of imazethapyr and bentazon, bentazon and pyridate, and imazethapyr and pyridate, with 50% reduced dose of each herbicide. Generally, herbicides applied along with the cytogate surfactant were more efficient for weed control, as well as for an increase of the product yields, as imazethapyr herbicide along with cytogate surfactant managed to control weeds for a rate of 87.43% and increase the product yields to 93.54%. Results showed that combination of herbicides can also be useful in controlling weeds in alfalfa fields and increasing product yields. Results also revealed that combination of bentazon and imazethapyr increased product yields to 94.47% and controlled weeds for a rate of 90.19%. In addition, this method can be proposed as a means to prevent or delay probable resistance to herbicides.
Keywords: *imazethapyr, bentazon, pyridate, reduced dose, surfactant*

Introduction

Alfalfa as a forage crop constitutes the largest area of planting in the world (Lanini et al., 1991; 1999) as Iran (Raoofi and Giti, 2015), and it plays an important role in feeding livestock due to its high protein content (Khanjani and SoleimaniPari, 2005). More than 25% of the dry weight of alfalfa consists of fiber (Meighan et al., 2011).

Unfortunately, particular attention has not been paid to the production of this plant in Iran (Raoofi and Giti, 2015; Raoofi et al., 2013c). One of the challenges of alfalfa production is the presence of weeds (Meighani et al., 2011; Raoofi et al., 2013b). Alfalfa are particularly susceptible to weed competition because they are not vigorous competitors and weeds emerging shortly after seeding can reduce alfalfa success (Zimdahl, 2004).

Weed interference can suppress alfalfa yield (Moyer, 1985; Wilson, 1981) and impact stand densities (Becker et al., 1998). Weeds also alter the composition of the forage, increasing drying time (Doll, 1984) and reducing palatability of the alfalfa (Marten et al., 1987). Generally, weeds will cause severe competition with the crop. In addition to competition with the alfalfa, weed cause a reduction in the quality and quantity of alfalfa and decrease the price by 33% to 60% (Khanjani and SoleimaniPari, 2005; Khanjani, 2000). Similar reduction of alfalfa density due to weeds has been shown by Wilson and Burgener (2009) and Bradley et al. (2010) who reported a 20–

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_249265

30% reduced alfalfa density through weed interference. Temme et al. (1979) found that weeds primarily were responsible for decreasing the quality of alfalfa. Frequently, weeds are comparable to alfalfa in quality; however, nutritive quality rapidly declines in weeds as they mature (Doll, 1986). Alfalfa seedlings are particularly susceptible to weed competition because they are not vigorous competitors and weeds emerging shortly after seeding can reduce alfalfa success (Fischer et al., 1988; Zimdahl, 2004). As with any crop, weed competition can reduce yields. Higher alfalfa seeding rate often resulted in greater alfalfa and total forage yield, decreased weed biomass, and increased alfalfa density (Calvin et al., 2011). Weeds interfere with alfalfa during establishment, reducing dry matter yields and plant persistence by competing for light, water, and nutrients (Fischer et al., 1988; Wolfe and Southwood, 1980; Raoofi et al., 2013d). The most damage by weeds in an alfalfa field occurs in the first harvest (Zand et al., 2010; Giti et al., 2013b), however, weeds in many areas, including Hamadan, damage all harvests (Raoofi et al., 2014b). Weed control is often accomplished by using herbicides in alfalfa fields (Myhre et al., 1998). Six herbicides are recommended for using in alfalfa (Zand et al., 2007). Effective use of herbicides is related to several factors, such as time of application, dosage, environmental conditions, method of use, desired plant, frequency of use, etc. Among the techniques to improve the performance of herbicides, use of mixed herbicides, use of integrated methods, none continuous use of one or more herbicides with the same mode of action, use of herbicides with the standard dosage at the right time, and use of additives to improve the performance of herbicides could be named.

Unfortunately, over the past few years, there have been no considerable researches on additives and the context of their use has not been provided practically by farmers. Consequently, only three additives have been recorded by the Pesticides Supervision Board in Iran.

Several herbicides are commonly used in alfalfa. Broadleaf weeds, such as thistles and Brassicaceae, are controlled with 2,4-DB. Flumetsulam and chlorimuron have also been recommended for controlling burning nettle, swinecress, and common chickweed, which are not controlled by 2,4-DB (Lopez and Romera, 1993; Tonks et al., 1991). Imazethapyr is registered for use in alfalfa and non-grazed Conservation Reserve Program lands containing legumes and forage grasses (Anonymous, 2006b). Imazethapyr reduced growth of orchardgrass when applied at the seedling stage and at first cutting (Curran et al., 1999). Paraquat applied during crop dormancy controls many emerged winter annual weeds in alfalfa (Wilson, 1997). These herbicides are safe for alfalfa, but the literature lacks published information on their safety for Dactylis glomerata. In pure orchardgrass (*Dactylis glomerata*), selective herbicides including 2, 4-D, clopyralid, and metsulfuron effectively control broadleaf weeds, but these herbicides cause unacceptable injury to alfalfa (Bradley et al., 2004).

Integrated weed management (IWM) is a combination of effective control methods, which reduces the weed interference to below the economic threshold (Thill et al., 1991). IWM often requires a minimum amount of herbicides (Zand et al., 2009). Evaluation of the impacts of herbicides on the environment is a necessity due to their harmful effects (Campagna, 1995). Unfortunately, the scientific application of herbicides, along with surfactants and their safety has not been studied enough to reduce the use of herbicides. The role of surfactants application were investigated by various researchers (Asmus et al., 2016; Chen et al., 2015). The interaction between the hydrophilic and lipophilic segments of adjuvants for the purpose of increasing the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_249265

efficiency of herbicides has attracted the interest of the relevant researchers (Hall et al., 1999) and remarkable successes have been achieved in application of adjuvants for controlling pests in numerous experiments since 2002 (Zand et al., 2012). This study investigated the use of herbicides with a reduced dosage, along with a cytogate surfactant, and a combination of two herbicides with a 50% reduction of dosage for each herbicide, in addition to the evaluation of weed control and forage production.

Materials and Methods

This experiment was conducted using a randomized complete block design in three and four-year alfalfa fields to investigate the application of chemical treatments with the standard and/or reduced doses (with and without the use of a cytogate surfactant) The study was conducted during two growing seasons of the spring and summer of 2012 and 2013, respectively. Farm under investigation, located at Km 7 Hamadan-Tehran road at latitude of 34° 51' N and longitude 48° 32' E.

Each plot consisted of ten rows with a distance of 25 cm and a length of 4 meters. The distance between the two plots was 60 cm and the distance between the two blocks was 130 cm. For proper evaluation, before performing treatments and concurrent with identifying plots and blocks, three fixed quadrants were installed, each with an area of one square meter per plot.

The design included the treatments with standard and reduced doses (20%), combination treatments and a control plot (complete weeding and no weeding). The treatments were applied in two levels: the standard treatment and reduced doses with the use of a cytogate surfactant. The combination treatments consisted of a mixture of the herbicide treatment with a reduced dose of each herbicide (50%).

The treatment included the use of Pursuit, Basagran and Lentagran herbicides as follows: Pursuit herbicide (0.4 l/hectare) along with cytogate surfactant (0.32 l/hectare), Basagran herbicide (3 l/hectare) along with cytogate surfactant (2.4 l/hectare) and Lentagran herbicide (3 l/hectare) along with cytogate surfactant (2.4 l/hectare). The combination treatments were prepared as a mixture of Pursuit and Basagran herbicides, Basagran and Lentagran herbicides, and Pursuit and Lentagran herbicides, in which a 50% reduced dose of each herbicide was used. In both years of the study, after a 50% flowering in each harvest, sampling took place to determine the weight of the alfalfa, as well as density and dry weight of weeds in a 50 × 50 m quadrat. The dry weight of alfalfa and weeds was determined after placing the alfalfa and weed samples in the oven at 70°C for 48 hours. Statistical analysis software (SAS) v. 9.1 was used for analysis all data, and the obtained averages were compared by means of the LSD least significant difference test.

Results

In the study of two cuttings of established alfalfa, the following weeds were observed and identified, and their distribution levels and importance are as follows, corresponding with the findings of Khanjani and SoleimaniPari (2005) and Raoofi and Giti (2015) (*Table 1*). Environmental condition of the test site are expressed in *Table 2*, and chemical analysis of farm's soil under investigation in the *Table 3*.

In this two-year field study, the following weeds were identified in high-density fractions: normal flixweed (*Descarainia sophia* L.), sorrel (*Rumex crispus* L.), bitter flixweed (*Sisimbrium irio* L.), dandelion (*Taraxacum officinalis*) and salsify (*Tragopogon* spp.). These weeds function as the main weeds in alfalfa fields. The effect of the treatments on weed density in all the four of the alfalfa harvests was significant at

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_249265

a level of 1% (*Table 4*). The comparison of the average of the treatments with the density of five identified weeds in the first harvest (*Table 5*) showed that the reduced treatment with cytogate and also, the integrated Pursuit and Basagran treatment had the best weed control on bitter flixweed. These results were also consistent with the results of Raoofi and Giti (2015). Normal flixweed was significantly controlled by the use of Pursuit treatments in standard doses, reduced dose of Pursuit along with cytogate, reduced dose of Basagran along with cytogate and combination of Basagran and Pursuit with a 50% reduced dose. It was found that the cytogate consumption as a good surfactant could increase the efficiency of herbicides and decrease their consumption down to 20%. The use of two herbicides, in combination with cytogate, delays the resistance to herbicides in weeds, and therefore, it is highly recommended, since one most important issue regarding herbicide use is cross and multiple resistance (Zand and Baghestani, 2002).

In the investigation of sorrel control in the first harvest, the Pursuit treatments with the standard and reduced doses along with cytogate and also, Pursuit combined with Basagran were analyzed and included in the group with the lowest density of sorrel. Also, in the first harvest, salsify was affected by the Pursuit treatment with the standard dose and had the lowest density. The first harvest of dandelion had the greatest impact from the treatment with a reduced dose of Pursuit along with cytogate and treatment with a combination of Pursuit and Basagran. Raoofi et al. (2013a) also stated that Pursuit along with cytogate is one of the best treatments for broadleaf weed control and can significantly reduce dandelion density. Moreover, Raoofi et al. (2014a) stated that surfactant consumption can significantly reduce the amount of pesticides. Researchers including Ozkan et al. (1993) have evaluated the effects of adjuvants on the performance of pesticide sprays. Some studies have shown that a number of polymers enjoy the ability of breaking down after leaving the sprayer pump in the same way that this process takes place in the return action through the lateral route or hydraulic mixers in ordinary sprayers (Zhu et al., 1997). Comparison of the treatment results in the second harvest (*Table 5*) showed that the best option to control bitter flixweed was the same as the option in the first harvest. The only difference was that the reduced dose of Basagran and accompanying cytogate, the Pursuit and accompanying cytogate treatment and a reduced dose of the combined Pursuit-Basagran were all placed in the same statistical group. These results point to the possibility of reducing the dose of herbicide. Gressel and Segel (1990a, 1990b) also emphasized reducing the use of this herbicide to 0.1 in the standard dose along with the cytogate surfactant. The results of the second harvest and control of normal flixweed were fully compatible with the first harvest. Sorrel, in the second harvest, had the largest decline using the Pursuit treatment with standard and reduced doses along with cytogate, and also the reduced dose of Basagran with cytogate and the Pursuit and Basagran combination. Investigation of the salsify weed density in the second harvest revealed that both the reduced doses of Pursuit and Basagran with cytogate surfactant along with the Pursuit-Basagran combination treatment were placed in the same group. The results of the second harvest for dandelion were fully in accordance with the first harvest results. It was found that the weed density in the second harvest had an exponential decline compared to the first harvest, but the presence of weeds was still evident in the second harvest. It should be noted that the decline of normal and bitter flixweed in the second harvest could have been related to the first harvest due to the cutting of their roots.

One of the non-chemical methods of weed control mentioned by Khanjani and SoleimaniPari (2005) is root cutting in the alfalfa field. According to the literature, there is no e investigation on sensitivity, tolerance or resistance of weeds to root cutting, except for grass at different growth stages (McCarthy et al., 2001). Thus, this study should be replicated on other weeds. The harvesting of alfalfa causes root cutting of the flixweed and thus, can be very effective in reducing flixweed density.

Alternation and repetition of eradication techniques, along with actions such as application of herbicides can increase the effectiveness of weed control. Accordingly, Ghorbani et al. (2009) stated that harvesting and eradicating accompanied with chemical pesticides improve the ability to control weeds. The two weed types, bitter and normal flixweed, were obviously reduced in the third harvest compared to the first and second harvest; however, some weeds still remained on the farm.

The results obtained from the third harvest conformed to the two previous harvests and revealed the favorable effect of the Pursuit and accompanying cytogate treatment. In fact, the controlling effect of the Pursuit and accompanying cytogate treatment was observed even after the study period. Comparison of the means of the experimental treatments on normal flixweed in the third harvest showed that the three Lentagran treatments with standard dose, Pursuit and Basagran with reduced dose and accompanying cytogate were placed in the same statistical group. Pursuit treatments with standard dose, Pursuit with reduced dose and accompanying cytogate and Basagran with reduced dose and accompanying cytogate, were the best and most successful treatments for sorrel weed control in the third harvest. The best treatments for salsify weed control in the third harvest were treatments with reduced herbicide dose, so that both Pursuit and Basagran treatments with reduced dose and accompanying cytogate had the greatest impact and were located in the same statistical group. Also, the reduced dose of Pursuit and accompanying cytogate consumption had a highly positive effect on controlling the dandelion weed in the third harvest (*Table 6*). This treatment also acted favorably in controlling dandelion in the first and second harvests. The study results were also in conformity with Beckie and Morrison's (1993) results and revealed that the reduced doses can be used in weed management if another agent compensates for such dose reduction. Application of Cytogate as an adjuvant in the chemical control of weeds on Alfalfa (*Medicago sativa* L.) has been evaluated before, and its synergistic effects have been confirmed (Raoofi and Giti, 2015; Giti et al., 2013b).

The results obtained from comparison of the means of the treatments in the fourth harvest (*Table 6*) showed that the best options for bitter flixweed control were Pursuit and Basagran treatments, both with a reduced dose and accompanying cytogate. Also, Lentagran treatment with the standard dose, as well as Pursuit and Basagran both with a reduced dose and accompanying cytogate were the best options for normal flixweed control. It should be noted that the problem of bitter and normal flixweed in the fourth harvest was almost insignificant and negligible. Existence of so little density of bitter and normal flixweed in the fourth harvest has been proven by Raoofi and Giti (2012), Khanjani and SoleimaniPari (2005) and Giti et al. (2013a). In a study on the density of these two weeds from the first harvest to the fourth, it was observed that, in the fourth harvest, the weed problem

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_249265

was nearly resolved and thus, there was little density of the two weeds in the control (no weeding). The density reduction in the two weeds can be related to eradication of these two weeds resulted from each harvest and passage of the growing season for the weeds, as well as the application of the experimental treatments. The Pursuit treatment accompanied with cytogate in the fourth harvest was introduced as the best option to control sorrel and dandelion weeds. Also, consumption of Basagran with a reduced dose and accompanying cytogate surfactant could transcend the other treatments to control the salsify weed in the fourth harvest.

The results obtained from variance analysis related to the dry weight of weeds showed that all the applied experimental treatments were statistically significant at the level of 1% in all the four harvests (*Table 4*). The results of the comparison of the means of dry weight in the first harvest, considering separated species, *Table 7* showed that the best choice for reducing the dry weight of bitter flixweed was the Pursuit treatment with reduced dose along with cytogate, as well asthe combination treatment of Pursuit and Basagran. Also, Pursuit with reduced dose along with cytogate caused the lowest dry weight of normal flixweed in the first harvest. Investigating the dry weight of sorrel in the first harvest, Pursuit and Basagran treatments, both with reduced dose along with cytogate, and also the combination treatment of Pursuit and Basagran were all in the same statistical group, and were the best treatments for reducing the dry weight of this weed. Pursuit treatment with reduced dose along with cytogate and the combination treatment of Pursuit and Basagran in the fourth harvest were in the same statistical group containing the lowest dry weight of salsify. The Pursuit treatment with reduced dose accompanied with cytogate consumption was the best option to reduce the dry weight of dandelion in the first harvest. Raoofi and Giti (2015) have also recommended these treatments for reducing the weed dry weight.

The results obtained from comparison of the means of the dry weight characteristic in the second harvest, considering separated species, (*Table 7*) showed that the best options for reducing the dry weight of bitter flixweed were the Pursuit and Basagran treatments, both with reduced dose and accompanying cytogate. The combined treatment of Pursuit and Basagran was placed in the same statistical group. The obtained results showed that no antagonistic effects were observed as a result of the combination of the two above-mentioned herbicides. The Pursuit treatment with standard dose and reduced dose accompanied with cytogate along with the Basagran treatment with reduced dose accompanied with cytogate caused the lowest dry weight of normal flixweed (*Table 7*). Investigating the dry weight of sorrel in the second harvest, Pursuit and Basagran treatments with standard dose and Pursuit and Basagran treatments with reduced dose and associated cytogate were in the same statistical group with the minimum weight of dry sorrel. The Pursuit and Basagran treatments with standard dose and Pursuit and Basagran treatments with reduced dose and associated cytogate, as well as the combined treatment of Pursuit and Basagran all led to a minimum dry weight of salsify in the second harvest. The Pursuit treatment with reduced dose and associated cytogate, and also the combined Pursuit and Basagran treatment were the best choices for reducing the dry weight of dandelion in the second harvest. Existence of bitter and normal flixweed dry matter in the third harvest was almost insignificant and negligible; however, among the experimental treatments, the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_249265

treatments of Pursuit and Basagran, both with reduced doses and associated cytogate and weed control treatment contained the lowest dry weight of bitter flixweed and thus, were placed in the same statistical group. Lentagran treatment with the standard dose along with the Pursuit and Basagran treatments, both with decreased doses and accompanying cytogate consumption, caused the lowest dry weight of normal flixweed in the second harvest. In the study of sorrel dry weight in the third harvest, the Pursuit and Basagran treatments with the standard dose, as well as the Pursuit and Basagran, both with reduced dose and associated cytogate, were revealed as the best treatments to reduce sorrel. Effective treatments to control salsify in the third harvest were consistent with the effective treatments to control sorrel, with the difference that the incorporated Pursuit and Basagran treatment associated with the above-mentioned treatments was placed in the same statistical group. Basagran, with both standard and reduced dose as well as associated cytogate, along with Pursuit with standard and decreased dose, as well as accompanying cytogate were the best treatments for reducing the dandelion dry weight in the third harvest.

