

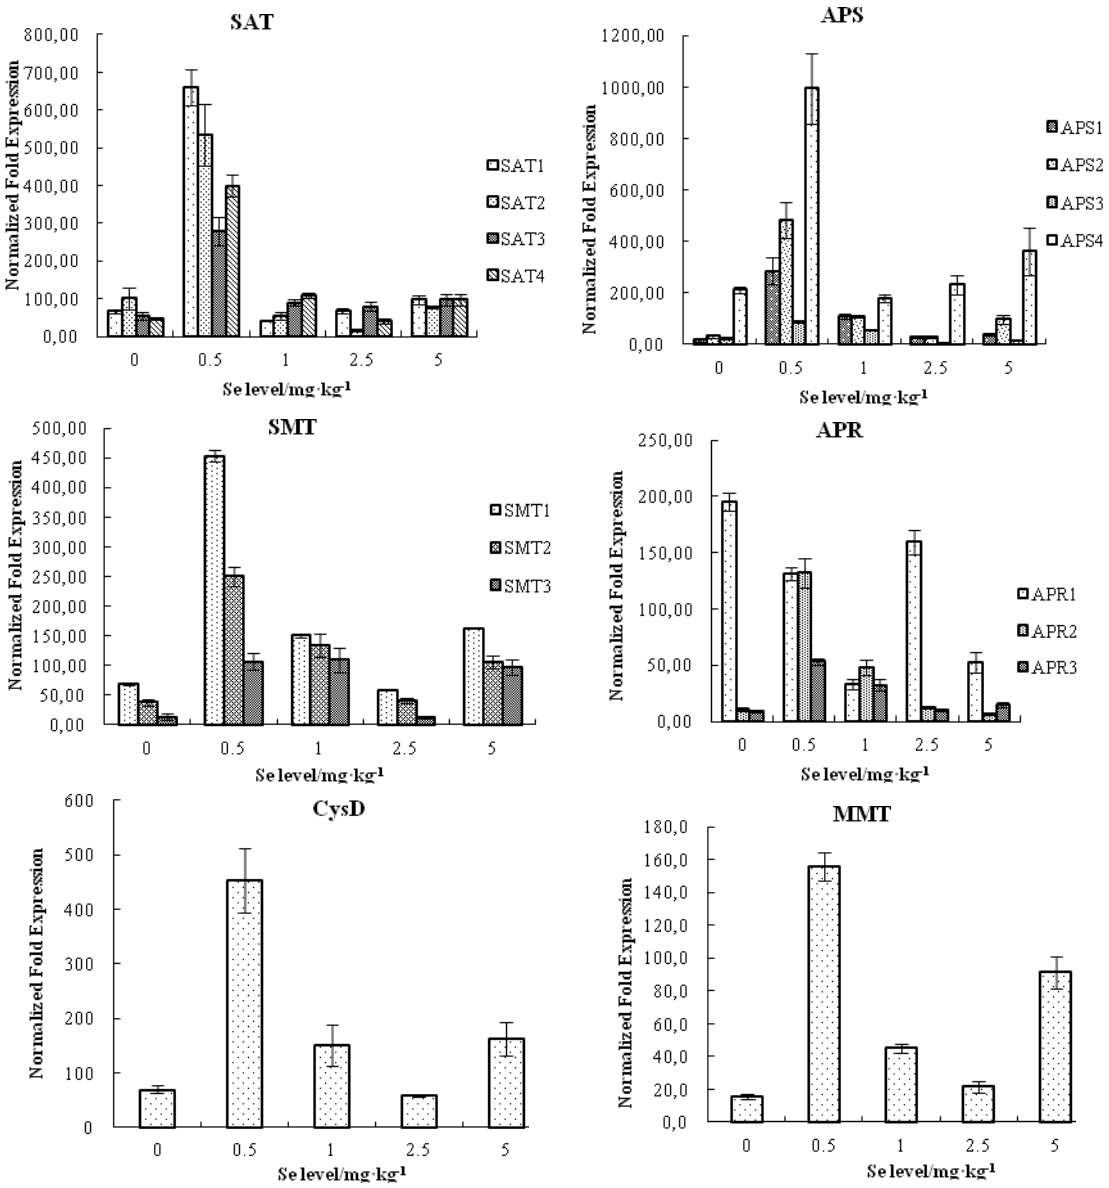

Figure 4. *Real-time PCR analysis of Se metabolism associated genes in leaf of Brassica oleracea var. capitata L.*

Discussion

In pot experiment, the accumulation of selenium in *Brassica* vegetables increased with the increase of soil selenium level, but selenium was extravagantly absorbed in *Brassica* vegetables at 5 mg·kg^{-1} selenium. This result was similar to that reported by Zhao et al. (2017). The uptake of selenium by plants varies according to the plant species (Šindelářová et al., 2015). For the three *Brassica* vegetables, *Brassica rapa ssp. chinensis* L. had the highest selenium uptake, while *Brassica oleracea* var. *capitata* L. had the lowest, probably because selenium action sites differ for different vegetables. To discover the specific reasons, in depth study is needed of the expression levels of selenium metabolism related genes.

Much of the selenite absorbed remains in the roots, with only a small fraction transported to the stems and leaves (Wiesner-Reinhold et al., 2017). In this experiment, $BCF_{root/soil} > BCF_{leaf/soil}$ of *Brassica rapa ssp. pekinensis* L. and *Brassica oleracea* var. *capitata* L. suggested that the selenium absorbed by the two *Brassica* vegetables mainly accumulated in the roots. $BCF_{stem/soil} < BCF_{root/soil} < BCF_{leaf/soil}$ of *Brassica rapa ssp. chinensis* L. indicated that it was more able to transport selenium to shoots. Moreover, during selenium transportation in the body of *Brassica rapa ssp. chinensis* L., there was no hindrance in selenium transport from root to leaf. In comparison among the three *Brassica v*egetables, $BCF_{leaevs/soil}$, $BCF_{stem/soil}$ and transport coefficient (TF) were the lowest in *Brassica oleracea* var. *capitata* L., indicating that it had relatively weak capacity of selenium uptake and selenium transport. In this experiment, selenium content, selenium enrichment coefficient and transport coefficient was the highest in *Brassica rapa ssp. chinensis* L. among the three *Brassica* vegetables, so *Brassica rapa ssp. chinensis* L. had the best selenium enrichment among the three *Brassica* vegetables.

Selenite has been found to be bioabsorbable by high-affinity proactive transport mechanism of ATP. Overexpression of ATP sulfurylase in transgenic plants accelerates this process and increases selenium tolerance and accumulation (Araie et al., 2008). Leduc et al. (2006) team over-expressed mustard ATP sulfurylase and SMT genes in Indian mustard at the same time, finding that mustard selenium content increased by 4-9 times. Terry et al. (2000) obtained transgenic plants that had increased selenium tolerance and enrichment by overexpression of seleno methyltransferase (SMT) in Arabidopsis and Indian mustard. In this experiment, ATP and APS expression levels of *Brassica rapa ssp. chinensis* L. and *Brassica oleracea* var. *capitata* L. increased significantly under selenium treatment. Meanwhile, exogenous selenium also increased SMT gene expression level, but high selenium level ($\leq$2.5 $mg \cdot kg^{-1}$) would down-regulate transcription level of SMT gene mRNA in *Brassica oleracea* var. *capitata* L., showing that SMT could enhance the tolerance of vegetables to selenium under high-selenium treatment, thus increasing the accumulation of selenium. SAT and CysD are two important enzymes involved in the synthesis and regulation of cysteine, and the two combine to form cysteine synthase (Çakır et al., 2012). In this experiment, SAT expression level in leaf of *Brassica rapa ssp. pekinensis* L. firstly increased and then decreased with the increase of soil selenium level. Exogenous selenium inhibited CysD expression in leaf of *Brassica rapa ssp. pekinensis* L., which may be due to the competitive effect of selenium and sulfur that caused inorganic sulfur hare to mix with cysteine, thus the transcription level of CysD gene mRNA was down-regulated. The expression levels of leaf genes SAT and CysD in the other two *Brassica* vegetables showed the same trend under the same treatment, probably due to the synergistic effect of the complexes formed by the two in plant cells (Liu et al., 2017). Methionine methyltransferase plays a key role in the production of volatile compounds in plants. SeMet and Met produce methyl-Semethionine (SeMM) and thiomethyl methionine (SMM) by homocysteine methyltransferase and methionine methyltransferase (MMT), and these compounds have toxic effects on non-selenium plants (Araie et al., 2008). In this experiment, the expression of MMT in leaves of *Brassica rapa ssp. chinensis* L. and *Brassica rapa ssp. pekinensis* L. was not significant at soil selenium level $\leq$ 2.5 $mg \cdot kg^{-1}$, but significantly increased at soil selenium level of 5 $mg \cdot kg^{-1}$. Under the same selenium level, the expression level of the same gene in different vegetables was significantly different, which may be related to the different transcriptional levels of mRNA.

Conclusion

The selenium concentrations in leaves, stems and roots of the three *Brassica* vegetables increased with the increase of soil selenium level, and selenium concentration in leaves was the highest at soil selenium level of 5 $mg \cdot kg^{-1}$. At 5 $mg \cdot kg^{-1}$ selenium level, the expression levels of SAT, SMT and MMT in leaves of *Brassica rapa ssp. chinensis* L. and the expression levels of SAT, APS, SMT, APR and MMT in leaves of *Brassica rapa ssp. pekinensis* L. were significantly increased, while expression levels of SAT, APS, SMT, APR, MMT and CysD in leaves of *Brassica oleracea* var. *capitata* L. were significantly decreased. Under the same exogenous selenium level, the selenium concentration, selenium enrichment coefficient and transport coefficient of edible parts were highest in *Brassica rapa ssp. chinensis* L. and the lowest in *Brassica oleracea* var. *capitata* L. among the three *Brassica* vegetables. *Brassica rapa ssp. chinensis* L. had the best selenium enrichment effect among the three *Brassica* vegetables. However, the field application of selenium-enriched vegetables should be studied in the future.

(Received 7th Feb 2018; accepted 3rd May 2018)

Abstract. In order to compare the application potential of alfalfa (*Medicago sativa* L.) and Indian mustard (*Brassica juncea* L.) on cadmium contaminated soil, difference in dry weight, Cd content and accumulation, transport and enrichment coefficient between alfalfa and Indian mustard were studied under different Cd levels (0, 75, 150, 300 and 600 $mg \cdot kg^{-1}$) using soil culture test. Also, Cd forms in soil were analyzed. The results showed that the dry weight of shoots and roots of alfalfa and Indian mustard decreased significantly ($P < 0.05$) with the increase of soil Cd levels, decreasing by 50.00-71.90% and 29.60-59.30% (alfalfa), 59.60-89.00% and 64.30-74.80% (Indian mustard) compared with the control. With the increase of soil Cd level, Cd concentration and Cd accumulation in shoots and roots of alfalfa and Indian mustard increased significantly ($P < 0.05$). At same soil Cd level, Cd concentration in shoots and roots was in order of alfalfa > Indian mustard, while Cd accumulation was in order of Indian mustard > alfalfa. At the soil Cd level of 75 $mg \cdot kg^{-1}$, Cd concentration in shoots of alfalfa and Indian mustard exceeded the critical value of Cd hyperaccumulator (100 $mg \cdot kg^{-1}$), 356.463 $mg \cdot kg^{-1}$ and 308.735 $mg \cdot kg^{-1}$ respectively. The enrichment coefficient (BCF) of alfalfa and Indian mustard was above 1 under all Cd levels, and the transport coefficient (TF) and BCF was in order of Indian mustard > alfalfa. Based on comprehensive consideration of biomass, Cd accumulation, transport coefficient and enrichment coefficient, Indian mustard is more suitable as repair material for soil Cd pollution.
Keywords: *soil Cd pollution, Cd hyperaccumulator, transfer coefficient, enrichment coefficient, soil Cd forms*

Introduction

Cadmium (Cd) is the top soil heavy metal pollutant. According to statistics, about 30,000 tons of Cd is released into the environment each year in the world, and of which Cd released into the soils reaches about 82-94% (Xiong et al., 2015). The total amount of Cd emitted into the environment from industrial waste is 680 tons per year in China (Ning et al., 2015). Cadmium pollution in farmland is 280,000 hm^2, and annual output of agricultural products with excessive Cd is nearly 1.5 million tons in China (Li et al., 2017b; Liu et al., 2017). Cadmium can be absorbed by plants and can be enriched in the human body through the food chain, endangering human health. Therefore, soil Cd pollution control and remediation has drawn wide attention from researchers (Li et al., 2017b; Marzban et al., 2017).

Indian mustard (*Brassica juncea* L.) is cruciferous *Brassica* with short growth cycle and great aboveground biomass. Capable of enriching a variety of heavy metals. When Cd was added at 0-200 $mg \cdot kg^{-1}$, the biomass of Indian mustard was unaffected, and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

shoot Cd concentration was up to 7.824-102.672 mg·kg^{-1}, and root Cd concentration was up to 0.374-191.910 mg·kg^{-1} (Yang et al., 2011). Alfalfa (*Medicago sativa* L.) a leguminous perennial herb, is a high-yielding cash crop. Sun and Song (2015) reported that Cd concentration below 25 mg·kg^{-1} can promote the growth of alfalfa shoot and root. With the increase of Cd level in soil, Cd concentrations in alfalfa shoot and root increase, and also has a higher enrichment effect on Cd ions. At present, there is little research on comparison of Cd uptake by alfalfa and Indian mustard. Therefore, in this study, the differences in biomass, Cd concentration and accumulation in alfalfa and Indian mustard, as well as Cd forms in soil were studied using soil culture test with different Cd concentrations, and plant suitable for soil Cd pollution remediation was screened out.

Materials and methods

Plant material, soil and Cd treatments

The seeds of alfalfa (*Medicago sativa* L.) were purchased from Jiangxi Scarecrow Agricultural Park, and the seeds of Indian mustard (*Brassica juncea* L.) were purchased from Angoo Plant Science and Technology, China. The soil was collected from the purple soil base of Southwest University in Beibei District of Chongqing, China. The soil pH was 5.23, the content of organic matter was 8.87 g·kg^{-1}, that of available phosphorus was 38.59 mg·kg^{-1}, that of available potassium was 65.07 mg·kg^{-1}, that of total nitrogen was 1.54 g·kg^{-1}, that of available nitrogen was 74.60 mg·kg^{-1}, that of total Cd was 0.110 mg·kg^{-1}, and that of available Cd < 0.005 mg·kg^{-1}.

The soil culture experiment was conducted in the glass greenhouse of College of Resources and Environment of Southwest University, China from March to May in 2015. An opaque black plastic basin (25 cm in diameter and 17 cm in height) was used in the experiment. The 5 kg of air-dried soil screened by 5 mm sieve was loaded in each basin. The $CdCl_2 \cdot 2.5\ H_2O$ solution was added to the soil and mixed well. The soil Cd^{2+} pollution levels were simulated at 0, 75, 150, 300 and 600 mg·kg^{-1}, and kept balance for two weeks. The seedlings of Indian mustard and alfalfa with 5 cm high were then transplanted 6 and 10 plants for each pot. The moisture content in soil was kept 70-75% of the maximum moisture in the fields with deionized water. Fast- measurement of Soil Moisture (TZS-IW, Zhejiang Tuopu Instrument Co., Ltd., China) was used to determine the moisture content in soil. In the basic fertilizer the used amount of P ($NH_4H_2PO_4$) and K (KCl) were 100 and 150 mg·L^{-1} respectively and Nitrogen content ($NH_4\ H_2\ PO_4$ and urea) was 180 mg·L^{-1}. N fertilizer was applied in three installments: 40% for basal and 60% each for seedling stages which applied with 15 days' interval after transplanting, each time 30%. All experiments were performed in triplicate and arranged at random. After 60 days, 6 (Indian mustard) and 10 (alfalfa) plants for each pot were harvested, and were separated into shoots and roots, washed free of soil with tap water and then rinsed with 0.1 M HCl followed by several rinses with deionized water (Kachenko and Singh, 2006). The harvested plants were oven-dried at 105 °C for 15 min, and oven drying to constant weight in 60 °C.

Analysis of soil physicochemical properties

The soil pH was ascertained in 1:5 (soil:water), and available phosphorus, available potassium and total nitrogen in soil was determined in term of a previously report

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_27952804
© 2018, ALÖKI Kft., Budapest, Hungary

(Rayment and Higginson, 1992). The soil organic matter content was determined on the basis of a previously published method (McCleod, 1975).

Analysis of Cd concentration in soil and plants

Soil containing Cd was first boiled with HNO_3–$HClO_4$ (*v*:*v* = 4:1), and its concentration was determined using an atomic absorption spectrophotometer (SIMMA 6000; PerkinElmer, Norwalk, CT, USA). The plant samples were first air-dried and ground and the Cd concentration in the plants was determined using a similar method to that used to quantify the levels of Cd in the soil. The results were monitored for quality control in following with plant standard reference material (GBW08513) and soil (GBW08303) obtained from the National Institute of Standards and Technology, China. The recovery rates of all the plants and soils were higher than 95%, and the relative standard deviation (RSD) for the precision of the tests was less than 10%.

1. Transport coefficient (TF) = Cd concentration in shoot ($mg \cdot kg^{-1}$) / Cd concentration in root ($mg \cdot kg^{-1}$) (Sun et al., 2016).
2. Enrichment coefficient (BCF) = Cd concentration in shoot (root) ($mg \cdot kg^{-1}$) / soil Cd ($mg \cdot kg^{-1}$) (Feng et al., 2016).

Soil Cd form determination

Method proposed by Tessier et al. (1979) was used to extract Cd from soil. The Cd concentration of each form was determined by atomic absorption spectrophotometry (Perkin Elmer SIMMA 6000, Norwalk, USA). The detection limit of atomic absorption spectrophotometer was 0.005 $mg \cdot kg^{-1}$. Soil standard substance (GBW # 08303) from the National Institute of Standards and Technology was used to monitor the quality of the results. The Cd recovery of all soil samples was higher than 95%, and the accuracy of relative standard deviation (RSD) was within 10%.

Statistical analysis

Three-way analysis of univariate ANOVA and correlation analysis were performed using SPSS version 21.0 package (SPSS, 2009). The variables analyzed separately were Cd concentration and Cd accumulation in alfalfa and Indian mustard, and Cd chemical forms in soil. The level of significance was 0.05.

Results

Biomass

As shown in *Table 1,* with the increase of soil Cd level, shoot and root dry weight of alfalfa and Indian mustard decreased significantly ($P < 0.05$), decreasing by 50.00-71.90% and 29.60-59.30% (alfalfa), 59.60-89.00% and 64.30-74.80% (Indian mustard) respectively. At same soil Cd levels, biomass of Indian mustard shoot and root was significantly higher than that of alfalfa. The tolerance coefficients of alfalfa shoot and root were 28.21-50.00% and 40.74-70.37% when exposed to Cd, respectively. When the Cd pollution level was above 150 $mg \cdot kg^{-1}$, the tolerance coefficients of each part were lower than 50%. The tolerance coefficients of Indian mustard shoot and root were 10.97-40.37% and 25.22-35.65% when exposed to Cd, respectively, both lower than 50%.

Under the same Cd level, the Cd concentration in roots of the two plants was higher than that in shoots, and Cd concentrations in shoot and root were in order of alfalfa > Indian mustard. At 75 mg·kg^{-1} soil Cd level, shoot Cd concentrations in alfalfa and Indian mustard passed the critical level of Cd hyperaccumulator (100 mg·kg^{-1}) which were 356.463 mg·kg^{-1} and 308.735 mg·kg^{-1} respectively.

Cd accumulation in shoot and root

As can be seen from *Figure 2,* with the increase of soil Cd levels, Cd accumulation in shoots and roots of the two plants increased with the increase of soil Cd level. At the 600 mg·kg^{-1} soil Cd level, Cd accumulations of shoot and root in alfalfa and Indian mustard reach the peak by 175.540, 101.632 and 324.70 μg·plant^{-1} respectively. Under the same Cd level in soil, Cd accumulations of shoot and root was in order of alfalfa < Indian mustard.

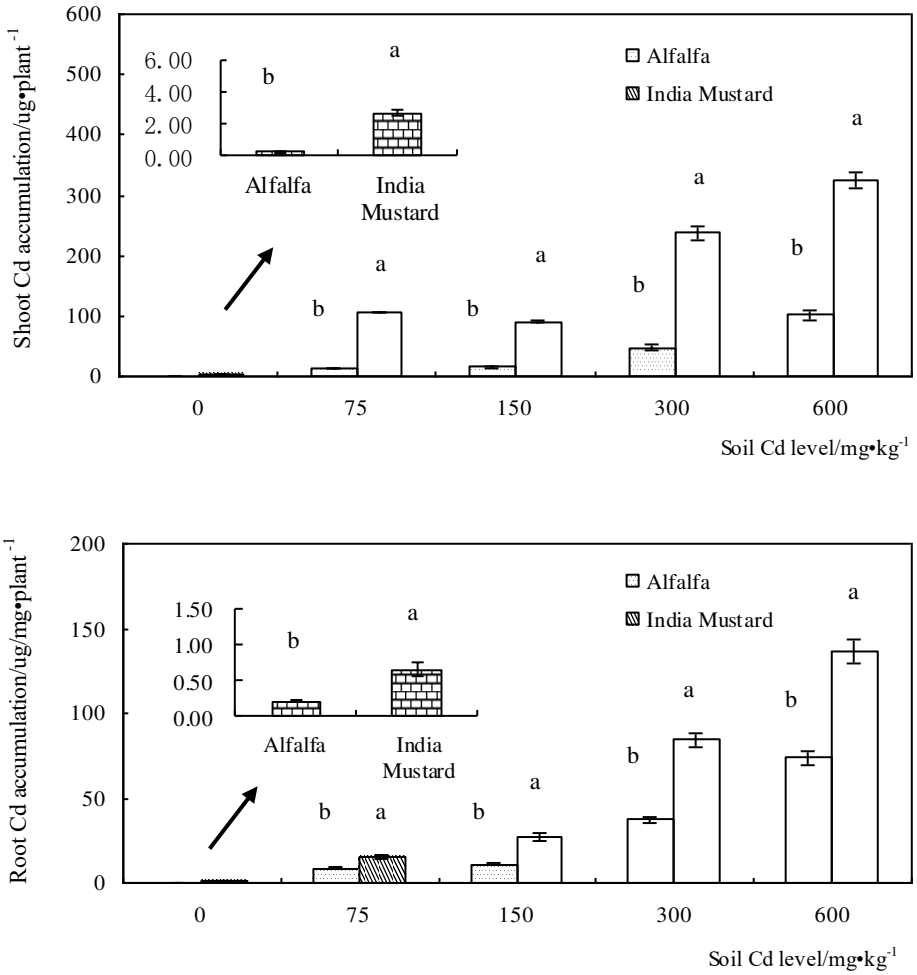

Figure 2. *Effect of different soil Cd levels on Cd accumulation in two plants*

Comparison of enrichment and transport capacity

As shown in *Table 2,* BCF of shoots of alfalfa and Indian mustard decreased firstly, reaching the lowest level at 150 mg·kg^{-1} Cd level, and then increased. Compared to that

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

at 150 mg·kg^{-1} Cd level, the BCF of shoots of alfalfa and Indian mustard increases by 62.94% and 76.16% (alfalfa), 47.30% and 50.85% (Indian mustard) at the 300 and 600 mg·kg^{-1} Cd levels. With the increase of soil Cd level, the $BCF_{root/soil}$ of alfalfa decreased first, reaching the lowest at 150 mg·kg^{-1} Cd level, down by 10.48% compared with that at 75 mg·kg^{-1} Cd level, and then increased. For Indian mustard, the $BCF_{root/soil}$ first increased and then decreased, reaching the peak at 300 mg·kg^{-1} Cd. The BCF of the two plants was above 1, with that of Indian mustard > alfalfa. The TF of alfalfa and Indian mustard decreased with the increase of soil Cd levels, and the TF value was below 1. Under the same Cd levels, the TF was in order of Indian alfalfa > alfalfa.

Table 2. *The values of BCF and TF in two plants*

Soil Cd levels mg·kg^{-1}	$BCF_{Shoot/Soil}$		$BCF_{Root/Soil}$		$BCF_{Plant/Soil}$		TF	
	Alfalfa	Indian mustard	Alfalfa	Indian mustard	Alfalfa	Indian mustard	Alfalfa	Indian mustard
0	-	-	-	-	-	-	-	-

Note: BCF (Enrichment coefficient) = Cd concentration in shoot (root) (mg·kg^{-1}) / soil Cd (mg·kg^{-1}) (Feng et al., 2016); TF (Transport coefficient) = Cd concentration in shoot (mg·kg^{-1}) / Cd concentration in root (mg·kg^{-1}) (Sun et al., 2016)

Soil Cd chemical forms

As shown in *Table 3* and *Figure 3,* the Cd content in different forms of soil (EXC, CAB, FeMn, OM and RES) increased significantly with the increase of soil Cd level ($P < 0.05$). Cadmium fraction distribution coefficient (FDC) also demonstrated a corresponding trend. At the same Cd level, soil Cd of the two plants mainly exists as EXC-Cd. Cadmium fraction distribution coefficient (FDC) of EXC-Cd in soil of alfalfa and Indian mustard were 63.92-81.87% and 57.97-80.71% respectively. The OM-Cd content had the lowest distribution proportion under the same soil Cd, with FDC at only 0.87-13.33%. At the 300 mg·kg^{-1} and 600 mg·kg^{-1} Cd levels, exchangeable Cd content in the soil planted with Indian mustard was significantly lower than that planted with alfalfa.

Discussion

Earlier reports suggested that Cd had no significant effect on plant growth at a low Cd level (Liu et al., 2013; Yu et al., 2017) and even stimulated and promoted plant growth (Wei et al., 2004). In this experiment, the biomass of alfalfa was significantly lower than that of the control at the 75 mg·kg^{-1} Cd level, indicating that 75 mg·kg^{-1} Cd had a serious injury to alfalfa growth. The results are consistent with those of Lou et al. (2015). In this study, with the increase of soil Cd level. It may be probable that growth and development of plants were directly related to Cd level, soil physicochemical property, fertility and soil type, but the specific reason remains to be further studied.

For Cd hyperaccumulator plants, Cd concentration in shoot should be 100 times higher than that of common plants (the critical value of Cd is 100 $mg \cdot kg^{-1}$); Cd concentration of plant root should be lower that of shoot; the plant growth does not appear obvious toxicity symptoms and has strong resistance to Cd (Li et al., 2017a; Lin and Feng, 2017; Sun and Song, 2015;). The results of this study showed that, Cd concentration in shoots of alfalfa and Indian mustard exceeded the 100 $mg \cdot kg^{-1}$ threshold of hyperaccumulator plant at the 75 $mg \cdot kg^{-1}$ Cd level. This result was similar to that reported by Yang et al. (2011). In comparison of Cd concentration in shoots and roots of the two plants under the same soil Cd level, that of alfalfa > Indian mustard. However, in the analysis of biomass and Cd accumulation, the biomass of Indian mustard was much higher than that of alfalfa, therefore, its Cd accumulation was also significantly higher than that of alfalfa. Different plant organs have different levels of heavy metals (Li et al., 2017b). In this experiment, it was found that, for both alfalfa and Indian mustard, that in root > shoot at different soil Cd levels, and their roots had strong Cd enrichment ability, but their ability to transport Cd to shoots was weak. Similar results were reported by Chen et al. (2014), Jiao et al. (2014), Hattab et al. (2013), and Sun et al. (2016), but different from the report by Yang et al. (2011). In this experiment, with the increase of Cd concentration, Cd transport index of Indian mustard first increased and then decreased, while alfalfa Cd transport index also increased. This result was different from earlier reports (Li and Song, 2016). In addition, BCF of alfalfa and Indian mustard were above 1 when exposed to Cd, while TF was lower than 1. The higher root BCF value of Indian mustard suggests that Indian mustard has the strongest Cd enrichment ability.

It has been reported that there is a significant difference in soil Cd form among different crops (Zhang et al., 2017). In this experiment, EXC-Cd, CAB-Cd and FeMn-Cd of alfalfa were significantly higher than that of Indian mustard under high concentration of Cd, while RES-Cd and OM-Cd were lower than that of Indian mustard, which was similar to the results of previous studies (Huang et al., 2000). It may be because different root exudates produced by different crops change Cd forms in the soil and mitigate Cd damage to the crop. In this experiment, the Cd in the two plants at different Cd levels both existed in the form of highly active EXC-Cd, and Cd concentration in different forms increased with the increase of Cd added concentration, which may be because Cd entered soil in the form of Cd solution with the highest activity (Xiong et al., 2015).

Conclusion

With the increase of soil Cd level, the biomass of shoots and roots of alfalfa and Indian mustard decreased significantly. The EXC-Cd was the dominating form of soil Cd. With the increase of Cd level in soil, the percentage of EXC-Cd in total Cd also increased continuously. At 75 and 150 $mg \cdot kg^{-1}$ Cd levels, Cd concentrations in shoots of alfalfa and Indian mustard exceeded the critical value of hyperaccumulators, The BCFs of both alfalfa and Indian mustard were above 1. At the same soil Cd level, for BCF and TF values, those of Indian mustard > alfalfa. Based on comprehensive consideration of biomass, Cd accumulation, transport coefficient and enrichment coefficient, Indian mustard has stronger Cd accumulation ability, thus more suitable as repair material for soil Cd pollution.

Abstract. Application of cystine capped silver nanoparticles synthesized using puer tea as the reducing agent to decorate lipase has been reported in the present work. Biodiesel production technology is competitive in terms of low cost and alternative source of energy which should be not only sustainable but also environmentally friendly. Designing of the lipase immobilization for biodiesel production has a remarkable impact and is still challenging. In this work, biodiesel production from soybean oil was enhanced and facilitated by using a novel biocatalyst consisting of commercial lipase (EC 3.1.1.3), silver nanoparticles, and polydopamine. Various parameters such as cystine concentration, pH, temperature and amount of reducing agent were standardized and their effect on the synthesis process has been initially evaluated by surface plasmon resonance peak analysis. Further the synthesized nanoparticles were also characterized using X-ray diffraction (XRD) and scanning electron microscope (SEM). The transesterification reaction conditions were as follows: oil/alcohol molar ratio 1:4; temperature 40 °C and total reaction time 6 h. Lipozyme TL-100L lipase provided the highest yield of fatty acid methyl esters as 92%. Operational stability was determined with immobilized lipase and it indicated that a small enzyme deactivation occurred after used repeatedly for 10 consecutive batches with each of 24 h. Since the process is yet effective and enzyme does not leak out from the polymer, the method can be proposed for industrial applications. Research highlights Lipozyme TL-100L and Novozym 388 were immobilized onto micro porous polymeric matrix by both physical adsorption and covalent linking. Immobilized enzymes were used for synthesis of fatty acid methyl esters by transesterification of canola oil and methanol using semi-continuous operation system. According to chromatographic analysis, Lipase Lipozyme TL-100L resulted in the highest yield of methyl ester as 92%. The bioconjugates saw 15% loss in its initial activity at the end of five reusability cycles. This decorated reusable system has the potential to be utilized for various applications pertaining to the exploitation of lipase in various industries.

Introduction

Biodiesel production from vegetable oil has been increasing in the last decade in ASEAN countries, for example, Thailand, Malaysia, Indonesia, Vietnam, and The Philippines, since many of them have diverse and high yield crops of oleaginous plants, for example, palm, soybean, and sunflower (Mukta et al., 2010; Murphy et al., 2012). This is relevant to the world's rapid industrialization and increasing population (Preechajarn et al., 2012). Since the use of enzyme in its free form makes the process very expensive, efforts are being made worldwide to develop a stable decorated enzyme system so that the enzyme can be reused and the processing can be made cost

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

effective. Transesterification of vegetable oils by short chain alcohols (methanol or ethanol) catalyzed by lipase (EC 3.1.1.3) is a worldwide biochemical mechanism to produce biodiesel (Fjerbaek et al., 2009; Fan et al., 2012) and there are two modes of lipase usage: free or soluble lipase and immobilized lipase. In early 2001, using free lipases from Candida rugosa and Pseudomonas cepacia along with methanol as acyl acceptor, a method was reported to yield biodiesel from soybean oil up to 80 and 90%, respectively (Kaieda et al., 2001). Various matrixes has been successfully used for enzyme immobilization application (to name some alginate, gelatin, polyacrylamide, cellulose, polyvinyl fibers, silica and nanoparticles etc.), among them nanoparticles can be a promising choice (Tan et al., 2010; Salis et al., 2008). Immobilized lipase methods have been introduced to improve lipase stability and reusability. Herein immobilized enzymes are defined as "enzyme physically confined or localized in a certain defined region of space with retention of their catalytic activities, which can be used repeatedly and continuously" (Lee et al., 2007).

Employed lipases for immobilization have been derived from microorganisms to animals, for example, from pancreatic porcine, Burkholderia cepacia, Pseudomonas spp., and Candida spp. (Bu et al., 2012; Peng et al., 2013). Immobilization methods are also various, for example, adsorption on acrylic resin, celite, and anion resin, covalent bonding using silica-PVA and styrene-divinylbenzene, entrapment using hydrophobic sol-gel support, and cross-linking using glutaraldehyde (Ren et al., 2011). These methods can yield biodiesel from soybean oil using adsorbed lipase (Lee et al., 2009) and from mahua oil using cross-linked lipase (Veerapandian et al., 2011). However, these techniques are still sophisticated and require multiple-steps material consumption in case of Pseudomonas cepacia cross-linked lipase (Jierwiriyapant et al., 1992), as well as time consumption for oil transesterification (49 h) in case of absorbed Pseudomonas fluorescens lipase on macroporous polypropylene matrix (Sangla et al., 2006).

In current study silver nanoparticles were synthesized using puer tea extract as the reducing agent. The formation and morphology of each composition were characterized by UV-Vis spectroscopy and scanning electron microscope (SEM). Polydopamine has also been studied for enzyme immobilization, for example, trypsin (Kanmani et al., 2016), glucose oxidase, and lipase (Rivera et al., 2012). Enzymes can be covalently immobilized on a polydopamine surface via nucleophiles (Walt and Agayn, 1994). The effects of various parameters like temperature, pH and reducing agent concentration were standardized during the course of nanoparticle synthesis. Therefore, nanoparticles were characterized for their surface morphology using SEM. Initial screening of the nanoparticle synthesis was done by monitoring the surface plasmon resonance with help of UV-Vis spectroscopy for each parameter under consideration. This study brings us one step closer to the continuous use of lipase for various biotechnological processes.

Materials and methods

Chemicals

Silver nitrate, glutaraldehyde, Triton X-100 and sodium dodecyl sulfate (SDS) were obtained from Aladdin Chemistry (Shanghai, China). P-nitrophenol palmitate (pNP) was obtained from sigma; L-Cystine was obtained from Aladdin Chemistry (Shanghai,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_28052813
© 2018, ALÖKI Kft., Budapest, Hungary

China). Deionized water was used throughout the process from Millipore and puer tea was procured from Puer, Yunnan province, China.

p-nitrophenol palmitate substrate preparation

420 μM of substrate solution was prepared in Tris-Cl buffer (0.1 M, 8.2 pH) by weighing 0.004 g of pNP and adding it to 25 mL of buffer along with 125 μL of Triton X-100 and 0.0045 g of SDS. The mixture was heated at 65 °C for 20 min and then stored at 4 °C to be used within a week.

Puer tea extract preparation

3.0 g of puer tea leaves were boiled with 50 mL of deionized water at 65 °C for 10 min in a closed container. The extract was first filtered through whatman filter paper No.1 and then centrifuged at 10000 rpm for 10 min at room temperature. The supernatant was collected in a clean falcon tube and stored at 4 °C for further use. The extract was used within a week.

Enzyme production and enzyme activity assay

Lipase was isolated from *B. subtilis* cultured in nutrient broth supplemented with 1% olive oil for 24 h. The broth was then centrifuged at 8000 rpm for 10 min at 4 °C. The supernatant was collected after centrifugation was stored at 4 °C as enzyme source for further use. The crude enzyme was tested for activity using assay mixture comprising of p-nitrophenol palmitate as a the substrate (Gupta et al., 2003). For the activity assay 2.5 mL of substrate was added to 1.5 mL of Tris-Cl buffer and 1 mL of crude enzyme preparation. The assay mixture was incubated at 37 °C for 30 min. The absorbance was recorded at 410 nm. The enzyme activity was calculated as U/mL based on the concentration of p-nitrophenol obtained from the standard curve. The total protein content of the crude enzyme was calculated using the method of (Lowry et al.).

Nanoparticle synthesis and characterization

The nanoparticles synthesis was initiated by mixing 100 mL of 1 mM silver nitrate solution and 1 mL of 1 mM L-cystine. This solution was slowly stirred at room temperature for 10 min. 5 mL of puer tea extract was then added slowly with continuous stirring at room temperature. pH of the reaction mixture was adjusted to 11 by dropwise addition of 1 M sodium hydroxide. The change in the colour of the reaction mixture was recorded at 65 °C for 30 min. The colour of reaction mixture changes from transparent (before addition of tea extract) to light brown (after addition of tea extract) to dark brown (after adjusting pH and heating at 65 °C for 30 min). This change in the colour of the reaction mixture corresponds to synthesis of silver nanoparticles. Thus obtained nanoparticles were then centrifuged at 20000 rpm for 40 min to pelletize the nanoparticles which were dried at 37 °C overnight. The formation of nanoparticles was also confirmed using nanodrop spectrophotometric method in terms of surface plasmon resonance (SPR) at 405 nm. The particles were analyzed by particle size analyzer to determine average size of the particles synthesized. Transmission electron microscopy was performed to observe the surface characteristics of the synthesized silver nanoparticles, while XRD analysis was done to confirm the crystalline structure of the synthesized nanoparticles.

Results and discussion

Optimization of nanoparticle synthesis parameters

Different parameters affecting the synthesis of silver nanoparticles were optimized so that mono- dispersed nanoparticles of uniform size and shape can be obtained. The parameters optimized were analyzed in terms of SPR peaks and the effect of each parameter was recorded on the basis of the SPR peaks achieved for each parameter. To check the consistency of data the experiments were carried out in triplicates.

Effect of varying concentrations of cystine

The effect of cystine concentration on nanoparticle synthesis was analyzed by changing the concentrations of cystine in the reaction mixture. Cystine concentration was varied from 0.5 mM, 1 mM, 2 mM, 5 mM and 10 mM. The effect was observed by monitoring SPR peaks in the complete UV-Vis range for each test concentration of cystine.

Effect of varying concentrations of reducing agent (puer tea)

Various concentrations of silver nitrate solutions: puer tea extract was used to carry out the synthesis of nanoparticles i.e. 100:1, 100:2, 100:3, 100:4 and 100:5. The effect of varying the concentration of reducing agent on the synthesis of nanoparticles was observed by viewing the SPR peaks. *Figure 1a* shows the effect of various concentrations of cystine on the synthesis of nanoparticles. Higher concentration of cystine resulted in slight shift of the peak towards higher wavelength with a broader peak size. This could be because of the aggregation of nanoparticles to form super clusters leading to redshift. Redshift is a phenomenon which is represented by increase in the emitted wavelength by the nanoparticles because of increase in the crystalline structure (size) of the particles. As the size of the particles increases, the distance between the valance band also increases resulting in the increase of the dielectric constant (Yon-Rui et al., 2013).

Effect of pH

pH plays an important role in the formation of nanoparticles since acidic conditions interfere and hinder the synthesis of nanoparticles in most of the cases studied and reported. Under our standard condition, also reduction of silver nitrate was not observed even with prolonged incubation under acidic conditions. Therefore, pH of the reaction mixture was set towards alkaline side by addition of 1 M sodium hydroxide. pH 8, 9 and 10 exhibited slight change in reaction mixture colour and it gave very low intensity peaks indicating low or negligible reduction rate. At pH 11 and 12, a very rapid change in the colour was observed with an intense peak within 30 min of incubation (*Fig. 1b*). Result shown in *Figure 1c* suggests that the synthesis was achieved significantly at high temperature.

Effect of reaction temperature

The study of temperature effect was performed at 3 different temperatures, such as 4 °C, room temperature (25 °C) and 65 °C. The effect of temperature on nanoparticle synthesis was observed by viewing the SPR peaks. Effect of temperature on the synthesis of nanoparticles was studied at three different temperatures i.e. 4 °C, RT and 65 °C. The temperatures selected were from low to medium to high range. Initiation of nanoparticle synthesis took place at every temperature tested which is evident from the colour development at all three temperatures. Result shown in *Figure 1c* suggests that the synthesis was achieved significantly at high temperature. Low temperature resulted into low intensity peaks after 12 h of incubation and did not enhance further even after prolonged incubation, while room temperature lead to medium intensity peaks in about 4 h of incubation and took 24 h to match the intensity observed at high temperature incubation. At 65 °C, a high intensity peak was obtained within 30 min of incubation.

Nanoparticle synthesis and characterization

The puer tea used as reducing agent for the synthesis of cystine capped silver nanoparticles in present work exhibits reducing properties mainly due to presence of anti-oxidant compounds such as catachins in it. The mechanism for the formation of cystine capped silver nanoparticles involves formation of silver cystine complex followed with reduction in presence of anti-oxidant components of puer tea at pH 11 at 65 °C. Cystine binds to silver through thiolate bonding (Mandal et al., 2001). Initially formation of nanoparticle was confirmed by checking SPR peaks spectrophotometrically. A sharp peak at 405 nm (*Fig. 2a*) indicates the formation of silver nanoparticles. The peak arises due to the absorption of electromagnetic waves in the visible region by the nanoparticles that provides them the ability to give a peak at a specific wavelength. The reaction colour changes from light brown to dark brown within 10 min of incubation at 65 °C under alkaline conditions (*Fig. 2b*). The time-dependent study was carried out for formation of silver nanoparticle for 2 h. It can be concluded from the SPR peaks obtained that the maximum nanoparticles synthesis is achieved within 30 min of incubation as there is no significant change in the peak value after that. A higher temperature mediated synthesis was preferred over synthesis at RT to avoid super-clustering of the nanoparticles due to carboxyl or amino group present on the cystine molecules. The peaks obtained from the spectrophotometric analysis even gave a rough idea about the size of nanoparticles since the SPR peaks obtained were broad; it indicates that the particles formed might be of larger size.

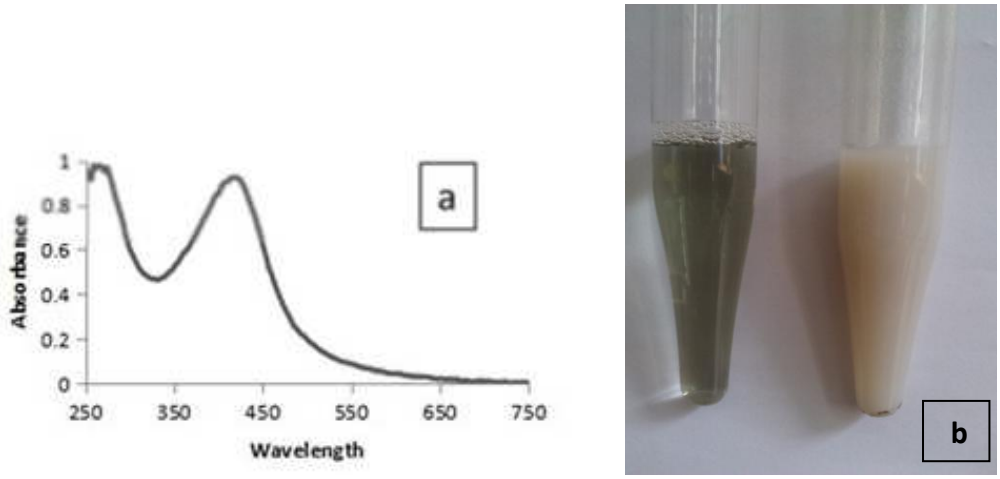

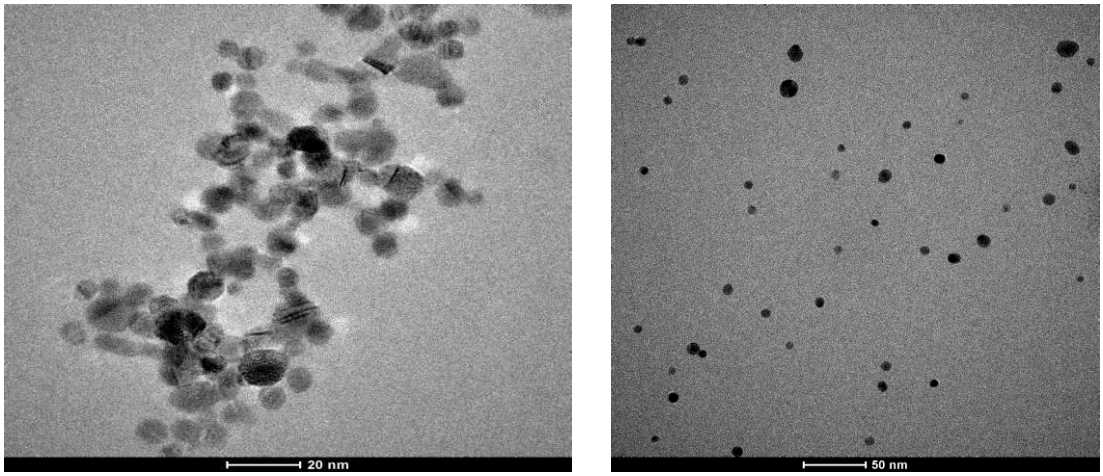

Figure 2. *(a) SPR analysis of synthesized cystine capped silver nanoparticles. (b) Confirmatory colour change during the synthesis of nanoparticles*

SEM analysis of nanoparticles

The particle size analysis of the nanoparticles revealed the average size of the particles to be around 20 nm (*Fig. 3a*). The same was also confirmed in the SEM analysis of the samples. Spherical nanoparticles which were around 20 nm in diameter can be clearly seen in the SEM analysis result represented in *Figure 3b*. Nanoparticles of different sizes have been reported using green synthesis like Prakasha et al. (2013) synthesized silver nanoparticles of 55-83 nm in size using leaf extract of *Mimusops elengi*. Another research by Jyoti et al. (2016) demonstrated the synthesis of silver nanoparticles of 36 nm in diameter using the leaf extract of *Urtica dioica*. Thus, it can be concluded that reducing agents and reaction conditions play very critical role in deciding the shape and size of the nanoparticles synthesized. These reflections correspond to the facets of face centered cubic crystal of silver nanoparticles (Jyoti et al., 2016).

Lipase isolation and activity assay

The crude lipase was isolated from strain of *Bacillus subtilis* (Acc. No. KT591343). The crude lipase was quantified for its activity using p-nitrophenol palmitate as the substrate. The lipase acts on the substrate and hydrolyzes the palmitate group resulting in release of p-nitrophenol. The release of p-nitrophenol brings a change in colour of the assay mixture from colorless to light yellow. The change in the colour intensity is spectrophotometrically recorded at 410 nm. The standard plot for pnitrophenol is represented in *Figure 4*. The activity of the enzyme was calculated as the amount of pnitrophenol released from 1 mole of p-nitrophenol palmitate per minute per mL of reaction mixture. The activity of lipase from an unidentified strain isolated from dairy waste (Sahu et al., 2011) and from a *Staphylococcus sp.* isolated from oil contaminated area has been reported by (Sirisha et al., 2010) to be 38-46 and 25 U/mL respectively.

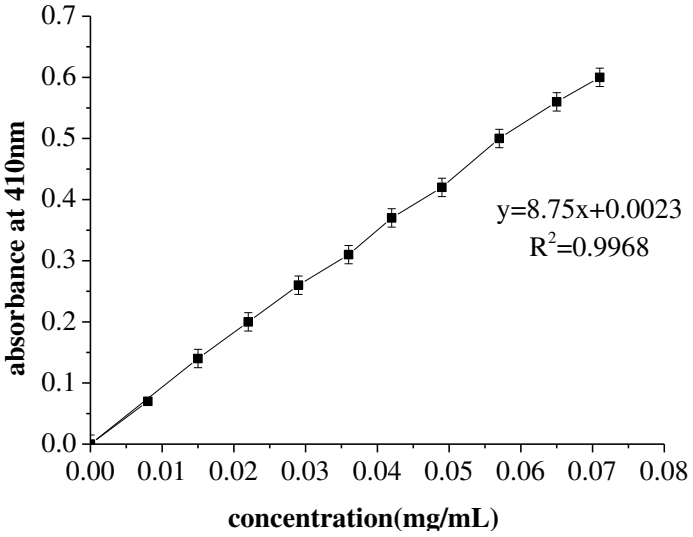

Figure 4. *Standard curve for p-nitrophenol*

Stability and reusability

The enzyme system so formed was stable for a period of 2 months with a loss of 15% of its original activity which is marginally better than the soluble enzyme which showed the loss of 25% from its original activity. Even though the activity lost comparison does not reflect a significant change, the reusability of the system gives it a significant advantage over the soluble enzyme. The use of enzyme system repeatedly showed the average loss of activity by 3-4% per cycle over the course of 5 cycles as shown in *Table 1.* This loss in the activity can also be attributed to the loss of nanoparticles after every assay cycle which could not be recovered during centrifugation step. The loss can also be possible because of leeching out of the enzyme from the decorated nanoparticles. Even though the covalent bond binds the nanoparticles with the enzyme the possibility of the nanoparticles releasing the enzyme into the system cannot be ruled out either during the activity assay or during the centrifugation step to pelletize the system.

Cycle 5	0.15	21.2

Conclusion

Original research article represents the immobilization of lipase on the surface of economically synthesized capped silver nanoparticles. The synthesis involved the production of cystine capped silver nanoparticles using puer tea as the reducing agent. The covalent coupling of the enzyme to the amino group present on the cystine capping acted as a bridge to decorate the enzyme to the nanoparticles. This improved the shelf life of expensive soluble enzyme with a reasonable specific activity in the decorated state. The development of such decorated system can be taken to the next level as to work on specific industrial applications with minor modifications as per application demand. This decorated reusable system has the potential to be utilized for various applications pertaining to the exploitation of lipase in various industries. Further experiments will include studies regarding the recovery of AgNPs from other media and the implementation of other metal nanoparticles (Au, Pt and Pd).

(Received 9th Feb 2018; accepted 2nd May 2018)

Abstract. In this study, two inventory methods, including use of plots with 300 m^2 fixed-area and Relascope with variable-area plots were compared to evaluate biodiversity, quantitative and qualitative characteristics of Arasbaran forest stands in the North West of Iran. For this purpose, 58 sample plots were specified using 100 m×100 m regular randomized grid and tree characteristics were measured by two inventory methods. In each plot, the quantitative characteristics including diameter at breast height (DBH), basal area at breast height, tree number (density) and volume per hectare, sampling time and the qualitative characteristics such as percentage of species composition, health and origin of trees were recorded. Species richness, Shannon Weiner diversity and Simpson evenness indices were calculated for each sample plot. Independent t-test was applied for comparing the means of quantitative characteristics and biodiversity indices between the two methods. The results indicated that the quantitative characteristics are significantly different between two methods, whereas, no significant differences were observed in richness, biodiversity indices and qualitative characteristics. Average inventory duration in the fixed-area plot method (706.10 s) was considerably higher than that of the variable-area plots method with Relascope (485.91 s). The square of sampling error by inventory time ($T \times E\%^2$) index was used to evaluate the two methods precisely. This coefficient was less for volume per hectare and basal area at breast height per hectare in the variable-area plot method.
Keywords: *Arasbaran forests, species diversity, fixed area plot, relascope, quantitative characteristics*

Introduction

Arasbaran area is a crossing zone among multi-habitats due to its vegetative elements related to numerous climates. Existence of specific climatic conditions, high biodiversity, presence of rare plant and animal species as well as existence of vegetative elements related to various climates are factors distinguishing these forests from other regions (Sagheb Talebi et al., 2005). Stand structure and species diversity are two important ecological and functional features of forest ecosystems (Pretzch, 1997), affecting the landscape beauty and recreational value of the forest (Su et al., 2012). According to the sustainable management criteria, maintaining and enhancing diversity are important factors in forest conservation (Nath et al., 2009). Protecting the natural ecosystems and biodiversity of Arasbaran forests is necessary due to its importance and status in a variety of aspects. They include species diversity, vital effects on water balance of the Aras River, preservation of biological reserves, impact on climate purification, preventing soil erosion, providing ecotourism values and achieving sustainable development (Mohammad Zadeh et al., 2014). Monitoring this valuable resource is the most important way to reach a management model and maintain ecosystem biodiversity, which can be achieved by quantitative and qualitative forest inventory and understanding the forest community dynamics, making possible subsequent planning (Eshaghi Rad et al., 2003; Islam et al., 2015; Motz et al., 2010; Hassanzad Navroodi et al., 2015). However, foresters often face problems with

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_28152825
© 2018, ALÖKI Kft., Budapest, Hungary

choosing the right method to measure and obtain accurate scientific information on biodiversity and forest structure (Pique et al., 2011).

An appropriate measurement method is one that offers reasonable information about the inventory area with suitable accuracy and cost (Parker, 1979; Husch et al., 1982; Avery and Burkhart, 2015). Accordingly, decision making on the measured variable and the appropriate measurement method is necessary (Pique et al., 2011). In forest inventory, various methods are used to design the sampling plots that are generally divided into two groups: sample plots with fixed area and sample plots with variable area (Zobeyri, 2007). Relascope is suggested for variable-area plot sampling method which is also known as n-tree sampling methodology (Bitterlich, 1984). In the fixed-area plot sampling method, the probability of selecting each one of the trees is the same within the sample unit, but in contrast with the variable-area plots method, the trees have a selection chance depending on their dimensions (Bitterlich, 1984; Ducey, 1999). In sampling with variable-area plot, it is attempted to increase sampling efficiency by overcoming the drawbacks associated with the fixed-area plot sampling method (Sheil et al., 2003). Zare et al (2016) selected a wild Pistachio stand in Fars Province of Iran where in a 100×100 m^2 grid, 46 sample points and six single-distance sampling methods were applied. In general, nearest single-distance methods were efficient enough to estimate the biometric characteristic of wild Pistachio trees precisely and accurately.

Relascope is a multipurpose device for measuring samples with variable area that is used by researchers for estimating biodiversity and stand structure (Barabesi and Fattoriu, 1999; Motz et al., 2010). In the Relascope method, the probability of choosing trees is proportional to their dimension and size (Piqueet al., 2011). In order to determine the best sampling method, several studies have been conducted. Some of these studies have introduced fixed-area plot sampling methods as the suitable ones for estimating quantitative, qualitative information and biodiversity (Motz et al., 2010). Whereas in the others, the sampling method with variable area or sample line has been introduced as the superior method (Eshaghi Rad et al., 2003; Alijanpour et al., 2003; Henttonen and Kangas, 2015).

Fallah et al. (2000) compared two sampling methods with fixed-area plots (10 acre) and variable-area plots (Relascope) in Loveh - Gorgan oak forests using characteristics including number of trees per hectare, basal area per hectare and time required for data recording. Results showed that the sampling method with 10 acre area was more suitable for the forest inventory. In another study, two methods of measuring with fixed-area plot and Relascope were used to study quantitative variables in northern Spain. It was found that the use of Relascope has a faster estimation of variables compared to the fixed-area sampling method. This means that although the Relascope is a costly sampling instrument, it significantly reduces the cost of inventory and, if needed, facilitates increased sampling density for a specific budget (Pique et al., 2011). Despite numerous studies in the Arasbaran region using sampling with fixed-area plots and sample line (Alijanpour et al., 2009; Moradi et al., 2015), the use of Relascope has not yet been used to measure quantitative and qualitative characteristics and species diversity.

This study intends to use two methods, namely circular sample plots with an area of three acre and Relascope (Band number of 2) to estimate the diversity of species, quantitative and qualitative characteristics (by the criterion of integrating inventory error and plot sampling time in the forest stands of the Kaleibar Chay watershed (Armeni Olan) of the Arasbaran region.

Material and methods

Study area

The Armeni Olan forests unit, with an area of 60 hectares, located at longitude of 46° 45' 7" to 46° 45' 52" East, and latitude of 38° 55' 43" to 38° 56' 22" North was selected for this research (*Fig. 1*).

Annual rainfall is about 500-600 mm. Relative humidity in June reaches its highest level, about 85%. Arasbaran dense forests are located at altitudes of 1000 to 1600 m above sea level (Alijanpour, 2011). The climate condition of the region is moderate semi-humid with cool and dry summers based on the De Martonne formula. The soil in the forest areas is mostly of brown and calcareous brown types. These soils are located on top of hard rock limestone, marl and sandstone (Alijanpour, 2011).

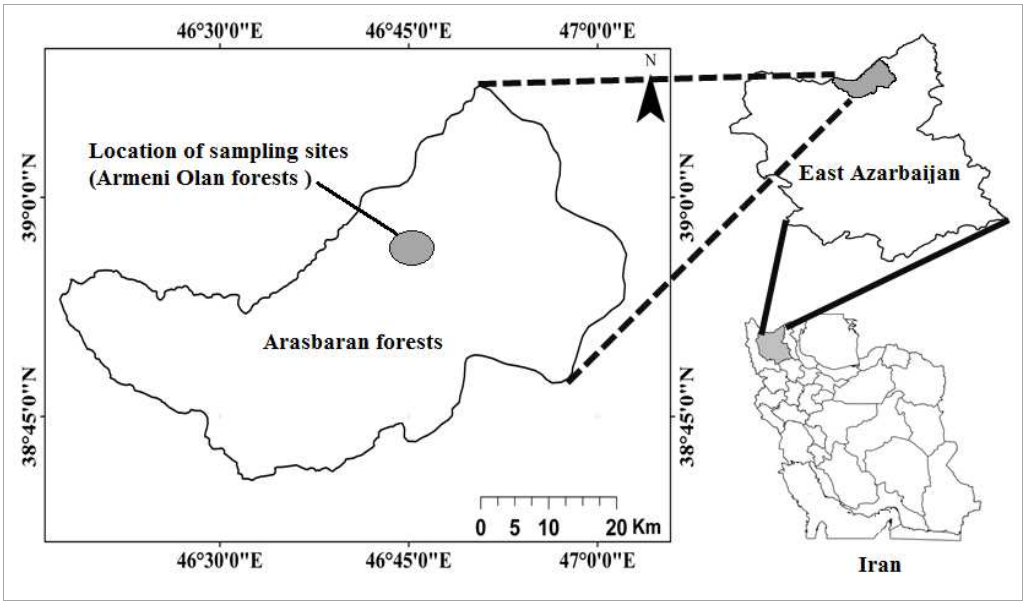

Figure 1. *Location of sampling site in Arasbaran forests*

Research methodology

Initially, a 60-hectare area was selected in the forest area. For the sampling of plots, a regular randomized grid system with 100 × 100 m dimensions was established.

Then, 58 points were specified on the map (1:10,000 scale) at the intersections of the network sides as plot centers. According to the conducted field survey and the previous studies carried out in the forest stands of the Arasbaran region and the placement of 15-10 trees in the sample, the area and shape of sample plots were decided to be circular fixed-area of three acre (Alijanpour et al., 2009; Alijanpour et al., 2011). At first, the general characteristics of each sampling plot location were recorded. Then, diameter at breast height (DBH) (cm) was measured using Calliper (Ushikata, Japan). Finally, the type of species, origin, and quality of trees were recorded.

The trees were studied in terms of the origin (seed regeneration stems and coppiced stems) as well as health status of the stem (healthy and unhealthy trees). Individuals infested by fungi or insect and also decayed trees were considered unhealthy. Then, the heights (m) of five trees, comprising of four trees close to the center of the sample plot

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_28152825
© 2018, ALÖKI Kft., Budapest, Hungary

in the four geographic directions, and one tree as the thickest one were measured (Suunto clinometer, Finland) in the sampling plot. Sampling time was also recorded by stopwatch. In order to record data with Relascope, based on the initial controlling of Band No. 2 and considering the placement of 10-15 trees in the sample plot, the quantitative and qualitative characteristics of the trees were measured (Spiegel Relascope, Austria) in accordance with the instructions for using the Relascope device (Avery and Burkhart, 2015). In this method, the sampling time of the plots was also recorded.

The measured DBH in each variable area-plot was entered into Microsoft Excel 2013 to calculate the basal area per hectare of fixed-area plot samples by using *Equation 1*.

The coefficient of basal area for Band 2 of Relascope was used to calculate basal area per hectare (Avery and Burkhart, 2015).

$$g = \frac{\pi}{4} \times d^2 \quad \text{(Eq.1)}$$

Where g is the basal area at breast height (m^2) and d is DBH (m).

In order to calculate the volume in a sample plot with fixed-area, it is necessary to use a local volume table, which unfortunately has not been yet provided for Arasbaran forest stands.

Therefore, the relationship between DBH and the measured heights of the trees in the fixed area plot (five stems per plot) was used to calculate such a table. Based on the calculated height graph and the estimation of the height of each diameter class, its volume was estimated using *Equation 2*.

Next, the volume in the sample plot and the volume per hectare of trees in the sample plot were calculated (Zobeyri, 2007).

$$V = 0.4 \times d^2 \times h \quad \text{(Eq.2)}$$

Where V is tree volume (m^3), d is DBH and h is tree height (m).

To calculate the volume per hectare for each sample plot in the Relascope method, the trees were arranged in diameter classes of 1 cm and the coefficient per hectare was calculated for each of the diameter classes.

Taking into account the selected strip coefficient for sampling and diameter class, the coefficient in hectare for each diameter class was calculated (Avery and Burkhart, 2015). *Equation 3* was used to calculate the coefficient per hectare.

$$F = 10000 \div (d^2 \times f^2 \times \pi) \quad \text{(Eq.3)}$$

Where F is the coefficient per hectare, d is the diameter of each class (m), f is the coefficient of each strip for the tree (in this study, tape number 2 was used for the sampling and the coefficient of the strip was 35.35).

Then, considering the number of trees in each diameter class, the number per hectare was calculated and, taking into account the volume of each class (by the volume table prepared in this study), the volume per hectare was calculated for each sample plot.

For statistical analysis of the species type data, DBH, quality, origin, slope and sampling time for each sample were entered in the SPSS software version 22 and, the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_28152825
© 2018, ALÖKI Kft., Budapest, Hungary

normal distribution of the quantitative data was evaluated using the Kolmogorov-Smirnov test.

The calculated mean DBH, basal area at breast height, volume and time for each of sample plot in two methods of sampling with fixed-area and variable-area plots were compared by using the independent t-test. Origin, species composition and quality of species were compared by the Chi-Square test.

In addition, the species frequency data were used in each sample plot to calculate the species evenness and diversity indices.

Species richness, Simpson diversity index, Shannon Wiener diversity and evenness indices for each plot were calculated using the PC-ORD software version 5. Then, the obtained indices were compared with the independent t-test using SPSS version 22.

Finally, in order to evaluate the two methods of inventory, *Equation 4* was used, where E% is the standard error of estimation at the specified confidence level and (T) is the sampling time (Husch et al., 1982).

$$A = (E\%)^2 \times T \quad \text{(Eq.4)}$$

Results

Quantitative characteristics of the studied stand

Obtained mean, standard error and percentage of standard error for DBH, number per hectare, basal area at breast height per hectare, volume per hectare and height of trees from 58 sampling plots with fixed and variable-areas (Relascope) are provided in *Table 1*. Based on this table, mean DBH, basal area at breast height, number per hectares and volume per hectare in the variable-area plots sampling method is higher than fixed-area plots.

Qualitative characteristics of the study stand

Percentage of mixture of species

As shown in *Table 2,* in the method of using plots with fixed-area, *Carpinus betulus* had the highest frequency (76.6%) and in the sampling method with variable-area plots, this species, with 74.4%, was the most frequent species in the stand.

The origin of the trees

The results of sampling with fixed-area plots showed that 86.3% of the trees in this stand were coppiced stems and 13.7% were seed regeneration stems. On the other hand, the results of sampling plots with variable-area showed that 84.1% of the trees in this stand were coppiced stems and 15.9% were seed regeneration stems (*Fig. 2*).

Tree health

Another characteristic studied for the trees was the health of the trees whose DBH values were measured.

From the total number of trees measured by the fixed-area plots sampling method, about 91.2% were healthy and 8.8% were unhealthy. While, Sampling by variable-area plots yielded 92.7% healthy and 7.3% unhealthy trees (*Fig. 3*).

Comparison of quantitative and qualitative characteristics of the studied stand in the two methods

The t-test results between the two inventory methods for parameters including mean diameter at breast height, mean basal area per hectare and average volume per hectare showed that there were significant differences at the 95% probability level (*Table 1*).

In addition, according to the Chi-Square test, it was found that the parameters including percentage of species composition, origin and health of the stems had no significant difference between the two inventory methods at 95% probability (*Table 3*).

Table 1. *Quantitative characteristics of the studied stand and t-test results*

Variables	Method of sampling	Mean	Standard error	% Standard error	t	Significance
DBH (cm)	Fixed area plot	12.34	0.19	3.08	-5.027	0.000*

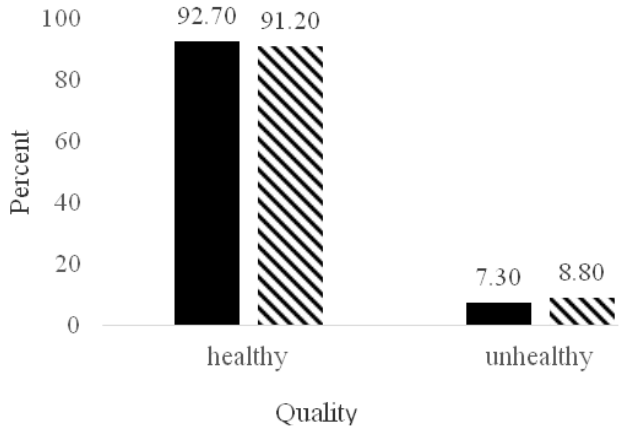

Figure 3. *Health of the stems in the fixed-area and variable-area sample plots*

Table 3. *Comparison of qualitative characteristics of the stand in the two methods using Chi-square test*

Variables	Chi-square	Degree of freedom	Significance
Percentages of mixture	9.8	8	0.28^{ns}
Origin	2.197	1	0.12^{ns}
Quality of species	1.805	1	0.179^{ns}

Sampling time

Comparison of average sampling time in the two methods showed that there was a significant difference between the two inventory methods at the 5% level (*Table 4*) and the recording time of the fixed-area plot was significantly higher than the recording time associated with the variable-area plot.

Table 4. *Comparison of plot sampling time for two methods*

Variables	Fixed area plot	Variable area plot	t	Significance
Mean sampling time for each plot (second)	706.10(20.24)	485.91(14.56)	8.83	0.000*

The significance is at 5% and the numbers in brackets indicate the standard error

Evaluation of the two inventory methods using the $(E\%)^2 \times T$ index

The evaluation of the two inventory methods, taking into account the time and accuracy of the inventory (*Equation 4*), showed that the calculated values of this index for the variables of volume and basal area per hectare were less in the sampling method with variable area (*Table 5*).

Table 5. *Comparison of two methods by using the $(E\ \%)^2 \times T$ index*

Variables	Fixed area plot	Variable area plot
Volume (m3/ha)	118780.77	36778.50
Basal area (m2/ha)	88573.18	31253.92

Species diversity

Mean and standard error of species richness, evenness and Shannon Wiener diversity and Simpson species diversity index of forest stands are shown in *Table 6*.

Although the evenness index and Simpson diversity derived from variable-area plots were higher than fixed-area plots and the species richness index and Shannon-Weiner species diversity index were higher in fixed-area plots, the t-test did not show a significant difference in the mean of different indices between the two methods ($\alpha = 5\%$).

Table 6. *Comparison of species diversity of the studied stand with t test results*

Variable	Fixed area plot	Variable area plot	t	Significance
Richness	2.79(0.16)	2.40(0.11)	1.960	0.52^{ns}
Simpson diversity indices	0.32(0.03)	0.33(0.03)	-0.125	0.9^{ns}
Shannon diversity indices	0.58(0.052)	0.55(0.045)	0.396	0.69^{ns}
Shannon evenness index	0.51(0.043)	0.58(0.043)	-1.108	0.27^{ns}

n.s: The difference is not significant

Discussion

In this research, the fixed-area and Relascope sampling methods were used (for the first time in Arasbaran forests) to obtain quantitative and qualitative characteristics and species diversity indices. Different stand characteristics can be used as indicators of management practices in forests. Meantime, some stand characteristics are sensitive to the measurement method (e.g., volume, quadratic mean diameter and small stem density and basal area); while others are less sensitive (Misik et al., 2013: Rice et al., 2014). The results showed that the estimated quantitative parameters of the forests in this research were similar to the other studies conducted in the same forest stand (Alijanpour et al., 2003, 2009, 2011; Moradi et al., 2015). However, there were significant differences between the two methods regarding DBH, basal area at breast height per hectare and volume per hectare values. These results were consistent with existing literature (Fallah et al., 2000; Sadiqi et al., 2014; Lowell, 1997; Rios et al., 2000; Motz et al., 2010; Pique et al., 2011).

In terms of accuracy of estimating quantitative characteristics, the results showed that the standard error of estimation for average volume per hectare, basal area per hectare and number per hectare when using Relascope were less than those of sampling method with a circular fixed-area plot. More accurate estimations were made regarding basal area at the breast height and volume per hectare by variable-area plot (Relascope) method in comparison to fixed-area sampling method. In addition, in a study the methods were used to estimate variables including basal area at breast height, density, and diameter distribution of trees. It has been shown that in multi-layered habitats and semi high-density forests, the Relascope had more precision in estimating basal area than density (Pique et al., 2011). It has been suggested that the precision of measurements made by Relascope in surveying the basal area at breast height per hectare, volume per hectare and DBH was generally higher than that of circular sampling method (Druszcz et al., 1995).

In the investigation of qualitative characteristics such as species composition percentage, species origin and stem health, the results of the present study were

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

consistent with the findings of the other researchers conducted in the same region (Amir ghasemi, 2001; Alijanpour et al., 2007; Moradi et al., 2015). Regarding the less measurement time using Relascope method, sampling method with variable-area plots (Relascope) for examining the species composition percentage and the origin and quality of the stems is suggested. Average time of sampling in fixed-area method was significantly higher than that of variable-area sampling method which was in good accordance with more recent report by Portela et al. (2016). Fallah et al. (2000) and Sadiqi et al. (2014) also reported the similar results. In determining the optimum method of sampling in Arasbaran forests stands, Alijanpour et al. (2003) showed that the average recording time of circular plots, rectangular and line samples were significantly different from each other and they reported that the time taken for line sampling was less than others.

In calculating the Shannon species diversity, Simpson species diversity and evenness, there was no significant difference between the two sampling methods. In this regard, other studies have shown that the accuracy of basal area and diversity indices were also similar (Motz et al., 2010). Moreover, by comparing the circle sample and distance methods in estimating diversity indices, the distance approach has been proposed for forest sampling strategies (Kint et al., 2004). Some researchers have introduced variable-area sampling for surveying species richness due to its speed and accuracy (Potela et al., 2016).

Conclusion

According to $(E\%)^2 \times$ index (Hush et al., 1982), It is concluded that for determining the characteristics of the basal area at breast height and volume per hectare, the sampling method with variable area was more appropriate regarding the standard error of estimation percentage and cost. In addition, due to the fact that there was no significant difference between the two methods for determining species diversity, using the Relascope could be suggested to estimate some quantitative characteristics as well as richness and diversity indices of the Arasbaran forests.

ABIOTIC AND BIOTIC FACTORS AFFECTING THE OCCURRENCE OF THRIPS ON LOTUS FLOWERS

BUMROONGSOOK, S.

Department of Plant Production Technology, Faculty of Agricultural Technology, King Mongkut's Institute of Technology Ladkrabang, Bangkok 10520, Thailand
(e-mail: suvarin.bu@kmitl.ac.th)

(Received 13th Feb 2018; accepted 9th May 2018)

Abstract. *Frankliniella schultzei* Trybom and *Scirtothrips dorsalis* Hood are two important insect pests of lotus flowers (*Nulumbo nucifera* Gearn). Both are active throughout the year and are difficult to control during pre- and post- harvest management. This study is focused on factors that influence the relationship among the thrips, their host plants and abiotic factors. Therefore, the distribution of these thrips species within lotus flowers of different flower ages was assessed using randomly sampling from commercially growing areas in Bangkok, Thailand and investigated thrips abundance on these flowers every week from April to September, 2016. The results revealed that there was a higher thrips population on older lotus flowers. *S. dorsalis* was much more abundant in summer than in the rainy season. It was found mainly on the pedicel and the outer corolla of the flowers. In the summer and rainy season, *F. schultzei* occurred most often and were found on the distal parts of lotus petals and pollen areas. Hindu lotus and East Indian lotus could support more of *F. schultzei* and *S. dorsalis* than Album Plenum and Roseum Plenum. The correlation among abiotic factors (temperature, amount of rainfall and relative humidity) and population fluctuations of *S. dorsalis* and *F. schultzei* was assessed. The studies showed a positive correlation of temperature (r = 0.7918) and a negative correction of relative humidity (r = -0.7588) to population of *S. dorsalis* but no relation with amount of rainfall (r = 0.0260). Whereas, there were non-significant correlations among *F. schultzei* and temperature (r = 0.43650, relative humidity (r = -0.2113) and rainfall (r = -0.4164). Interactions between different temperatures, relative humidity and rainfall effects on the abundance of the thrips were seen here. Both fundamental and applied perspectives will provide better understanding the thrips population abundance, and help to develop management plans for thrips control.
Keywords: *F. schultzei, population fluctuation, S. dorsalis, relative humidity, rainfall*

Introduction

Currently, insect pests are an important factor in lotus farming that affect the quantity and quality of the agricultural product. Farmers use chemicals as the primary measure to prevent damage caused by insects. Thrips are major enemies of both vegetable crops and ornamental plants. They use their stylets to obtain water and liquid nutrients from various plant cells including shoots, flowers and leaves, which results in a pale color or dry edges of affected plant tissue. The insects are highly polyphagous. Both *Scirtothrips dorsalis* Hood (chilli thrips) and *Frankliniella schultzei* Trybom (common blossom thrips) are two important insect pests of lotus flowers (*Nulumbo nucifera* Gearn) grown for export (Mungnimitr and Bumroongsook, 2007). The chilli thrips is a serious insect pest of lotus, agricultural crops and various floral plants. It is most often found feeding on young shoots and leaves and causes scars on fruit surface (Seal and Klassen, 2008).

The common blossom thrips are abundant on sacred lotus in Thailand (Mound and Palmer, 1981). It is an anthophilous insect and often feed on the floral parts of its host plant (Kakkar et al., 2012b), and is capable of destroying parts of the lotus flower. Both larvae and adults usually stay at the base of the petals and feed on plant cells (Mungnimitr and Bumroongsook, 2007), but can feed on other plant parts such as petals and leaves (Milne et al., 1996). It is a highly polyphagous insect, infesting a wide range of vegetable

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

crops and ornamental plants (Moritz et al., 2013). The thrips aggregate and colonize on plant petals (Milne et al., 2002) and can also pollinate various host plants (Kirk, 1997), although they can disfigure ornamental flowers in the process. Heavy infestation can discolor of flowers and distort the growth of young shoots (Amin and Palmer, 1985). Both forms of *F. schultzei* (dark and pale forms) can also be insect vectors for virus transmission (Nagata and De Avila, 2000; Cho et al., 1988).

Abiotic and biotic factors work in combination to shape species distributions and abundance (Lewis et al., 2017). Temperature is one of the important abiotic factors that affects abundance, distribution and population dynamics of insects (Kang et al., 2009; Yadav and Chang, 2014). Thrips population had a positive correlation with temperature and showed a negative correlation with relative humidity (Shuaib et al., 2008). Climatic factors are important factors that significantly influence thrips density as well (Kirk, 1997; Waiganjo et al., 2008). High temperatures with no rainfall increased thrips populations, while high relative humidity and rainfall had a negative relationship (Hamdy and Salem, 1994).

Biotic factors associated with host plants can affect species distributions and abundance. Plant aging increased mortality and influenced larval development of thrips (Campos et al., 2003). A nutrient supplement (nectar/pollen) is essential for insect survival in the absence of prey, or a modified microhabitat which can protect it against severe abiotic conditions (Xiao et al., 2011). Asian lotus flower is a concave shape and without nectar, having a cavity surrounded by petals and stamens and releasing scent. The flower has a thermoregulation process that can control temperature during anthesis and an optimum temperature between 30 and 36 °C when the environmental temperature is between 10 and 45 °C (Seymour et al., 1998; Seymour and Schultze-Motel, 1996; Xiao et al., 2011). Thrips are a lotus flower pollinator. The level of plant damage is dependent on *S. dorsalis* density (Mannion et al., 2014).

The objectives of this research are to determine seasonal population fluctuation and within lotus flower distribution of *F. schultzei* and *S. dorsalis*. The correlation of abiotic factors: temperature, relative humidity and amount of rainfall and population abundance of thrips on lotus flowers were evaluated. Understanding the influence of these abiotic and biotic factors on thrips abundance can help to further develop more efficient management programs for thrips control.

Materials and methods

Location of the sample sites

The experimental sites were located in Ladkrabang district of Bangkok province. Eleven sites of sample collection were chosen based on lotus varieties and non pesticide-treated areas (*Fig. 1*). GPS coordinates for location and the distance from sample sites to the data logger including the lotus plant variety were illustrated in *Table 1*. S1 and S2 are the experimental sites for collection of Hindu lotus (a single white flower); S3 and S4 for Album Plenum (a double white flower); S5-S6 for East Indian lotus (a single pink flower); and S7-S11 for Roseum Plenum (a double pink flower, *Table 1*).

Population density of S. dorsalis and F. schultzei on different stages of lotus flowers

Differently aged lotus flowers (*N. nucifera* var. Roseum Plenum), i.e., small bud, standard bud and full bloom (5, 9 and 13 days above water level, respectively; n = 30),

Comparison of the abundance of S. dorsalis and F. schultzei on different parts of lotus flower

Standard buds of Roseum Plenum lotus flowers (n = 30) were collected and thrips count on its pedicel, petals and pollen areas of lotus cut flower were performed. Thrips density of *S. dorsalis* and *F. schultzei* from these flower parts was identified and recorded**.**

Number of thrips on the different corolla of lotus flowers

Roseum Plenum lotus flowers are composed of six corolla: the first corolla are the outermost petas, and the innermost petals are the sixth corolla. Standard lotus flowers var. Roseum Plenum (n = 30) were collected weekly. Thrips count on each corolla were investigated.

Thrips abundance on different varieties of lotus flowers

A total of 30 lotus flowers were randomly selected from each of four varieties of *N. nucifera*: Hindu lotus (a single white flower), Album Plenum (a double white flower), East Indian lotus (a single pink flower) and Roseum Plenum (a double pink flower). Number of thrips found on lotus was investigated and recorded.

Correlation among thrips population abundance and temperature, relative humidity and rainfall

A total of 30 Roseum Plenum lotus flowers were randomly selected. Thrips counts of *S. dorsalis* and *F. schultzei* on each flower and its pedicel was performed. For the temperature and relative humidity dataset, a data logger (DT172-CEM G M Electronics) was used to record air temperature and relative humidity every hour The weather data (daily average observation for air temperature and relative humidity) was computed. The data logger was placed on the wall of the storage house (5 m from S7) at 1.5 m above the ground with protective roof. The amount of rainfall at Ladkrabang area obtained from the Thai Meteorological Department.