Mamnooie and Shimi (2012) and Meighani et al. (2011) have also shown that the application of the Pursuit herbicide in alfalfa fields caused significant reduction in weed dry weight. Results of a comparison of the weed dry weight characteristic, considering separated species, in the fourth harvest (*Table 8*) revealed a significant decrease in most of the weeds. A further reduction was observed in both the bitter and normal flixweed, and there was almost no interference problem related to the bitter and normal flixweed in the fourth harvest. However, some weeds were still observed in the fourth harvest. Sorrel, salsify, and dandelion weeds continued to exist until the fourth harvest, because their growth season still caused damage until the late summer. The Pursuit and Basagran treatments, both with standard dose, reduced dose and associated cytogate consumption, caused the lowest sorrel dry weight in the fourth harvest. Also, salsify, as the result of the Basagran treatment with reduced dose and accompanying cytogate consumption had the lowest dry weight in the fourth harvest. Effective treatments on dandelion dry weight reduction in the fourth harvest included the Pursuit and Basagran treatments with standard dose, reduced dose and associated cytogate, which were in the same statistical group. The results of density analysis and alfalfa dry weight in all the four harvests showed that, at the level of 1%, application of the treatment had a significant effect on this characteristic (*Table 9*). The comparison of the means of the experimental treatments showed that the treatments exertion were significantly different from each other, so that from the first harvest until the third harvest, after blank treatment (hand weeding), the Pursuit treatment with reduced dose and associated cytogate consumption accounted for the highest density of alfalfa and was considered the best treatment.

The Pursuit herbicide is a chemical treatment of the ALS family, which can be effective in broadleaf weed control. Cytogate can also increase the controlling power of this treatment, as seen in most of the harvests; this treatment could be preferred over other treatments as it appropriately controls weeds. A reduction in the density of weeds provides space for growing of alfalfa and allows it to benefit from the existing resources and conditions. In the fourth harvest, this treatment accompanied with the reduced dose Basagran treatment with associated cytogate consumption was placed in the same statistical group (*Table 10*). In all the four harvests, the Pursuit treatment with reduced dose and associated cytogate was determined to be the desirable treatment for increasing the alfalfa dry weight (*Table 11*). However, a combined treatment of Pursuit and Basagran in the second and third harvests, the Basagran treatment with reduced dose and associated cytogate consumption in the fourth harvest, and the Pursuit treatment with decreased dose and associated cytogate consumption in each harvest were found in the same statistical group and recognized to be among the best treatments for increasing the alfalfa dry weight. The results obtained from the increased pattern of the alfalfa dry weight from the first harvest to the fourth show conformity to the results from the decreased pattern of weeds, so that in the fourth harvest, the density of weed dry weight was observed to be almost the lowest, and the highest alfalfa dry weight was witnessed. In perennial alfalfa farms, in which deep-seated broadleaf weeds exist, Pursuit treatment can be effective in controlling the weeds. In addition, while the decreased dose of the herbicide can be used, such a dose reduction must be compensated for by using a cytogate surfactant so that the amount of poison drift decreases and the control percent increases.

Discussion

In general, adjuvants greatly vary with respect to chemical structure and performance, but most of them have a hydrophilic and a lipophilic segment. Herbicides applied along with the cytogate surfactant were more efficient for weed control, as well as for an increase of the product yields, as imazethapyr herbicide along with cytogate surfactant managed to control weeds for a rate of 87.43% and increase the product yields to 93.54%. Results showed that combination of herbicides can also be useful in controlling weeds in alfalfa fields and increasing product yields. Results also revealed that combination of bentazon and imazethapyr increased product yields to 94.47% and controlled weeds for a rate of 90.19%. The equilibrium between the hydrophilicity and lipophilicity of adjuvants is a criterion of the relative distribution of the hydrophilic and hydrophobic components of adjuvants. This important feature has a clear influence on herbicide performance, which was clearly demonstrated in the present research. Certainly, adjuvants are extremely efficient in weed control because they facilitate the spreading of spray particles and absorption of active ingredients and improve herbicide efficiency through reducing surface tension (which was clearly demonstrated in the present study). Since the positive effect of Cytogate in increasing the efficiency of the mentioned herbicides was evaluated and effective results were obtained, it is recommended that this adjuvant should be employed in fields where the spectrum of the mentioned herbicides is used. Although the positive effect of applying Cytogate in improving weed control in fields has been proved, yet it is suggested that other adjuvants be evaluated together with other types of herbicides by researchers so that the synergistic and antagonistic effects of these adjuvants on these herbicides can be determined.

(Received 3rd Apr 2017; accepted 2nd Jun 2017)

Abstract. Mountain grasslands are among the most species-rich plant communities in Europe. This is due to the large variability of abiotic conditions and ways of management. However, a significant change in the rural economy has taken place in recent decades. Some grasslands have become forested, while others have been overgrown as a result of succession. Fodder for domestic animals is produced on grasslands created on former arable land. The aim of this study was to estimate the effect of topographic factors (altitude, slope, exposure) and land use (grassland, arable land) in the mid-nineteenth century and the 1930s on the present biodiversity of mountain grasslands. The study was carried out in the basin of the Łomniczanka and Wierchomlanka Rivers in the Beskid Sądecki (Polish Carpathians). A total of 73 phytosociological relevés in an altitude gradient ranging from 660 to 1,060 m a.s.l were made. Past land use was determined on the basis of archival cadastral and topographic maps. The altitude above sea level was the main factor influencing the botanical composition of vegetation. No difference was observed in species composition depending on past land use. The results show the crucial role of altitude in determining the species composition of mountain meadows.
Keywords: *semi-natural grasslands, grasslands management, species diversity, historical land use*

Introduction

Many habitats, such as semi-natural grasslands, are associated with the centuries-long human activity. The long-term effects of mowing, grazing and fertilization has enabled the emergence of plant communities with numerous species occurring exclusively in these habitats. Mountain grasslands used in a traditional, extensive manner are particularly valuable. These are among the most species-diverse plant communities in the world (Wilson et al., 2012; Chytrý et al., 2015). Grassland communities are also associated with invertebrate species, particularly arthropods (Schaffers et al., 2008). Research also shows that an open landscape is essential for numerous bird species (Siramia et al., 2008; Shi et al., 2014).

The existence of such species-rich communities is the result of the interaction of abiotic habitat factors and extensive use. These communities are found in places with low fertility, which prevents dominance by few highly competitive species, as in fertilized grasslands. On the one hand agricultural production is intensified, while on the other hand marginal areas are no longer being used (Strijker, 2005). Both of these factors lead to a decline in biological diversity and the disappearance of many rare species, which usually have a narrow ecological amplitude (Ellenberg, 1985; Cousins et al., 2015).

In the Polish Carpathian Mountains the problem of abandonment of agricultural land is particularly acute. At the start of the 20th century arable land still dominated the landscape up to an altitude of 1,000 m a.s.l. (Bielecka, 1969) and grasslands occupied

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_267278

higher areas or other places that were unsuitable as cropland. In recent decades most former grasslands have become afforested or spontaneous forest succession is taking place on them (Bucała, 2014; Kolecka et al., 2015; Morzyniec et al., 2015). At the same time, arable land has been transformed into grassland, although its total area has not decreased (Twardy, 2008). The grassland communities arising in this manner are usually characterized by lower species diversity (Cousins and Eriksson, 2002).

In mountainous areas the current state of grassland communities is influenced by the high degree of variation in topographic factors such as: altitude a.s.l., exposure, inclination, and soil fertility and moisture. These factors usually act together and it is usually difficult to single out the ones with the greatest effect (Janišová et al., 2010; Klimek et al., 2008). Botanical composition is also linked to the process of immigration of species from other grassland areas and their adaptation to habitat conditions and management. Immigration processes of grassland species, in the case of areas isolated from sources of diaspores, may last a long time. This is most likely why ‘old’ grasslands with a long, uninterrupted history of use are usually richest in species and thus the most ecologically valuable (Reitalu et al., 2010; Pitkänen et al., 2016). The main questions posed in the study were as follows: (i) what is the main factor responsible for the species composition of grassland communities in mountainous areas? (ii) Do grasslands formed on former arable land differ in species composition from those situated in places that were never used to grow crops?

Materials and methods

The study was carried out on clearings located in the Pasmo Jaworzyny mountain range (catchment of the Łomniczanka and Wierchomlanka Rivers), which is part of Beskid Sądecki (Western Carpathians) in the forest zone, in an altitude range of 600–1000 m a.s.l. (*Figure 1*). Bedrock of the Jaworzyna mountain range is composed of flysch sandstones and shales. The soil of all the plots were Haplic Cambisol (Dystric).

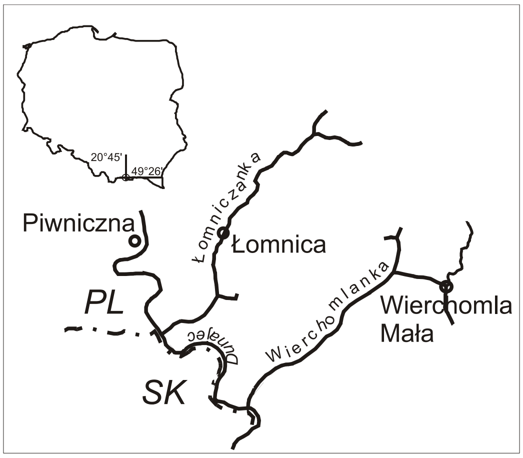

Figure 1. *Localization of research area*

In 2009 73 phytosociological relevés with an area of 100 m^2 were made; a list of plant species was compiled and their coverage were estimated on the five-point scale (Braun-Blanquet, 1964). Species names were taken after Mirek et al. (2002). In each

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_267278

place basic topographic parameters were determined: altitude a.s.l., inclination, and exposure. The values for exposure were transformed using trigonometric functions (Roberts, 1986) to create two new variables: northness = cos (exsposure in degrees) and eastness = sin (exsposure in degrees). Cartographic materials were used to determine the type of land use (grassland or arable land) in the mid-nineteenth century, the 1930s and the 1980s. The analysis of past land use was based on Austrian cadastral maps from 1846, a Military Geographical Institute map from 1936 and topographic maps published by the Surveyor General of Poland from 1988. Habitat conditions were evaluated indirectly on the basis of unweighted means of Ellenberg's indicator values (Ellenberg et al., 1992). These were calculated for each relevé for nutrients (N), temperature (T) and soil reaction (R) using JUICE software (Tichý, 2002).

Classification of the phytosociological relevés was based on the similarity of species composition using a modification of TWINSPAN (Roleček et al., 2002). Association of species to vegetation units and statistical significance at $p < 0.05$ (Fisher test) was calculated with JUICE (Tichý, 2002). Syntaxonomic system by Matuszkiewicz (2001) was applied. The ordination analyses were carried out using CANOCO ver. 4.5 software (ter Braak and Smilauer, 2002). In detrended correspondence analysis (DCA) the length of the gradient was 3.6 of the standard deviation and canonical correspondence analysis (CCA) was used to test the effect of topographical factors and use on species composition. Statistical significance was determined by a Monte Carlo permutation test.

Results

Analysis of the phytosociological relevés allowed them to be classified into three main plant communities, forming visible groups with respect to the first DCA axis (*Figure 2A*):

Class: *Vaccinio-Piceetea* Br.-Bl. 1939
Order: *Vaccinio-Piceetalia* Br.-Bl. 1939
Alliance: *Piceion abietis* Pawł. et al.1928

1. Community: *Vaccinium myrtillus*

Class: *Nardo-Callunetea* Prsg 1949
Order: *Nardetalia* Prsg 1949
Alliance: *Eu-Nardion* Br.-Bl. 1926 em. Oberd. 1959

2. Association: *Hieracio-Nardetum* Kornaś 1955 n.n.

Class: *Molinio-Arrhenatheretea* R.Tx. 1937
Order: *Arrhenatheretalia* Pawł. 1928
Alliance: *Arrhenatherion elatioris* (Br.-Bl. 1925) W.Koch 1926

3. Association: *Gladiolo-Agrostietum capillaris* (Br.-Bl. 1931) Pawł. et Wal. 1949

The *Vaccinium myrtillus* community, apart from a large share of this species, was characterized by a substantial share in the area cover of species characteristic of *Hieracio-Nardetum* association: *Nardus stricta*, *Potentilla erecta*, *Deschampsia caespitosa* and herbaceous species: *Hypericum maculatum* and *Luzula luzuloides* (*Table 1*).

This community usually constitutes a stage of overgrowth of unused grasslands and pastures. The number of species in the phytosociological relevé ranged from 7 to 22 (on average 14.1). This community is found in clearings in the upper part of the massif at altitudes from 880 m a.s.l. to at 1060 m a.s.l. (*Table 2*).

Patches of multi-species *Hieracio-Nardetum* association are the remains of once dominant in the Beskid Sądecki type of grassland (Pawłowski, 1925). The sward includes a large share of *Nardus stricta* together with other species characteristic of this association, such as *Carex pilulifera*, *Potentilla erecta* and *Veronica officinalis*. Many species can be found here that are also found in *Gladiolo-Agrostietum* association. These include *Achillea millefolium*, *Veronica chamaedrys*, and *Plantago lanceolata*. Often, however, the dominant species are *Festuca rubra* or *Agrostis capillaris* (*Table 1*). This community is found at lower altitudes (700-970 m a.s.l.). The number of species in the phytosociological relevé ranges from 19 to 41 (on average 28.8) (*Table 2*). The community with the greatest species diversity is *Gladiolo-Agrostietum* association. In the patches of this community 128 plant species were recorded, and in individual relevés from 28 to even 55 species (on average 39). Such meadows are usually found in the lower parts of the massif (600–900 m a.s.l.) (*Table 2*). The sward is often dominated by *Agrostis capillaris*, and the presence of species associated with fertile grassland, such as *Dactylis glomerata*, *Trifolium pratense* and *Trifolium repens* is typical. Sporadic use as pasture is indicated by the small but frequent share of *Cynosurus cristatus* (*Table 1*). The indicator values show that the communities do not differ significantly in terms of temperature (T) and moisture (F) requirements. However, substantial differences were noted with respect to soil reaction (R) and nutrients (N), which were highest in the case of the *Gladiolo-Agrostietum* association, and lowest in the V*accinium myrtillus* community (*Table 2*). Analysis of the archival maps indicated that most of the 73 phytosociological relevés were situated in sites that had been used as arable land in the mid-nineteenth century and still in the 1930s. Only in the case of one relevé was it found in a location marked as arable land in the 1980s (*Table 3*).

Table 3. *The number of phytosociological relevés on areas with the same type of land use in the past*

Land use	Period of time		
	mid-nineteenth century	1930s	1980s
Arable land	46	51	1
Grassland	27	22	72

The variation in the species composition of communities present in clearings in the Łomniczanka and Wierchomlanka catchment indicate that altitude was a decisive factor. The grasslands analyzed were separated by short distances, but with considerable variation in altitude, up to 400 m. Increasing altitude above sea level was accompanied by a decrease in species variation, expressed both as number of species and the Shannon-Wiener index, and by an increase in the mean indicator value of the plants for nutrients (N) and reaction (R) (*Figure 2B*). Due to an autocorrelation between the way of management in the 1930s and in the mid-19th century, the analysis took into account only the way of management in the 19th century. The selected variables (altitude, exposure, land use in the past, slope) described 17.58% of the total variance in species composition. Altitude above sea level was responsible for the largest part of it - 9.86% and even for 10.29% after eliminating the influence of the remaining variables (pure effect) (*Table 4*).

Total	17.58		16.29	

Discussion

In contrast with our results, many studies on the biodiversity of semi-natural grassland communities have not shown one main factor influencing species composition (Janišová et al., 2010; Pruchniewicz and Żołnierz, 2014). This may be due to differences in the size of the areas studied. The factors determining species composition in a relatively small area may be different than those acting on a larger scale (Vandvik and Birks, 2002). In the catchment of the Łomniczanka and Wierchomlanka Rivers the variation caused by the altitude above sea level was nearly 10%. This is relatively high, considering that in a study on the effect of factors on the formation of grassland communities in Slovakia the total variance explained by all variables together was only 12% (Klimek et al., 2008). The low percentage of explained variance is typical of data containing many zero values (ter Braak and Verdonschot, 1995), as is usually the case with phytosociological data.

As altitude increased climatic determinants change. The mean air temperature falls by 0.72°C/100 m a.s.l., and the length of the growing period in the conditions of Beskidu Sądecki is reduced by 6.2 day per 100 m a.s.l. (Brzeźniak and Czemerda, 1987), while precipitation increases (Brzeźniak et al., 1984). The indicator values for temperature (T) decreased as altitude increased, but this correlation was weak. This may be due to the relatively low variation in plant species in relation to this factor, as manifested by the large number of species for which no T values are given. Changes in altitude are also accompanied by changes in soil conditions (Manojlović, 2011) differences occur in particular between locations on the sides of mountains and on their hilltops (Maciaszek, 2000). The substantial effect of altitude is linked not only to a change in climate and soil conditions, but also to the possibility and profitability of agricultural use (Tasser and Tappeiner, 2002). Thus the change from arable land to grassland, and then to abandonment of agricultural practices , occurs first in areas that are the most difficult to access, usually at higher altitudes (Twardy, 2008; Tasser and Tappeiner, 2002). Influence of altitude on biodiversity is of common nature and concerned different groups of organisms (Sergio and Pedrini, 2007). Grasslands as semi-natural communities arose in the place of forest and are dependent on mowing or grazing to stop the succession process (Szydłowska, 2010; Hejcman et al., 2013; Tälle et al., 2015). For their existence, apart from suitable soil and climate conditions, diaspores of grassland species must appear. This takes place mainly through anemochory (Tackenberg et al., 2003) and zoochory (Cosyns et al., 2006; Purschke et

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_267278

al., 2014), but in either case it takes time (Hutchings and Booth, 1996). This time period may vary, depending mainly on the distance from the sources of the diaspores. In a traditional, alternating system of grassland management in the mountains, when at regular intervals the grassland was ploughed and after a few years grassland use was resumed, meadows and arable fields were present in a spatial mosaic. The flow of diaspores from the meadows to the arable fields was easy and the newly formed meadows rapidly regained a rich species composition (Włodarczyk, 1956). Similar fast process of species immigration to old fields from nearby grasslands was observed in case of xerothermic vegetation (Woch, 2011). In the case of forest clearings this process may last a long time (Winsa et al., 2015). One factor that may influence species composition on former arable land is cultivation procedures, particularly fertilizers that alter the chemical and physical properties of the soil (Chmolowska et al., 2016). For this reason many studies have found that the species composition of grasslands depends on how long the land has been used as grassland (Pitkänen et al., 2016, Purschke et al., 2014). In mountain grasslands in Norway, Austrheim and Olsson (1995) found that the most rapid and greatest changes in species composition took place over a period of up to 23 years from the abandonment of ploughing. Cartographical data indicate that during the period between the mid-nineteenth century and the 1930s there were no fundamental changes in land use in the study area. Arable land stretched as far as to altitudes above 1,000 m. a.s.l. (Kubijowicz, 1927). Fundamental changes in land use took place later. The very small percentage of variance (1.72%) explained by the land management in the past shows that the time elapsed from the transformation of the land into grassland was long enough for typical grassland communities to form. The time needed for the formation of typical grassland communities is highly varied and depends on a number of factors. In the case of xerothermic grasslands the effect of arable land use was demonstrated after more than 100 years (Forey and Dutoit, 2012) while in a study by Chýlová and Münzbergová (2008) the presence of xerothermic communities was noted in places that had been managed in different ways 50 years before. In these studies, however, there was no single factor as strong as altitude above sea level determining the species composition of plant communities. Semi-natural grasslands in a forest zone were created by human activities and their existence depends entirely on their current management (Valkó et al., 2012; Pavlů et al., 2016; Kulik, 2014). Hence, abandonment of farming practices is a more important than the way of land use in the past. *Hieracio-Nardetum* association which dominated in the upper parts of Polish Carpathians in the past (Korzeniak, 2016) has been replaced by V*accinium myrtillus* community as a stage of succession of unmanaged grasslands.