Data collection and statistical analysis

The experimental period was spread out across two seasons: summer (April-May, 2016) and rainy season (June-September, 2016). Samples were collected once a month for six months and processed independently for each experiment. To reduce light intensity variation effect on thrips population, all samples were collected between 7 and 9 am. Thrips were collected from plant parts, then transferred in 70% ethanol for later analysis. They were identified to species using a stereomicroscope. The SPSS statistical software was used to perform data analysis. Population density of thrips were analyzed separately for each experiment using the paired sample t-test to determine the mean difference between density of *S. dorsalis* and *F. schultzei*. ANOVA was applied to assess the mean difference of thrips occurrence among lotus varieties. Linear regression analysis was used to assess correlation among thrips occurrence and abiotic factors**.**

Results

Population density of S. dorsalis and F. schultzei on different stages of Roseum Plenum lotus flowers

Thrips counts on the same type of flower buds were compared and the results showed that the older the flower buds were, the more thrips were found. In the small flower buds, no difference was found in the density of *F. schultzei* detected than *S. dorsalis* (t-value = 1.29 and p = 0.1125). *F. schultzei* were found more than *S. dorsalis* in the standard-sized buds (t = 2.19 and p = 0.0264) and the full bloom lotus flowers

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

(t = 3.11 and p = 0.0054; *Table 2*). *F. schultzei* was found the most on full bloom lotus flowers.

Comparison of the abundance of S. dorsalis and F. schultzei on diffirent parts of Roseum Plenum lotus flowers

S. dorsalis was found on flower pedicel and petals and none were detected in the middle area of flowers (containing pollen and stamen). Comparing *S. dorsalis* and *F. schultzei* occurrence on flower pedicels, the result showed no significant difference (t = 1.46 and p = 0.0869). *F. schultzei* were detected more than *S. dorsalis* on lotus flower petals (t = 2.82 and p = 0.0091), as well as stamen and pollen areas (t = 2.56 and p = 0.0141; *Table 3*).

Correlation among thrips population abundance and temperature, relative humidity and rainfall

The climatic conditions from April to September, 2016 in the study area ranged from 27.20–32.57 °C, RH 72–83% and rainfall 0–19 mm (*Table 8*). *S. dorsalis* density on lotus flower was highest in April and deceased gradually to 10.85, 11.68 and 7.85 in May, June and July, respectively. In August and September, there were 1.17 and 1.45 thrips/flower, respectively (*Fig. 2*). *F. schultzei* density was highest in August and lowest in June. The correlation between the amount of thrips on lotus flower over the five months of sampling and the abiotic factors temperature, relative humidity and rainfall was statistically analyzed. The results showed that temperature and relative humidity were significantly correlated with the change in *S. dorsalis* (r = 0.7918 and -0.7588, respectively). *F. schultzei* density on lotus flowers was not significantly correlated to temperature, relative humidity and rainfall (*Table 9*).

Table 8. *Abiotic condition of temperature, relative humidity and rainfall during the sampling periods*

Months (2016)	Temp (^{o}C)	RH (%)	Rainfall (mm)
April	32.57	72	0.00
May	28.20	80	8.95
June	30.36	75	19.00
July	28.60	79	1.50
August	29.50	75	0.68
September	27.20	83	0.00

Discussion

Both abiotic and biotic factors affect insect population abundance (Lewis et al., 2017). *S. dorsalis* is a polyphagous insect pest with a global distribution (Dickey et al., 2015). It feeds on meristem and young plant parts. *S. dorsalis* prefers the outer corolla of lotus flower and its pedicel. In addition, it feeds on lotus leaves (Mungnimitr and Bumroongsook, 2007). *F. schultzei* primarily attacked lotus flowers and caused discoloration. The female deposits egg on flower tissue and it takes about 13 days to complete life cycle (Kakkar et al., 2012a). *F. schultzei* was observed on full bloom lotus flowers. Aggregation density of insects on host plant corollas induce mating success (Kang et al., 2009). High density of *F. schultzei* on lotus flowers was similar to the finding of Kakkar et al. (2012b), who reported that adult are the most numerous in tomato flower.

As noted above, Hindu lotus and East Indian lotus are categorized as a single flower and Album Plenum and Roseum Plenum are a double flower (Mandal and Bar, 2013). The structure of single lotus flowers could allow *F. schultzei* to build up populations more easily than double lotus flowers. Further studies should be investigated if various colors of lotus flowers attract thrips to different degrees.

The lower the relative humidity value and the higher the temperature, the higher the number of *S. dorsalis* observed. Previous research reported similar results on relationship among temperature, relative humidity and thrips population (Hamdy and Salem, 1994). *S. dorsalis* was found on leaves and the outer parts of lotus flowers, therefore it is more exposed to the environmental condition than *F. schultzei*. On the contrary, *F. schultzei* density on lotus flowers might not depend on the abiotic factors

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

like temperature, relative humidity and rainfall due to its cryptic habitat. The microhabitat within flowers could play important roles on observed population of thrips (Salguero_Navas et al., 1991).

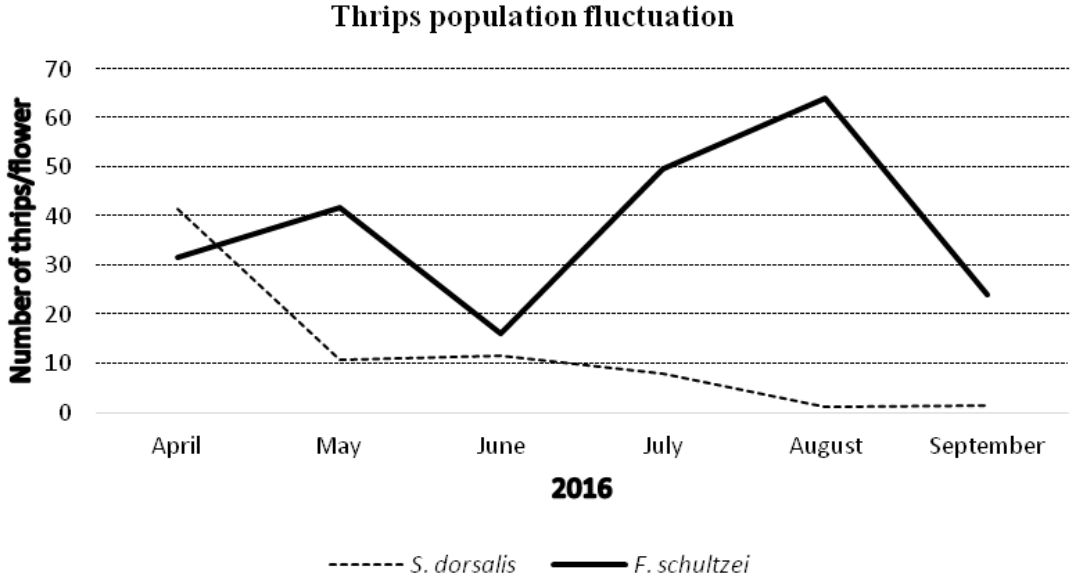

Figure 2. *Population density of thrips on lotus flowers*

Thrips species	Correlation coefficient		
	Temperature	**Relative humidity**	**Rainfall**
S. dorsalis	0.7918*	-0.7588*	-0.0260
	(0.8899)	(0.8711)	(0.1613)
F. schultzei	0.4365	0.2113	0.4164
	(0.6607)	(0.4597)	(0.6453)

(R) = values in parentheses are R adjusted
*Statistically difference at p = 0.05

Conclusions

S. dorsalis attacked flower pedicels and the outer part of lotus petals and population peak during high temperature and dry weather. Abiotic factors such as the temperature and relative humidity played a remarkable role on *S. dorsalis* abundance. Regarding *F. schultzei*, this is the first report that they attack four varieties of lotus flowers. The *F. schultzei* mainly inhabit and feed on the petals and the pollen areas of lotus flower. Biotic factors (age of host plant and food selection) shaped the distribution and abundance of *F. schulzei*. In addition, lotus flower structures as protective shelter and microclimate within the flowers are factors that influenced the population abundance of *F. schulzei*. Size and cryptic behavior of these thrips make them difficult to control. Therefore, phytosanitary treatment of these thrips for lotus cut flowers export is probably the most challenging task.

EFFECT OF MICROWAVE RADIATION ON GROWTH AND GERMINATION OF STONE PINE (*PINUS PINEA* L.) SEEDLINGS

KUZUGUDENLI, E.

Department of Forestry, Suleyman Demirel University, Isparta, Turkey
e-mail: emrekuzugudenli@sdu.edu.tr

(Received 15th Feb 2018; accepted 9th May 2018)

Abstract. Highly successful afforestation applications and good performance development is linked to adoption of correct afforestation techniques, quality of seedling material, selection of appropriate origin, seed material, and treatment of seedlings. One of these treatment processes is subjecting seeds to a magnetic field. The aim of this study is to determine the effects of magnetic field on the germination of seeds and growth of seedlings of stone pine (*Pinus pinea* L.). For this purpose, seeds (Aydın-Koçarlı origin) were used in nursery garden beds (Isparta, Turkey) with three replications based on completely randomized design. A magnetron tube setup was used to generate a magnetic field. A 220V AC magnetron tube was positioned 15 cm above the seed container, and 280, 336, 462, and 595 W output for 15, 30, and 60 s was applied, respectively. As a result of being subjected to the magnetic field, stone pine seeds experienced changes in seedling morphological characteristics and positive effects on seedling growth and development. It is believed that application of 280 W microwave of 160 micro Tesla intensity for 60 s could suppress live plants by encouraging quick seedling development, help seedlings benefit from water and nutrient elements in the earth, and contribute to the economy of the country by reducing development time.
Keywords: *magnetic field, seed, morphological characteristics, seedling quality, afforestration*

Introduction

Forests in Turkey cover 21.7 ha, or 27.6% of total area. The country has a tree value of total 1.49 billion m^3 and rich bio-diversity. Half of the forest resources of the country consist of pervasive and infertile needle-leaved and broad-leaved forests. The fertiliy of our forests is low, at approximately 0.750 m^3/ha per year (Urgenc, 1998). Therefore, it is necessary to fertilise pervasive forest areas with artificial rejuvenation techniques in the near future and create new forest areas with afforestation applications.

Today, in developed countries where intensive forestry techniques have been applied, determining afforestation areas only to obtain wood raw materials has been abandoned. These applications were replaced with multi-functional afforestation techniques that aim to produce raw wood material and by-products (Ilter and Ok, 2004). Through such multi-functional afforestation as used in Mediterranean and south European countries, it is obvious that such countries commonly prefer stone pine (*Pinus pinea* L.) because it is more durable than other pine types, adapts to high temperatures and drought, tolerates water stress with its deep roots, provides effective protection against erosion, and has economic benefits (Ansin, 2001).

In terms of worldwide distribution of stone pine, large forests are observed in Spain, Portugal, Turkey, and Italy, as well as Greece, Syria, Lebanon, France, Yugoslavia, Montenegro, and other North Africa countries (Firat, 1943).

The stone pine is a typical Mediterranean tree, and it is one of five pine species that naturally grow in our country. Stone pine generally has a natural distribution in regions with a Mediterranean climate, which have an annual temperature average of 11.4-18.7ºC, relatively high annual precipitation average of 635.7-1288.1 mm, and relative humidity of 58-80.8% (Sayman et al., 2006).

Highly successful afforestation applications and good performance development is linked with adoption of correct afforestation techniques, quality of seedling material, selection of appropriate origin, seed material, and treatment of seedlings (Urgenc, 1998). One of these treatment processes involves subjecting seeds to a magnetic field. The effects of magnetic fields on growth and development of plants and practical applications have long been discussed. Recently, some studies have indicated positive effects of magnetic fields on plant growth. Magnetic fields have been found to have positive effects on fertility and number of flowers (Matsuda et al., 1992), seed germination ratio and speed (Souza Torres et al., 1999), and earliness of flowering (Samy, 1998) of various plant types and species.

Accordingly, in afforestation applications with stone pine, which has economic and forestry importance for manufacturing of by-products, it is possible to discuss the significant effects that magnetic fields have on product yield and growth performance (Kirdar et al., 2016). Based on these facts, this study was conducted to evaluate the effects of magnetic fields on stone pine (*Pinus pinea* L.) seed germination and seedling growth.

Materials and methods

The material of this study consisted of seeds collected in December 2015 from naturally grown stone pine stands in the Aydın-Koçarlı region (Turkey) (37.690503 north latitude, 27.688276 east longitude, 796 m altitude) that showed superiority to other individuals in the stand in terms of height, diameter, and body smoothness. Before harvested seeds were planted, they were divided into 6 groups (including a control group) and subjected to magnetic fields of varying microwave power and duration via magnetron tube (*Table 1*).

Table 1. *Properties of microwave application by the groups*

Group	Microwave intensity (μT)	Microwave output power (W)	Duration of exposure (s)	Post-Exposure seed temperature (ºC)
1	160	280	60	40
2	192	336	30	60
3	192	336	60	78
4	264	462	15	94
5	340	595	15	108
Control Group				

A magnetron tube setup was used for generating the magnetic field. A 220V AC magnetron tube was positioned 15 cm above the seed container, and 280, 336, 462, and 595 W output power was applied for 15, 30, and 60 s. Seeds were not applied at high output powers (462 and 595 W) for 30 and 60 s due to overheating. The frequency of the microwave was 2450 MHz.

Seeds were planted in 2016 in the Suleyman Demirel University-Yenisarbademli Vocational School application nursery garden beds with three replications based on completely randomized design. The nursery garden field has a semi-continental climate in a Mediterranean climate transition area and an altitude of 1178 m. Annual average temperature was 11.2ºC, and annual average precipitation was 727.2 mm. The 0-30 cm

© 2018, ALÖKI Kft., Budapest, Hungary

deep planting bed on the trial's planting parcel was 57.9% sand, 23.3% silt, and 18.8% clay with a silty loam texture (*Figure 1*).

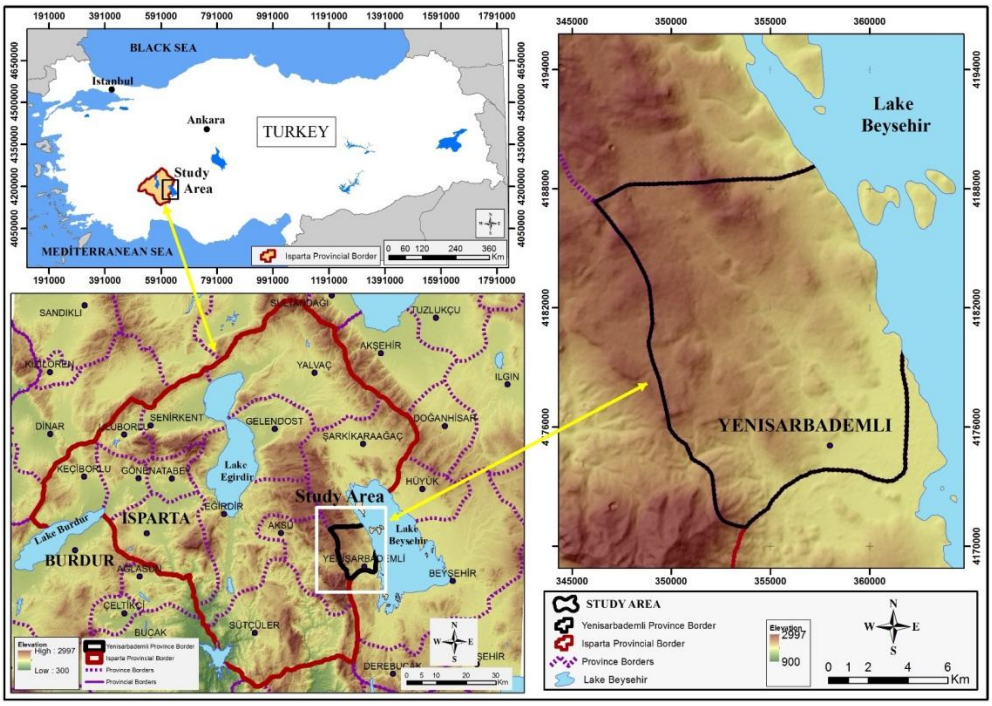

Figure 1. *Study area*

Germinated seeds were counted once every 3-4 days starting from the first germination. Germination percentage (GP) was calculated for each treatment. The formula used for calculating the germination percentage is as follows (Eq. 1):

$$GP = \frac{\sum ni}{N} x100 \qquad \text{(Eq.1)}$$

with ni as the number of seeds germinated on the i^{th} day, and N indicating the total number of seeds in the germination experiment.

During the 1-year growth period, routine seedling growth applications of weeding, hoeing, and irrigation were applied. Seedling removal was conducted without harming the roots of seedlings in the fall season when growth and development was completed. After removing the seedlings, they were placed in a bucket with water without harming roots or offshoots and were monitored carefully. Later, the shoot height (cm), shoot fresh weight (g), root collar diameter (mm), tap root length (cm), and root fresh weight (g) of seedlings were measured. For this purpose, a total of 540 seedlings, or 90 seedlings in each group, were measured. Heights were measured with a ruler with 1 mm sensitivity, weights were measured with a sensitive scale, and root collar diameters were measured with an electronic calliper with 0.01 mm sensitivity.

SPSS 20.0 Windows package program was used for comparing the measured morphological and physiological characteristics, and variance analysis and the Duncan test were applied.

Results

Germinations were recorded to measure the germination percentage of planted seeds. Germinations were completed at the end of 1 month. First germination was observed in seeds in the control group, which had the highest germination percentage (61%). Based on this information, after the 1-month period, the number of germinated seeds was divided by the total number of planted seeds and germination percentages were calculated (*Figure 2*).

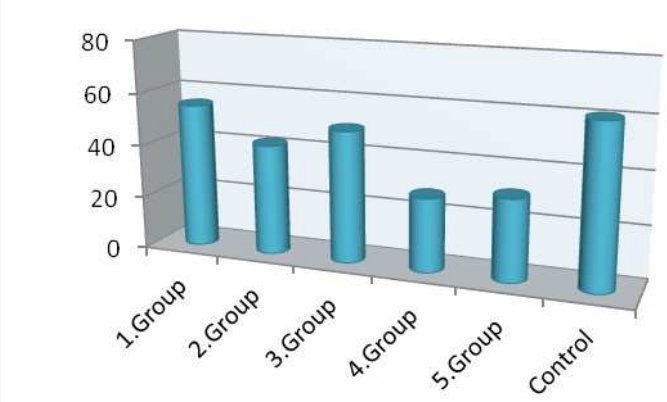

Figure 2. *Germination percentage (%) of groups*

Based on variance analysis of seedling morphological characteristic and following Duncan test results, it was shown that magnetic fields have statistically significant ($p < 0.001$) effects on shoot height (SH), shoot fresh weight (SFW), root collar diameter (RCD), tap root length (TRL), and root fresh weight (RFW) of stone pine. Average values, standard deviation, F value, importance level, and classification of groups are given in *Table 2*. When groups were analyzed in terms of seedling morphological characteristics, seedlings in group 1 had higher average values compared to the other groups, whereas most of groups 3, 4, and 5 had the lowest values.

According to variance analysis results, it was determined that in terms of morphological characteristics, the highest F value was observed in tap root length and the lowest F value was observed in root fresh weight, where all groups were differentiated with the same significance level ($p < 0.001$) (*Table 2*).

Stone pine seedlings were classified according to shoot height and root collar diameter as specified in the Turkish Standards Institute's Seedling Standards (TSE, 1988). Based on this classification, group 1 had the highest percentage (92%) and group 5 had the lowest percentage (4%) among 1st-grade seedlings in terms of shoot height. For root collar diameter, group 1 and group 3 had the highest values (both 100%) and group 4 had the lowest value (52%) among 1st-grade seedlings (*Table 3*).

Table 3. *Distribution to quality classes of shoot height and root collar diameter based on TSI Seedling Standards*

	TSI Seedling Standards (1988)		**Distribution to Quality Classes (%) of Group**					
	Class	Range	1	2	3	4	5	Control
Shoot Height (SH)	I	SH>12cm	92	64	48	68	4	70
	II	10cm<SH<12cm	8	20	22	22	32	22
	Cull	SH<12cm	0	16	30	10	64	8
Root Collar Diameter (RCD)	I	RCD>2mm	100	60	100	52	98	93
	Cull	RCD<2mm	0	40	0	48	2	7

Discussion and conclusions

In this study, the effects of magnetic fields on certain morphological characteristics of germinating seedling stone pine trees were investigated. Stone pine seeds were subjected to microwaves of different power settings (280, 336, 462, and 595 W) and durations (15, 30, or 60 s) and were planted along with control group seeds. At the end of one vegetation period, the germination status of seeds and shoot height, shoot fresh weight, root collar diameter, tap root length, and root fresh weight of 1+0 seedlings were investigated.

Based on the findings of this study, it was determined that magnetic field application influenced the development of seedlings with 99.9% statistical confidence. It was determined that seeds subjected to a magnetic field had a lower germination percentage compared to the control group. A similar study that investigated the effects of magnetic fields on germination of mung bean plants indicated that certain magnetic field groups (30, 40, and F50 Hz) had a lower germination percentage compared to the control group (Huang and Wang, 2008).

When seeds are subjected to microwave radiation, the microwaves first pass through the cell wall and later are absorbed by the water molecules in the seed. As a result, tissues containing water heat significantly, and cytoplasm collapses the cell wall and leaks out. Furthermore, due to excessive heating, proteins in the seed may denature and lose functionality. Therefore, it is believed that certain seeds subjected to microwave energy were deformed and had a lower germination percentage compared to the control group (Brodie et al., 2012).

It is also believed that this negative effect is due to increased gibberellin and cytokinin synthesis or activity. In particular, gibberellin has a high ratio in developing seeds. It plays a significant role in controlling and stimulating seed germination. Gibberellin stimulates enzymes for germination of seeds and the α-amylase enzyme that carries those enzymes from embryo to endosperm to convert starch to sugar for energy supply. Cytokinin has a role in cell multiplication and stimulation of cell expansion

© 2018, ALÖKI Kft., Budapest, Hungary

(Hartmann et al., 1997; Hilhorst and Karssen, 1992). For these reasons, gibberellin and cytokinin may cause lower a germination percentage in test groups compared to the control group.

One-way variance analysis (ANOVA) was conducted to test whether there was significant difference between groups' averages in seedling morphological characteristics. Test results indicated that there was a statistically significant difference between groups ($p < 0.001$). The Duncan test was applied to determine which group(s) caused such difference. Test results indicated that the magnetic field had a statistically significant effect ($p < 0.001$) on shoot height, shoot fresh weight, root collar diameter, tap root length, and root fresh weight of stone pine. When groups were analysed in terms of all morphological characteristics, the highest average of germinated seeds was identified in the group that was subjected to 280 W microwave energy with 160 micro Tesla intensity for 60 seconds.

Another study that investigated the relationship between certain magnetic field applications and development of stone pine indicated that a magnetic field with 9.42 mT intensity had positive effects on development of seedlings (Kirdar et al., 2016). Similar results were obtained for different plants, such as by Matsuda et al. (1992) for strawberry (Fragaria sp.); Vashisth and Nagarajan (2008) for chickpea (Cicer arietinum L.); Souza Torres et al. (1999) and Martinez et al. (2009) for tomato (Lycopersicon esculentum Mill.); Cakmak et al. (2010) for wheat (Triticumaestivum L. cv. Bezostaya) and bean (Phaseolus vulgaris L. cv. Gina); Tanvir et al. (2012) for white siris (Albizia procera Benth.); Racuciu (2012) for corn (Zea mays L.); and Cramariuc et al. (2005) for potato.

Magnetic fields may increase seedling development in particular due to effects on auxin, cytosine, and gibberellin metabolism. The most important effect of cytokinin in plants is in cell multiplication, and the most important effect of auxin and gibberellin is in increasing cell elongation (Jansen, 1982; Arteca, 1996). Increased synthesis or activity of auxin, cytokinin, and gibberellin may cause an increase in shoot height, shoot fresh weight, root collar diameter, tap root length, and root fresh weight of seedlings.

When groups were analysed, the highest average in terms of morphological characteristics was found in seedlings in group 1. It is believed that the lower seedling morphological characteristics of other groups was caused by an increase in seed temperature in line with increased magnetic field intensity and duration (*Table 1*). Similarly, Kazanci (2014) investigated the effects of high temperature on seed germination and found that among 37 of 71 taxa, high temperature (100-140ºC) had negative effects on seed germination.

As a result, the magnetic field applied to stone pine seeds had effects on seedling morphological characteristics and positive effects on seedling growth and development. In this sense, in afforestation applications with stone pine, which has economic and forestry importance for manufacturing of by-products, it is believed that application of 280 W microwaves with an 160 μT intensity for 60 s could suppress live plants by developing seedlings quickly, help seedlings to benefit from water and nutrient elements in the earth, and contribute to the economy of the country by reducing development time. Seeds should not applied at high output power (minimum 462 W) for more than 15 s due to overheating. It is recommended to applied at low output powers for more than 60 s for further studies. A study that investigated the relationship between certain magnetic field applications and development of stone pine indicated that a magnetic field (9.42 mT intensity) with 45 m had positive effects on development of

© 2018, ALÖKI Kft., Budapest, Hungary

seedlings (Kirdar et al., 2016). Similarly, Vashisth and Nagarajan (2010) investigated the effects of magnetic field applications on sunflower (*Helianthus annuus* L.) seeds germination and found that 50 and 200 mT for 2 h exposure yielded superior results.

Studies of the effect of the microwave on the seeds of the forest trees are very limited. So it is thought that it will lead similar studies to be done in this field.

Abstract. Effective management of the special-use forests in Vietnam, e.g. nature reserves and national parks, depends on information about disturbances of illegal activities due to the effective protection as patrol ranger efforts (PREs). Patrol rangers are indispensable for protecting forest in conservation areas. Moreover, to enhance PREs efficiency is regularly to reject illegal activities and support conservation. This paper explores the quantification of PREs in terms of illegal activity encounters collected by rangers in Nam Tien Forest Station (FS). Based on a monitoring system of ranger's efforts, the study conducted surveys for monthly activity reports at the central office. The results revealed that the patrol efforts such as patrol-day and distance were inversely proportional to the number of illegal activity encounters and fluctuated in accordance with the time when they were conducted each year. This study will be useful for forest management at the local level in relation to the planning and monitoring of patrol activities. Usefully, this study's finding are critical for application to the various protected areas with respect to curbing illegal activity and enhancing forest resources-based forest management practices.

Introduction

Globally, continued biodiversity loss is undoubted (Squires, 2014; Adhikari et al., 2017) and even forest managers of Protected Areas (PAs) have variable success in protecting the biodiversity of their areas (Bradshaw et al., 2015). In particular, tropical forest areas all over the world have been experiencing widespread and rapid deforestation and forest degradation, because of pressures of logging, fire, cultivated encroachments, and poaching in their immediate surroundings, and inadequate protection inside the reserves (Baillie et al., 2004; Koh et al., 2013; Bradshaw et al., 2015) such as biodiversity declines and this cause a massive loss of species (Brooks et al., 1997; Harrison et al., 2016). Protected areas such as nature reserves and national

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_28452859
© 2018, ALÖKI Kft., Budapest, Hungary

parks, which often present viable biodiversity, are extremely important in conservation (Gray and Kalpers, 2005; Kimdung et al., 2013). The striking economic growth in the regional buffer zone of PAs shows several profits, but also brings impacts to its ecosystems and biodiversity. On the other side, it has advanced conservation opportunities (Squires, 2014).

The decline in natural resources in the tropical forest requires much attention and the efforts to arrest these declines have become a part of the Ghana government policies and law enforcement efforts (Wiafe, 2016). Much of the flora and fauna of the region in Southeast Asia like Vietnam is not found elsewhere in the world (endemic) (Koh et al., 2013). It has the highest recorded relative rate of deforestation, compared to other tropical forest areas and it could lose three-quarters of its original forests and up to 42% of its biodiversity by 2100 (Sodhi et al., 2004; Miettinen et al., 2011). The impact of human activities on natural resources might have a cascading effect on the whole biodiversity (Wright, 2003). The exploitation of any species of fauna and flora is commonly prohibited and controlled in PAs (Mubalama, 2010). Yet knowledge of protection effort is often limited because the true extent of natural resource exploitation is hard to recognize, especially if it is illegal (Nuno et al., 2013).

As a result of conservation targets, a number of the PAs have been established over the world over the last few decades. It aims is to reduce the first humanity's pressures on the natural environment (Steffen et al., 2015; Venter et al., 2016) and secondly, the source of the primary threats to a country's natural resources and its long-term persistence regarding its biological diversity (Lan et al., 2002). The arious activities are essential for human subsistence but lead to biodiversity loss, and this trend is likely to continue in the future (Baillie et al., 2004). Recent policy commitments aim to reduce biodiversity loss (Dulvy et al., 2006) because a consequence of illegal activities is their increasingly serious effect on natural resources (Gray and Kalpers, 2005) which cause biodiversity loss (Critchlow et al., 2015). Previous researchers have noted that illegal activities seem to vary in accordance with law enforcement efforts (Gandiwa et al., 2013). For example, poor law enforcement performances have been significantly linked to decreases in conservation as a result of increase illegal activities (Bassett, 2005; Ogutu et al., 2011). Additionally, effective law enforcement mechanisms are only weakly implemented by voluntary compliance in the PAs (Rowcliffe et al., 2004). Enhancing law enforcement performance like PEFs, by contrast, has been linked to declines in illegal activities such as poaching (Jachmann, 2008a, b; Martin, 2010; Wiafe, 2016).

The uninterrupted struggle between law enforcement practice and illegal activities suggests some difficulties in enforcing conservation (Lamarque et al., 2009; Wiafe, 2016). Key to biodiversity conservation and the target of forest management is to retain the representative biodiversity of all ecological regions and to conserve the integrity of ecosystems along with their biodiversity from illegal activities (Wiafe, 2016). The stakeholders as rangers in forest stations respond to the threats to conservation in several ways (Albers and Grinspoon, 1997). Previous studies have provided proof which suggests that illegal activities such as illegal logging and agricultural expansion (Khoi and Murayama, 2010) and poaching (Mubalama, 2010) have emerged as serious threats to conservation.

In Vietnam, PEFs in PAs have been applied as conservation tools of forest management. There is little doubt that planning, monitoring, and evaluation by patrol ranger efforts (PREs) are essential tools for enhancing law enforcement practices and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_28452859
© 2018, ALÖKI Kft., Budapest, Hungary

compliance in such areas (Monteiro et al., 2010). Furthermore, there is proof that that investment in conservation law enforcement is effective (St. John et al., 2014). For example, anti-poaching patrols increased the effectiveness of patrol efforts to deter hunting (Jachmann, 2008a). However, there is a gap in the research considering the occurrence of illegal activity and law enforcement efforts in PAs. In Vietnam, all illegal activities have been politically observed and controlled by forest officers and a management board (Vietnam Government, 2010). Additionally, law enforcement efforts have continually been identified as one of the most important factors in making parks work (Mubalama, 2010). This research focused on contributing to the understanding of patrol efforts and illegal activity in natural resources management, specifically Nam Tien FS in Pu Hu Nature Reserve (NR). Understanding the patterns and extent of illegal activities is vital for effective patrol efforts, which constitute essential elements of illegal activities reduction (Critchlow et al., 2016) and of biodiversity loss prevention (Critchlow et al., 2015).

The aim of this study was to focus on patrol ranger efforts (PREs) carried out at the largest forest station in Pu Hu NR, namely the Nam Tien Forest Station (FS) when the short-term law enforcement dataset was available. Therefore, from January to December 2017, the objectives of this study were to: (i) evaluate the quantified patrol ranger efforts against illegal activities; (ii) find out the relationship among relevant factors that might influence patrol effort and illegal activity encounters; and, (iii) recognize fluctuations in the illegal activities encountered during the study months. This exploratory research provided insight into patrol performance related to law enforcement ranger's efforts in patrol planning, which could resulting in PAs in Vietnam and a simple analysis of them that could be applied in enforcement patrolling, which could result in illegal activities reduction aimed at halting decreases in species of conservation concern (Plumptre et al., 2014).

Material and methods

Location and general description

Pu Hu NR lies in two districts (including Quan Hoa and Muong Lat) in Thanh Hoa province. The area covers over 28.000 ha, is rugged and is located at latitude 20°30' to 20°40'N and longitude 104°40' to 105°05'E in northeast Vietnam. Amongst the six forest stations and one sub-forest station in Pu Hu, Nam Tien FS is one of the extreme pressure from illegal activities occurrence because of its dense population and the people's demands, compared to other forest stations. As explained above, this research focuses on Nam Tien FS, which is supposed to control an area of around 5,700 ha divided into nine forest sub-area plots of the Pu Hu NR. The three permanent forest officers are responsible for protecting the forest, and there are 423 households and 1,512 inhabitants in 12 villages of 2 communities in the buffer zone, namely the settlements Nam Tien and Thien Phu communities. These are the villages with the highest population density and they have the most crowded immediate inhabitants in the buffer zone areas under Nam Tien FS, compared to other buffer zones in Pu Hu. The protection efforts needed to meet conservation objectives are often different from the requirements of the fringe residents (Ormsby and Kaplin, 2005). As in the NR areas, there have been hunting, logging, cutting, and grazing illegal activity encounters. Once a nature reserve area has been established, all extraction of activities by the immediate population area is illegal (Dong et al., 2017). Rangers in Nam Tien FS have protected

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_28452859
© 2018, ALÖKI Kft., Budapest, Hungary

inside the NR through the forbidding of logging, poaching, and grazing by the local population, and other confrontations with forest-edge communities (Plumptre et al., 2014; Risdianto et al., 2016).

Data collection

The data on illegal activities during patrols were collected from January to December 2017. Feasible patrols recorded any observations indicating non-permitted activities by humans or livestock. Basically, rangers had been properly trained in how to record GPS-tracks through an area that had illegal activities or drastic negative effects on biodiversity conservation.

In Nam Tien FS and other stations in Pu Hu, administrative management still use conventional law enforcement in the form of foot patrols that frequently start from each of the sub-stations or from the central stations (Albers and Grinspoon, 1997; Jachmann, 1998, 2008a, b; Burton, 2010; Gandiwa et al., 2014; Wiafe, 2016). Simple patrol forms were applied for record: the numbers of rangers on patrol, and the types, quantities, and places of illegal activity encountered. They presented the exact duration of using the Global Positioning System (GPS) (Mubalama, 2010). After each patrol, field data were collected on data sheets or in patrol staff logbooks (Burton, 2010; Gandiwa et al., 2014), which were summarily tabulated in Excel sheets, then submitted to the head office at the end of each month.

For each sighting, GPS waypoints and tracks, types of human signs were legally identified and the management area where the species or signs had been detected was noted accordingly (Mubalama and Mushenzi, 2004). The typical patrol was conducted by one or two rangers patrolling and recording the patrol route, using a GPS unit in liaison with a topographic map of the particular area (Burton, 2010; Gandiwa et al., 2014). Any apparent changes or unusual situations along the patrol track were recorded (Burton, 2010). After recording for different points, it was properly compared with information from the ranger's patrolling, and added into map software for accounting the new appearances of illegal activity found (Gandiwa et al., 2014). Regularly, rangers were conducted at the Nam Tien FS, although sometimes mobile teams from central office were also deployed and re-evaluated the previous information about the site. Location points (waypoints) of illegal activities were recorded and written down, including the current name and number of officers on patrol, duration of patrol, name of the forest sub-area plot, and numbers as well as longitude and latitude of the illegal activities discovered (Jachmann, 1998, 2008a, b; Burton, 2010; Gandiwa et al., 2014; Wiafe, 2016).

Informal patrol efforts planning

Officially, regular monthly meetings and discussions were held at the Pu Hu office by The Management Board to analyse each station's patrol efforts. Due to the number of patrol tracks and the collected information from each patrol track, a short patrol report was presented in detail about the sub-area forest plot. According to the current information and planning from the monthly meeting, Nam Tien FS prepared its own plans for patrolling during the following month (Gandiwa et al., 2014; Wiafe, 2016). Additionally, patrol movements and starting times from the forest station had to be unpredictable (Jachmann, 2008b). However, the patrol teams could not always follow the given patrol plan, often made a change of strategy necessary.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_28452859
© 2018, ALÖKI Kft., Budapest, Hungary

Plans for patrol routes were produced by the head of the forest station and patrollers assembled the team for each patrol of the sub-area forest (Jachmann, 1998, 2008a, b; Gandiwa et al., 2014; Wiafe, 2016). During the patrolling, the leader of a team had a decision to make about whether to use an 'arrow head' or a 'single file' formation for his officers, depending on previous information obtained from the earlier patrols (Wiafe, 2016). Based on specific planning, each ranger had to patrol at least five-time patrols per month in their protected areas.

Data analysis

The Finding per Effort index (F/E) was applied which gives an overview of indicators of illegal activities per unit (Jachmann, 1998b; Wiafe, 2016). Monthly, finding is the total number of illegal activity encounters, and effort refers to the total number of effective patrol-days (patrol-time) (Jachmann, 2008b, c). Kilometric Index of Abundance (KIA) is the proportion of illegitimate activities that were encountered to distance per kilometers (km) walked per month (Groupe, 1991). Kilometers (km) per Effort index (P/E) is the rate of the distance in kilometer (km) walked on the effective patrol-day or patrol-time per unit. Data were analyzed using Microsoft Excel software for descriptive statistics using the Statistical Package Social Sciences (SPSS) version 20.0 to determine any significant difference among various variables by testing function ($p = 0.05$); and mean values were presented as mean ± SD (standard deviation). In particular, descriptive statistics were used to summarize the illegal activity found in the data set. Data on illegal activity by different tracks were grouped together and totals, averages and percentages for patrolling routes were calculated. Burton (2010) showed that given trait data were not the normal distribution, therefore, non-parametric statistics were used to analyze correlation and compare means (Spearman rank correlation and Kruskal-Wallis test if more than two events and Man-Whitney test with two variables). So, data were analyzed by using both tests in SPSS to determine if there is any significant ($a = 0.05$) in the variables of two, or more than two events.

Results and discussion

The brief description of possible patrol routes through each sub-area forest plot presented (*Table 1*; *Fig. 1*). Establishment of all patrol routes covered sensitive biodiversity loss and illegal activity occurrence. Rangers (FS) reached to the sub-area forests from Nam Tien forest station by motorbike.

Patrol ranger efforts

The average patrol-days (patrol-hours) in the period of the first quarter to the fourth quarter in 2017 were as follows: 0.82 (SD = 0.49), 0.68 (SD = 0.51), 0.57 (SD = 0.43), and 0.69 (SD = 0.56) respectively. The average quarterly patrol-days of patrol effort fluctuated from the first quarter to the fourth quarter in 2017, i.e., from 0.82 (SD = 0.49) to 0.69 (SD = 0.56) respectively. In particular, the mean for the monthly patrol-days was not significantly different among these months ($H = 18.14$, $p > 0.05$; *Fig. 2*). Despite potentially large punishment costs (Jachmann, 2008b, c), the enforcement efforts might be sufficient, possibly due to fitting staff to salary, to create a low expected cost of the punishment relative to the gains from illegal activities (Albers and Grinspoon, 1997; Wiafe, 2016).

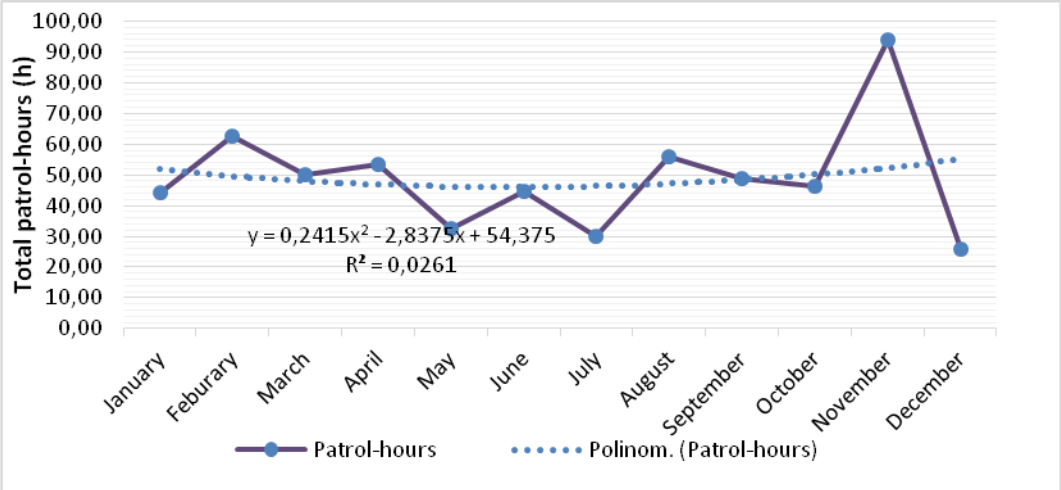

Figure 2. *The total of average patrol-day*

Nonetheless, the distance of patrol rangers differently walked was a quarterly average of 9.25 (SD = 6.18) km in the first quarter; 8.98 (SD = 6.19) in the second one; 8.10 (SD = 6.40) and 8.61 (SD = 5.93) in the last two quarters of 2017 respectively. However, quarterly distances walked during this year did not differ among months ($H = 1.81$, $p > 0.05$). Monthly distances covered that significantly varied months ($H = 20.39$, $p < 0.05$) and the trend of the distance merely increased, after being constant in August (*Fig. 3*).

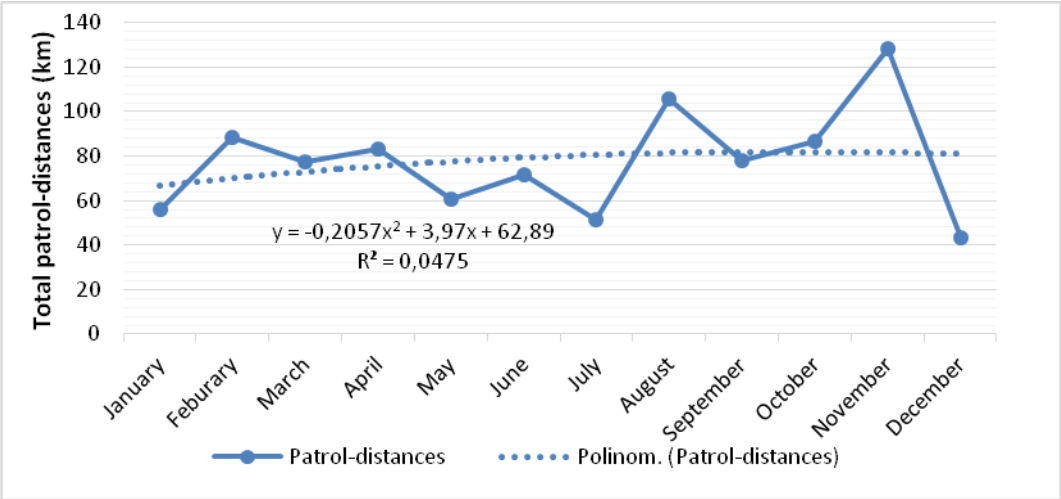

Figure 3. *The total of average patrol distances walked out by rangers*

Generally, during 1-year of patrolling, the number of patrol-days per month was positively correlated with the number of kilometers walked in those months ($rs = 0.88$, $p < 0.01$) similar to Wiafe's (2016) findings in the research on Ghana. The greater number of staff on patrol the larger the area covered and the longer the distance because of increasing patrol-days and so patrol distances ($rs = 0.61$, $p < 0.01$; $rs = 0.65$, $p < 0.01$ respectively) (Jachmann, 1998, 2008a, b; Gandiwa et al., 2014; Risdianto et al., 2016; Wiafe, 2016). The influence of patrol-day on the distance covered could be accounted

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_28452859
© 2018, ALÖKI Kft., Budapest, Hungary

for with the increase in the number of staff patrolling in the field, who were able to patrol for a long period and covered longer distances (Jachmann, 2008a, b; Dhanjal-Adams et al., 2016; Wiafe, 2016).

Crucially, the factors of elevation area, and dissatisfied rangers, correlated with patrol-day and walked distance ($rs = 0.47$, $p < 0.01$; $rs = 0.38$, $p < 0.01$ respectively). Nonetheless, the trend of average elevation area was significantly stable within 12 months (*Fig. 4*). Actually, the patrol routes, based on previous small paths, were identical and rangers did not attempt to open new routes since they had used the same way of coming to NRs. Similarly, the speed of patrolling was negatively correlated with the patrol-day and patrol-elevation ($rs = -0.36$, $p < 0.05$; $rs = -0.25$, $p < 0.01$ respectively). By contrast, it was not correlated with distance ($rs = 0.72$, $p > 0.05$). The monthly speed of patrolling during this year did not vary significantly ($H = 23.62$, $p > 0.05$), even when the trend of patrol-speed was marginally increased (*Fig. 5*).

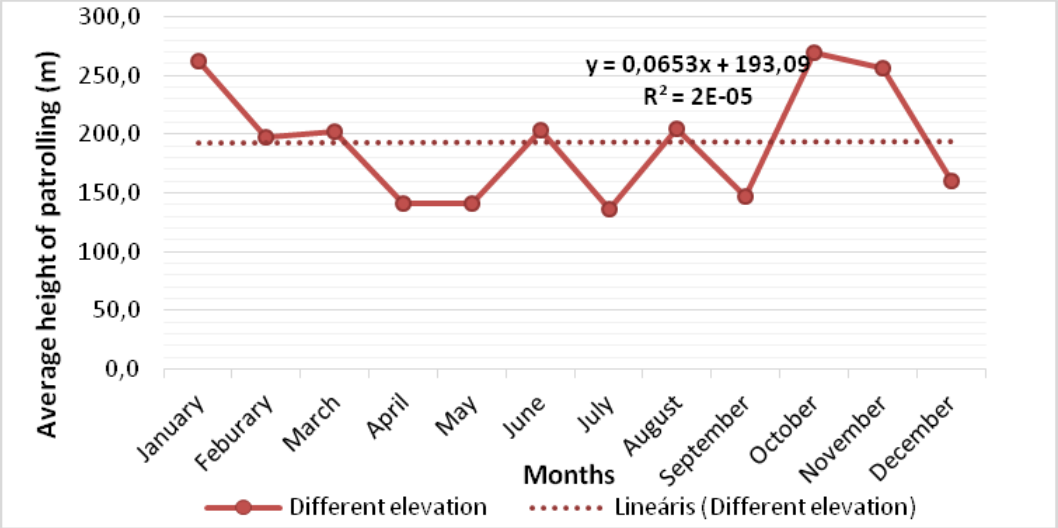

Figure 4. *The average patrol-elevation by ranger's performance*

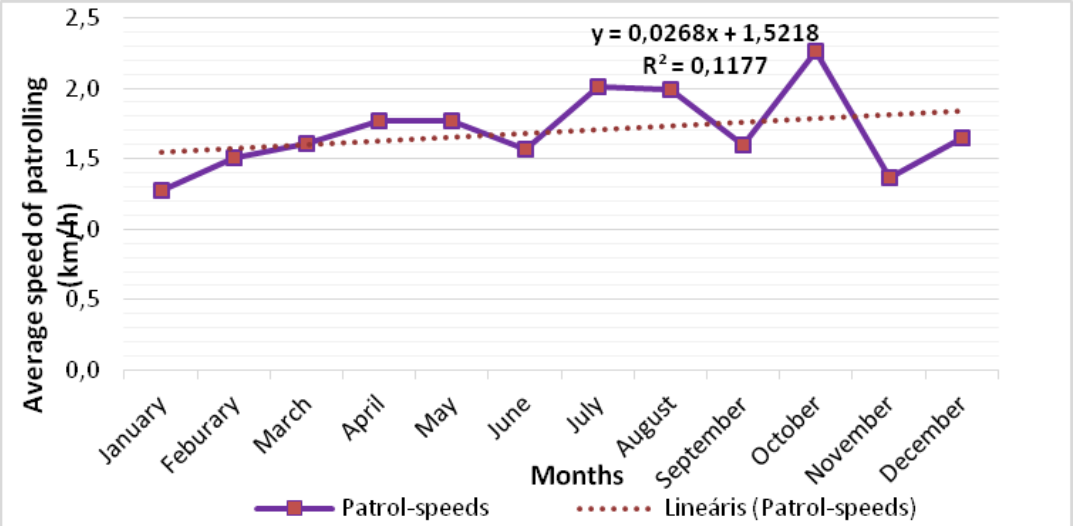

Figure 5. *The average patrol-speeds by ranger's performance*

Illegal activities encountered from patrol efforts

Considering on the number of illegal activities found was fluctuated during the period of time (the specific quarters), the average number of illegal activities was recorded for the four quarters in 2017 as follows: 6.83 (SD = 3.69), 3.00 (SD = 1.29), 2.41 (SD = 1.45), and 4.3 (SD = 1.58) respectively. The average quarterly number of illegal activity encounters from patrol efforts declined from the first quarter to the fourth quarter in 2017, from 6.83 (SD = 3.69) to 4.3 (SD = 1.58) respectively. When rangers pushed their efforts at patrolling on the field related to the increasing hour-patrol and distance (*Figs. 2* and *3*), the illegal activity seemed to reduce. Further, there were significant differences in illegal activities found during the months ($H = 57.27$, $p < 0.001$). The increasing number of illegal activity encounters in terms of patrol-days and distance significantly increased after sharply declining in August (*Figs. 6* and *7*).

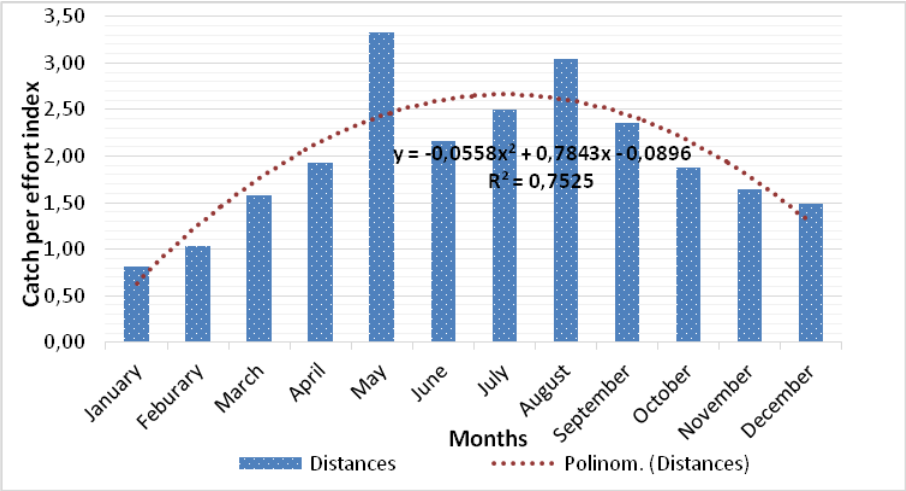

Figure 6. *The distance of indicators of illegal activities found*

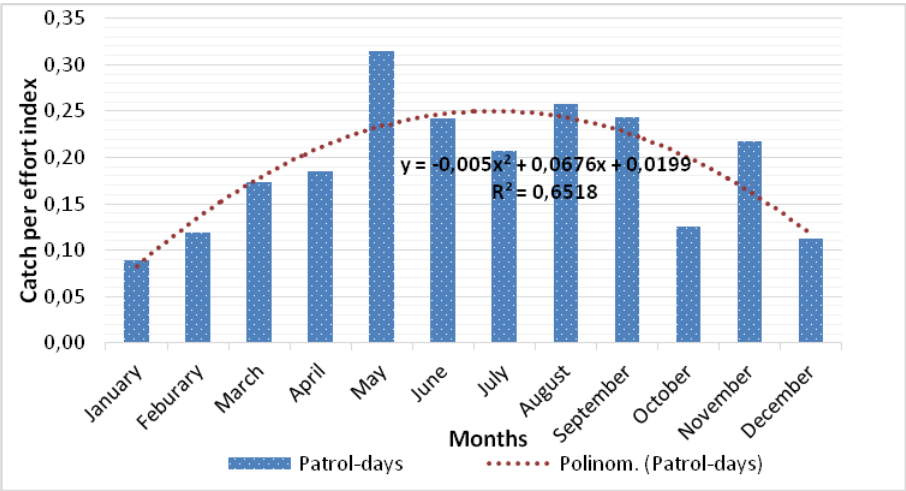

Figure 7. *The patrol-days (hours) for indicators of illegal activities found*

However, the number of illegal activities encountered was significantly correlated with patrol-day and walked distance ($rs = 0.55$, $p < 0.01$ and $rs = 0.46$, $p < 0.01$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_28452859
© 2018, ALÖKI Kft., Budapest, Hungary

respectively) similar to the finding by Gandiwa et al. (2013) and Wiafe (2016). In contrast to Jachmann (2008), Risdianto et al. (2016), and Wiafe (2016), this study found that there was not a significant relationship between illegal activities found and the number of patrol rangers ($rs = 0.14$, $p > 0.05$). When illegal activity significantly declined at the current place, increasing the number of patrol staff was not a great conservation choice.

Patrol rangers in each sub-forest area plot were at liberty to alter their patrol planning and style, depending on whether or not they had attained the information on patrolling practises and in doing so they also relied on the experience (Wiafe, 2016), education and motivation of rangers (Jachmann, 2008a, b). In addition to this, patrol efforts in Nam Tien FS were also strengthened by the involvement of the Pu Hu NR which had more resources available for law enforcement practices (Gandiwa et al., 2013). Interestingly, the fluctuation of encounter rates in terms of patrol-days and distance was merely different during months (*Fig. 8*). Thus, there was no doubt that Pu Hu managers could consider pushing their staff to prevent illegal activity efficiently with their indicators of patrol-day or distance in the field.

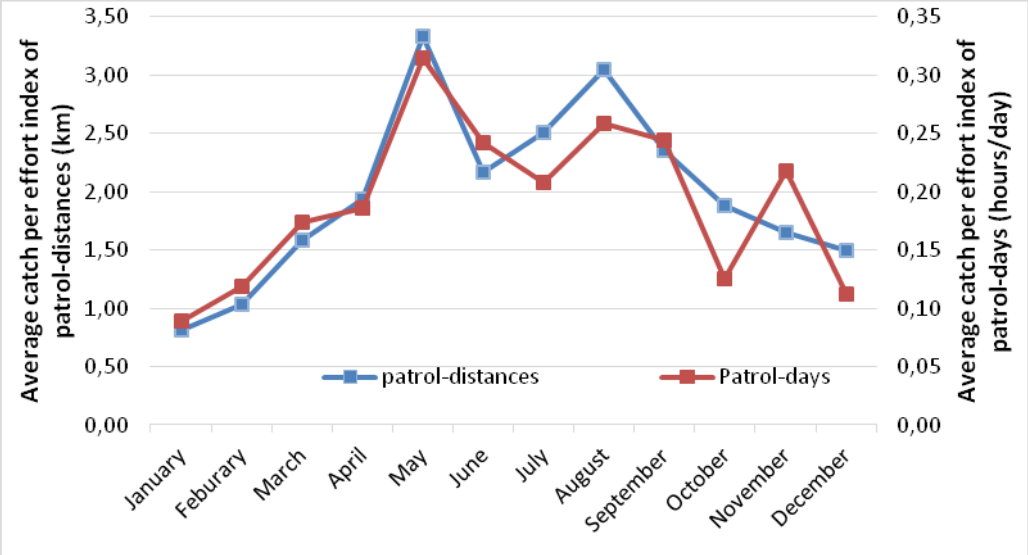

Figure 8. *Trend of illegal activities encounters in terms of patrol-day and distance*

Fluctuation in patrol ranger efforts

Almost all rangers in forest stations have regularly declined to patrol during the Lunar New Year (holiday) and rainy season (limited patrol efforts) because of difficult situation on the fields. It has therefore been speculated that these periods of time disrupt patrol efforts indicators such as days, rangers, distance, and time (Wiafe, 2016). Lunar New Year is in February-March, it confronted with inadequate staff (Moreto, 2016), because a half of staff in Nam Tien FS haves vocation with several days off. Local people attempted to enjoy the NRs by buying something for welcoming the New Year. Interestingly, the number of patrollers still correlated with patrol-distance in 2016 ($rs = 0.62$, $p < 0.05$). The monthly average number of patrol-days and illegal activity encounters were significantly different between the period of February-March and other months ($U = 411$; $p < 0.05$) and ($U = 95$; $p < 0.001$), and opposite to total of patrol-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_28452859
© 2018, ALÖKI Kft., Budapest, Hungary

distances, there was no difference in two period of time ($U = 537$; $p > 0.05$). Rangers strived for covering forest areas in terms of distances; however, the insufficient number of rangers affected the number of patrol-days. Especially, rangers had issues living at forest station locations, as they were homesick because a few rangers lived in such areas (Moreto, 2016). There was no doubt that shifting patrollers might be necessary for patrolling during these months. Furthermore, as mentioned above, the potential for illegal activity significantly increased because of greater demand from society. The mean number of patrol-days and patrol-distance was higher for the day-off months 0.89 (SD = 0.43) and 9.63 (SD = 5.61) compared to other periods: 0.65 (SD = 0.51), and 8.55 (SD = 6.19) respectively.

Commonly, there are two months August and September in each year, when the number of illegal activities was significant between the precipitation season and other seasons ($U = 450$; $P < 0.05$). Locally, influences on illegal activity occurrence could be considered in terms of different seasons. By contrast, the number of patrol-days and distances in the rainy season was not different in other seasons ($U = 868$; $P > 0.05$) and ($U = 862.05$; $P > 0.05$) respectively. Interestingly, the number of illegal activities in the rainy season was also found to be significant when correlated with number of patrol-days ($rs = 0.70$, $p < 0.01$) and distance ($rs = 0.53$, $p < 0.05$), but it was not correlated with staff number ($rs = 0.22$, $p > 0.05$). This is different from Wiafe (2016), who reported that precipitation disturbed patrol efforts when the number of patrol staff was significantly correlated with patrol-days ($rs = 0.65$, $p > 0.01$) and distances ($rs = 0.69$, $p < 0.01$) that was also found to be not significantly correlated with illegal activity encounters. Almost all patrollers as rangers still prevented to the illegal hunting activities even under uncomfortable weather conditions when the criminals might have taken the opportunity to carry out their activities (Wiafe, 2016).

Conclusion

This study may be applied for evaluation of the protection efforts made by management in PAs. Locally, the leader of each forest station should pay attention to whether or not each ranger could carry out the job of protecting its natural resources effectively. From the results, it could be seen that there was a trend of illegal activity encounters that proportionately fluctuated with patrol-distances and patrol-days or patrol-times. There is an urgent need for management boards of nature reserves to increase law enforcement, based on the recording of information (Damnyag et al., 2013) and on current staff levels. In addition to this, this study focused on all the illegal activities that could similarly impacted conservation aspects. There is a need for a specific research on different activities. Moreover, the PEFs were analyzed only in a short-term period of patrolling - around one year - and extension needs to be considered in the future.

The advantage of this paper was that it presented a strategy for activity that provides planning that can be enhanced for sustainable forest protection at the local level. Improvement of law enforcement performance by inspection activity is extremely important for increasing biodiversity conservation. In some areas, the main driver of the chronic factors is the large in-migration of people to the local communities, particularly into the short and medium paths of the conservation protection areas. The energetic patrolling efforts also plays a warning role and helps prevent illicit activity in several situations in the forestry fields.

As Wiafe (2016) reported there were various external factors (such as local policy, illegal activity occurrence, number of rangers, and financial support) that needed the increasing contribution of illegal activity and effort to bring it down. Additionally, factors like work experience, leadership style, qualification, and logistics provided could influence the walking field. However, this research did not consider it. Further research should explore the essential relationship between ranger's social aspects and patrol efforts. A step change involving increased funding support and education is urgently needed for fulfilling the improvement of motivated rangers (Watson et al., 2014). Overall, this study highlights the fact that management boards should evaluate locations of forest stations based on the final results of threat reduction and management effort (Gong et al., 2017).

(Received 19th Dec 2017; accepted 1st May 2018)

Abstract. This research was conducted to determine the potentialities of organic rice cultivation in Karacadag region and to set an example for farmers in transition to organic farming. The Local Karacadag paddy the variety grown in the Karacadag region and the Osmancık-97 breeding variety, the most cultivated variety in Turkey, were used as material. The research was carried out in three replications according to the split parcel trial design in random blocks in the 2011-2012-14 rice growing periods on the farmer field in Karahan village of Karacadag region, in Turkey. As a result of the agricultural researches made, organic values showed superior rates compared to conventional applications in terms of the number of days of flowering (92.3 days) and non-fractured rice yield (65.6%). It was observed that regarding the kernel yield in unit area the Karacadag variety was highest at 4 816 kg ha^{-1} in the conventional application while the organic application of the Karacadag variety was in second place with 4 179 kg ha^{-1}. It is concluded that the organic rice farming is thought to be economical when the organic rice in the market is sold with about 30% more the price compared to the conventional rice.
Keywords: *Karacadag region, organic rice, rice cultivation, yield and yield components*

Introduction

Rice is an important cereal type that is used as a food source for the human nutrition in the world's cereal production with 672 021 180 tons and it ranks second after the corn production. Rice obtained after processing is an important staple food in the far eastern countries especially where it is consumed intensively, it is rich in amino acids even has small amounts of protein in its composition. According to the data in 2010, the countries where rice cultivation is intensively carried out were: 197 million t with China, 120.6 million t with India, 66.4 million t with Indonesia, 49.4 million t with Bangladesh, 40 million t with Vietnam, 70% of total rice production in the world is carried out in these countries (Anonymous, 2013).

According to the agricultural statistics, there are approximately 37.2 million ha of organic farming area in 160 countries in the world in 2009. These areas constitute only 0.9% of the total agricultural land in the world (Willer and Klicher, 2011).

Although the rice cultivation area in our country shows fluctuations from year to year, the rice cultivation area was 115 856 ha, production was 920 000 t and the yield was 7 940 kg ha^{-1} in 2015. Rapid population growth and the difficulty of sowing in certain areas limit paddy production by making imports inevitable. There are about 40 provinces in Turkey which conduct rice cultivation. Some of them are 386 907 t with Edirne, 122 600 t with Samsun, 113 994 t with Balıkesir, 91 880 t with Çanakkale and

© 2018, ALÖKI Kft., Budapest, Hungary

52 298 t with Çorum. The rice production in the country cannot meet the needs (Anonymous, 2015).

In the Southeast Anatolia Region, rice cultivation is 2 356 ha, production is 11 250 t and the yield is 4 770 kg ha^{-1}. All of the rice production in the region takes place in Diyarbakır and Sanlıurfa provinces. The total area of rice cultivation in Diyarbakır is 1 747 ha with 8 514 t of production and in Sanlıurfa the cultivated area is 608 ha with 2 736 t of production (Anonymous, 2015).

According to the organic agricultural statistics, there are approximately 558 837 ha, where production was 922 682 t in Turkey in 2013. Organic paddy production are 49 t with Samsun, 42.5 t with Diyarbakır and 4.38 t with Artvin (Anonymous, 2013).

In Karacadag region, the main sources of livelihood in the villages where rice is grown, are rice production and small ruminant livestock. The local rice is produced based on traditional techniques inherited through hundreds of years. As the fields are stony, no machine tillage is possible and all practices are done by hand. The water for irrigation is used from an artifical lake with gravity, so no energy is used. This variety is only produced and consumed in this area.

Karacadag is in Southeastern Anatolia Region. Its soil is very rich in minerals. But all the surface is full of rocks and stones. The local community has been producing 'Karacadag rice' since hundreds of years with the local knowledge heritage from their fathers. They sow rice once in two or seven years in the stony and sloping field, without tillage.

Organic agriculture, a form of agricultural production that protects human and environmental health, including the use of natural substances and methods instead of synthetic chemical pesticides, hormones and mineral fertilizers, has been gradually increasing in recent years in the world and in Turkey as a result of conventional agricultural practices (Inci and Sonmez, 2006).

The Southeast Anatolia Region has a considerable potential for organic agriculture production when taking into consideration the surplus of agricultural population, climate and soil structure of the area (Gursoy et al., 2009). With the Southeast Anatolia Project (GAP), an irrigation water deficiency which is the biggest bottleneck in the rice farming will be eliminated largely. The soil of the region has not been contaminated with excessive fertilizers and chemicals. As the soil is fertile, productivity can be achieved at low costs in agricultural production. The Karacadag rice variety is the reason for the success of the critical years with bad environmental conditions as well as its quality characteristics that meet the local consumers demands.

Clearing the stony areas which covers large areas and opening these areas to the organic farming will raise the life standards of the local farmers in the Karacadag region. Thus, the non-contaminated areas outside the farming land will be cultivated and high value added products will be manufactured. In addition, appropriate breeding techniques in terms of water, soil and environmental protection will bring display to the local farmers. However, the ecology of the Southeast Anatolia Region is extremely suitable for rice farming.

The Karacadag rice is a high quality local variety that adapts to the ecological conditions of the region. The fact that the region has adapted to the special soil structure and irrigation water distinguishes paddy product from the other varieties. The most important feature of the Karacadag rice variety is that it is the kind that the people in the region look for the most with its colour, flavour and taste. The ability of its kernels to draw water during cooking is high. It does not have lapping and sticky properties. Its

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_28612872
© 2018, ALÖKI Kft., Budapest, Hungary

shape and size are also important distinguishing features. The Karacadag rice variety has medium kernel size. The high amount of protein and starch in the rice makes pilaf (traditional food) delicious. It can be said that it has adapted to the local ecology and it is resistant to some stressful conditions, especially diseases and pests. Because of these properties, it has value as breeding material. This variety is highly resistant to the cold snow waters of Karacadag; it has a stable yield potential. This variety is cultivated for centuries and it has been genetically clarified (Alp, 2011).

Primitive forms and local varieties are important genetic repositories of cultural herbs in resolving future problems or transferring new traits to the culture plants. Because local varieties have been selected for many years in a certain region, they are well adapted to the environment and succeed in extreme climatic conditions of some years. It should be kept in mind that genetically clarified local varieties that have completed their ecological adaptation are genitors that can be used more easily than the wild plant in modern breed development studies.

Recently, with the introduction of the advanced technology-based farming and entrance of highly productive varieties into the production areas, many of the local varieties have disappeared and many of them are still disappearing. Continuity in crop production will only be possible with the protection of the wild and local varieties.

The Karacadag is one of the important planting areas of the endemic and rare crops as well as wild relatives of many Gramineae and leguminous plants. The Karacadag is an extinct volcano in the Southeast Anatolia Region and it is located on the southwest side of the Diyarbakır province. The volcano mass of the Karacadag has a very small slope towards the peak of the surrounding areas and extends in three directions: Diyarbakır, Viransehir and Hilvan. The part of the Karacadag in the direction of the Diyarbakır which is spread over an area of approximately 7.200 km^2 is suitable for plant production (Alp, 2011).

General position, when considering its unpolluted nature and climate, is that Karacadag region has a great potential in organic production. The promotion of organic farming, rice flour, baby food, healthy food will present significant contribution in terms of accessibility and sustainability.

With the help of this work, in the first stage it is aimed to reveal the differences between the conventional and organic farming and to show the potentialities of utilizing local rice varieties in organic production conditions.

Materials and methods

This research was conducted to determine the potentialities of organic rice cultivation in Karacadag region and to set an example for farmers in transition to organic farming. The Local Karacadag paddy the variety grown in the Karacadag region and the Osmancık-97 breeding variety, the most cultivated variety in Turkey, were used as material. The research was carried out in three replications according to the split parcel trial design in random blocks in the 2011-2012-14 rice growing periods on the farmer field in Karahan village of Karacadag region, in Turkey.

Karacadag Local rice variety is a late bloomer and its vegetation duration is over about 130-140 days, it is also resistant to cold and drought. It has poor durability to inclination, it is tall and stringy. The Osmancık-97 rice variety has an Italian origin. Its structure is stemmed, and it is resistant to inclination. The structure of the variety is without strings and it does not spill its kernels.

The soil samples taken from soil at 0-20 cm depth were analysed and the results were: total salt concentration was 0.011%, soil pH was 7.68, the ratio of phosphorus from the useful nutrients from the plants was 1.75, the organic matter was 1.42%.

The location is approximately 900-1000 m above the sea level. In the province of Diyarbakır where the field experiments were conducted the annual rainfall is almost completely happens between September and June in the summer months, rainfall is almost never seen and the proportional humidity rate is quite low. The annual average rainfall of the zone is 488.1 mm, the relative humidity is 53% and the average temperature is around 14.8 °C (*Table 1*).

In the experiment made, pre-germinated seeds were planted as 400 units per square meter for conventional parcels and 440 units for organic parcels with the spreading sowing method on 23.05.2011, 30.04.2012 and 12.05.2014. The size of the parcel was set on 15 m^2 (3 x 5 m) and 10.0 m^2 (2.5 x 4.0 m) at harvest. Soil cultivation was not applied before the sowing in the stony terrain. Less seeds were used in the local experiment was due to the fact that about 20-30% of the land is stony. That 10% more seeds were used in the organic plot is for fighting weeds.

In the conventional rice parcels, 120 kg/ha pure nitrogen and 60 kg/ha pure phosphorus were dropped. 1/3 of the nitrogen and all of the phosphorus were used at the same time with planting. The second 1/3 of the nitrogen was provided during the tillering and the last 1/3 was given as sprinkles before the earing period.

In the organic rice parcels, the solid fertilizer was planted at 1 400 kg/ha and half the B5A liquid organic fertilizer (4 000 g/ha) was sown at the planting site. The other half of the liquid organic fertilizer was given one month before harvesting through the leaves.

Chemical herbicide was applied against wild weeds in conventional rice parcels while weeds in organic parcels were picked by hand. Chemical pesticide was applied against grasshoppers in conventional rice parcels while against grasshoppers in organic parcels was applied by NeemAzal organic certified pesticide (active substance 'Azadirachtin A').

Irrigation water was provided from the pond in the countryside. Irrigation was done in the form of surface irrigation. Irrigation was interrupted 10 days before full ripening to ensure the dryness of the harvest fields. The harvesting took place on 10.10.2011, 24.09.2012 and 02.10.2014 when the rice plants turned yellow and bunches dangled from trunks.

Observations and the measurements of the following features were made in 10 plants: number of days of flowering (day), number of maturation days (day), plant height (cm), number of tillering in plants (number), kernel number of a bunch (gram), kernel weight of a bunch (gram), thousand kernel weight (gram), length of the bunch (cm), non-fractured rice yield (%), and the measurements were made on 10 m^2: biological yield (kg/ha), unit area kernel weight (kg/ha).

The data obtained from the study were analysed in the JUMP statistical package program. The LSD test was applied and the coefficient of variation (CV) was calculated with the differences between the averages (Yurtsever, 1984; Duzgunes et al., 1987).

Results

In this research, when the average values of varieties were examined in terms of number of days of flowering; 96.7 days in conventional conditions, 97.6 days in organic condition for Karacadag variety; 86.7 days in conventional conditions and 87.1 days in organic conditions for Osmancık-97 variety. The average values of the varieties with regard to the growing conditions were 92.3 days in organic farming and 91.7 days in conventional farming. The average values of the varieties were found to be 97.1 days for Karacadag variety and 86.9 days for Osmancık-97 variety (*Table 2*).

in organic conditions; Osmancık-97 variety was 127.2 days in conventional conditions and 126.6 days in organic conditions. The average values of the varieties with regard to the growing conditions were 133.8 days in organic farming and 134.4 days in conventional farming. The average values of the varieties were found to be 141.2 days for Karacadag variety and 126.9 days for Osmancık-97 variety (*Table 2*).

When the average values of the varieties were examined with regard to the plant height; Karacadag variety was 95.4 cm in conventional conditions and 92.1 cm in organic conditions; Osmancık-97 was 77.1 cm in conventional conditions and 75.1 cm in organic conditions. It is concluded that the average values of the varieties were 83.6 cm in organic application and 86.2 cm in conventional application. The average values of the varieties were found to be 93.7 cm for Karacadag variety and 76.1 cm for Osmancık-97 variety (*Table 3*). Karacadag Local variety showed longer plant height values in both conventional and organic conditions than Osmancık-97 variety.

When the average values of the varieties were examined with regard to the number of tillering in plants, the Local Karacadag variety was 2.61 in conventional conditions and 2.59 in organic conditions; the Osmancık-97 was 1.66 number both in conventional and organic conditions. In terms of growing conditions, the average values of the varieties were 2.12 in organic application and 2.13 in conventional application. The average values of the varieties were found to be 2.60 for Karacadag variety and 1.66 for Osmancık-97 variety (*Table 3*). It has been observed that the Local Karacadag rice variety is more abundant in terms of tillering in both farming conditions than the Osmancık-97 variety.

Table 3. *Average values of plant height (cm), number of tillering (number) and the formed groups according to the LSD (least significant difference) test*

Applications	Plant height		Average	Number of tillering		Average

In this research, when the number of bunches in per m^2 was examined, the Local Karacadag variety was 393.9 in conventional conditions and 376.0 in the organic conditions; Osmancık-97 variety was 313.7 in conventional conditions and 307.6 in organic conditions. In terms of growing conditions, the average number of bunches in per m^2 was found to be 341.8 in organic application and 353.8 in conventional application. The average values of the varieties were found to be 384.9 for Karacadag variety and 310.6 for Osmancık-97 variety (*Table 4*). It is observed that the Local Karacadag rice variety yields a larger number of bunches than the Osmancık-97 variety in both conventional and organic conditions.

When the average values of varieties were examined with regard to the kernel number of bunch, the Karacadag variety was 60.1 in conventional conditions and 53.4 in organic conditions; the Osmancık-97 was 63.9 in conventional conditions and 60.1 in organic conditions. In terms of growing conditions, the average number of kernel in bunch was found to be 56.8 in organic conditions and 62.0 in conventional conditions. The average values of the varieties were found to be 56.8 for Karacadag variety and 62.0 for Osmancık-97 variety (*Table 4*).

In this research, when the average values of the varieties were examined related to the kernel weight of bunch; the Local Karacadag variety was 1.79 g in conventional conditions, 1.57 g in organic conditions; Osmancık-97 variety was 2.08 g in conventional conditions and 1.97 g in organic conditions. In terms of growing conditions, the average kernel weight of bunch was 1.77 g in organic conditions and 1.93 g in conventional conditions. The average values of the varieties were found to be 1.68 g for Karacadag variety and 2.02 g for Osmancık-97 variety (*Table 5*).

In this research, when the average values of the varieties were examined related to the thousand kernel weight it was found that the Local Karacadag variety was 29.65 g in conventional conditions and 29.43 g in organic conditions; the Osmancık-97 variety was 32.68 g in conventional conditions and 32.45 g in organic conditions. In terms of growing conditions, the average thousand kernel weight of varieties was determined as 30.94 g in organic application and 31.16 g in conventional application. The average values of the varieties were found to be 29.54 g for Karacadag variety and 32.56 g for Osmancık-97 variety (*Table 5*).

When the average values of the varieties were examined with regard to bunch length, it was determined that the Local Karacadag variety was 16.3 cm in conventional conditions and 16.1 cm in organic conditions; the Osmancık-97 was 12.7 cm in conventional conditions and 12.4 cm in organic conditions. In terms of growing conditions, the average values of bunch lengths of the varieties were 14.2 cm in organic applications and 14.5 cm in conventional application. The average values of the varieties were found found to be 16.2 cm for Karacadag variety and 12.5 cm for Osmancık-97 variety (*Table 6*).

When the average values of varieties were examined with regard to the biological yield, it was determined that the Local Karacadag variety was 13 514 kg ha^{-1} in conventional conditions and 11 663 kg ha^{-1} in organic conditions; the Osmancık-97 variety was 10 332 kg ha^{-1} in conventional conditions and 9 057 kg ha^{-1} in organic conditions. In terms of growing conditions, the average values of the biological yields of the varieties were 10 360 kg ha^{-1} in organic application and 11 923 kg ha^{-1} in conventional application. The average values of the varieties were found to be 12 589 kg ha^{-1} for Karacadag variety and 9 694 kg ha^{-1} for Osmancık-97 variety (*Table 6*).

Table 6. *The average values of bunch length (cm), biological yield (kg/ha) and the formed groups according to the LSD (least significant difference) test*

When the average values of the varieties were examined with regard to the kernel yield in unit area, it was determined that the Local Karacadag variety was 4 816 kg ha^{-1} in conventional conditions and 4 179 kg ha^{-1} in organic conditions; the Osmancık-97 variety was 3 784 kg ha^{-1} in conventional conditions and 3 234 kg ha^{-1} in organic conditions. In terms of growing conditions, the average kernel yield in unit area was 3 706 kg ha^{-1} in organic application and 4 300 kg ha^{-1} in conventional application. The average values of the varieties were found to be 4 498 kg ha^{-1} for Karacadag variety and 3 509 kg ha^{-1} for Osmancık-97 variety (*Table 7*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

In this research when the average values of varieties were examined with regard to the non-fractured rice yield it was found that the Local Karacadag variety was 64.9% in conventional conditions and 67.5% in organic conditions; the Osmancık-97 variety was 62.9% in conventional conditions and 63.7% in organic conditions. The average non-fractured rice yield of the varieties in terms of growing conditions was found 65.6% in organic application and 63.9% in conventional application. The average values of the varieties were found to be 66.2% for Karacadag variety and 63.3% for Osmancık-97 variety (*Table 7*). It has been observed that the Local Karacadag variety has a significant superiority over the Osmancık-97 variety both in conventional and organic conditions.

Table 7. *The average values kernel yield in unit area (kg/ha), non-fractured rice yield and the formed groups according to the LSD (least significant difference) test*

Discussion

Kıran (1992) found that the number of days of flowering in Diyarbakır was between 64-118 days. Savsatlı and Gulumser (2006) stated that in the ecological conditions of Samsun, the number of days of flowering rice changes between 79-89 days with the broadcast seeding method according to the variety used. Savsatlı et al. (2008) determined the number of days of flowering in rice between 82-110 days.

Savsatlı and Gulumser (2006) stated that the number of ripening days in rice is between 120-136 days with the help of broadcast seeding method among the varieties used. Kıran (1992) found that the number of ripening days in Diyarbakır conditions ranged between 96-143 days. Genctan et al. (1994) reported that the number of ripening days varies between 119-143 days in a research conducted on a total of 10 different rice varieties.

The plant height affecting rice farming indirectly depends on the level of fertility of the soil, the method of sowing, the amount of applied fertilizer, environmental conditions and the genetic structure of the variety. Alp et al. (2010) stated that plant height of rice farming in the conditions of Diyarbakır changes between 81.82-99.50 cm. Taşer (2011) stated that the average plant height varied between 67.5-110.3 cm in the Southeast Anatolia Region and Karacadag Local rice variety is longer than any other variety.

The number of tillering in plants depends on the genetic characteristics of the varieties and it is greatly influenced by the environmental conditions (Kun, 1988). Lin (1974) stated that the number of tillering per plant decreased when the rice was planted frequently in the field, and the companions that formed after the maximum period of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_28612872
© 2018, ALÖKI Kft., Budapest, Hungary

tillering decreased because of their inability to complete their development. Gevrek (2000) pointed out that the average number of tillering between applications in the rice plants varied between 1.3-2.9.