Species-rich *Nardus* grasslands (6230 Natura 2000 code) are currently among the most threatened habitats in Poland and Europe (EIONET) and has been considered as a priority habitat in Natura 2000 network (European Commission). The preservation of such high natural value communities requires their mowing or grazing, which is not possible without subsidies under agrienvironmental programs (Jellinek, 2016).

Conclusions

1. The varied species composition of the grassland communities in the study area was mainly due to the effect of their location at different altitudes above sea level.

2. The highest species diversity was noted for the *Gladiolo-Agrostietum* association, situated at low altitudes, and the lowest for the *Vaccinium myrtillus* community, located in the higher parts of the massif.

3. As the altitude above sea level increased, the fertility and pH of the soils decreased, expressed as the indicator value of the plant species.

4. The influence of the type of land use in the mid-nineteenth century and the 1930s on the species composition was small. All three types of communities were found in both the fields that had been used as arable land and in those used as grassland in the mid-nineteenth century and the 1930s.

5. None of the plots in the study area (except one) had been ploughed for at least 30 years. This period was sufficient for the formation of grassland communities.

6. The abandonment of plant communities management is one of the most important factors that influenced botanical composition of grasslands.

Acknowledgments. The research was realized within the Project no. DS-3337/KEKiOP financed from the research grant allocated by the Ministry of Science and Higher Education.

(Received 4th Apr 2017; accepted 3rd Jul 2017)

Abstract. Recent studies show that urbanization is most affected form of land transformation that intensely influences biological diversity and human life. Quantifying urban landscape pattern is essential for monitoring and assessment of urbanization. The aim of this contribution is monitoring short term changes in urban landscape pattern of Hatay province located in Mediterranean region of Turkey. Hatay is a key region in the ongoing conflict in Syria because of the border and will remain so during the post-conflict transition period. As a result of this situation the urban area has recently undergone extensive land transformations. These land transformations were detected by satellite images of Alos Avnir-2 (2008) and WorldView-2 (2014) using geographic information system (GIS) and remote sensing (RS). Methodology comprised three stages; (1) collecting data and image pre-processing, (2) land cover mapping using object- based image analysis and accuracy assessment (3) landscape change analysis. Landscape change analyses were employed to quantify land cover changes from 2008 to 2014. As a results of the study, forest area decreased from 23,2% to 14,6%. On the other hand urban area increased from 22,5% to 29,9%. This paper demonstrated that urban and forest changed rapidly in this part of the Mediterranean region of Turkey.
Keywords: *Hatay, landscape change analysis, quantify, object-based classification*

Introduction

Monitoring land change science has recently emerged as a fundamental component of global environmental change and sustainability research (Gutman et al., 2004, Rindfuss et al., 2004; Turner et al., 2007; Liu and Yang, 2015; Janisova, 2014). Rapid urbanization and urban sprawl have significant impact on conditions of urban ecosystems. Accurate and updated information on the status and trends of urban ecosystems is needed to develop strategies for sustainable development and to improve the livelihood of cities. The ability to monitor urban land-cover/land-use changes is highly desirable by local communities and by policy decision makers alike. With increased availability and improved quality of multi-spatial and multi-temporal remote sensing data as well as new analytical techniques, it is now possible to monitor urban land cover/ land-use changes and urban sprawl in a timely and cost-effective way (Yang et al., 2011; Güzelmansur and Kılıç, 2013). Since urbanization interferes with many ecological systems and processes, geospatial information on its implications is essential for land use planning and management.

Different classification methodologies and data types have been used for land use/land cover (LU/LC) change detection and database updating. In particular, object-based image analysis (OBIA) techniques enable connecting information from the image with database information (Berberoglu and Curran, 2004; Ming et al., 2015). In OBIA approaches, the pixels are not individually classified but combined into homogenous

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_279290

groups (objects) and classified together (Walter, 2004; Mui et al., 2015). Unlike spectral methods employed in pixel based classifications, OBIA are based on segmenting the image into homogeneous pixels (Image objects) and classifying these objects using spectral, spatial, textural, relational and contextual methods. Rather than treating the image as a collection of pixels to be classified on their individual spectral properties, the image pixels can be initially grouped into segments and the object segments can then be classified according to spectral and other criteria, such as shape, size and relationship to neighboring objects. In this way, objects with heterogeneous reflectance values, such as tree canopy, can still be recognized despite their heterogeneity (Zhou and Troy, 2008; Bhaskaran et al., 2010). In comparison with pixel approaches, additional spatial and contextual information can be obtained from objects in OBIA (Blaschke, 2010, Ruiz et al., 2011, Hussain et al., 2013; Wu et al., 2015), which can be easily stored and linked to a database as attributes or features (Gill-Yepes et al., 2016).

Object-based image analysis is quickly gaining acceptance among remote sensors, and has demonstrated great potential for classification and change detection, compared to pixel-based approach (Blanschke, 2010; Myint et al., 2011; Zhou and Troy, 2008; Yu et al., 2016). The advantage of the object-based approach is that it offers new possibilities for image analysis because image objects can be characterised by features of different origin incorporating spectral values, texture, shape, context relationships and thematic or continuous information supplied by ancillary data. Integration of additional knowledge is a valuable means to distinguish ecologically meaningful habitat types that don't have necessarily very distinct spectral features. Moreover integration with existing vector-databases can be achieved during all steps of the classification proces (Bock et al., 2005; Gürkan, 2016)

RS provides a cost-effective alternative to the ground-based survey for land use/landcover mapping and change analysis. (Jensen, 2004; Liu and Yang, 2015; Cserhalmi and Erdős, 2016).

The study employed in hatay province. It is located in the Mediterranean region of Turkey and it is in the border of Syria. So, Hatay is a key region in the ongoing conflict in Syria and will remain so during the post-conflict transition period. Massive population displacements and widespread destruction are linked to the highly strategic nature of the city due to the ethnic and sectarian diversity of the population (Asaad and Shamaly, 2016). Approximatly 500.000 Syrian refugees has been settled to Hatay after conflict acording to local goverments. Some of the refugees settled in the urban area. Therefore, the urban area has recently undergone extensive land transformations. Building development is the most important drive that led to these changes. Hence, the aim of this contribution is to monitor short term changes in urban landscape pattern of Hatay province for 6-year time period between 2008 and 2014. For this purpose, Alos Avnir-2 (2008) and WorldView-2 (2014) images were used.

Urban changes were detected by rectified satellite images of Alos Avnir-2 and Worldwiev-2. The study which performed with the help of RS and GIS mainly consists of three objectives: (1) to land cover mapping using object- based image analysis (2) to make accuracy assesment (3) to quantify land use changes.

Materials and Methods

Study area

Hatay is a city in the Mediterranean region of the southern part of Turkey, with a population of 500.749 (TÜİK, 2016) *(Fig.1).* The study area is a 8*9 km area including the Hatay city center. It is surrounded by forests of Amanos Mountain in the west, Amik Plain in the north and Habibi Neccar Mountain in the east. Orontes River is the main river crossing the urban area. Climate regime is Mediterranean climate characterized by a mild winter during which about 67 % of the annual precipitation of 1124 mm falls, and a hot dry summer. Average annual temperature reaches a maximum of 44° in the summer and a minimum of -15 C° in the winter, with an average annual temperature of 18 °C. Parent material consists mostly of conglomera, calcaire and alluvial. Mediterranean vegetation consists of evergreen forest of *Pinus brutia*, and shrublands composed of maquis, and garrigues (Guzelmansur and Kılıç, 2013).

Data sets

Alos (Avnir-2): The image collected on 2008 from Advanced Visible and Near Infrared Radiometer type 2 (Avnir-2) of the Alos Avnir-2 were used in this study. The image data has 100 cm spatial resolution and comprise four visible wavebands corresponding to blue (0, 42 to 0, 50 µm), green (0, 52 to 0, 60 µm), red (0, 61 to 0, 69 µm) and near infra-red (0, 76 to 0, 89 µm).

WorldView-2: The image collected on September 2014 from WorldView-2 Ortoready Pansharpened (WV2-NT/ORPNP). The image data has 50 cm spatial resolution and comprise tree wavebands and 16 bites.

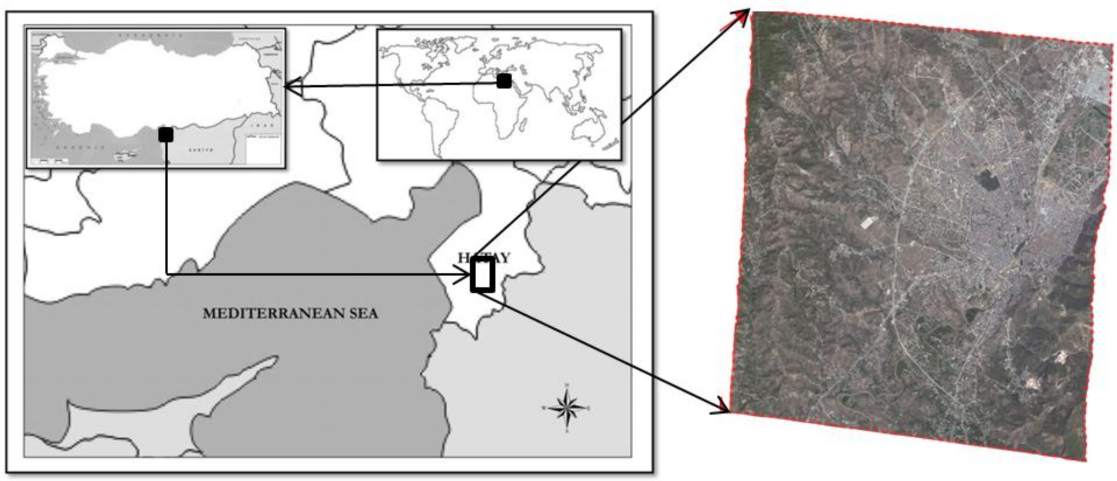

Figure 1. *Site location of study area*

Methodology

The study comprises 3 stages: (1) collecting data and image pre-processing, (2) land cover mapping using object based image analysis and accuracy assesment (3) landscape change analysis.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_279290

Image preprocessing

The image was geometrically corrected and geocoded to the Universal Transverse Mercator (UTM), WGS-84 zone 37 coordinate system using 1/25.000 scale topographic maps. A minimum of 20 regularly distributed ground control points (GCPs) were selected from the image. Resembling was performed using a nearest neighbor algorithm. The transformation had a root mean square (RMS) error of less than <0.5 pixels indicating that the image was accurate within one pixel. A nearest neighbor algorithm takes the value of the pixel in the input image that is closest to computed co-ordinate.

Object-based image classifications

Object-based methodology was adopted for image classification performed for each images captured between 2008 and 2014. Object based image analysis provides rich opportunities for expert (predefined) knowledge integration for the classification process, it also makes the classification more vulnerable to operator-/scene-/ sensor-/target-dependency, which in turn hampers the repeatability and transferability of rules (Witharana and Lynch, 2016). It was preferred in the classification process. Image objects are described and classified by using a wide range of attributes including image features such as spectral variables, shape, texture, size, but also potentially thematic data such as slope, aspect, soil properties provided by digital maps. Image objects may also be classified by reference to expert rules such as rules based on the spatial relationship between objects (contiguity) or the distance between objects (Mathieu et al., 2007). The software used in this research was ArcGIS 10.2. Object-based classification have been recently used in a wide range of application fields (Bock, 2003), landscape pattern analysis (Ivits et al., 2005), fire monitoring (Gitas et al., 2004), land cover/land use mapping in rural (Van der Sande et al., 2003) or urban environments (Meinel et al., 2001) and topographic feature extraction (Repaka et al., 2004; Mathieu et al., 2007; Gürkan, 2016). Seven main categories of land cover types were identified: urban area, agriculture, forest, shrubland, bare soil, water, industry. Additionally, field surveys were carried out to verify these land cover types.

Accuracy assessment

An error matrix, and a Kappa coefficient for each classification were generated. Once a classification exercise has been carried out, there is a need to determine the degree of error in the end-product. These errors could be thought of as being due to incorrect labelling of the pixels. Conversely, the degree of accuracy could be sought. First of all, if a method allowing a 'reject' class has been used then the number of pixels assigned to this class (which is conventionally labelled as “0”) will be an indication of the overall representativeness of the training classes. If large numbers of pixels are labelled as “0” then the representativeness o the training data sets is called into question - do they adequately sample the feature space? The most manly used method of representing the degree of accuracy of a classification is to build confusion matrix (error matrix) (Mather, 1999).

Kappa Statistic is an index that compares the agreement against what might be expected by chance (Eq. 1):

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_279290

$$\kappa = \frac{N\sum_{i=1}^{r} x_{ii} - \sum_{i=1}^{r}(x_{i+} * x_{+i})}{N^2 - \sum_{i=1}^{r}(x_{i+} * x_{+i})} \quad \text{(Eq.1)}$$

Kappa coefficient (k) is used to summarise the information provided by the error matrix. The x_{ii} are the diagonal entries of the confusion matrix. The notation x_{i+} and x_{+i} indicates, respectively, are the sum of row I and the sum of column I of the confusion matrix. N is the number of elements in the confusion matrix. Rows total (x_{i+}) for the confusion matrix shown in Table 1 are listed in the column headed (I) and columns totals are given in the last row (Mather, 1999).

Landscape change analysis

Early approaches to measure urban expansion with RS focused on simple band ratios, image thresholding, and image differencing to discern broad-scale changes at the urban–rural fringe (Howarth and Boasson, 1983; Jensen and Toll, 1982; Martin and Howarth, 1989; Shalaby and Tateishi, 2007), while more recent developments accommodate the high spectral variability of urban areas by exploiting spatial or polarimetric dimensions in satellite datasets (Bhaskaran, et al., 2010; Ghimire, et al., 2010; Shaban and Dikshit, 2001; Taubenböck et al., 2012; Shalaby and Tateishi, 2007).

Landscape change analysis was based on image classification. The 2008 and 2014 images classified using object-oriented methodology. Classified images were overlaid to extract landscape change information. Quantitative areal data of the overall land cover changes as well as gains and losses in each category between 2008 and 2014 can be compiled. In order to analyze the rate, and location of land cover changes, a set of 'gains' and 'losses' images for each category was also produced. These 'change' images were overlaid with an image of the city, which was constructed in a vector GIS and it converted into a raster format with the resolution of 10 meters. This GIS overlay intended to find landscape change information within the city.

Results

Land cover mapping

Images of 2008 and 2014 were preprocessed and classified to create land cover maps. The two land-cover maps discriminated seven classes: urban, agriculture, forest, shrub land, bare, water and industry (*Fig. 2*). The urban class included settlement area, cemetery, educational institutions, parks and their roads. Agricultural lands were split in two classes to increase their discrete with other land-cover classes; annual agriculture and horticulture. The forest class included natural forest areas (*Pinus brutia* Ten.) and maquies vegetation. Shrubland is easily sacrificed for different land uses to *Sarcopoterium spinosum* (L.) Spach. The most important water flow of the City is Asi (Orontes) River classified as water. Industry consists from commercial (small industrial site) and the other minor saleable area in the city and it's around.

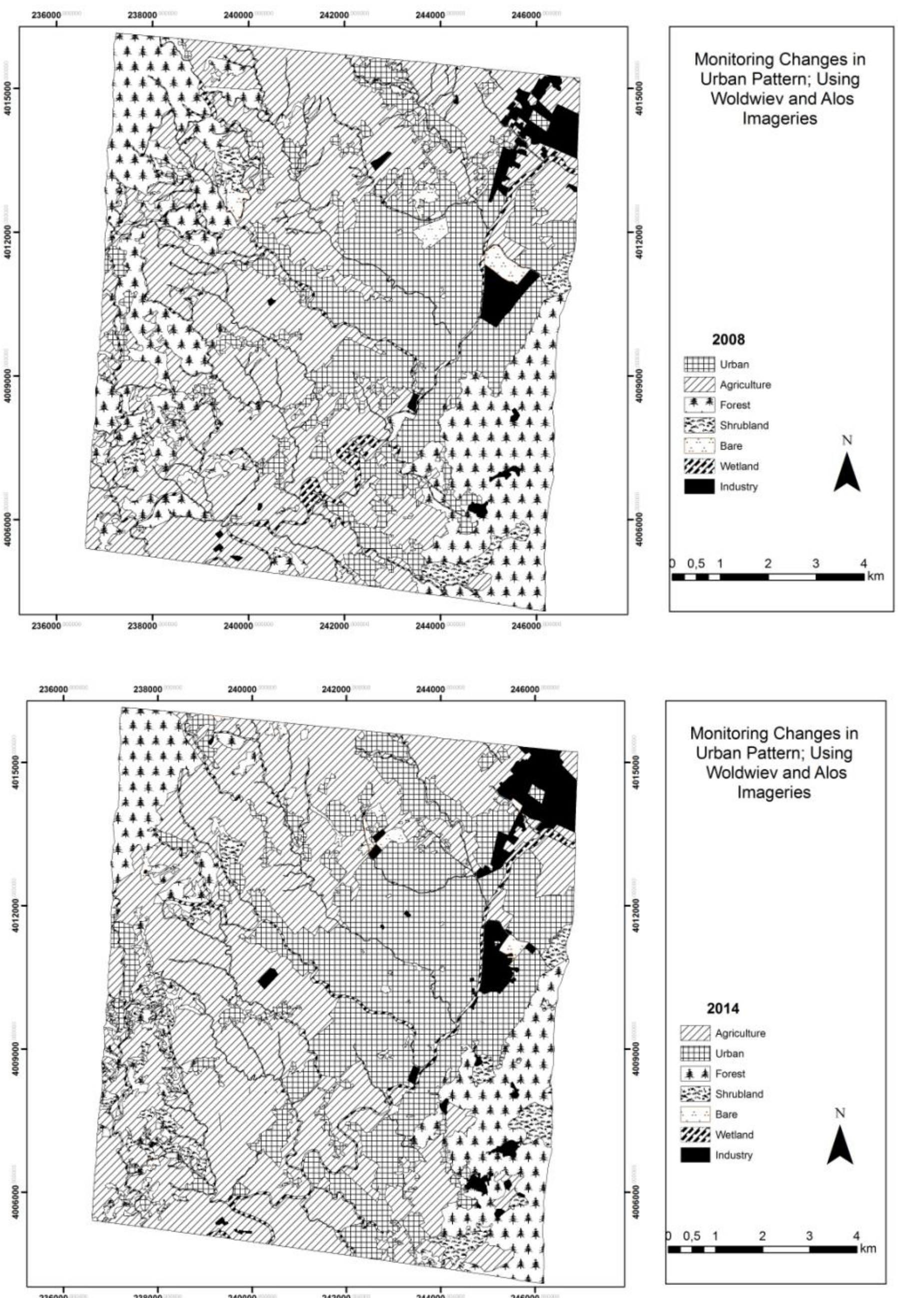

Figure 2. *Land cover in 2008 and 2014*

Validating classification results

Table 1 and *Table 2* shows that indicate the level of consistency between observed land cover for 2008 and 2014. Confusion or error matrix consist for seven classes. The row labels are those given by an operator using ground reference data. The column labels are those generated by the classification procedure. The four right-hand columns are as follows: (I) number of pixels in class from ground reference data; (II) estimated classification accuracy (percent); (III) class i pixels in reference data but not given label by classifier; and (IV) pixels given label I by classifier but not class I in reference data (Mather, 1999). The sum of the diagonal elements of the confusion matrix is for year of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_279290

2008 is 160, and the overall accuracy is therefore (160/179) x 100 = 90,67% (*Table 1*). The sum of the diagonal elements of the confusion matrix for year of 2014 is 185, and the overall accuracy is therefore (185/204) x 100 = 90,68% (*Table 2*).