In a research Choi et al. (2002) conducted in South Korea, they stated that the number of bunches per m^2 was found to be 364 in conventional application and in organic application it was 420-444. Kıran and Oktar (1994) stated that the number of bunches in m^2 varies between 372-639 in Diyarbakır conditions and the number of bunches in m^2 of Karacadag variety is higher than other varieties and lines.

In a research conducted in South Korea, Choi et al. (2002) found that the kernel number of bunches was 79.6-88.0. Kıran and Oktar (1994) found that the kernel number of bunches varies 52-147 with Diyarbakır conditions. Alp et al. (2010) stated that the kernel number of bunches in rice farming varies 42.08-99.50 with Diyarbakır conditions. Sahin et al. (2012) determined the kernel number of bunches to be 43.6 to 113.1. Taser (2011) stated that the kernel number of bunches changes between 89.33-164.0 and the values of local rice samples were higher than those of many breeding varieties with regard to the kernel number of bunches.

Alp et al. (2010) stated that the kernel weight of bunch varies between 1.22-2.69 g in Diyarbakır conditions. Taser (2011) stated that the kernel weight of bunch varies between 1.463-1.942 g under the conditions of the Southeast Anatolian Region.

Taser (2011) determined that the bunch length changes between 12.40-23.20 cm, the bunch length of Osmancık-97 variety was 14.17 cm and the average of Karacadag population lines was around 21.06 cm. Sahin et al. (2012) determined that the bunch length varies between 11.7-18.5 cm.

It has been observed that the Local Karacadag variety has a significant superiority compared to the Osmancık-97 variety with regard to the biological yield in both conventional and organic conditions. It can be said by looking at the results of the research that biological yield decreases significantly under organic conditions.

It has been observed that the Local Karacadag variety has a distinctive superiority with regard to the kernel yield in unit area compared to the Osmancık-97 variety in both conventional and organic conditions. It can be said that the Osmancık-97 variety showed a lower kernel yield in unit area than the Local Karacadag variety due to the fact that the ripening period corresponds to high temperatures and it does not adjust to the Diyarbakır's ecological environment. In a research conducted in South Korea, Choi et al. (2002) found the kernel yield of the hairy vetch as 5 680-5 870 kg ha^{-1} in organic conditions and 5 760 kg ha^{-1} in conventional conditions. They also stated that in farmyard manure application, the kernel yield was 5 340-6 660 kg ha^{-1} and 6 210 kg ha^{-1} in conventional application. They pointed out that farmyard manure can be used in the production of hairy vetch. In an organic research conducted in South Korea, Lee et al. (2003) stated that the application of 100 kg nitrogen and 30 kg phosphorus per hectare yielded the highest number of yield with 5 690 kg ha^{-1}, 20 t of hairy vetch application for hectare yielded 5 290 kg ha^{-1}, 12 t compost application for hectare yielded 4 380 kg ha^{-1}. In a research conducted in Malaysia, Abu Bakar et al. (2003) reported that they achieved a yield of 1 760-4 100 kg ha^{-1} with organic applications, the average yield value was obtained as 3 200 kg ha^{-1}, and the rice yield in the region was around 5 000 kg ha^{-1}. Beser and Genctan (1999) stated that the yields of rice vary according to the ecological conditions, variety and technology used.

Savsatlı and Gulumser (2006) stated that the factors affecting the rice yield are kernel length, kernel shape and thousand kernel weight; for instance K-424 rice variety is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_28612872
© 2018, ALÖKI Kft., Budapest, Hungary

shorter and fuller than the other varieties which leads the variety to have high rates of fractured and non-fractured rice yield. Therefore, they expressed that the genetic properties of the varieties affect rice yield to a great extent. Taser (2011) stated that the yield values of rice samples varied between 51.67-68.67% in the conditions of the Southeast Anatolian Region, and the highest non-fractured rice yield was found in the samples of the Local Karacadag rice variety.

Conclusions

As a result of agricultural research, organic and conventional applications; organic application showed higher values compared to the conventional application with regard to the number of days of flowering (92.3 days), and non-fractured rice yield (65.6%). However, it was observed that following values fell behind in organic conditions compared to the conventional conditions: the number of ripening days, plant height, number of tillering, bunch number in m^2, kernel number of bunch, thousand kernel weight, kernel weight of bunch, bunch length, biological yield and kernel yield in unit area.

Local Karacadag rice paddy variety which is cultivated under the organic conditions performed superior values compared to the Osmancık-97 breeding variety in terms of number of days of flowering (97.6 days), number of ripening days (140.9), plant height (92.1 cm), number of tillering in plants (2.59), number of bunches in m^2 (376.0 piece), bunch length (16.1 cm), biological yield (11 663 kg ha^{-1}), yield for unit area (4 179 kg ha^{-1}) and non-fractured rice yield (67.5%).

The Local Karacadag rice variety cultivated in conventional and organic conditions showed superior values compared to the Osmancık-97 variety in terms of number of days of flowering, number of ripening days, plant height, number of tillering in plants, bunch number in m^2, bunch length, biological yield, kernel yield in unit area, and non-fractured rice yield. However, it was observed that the Local Karacadag variety fell behind the Osmancık-97 variety with regard to the kernel weight of bunch, kernel number in bunch and thousand kernel weight.

When all the features examined in the research were taken into consideration, in addition to many features of the Karacadag variety, it was observed that the kernel yield in unit area was highest at 4 816 kg ha^{-1} in the conventional application while the organic application of the Karacadag variety was in second place with 4 179 kg ha^{-1}. It is concluded that the organic rice farming is thought to be economical when the organic rice in the market can be sold with about 30% higher price compared to the conventional rice. It is concluded that the use of Karacadag variety in organic agriculture may extend the organic agriculture in the region.

Abstract. Present study was conducted to check the ameliorative effect of foliar applications on iron (Fe) deficiency in peanut. The hydroponics experiments were performed at National Agriculture Research Centre, Islamabad, Pakistan. Various foliar treatments were used to check $FeSO_4$ alone and its combined effect with citric acid and surfactants. $FeSO_4$ alone and in combination with citric acid showed ameliorative effect on Fe deficiency in peanut. Active Fe concentration of BARI-2000 and BARD-699 increased up to 52% and 25% as compared to control, when foliar treatment of $FeSO_4$ was applied. Combined effect of $FeSO_4$ and citric acid resulted 55% and 56% increase of active Fe concentrations compared to control. However, foliar application of surfactant (sodium dodecyl sulphate) suppressed the growth of peanut. Various morpho physiological parameters showed that BARD-699 was more responsive to foliar applications, while citric acid alone and in combination can be used in correcting Fe deficiency in both genotypes.
Keywords: *BARI-2000, BARD-699, Calcareous soils, Pothwar region, hydroponics experiments*

Introduction

Iron (Fe) deficiency chlorosis is a common problem in calcareous soils reducing yield significantly (Inal et al., 2007; Boodi et al., 2016). Peanut is susceptible to Fe deficiency while grown on calcareous soils with high pH and high bicarbonate levels.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_28732884

The problem is common in Pothwar tract of Pakistan (Rashid et al., 1997). Various strategies are in practice to combat Fe deficiency. These strategies include either improving the mechanism of Fe uptake or enhancing the Fe in soil solution. Among various fertilizers in practice, EDDHA and analogues (the most stable chelates) proved to be effective in maintaining Fe in soil and transporting it to the roots of plants (Lucena, 2003).

Breeding (Cianzio, 1995) and genetic modifications (Robinson et al., 1999) are commonly used strategies for uptake of Fe from soil. Due to high cost of these strategies, other solutions should also be focused. Other methods to provide Fe to the plant are foliar applications and trunk injection. Foliar applications has been advocated by various researchers (Tagliavini and Rombola, 2001; Reed et al., 1988). Foliar applications produced good results and can be practically used (Song et al., 2017a,b). Being an expensive strategy, trunk injection is used for garden trees only (Fernández-Escobar et al., 1993).

Foliar applications are useful in mitigation of Fe deficiency. Foliar applications of $FeSO_4$ increased leaf Fe concentration, however, basal treatments are more effective for long results (Mann et al., 2017). Foliar applications of salicylic acid and sodium nitroprusside in combination can increase chlorophyll, active Fe and increased Fe accumulation in cell organelles by decreasing interveinal Chlorosis (Kong et al., 2014). In *Prunus persica* L. foliar applications of Fe(III)-EDTA, Fe(III)-citrate, $FeSO_4.7H_2O$ and Fe(III)-DTPA, Fe(III)-IDHA always resulted in leaf chlorophyll increase. Re-greening varies with application of different compounds (Fernández et al., 2006).

Fe-sulphate, Fe-citrate and Fe-EDTA were very effective in re-greening of effected leaves of peach (*Prunus persica* L.). After one week of spraying, Fe sources induced physiological and biochemical responses in Fe deficient low-chill peach plants in the following order Fe-sulphate>Fe-citrate>Fe-EDTA. Different peach cultivars showed different responses towards different Fe sources (Chakraborty et al., 2012). Foliar applications are cheap source to recover Fe deficiency symptoms (Song et al., 2017a). Present study was aimed to explore the effect of different foliar application alone and in combination in correcting Fe deficiency in BARI-2000 and BARD-699.

Materials and Methods

Purpose of Experiment

The purpose of this experiment was to check the effect of $FeSO_4$ alone and with different treatments on the morpho-physiological parameters of peanut. As $FeSO_4$ is cheaper than other chemicals so it can be used alone or in combination with other chemicals for correction of Fe deficiency induced chlorosis.

Selection of Genotypes

The experiments were performed at National Agriculture Research Centre, Islamabad, Pakistan. Two genotypes were selected as Fe deficiency tolerant (BARI-2000) and Fe deficiency sensitive (BARD-699) genotypes based on previous hydroponics and pot experiments (Akhtar et al., 2014; Akhtar et al., 2013).

Seed Germination

After surface sterilization with H_2O_2, seeds of two genotypes were washed with distilled water and germinated on wet sterile sand at 25°C in the darkness.

Hydroponics Setup

After germination uniform seedlings were transferred to aerated Hoagland's nutrient solution (Epstein, 1972). The seedlings were aerated for 24 h. The setup was kept in controlled conditions of 14/10 light /dark period with 30/20°C ± 2°C temperature and 800 cd of light. The pH of nutrient solution was maintained at 6.2. The experiment was performed in four replications.

Foliar Treatments

Following treatments were made to two weeks old seedlings;(a) Fe limited (without any treatment) (b) 0.1% citric acid (c) 0.5%$FeSO_4$ (d) 0.5%$FeSO_4$+0.1%citric acid (e) 0.5% $FeSO_4$+0.1%citric acid+1%surfactants and (f) 1%surfactant. SDS (sodium dodecyl sulphate) was used as surfactant.

SPAD Values

Young fully expanded leaves from three plants were used to record chlorophyll content by SPAD-502 (Minolta, Japan). The average of three leaves of one plant was considered as one replication and data was recorded for four replications. During the experiment, after every week data was recorded for SPAD values and average values were calculated.

Active Fe Content

Active Fe content was measured from young fully expanded leaves (Gao and Shi, 2007). Each plant was considered a single replication.

Photosynthetic and Transpiration Rates

At first detection of chlorotic symptoms, Photosynthetic rate (A) and transpiration rate (E) were recorded using Infra-Red Gas Analyzer (LCA4 Bioscientific Ltd.).

Morphological Parameters

Seedlings were harvested before the anthesis stage (Three weeks after emergence) and number of leaves was counted. Root lengths, plant height and root and shoot fresh weights were recorded. The samples were dried at 60°C for three days to record dry weights of root and shoots.

Total Fe Content

Total Fe content was measured by dry ash method by considering single plant a replication and data was recorded for four replications (Rashid et al., 2001).

Data Analysis

Pearson's correlation coefficients were recorded by Minitab 13 at 5% confidence interval. Mean ± S.E was calculated by MS Excel. Percentage increase was calculated by formula:

$$\frac{(100 - \text{Values in control(-Fe)} \times 100)}{(\text{Values in treatment})} \quad \text{(Eq.1)}$$

Replications were compared by using SPSS. Pairwise comparison was done by applying t-test using SPSS.

Results

Photosynthetic Rate

Fe deficiency is a widespread problem in calcareous soils. Significantly higher photosynthetic rate was recorded for BARD-699 with foliar application of $FeSO_4$, 53% increase was recorded as compared to Fe deficient treatment. With same treatment, BARI-2000 showed 44% increase in photosynthetic rate as compared to its Fe limited condition. Surfactant significantly lowered the photosynthetic rate of BARI-2000 (56%) as well as BARD-699 (20%). With foliar application of citric acid, $FeSO_4$+citric acid and combination of $FeSO_4$, citric acid and surfactant resulted increased photosynthetic rate of both genotypes. In case of BARI-2000, 3, 27 and 23% increase in photosynthetic rate was recorded as compared to Fe deficient treatment. With same treatments BARD-699 showed 35, 39 and 30% increase in photosynthetic rate as compared to Fe deficient treatment (*Figure 1*).

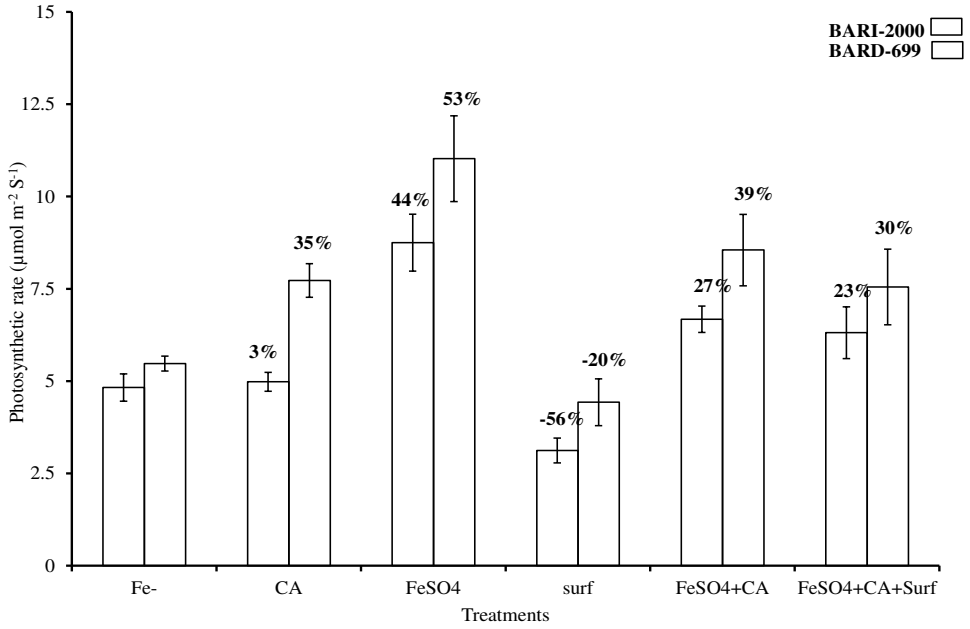

Figure 1. *Photosynthetic rates of Peanut genotypes in response to different foliar applications of equal concentration of Fe (CA: Citric acid; Surf: Surfactant)*

© 2018, ALÖKI Kft., Budapest, Hungary

Transpiration Rate

Foliar application of $FeSO_4$ along with citric acid significantly increased the transpiration rate of BARI-2000 (28%) and BARD-699 (35%) as compared to the respective Fe limited conditions. Transpiration rate with foliar application of citric acid, $FeSO_4$ and citric acid+$FeSO_4$+surfactant resulted increase of transpiration rate for both genotypes as compared to their respective Fe limited treatments. BARI-2000 resulted 20, 21 and 1% increase in transpiration rate, whereas BARD-699 showed 11,13 and 9% increase as compared to their respective Fe limited treatments. Surfactants resulted decreased transpiration rate of both genotypes *(Figure 2*).

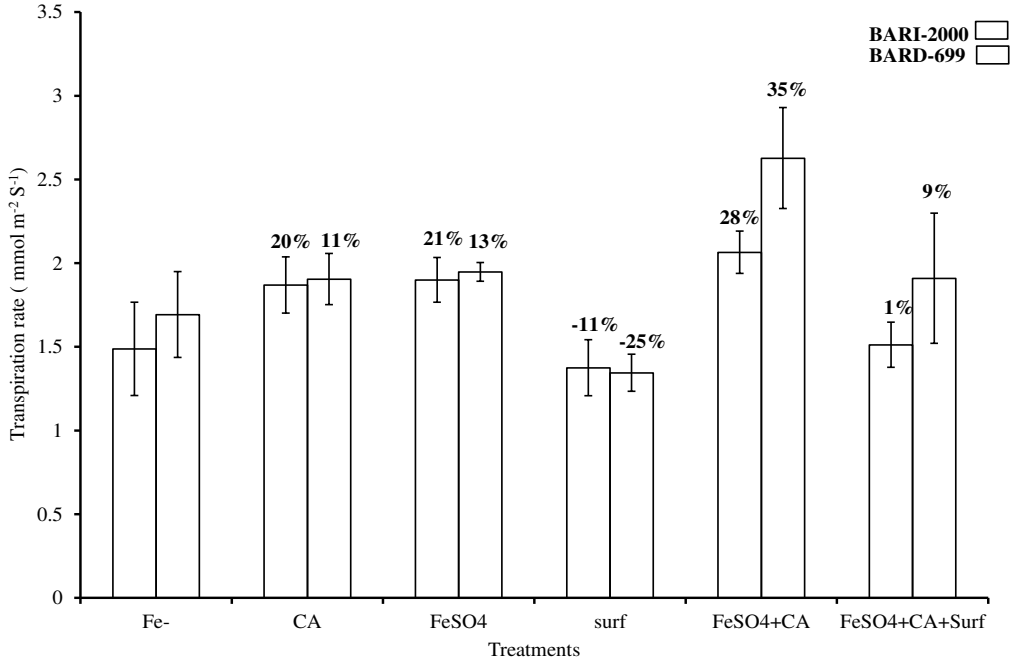

Figure 2. *Transpiration rate of Peanut genotypes in response to different foliar applications of equal concentration of Fe (CA: Citric acid; Surf: Surfactant)*

SPAD Values

More chlorotic symptoms will result in lower SPAD values. SPAD values decreased significantly with foliar application of surfactant. The decrease was 61% in BARI-2000 and 15% in case of BARD-699 as compared to their respective Fe limited conditions. This showed that surfactant disturbed plant functions resulting in decreased SPAD values. Other treatments including citric acid, $FeSO_4$, combination of citric acid and $FeSO_4$ and citric acid+$FeSO_4$+surfactant resulted increase in SPAD values of both genotypes. With these treatments BARI-2000 showed 24, 24, 25 and 12% increase in SPAD values as compared to Fe limited treatments. BARD-699 showed 28, 24, 28 and 17% increase in SPAD values in respective treatments as compared to Fe limited treatments (*Figure 3*).

Active Fe concentration was significantly higher with foliar application of $FeSO_4$ alone and in combination with citric acid.

Active Fe Content

In case of $FeSO_4$ increase in active Fe for BARI-2000 was 53% and BARD-699 gave value 58%. Similarly with combination of citric acid and $FeSO_4$, BARI-2000 showed 56% while BARD-699 showed 55% increase as compared to their respective Fe limited treatments. Citric acid showed 25% increase of active Fe of BARI-2000 and 52% increase in case of BARD-699 as compared to Fe limited treatment. $FeSO_4$ in combination with citric acid and surfactant showed 25% increase in BARI-2000 while 34% increase in BARD-699 as compared to Fe limited treatments. Surfactant resulted decrease in active Fe concentration of both genotypes as compared to Fe limited treatments (*Figure 4*).

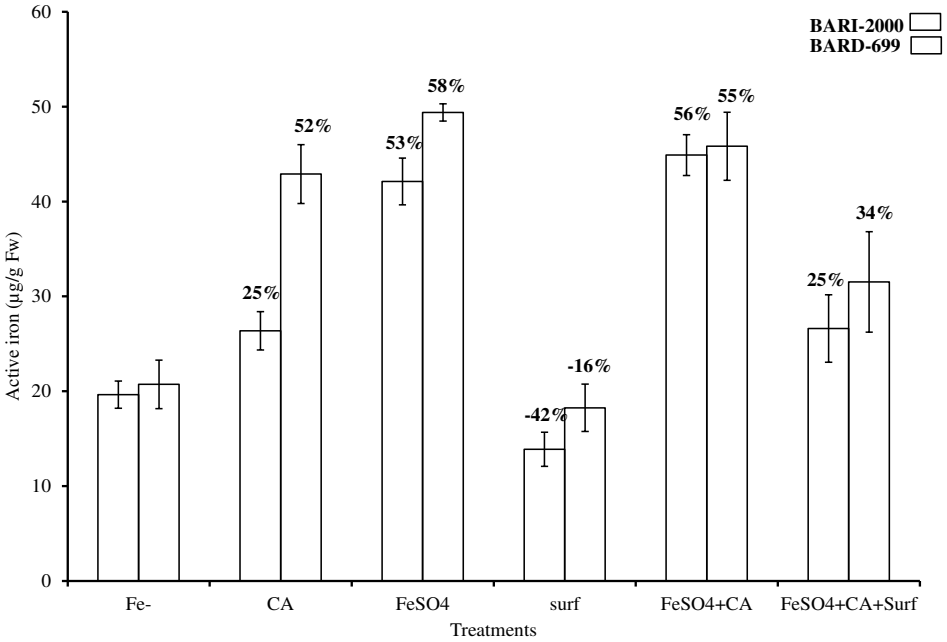

Figure 4. *Active Fe content of Peanut genotypes in response to different foliar applications of equal concentration of Fe (CA: Citric acid; Surf: Surfactant)*

Total Fe Content

Total Fe content increased significantly in BARD-699 with foliar application of $FeSO_4$ (66%) and citric acid +$FeSO_4$ (68%) as compared to Fe limited treatments. With same treatments, BARI-2000 showed 43% and 35% increase in total Fe respectively as compared to Fe deficient conditions. Citric acid resulted 6% increase in BARI-2000 while 45% increase in total Fe of BARD-699 as compared to their respective Fe deficient treatments. $FeSO_4$ in combination with citric acid and surfactant increased the total Fe concentration of BARI-2000 up to 11% while that of BARD-699 up to 44% as compared to Fe limited conditions. Foliar application of surfactant decreased the concentration of total Fe of both genotypes when compared to total Fe in Fe limited conditions (*Figure 5*). Total Fe concentration was positively correlated with active Fe concentrations (R^2=0.853) (*Table 1*).

Rep	324.295	3	108.098	0.137	0.938

Pairwise Comparison of Genotypes

Pairwise comparison showed that both the genotypes were highly significant in few parameters when different foliar applications were made. The genotypes were non-significant in –Fe conditions except for shoot dry weight and transpiration rate. No. of leaves and root lengths were significantly different, when foliar applications of $FeSO_4$ were made. Shoot fresh weights and SPAD values were significantly different with foliar applications $FeSO_4$ were made in combination with citric acid. Foliar applications of Citric acid and $FeSO_4$ showed significant differences for Active Fe and total Fe content in both genotypes. SPAD values and total Fe content were significantly different with foliar applications of $FeSO_4$ and Citric acid when applied in combination. Genotypes were significantly different with respect to total Fe when $FeSO_4$+Citric acid +Surfactants were applied in combination (*Table 3*).

Discussion

Being an important oil seed crop, peanut ranks fifth in vegetable oil seed production throughout the world (Song et al., 2017a). The Fe deficiency is the yield limiting factor in dicot plants with main symptoms of interveinal chlorosis due to inhibition in chlorophyll synthesis (Song et al., 2017b). The problem is more pronounced in the Pothwar tract of Pakistan with calcareous soils resulting in reduced peanut yield. The study was planned to check the effect of foliar applications on the Fe deficiency induced chlorosis in peanut. When nutrients are applied in the form of foliar application, leaf cuticle is the first obstacle to absorb nutrients (Kannan, 1990). In our results foliar applications increased the SPAD values, Photosynthetic rate, transpiration rate, active and total Fe content of peanut. Similarly foliar applications of Salicyclic acid and Sodium Nitroprusside alleviated the Fe deficiency of peanut by increasing the photosynthetic rate and carbohydrate increase (Kong et al., 2014). Similar results were also reported by Song et al. (2017b), where lower SPAD values were recorded in Fe deficient plants as compared to the plants treated with foliar applications.

Active Fe content is an important parameter that shows the concentration of physiologically active Fe in plant tissue (Rashid et al., 1997). Our results showed an increase in active and total Fe content when foliar applications were applied. Similar results were reported by Kong et al. (2014). In peanut plants, foliar applications of SNP and NA enhanced the active Fe content. As compared to total Fe, physiologically active Fe is considered a better nutritional Fe indicator (Hakan and Vahap, 2007). Active Fe content was increased after foliar application of SNP and SA (Song et al., 2017b). In another study, exogenous application of Nitric oxide improved Fe availability in plants (Graziano et al., 2002), that could improve Fe storage by ferritin protein (Briat et al., 2010). Active Fe content was significantly different by foliar applications as described

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_28732884
© 2018, ALÖKI Kft., Budapest, Hungary

by Pairwise comparison of BARD-699 and BARI-2000. This suggests the different responses of genotypes towards foliar applications. BARD-699 showed earlier response towards foliar applications, that may be related to its sensitive nature. In order to cope with Fe deficiency, the genotypes increased the uptake of Fe.

SPAD values were positively correlated with active Fe and total Fe content. Photosynthetic and transpiration rates were also positively correlated. This shows that by applying Fe exogenously, Fe deficiency induced chlorosis can be recovered and hence yield can be improved. SPAD values were significantly different in both genotypes when citric acid was applied in the form of foliar application. Foliar application of Fe is a common mean to correct Fe deficiency in agricultural crops (Salahi et al., 2017; Álvarez-Fernández et al., 2005). These applications included the foliar sprays of sequestrene (FeEDDHA, $FeSO_4$, FeEDTA) and other treatments (Lucena, 2003; Rashid et al., 1997). The treatments are used either alone or in combination with acids to lower down the pH of leaf tissues (Kumawat et al., 2006). With all foliar treatments, total Fe was significantly different among two genotypes. Citric acid is a good source to recover Fe deficiency induced chlorosis by reducing the pH as indicated by our study. FeEDDHA is the most common in Fe deficiency areas for correction of Fe chlorosis in fruit trees (Lucena, 2003). After foliar Fe treatment to chlorotic plants, various effects have been reported due to many factors involved in the process of leaf penetration, plant translocation and cell Fe uptake (Curie and Briat, 2003). When subjected to Fe deficiency, plants responded in different ways (Rombolà et al., 2002), such as chlorophyll synthesis inhibition and disturbed enzyme activities, which requires Fe as cofactor (Bisht et al., 2002). Surfactants are frequently added to the different foliar sprays, as they can increase the penetration of these substances to the leaf cuticle (Stock and Holloway, 2006). However, few surfactants are considered less toxic or less effective, as Agarol-600 resulted negative effect on wheat shoot growth when combined with $ZnSO_4$ (Haslett et al., 2001), while other surfactants are not effective at all (Kannan, 1984). Our results suggested that Sodium Dodicyl Sulphate cannot be used as surfactant as SDS alone resulted decreased growth of both genotypes. It may be concluded that citric acid and $FeSO_4$ alone and in combination can increase the growth of both genotypes particularly of BARD-699.

Conclusion

It may be concluded that citric acid and $FeSO_4$ alone or in combination can increase the growth of both genotypes particularly of BARD-699. Citric acid and $FeSO_4$ together was most effective among all treatments tested. Both the treatments can be successfully used to ameliorate Fe deficiency induced chlorosis. SDS can not be recommended as a surfactant.

Acknowledgements. We are thankful to Dr. Iftikhar Ahmed from National Agriculture Research Centre, Islamabad, Pakistan and Dr. Rahmatullah Qureshi from PMAS Arid Agriculture University, Rawalpindi, Pakistan, who provided insight and expertise that greatly assisted the research. No words to say thanks to Mr. Muhammad Jabbar from Satistics department, University of Gujrat, Pakistan for his cooperation in data analysis. We are also very thankful to Higher Education Commission, Pakistan for providing financial assistance.

Abstract. In order to make full use of well logging information to accurately predict the fracture distribution of carbonate reservoir, we use several log curves to comprehensively identify and delineate the structural fractures, dissolved fractures and sutured fractures of different occurrences, scales and geneses in the North Truwa oilfield of the Pre-Caspian Basin in Kazakhstan. The resistivity difference-ratio method may be used to identify high-angle fractures. The 3-porosity ratio method, which tends to be affected by dissolved pores and vugs, is applicable to low-angle fractures and microfractures. By using each single method separately, only 54.8% of fractures on the average may be identified. The comprehensive probability density method which integrates the above two methods improves the accuracy of fracture identification to 73.6% as per the validation of core and imaging logging data. Fracture distribution in the study area is dominated by sedimentation, structure and diagenesis. In the lateral direction, the structural highs and areas with intense karstification may demonstrate high fracture probability density and thus areinterpreted to be rich in structural and dissolved fractures. In the vertical direction, more fractures may occur in the brittle intervals with small shale and gypsum contents. The results of fracture prediction are consistent with the sedimentary diagenesis of carbonate reservoirs, indicating that the method is feasible to predict the fracture.
Keywords: *fracture classification, fracture signatures, fracture prediction, conventional logging, comprehensive probability density, distribution*

Introduction

It is challenging to characterize the fractures in carbonate formations. Carbonate fractures may be delineated in the perspective of genesis and geometry by using seismic, logging and stress data (Lai et al., 2017; Ameen et al., 2012; Kazatchenko et al., 2007). In a field with a number of wells drilled, fracture characterization tends to be accomplished by using logging methods, such as the method of Wavelet Transform (Dong et al., 2013) which obtain the high-frequency weak signal of fracture in logs by means of wavelet decomposition and reconstruction, Matrix index method (Sun et al., 1999) which identify the fracture by calculating the acoustic skeleton index and the density skeleton index and constructing the rendezvous skeleton index, 3-porosity ratio (Gong et al., 2007; Luo et al., 2001) which characterize fracture development by density, neutron and acoustic plot, fractal dimension method (Tang et al., 2012) which determine the fractal dimension that reflects the complexity of fracture reservoir by multiple mesh encryption, and resistivity difference-ratio (Yan et al., 2009; Cai et al., 2003) which characterize fracture development by the difference ratio of deep and shallow resistivities. But the accuracy of the methods is related to fracture geometry,

occurrence and scale, especially when only a single method is used to identify multi-geometry multi-occurrence fractures of complex origins. A solution is comprehensive identification by using a combination of various log curves. We make a case study on the North Truwa oilfield at the east margin of the Pre-Caspian Basin in Kazakhstan. The objective is to improve fracture characterization by analyzing fracture signatures and the capability of existing methods and finding improved methods with conventional log curves.

Materials

Geological setting

The North Truwa oilfield tectonically lies in the eastern slope of the Zharkamys-Enbek palaeohigh at the east margin of the Pre-Caspian Basin in Kazakhstan. It is a faulted anticlinal structure whichextends in the NE direction and is bounded by a NE-strike boundary fault on the east (*Fig. 1*). A package of thick carbonate rocks were deposited in the Paleozoic Carboniferous Period (He et al., 2014; Zhao et al., 2013; Zhao et al., 2010; Bian et al., 2011; Zheng et al., 2005). KT-I in the Middle and Upper Carboniferous Series is the major hydrocarbon bearing formation and is vertically subdivided into three oil layers, i.e. A, Б and B. During KT-I deposition, the open platform in southeastern deep water changed into restricted platform and evaporate platform in shallow water toward the northwest.

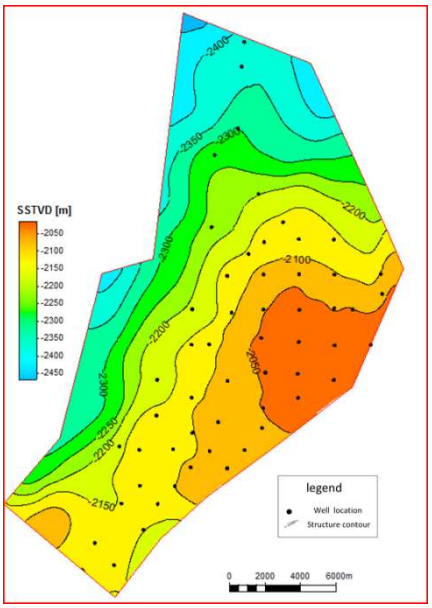

Figure 1. *Location and structure map of the study area. (SSTVD: subsea true vertical depth)*

Due to the elevation of the whole area before Permian deposition, the layer A at the top experienced differential denudation and early deposited carbonate rocks were exposed to the leaching process of atmospheric water (Wang et al., 2012). Lithologies vary with sedimentary environment and change from grainstone in the open platform to dolomitic limestone and limy dolostone to dolostone, gypseous dolostone and gypsum rocks in the evaporate platform (*Fig. 2*). Vertically B3-B5 in the lower section deposited

© 2018, ALÖKI Kft., Budapest, Hungary

in deep water at the early stage of KT-I deposition has a high shale content of 19.9% on the average, dolomite content of 10.7% and average calcite content of 69.4%. Б1-B2 is composed of relatively clean limestone and dolomitic limestone with small shale content of 7.0% on the average and increased dolomite content of 10.6% and calcite content of 82.3%. A2-A3 in the upper section has an increased average shale content of 15.7% as well as increased average dolomite content of 24.0%, average anhydrite content of 5%, and average calcite content of 55.4% in the evaporate platform.

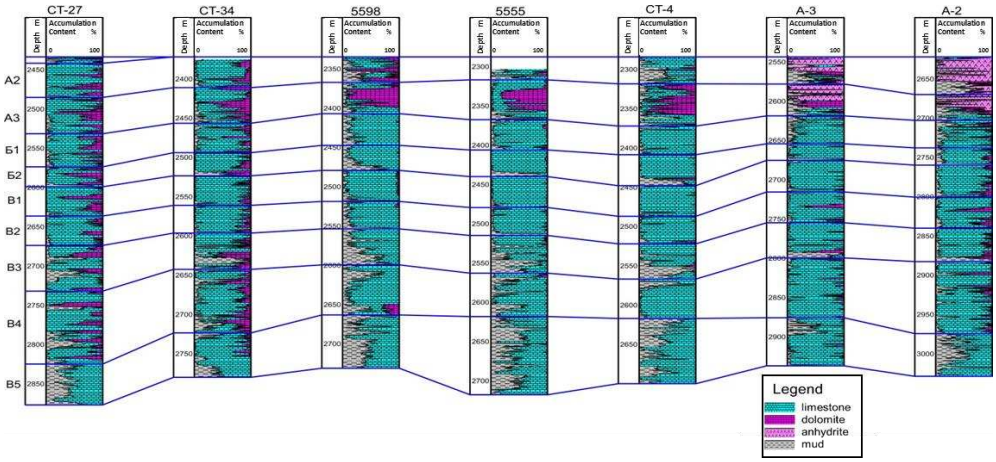

Figure 2. *Lithologic section of the study area*

Fractures

As per fracture geneses, three types of fractures, i.e. structural fracture, dissolved fracture and sutured fracture, could be observed on cores and image logs. Large fractures could be visually inspected and microfractures of which the apertures are generally less than 0.1 mm (Anders et al., 2014; Lai et al., 2017) may only be examined by using a microscope. Fracture dip ranges from 10° to 90° and there are also irregular fractures. Most fractures in the oil field are open seams, and only few are filled with calcite.

Structural fractures

Structural fractures are common in the study area due to the effect of tectonic stress. Fracture surface is flat or distributes in en-echelon (*Fig. 3a*). Two groups of fractures with different occurrences may co-exist (*Fig. 3b*). These fractures vary greatly from large fractures which could be identified on seismic sections to small fractures which could be identified on cores and imaging log curves to microfractures which may only be observed by using a microscope (*Fig. 3c*). Fracture dip Angle is widely distributed from 10° to 90° (*Fig. 3d*).

Dissolved fractures

Dissolved fractures surface is irregular and fracture width is in the range of 0.1-5 mm. Both large fractures and microfractures could be inspected (*Fig. 3e, f*). Generally there are no oriented fractures. Some oriented fractures are early structural fractures

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

corroded and enlarged by acidic fluids at the late stage (*Fig. 3g*). Fluids usually flowed through fractures; thus dissolved fractures are often associated with structural fractures.

Sutured fractures

According to the core observation, most sutured fractures are opened and filled with crude oil; this means the existence of sutured fractures is important to oil accumulation and flow. Sutured fractures exhibit various occurrences, including intra-stratal low-angle sutured fractures, vertical sutured fractures and high-angle oblique sutured fractures. A single or a group of sutured fractures may be examined (*Fig. 3h*). Dissolved fractures may also occur together with sutured fractures (*Fig. 3i*) because of fluid flow through sutured fractures.

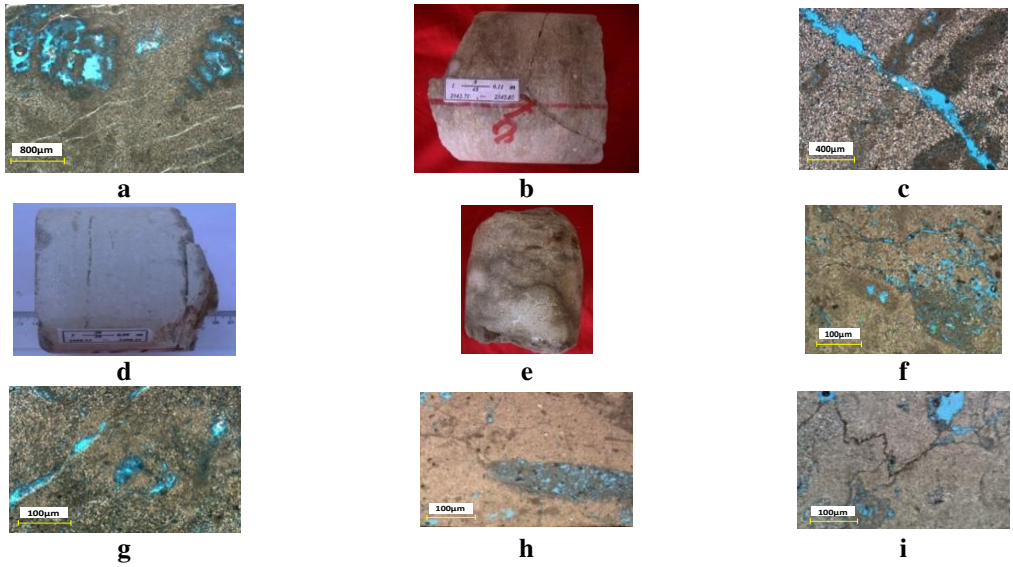

Figure 3. *Fractures in the study area.* ***a.*** *En-echelon structural fractures.* ***b.*** *Structural fractures with two occurrences.* ***c.*** *Microstructural fractures observed under a microscope.* ***d.*** *Low-angle structural fractures.* ***e.*** *Macro dissolved fractures.* ***f.*** *Micro dissolved fractures.* ***g.*** *Early structural fractures corroded and enlarged.* ***h.*** *Net-shaped sutured fractures.* ***i.*** *Corroded sutured fractures*

There are seldom fractures with single genesis, single occurrence or single scale separately occurring in the area. Fractures with various geneses and occurrences usually exist together with varying degrees of development. In this circumstance, it is hard to identify single-genesis or single-scale fractures by using conventional log curves. But it is possible and significant to quantitatively predict fractures in an interval.

Methods

We used some published techniques, i.e. resistivity difference-ratio and 3-porosity ratio, based on conventional logs to identify fractures in the North Truwa oilfield and validated the results with core and imaging log data. Both techniques were demonstrated to be of low credibility. In view of the complexity of fracture geneses and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_28852898
© 2018, ALÖKI Kft., Budapest, Hungary

occurrences, two techniques were combined to identify multi-genesis multi-occurrence fractures in carbonate rocks.

Resistivity difference-ratio

The resistivity close to and far away from the wellbore will be measured by deep and shallow resistivity logging. The resistivity around the wellbore will decrease if the mud in the wellbore flows into the formations through fractures (Babadagli and Al-Salmi, 2004). For high-angle fractures (above 75°), both deep and shallow resistivity curves exhibit remarkable decrease, especially the shallow resistivity due to more impact of mud invasion on near-hole area. Consequently there is a positive difference between deep and shallow resistivity (Sibbit and Faivre, 1985) (*Fig. 4a*). The magnitude is much higher than that caused by the existence of pores. For low-angle fractures (below 30°) or horizontal fractures, the mud may flowperpendicularly to the wellbore into the fractures far away from the wellbore; thus deep resistivity exhibits larger decrease than shallow resistivity because various fluids (oil, gas, water or mud) in the fractures have much lower resistivity than tight rocks. This negative difference reaches a maximum at the interval with horizontal fractures (Sima, 2009) (*Fig. 4b*). Owing to the impact of fluids and filling materials in fractures, positive difference or zero difference may also occur in addition to negative difference at the interval with low-angle fractures.

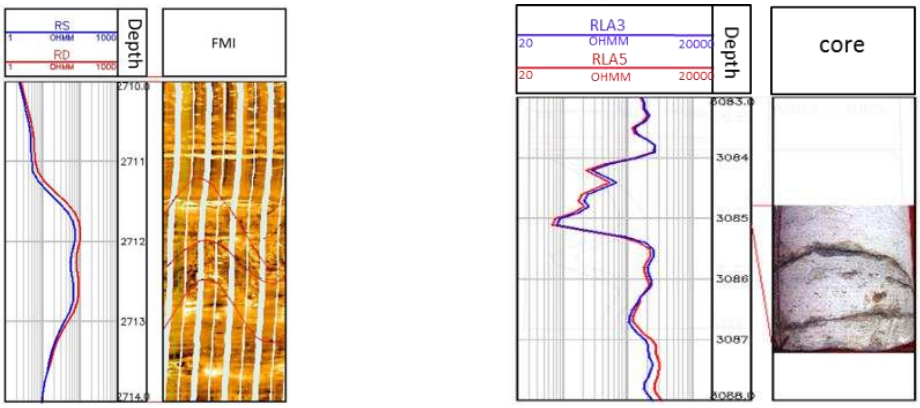

Figure 4. *Fractures and corresponding resistivity responses*

Inaccordance with resistivity responses to fractures, the method of resistivity difference-ratio was widely applied to fracture identification and prediction (Sun et al., 1999; Dond et al., 2013) by using the equation $RTC = (R_t - R_{lls}) / R_{lls}$, where RTC is deep-shallow resistivity difference ratio, R_{lls} is the shallow resistivity, R_t is the true resistivity after invasion correction by $R_t = 2.589\ R_{lld} - 1.589\ R_{lls}$, and R_{lld} is the deep resistivity.

In view of the uncertainty of resistivity difference for low-angle fractures, we substitute the deep resistivity with true resistivity to calculate the difference for fracture and pore discrimination. Generally at the interval with fractured hydrocarbon reservoirs, $R_t > R_{lls}$ and $RTC > 0$; RTC shows positive anomalies higher than the base line. At the fractured interval with water or tight interval, $R_t \approx R_{lls}$ and $RTC \approx 0$.

© 2018, ALÖKI Kft., Budapest, Hungary

Three-porosity ratio

Acoustic log curve also demonstrates some responses to the existence of fractures because of acoustic attenuation by fractures. At the fractured interval, later arrivals instead of the head wave will be recorded; thus the log curve exhibits increased acoustic time or cycle skip. This leads to large acoustic porosity. At the interval with high-angle fractures, there are no distinct responses on the curve because acoustic waves bypass the fractures as per the principle of least distance. At the interval with oblique, horizontal or net-shaped fractures, the log curve exhibits slightly jagged profile due to increased acoustic time or cycle skip caused by severe acoustic attenuation (He et al., 2014; Bian et al., 2011) (*Fig. 5*). Therefore the variations in acoustic porosity somewhat indicate the existence of fractures, especially horizontal, net-shaped and micro fractures (Sima et al., 2009; Wang et al., 2006). Acoustic wave is compressional wave and thus more sensitive to matrix pores uniformly distributing in the rock and less sensitive to secondary dissolved pores irregularly appearing in the rock. In such a circumstance, the increment of acoustic porosity is small (Li et al., 2013).

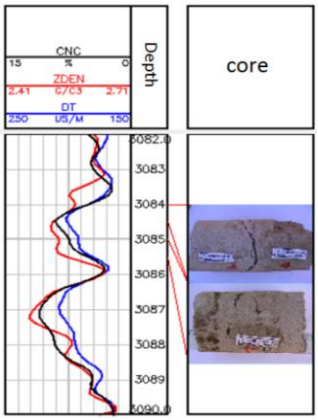

Figure 5. *Responses of porosity logs to fractures*

Neutron porosity and density porosity indicate the total porosity of matrix pores, secondary dissolved pores and fractures. The existence of fractures and secondary dissolved pores may lead to larger increments of neutron porosity and density porosity than that of acoustic porosity. In other words, the gap between total porosity (neutron porosity and density porosity) and acoustic porosity will increase at the interval with secondary dissolved pores and fractures.

The porosity difference-ratio, RP, is used for fracture characterization and defined as the function of neutron porosity Φ_N, density porosity Φ_D, acoustic porosity Φ_S and total porosity Φ_T, as shown by (*Eqs. 1* and *2*).

$$\Phi_T = \sqrt{\frac{\Phi_D^{\,2} + \Phi_N^{\,2}}{2}} \qquad \text{(Eq.1)}$$

$$R_p = \frac{|\Phi_T - \Phi_S|}{\Phi_T} \qquad \text{(Eq.2)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_28852898
© 2018, ALÖKI Kft., Budapest, Hungary

When RP > 0, the development of secondary reservoir space such as fracture is indicated. A large RP indicates more secondary pore space including fractures, dissolved pores and microfractures.

Comprehensive probability density

The area has more low-angle fractures than high-angle fractures, so the resistivity difference-ratio method is inferior to 3-porosity ratio method in fracture identification. For both methods, only 55% of fractures could be identified on the average. It is hard to identify the fractures with multi-genesis, multi-scale and multi-occurrence by using a single method. Thus two methods were combined to determine the comprehensive probability density of fracture. The procedure is described as follows.

Step 1 (*Eqs. 3* and *4*): calculate the normal or nearly normal distribution of resistivity (Yan et al., 2009) because of the original skewed distribution (non-uniform numerical distribution).

$$RTC' = \ln(RTC+1) \quad \text{(Eq.3)}$$

$$RP'=\ln(RP+1) \quad \text{(Eq.4)}$$

Step 2 (*Eqs. 5, 6, 7* and *8*): normalize RTC derived from the resistivity difference-ratio method and RP derived from the 3-porosity ratio method, and then calculate corresponding probability density for fracture characterization.

$$RTC' \geq 0: P_{RTC}=1-\exp(-RTC') \quad \text{(Eq.5)}$$

$$RTC' \leq 0: P_{RTC}=0 \quad \text{(Eq.6)}$$

$$RP' \geq 0: P_{RP}=1-\exp(-RP') \quad \text{(Eq.7)}$$

$$RP' \leq 0: P_{RP}=0 \quad \text{(Eq.8)}$$

Step 3 (*Eqs. 9* and *10*): validate the results and feasibility for reservoir characterization by using core and imaging log data. The thickness of the fractured interval was calculated based on above two methods and core and imaging log data. The percentage of accuracy was then used as the weighting factor for each method.

$$X_{RTC} = H_{RTC} / H \quad \text{(Eq.9)}$$

$$X_{RP} = H_{RP} / H \quad \text{(Eq.10)}$$

Here, H_{RTC}, H_{RP} and H represent the thickness of the fractured interval calculated by above two methods and core or imaging log data, respectively (*Eqs. 11* and *12*).

$$W_{RTC}=X_{RTC}/(X_{RTC}+X_{RP}) \quad \text{(Eq.11)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_28852898
© 2018, ALÖKI Kft., Budapest, Hungary

$$W_{RP}=X_{RP}/(X_{RTC}+X_{RP}) \quad \text{(Eq.12)}$$

Here, W_{RTC} and W_{RP} represent the weighting factor for each method, respectively.

Step 4 (*Eqs. 13*): calculate the comprehensive probability density.

$$P= W_{RTC}\times P_{RTC}+W_{RP}\times P_{RP} \quad \text{(Eq.13)}$$

Results

As per the validation by core and image logs data from 5 wells, RTC results are more sensitive to high-angle fractures and less sensitive to low-angle and horizontal fractures; 82% of high-angle fractures on the average were identified and only 26% of low-angle fractures were identified. Due to the complexity of fracture occurrence, on the whole, 31.9-74.1% of fractures, with an average of 49.5%, were identified in the study area. As shown in *Figure 6a,* Well UT-1 was examined to have high-angle fractures at 2707-2714 m and the average dip angle is 70.6°. The fractured interval was interpreted to be 1.8 m thick on the imaging log curve, which is reconciled with the thickness of 2 m in terms of high positive RTCs. As shown in *Figure 6b,* Well CT-20 was observed to have nearly horizontal fractures at 3164.4-3165.1 m and 3167.5-3168.1 m. The fractured intervals were interpreted to be 0.7 and 0.6 m thick, respectively. But on the RTC profile, the upper interval with apparent positive anomalies was interpreted to be a fractured interval of 0.6 m thick, whereas the lower interval with no distinct anomalies was interpreted to have 0 m fractured interval. This means only 46.2% of fractured intervals were identified.

a **b**

Figure 6. *RTC-based fracture identification*

The Three-porosity ratio result was validated by core and imaging log data to be of limited accuracy. For example, the existence of low-angle fractures at 3101-3104 m in Well CT-20 is in agreement with high RP (*Fig. 7a*) and microfractures at 3213.47-3213.53 m in Well CT-4 is in agreement with the average RP of 5.7 (*Fig. 7*b). The interval at 2600-2601 m in Well CT-10 with no fractures but with secondary dissolved pores also exhibits high RP (*Fig. 7c*), whereas the interval at 2711-2712 m in Well UT-I with abundant high-angle fractures does not illustrate significant RP variations (*Fig. 7d*). This means that the method is applicable to the identification of low-angle fractures and microfractures. The results are not affected by the existence of water layers but tend to be affected by secondary dissolved pores. In addition, high-angle

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_28852898
© 2018, ALÖKI Kft., Budapest, Hungary

fractures cannot be identified accurately. As per the statistics of 5 wells, 48-72.5%, with an average of 61.5%, of fractures could be identified.

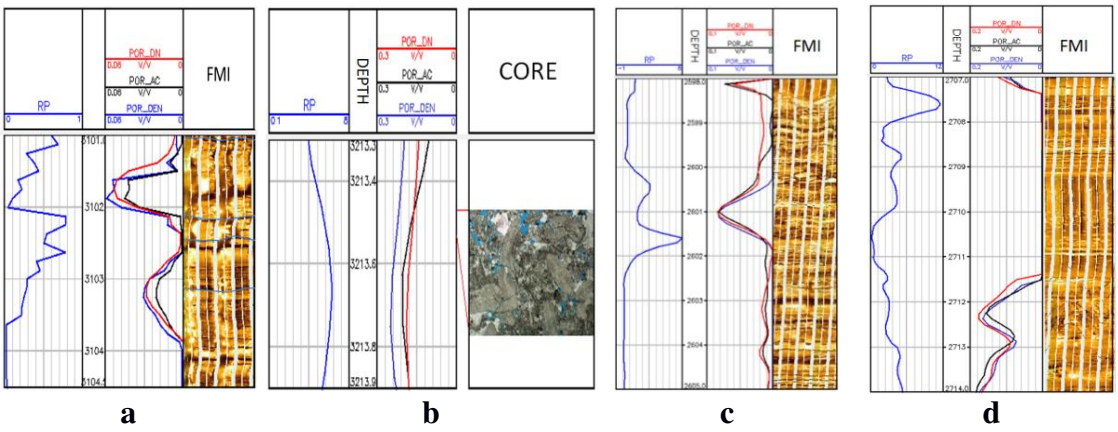

Figure 7. *Fracture identification by 3-porosity ratio method*

According to core and image logs, the P value of fracture development period is generally greater than 20%. Therefore, the position of 20% above the baseline of P value is used as the lower limit of fracture development, and the further the deviation from the baseline, the higher the degree of fracture development. Five cored wells were included in the calculation. The weighting factor for the resistivity difference-ratio method was estimated to be 0.395-0.531 with an average of 0.44; the factor for the 3-porosity ratio method was estimated to be 0.469-0.635 with an average of 0.56 (*Table 1*).

Table 1. *Parameters for the comprehensiveprobability density method*

Type	Well no.	Thickness of cored interval by core observation (m)	Thickness of cored interval by RTC method (m)	Thickness of cored interval by RP method (m)	X_{RTC}	X_{RP}	W_{RTC}	W_{RP}	Thickness of cored interval by P interpretation (m)	Percentage of P accuracy
Parametric calculation well	CT4	63.5	34.5	30.5	0.544	0.48	0.531	0.469	47.685	75.09%
	CT10	32.9	10.5	19.3	0.319	0.555	0.365	0.635	22.376	68.01%
	CT22	70	51.9	50.8	0.741	0.725	0.506	0.494	50.943	72.78%
	CT41	34.2	14.2	20.9	0.415	0.612	0.404	0.596	28.1288	77.40%
	5555	40.5	18.5	28.4	0.457	0.701	0.395	0.605	29.646	73.20%
	Avg.	48.2	25.9	30.0	0.495	0.615	0.4402	0.5598	35.75576	73.30%
Verified well	5598	12.6	5.3	7.2	0.424	0.568			9.475	75.20%

The average weighting factors were then used to calculate the comprehensive probability density, P. For these 5 cored wells, the percentage of accuracy (X_{RTC}) for the resistivity difference-ratio method was 31.9-74.1% with an average of 49.5% and the accuracy (X_{RP}) for the 3-porosity ratio method was 48-72.5% with an average of 61.5%. The accuracy for the comprehensive method was 68.01-77.4% with the increase by 23.8% and 11.8%, respectively, to 73.3% on the average. According to the weight

parameters Calculated using 5 coring Wells, with another 1 new coring well 5598 as testing well, P is calculated. The thickness of fracture development of this well is 12.6 m. The RTC recognition rate is 42.4%, and the RP recognition rate is 7.2%. The fracture development thickness predicted using comprehensive probability density P is 9.5 m, and the recognition rate is 75.2 (*Table 1* and *Fig. 8*). For example, there are 4 fractured intervals at 3084.5-3085.5 m, 3086.2-3087.2 m, 3090-3091 m and 3092-3093.5 m, respectively, in the cored interval from 3084.5-3098 m in Well CT-4. The fracture density is 38, 12, 13 and 28/m, respectively. These observations basically answer to the P-based results.

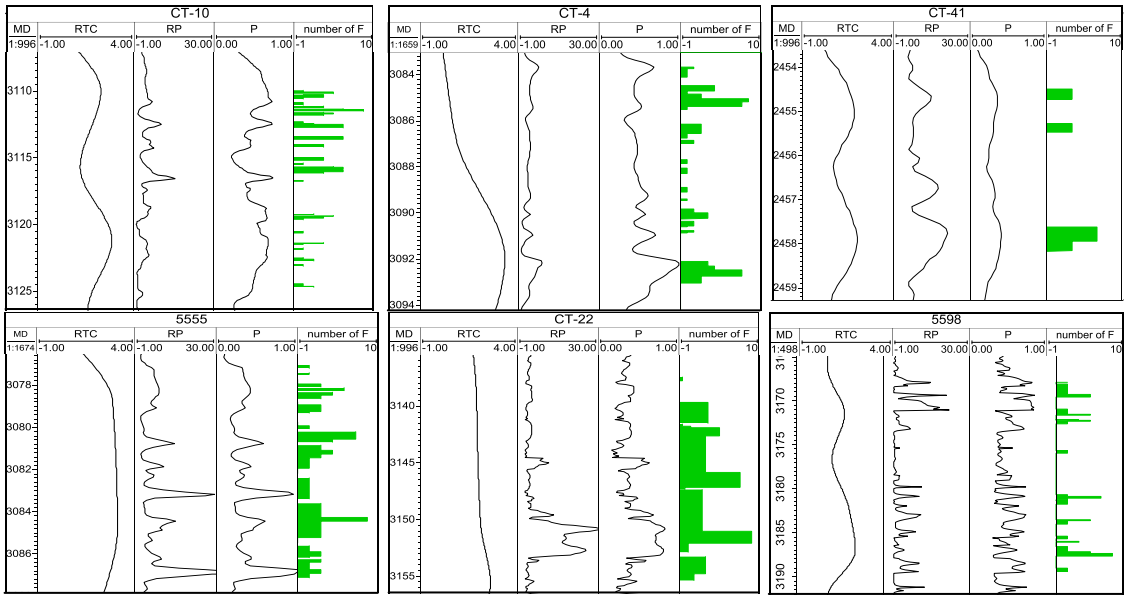

Figure 8. *Fracture predictions and core observations*

Discussion

Lateral and vertical distributions of fractures (*Figs. 9* and *11*) were delineated by the probability density calculated above. These maps and sections show that fracture distribution is related to sedimentation, karstification and tectonic movements (Braissant, 2003; Zhang et al., 2004).

Laterally more fractures occur at the structural high of the anticline, where there are 3-4 zones rich in fractures. In lower Б and B layers, the appearance of more fractures at the structural high is attributed to large tectonic stress, where the probability density of fracture is high. The appearance of more fractures at the structural high in the upper layer A is related to two factors. One is large tectonic stress which gave rise to structural fractures. The other is the leaching process which was caused by the uplifting before the Permian Period and resulted in dissolved fractures at the structural high. Early fractures were also enlarged by the chemical erosion of atmospheric water. Thus both structural fractures and dissolved fractures occur at the structural high of the anticline in layer A.

In the intervals with shale content of 4%-6% and gypsum content of 0 in B2, the probability density of fracture is related to structural location. For the same lithofacies, the structural high tends to exhibit more fractures than the structural low (Andrea et al., 2016) (*Fig. 10*).

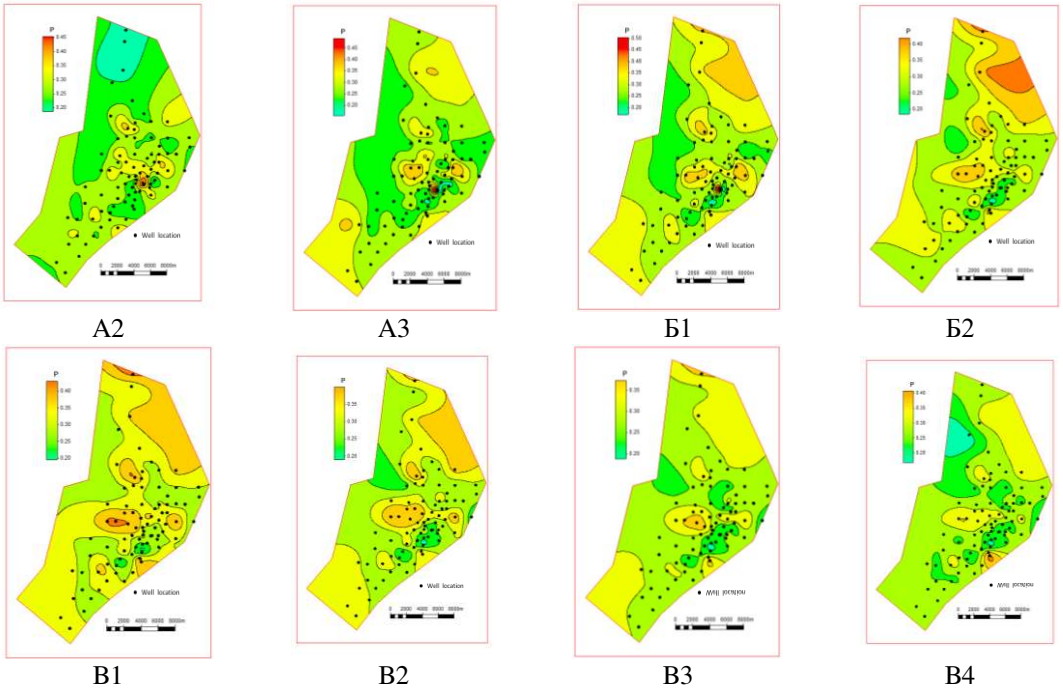

Figure 9. *P contour maps for layers*

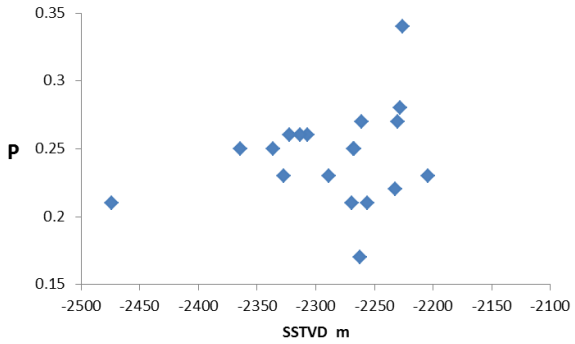

Figure 10. *Fracture probability density vs. structural location. (P: the comprehensive probability density; SSTVD: subsea true vertical depth)*

Vertically the appearance of fractures is dominated by sedimentary environment and varies with lithofacies. In lower B3-B5 with high shale content, fractures tend to occur in the intervals with high calcareous content instead of the ductile intervals with plastic deformation under tectonic stress (Lander and Laubach, 2015; Olson et al., 2009; Mauro et al., 2013). The probability density of fracture is only 0.21 on the average in this layer. In middle Б1-B2 with minute shale content, limestone and dolomitic limestone tend to break under tectonic stress to form structural fractures; thus the probability density of fracture is 0.069-1 with an average of 0.32. In upper A with shallow water and high shale content, the evaporate platform with gypsum rocks has strong plasticity. Except local fractures at the structural high, other areas are less fractured. The probability density of fracture is 0.28 on the average. Layers A and B3-B5 at the bottom have similar shale content. But due to the effect of the leaching process, layer A has more

© 2018, ALÖKI Kft., Budapest, Hungary

dissolved fractures than B3-B5 (*Table 2* and *Fig. 11*). Generally the probability density of fracture is negatively correlated with shale and gypsum contents and positively correlated with calcareous (calcite) content. The dolomite in the study area is mainly powder crystalline dolomite. A reservoir rock with high dolomite content is usually less fractured due to its high porosity and consequent small brittleness. Thus the appearance of fractures is negatively correlated with dolomite content (*Fig. 12*).

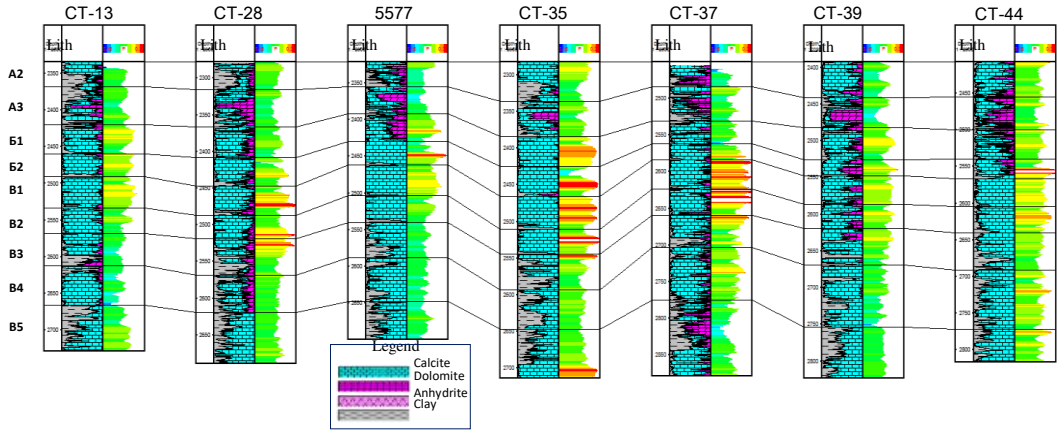

Figure 11. *Vertical fracture probability density and lithologies*

Table 2. *Lithologies and fracture signatures in layers*

Layer	Sedimentary environment	Lithology	Shale content (%)	Dolomite content (%)	Calcite content (%)	Anhydrite content (%)	P
A	Restricted platform – evaporate platform, shallow water	Dolostone, limy dolostone, gypseousdolostone, gypsum rocks, dolomitic limestone and limestone	15.7	24.0	55.4	5.0	0.28
Б1-B2	Open platform - restricted platform, shallow water	Limestone, dolomite-bearing limestone, dolomitic limestone and limy dolostone	7.0	10.6	82.3	0.0	0.32
B3-B5	Open platform, deep water	Argillaceous limestone, shale-bearing limestone and limy mudstone	19.9	10.7	69.4	0.0	0.21

Conclusions

Due to the impacts of sedimentary environment, karstification and tectonic movements, the North Truwa oilfield at the east margin of the Pre-Caspian Basin has various low-angle, high-angle and net-shaped structural fractures, dissolved fractures and sutured fractures. By using a single method, i.e. resistivity difference-ratio or 3-porosity ratio, only 55% of fractures on the average were identified. The fracture probability density method which integrates above two methods improves the accuracy to 73.6%. The results show fracture distribution in this area is related to sedimentation, structure and diagenesis. Laterally dominated by structures and karstification, more fractures may occur at the structural high. Vertically dominated by lithofacies, more fractures occur in the brittle intervals with small shale and gypsum contents.

The purpose of carbonate reservoir fractures studing is to improve the of oil fields, so how and how much the fracture effect the production is strongly recommended to study in the future.

Abstract. Litterfall is considered a key process in determining the carbon and nutrient cycle of the forest ecosystems, and in controlling the main respiration substrates on the forest floor. Litterfall and its seasonal changes were measured monthly for one year, in two sites and three stands of oak forests in Northwest Tunisia. The results show that the total annual litterfall varied significantly according to forest types ($P<0.01$) in the range of 7.71–9.89 t ha^{-1} yr^{-1}. Litterfall of *Quercus suber*, *Quercus canariensis* and mixed stand occur mostly in autumn, winter, spring and summer seasons, respectively. An annual decay coefficient is calculated from litter accumulation data, which varies according to the site and the stand. The decomposition rate is more pronounced in the *Quercus canariensis* stand, followed by the mixed stand and a slow decomposition in *Quercus suber* stand.
Keywords: *forest ecosystem, Quercus canariensis, Quercus suber, decomposition, annual decay coefficient*

Introduction

In the biogeochemical cycle of organic matter and mineral elements, litterfall plays an important part in the relations of soil, vegetation and surrounding environment, constituting one of the essential ecological phenomena in the wooded ecosystems (Vitousek et al., 1995).

The environmental signals activate a series of events leading to the fall of the leaves. The fallen leaves on the soil degraded by the microorganisms allow the recycling of the constituents of the plant material, which are uptaken again by the tree.

The fall of the leaves is not considered as a great loss for the tree because their metabolism is slowed down due to ceased photosynthesis and their constituents are recycled and reused.

Litter dynamics play an important part in the return of nutrients to the forest soil. It is considered an important component in the accumulation of soil organic matter (SOM). It is also one of the major inputs of C to the soil and an important C source for SOM (Sayer, 2006). Therefore, litterfall is a key parameter in measuring and predicting soil C sequestration (Liski et al., 2005) and one of the most important variables in the global C cycle (Janssens et al., 2003). The litterfall is characterized by a regular rate from one year to another.

The estimation of the foliar proportion of litter is, however, directly tributary of the other components of the litter whose production is rather variable from one year to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

another because it depends on events which occur with irregular time intervals. Such factors are likely to vary the annual litterfall (Ben Yahia et al., 2016).

The fall of the leaves is considered a very important periodic event in these forests. It represents approximately 65% of the total litterfall (Vogt et al., 1986) and it contributes to the mobilization of the organic matter. The litterfall is influenced by climate variability and latitude. Berg and Meentmeyer (2001) observed that litterfall is positively correlated with annual evapotranspiration or other climatic indices including average air temperature. Litterfall decreases with the increase in latitude (Bray and Gorham, 1964).

In Tunisia, few studies have been made on the leaf fall and decomposition of organic matter in forests. In this context, the aim of our study is to analyse the seasonal variation of litterfall in *Quercus canariensis* and *Quercus suber* forest in Northwest Tunisia and to estimate the decay coefficient from the litter stock.

Materials and methods

Study area

The study was carried out in a natural oak forest site in Northwest Tunisia, the site of Khroufa (36° 55.5' N; 08° 56' E) and the site of Ain Zena (36° 46.98' N; 8° 43.79 E). These sites belong to the forest subdivision of Tabarka and Ain Draham, respectively (*Fig. 1*).

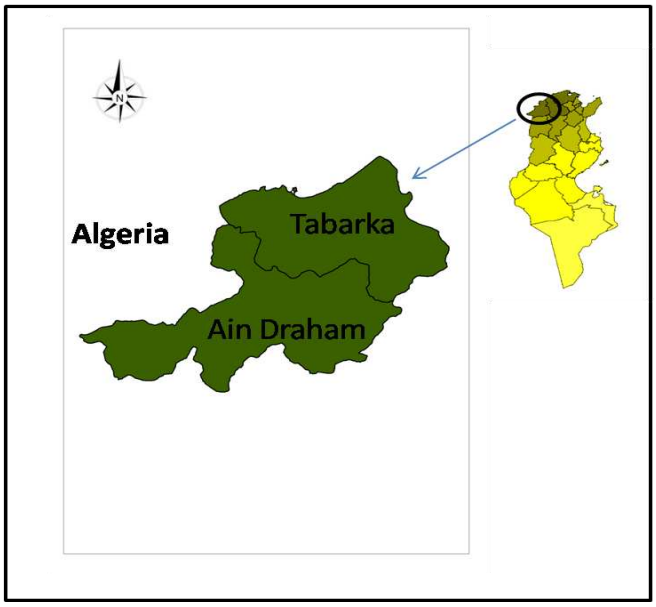

Figure 1. *Study area in Northwest Tunisia*

The climate of Khroufa forest is characterized by mild winters while the climate of Ain Zena forest is described as having temperate winter with snowy precipitations (*Fig. 2*).

Each of the two study sites consists of three stands. The dominant species in stand 1, 2 and 3 are *Quercus canariensis* (*QC*), *Quercus suber* (*QS*) and *Quercus canariensis* and *Quercus suber* (mixed), respectively (*Fig. 3*). A detailed description of the sites is indicated in *Table 1*.

Quercus suber and *Quercus canariensis* are important forest species in the Mediterranean region, specifically in Tunisia. They cover 69.870 ha and 6614 ha, respectively

Litterfall collection

Litterfall was collected monthly throughout a year (from June 2011 to May 2012) for two species (*Quercus Canariensis* and *Quercus Suber*) at all sites and stands.

Five plots are established at each stand to measure the litterfall. Five litter traps in each plot (1 m^2 collecting surface) were installed and located randomly at each plot.

The samples were collected from the five traps and transported to the laboratory, where they were dried at 75 °C for 48 h, and weighed each month throughout a whole year. The samples were sorted into four components: leaves, twigs, fruits and flowers. Twigs with a diameter of more than 2 cm were discarded.

After calculating for each plot the litter quantity per litter trap and per year for each fraction, an average value per plot were used to extrapolate litterfall per hectare and per year.

Data analysis was performed using SAS software: Statistical significance of differences between means of different variables were determined by the Student Newman Keuls (SNK) test using a significance threshold of 5%.

Results

The litterfall of the two species in the two study sites was estimated. The results show that the dynamics of the litterfall differ significantly with time, sites and stand (*Table 2*). In the pure *Quercus canariensis* stand, we noted that the litterfall is highly important during the months of January, February and March.

We noticed that the fall of the leaves and twigs in the pure *Quercus canariensis* stands in the Khroufa and Ain zena sites are important in winter season (*Fig. 4*).

Table 2. *Variance analysis of the different fractions of the litterfall. Correlation is significant at the 0.05, 0.01 and 0.001 level. (*P < 0.05, **P < 0.01, ***P < 0.001)*

Variables	Leaves	Twigs	Flowers	Fruits	Total litterfall
Sites	0.43	22.09***	0.71	54.97***	2.31
Stands	17.20***	3.41*	33.94***	16.51***	8.86**
Times	27.67***	8.42***	10.94***	9.03***	22.87***

We observed in the two sites that in the pure *Quercus suber* stand, the highest number of falling leaves was observed during May and June.

At Khroufa's site, the highest number of falling twigs is in June, November and January, whereas it is higher in the summer at Ain Zena's site. The maximum number of leaves dropped in the mixed *Quercus canariensis* and *Quercus suber* stands, is in May, January and March in Khroufa, while in Ain zena stands, the highest number of leaves fallen occur from May to July.

The fall of the twigs is intense during winter and summer season in Khroufa and Ain Zena, respectively (*Fig. 4*).

Leaf litter contributes to total litterfall, substantially. The percents of leaf litter vary slightly among forest types in a range of 77.3–85%, followed by twigs.

Regarding fruits and flowers (mentioned as other in *Fig. 4*), there is a significant difference among stands and times ($P < 0.001$), it is observed that the rates are very low in the two sites and stands. The fall of flowers generally occurs during summer months.

For fruits, the values found are low, especially, in Ain Zena stand; this is probably due to the cattle action in this station.

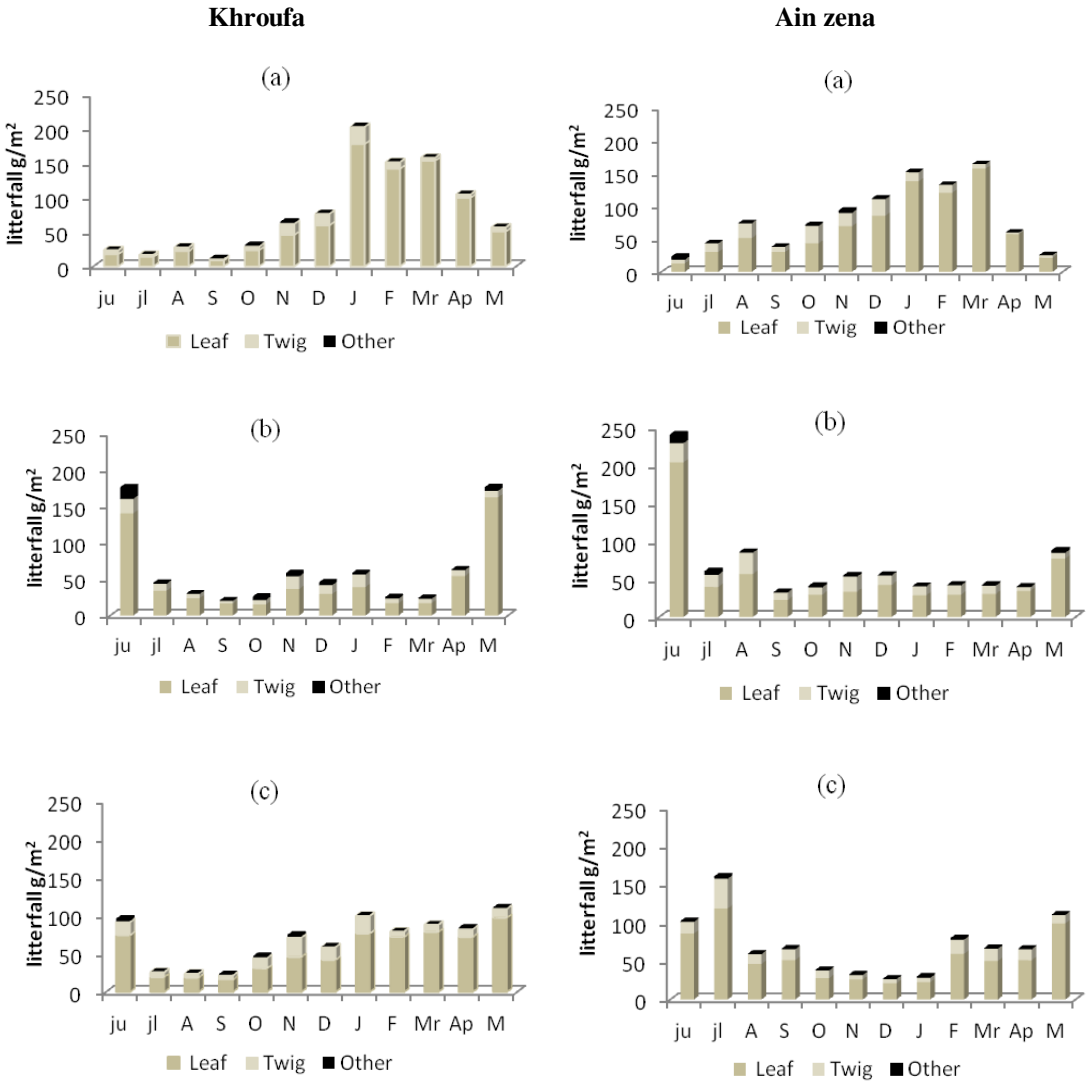

Figure 4. *Monthly variation of litterfall in (a) stand 1, (b) stand 2 and (c) stand 3 in Khroufa and Ain Zena sites in northwestern Tunisia*

The total litterfall is the most pronounced in the pure *Quercus canariensis* stand, it is on the order of 9.33 t ha^{-1} yr^{-1} and 9.89 t ha^{-1} yr^{-1} respectively at Khroufa and Ain Zena sites, moderate in the mixed stand (8.18 and 8.45 t ha^{-1} yr^{-1}) and low in *Quercus suber* stand (7.71 and 8.26 t ha^{-1} yr^{-1}) (*Table 3*).

Litter decomposition rate

Mass balance techniques are used to estimate litter decomposition for the whole ecosystem. The mass balance for the aboveground litter decomposition, suggests that annual litter decomposition should equal the annual input of fresh litter as long as the mass of stock litter stored in the ecosystem remains constant (Olson, 1963; Schlesinger, 1997).

The coefficient $k = \frac{A}{L}$ (for which A = annual litterfall and L = litter stock) can be used to estimate the percentage of litter decomposed by year. Thus, it is possible to obtain the necessary time for the litter to disappear to 100% (in the absence of input).

The results obtained (*Table 3*) highlight that the decomposition rate is higher in Khroufa site than Ain Zena. Similarly, the decomposition rate is more pronounced in *Quercus canariensis* stand; this rate reached 99% yr^{-1} at Khroufa and 81% yr^{-1} at Ain Zena sites, followed by the mixed stand (90.1% yr^{-1} and 75% yr^{-1}) and, finally, a slow decomposition in *Quercus suber* stand 75% yr^{-1} and 67% yr^{-1}).

Table 3. *Annual litterfall, litter decomposition rate (k) and time of 100% litter decomposition for the different sites and stands*

Sites	Stands	Annual litterfall (t ha^{-1} yr^{-1})	k (% yr^{-1})	Time of 100% litter decomposition (days)
Khroufa	QC	9.33	99	369
	Mixed	6.45	90.1	405
	QS	6.06	75	487
Ain Zena	QC	9.89	81	451
	Mixed	8.45	75	487
	QS	8.26	67	545

Discussion

The litter input of the present study (7.71 to 9.89 t ha^{-1} yr^{-1}) in the forest stands is higher than the values of 5 t ha^{-1} yr^{-1} recorded by Selmi (1985); and other studies carried out on the oak forests of the Mediterranean Basin.

The litterfall of the *Quercus suber* is about 5.6 t ha^{-1} yr^{-1} in Portugal and Spain (Sa et al., 2001; Caritat et al., 2006). In May and June, the peak of the leaf fall changes depending on the year (Bellot et al., 1992; Caritat et al., 1996; Martin et al., 1996). The fall of leaves at the end of spring may be due to an adaptation to the hydric deficit that can occur during the dry season (July and August), in the Mediterranean areas (Escudero et al., 1987).

However, the estimation of the proportion of leaf litter is directly dependent on other components of litter (Ben Yahia et al., 2016). The input is variable from one year to another because it depends on events that occur at irregular intervals. Therefore, some factors are likely to vary the annual litter production. The high values found in our study are probably due to higher temperatures and lower precipitation.

Dendroclimatological studies in Tunisia and Morocco (Aloui, 1982; Raouane, 1985) have shown that *Quercus canariensis* has a greater sensitivity to precipitation than to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

temperatures. But on the other hand, it is indifferent to the physico-chemical nature of the soil.

Our study shows that the fall of the twigs takes place in winter for *Quercus canariensis* stand and at the beginning of summer and winter for the two others stands. This may vary from one study to another since the twig fall depends significantly on wind and storms. According to Caritat et al. (2006), the fall period takes place mostly at the beginning of springtime and at the end of autumn, and it varies a lot depending on the year as observed for the same species in Sicily (Leonardi et al., 1992).

According to Pérez-Suarez (2009), the strong seasonality in leaf-litterfall recorded in other ecosystems with a variety of deciduous and evergreen species (West, 1985; Berg and Meentemeyer, 2001; Liu et al., 2001) has been attributed to interactive effects of weather patterns (e.g. drought), species phenology (Binkley et al., 1992; Liu et al., 2001; Berg and Meentemeyer, 2001) and the temporal distribution of precipitation events (Liu et al., 2004).

For the decomposition rate, the values observed for *Quercus canariensis* stand at Khroufa indicate that the decomposition of litter is relatively fast (369 days), which can be explained by the climatic conditions favorable to the decomposers and the biological activity in this stand. On the other hand, it has been found that there is a significant difference with the coefficients found following the decomposition experiment using the litterbag method.

Van Wesemael (1992) studied decomposition in the Mediterranean forests of Italy (Tuscany) by the litterbag method, and found a rate of decomposition respectively equal to 50% yr^{-1} and 47% yr^{-1} in *Quercus cerris* and *Quercus suber* after one year of decomposition.

This difference highlights the critical importance of mesofauna, prevented from acting by using litterbag method (Bernhard, 1970).

The decomposition rate of *Quercus canariensis* and *Quercus suber* reached 1.69 yr^{-1} and 1.1 yr^{-1} in Southern Spain (Aponte et al., 2012). Moreover, the decomposition of *Quercus serrata* is rapid over time. For instance, according to Pandey et al. (2007) the decomposition rate is 2.37 yr^{-1} and the half life time is 107 days.

These high values are due to the climate characterized by an alternation of dry and wet periods which play an essential part in the regulation of decomposition rates (Tripathi and Singh, 1992) by changing microbial communities in the process of organic matter decomposition (Arunachalam et al., 1997).

Conclusion

The examination of the seasonal variation of litterfall at different oak forests in Tunisia shows that there are no differences between the two study sites of Khroufa and Ain Zena; the only difference is between stands. This could be related to the differences phenological alterations of the species studied. The results suggested that total annual litterfall vary significantly according to forests, with a range of 6.06–9.89 t ha^{-1} yr^{-1}, and that leaf litter is the main component.

In *Quercus suber* the observed links between leaf fall and climatic variables are as they were be expected in typical Mediterranean forests, in which low rainfall and high temperatures favor leaf fall in spring. As for deciduous species, the opposite is true.

Our results will help develop litterfall models in response to climate change in the future studies.

In addition, the litterfall is an important phase in the biogeochemical cycle of nutrients that ensure the productivity of ecosystems. The knowledge of the quantities of biomass returning to the soil and the released minerals allow, with other criteria such as decomposition rate, to give an idea about their use by plants and to determine the excesses or deficiencies in a given ecosystem.

(Received 24th Jan 2018; accepted 2nd May 2018)

Abstract. This study was conducted in order to examine the effects of irrigation intervals and drought stress on crop yield and its components for four maize cultivars. The split-plot in the (RCBD) design was employed to conduct this study with three replications over a period of two years. After the establishment of all plants the irrigation was controlled in the following intervals at seven treatments: 7 days, 10 days, 12 days, 14 days until the end of the growing period and from the 3-leaf to 7-leaf stages withholding the irrigation. After that, irrigation was performed every 10 days, 12 days and 14 days respectively as the main factor. The cultivars included KSC 704, 703, 705, and KSC706 as a sub-factor. As expected, there were significant differences between the cultivars: KSC705 and KSC704 showed the highest mean yield (199.9 g/plant) and the lowest mean yield (184.4 g/plant), respectively. Under conditions of severe stress, the best cultivar was KSC705 with a yield of 189.9 g/plant. In addition, under normal conditions, KSC705 turned out to be the best cultivar with a yield of 594.3 g/plant with a 10-day irrigation interval. Therefore, this cultivar has been introduced as the most stable cultivar under the conditions of drought stress.
Keywords: *corn, cultivars, drought stress, irrigation interval, yield*

Introduction

Maize (*Zea maize L.*) is one of the most important cereal crops, grown principally during the summer season, in Iran and other Middle East countries. Corn is the staple food for many human populations in the world. It is a tropical plant, but, at present, it is intensively cultivated worldwide in subtropical and temperate regions. It can be successfully cultivated twice in a year. In developing countries, maize is a major source of income for many farmers, and is widely used in the food industry (Tagne et al., 2008).

Drought is one of the main environmental constraints that affects crop growth and production (Ashraf and Harris, 2004; Farooq et al., 2009). It has been estimated that up to 45% of the world's agricultural lands are subjected to drought (Bot et al., 2000). Moisture stress in crops depends on the different developmental stages and it could significantly affect the yield and other physiological traits (Chaves et al., 2009). An adequate supply of water for irrigation is one of the main factors that directly affects the growth and productivity of corn plants. Frequent water deficit is the primary limiting factor for crop production under arid and semi-arid conditions (Hussain et al., 2004). It

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

affects nearly all the growth processes of the plant. The stress response depends upon the intensity, rate and duration of exposure, and the stage of crop growth (Wajid et al., 2004). Sun et al. (2006), stated that the critical plants were more sensitive to water stress, which is reflected in the significant reduction in most of the growth parameters. Ibrahim et al. (2007) reported that the highest values of plant height, ear characteristics (length, diameter, and weight) as well as the ear and kernel yields of the corn plants per feddan (f.e: 1 feddan = 0.42 ha) in both seasons were obtained under the irrigation interval of 10 days, followed by 14, and 18 days. Aydinsakir et al. (2013) showed that different irrigation levels, when applied (full irrigation with no water stress and slight, mild, severe water stress, and no irrigation), have statistically significant effects on the yield components, such as the anthesis-silking interval, plant height, ear diameter, ear length, kernel number, and 100 kernels weight, except for the ear number. In addition, it was found that the cultivars had significantly different responses to water deficit. In another research, Jafari et al. (2012), showed that BC504 and BC652 produced the highest yields, and BC678 and NS504 produced the lowest yields under optimal, and stress conditions, respectively.

The aim of this study was to evaluate the effects of irrigation intervals at the critical stages of phonological, morphological, and physiological growth on yield and yield components of the four maize cultivars.

Materials and methods

Research studies were performed in 2015 and 2016 in a field experiment. The split-plot in the Randomized Complete Block Design (RCBD) was employed to conduct this study with three replications during a period of 2 years in the Islamic Azad University of Arak in the Markazi Province in Iran. Arak is the capital of Markazi province in Iran located with the latitude of 34.09 and the longitude of 49.69 at a mean elevation of 1748 m above sea level. Based on coupon divisions, this area is considered to be a desert temperate zone. The annual temperature difference is high. The average temperature and precipitation in this region are 18 °C and 255 mm respectively; July with an average temperature of 37 °C the warmest month and February with an average of -5 °C the coldest month. Weather data were collected from the weather station was located 1 km from the trial location. Average weather conditions at Arak area during the study are shown in *Table 1*. The soil at the trial site with its main characteristics presented in *Table 2*.

The irrigation intervals were as follows: I1: 7 days (control); I2: 10 days; I3: 12 days; I4: 14 days; and from the 3-leaf to 7-leaf stages the irrigation was withheld. After that, irrigation treated as the main factor was performed every I5: 10 days; I6: 12 days; I7: 14 days which was treated as the main factor. The cultivars included KSC 704(B73×MO17), KSC 703 (K47/3×MO17), KSC 705 (K3640/3×MO17), and KSC 706 (K3547/4×MO17) as sub-factors.

The land preparation was carried out by plowing, discing, land leveling, and furrowing before planting the seeds. The seeds were planted manually, and each plot contained 5 rows with a length of 4 m, and a distance of 0.5 m was maintained between each row. All plots were uniformly irrigated every 7 days for a month until the establishment of the seedlings (3-leaf stage). After matured physiological, selecting ten plants randomly from each subplot, some of the properties were studied, such as plant height, ear length, length of the non-inseminated ear, ear diameter, cob diameter, cob

The kernel yield was reported at moisture content of 14% and calculated in plant/g. To determine kernel yield, biological yield and harvest index, produced within two central rows in the field. Biological yield was recorded by weighing all the plants harvested from each plot and then converted into (plant/g). Then kernel yield and biological yield recorded on a dry weight basis. The harvest index was determined as follows:

$$HI = \left(\text{Economical yield} / \text{Biological yield}\right) \times 100$$

Data regarding 100 kernels weight was recorded by counting actual number of 100 kernels at random and then were weighed with electronic balance.

The analysis of the variance (ANOVA) and the comparison of the mean values were performed by the SAS statistical software, and the Duncan test both at 5% level.

Results

The results of the ANOVA indicated that the simple effects of the treatments (irrigation interval, and cultivars) were statistically significant for all the studied traits at $p < 0.01$. In addition, all traits were subjected to treatments ($p < 0.01$) (*Table 3*). The data showed that withholding irrigation between the 3-leaf and 7-leaf stages resulted in height loss of the plant. According to the comparison of the mean values, the I1 and I7 treatments showed the highest (168.6 cm), and the lowest (93.43 cm) mean values of plant height, respectively. The height of the plants subjected to both irrigation intervals and withholding of water was dramatically lower than that of the plants under controlled irrigation. In addition, the irrigation intervals I5 and I6 showed 33% and 44% reduction in plant height, respectively, in comparison with those under controlled irrigation. The cultivars showed no significant effects on plant height, in relation to the treatments interaction, for controlled irrigation; KSC704 showed the highest plant height, however for the irrigation interval of 14 days and withholding irrigation, the highest mean height was obtained for KSC705 (*Fig. 1*).

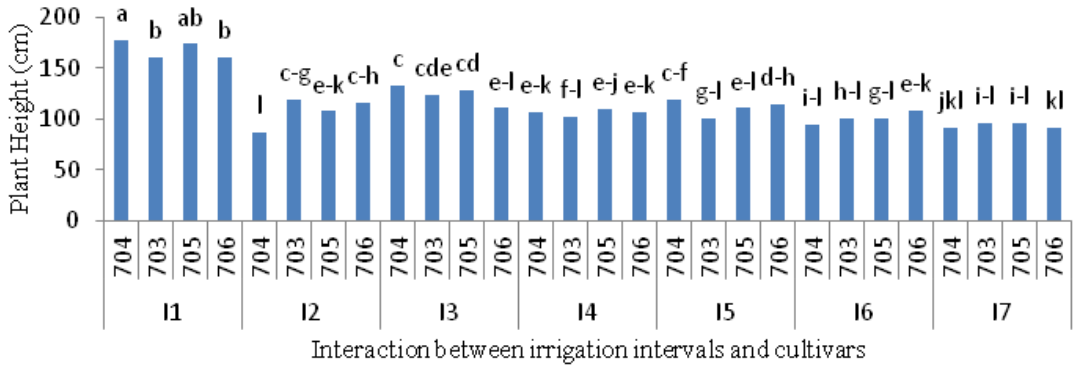

Figure 1. *Comparison of mean values of interaction treatments on plant height. Mean values in each column marked by similar letters are not significantly different at the 5% probability level (Duncan 5%)*

A reduction of 5.8% in the ear length was observed in the case of I7 in comparison with I1 (controlled irrigation) (*Fig. 2*). The effects of interaction between irrigation and cultivars showed that the highest mean height (18.33 cm) and lowest mean height (12.86 cm) were obtained by I4V4, and I3V4, respectively. The non-inseminated ear length measured under controlled conditions was significantly lower than what was observed for the other irrigation intervals. The I6 treatment led to an increase of 9.6% in the non-inseminated ear length. In addition, KSC704 showed the lowest mean height (1.31 cm) among the cultivars. KSC706 demonstrated the lowest non-inseminated ear length for the 14 days irrigation interval along with withholding the irrigation effects between the 3-leaf and 7-leaf stages (*Fig. 3*).

Drought stress led to the reduction in the ear and cob diameter as compared to controlled irrigation. As drought stress increased, the ear and cob diameter significantly decreased. Among the cultivars, KSC705 showed the highest mean ear diameter (4.15 cm), and KSC706 showed the highest mean cob diameter (3.07 cm); however, the other cultivars showed no significant differences (*Figs. 4* and *5*). In the case of the I3 irrigation treatment, KSC703 showed the highest mean ear diameter, whereas KSC705 demonstrated the highest mean cob diameter. At the highest level of drought stress (I7), the highest ear diameter (4.39 cm), and cob diameter (3.07 cm) were obtained in KSC706.

The number of kernels decreased steadily from 1:176 per plant at I1 to 825 per plant in the I7 treatment. Among the cultivars, KSC705 yielded the highest mean value for the number of kernels per plant (1047.17). KSC704 yielded the highest number of

The weight of 100 kernels of the severely stressed plants was the least compared to mildly stressed and well-watered plants. The irrigation interval of 14 days along with withholding the irrigation led to a significant reduction of 25% in the kernel weight compared to the kernel weight from plants under the controlled irrigation. The highest (24.27 g), and lowest (21.81 g) mean kernel weights were obtained for KSC703 and KSC705; however, KSC706: and KSC705 showed no significant differences (*Figs. 12* and *13*).

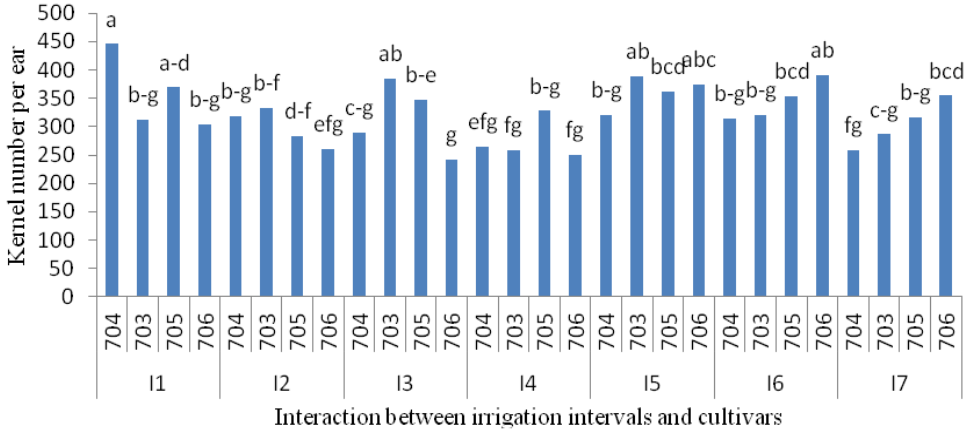

Figure 13. *Comparison of mean values of interaction treatments on kernel number per ear. Mean values in each column marked by similar letters are not significantly different at the 5% probability level (Duncan 5%)*

All the treatments showed a reduction in yield and yield components in comparison with controlled irrigation but the 10-day, 12-day irrigation intervals showed a similar effect on the yield. Among the irrigation intervals, the highest mean yield (327.47 g/plant) was obtained under controlled irrigation (I1), whereas the lowest mean yield (158.7 g/plant) was obtained in the I7 interval (*Fig. 9*). As expected, there were

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

some significant differences among the cultivars; KSC705 showed the highest mean yield (248.8 g/plant), whereas KSC704 showed the lowest mean yield (194.6 g/plant). Regarding the different irrigation intervals, the cultivars had different responses, such that, under the I1 and I7 treatments, the highest yields obtained from KSC705 were 594.3 g/plant, and 189.5 g/plant, respectively.

The biological yield represents the total dry matter at the time of harvest (*Figs. 14* and *15*).

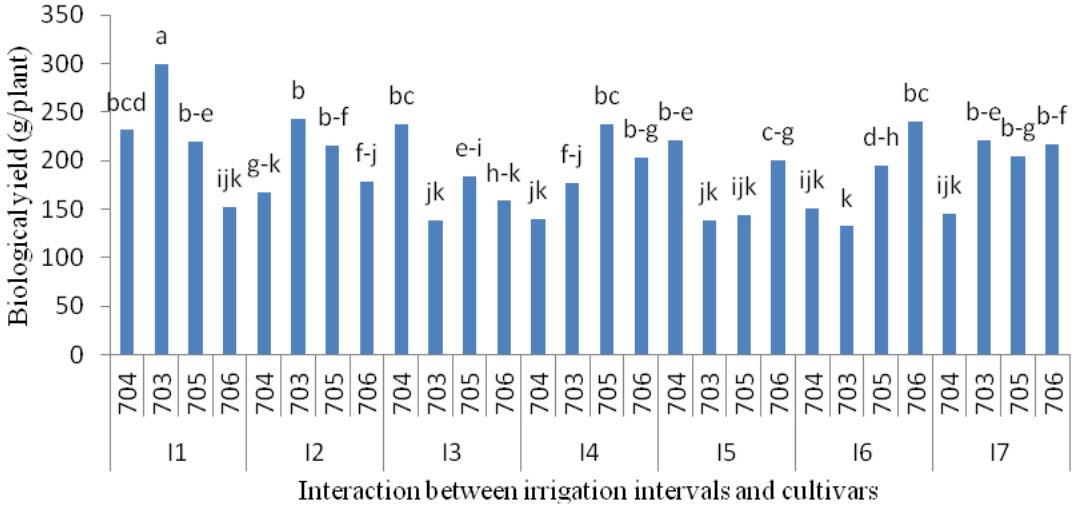

Figure 14. *Comparison of mean values of interaction treatments on biological yield. Mean values in each column marked by similar letters are not significantly different at the 5% probability level (Duncan 5%)*

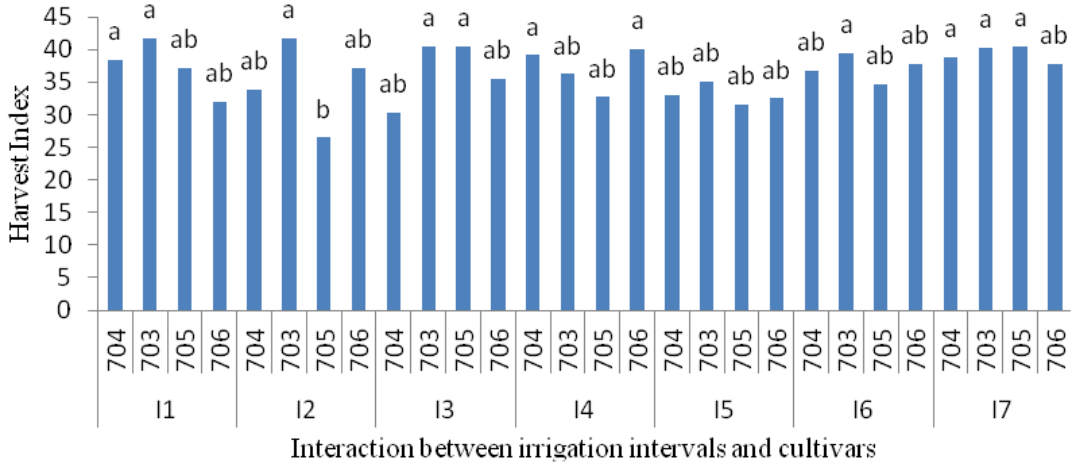

Figure 15. *Comparison of mean values of interaction treatments on harvest index. Mean values in each column marked by similar letters are not significantly different at the 5% probability level (Duncan 5%)*

The irrigation intervals I2, I3, I4, I5, I6, and I7 showed 10%, 20%, 16%, 21%, 20%, and 12% reduction in yield, respectively, as compared to the yield in controlled irrigation. A longer stay in the green period under optimum irrigation led to an increase in the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_29092921
© 2018, ALÖKI Kft., Budapest, Hungary

biological yield. It seems that for hybrids with a shorter growth, the biological yield is less, as KSC705 and KSC704 had the highest (199.9 g/plant) and lowest (184.4 g/plant) mean yields, respectively.

Discussion

Under drought stress, the rate of water intake by the plant is not high enough to maintain the turgidity of the leaves, and resultantly, the dry yield per unit of water consumed decreases (Kramer, 1949). The reduction in the growth and yield parameters under the irrigation interval of 14 days may also occur due to the imbalance of soil–water–air relation under these conditions, which leads to a reduction in the photosynthetic activity as well as inducing adverse relations between the hormones and biological processes in all organs of the plant (Ibrahim et al., 2005). Badr et al. (2003) and Thalooth et al. (2006) stated that plants grown under water-stress conditions show significant reduction in all the photosynthetic pigment content compared to unstressed plants. In accordance with our results, Ibrahim et al. (2007) mentioned that corn plants showed significant reduction in yield when the soil moisture content was decreased under an irrigation interval of 18 days. This effect could be attributed mainly to the excessive water stress in the root-zone causing an imbalance in the plant's nutrition. These results are in concurrence with those reported by many investigators, such as Larson (1975), Navari-Izzo et al. (1990), Osman et al. (1994), Kramer (1995), Ibrahim et al. (2005), and Thalooth et al. (2006); they noticed that under water depletion, the total nitrogen content, protein content as well as amino acids decreased in *Zea mays* and *Helianthus annuus*. They related this effect to the unbalanced soil–water–air relations that lead to the reduction in the photosynthetic activity as well as the induction of adverse relations between hormones and biological processes in all organs of the plants. In addition, Badr et al. (2003) stated that the uptake of nutrients is closely linked to the water–soil conditions. It is expected that a decline in the available moisture in the soil might decrease the diffusion rate of nutrients from the soil matrix to the roots.

Conclusion

This study was performed to evaluate the effects of irrigation intervals and drought stress on yield and yield components of four maize cultivars. Our results demonstrated that all treatments showed a reduction in yield when compared to control irrigation; however, the irrigation intervals of 10 days and 12 days showed a similar effect. Controlled irrigation (I1) demonstrated the highest mean yield of 327.4 g/plant, whereas the lowest mean yield was 158.6 g/plant obtained under the I7 irrigation interval. As expected, there were significant differences between the cultivars; KSC705 and KSC704 showed the highest (199.9 g/plant) and lowest (184.4 g/plant) mean yields, respectively. Therefore, in comparing cultivar KSC704 with other cultivars under low irrigation conditions, KSC704 was affected by drought stress, while other cultivars showed less effect on irrigation conditions.

Irrigation methods contribute to increase the water use efficiency and decrease the amount of irrigation water each time and ultimately to increase the net profits. This experiment demonstrates the traits and indices have the highest correlation with yield and by these two factors identify sensitivity and tolerant cultivars are recognized.

Irrigation intervals are effective on the performance and water use efficiency of different maize hybrids.

A professional management is required to get the best results from the cultivation of each product. Well-timed irrigation is an important factor meaning that the plant receives water at the right time and as it needs. With proper irrigation, the product is not affected by water stress, and water waste and energy losses are minimized. On the other hand, one of the basic steps in managing irrigation is right planning.

It is imperative to calculate the appropriate irrigation interval for other crops, which is suggested to be in different geographic latitudes.

Abstract. The traffic noise on a highway with a non-negligible negative impact on the behavior of wild animals has a great ecological impact on wildlife near the road area. To analyze the impact of traffic noise on Tibetan antelopes, field experiments were carried out to measure the traffic noise intensity and observe the behavior of the Tibetan antelope within 500 m of the Qinghai–Tibet Highway from Kunlun Mountain Pass to Wudaoliang on the Qinghai–Tibet Plateau, China. A relationship between different levels of traffic noise intensity and the behavior of Tibetan antelope was established by data analysis. Traffic levels were found to have the most significant effect on Tibetan antelope behavior within 150 m of the highway. The changes in the Tibetan antelope behavior before and after changes in noise mainly manifested as decreased foraging and increased movement. The results of this study can guide road construction and engineering measures to protect wildlife on the Qinghai–Tibet Plateau and other areas with high altitude.
Keywords: *road ecology, traffic noise, noise pollution, Tibetan antelope behavior, high altitude area*

Introduction

The traffic noise from a highway has a large ecological impact on wild animals near road area (Forman et al., 1998). Growing evidence has shown that traffic noise has a non-negligible negative impact on wild animals' behavior. The impact mainly manifests as avoidance of the road vicinity (Zande et al., 1980). Traffic noise may also obstruct acoustic communication among wild animals that depend on it, including frogs, birds, and mammals (Parris et al., 2009). The negative impact on wild animal fitness at the individual level may have severe population-level consequences because most of such wildlife are social animals. Thus, wildlife populations living near road areas exposed to traffic noise have a high potential for reduced reproductive success, which may ultimately break the local ecological balance.

The impact of roads on wildlife has drawn wide attention in recent years. A study in Canada measured the extent and type of relationship underlying the road-effect zones of a motorway with a high proportion of heavy-truck traffic for anuran species richness (Eigenbrod et al., 2009). Field experiments were performed to study the road-effect zones of ungulate wild animals in the USA (Gagnon et al., 2007). To analyze the effect of vehicular traffic on wild animals, a study in India estimated the road kills on state highways (Samson et al., 2016). New technologies have also been used in various studies. To analyze the effects of the highway transportation corridors on wildlife, a

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_29232932
© 2018, ALÖKI Kft., Budapest, Hungary

study used a geographic information system (GIS) to identify landscape attributes associated with species movement in Banff National Parka, Canada (Alexander et al., 2000). To locate accident points and acquire spatial statistics for analysis, a study utilized a GIS to research methods for mitigating wildlife–vehicle collisions in Spain (Diaz-Varela et al., 2011).

Most existing research on the impact of traffic noise on wildlife has mainly focused on birds. Field experiments have indicated a range of behavioral responses to urban noise in North America and Seville, Spain (Wood et al., 2006; Slabbekoorn et al., 2008). Traffic noise has also been shown to affect wildlife migration and reproduction. Parris and Schneider investigated the impact of traffic noise and traffic volume on two bird species in Australia, and found that traffic noise may reduce breeding success in noisy roadside habitats (Parris et al., 2009). The negative impact of traffic noise on avian reproductive success was analyzed in Netherlands (Halfwerk et al., 2011). However, there have been only a few studies that focused on the impact of traffic noise on mammals around the world.

The impact of traffic noise on wildlife has been extensively studied for various geographic topographies around the world. For instance, road kills were analyzed for state highways on Sigur Plateau, India (Gagnon et al., 2007). The effects of traffic noise on bird populations were studied for mountain forests in Idaho, USA (Mcclure et al., 2013). In China, the Qinghai–Tibet Plateau is a unique region with a high altitude and fragile ecological environment. Many wild animals, especially Tibetan antelope, are distributed around the Qinghai–Tibet Highway. The impact of roads on Tibetan antelope has received attention in recent years. Research has mainly focused on the road-effect zone (i.e., extent of significant ecologic effects from the edge of a road) and the impact on migration and protection measures of Tibetan antelopes (Lian et al., 2012; Lin et al., 2007). Traffic noise is known to have an impact on wildlife behavior. However, there has been no research on the impact of traffic noise on Tibetan antelopes and the extent of this impact.

In this study, the impact of different levels of traffic noise intensity on the population behavior of Tibetan antelopes was examined. Field experiments were performed to measure the traffic noise intensity and observe the behavior of the Tibetan antelope within 500 m of the Qinghai–Tibet Highway from Kunlun Mountain Pass to Wudaoliang on the Qinghai–Tibet Plateau, China. The relationship between different levels of traffic noise intensity and the behavior of Tibetan antelope was analyzed based on the traffic noise intensity data and corresponding proportions of different kinds of Tibetan antelope behaviors at different distances from the highway.

The remainder of the paper is organized as follows. First, the field experiments and data collection process are described in detail. Then the experimental results are analyzed, followed by a discussion and insights for future research.

Materials and Methods

Research Area

The research area was located at the junction connecting Hoh Xil National Nature Reserve and Sanjiang Yuan Nature Reserve: the crossing of Qinghai–Tibet Highway from Kunlun Mountain Pass (K2900, 4767 m ASL) to Wudaoliang (K3005, 4800 m ASL) (*Fig. 1*). The geographic structures of the research area include a plateau mountain and plateau grassland for a high-altitude environment. This is a favorable

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_29232932
© 2018, ALÖKI Kft., Budapest, Hungary

habitat for Tibetan antelope, especially from Chumar River to Wudaoliang. The migration season of Tibetan antelope is usually from June to August, so June was selected for surveying. Qinghai–Tibet Highway traverses the annual migration path of Tibetan antelopes. The geographic location of Qinghai–Tibet highway ensures that the main source of noise pollution is traffic. Thus, this 105 km long stretch of the highway from Kunlun Mountain Pass to Wudaoliang was selected for surveying.

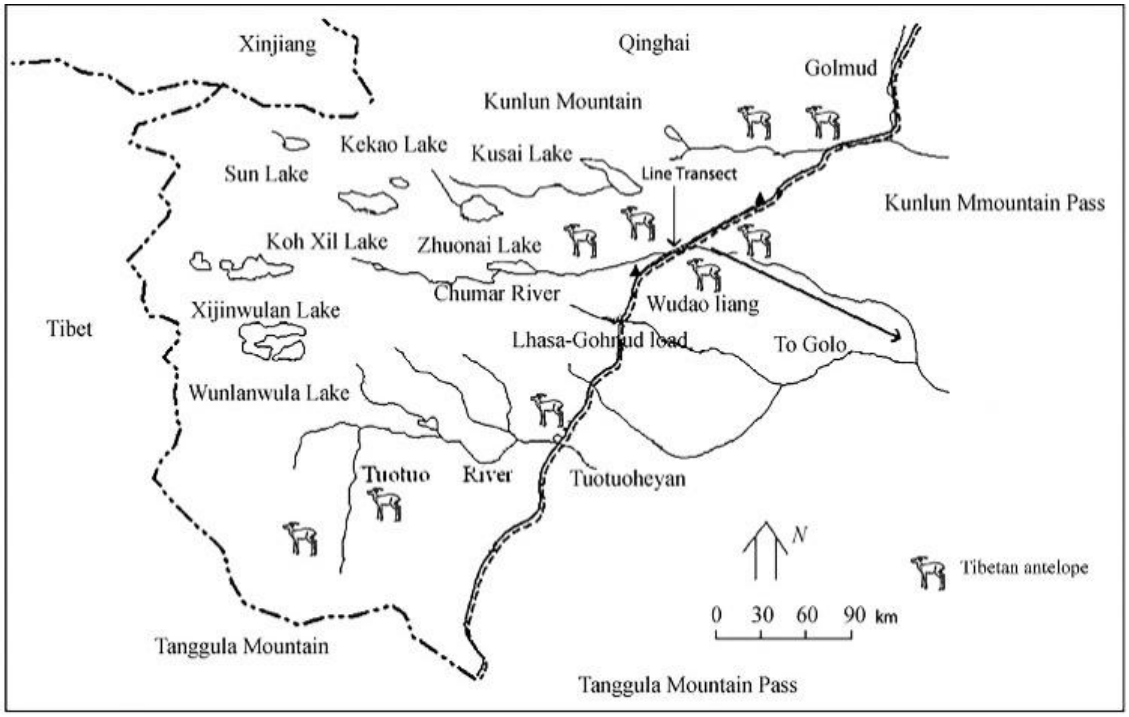

Figure 1. *Survey area*

Field Experiment

To analyze the impact of traffic noise on Tibetan antelope behavior, the influence of different levels of traffic noise intensity on the behavior of Tibetan antelope was measured. There are three key nodes in the research area along the migration path of Tibetan antelope: K2904 (i.e., the wildlife channel between the Kunlun Mountains and Qingshui River), K2965 (i.e., Chubei Channel), and K2998 (i.e., the channel between Chumar River and Hoh Xil). To determine the experiment site, these three nodes were surveyed three full daytime in June 1st and 3rd, 2016. The results showed that a large amount of Tibetan antelope was distributed on the east side of the highway at K2998 (*Fig. 2*). For further research, the hourly traffic volume at K2998 was collected by using the AXLELIGHT Roadside Laser Vehicle Classification System in daytime June 4th to 6th, 2016. The daily difference in traffic volume at K2998 was collected, and the results showed slight differences in the daily traffic volume. The traffic volume was greatest from 8:00 am to 10:00 am (126–138 pcu/h) and corresponds to the most unfavorable condition for Tibetan antelope. Therefore, the east side of Qinghai–Tibet Highway (K2998) from 8:00 am to 10:00 am was set as the experimental site for determining the impact of traffic noise on the behavior of Tibetan antelope.

Figure 2. *Tibetan antelope population at K2998*

Noise Measures

To avoid adverse factors that may affect the accuracy of the experimental results, such as visual or aural interference for Tibetan antelope during the noise intensity measurement, the traffic noise intensity was measured before the observation of Tibetan antelope behavior. To avoid visual interference, observers did not appear in front of the Tibetan antelope but stayed in the test vehicle. With the aim of keep consistency in weather for observation, four sunny days without windy were selected to measure noise during the date from Jun 4th to Jun 11st, 2016, here it is worth to mention again that the observation time is identical four all the four discrete days for noise measures, from 8:00 am to 10:00 am.

The distance from the east roadside was demarcated along the highway by using a laser range finder. Within 500 m of the roadside, signs were marked every 50 m to acquire the approximate behavior of Tibetan antelope at different distances. The average noise intensity was measured with a noise meter having a resolution of 10 m. The average noise intensity at a certain distance during a certain time period was calculated as follows:

$$X_j = \sum \bar{x}_{ij} \qquad \text{(Eq.1)}$$

where, X_j is the level of average noise intensity at distance j during a certain time period and $\bar{x}_{ij}$ is the average noise intensity at distance j and time i during a certain time period. When a vehicle passed through the vertical intersection (i.e., shortest distance) between the experiment site and highway, the level of instantaneous noise was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_29232932
© 2018, ALÖKI Kft., Budapest, Hungary

measured immediately, and the maximum value was selected as the maximum noise level during a certain time period.

Behavioral Observations

There are significant differences in the behavioral characteristics of Tibetan antelope depending on the research objective. Such behaviors can be classified as follows: foraging, vigilance, movement, rest, and others. *Table 1* presents the main behavioral variables.

Table 1. *Definitions of the behavioral variables for Tibetan antelope*

Behavior	Definitions of Behavioral Variables
Foraging	Standing or walking with the head below the horizontal line of the shoulder
Vigilance	Standing and watching a certain direction
Movement	Displacement of a single individual with the head parallel or above the horizontal line of the shoulder
Rest	Lying down on the ground
Others	Playing, breastfeeding, defecation, etc.

Field experiments for seven days were carried out to observe the behavior of the Tibetan antelope during the date from 12nd to 19th June, 2016. Based on the statistical data, the average driving speed on this road section was around 50 km/h. Thus, the test vehicle was driven back and forth in the experiment site at a cruise speed of around 50 km/h. Meanwhile, three observers sitting in the test vehicle observed the proportions of different behaviors exhibited by the antelope being passed by at different distances within 500 m of the east roadside with the help of a high-powered telescope.

Results

Level of Noise Changes at Different Distances from the Highway

In this study, 500 datasets were collected regarding the level of average noise intensity and instantaneous noise intensity at different distances within 500 m along the east roadside. The levels of the average noise intensity and maximum noise intensity were calculated at different distances away from the roadside from 8:00 am to 10:00 am. The noise level intensity was associated with different distances from the highway, as shown in *Figure 3*. The horizontal axis represents the distance from the highway, and the vertical axis represents the noise in decibels.

The levels of average noise and maximum noise within 500 m of the highway differed by 3.58–21.15 dB. The difference between them gradually decreased with increasing distance from the highway and then tended to a stable value. However, the two curves representing the levels of average noise and maximum noise showed a generally consistent trend (i.e., nonlinear negative correlation): the noise level decreased with increasing distance from the highway. The noise level decreased sharply with increasing distance up to 150 m from the highway, but the two curves declined gently beyond this range.

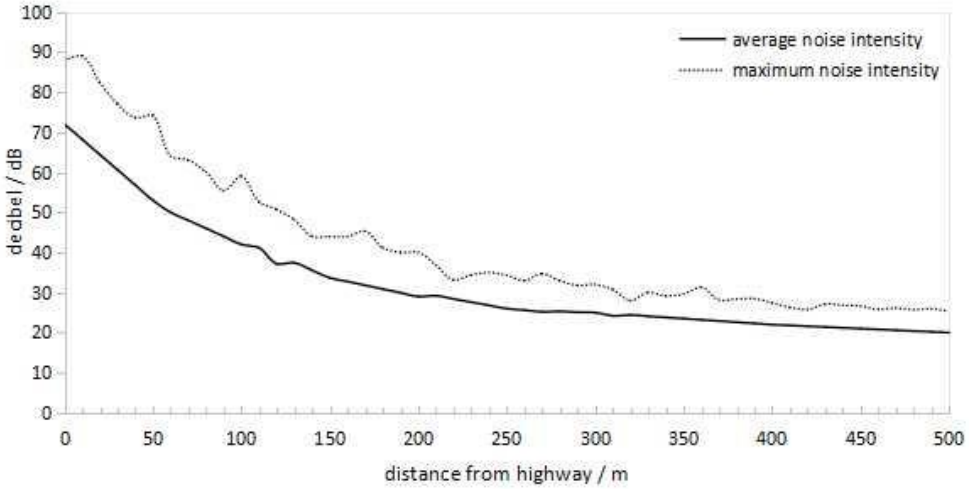

Figure 3. *Change in noise level with distance*

SPSS statistics 17.0 was used for statistical analysis to validate the data. Based on the normal distribution test method and the experimental data, two histograms were obtained, as shown in *Figure 4*. The horizontal axis represents the average noise and instantaneous noise in decibels, and the vertical axis represents the frequency that each decibel value occurred. The absolute values of the skewness and kurtosis were all less than 1. Therefore, the frequencies of the average and instantaneous noise intensity obeyed an approximately normal distribution.

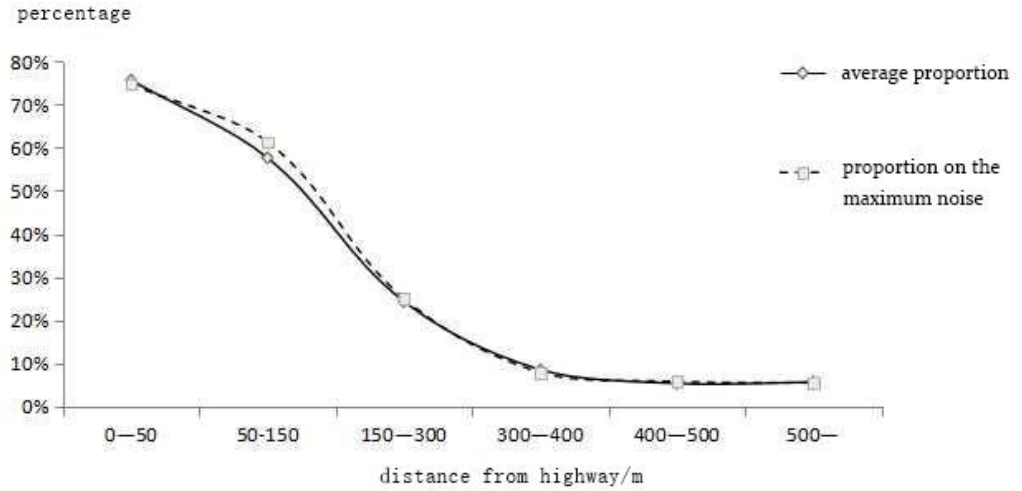
Changes in Tibetan Antelope Behavior with Different Levels of Traffic Noise



In this study, 1033 Tibetan antelopes were observed, and their behaviors such as foraging, vigilance, movement, rest, and others were recorded. To analyze the association between the Tibetan antelope behavior and noise level, the proportions of

(d) Rest and others

Figure 5. *Changes in Tibetan antelope behavior with different levels of traffic noise intensity*

The proportions of the four main types of Tibetan antelope behavior changed with the distance and level of traffic noise intensity. The analysis showed similarities in how each kind of behavior was affected by the level of traffic noise intensity. The percentage of each behavior for the average noise and maximum noise at the same distance from the highway were slightly different, which indicates different impacts of different levels of traffic noise intensity on all types of Tibetan antelope behavior. However, the changes in the proportions of Tibetan antelope behaviors due to the average noise and maximum noise were not significant.

As shown in *Figure 4(a)*, the proportion of foraging behavior before and after traffic noise showed a significant change (4.19%) 0–50 m from the highway. The proportion showed a comparatively small change (1.06%) 150–300 m from the highway. There were also changes in the proportion at 50–100 m and 300 m from the highway, but the changes were less than 1%. Therefore, the noise-effect zone of the highway for the foraging behavior of Tibetan antelope was 0–50 m from the highway.

As shown in *Figure 4(b)*, the most significant change (3.69%) in the proportion of vigilance behavior before and after traffic noise was at 50–150 m from the highway. Changes at 0–50 m and 100 m from the highway did not exceed 1%. Therefore, the noise-effect zone of the highway for the vigilance behavior of Tibetan antelope was 50–150 m from the highway.

As shown in *Figure 4(c)*, the proportion of movement behavior changed significantly (5.18%) before and after traffic noise at 0–50 m from the highway. There were relatively small changes of 2.27% and 1.12% at 0–50 m and 50–100 m, respectively, from the highway. However, the change was less than 1% at 100 m from the highway. Therefore, the noise-effect zone of the highway for the movement behavior of Tibetan antelope was 0–300 m from the highway with a particularly strong effect within 50 m.

As shown in *Figure 4(d)*, there were no significant changes in the proportions of rest and other behaviors before and after traffic noise at different distances from the highway. Thus, the noise-effect zone of the highway for the rest and other behaviors of Tibetan antelope could not be determined.

In conclusion, the main significant changes in the proportions of four kinds of Tibetan antelope behavior before and after traffic noise changed within 150 m from the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_29232932
© 2018, ALÖKI Kft., Budapest, Hungary

highway. In other words, the noise-effect zone of the highway on the behavior of Tibetan antelope was 0–150 m from the highway.

At 0–50 m, the Tibetan antelope before and after traffic noise mainly exhibited decreased foraging behavior and increased movement behavior. In addition, the vigilance behavior fluctuated. When the vehicle was closer to the Tibetan antelope, some individuals stopped foraging and moved away from the highway, which caused the foraging behavior to decrease and movement behavior to increase. The vigilance behavior did not show a significant increase as expected but showed no irregular fluctuations. This is because the Tibetan antelope maintained a high degree of vigilance within 50 m from the highway with no radical reactions.

At 50–150 m, the Tibetan antelope behavior before and after traffic noise mainly exhibited decreased movement behavior and increased vigilance behavior. When the vehicle was closer to the Tibetan antelope population, some individuals stopped moving and exhibited vigilance behavior.

Discussion

The impact of traffic noise on wildlife has been extensively studied in other countries, although not for high-altitude areas like the Qinghai–Tibet Plateaus. In this study, 500 datasets for the average and instantaneous noise levels at different distances along the roadside within 500 m from the highway were collected, and 1033 Tibetan antelopes were observed in a field experiment.

The behavior of wild ungulates in the area of 0–500 m had a significant difference from 2000 m–3000 m from the highway (Ying et al., 2007). And the avoidance distance of Tibetan antelope is 286.31 m from the highway (Lian et al., 2012). In this study, the results indicate that the noise-effect zone for the behavior of Tibetan antelope was 0–150 m from the highway. This suggests that new highways built in high-altitude areas should be at least 500 m from the activity area of Tibetan antelopes to protect them from the noise-effect zone. More careful consideration of the impact of traffic noise on wildlife is important when planning a new highway. Measures that can be taken in the design phase include changing the pavement material or decreasing the designed speed of vehicles. For Qinghai–Tibet Highway, sound insulation measures may help with avoiding the negative effects of traffic noise on the migration and reproduction of the Tibetan antelope population. For instance, sound barriers can be set on both side of the route along the animal channel, and natural shelter and traffic signs can be set up to prompt drivers to slow down and ban the horn.

The present study was preliminary in nature because it was a short-term study. The long-term impact of traffic noise on wildlife was not considered. More year-round research is needed to better understand the impact of traffic noise on Tibetan antelope and other wildlife. And further research can focus on the performance of sound monitoring at different heights and distances from the highway.

Conclusion

In our study, the noise intensity level showed a nonlinear negative correlation with the distance from the highway. Different levels of traffic noise intensity were found to have different impacts on all types of Tibetan antelope behaviors. Traffic levels were found to have the most significant effect on Tibetan antelope behavior within 150 m of

© 2018, ALÖKI Kft., Budapest, Hungary

the highway. The Tibetan antelope before and after impacted by traffic noise mainly exhibited decreased foraging behavior and increased movement behavior.

(Received 10th Feb 2018; Accepted 10th May 2018)

Abstract. The genetic diversity of honeybee populations (240 individual) *Apis mellifera* from ten various locations of China and Pakistan was investigated by using COI (Cytochrome Oxidase Subunit I) gene. After screening of sequences, BioEdit was used for the alignment, and these aligned sequences were employed to MEGA-7 software, to find out the phylogenetic relationship with all available subspecies through Neighbor-Joining method. On the other hand, genetic divergence was calculated via Kimura-2-Parameter using MEGA7, whereas genetic diversity was calculated by DnaSP v5. Phylogenetic tree results divided all populations into seven subspecies within two groups and maximum genetic divergence was observed overall at 3.88%, followed by Pakistan at 2.65% while minimum divergence value (2.02%) was observed for China. Likewise, significant genetic diversity overall was observed with 23 mutations, confirmed with the probability value of Fu's *Fu* at 0.019. Country-wise observations revealed that Pakistan had much highly significant variability through Fu's *Fu* and *D* tests, along with 17 mutations whereas China had shown less diversity with ten mutations. Moreover, the calculation of nucleotide mismatch distribution had also confirmed genetic variability among all our sequenced data. Thus, our findings have revealed the strong genetic interaction and a significant genetic variation among all seven subspecies of *A. mellifera* from two different countries. These results could be more helpful to investigate the genetic relationship among other subspecies of *A. mellifera* from different ecological zones.

Introduction

Honeybee rearing is worldwide accepted for its commercial values, and Chinese people are dependent on reared animals, including honeybee, along the sides of various rivers in China. In earlier records of China, honeybee was known as Mi-feng (Li and Luo, 2003). Rearing of honeybees covers more than six million colonies across the country, and is dominated by two species, i.e., *Apis mellifera*, and *A. cerana*. Although, *A. cerana* is being replaced by *A. mellifera* in whole China due to transportation of *A. mellifera* (Yang, 1984), through natural mating and hybridization. Similarly, Pakistan is also involved in the rearing of *A. mellifera*, and has more than 0.3 million colonies along the entire country (Waghchoure-Camphor and Martin, 2008). Unfortunately, honeybees are facing mortality due to the random applications of pesticides worldwide (Husain et al., 2014; Williams et al., 2015), due to which all types of commercial products are being costly.

A wide range of subspecies of *Apis mellifera* inhabit in natural distribution and have differences on the basis of behavioral and morphological features (Koca and Kandemir, 2013; Tofilski, 2008). The evolutionary study for the characterization of the species of *Apis mellifera* (Linnaeus, 1758) was first demonstrated based on morphometric

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_29332945
© 2018, ALÖKI Kft., Budapest, Hungary

parameters (Ruttner et al., 1978). *A. mellifera* has almost 30 subspecies all over the world (Ruttner, 1988), and can be classified into four categories, i) lineage A covers African subspecies; ii) lineage C covers northern Mediterranean subspecies; iii) lineage M contains northern European subspecies and iv) lineage O includes subspecies from the Middle East (Garnery et al., 1992; Whitfield et al., 2006). The new sophisticated molecular techniques have made it easy to further confirm these groups more precisely (Wallberg et al., 2014). Furthermore, this classification has been expanded with the addition of two new lineages, e.g., lineage Y and Z cover Ethiopia (Franck et al., 2001) and Libya (Alburaki et al., 2013), respectively.

A number of studies have been carried out to identify *Apis mellifera* subspecies on the basis of geometric morphometrical features, using programs of automatic identification (Tofilski, 2008). Due to the importation of *A. m. carnica* and *A. m. ligustica* in Europe, the conservation of local subspecies or ecotypes has been damaged by gene flow and replacement over longer distances (De la Rúa et al., 2009; Jensen and Pedersen, 2005; Maul and Hähnle, 1994; Moritz et al., 2005; Peer, 1957). The two races of the Western honeybee are closely related and live in neighboring climatic regions, i.e., *A. m. carnica* Pollmann and *A. m. ligustica* Spinola (Ruttner, 1988). Mitochondrial DNA (mtDNA) is a commonly used approach to explore the genetic evolution and diversity of species due to its conserved gene content and nucleotide substitutions. The honeybees were being identified through the intergenic region of cytochrome oxidase subunit I and II (COI–COII), to find out the evolutionary relationships of honeybees (Chen et al., 2016; Magnus et al., 2014; Techer et al., 2017) under the length and sequence variations of mtDNA (Franck et al., 2000; Hall and Smith, 1991). Out of Hymenopteran subspecies, *A. m. ligustica* is first subspecies for which a complete mitochondrial genome was sequenced (Crozier and Crozier, 1993), and later on, many mitochondrial regions were selected and sequenced for the description of phylogenetic relationships (Cao et al., 2017; Magnus and Szalanski, 2010; Muñoz et al., 2012; Techer et al., 2017).

Even the mitochondrial genome information about the other regions is limited, but some particular regions are being employed regularly to differentiate evolutionary lineages and subspecies of honeybees, like 16S ribosomal DNA (rDNA) (Bouga et al., 2005; Kek et al., 2017), NADH dehydrogenase-2 (ND2) (Kandemir et al., 2006; Techer et al., 2017), and NADH dehydrogenase-5 (ND5) (Bouga et al., 2005; Martimianakis et al., 2011; Özdil and İlhan, 2012), as well as COI regions (Bouga et al., 2005; Kekeçoglu et al., 2009; Marino et al., 2002; Sheffield et al., 2009). As previous studies explored that mitochondrial DNA is transferred maternally and can face high range of polymorphism, therefore, this region of *A. mellifera* genome has been utilized for phylogenetic studies (Ilyasov et al., 2011; Kek et al., 2017; Radoslavov et al., 2017). Likewise, from mitochondrial study consisting two DNA segments, the highest genetic divergence values were observed in COI. For this purpose, different methods were employed to construct phylogenetic trees for COI region of mitochondrial DNA, such as Bayesian Inference; Maximum Parsimony and Neighbour-Joining (Kek et al., 2017; Martimianakis et al., 2011). The present study was designed to determine the mitochondrial diversity and phylogenetic relationships of *Apis mellifera* subspecies of China and Pakistan through COI gene.

Materials and methods

Sample collection

We sampled a total 240 adult worker honeybees from three different ecological zones of China and Pakistan in year 2017 and immediately froze them in dry ice and brought the samples to the College of Bee Science of Fujian Agriculture and Forestry University, China (*Suppl. Table 1*).

DNA extraction, PCR amplification and sequencing

Total nucleic acid was obtained from the thorax of honeybee samples by applying king Fisher^{tm}cell and tissue kit as per manufacturer's instructions. Several primers have been designed to amplify the COI gene. Polymerase Chain Reaction (PCR) amplification was conducted using the following primer, COI-F1: 5'-TTTGATTACTTCCTCCCTC-3' and COI-R1: 5'-GCACCTATTGAAAGAACA-3', designed on NCBI tool. The total volume 25 µL, containing, 2 µL DNA template, 1 µL each primer (forward and reverse), ddH_2O 8.5 µL and 12.5 µL 2X Easy Taq Super Mix Trans solution. The amplification program started with 94 °C for 4 min, followed by 36 cycles of 94 °C for 20 s, 56 °C for 30 s, 72 °C for 60 s, and a final step of 72 °C for 5 min. The amplified PCR products were visualized in 1.5% agarose gel stained with ethidium bromide and purified with E.Z.N.A® Gel Extraction Kit. After purification of PCR products, all samples were sent to a local company (Biomarker Pvt, Ltd.) for bidirectional sequencing (Islam et al., 2018a). COI sequences were analyzed and edited using BioEdit 7 (Hall, 1999; Islam et al., 2018b). The sequences were preliminarily aligned using Clustal X (Thompson et al., 1997) and subsequently aligned manually. Unique COI sequences of all samples were deposited in the NCBI GenBank database via accession numbers MF416679–MF416918.

Phylogenetic and genetic distance analysis

Along with our 240 sequences, 67 COI sequences of fourteen subspecies were collected from NCBI database, to represent all available subspecies as well as one sequence of *Apis florea* (JX982136) as an out-group member. The portion (738bp to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_29332945
© 2018, ALÖKI Kft., Budapest, Hungary

831bp) of the COI5′ gene sequence utilized in our analysis existed between nucleotide 298-1150bp (COI complete sequence 1566bp) (Arias et al., 2008; Crozier and Crozier, 1993). MEGA-7 was used to perform phylogenetic analysis and nucleotide identity percentage within and among other major subgroups (Jan et al., 2017; Thompson et al., 1997). Likewise, genetic distances were also calculated by MEGA-7 under Kimura-2-Parameter (K2P) model.

Genetic diversity

For mitochondrial diversity, all indices were performed in DnaSP v5 (Librado and Rozas, 2009), under two neutrality tests [Fu's *Fs* (Fu, 1997) and Tajima's *D* (Tajima, 1989)]. For all blasted sequences of *A. mellifera* in the present study, a phylogenetic tree was constructed to understand the species network with relation to out-group member.

Results

Two hundred and forty honeybee samples were collected during 2015–2017 from various localities of China and Pakistan. The 240 COI-5' sequences (GenBank MF416679–MF416918) were blasted to determine the similarity index and identification of each isolate and are represented in the phylogenetic trees depicted in this study. Overall, there was 98%-100% nucleotide identity when all sequences were blasted in the NCBI database, along with zero percent E value.

Phylogenetic analysis

The phylogenetic tree grouped the entire collection of *A. mellifera* into two groups, and biggest group consists of individuals from all localities, except ID, along with seven subspecies. On the other hand, second group had covered only ID-sequences, along with two sequences from FD location and *A. m. ligustica* subspecies. The biggest group had shown that honeybees from all localities have good genetic interaction and diversity among the various colonies. On the other hand, it was observed that honeybee colonies from ID had least genetic diversity, due to which they had grouped into a single group that have little interaction with the colonies from FD. While two sequences of *A. florea* were kept as out-group member (*Fig. 1*). From all blasted sequences, it was observed that honeybee colonies from ID (Pakistan) have strong genetic interaction with each other as well as two colonies from FD (Pakistan) (*Suppl. Fig. 1*). Moreover, this group had presented resemblance up to 95%, as shown in *Figure 1*.

Colonies from other locations have huge genetic interaction among various colonies, due to enough diversity. As we know that FD colonies have different eco-geography, along with certain range of diversity, however, it was observed that most of the colonies built intermingled relationship with all Chinese colonies (*Fig. 1*). Likewise, a huge genetic interaction was also observed among all other Chinese colonies on the base of COI-5' DNA. Moreover, it was also observed that colonies from all locations had strong and random relationship with all seven subspecies in biggest group, like *A. m. ligustica*, *A. m. carnica*, *A. m. adami, A. m. macedonica, A. m. anatoliaca, A. m. caucasica* and *A. m. meda* (*Suppl. Fig. 1*). In short, our COI-5' DNA sequences had revealed that colonies from ID have minimum genetic variation and strong interaction with each other while all other colonies had enough variation, leading towards huge genetic interaction with *A. m. ligustica*.

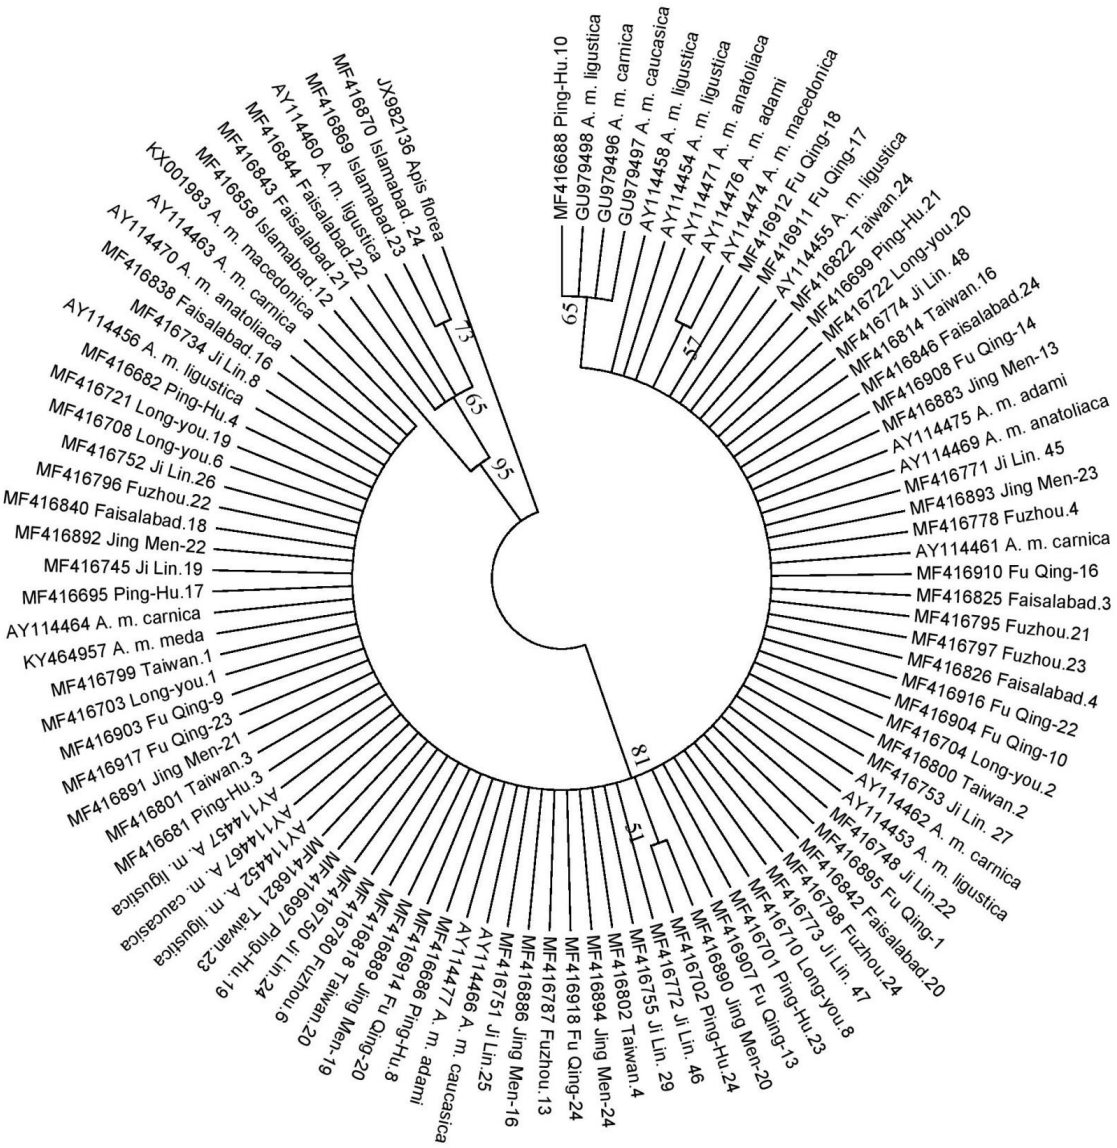

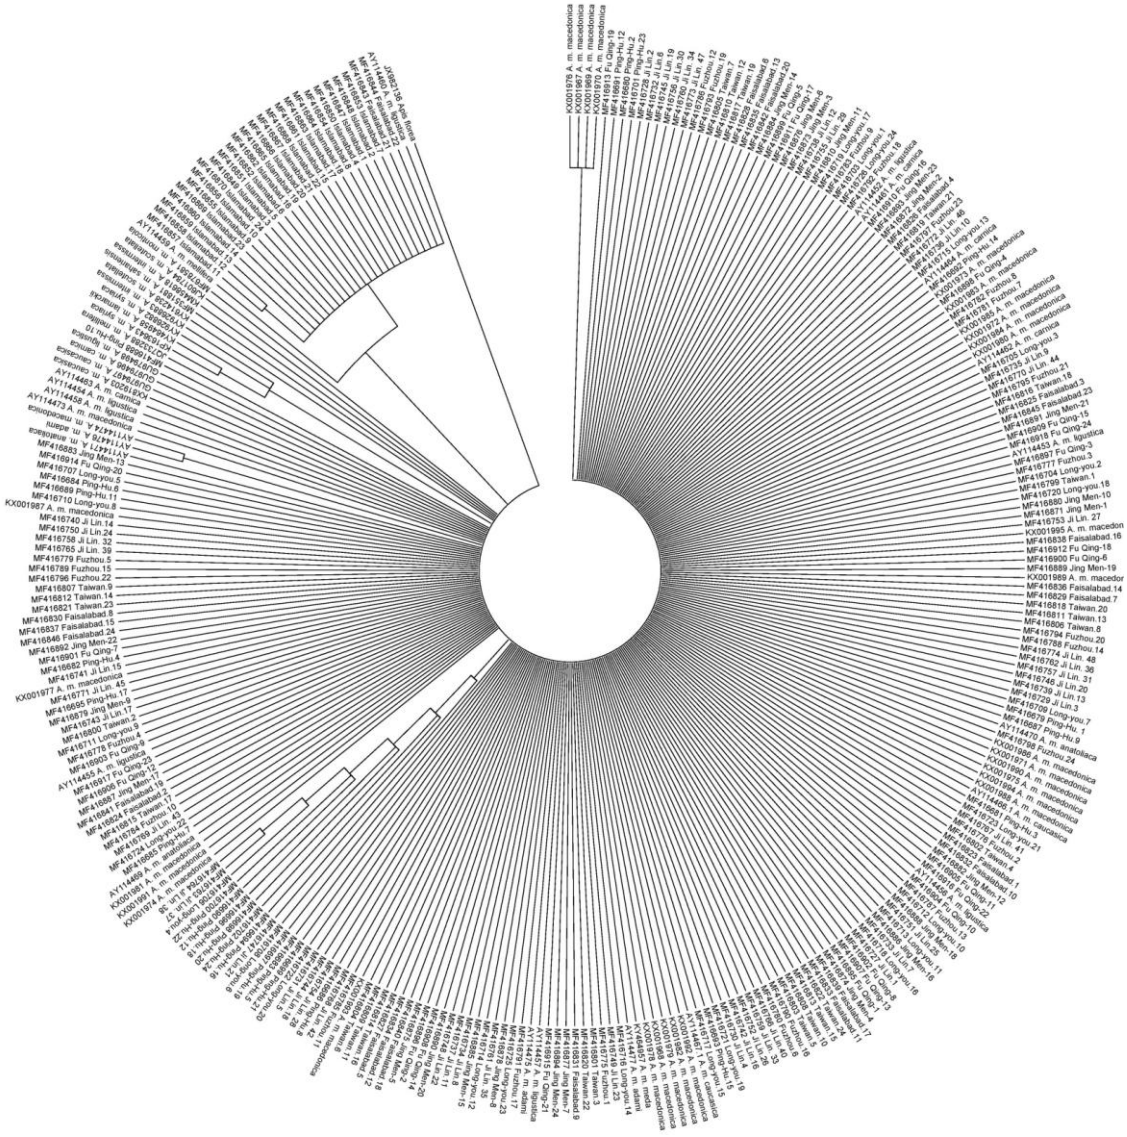

Figure 1. *Phylogenetic relationship of Apis mellifera sub-species in South-China and Pakistan. Phylogenetic tree was constructed through neighbor-joining method by using Kimura-2-Parameter model. For tree construction, we used 73 mtCOI-5' DNA sequences from our data collection, after choosing selected sequences, along with one complete mtCOI DNA sequence of A. florea (JX982136) as an out-group. Two main groups were developed after alignment. This tree shows percent similarity among different colonies from various locations. For both trees, bootstrap value was replicated 1000 times*

Genetic distance among subspecies

According to our sequenced database, pairwise maximum distances for our ten locations cumulatively range between 3.88%. As well, country-wise divergence was observed up to 2.65% and 2.02% for Pakistan and China, respectively. Moreover, maximum interspecific distance (2.36%) was observed for FD-location sequences, followed by PH-location (2.02%) whereas lowest value of maximum interspecific distance was observed for FQ-location and JL *carnica* sequences (0.26% for both). On

the other hand, maximum intraspecific distance was observed for FD-location as well as FQ-location/JL *carnica*, which was up to 2.10% (*Table 1*).

Supplementary Figure 1. *Phylogenetic tree construction by MEGA 7. Phylogenetic tree was constructed for our 240 sequences and 67 sequences, taken from NCBI, representing 14 subspecies of Apis mellifera. On the other hand, A. florea (JX982136) was taken as out-group member. Tree was constructed through Neighbor-Joining Method under K2P model, and bootstrap value was 1000*

Genetic diversity

As colonies were collected from different locations, therefore, there must be some genetic variation based on their geographical zones. All sequences were subjected to the genetic diversity analysis, and diversity indices were calculated through two neutrality tests, i.e., *D* and *Fs* tests, based on pairwise nucleotide diversity. Maximum genetic diversity, based on Eta value, was observed in FD colonies, showing up to 14 mutations within all colonies, followed by PH location (12 mutations). The significance of genetic

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_29332945
© 2018, ALÖKI Kft., Budapest, Hungary

diversity was confirmed by both neutrality tests, which shown that FD and PH locations had significant variation based on the *p*-value of Fu's *Fs* test (0.016) and *p*-value of Tajima's *D* test (0.01), respectively. On the other hand, most of the Chinese colonies from various locations (FQ, JL *ligustica*, JL *carnica*, LY and TW) presented least value of genetic diversity (*Table 2*).

Country based cumulative genetic diversity was determined, and colonies from Pakistan had shown maximum variation, representing 17 mutations among all colonies, whereas China had presented only ten mutations. High significance was noted for Pakistani colonies cumulatively, representing *p*-value 0.000 and 0.001 for Fu's *Fu* and *D* tests, respectively. However, overall cumulative genetic diversity of all sequences was significant at the utmost level, presenting 23 mutations, and this diversity was confirmed by Fu's *Fs* test (*Table 2, Fig. 2*).

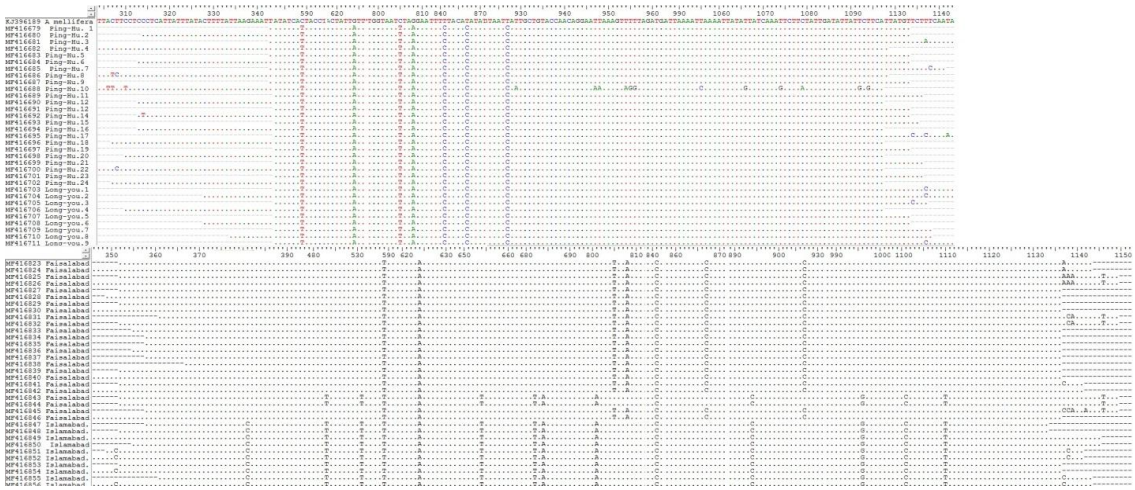

Figure 2. *Number of variable sites in COI region of our aligned sequences through BioEdit*

To confirm all the indices of genetic diversity, all blasted sequences were evaluated for population size changes, to calculate pairwise mismatch distribution for all sequences of subspecies. Overall and country-wise results had expressed a significant genetic variation for COI gene, but there was no population expansion of any subspecies in both countries (*Fig. 3*).

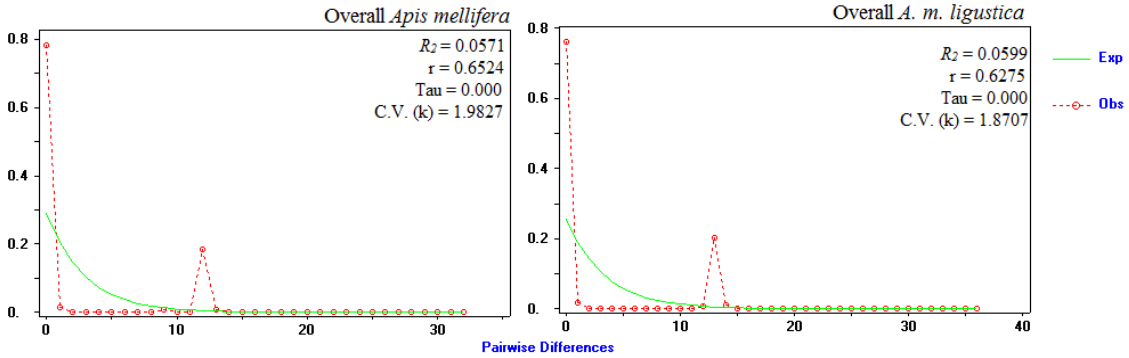

Figure 3. *Pairwise mismatch distributions for Apis mellifera sub-species, based on COI gene sequences by DnaSP v5. The X-axis shows the observed distribution of pairwise genetic variation, and the Y-axis represents the frequencies*

Discussion

The COI-5' DNA study was organized to characterize the genetic interaction and variability of *Apis mellifera* subspecies from two countries on a vast geographical zones.

Therefore, we collected 240 colonies, and sequenced them to assess phylogenetic relationship among different colonies as well as their genetic diversity and interaction.

Phylogenetic relationship of all sequences has defined the genetic interaction among the colonies from various locations as well as diversity within the colonies of same location, based on COI DNA. The phylogenetic tree of *Apis mellifera* along with 14 referenced subspecies, presented two groups (*Suppl. Fig. 1*). The largest group has been consisted of populations from all localities, except ID, representing vast genetic interaction among all populations. However, *A. m. ligustica* and *A. m. carnica* were dominant in our sequences. On the other hand, populations from ID location also presented huge genetic interaction within locality and least diversity, represented strong relationship with *A. m. ligustica* (*Fig. 1*). Same trend of genetic interaction was observed by mitochondrial study of Martimianakis et al. (2011), in which they described that various subspecies of *A. mellifera* built relationship with each other from different localities. Such earlier studies support our results of genetic interaction among two different subspecies as well as different localities in this study. Furthermore, such phylogenetic relationship among different subspecies of *A. mellifera* was also described by other people across the world, based on the COI gene (Özdil and İlhan, 2012; Radoslavov et al., 2017) and other distinct genes (Ilyasov et al., 2016a, b; Techer et al., 2017).

In our study, all nucleotide substitutions were occurred between 298-1150bp. However, there were only seven main nucleotide substitution sites in our sequence whereas minor substitutions were observed at many sites of COI region. Due to such minor substitutions, colonies of both subspecies from all locations were clustered together in different groups (*Figs. 1* and *2*), except ID locations.

The genetic divergence and interaction for DNA sequences were explained by many researchers for different classifications of organisms, i.e., plant, animal, arthropod as well as prokaryotic species (Goraya et al., 2015; Islam et al., 2018a; Qasim et al., 2018a, b). Likewise, Radoslavov et al. (2017) explained the interaction and divergence of various *Apis* subspecies under various genes. Since, based on COI gene sequences, a comprehensive divergence was calculated for various localities as well as country wise, and all sequences were grouped into two groups, and determined their inter-specific maximum as well as interspecific mean distances by MEGA 7 (*Table 1*). The maximum interspecific distance (2.36%) was observed for FD colonies whereas maximum intraspecific distance was noted among FD and FQ colonies, also at 2.10%, because FQ colonies presented minor percent distance within the entire location. Likewise, maximum mean intraspecific distance was observed between FD and TW location, which was 0.31% only. However, overall highest mean value of divergence was observed for Pakistan (1.10%), while highest maximum value of divergence was observed for overall locations (3.88%) (*Table 1*).

Genetic variability indices were calculated up to various levels, like species, genus and family, to find out genetic diversity in the mitochondrial DNA. For this purpose, different genes were selected by several researchers, like ND5 (Ozdil and İIlhan, 2014) and COI-COII inter-genic region genes (Pinto et al., 2014; Rahimi, 2015). Therefore, for mitochondrial DNA diversity of our sampled *A. mellifera* colonies, mutations were calculated in the COI region of various locations (*Fig. 2; Table 2*). Most of the colonies from various locations had shown minor genetic diversity due to commercial rearing. However, FD location had shown maximum genetic variability within the colonies. Therefore, colonies from FD location have genetic interaction with all other colonies of whole collection (*Fig. 1*). A recent study of Özdil and İlhan (2012) confirms our results

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_29332945
© 2018, ALÖKI Kft., Budapest, Hungary

that there are many sequence mutations within and among the colonies. However, p-values of Fu's *Fu* and Tajima's *D* test for colonies of most locations are non-significant, which proves minor variation. On the other hand, genetic variability has shown significant impact for overall country wise colonies.

Conclusion

Conclusively, we can say that the honeybee colonies collected from all locations present a hybrid situation between *A. m. ligustica* and *A. m. carnica*, as both subspecies are capable of interbreeding and are dominant in our collection. Likewise, Wu et al. (2017) has described that *A. ligustica* has been originated from two different sources in Taiwan, which supports our hypothesis that there is some possibility of hybridization between different colonies. On the basis of hybridization, there are seven subspecies in our entire collection on the base of mitochondrial DNA. This mitochondrial characterization of honeybees from different localities of Asia further extends our understanding on the genetic diversity and interaction of honeybee based on COI gene, in spite of rearing in the confined environment, as compared to wild environment. Thus, on the base of our findings, we conclude that there could be many other interactions among honeybee colonies from various locations, based on more prominent traits, like honey production, royal jelly production, reproduction as well as behavior. Therefore, with respect of our results, we suggest the use of other genes to find out genetic interaction among different countries' colonies, to improve the potential of honey and royal jelly production, as well as to assess the genetic diversity based on other genes.

Acknowledgements. This research was funded by National Natural Science Foundation of China (No. 31772684), the Fujian Provincial Department of Education for Provincial University (No. JK2017014) and the Earmarked Fund for Modern Agro-industry Technology Research System (No.CARS-45-KXJ3). We appreciate the efforts of Dr. Asif Aziz who helped us for sample collection from Pakistan, Professor Qingsheng Niu who collected samples from Apiculture Science Institute of Jilin Province.

Abstract. Waste of batik industry that is not well processed potentially contaminate the aquatic environment. Liquid waste concentration of 0%, 50%, 75%, and 100% was applied to vetiver (*Chrysopogon zizanioides* L.) grown in floating wetland system for treatment of batik industry liquid waste. Research was conducted in Akademi Kimia Analis (AKA) Bogor, Indonesia. This study aimed to determine the ability of vetiver for reducing the concentration of NH_3 and NH_4^+, TAN, BOD, COD, and total chromium. 50% of batik waste water was revealed to be the most suitable concentration treated by vetiver in floating wetland, since it could reduce not only ammonia, confirmed by biplot analysis, but also 40.29% total chromium concentration.
Keywords: *ammonia, batik, chromium, wastewater, wetland*

Introduction

The batik industry in Indonesia has been progressing very rapidly, especially after UNESCO designated Indonesian batik as a Masterpiece of Oral and Intangible Heritage of Humanity on 2 October, 2009. Raw materials for batik production such as chemicals in the form of dyes and supporting materials such as water used in the washing and rinsing process, potentially become batik liquid waste. Batik is mostly produced in home industries that do not have wastewater treatment. The batik liquid waste is directly disposed to canals or rivers, causing a negative impact on the environment. There are two types of dyes used in batik product, namely natural and synthetic. Natural dyes include indigosol and remazol black B (Holkar et al., 2014) and synthetic dyes are nitroso, nitro, azo, stilben, diphenyl methane, triphenyl methane, acridine, kinolin, indigoida, aminokinone, anine and indophenol (Al-kdasi, 2004). Various metal complex dyes (chromium, cobalt, copper and nickel complex dyes) are widely used in textile industries as coloring agent (Aksu and Balibek, 2010). The use of chromium metal in the textile dyeing process will have an impact on the environment and cause poisoning in waters (Akar and Tunali, 2006). The presence of chromium in waters is found in two forms: chromium valence III (Cr^{3+}) and Chromium VI (Cr^{6+}) ions. Chromium valence VI is more toxic than Chromium valence III as it is difficult to decompose.

Phytoremediation is a cost effective and ecofriendly technique to clean contaminated soil and wastewater. Phytoremediation is the use of green plants including forb grass and wood species to remove environmental contamination such as heavy metals, trace

elements, organic compounds, and radioactive compounds in soil or water (Hegazy et al., 2011; Mojiri, 2012) to absorb pollutants. *C. zizanioides* exhibits good growth when grown on some types of wastes, such as fish farming wastes in aquaponic systems (Effendi et al., 2015a, b, c, 2016), crude oil contaminated waters (Effendi et al., 2017), tofu production wastewater (Seroja et al., 2018). It can improve the quality of the wastewater (Bedewe, 2010; Boonsong and Chansiri, 2008; Yeboah et al., 2015) and decrease Trichloroethylene (TCE) from contaminated soil by 98% (Janngam, 2010). In addition, *C. zizanioides* is able to absorb N and P (Darajeh, 2014), heavy metals, tolerant to herbicides and pesticides (Truong et al., 2010); to utilize tilapia cultivation waste (Delis et al., 2015), freshwater crayfish cultivation waste (Effendi et al., 2015b), and vaname shrimp aquaculture waste (Syafrudin, 2015); lowering chromium content in mud (Rodríguez et al., 2010). The research aimed at using vetiver plant in reducing NH_3, NH_4, TAN, BOD, COD, and total chromium of batik liquid waste in floating wetland system.

Materials and method

Liquid waste originated from batik industry in Jababeka Cikarang industrial area, Indonesia. Water quality analysis was conducted at the Laboratory of Environmental Test and Laboratory of Polytechnique of Akademi Kimia Analis (AKA) Bogor. The study used *C. zizanioides* as a pyhtoremediator plant. The treatments consisted of wastewater concentration of PL0 control (0% waste), PL50 (50% waste), PL75 (75% waste), and PL100 (100% waste) with triplicates. Into each batik liquid waste treatment was spiked Potassium dichromate as Cr^{6+} to increase chromium concentration up to 2 ppm. Concentration of the added chromium content refers to the Regulation of the Minister of Environment No. 5 of 2014 on waste of batik and textile industry of 0.5-1 ppm.