Overall acuuracies and Kappa values were over %86 in most cases which is acceptable rate for accuracy (Foody, 2010). Water had the highest accuracy values. Forest, urban, bare, industry, agriculture follow respectively. Accuracies for urban areas in 2008 classification are slightly lower than 2014 but still around 90%. Resolution of the image of 2008 lower than 2014, that is why the accuracy is higher than 2008. High classification accuracies showed that, use of enhanced images provided opportunities for mapping this variability effectively. The fact that an object-based image analysis was adopted also helped to produce very accurate classifications.

Table 1. *The sum of the diagonal elements of confusion matrix for 2008*

Quantifying from to changes

In this study, landscape change analyses technique was applied. It is the most obvious method of change detection, which requires the comparison of independently produced classified images.

Fig. 2 show the result maps of land cover in 2008 and 2014. These resulting maps were investigated and compared. Urbanization increased from 22,5% to 29% which it means approximately 7.000 hectar *(Table 3).* Additionally, agricultural areas icreased from 44,4% to 45,6%. Shrubland and industry also increased from year of 2008 to 2014. On the other hand, forest area decreased from 23,2% to 14,6%. The most prominent change in the study area was replacement of forest by urbanization, agriculture and shrubland. Replacement from forests to urban areas was observed. These changes occured especially around the villages of Ballıöz, Doğanköy, Günyazı and Toygarlı. These areas have been used for recreational activities in the recent years. Additionally,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_279290

the figure show that expansion of agriculture over shrubland, resulted in a decrease in this cover type. Rapid urbanization is evident in the study area.

Table 3. *LU/LC of 2008 and 2014*

LU/LC Type	2008(ha)	2008(%)	2014(ha)	2014(%)
Urban	23.773	**22,5**	30.635	**29,0**
Agriculture	46.941	44,4	48.174	45,6
Forest	24.550	**23,2**	15.423	**14,6**
Schrubland	1.771	1,7	3.113	2,9
Bare	1.047	1,0	989	0,9
Water	4.689	4,4	3.442	3,3
Industry	2.852	2,7	3.846	3,6
Total	105.623	100,0	105.623	100

Analysis results showed that area coverage of various LU/LC types is unbalanced. Agriculture and urban are the most extensive LU/LC types in the study period. Agriculture covered 46941 hectar of land, which made up 44% of the study area in 2008. This reached to 48174 hectar in 2014, corresponding to 46% of total area. Urban cover that occupied 23773 and 30635 hectar of land in 2008 and 2014, respectively, has the second largest extent. Forest areas covered 24550 hectar, in 2008. However, this area decreased because of urban, agriculture and shrubland. It declined from 24550 ha in 2008 to 15423 in 2014. Maquies are trimmed to plantation of olive trees. These cause to replacement from forest to agriculture. Additionally, some recreational activities like picnic, ect. couse the urbanisation of forest area.

Fig. 3 provide information about the LU/LC conversions, which showed that most of the changes took place in urban, agricultural and forest areas. Maquie vegetation and pine forest make up the forest in the study area. As previously mentioned, agriculture-related changes comprised conversions from/to agriculture. Urbanization mostly took place at the expense of agriculture, forest, bare areas, shrubland and industry. The fact that higher rates of urbanization takes place on agriculture areas is an important finding worthy of consideration and it requires attention in development planning for the region. Forest area decreased in the study period of the years from 2008 to 2014.

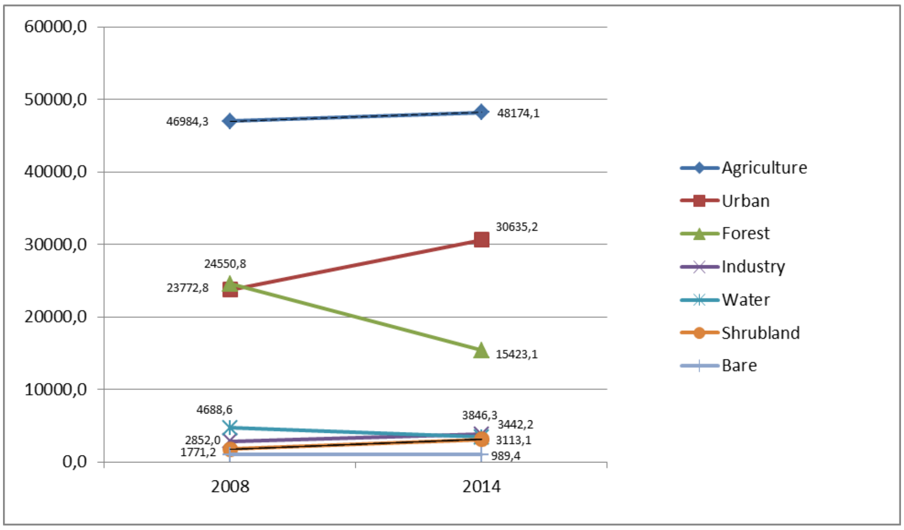

Figure 3. *LU/LC changes from 2008 to 2014*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_279290

Forest areas have been turned into cultivated, urban or shrub areas. Although the same classification method is used in some areas in both images, it is found that forest areas have been transformed into areas used for other purposes as a result of the difference in image resolution of two images. Worldview-2 image resolution was 50 cm while the other was 100 cm. Some shrubland areas around the forest patches classified as forest areas because of resolution of image. This is one reason for the decrasing the forest area from 2008 to 2014. However, urban area has been extensive and some natural areas convert to some cultural land uses such as urbanization and agriculture.

Discussion

Alphan and Çelik (2016), used landscape pattern while Esbah et al. (2010) used landscape stucture metrics. Esbah et al, employed change analyses that highlighted the increase in artificial surfaces and decrease in arable lands and forests in a protected area. Alphan and Çelik (2016), used landscape pattern to monitore changes in coastal zone. They highlited dramatic transformations from agriculture to build-up areas. Similar results were obtained in our study; urban area increased rapidly between 2008 and 2014. However, forest area decreased dramatically between this time period. From environmental planning and management point of view, degredation of forest areas is an important disquiet.

Conclusions

The contribution assessed urban landscape changes using landscape change analysis. The analysis included classifications of two different sensors of Alos Avnır-2 and Worldview-2 which have high spatial resolution. As a consequence of landscape change analysis, there is an increase in urban development and forest related changes occured. This makes it essential to properly analyze changes for establishing appropriate local development strategies and monitoring of development in the urban area. When facing such severe and rapid land-cover changes, one requirement for decision-making is to be able project future changes under certain assumptions. Such projections also contribute to increase awareness of the ecological consequences of growing pressures. However, this study focused on a period of time which is probably too short to understand the land-cover change process in all its complexity. Yet, this period is important because of the ongoing conflict in Syria which led to the settlement of Syrian refegees in Hatay's urban area. Attempts must now be made to increase the period of observation of the past (i.e. before the resettlement) by analyzing longer temporal series of land cover data.

Current remote sensing techniques enable the application of monitoring in temperate regions of the world (Berberoglu et al., 2000; Berberoğlu and Akın, 2009). The contribution presents the results of OBIA classification-based mapping of an area around the city of Hatay in Turkey, using images from two different high resolution sensors of Alos Avnır-2 and Worldview -2. Land cover changes were quantified in terms of percentage of area affected and rates or change.

The results presented in the paper show that OBIA is a valuable method for monitoring changes in urban landscape pattern which are useful for urban planners and may be interpreted to raise awareness for the use of natural resources. OBIA is performing very well when applied to Worldview-2 and Alos Avnir-2 imagery. The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_279290

method provides flexibility in the ability to transfer classification schemes developed recent images where a fair set of ground truth data is available.

High resolution satellite images like WorldView-2 and Alos Avnir-2 images can be used for these kinds of studies. It can save time and effort for fieldwork. But some disadvantage in the study was, if the both images have same spatial resolution the classification results will be more accurate. Additionally there are also some disadvantages such as high price of digital imagery, difficulty in finding qualified staff to work about GIS.

Abstract. In developing countries, such as Pakistan, the food and financial security of smallholder farmers are increasingly threatened by climate change, contributing to considerable increases in input costs and market price volatility for agricultural commodities. This study aimed to identify and investigate factors contributing to smallholder farmers' vulnerability to climate changes and to develop vulnerability indices in Punjab province, Pakistan. Three different composite indices were used to assess the vulnerability of smallholder farmers to climate changes: Livelihood Vulnerability Index, Livelihood Vulnerability Index-Intergovernmental Penal on Climate Change, and Livelihood Effect Index. The weakness of social networks in Rawalpindi district is majorly important to enable the adoption of appropriate mitigating strategies. For both districts, lack of education had the highest effect on social vulnerability. Adoption of strategies towards mitigation of climate changes seems to be possible by the respondents in Chakwal district, with higher illiteracy rate, higher dependency ratio, and greater financial vulnerability. The natural and financial capital had the highest impact on the livelihoods of smallholder farmers in both districts. Ultimately, this research can provide a scientific basis for the decision-making process and risk analysis of climate change impacts in developing countries, where most of the smallholder farmers, as a major social group worldwide, are located.
Keywords: *environmental change, livelihood, livelihood vulnerability index, sustainable development, Potohar*

Introduction

Agriculture is one of the sectors most sensitive to climate change because any degree of climate change can be associated with severe negative impacts on agricultural production and related processes (Lin et al., 2007). Such impacts are predicted to be particularly harsh in the tropical countries, lowlands, and areas affected by reduced snowfall and melting glaciers. In the tropical countries, any increase in temperature can contribute to a considerable decrease in crop yields due to already reached the threshold of heat and drought tolerance by the crops (Burch et al., 2007). Lowlands can be adversely affected by flooding and soil salinization due to predicted sea level rise and groundwater salinization. The areas impacted by reduced snowfall and melting glaciers can face severe droughts due to a decrease in water availability for meeting crop water requirements (IFAD, 2013).

DOI: http://dx.doi.org/10.15666/aeer/1504_291312

For the last two decades, the vulnerability of agricultural production to climate change effects increasingly became the focus of comprehensive research (Tan, 2004). However, despite worldwide recognized the potential of climate change for negative impacts on agriculture, research work on assessment and mitigation of these impacts remains scarce in developing countries, particularly on smallholder farms (Morton, 2007; Ahmed and Schmitz, 2015). It is significantly important because smallholder farmers have been identified as most vulnerable to climate change impacts, both in developed and developing countries (Adger, 2006). Therefore, research on the implications of climate change on agriculture and decrease in farmers' livelihood vulnerability to these impacts in the most exposed regions, as mentioned above, is highly required for developing effective adaptation measures and ensuring sustainable agricultural development. Such research would also provide a scientific basis for the decision-making process and risk analysis of climate change impacts in the investigated locations (Tao et al., 2011).

Smallholder farmers are a distinct social group regarding numbers and food security. They are estimated at 400-450 million of world population and 87% of Asian population (Von Braun and Pandya-Lorch, 2007). They are also assessed as representing the insecure food half of global population (Nagayets, 2005; Sanchez and Swaminathan, 2005). The term ''Smallholder Agriculture'', as used in under-developed countries, commonly defines rural producers who generate income from the family labor farming (Cornish, 1998) and hold less than 2 hectares (ha) of land (Csaki and de Haan, 2003). The food security is increasingly threatened by climate change effects, such as severe pest breakouts, extreme weather conditions, and water scarcity, contributing to considerable increases in input costs and market price volatility for agricultural commodities (O'Brien et al., 2004; Morton, 2007; Makondo et al., 2014) . In this light, and considering agriculture as primary source of their income, smallholder farmers are particularly vulnerable to climate change impacts. Such as the above mentioned ones, mainly due to high risk of yield losses, with further negative impacts not only on their food but also financial security and, ultimately, in their living conditions (Rosch and Hertel, 2010; McDowell and Hess, 2012)

Pakistan is a developing country where agriculture contributes 20.9 % to GDP and 43.5% of the national labor force, but with generally little opportunity for income generation and small market returns in the rural areas (Farooq and Wasti, 2015). The climatic conditions are characterized by arid and hot climate, with the occurrence of droughts and floods negatively impacting on agricultural production (Yu et al., 2013). In this light, and considering the farmers' low level of awareness of climate changes, it can be deduced their high vulnerability to these changes and the need to assess this vulnerability.

In this context, this work aimed to identify and investigate factors contributing to smallholder farmers' vulnerability to climate changes and to develop and adapt vulnerability indices in two districts of arid region in Punjab province, Pakistan.

Methods

Study area

This study combines methods from different schools of climate change assessments to assess livelihood vulnerability in two districts, Chakwal and Rawalpindi, of the arid region in Pakistan. This region has been considered as having the considerable

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_291312

agricultural potential to reduce imports of agricultural commodities at the national level (Ijaz and Ahmad, 2006). Fragmentation characterizes the agricultural land, and the region contributes around 10 percent of national aggregated agricultural production (Ashraf et al., 2004). Chakwal district has an estimated population of 1.4 million within an area of 6.524 Km^2 (Rafique, 2015). There are 151989 farms in this district, out of which 65 percent are considered as smallholder farms and occupy 29 percent of the cultivated area (Pakistan-Bureau-of-Statistics, 2010). The climate is arid, characterized by hot and dry summers and cold and dry winters. The average annual rainfall is 880 mm. The average temperature is 8ºC during winter, rising to 42ºC during summer. The landscape is diverse, with plains and hills (Sheikh, 2012a). Rawalpindi district has an estimated population of 4.7 million within an area of 5.285 Km^2 (Rafique, 2015). There are 182186 agricultural farms in the district, out of which 85 percent are smallholder farms occupying 41 percent of the total cultivated area (Pakistan-Bureau-of-Statistics, 2010). The climate varies from district to district, as winter is remarkably cold, and summer is mild in Murree Tehsil, whereas summer is tolerably hot, and winter is mild in Gujar Khan and Rawalpindi tehsils. The average annual rainfall in the district is 1550 mm. The landscape is dominated by plains in Gujjar Khan and Rawalpindi tehsils (Sheikh, 2012b). In both districts, the major known crops are wheat, groundnut, rapeseed, and mustard, with additional vegetables such as onion, potato, tomato and peas.

Data collection and analyses

Household survey, of 120 randomly selected smallholder farms with less than 2 hectares, was used for data collection. Three different composite indices were used to assess the vulnerability of smallholder farmers to climate change: Livelihood Vulnerability Index (LVI), Livelihood Vulnerability Index- Intergovernmental Penal on Climate Change (LVI- IPCC), and Livelihood Effect Index (LEI). The methodology used for calculating the indices was adapted from (Hahn et al., 2009) and (Khajuria and Ravindranath, 2012), so as to include specific climatic and contextual conditions (Parry et al., 2007). In this study the index LEI is constructed on Sustainable Livelihood Framework to understand vulnerability regarding livelihood. The framework for sustainable livelihoods has been presented in *Fig. 1* which shows that processes and structures, livelihood outcome and livelihood strategies of a community are influenced by the vulnerability context and that is determining factor for sustainable livelihoods. More precisely, in Pakistan, the financial security of smallholder farmers is seriously threatened by the occurrence of droughts and floods negatively impacting on agricultural production, with further negative impacts on market price volatility for agriculture commodities, as well as by heavy reliance on agriculture as a single source for income generation. Knowing that reduced financial resources and lack of alternative sources for income generation have been identified as contributors to environmental degradation (Tripathi and Vasan, 2014), two more components, Finance and Knowledge and skills, have been taken into consideration, besides the original ones, for calculating vulnerability more precisely.

DOI: http://dx.doi.org/10.15666/aeer/1504_291312

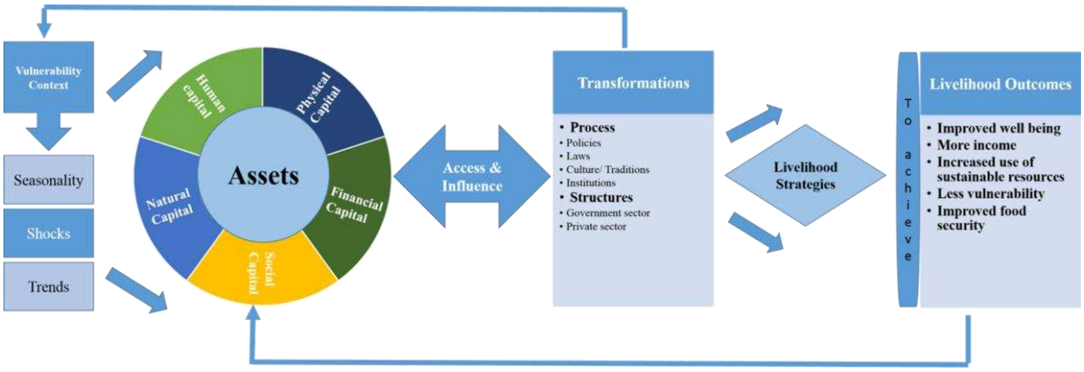

***Figure 1.** Framework for Sustainable livelihoods*

Calculating Livelihood Vulnerability Index

Both internal and external factors relating to smallholder farmer's vulnerability to climate change were taken into consideration for calculating LVI. Balance weighted approach was employed to calculate LVI.

The LVI includes nine essential elements: Socio-Demographic Profile (SDP), Livelihood Strategies (LS), Finance (Fi), Knowledge and Skills (KS), Social Networks (KS), Health (H), Water (W), Food (F), and Natural Vulnerability and Climate Variability (NVCV). Each of these elements is comprised of several sub-components identified in the literature reviewed and presented in *Table 1*. Because of different measuring scale of each of the sub-components, it was first necessary to standardize each of them as an index by using equation (1).

$$Index\ s_d = \frac{S_d - S_{min}}{S_{max} - S_{min}} \qquad \text{(Eq. 1)}$$

Where S_d is the originally observed value of the sub-component for district d, and S_{min} and S_{max} are the minimum and maximum values, respectively, for each sub-component determined using data from both districts. After each sub-component, has been standardized, the obtained values were averaged by using equation (2) to calculate the value of the major component.

$$M_d = \frac{\sum_{i=1}^{n} Index\ s_{d^i}}{n} \qquad \text{(Eq. 2)}$$

Where M_d represents one of the nine major components for district d, denotes the sub-components, indexed by i, that make up each major component, and n is the number of sub-components in each major component. The resulted values of each of the nine principal components were averaged by using the following equation (3) to calculate LVI at the district level.

$$LVI_d = \frac{\sum_{i=1}^{9} w_{Mi}\, M_{di}}{\sum_{i=1}^{9} w_{Mi}} \qquad \text{(Eq. 3)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_291312

Where LVI_d denotes the Livelihood Vulnerability Index for District d, obtained by the weighted average of the nine major components. The weights of each major component, w_{Mi}, were determined by the number of sub-components of each major component and are included to ensure that all sub-components contribute equally to the overall LVI (Sullivan, 2002; Hahn et al., 2009; González Botero et al., 2013). In this study, the LVI is scaled from 0 (least vulnerable) to 1 (most vulnerable).

Calculating Livelihood Vulnerability Index- Intergovernmental Penal on Climate Change

Exposure, Adaptive capacity and Sensitivity are the three contributing factors to livelihood vulnerability, according to IPCC definition of vulnerability to climate change. Organization and arrangements of the nine major components used to calculate LVI-IPCC is presented in *Table 2*. The sub-components in *Table 1*, and equation (1), (2), and (3) were used for the calculation of LVI-IPCC. The LVI–IPCC deviates from the LVI when the major components are combined. The major components were connected according to the categorization scheme in *Table 2*, rather than to merge into the LVI in one step, by using the following equation (4).

$$LVI_d = \frac{\sum_{i=1}^{n} w_{Mi}\ M_{di}}{\sum_{i=1}^{n} w_{Mi}} \qquad \text{(Eq.4)}$$

Where CF_d represents IPCC-defined contributing factor (exposure, adaptive capacity, or sensitivity) for district d, M_{di} denotes major components of the district d indexed by i; w_{Mi} indicates the weight of each major component, and n is the number of major components in each contributing factor. The calculated contributing factors were combined by using the following equation (5)

$$LVI - IPCC_d = (e_d - a_d) \times S_d \qquad \text{(Eq.5)}$$

Where LVI-IPCCd indicates the vulnerability index for district d calculated by using IPCC vulnerability framework, whereas ed, ad, and sd represent the scores of exposure, adaptive capacity and sensitivity for district d respectively. The scale for LVI-IPCC ranges from -1 (least vulnerable) to 1(most vulnerable).

Table 1. *Major and sub-components with the explanation and source for comprising LVI for two districts*

Major Components	Sub-components	Explanation of Sub-components	Source
Socio Demographic Profile	Dependency ratio	Ratio of the population under 15 and over 65 years of age to the population between 16 and 64 years of age.	(Hahn et al., 2009, González Botero et al., 2013, DHS, 2006)
	Female- headed household	If a male head is away from the home >6 months per year, the female is counted as the head of the household.	(Hahn et al., 2009, González Botero et al., 2013, DHS, 2006)
	Age of the household head	Average age of the household head	(González Botero et al., 2013)
	Households head not attended school	Percentage of households where the head of the household reports that they have attended 0 years of school.	(Hahn et al., 2009, González Botero et al., 2013, DHS, 2006)
	Household family size	Average family members in household	(González Botero et al., 2013)
	Number of years of employment in agriculture	Average agriculture experience of the household head	(González Botero et al., 2013)
Livelihood Strategies	Household family members working outside/ different community	Percentage of households that report at least 1 family member who works outside of the community for their primary work activity	(Hahn et al., 2009, González Botero et al., 2013)
	Household totally dependent on agriculture	Percentage of households that report only agriculture as a source of income.	(González Botero et al., 2013)
	Average agricultural Livelihood diversification index	The inverse of (the number of agricultural livelihood activities +1) reported by a household, e.g., A household that farms, raises animals, and collects natural resources will have a Livelihood, Diversification Index = 1/(3 + 1) = 0.25.	(Hahn et al., 2009, González Botero et al., 2013, DHS, 2006)
	Cultivated Land	Average of the total land cultivated by the Household	(González Botero et al., 2013)
Knowledge and Skills	Farmers not having T. V	Percent of household not having T.V at home	(González Botero et al., 2013)
	Farmers don't share knowledge with each other	Percent of households don't participate in knowledge exchange with others	(González Botero et al., 2013)
	Farmers think they lack in education	Percent of households that think they lack in education	(González Botero et al., 2013)

APPLIED ECOLOGY AND ENVIRONMENTAL RESEARCH 15(4):291-312.
http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_291312

Finance	Household having more expense than income	Percent of household having more expenditures than income	(González Botero et al., 2013)
	Household family member work at developed place	Percent of household with any family member working developed place not farming	(González Botero et al., 2013)
	Farmers taken loan	Percent of Household who taken loan in past five years	(Corbett, 1988, Tewari and Bhowmick, 2014)
Food	Farmers depend on land for food	Percentage of households that get their food primarily from their personal farms	(González Botero et al., 2013, Hahn et al., 2009)
	Average Crop Diversity Index	The inverse of (the number of crops grown by a household +1)	(Hahn et al., 2009, Tewari and Bhowmick, 2014, González Botero et al., 2013)
	Farmers that don't save crop	Percentage of households that do not save crops	(Hahn et al., 2009; Tewari and Bhowmick, 2014)
	Farmers that don't save seed	Percentage of households that do not save seed	(Hahn et al., 2009; Tewari and Bhowmick, 2014)
Health	Household family member with chronic diseases	Percentage of households that report at least 1 family member with chronic illness	(Hahn et al., 2009, Tewari and Bhowmick, 2014, DHS, 2006)
	Farmers receiving treatment in hospitals	Percentage of households receiving treatment from government or private hospitals	(Tewari and Bhowmick, 2014, Bhat et al., 2007)
	Time needed to reach hospital	Average time it takes the households to get to the nearest health facility.	(Hahn et al., 2009)
Water	Farmers utilize natural water source	Percentage of households that report a river, lake, or wells as their primary water source.	(Hahn et al., 2009, DHS, 2006)
	Farmers that store water	Percentage of households that store water for household activities and drinking	(Tewari and Bhowmick, 2014)
	Household with depleted water source	Percent of households reported their water source depleted	(González Botero et al., 2013)
	Household without water supply	Percentage of households that report that water is not available at their primary water source everyday	World Bank (1997); (Hahn et al., 2009, González Botero et al., 2013, Tewari and Bhowmick, 2014)
Social networks	Household received help and given help	Help given and received in kind in the past few months	(Hahn et al., 2009, DHS, 2006)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_291312

	Household borrowed or lent money	Percentage of households who borrowed more money than it lent in the past month	World Bank (1998); (Hahn et al., 2009)
	Household not affiliated to any organization	Percent of the households where none of the family member is affiliated with any social institution or organization	(González Botero et al., 2013)
Natural Vulnerability and Climate Variability	Household reported less rain during last few years	Percent of household reported less rain during past few years	(González Botero et al., 2013)
	Household reported more drought	Percent of household reported more drought in past few years	(González Botero et al., 2013)
	Household reported unusual rains	Percent of household reported unusual rains in past few years	(González Botero et al., 2013)
	Household reported increase in temperature	Percent of household reported increase in temperature in past few years	(González Botero et al., 2013)
	Household feel problems in agriculture due to climate change	Percent of household feel problems in agriculture due to climate change	(González Botero et al., 2013)
	Household don't receive warnings regarding severe weather	Percent of Household don't receive warnings regarding severe weather	(González Botero et al., 2013, Hahn et al., 2009, Tewari and Bhowmick, 2014)
	Household change in crop choices/ calendar due to climate change	Percent of household that change their crop choice due to climate change	(González Botero et al., 2013)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

Table 2. *Categorization of the major components for calculation of LVI-IPCC*

Contributing Factors	Major Components
Exposure	Natural vulnerability and climate variability
Adaptive Capacity	Socio demographic profile, Livelihood strategies, Knowledge and skills, Finance, Social networks
Sensitivity	Health, Food, Water

Calculating Livelihood Effect Index

The LEI was determined with the index values of five indicators, namely Human Capital, Natural Capital, Social Capital, Financial Capital and Physical capital. Categorization of the major components into these indicators is shown in *Table 3*. Each value of the five indicators was calculated by using the following equation (6).

$$Cv_d = \frac{\sum_{i=1}^{n} L_{di}}{n} \quad \text{(Eq. 6)}$$

Where Cv_d is the value of each capital of LEI for district d, whereas L_{di} and n represent the value of each effect dimension for capital i of district d and total sub-dimensions forming a capital. After calculating the value of each capital, these values were averaged to compute the LEI of the district by using the equation (7).

$$LEI_d = \frac{\sum_{i=1}^{5} W_i\, Cv_{di}}{\Sigma W_i} \quad \text{(Eq. 7)}$$

Where W_i and Cv_{di} indicate the weight of each capital and value of each capital of district d indexed by i. The LEI scale ranged from 0 (least affected) to 1 (most affected).

Table 3. *Arrangements of major components into different indicators for calculation of LEI*

Indicators	Effect Dimensions
Human Capital	Health, Food, Knowledge and Skills
Social Capital	Socio demographic profile, Social networks
Natural Capital	Water, Natural vulnerability and climate variability
Financial Capital	Finances
Physical Capital	Livelihood strategies

Results

Livelihood Vulnerability Index (LVI)

The average overall indexed values of socio-demographic profile vulnerability index (SDPVI) indicated Chakwal as more vulnerable (0.424) compared to Rawalpindi district (0.356). Among the 120 farmers interviewed in both districts, the average age of the respondents was 51 years. The average percentage of females was 7 and 8, respectively. The average number of years of employment in farming activities was 29 for both districts.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_291312

The average indexed value of the dependency ratio was higher (0.334) for Chakwal compared to Rawalpindi district (0.259). There was a slight difference in the pre-indexed value for female family heads in Chakwal (7%) and Rawalpindi district (8%). The average pre-indexed value for household heads not attended school was higher in Chakwal (70%), as compared to Rawalpindi district (48%). The average pre-indexed value for household family size in both districts was slightly different, with 7.37 persons in Chakwal and 8.07 persons in Rawalpindi district. The average pre-indexed value for the number of years of employment in agriculture was higher in Chakwal (31 years) compared with Rawalpindi District (25 years).

The average overall indexed value of Livelihood strategies vulnerability index (LSVI) was slightly higher for Rawalpindi (0.487) compared with Chakwal district (0.478), whereas a higher percent of farmers in Chakwal (0.71) were solely dependent on agriculture for income generation compared with Rawalpindi district (0.68). The average indexed value of family members employed outside the community was higher for Rawalpindi (0.479) compared to Chakwal district (0.306). The average indexed value for livelihood agricultural diversification index was lower for Rawalpindi (0.167) compared to Chakwal district (0.370). Pre-indexed values showed differences in terms of farmer's family members who are working outside, or in a different community (31 percent in Chakwal and 48 percent in Rawalpindi), percentage of farmers entirely dependent on agriculture (71 percent in Chakwal and 68 percent in Rawalpindi), along with average livelihood diversification index (0.311 in Chakwal and 0.250 in Rawalpindi). While slightly low differences were seen in terms of average cultivated land (3.1 and 3.3 acres in Chakwal and Rawalpindi district, respectively).

The average indexed value for knowledge and skills vulnerability index (KSVI) was slightly higher in Chakwal (0.293) compared with Rawalpindi district (0.246). The average pre-indexed values of KSVI subcomponents indicated very low percentage of farmers not having T.V. (six percent in Chakwal and two percent in Rawalpindi district, respectively), as well as low percentage of farmers who don't share knowledge with each other (four percent in Chakwal and eleven percent in Rawalpindi district, respectively). There was a considerable percentage of farmers who think they lack education (78 percent in Chakwal and 61 percent in Rawalpindi district, respectively).

The average indexed value of FiVI was higher for Rawalpindi (0.593) compared with Chakwal district (0.461). The average pre-indexed values of FiVI indicated a considerable percentage of farmers having more expenses than their income (95.8 percent in Chakwal and 83 percent in Rawalpindi district, respectively) and a comparably low percentage of household family members who worked at developed place (23.6 percent in Chakwal and 56 in Rawalpindi district, respectively. The average pre-indexed value for the percentage of farmers who took loans was considerably higher in Rawalpindi (39 percent) compared with Chakwal district (19 percent).

The average indexed value of the Food Vulnerability Index (FVI) indicated a rather low effect on the vulnerability in Chakwal (0.299) and Rawalpindi (0.349) district. The average pre-indexed value for the percentage of household depending on land for food was higher in Chakwal (71 percent) compared with Rawalpindi (56 percent) district. Similarly, the average indexed value for the same FVI sub-component was higher in Chakwal (0.71) compared with Rawalpindi (0.56) district. The percentage of farmers who don't save crop and seed was low in Chakwal (3.3 and 28.6 percent respectively) as compared to Rawalpindi (8.9 and 58.1 percent respectively) district.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_291312

The average overall indexed value for the health vulnerability index (HVI) value was slightly a higher for Rawalpindi (0.406) compared with Chakwal (0.393) district. The average pre-indexed values of HVI subcomponents indicated higher percentage of household family members with chronic diseases in Chakwal (31 percent) compared with Rawalpindi (21 percent) district, but a comparably lower percentage of farmers receiving treatment in hospitals in Chakwal (37 percent) compared with Rawalpindi (49 percent) district. The average pre-indexed value for the recorded time needed to reach the hospital was higher for Chakwal (150 minutes) compared with Rawalpindi (121 minutes) district.

The average overall indexed value for the water vulnerability index (WVI) was slightly higher for Chakwal (0.453) compared with Rawalpindi (0.396) district. The average pre-indexed values of WVI sub-components indicated considerably low percentage of farmers who utilized natural water source (8 percent in Chakwal and 5 percent in Rawalpindi district, respectively); a moderate percentage of farmers who stored water (29 percent in Chakwal, and 33 percent in Rawalpindi district); and considerably high percentages of farmers who complained that their water source was depleted (48 percent in Chakwal, and 69 percent in Rawalpindi district) and of farmers living without water supply (96 percent in Chakwal, and 51.4 percent in Rawalpindi district).

The average overall indexed value for the social networks vulnerability index (SNVI) was slightly higher for Chakwal (0.519) compared with Rawalpindi (0.476) district. The average pre-indexed values of SNVI sub-components also indicated slight differences in the ratio of farmers not receiving and giving help (1.31 in Chakwal, and 1.35 in Rawalpindi district, respectively), the ratio of farmers who borrowed and lent money (1.5 in Chakwal, and 2 in Rawalpindi district, respectively). The average pre-indexed value for the percentage of farmers not affiliated with any organization was higher in Chakwal (82 percent) compared with Rawalpindi (69 percent) district.

The average overall indexed value for the natural vulnerability and climate variability vulnerability index (NVCVVI) was high for both Chakwal (0.777) and Rawalpindi (0.813) district. The average pre-indexed values of NVCVVI sub-components indicated considerably high percentages of farmers, reporting reduced rainfall during the last year (61 and 81 percent), severe drought (79 and 88 percent), and unusual rain (81 and 85 percent); as well as an increase in temperature (85 and 96 percent) in Chakwal and Rawalpindi district, respectively. Similarly, it was observed that problems in agriculture due to climate change (82 and 93 percent), lack of warnings regarding severe weather (88 and 51 percent), change in crop choices or crop calendar (68 and 75 percent) in Chakwal and Rawalpindi district, respectively. However, these values, except for warning regarding severe weather, were higher for Rawalpindi compared with Chakwal.

The overall average indexed LVI value was higher for Rawalpindi (0.493) compared with Chakwal (0.479) district. The average indexed values of the nine major components of LVI (SDP, LS, KS, Fi, F, H, W, SN and NVCV) for both districts are also illustrated in *Fig. 2* which indicates KSVI as one of the major components with moderate effect on vulnerability. Likewise, *Fig. 2* also indicated FiVI as one of the major components with considerable effect on the vulnerability in both districts.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_291312

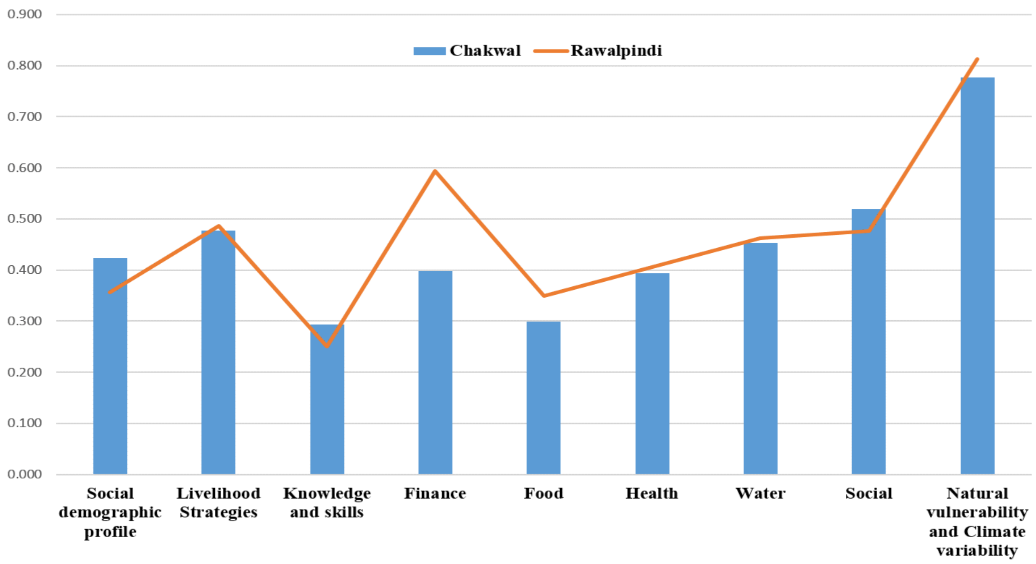

***Figure 2.** Major components of LVI for both districts*

Livelihood vulnerability index- Intergovernmental Panel on Climate Change (LVI-IPCC)

The overall average indexed values of LVI-IPCC were slightly different for Chakwal (0.106) and Rawalpindi (0.089) district. The average indexed values of the three contributing factors (Exposure, Adaptive Capacity, and Sensitivity) indicated slight differences between the two districts in terms of exposure (0.777 and 0.813), adaptive capacity (0.498 and 0.579) and sensitivity (0.381 and 0.382) in Chakwal and Rawalpindi district, respectively. The average indexed values of the three contributing factors, are also illustrated in *Fig. 3*, indicate that district Chakwal has the more adaptive capacity by showing lower vulnerability index compared with Rawalpindi district, whereas people of Rawalpindi are more exposed to climate change compared with Chakwal district. Regarding sensitivity, both districts are shown to be equally sensitive to climate change.