C. zizanioides are washed and placed in a plastic tube stored in a container (25 L) of water and nutrient solution of A & B mix consisting of N, P, K, Mg, B, Cu, Mn, Mo, and Fe. Each container comprised of 6 pots containing 3 clumps vetiver of each pot. The plants were acclimatized for 3 weeks in floating wetland system where the roots were submerged in the water (Darajeh, 2014) before used.

Water quality parameters of temperature, Total Suspended Solid (TSS), pH, total ammonia (NH_3), ammonium (NH_4), Total Ammonia Nitrogen (TAN), Biochemical Oxygen Demand (BOD), Chemical Oxygen Demand (COD) and total chromium (in water, root, leaf) were determined. Measurements were taken weekly, referring to APHA (2012). NH_4^+ (*Eq. 1*) and NH_3 (*Eq. 2*) concentrations were calculated as follows (*Table 1*) (Strickland and Parsons, 1972).

$$NH_{4^+}(mg/l) = \frac{TAN}{1 + \text{antilog}(pH - pKa)}^{+} \quad \text{(Eq.1)}$$

$$NH_3(mg/L) = TAN - NH_{4^+} \quad \text{(Eq.2)}$$

Table 1. *Value of pKa according to value of temperature*

Temperature (°C)	5	10	15	20	25	30
pKa	9.90	9.73	9.56	9.40	9.24	9.09

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

Statistical analysis was performed using ANOVA followed by Duncan test ($p < 0.05$). Correlation of Pearson and biplot analysis were also calculated using SAS software version 9.1.

Results and discussion

Growth performance of vetiver as phytoremediator of batik production wastewater is elaborated in detail and published elsewhere (Tambunan et al., 2018). Below water quality improvement is described following remediation process, considering especially nitrogen concentrations (TAN, NH_4^+, NH_3) and chromium reduction. Initial characteristic of batik wastewater is presented in *Table 2*.

Table 2. *Characteristics of inlet of batik wastewater (Tambunan et al., 2018)*

Parameter	Unit	Batik/textiles wastewater	Regulation of the Minister of Environment No 5, 2014
Temperature	°C	30	----
TSS	mg/L	268	50
pH	-	9.8	6.0 – 9.0
Total ammonia	mg/L	1.27	8.0
BOD	mg/L	966.83	60
COD	mg/L	2900.48	150
Total chromium	mg/L	2.34 (spike)	1.0

Temperature ranged from 28.10 to 29.10 °C. Based on statistical analysis, the temperature during the treatment was not significantly different, but observation time had significant effect on temperature ($p < 0.05$). The pH ranged between 7.30-9.76, pH on day T0-T28 was not significantly different ($p > 0.05$), however when compared with day T35-T49 it was significantly different ($p < 0.05$). According to Singh et al. (2014) plants effectively absorbed waste at pH of 6-9. pH 7-8 is the optimal pH for vetiver in removing BOD, while at pH < 5 vetiver performance in eliminating BOD ranged 10-40%. High pH (12) can inhibit vetiver performance (Darajeh, 2016).

BOD in all treatments ranged 1.80 – 3.68 mg/L, meanwhile before treatment BOD was 117.28 mg/L (PL50), undergoing reduction (97.76-98.47%) after treatment. Each treatment and observation time had significant effect on BOD ($p < 0.05$). *Figure 1* shows the fluctuations of the BOD during observation time. Drastic decline occurred on day T7 and T14, reducing BOD concentration occurred until T49. COD after treatment ranged 60.89-95.18 mg/L (initial range of 773.50-806.00 mg/L). Statistical analysis of each treatment and time of observation pointed out significant effect on COD ($p < 0.05$). It is shown in *Figure 2* that from T0 to the end of the observation for each treatment, COD showed the same pattern of decline, but from T14 to T21 increased from 152 mg/L to 262 mg/L, followed by a subsequent decrease at the end of the observation.

Total Ammonia Nitrogen (TAN) consists of unionized ammonia (NH_3) and ionized ammonia (NH_4^+). Ammonia (NH_3) is toxic to aquatic organisms, while ammonium (NH_4^+) is harmless and it is in a form that plants can harness as a source of nutrient (Effendi, 2003). The percentage of NH_3 in the waters decreased with decreasing pH and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

water temperature. TAN concentration increased from day T0-T7, then decreased drastically on day T14 (*Fig. 3*). Degradation of organic matter inhibits the rate of nitrification thus disrupting bacterial growth, inhibiting ammonia oxidation, and causing accumulation of TAN (Chen et al., 2005). Ammonia is water-soluble and very harmful to fish, and most tropical species that are generally more sensitive to ammonia (Effendi et al., 2015c; Wang and Leung, 2015). In this study the ammonia concentration increased on day 7, then decreased on day 14 drastically (*Fig. 4*).

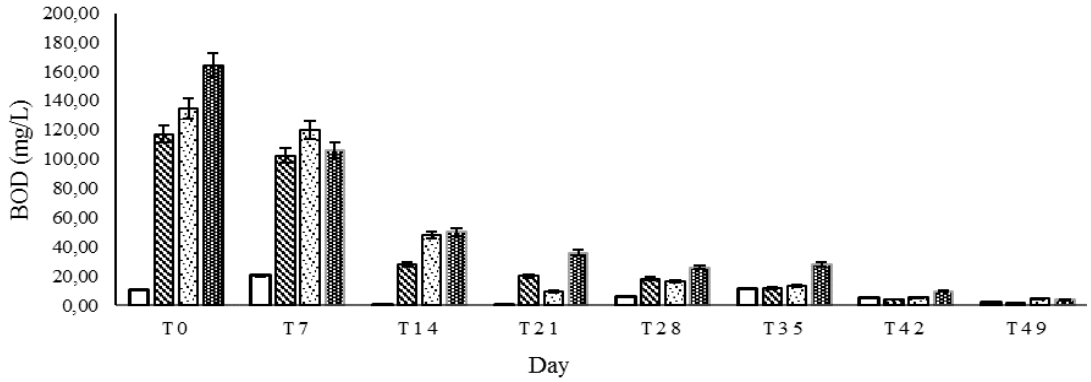

Figure 1. *BOD decrease during the observation period. Description: PL0 (without waste 0%), PL50 (50% waste), PL75 (75% waste), PL100 (100% waste)*

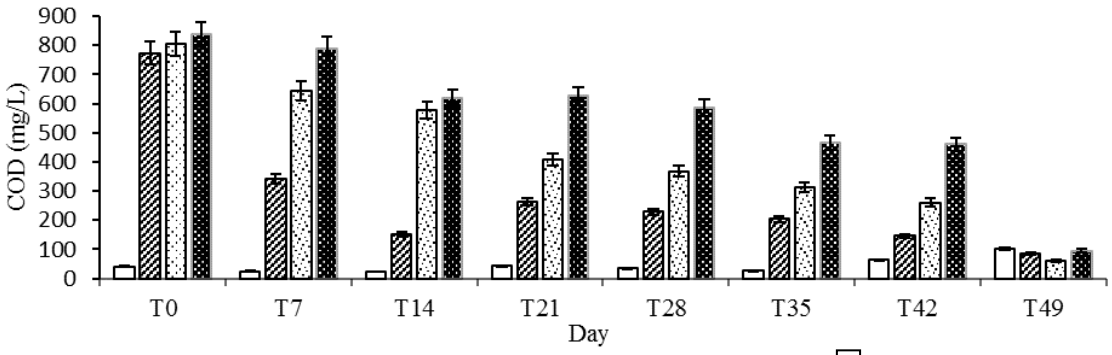

Figure 2. *COD decrease during the observation period. Description: PL0 (without waste 0%), PL50 (50% waste), PL75 (75% waste), PL100 (100% waste)*

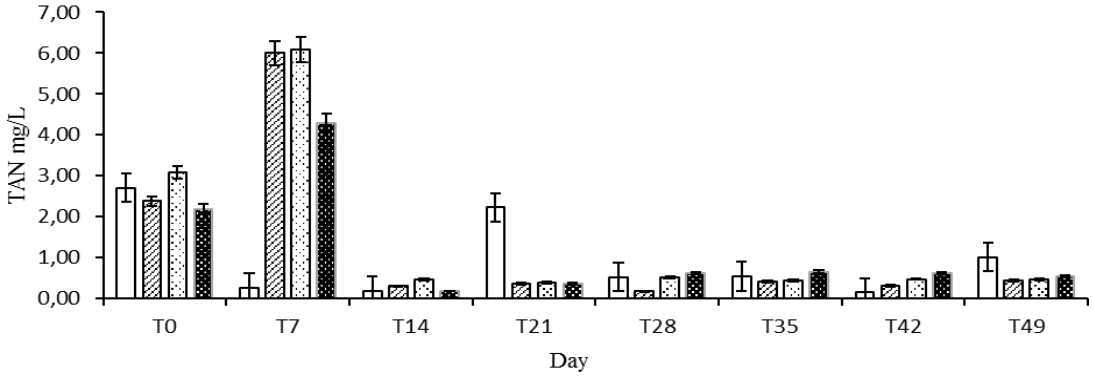

Figure 3. *Total ammonia nitrogen (TAN) reduction during observation period. Description: PL0 (without waste 0%), PL50 (50% waste), PL75 (75% waste), PL100 (100% waste)*

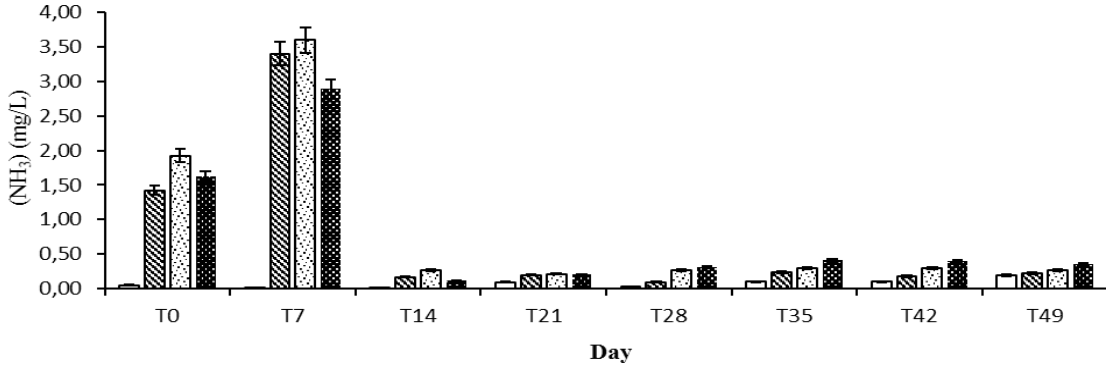

Figure 4. *Ammonia reduction during observation period. Description: ☐ PL0 (without waste 0%), ▨ PL50 (50% waste), ⊡ PL75 (75% waste), ▩PL100 (100% waste)*

The NH_3 concentrations at the end of the observations for the PL0, PL50, PL75 and PL100 treatments were 0.19 mg/L, 0.22 mg/L, 0.26 mg/L, 0.35 mg/L, respectively. Initial total ammonia concentration was 1.42-1.92 mg/L. The NH_3 difference occurred at day 14. Percentage of NH_3 removal in each treatment of PL50, PL75 and PL100 was 84.51%, 86.47% and 78.14%, respectively. The results of this study are not much different from the research of Effendi et al. (2015b) of 84.6% NH_3 removal in freshwater lobster cultivation waste using kale, but this result is higher than the result of Delis et al. (2015) with NH_3 removal percentage of 31.3-48.36%, and Syafrudin et al. (2015) of 37.14-43.83% NH_3 removal in shrimp farming waste in wetland system.

Figure 5 shows the NH_4^+ concentration which increased on day 7, then decreased until day 49. Decreasing NH_4^+ during the experiment indicated that the vetiver could absorb and utilize NH_4^+. High NH_4^+ fluctuations during the study were observed in PL0 (control), where day T0 and day T21 increased and decreased until day T49. The highest percentage of NH_4^+ degradation (82.57%) existed at PL75, greater than the result of research on shrimp farming waste in hydroponic system (Syafrudin et al., 2015).

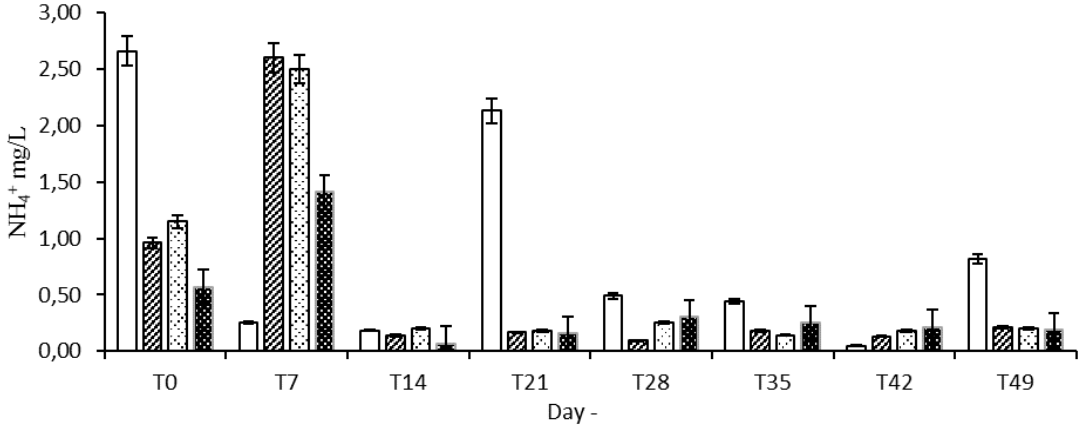

Figure 5. *Ammonium (NH_4^+) reduction during observation period. Description: ☐ PL0 (without waste 0%), ▨ PL50 (50% waste), ▨ PL75 (75% waste), ▩ PL100 (100% waste)*

Percentage of TSS decreases at PL50, PL75, and PL100 were -38%, -49%, and -72% respectively, indicating that an increase of TSS took place (*Table 3*). This is likely due

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_29472956
© 2018, ALÖKI Kft., Budapest, Hungary

to the addition of AB mix nutrients and remediation process with vetiver, so that TSS at the end of the observation (1183 mg/L) was greater than that at the beginning of the experiment (1673 mg/L). The higher the concentration of waste was the higher TSS concentration could be observed. The organic and inorganic compounds contained in the wastewater are bonded in suspended material (Effendi, 2003). Water quality parameters at PL100 generally had the smallest percentage of decline compared to those at PL50 and PL75.

Table 3. *Reduction percentage of all water quality parameters of each treatment*

Parameter	Unit	PL50		Reduction (%)	PL75		Reduction (%)	PL100		Reduction (%)
		Start	End		Start	End		Start	End	
TSS	mg/L	1183	1637	-38	1579	2346	-49	2127	3668	-72
pH	-	9.30	9.13	1.75	9.35	9.24	1.08	9.56	9.39	1.72
TAN	mg/L	2.38	0.44	81.69	3.07	0.46	85.01	2.19	0.54	75.52
NH_4^+	mg/L	0.96	0.56	77.50	1.15	0.60	82.57	0.57	0.39	67.17
NH_3	mg/L	1.42	0.22	84.51	1.92	0.26	86.47	1.62	0.35	78.46
BOD	mg/L	117.28	1.80	98.47	134.77	2.52	98.13	164.21	3.68	97.76
COD	mg/L	773.50	84.72	89.05	806.00	60.89	92.45	788.64	95.18	88.65
Total chromium	mg/L	1.07	0.64	40.29	1.52	0.99	34.87	2.17	1.98	8.85

TAN at each treatment was significantly different, but ammonium (NH_4^+) was not significantly different. Meanwhile, NH_3 concentration at PL0 was significantly different from NH_3 at PL50, PL75, and PL100. The percentage of NH_3 reduction for each treatment was PL50 (84.51%), PL75 (86.47%), and PL100 (78.46%). Fluctuation of TAN and ammonium at PL0 throughout the experiment might be related to the fact that the plant is naturally associated with bacteria living in its root submerged in the system.

The results of this study are still lower than the research using lettuce with percentage of NH_3 decrease of 90.1% (Effendi et al., 2015c), but higher than research using the combination of *Ipomea aquatica* and bacteria in the aquaponic system as much as 81% (Effendi et al., 2015d). Ammonia when discharged into the waters will disturb the life of aquatic biota such as fish (Effendi et al., 2015c). Meanwhile total chromium was significantly different in all treatments. In addition, total chromium reduction decreased with increasing waste concentration namely 40.29% (50% waste), 34.87% (75% waste), and 8.85% (100% waste). Bioremediation of chromium complex dyes in synthetic solutions and actual effluent was performed using growing *Aspergillus tamarii* in batch and continuous bioreactors. Maximum removal of chromium (94.00 ± 0.10 and 77.50 ± 0.10%) was obtained from synthetic solutions (100 mg/L) of acid brown 45 and acid blue 158 dyes, respectively in batch mode using *Aspergillus tamarii* (Ghosh et al., 2017). Chromium accumulation in root and leaf is presented in *Table 4*.

Plant growth parameters (clump, wet weight) correlated positively with nitrogen (TAN, NH_4, NH_3), BOD and COD with significant level of 0.05. This illustrated that plant might utilize nutrient resulting from organic substance decomposition. Meanwhile wet weight and Relative Growth Rate (RGR) correlated negatively with TSS (-0.761) and total chromium (-0.310), implying that both parameters disrupted the growth of plant (*Table 5*).

Different treatments (PL0, PL50, PL75 and PL100) are illustrated by bold dots. These four points show the proximity of treatment with growth and water quality parameter. The parameters that have dominant proximity to PL0 and PL50 are mostly plant growth parameters (clump number, height, weight wet, RGR). This phenomena denoted that 50% waste was better for supporting the growth of plant compared to 75% and 100% waste. Meanwhile PL75 and PL100 were surrounded by water quality parameters (TAN, NH_4, BOD, COD, pH, TSS, chromium in water), as consequences of larger concentration of waste. Conversely, growth of plants in the form of plant height, wet weight and number of clumps become lower with increasing concentration of waste, since those parameters were away from PL75 and PL100 in biplot analysis.

Conclusion

In this particular research, 50% of batik waste water treated by vetiver in floating wetland was revealed as the most suitable concentration, resulting in better water quality parameter reduction, and total ammonia concentration reduction.

This research result provides simple promising biological treatment of batik production wastewater instead of chemical treatment. The application of this research in batik production wastewater location will soon be pursued.

(Received 17th Feb 2018; accepted 9th May 2018)

Abstract. This study was carried out on the fatty acid, mineral and proximate compositions of ten sweet almond genotypes and two commercial varieties named as Ferragnes and Ferraduel grown in the same ecological conditions known as the Firat riverside region during two consecutive years. In this context, the crude oil (Co), crude protein (Cp), total sugar (Ts), total ash (Ta) and moisture (Mo) contents from the almond genotypes and cultivars ranged from 48.69 to 55.8%, 20.41 to 25.82%, 2.92 to 5.27%, 3.29 to 4.66% and 2.52 to 3.75%, respectively. The genotypes and cultivars showed a varied mineral content as well. Potassium (K) was the main mineral in all genotypes and cultivars, ranging from 679.53 to 986.63 mg100 g^{-1}; phosphorus (P) was the second most abundant mineral, ranging from 584.57 to 697.31 mg100 g^{-1}; followed by magnesium (Mg) and calcium (Ca), ranging from 325.27 to 381.93 mg100 g^{-1}, 250.15 to 332.19 mg100 g^{-1}, respectively. Of the identified fatty acids, oleic acid (Oa) (69.76–72.02%) was the predominant fatty acid, followed by linoleic acid (La) (18.82–21.62%), palmitic acid (Pa) (5.62–7.76%), and stearic acid (Sa) (1.20-1.69%). Other fatty acids were present at trace amounts. The unsaturated (Ufa)/saturated fatty acid (Sfa) ratios ranged from 9.29 to 12.12. From the results of the present study, we can conclude that the kernels of almond genotypes and cultivars are being potential sources of valuable oil which might be used for edible and other industrial purposes.
Keywords: *nut, ecology, chemical content, ANOVA, Turkey*

Introduction

Sweet almond (*Prunus amygdalus* L.) is one of the important nut crops. It is cultivated and produced for multipurpose comparing to other commercial nuts in the world (Kester et al., 1991). Turkey is one of the significant countries in the world with respect to almond production. The total annual world almond production is about 3.214.303 tons. USA, Australia, Spain, Morocco, Iran and Syria produce 2.002.742,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_29572971
© 2018, ALÖKI Kft., Budapest, Hungary

72.709, 202.339, 112.681, 147.863 and 88.841 tons of almond annually, respectively. Turkey ranks seventh in the world, producing 85.000 tons of almond (FAO, 2016).

The fruits such as almond, walnut, pistachios and hazelnut, in which classification the almond seeds are generally included, are very requested products and their destinations are the direct consumption after toasting, the confectionery industry and the production of cakes, sweets, and almond candies (Piscopo et al., 2010; Simsek, 2016; Simsek et al., 2017). These fruits are typically high in fat but their fatty acid composition is advantageous in relation to risk of coronary heart disease (Lei et al., 2014). From the pre-agricultural era to the present day, almonds have been significant part of the human diet, providing micronutrients, macronutrients, and various bioactive constituents (Simsek, 2016). Kernels of almond genotypes and cultivars have been used to combat important diseases of the heart and autoimmune system, rheumatoid arthritis, and cancer in recent years (Jenkins et al., 2002).

The chemical composition of almond fruit is of great importance to establish its nutritive value and its quality for the recent concern of consumers over ensuring a healthy life style (Nanos et al., 2002; Simsek and Kizmaz, 2017). Fatty acid, mineral and proximate compositions of almond, pistachio, walnut, hazelnut and chestnut kernels are nutritionally very valuable (Bliss, 1999). These chemical contents can be influenced by ecological conditions, location and technical and cultural practices (Askin et al., 2007).

The proximate composition of ten sweet almond genotypes in Diyarbakir region ranged from 43.50 to 54.81% crude oil (Co), from 21.18 to 32.90% crude protein (Cp), from 3.08 to 4.43% moisture (Mo) and from 2.54 to 4.42% total ash (Ta) (Simsek and Demirkiran, 2010). The fatty acid compositions of almond genotypes ranged from 48.80 to 88.40% oleic acid (Oa), from 11.30 to 33.20% linoleic acid (La), from 4.60 to 9.50% palmitic acid (Pa) and from 1.00 to 3.40% stearic acid (Sa) (Kiani et al., 2015). In addition, the mineral contents of almond cultivars ranged from 525.46 to 793.86 mg100 g^{-1} potassium (K), from 154.15 to 275.87 mg100 g^{-1} magnesium (Mg) and from 89.97 to 176.50 mg100 g^{-1} calcium (Ca) (Piscopo et al., 2010).

Many studies have been carried out especially dealing with the proximate, fatty acid and mineral compositions of almond genotypes grown in Turkey (Simsek and Demirkiran, 2010; Agar et al., 1998; Aslantas et al., 2001; Askin et al., 2007; Celik et al., 2010; Beyhan et al., 2011; Celik and Balta, 2011; Ozcan et al., 2011; Balta, 2013; Simsek and Kizmaz, 2017).

Hundreds of almond genotypes are grown in this location. They have grown heterozygously due to generative reproduction. So, the fruits that are handled may not be similar to each other as they can be. These genotypes have not been cultivated under regular care conditions. Ferragnes and Ferraduel almond varieties are also grown under good maintenance conditions. Because these varieties are vegetatively propagated, these have homozygote properties, the fruits obtained from these varieties are similar.

To our best of knowledge, no fatty acid, proximate and mineral composition studies on almond genotypes and cultivars have been reported in this area. Therefore, the present study is very significant. Therefore, the objectives of the present work were to determine the levels of significant fatty acid, mineral and proximate compositions in kernels of various genotypes and commercial cultivars of sweet almond. The study results are expected to contribute to breeding studies, commercial production, nutritional and technical applications, and healthy diets in future.

Materials and methods

Materials

This study was carried out in the Firat riverside region of Hilvan district (Sanliurfa) of Southeast Turkey (FRH, 2018) in *Figure 1*. It has been stated that the soils in this region are sandy-loamy, calcified and / or humus and mostly rich in plant nutrients. In this area, a warm and temperate climate is prevalent. It receives more rainfall during winter time. Summers are generally hot and draught and as winters are temperate and wet and wet in Hilvan district with an altitude 591 m asl (CDO, 2018) and with an annual precipitation of 771.8 mm (Sanliurfa, 2018). In addition, temperature values of this region are given in *Table 1* (CDO, 2018). Summers are arid and very hot, winters are rainy and partly temperate. The area of the province which is 55 km away from Sanliurfa is 1.278 km^2 (IHI, 2018). In the Southeastern Anatolia Region, Şanlıurfa province is surrounded by an illegal district of Hilvan, with Adiyaman and Siverek in the north, Siverek in the east, Central district in the south, Bozova in the south, and Adiyaman in the west. The district lands located in the northeastern part of Şanlıurfa Plateau have a wavy land structure decreasing from the southeast to the southwest (IHI, 2018). The Firat riverside region of Hilvan district (Sanliurfa) of Southeast Turkey has a distinctive microclimatic environment derived from the Firat River. Ecological conditions around this river are similar mostly to those of Mediterranean region but are not similar to those of Sanliurfa province in the Southeast Anatolia region. In this ecology, there are also fruit trees such as almond, mulberry, pomegranate, figs, walnut, apricot, pistachio, cherry and forest trees such as pine, poplar and sycamore flourish (TSI, 2017). The fruits for determination of fatty acid, mineral and proximate compositions of ten genotypes and two commercial cultivars (Ferragnes and Ferraduel) of almond were harvested by hand during the years 2016-2017. After harvest, all samples of kernels were immediately dried and stored in their shells at room temperature until analysis.

Figure 1. *Map of districts in Sanliurfa province*

Table 1. *Temperature parameters of Hilvan district of Sanliurfa province*

Climatical parameters	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec
Avg. temp. (°C)	4.60	6.10	10.10	15.10	20.60	26.40	30.60	30.2	26.20	19.40	12.40	7.00
Min. temp. (°C)	1.00	2.20	5.30	9.50	14.10	19.50	23.50	23.10	19.10	13.30	7.30	3.10
Max. temp. (°C)	8.30	10.10	15.00	20.80	27.10	33.30	37.80	37.40	33.30	25.60	17.50	10.90

Since the characteristics of local almond genotypes and varieties were not affected by any year, the average values of 2 years were evaluated as a whole. Furthermore, chemical analysis for fatty acids, proximate acids and minerals is very expensive. Therefore, in a number of previous studies averages of a maximum of 2 years are evaluated on their contents. Therefore, samples of 30 g (10 g kernel x three replications) for every genotype or cultivar were taken from ten sweet almond genotypes and from two commercial varieties in each year.

Proximate composition of sweet almond genotypes and cultivars

The almonds were dried and stored in their shells at room temperature prior to analysis. The samples were finely grinded and their moisture (Mo) content was determined before the proximate analysis. Moisture (Mo) content was analyzed and calculated according to the methods given by the Turkish Standard Institute (AOAC, 1990). For crude oil (Co) analyses, the samples were homogenized and subjected to extraction for 6 h with petroleum ether (boiling range 30-60 °C) in a Soxhlet apparatus. The extracted total crude oil was dried over anhydrous sodium sulphate and the solvent was removed under reduced pressure in a rotary film evaporator. Crude oil (Co) percentages of the genotypes and cultivars were determined by weight difference (AOAC, 1990). Total ash (Ta) content was determined in crucible to a muffle furnace at 900 °C for 8 h (AOAC, 1990). Total sugar (Ts) content was determined by the Anthrone method (Kaplankiran, 1984). The nitrogen content was estimated by the Kjeldahl method and was converted to crude protein (Cp) content by using the conversion factor 6.25 (AOAC, 1990).

Mineral composition of sweet almond genotypes and cultivars

The magnesium (Mg), calcium (Ca), iron (Fe), copper (Cu), zinc (Zn) and manganese (Mn) contents were determined via Perkin Elmer 703 atomic absorption spectrophotometry, and the sodium and potassium (K) contents were measured via flame emission spectrometry. Phosphorus (P) was measured by colorimetric method (Saura Calixto and Canellās, 1982; Simsek and Kizmaz, 2017).

Fatty acid composition of sweet almond genotypes and cultivars

The crude oil (Co) contents were determined according to standard procedure (AOAC, 1990). For the preparation of fatty acid methyl esters (FAMEs) 0.4 g crude oil (Co) of the kernel samples were dissolved in 4 mL of isooctane and methylated in 0.2 mL 2 M methanolic KOH. Analysis of FAMEs was performed on an Agilent 6890

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_29572971
© 2018, ALÖKI Kft., Budapest, Hungary

series Gas Chromatography equipped with flame-ionization detector and a 60 m capillary column (internal diameter = 0.25 mm) coated with 0.25 μm of 50%-cyanopropyl-methylpolysiloxane (J&W Scientific, Folsom, CA, USA). Helium was used as a carrier gas at a flow rate of 1.5 mL min^{-1} and a split ratio of 1:10. The temperatures of the injector and detector were 250 °C and 260 °C, respectively. The oven was programmed to hold at 120 °C for a 5 min, and then to increase the temperature to 240 °C at a rate of 15 °C min^{-1} and to hold that temperature for 20 min (Basturk et al., 2007). FAMEs were identified by comparison of their retention times and equivalent chain lengths in terms of standard FAMEs (Supelco. 47885-U). FAMEs of samples were quantified according to their percentage areas (AOAC, 1990).

Statistical analysis of sweet almond genotypes and cultivars

Statistical analyses of proximate, fatty acid and mineral compositions of sweet almond genotypes and cultivars were performed in triplicate. All data were subjected to analysis of variance using JMP 5.0.1 (one-way ANOVA).

Results

Proximate composition of sweet almond genotypes and cultivars are shown in *Table 2.* According to this table, crude oil (Co), crude protein (Cp), total ash (Ta), moisture (Mo) and total sugar (Ts) contents of 10 almond genotypes and two commercial almond cultivars ranged from 48.69 (SAHI301) to 55.81% (FERRAGNES), from 20.41 (FERRAGNES) to 25.82% (SAHI301), from 3.29 (SAHI278) to 4.66% (SAHI6), from 2.52 (SAHI6) to 3.96% (SAHI324) and from 2.97 (FERRADUEL) to 5.27% (SAHI72), respectively.

The amount of the minerals studied in the sweet almond genotypes and cultivars are shown in *Table 3,* referred to non-dried matter. According to this table, among the genotypes and cultivars studied, SAHI36 genotype contained the highest potassium (K) (986.63 mg100 g^{-1}). The phosphorus (P), magnesium (Mg), and calcium (Ca) contents ranged from 584.57 (FERRADUEL) to 697.31 mg100 g^{-1} (SAHI36), from 325.27 (SAHI132) to 381.93 mg100 g^{-1} (SAHI324) and from 250.15 (SAHI250) to 332.19 mg100 g^{-1} (SAHI198), respectively. Sodium (Na), iron (Fe), zinc (Zn), manganese (Mn) and copper (Cu) amounts ranged from 9.20 (SAHI301) to 16.06 mg100 g^{-1} (SAHI72), from 6.08 (FERRAGNES) to 10.62 mg100 g^{-1} (SAHI6), from 4.80 (FERRAGNES) to 9.53 mg100 g^{-1} (SAHI6), from 2.52 (SAHI36) to 4.76 mg100 g^{-1} (SAHI72) and from 2.02 mg100 g^{-1} (SAHI250) to 3.97 (SAHI232), respectively.

Fatty acid composition of promising almond genotypes and cultivars are shown in *Table 4*. According to this table, while oleic acid (Oa) content ranged from 69.76 (SAHI232) and 72.02% (SAHI250), linoleic acid (La) content changed from 18.82 (SAHI72) to 21.62% (SAHI232) in the samples. Palmitic acid (Pa) contents were found from 5.62 (SAHI132) and 7.76% (SAHI301) in the samples (*Table 3*). The stearic (Sa), myristic (Ma), palmitoleic (Paa) and linolenic acid (Lia) contents ranged from 1.20 (SAHI198) to 1.69% (SAHI72), from 0.27 (SAHI250) to 0.55% (FERRADUEL), from 0.19 (SAHI301) to 0.54% (SAHI72), and from 0.07 to 0.09%, respectively.

Discussion

Proximate composition of sweet almond genotypes and cultivars

This study was carried out on the almond genotypes and commercial varieties named as Ferragnes and Ferraduel grown in the same location known as the Firat riverside region during two consecutive years. In this study, proximate contents of the genotypes and varieties were compared at the same location. According to the results from the one-way ANOVA analysis, the differences between the proximate composition of the genotypes and/or the varieties were shown in different letters statistically and were presented in *Table 2*. In this context in this study, the samples of sweet almond genotypes and cultivars showed only a relatively small variation. Crude oil (Co) content is a relatively stable feature independent on the different almond genotypes and cultivars. All genotypes and varieties except for SAHI250 and SAHI301 genotypes are rich in crude oil because their crude oil content is greater than 50%. In various almond

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_29572971
© 2018, ALÖKI Kft., Budapest, Hungary

varieties that differed in genotypes, the oil (Co) contents were previously reported to range from 43.50 to 54.81% (Simsek and Demirkiran, 2010), from 52.08 to 57.49% (Agar et al., 1998), from 48.80% to 55.70% (Ozcan et al., 2011), from 52.00 to 56.00% (Barbera et al., 1984), from 53.00 to 62.00% (García-López et al., 1996), from 30.0 to 51.00% (Martins et al., 2000) and from 48.93 to 55.96% (Simsek and Kizmaz, 2017). In the present study, the oil (Co) contents were partly similar to those previously recorded. The almond kernel has high crude oil (Co) content, and the kernels do not constitute a bulky diet. Since all genotypes and varieties have crude protein values greater than 20%, they are protein rich. In various works, the crude protein (Cp) content varied from 22.50 to 25.80% (Barbera et al., 1984), from 18.00 to 25.00% (Soler et al., 1989), from 14.50 to 24.00% (Mbah et al., 2013) and from 20.81 to 25.99% (Simsek and Kizmaz, 2017). In the present study, the crude protein (Cp) contents agreed mostly well with earlier reports (Barbera et al., 1984; Soler et al., 1989; Mbah et al., 2013; Simsek and Kizmaz, 2017). Because the crude protein (Cp) content is high, the almond genotypes and cultivars may serve as dietary supplements for unhealthy people who require crude protein and suffer from hypertension. Sugar is found in both almond kernels and other plant tissues, and can be digested, absorbed and metabolised by humans to provide energy**.** In this study, because the genotypes SAHI232, SAHI250, SAHI278, SAHI301 and SAHI324, and the variety FERRAGNES have a sugar content greater than 4%, they are rich of sugar. In previous works, the total sugar (Ts) content ranged from 2.56 to 4.17% (Aslantas et al., 2001), from 3.10 to 5.30% (Romojaro et al., 1988), from 2.60 to 4.00% (Kazantzis et al., 2003), from 2.10 to 7.40% (Ahrens et al., 2005) from 2.10 to 5.50% (Amrein et al., 2005) and from 2.91 to 4.06% (Simsek and Kizmaz, 2017). In the present study, total sugar (Ts) content in harmony with earlier studies (Aslantas et al., 2001; Romojaro et al., 1988; Kazantzis et al., 2003; Ahrens et al., 2005; Amrein et al., 2005; Simsek and Kizmaz, 2017).

The importance of the moisture content of the kernels is great. Enzymatic activities in fruit with high moisture are higher than those in dry fruits. In general, the availability of moisture (Mo) encourages the growth of microorganisms and hence microbial spoilage of food, so it is not advisable to store almond kernels fresh. It has been determined that genotypes and varieties in this study do not have high moisture. In various studies, the moisture (Mo) contents changed from 3.08 to 4.43% (Simsek and Demirkiran, 2010), from 3.49 to 4.96% (Oliveira Sousa et al., 2011) and from 2.28 to 3.70% (Simsek and Kizmaz, 2017). In the present study, the moisture (Mo) content agreed with earlier data (Simsek and Demirkiran, 2010; Oliveira Sousa et al., 2011). The moisture (Mo) content should be reduced by drying to increase the safe storage time. The total ash (Ta) content was reported from 2.54 to 4.42% (Simsek and Demirkiran, 2010), from 2.74 to 3.05% (Ozcan et al., 2011), from 3.50 to 4.10% (Mbah et al., 2013), from 2.60 to 4.60% (Ahrens et al., 2005), from 2.30 to 3.70% (Ruggeri et al., 1998) and from 3.12 to 4.69% (Simsek and Kizmaz, 2017). Ash contents are in harmony with earlier reports (Simsek and Demirkiran, 2010; Ozcan et al., 2011; Mbah et al., 2013; Ahrens et al., 2005; Ruggeri et al., 1998; Simsek and Kizmaz, 20017). All genotypes and varieties except for SAHI250 and SAHI301 genotypes with respect to crude oil, all genotypes with respect to crude protein values and the genotypes SAHI232, SAHI250, SAHI278, SAHI301 and SAHI324, and the variety FERRAGNES with respect to sugar contents in this study are very important. Proximate acid compositions of almond genotypes and cultivars can change according to the genetic differences, maintenance and ecological conditions.

Mineral composition of sweet almond genotypes and cultivars

In this study carried out on the almond genotypes and commercial varieties named as Ferragnes and Ferraduel grown in the same location known as the Firat riverside region during two consecutive years, the mineral composition of the genotypes and varieties were compared at the same location. According to the results from the one-way ANOVA analysis, the differences between the mineral contents of the genotypes and/or the varieties were shown in different letters statistically and were presented in *Table 3*. In this context, the most abundant minerals are potassium (K) and phosphorus (P), followed by magnesium (Mg) and calcium (Ca), while sodium, (Na) iron (Fe), zinc (Zn), manganese (Mg) and copper (Cu) are scarce. Among the minerals studied, potassium (K), the phosphorus (P), magnesium (Mg), and calcium (Ca) contents were the highest compared to the other minerals. However, all of the sodium (Na), iron (Fe), zinc (Zn), manganese (Mg) and copper (Cu) were only present at trace amounts. Our results are in agreement with the mineral contents for kernels of several almond genotypes and cultivars described in previous studies. In this context, Aslantas et al. (2001) found that mineral contents of selected almond genotypes naturally grown in Kemaliye district ranged from 98.50 to 187.00 mg100 g^{-1} for Calcium (Ca), from 360.80 to 513.40 mg100 g^{-1} for Magnesium (Mg), from 403.90 to 800.00 mg100 g^{-1} for phosphorous (P), from 1677.30 to 2051.10 mg100 g^{-1} for potassium (K). Ozcan et al. (2011) determined that mineral contents of five almond cultivars collected in Antalya and Mugla provinces ranged from 1315.00 to 1510.00 mg100 g^{-1} potassium (K), from 793.00 to 938.00 mg100 g^{-1} phosphorous (P), from 298.00 to 404.00 mg100 g^{-1} magnesium (Mg), from 183.00 to 294.00 mg100 g^{-1} calcium (Ca), from 29.00 to 38.00 mg100 g^{-1} sodium (Na), from 20.00 to 27.00 mg100 g^{-1} iron (Fe) and from 4.00 to 6.00 mg100 g^{-1} zinc (Zn), respectively. Simsek and Kizmaz (2017) determined that mineral contents of almond genotypes grown in Beyazsu district ranged from 646.27 to 925.13 mg 100 g^{-1} potassium (K), from 562.53 to 701.93 mg 100 g^{-1} phosphorous (P), from 217.13 to 367.27 mg 100 g^{-1} magnesium (Mg) and from 190.97 to 317.13 mg 100 g^{-1} calcium (Ca), respectively. Saura Calixto and Canellās (1982) observed that mineral composition of seven sweet almond varieties ranged from 649.00 to 824.00 mg100 g^{-1} potassium (K), from 462.00 to 595.00 mg100 g^{-1} phosphorous (P), from 239.00 to 280.00 mg100 g^{-1} magnesium (Mg), from 218.00 to 299.00 mg100 g^{-1} calcium (Ca), from 4.80 to 12.50 mg100 g^{-1} sodium (Na), from 3.10 to 4.40 mg100 g^{-1} iron (Fe) and from 0.90 to 1.30 mg100 g^{-1} copper (Cu). Barbera et al. (1984) reported that mineral composition of two almond varieties changed from 1546.00 to 1685.00 mg100 g^{-1} potassium (K), from 253.00 to 259.00 mg100 g^{-1} phosphorous (P), from 640.00 to 678.00 mg100 g^{-1} calcium (Ca), from 447.00 to 494.00 mg100 g^{-1} magnesium (Mg), from 24.30 to 25.80 mg100 g^{-1} copper (Cu). Saura Calixto et al. (1981) also reported that mineral contents of almond cultivars consisted of 766.00 mg100 g^{-1} potassium (K), 364.00 mg100 g^{-1} phosphorous (P), 227.00 mg100 g^{-1} magnesium (Mg) and 185.00 mg100 g^{-1} calcium (Ca). In general, the mineral contents in this study agreed with earlier reports (Barbera et al., 1984; Saura Calixto et al., 1981; Saura Calixto and Canellās, 1982; García-López et al., 1996; Aslantas et al., 2001; Ozcan et al., 2011; Simsek and Kizmaz, 2017). Considering macro and micronutrient values in this study, K, P, Ca and Mg (macro nutrients) and Na, Mn, Fe, Cu and Zn (micro nutrients) in all genotypes and varieties are important and statistically significant.

The minerals of almonds and other nuts are obtained from the soil and water applied during production. Thus, the mineral contents of almond kernels are affected by many

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_29572971
© 2018, ALÖKI Kft., Budapest, Hungary

ecological factors and agronomic practices including geographic location, soil composition, water source, irrigation regime, fertiliser components, and other aids to agronomic production. The mineral content can be influenced by plant genotypes, cultivars, maintenance and ecological conditions.

Fatty acid composition of sweet almond genotypes and cultivars

Fatty acid content is the most common feature for fat and oil characterization. It is related to oxidative stability as well as to some nutritional characteristics. In this study carried out on the almond genotypes and commercial varieties named as Ferragnes and Ferraduel grown in the same location known as the Firat riverside region during two consecutive years, the fatty acid compositions of the genotypes and varieties were compared at the same location. According to the results from the one-way ANOVA analysis, the differences between the proximate composition of the genotypes and/or the varieties were shown in different letters statistically and were presented in *Table 4*. Fatty acid composition of sweet almond genotypes and cultivars were presented in *Table 4*. Oleic (Oa) and linoleic acid (La) contents of sweet almond genotypes and cultivars were established as major fatty acids. The samples are rich in both oleic (Oa) and linoleic acids (La). However, they may be used as edible cooking and salad oils.

In previous works, Kiani et al. (2015) reported that some fatty acid contents of 40 wild-growing almond accessions ranged from 0.40 to 0.80% palmitoleic acid (Paa), from 1.00 to 3.40% stearic acid (Sa), from 4.60 to 9.50% palmitic acid (Pa), from 11.30 to 33.20% linoleic acid (La) and from 48.80 to 88.40% oleic acid (Oa). Askin et al. (2007) reported that some fatty acid contents in several almond genotypes ranged from 5.46 to 15.78% palmitic acid (Pa), from 0.36 to 2.52% palmitoleic acid (Paa), from 0.80 to 3.83% stearic acid (Sa), from 50.41 to 81.20% oleic acid (Oa) and from 6.21 to 37.13% linoleic acid (La). Celik and Balta (2011) determined that fatty acid contents of some almond genotypes ranged from 6.48 to 6.29% palmitic acid (Pa), from 0.41 to 0.64% palmitoleic acid (Paa), from 1.76 to 1.60% stearic acid (Sa), from 72.02 to 76.41% oleic acid (Oa) and from 18.92 to 14.71% linoleic acid (La). Balta (2013) reported that the fatty acid contents of seven almond genotypes ranged from 5.26 to 6.69% palmitic acid (Pa), from 0.33 to 0.45.00% palmitoleic acid (Paa), from 1.61 to 2.40% stearic acid (Sa), from 65.33 to 74.73% oleic acid (Oa) and from 17.36 to 25.17% linoleic acid (La). Martins et al. (2000) determied that fatty acid contents for twelve almond varieties ranged from 2.15 to 3.13% stearic acid (Sa), from 5.94 to 7.31% palmitic acid (Pa), from 17.52 to 29.89% linoleic acid (La) and from 58.96 to 69.68% oleic acid (Oa). Kodad and Socias I Company (2008) found that fatty acid contents of eight varieties and forty seven almond genotypes ranged from 63.00 to 78.00% oleic acid (Oa), from 12.00 to 27.00% linoleic acid (La), from 5.00 to 7.00% palmitic acid (Pa), from 1.20 to 2.50% stearic acid (Sa) and from 0.30 to 0.80% palmitoleic acid (Paa). Sathe et al. (2008) reported that fatty acid contents of eight almond cultivars ranged from 5.07 to 6.78% palmitic acid (Pa), from 57.54 to 73.94% oleic acid (Oa), from 19.32 to 35.18% linoleic acid (La) and from 0.04 to 0.10% linolenic acid (Lia). The results in this study are consistent with previous works (Kiani et al., 2015; Askin et al., 2007; Celik and Balta, 2011; Balta, 2013; Martins et al., 2000; Kodad and Socias I Company, 2008; Sathe et al., 2008).

Saturated fatty acid (SFA), unsaturated fatty acid contents (UFA) and UFA/SFA ratios in this study were presented in *Figures 2, 3* and *4,* respectively. Increased uptake of unsaturated fatty acids reduces risk of coronary artery disease. From this point of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_29572971
© 2018, ALÖKI Kft., Budapest, Hungary

view, it is very important to prevent and treat chronic diseases such as cancer, because it is rich in unsaturated fatty acids, contain significant amounts of antioxidants and phytochemicals. In previous studies, Celik and Balta (2011) reported that fatty acid contents of twenty five almond genotypes ranged from 90.99 to 91.17% UFA, from 8.82 to 9.00% SFA and from 10.10 to 10.40 UFA/SFA, respectively. Balta (2013) found that fatty acid contents of almond genotypes ranged from 87.85 to 91.97% UFA, from 7.99 to 11.59% SFA and from 7.60 to 11.50 UFA/SFA. SFA and UFA compositions and UFA/SFA in the present study agreed with earlier studies (Celik and Balta, 2011; Balta, 2013). The use of samples with higher fatty acid levels might contribute to almond improvements directed at increasing nutritional value. In addition, fatty acid composition of kernel crude oils (Co) can vary widely among different plant genotypes and cultivars (Ozcan et al., 2011; Aitzetmüller, 1993), county (Sathe et al., 2008), irrigation status (Nanos et al., 2002), climatic conditions, maturity level and soil composition (Kodad and Socias I Company, 2008; Kornsteiner et al., 2006; Moayedi et al., 2011).

Conclusion

When evaluated statistically, the results in this study show that the sweet almond genotypes and cultivars have high levels of very valuable components. Fatty acids, proximate and mineral contents in particular almond kernel have a very important effect on health and can be included in the diet to improve human health. In this context, All genotypes and varieties except for SAHI250 and SAHI301 genotypes are rich in crude oil because their crude oil content is greater than 50%. Since all genotypes and varieties have crude protein values greater than 20%, they are protein rich. Because the genotypes SAHI232, SAHI250, SAHI278, SAHI301 and SAHI324, and the variety FERRAGNES have a sugar content greater than 4%, they are rich of sugar. It has been determined that genotypes and varieties in this study do not have high moisture. However, very few studies on minerals have thoroughly assessed different almond genotypes and cultivars in Turkey up to now. Considering macro and micro nutrient values, all genotypes and varieties are important and statistically significant. Almond has beneficial effects on human health since it contains a high level of unsaturated fatty acids / saturated fatty acids (UFA/SFA). UFA/SFA ratios of the genotypes SAHI132, SAHI198, SAHI250, SAHI278, and SAHI302 are greater than 11. Therefore, Adaptation studies should be performed in different ecological conditions with the genotypes SAHI132, SAHI198, SAHI232, SAHI250, SAHI278, SAHI301, SAHI302 and SAHI324, and variety FERRAGNES with other standard almond varieties for determination of commercial purposes and the food industrial applications. As a result, we believe that this study will be of considerable value in light of more detailed work.

THE MERCURY (Hg) CONCENTRATIONS IN FEATHERS OF WILD BIRDS

DURMUŞ, A.

Department of Biology, Science Faculty, Van Yuzuncu Yil University, 65080 Van, Turkey (e-mail: atilla@yyu.edu.tr)

(Received 19th Feb 2018; accepted 9th May 2018)

Abstract. In this study, mercury (Hg) concentrations were detected in feathers of 22 bird species from 10 different families living in terrestrial and aquatic ecosystems in Van Lake Basin in Turkey. The mercury rates in feathers were detected based on nutrition status and taxonomic classifications of bird species. Mercury levels were detected in 0.002 ± 0.007 mg/kg and 2.700 ± 0.560 mg/kg dry weight range. It was observed that there was a significant difference between the groups classified taxonomically ($p < 0.05$). The highest concentrations were detected in European Honey-buzzard (*Pernis apivorus*) 2.7 mg/kg, Lammergeier (*Gypaetus barbatus*) 0.45 mg/kg and Long-legged Buzzard (*Buteo rufinus*) 0.28 mg/kg species from Accipitridae family. And the lowest mercury concentration was detected in Golden Eagle (*Aquila chrysaetos*) from the same family (0.002 ± 0.007 mg/kg). Mercury was detected in the feather samples taken from the Egyptian Vulture, Lammergeier, Northern Lapwing, and Great Bustard, and these species were determined to be within different endangered categories according to the International Union for Conservation Nature (IUCN). Considering the trophic level (type of food) and systematic groups of the sampled species, it was determined that average mercury level was statistically significant in both cases. It was suggested that the mercury level of the carnivorous ones were higher than that of the herbivorous ones.
Keywords: *heavy metal, raptor birds, toxicology, endangered, East Anatolia, Turkey*

Introduction

Most heavy metals play an important role in the lives of living species. Heavy metals as an integral part of nature must be present in the structure of all living creatures in trace levels. If, these trace levels are exceeded, it shows toxic effect in the organism (Zolfaghari et al., 2007; Manjula et al., 2015).

As a result of developing technology and increasing human population, natural resources are consumed exceedingly and in consequence, overmuch waste is discharged into the nature. These wastes exceeding the bearing capacity of the nature accumulate in bodies of living species within the food web of the ecosystem through nutrition and environmental contact and consequently create risk (Nriagu and Pacyna, 1988; Dudka and Miller, 1999; Metcheva et al., 2010). The best indicator of a biological pollution of an environment is analyzing the creatures living in that environment and detecting toxic materials accumulated in their bodies.

Birds are ideal bio-indicator animals showing the best reaction about the structure of an ecosystem they live in. Analyzing these species located on the upper of the food web provides information on the status and condition of the related ecosystem (Burger, 1993). While, conducting these studies, present species should not be harmed in anyway. Therefore, analyzing the feathers taken from their bodies provides information on heavy metal rate of their environment. This does not only provide information on heavy metal concentrations in bird species but also the heavy metal concentrations in other living creatures under lower steps of the food web of birds which are foods of them (Battaglia et al., 2005).

The metals taken by birds through nutrition during their growth are carried to their feathers through blood vessels and accumulate there by bonding with protein molecules (Burger, 1993; Dauwe et al., 2000; Goutner et al., 2001; Dauwe et al., 2003). The source of heavy metal concentrations in feathers is not only nutrition, but also some environmental factors such as contact with soil, water, atmospheric pollution and precipitations (Burger and Gochfeld, 1997; Movalli, 2000; Jasper et al., 2004; Muralidharan et al., 2004; Cardiel et al., 2011).

Using feathers for detecting heavy metals such as mercury provides advantages compared to other tissues (Furness et al., 1986, 1989; Burger, 1996; Movalli, 2000). These advantages are taking feather samples from living creatures without harming them, storing feathers easily and preserving them for a long time in a refrigerator without needing anything.

The purpose of this study is to determine the amount of mercury accumulated in structures of the birds located at an upper step of food web and living in different ecosystems of Van Lake Basin (Turkey) through nutrition. It is to reveal the differences between mercury concentrations by considering the birds' nutrition styles and places in systematic category.

Materials and methods

The feather samples used in this study were taken from 102 birds from 22 bird species. 22 bird species used in this study are the resident and migratory species living in aquatic and terrestrial ecosystems of Van Lake Basin (*Fig.1;* Adızel et al., 2010; Nergiz and Durmuş, 2017).

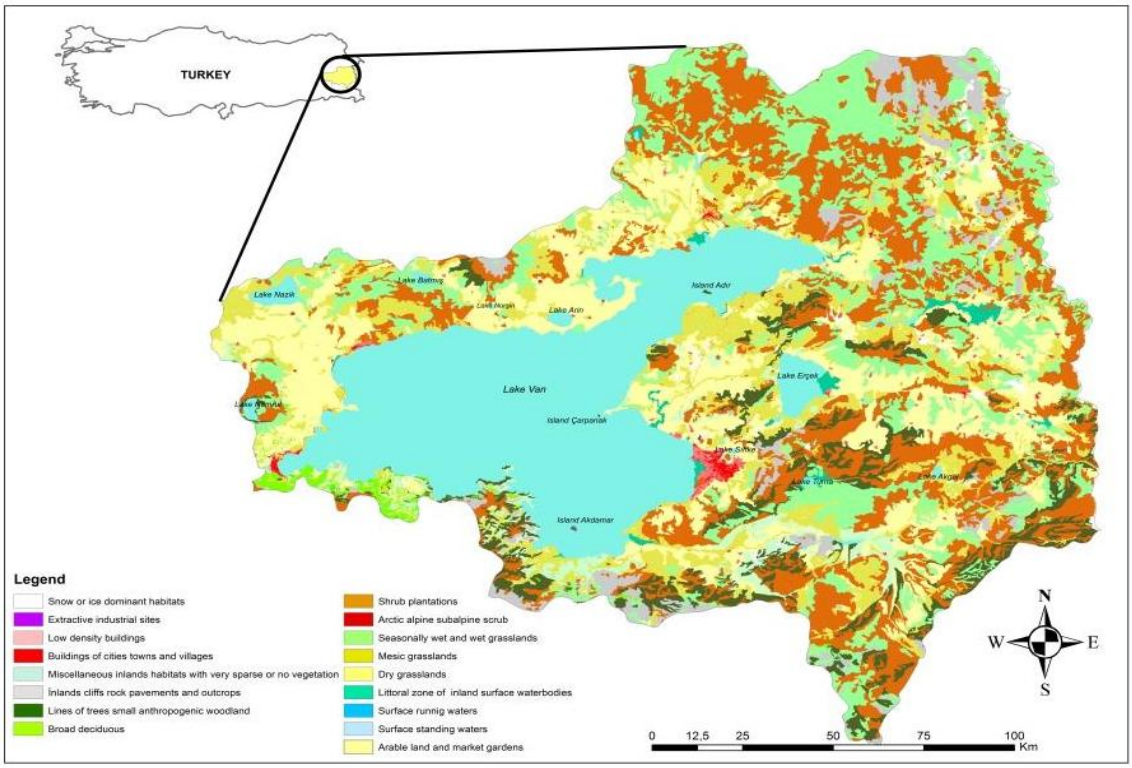

Figure 1. *Van Lake Basin and habitat types*

DOI: http://dx.doi.org/10.15666/aeer/1603_29732981
© 2018, ALÖKI Kft., Budapest, Hungary

These species were found injured or diseased in their ecosystems, taken to the Rehabilitation Center for Wild Animals of Van Yuzuncu Yil University, treated but then died. The feather samples were taken from these birds died between May 2016 and June 2017. Half of the sampled species were raptors.

Analysis of samples

The samples were transferred to the Science Application and Research Center of Van Yuzuncu Yil University for analysis. Feathers were washed with deionized water and acetone three times and then put in metal free polypropylene vials. All external pollution available in the feathers can be removed by washing the samples (Goede and Bruin, 1984).

The weights of the dry feather samples were detected and then they were put in an oven (70 °C) for 24 h. The dried feathers were cut with steel scissors and weighed on a precision scale at least 2 g (dry weight) from each sample and placed in glass containers. The prepared feather samples were burned with the tissue sample program in a microwave heating unit (Ethos Easy Advanced Microwave Digestion System, Milestone, 230/50 Hz, Italy) by adding 8 ml of 65% HNO_3 and 2 ml of H_2O_2 (Blust et al., 1988; Janssens et al., 2001). The 2 ml solution from the incinerated samples was diluted with distilled water to 10 ml and analyzed on the ICP-AAS (Thermo Scientific ICAP 600 series) instrument.

Calibration of the instrument was done with a certified solution (Multi element ICP QC standard solution-QCS-01-23E, Belgium). Mercury checked by National Institute of Standards and Technology (NIST) and Standard Reference Material (SRM). Accepted recoveries ranged from 95 to 105%.

Statistical analysis

The statistical analysis was done by the SPSS software (Version 23). Means and standard deviations were given in tables. We used one-way ANOVA and Tukey post-hoc comparison for evaluate effects of systematic categories and food manner on feather Mercury (Hg) levels.

Results and discussion

Average mercury concentrations in feather samples taken from 102 birds from 22 species and 10 families were taxonomically compared (*Tables 1–3*). Different levels of mercury were detected in all samples. According to the statistical analysis with 95% confidence range conducted in accordance with the trophic levels and taxonomic groups, it was observed that there were meaningful differences ($p < 0.05$).

The average mercury concentration varied from 0.002 mg/kg (Golden eagle) to 2.7 mg/kg-dry weight (European Honey-buzzard) (*Table 1*). The order of ten families from higher to lower Hg concentration is as follows: Accipitridae, Phasianidae, Otididae, Phoenicopteridae, Ardeidae, Falconidae, Strigidae, Anatidae, Ciconiidae, Charadriidae were compared (*Table 2*).

In the taxonomic evaluation conducted among the families, it was determined that the Accipitridae family had the highest mercury concentration while the Charadriidae had the lowest mercury concentration. It was observed that these differences between families were based on the nutrition and environmental differences between species.

The highest Hg concentration determined in European Honey-buzzard (2.7 mg/kg), Lammergeier (0.45 mg/kg), and Long-legged Buzzard (0.28 mg/kg) belonging to Accipitridae family and Grey Heron (0.22 mg/kg-Ardeidae). Intermediate Hg concentration values were found in Grey Partridge (Phasianidae), Great Bustard (Otididae), Greater Flamingo (Phoenicopteridae), Great Bittern (Ardeidae), Little Egret (Ardeidae), Common Kestrel (Falconidae), Western Marsh-harrier (Accipitridae), Eurasian Eagle-owl (Strigidae), Black-crowned Night-heron (Ardeidae), Egyptian Vulture (Accipitridae), Ruddy Shelduck (Anatidae), Common Teal (Anatidae), Northern Lapwing (Charadriidae), and Griffon Vulture (Accipitridae) species; whereas the lowest Hg concentration values were found in White-tailed Eagle (Accipitridae), White Stork (Ciconiidae), Northern Pintail (Anatidae), and Golden Eagle (Accipitridae) species.

Birds of prey families (Accipitridae, Falconidae and Strigidae) have more than 2.5 times higher average Hg concentrations (overall average of average 0.178 mg/kg) than the rest of other families (overall average of average 0.08 mg/kg) (*Table 2*). With the exception of Strigidae and Otididae families, there was significant difference in other families ($p < 0.05$).

According to trophic level, species were separated into 4 classes as Carnivorous (41 samples belonging to 10 species), mix (vertebrate and invertebrate predator, 28 samples belonging to 5 species), invertebrate predators (11 samples belonging to 2 species) and herbivore (22 samples belonging to 5 species) (*Table 3; Fig. 2*).

Table 3. *Mercury concentration (mg/kg dry weight) in the trophic level of birds*

Family	Number	Mean	Std. d.	p	95% confidence interval for mean	
					Lower	Upper
Carnivore	41	0.358	0.136	0.012	0.082	0.633
Mix (vertebrate and invertebrate predator)	28	0.098	0.024	0.003	0.015	0.181
Invertebrate predator	11	0.095	0.028	0.025	0.035	0.152
Herbivore	22	0.056	0.013	0.001	0.027	0.085

Accipitridae, Falconidae, and Strigidae families which eat vertebrates provided the highest mean mercury concentration in feathers (0.358 mg/kg), whereas the lowest mean Hg concentration value was found in the feathers of herbivorous birds (0.056 mg/kg).

Additionally, Mercury (hg) was detected in the feather samples taken from the Egyptian Vulture, Lammergeier, Northern Lapwing, and Great Bustard, and these species were determined to be within different endangered categories according to the International Union for Conservation Nature (IUCN). Related these species no work was done in Turkey. Egyptian Vulture listed in Endangered (EN) category in IUCN has mercury concentration of 0.033 mg/kg, Lammergeier and Northern Lapwing listed in Near Threatened (NT) have mercury concentrations of 0.45 mg/kg and 0.02 mg/kg, respectively. Great Bustard listed in Vulnerable (VU) category has mercury concentration of 0.14 mg/kg. In the literature Hg concentration was determined as 0.055-0.139 ppm (Xiuhua et al., 1998).

In the analysis and studies, it was observed that taxonomically different mercury (Hg) levels were influenced species-related factors such as age, gender and etc. and from environmental factors such as climate (Monteiro and Furness, 1995). However, the individuals taken as samples in our study were completely adults and the same gender so no difference was observed in specie-related individual variations. It was suggested that climatic factors and consequent migration activities as well as pubescence influence mercury concentration (Stewart et al., 1999; Mashroofeh et al., 2015). The species sampled in this study are the species which have not influenced from migration activities, yet, have been present in the region since last spring and the resident ones permanent in the field. Organic mercury is stored at the bottom of feathers grown post incubation period based on nutrition density (Zolfaghari et al,. 2007).

Several studies indicate that the mercury concentration in feathers vary based on types of nutrition and the environment where species are present (Braune and Gaskin, 1987; Cifuentes et al., 2003; Burger, 2013). Especially, the raptors at the top of food web are influenced more from bio-accumulation as they always have carnivorous food. Within this respect, they are more sensitive and under higher risk than other bird species.

In our study, mercury concentration was detected in the samples from all taxonomic groups. However, it was observed that the mercury concentration levels in Accipitridae family covering raptors has significantly higher mercury concentration compared to other families ($p < 0.05$; *Table 3*). In general, although, mercury concentration is high in raptors, the concentration was found the lowest in White-tailed Eagle and Golden Eagle species (*Table 1*). It is because that these species live in high-altitude natural areas and stay away from pollutive fields with anthropogenic source.

According to a study based on Family taxonomy which was conducted in Iran as the closest country to the study region, the highest mercury concentration was detected in Strigidae family (0.88 mg/kg) (Zolfaghari et al., 2007), in our study, the value for this family was 0.05 mg/kg. In the same study, average mercury concentration detected for the Accipitridae family was 1.25 mg/kg while, in our study, the value for this family was about two times higher and detected as 2.7 mg/kg. In both studies, the lowest concentration value was detected in the Charadriidae family. The reasons of basic differences between these two studies conducted in close regions are different numbers of sampled individuals and density of pollutant factors in nutrition environment of species.

Mercury level also varies between the Carnivorous species based on types of nutrients. Concentration differences may be observed on the birds consuming high amounts of fish or the ones eating large fish. In the study, it was observed that the species of Ardeidae family have higher levels of mercury concentration compared with the members of another family which eats little fish (Burger, 2002). However, the level of mercury concentration detected in the members of Ardeidae family is around midlevel, not high.

The bird species feeding on primary producers such as vegetal nutrients, seeds, leaves, roots, fruits and algae are the group which are influenced the least from environmental pollutants (Zolfaghari et al.,2007; Behrooz et al.,2009). Parallel to other studies on this subject, the mercury concentration level was also found the lowest in the birds feeding on plants in our study (0.56 mg/kg). However, it was observed high in Great Bustard and Grey Partridge species feeding on seeds in agricultural fields and located in areas where agricultural pesticides are extensively used (*Table 1*).

Conclusion

The main purpose of this study is to determine the mercury level accumulated in feathers of the bird species living in terrestrial and aquatic ecosystems of Van Lake Basin located in the Eastern Region of Turkey. This study is the region's first heavy metal study conducted on the birds. In this study, the highest mercury concentration was detected in the Accipitridae family at the top of the food web (chain) with raptor species feeding in agricultural areas. Four raptor bird species that lives in rural habitats (*Gypaetus barbatus, Neophron percnopterus, Otis tarda, Vanellus vanellus*) were within the endangered species of the IUCN category.

With this study, it was suggested that the mercury level is correlated with nutrition style and habitat characteristics. While, the mercury level was found high for the regions of Van Lake Basin with agricultural activities and city pollution, it was determined that the species living in rural and high-altitude areas without pollution have lower mercury levels.

As the mercury concentrations detected in feathers reflect the amounts in their blood, they reveal the risk the species are exposed to. At the same time, it provides insight on other groups of the food web at lower steps of the birds.

Abstract. In this study, while Osmanli strawberry, which has some superior characteristics like taste, aroma and male sterility that makes breeding studies easier, has been used as maternal parent, three local (Karacilek, Tuylu and Deli) cultivars in Turkey and three standard (Kabarla, Sweet Ann and Sweet Charlie) strawberry cultivars were used as paternal parents. Molecular analyses were conducted for determination of polymorphism levels by using 14 UBC-ISSR primers for the examination of 52 F1 genotypes that included selections as a result of hybridization studies, parents that were used in hybridization studies, and *Fragaria chiloensis*. 76 DNA bands were obtained in total and 60 of them were determined as polymorphic. The resulting data of the evaluation of ISSR-PCR bands, were analysed in Popgene32 and MEGA5.0 packaged software and the dendrogram was obtained according to the UPGMA method. The dendrogram was separated into two major groups at the 20% difference level, one is larger and the other is smaller. While *Fragaria chiloensis*, Tuylu-2 local cultivar, CC48 and CA97 F1 genotypes participated in the small group, the other F1 genotypes and parents participated in the larger group.
Keywords: *hybridization breeding, ISSR, molecular, Osmanli cultivar, strawberry*

Introduction

Strawberry is one of the rare fruit species that can be grown in large ecological zones, and it is known and grown in Turkey for a long time (Konarli, 1986). When the strawberry was classified botanically in the world, it was placed in *Rosales* family and *Fragaria* genus (Hancock and Luby, 1993). Most of strawberries that are grown commercially, belong *Fragaria x ananassa* species that was derived from hybridization of two local American species (*F. chiloensis* X *F. virginiana*) (Hancock, 1999).

More than 20 strawberry species with different ploidy levels were identified. *F. vesca* and *F. viridis* (2n = 2x = 14) are found as diploid species in the flora of Turkey. As well as these wild species, octoploid *F.* × *ananassa* were used for cultivation in Turkey for a long time, generating strawberry genetic resources. Osmanli and Arnavutkoy local cultivars were started to grown in limited areas because of cultivation of the new cultivars with higher quality and yield from another countries has become more common Osmanli cultivar that is known by its taste, colour and aroma, is only grown in a very small area in Eregli and Bartin regions in the West Black Sea Region of Turkey by few growers (Demirsoy and Serce, 2016). Dokuzoguz (1963) also reported that Eregli, Karsiyaka, and Kestel have specific characteristics comparing to the cultivars of Arnavutkoy, Eregli, Madame Moutot and Mangro, which are all called Osmanli or Arnavutkoy with small, oval-shaped, light-coloured fruits but have different other characteristics.

Modern strawberry cultivation started in the 1960s in Turkey (Konarli and Philippe, 1968). Since the strawberry cultivation started, the main purpose is having a corner on the domestic and foreign market by doing high quality and early-grown cultivation. Besides the superior aromatic characteristics, profitable cultivation with local cultivars is not possible due to low yield, soft fruit flesh and small fruits. Although strawberry cultivars that is originated from another countries have earliness and high yield characteristics, they have middle level aromatic characteristics. Because of these reasons, breeding studies have being conducted that local cultivars have been used as parents since 1960. In the most of these studies, Osmanli strawberry, which have some superior characteristics (taste, aroma, the situation of fruit stalk, etc.) and male sterility that makes breeding studies easier, has been used as maternal parent (Kaska and Paydas, 1986; Ustun and Paydas, 1995; Paydas et al., 1996; Caglar and Paydas, 2002; Kiyga, 2009).

Modern breeding methods were developed especially after the beginning of the 20th century. In the last 30 years, 38 cultivars in Turkey and more than 900 cultivars in the world have been developed and registered (Della Strada and Fideghelli, 2011; Chandler et al., 2012; Turemis and Agaoglu, 2013; Faedi and Baruzzi, 2016).

The knowledge about genetic structure is important, especially when it is worked with wild species (Ahmadi and Bringhurst, 1991). Morphological, physiological and cytological characteristics were used at the beginning for the determination of genetic variation, afterwards, biochemical markers were developed. Furthermore, molecular studies are conducted recently (Scarano et al., 2002).

Molecular markers are derived from the DNA in the cell of the plants. Thus, molecular markers are almost 100% reliable for the determination of the diversity between plant populations and plant genotypes. Today, molecular markers are used commonly in plant taxonomy studies, breeding and evaluation of genetic resources (Gulsen and Mutlu, 2005).

DNA markers are more preferred than isoenzyme, biochemical and morphological markers in the studies about the determination of species and cultivars. PCR based DNA markers; AFLP Amplified Fragment Length Polymorphism), CAPS (Cleaved Amplified Polymorphic Sequences), ISSR (Inter Simple Sequence Repeats), SSR (Simple Sequence Repeats) and RAPD (Random Amplified Polymorphic DNA) were used on many studies about strawberry (Tyrkal et al., 2002; Kunihisa et al., 2003, 2005; Kashyap et al., 2005; Bassil et al., 2006; Milella et al., 2006; Serce et al., 2007). While CAPS, RFLP and SSR are codominant, AFLP, ISSR and RAPD are dominant molecular markers (Kafkas, 2006).

In ISSR (Inter Simple Sequence Repeats) method, one primer is used and it has two, three and four sequence repeat on it. This method is used commonly in the determination of DNA fingerprint and genetic relationships (Cekic et al., 2001; Arnau et al., 2002; Kuras et al., 2004; Debnath et al., 2008; Nunes et al., 2013).

Arnau et al. (2002) scanned eighteen ISSR primers and selected five of them. They used those primers for characterization of genotypes of 30 different strawberry (*F. x ananassa* L.) cultivars and they obtained 113 polymorphic bands.

Serçe et al. (2006) studied with 16 cultivars belong to *F. chiloensis, F. virginiana* and *Fragaria x ananassa*, and Osmanli, Karacilek, Tuylu and Arnavutkoy local cultivars. Although Osmanli strawberry was morphologically similar with *F. chiloensis* clones, it was observed in the dendrogram obtained by 13 SSR primers that Osmanli, Karacilek, Tuylu and Arnavutkoy cultivars were different with the other three species

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

and generated different group. Moreover, researchers suggested that more primers should be used with the purpose of obtaining more reliable results.

The aim of this study was the determination of genetic relationships by using ISSR markers between 52 F1 genotypes that were selected according to their superior morphological, pomological and physiological characteristics, parents that were used in hybridization studies, and *Fragaria chiloensis* within the scope of 'Osmanli Strawberry Breeding' project that is conducted in University of Gaziosmanpasa. Obtained data were evaluated according to the UPGMA dendrogram and Principal coordinate analysis

Material and method

Material

In this study, within the scope of 'Osmanli Strawberry Breeding' project that is conducted at the University of Gaziosmanpasa in Turkey, 52 selected F1 genotypes, the parents (Osmanli and eleven pollinators) as well as *Fragaria chiloensis* for comparision were used in molecular analysis.

In the hybridization programme, while Osmanli strawberry cultivar which is morphologically male sterile was used as maternal parent, 8 local genotypes ('Osmanli-1', 'Osmanli-2', 'Osmanli-3', 'Osmanli-4', 'Tuylu-1', 'Tuylu-2', 'Karacilek-1', 'Karacilek-2') (*Table 1*), from Eregli district of Zonguldak province and 3 standard cultivars ('Kabarla', 'Sweet Ann' and 'Sweet Charlie') provided from private seedling companies were used as pollinators.

Method

DNA isolation

DNA isolation was done from 1.5-2 cm length young leaf samples from each genotype according to the Mini-CTAB method belongs to Doyle and Doyle (1987).

PCR amplification

ISSR method was used because generated bands are reproducible (reliability) and have high polymorphism (scorability), and also, scanning large number of different locus is possible (Prevost and Wilkinson, 1999; Cekic et al., 2001).

For the determination of polymorphism levels, 14 primers were used that were selected from 100 UBC primers, which was used for '*Fragaria vesca'* before (*Table 2*) (Cekic et al., 2001). PCR method with constant annealing temperature that was used by Cekic et al. (2001) and Touchdown PCR method by Sargent et al. (2003) were modified and used. ISSR PCR reaction was done with 2 µL DNA (10 ng/µL) and 23 µL reaction composition [5 µL 10X PCR buffer solution, 2 µL 25 mM Mg^{+2}, 1.25 µL 2.5 mM dNTP, 0.1 µL Taq DNA Polymerase, 1 µL 0.5 µM primer and 13.65 µL PCR water]. PCR products were separated in 100V constant voltage during 2 hours by using 1 X TBE buffer as a gelling agent and the electrode buffer solution, and 2% agarose gel for electrophoresis. Afterwards, DNA bands were imaged under ultraviolet lights.

Data analyses

Data, which were used in the statistical analyses, were obtained by the method that is about scoring one (1) when there was ISSR band and scoring zero (0) when there was not ISSR band. Similarities and differences between genotypes were determined in the molecular level. Principal Coordinates Analysis (PCoA) was done by similarity coefficient. Data were analysed in Popgene32 version 1.32 (Population Genetic

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

Analysis) and MEGA 5.0 (Molecular Evolutionary Genetic Analysis) packaged software and the dendrogram was obtained according to the UPGMA (Unweighted Pair-Group Method With Arithmetic Average) method (Parmaksiz and Ozcan, 2011). Furthermore, generating similarities/differences matrix between genotypes and Principal Coordinates Analysis (PCoA) were done by using NTSYS-pc ver. 2.10d (Numerical Taxonomy and Multivariate Analysis System) packaged software that was developed by Rohlf (2002).

Table 2. *ISSR primers*

Primer name	5' – 3' sequence	Degree of dissociation (C)	Primer name	5' – 3' sequence	Degree of dissociation (C)
807	AGAGAGAGAGAGAGAGT	50	888	BDBCACACACACACACA	52
808	AGAGAGAGAGAGAGAGC	53	889	DBDACACACACACACAC	52

842	GAGAGAGAGAGAGAGAYG	55	844	CTCTCTCTCTCTCTCTRC	53

Results

Some DNA bands were not clear may be due to PCR gel imaging system or ethidium bromide. Therefore, scoring studies were done with clear DNA bands. 76 DNA bands were determined at the end of the study and 60 of them were polymorphic. Band number obtained from primers varied between 3 and 8, additionally, the average band number was 5.43 and the average polymorphic band number was 4.29. The highest band number was obtained from primer-810 (8 bands) and the lowest band number was obtained from primer-841 (3 bands). DNA bands, which were generated by primer-835, 841, 844 and 888, were observed as polymorphic. The lowest polymorphism rate was determined on primer-842 with 50%. The polymorphic band rate average was determined as 80.14% on 14 primers.

A dendrogram was obtained according to the UPGMA method (*Fig. 1*). The dendrogram was separated into two major groups at the 20% difference level, one is big and other is small. While *Fragaria chiloensis*, Tuylu-2 local cultivar, CC48 (Osmanlı-3 x Sweet Charlie) and CA97 (Osmanlı-3 x Sweet Ann) F1 genotypes participated in the small group, the other F1 genotypes and parents participated in the big group. It was observed that the big major group was separated again into groups with 17% level.

In this study, the highest similarity was determined between Osmanli-3 and Osmanli-4 with 3%, and the second highest similarity was determined between Sweet Charlie and Kabarla. It was also observed that Osmanli-1, Osmanli-2 and Osmanli-3 were in the same subgroup.

It is known that Scatterplot PCo1 and PCo2 analyses support the results of the distribution of dendrogram (Ozyurt, 2011). In this study, it was determined that the distribution of genotypes on the Scatterplot (*Fig. 2*) obtained with Principal

Coordinates Analysis (PCoA), showed similarity with distribution on the dendrogram (*Fig. 1*). 'Osmanli-1 (OsmA)', 'Karacilek-2 (Kara-C)', 'Tuylu-2 (Tuylu-D)', 'CA-97' and '*Fragaria chiloensis* (FC)' were out of the high-density group according to Principal Coordinates Analysis 1 and 2. Furthermore, 'Karacilek-2 (Kara-C)', 'Tuylu-2 (Tuylu-D)', 'Sweet Charlie', '*Fragaria chiloensis* (FC)', 'CC-48', 'CA-97' and 'DB-97' were out of the high-density group according to Principal Coordinates Analysis 1 and 3.

Discussion and conclusion

76 DNA bands were determined at the end of the study and 60 of them were polymorphic. Cao et al. (2000) stated that 50 polymorphic bands are sufficient to determine similarities and differences between genotypes successfully. It was observed that 60 obtained polymorphic bands are sufficient to work with. The polymorphic band rate average was determined as 80.14% on 14 primers. Arnau et al. (2002) used 5 ISSR primers on characterization of 30 different strawberry (*F. x ananassa* L.) genotypes and it was stated that 113 polymorphic bands were obtained.

Kuras et al. (2004) used ISSR and RAPD marker methods for determination of genetic relationships between 24 strawberry cultivars, which were obtained by breeding program conducted in Poland. Moreover, these two marker methods were compared in the same study. 41 of 90 ISSR primers and 23 of 48 RAPD primers were found as polymorphic. As a result of the UPGMA analyses, genetic relationships were determined and the family tree was generated. As a result of comparison of marker methods, ISSR was found better than RAPD in terms of genetic relationships.

The dendrogram obtained from genotypes was separated into two major groups, one is big and other is small, and the separation was done successfully with 14 ISSR primers. Debnath et al. (2008) determined genetic relationship of 27 strawberry cultivars by using 17 ISSR primers, and they obtained 225 polymorphic bands. The results were evaluated with UPGMA analysis, and it was stated that genetic relationship between cultivars varied between 63-77%.

In the literature, it was stated that 'Osmanli' local cultivar and *F. chiloensis* show similarity, however, Tuylu-2 genotype and *F. chiloensis* showed similarity with 14.00% in this study. All the local genotypes were collected from Eregli district in Black Sea Region, also, it was observed that Tuylu and Osmanli local cultivars showed similarity in terms of fruit structure. *F. chiloensis* and Tuylu local cultivars were in the same group, thus, it is thought that Osmanli local cultivar changed by the time due to cross pollination.

Selected F1 genotypes will be used in the further studies leading to obtain new strawberry cultivars. Specific molecular markers could also be generated using these F1 genotypes.