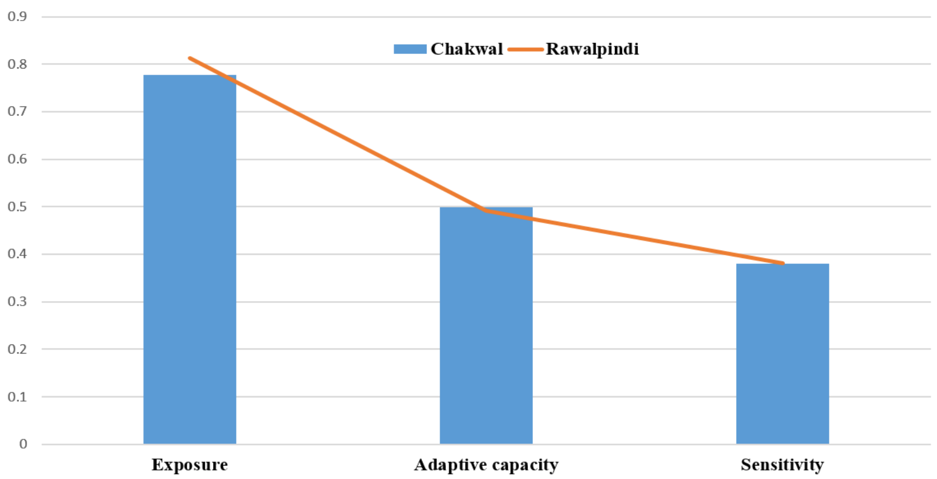

***Figure 3.** Contributing factors of LVI-IPCC for both districts*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_291312

Livelihood Effect index (LEI)

The average overall indexed value of LEI was a little difference for Chakwal (0.454) and Rawalpindi (0.474) district. The major components of LEI are described in *Table 3* and the average pre-indexed, and indexed values of these components are presented in *Table 4*. The arrangement of major components into different indicators used for the calculation of LEI is described in *Table 3*. The average overall indexed value for the human capital was slightly higher in Rawalpindi (0.341) compared with Chakwal (0.326) district. The average overall indexed value for the social capital was slightly higher for Chakwal (0.455) compared with Rawalpindi (0.396) district. The average overall indexed values showed no, or very little, difference for the natural capital (0.659 and 0.685), the financial capital (0.398 and 0.593) and the physical capital (0.478 and 0.487) in both Chakwal and Rawalpindi districts, respectively.

The average overall indexed values for these indicators are also illustrated in *Fig. 4* which showed both districts are more vulnerable to natural capital and less to human capital. Physical capital contributed almost equally to the vulnerability in both districts. People of Rawalpindi district were more vulnerable to financial capital while social capital contributed to vulnerability more in Chakwal compared to Rawalpindi district.

Discussion

Livelihood Vulnerability Index (LVI)

The results for SDPVI indicated Chakwal as more vulnerable compared with Rawalpindi district. The higher average overall indexed value of SDPVI for Chakwal district was mostly due to higher average pre-indexed values for the dependency ratio, household head without education, and many years of employment in agriculture, as well as to the indexed value of the household head. This reads as the farmers in Chakwal district were mostly in the range of age not allowing off-farm employment and self-sufficiency (Hahn et al., 2009; González Botero et al., 2013; DHS, 2006), illiterate, and could only be employed in agriculture, which is known as a sector associated with low income in Pakistan. Among these sub-components, lack of education registered the highest values for both districts and therefore had the highest effect on social vulnerability. This is because the lack of education was found to be associated with less income enhancing and diversification opportunity, generally low levels of income and social exclusion (Van der Berg, 2002; Green, 2006; Gebru and Beyene, 2012). The percentage of female farmers showed little differences in both districts, as females were mostly recorded as household head when husbands or sons lived off-farm for more than six months. The similarity of average pre-indexed values for the percentage of the female household head was due to similar trends of males working outside the community.

The results for LSVI indicated Chakwal and Rawalpindi districts as similarly vulnerable. The close similarity of the average overall indexed values of LSVI for both districts was partially due to similar average pre-indexed values for percentage of farmers entirely dependent on agriculture and surface of the cultivated land for Chakwal and Rawalpindi districts. The remaining part can be explained by lower average pre-indexed value for family members working outside the community but higher average pre-indexed value for agricultural livelihood diversification index in Chakwal compared with Rawalpindi district, which balanced the average overall indexed values of LSVI for both districts. The lower percentage of farmers, exclusively males, working outside the community in Chakwal district was due to the age limitation of the respondents (mostly 16 and 64 years) not allowing them to get employed in off-farm activities. The higher average pre-indexed value for agricultural livelihood diversification index in Chakwal district was mostly due to a higher number of years of employment in agriculture providing the farmers with better skills needed for diversifying agricultural production, on one hand, and the lower income generated from these activities compared with income generated from off-farm activities. Therefore, the respondents from Chakwal district, and to the lower extent from Rawalpindi district, grew crops but also raised livestock and poultry and sold the production surplus on the nearby markets to diversify their income.

The results for KSVI indicated Chakwal as more vulnerable compared with Rawalpindi district. The higher average overall indexed value of KSVI in Chakwal district was mostly due to higher average pre-indexed values for the percentage of farmers who thought they lacked education and the percentage of farmers not having TV. The higher percentage of farmers who thought they lacked education in Chakwal district can be explained by the considerably higher percentage of household heads without education compared with Rawalpindi district. Therefore, the respondents from Chakwal district might have more narrow perspectives on livelihood issues and fewer

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_291312

opportunities for improving their living conditions by, for example, adopting new agricultural techniques (Kalinda, 2014; Aasoglenang and Bonye, 2013). There is a need to educate the farmers to cope with the climatic stressors and protect their livelihoods from environmental hazards (Hsueh and Su, 2017).

The results for FiVI indicated Rawalpindi as less vulnerable compared with Chakwal district. The higher average overall indexed value of FiVI for Rawalpindi district was mostly due to the considerably higher pre-indexed values for the percentage of family members working at developed places and the percentage of farmers who took a loan. The higher values were due to a higher percentage of family members working outside the community, and having higher income, but also a higher percentage of farmers taking loans. The social mobility outside the community in Rawalpindi district may have been an attempt to ensure the financial security for the time being and future (Snel and Staring, 2001). One of the main reason for which financial component showed such effect on vulnerability was a much higher percentage of farmers in Chakwal reporting higher expenses than income and taking loans compared with Rawalpindi district. However, the average pre-indexed values for the percentage of farmers taking loans were rather low for both districts, due to the high-interest rates, terms and conditions for receiving loans, and low availability of appropriate institutions in rural areas.

The higher average pre-indexed value for the percentage of households having more expenses than income in Chakwal district was mostly due to the large percentage of the respondents employed in low-income activities, compared with Rawalpindi district. The results for FVI indicated Rawalpindi as more vulnerable compared with Chakwal district. The higher average indexed value of FVI in Rawalpindi district was mostly due to considerably higher average pre-indexed values for the percentage of farmers who did not save crop products and seeds. These higher values can be explained by a higher percentage of farmers employed in off-farm work in Rawalpindi district, on one hand, and by a higher percentage of self-sufficient farmers employed in agriculture in Chakwal district. Therefore, the lower average pre-indexed value for the percentage of farmers totally dependent on land for food in Rawalpindi district. The similarity of average pre-indexed value for average crop diversity index was due to similar crops in both districts.

The results for HVI indicated Chakwal and Rawalpindi district similarly vulnerable. The close similarity of average overall indexed values of HVI for both districts was mostly due to average pre-indexed values for the percentage of household family members with chronic diseases - higher in Chakwal and lower in Rawalpindi district; the percentage of farmers receiving treatment in hospitals - lower in Chakwal and higher in Rawalpindi district; and the time needed to reach the hospital - higher in Chakwal and lower in Rawalpindi district, all contributing to balanced average overall indexed values of HVI for both districts. The slightly lower values for Rawalpindi district were likely due to increased availability of health facilities.

The results for WVI indicated Chakwal as more vulnerable compared with Rawalpindi district. The higher average overall indexed value for WVI in Chakwal district was mostly due to higher average pre-indexed values for percentage of households without water supply, in particular, and, implicitly, the percentage of farmers utilizing natural water sources (i.e. rainwater). The considerably lower corresponding values for Rawalpindi district can be explained by additional income from off-farm activities allowing for investments inadequate farm endowments. Surprisingly, the pre-indexed average values were lower for the percentage of farmers

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_291312

storing water and the percentage of households with a depleted water source in Chakwal district. However, no conflict was reported and observed in Chakwal and Rawalpindi districts due to heavy reliance on the rainfall, and, to some extent, the existence of wells ensuring subsistence water supply in the area.

The results for SNVI indicated Chakwal as more vulnerable compared with Rawalpindi district. The higher average overall indexed value of SNVI for Chakwal district was mostly due to considerably higher average pre-indexed value for the percentage of households not affiliated with any organization such as governmental or non-governmental agricultural organizations. These types of organizations are known for their contribution to social capital through knowledge and information transfer, as well as technical support to farmers (Eakin and Bojorquez-Tapia, 2008). The low average pre-indexed values for the ratio of farmers receiving and giving help and the ratio of farmers lending money in both Chakwal and Rawalpindi districts indicated the weakness of social networks. This weakness was found to contribute to increased livelihood vulnerability (Thomas et al., 2005). Therefore, the weakness of social networks, as an aggregate component of LVI, LVI-IPCC, and LEI (*Tables 1, 2 and 3*), is majorly important to reducing livelihood vulnerability and farmers' vulnerability to climate change mostly through enabling the adoption of appropriate mitigating strategies (Hahn et al., 2009). However, the similarly high values for borrowing and lending money components indicate rather stable social networks in both districts.

The results for NVCVVI indicated Rawalpindi as more vulnerable compared with Chakwal district. The higher average overall indexed value of NVCVVI for Rawalpindi district was due to considerably higher average pre-indexed values of all sub-components, except the percentage of farmers not receiving warnings regarding severe weather, compared with Chakwal district. However, all the average pre-indexed value of NVCVVI sub-components were considerably high for both districts. Ahmad et al. (2010) also reported increases in temperature and unusual trend in rainfall for the last five to ten years in both districts. While in another study, Baniasadi et al. (2016) realized that less ground water reserves, low vegetation cover, soil erosion and increased flooding are some of the worst environmental externalities. Nevertheless, these calculated values, based on farmers' inaccurate estimates (Fowler, 2002), need to be compared with values from a natural hazard database at the district level for more accurate prediction of their impact on livelihood vulnerability (Hahn et al., 2009).

The results for the average indexed value of LVI indicated Rawalpindi as slightly more vulnerable concerning livelihood compared with Chakwal district. This was mostly due to higher average indexed values for NVCVVI, lower average indexed values for SNVI and SDPVI. The major components of LVI indicate household characteristics as contributing most to climate change vulnerability in both districts. Among these characteristics, the gender of household head, family size, dependency ratio, and illiteracy level registered values indicating Chakwal district as being socio-demographically highly vulnerable compared with Rawalpindi.

Livelihood Vulnerability Index–Intergovernmental Panel for Climate Change (LVI-IPCC)

The results for the average overall indexed value of LVI-IPCC indicated Chakwal and Rawalpindi district as similarly vulnerable to climate changes. This was due to similar average pre-indexed values for exposure and sensitivity. The higher average pre-indexed value for the adaptive capacity in Rawalpindi district was likely due to reduced

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_291312

vulnerability in terms of socio-demographic profile, social networks, and financial situation. Moreover, considerably higher average indexed values for exposure compared with average indexed values for adaptive capacity in both districts indicated their high vulnerability to climate change and their low capacity to adapt to climate changes (González Botero et al., 2013). Moreover, adoption of strategies towards mitigation of climate changes seems to be less possible by the respondents in Chakwal district, with higher illiteracy rate, higher dependency ratio, and higher financial vulnerability, compared with respondents in Rawalpindi district. However, Booysen et al. (2004) argued that if socio-demographic profile changes towards lower dependency ratio and reduced percentage of single-headed households, the adoption of these strategies can increase.

Livelihood Effect Index (LEI)

The results for the average overall indexed value of LEI indicated Chakwal and Rawalpindi districts as similarly vulnerable to livelihood effects. This was mostly due to closely similar average overall indexed values for natural, financial and physical capital. The slightly higher average overall indexed values for human capital in Rawalpindi was mostly due to lower vulnerability in terms of food compared with Chakwal district. The slightly higher average overall indexed values for social capital in Chakwal was mostly due to a higher vulnerability about the socio-demographic profile and social networks.

Natural and financial capital had the highest impact on the livelihoods of smallholder farmers in both Chakwal and Rawalpindi districts. These two types of capitals have been associated with increased livelihood vulnerability (Cobbinah et al., 2013). Surprisingly, the human capital, comprised of health, food, and knowledge and skills components, was associated with the lowest impact on the livelihoods of farmers in both Chakwal and Rawalpindi districts. This could be due to LEI values were based on qualitative estimations, indicating if a person is affected or not by individual factors, without quantifying these effects (Urothody and Larsen, 2010).

Conclusions

Our study has highlighted the problematic state of smallholder farmers in Pakistan, their high exposure to the climatic hazards and the earnest need to decrease both their present and future vulnerability to these dangers. Small landholdings, less innovation, low capitalization and various non-climatic stressors tend to build vulnerability however the strength components, family labor, crop expansion and indigenous knowledge cannot be depreciated. Expanding the profitability of smallholder farming systems is a big challenge that will require a critical and specialized, budgetary and political support at national and global levels. However, these indices will be helpful for planners to assess livelihood vulnerability to climate change sways in the regions of Pakistan and to create projects to reinforce the most vulnerable segments. Replication of this study in the same areas and other locations over the reality of the situation will become obvious eventually how the adaptive capacity, exposure and sensitivity of the districts change as adaptation practices started.

This research work on assessment of smallholder farmers' livelihood vulnerability to climate changes can contribute to developing effective adaptation measures and ensuring sustainable agricultural development. Such research can also provide a scientific basis for the decision-making process and risk analysis of climate change

impacts in developing countries, where the majority of smallholder farmers, as an important social group worldwide, are located.

Acknowledgements. We thank Mr. Muhammad Muqaddas and Syed Shah Mohioudin Gillani for their support in conducting surveys in both districts. This research was carried out under scholarship grant from China's National Social Science Funding in 2014, code #14DA064.

(Received 12th Apr 2017; accepted 8th Jun 2017)

Abstract. The aim of this study was to identify selected factors that influence the preferences of European beavers *Castor fiber* for various tree species in three different riparian zones. The study was realized during the November and December of 2015, in 8 research sites located in the immediate vicinity of watercourses. To determine the foraging preferences of beavers, there were analyzed the species and diameter of trees in each riparian zone. Beavers cut down 33.44% trees and partly cut 5.2% trees from 2500 total identified. The results of this study indicate that willows, aspens and alders are most commonly cut by beavers in the fall and winter. In addition to tree species and diameter, beaver foraging preferences are also affected by the distance from the shoreline of a river, watercourse or a water body.
Keywords: *Castor fiber, food, cutting tree*

Introduction

The European beaver *Castor fiber* is a herbivore whose digestive system has adapted to plant foods. The beaver has a relatively long small intestine which is equal to around six-times its body length. The large intestine is also relatively large, and its capacity corresponds to twice the volume of the beaver stomach (Vecherskii et al., 2006). According to Dezhkin et al. (1986), stomach capacity in adult beavers is 350-1400 cm^3, and the digestion process lasts 30-48 hours. In a study conducted in the Voronezh Nature Reserve in Russia, Dezhkin et al. (1986) demonstrated that the daily energy demand of one-year-old beavers reached 1400 calories, whereas two-year-old and older beavers required 1 700 calories per day. The daily energy intake of young animals up to one year of age was estimated at 900 calories.

The annual food intake of an adult European beaver can be as high as 241 kg. In Ural, adult individuals consumed around 111.8 kg of food annually in areas overgrown mainly with birches and alders, and 159.8 kg in sites with a predominance of aspens (Janiszewski and Misiukiewicz, 2012). According to Starinovic (1998), beavers consume around 100 kg of aspens and 230 kg of grass per year. Wood cutting is an important element of beaver behavior (Danilov and Fyodorov, 2015), and it plays a vital role in plant succession and biotope transformations in beaver habitats (Janiszewski et al., 2014, Logofet et al., 2016). Information about beaver foraging preferences can be used to model the utilization of plant foods by beaver families (Nummi, 1989) and to describe environmental changes in riparian zones inhabited by beavers (Rosell et al., 2005). Therefore, the aim of this study was to identify selected factors that influence the preferences of European beavers for various tree species in riparian zones.

Materials and Methods

We conducted the study in the Polesie National Park in eastern Poland (51°27′19″N; 23°10′24″E) (*Figure 1*). The Park occupies a total area of 9 764 ha, of which 1 211 ha is privately owned.