(Received 26th Feb 2018; accepted 10th May 2018)

Abstract. The adverse effects of the weed flora on the agricultural yield are well documented. In an agro-ecosystem, weed species distribution pattern depends on both surrounding environment and farming practices. This first ever study was designed to compare and determine the weed species richness, distribution pattern and their ecologically meaningful groups in wheat and maize field of Gujrat, Pakistan. In this study, seasonal variation variable and satellite derived measurements like normalized difference vegetation index (NDVI), normalized difference moisture index (NDMI) and topographic wetness index (TWI) were calculated for each vegetation sample and their contribution towards explaining variations in the weed species data was tested by using direct unimodal ordination method. Phytosociological data was collected from 50 crop fields (25 each from wheat and maize fields during winter and monsoon season respectively) comprising of 250 sub-samples/plots (size 1 × 1 m) during 2016. The results of Monte Carlo testing and cluster analysis showed that there were four statistically significant weeds groups (i.e. 1. *Anagallis-Medicago-Phalaris* or AMP-Wheat weed group; 2. *Chenopodium-Convolvulus-Vicia* or CCV-Wheat weed group; 3. *Cyperus Malva-Amaranthus* or CMA-Maize weed group; 4. *Cannabis-Cynodon-Digera* or CCD-Maize weed group). A total of 60 weed species were recorded and the majority of them belongs to Poaceae and Amaranthaceae families. The majority of weed species flowered during monsoon season whereas therophytic life form and microphyllous leaf size categories were the most dominant. The highest mean weed diversity, NDVI and NDMI values were recorded for the weed communities of maize fields whereas the higher mean TWI value was recorded for the weed groups of wheat fields, suggesting strong linkage with the local climatic conditions. Canonical correspondence analysis (net effects) suggested that sum of local climatic conditions (seasonality variable) was found to be the most important in controlling the variations in the weed species data followed by longitude and altitude variables and least by the NDVI, NDMI and TWI. It is concluded that effective weed management activities are required to enhance the yield of these two important crops in the area. Thus, further studies related to determination of weed types and their distribution pattern by using factors like fertilization (type, timing, quantity), wheat and maize cultivar, land preparation (types, timing and intensities), soil management, pesticides (usage, type, quantity, quality), irrigation (type like rain-fed, tube-well, canals; timing, quantity), socio-economic and anthropogenic activities, and their relationship with the yield variable on temporal and spatial scales are recommended for this agro-ecosystem of the study area.

Keywords: *wheat and maize crops, normalized difference vegetation index, normalized difference moisture index, topographic wetness index, cluster analysis and ordination*

Introduction

The weed species though might be useful as ecosystem services providing agents but due to their competitive nature (Anderson, 1996), their occurrence in a maintained agro-ecosystem is considered hazardous for agricultural yield. The control and management of weed species in such systems is desirable and practiced since centuries. Pakistan is a rapidly developing country and agriculture sector provides leading share in country's economy. A large number of factors like inappropriate land preparation, modest understanding about crop varieties, seed quality under varied micro-habitats amongst the farmers, water logging, salinity, fertilizers and pesticides types, their effectiveness including high cost and poor availability, agri-land fragmentation, small holdings, availability of water for irrigation and poor weed management are responsible of reduced agricultural production. The latter factor is most important and can reduce the crop yield from 15-50%, thus these are undesired plant species growing in any agro-ecosystem (Qureshi and Bhatti, 2001). They consume three to four time more soil nutrients than a weeds free crop. Their seeds becomes dormant and remained viable for many year, and their seed coat can resist adverse climatic and edaphic conditions (Qureshi and Bhatti, 2001). Similarly even some alien invasive weeds like *Parthenium hysterophorus* L. (Compositae) are threatening local biodiversity and agricultural production (Shabbir and Bajwa, 2006). The weed species synthesize and deliver different phytotoxins or allelochemicals in surrounding, thus causing increase in the costs of different cultural practices, decrease the effectiveness of agricultural tools, fertile lands and germination capability of crops seeds (Algandaby and Salama, 2016).

Agriculture is the major source of earning livelihood in Pakistan whereas wheat is a globally important Rabi cereal crop including Pakistan. It is cultivated at variety of micro-habitats from the sea level to high altitude mountains (Hussain et al., 2004). About more than 1/3rd of the world population is dependent on this crop for their dietary mainstay (Jakhar et al., 2005). But national losses in wheat yield due to weed infestation estimated about 28 billion/year in Pakistani rupees (Hussain et al., 2004). Wheat yield increases in the country during the last few decades but still its average yield/ha is far behind (only 30 to 35% of potential yield) than the developed countries (Hussain et al., 2007). Total global wheat production was about 724 million tons during 2017, whereas it was only about 25.5 million tons in Pakistan although cultivated on an area of 8494 million hectares. Thus, Pakistan average wheat yield was 2585 kg/ha, and was very low compared to European Union, India, China and Russian Federation (Iqbal et al., 2018).

Maize (*Zea mays* L.) is an annual, cross pollinated, short day plant. It was grown on an area of 132 million hectare with yield of 570 metric tons globally (Ashique et al., 1997). Within Pakistan, it is continuously gaining significant position in crop husbandry. This species has higher yield potential and complete its life cycle within short duration. During 2012-13, Pakistan maize yields was about 36.581 metric tons and cultivated on the total area of 0.981 million hectare, whereas during 2017, the production was about 5.8 million tonnes (FAO, 2017). Many weed species as tough competitors, compete with the maize crop for available resources (Malik et al., 2006; Ahmad et al., 2016a). Weed species can severely reduce maize production during initial stage of growth and ultimately effect yield. The loss of maize yield due to weed infestation was recorded quite high (about 16-40%) in Pakistan (Ahmad et al., 2016b).

By using satellite remote sensing (SRS) data, monitoring of vegetation change pattern can be conveniently understood and improve our knowledge about the spatial distribution and characteristics of vegetation of any area. Similarly, changes in the land

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_29953018
© 2018, ALÖKI Kft., Budapest, Hungary

use pattern can be used to investigate the relationship between population density and vegetation pattern changes on both spatial and temporal scale. The SRS data can illustrate the type, size and condition of the vegetation of any area. Sultana et al. (2014) found a significant correlation between the normalized difference vegetation index (NDVI) and yield behavior of the different wheat cultivars and nitrogen fertilization, and thus concluded that NDVI is a good tools for wheat yield prediction especially at crop maturity stage.

No record exists for such ecological exploration, and to fill this gap, this study was aimed to answer the following research questions for the first time from the study area. 1. What are the number of ecologically meaningful weed groups of wheat and maize crops, community types, composition and diversity? 2. What are the indicators species and their strength of association with their associated groups? 3. What about the leading weed families, genera, species, weeds flowering response (timing), life form and leaf size spectra? 4. How seasonality (wheat plots = winter = 1; maize plots = monsoon = 2), topographic and SRS variable are related amongst themselves, and with the weed species distribution pattern in the study area? Although this study, targeted the agro-ecological system of wheat and maize fields, the collected SRS data will be used to explore the pattern of relationship between SRS variables and weed distribution pattern (if any) instead of crop yield attributes in the study area. This study will serve as the first baseline survey and also be useful for future related agro-ecosystem explorations in the region.

Materials and Methods

Study Area

Gujrat district is located in the Punjab province, Pakistan and between two famous rivers, the Chenab and Jhelum. It is situated between the 73°33′ to 74°24′ E longitude and 32°24′ to 33°10′ N latitude. It is bounded by the Jhelum district towards the west and northwest, district Sialkot on the east, district Gujranwala on the southeast, district Mandi Bahauddin on the southwest, district Mirpur and Bhimber of Azad Jammu and Kashmir on the north and northeast (*Fig. 1*). It is further administratively divided into 4 tehsils (Sarai-Alamgir, Kharian, Gujrat and Jalalpur Jattan), 119 union councils and 1065 villages. The total land area of the district is 3192 km^2. The study area is comprised of many historic towns like Jalalpur Jattan, Lalamusa, Kharian, Sarai-Alamgir, Dinga and Kunjah. The total human population of the district is 2.756 million (i.e. Urban 827396; Rural 1928714; Household 442399), and comprising of 43% urban population. The human density is about 863 persons/km^2 (DCR, 2017), whereas population of Gujrat city is about 0.39 million. The district has moderate climate with hot summer and cool winter. The highest temperature during the peak of summer shoot up to 50°C whereas minimum temperature during winter peak might fall below 2°C. The average rainfall varies from 1000 mm to 500 mm in the different parts of the district, usually higher in the northern parts and decreases continuously towards the southern parts (Parvaiz, 2014). Monthly mean climatic data of temperature and rainfall variations of the study area is given in *Table 1*. The total area under cultivation was about 0.321 million hectare (25.68%), out of this, wheat was cultivated on about 158.2 hectare and its production was about 1.85 tons/ha. Maize crop was sporadically

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

cultivated in the study area. A very small area (31000 ha) is being irrigated through canal irrigation system whereas majority of area under cultivation is always irrigated through tube wells (Anonymous, 2018).

The study area is represented by sub-tropical deciduous vegetation with *Acacia modesta* Wall., *Acacia nilotica* (L.) Delile, *Albizia lebbeck* (L.) Benth., *Cassia fistula* L., *Dalbergia sissoo* DC., *Melia azedarach* L., and *Morus alba* L. as indicator tree species, and *Datura innoxia* Mill., *Dodonaea viscosa* (L.) Jacq., *Justicia adhatoda* L., and *Ziziphus nummularia* (Burm.f.) Wight & Arn. were important components of shrub layer. Soil of the study area is poor in calcium carbonate (about 6%) and its texture varied from sandy loam to clayey loam, and located in the lower end of piedmont plains. The bedrock comprised of semi-consolidated and weakly cemented, coarse sandstone with underlying clay and shale layers (Ullah et al., 2007). These materials were deposited probably during Late Pleistocene and Subrecent periods. Application of advanced weed management activities for the crop protection were uncommon in the study area. Only 6% farmers claimed the use of these protocols especially the use of weedicides (Trade name: Buctril Super; Puma Super; Logran and Topik etc.) during different stages of crops growth and development. The majority of farmers belonging to remote areas are still using traditional weed management practices like timing and number of field ploughs, and weed up-rooting (by hand).

Plant Collection and Sampling Protocols

The detailed floristic surveys were conducted during each month from January-December, 2016. The voucher specimens were collected, pressed, dried and mounted on standard sized herbarium sheets. The same were identified by using the available regional taxonomic literature and online floral databases (Stewart, 1972; Nasir and Ali, 1971-1995; Ali and Qaiser, 1995-2009; EFLORAS, 2012; TROPICOS, 2012). After

© 2018, ALÖKI Kft., Budapest, Hungary

identification, all the familial and species binomials were copied from the website; www.theplantlist.org (TPL, 2013) to attain global homogeneity with respect to updated taxonomic views (Khan et al., 2015; 2016). The same were deposited in the PMAS Herbarium of Department of Botany, Pir Mehr Ali Shah Arid Agriculture University Rawalpindi, Pakistan for future references and record. The Raunkiaer's life form, leaf size, local names and flowering duration of each weed species were recorded and calculated for each weed community.

For vegetation sampling, stratified random method was adopted. For this, five different sites were randomly selected to record weed composition of each of bread wheat (during winter season) and maize crops (monsoon season) in the study area. Followed by this, at each site, five different fields were randomly selected and again, at each field, five plots/quadrats (size; 1×1 meter) were studied for collection of density, frequency and cover data of the weed species. The averaged values of these variable were then used to get their relative values, which were further used to get importance value index (IVI) value for each weed species (Iqbal et al., 2018). Thus, a total of 50 weed samples comprising of 250 plots [25 wheat weed samples: 5sites×5fields×5plots = 125 plots were studied during January-February and the same number of samples/subsamples were recorded from maize fields during July-August, 2016] were studied in the area.

Satellite Data

Satellite derived measurements related to 50 studied field locations of the study period, Landsat 8 (launched: 2013) satellite data was used that has spatial resolution of 30 m. Two instruments viz. operational land imager (OLI) and thermal infrared sensor (TIRS) are onboard at Landsat 8 satellite, and the satellite collects images of the Earth with a 16-day repeat cycle. It provides 8-band multispectral scenes at 30 meter resolution along with band-8 (Panchromatic; 15 meter resolution) and two Thermal infrared sensor bands including TIRS-1 and TIRS-2 as band-10 and 11 respectively at 100 meter resolution but are registered to and delivered with the 30-meter OLI data product as they were resampled to 30 meters to match multispectral bands. A median of the reflectance of all the images available for the study area and time period (after masking clouds) was created in Google Earth Engine and subsequent functional gradients/variables were derived from the median image. The reflectance values were corrected with respect to sun angle (Ganie and Nusrath, 2016). The following satellite measures were calculated;

The normalized difference vegetation index (NDVI) was calculated by using equation 1 as under;

$$NDVI = \frac{NIR - RED}{NIR + RED} \qquad \text{(Eq.1)}$$

Where, NIR=Near-infrared=band 5 (wavelength vegetation emits) and RED=band 4 (wavelength vegetation absorb).

The NDVI value ranges between -1 to +1. Higher NDVI value represent more abundance of live, healthy, green plants whereas small positive values (≤ 0.1) depicts non vegetated areas such as barren land, rocks, sand, urbanized area, snow, and negative values by water bodies.

DOI: http://dx.doi.org/10.15666/aeer/1603_29953018
© 2018, ALÖKI Kft., Budapest, Hungary

The normalized difference moisture index (NDMI) estimate the levels of moisture in the vegetation. The NDMI was calculated by using corrected value of the band 5 (NIR), being sensitive to the reflectance of leaf chlorophyll content to the band 6 (Short-wave infrared-1; SWIR-1) and sensitive to the absorbance of leaf moisture as communicated by Gao (1996) and represented as equation 2 as under;

$$NDMI = \frac{NIR - SWIR - 1}{NIR + SWIR - 1} \quad \text{(Eq.2)}$$

Here, NIR=Near-infrared=band 5 and SWIR-1=Short-wave infrared-1=band 6. NDMI value also ranges between -1 to +1 and the positive values represents moist areas and the negative ones to the non-moist features.

The location of sampling plots were determined by using Garmin, 76CSx handheld GPS device and two topographic variables namely altitude (meter) and topographic wetness index (TWI) were calculated through modelling 30 m digital elevation model (DEM) of the study area (download link; https://asterweb.jpl.nasa.gov/gdem.asp). The topographic wetness index (TWI) also known as compound topographic index (CTI) was developed by the Beven and Kirkby (1979), and shown in equation 3, to study the spatial scale effects on hydrological processes, flow paths, and biological processes like vegetation patterns and net primary productivity etc. The TWI was calculated as under as communicated by the Wilson and Gallant (2000).

$$TWI = \ln \frac{\alpha}{\tan \beta} \quad \text{(Eq.3)}$$

Where α is the local upslope area draining through a certain point per unit contour length and tan β is the local slope in radians. The TWI values were extracted from the sample point coordinate data using the distance-weighted average of the four nearest grid cells (bilinear interpolation) rather than a simple point extraction. ArcGIS was also used for mapping of bread wheat (winter) and maize (monsoon) crops weed samples distribution in the study area.

Table 1. *Mean Monthly rainfall and temperature variations in the study area for the period of 5 years from 2012-2016.*

Months	Min. Temperature °C	Max. Temperature °C	Rainfall (mm)	Rainy days
January	11.8	22.6	21.422	4.2
February	14.4	24	79.92	9.2
March	19.8	28.6	100.656	12.2

Statistical Analyses

The decision about the number of ecological meaningful weed communities in the study area was determined by using the criteria as conveyed by Khan et al. (2017). For this, two to eight (2-8) possible groups were tested by using the Monte Carlo permutation test, and suitable level was selected, where mean p-value become minimized or significant species become maximized (McCune et al., 2002). The same appropriate grouping variable for the studied weed samples was further used in the hierarchical clustering (distance "relative euclidean"; linkage "ward") of studied samples and their associated weed species by using PC-ORD ver. 5 (McCune and Mefford, 2006), whereas the same for study sites was done by using R statistical software's (R Core Team, 2017). For this, package "decostand" was used to normalize vegetation data first followed by clustering through "hclust" package to use relative euclidean as distance method. For further confirmation, a non-parametric method (Multi-response permutation procedure "MRPP") as communicated by McCune et al. (2002) was used for pairwise comparasion of identified weed communities of wheat and maize crops and seasonality groups (i.e. winter and monsoon) to determine the significant difference with respect to their weeds composition. Indicator species analysis (Dufrêne and Legendre, 1997) was also performed to seek the indicator values of the weed species for the different groups defined by the cluster analysis. Species richness (Margalef, 1958), Shannon's diversity (Shannon and Weaver. 1949) Simpson's diversity index (1-D), Simpson's reciprocal diversity index (1/D) as conveyed by Magurran (1988) and evenness (Pielou, 1975) were calculated for each weeds community by using the "diversity(vegan)" package in R statistical software. The Kruskal-Wallis test was used to seek the significant difference in the weed communities with respect to their diversity, topographic and satellite-derived measurements like NDVI, NDMI and TWI variations. The direct unimodal ordination model (canonical correspondence analysis) was used to seek the weed species-environment relationship. The conditional or net terms effects of the studied variables and significance of constrained axes were tested by using the permutation test in Canoco ver. 5 (Ter Braak and Smilauer, 2012).

Results

A total of 60 weed species were recorded including 23 species in wheat, 28 in maize and 9 species as common in both types of fields in the study area. All these species (monocot 15; dicot 45) belongs to 26 plant families (monocot 3; dicot 23) and 52 genera (monocot 13; dicot 39) (*Table 2*). The leading plant family with maximum number of weed species was Poaceae (12 spp., 20%) followed by Amaranthaceae (7 spp., 11.67%), Compositae (6 spp., 10%), Leguminosae (5 spp., 8.34%), Solanaceae (4 spp., 6.67%), Euphorbiaceae (3 spp., 5%) and Convolvulaceae, Cyperaceae, Malvaceae with 2 species (3.34%) each. Similarly the leading genus was *Euphorbia* (3 spp., 5%) followed by *Amaranthus, Chenopodium, Cyperus, Dactyloctenium, Medicago* and *Solanum* with 2 species (3.34%) each (*Fig. 2*). The majority of weed species were found in the flowering stage during the month of August (42 spp., 70%) followed by July (41 spp., 68.34%), September (41 spp., 68.34%), June (35 spp., 58.34%), May (30 spp., 50%), April (27 spp., 45%), October (26 spp., 43.34%), March (24 spp., 40%), February (12 spp., 20%), January and November (8 spp., 13.34% each) and least during the month of December (8 spp., 13.34%) (*Fig. 3*). Based on Raunkiaer's life form, therophytes weed

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_29953018
© 2018, ALÖKI Kft., Budapest, Hungary

species were dominant (42 spp., 70%) in the study area followed by hemicryptophytes (9 spp., 15%), chamaephytes and lianas (3 spp., 5% each), geophytes (2 spp., 3.34%) and 1 weed species (1.67%) of nanophanerophyte. Similarly, leaf size spectra studies depicted that microphylls weed species were dominant (25 spp., 41.67%) in the study area followed by nanophylls (19 spp., 31.67%), leptophylls (11 spp., 18.34%) and least number of mesophyll (5 spp., 8.34%) weed species were recorded (*Fig. 8*).

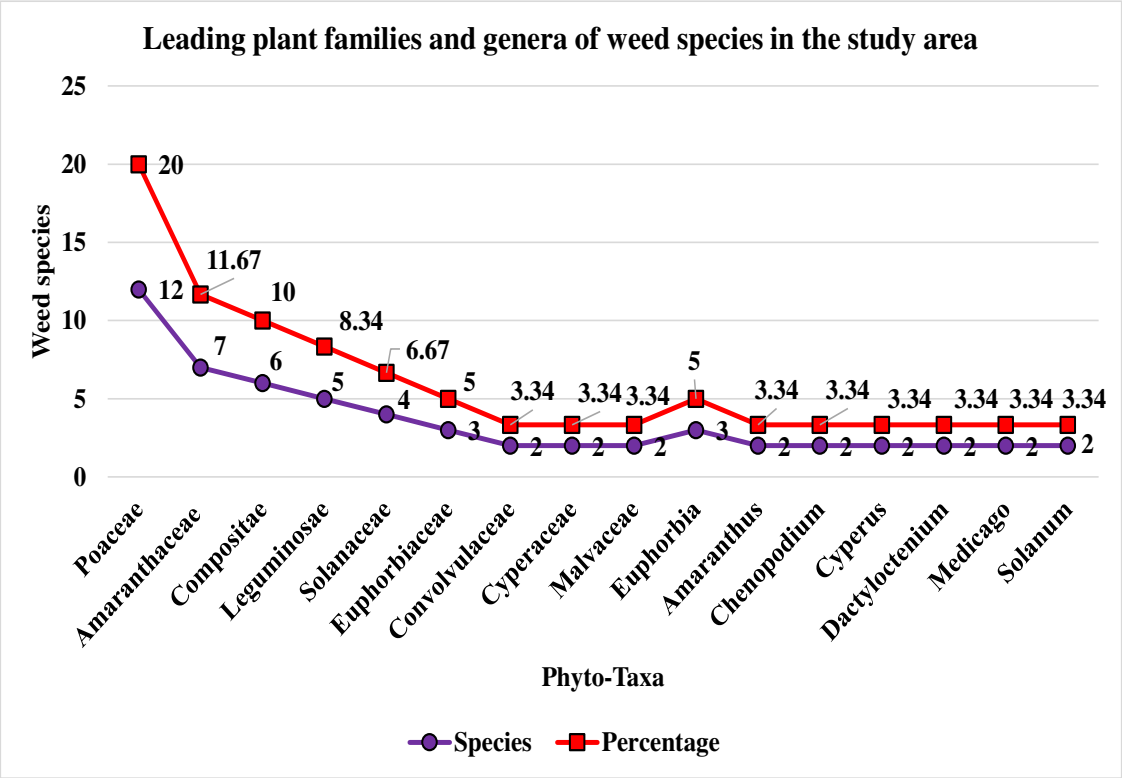

Figure 2. *Leading plant families and genera of weed species of wheat and maize crops of Gujrat, Pakistan.*

Indicator Species Analysis and Weed Communities of the Study Area

The number of ecologically meaningful weed groups were determined first by using Monte Carlo permutation test. The results for two to eight possible groups depicted that there were four (4) biologically meaningful weed communities of both wheat and maize crops in the study area. At fourth level, minimized mean p-value of 0.099 and maximized number of significant p-values or 32 significant indicator weed species were recorded (*Fig. 4*). For classification, and to seek relationship of 50 weed samples and their associated 60 weed species, hierarchical clustering dendrogram was developed. This not only showed that 25 wheat weed samples were sufficiently different from the same number of maize weed samples with respect to their weed species composition but also showed that each of both these major clusters were further comprised of reasonably different two minor clusters or weed communities (*Fig. 5*). Thus, we recorded a total of four significant weed communities in the study area, two each for wheat and maize crop fields. Our results in this regard do not match with any of related studies from Pakistan,

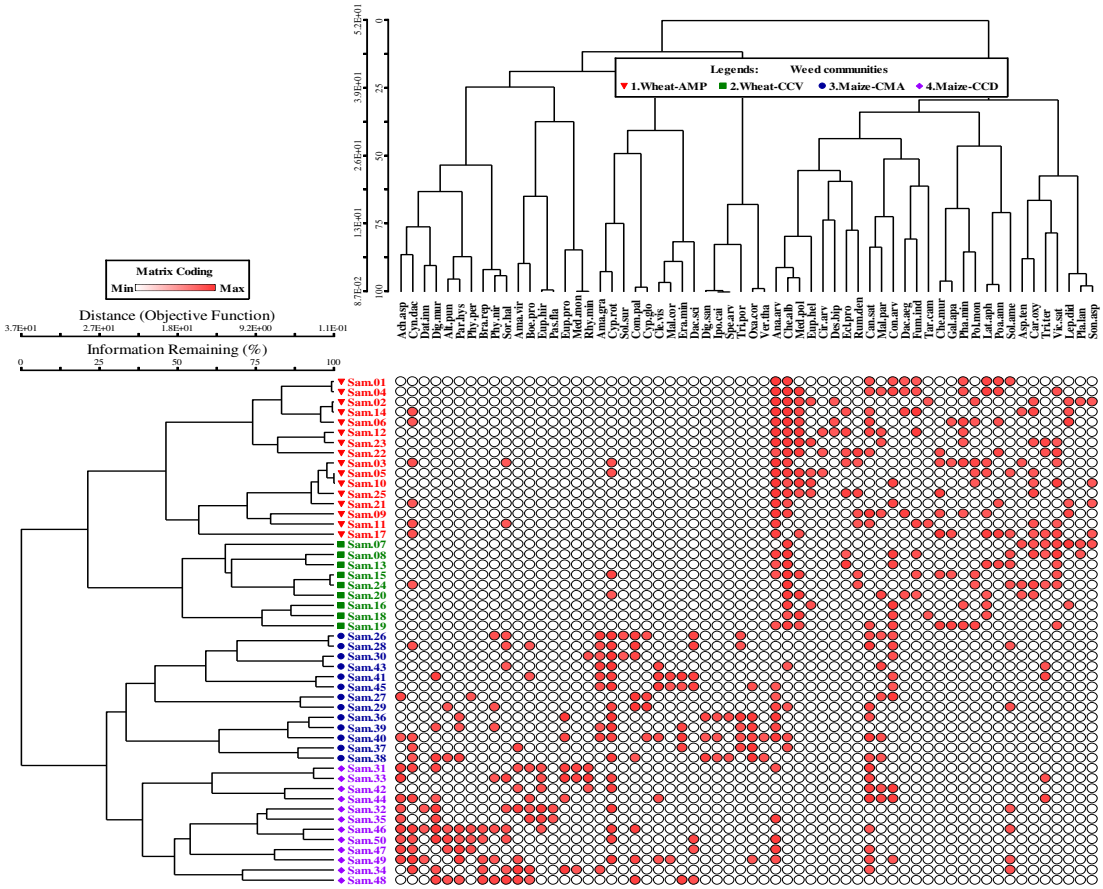

Figure 5. *Hierarchical clustering of weed samples and their associated plant species, showing four biologically meaningful clusters/groups.*

Wheat Fields Communities

Anagallis-Medicago-Phalaris (AMP) Weed Community

This, AMP weed community was recorded at 16 different wheat fields (samples) of Bhojpur, Ghaiyan, Jalalpur Jattan, Karianwala and Sabowal localities (*Figs. 5* and *6*). A total of 31 weed species including 15 indictor weed species were found associated with this group. There were 5 significant (p-value ≤ 0.05) indicator species in this community. This group was dominated by *Anagallis arvensis*, *Medicago polymorpha* and *Phalaris minor* species having mean indicator value of 24.8, 17.1 and 13.1 respectively, thus named as AMP group. The other co-dominant species were *Fumaria indica* (12.9), *Chenopodium murale* (12.4), *Lepidium didymum* (12.3), *Eclipta prostrata* (12.2), *Rumex dentatus* (12), *Poa annua* (11.8) followed by less common species like *Euphorbia helioscopia* (11.1), *Sonchus asper* (10.6) and *Dactyloctenium aegyptium* (10.5). The rare species of this group were *Cirsium arvense*, *Desmostachya bipinnata* and *Taraxacum campylodes* with mean indicator value of 8.8 for each (*Table 2*). The number of weed species in all 16 studied fields varied from 7-14 with average count of 10.25±1.64 species. Similarly the mean values of Margalef richness, Shannon's diversity (H′), Simpson's diversity, reciprocal Simpson's diversity and Pielou evenness of this community were 2.69±0.39, 2.08±0.18, 0.84±0.04, 6.66±1.36 and 0.9±0.05 respectively. It was studied at the mean elevation of 210.5±23.58 m a.s.l. which varied

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

from 183-251 m a.s.l. It was located at latitude range of 32.61-32.82 DD (North) and longitude range of 74.06-74.32 DD (East). The mean NDVI, NDMI and TWI values were 0.38±0.05 (0.31-0.49), 0.15±0.05 (0.05-0.25) and 7.83±0.2 (7.47-8.15) respectively and found higher than the following weed community (CCV community) of wheat crop (*Fig. 7*). Raunkiaer's life form classification of weed species depicted the dominancy of therophytes (22 spp., 70.97%), followed by hemicryptophytes (4 spp., 12.91%), whereas geophytes and lianas were represented by 2 species each (6.46%) followed by chamaephytes (1 spp., 3.23%). Leaf size spectra showed the leading share of microphylls with 13 species (41.94%) followed by leptophylls and nanophylls with 8 species each (25.81%) whereas least number of mesophylls (2 spp., 6.46%) were recorded in this community (*Fig. 8*).

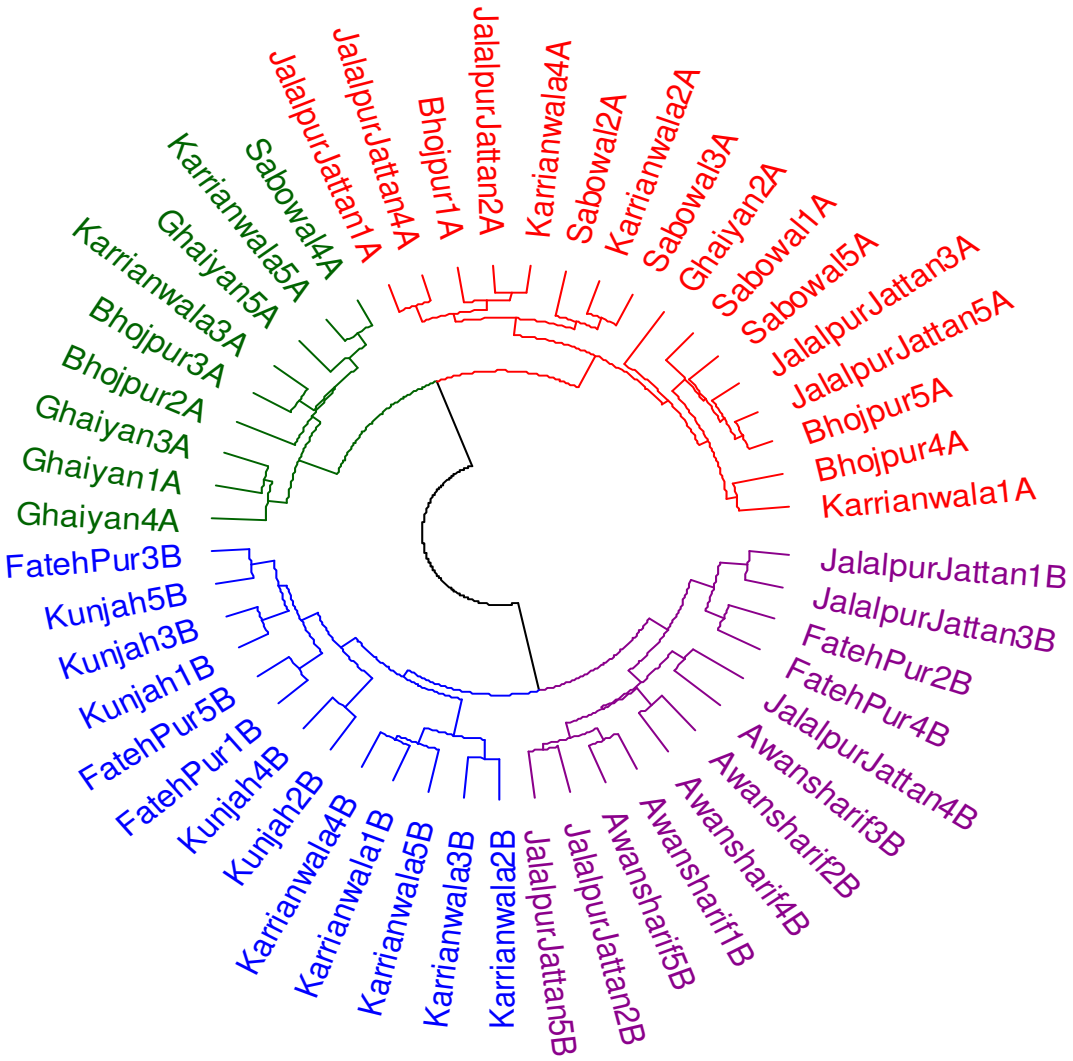

Figure 6. *Fan (polar) shaped hierarchical clustering dendrogram showing grouping pattern of study sites (Red=AMP; Green=CCV; Blue=CMA; Violet=CCD weed community).*

Chenopodium-Convolvulus-Vicia (CCV) Weed Community

This community was recorded at 9 different wheat field of Bhojpur, Ghaiyan, Karianwala and Sabowal localities (*Figs. 5* and *6*). It was comprised of 28 weed species

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_29953018
© 2018, ALÖKI Kft., Budapest, Hungary

including 11 indicators which further includes 3 significant indicators species. The maximum mean indicator value (IV) was recorded for *Chenopodium album* (23.2), *Convolvulus arvensis* (18.3) and *Vicia sativa* (15.9) hence named as CCV community. Co-dominants of this group includes, *Carthamus oxyacantha* (15.1), *Solanum americanum* (15.1), *Lathyrus aphaca* (13.9), *Tribulus terrestris* (13.8) and *Polypogon monspeliensis* (12.6) whereas *Galium aparine* (10.5), *Asphodelus tenuifolius* (10.4) were recorded as less common species. *Plantago lanceolata* (8.8) was measured as rare species of this group (*Table 2*). Average species count of this community was 8.34±1.7, and species number per sample/field ranges from 5 to 10. Values of Margalef richness, Shannon's diversity (H′), Simpson's diversity, reciprocal Simpson's diversity and Pielou evenness of this community were 2.34±0.4 (1.6-2.73), 1.93±0.22 (1.51-2.27), 0.83±0.05 (0.76-0.89), 6.09±1.55 (4.23-9.46) and 0.92±0.05 (0.84-0.98) respectively. It was recorded at an average altitude of 235.34±22.4 m a.s.l. (186-260 m a.s.l.) and located at latitude range of 32.61-32.82 DD (North) and longitude range of 74.06-74.32 DD (East). Similarly, mean NDVI, NDMI and TWI values were 0.34±0.06 (0.25-0.45), 0.12±0.05 (0.04-0.19) and 7.93±0.51 (7.41-8.81) respectively (*Fig. 7*). Life form categorization of 28 weed species of this community depicted the leading abundance of therophytes (21 spp., 77.78%) followed by hemicryptophytes (3 spp., 7.41%), lianas (2 spp., 7.41%) and 1 species (3.71%) each of chamaephytes and geophytes. Leaf size spectra results of this community again showed the dominancy of microphylls (12 spp., 42.86%), followed by leptophylls and nanophylls with 8 species each (28.58%) (*Fig. 8*).

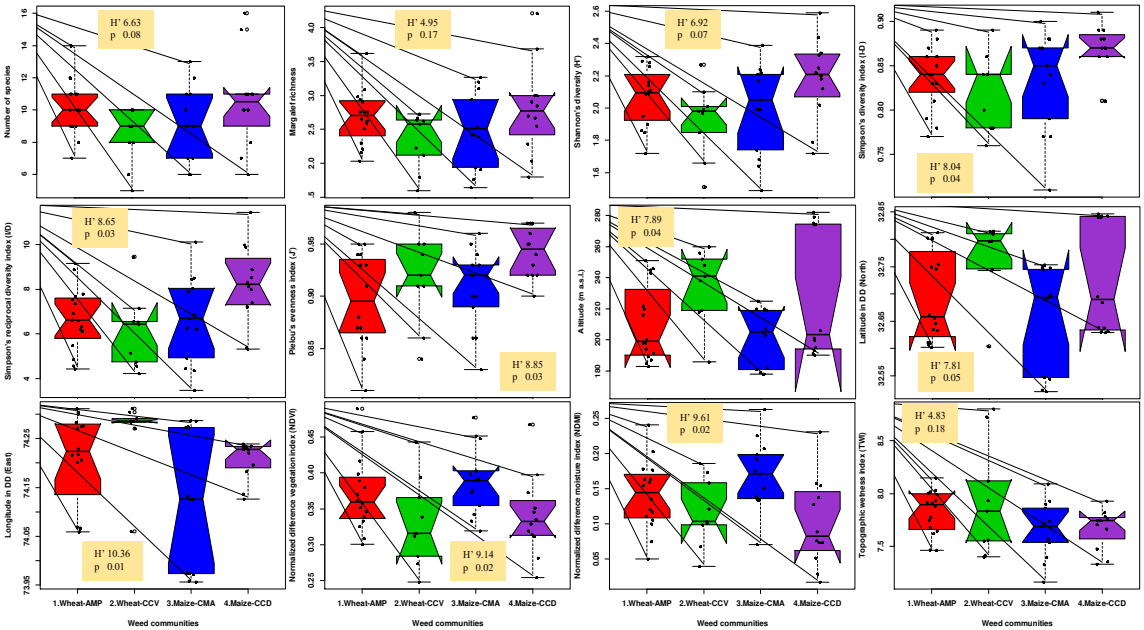

Figure 7. *Boxplots with Kruskal-Wallis H test and its associated p-values of environmental and biotic variables of weed communities in the study area*

Maize Fields Communities

Cyperus-Malva-Amaranthus (CMA) Weed Community

This significant group was studied at 13 different maize fields of Fatehpur, Karianwala and Kunjah localities (*Figs. 5* and *6*). It includes 34 weed species including 16 indicator

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_29953018
© 2018, ALÖKI Kft., Budapest, Hungary

and 10 significant indicator of this group. *Cyperus rotundus, Malva parviflora* and *Amaranthus graecizans* subsp. *silvestris* were leading three species with mean IV of 20.1, 15.3 and 13.4 respectively. Co-dominant species were *Commelina paludosa* (13.3), *Oxalis corniculata* (12.4) whereas, common ones were *Dactyloctenium scindicum* (11.8), *Trianthema portulacastrum* (11.4), *Cleome viscosa* (11.2), *Eragrostis minor* (11.2), *Cyperus glomeratus* (9.7) and *Malvastrum coromandelianum* (9). Less common and rare ones includes *Digitaria sanguinalis* (8.9), *Ipomoea cairica* (8.8), *Verbascum thapsus* (8.1) and *Spergula arvensis* (8), *Solanum surattense* (7.9) respectively (*Table 2*). Average number of species were 9.24±2.16 with range of 6 to 13 whereas Margalef richness, Shannon's diversity (H′), Simpson's diversity, reciprocal Simpson's diversity and Pielou evenness values of this community were 2.48±0.53 (1.64-3.27), 2.01±0.27 (1.49-2.39), 0.84±0.06 (0.71-0.9), 6.64±1.88 (3.48-10.11) and 0.91±0.04 (0.83-0.96) respectively. This group was studied at an average altitude of 201.24±18.2 m a.s.l. (178-225 m a.s.l.) and located at latitude range of 32.53-32.76 DD (North) and longitude range of 73.96-74.29 DD (East). Mean NDVI, NDMI and TWI values of this group were 0.39±0.05 (0.32-0.48), 0.17±0.05 (0.08-0.27) and 7.67±0.26 (7.17-8.1) respectively (*Fig. 7*). Results of Raunkiaer's life form classification of 34 weed species of this community suggested the maximum abundance of therophytes (23 spp., 67.65%), followed by the hemicryptophytes (5 spp., 14.71%), and 2 species (5.89%) each for chamaephytes, geophytes and lianas species. Leaf size spectra results showed the dominance of microphyllous species (16 spp., 47.06%), followed by nanophylls (11 spp., 32.36%), leptophylls (4 spp., 11.77%) and least species of mesophylls (3 spp., 8.83%) (*Fig. 8*).

Cannabis-Cynodon-Digera (CCD) Weed Community

This community was recorded at 12 different maize fields of Awan Sharif, Fatehpur and Jalalpur Jattan localities (*Figs. 5* and *6*). It was comprised 31 weed species including 18 indicator and 14 significant indicator species. Three leading species were *Cannabis sativa* (21.2), *Cynodon dactylon* (18.5) and *Digera muricata* (15.1), hence renamed as CCD community. Associated co-dominants were *Sorghum halepense* (14.7), *Achyranthes aspera* (14.5), *Boerhavia procumbens* (12.8), *Parthenium hysterophorus* (12.7), *Amaranthus viridis* (12.1), *Phyllanthus niruri* (11.9) and *Euphorbia hirta* (11.6), whereas less common were *Alternanthera pungens* (11.1), *Euphorbia prostrata* (11.1), *Brachiaria reptans* (10.4), *Rhynchosia minima* (9.8) and *Physalis peruviana* (9.7). The rare species of this group were *Datura innoxia* (8.8), *Medicago monantha* (8.8) and *Paspalidium flavidum* (8.2) (*Table 2*). Mean species count of this community was 10.5±2.76 with range of 6 to 16 weed species/sample, whereas Margalef richness, Shannon's diversity (H′), Simpson's diversity, reciprocal Simpson's diversity and Pielou evenness values of this community were 2.81±0.64 (1.8-4.21), 2.19±0.24 (1.72-2.59), 0.87±0.03 (0.81-0.91), 8.21±1.71 (5.33-11.44) and 0.95±0.03 (0.9-0.97) respectively. Mean elevation value was 230±39.83 m a.s.l. (190-282 m a.s.l.) and located at latitude range of 32.63-32.85 DD (North) and longitude range of 74.13-74.24 DD (East). Mean NDVI, NDMI and TWI values were 0.34±0.06 (0.26-0.47), 0.11±0.06 (0.02-0.24) and 7.68±0.18 (7.33-7.93) respectively (*Fig. 7*). Therophytes were recorded dominant (20 spp., 64.52%) in this community followed by hemicryptophytes (5 spp., 16.13%), chamaephytes and geophytes with 2 species (6.46%) each and one species (3.23%) each of lianas and nanophanerophytes. Leaf size categorization of weed species of this community depicted that microphylls were dominant (15 spp., 48.39%), followed by nanophylls (10 spp., 32.26%), and three species (9.68%) each of leptophylls and mesophylls (*Fig. 8*).

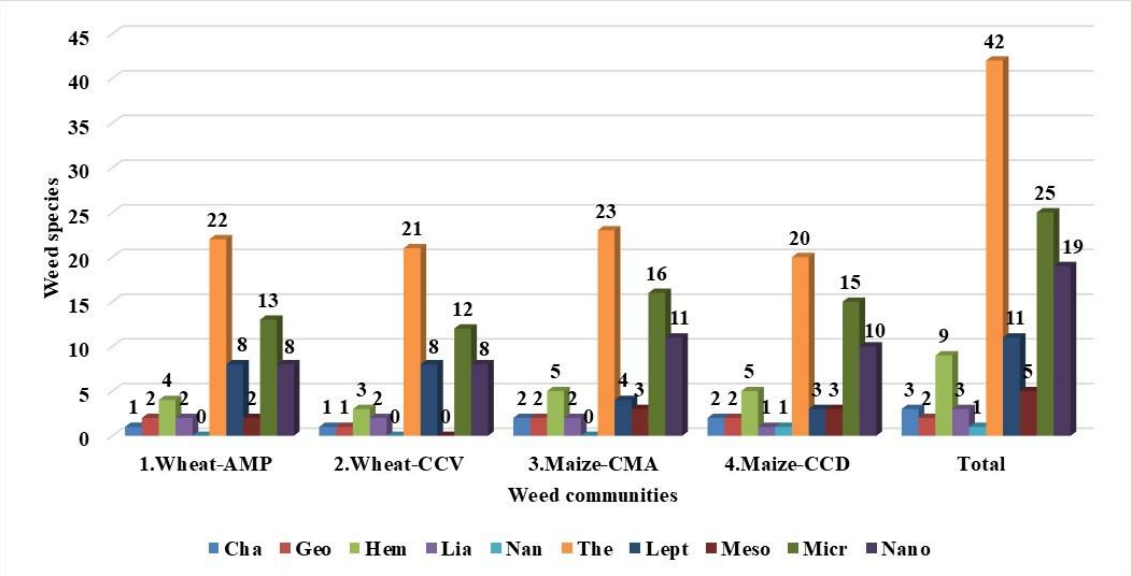

Figure 8. *Raunkiaer's life forms and leaf size spectra of weed communities of the agro-ecological system of the study area (for abbreviation see legends of Table 2).*

Seasonal and Weed Communities Significance

Pairwise comparasion of the two seasons (1. winter weed recorded in wheat fields; 2. monsoon weeds recorded in maize fields) and four weed communities were tested by using Multi-response permutation procedure (MRPP) test. The results depicted that all comparasion were significant (p-value ≤0.05) with respect to weed composition of either both winter and monsoon seasons, and for four weed communities. Similarly, A-values (within group agreement values) for all the comparasion were close to zero, thus depicting heterogeneity within group's equal's expectation by chance (*Table 3*).

Table 3. *Multi-response permutation procedure (MRPP) test results for pairwise comparasion of the seasonal and weed communities groups.*

Groups compared	T	A	p-value
Winter vs. Monsoon crop weeds	-24.376921	0.10575423	0.00000001

Canonical Correspondence Analysis (CCA)

The gradient length of compositional response data was more than 4 SD unit long, thus unimodal direct ordination model (CCA) was selected along with down weightage of rare species. It was used to seek species-environment relationship, contribution and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_29953018
© 2018, ALÖKI Kft., Budapest, Hungary

ranking of explanatory variables towards explaining variations in the species data. A total of 7 variables including seasonality (1=samples studied during winter in wheat fields; 2=samples studied during monsoon in maize fields), longitude, latitude, altitude, NDVI, NDMI and TWI were tested for their influence on species response data (samples, 50; species, 60). Total variation in the species data were 4.87, whereas explanatory variable account for 1.5487 or 31.8% variations. Eigenvalues of CCA axis-1 and 2 were 0.73 and 0.25 respectively whereas species-environment relationship strength of the same was 0.9892 and 0.8912 respectively. Thus, first two constrained axes cumulatively explained 63.67% of fitted variations. Overall CCA model was significant thus further permutation test to seek the significance of explanatory variables and constrained axes (conditional or net term affects) were also performed. This depicted that four variables namely seasonality, longitude, altitude and latitude (in decreasing order) significantly (p-value <0.05) explained variations in the weed species data, whereas satellite derived variables were found non-significant in this regard. Out of 7, first three constrained axes were also found significant (*Table 4*). CCA graphical results (CCA biplot) for species and variables showed that seasonality gradient was the most important and clearly distribute weed species in the ordination space (right=winter/wheat weeds; left=monsoon/maize weeds; center=common weeds of both seasons) and strongly related with CCA axis-1 (*Fig. 9*). It was followed by the longitude (lower=high longitude species; upper= low longitude species) and related to CCA axis-2 and 3. The other important variables like altitude and latitude was found more related to CCA axis-4 (r = 0.74 and 0.75 respectively), followed by NDVI with axis-5 (r = 0.51), NDMI with axis-6 (r = -0.59) and TWI with axis-7 (r = 0.54).

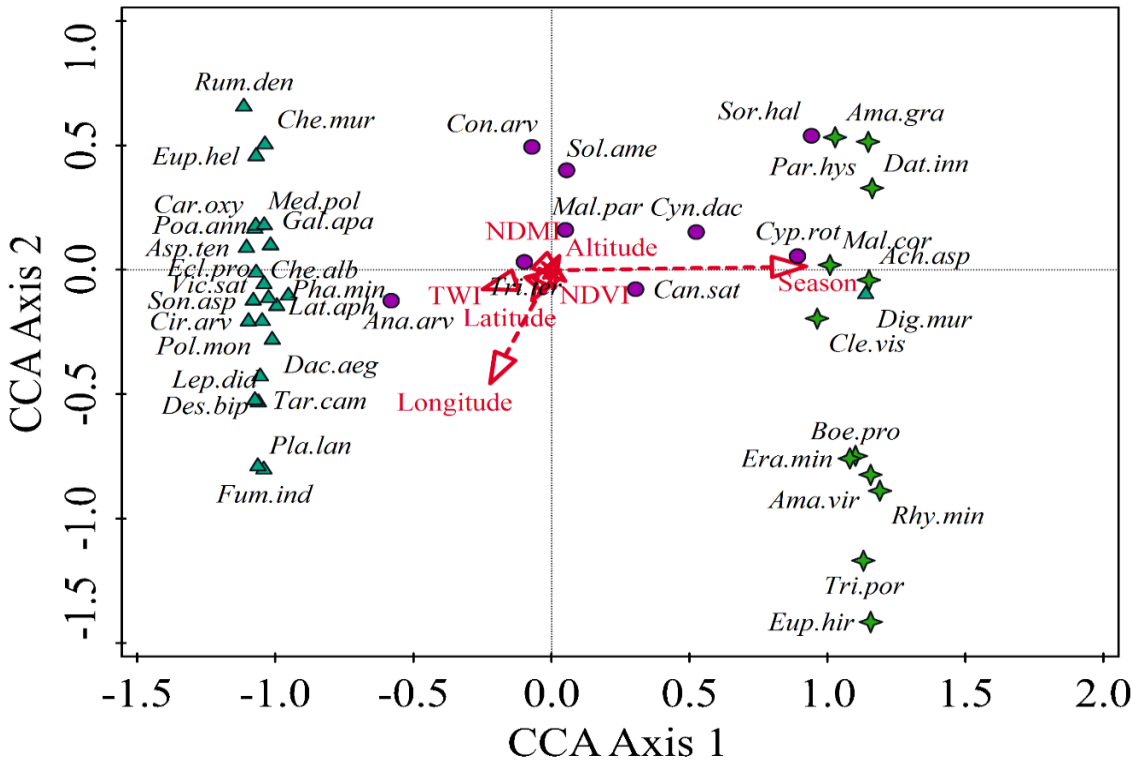

Figure 9. *Canonical correspondence analysis biplot showing the weed species-environment relationships and species groups based on seasonality variable viz. Wheat weeds (left), Maize weeds (right) and common of both crops/seasons (center).*

Discussion

Phytosociological approaches are commonly used to assess the abundance, composition and classification of the weed species of agricultural crops (Anderson, 1996; Qureshi and Bhatti, 2001; Hussain et al., 2004; Jakhar et al., 2005; Hussain et al., 2007; Waheed et al., 2009; Iqbal et al., 2015; Iqbal et al., 2018). Such studies play an important role in the development of weed management to increase the agricultural yield. Additionally, invasiveness capabilities especially of the alien weeds can disrupt local biodiversity (Shabbir and Bajwa, 2006), thus their management is essential to avoid hazardous impacts especially on the crop yield. The satellite remote sensing (SRS) data can be used to study the different bio-physical features of planet earth like vegetation pattern, land cover changes and classification, agricultural yield, land surveying, hydrology and geology etc. For this, different measures like NDVI, NDMI and TWI can be calculated to assess the past, present and future scenario. Sultana et al. (2014) used NDVI values for prediction of wheat crop yield under varied experimental treatments like fertilization and cultivars quality. Thus use of these indices is common to seek vegetation pattern or in the prediction of crop yield pattern. Instead, this novel study was designed to use seasonality (micro-climatic variations) and satellite derived measurements for the exploration of their relationship with the weed distribution pattern of an agro-ecosystem (if any) of Gujrat, Pakistan.

A rich diversity of weed flora was recorded associated with the two important crops (wheat and maize) in district Gujrat, Pakistan. A total of 60 weed species were recorded and the majority of them belongs to Poaceae and Amaranthaceae families (*Fig. 2*). Iqbal et al. (2015) also recorded the dominancy of Poaceae weeds in the wheat crop from Malakand area of Pakistan. The majority of weed species flowered during monsoon season (July to August) due to micro-climatic suitability like higher temperature along with increased rainfall. Similar results were also recorded by Khan et al. (2018) from

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

Muzaffarabad, Azad Jammu and Kashmir, Pakistan. Thus, during this season, therophytic weed species (42 spp., 70%) having microphyllous leaf size (25 spp., 42%) becomes dominant (*Fig. 8*). Similarly Kovačević et al. (2008) also concluded that therophytic weeds group was the dominant character from Herzegovina vineyard region.

Qureshi and Bhatti (2001), Hussain et al. (2004), Jakhar et al. (2005), Waheed et al. (2009), Iqbal et al. (2017) and Iqbal et al. (2018) recorded 5, 3, 3, 5, 5 and 5 weed communities respectively in the wheat fields whereas Ahmad et al. (2016a and 2016b) recorded 4 weed communities each from maize fields of different regions of Pakistan. The decision about the number of the weed communities in the aforementioned studies was made on physiognomic basis and no test statistics was employed. Thus, results of this study about the number of weed groups in both wheat and maize crops do not match with any earlier studies especially from related areas of Pakistan. By using the Monte Carlo testing, this study identified a total of four significant weed groups (*Fig. 4*), two each in wheat and maize fields, followed by hierarchical clustering for classification (*Figs. 5* and *6*) and indicator species analysis for species composition and their strength of association with the each group (*Table 2*). The same groups were further confirmed through MRPP testing (*Table 3*). Thus, weed species composition of each group of this study appeared distinct when compared with the earlier studies. However, the status of overall dominant weed species of both types of crops (i.e. *Anagallis arvensis*, *Medicago polymorpha*, *Phalaris minor*, *Chenopodium album*, *Convolvulus arvensis* and *Vicia sativa* weed species of wheat and *Cyperus rotundus, Malva parviflora*, *Amaranthus graecizans* subsp. *silvestris*, *Cannabis sativa*, *Cynodon dactylon* and *Digera muricata* weed species of maize fields) of this study was mostly comparable and remained the same. On the basis of seasonality difference, 9 weed species were found common in both wheat (winter season weeds) and maize (monsoon season weeds) fields. Out of these, four species named *Anagallis arvensis*, *Convolvulus arvensis*, *Solanum americanum* and *Tribulus terrestris* showed their maximum abundance in samples recorded from the wheat fields, thus appeared as indicator of the wheat communities. Similarly, based on abundance, the other five common weed species including *Cyperus rotundus*, *Malva parviflora, Cannabis sativa*, *Cynodon dactylon* and *Sorghum halepense* were become indicator of the maize communities (*Table 2*). The diversity values like Margalef richness, Shannon's diversity (H′), Simpson's diversity or Pielou evenness for each of weed community and their significance testing by using a non-parametric test (Kruskal-Wallis H test) was performed for the first time from Pakistan. These results depicted that longitude, NDVI, NDMI, reciprocal Simpson's diversity, Pielou evenness Simpson's diversity, altitude and latitude values (in decreasing order) of the studied fields of the four weed communities were significant (p-value ≤ 0.05). The highest mean weed diversity values were recorded for the maize field communities in monsoon season (*Fig. 7*). However, contribution of each studied variable for explaining variations in the species data was tested by using CCA ordination model. Results of CCA suggested that the local micro-climatic conditions (seasonality factor) were to be the most important in controlling the variations in the weed species data. By using CCA, Ahmad et al. (2016a) reported the importance of organic matter, potassium, sandy soil and farming practices as driving factor in controlling the weed distribution pattern

in maize fields of Mardan, Pakistan. Similarly Iqbal et al. (2018) reported the importance of temperature, electrical conductivity, soil structure, organic matter, lime content, preceding crops, soil pH, herbicides usage, timing and quantity of manure as driving factor in wheat fields of Malakand, Pakistan.

No significant contribution of the NDVI, NDMI and TWI variables was recorded towards explaining the variations in the weed species data (*Table 4*). This depicted that crop health would be related to satellite derived measures undoubtedly but due to too much higher abundance of the wheat or maize individuals in comparison to their competing weed species individuals in the fields, these explanatory variables were not significant predictors of weed distribution pattern in any agro-ecosystem. The higher NDVI and NDMI values were recorded for the maize field communities in the monsoon season depicting higher greenness and moisture, whereas higher mean TWI value was recorded for the wheat fields, thus suggesting a strong linkage with the local micro-climatic conditions (*Fig. 7*). The overall variations of the SRS variables in the study area are also presented (*Fig. 10*).

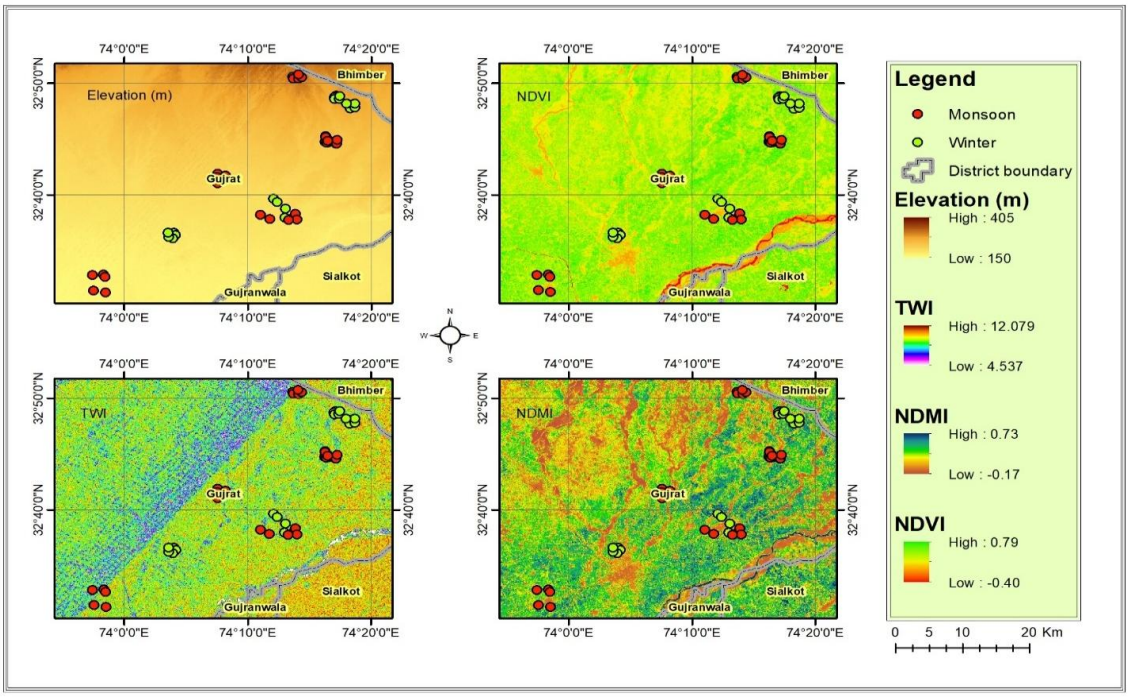

Figure 10. *Map showing satellite derived measurement variations in the study area of Gujrat, Pakistan during 2016.*

This study concluded that effective weed management activities are required to further enhance the yield of these two important crops in the area. Similarly, further studies related to determination of weed types and their distribution pattern by using factors like fertilization (type, timing, quantity), wheat and maize cultivar, land preparation (types, timing and intensities), soil management, pesticides (usage, type, quantity, quality), irrigation (type like rain-fed, tube-well, canals; timing, quantity), socio-economic and anthropogenic activities, and their relationship with the yield variable on temporal and spatial scales are recommended.

Abstract. The variety of the arbuscular mycorrhizal fungi (AMF) under the different forest stands is significant in terms of forest and rangeland ecosystems. In this study, dependent upon the morphological analyses, the diversity of the AMF within the pure oak forest (POF), fir-beech forest (FBF) stands, and gap in forest (GF) soils were compared in Bartın Province, Black Sea Region in northwestern of Turkey. The AMF community composition in POF, FBF and GF soil samples showed variation. Soil organic carbon, available P, number of AMF spores, species richness, diversity index, and dominance index were the main parameters differing among the three studied environments. In particular, the most prevalent "order" in these soils was Glomerales. The most frequent AMF genus in the soils of all these fields was *Glomus.* Varieties in AMF diversity were due to the: (1) changes in soil characteristics (e.g. soil available P and organic carbon); and (2) plant communities in the study fields. These findings support the detailed knowledge of AMF community compositions in soils from Turkey, and introduce new comprehension in order to analyze the ecological processes including the AMF species and native plant species in the northwestern Black Sea Region of Turkey.
Keywords: *Glomeromycota, native plant species, AMF diversity, AMF community composition, ecological processes*

Introduction

Temperate broadleaf and mixed forests constitute several ecoregions within the northwestern Black Sea Region, also referred to as temperate climate terrestrial biome. The temperate climate terrestrial biome was defined by Knudsen et al. (2017) as a "type of forest, which involves tall mature trees, shade-tolerant understory, small mature trees, saplings, suppressed juvenile canopy trees, low growing woody plants and herbaceous plants". This ecoregion is composed of variable vegetation types (usually, classified as four-layered vegetation structure). The ecoregion has dominant broadleaf tree species (e.g., *Quercus* spp. L., *Fagus* spp. L., *Acer* spp. L., *Betula* spp. L.) and coniferous tree species (*Pinus* spp. L., *Abies* spp. Mill., and *Picea* spp. Mill.). However, it is still unclear whether these vegetation types and soil properties have positive impacts on the native arbuscular mycorrhizal fungal (AMF) community (de Souza and Freitas, 2017).

Symbiosis between plant species and AMF is probably the oldest plant-microbes mutualistic relationship (Brundrett, 2002; Parniske, 2008). AMF are important biological component of soil and are closely associated with many ecosystem processes, including: (1) Plant community composition; (2) Soil microbial communities' structure;

(3) Host-plant physiology; and (4) Ecosystem homeostasis (Rillig, 2004; Closa and Goicoeche, 2011; Ortiz et al., 2015; de Souza and Freitas, 2017). They can establish a symbiotic mutualistic connection (with the majority of terrestrial plant species), that is featured by the occurrence of intracellular structures such as arbuscules (Smith and Read, 2008; Hodge and Storer, 2014). AMF also occurs in several terrestrial ecosystems, from forests to grasslands, and from agroecosystems to deserts (Öpik et al., 2006).

In fact, AMF provides water and mineral nutrients (e.g. nitrogen and phosphorus) to the host-plant while plants provide energy (e.g. carbohydrates) to the AMF (Smith and Smith, 2011; Hodge and Storer, 2014). As reported by Rillig (2004), the changes in the physiology (e.g. root exudates, photosynthesis) of the host plant that are induced by the AMF and nutrient uptake, can be conveyed to the ecosystem processes. These ecosystem processes can directly and indirectly affect the diversity of the arbuscular mycorrhizal fungi (AMF) community and their function by altering (1) soil properties and (2) plant community composition (Clapp et al., 1998; de Souza et al., 2016a; Esch et al., 2017; de Souza and Freitas, 2017). AMF community diversity is positively correlated with the plant richness as reported by Zubek et al. (2013). Therefore, decreasing the diversity of plants hosting the AMF community, leads to the reduction in the growth and proliferation of AMF at the sites lacking diversity of host-plant community (Burrows and Pfleger, 2002; de Souza et al., 2016b;).

Development of arbuscular mycorrhizal fungi can strongly be influenced by the plant community composition (de Souza and Freitas, 2017). AMF sporulation and colonization have significantly been affected by the plant diversity (Zubek et al., 2013; de Souza et al., 2016a, b). AMF colonization diminishes due to the host-plant response, soil type and availability of the soil nutrient (Smith and Read, 2008). It is emphasized that the type of forest and host plant might be the determinants for influencing the AMF spore density and biodiversity. The highest AMF spore density along the year was registered from the pine-oak mixed stand, pure pine and oak stands and the agricultural land respectively in India (Chaturvedi et al., 2012).

We investigated the AMF community composition under the pure oak forest (POF), fir-beech mixed forest (FBF) and gap in forest (GF) from Bartın Province, in Black Sea Region at the northwest of Turkey, using morphological analyses. We hypothesized the existence of a diversification of AMF community within the areas that present a high variability of plant community regarding the trees, shrubs and herbs. Several studies were conducted about the interactions among AMF, soil characteristics, and plant community (de Souza et al., 2016a, b; de Souza and Freitas, 2017). In order to achieve our target, we investigated the soil samples collected from the root zones to analyze the soil characteristics and AMF community composition.

Materials and methods

Study sites

The study areas were located in Bartın Province, Turkey. The study areas which are about 61 km away from the city centre of Bartın Province, are located within the 41°32′ Northern latitudes and 32°50′ Eastern longitudes (*Fig. 1*). These areas are located in the northwestern Black Sea Region. The exposures of the pure oak stand and mixed fir-beech stand are South-East and North respectively. The gap in forest exposure is flat. The meteorological parameters used in this research were provided by the

DOI: http://dx.doi.org/10.15666/aeer/1603_30193033
© 2018, ALÖKI Kft., Budapest, Hungary

meteorological station of Bartın province. Relative humidity of the study areas ranges from 66.8% to 71.4% (Topay, 2003). The soil type is Ultisol according to the soil taxonomy of USDA (Kara et al., 2008; Palta et al., 2016). According to the Thornthwaite method, the study area is included into the humid mesothermal climate regime. Climatological data indicated that the annual average temperature is about 8.0°C. On the other hand, the average temperatures of the two hottest months, July and August, are 18.0 and 17.5°C, respectively. The mean annual precipitation in the study area is around 1534 mm (Şengönül et al., 2009).

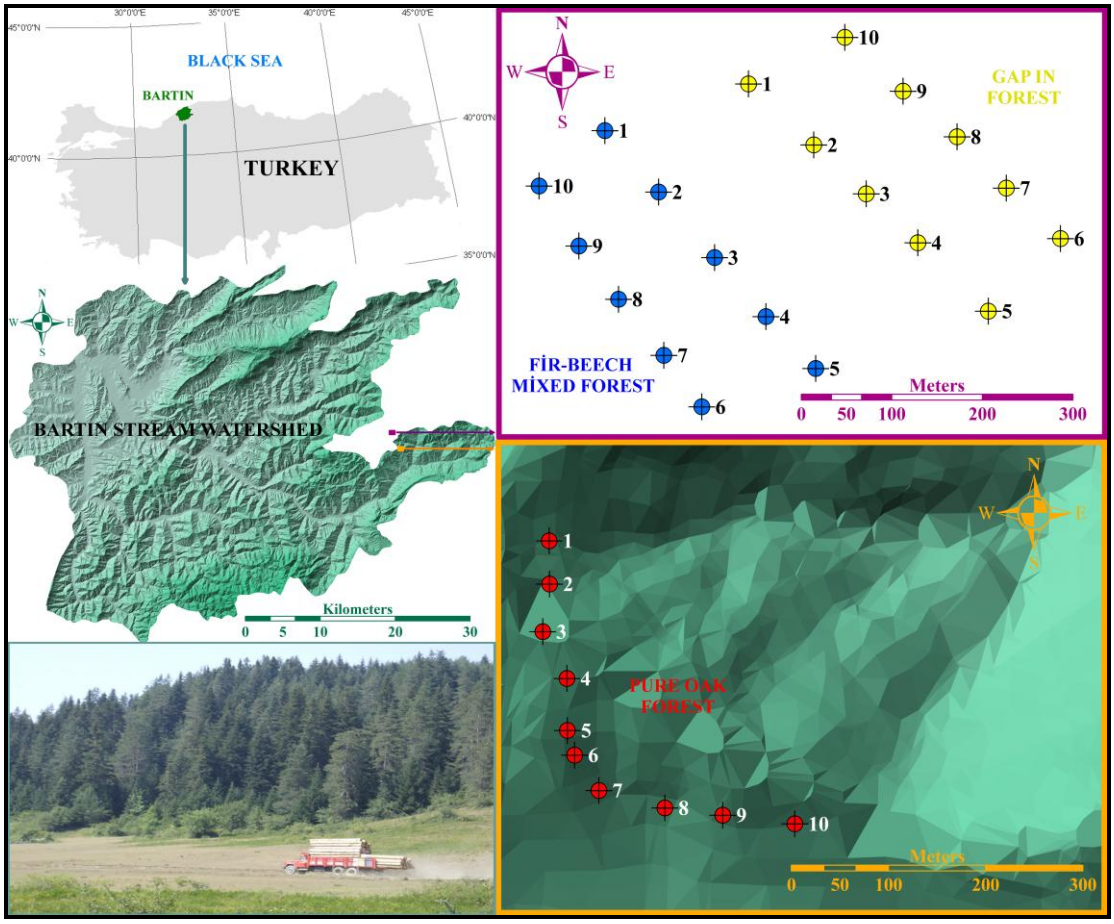

Figure 1. *Sampling points of pure oak, fir-beech mixed forest stands and gap in forest within Bartın Stream Watershed, Turkey. A field photograph is also attached to the figure*

Sampling was conducted on three different sites: (1) pure oak stand (1067 m asl.), (2) fir-beech mixed stand (1004 m asl.) and (3) gap in forest (976 m asl.). The following plant families were relatively common for the three areas: Fabaceae and Gramineae. The soil samples were collected from the rhizosphere of these plants. *Table 1* demonstrates the explicit presentation of the plant taxons and their families within the study fields.

Soil sampling

Soil sampling was conducted during June and July 2015 (dry season). In each area, ten different composite root zone samples that involve soil and root fragments, were

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

randomly taken from the near drip line and beyond (0-30 cm deep) of different plant taxa. The root zone samples from each treatment were sieved by a 2-mm sieve, put in polyethylene bags, and stored at 4°C until analyses dates. Thus, we analyzed 10 samples (n = 10) for each studied area. In addition, along the dry season, the sampling was conducted since the fungal sporulation was estimated to be higher during that period in both arid and semi-arid ecosystems (Silva et al., 2014). The rhizosphere samples gathered from the study areas were separated into the portions in order to assess some of the chemical and physical characteristics of soil and AMF community.

Isolation and identification of arbuscular mycorrhizal fungi

Wet sieving methodology was referred during the isolation of the AMF spores (Gerdemann and Nicolson, 1963), which then was followed by the sucrose centrifugation (Jenkins, 1964). First of all, isolated spores were analyzed under water through a microscope. The spores were classified dependent upon their morphological characteristics. The species definition relied on the diagnosis based on Schenck and Perez (1990), and on scientific literatures about the new genera and families (i.e. Oehl et al., 2008; http://invam.caf.wvu.edu). For this study, we applied the classification suggested by Oehl et al. (2011), involving relatively recent identified new taxa (i.e. Goto et al., 2012; Sieverding et al., 2014). Furthermore, we investigated the AMF spore

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_30193033
© 2018, ALÖKI Kft., Budapest, Hungary

density and the species occurrence frequency (FO_i) of each AMF species. FO_i was computed based on this equation: $FO_i = n_i/N$, where n_i is the number of times an AMF species was examined and N is the total of AMF spores diagnosed from each treatment. Findings of FO_i was classified dependent upon Zhang's frequency of occurrence classification: dominant ($FO_i > 50\%$), most common ($31\% \leq FO_i \leq 50\%$), common ($10\% \leq FO_i \leq 30\%$) and rare ($FO_i < 10\%$) (Zhang et al., 2004; de Souza et al., 2016c).

Chemical and physical characteristics of soils

The standard methods were applied for the analysis of the soil chemical and physical characteristics. These standard methods include the hydrometer method (Bouyoucos, 1962) for the identification of the soil particle size distribution. The pH-meter (Rowell, 1994) was used for the identification of pH in 1:2.5 soil/water suspension. The electrical conductivity meter (Rhoades, 1982) was preferred for the determination of electrical conductivity in 1:5 soil/water suspension. The Walkley-Black wet oxidation method (Walkley and Black, 1934) and Kjeldahl method (Bremner and Mulvaney, 1982) was applied for the analysis of soil organic carbon and total nitrogen, respectively. The available phosphorus was determined based on Olsen et al. (1954). The Scheibler calcimeter method (Allison and Moodie, 1965) was practiced for identifying the $CaCO_3$ content.

Ecological and statistical analysis

In order to analyze the significance of the overall variation in spore density, and soil properties among studied areas, the one-way ANOVA was performed. Data sets were conveyed (arc sin square root for percentage variables and logarithmic for other variables), but the findings were shown in their original scale of measurement (means with standard deviation) (Zar, 1984). When appropriate, the averages were compared by the Duncan test ($p < 0.05$). AMF species richness, spore abundance, species occurrence frequency were also determined. Two ecological indices (Shannon and Simpson) were referred in this research (Shannon and Weaver, 1949; Simpson, 1949). Pearson correlation was also used to examine the relationships between AMF community composition and soil properties. The Statistical Package for the Social Sciences (SPSS), version 16.0 (SPSS 16.0, 2007) was applied for the statistical analyses.

Results

Arbuscular mycorrhizal fungi community composition

There were significant differences on number of AMF identified species ($F_{2,27} = 21.85$, $p < 0.001$), number of spores ($F_{2,27} = 28.45$, $p < 0.001$), diversity index ($F_{2,27} = 13.98$, $p < 0.001$) and dominance index ($F_{2,27} = 12.22$, $p < 0.001$) among the studied sites. It was recognized that the samples from gap in forest had included the highest AMF diagnosed species, with 7.0 identified species, followed by pure oak forest stand (2.2 AMF species) and fir-beech mixed forest stand (1.3 AMF species). The spore density of AMF was 7.6 spores/25 g soil in pure oak forest stand; 2.8 spores/25 g soil in fir-beech mixed forest stand; and 28.2 spores/25 g soil in gap in forest. Diversity (H, Shannon's index) and dominance (C, Simpson's index) in the pure oak forest stand, fir-beech mixed forest stand and gap in forest were 1.63 and 0.21; 1.12 and 0.37; and 2.79 and 0.08 respectively (*Table 2*).

Table 2. *Average of AMF identified species (IS), number of spores (NS), diversity (H) and dominance index (C) of each site (mean ± SD, n = 10) for each analyzed parameter*

Parameter	POF	FBMF	GF
IS	2.20 ± 0.40^{b}	1.30 ± 0.10^{b}	7.00 ± 0.80^{a}
NS (25 g $soil^{-1}$)	7.60 ± 3.71^{b}	2.80 ± 1.98^{b}	28.20 ± 13.19^{a}
H	1.63 ± 0.32^{b}	1.12 ± 0.15^{b}	2.79 ± 0.28^{a}
C	0.21 ± 0.02^{b}	0.37 ± 0.03^{a}	0.08 ± 0.02^{c}

Pure oak forest stand (POF), fir-beech mixed forest stand (FBMF), and gap in forest (GF). Different letters mean significant differences by Duncan test ($p < 0.05$) after one-way ANOVA

Including all the study areas, 27 different AMF species were diagnosed belonging to 15 genera – *Acaulospora* (2), *Cetraspora* (1), *Claroideoglomus* (3), *Corymbiglomus* (1), *Dentiscutata* (3), *Diversispora* (2), *Entrophospora* (1), *Funneliformis* (2), *Gigaspora* (3), *Glomus* (2), *Racocetra* (1), *Rhizoglomus* (2), *Scutellospora* (2), and *Septoglomus* (1) (*Table 3*). Among the total AMF species, 2 (7.41%) were classified as most common species: *Glomus ambisporum* and *Glomus* spp.; 6 (22.23%) were classified as intermediate species: *Acaulospora capsicula, A. foveata, Corymbiglomus tortuosum, Funneliformis caledonium, Rhizoglomus aggregatum,* and *R. fasciculatum*; and 18 (70.36%) were classified as exclusive: *Cetraspora pellucida, Claroideoglomus claroideum*, *C. Lamellosum, C. Luteum, Dentiscutata erytrropus, D. heterogama, Dentiscutata spp., Diversispora eburnea, D. epigaea, Entrophospora infrequens, Funneliformis geosporum, Gigaspora albida, G. decipiens, G. gigantea, Racocetra verrucosa*, *Scutellospora calospora, Sclerocystis sinuosa, Scutellospora* spp., and *Septoglomus constrictum* (*Table 3*; *Figs. 2* and *3*).

Chemical and physical properties of soils

All the chemical and physical properties of soil varied significantly among the studied areas. The highest values of organic carbon, available phosphorous (P), total nitrogen (N) and soil moisture were found in the gap in forest (GP). Soil pH was higher in the fir-beech mixed forest stand (FBMF) compared to the other treatments. For the physical properties, we found the highest values of sand, clay and silt in the pure oak forest (PO) stand (*Table 4*).

Correlation analysis

According to the correlation analysis, a positive correlation was found between the AMF spore density, and organic carbon, available phosphorus, total nitrogen and the moisture of soil with *r-values*; 0.683, 0.534, 0.661 and 0.660, respectively (*Table 5*).

Discussion

Arbuscular mycorrhizal fungi

Our results indicate that the changes in arbuscular mycorrhizal community were led by differences in: (1) plant community composition among the gap in forest and the other two studied forested sites; and (2) soil properties among all the studied sites in the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

northwestern Black Sea Region, Turkey. In fact, these two factors may influence AMF community structure in different ways (Olsson et al., 2010; Zubek et al., 2016; de Souza and Freitas, 2017). In the pure oak forest and fir-beech mixed forest, both plant community and soil properties significantly affected the AMF diversity and dominance. These results are consistent with the former studies (Gehring, 2003; Heinemeyer et. al., 2004; Shukla et al., 2009; Shi et al., 2014), and support our hypothesis that a diversified AMF community is associated with the areas that present a high diversity of plant community involving trees, shrubs and herbs. As a consequence, areas with low diversity of plant species (pure oak forest and gap in forest) are likely to decrease mycorrhizal root colonization (Johnson, 2010; Shi et al., 2014).

Table 4. *Mean of physical and chemical soil characteristics (mean ± SD, n = 10) of the studied areas*

Soil characteristics	POF	FBMF	GF
Sand (%)	35.20(±6.51)^a	47.20(±3.32)^b	41.05(±7.51)^b
Clay (%)	27.30(±5.46)^a	18.60(±2.12)^b	20.05(±5.25)^b
Silt (%)	37.50(±3.95)^a	34.20(±2.35)^b	38.90(±3.60)^a
pH(H_2O)	5.09(±0.16)^a	5.33(±0.36)^a	5.30(±0.58)^a
Soil texture	Clay Loam	Loam	Loam
$CaCO_3$ (%)	0.26(±0.09)^a	0.29(±0.08)^a	0.27(±0.12)^a
Electrical conductivity (dS m^{-1})	0.03(±0.01)^a	0.03(±0.02)^a	0.06(±0.02)^b
Organic carbon (%)	5.18(±0.73)^a	5.46(±1.37)^a	8.10(±0.81)^b
Available P (mg/kg)	46.92(±14.48)^a	50.07(±8.18)^a	71.92(±16.98)^b
Total N (mg/lt)	0.39(±0.08)^a	0.41(±0.09)^a	0.56(±0.13)^b
Soil moisture (%)	33.02(±9.65)^a	26.53(±7.24)^a	43.37(±7.54)^b

The values in the same row that are followed by the different letter demonstrate significant ($p < 0.05$) differences between the means

Table 5. *Pearson's correlation coefficient values (r-values) for AMF spore density (SD), soil organic carbon (C_{org}), available phosphorous (AP), total nitrogen (TN), and soil moisture (SM) from the studied areas (n = 30)*

Variables	SD	C_{org}	AP	TN	SM
SD	-	0.683**	0.534**	0.661**	0.660**
C_{org}			0.637**	0.812**	0.375**
AP				0.709**	0.409*
TN					0.395*

Asterisks indicate significant differences by Pearson correlation analysis (*$p < 0.05$; **$p < 0.01$)

The variety in the AMF community structure among the study areas is due to the decreased vegetation species richness, decreased spore density, decreased biodiversity of arbuscular mycorrhizal fungi species (diversity index), and increased canopy closure of the stands. According to some particular studies also (e.g. Heinemeyer et al., 2004; Shukla et al., 2009; Shi et al., 2014), we hypothesize that the below factors may be drivers of the results observed for the AMF community composition. First, shade may have reduced the carbon allocation from shrubs and herbs by mycorrhizas. Thus,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_30193033
© 2018, ALÖKI Kft., Budapest, Hungary

increasing canopy closure above understory may have reduced light intensity below understory and decreased the photosynthetic ability of host-plants (e.g. *Anthoxanthum odoratum* L, *Carex sp.* L., *Dactylis glomerata* L., *Festuca sp.* L., *Hordeum violaceum* Boiss & Huet., *Lathyrus aphaca* L., and *Sophora jauberii* Spach). Consequently, these two processes may have reduced AM colonization and spore abundance (Heinemeyer et al., 2004; Shukla et al., 2009).