Figure 1. *Localization of Polesie National Park in Poland*

The Polesie National Park covers wetlands and peat bogs which create an ideal habitat for beavers. The park features lakes (Łukie, Długie, Moszne and Karaśne) which are characterized by varied trophic levels, small area and relatively small depth. The watercourse network in the Polesie National Park is composed of small and highly anthropogenic rivers (Mietiułka, Piwonia and Włodawa). Numerous ditches, channels and canals, which are permanently or seasonally filled with water, constitute an ideal habitat for beavers. Small water bodies, such as former peat pits, marshes and astatic reservoirs, also play an important role in the ecosystem. Around 5% of the park's area is covered with water. The Scots pine *Pinus sylvestris* is the predominant tree species in the Polesie National Park (36.7% of woodland area). Other dominant species that form tree stands are the downy birch *Betula pubescens* (31.9%) and the black alder *Alnus glutinosa* (20.8%) (Radwan, 2002).

We conducted the study in November and December of 2015, in 8 research sites located in the immediate vicinity of watercourses. For the needs of the study, we labeled the research sites with numbers 1 to 8. Every study area was composed of a riparian zone with a length of 200 m and a width of 15 m. We permanently marked the limits of every research site during the study. We found lodges, burrows and dams in all study areas or in their immediate vicinity, which indicated the presence of active beaver families that had been previously monitored by the Park's employees.

The study areas covered various plant formations. Four sites occupied woodlands (sites 1, 2, 3 and 4), two study areas were composed of meadows (sites 5 and 6), and two study areas occupied non-forest tree and shrub communities (sites 7 and 8). We searched for and identified the species of trees and shrubs in the examined study areas (*Table 1*).

We determined the number and percentage of each tree species in every study area. We measured the diameter of all tree trunks 20 cm above ground, to the nearest 1 cm, with the use of a caliper. We divided the trees growing in the study areas into three classes based on the degree of damage caused by beavers:

- I – trees cut down by beavers,
- II – partly cut trees,
- 0 – undamaged trees.

We divided every study area into the following zones (belts):

- 5 m from the shoreline (riparian zone A),
- 5 m to 10 m from the shoreline (riparian zone B),
- 10 m to 15 m from the shoreline (riparian zone C).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_313327

To determine the foraging preferences of beavers, we analyzed the species and diameter of trees in each riparian zone. We also described the influence of environmental factors on beaver preferences for the analyzed tree species.

Statistical analyses were processed by on way ANOVA in non-orthogonal design using Tukey HSD test and with Fisher's exact test.

Results

We found a total of 17 tree species in the examined study areas (*Table 1*). The study areas were occupied by a total of 2500 trees. The predominant species were the downy birch (724 trees), black alder (719 trees) and aspen (257 trees).

Beavers cut down 836 trees (33.44%) and partly cut 130 trees (5.2%). We found the highest number of trees (495) in study area No. 8, which accounted for 19.8% of trees in all research sites. We also observed the highest number of cut trees (264) in study area No. 8, which accounted for 31.58% of trees cut in all research sites (*Table 2*).

In the group of identified tree species (*Table 1*), the only species that were not damaged by beavers were Scots pines, common spruces, rowans and field elms (*Table 2*).

Downy birch (*Betula pubescens*) was the predominant tree species in all the study areas, and of the 724 identified trees, 217 trees (29.9%) were cut by beavers (*Table 2*). We found the highest number of birches (238) in study area No. 1, which accounted for 32.87% of birches in all research sites (*Table 2*). We also identified the highest number of cut birches (68) in research site No. 1 which occupied a wooded area. In site No. 1, cut birches accounted for 31.34% of all birches cut by beavers.

Downy birch was most prevalent in riparian zone A where we identified 329 trees (45.4%). We found 185 birches (25.6%) in riparian zone B, and 210 birches (29%) in riparian zone C. The highest number of birches was cut in zone A (151 trees, 45.9%), followed by zone B (38 trees, 20.54%) and zone C (28 trees, 13.33%) (*Tables 5, 6, 7*).

The diameter of birches in the study areas ranged from 3 to 46 cm. The mean diameter of all analyzed birches was 11 cm. The mean diameter of birches was 10.8 cm

Black alder (*Alnus glutinosa*) was represented by 719 trees, of which 63 (8.76%) were cut by beavers. The species was most prevalent (359 trees) in study area No. 3, where it accounted for 49.93% of all black alder trees (*Table 1*). We observed the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_313327

highest number of cut black alders (27) in study area No. 8 which was occupied by non-forest tree and shrub communities. In site No. 8, cut black alders represented 42.86% of all black alders cut by beavers.

Black alder was most prevalent in zone A (587 trees, 81.6%). Zone B was occupied by 81 black alders (11.3%), and zone C – by 51 (7.1%). We found the highest number of cut black alders in zone A (52 trees, 8.9%). Beavers cut 8 black alders in zone B (9.9%) and only 3 trees in zone C (5.9%) (*Tables 5, 6, 7*).

The diameter of black alders in the study areas ranged from 1 to 39 cm. The mean diameter of all black alders was 12.3 cm. The mean diameter of trees was 11.4 cm in zone A, 14.5 cm in zone B, and 19.0 cm in zone C. The mean diameter of all cut black alders was 10.5 cm.

Common aspen (*Populus tremula*) was represented by 257 trees, of which 117 (45.5%) were cut by beavers. The species was most prevalent (119 trees) in study area No. 2, where it accounted for 46.3% of all aspens (*Table 1*). We observed the highest number of cut aspens (43) in research site No. 1 which occupied a woodland. In site No. 1, cut aspens represented 36.75% of all aspens cut by beavers.

Common aspen was most prevalent in zone A (92 trees, 35.8%), followed by zone B (91 trees, 35.4%), and zone C (51 trees, 19.8%). We found the highest number of cut aspens in zone A - 56 trees (60.9%). Beavers cut 33 aspens in zone B (36.3%) and 28 trees in zone C (37.8%) (*Tables 5, 6, 7*).

The diameter of aspens in the study areas ranged from 2 to 40 cm. The mean diameter of all aspens was 17.3 cm. The mean diameter of aspens was 16.7 cm in zone A, 18.6 cm in zone B, and 16.4 cm in zone C. The mean diameter of all cut aspens was 15.8 cm.

Gray willow (*Salix cinerea*) was represented by 215 trees, of which 213 (98.6%) were cut by beavers. The species was most prevalent (129 trees) in study area No. 8, where it accounted for 60% of all gray willows (*Table 1*). We observed the highest number of cut gray willows (128) in research site No. 8 which was occupied by non-forest tree and shrub communities. In site No. 8, cut willows represented 60.38% of all gray willows cut by beavers.

Gray willow was most prevalent in zone A (157 trees, 73%). Zone B was occupied by 18 gray willows (8.4%), and zone C – by 40 (18.6%). We found the highest number of cut gray willows in zone A (154 trees, 98.1%). Beavers cut 18 gray willows in zone B (100%) and 40 trees in zone C (100%) (*Tables 5, 6, 7*).

The diameter of gray willows in the study areas ranged from 1 to 11 cm. The mean diameter of all gray willows was 2.9 cm. The mean diameter of gray willows was 3.1 cm in zone A, 2.4 cm in zone B, and 2.6 cm in zone C. The mean diameter of all cut gray willows was 2.9 cm.

White willow (*Salix alba*) was represented by 142 trees, of which 105 (73.9%) were cut by beavers. The species was most prevalent (107 trees) in study area No. 4, where it accounted for 75.35% of all white willows (*Table 1*). We observed the highest number of cut white willows (89) in research site No. 4 which occupied a woodland. In site No. 4, cut willows represented 84.76% of all white willows cut by beavers.

White willow was most prevalent in zone A (107 trees, 75.4%). Zone B was occupied by 25 white willows (17.6%), and zone C – by 10 (7%). We found the highest number of cut white willows in zone A (74 trees, 69.2%). Beavers cut 25 white willows in zone B (100%) and 6 trees in zone C (60%) (*Tables 5, 6, 7*).

The diameter of white willows in the study areas ranged from 2 to 50 cm. The mean diameter of all white willows was 9.7 cm. The mean diameter of white willows was 8.6 cm in zone A, 8.0 cm in zone B, and 26.5 cm in zone C. The mean diameter of all cut white willows was 9.0 cm.

Small-leaved lime (*Tilia cordata*) was represented by 117 trees, of which 65 (55.6%) were cut by beavers. The species was most prevalent (60 trees) in study area No. 7, where it accounted for 51.28% of all limes (*Table 1*). We also observed the highest number of cut limes (33) in research site No. 7 which was occupied by non-forest tree and shrub communities. In site No. 7, cut limes represented 50.77% of all limes cut by beavers.

Small-leaved lime was most prevalent in zone A (54 trees, 46.2%). Zone B was occupied by 37 limes (31.6%), and zone C – by 26 (22.2%). We found the highest number of cut limes in zone A (41 trees, 75.9%). Beavers cut 19 limes in zone B (51.4%) and 5 limes in zone C (19.2%) (*Tables 5, 6, 7*).

The diameter of limes in the study areas ranged from 2 to 27 cm. The mean diameter of all limes was 5.0 cm. The mean diameter of limes was 5.1 cm in zone A, 4.4 cm in zone B, and 5.8 cm in zone C. The mean diameter of all cut limes was 4.4 cm.

Pedunculate oak (*Quercus robur*) was represented by 92 trees, of which 16 (17.4%) were cut by beavers. The species was most prevalent (40 trees) in study area No. 2, where it accounted for 43.48% of all oaks (*Table 1*). We observed the highest number of cut oaks in research sites No. 3 (5) and 4 (5) which occupied woodlands. In those study areas, cut oaks represented 29.41 % of all pedunculate oaks cut by beavers.

Pedunculate oak was most prevalent in zone C (47 trees, 51.1%). Zone A was occupied by 29 oaks (31.5%), and zone B – by 16 (17.4%). We found the highest number of cut oaks in zone C (10 trees, 21.3%). Beavers cut 4 oaks in zone B (25.0%) and only 3 trees in zone C (10.3%) (*Tables 5, 6, 7*).

The diameter of oaks in the study areas ranged from 2 to 36 cm. The mean diameter of all oaks was 13.0 cm. The mean diameter of oaks was 7.9 cm in zone A, 7.4 cm in zone B, and 16.9 cm in zone C. The mean diameter of all cut oaks was 12.1 cm.

Alder buckthorn (*Frangula alnus*) was represented by 68 trees, of which 17 (26.0%) were cut by beavers. The species was most prevalent (28 trees) in study area No. 3, where it accounted for 41.18% of all alder buckthorns (*Table 1*). We observed the highest number of cut alder buckthorns (8) in research site No. 7 which was occupied by non-forest tree and shrub communities. In study area No. 7, cut trees of the discussed species represented 47.06% of all alder buckthorns cut by beavers.

Alder buckthorn was most prevalent in zone A (48 trees, 70.6%); only 2 alder buckthorns (2.9%) were found in zone B, and 18 (26.5%) in zone C. We found the highest number of cut alder buckthorns in zone C (10 trees, 55.6%) and zone A (7 trees, 14.6%) (*Tables 5, 6, 7*).

The diameter of alder buckthorns in the study areas ranged from 1 to 12 cm. The mean diameter of all alder buckthorns was 4.8 cm. The mean diameter of alder buckthorns was 4.8 cm in zone A, 5 cm in zone B, and 4.9 cm in zone C. The mean diameter of all cut alder buckthorns was 4.2 cm.

Scots pine (*Pinus sylvestris*) was represented by 52 trees, of which only 2 (4%) were partially cut by beavers, and no trees were felled. The species was most prevalent (24 trees) in study area No. 2, where it accounted for 46.15% of all pines.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_313327

Scots pine was most prevalent in zone C (38 trees, 73.1%). Zone B was occupied by 9 pines (17.3%), and zone A – by 5 (9.6%). The mean diameter of all pines was 22.4 cm. The mean diameter of pines was 16 cm in zone A, 19 cm in zone B, and 24 cm in zone C.

Norway maple (*Acer platanoides*) was represented by 34 trees, of which only 1 (3.0%) was cut by beavers. The species was most prevalent (30 trees) in study area No. 4, where it accounted for 88.24% of all maples (*Table 1*). Beavers cut only 1 maple in research site No. 4 comprised of wooded areas. Norway maple occupied only riparian zone C.

Common spruce (*Picea abies*) was represented by 25 trees, and it accounted for only 1% of all analyzed tree species. Common spruces were not cut down by beavers.

The remaining tree species (common ash, common hawthorn, European pear, field elm, common hornbeam and rowan) accounted for less than 1% of all identified taxa. Riparian zone A was occupied by a total of 1431 trees, of which 551 (38.5%) were cut and 98 (6.85%) were partly cut by beavers. Riparian zone B was occupied by 503 trees, of which 152 (30.22%) were cut and 17 (3.38%) were partly cut by beavers. Riparian zone C was occupied by 566 trees, of which 133 (23.5%) were cut and 15 (2.65%) were partly cut by beavers (*Tables 5, 6, 7*).

In all study areas, 1427 trees (57.08%) were less than 10 cm in diameter. We determined the number of trees with a diameter smaller than 10 cm at 844 (61.77%) in zone A, at 224 (44.53%) in zone B, and at 319 (56.36%) in zone C. In the total number of trees cut in all study areas, 101 (12.08%) were larger than 15 cm in diameter. We determined the number of cut trees with a diameter larger than 15 cm at 50 (9.1%) in zone A, at 32 (21%) in zone B, and at 19 (14.28%) in zone C (*Table 4*).

Discussion

The results of this study and the findings of other authors clearly indicate that willows, aspens and alders are most commonly cut by beavers in the fall and winter (Ficek, 2003; Vorel et al., 2015; O'Connell et al., 2008; Goryainova et al., 2014). In some studies, beavers chose other species of trees and shrubs, such as *Corylus avellana* (Margaletic et al., 2006). Interestingly, beavers relatively often opted for alder buckthorn (26% trees cut) and pedunculate oak (more than 17% trees cut) in the current study. Gorshkov and Gorshkov (2011) investigated the foraging behavior of the European beaver in the Republic of Tatarstan (European Russia). The authors analyzed 14 000 cut trees and concluded that the foraging preferences of beavers are largely determined by the availability of different tree species in the riparian zone. In the cited study, beavers cut mostly willows (*Salix triandria* and *Salix dasyclados*), which accounted for 92% of all cut trees; whereas willows that were less than 10 cm in diameter accounted for 81% of cut trees. Alder was the second most frequently felled tree, and it accounted for 3% of all cut trees. The cited authors did not report correlations between beaver foraging preferences and the diameter of most tree species, excluding willows and aspens. To cut thicker trees, beavers have to spend more time on land, which increases the risk of a predatory attack. For this reason, beavers select trees not only based on the species, but also based on the diameter of the trunk. In the present study, differences were noted in beavers' preferences for trees that were up to 15 cm in diameter and trees that were larger than 15 in diameter, across the analyzed riparian zones (*Table 4*). On average, nearly 88% (79.0% to 90.9%) of the trees cut by beavers had diameters of up to 15 cm.

Information about the foraging behavior and preferences of beavers not only expands our knowledge about the species, but also has practical implications. Based on the choices made by beavers, researchers are able to identify the optimal habitats for beavers and estimate the rate at which these animals utilize riparian vegetation. Selective foraging on tree species by beavers in different biotopes is another important consideration. In our study, we observed the highest number of trees damaged by beavers in woodlands and in non-forest tree and shrub communities. Czyżowski et al. (2009) also reported valuable data in a study comparing the foraging preferences of beavers in an urban area (city of Lublin, Poland) and a nature reserve. Their research was conducted near the study areas analyzed in our experiment. In the cited study, white willow and black alder were also most frequently selected by beavers, which can be attributed to the prevalence of these species in the investigated area. In the nature reserve, beavers opted mostly for trees with thinner trunks. The number of damaged trees decreased with an increase in their breast height diameter. The cited authors did not report such a correlation in the analyzed urban area. Beavers also showed a preference for trees representing the most common diameter ranges. The above results suggest that beavers actively select their food sources in natural habitats that are not exposed to external pressures.

In addition to tree species and diameter, beaver foraging preferences are also affected by the distance from the shoreline of a river, watercourse or a water body. Czyżowski et al. (2009) analyzed the depth of incisions made by beavers in trees, subject to the distance from the shoreline. Their findings revealed that beavers most readily foraged for trees and shrubs situated within a distance of 50 m from a watercourse. Trees were most frequently cut in the immediate vicinity of water bodies, but damage to shrubs was noted even within a distance of 80 m from the shore. Shrubs are easy to cut and transport, which prompts beavers to travel greater distances in search of this source of food and building material. The majority of trees cut by beavers were situated within a distance of 10 m from the shoreline (Czyżowski et al., 2009). In the Jamy Forest Division in central Poland, beavers showed a preference for trees with a diameter of up to 15 cm, growing within a distance of 15 m from the shore (Janiszewski et al., 2012). The results of our study and the findings of other authors suggest that beavers concentrate their feeding activity in riparian zones that are 15 m in width. According to Goryainova et al. (2014), beavers generally do not forage further than 50 m away from the shore in early stages of habitat colonization. When local food resources are depleted, the foraging zone can be expanded to 165 m from the shoreline in the absence of pressure from predators. Gorshkov and Gorshkov (2011) demonstrated that the foraging preferences of beavers were more strongly manifested at greater distances from a water body. Aspens were cut at a distance of up to 60 m from the shore, whereas other tree species were damaged mostly within a 10-meter-wide riparian zone.

Nolet et al. (1994) suggested that beaver preferences for tree species could be influenced by the demand for specific nutrients. Beavers could choose hazels and ashes due to their high sodium content, and plum trees and poplars on account of their high phosphorus levels. Therefore, the collection and selection of varied food resources could be a strategy that minimizes the risk of nutrient deficiencies in the European beaver.

Douced and Fryxell (1993) analyzed the relationships between the nutritional value of plant material and the foraging preferences of the Canadian beaver *Castor canadensis*. They found that feeding preferences were not significantly correlated with the energy value or the content of dry matter, energy, total protein or fiber in the analyzed food resources. The cited

DOI: http://dx.doi.org/10.15666/aeer/1504_313327

authors suggested that beavers and many other herbivorous vertebrates choose foods that are ample sources of energy. Similar results were reported by Jenkins (1981) who observed that beavers require diverse diets containing various species of plants. When captive beavers were fed monotonous diets composed of aspens only, their body weights decreased. The animals lost more nitrogen than they took in, and their calcium and phosphorus levels were unbalanced. For this reason, free living beavers supplement their diets with aquatic vegetation in the fall and winter when the availability of herbage is limited (Dezhkin et al., 1986). This is particularly important during breeding and nursing when the nitrogen and phosphorus requirements of animals increase six-fold relative to other seasons of the year. Beavers compensate for these demands by foraging on aquatic and herbaceous vegetation (Nolet et al., 1995). In the fall and winter, the animals cut down *Corylus*, *Fraxinus* (Na), *Prunus* and *Populus* (P) to avoid the above macronutrient deficiencies (Nolet et al., 1994).

The biomass of cut trees and shrubs is not fully utilized as food or building material by beavers. On average, beavers eat only round 30% of the collected woody plants, and the remaining resources are left to decompose naturally in the ecosystem. The animals have strong preferences for willows and aspens, which can slow down the succession of these species in floodplains. This process contributes to the growth of other plant species and creates a supportive habitat for aquatic fauna (Janiszewski et al., 2014). Beavers also use shoots and branches from cut trees to build dams. The selection of building materials is determined by the availability of trees in riparian zones, and beavers do not discriminate tree and shrub species based on their suitability for dam construction (Janiszewski et al., 2006).

(Received 14th Apr 2017; accepted 8th Jun 2017)

Abstract. Soil microorganisms are important components of terrestrial ecosystems and play an important role in organic matter fragmentation and nutrient cycling. In our study, microbial diversity of different plant communities and differences in the use of carbon sources in Tokatlı and Sırçalı Canyons were investigated. The canyons were investigated in three stages (tree, shrub and herb). Although there was no significant difference in developmental processes between different vegetation stages, differences between plant communities were significant ($P< 0.05$ and $P< 0.01$). In addition, the groups with the highest variation in carbon sources are *Quercus infectoria* OLIVIER-*Carpinus betulus* L. community in Tokatlı Canyon, and *Quercus pubescens* WILLD-*Pinus nigra* J.F.ARNOLD community in Sırçalı Canyon. The soil carbon content has the most important effect on the diversity of the carbon sources used by microbial communities in both canyons. Carbon source use of microbial communities in soil is affected by dominant species that control environmental factors above the soil.
Keywords: *diversity; plant community; vegetation stages; carbon sources; nutrient cycle*

Introduction

Biodiversity at ecosystem level reveals that not only species or species groups, but also features and processes should be protected (Atik et al., 2010). Soil microorganisms are important components of terrestrial ecosystems. The soil effects nutrient content and primary production. Thus, soil nutrient content and primary production is affected by microorganisms (Rutigliano et al., 2004). Topographic and edaphic factors are significantly influenced by species diversity (Gülsoy and Özkan, 2008). Plants and soil biota have a strong functional relationship as producers and decomposers of terrestrial ecosystems; plants provides organic carbon for soil biota through litter and root exudates, while soil biota decompose organic matter and release mineral nitrogen and phosphorus which are essential for plant growth (Zhang et al., 2010). In general, high plant species richness or functional diversity causes high heterogeneity of resource environments and as a result various microbial groups develop (Sugiyama et al., 2008). Although nitrogen mineralization in soil occurs under control of main soil characteristics, plants also have important functions in this process. Hence, dominant plant species in a region control productivity of an ecosystem by affecting degradation of nitrogen (van Vuuren et al., 1992). Plant species affect soil microbial activity through the quantity and quality of litter they produce. They also affect soil nitrogen conversion rates indirectly. There are important differences in quantity and decomposition characteristics of produced litter between species (Aerts et al., 2006). Also, soil microbial communities play an important to ecological indicator role in maintaining soil fertility and to evaluated soil health (Kumar et al., 2017). Decomposition and mineralization characteristics of organic matter by soil microorganisms are dependent on C / N rate of soil as well as chemical structure of carbon compounds (Krauss et al., 2004).

There are two determinants that shape species diversity in plant communities; species

pool and ecological connections. Soil organisms such as bacteria, fungi, algae, protozoa and some nematodes play a vital role in preserving soil fertility in organic matter degradation, humus formation and nutrient contents (Smith and Paul, 1990; Lin et al., 2004). Decomposition, cycling and microbial diversity in soil are important indicators of soil microbial function (Fox and Macdonald, 2003). Soil properties are influenced by, for example, soil acidity and nutrient elements of vegetation types (Finzi et al., 1998; van Breemen and Finzi, 1998). Slope differences affect the distribution and development of vegetation and the biological uptake of soil nutrients (Kubota et al., 1998). Soil microorganisms perform in many ecosystem processes, such as nutrient conversion, litter decomposition by regulating the structural and hydrological properties of the soil (Gallardo and Schlesinger, 1994; Kennedy, 1999). Although the effects of soil activity on these processes are well known, we know less about the structure of microbial communities (Derry et al., 1999). Over the last decade, the diversity of soil microbial communities were characterized using commercially available individual Biolog microtiter plates and by production of individual carbon (C) substrates (Insam, 1997). This technique is an ecologically relevant method for measuring microbial biodiversity because it determines the differences in carbon use between communities, which is an important factor. Although the community approach to measure biological diversity is not related to the functioning of the community as a whole, measuring the presence of individuals in the communities can provide more information. Many studies have been carried out on plant diversity in different ecosystems. However, few studies have been undertaken for microbial diversity that contributes to plant diversity for each different habitat (Derry et al., 1999). Canyon ecosystems are special and isolated habitats. Plant diversity of these areas has been studied, but soil microbial diversity and carbon source used has not been studied. This study aimed to determine the effects of biotic factors on diversity of soil microbial communities in isolated canyons and the differences in carbon use between two canyons.

Material and methods

Field study and sampling

The study was carried out in Tokatlı and Sırçalı Canyons, (Tokatlı Canyon: 41° 16′ 0.49″ N - 32° 41′ 0.85″E; Sırçalı Canyon: 41° 15′ 1.20″N - 32° 46′ 9.67″E), mainly covered by enclave mediterranean maquis, rocky slopes, stream coasts and meadows (*Fig. 1*). The vegetation of the area is a mosaic of plant patches of different ages, such as low maquis, high maquis, grassland and rock surface plants (*Fig. 2*). There were a total of 7 different plant communities in canyons, 4 communities in Tokatlı Canyon (*Sedum pallidum*, *Quercus infectoria-Carpinus betulus, Arbutus andrache-Cistus creticus*, *Corylus avellana*) and 3 communities in Sırçalı Canyon (*Fumana aciphylla- Helianthemum nummularium*, *Quercus pubescens-Pinus nigra*, *Juniperus excelsa*). Soil samples (n = 21) were collected in autumn, 2016. Representative surface soil samples (0–10 cm) and total 21 soil sample were taken from plots. All samples were kept at 4 °C from field to laboratory. Soil C was usually oxidized by combustion or wet oxidation and measured by conductivity. Soil pH values were measured in 1:2.5 soil/water extract (Richards, 1954). For electrical conductivity assessment with 1:2.5 ratio, 20 g soil sample was weighed within a conical flask. 50 ml distilled water was added and shaken on horizontal shaker for 15 minutes. Then, the solution in the conical flask was transferred into 100 beaker and left for 15 minutes. At the end of this period, a conductimeter electrode was soaked into clear upper phase and electrical conductivity (EC) value was read when it was stabilized.

Community level physiological profiling (CLPP) analysis

Biolog EcoPlates that are 96-well plates, containing 31 different carbon sources plus a control well, in three replications. The carbon utilization rate was determined with the purple color change of the colorless microorganisms by tetrazolium violet redox. Soil samples (10 g) were shaken for 60 min in 20 ml of a 10 mM Bis–Tris solution (pH 7) and then solutions were inoculated on microplates (100 µl per well) and incubated at 28 °C and allowed to settle for 30 min. Substrate utilization was measured with a spectrophotometer (Multiskan Microplate Photometer–Thermo Fisher Scientific) at 590 nm after 24, 48, 72, 96, 120 and 144 h incubation (Boivin, 2005). ODi (optical density) values obtained at 96 h incubation represented the optimal range of optical density values, so 96 h incubation readings were used for the assessment of microbial functional diversity and determination of carbon sources utilization. Microbial activity in each microplate was determined as average well color development (AWCD). Substrate richness values (R) were calculated as number of wells with color development (Zak et al., 1994). The AWCD was calculated using the equation: $AWCD = \Sigma\ ODi / 31$; the Shannon diversity (H’) was calculated using the equation: $H = -\Sigma\ pi\ (\ln pi)$ (Pi was called proportional color development of the well over total color development of all wells of a plate); and Evenness (E) was calculated using the equation: $E = H / \ln S$ (S = Richness was called number of wells with color development) (Garland, 1997).

Results

AWCD values of metabolized substrates in Biolog EcoPlates were obtained during 144 h for both study areas in two canyons. AWCD generally followed the same pattern of incubation time in both canyons (*Figs. 3* and *4*). There is no difference (*P value* = 0.065) in microbial diversity between different successive processes in Tokatlı Canyon. Significant differences in species diversity (H ') and richness (R) ($P < 0.001$) were found among different communities, while there was no difference between the processes (*P value* = 0.917). The group that caused the difference is *Arbutus andrache* plant community, which is the Mediterranean enclave. In Sırçalı Canyon, there is no significant difference in terms of successions processes and communities. In Tokatlı and Sırçalı canyons, significant differences were found ($P < 0.05$) in succession process levels in terms of AWCD values (*Table 1*). Significant differences ($P < 0.001$) and ($P < 0.05$) were found in R, H and AWCD between different plant communities in Tokatlı Canyon.

Regarding carbon source use in Tokatlı and Sırçalı Canyons, no differences were found in terms of successional processes. However, significant differences were found ($P < 0.0$, $P < 0.05$) for different plant communities. The differences in the use of complex carbons, carboxylic acids, amino acids and carbohydrates in the Tokatlı were found to be highest in *Quercus infectoria - Carpinus betulus* community. The use of amines and phosphate carbon in *Arbutus andrache* community has been found to be at minimum rate. Significant differences were found ($P < 0.01$, $P < 0.05$) in the use of complex carbons, carbonic acids, amino acids and amines as carbon source in Sırçalı Canyon. According to the Tukey’s test, the differences were found to be highest in *Quercus pubescens - Pinus nigra* communities in terms of their complex carbon, amino acids, carboxylic acids and amine amounts (*Table 2* and *Figs. 5, 6*).

In surface soil samples of both canyons, there are large variations between the carbon sources used by different plant communities on rocky surfaces (*Figs. 7, 8*). This proofs that microbial community varies depending on plant community structure. The first and second factors (PC1 and PC2) accounted for 28.31 and 20.21% of the variance, with a cumulative variance sum of 48.52%, respectively to Tokatlı Canyon. The effectiveness of ecological parameters contributing to the separation of carbon sources used by microbial communities in the field. CCA is indicated by the ordination analysis (*Fig. 9* and *Table 8*).

Discussion

As the succession stages progress, symbiotic interactions, mineral cycles, energy and nutrients are increasingly being used effectively. These events lead to the emergence of potential niches. While increasing the number of niches increases species diversity, competition and life span are also increasing. As this situation dominates some living species in the ecosystem, there are emerging elements of balancing species diversity. For this reason, the change of species diversity is not a direct effect of succession but a consequence of its indirect effects. The level of diversity reached determines the energetic relationships in the environment (Odum, 1997). The 95 substrate in the Biolog microplate provides prediction of the relative metabolic potential and responses of the microbiological community (Gomez et al., 2004). Nutrient availability is the main limiting factor for growth in forest ecosystems, and this is highly influenced by the processes in the rhizosphere. In rhizosphere the structure of microbial communities has been shown to vary depending on the type of tree. Microbial growth in soil is limited by carbon sources. As a result of rhizodeposition, carbon in rhizosphere increases microbial activity at high concentrations. Microbial diversity in different plant rhizospheres arise from the diversity of compounds leak from the plants. The data on the interactions between the microbial community and the soil is still insufficient (Graystone and Campbell, 1996). The carbon source utilization diversity of the samples in the Biolog microplate is related to the amount of carbon in the soil, soil pH and electrical conductivity. The soil carbon content is the most important effect on the diversity of the carbon sources used by microbial communities in both canyon areas. These results are similar to Bossio and Scow (1995) and Ritz et al. (1992). Tree layer in Tokatlı Canyon and grass layer in Sırçalı Canyon were responsible for these differences. Long carbon residence times in soil depend on quality and low quantity of litter and lower mineralization rate. Besides, at community level traits that support primary productivity and increase the availability of nutrients are slow degradation and traits that support soil carbon stability. This situation is related with coexistence of species with different growth rates (Hooper et al., 2005). Significant difference was found in terms of carbon use between communities.

Complex carbons, carboxylic acids, amino acids and carbohydrates in Tokatlı canyon were used most effectively by *Quercus infectoria - Carpinus betulus* communities. A mediterranean enclave *Arbutus andrache* community has the lowest use rate in amine and phosphate use as carbon sources. Drought and stress factors reduce the rate of carbon use in mediterranean enclaves while *Quercus - Carpinus* communities form more humid environment and thus affect mineralization level and provide more efficient use of carbon sources. Microbial communities in soil are controlled by climate, edaphic and topographic factors and even by fauna of the area (Zornoza et al., 2009). Dominant plant strategy within an ecosystem depends on the environmental conditions because dominance of species with high growth rates require highly available light and nutrients. Therefore, soil carbon input will be mainly derived from poor-quality litter in biomes with a short growing season and low nutrient availability, whereas primary productivity will be the main driver of soil carbon sequestration in more productive biomes (de Deyn et al., 2008). In this study, factors affecting substrate use in Sırçalı Canyon were pH, EC and soil carbon content. Among these factors, pH caused the most significant effect. Therefore in the area is controlled by nitrate use, because soil pH is influential in mineralization of nitrogen by

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_329340

determining the activity of microorganisms that decompose organic matter. In general, nitrate is formed in slightly acidic and slightly alkali (pH 6.0-8.0) soil and an increase in ammonium is seen due to increasing acidity (Doğan, 2012). In Tokatlı Canyon, factors influencing substrate use are EC and soil carbon content, respectively. Microbial markers of soil quality involves various variable parameters at ecosystem, community and population levels. Chemical properties are accepted as essential measurements although they are not sensitive markers as C and N contents (Ros et al., 2006). In our study, the difference in communities affects carbon sources, microbial diversity and richness, while no difference is found in terms of microbial communities for different successive processes (tree, shrub and grassy). Because, in the study areas in two canyons, the formation processes of plant communities on rock surfaces were at the beginning stages, indicating that the development in these areas were at early stages. At canyon surfaces, different plant communities show different carbon use rates. This proofs that microbial communities vary depending on plant community structure. The difference between communities is evidence that the soil microbial content is changing by plant communities settled in the area. Global changes are affecting carbon cycle pathways. Regarding this issue only a few biomes has been studied to date. Therefore, the number of studies on this topic should increase in order to determine the effects of climate change (de Deyn et al., 2008).

Acknowledgements. We would like to extend our thanks to Ordu University to Scientific Research Unit for the financial support they provided for the performance of this study within the framework of our project numbered AR-1368. Thanks also due to Prof. Hasan SEVGİLİ for he allows me to use the spectrophotometer in his laboratory.

Abstract. Pest insect species cause important economic losses in Turkish forests by feeding on various parts of forest trees. To combat them, control methods such as chemical, biotechnical, mechanical and biological applications are used. Among them, biological control is the most important method for the ecological aspect. Technically, the first biological control practice in Turkish forests was launched in the last part of the 1960s. This study aimed to evaluate current control methods for Turkish forestry. For this purpose, biological and chemical control applications in Turkey have been examined and compared. Necessary data were obtained from the 28 Regional Directorates of Forestry in Turkey using a developed data collecting method. Collected data were classified as insect production numbers, control areas and expenditures according to years. Subsequently, the total and unit costs were calculated and the gain and loss amounts obtained were estimated. Based on the comparison between chemical and biological control methods, chemical control is approximately 1.4 times more expensive than biological control in Turkey. This indicates that chemical control is causing economic loss in addition to ecological damages. In conclusion, the primary benefit of biological control is that it restores ecological balance and thus ensures the continuity of ecosystem services. The secondary benefit is savings from lower costs. Therefore, the use of biological control to mitigate damage from insects in forest ecosystems is important for the ecological and economic sustainability of forest ecosystems. To this end, predatory species such as *Rhizophagus grandis* Gyll, *Rhizophagus depressus* (F.), *Formica rufa* L., *Calosoma sycophanta* (L.) and *Thanasimus formicarius* (L.) have been used for biological control operations in Turkish forestry in recent years.
Keywords: *ecological-economic sustainability, pest control, natural balance, forest ecosystem*

Introduction

The forest ecosystem is the most fundamental and indispensible element of human life on earth. The history of utilization of forest resources is as old as humanity. Ecosytem services like carbon sequestration, non wood forest products, biodiversity and other attemps to adress climate change have vital importance for humankind. For the sustainable management of an ecosystem, the factors that compose the ecosystem should also be in balance. From this perspective, insects that had a natural role in a forest ecosystem may proliferate excessively due to various reasons, including human impact. It is of great importance to restore the forest ecosystem back to its natural balance. In order to do so, it is necessary to identify the factors and take the required measures. It is imperative to protect and ensure the sustainability of this vital and indispensible element of life (Tolunay and Türkoğlu, 2014). Given that forest ecosystems constitute a whole with their specific soil structures, plant communities and other organisms, it is important to protect and develop forest ecosystems with a view to ensuring their long term sustainability (Akyol and Tolunay, 2014).

Insects are among the most crucial threats to forests. In recent years, biological control methods that do not harm trees were proposed and put in practice to adress the disadvantages of chemical methods. The chemical insecticides that have negative effects and are dangerous for human health also lead to an insect resistance problem, which increases the pesticide cost because new compounds are needed. Today, it is understood that insecticides cannot provide a permanent solution for the control of insects. Biological control in which natural enemies of the pest insects are used avoids the negative consequences of chemical control on forest ecosystems.

Biological control can also be used to restore the natural balance from the human health perspective. The general principle of biological control is to protect, strengthen the natural enemy populations that have an impact on pest insects, and supplement them with imported species when needed. Technically, the first biological control practice in Turkish forests was launched in 1967 when *Formica rufa* was transplanted from the forest stands in North Anatolia to the Mediterranean region (Oğurlu, 2000). Predatory species such as *Rhizophagus grandis* Gyll, *R. depressus* (F.), *Formica rufa* L., *Calosoma sycophanta* (L.), *Thanasimus formicarius* (L.), as well as insectivore birds are used in biological control operations in Turkish forests; the rearing of predatory species was given priority after 2000s.

The ecological effects and consequences of insect control have been studied in the literature (Greatheat, 1976; Dijken, 1986; Brower, 1991; Van Lenteren, 2003; Orr, 2009; Uygun et al., 2010). However, there are only a limited number of studies that explore the economic aspects of insect control (Bokonon-Ganta, 2002; Born et al., 2005; Mc Fdyent, 2008; Fowler et al., 2016). In particular, there are very few studies in Turkey that explore the economic aspects of insect control methods. Existing studies mainly focus on the damage caused by insects to raw wood material and the associated economic loss. For example, Güngör and Daşdemir (2014) analysed the economic effects of *Pityokteines curvidens* Germ. on the sales of fir wood.