Chemical and physical properties of soils

The results of soil analysis revealed that some of the soil chemical and physical characteristics altered within the study areas. The results observed in the Black Sea Region indicated that the soil pH(H_2O) of forest, tillage and rangeland ranged from 5.0 to 7.8 (Korkanç, 2003; Kara et al., 2008; Şengönül et al., 2009; Palta et al., 2012, 2013). Compatible with the findings of the former studies, our results indicated that the average soil pH(H_2O) values of the pure oak stand, the fir-beech stand and the gap in the forest, were 5.09, 5.33 and 5.30, respectively (*Table 5*).

The observed results demonstrated that the soil organic carbon contents ranged from 4.2 to 7.3% in the rangelands of the Black Sea Region (Okatan, 1987; Şengönül, et al., 2009; Palta et al., 2012, 2013). The average soil organic carbon contents were determined for the pure oak stand, the fir-beech stand and the gap in the forest as 5.18%, 5.46%, 8.10%, respectively (*Table 5*). In this study, the highest organic carbon content was found for the gap in the forest. This may be due to the exposure, slope and non-grazing in the study area. In addition, the gap in the forest field was relatively flat land but the stands were located on the sloping land. The toe of slope positions had superior soil organic carbon content due to the higher infiltration rate (Guzman and Al-Kaisi, 2011) and soil erosion (Gregorich et al., 1998). The highest number of forage legumes were found in the gap in the forest (Şengönül et al., 2009) and it was stated that legumes could supply nitrogen thanks to the biological fixation of N from the atmosphere (Monegat, 1991) and increased the rates of accumulation of both soil nitrogen and carbon (Knops and Tilman, 2000). In addition, it was stated that the soil organic carbon was influenced by the soil properties (Tisdall and Oades, 1982; Kay, 1998; Jones et al., 2004).

Conclusions

This research demonstrated that the arbuscular mycorrhizal fungi biodiversity was influenced by the stand types; the pure oak stand, mixed fir-beech stand and the gap in forest. It was showed that the higher AMF biodiversity and associated AMF spore density were determined for the gap in forest, pure oak forest stand and fir-beech mixed forest stand, respectively. Furthermore, AMF spore density was positively correlated with the organic carbon content, available phosphorus, total nitrogen and moisture of soil. The main results of this study overall indicate: (1) changes in plant community compositions and soil properties alter the AMF diversity and community structure; and (2) plant community composition below the understory can influence AMF biodiversity indicating that the overall vegetation diversity is significant for the AMF diversity. The studies on AMF are currently and relatively inadequate in the northwestern Black Sea Region. Therefore, similar researches should spatially be spread and favoured within the region in order to delineate the map of AMF distribution. Besides, genus of native AMF should be isolated

PRODUCER FIGHT AGAINST CROWN GALL DISEASE

YAĞCI, A.

Department of Horticulture, Gaziosmanpaşa University, 60240 Tokat, Turkey
(e-mail: adem.yagci@gop.edu.tr; phone: +90-356-252-1486; fax: +90-356-252-1488)

(Received 1st Mar 2018; accepted 10th May 2018)

Abstract. *Agrobacterium vitis*-induced crown gall disease (tumor) is the greatest problem in vineyards. Much proceed has not been achieved in fight against crown gall disease. Producers either totally stub out the vines from already established vineyards or keep viticulture activities with palliative measures. This study was conducted for two years to investigate the effects of shoot regeneration on yield, quality and development of *A. vitis*-infected grapevines. Initially the grapevines with morphologic *A. vitis* symptoms were determined in experimental vineyard. Then, deep pruning (cutting) was performed 10-15 cm below the tumorous sections of the stems in 2010, 2011 and 2012 and shoot regeneration was stimulated. Data were gathered about yield, quality (number of clusters, cluster weight, berry weight, must TSS content, TA, maturation index) and vine growth parameters (number of buds, number of shoots, burst ratio, pruning weight). About 15% less development was observed in grapevines with shoot regeneration treatments in 2012, 25% in grapevines with shoot regeneration treatments in 2011 and 37% in grapevines with shoot regeneration treatments in 2010. With shoot regenerations in 2012, 2011 and 2010, yields decreased respectively by 49, 58 and 66%; cluster weights decreased respectively by 32, 37 and 47% and berry weights decreased respectively by 14, 19 and 21%.
Keywords: *pruning, Narince, yield, development, percent change*

Introduction

The yield and quality in viticulture are largely dominated by the rootstocks, training systems, irrigation methods, fertilization and relevant technical and cultural practices (Winkler et al., 1974; Çelik et al., 1998; Noar and Gal, 2002; Keller, 2010). Pests and disease management is also another factor significantly influencing yield and quality in viticulture. It was reported that without the proper control practices, 66% yield loss was caused by powdery mildew (Çetinkaya and Onoğur, 2006) and 10-15% yield loss was caused by dead-arm (*Phomopsis viticola*) (Anonymous, 2013). Pest and diseases result in significant changes in number of clusters, cluster weights, berry weights and physico-chemical attributes of the berries (Pool et al., 1984; Stummer et al., 2003; Akgül et al., 2017).

Pests and disease prevention and control measures are not either taken or such measures are uneconomic in vineyards. Common pests and diseases include bacterial crown gall (crown gall disease) (*Agrobacterium vitis* or *Rhizobium vitis*), Eutypa *(Eutypa lata)*, viral infections (*Grapevine Leafroll, Grapevine Fanleaf)* and phylloxera pest (*Viteus vitifoliae*). Crown gall (*A. vitis*) disease is a bacterial disease (Ophel and Kerr, 1990). Disease progress is closely related to climate conditions. The disease result is significant yield and quality losses in grapevines (Schroth et al., 1988; Çelik et al., 2000; Diana and Dejeu, 2011; Akgül et al., 2016).

A. vitis is transported through xylem and phloem transportation vessels (Lehoczky, 1971; Burr et al., 1998). The bacterium usually causes tumor formations over grapevine stem. The disease also encountered in roots and shoots (Lehoczky, 1971; Burr et al., 1987; Keller, 2010). The tumors formed over various parts of the plant limit water and nutrient transport throughout the plant. Then vine growth and development, yield and quality decreases in time (Schroth et al., 1988; Ferreira et al., 1992; Keller, 2010; Diana

© 2018, ALÖKI Kft., Budapest, Hungary

and Dejeu, 2011). Scrapping the tumors over the stem and 5-7% Bordeaux mixture applications over the lesions (Saygılı et al., 2008) may prolong grapevine life for couple years, but cannot prevent ultimate deaths (Burr and Katz, 1984; Schroth et al., 1988).

In present research region, 75.35% of the vineyards are infected with *A. vitis* (Durak et al., 2017). Therefore, farmers are still making productions with generally infected grapevines. Some producers cut *A. vitis*-infected grapevines 10 cm below the tumors and apply high concentration (7-8%) Bordeaux mixture over the lesion. Then, adventive buds over the stem shoot out and new shoots are formed (*Figs. 1* and *2*). Such a practice is shortly defined as shoot regeneration.

This study was conducted to investigate the effects of shoot regeneration treatments on grape yield, quality and development of *A. vitis*-infected grapevines.

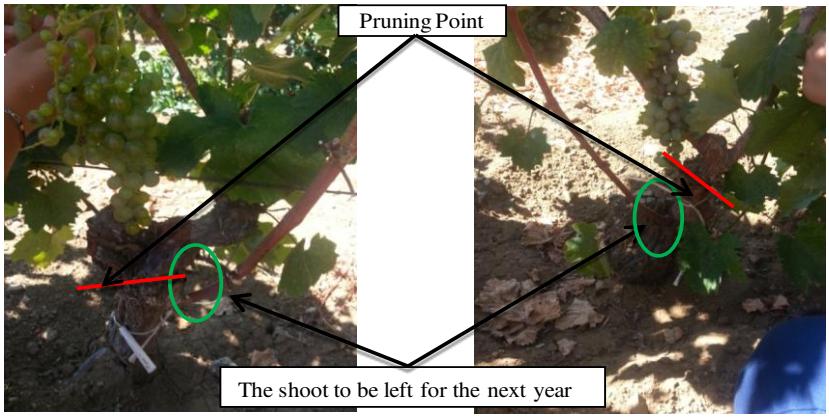

Figure 1. *The grapevines to be shoot regenerated in the next year: pruning locations and the shoots to be left*

Figure 2. *Shoot regenerated in 2013 (harvest time of 2013)*

Materials and methods

Experiments were conducted in a producer vineyard (Tokat-Turkey; located at 40° 37' 10.99" N, 36° 43' 27.87" E) in 2013 and 2014. Narince/1103 Paulsen grape cultivar planted at 3.0 x 1.5 m planting density in 2000 was used as the plant material. Narince is a significant white wine cultivar of Turkey. International *Vitis* code of the cultivar is 8351. Bilateral cordon system was used as training system. Dry farming was practiced

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_30353042
© 2018, ALÖKI Kft., Budapest, Hungary

without any irrigations. Standard care practices were performed throughout the experiments.

The first *A. vitis* symptoms were observed by the owner in 2008. From the year 2010, severe/deep pruning was performed 10-15 cm below tumorous section of the grapevine stem (*Figs. 1* and *2*). This process was kept on in 2011 and 2012. New shoots of the grapevines were long-pruned (10-12 buds) in the second year. The grapevines with shoot regeneration treatments were marked in each year. Brief information about the grapevines considered in this study is provided in *Table 1*.

Table 1. *Stem regeneration year, stem diameter and number of grapevines*

Stem regeneration year	Stem diameter (mm)	Number of grapevines
Non-tumorous (2000)	78.0-82.0 mm	6
GY-1 (year 2012)	13.0-19.0 mm	6
GY-2 (year 2011)	15.0-20.0 mm	6
GY-3 (year 2010)	15.0-22.0 mm	6

Experiments were conducted in 2013 and 2014. Therefore, the time elapsed between shoot regeneration and yielding years in grapevines with stem regeneration in 2010, 2011 and 2012 was expressed as: 1-2 years (GY-1) (for 2012), 2-3 years (GY-2) (for 2011) and 3-4 years (GY-3) (for 2010).

In 2013, pathogen existence and diagnosis analysis was performed in experimental vineyard. *A. vitis* pathogen was diagnosed in all of the shoot-regenerated grapevines. For diagnosis; DNA extractions were performed in accordance with Benlioğlu et al. (1998) and PCR tests were performed in accordance with Szegedi and Bottka (2002). Within the same vineyard, the grapevines without tumor development and with negative analysis results were considered as control vines.

Methods

Development, yield and some quality parameters were measured on grapevines.

Development values

Number of buds: The buds left over the grapevines were counted after pruning (*Eq. 1*).

Number of shoots: The shoots in each grapevine were counted.

$$\text{Burst ratio (\%)} = \left(\frac{\text{Number of bursted buds}}{\text{Total number of buds}}\right) \text{x } 100 \qquad \text{(Eq.1)}$$

Pruning weight (kg/vine): Pruning was performed after defoliation and 1-year-old wood (shoot) were weighted.

Yield and quality values

Harvest was performed at The Soluble Solid (TSS) contents of between 19.0-23.0% (Rieger, 2006).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_30353042
© 2018, ALÖKI Kft., Budapest, Hungary

Yield (kg/vine): The grapes harvested from each vine were weighted with a digital balance (Densi PC-300) to get the yield per vine.

Number of clusters (cluster/vine): Clusters were counted at harvest.

Cluster and berry weights (g) were determined with a digital balance (Precisa BJ 1200C); TSS contents were determined with a refractometer (Atago Master-93H); must pH values were determined with a pH meter (WTW Inolab pH 7310); titratable acid (TA) (g/l) was measured in accordance with Cemeroğlu (1992); maturation index was calculated as TSS/TA ratio.

Statistical analysis

Experiments were designed in randomized plots with six replications. Descriptive statistics for the continuous variables were presented as Mean and Standard Error of Mean while count and percentages for categorical variables. One-way ANOVA was used to compare group means. LSD multiple comparison test was performed to identify different group means followed by ANOVA. Statistical significance level was considered as 5% and SPSS (ver: 13) statistical program was used for all statistical computations.

Percent change: Percent change in investigated parameters indicates positive or negative changes in data as compared to the control. Percent changes were calculated by using *Equation 2*.

$$\text{Percent Change} = \left(\frac{\text{Control}}{\text{Treatment}} - 1\right) \text{x } 100 \qquad \text{(Eq.2)}$$

Results and discussion

Development values

In observations made at the period in which inflorescences were started to be seen, number of buds left per vine, number of shoots and pruning weights were significantly different in both years, but the differences in bursting ratios were not found to be significant. Pruning weight is a significant indicator of vine growth and development and the values were higher in healthy grapevines. Pruning weights proportionally decreased with the shoot age. In other words, the grapevines with earlier shoot regeneration were more influenced by disease severity. Such a case then regressed vine development (*Tables 2* and *3*). When the vine growth in healthy vines are assumed to be 100, the development values in 2013 and 2014 were respectively 19-15% less in GY-1, 26-25% less in GY-2, 41-37% less in GY-3.

Yield and quality values

The grapevines subjected to shoot regenerations due to *A. vitis* had significantly different yield and quality values from the healthy vines. With regard to yield, number of cluster, cluster weight, berry weight and maturation index values, while healthy vines were placed in one group, shoot-regenerated vines were placed in two different groups. The lowest values were observed in the oldest shoot-regenerated (year 2010) vines (*Tables 4* and *5*).

When the shoot-regenerated vines were compared with the healthy vines, it was observed that yield values in 2013 and 2014 respectively decreased by 47-50% in GY-1, 58-58% in GY-2 and 67-64% in GY-3.

According to two-year averages, grape yield of healthy vines was 7.70 kg, cluster weight was 328 g, 100 berry weight was 307 g and pruning weight was 2.81 kg/vine. In shoot-regenerated grapevines, grape yields varied between 2.65-3.94 kg, cluster weights varied between 175-223 g, 100 berry weights varied between 244-266 g and pruning weights varied between 1.78-2.39 kg/vine. Regression analyses revealed continuous

decrease in yield, cluster weight, berry weight and pruning weights with the years. Such decreases were found to be significant in all four parameters (*Fig. 3a-d*).

According to two-year averages, as compared to control treatments, percent change in yield and quality parameters of *A. vitis*-infected oldest shoot-regenerated grapevines was quite greater than the other vines (*Fig. 4*).

Present findings on *A. vitis*-induced decreases in yield, growth and development of grapevines comply with the results of Schroth et al. (1988) and Ferreira et al. (1992). Negative trends in changes in infected grapevines (yield, number of clusters, cluster weight, berry weight, TTS and TA) were mostly resulted from growth weakening effect of *A. vitis*.

Pruning weight is a significant indicator of grapevine growth and development (Noar and Gal, 2002; Çelik and Çağdaş, 2007; Keller, 2010). With the weakening in vine growth and development, especially carbohydrate mechanism of the grapevines is negatively influenced (Ağaoğlu, 2002; Keller, 2010) and resultant tumors significantly limit or restrict nutrient transport through various parts of the plants (Lehoczky, 1971; Burr et al., 1998).

Conclusion

Producers usually try or employ various methods to overcome the problems they experienced in viticulture practices. Significant *A. vitis*-induced decreases in yield and quality parameters were also reported by the growers. Instead of totally stubbing already established vineyard and waiting 4-5 years to reestablish the new one, deep pruning for shoot regeneration and to rejuvenate the grapevines may provide a practical solution for *A. vitis*-infected grapevines. However, such practices can only serve a short-term solution, may prolong vine life and allow growers to get yields for couple more years. *A. vitis*-infected vines ultimately end up with total die outs. For now, in present fight, the winner is still *A. vitis* …

Abstract. Remote sensing data are important data sources in the management and planning of forest ecosystems. In this study, we aimed to estimate forest stand parameters using the spectral (*Average Brightness Value*) and textural features (*Standard Deviation of Gray Levels, Entropy, Contrast, Correlation, Homogeneity*) derived from digital aerial images. Study was carried out in Adıyaman Forestry Operation Directorate in Turkey. Relationships between image features and stand parameters (diameter at breast height-DBH, mean height, stand volume, basal area, and number of trees) were tested by using Pearson's correlation coefficient. Image features exhibiting the highest correlation with stand parameters were modelled by a linear regression analysis. The validity of the models developed was then tested using the leave-one-out cross-validation method. The '*Contrast*' values derived from the infrared band showed the highest correlation with DBH and mean height, the '*Contrast*' values from the red band showed the highest correlation with stand volume and basal area, and the '*Homogeneity*' values from the infrared band showed the highest correlation with the number of trees. The adjusted coefficients of determination (R^2_{adj}) of the estimation models were calculated 0.48 for DBH, 0.38 for mean height, 0.41 for stand volume, 0.45 for basal area and 0.43 for tree number. The relative root mean square error (RMSE%) values were for each parameters 11.91%, 23.57%, 20.96%, 15.81% and 16.20%, respectively.
Keywords: *forest inventory, remote sensing, digital aerial image, forest properties, image features*

Introduction

Effective management and planning of forest ecosystems requires up-to-date and reliable data. Remote sensing data have great potential as an auxiliary data source in estimating forest structural variables (Kayitakire et al., 2006). Forest inventory for forest management planning is traditionally based on the combination of field measurement and aerial photographs. In this method, forest stands are delineated on the basis of aerial photographs and forest stand parameters (e.g. volume, basal area, density) are calculated using some empirical formulas after necessary measures on the sample plots. Aerial photographs are widely used in mapping forest stands. However, as this approach usually necessitates visual photo interpretation, its success depends on the experience of interpreter. Therefore, it is time-consuming and subjective particularly on large areas (Gong et al., 1999; Tuominen and Pekkarinen, 2005; Morgan and Gergel, 2013; Balenovic et al., 2015). Moreover, field measurements are the most widely used data source in forest inventory. Periodical field measurements yield the most accurate results. Nevertheless, its cost, time-consuming and labour-intensive nature removes these advantages (Müllerová, 2005; Gonzalez-Benecke et al., 2014).

Apart from these disadvantages of traditional methods, improvements in computer technologies and satellite images have caused a gradual transition from traditional methods to semi-automatic and automatic methods (Hájek, 2008; Balenovic et al.,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

2015). Multispectral remote sensing images produce reliable digital data for the automatic estimation of forest stand parameters. Automatic image analysis techniques also provide a rapid estimation of the forest stand parameters through these images (Hayitakire et al., 2006; Huang et al., 2013). Taking advantage of satellite image data in forest inventory has increased interest since the first satellite of LANDSAT program launched in 1972. With the advances in technology, the production of sensors which provide high resolution and multispectral image has raised more interest (Franco-Lopez et al., 2001; Katila et al., 2001). Several studies carried out so far have focused on using multispectral satellite images such as Landsat, SPOT, IKONOS, QuickBird and WorldView to estimate forest stand parameters. For instance, Hyyppä et al. (2000) evaluated SPOT XS, SPOT Pan and Landsat TM satellite images in terms of the estimation accuracy of stand volume, mean tree height and basal area. Ozkan (2006) investigated the possibilities of estimating the forest stand parameters (number of trees, stand volume, basal area, mean diameter and mean height) with the spectral features derived from SPOT-5 satellite data. In another study carried out by Kayitakire et al. (2006), the estimation capabilities of IKONOS satellite image in spruce forest stands for five main forest variables (age, top height, circumference, stand density and basal area) was evaluated. Hall et al. (2006) developed a forest stand volume model using the relation between forest structural features and spectral features from Landsat ETM+ image. Similarly, Ozdemir and Karnieli (2011) evaluated the determination of forest structural parameters using image textural features derived from WorldView-2 satellite image. The obtained results indicated that satellite images can be used for the estimation of forest structural features on large areas. However, the accuracy of estimations models failed to satisfy at sample plot or forest stand level. Therefore, their suitability is thought to be low in forest management planning studies.

Recent studies have focused on estimating forest stand parameters using digital aerial images due to the less accuracy of satellite images (Kayitakire et al., 2006; Balenovic et al., 2015). Aerial photographs are an important data source for sample plot or forest stand level forest inventory (Morgan et al., 2010). Over the last 30 years, there has been a transition from analogous photogrammetry to digital photogrammetry as analogous aerial photographs are replaced with digital aerial images (Balenovic et al., 2015). In addition to high spatial resolution, RGBIR (Red, Green, Blue, Infrared) bands and digital data flow of digital aerial images provide a great advantage in estimating forest stand parameters and producing forest stand maps (Hájek, 2008). While some of the forest stand parameters (such as tree height, crown diameter, crown closure) can be measured directly from digital images, some others can be calculated using empirical formulas or estimated using image features. For the estimation of forest stand parameters, spectral and textural properties of remote sensed images are the most important characteristics (Zhou and Sun, 1995; Mäkinen et al., 2006; Ozdemir and Karnieli, 2011).

In addition to image spectral features, textural features can also be calculated through original pixel values. The spectral features can be defined as average reflection value of an image window (Anttila, 2005). 'first-order texture' which includes statistical variation measurements and 'second-order texture' which includes *Grey Level Co-occurence Matrix (GLCM)* proposed by Haralick et al. (1973) are the most widely used textural features of digital images to define (Ozdemir et al., 2008; Ozdemir and Donoghue, 2013). Recently, *GLCM* Textural features have been widely used (Levesque and King, 2003; Coburn and Roberts, 2004; Tuominen and Pekkarinen, 2005;

Kayitakire et al., 2006; Maltamo et al., 2006; Hájek, 2008; Ozdemir and Karnieli, 2011; Tuominen and Haapanen, 2011; Sarker et al., 2012; Ozdemir et al., 2012; Ozdemir and Donoghue, 2013; Ozkan, 2014; Walner et al., 2014; Lu et al., 2016; Ozkan et al., 2016; Ozkan et al., 2017). Nevertheless, these studies are mostly carried out using satellite images. It is stated that the textural features can be an important explanatory variable to estimate the stand parameters from high-spatial resolution images such as digital aerial images. And also textural features as well as spectral features can improve the estimation accuracy (Tuominen and Pekkarinen, 2005; Anttila, 2005; Packalén, 2009). Nevertheless, estimation of forest stand parameters using spectral and textural features of digital aerial images has not been studied adequately. Further studies are still necessary for operational using of spectral and textural features in forest management planning.

Effective use of digital aerial images in forest management planning relies on the relation between the scale of target object (tree, forest stand, etc.) and spatial resolution of digital aerial image (Falkowski et al., 2009). Target objects are much larger than image pixel size and a single pixel does not contain significant data when considering target objects. Therefore, related parameter should be extracted from a larger area than a single pixel. For example, although forest stand is defined as a homogenous area in forest management practice, forest stand is not an entirely homogenous object in terms of image features. Forest stands in remote sensed images comprise of a composition of various spectral classes such as small gaps, shadowy and sunny crown. Object-based image analysis is considered as an important approach for extracting significant information from high spatial resolution remote sensed images (Antunes et al., 2003; Huang et al., 2013). On forest stand level, image segmentation which is the first step in object-based image analysis, is a useful algorithm that increase accuracy of forest stand parameters estimation (Anttila, 2005).

The purpose of this study is to predict forest stand parameters using the spectral and textural features derived from digital aerial image. To achieve this goal, firstly, the relations between forest stand parameters and image features were analyzed and investigated to determine which one of them are suitable options for estimation models. Then, linear regression analysis utilized for estimation models with considering image features and also validity of the models were tested using adjusted coefficient of determination (R^2_{adj}), root mean square error (RMSE) and relative root mean square error (RMSE%).

Materials and methods

Study area

Study area is located between 37°59’29”–37°24’02” north latitude and 38°31’30”–37°25’44” east longitude in Şanlıurfa Regional Directorate of Forestry, Adıyaman Forestry Operation Directorate in Turkey (*Figure 1*). The study area covers 439621 hectares which general land comprise of 105771 hectare forested land. Dominant tree species of study area is Brutian pine (*Pinus brutia Ten.*) and Oak (*Quercus brantii var. persica, Quercus libani var. angustifolia, Quercus infectoria var. boissieri, Quercus cerris var. variegata*). Besides these, Juniper (*Juniperus excelsa var. excelsa, Juniperus oxycedrus var. oxycedrus*) species are found at high altitude areas. Oak stands are managed as coppice and juniper stands are located fragmentary. This study covers Brutian pine plantations.

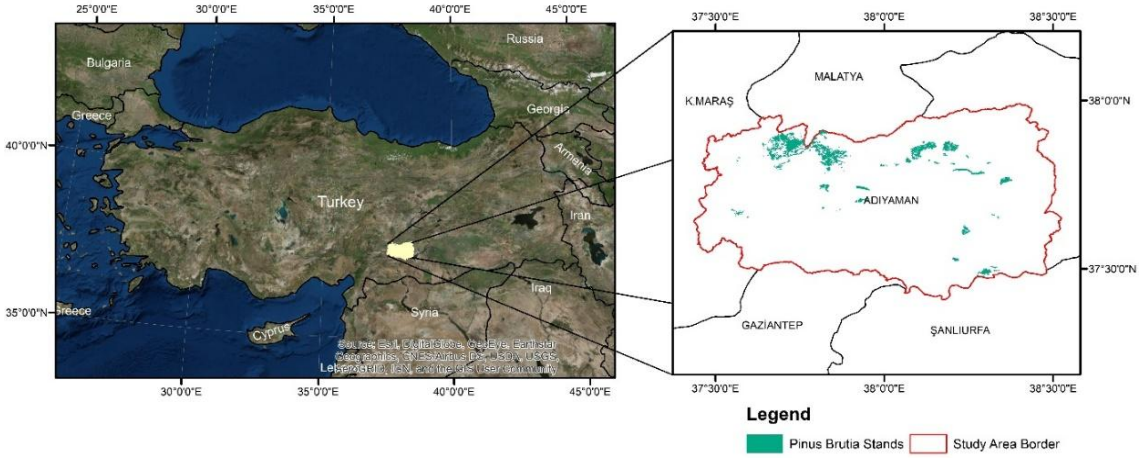

Figure 1. *Geographical location of study area*

Digital aerial imagery

Aerial images used in the study are totally comprised of four bands which are Red (580-700 nm), Green (480-630 nm), Blue (410-540 nm) and Infrared (690-1000 nm) bands. These images are taken as stereo from altitude of 7200 meters, 70 % forward and 30 % side overlap, by airborne using UltraCamX (Microsoft, Vexcel Imaging GmbH) digital aerial camera which has 7.2 µm physical pixel size, in 2011. For each stereo image pair, geometric calibration and radiometric correction utilized in ERDAS LPS (Hexagon Geospatial) software using interior (focal length, coordinates of the principal point) and exterior (position and rotation of the camera) orientation parameters of raw images.

Vegetation indexes were developed using the original bands in order to provide more detailed data concerning the areas covered with vegetation in multi-channel images, (Jensen and Lulla, 1987). In the present study, 3 vegetation indexes (Difference Vegetation Index-DVI; Infrared Percentage Vegetation Index-IPVI; Normalized Difference Vegetation Index-NDVI) were used (*Table 1*).

Table 1. *Vegetation indexes used in the study*

Vegetation index	Equation	Author
DVI	$NIR - RED$	Tucker 1979
IPVI	$\frac{NIR}{NIR + RED}$	Crippen 1990
NDVI	$\frac{NIR - RED}{NIR + RED}$	Rouse et al. 1974

Besides, Principal Component Analysis (PCA) was applied to digital image in order to form a new data group including more information (Jensen and Lulla, 1987) by pushing similar channels. PCA can be repeated more than once with the purpose of increasing

detail, new data group which are produced in this way are also named as PC1, PC2. However, many studies have indicated that PC1 involves the most details for remote sensing data (Sena et al., 2002; Çam et al., 2015). PCA image, vegetation indexes and original bands used in the study are shown in *Figure 2*.

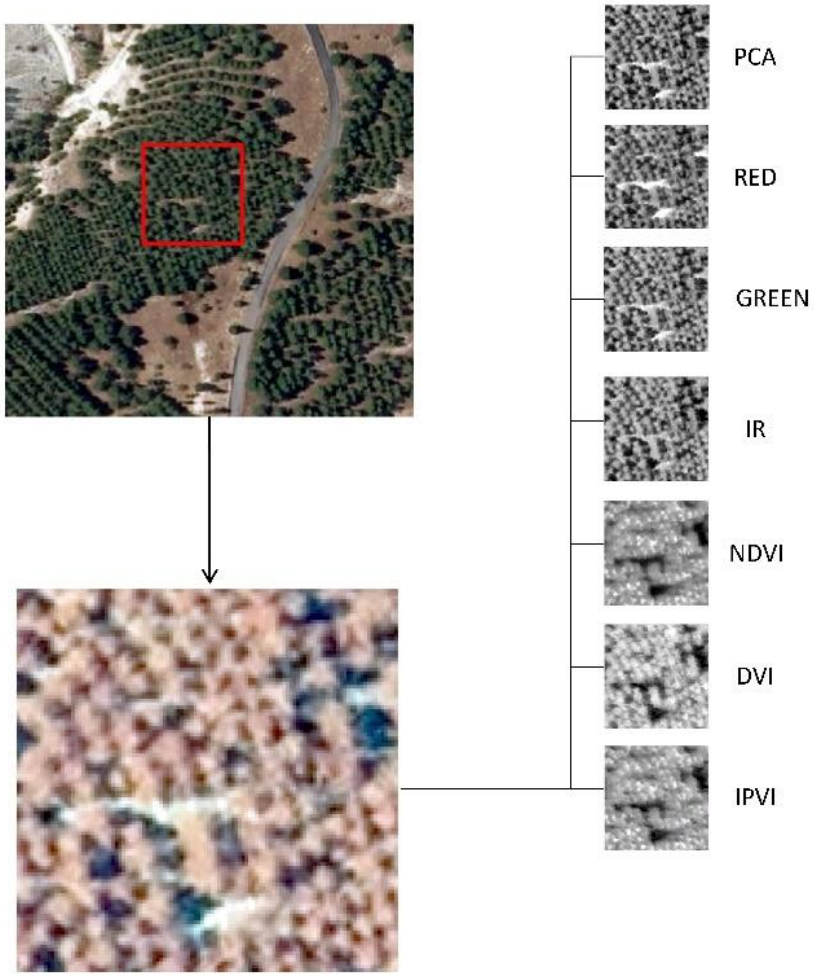

Figure 2. *Original bands, vegetation indexes and PCA image*

Field data

Field data were used with the purpose of revealing the relation between forest stand parameters and image features. Fieldwork was carried out in sampling clusters of four plots which had size of 50 x 50 m during July-August 2013. Sampling clusters, as 20 items in total, were randomly chosen from image objects formed with image segmentation process. Sample plots in sampling clusters were located as 50 m distance from the center to center. The centers of sample plots were located with the distance of 25 m from the center of sampling clusters to North, South, East and West directions. Sample plots were established as 400 or 600 m^2 circle (*Figure 3*).

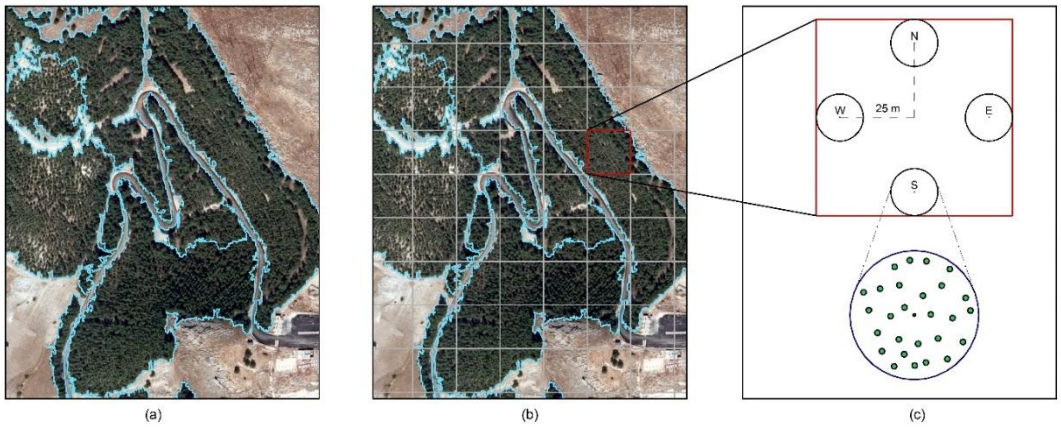

Figure 3. *a) Multi-resolution segmentation b) Chessboard segmentation c) Sample plots*

The size of sample plots were determined considering stand development age and crown closure. The measurements were carried out considering conventional forest inventory rules in totally 80 sample plots. Diameter of all trees inside the sample plot with the diameter at breast height (DBH) more than 8 cm, the height (m) and age according to the %40 rule were measured. Stand volume (m^3/ha), basal area (m^2/ha), number of trees (stems/ha), DBH (cm) and mean height (m) of each sample plot were calculated using the equations given in *Table 2*. For sampling clusters, forest stand parameters per hectare were determined as the average of (4) sample plots in each sampling cluster. Descriptive statistics related to forest stand parameters determined with field measurements are presented in *Table 3*.

Image segmentation

Sampling clusters obtained by image segmentation are stated to be a better estimation unit than sample plots (Anttila, 2005; Hyvönen et al., 2005). The segmentation is an algorithm which creates meaningful objects in an image by grouping the individual pixels according to their spatial and spectral features and is performed using the scale parameter and homogeneity criteria (Benz et al., 2004). The main objective of this process is to obtain more meaningful sub-objects from the heterogeneous structure of images (Blaschke et al., 2014; Li et al., 2015). A number of segmentation techniques have been developed (Definiens, 2006). In this study, image segments were firstly obtained from digital aerial image by using Multi-resolution Segmentation algorithm on forest stand level. For this purpose, the image segmentation process was implemented by testing different scale and color/shape parameters which represents the forest stands in the study area. As a result of visual evaluations, the most suitable image objects were obtained by using scale parameter: 175, color: 0.7 and shape: 0.3. Then, chessboard segmentation approach was implemented to achieve image windows representing ground sampling clusters into the obtained image objects. In this way, the size of image objects was segmented into 50 x 50 m cells (*Figure 3*).

Extraction of the image features

In the study, spectral and textural features of digital aerial image were used for the estimation of forest stand parameters (*Table 4*).

Table 4. *Image features used in the study*

Image Features		**Relationship model***
Average brightness value		$\frac{1}{\#P_v}\sum_{(x,y)\in P} C_k(x,y)$
First-order	*Standard Deviation of Gray Levels*	$\sigma_k(v) \coloneqq \sigma_k(P_v) = \sqrt{\frac{1}{\#P_v}\left(\sum_{(x,y)\in P} {c_k}^2(x,y) - \frac{1}{\#P_v}\sum_{(x,y)\in P} C_k(x,y)\sum_{(x,y)\in P} C_k(x,y)\right)}$

Average Brightness Value (ABV) of pixels in an image window corresponding sampling clusters was taken into consideration as spectral property. The first-order (*Standard Deviation of Gray Levels-SDGL*) and second-order texture features were used as textural features as well. The first-order texture features are calculated using statistical properties of pixel brightness values in an image area. Furthermore, the second-order texture features are calculated based on *Grey Level Co-occurence Matrix (GLCM)*. *GLCM* is a tabulation of how often different combinations of pixel grey levels occur in an image object (Harralick et al., 1973). According to *GLCM*, many textural features can be determined which are categorized in three main groups as *Contrast, Orderliness* and *Descriptive statistics* (Ozdemir and Karnieli, 2011). *Homogeneity (HOM), Contrast (CON), Correlation (COR) and Entropy (ENT)*, which habe been used widely in previous studies, were chosen to be used in the current study. Image features were derived from 3 digital bands (R, G, NIR), PCA and 3 vegetation indexes (NDVI, DVI, IPVI). Image features were extracted from image objects which segmented into 50 x 50 m cells by Definiens image processing software

Statistical analysis

SPSS 16 (SPSS Chicago, IL, USA) statistical software was used to perform statistical analysis. Pearson Correlation analysis was used for the determining the statistical relation between forest stand parameters and image features. Pearson correlation coefficient can be used in the cases in which the data have a normal or near-normal distribution. The normality of the distribution of the variables were tested based on Shapiro-Wilk method. Variable was regarded as having normal distribution when P>0.05 (Kalaycı, 2006; Kayitakire et al., 2006).

The linear regression analysis was utilized to develop forest stand parameter estimation models, using image features derived from the digital aerial image. Forest stand parameters which were calculated based on field measurements were considered as dependent variable and image features which were derived from image windows were considered as independent variable in the regression analysis. In the regression analysis, one of the important issues is the variable choice when there are a large amount of predictor variables (Shinzato et al., 2016). For choising the proper variable, the highest correlation coefficient between forest stand parameters and image features was considered. By Kayitakire et al. (2006) a simple linear model of the form $y = b_0 + b_1x$ has been proposed to present a simple and interpretable model, emphasizing that there are no theoretical functional forms for the forest variable estimation models using textural features.y refers to forest stand parameters, x refers to image features, b_0 and b_1 refer to coefficients of the model. In the present study, this approach was adopted to model relation between forest stand parameters and image features. Each forest stand parameter was evaluated separately and a different model was developed for each one. Then, the validity of the estimation models was tested using the leave-one-out cross-validation test. In this method, one sampling cluster from dataset was eliminated and a model was developed using left sampling cluster. The forest parameters of eliminated sampling cluster were predicted according to the model that was not include leaved out. The predicted values for 20 sampling clusters were obtained by repeating the same process for each sampling clusters. Then, the adjusted coefficient of determination (R^2_{adj}), the root mean square error (RMSE) and the relative root mean square error (RMSE%) values were calculated by comparing predicted values with ground truth data.

Results

Correlation analysis

Data should exhibit a normal distribution to reveal the direction and power of a linear relationship between image features and forest stand parameters by performing a correlation analysis. According to the normal distribution test conducted, it was determined that the all forest stand parameters obtained from field measurements in the sample plots exhibited a normal distribution. Following the normal distribution test, a relationship between the image features and forest stand parameters was evaluated by Pearson's correlation coefficient.

As a result of the evaluation performed, statistically significant relationships were found between DBH, mean height, stand volume, basal area, and the number of trees calculated based on the sampling clusters and brightness and textural features derived from a digital aerial image. The relationships between the forest stand parameters and image features are presented in *Table 5*.

The relevant table shows the image features having the best correlation with the forest stand parameters. In summary, the highest correlation between DBH and image features was obtained with the *CON* values derived from the infrared band ($r=0.708$, $p<0.01$). A significant and negative correlation was found between the *CON* value derived from the red band and DBH ($r=0.604$, $p<0.01$). A significant and positive correlation was observed between the *HOM*, *COR* values derived from the red and infrared bands and DBH ($r=0.641$, 0.535 and 0.58, 0.690 $p<0.01$, respectively). Besides, significant relationships were determined between the *CON*, *HOM, COR*, and *ENT* values derived from PCA and DBH. In addition to these, relationships between other textural features and brightness values and DBH were generally weak. The highest correlation between the mean height and the image features was also calculated with the *CON* values derived from the infrared band ($r=0.641$, $p<0.01$). While significant relationships were observed between the *HOM, CON, COR* values derived from the red band and the *CON, ENT, COR* values derived from PCA and the mean height, the relationships between the mean height and other image features (*ABV* and *SDGL*) were generally weak.

Significant correlations were also calculated between the stand volume and some textural features. On the other hand, it was observed that relationships between the stand volume and brightness values were weak. The highest correlation with the stand volume was calculated with the *CON* values derived from the red band ($r=0.663$, $p<0.01$). Furthermore, stand volume had significant positive relationships with the *HOM, COR* values and significant negative relationships with *CON, ENT* values derived from red band, infrared band and PCA. Similarly, while the basal area exhibited significant correlations with some textural features, exhibited a weak correlation with brightness values. The highest correlation for the basal area was obtained with the *CON* values derived from the red band ($r=0.692$, $p<0.01$). The highest correlation in the number of trees was obtained with the *HOM* values derived from the infrared band ($r=0.679$, $p<0.01$). Moreover, it was determined that there was a significant and positive correlation between the number of trees and the *CON* values derived from the infrared band and the *ENT* values derived from PCA ($r=0.668$, 0.519, $p<0.01$). Apart from these, it was understood that the relationships between the *ABV, SDGL, COR* values and the number of trees were generally weak.

Estimation of forest stand parameters

In order to estimate the forest stand parameters based on the image features, the relationship between the forest stand parameters and the image features was modeled by a linear regression analysis. According to the results of the correlation analysis, various textural features exhibited a statistically significant correlation with the forest stand parameters. The image features to be used as independent variables of the model were selected from those having the highest correlation with the forest stand parameters. Accordingly, the *CON* values derived from the infrared band were modeled as the best indicators of DBH and mean height. The *CON* values derived from the red band were the independent variables of the model as the best indicators of the forest stand volume and basal area. The *HOM* values derived from the infrared band were used as independent variables of the model estimating the number of trees. The accuracy of the estimates provided by the regression models was explained by the R^2_{adj}, RMSE, and RMSE% values. The R^2_{adj}, RMSE, and RMSE% values related to the regression models developed for each forest stand parameter and the estimates obtained from the models are presented in *Table 6*.

As seen from *Table 6*, the model coefficients were found as statistically significant ($p<0.001$) in the models developed to estimate DBH, mean height, stand volume, basal area, and the number of trees. Upon evaluating the results, it was found out that the model providing the highest estimation accuracy among the estimation models was the model developed to estimate DBH. The adjusted coefficient of determination (R^2_{adj}) of the relevant model was calculated to be 0.48. Accordingly, the linear regression model, in which the *CON* values derived from the infrared band were used as independent variables, estimated 48% of the change in DBH. In terms of the estimation accuracy, this model was followed by estimation models developed to calculate the basal area, number of trees, and stand volume. The estimation accuracy of the model developed for the mean height was relatively low compared to the others. The R^2_{adj} values of these models calculated using all datasets were found to be 0.45, 0.43, 0.41 and 0.38, respectively. Upon comparing the DBH values estimated from the model with the ground truth DBH values, RMSE was calculated to be 2.02 cm (RMSE 11.91%). Similarly, upon comparing the other stand parameters estimated from the developed models with the ground truth data, RMSE was calculated to be 1.92 m for the mean height, 9.55 m^3/ha for the stand volume, 1.64 m^2/ha for the basal area, and 79.01 stems/ha for the number of trees. RMSE% was found to be 23.57% for the mean height, 20.96% for the stand volume, 15.81% for the basal area, and 16.20% for the number of trees.

Table 6. *Estimation models based on image textural features of forest stand parameters and their statistical summaries*

Discussion

Our study goal was to reveal the potential of spectral and textural features derived from digital aerial image in predicting forest stand parameters. The results of correlation analysis revealed that there were statistically significant correlations especially between the image textural features and forest stand parameters. DBH, among the forest stand parameters, exhibited the highest correlation with the *CON* values derived from the infrared band ($r=0.708$, $p<0.01$). Furthermore, significant correlations were observed between some textural features (*CON, HOM, COR, ENT*) derived from the red, infrared bands, and PCA, and the DBH. Again, while there were significant correlations between the textural features such as *CON, HOM, COR*, and *ENT* with the mean height, the highest correlation was obtained with the mean height and the *CON* values derived from the infrared band ($r=0.641$, $p<0.01$). Significant correlations were observed between the stand volume and basal area and some textural features. The highest correlation with the stand volume and the basal area was achieved with the *CON* values derived from the red band ($r=0.663$, 0.692, $p<0.01$). While the number of trees had significant correlations with the textural features such as *HOM, CON*, and *ENT*, it exhibited the highest correlation with the *HOM* values derived from the infrared band ($r=0.679$, $p<0.01$).

According to these results, while the correlations between *ABV* and *SDGL* derived from the digital image and forest stand parameters were generally weak, *GLCM* textural features gave the best results for the estimation of the forest stand parameters. Therefore, based on the correlation coefficient values, the *CON* property derived from the infrared band was the best indicator in the estimation of DBH and mean height parameters. While the *CON* property derived from the red band was the best indicator in the estimation of the stand volume and basal area, the *HOM* property derived from the infrared band was the most appropriate indicator in the estimation of the number of trees. Furthermore, it was revealed that the original bands of the digital aerial image (RED, IR) were more appropriate than vegetation indexes and PCA for the estimation. Significant differences were also found between the vegetation indexes and PCA. PCA was found to have a better correlation with the forest stand parameters than the vegetation indexes.

The results of our study are consistent with the relevant literature. For example, in the study conducted by Tuominen and Pekkarinen (2005), the estimation accuracy of the forest properties (DBH, height, basal area, and volume) was examined by using the spectral and textural features derived from the digital aerial image. As a result of the study, textural features generally exhibited higher correlations with forest properties than spectral features. Again in the same study, differently from the present study, image features derived from the original image bands generally exhibited a weaker correlation with forest properties. Kayitakire et al. (2006) evaluated the ability to estimate forest properties based on the textural features of a 1 m resolution IKONOS-2 satellite image. It was stated that there was a very high correlation (R^2= from 0.76 to 0.80) between the top height, circumference, stand density, and age and *GLCM* textural features (*COR* and *CON*). A weak correlation (R^2=0.48) was determined between the basal area and textural features. In a study conducted by Ozdemir et al. (2008) on natural forests using ASTER satellite images, it was determined that there was a significant correlation between the tree size diversity based on the basal area and *HOM*. In a study conducted to estimate the tropical forest properties from a SPOT-5 satellite image using textural features, Castillo-Santiago et al. (2010) revealed that textural features may be a determinant of forest properties. In another study conducted by Ozdemir and Karnieli (2011), it was aimed to estimate the forest structural parameters by using the image textural features derived from a WorldView-2 satellite image. As a result of the study, it was stated that there were significant correlations between the first-order and second-order textural properties and structural parameters. It was expressed that the strongest correlation was calculated between the *CON* derived from the red band and the Standard Deviation of Diameters at Breast Heights (R^2=0.56) and between the *ENT* derived from the blue band and the basal area (R^2=0.53). In a study conducted by Ozkan et al. (2017) in urban forests using Landsat-8, ASTER, and RapidEye satellite images with different resolutions, it was emphasized that image textural features can be a good indicator for evaluating the structural diversity of urban forest stands.

Our results showed that textural features is likely a better indicator than spectral features in estimating stand parameters from digital aerial images. The second-order textural features had more advantageous than first-order textural features. According to the results of the leave-one-out cross-validation analysis, the R^2_{adj} values of the linear regression models developed for the estimation of forest stand parameters varied between 0.38 and 0.48. The DBH and the mean height estimation models developed

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_30433060
© 2018, ALÖKI Kft., Budapest, Hungary

based on the *CON* property derived from the infrared band had 0.48 and 0.38 R^2_{adj}, 2.02 cm and 1.92 m RMSE. The forest stand volume and the basal area models developed using the *CON* property derived from the red band had 0.41 and 0.45 R^2_{adj}, 9.55 m^3/ha and 1.64 m^2/ha RMSE. The estimation model of the number of trees developed based on the *HOM* property derived from the infrared band had 0.43 R^2_{adj}, 79.01 stems/ha RMSE.

Due to the lack of studies on the estimation of forest stand parameters based on textural features from digital aerial images, the results of the present study could not be directly compared with the relevant literature. Therefore, studies in which estimation models were developed based on satellite images were used in the comparison of results. In the study conducted by Tuominen and Pekkarinen (2005), the DBH, height, basal area, and volume were attempted to be estimated by using spectral and textural features (such as *COR, CON, ENT*) derived from color-infrared aerial photographs. In the study in which forest stand parameters were estimated using the k-NN method, the RMSE values of the estimation model based on a single image property were calculated to be 8.54 cm for DBH, 6.69 m for height, 8.40 m^2/ha for basal area, and 78.75 m^3/ha for volume. In the study, it was also stated that the use of textural features improved the estimation accuracy. Kayitakire et al. (2006) modeled the forest stand parameters including the age, top height, circumference, stand density, and basal area using the image textural features derived from 1-m resolution IKONOS-2 imagery. The estimation errors of the models were estimated by using the leave-one-out cross-validation method. In the model in which the *CON* property was used, the R^2 value for the basal area was calculated to be 0.35, and in the model in which the *COR* property was used, the R^2 value for the height was calculated to be 0.76. Wunderle et al. (2007) tried to develop models that best describe forest stand parameters such as the diameter at breast height, height, stem density, and basal area, using the spectral and textural features derived from a pan-sharpened SPOT-5 image. It was emphasized that the first-order (standard deviation) and second-order (correlation) textural features explain the change in forest stand parameters better in the models developed with the stepwise regression analysis. In a study conducted by Ozdemir and Karnieli (2011), forest stand parameters were modelled as the function of textural features derived from the original bands of a WorldView satellite image. The models were developed by using the linear regression analysis. The second-order texture features (*CON* and *ENT*) gave the best result for the DBH, basal area, and stand volume and the first-order texture features (*SDGL*) gave the best result for the number of trees. The R^2 values of the most appropriate model were calculated to be 0.67 for DBH, 0.54 for the basal area, 0.42 for the stand volume, and 0.38 for the number of trees. Wallner et al. (2014) modelled forest stand parameters based on spectral and textural features derived from a RapidEye image. The R^2 values of the developed models were calculated to be in the range of 0.37-0.55 for the mean diameter, 0.40-0.58 for the basal area, 0.30-0.41 for the stem number, and 0.42-0.63 for the volume.

In the literature on the subject, there are mostly studies using spectral features derived from digital aerial images and usually satellite images. In a study conducted by Hyypä et al. (2000), estimation models were developed for the mean height, basal area, and stem volume using aerial images and SPOT PAN. As a result of the study, it was observed that the model based on the aerial image (R^2= 0.34, 0.48, 0.48) provides a higher estimation accuracy than SPOT PAN (R^2= 0.17, 0.38, 0.35). Mallinis et al. (2004) revealed that R^2_{adj} values varied between 0.24-0.31, 0.29-0.32, and 0.20-0.32,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

respectively, in the estimation of volume, basal area, and number of trees with models developed based on the spectral features of a Landsat TM satellite image. Peuhkurinen et al. (2008) reported RMSE values to be 52.2 m^3/ha, 5.6 m^2/ha, and 3.1, respectively, in the estimation of stand volume, basal area, and mean height estimation by using the Ikonos satellite image and k-MSN method. In a study conducted by Günlü et al. (2013), the R^2_{adj} values of the regression models in which the spectral feature derived from a Quickbird satellite image was an independent variable, varied between 0.19 and 0.70 for the forest stand volume. In another study conducted by Günlü et al. (2014), the correlation between spectral features and some forest stand parameters was modeled by using a Pan-Sharpened IKONOS satellite image. The R^2_{adj} values of the best models were determined to be 0.41 for the stand volume, 0.43 for the basal area, and 0.45 for the dominant height. Çil et al. (2015) modelled the tree number, stand volume, and basal area as a function of spectral features derived from Göktürk-2, Rasat, Landsat-8 and the digital aerial image. The R^2_{adj} values of the model developed based on the aerial image were found to be 0.23, 0.48, and 0.55, respectively, for the relevant parameters. The R^2_{adj} values of the model developed based on satellite images varied between 0.34 and 0.67. It was also stated in the study that the original bands gave better results than the vegetation indexes and ratio images.

As a result, the adjusted coefficient of determination values of the estimation models developed for forest stand parameters varied between 0.38 and 0.48 and these values are in line with the literature results. However, these values do not seem to be sufficient in terms of practical forest management. In order for estimation models to be transferred to the practical application, the estimation accuracy should be improved. Therefore, further studies on this subject can evaluate other *GLCM* textural features of the contrast, orderliness, and descriptive statistics groups and models using different image features together can be developed. Another alternative is the combined use of digital aerial images and airborne laser scanning (ALS) data. Studies conducted by Mohammadi et al. (2017) and Jayathunga et al. (2018) revealed promising results for the modeling of forest stand parameters with the combination of digital aerial images and ALS data. Furthermore, the study we conducted was carried out in a conifer plantation forest. The results of the previous studies show differences according to tree species. There is a need for this study to be conducted on different forest types.

Conclusion

The most important result of this study, which was conducted to estimate forest stand parameters based on the spectral and the textural features derived from digital aerial images, is that the second-order texture features gave the best results compared to the spectral and first-order textural features. Among the second-order textural features, '*Contrast*' exhibited better performance than the others. The models developed by using the '*Contrast*' property enabled the better estimation of DBH, mean height, stand volume, and basal area. Nevertheless, the model developed by using the '*Homogeneity*' property allows better estimation of the tree number. Another result that can be obtained from this study is that the original bands of digital aerial image is more capable than the bands obtained by the combination of the original bands in estimating the forest stand parameter. Textural features derived from the infrared band exhibited better performance for DBH, mean height, and tree number, and textural features derived from the red band exhibited better performance for the stand volume and the basal area. For

the operational use of the method in forest management planning, further studies are required to improve the estimation accuracy. Furthermore, future studies should be conducted in pure and complex forest stands in different ecological regions to better understand the potential digital aerial photos.

(Received 14th Mar 2018; accepted 21st May 2018)

Abstract. Time series analysis techniques and Seasonal Autoregressive Integrated Moving Average (SARIMA) models were used to analyze monthly fish and shrimp catch landing trends recorded for Songkhla shallow lagoon in Thailand (2003-2016). Autocorrelation (AC) and Partial Autocorrelation (PAC) functions were calculated to build seasonal ARIMA models. These models were well-chosen for explaining the time series and forecasting future catch landings. It is found that both fish and shrimp catch landings tend to fluctuate steadily. The fish catch from 2017 to 2020 is steadily increasing on the average catch for the period 2003-2016 by up to 36.06%, while the shrimp catch is decreasing by around 15.47% for the same period. This study demonstrates the importance of undertaking detailed studies of ecological and economic sustainable development to support the comprehensive fisheries management policy for Songkhla Lagoon. The present study shows an effective tool for making accurate forecasts; it also helps in decision making about, and fisheries management of the Songkhla Lagoon.
Keywords: *seasonal ARIMA models, artificial neural networks, time series forecasting, fishery trend, Songkhla lagoon*

Introduction

Time series analysis of fishery landings plays a vital role in fisheries management and decision making due to its capacity for demonstrating the trends and seasonality patterns of the data (Koutroumanidis et al., 2006; Tsitsika et al., 2007). In the fishery field, time series analysis qualifies for forecasting because it expresses past patterns and projects into the future (Stergiou et al., 1997).

Forecasting has been applied to all sectors of the economy. During the last three decades, forecasting has been rapidly developing in the field of fisheries, in describing fishery units (Murawski et al., 1983) and the state of fisheries' resources and management (Fox, 1970; Pauly, 1989; Sparre et al., 1989; Stergiou and Petrakis, 1993). Various statistical models have been used to analyze trends and to forecast fish catches.

Significant regression, univariate and multivariate time series models were used to forecast monthly and annual marine fisheries' catches (Stergiou and Christow, 1996; Stergiou et al., 1997) of Loliginid and Ommastrephid (Georgakarakos et al., 2002, 2006).

The forecasting of fisheries' landings has been studied by many researchers using the Autoregressive Integrated Moving Average (ARIMA) methodology. So far, this method has been successful in describing and forecasting fishery dynamics of broadly different species-significantly, demersal and pelagic species (Stergiou, 1990; Stergiou and Christow, 1996; Stergiou et al., 1997; Tsitsika et al., 2007), squid (Pierce and Boyle, 2003), mackerel (Lloret et al., 2000; Punzón et al., 2004), loliginid and ommastrephid (Georgakarakos et al., 2002, 2006).

Songkhla Lagoon is one of the two lagoons in the world that has Irrawaddy dolphins, an endangered species. The lagoon's multitude of flora and fauna species makes it rich in biodiversity and it provides resources for local fisheries' fishermen all year around. The livelihood of the more than 1.9 million people of the 25 districts located in the three provinces of Southern Thailand rely on this fishery resource. The lagoon provides both economic benefits and nutrition for the local people. It is not only an important source of livelihood for men, but also for women, who do fish processing.

Small-scale fishing has been the main livelihood for local fishermen around Songkhla Lagoon for many generations. However, as in many places in the world, the numbers of fish have been declining sharply. Many fishermen of Songkhla Lagoon are wondering whether they can survive in fishing or if they must convert to another occupation. Many of them are moving to other fishing areas or changing their work.

For the effective socio-economic and environmental management of Songkhla Lagoon, and in aiming for sustainable development of fisheries' resources, it is vital to know the seasons and the trends of fish catch in the future, as well as the factors that affect any changes in these. Forecasting fish catch trends in Songkhla Lagoon is necessary.

There is a growing body of literature that recognizes the importance of statistical models in forecasting as well as in analyzing fish catches in Songkhla Lagoon over the last few decades. Significantly, Chesoh and Lim (2008) used a linear regression model for forecasting fish catches during 1977-2006. The structure of the fish community was analyzed using a clustering model (Chesoh and Choonpradub, 2011), the method for analyzing fish assemblage distribution (Chesoh and Choonpradub, 2009). However, historical time series fish catch data usually cover a long time, which includes seasonal and non-seasonal periods. The seasonal ARIMA model, therefore, is widely used for time series forecasting and resolves the problems of season and non-season of the data by describing the autocorrelations of the data.

Fish catch landing data depends not only on human activities, but also very much on the weather. Normally this data changes over time. Artificial neural network (ANNs) models were used in this study to compare with SARIMA models because ANNs have some advantage over other forecasting models. ANNs are powerful nonlinear regression techniques (Bishop, 1995; Ripley, 1996; Titterington, 2010). Nowadays, ANNs have been used widely in time series forecasting due to their ability to approximate various nonlinearities in the data (Zhang, 2003). The significant advantage of ANNs is no prior assumption of the model form is required in the model building process; moreover, the network model is mainly determined by the characteristics of the data.

This study used monthly fish catch landings in Songkhla Lagoon data from 2003 to 2016 to evaluate the accuracy of SARIMA and ANNs models. The better model was chosen to forecast the fish and shrimp catch landing trends in Songkhla Lagoon to 2020.

Materials and Methods

Study site and sample collection

The total of fish and shrimp catch landings were collected for Songkhla Lagoon every month during 2003-2016 by the National Institute of Coastal Aquaculture (NICA), Thailand *(Fig. 1)*.

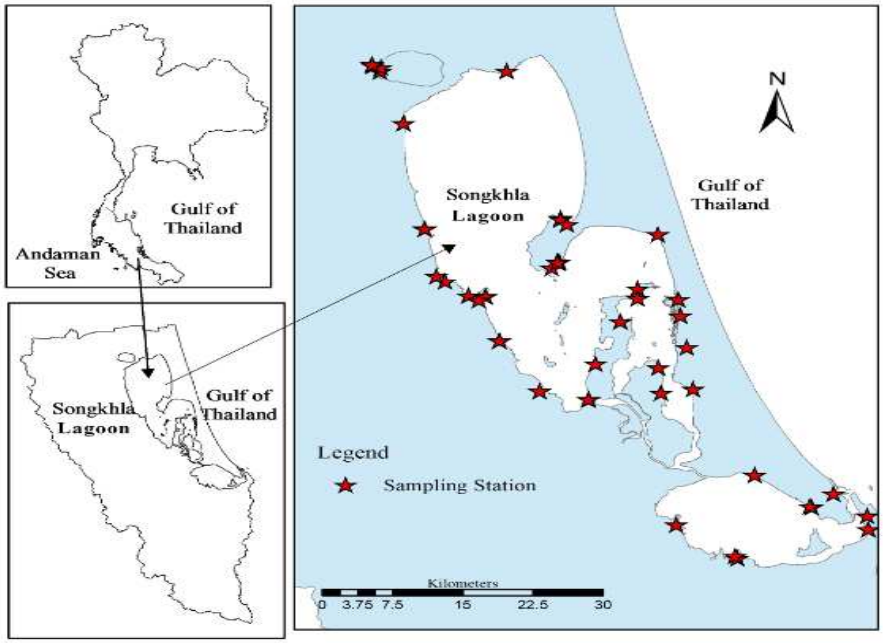

Figure 1. *Sampling stations in Songkhla Lagoon*

During 14 years of data collecting, 21 shrimp species and 158 fish species were collected every month in 37 stations around Songkhla Lagoon. The main types of fishing gear that have been used in Songkhla Lagoon include traps, set-bag nets and gill nets; and fishing activities that use such gear affect fish stock dynamics and the ecosystem (Chesoh and Choonpradub, 2011).

Time series forecasting models

SARIMA models

A time series $\{Z_t \mid t = 1, 2, ..., k\}$ is built using the SARIMA $(p, d, q)(P, D, Q)_s$ process with the mean μ of the Box and Jenkins (1976) time series model if

$$\varphi(B)\phi(B^s)(1-B)^d(1-B^s)^D(Z_t-\mu) = \theta(B)\Theta(B^s)a_t \qquad \text{(Eq.1)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_30613078
© 2018, ALÖKI Kft., Budapest, Hungary

where, Z_t denotes the observed value at time t, t=1, 2,…, k and a_t is the estimated residual at time t (*Eq. 1*); *p, d, q* denote the order of autoregressive (AR), degree of differencing or moving average (MA) of the non-seasonal part of the model to reach to stationary; *P, D, Q* are autoregressive (AR), order or moving average (MA) of the seasonal part of the model; *s* denotes the number of periods of the season;

$\varphi(B) = 1 - \varphi_1 B - \varphi_2 B^2 - ... - \varphi_p B^p$, $\phi(B^s) = 1 - \phi_1 B^s - \phi_2 B^{2s} - ... - \phi_p B^{ps}$,

$\theta(B) = 1 - \theta_1 B - \theta_2 B^2 - ... - \theta_q B^q$, and $\Theta(B^s) = 1 - \Theta_1 B^s - \Theta_2 B^{2s} - ... - \Theta_Q B^{Qs}$

are polynomials in *B* of degree *p, q, P* and *Q; B* is the backward shift operator.

The SARIMA model includes four basic steps:

- Identification of the SARIMA $(p,d,q)(P,D,Q)_s$ structure.
- Estimation of the unknown parameters.
- Goodness-of-fit tests on the estimated residuals (Box and Jenkins, 1976; Makridakis,1990).
- Forecast future outcomes based on the known data.

The a_t should be independently and identically distributed as normal random variables with mean = 0 and variance σ^2. The roots of $\varphi(Z) = 0$ and $\theta(Z) = 0$ should all lie outside the unit circle. The SARIMA model should use at least 50, or preferably 100 observations (Box and Jenkins, 1976). This data includes more than 100 months, which is adequate for a proper time-series analysis (Tsitsika et al., 2007).

The autocorrelation (ACF) and partial autocorrelation functions (PACF) of a series together are the most powerful tool usually applied to reveal the correct values of the model parameters. The ACF gives the autocorrelations calculated at lags 1, 2 and so on, while PACF gives the corresponding partial autocorrelations, controlling for autocorrelations at intervening lags. Parameter estimation of tentative models was determined using maximum-likelihood methods. The results included the parameter estimates, standard errors, estimate of residual variance, standard error of the estimate, natural log likelihood Akaike's information criterion (AIC), and Schwartz's Bayesian criterion (SBC). Model selection was based on the minimization of AIC and SBC. These criteria were descriptors of the model's parsimony as they simultaneously account for the model's fit onto the observed series alongside the number of parameters used in the fit.

Building SARIMA models

Monthly fish and shrimp catch landing data during 2003-2016 in Songkhla Lagoon were divided into two data sets. The training data set was applied for the period (January 2003 to September 2015), and was transformed by taking the natural logarithm. The transformed data sets then were White Neural Network, tested for nonlinearity by the package "nonlinearityTseries" in R (Garcia, 2015). Both transformed shrimp and fish tests had p value >0.05, which means that there is no evidence to reject the null hypothesis of linearity (Varvey and Leybourne, 2007). The transformed training data of both shrimp and fish catch landings were tested for normality by using the Shapiro-Wilk normality test. The shrimp data test results were w=0.95967, p values > 0.05 and the fish data test results were (w= 0.9843, p values >0.05). Therefore, the study had evidence to confirm that both transformed data sets

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_30613078
© 2018, ALÖKI Kft., Budapest, Hungary

were of normal distribution (Royston, 1995). Then, the data sets were tested the stationarity by the Box-Ljung test, Augmented Dickey-Fuller Test and KPSS Test. All these stationary test results had evidence to confirm that the transformed data of fish and shrimp catch landings were non-stationary time series; therefore, we can apply seasonal ARIMA models for forecasting shrimp and fish catches in the short term.

However, to get forecasts for shrimp and fish catch landings back to the original unit, the forecasted data were back-transformed after using a fitting model by taking exponentiation of the coefficients and the forecast is then the mean of the catches.

Twelve last months of data (October 2015 to September 2016) were used to validate the models.

The data was strongly seasonal and obviously non-stationary; therefore, seasonal differencing was used. The seasonally differenced monthly shrimp and fish catch landing data are shown in *Fig. 2*.

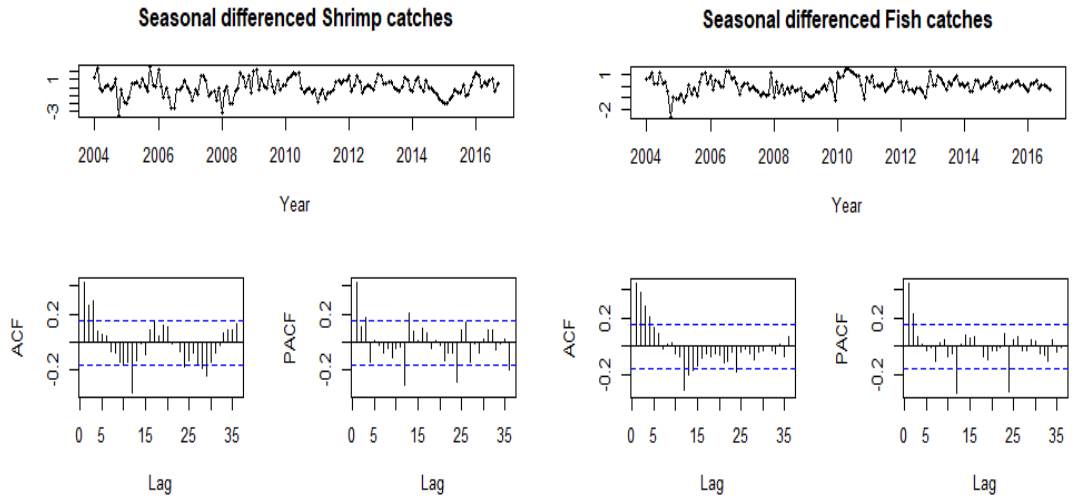

Figure 2. *First differencing log monthly shrimp and fish catches landings data*

The ACF and PACF of the transformed data sets showed spikes at periodic lags 12 and 24 *(Fig. 2)*, which declined slowly, indicating that seasonal differencing was required to achieve stationary. Abrupt fluctuations in the seasonal ACF and PACF had been leveled out.

Based on the first differencing correlograms of autocorrelation (ACF) and partial autocorrelation (PACF) of natural log transformed data of shrimp and fish catch landings, this result was combined with the Akaike information criterion (AIC) to determine the best model. The values for SARIMA $(p,d,q)(P,D,Q)_s$ models were applied as follows:

- Shrimp catch landing, the SARIMA model $(1,1,2)(0,0,3)_{12}$ was considered as the most appropriate, and due to this model passing all required checks (all the spikes are now within the significant limits), the residuals appear to be white noise. A Ljung-Box test also shows that the residuals have no remaining autocorrelations; additionally, this model has the smallest AIC and RMSE and gives the smallest mean error (ME) (0.0456). This statement is shown in *Fig. 3*.

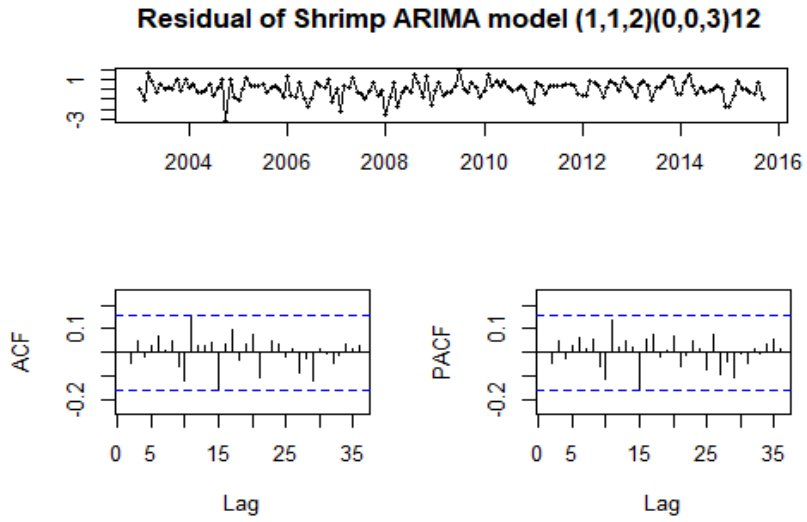

Figure 3. *Residual of shrimp seasonal ARIMA model* $(1,1,2)(0,0,3)_{12}$

- For fish catch landings, the seasonal ARIMA model $(1,1,1)(1,0,1)_{12}$ was considered as the most appropriate, due to this model having passed all requried checks (all the spikes are now within the significant limits, and the residuals appear to be white noise). A Ljung-Box test also shows that the residuals have no remaining autocorrelations. Jarque Bera Test result with X-squared = 4.0196, df = 2, p-value = 0.134 means that the data is consistent with having skewness and excess kurtosis zero; as well as this, this model has the smallest AIC and RMSE and gives the smallest of mean errors (ME) (0.018). This declaration is shown in *Fig. 4*.

Artificial neural networks (ANNs)

In this study we used single hidden layer feed forward network, this is the model form that is the most widely used for time series modeling and forecasting (Zhang et al., 1998). The model is described by a network of three layers of simple processing units connected by acyclic links. The relationship between the output (y_t) and the inputs $(y_{t-1}, y_{t-2}, ..., y_{t-p})$ follows the mathematical equation:

$$y_t = \alpha_0 + \sum_{j=1}^{q} \alpha_j g(\beta_{0j} + \sum_{i=1}^{p} \beta_{ij} y_{t-i}) + \varepsilon_t \quad \text{(Eq.2)}$$

where, $\alpha_j (j = 0,1,2,...,q)$ and $\beta_{ij} (i = 0,1,2,..., p; j = 1,2,...,q)$ are the model parameters, often called the connection weights; p is the number of input nodes; and q is the number of hidden nodes. The logistic function is often used as the hidden layer transfer function:

$$g(x) = \frac{1}{1 + \exp(-x)} \quad \text{(Eq.3)}$$

Thus, the ANN model (2) in fact performs a nonlinear functional capturing from the past observations $(y_{t-1}, y_{t-2}, ..., y_{t-p})$ to the future value y_t ; therefore, y_t can be written:

$$y_t = f(y_{t-1}, y_{t-2}, ..., y_{t-p}, w) + \varepsilon_t \quad \text{(Eq.4)}$$

where, w is a vector of all parameters and f is a function identified by the network structure and connection weights. Hence, the neural network is equivalent to a nonlinear autoregressive model. The *Eq. 2* implies one output node in the output layer which is typically used for one step ahead forecasting.

Building ANN model

Like SARIMA model building, the training data set was natural logarithm transformed to get the best results and was used to build the ANN model, then the testing data was used to validate the model. While the SARIMA model uses one sample for model identification, estimation and evaluation, the ANNs estimated model is usually evaluated using a separate hold-out sample that is not displayed to the training process (Zhang, 2003). The model with the smallest mean squared error (MSE) will be chosen. The authors used the package nnfor (Nikolaos, 2017) from R software to create the ANNs model. The forecast statistical packages from R software were used to formulate the SARIMA models (Hyndman, 2017). All graphics and statistics were implemented by R software (R Core Team, 2018).

The best ANNs model was chosen to forecast shrimp fit with 5 hidden nodes and 20 repetitions, series modelled in differences: D1, univariate lags: (1,2,3,4,5,6,7,10) due to its smallest MSE (0.0078). The procedure demonstration is expressed in *Fig. 5*.

The best ANNs model was chosen to forecast fish fit with 5 hidden nodes and 20 repetitions. Series modelled in differences: D1, univariate lags: (1, 2, 3, 4, 5, 6, 7, 8, 12) due to its smallest MSE (0.0372) is shown in *Fig. 6*.

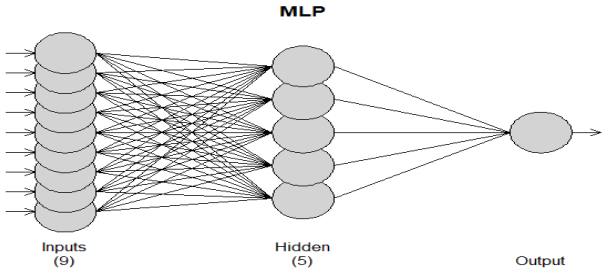

Figure 6. *Structures of the best fitted artificial neural network model for fish*

Results

Comparison between the SARIMA and ANNs models

To estimate the accuracy of the two models, the authors calculated the percentage improvement of SARIMA and ANNs models through Mean Absolute Error (MAE). The percentage MAE was calculated on the average over the validation samples of fish and shrimp catch landings from October 2015 to September 2016. The equation to measure percentage of MAE is as below:

$$MAE(\%) = \frac{1}{n}\sum_{i=1}^{n}\left(\frac{|y_i - \hat{y_i}|}{y_i}\right)x100\% \qquad \text{(Eq.5)}$$

where, $|y_i - \hat{y_i}|$ is absolute difference between prediction and actual observation; n is the number of observations. The optimum model with the smaller percentage of MAE will be chosen for forecasting. The percentage MAE of SARIMA and ANNs models are shown in *Table 1*.

As can be seen from *Table 1*, the ANNs models used for forecasting shrimp and fish catch have higher percentage MAE than SARIMA models, especially in the shrimp data set. These results are clearly described by the amount of the fish and shrimp catch in validated data sets. These are shown in *Fig. 7*.

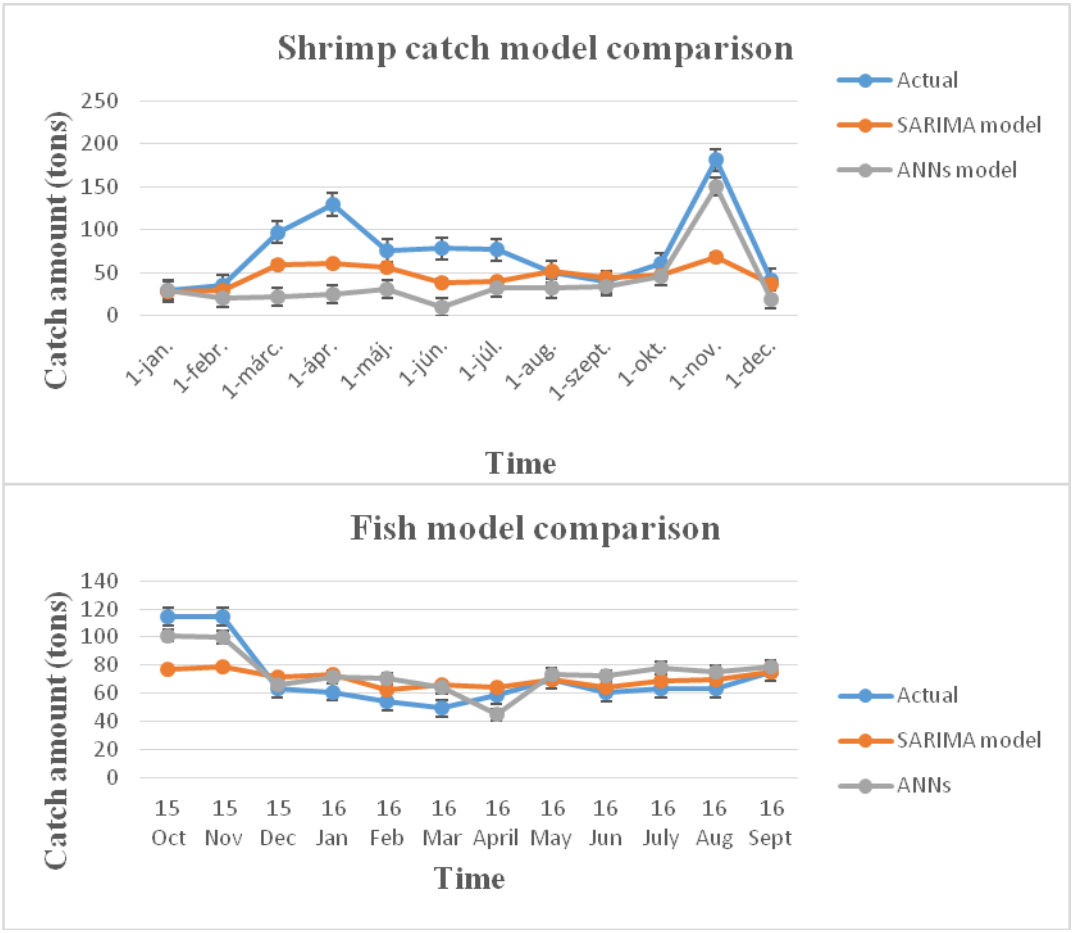

Figure 7. *Fish and shrimp model comparisons*

In both the shrimp and fish models, the 'forecast' line for the SARIMA model has the smaller distance, along with the Actual line, than the ANN model *(Fig. 7)*. Therefore, this study uses SARIMA models for forecasting shrimp and fish catch landings in Songkhla Lagoon until 2020.

Shrimp and fish catch landing trends in Songkhla Lagoon during 2016-2020

The monthly catch landings of fish and shrimp groups during 2003-2016, fits and forecasts for coming years, that were produced by the best fitting and best seasonal ARIMA forecasting model per group species, are shown in *Fig. 8*. Overall, the amplitude and the duration of the between–month fluctuations are adequately described and forecasted by the model with few exceptions.

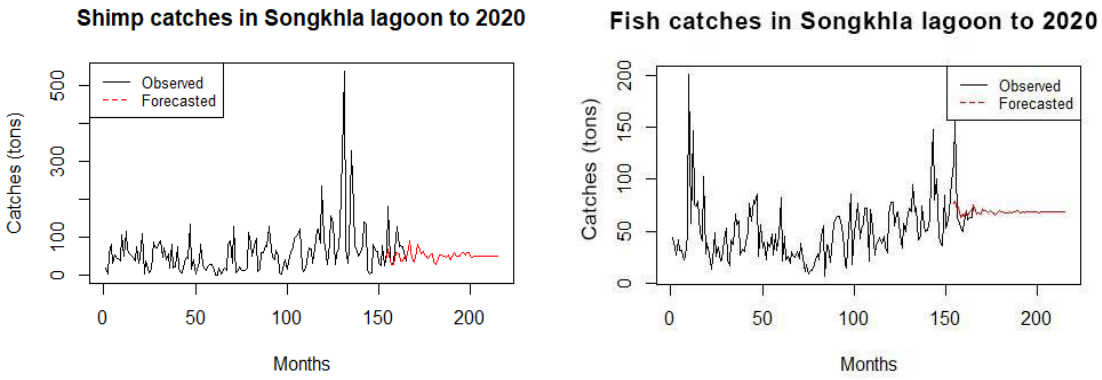

Figure 8. *Shrimp and fish catch forecasted in Songkhla Lagoon to 2020*

The result of shrimp and fish catch landings to 2020 is shown in the *Fig. 8*. It can be seen clearly that, during the period between 2017 and 2020, the shrimp catch landing in Songkhla Lagoon fluctuates at around 53 tons per month, compared with the mean catch (62.5 tons per month) during 2003-2016. Moreover, the fish catch will be around 68 tons per month, compared with the mean catch of around 49 tons during the period 2003-2016. The detailed trends of fish and shrimp catch landings in Songkhla Lagoon until 2020 are clearly described in *Fig. 9*.

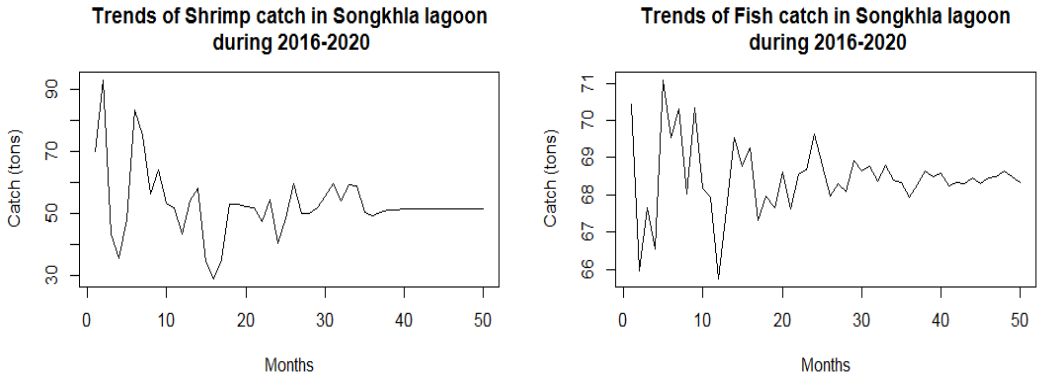

Figure 9. *Shrimp and fish catch forecasted for Songkhla Lagoon during 2016- 2020*

In *Fig. 9*, the fluctuations of the shrimp and fish catch landings during 50 upcoming months are somehow similar. During the two first years (from month 1 to month 24), the catch amount fluctuated sharply between months; after that, the catch amount was more stable. The difference between the lowest and highest catch amounts of shrimp are significant bigger than for fish. The lowest shrimp catch was January 2018 (28.95 tons) and the highest catch in November 2016 (92.94 tons), the difference being approximately 64 tons. The lowest fish catch was September 2017 (65.75 tons) and the highest fish catch was February 2017 (71.08 tons), with a difference of only 5.33 tons.

Seasonal factor

The overview of monthly shrimp and fish catch landings in Songkhla Lagoon during 2003-2016 are presented in *Fig. 10*.

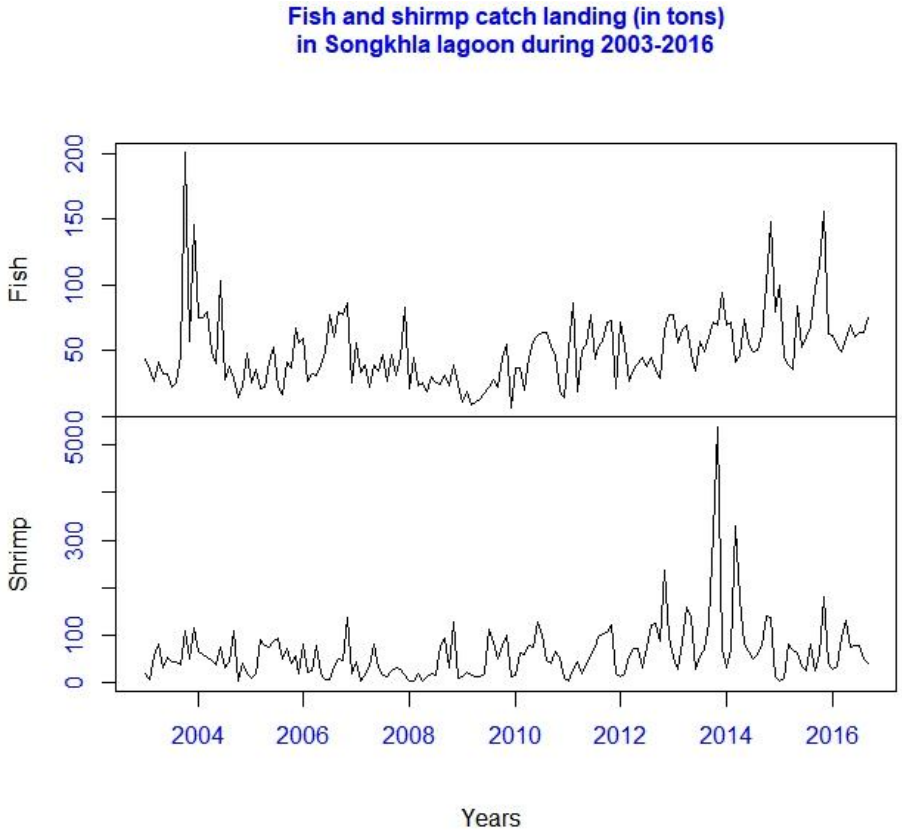

Figure 10. *Monthly shrimp and fish catch landings in Songkhla Lagoon during 2003-2016*

As shown in *Fig. 10*, the lowest shrimp catch landing was in January 2008, with only 1.77 tons; and the highest catch amount was in November 2013, the shrimp catch reached a peak with 537.41 tons. The mean shrimp catch was estimated at around 62.56 tons. The results obtained for the monthly fish landings were also shown in *Fig. 2*, when the most significant catch amount topped 200.78 tons in October 2003; and the lowest in this 2003-2016 period was in December 2009 (6.96 tons). The average monthly catch was around 50.31 tons for this period.

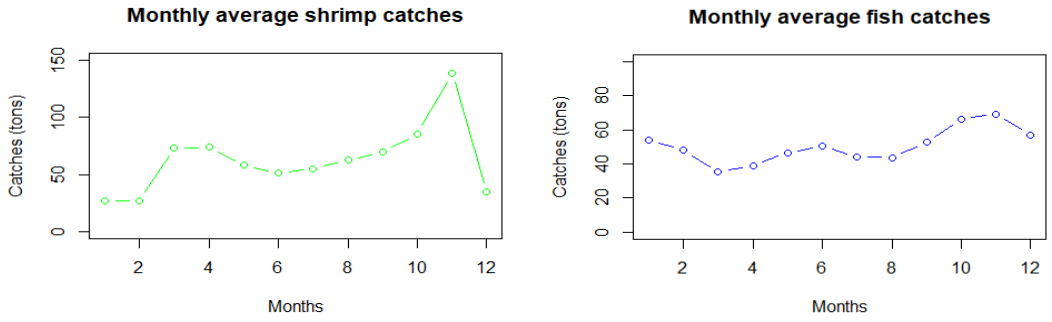
Using Seasonal Factors is the way to analyze data to reveal regular recurring changes associated with the calendar. A seasonal factor measures the percentage amount when, on average, a month is higher or lower than normal (Austin, 1981). From *Fig. 10*, it can be seen that the size of the seasonal fluctuations in both shrimp and fish time series data seems to be roughly constant over time, and does not depend on the level of the time series. Thus, to know exactly the seasonal trend of monthly shrimp and fish catches, the study estimated seasonal factors affecting shrimp and fish for the particular month from January to December. These factors are the same for each particular month, each year. Before monsoon season in Southern Thailand, December, is the best season for both shrimp and fish catching, which is shown by the high seasonal factors (from September

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_30613078
© 2018, ALÖKI Kft., Budapest, Hungary

to November). However, during monsoon season (December to February), the seasonal factors for shrimp catch landings are significant low while the factors for fish catch are really low during the dry season (March to May). The details for these claims are given in *Table 2* and *Fig. 11*. November provides the best seasonal factors for both shrimp catch landings (about 0.88) and fish (about 0.31); while the lowest seasonal factor for shrimp catch (about -0.96) is in January, and for the fish catch (about -0.36) in March, indicating that there seems to be a peak in both shrimp and fish catch landings in November with the bottom for shrimp catch in January, and for the fish catch in March in each year.

Table 2. *Seasonal factors for shrimp and fish catch in Songkhla Lagoon during 2003-2016*

Months	Shrimp seasonal factors	Fish seasonal factors
January	-0.96	0.09
February	-0.76	0.03
March	0.20	-0.36
April	0.14	-0.23
May	0.13	-0.03
June	-0.10	0.09
July	-0.005	-0.08
August	0.30	-0.10
September	0.41	0.09
October	0.33	0.19
November	0.88	0.31
December	-0.59	-0.01



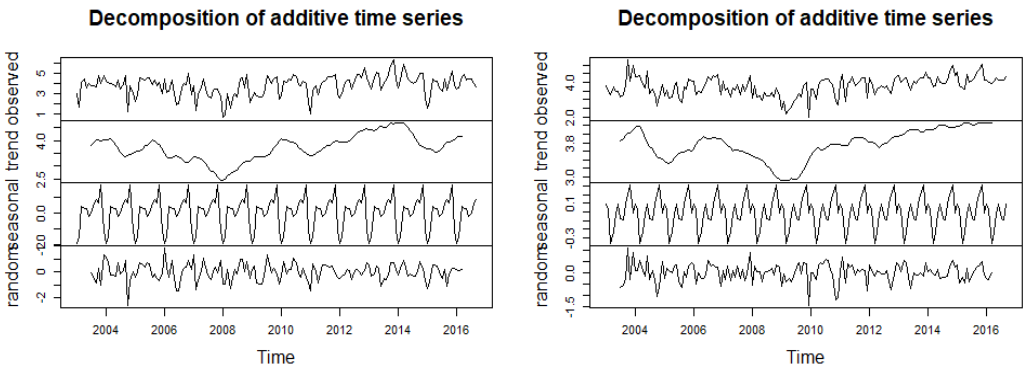


Figure 11. *The average catch of fish and shrimp per month in Songkhla Lagoon during 2003-2016*

According to the data for the total fish and shrimp catch from January to December for January 2003 through to the first 9 months of 2016, the total catch in months of the two species was different with reference to both the amount and the time of catch in the year. The amount of shrimp caught was lowest in January (estimate 27.06 tons) and highest in November, up to 138.55 tons. The amount of fish caught was lowest in March (only 35.13 tons) and highest in November, around 69.36 tons. In general, there was a sharp fluctuation in the average catch between months in year, particularly with reference to shrimp catch landings.

The trend and season of monthly shrimp and fish catch landings is shown clearly in *Fig. 12*.

Discussion

Model fitting and forecasting performances

In this study, the percentage improvement figures for SARIMA and the ANN model for shrimp catch are significantly different (16.9%). In contrast with this result, the improvement figures for fish are very little different (1.56%). In the past, the percentage improvement of ARIMA and the ANN model has been different according to the data set and the period of the forecasting, which was confirmed by Khashei and Bijari (2011) when they used sunspot, Canadian lynx, and exchange rate data sets to compare percentage improvements of ARIMA and the ANN model. Almost all the results showed the better percentage improvement for ANNs over the ARIMA model at different levels. However, when they forecasted 67 points ahead from sunspot data set, percentage MAE of ANNs model is 3.32% bigger than ARIMA model. Again, this statement was proved by Tseng et al. (2002), when the SARIMA model of machinery production time series showed the better result compared to the neural network (NN) with 60 historical forecasting items of data, but the SARIMA model's results were not as good as NN when they forecast 36 points ahead.

In the past, Stergiow (1989) found two suitable ARIMA models to forecast pilchard (*sardina pilchardus*) catches up to 12 months ahead with mean errors (ME) of 14.6% and 12% for the two models. Suitable SARIMA models were found in this study for shrimp and fish with mean errors of 4.56% and 1.83%.

Univariate SARIMA models satisfactorily predicted the total fish and shrimp catch landings. So far, linear regression models developed for total fish catch in Songkhla Lagoon have illustrated little forecasting power (the percentage improvement was 34.6%) (Chesoh and Lim, 2008). In the present study, the univariate SARIMA models that were built show good performance in terms of explained variability and predicting power. The results demonstrate a strong autoregressive character of the time series, i.e. the fish catch landing value at month t depends on the catch at month t-12. SARIMA models provided satisfactory forecasts that were close to the recorded fish and shrimp catch values. The seasonal ARIMA models were found not to be appropriate for both shrimp and fish catch landing, suggesting that the catch landings of fish and shrimp had a different statistical structure. The present findings also imply the clear existence of a

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_30613078
© 2018, ALÖKI Kft., Budapest, Hungary

seasonal pattern in the monthly fish/shrimp catch landing, which is shown both in the original data and seasonal factor *(Table 2 and Fig. 11).*

Seasonal fish and shrimp catch landing

There are major peaks for seasonal fish and shrimp catch landing in the rainy season (from September to November), however, they quickly reduce in December-January. The seasonal cycle is most likely related to the nature of the lagoon ecosystem. In the monsoon seasons (October-January), there is intrusion of sea water from the Gulf of Thailand into the lagoon through a short narrow channel (about 8m in depth) in the outer section. Where the most intensive fishing activities occur, the average depth is very shallow, 1.0-1.5 m. The dry season in southeast Thailand extends from February to April. Most of the brackish and saltwater fish populations migrate to the open sea, whereas the freshwater fish in the upper lake migrate to deeper pools. This phenomenon is consistent with the seasonal migration of some fishermen to find work in the cities (Chesoh and Lim, 2008). The fishing is more intense during the first months of the monsoon season and decreases in December, due to such heavy rain and flooding that the fishermen cannot go fishing. The seasonal catch of shrimp and fish during 2003-2016 was different: while the shrimp catch decreased sharply from December to February, the fish catch decreased significant in the dry season, mostly concentrated in March to May, and before the rainy season (July and August). During the dry season, the fish from Songkhla Lagoon migrate back to the sea (the Gulf of Thailand) for breeding, spawning and larval nursing (Choonhapran, 1996; Chesoh and Samphantharaga, 2004). This claim is also confirmed by the composition of the first finding species found in both Songkhla Lagoon and Sathing Pra (a coastal area in Songkhla province that the author is studying). The seasonal shrimp catch landing is somehow different from the seasonal fish catch, the explanation coming from the effect of the restocking program during this period.

Factors involved in the seasonal variation in fish and shrimp catches may be due to regional climate, especially the effect of the monsoon season in the Southern Thailand, for during these months, the catch in coastal provinces decreases sharply (Komontree et al., 2006), and the catch in the lagoon tends to increase. Seasonal difference effects on monthly fish catch also have been found in previous studies (Stergiou and Christou, 1996; Komontree et al., 2006). Even though the fish catch is very low during March to May, the shrimp catch tends to increase which may be due to the effect of seasonal difference, as the annual closure of the fishing area of the Gulf of Thailand from February 16 to May 15 does not affect the fish catch in the lagoon. The changes of season lead to the changes in zooplankton (Brysiewicz et al., 2006), which would be one of the reasons for the difference in fish and shrimp catch between seasons.

Fish and shrimp catch trends in Songkhla Lagoon

In the monthly fish and shrimp catch landings until 2020, both shrimp and fish catch fluctuated sharply during the two first years of forecasting, then they fluctuated steadily. The shrimp catch reduced to 52.88 tons, by around 15.47% of the catch average during 2003-2016. In contrast with the shrimp catch, the fish catch increased to 68.45 tons, estimated at a 36.05% increase in comparison with the mean fish for the same period in 2003-2016. This result reflects the reality of fishing activities in Songkhla: the general trends of shrimp catch reduce due to the decrease in the number of juvenile shrimps from the stocking program.

During the past four decades, only two papers have reported the annual catches in the main Songkhla Lagoon. The first study was conducted during 1984-1986 (Tonkwinas et al., 1986) and the second during 1994-1995 (Choonhapran et al., 1996). These studies reported the total annual fish catch during 1994-1995, a decrease of 22% compared to the catch in 1984-1986. The monthly report of total fish catches during 1977 to 2006 was 219.9 tons (Chesoh and Lim, 2008).

Conclusion

Knowing the seasons and forecasting both play an important role in fisheries' management, as they constitute the first steps of the planning and decision-making process (Stergiou and Christow, 1996; Stergiou et al., 1997). The facts of the good performance of the final ARIMA models applied to shrimp and fish catch landings in this paper in terms of short term forecasting of up to 12 months in advance, as well as the results that the models provided for insight into the seasonal components of the time series, all justify their use in fisheries' management. Accurate forecasts for 1-2 years may provide useful information to fishery policy makers as well as fishermen. For small scale fishing, the conditions for fishing do not seem to change much inside the lagoon and there are limited budgets for organizing the usual surveys, so SARIMA models can be considered as suitable tools to forecast the persistence of fish and shrimp catches. The performance of the models could be improved by additional information about environmental factors (e.g. temperature, salinity…) and other factors (market prices and biological information) put into the multivariate models.

Acknowledgments. This paper has been partly prepared with the support from the Higher Education Research Promotion and the Thailand's Education Hub for the Southern Region of ASEAN Countries Project Office of the Higher Education Commission. Financial support was granted by the Graduate School, Prince of Songkla University, Thailand. The authors would like to thank the National Institute of Coastal Aquaculture (NICA) staff for giving them the chance to join in data collection and for providing data for the research.

Conflict of interest. The authors definitely confirm that there is no conflict of interest concerning this article.

(Received 16th Mar 2018; accepted 21st May 2018)

Abstract. This study was conducted to determine volatile oil components for leaf and flowers of *Stachys cretica* subsp. *anatolica* Rech. and *Stachys lavandulifolia* Vahl. in different reaping periods, such as pre-flowering, flowering, and post-flowering by gas chromatography mass spectroscopy (GC-MS) after solid phase micro extraction (SPME). To achieve this aim, leaf and flower samples were collected from Tınaztepe Cavern province of Seydisehir, in 2015 and 2016. A total of 62 components were determined for *Stachys cretica* subsp. *anatolica*, with benzaldehyde (46.34%), β-caryophyllene (11.23%) and (E)-2-hexenal (8.50%) being the main components. Additionally, 55 volatile components were found for *S. lavandulifolia,* and the main components were β-phellandrene, myrcene, and α-pinene at 27.71%, 11.56% and 11.20% respectively.
Keywords: *Stachys, SPME, (E)-2-Hexenal, Benzaldehyde, β-phellandrene, Turkey*

Introduction

Turkey is situated at the intersection of different climate zones due to its geographical location. Therefore, it is rich in plant species and diversity. Turkey is also an important germplasm for the plants in the Lamiaceae family, which is the number one plant species traded across the world that has an important place in alternative medicine (Anonymous, 1996; Arslan et al., 2000; Ozkan, 2007). The members of the Lamiaceae family represented by 45 genera and more than 546 species in Turkey are vital for the pharmacology and perfumery industry thanks to their volatile and aromatic oil content (Secmen et al., 2000).

The economic value of the Lamiaceae family members is very high, as they contain the aromatic compounds and essential oils. Some taxa in the *Pogestemon* and *Lavandula* genera are used in the perfumery industry while *Thymus*, *Mentha* and *Origanum* species are used in the food industry (Watson and Dallwitz, 1978; Clive and Stace, 1980; Baytop, 1991; Ozkan, 2007). Furthermore, several species in the family (*Stachys*, *Sideritis*, *Salvia*, *Lamium*, *Ajuga*, *Teucrium*, *Thymus*, *Phlomis* etc.) are known to be used for therapeutic purpose (Baytop, 1984, 1991; Ozkan, 2007).

The genus *Stachys* from the Lamiaceae family, which was the research material, in this study, comprises nearly 200 taxa. The members of *Stachys* L. are found almost everywhere in the world except Australia and New Zealand. The Balkans, South and East Anatolia, Caucasians, Northwest Iran and north of Iraq are the regions where these species grow intensively (Bhattacharjee, 1974; Davis, 1988). They are represented by 121 taxa in Turkey with an endemism rate of 43.4%.

Stachys species are medicinal plants used by people for the treatment of diseases. *Stachys annua* is used to heal insomnia and menstrual irregularities; *S. sylvatica* is used as antispasmodic, diuretic, tonic and astringent agent, *S. officinalis* is used as tonic and

© 2018, ALÖKI Kft., Budapest, Hungary

for the treatment of insomnia, headache and cough, while *S. palustris* is used externally to heal wounds (Steinmetz, 1954; Garnier et al., 1961).

Stachys cretica is perennial with basal sterile rosettes. Flowering stems are 25-100 cm, erect, they can be branched or unbranched, usually densely or sparsely adpressed greyish tomentose, rarely patent-pilose with glandular hairs being less frequent than eglandular hairs. Basal leaves are oblong-spathulate, 4-10 x 1-3.5 cm, obscurely crenulate to faintly crenate, apex obtuse sometimes acute, attenuate or rarely rounded to subcordate at base, petiole 2-8 cm. Cauline leaves are like basal but gradually become smaller above, shortly petiolate to subsessile or sessile. Floral leaves are oblong-lanceolate to lanceolate, 1-6 x 0.5-1.2 cm, the same lenght or longer compared to verticillasters. Additionally, verticillasters usually remote throughout, rarely approximate above, 10-16-flowered. Brachteoles ovate-lanceolate to lanceolate, 5-16 mm, herbaceous, not spinescent. Pedicels 1-2.5 mm. Calyx sub-bilabiate, subcampanulate to tubular, 12-16 mm, densely tomentose, teeth subequal, ovate to lanceolate, 1/3-1 x tube; mucro 1-3 mm. Corolla rose-pink, 18-20mm, tube subexserted. Nutlets obovoid, 2 x 1.5 mm, smooth (Davis, 1982).

S. lavandulifolia is suffrutescent perennial with basal rosettes of sterile shoots. Flowering stems numerous, 10-30 cm, sparsely to densely pilose, sometimes absent, rarely white-tomentose with unequal stellate hairs. Basal leaves subsessile to sessile, oblong-lanceolate to oblanceolate, 2-6 x 0.4-1.5 cm, entire to faintiy serrate, attenuate at base, cauline similar. Floral leaves oblong to ovate, 1.2-2 x 0.25-0.8 cm, shorter than verticillasters. Verticillasters (at least lower ones) usually remote, (2-)4-6-flowered. Brachteoles few, linear, 2-3 mm, hirsute. Pedicels 1.5-2 mm. Calyx ± regular, subcampanulate, patently pilose, tip softly spinescent. Corolla purple to mauve, 13-15 mm, tube subincluded. Nutlets obovoid, 2.5-3 x 2-2.5 mm (Davis, 1982).

Stachys species are becoming increasingly important due to the aromatic compounds and essential oils they contain. In this study, we analyzed the volatile compounds in the leaves and flowers of *Stachys cretica* subsp. *anatolica* and *S. lavadulifolia* species at three different vegetation stages, pre-flowering, flowering and post-flowering.

Materials and Methods

The material of the study conducted in 2015 and 2016 comprised of *Stachys cretica* subsp. *anatolica* and *S. lavandulifolia* samples collected during pre-flowering, flowering and post-flowering stages from two different sampling sites in Konya-Seydisehir, Tınaztepe Cavern province that is situated N 37° 14', E 31° 55', and 1525 m elevation (*Figure 1*). Samples of *S. cretica* subsp. *anatolica* were collected in April, May, and June of both 2015 and 2016 at pre-flowering, flowering, and post-flowering stages. Additionally, *S. lavandulifolia* samples were collected in May, June, and July of both years.

The leaves and flower samples that were collected were put into paper packages and transferred to the laboratory the same day to avoid exposure to sunlight. After the collected plant materials were dried at room temperature (25°C), and flower and leaf samples were subjected to solid phase microextraction (SPME). 2 g of samples were placed into a 10 mL vial. After incubation for 30 min at 60°C, SPME fibre was pushed through the headspace of a sample vial to absorb the volatiles and then inserted directly into the injection port of the GC-MS (Shimadzu 2010 Plus GC-MS with the capillary column, Restek Rxi®-5Sil MS 30 m x 0.25 mm, 0.25 μm) at a temperature of 250°C for

desorption (5 min) of the adsorbed volatile compounds. The constituents were identified using retention times of standard substances by aligning mass spectra with the data given in the Wiley, NIST Tutor, FFNSC library.

Figure 1. *Sampling area for Stachys materials*

Results

The volatile compounds in the leaves and flowers of *Stachys cretica* subsp. *anatolica* and *S. lavandulifolia* species were collected at pre-flowering, flowering, and post-flowering stages were analyzed by SPME (solid phase microextraction) method. With SPME method, 62 different volatile compounds were identified in *Stachys cretica* and 55 in *S. lavandulifolia*. These results are shown in *Table 1*. (E)-2-Hexenal, Benzaldehyde, and β-caryophyllene *Stachys cretica* were identified as the main compounds of *Stachys cretica*. Specifically, it contained 7.82% (E)-2-Hexenal, 40.54% Benzaldehyde, and 8.36% β-caryophyllene at the pre-flowering stage; 8.50% (E)-2-hexena, 46.34% Benzaldehyde and 11.23% β-caryophyllene at the flowering stage; and 6.62% (E)-2-Hexenal, 41.80% Benzaldehyde and 10.93% β-caryophyllene at the post-flowering stage. Additionally, α-pinene, myrcene and β-phellandrene were found to be the main compounds of *Stachys lavandulifolia*. Specifically, these flowers contained 10.70% α-pinene, 10.98% myrcene and 26.12% β-phellandrene at the pre-flowering stage; 11.20% α-pinene, 11.56% myrcene and 27.71% β-phellandrene at the flowering stage; and 10.90% α-pinene, 10.25% myrcene and 26.06% β-phellandrene at the post-flowering stage (*Table 1*).

Discussion and Conclusions

Stachys cretica subsp. *anatolica* was found to have 62 different volatile compounds, with (E)-2-Hexenal (8.50%), Benzaldehyde (46.34%), and β-caryophyllene (11.23%) being its main compounds.

Ozkan et al. (2005) found that the main component of *Stachys cretica* subsp. *mersinaea* was α-curcumene (34.10%). In another study, Ozturk et al. (2009), identified 37 components of *Stachys cretica* subsp. *smyrnaea* using GC-MS analyses, with β-caryophyllene (51.0%), germacrene-D (32.8%), a-humulene (3.1%), Δ-cadinene (2.1%), and Δ-elemene (2.1%) being its main components. β-caryophyllene was found to be the main compound in both studies. The results for the other compounds was different from our findings. The other main compounds identified in our study were (E)-2-Hexenal and Benzaldehyde.

Goren et al. (2011) identified 24 main components of two *Stachys cretica* subsp. *cassia* and *S. cretica* subsp. *garana*, and 27, 26 and, 23 components of *S. cretica* subsp. *lesbiaca*, *S. cretica* subsp. *kutahyensis* and *S. cretica* subsp. *symrnaea* respectively. As results, germacrene-D (27.8%), δ-elemene (14.9%), and β-caryophyllene (8.9%) were identified for *Stachys cretica* subsp. *cassia*, however α-cadinol (16.4%), verbenol (11.4%) and dodecanoic acid (8.9%) were found for *S. cretica* subsp. *garana*. Additionally, germacrene-D, β-caryophyllene, and α-cadinol were found to be the main components of *S. cretica* subsp. *lesbiaca* at 13.9%, 12.5%, and 7.4% respectively. In the same study, they found germacrene-D (38.9%), β-caryophyllene (14.8%), and caryophyllene oxide (8.7%) to be the main components of *S. cretica* subsp. *symrnaea* and germacrene-D (28.1%), τ-muurolol (9.3%) and cubenol (8.8%) to be the main components of *S. cretica* subsp. *kutahyensis*. β- caryophyllene in both studies. The results for the other compounds differed from our findings. Goren et al. (2011) identified germacrene-D as the other dominant compound. The other main compounds identified in our study were (E)-2-Hexenal and Benzaldehyde.

Through SPME analysis, *Stachys lavandulifolia* was found to have 55 different volatile compounds, with α-pinene (11.20%), myrcene (11.56%), and β-phellandrene (27.71%) being its main compounds.

In another study conducted in Iran by Feizbaksh et al. (2003), 55 components of *Stachys lavandulifolia,* which is endemic to Iran, were identified, and α-pinene (20.1%), β-pinene (12.1%), and spathulenol (7.2%) were found to be its main components. Moreover, α-pinene was found to be the main compound in both analyses. Their results for the other compounds differed from our findings. Feizbaksh et al. (2003) found that the other dominant compounds were β-pinene and spathulenol while the other main compounds identified in our study were myrcene and β-phellandrene.

The studies of Javidnia et al. (2004) found that germacrene-D (13.2%), β-phellandrene (12.7%), β-pinene (10.2%), myrcene (9.4%), α-pinene (8.4%), and Z-β-ocimene (5.8%) are the main components of *Stachys lavandulifolia*, however, Morteza-Semnani et al. (2005) identified 4-hydroxy-4-methyl-2-pentanone (9.3%), α-pinene (7.9%), and hexadecanoic acid (5.2%). In both studies, α-pinene was found to be the main compound. The result for the other compounds differed from our findings. Morteza-Semnani et al. (2005) found that the other dominant compounds were 4-hydroxy-4-methyl-2-pentanone and hexadecanoic acid. The other main compounds identified in our study were Myrcene and β-phellandrene.

Meshkatalsadat et al. (2007) reported that the main components of *Stachys lavandulifolia* are α-pinene (25.66%), myrcene (17.33 %), β-phellandrene (21.96 %),

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_30793086
© 2018, ALÖKI Kft., Budapest, Hungary

and β- caryophylene (14.3 %). In another study, Sajjadi ve Amiri (2007) determined the components as α-pinene (27.25, 25.66, 8.52%), myrcene (17.33, 9.33, 23.85%), and β-phellandrene (21.96, 37.49, 12.58%) for pre-flowering, flowering, and post-flowering periods of *S. lavandulifolia,* respectively. These studies supported our results.

Among 37 compounds of *Stachys lavandulifolia* Vahl. subsp. *lavandulifolia,* Iscan et al. (2012) found β-phellandrene (27%), α-pinene (18.5%), and germacrene-D (13%) to be the major components. In both studies, β-phellandrene and alpha-pinene were found to be the main components. In their study, germacrene-D was another dominant compound. The other main compounds identified in our study were myrcene and β-Phellandrene. Additionally, Pirbalouti et al. (2013) determined α-thujone (0.3%–32.3%), α-pinene (trace to 37.3%), myrcene (0.5%–15.9%), β-phellandrene (1.1%–37.9%), germacrene-D (0.4%–11.3%), Δ-cadinene (trace to 11.6%) and 1, 4-methano-1 H-indene (trace to 10.1%) to be the main components of *S. lavandulifolia*. These studies also supported our results.

In conclusion, *Stachys cretica* subsp. *anatolica* and *Stachys lavandulifolia*, the leaves and flowers of which were collected from the field, had the highest efficiency in terms of volatile compounds when they were collected during the flowering stage. The findings of this study inform the merchants and local people about the collection time to prevent random plant collection and potential economic losses.

Abstract. A field experiment was conducted to evaluate the effect of crop rotation and tillage system on the yield and weed infestation of spring wheat as well as on the chemical properties of soil and number of earthworms. The first experimental factor was the cropping system: 1) crop rotation A: pea – spring wheat – durum wheat, 2) crop rotation B: pea – spring barley – spring wheat, 3) cereal monoculture: spring barley – spring wheat – durum wheat, whereas the second one was the tillage system: a) conventional (CT), b) reduced (RT), and c) no-tillage (NT). Spring wheat produced a higher grain yield in crop rotation A than in crop rotation B and cereal monoculture. Its higher yield was also achieved in the CT system than in the NT and RT systems. A higher number and weight of weeds was noted in the cereal monoculture compared to crop rotations A and B. Greater weed infestation occurred also in RT and NT systems than in the CT system. In soil samples from crop rotations A and B, analyses demonstrated higher contents of organic C and total N and a lower C/N ratio than in the cereal monoculture. The increased contents of organic C and total N in the soil were also affected by NT and RT systems, then by the CT system. Also the number of earthworms in soil m^{-2} was significantly higher in RT and NT than in CT system.
Keywords: *cropping system, earthworms, organic carbon, soil tillage, weeds*

Introduction

Crop rotation and soil tillage exert a significant influence on crop yield, weed infestation, and soil properties. Cereals cultivation in a monoculture contributes to increased weed infestation of the crop (Poggio, 2005; Woźniak and Soroka, 2015), deteriorated plant health (Hernandez-Restrepo et al., 2016), and consequently to a decreased crop yield (Nevens and Reheul, 2001; Sieling et al., 2005). The extent of yield decrease varies and depends on multiple factors including species and cultivar, weather course, fertilization, plant protection, and soil tillage (Hernanz et al., 2014). However, these factors act comprehensively, therefore have different effects on the productivity of plants (Shahzad et al., 2016). As demonstrated by De Vita et al. (2007) and by Montemurro and Maiorana (2014), in warm and arid areas higher yields of cereals are achieved in the no-till than in the conventional tillage system, whereas in moderately humid conditions better effects are obtained in the conventional than in the no-till system (Lahmar, 2010; Woźniak and Soroka, 2014).

Other outcomes of cereals cultivation in the monoculture include adverse changes in the soil including mainly loss of organic matter and organic carbon (Maillard et al., 2016), as well as suppressed enzymatic and biological activity of the soil (Kretzschmar and Monestiez, 1992; Woźniak and Kawecka-Radomska, 2016). In general, it may be

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_30873096
© 2018, ALÖKI Kft., Budapest, Hungary

stated that cereal monoculture leaves little diversified post-harvest residues, which leads to a reduction in the number of soil saprophytes (Olsson and Alström, 2000; Balota et al., 2004). Soil properties are also determined by its tillage systems. Many studies have demonstrated the no-till system to increase organic carbon content (West and Marland, 2002; Tabaglio et al., 2008; Ernst and Emmerling, 2009), to stabilize soil structure (Madari et al., 2005; Celik et al., 2012), to prevent soil erosion (Jordan et al., 2000), and to increase the enzymatic activity of soil and the number of earthworms in the soil (Woźniak and Kawecka-Radomska, 2016). A higher number of earthworms is indicative of the good condition of the soil environment (Lenart and Sławiński, 2010). Earthworms intensify organic matter decomposition in the soil, take part in the formation of mineral-organic colloids, regulate water-air balance in the topsoil (Laossi et al., 2010), and even indirectly alleviate the soil-borne diseases of plants induced e.g. by *Gaeumannomyces graminis* var. *tritici* (Clapperton et al., 2001).

This study aimed to evaluate the effect of crop rotation and tillage system on the yield and weed infestation of spring wheat as well as on soil properties and the number of earthworms.

Material and Methods

Location and design of the experiment

An exact field experiment was established in 2007 at the Experimental Station Uhrusk (51°18'10"N, 23°36'45"E), belonging to the University of Life Sciences in Lublin, south-eastern Poland, whereas data presented in this manuscript was collected in the years 2015–2017. The experiment was established with the method of complete sub-blocks (6×25 m) in 3 replications. The first experimental factor was the cropping system: 1) crop rotation A: pea – spring wheat – durum wheat, 2) crop rotation B: pea – spring barley – spring wheat, 3) cereal monoculture: spring barley – spring wheat – durum wheat, whereas the second one was the tillage system: a) conventional (CT), b) reduced (RT), and c) no-tillage (NT). In the CT system, a shallow ploughing (at a depth of 10-12 cm) and pre-winter ploughing (25-30 cm) were applied under all crops. In RT, both ploughing treatments were replaced by cultivation, whereas only glyphosate (4 L ha^{-1}) was applied in NT. A cultivator and a tillage set were used on all plots in the spring time.

Soil and agroclimatic conditions

The soil the experiment was established on was Rendzic Phaeozem (IUSS Working Group WRB, 2015) with the composition of sandy loam and with silty fraction content of 24.4% and dusty fraction content of 13.3%, with a slightly alkaline pH (pH_{kCL}=7.2), high contents of available forms of phosphorus (127 mg P kg^{-1} d.m.) and potassium (223 mg K kg^{-1}), and a medium content of magnesium (69 mg Mg kg^{-1}).

The annual sum of atmospheric precipitation on the study area reached 620 mm, including over 380 mm in the period since March till August (since the sowing to harvest of spring wheat). The highest average monthly sums of precipitation accounted for 71 mm in May, 73 mm in June, 84 mm in July, and 72 mm in August, whereas distribution of average daily air temperatures was as follows: 14.0 °C in May, 17.1 °C in June, 19.4 °C in July, and 18.4 °C in August.

Fertilization and protection of plants

In all study years, spring wheat and other crops cultivated in crop rotations were sown between the 1st and 5th of April. Spring wheat of Sonett cultivar was sown at the density of 450 seeds m^{-2}. It was fertilized with nitrogen in a total dose of 140 kg N ha^{-1} applied in the following terms: 50 kg N ha^{-1} before sowing, 40 kg N ha^{-1} at the tillering stage, 30 kg N ha^{-1} at the shooting stage, and 20 kg N ha^{-1} at the earing stage. Fertilization with phosphorus and potassium was applied before wheat sowing in doses of 35 kg P ha^{-1} and 99 kg K ha^{-1}. Spring wheat was protected against fungi with the following fungicides: flusilazole + carbendazim at the 32-33 stage in Zadoks scale (Zadoks et al., 1974), and propiconazole + fenpropidin at the 53-54 stage. Weed infestation was reduced by applying a herbicide with a.i. mecoprop + MCPA + dicamba at the 23-24 stage.

Yield components and statistical analysis

The following traits were evaluated: 1) grain yield (t ha^{-1}), 2) 1000 grain weight (g), 3) spike number m^{-2} before harvest, 4) grain weight per spike (g), 5) number and air-dry weight of weeds (g m^{-2}), 6) species composition of weeds (m^{-2}), 7) organic C content in the soil (g kg^{-1}) (with Tiurin method); 8) total N content in the soil (g kg^{-1}) (with Kjeldahl method), 9) C/N ratio in soil samples, and 10) number of earthworms in the soil (m^{-2}). Grain was harvested using a Wintersteiger plot harvester, 1000 grain weight was determined by measuring out 2×500 grains, the number of spikes m^{-2} was calculated twice from the surface area of 0.5×1.0 m of each plot, whereas grain weight per spike was established based on 40 spikes collected at random. Weed infestation was evaluated with the botanical-gravimetric method at the waxy maturity stage (stage 83-84), by determining species composition of weeds and air-dry weight of weeds collected from m^2 of a plot. This area was marked at random (twice) using a frame 0.5×1.0 m in size. The air-dry weight of weeds was determined by collecting all weeds from the frame area, removing their root system, and keeping them in a well-ventilated room until constant weight has been achieved (Woźniak and Soroka, 2015). The number of earthworms m^{-2} was calculated in each study year at the end of May, by manual picking of the earthworms and calculating their number in 2 soil samples collected from the surface area of 0.25×1.0 m and depth of 0.30 m from each plot (Woźniak and Kawecka-Radomska, 2016).

Results obtained were elaborated statistically with the method of the analysis of variance (ANOVA) using Statistica PL software (StatSoft Poland). The significance of differences between mean values was evaluated with the HSD Tukey's test at $P<0.05$.

Results

Grain yield and its components

The highest grain yield was determined for spring wheat sown in crop rotation A, and a significantly lower one for wheat grown in crop rotation B (by 9.1%) and cereal monoculture (by 23%) – *Table 1*. Significant differences in grain yield occurred also between crop rotation B and cereal monoculture. Grain yield was also affected by soil tillage. Its higher value was achieved in the CT than in the NT and RT systems (by 9.8% and 19.2%, respectively). It was also demonstrated that in crop rotations A and B

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

a higher yield of wheat was obtained in the CT than in the RT and NT systems, whereas in cereal monoculture – in the NT and CT compared to the RT system. The evaluation of variance analysis components indicated that grain yield was affected to a greater extent by CS than by TS (*Table 2*).

Table 1. *Effect of cropping system and tillage system on grain yield of spring wheat and its components (mean from 2015-2017)*

Cropping system (CS)	Tillage system (TS)			Mean
	[a]CT	RT	NT	
	Grain yield (t ha^{-1})

[1]Crop rotation A: p – sw – dw (pea – spring wheat – durum wheat), [2]Crop rotation B: p – sb – sw (pea – spring barley - spring wheat), [3]Cereal monoculture: sb – sw – dw (spring barley – spring wheat – durum wheat), [a]CT – conventional tillage, RT – reduced tillage, NT – no-tillage,
ns – not significant, $P<0.05$

Cropping and tillage systems affected the values of grain yield components. The 1000 grain weight was significantly higher in crop rotations A and B than in the cereal monoculture. More plump grain was also produced by wheat in the CT than in NT and RT systems. Significant differences in 1000 grain weight occurred also between NT and RT systems. Based on variance analysis components, it may be concluded that the 1000 grain weight depended to a greater extent on CS than on TS.

The number of spikes m^{-2} was significantly higher in crop rotation A than in crop rotation B (by 27 spikes m^{-2}) and cereal monoculture (by 68 spikes m^{-2}). Differences in spike number m^{-2} were also observed between crop rotation B and the cereal monoculture. A higher spike number m^{-2} was also demonstrated in the CT system than in the NT (by 28 spikes m^{-2}) and RT (by 43 spikes m^{-2}) systems. The value of this yield component was affect to a greater extent by CS than by TS.

Grain weight per spike was significantly higher in crop rotations A and B than in the cereal monoculture. A higher grain weight per spike was also produced by wheat grown in the CT and NT systems compared to the RT system, however the evaluation of variance analysis components indicated that CS and TS had a similar effect upon this trait.

Number, air-dry weight, and species composition of weeds

Wheat cultivation in the cereal monoculture caused an increase in weed number m^{-2} (by ca. 30%), compared to crop rotations A and B (*Table 3*). The number of weeds m^{-2} was also higher in plots cultivated in the RT system than in the CT and NT systems.

Table 3. *Effect of cropping system and tillage system on the number of weeds and air-dry weight of weeds in spring wheat crop (mean from 2015-2017)*

Likewise, total N content was higher in the soil sampled from crop rotation A and B than from the cereal monoculture as well as from NT and RT plots compared to CT plots. In crop rotations A and B, the C/N ratio was lower than in the cereal monoculture. In turn, the C/N ratio was not affected by tillage systems, though its lower value was determined in soil samples from CT compared to NT plots. The number of earthworms in soil m^{-2} was significantly higher in RT and NT than in CT system. The evaluation of variance analysis components indicated that contents of organic C and total N and number of earthworms in the soil were affected to a greater extent by TS than by CS, whereas the value of C/N ratio – by CS (*Table 7*).

Discussion

The reduced grain yield in the monoculture results from increased weed infestation (Woźniak and Soroka, 2015; Shahzad et al., 2016) and from crop infestation with fungal diseases, mainly these of stalk base and roots (Hernandez-Restrepo et al., 2016). In addition, some adverse changes occur in the soil under cereal monoculture including especially decreased contents of organic matter and organic C (Maillard et al., 2016), suppressed enzymatic activity of soil (Woźniak and Kawecka-Radomska, 2016), but also a reduced number of earthworms (Kretzschmar and Monestiez, 1992; Laossi et al., 2010). It may be speculated that this is due to little diversified post-harvest residues left from this type of cultivation, which leads to reduced numbers of soil saprophytes and increased counts of soil pathogens (Olsson and Alström, 2000; Balota et al. 2004). In this context, interesting findings are provided by a work of Clapperton et al. (2001) on the role of earthworm in the indirect reduction of soil-borne diseases of plants induced by *Gaeumannomyces graminis*. In our experiment, a higher number of earthworms in soil m^{-2} was determined in RT and NT than in the CT system. Likewise research conducted by Maillard et al. (2016) and by Nevens and Reheul (2001), our study showed a decrease in contents of organic C and total N in the soil sampled from the cereal monoculture, which consequently caused a less favorable C/N ratio than in crop rotations A and B. The higher contents of organic C and total N were also found in soil samples from NT and RT plots compared to CT plots. Similarly to findings reported by Poggio (2005), Shahzad et al. (2016), and by Woźniak and Soroka (2015), wheat cultivation in the monoculture resulted in increased weed infestation of the crop, i.e. weed number increase by ca. 30% and weed weight increase by over 33%, compared to crop rotations. As a result, grain yield of spring wheat grown in the monoculture was lower than in crop rotations. The reduction in yield was due to a lower number of spikes m^{-2}, a lower grain weight per spike, and a lower 1000 grain weight than in crop rotations. Higher wheat grain yields were also obtained in the CT system than in the NT and RT systems, which also resulted from higher values of yield components in this system of soil tillage.

Conclusion

To recapitulate, cultivation of spring wheat in the cereal monoculture led to unbeneficial changes in soil properties including mainly decreased contents of organic C and total N. Spring wheat cultivation in the cereal monoculture resulted also in a significant increase in the number and air-dry weight of weeds, compared to crop rotations. Soil properties were also influenced by its tillage system. In soil sampled from RT and NT plots analyses demonstrated higher contents of organic C and total N, and the number of earthworms in soil m^{-2}, compared to CT plots. In turn, wheat cultivation in RT and NT systems caused a significant increase in the number and weight of weeds compared to the CT system. In a consequence, spring wheat grown in the cereal

© 2018, ALÖKI Kft., Budapest, Hungary

monoculture produced a significantly lower grain yield than in crop rotation A and B. Yield decrease resulted from a lower number of spikes m^{-2}, lower grain weight per spike, and a lower 1000 grain weight than in the crop rotations. The higher yield of wheat was also demonstrated in the CT than in the NT and RT systems, which was due to higher values of yield components in this system of soil tillage.

Abstract. In addition to enhancing wheat's photosynthesis, growth and ability to cope with stress, the foliar application of zinc and iron can play an effective role in improving consumer nutrition. Therefore, the aim of this study was investigation of zinc and iron foliar application in irrigation water acidity on wheat (*Triticum aestivum* L.). This experiment was conducted as a triple factorial using a randomized complete blocks design with three replications in Tehran, Iran in 2014-15 and 2015-16. The treatments were two irrigation water acidity (pH value = 8.14 and 5), and the foliar application of iron and zinc sulfate (0, 2.5, and 5 g L^{-1}). The results revealed that the most grain yield was produced at a pH value = 5, with 5 g L^{-1} zinc application. The main cause for increasing the grain yield was enhancement of spike length, tillers and grains per plant. The greatest grain protein content was measured at a pH value = 5, with a 5 g L^{-1} zinc application. The maximum grain iron content was calculated at a pH value = 5, with 5 g L^{-1} zinc usage. The highest grain zinc content was obtained at a pH value = 5, with 5 g L^{-1} zinc consumption. The maximum zinc utilization efficiency was observed for the iron control treatment with 5 g L^{-1} zinc consumption. Therefore, the treatments that were irrigated with water with an acidic pH of 5 along with 5 g L^{-1} zinc and iron foliar application had the highest yield and the best qualitative traits.
Keywords: *grain yield, harvest index, micronutrient nutrition, protein percentage, utilization efficiency*

Introduction

Agricultural production in the twenty-first century has to go along and result in increased food security and it has to be less dependent on fairly rare resources such as agricultural lands, water, fossil fuels, and non-renewable energies (Uphoff, 2012; Pazouki et al., 2017). Wheat crops are grown in a wide range of environments that affect overall performance, particularly grain yield and end-use quality (Yadi et al., 2016). According to the official statistics released by FAO, the wheat cultivation area in the world during the past years has been between 230 million hectares (FAO, 2016). The last set of global statistics showed that the grain yield production was 750 million tons (FAO, 2016). Iran has 6.2 million hectares of wheat field area and 12.3 million tons of wheat production (Ministry of Jihad-e-Agriculture of Iran, 2016).

However, staple grains, such as wheat often contain suboptimal quantities of micronutrients, especially zinc and iron, and most of this content is removed by milling (Borrill et al., 2014). The World Health Organization estimates that approximately 25% of the world's population suffers from anemia (WHO, 2008); and that iron-deficiency anemia led to the loss of over 46,000 disability-adjusted life years (DALYs) in 2010 alone (Murray and Lopez, 2013). An estimated 17.3% of people worldwide are at risk of inadequate zinc intake (Wessells and Brown, 2012), and zinc-deficiency leads to the

© 2018, ALÖKI Kft., Budapest, Hungary

estimated annual deaths of 433,000 children under the age of five (WHO, 2009). By taking the geological experiments in Iran into consideration, it becomes clear that 37% of the lands under irrigated wheat cultivation have problems regarding zinc deficiency (40%), manganese deficiency (25%), and supply of copper, which can be absorbed equals 24% (Ministry of Jihad-e-Agriculture of Iran, 2016). World statistics also show that approximately 50% and 30% of the soils under grain cultivation all around the world have problems regarding the deficiency of available zinc and iron, respectively (FAO, 2016).

When nutrition is not properly absorbed in the soil, the foliar application of different elements is an efficient way for solving the problem of the deficiency of these elements (Cakmak, 2008). Based on the studies of many researchers, it was revealed that there are wide variations in grain iron and zinc contents in the wild relatives of modern wheat, and it was found that the contents can significantly exceed those found in modern elite cultivars (Cakmak et al., 2000; Monasterio and Graham, 2000). This natural variation can be utilized for wheat bio-fortification by zinc and iron (Uauy et al., 2006), which was originally identified for increasing the protein content in wild emmer (*Triticum turgidum* ssp dicoccoides). In isogenic lines, the zinc and iron content of grain increased by 12 and 18%, respectively (Distelfeld et al., 2007). Zhang et al. (2010) revealed that the iron content of grain had increased significantly from the control treatment to ferric citrate, ferric citrate plus $ZnSO_4$ and $FeSO_4$ application, respectively. Moreover, the grain zinc and the iron content were increased by using zinc and iron fertilizer resources in comparison to the control treatment. Other researchers have shown that micronutrients spraying, particularly zinc, iron, and manganese on leaves, leads to significantly increased wheat grain yield (Wissuwa et al., 2008). Mohammad et al. (2000) reported that zinc and iron application with different methods increased grain yield in comparison to control, and using zinc by the spraying method, maximum grain yield, and zinc concentration were obtained in the grain; using the soil and the spraying method recorded the highest grain yield and grain iron content. Given that micronutrients increase crop production and also influence human well-being and health, one of the simple and economical ways for achieving self-sufficiency and a healthy society is through the addition of micronutrients, especially iron and zinc, to the soil or consuming it through foliar application. In this was, in addition to enhancing the production of crops, the concentration of micronutrients in agricultural crops, including wheat, which is a central part of the food that Iranian people eat, can be increased. By taking into account issues such as the high costs of supplying nutrients from chemical resources, deficiency of nutrients in basic soils, paying attention toward finding an effective and economical method, and replacing the current methods with it with the purpose of fulfilling the needs of agricultural plants, and enriching the diets of humans and animals, seems necessary. Therefore, the aim of this study was to implement the foliar application of zinc and iron in irrigation water with an acidic and a basic pH value on the yield and the qualitative traits of wheat.

Material and Methods

Description of the site

The study was conducted in the University of Shahed, Tehran Province, Iran in 2014-15 and 2015-16. The experimental farm is geographically situated at 35°, 33' N latitude,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

and 51°, 20' E longitude. Tehran is located between mountainous region and plains. Three factors of the Alborz mountain range, the desert, and the western wet winds play an important role in the climate of Tehran. Different weather conditions have been formed in the various regions of Tehran due to its special geographical location. The climate of the Tehran Province is warm and dry in the dry area, cold and semi-humid in the mountain range, and cold with longer winters in high mountains. This experiment was carried out in a warm and dry area. Local weather data during the rice growing period were collected daily from the synoptic meteorological station nearest to the paddy fields (*Table 1*). In addition, the soil properties at a depth of 0-30 cm are detailed in *Table 2*.

Description of the experiment

The investigated wheat cultivar in this experiment was Pishtaz. This experiment was conducted as a triple factorial using a randomized complete blocks design with three replications. The treatments were as follows: two irrigation water acidity (water of the area with a pH value = 8.14 and water with a pH value = 5, which were created by sulfuric acid), and the foliar application of iron sulfate fertilizer (0, 2.5, and 5 gr L^{-1}), and zinc sulfate fertilizer (0, 2.5, and 5 gr L^{-1}).

Nitrogen, phosphorus, and potassium were added to the soil based on the soil test. In terms of fertilizer application, a basal dose of 75 kg P_2O_5 ha^{-1} was applied in the form of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_30973112
© 2018, ALÖKI Kft., Budapest, Hungary

triple super phosphate. Nitrogen was applied in the form of urea (115 kg N ha^{-1}). Potassium was applied in the form of potassium sulfate (75 kg K_2O ha^{-1}). Phosphorus and potassium were applied as basal dressing. Nitrogen application was split: 20% at planting stage, 25% of top-dressed at the early tillering stage, and 25% of nitrogen was applied at the booting stage. The planting row spaces were 12×2 cm^2 at a seed rate of 250 kg per hectare. Standard agronomic practices were followed throughout the growing season. It is necessary to note that the experimental site was used for wheat and corn cultivation in the previous crop year. To control the weeds, herbicide Topic was applied at 1 litre per hectare, once on narrow leaf weeds, and simultaneously, herbicide Granestar was applied at 25 gram per hectare on wide leaf weeds. The protection operation for fighting pests and diseases was performed according to the recommendations of the region.

Evaluation traits

Quantitative parameters

During the growth period, after the removal of marginal effects in each site, traits were randomly measured according to the standard evaluation system. Thus, 10 plants were randomly selected from each experimental plot and their average was analyzed.

Data on agronomical traits such as spike length, number of tillers per plant, number of grains per plant, grain yield, and harvest index were recorded. Tillers per plant were reordered by counting the number of tillers per plant in each experimental plot. Grain yield in each experimental plot was determined at the physiologically matured stage and then converted into kg ha^{-1}.

Qualitative parameters

The dry digestion method was used for measuring the zinc and the iron in the plant samples. The dried plant samples were crushed and made into powder at 70℃ so that they would pass through a 20-mesh sieve (of 0.86 centimeter diameter). Moreover, in order to measure the protein content of the grain, the micro Kjeldahl method was used and nitrogen was measured, and by multiplying the amount of nitrogen by 5.7, protein content was calculated. The protein content per hectare was calculated from the product of the protein percentage multiplied by grain yield (Martre et al., 2003; Samonte et al., 2006). To determine the qualitative properties related to the iron and the zinc elements, the following instructions were applied (Dobermann, 2005; Fan et al., 2004).

Iron and zinc uptake by the grain was achieved by the element content in the grain multiplied by the grain yield. The iron and zinc uptake by straw (stem and leaf) was achieved by the element content in the straw (stem and leaf) multiplied by straw yield. The efficiency utilization of the elements was calculated from the ratio of grain weight to the amount of the absorbed element by the plant. This index was expressed in kilograms per kilogram. By determining the amount of iron and zinc uptake by grain and shoot, the harvest index was calculated through the amount of element absorbed by the grain to the total amount of absorbed element, which are expressed as percentages.

Statistical analysis

After normalization and the Kaiser-Meyer-Olkin (KMO) test, the data analyzed by the statistical analysis software (SAS) and the comparison of averages were calculated by least significant differences (LSD) tests at a 5% probability level.

Results

In order to evaluate the studied traits in the experiment, the obtained data were analyzed using the variance homogeneity test by the Bartlett method. The results showed that the traits were not significant in Bartlett's test. Therefore, data analysis was performed based on compound analysis.

Quantitative parameters

Data concerning quantitative parameters is presented in *Table 3*. The combined statistical analysis of the data revealed that all the quantitative parameters (spike length, number of tillers per hill, number of grains per plant, grain yield, and harvest index) were significantly statistically ($P \leq 0.01; 0.05$) affected by water acidity (pH) and iron (Fe) foliar application; furthermore, except for the harvest index, all the quantitative parameters were significant statistically ($P \leq 0.01$) on zinc (Zn) treatment and plant height, spike length, the number of tillers and grains per plant, and grain yield were significant at the 1% probability level under the effect of the year (*Table 3*). At double interaction of year and water acidity, spike length, and the number of tillers per plant were significant statistically at the 1% and the 5% probability level.

ns, * and **: non significant and significant in 5 % and 1 % probability level, respectively

Moreover, spike length, the number of tillers per plant, grain yield, and harvest index were significant at the 1% probability level under the interaction of water acidity and iron (Fe). Only the spike length was significant at the 5% probability level under the interaction of water acidity and the zinc fertilizer (*Table 3*). A mean comparison showed that the at the P×F interaction, the greatest spike length was obtained at a pH value = 5 for 2.5 and 5 g L^{-1} iron (7.14 and 7.45 cm, respectively). The lowest spike length (5.35 cm) was obtained at a pH value = 8.14 and iron control treatment (*Table 4*).

* P_1 and P_2 are pH of irrigation water including 8.14 and 5 respectively
F_1, F_2 and F_3 are iron fertilizer including 0, 2.5 and 5 g L^{-1} respectively

With attention to the interaction of water acidity and zinc fertilizer, it was found that the maximum spike length was produced at a pH value = 5 with 2.5 and 5 g L^{-1} zinc application. The minimum spike length had been observed at a pH value = 8.14 with control treatment and 2 g L^{-1} Zn usage (*Table 5*).

Table 5. *Double interaction of pH of water and zinc fertilizer on qualitative and quantitative parameters of wheat*

* P_1 and P_2 are pH of irrigation water including 8.14 and 5 respectively
Z_1, Z_2 and Z_3 are zinc fertilizer including 0, 2.5 and 5 g L^{-1} respectively

With regard to the mean comparison results, with 5 g L^{-1} zinc fertilizer application, the number of tillers per plant was increased compared to 0 and 2.5 g L^{-1} zinc application (*Table 6*). In terms of the double interaction of the year and the water acidity, it was found that the maximum number of tillers per plant (3.19 tillers) was obtained in the first year for a pH value = 5. The minimum number of tillers per plant (2.51 tillers) was obtained in the second year for a pH value = 8.14 (*Table 7*). Moreover, at the double interaction of water acidity and the iron (Fe) fertilizer, the most tillers per plant (3.32 tillers) was obtained for a pH value = 5, with 5 m L^{-1} iron application. The minimum tillers per plant (2.40 tillers) was produced at a pH value = 8.14 and a control treatment (*Table 4*). At the triple interaction of water acidity, and iron (Fe) and zinc (Zn) application, the highest number of grains per plant was observed for $P_2F_2Z_3$ (64.68 grains) and at a pH value = 5, with 5 g L^{-1} of iron consumption, and all three zinc fertilizer levels equaling 63.51, 65.37, and 67.56 grains, respectively (*Table 8*).

The mean comparison shows that with 5 g L^{-1} zinc foliar application, the grain yield was enhanced to 13.08 and 6.12% in comparison to 0 and 2.5 g L^{-1}, respectively. The main cause for increasing the grain yield in the 5 g L^{-1} zinc foliar application involved the enhancement of spike length, and the number of tillers and grains per plant in this treatment (*Table 6*). At the double interaction of water acidity and iron consumption, it was found that the most grain yield (6,018 kg ha^{-1}) was produced at a pH value = 5, with 5 g L^{-1} zinc foliar application. The least grain yield (3,371 kg ha^{-1}) was obtained at a pH value = 5 and control treatment (*Table 4*). Moreover, at water acidity and iron interaction, the highest harvest index was observed at both pH levels, with 5 g L^{-1} iron foliar application (43.12% and 43.73%, respectively). The least harvest index (31.89%) was calculated at pH value =5 and the control iron treatment (*Table 4*).

Qualitative parameters

The combined variance analysis of the qualitative parameters indicated that all qualitative parameters except the zinc harvest index showed a significant difference under the effect of water acidity (pH value) and iron (Fe) for foliar application in 1% and 5% probability levels, respectively (*Table 9*). Moreover, some qualitative parameters including grain protein content, protein yield, grain iron uptake, grain and straw zinc uptake, zinc utilization efficiency, and zinc harvest index had significant differences ($P \leq 0.01$) under the effect of zinc (Zn) foliar application. In addition, all the qualitative parameters, except iron harvest index, zinc utilization efficiency, and zinc harvest index, were significant at the 1% probability level on year effect (*Table 9*). At the double interaction of year and water acidity straw iron content, the iron utilization efficiency and the harvest index, and the straw zinc content and the zinc harvest index were statistically significant. Moreover, at year and iron double interaction, protein yield, grain iron uptake, and grain zinc uptake were significant statistically (*Table 9*). At the interaction of year and zinc foliar application, only the grain zinc uptake was significant statistically with a 1% probability level. In addition, at the double interaction of water acidity and iron fertilizer grain protein content, the protein yield, grain iron uptake, iron utilization efficiency, iron harvest index, grain zinc uptake, zinc utilization efficiency, and zinc harvest index were significant statistically at a 1% probability level (*Table 9*). At the double interaction of water acidity and zinc foliar application, it was found that the grain protein content, protein yield, and the grain zinc uptake were significant statistically. In iron and zinc double interaction, certain parameters, including iron harvest index, grain zinc uptake, zinc utilization efficiency, and zinc harvest index showed significant differences in the 1% and the 5% probability levels.

At the triple interactions of year, water acidity, and iron consumption, only the iron utilization efficiency demonstrated a significant difference of 5% in the probability level. Moreover, in the triple interaction of water acidity, iron, and zinc foliar application, it was found that the iron harvest index and the straw zinc content statistically revealed significant differences at 1% and 5% probability levels (*Table 9*).

At the double interaction of water acidity and the iron foliar application, the greatest grain protein content (11.57%) was observed at a pH value = 5, with a 5 g L^{-1} zinc foliar application. The least grain protein content (8.88, 8.81, and 8.90%) was observed at a pH value = 8.14 in the all the three zinc fertilizer levels (*Table 10*). Moreover, the double interaction of water acidity and zinc foliar application revealed that the maximum grain protein contents (11.06 and 11.50%) were obtained at a pH value = 5, with 2.5 and 5 g L^{-1} zinc foliar applications. The minimum grain protein content (8.49%) was observed at a pH value = 8.14 and control treatment (*Table 5*). At the double interaction of the year and the iron foliar application, the highest protein yield (629.69 kg ha^{-1}) was produced in the first year for 5 g L^{-1} iron consumption. The least protein yield (305.72 kg ha^{-1}) was obtained in the second year for control treatment (*Table 10*). Moreover, at the double interaction of water acidity and iron foliar application, the greatest protein yield (698.17 kg ha^{-1}) was produced for a pH value = 5 and 5 gL^{-1} iron consumption. The least protein yield (335.35 kg ha^{-1}) was observed at a pH value = 8.14 and control treatment (*Table 5*).

The mean comparison of the treatments showed that the grain iron uptake was increased in 5 g L^{-1} zinc foliar application compared to other levels (*Table 11*). At the double interaction of the year and the iron foliar application, the most grain iron uptake was obtained in the first year for 5 g L^{-1} iron consumption (323.45 kg ha^{-1}). The least grain iron uptake (105.11 kg ha^{-1}) was recorded in the second year for the control treatment (*Table 12*). In addition, at the double interaction of water acidity and iron foliar application, the highest grain iron uptake (378.87 kg ha^{-1}) was observed at a pH value = 5, with a 5 g L^{-1} iron foliar application, but the least grain iron uptake (335.35 kg ha^{-1}) was observed at a pH value = 8.14 and control treatment (*Table 5*).

** P_1 and P_2 are pH of irrigation water including 8.14 and 5 respectively*
F_1, F_2 and F_3 are iron fertilizer including 0, 2.5 and 5 g L^{-1} respectively

According to the double interaction of year and water acidity, the highest grain zinc uptake (159.12 kg ha^{-1}) was recorded in the first year with 5 g L^{-1} iron consumption, but the least grain zinc uptake (68.60 kg ha^{-1}) was obtained in the first year for control treatment (*Table 12*). At the double interaction of water acidity and iron consumption, the greatest grain zinc uptake (177.84 kg ha^{-1}) was recorded at pH value = 5, with 5 g L^{-1} iron usage, but the least grain zinc uptake was observed at pH value = 8.14 for the control treatment (*Table 10*). Moreover, at the double interaction of water acidity and the zinc foliar application, the highest grain zinc uptake (190.94 kg ha^{-1}) was calculated at pH value = 5, with 5 g L^{-1} zinc consumption; but the least grain zinc uptake was recorded at pH value = 8.14 for the control treatment (*Table 5*). In addition, at the double interaction of the iron and zinc foliar application, the maximum grain zinc uptake (208.23 kg ha^{-1}) was produced for 5 g L^{-1} iron and zinc consumption, but the least grain zinc uptake (32.16 kg ha^{-1}) was observed for the control treatment (*Table 13*). According to the double interaction of water acidity and the iron foliar application, the greatest zinc utilization efficiency was calculated at a pH value = 8.14 for all the three iron consumption levels equaling 37.76, 37.18, and 38.23 kg ka^{-1}, respectively. The least zinc utilization efficiency (31.13 kg kg^{-1}) was observed at pH value = 5 for the control treatment (*Table 10*). At the double interaction of iron and zinc foliar application, the maximum zinc utilization efficiency (47.11 kg kg^{-1}) was obtained for the iron control treatment with 5 g L^{-1} zinc consumption. The least zinc utilization efficiency (30.55 kg kg^{-1}) was obtained for 2.5 g L^{-1} iron usage with 5 g L^{-1} zinc consumption, and 5 g L^{-1} iron and zinc consumption (*Table 13*).

Discussion

Low soil reaction is associated with a number of adverse chemical and biological properties that cause problems for plant growth. Chemical pH-dependent changes limit the accessibility of essential elements and increase the availability of toxic metals, such as aluminum and manganese (Holier and Rutherglen, 2005). Zinc seems to increase plant height by increasing the CO_2 assimilation, increasing photosynthesis (Thalooth et al., 2006), and increasing the water use efficiency (Khan, 2004). Mohammad et al. (2000) reported that zinc and iron application with different methods increased grain yield in comparison to control, and using zinc by the spraying method, maximum grain yield, and zinc concentration were obtained in the grain; using the soil and the spraying method recorded the highest grain yield and grain iron content. The presence of a factor, such as acidity, which restricts access to nutrients in the soil, reduces the expected use of fertilizers. Under these conditions, the nutrient elements for plants can be provided by the use of a leaf (Altındişli et al., 2004). Foliar application is the spraying of nutrients on leaves and stems, and their absorption from these places (Kapoor et al., 2003). Leaf consumption can guarantee plant access to nutrients to achieve high yields. Ecologically, foliar fertilization is more acceptable because lower quantities of nutrients are provided for quick consumption by the plant (Stampar et al., 2008).

There is a negative interaction between iron intake and zinc concentration in the grain. When the amount of zinc absorbed by the soil is low, it is possible that the iron application intensifies the zinc deficiency. The absorption of elements such as iron, zinc, magnesium, phosphorus, and molybdenum depends on the acidity of the soil. In addition to the above elements, the nitrogen uptake by the root also depends on the acidity of the soil; thus nitrogen uptake in alkaline soils has a higher limitation than in acidic soils (Nyachiro and Briggs, 1994). Iran's irrigated soils have severe micronutrient deficiencies, especially zinc and iron, for reasons such as calcareous soils, un-carbonated irrigation water, low organic matter, and excessive consumption of phosphate fertilizers. Sadana et al. (2006) concluded that iron soil and foliar application increased the growth and the yield of wheat compared to control treatment, and the amount of iron in grains and straw increased. According to some researchers, zinc foliar application increases photosynthesis, promotes plant growth, improves nitrogen uptake, grain protein and grain yield, and zinc deficiency leads to poor grain formation (Thalooth et al., 2006). In other research for rice plant, the most zinc content in grain and straw were produced with 40 kg zinc per hectare (Yadi and Dastan, 2012). The reduction of wheat yield in alkaline acidity has been attributed to many factors. In addition, in alkaline acidity, the plant's access to nitrogen compounds is very low; reducing the amount of nitrogen utilized by soil is the main factor for reducing the grain yield. The acidity of alkali causes changes in the permeability of the membrane of the rooted cells and prevents the entry of elements such as iron and zinc into the plant (Nyachiro and Briggs, 1994).

Conclusion

The application of micronutrient fertilizers affected the yield and the absorption of iron and zinc on wheat and increased the net production. An increase in acidity leads to the precipitation of nutrients (reduction of solubility) and a decrease in the soil's ability to absorb the elements; this is why the plant consumes more energy and decreases the pH of the environment surrounding the root of the plant so that it would be able to

© 2018, ALÖKI Kft., Budapest, Hungary

absorb the necessary nutrients. Therefore, the energy that is consumed for growth and production under normal conditions is consumed for absorbing the necessary nutrients at higher acidities. On the other hand, a severe reduction of acidity is very harmful because as the solubility of the elements increase, the plant becomes more toxic, which is in itself a limiting factor and the plant copes with the oxidative stress by consuming energy. Therefore, this research should be conducted in the other region to determine the best finding for extensions.

Abstract. Water is known as a critical and rare source that humans and ecological systems depend on. With growing population and developing technologies in many countries, availability to this critical source has been decreased. This research was conducted in a split plot experiment in a randomized complete block design with 3 replications in Iran (the north of Iran, Astaneh-ye-Ashrafiyeh). The main treatments were irrigation with 40, 60, 80 and 100% water requirement using water balance and direct method and the second treatments were 0 and 30, 60 and 90 kg N ha^{-1}, and two bean cultivars were tested (local Dehsari and Cowpea). Seed yield in 2016 and 2017, in the case of irrigation with100% water requirement and 60 kg N ha^{-1} was higher in common bean cultivar than in Cowpea and yields were 3486 and 3646 kg ha^{-1}, respectively. The highest water use productivity in seed yield in 2016 and 2017 was in common bean cultivar, and in the case of irrigation with 100% water requirement and 60 kg N ha^{-1} fertilizer added, levels were 0.70 and 0.69 kg m^{-3}, respectively.
Keywords: *fertilizer, plant production, water requirements, water productivity, yield component*

Introduction

Agricultural sections, known as the largest consumers of water, create many challenges in producing foods with less consumed water. In recent years, competitions for getting more water sources among industry, agriculture and urban sections have increased, therefore, the optimum water consumption is a priority for the agricultural industry. Legumes, after cereals, are the second main food. The protein content in legumes is two or three times higher than in cereals and Iran is the second largest producer of legumes. Cowpeas are summer crops which grow in African tropical and subtropical regions (Jean-Martial et al., 2013). Cowpea is cultivated in north of Mexico and south-west of America and since they are resistant to high temperature, they have known as an important crop for hot regions (Jean-Martial et al., 2013; Singh, 2004; Hall et al., 2003; Clavel et al., 2005; Shardendu et al., 2011). Common bean contains 20-25% protein and 50-56% carbohydrate, and comparing to cereal and starch crops, it contains 2-3 and 10-20 times more protein, respectively (Carmona-Garcia et al., 2007). Water is a critical parameter which influences these crops significantly (Kotchoni and Bartels, 2003). Drought stress is known as one of the main reasons for crop loss which leads to 50% decrease in efficiency (Singh, 2007). Water shortage stress resulted in the

© 2018, ALÖKI Kft., Budapest, Hungary

decrease of growth of the crops and decreased the efficiency (Korir et al., 2006). About 60% of beans experienced alternative droughts and/or droughts for the end of the season (Beebe et al., 2008). The vegetative growth period of crops is an important and long period in crop cultivation (Baker and Rosenqvist, 2004). The decrease of this period in beans resulted in significant changes in growth and biological functions (Baker and Rosenqvist, 2004). Nitrogen is a critical element and is involved in producing the chlorophyll molecule that plays an important role in photosynthesis (Fageria and Santos, 2008). One-third of the world's most cultivated lands faces a shortage of water for agriculture, which is characterized by climate change and the increasing population will make this problem more serious in the future. Understanding the detrimental effects of drought on plant processes and mechanisms of drought tolerance in crop species, particularly those adapted to dry conditions will help to improve their agronomic performance by incorporating the superior traits into new species or cultivars (Clavel et al., 2005; Shardendu et al., 2011). Therefore, identification of plants resistant to dryness or dehydrated condition with proper performance and their resistance mechanisms is one of the most important solutions to combat drought stress. Due to limited water resources and low rainfall in the Country, the prospect is uncertain for agricultural production. According to forecasts, with the warming of the Earth's crust in the Future, the water requirement of plants will increase and the use of water resources will be very limited. Increasing competition for obtaining water and supplying water needs for growth of products should be done with regular irrigation to prevent irrigation from drought and flooding, and provide a basis for optimizing water use (Aujla et al., 2005).

Water productivity is defined as the ratio of dry matter production to water use (Anyia and Herzog, 2004). water productivity might not provide much information about the competitive or yield advantage of one particular species over another because improved water productivity may actually restrict growth. However, it is one trait that has been studied a great deal because it can give an idea of the variation amongst genotypes in ability where water is limited. Nitrogen plays a critical role in synthesis of proteins and nucleic acids and the shortage of nitrogen is easily seen in old leaves (Fageria and Santos, 2008). This research aims to evaluate the effect of nitrogen and water requirement on bean crops in the region of the study.

Materials and methods

This study was conducted in north of Iran (Astaneh-ye-Ashrafiyeh) located in latitude 37 and 29 min and longitude 49 and 95 53 min, 3 m below sea level on average in 2016 and 2017. In 2016 and 2017 rainfall was 65.7 and 76 mm, respectively. The meteorology and soil physicochemical traits are shown in *Table 1* and *2*. This research was implemented in split plot and random complete block in Astaneh-ye-Ashrafiyeh and all experiments were repeated 3 times. The main variables were irrigation with 40, 60, 80 and 100% water requirement, 0, 30, 60 and 90 kg nitrogen added per hectare and two bean varieties were tested (local Dehsari and Cowpea). In a plot, two rows were omitted and 12 crops were chosen randomly to evaluate the seed yield. The beans were removed and dried in oven with 70 °C for 48 h. After drying, the samples were weighed with precision of 0.01 and converted to kg ha^{-1}. Cowpea was harvested in several turns and the average of 6 turns was evaluated. The drainage of soil moisture was considered as irrigation variable and the water requirement was considered to be 100% of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

irrigation. Other variables were calculated based on irrigation value. In order to achieve 100% irrigation, the soil moisture near crops root was calculated using *Equation 1*.

$$d_n = (\theta_{Fc} - \theta_i)\ \rho_b D_r \quad \text{(Eq.1)}$$

The soil moisture to height of root showed the farm capacity. The duration of irrigation was calculated based on receiving moisture by soil. The θ_{Fc} is moisture percent of cultivation (%w), θ_i is soil moisture (%w), ρ_b is density (gr cm^{-3}) and D_r is effective root height (cm). The efficiency of water was determined by dividing seed yield on consuming water (Passioura, 2006). The irrigation and consumed water in each sample during growing phase is shown in *Table 3*.

Water productivity (WP; *Eq. 2*) is the seed yield (kg) per water use (m^3):

$$WP\ (kg\ m^{-3}) = \frac{\text{seed yield } (kg)}{\text{water use } (m^3)} \quad \text{(Eq.2)}$$

Variance analysis and average comparison were conducted by MSTATC software (Duncan test 5%) and all figures were drawn in Excel software.

Results

Seed yield

The relations between bean crops and nitrogen fertilizer in seed yield in 2016 and 2017 were significant in level 5% and other changes were observed in level 1% (*Tables 4* and *5*). The highest seed yield in two bean species in 100% water requirements and in 2016 and 2017, were 1700 and 1776 kg ha^{-1} (*Fig. 1*). The highest seed yield in 30 and 60 kg N ha^{-1} fertilizer in 2016 was 1076 and 1173 kg ha^{-1} (*Fig. 2*). The highest seed yield in 30 and 60 kg N ha^{-1} fertilizers in 2017 were 1107 and 1209 kg ha^{-1} (*Fig. 3*). The interaction between bean crops and fertilizer in normal beans and in 60 kg N ha^{-1} fertilizer were 2400 and 2512 kg ha^{-1} (*Fig. 4*). The highest seed yield in 2016 and 2017 in 100% water requirements and 60 kg N ha^{-1} fertilizers were 2169 and 2253 kg ha^{-1} (*Fig. 5*). The highest seed yield in 2016 and 2017 in 100% water requirements and 60 kg N ha^{-1} fertilizers for common bean were 3486 and 3646 kg ha^{-1} (*Table 6*).

Number of pods per plant

The effect of varieties was not significant during two years but in other references it was 1% (*Table 4*). The highest Number of pods per plant varieties in 100% water requirement in 2016 and 2017 were 31 and 32 (*Fig. 11*). The highest number of pods in 2016 and 2017, in 100% water requirement for Cowpea were 43 and 45 (*Fig. 12*). The highest number of pods in 2016 and 2017, in 30 kg N ha^{-1} were 27 and 26 (*Fig. 13*). The highest number of pods in reaction of varieties and Nitrogen fertilizer in 2016 and 2017 were 42 and 41 in Cowpea and in 30 kg N ha^{-1} (*Fig. 14*). The highest number of pods in 2016, in 60% and 80% water requirement and 30 and 60 kg N ha^{-1} were 36 and 35 (*Fig. 15*). The highest number of pods in 2017, in 60% and 80% water requirement and 30 and 60 kg N ha^{-1} in Cowpea were 37 and 36 (*Fig. 15*).

Plant height

Plant height was significant during 2 years in 5% and other changes were significant in 1% (*Table 5*). The maximum height of Cowpea plant in 2016 and 2017 were 95.8 and 94 cm (*Fig. 16*). The maximum Plant height in bean varieties in 100% water requirement were 87 and 88.9 cm in 2016 and 2017 (*Fig. 17*). Maximum plant height in bean varieties in 100% water requirement and Cowpea varieties were 104.6 and 110.6 cm in 2016 and 2017 (*Fig. 18*). The maximum plant height in 2016 in 30 and 60 kg N ha^{-1} was 74.5 cm (*Fig. 19*). The maximum plant height in 2016 in 30 and 60 kg N ha^{-1} fertilizer were 72 and 72.5 cm (*Fig. 19*). Maximum Plant height in relations of varieties and Nitrogen fertilizer during 2 years in 30 kg N ha^{-1} were 101.5 and 100.1 cm (*Fig. 20*). Maximum plant height in 2016 in 100% water requirement and in 30 and 60 kg N ha^{-1} were 98.2 and 95.7 cm (*Fig. 21*). Maximum plant height in 2017 in 100% water requirement and in 30 and 60 kg N ha^{-1} fertilizer were 100.9 and 99 cm (*Fig. 21*). Maximum plant height in 2016 and 2017 in 100% water requirement and 30 kg N ha^{-1} fertilizer were 116.3 and 122.2 cm for Cowpea (*Table 5*).

Water productivity (WP)

The Water productivity on seed yield regarding to bean varieties and interaction of varieties and fertilizer in 2016 and 2017 were not significant. However, the other sources were significant in 1% (*Table 5*). The highest efficiency of water consumption in 2016 and 2017 in 100% water requirements were 0.36 and 0.34 kg m^{-3} (*Fig. 22*). The highest efficiency of water consumption in 2016 and 2017 for normal beans in 100% water requirement were 0.48 and 0.47 kg m^{-3} (*Fig. 23*). The highest efficiency of water consumption in 2016 and 2017 in 60 kg N ha^{-1} fertilizer were 0.31 and 0.29 kg m^{-3} (*Fig. 24*). The highest efficiency of water consumption in 2016 and 2017 was observed in 30 and 60 kg N ha^{-1} fertilizer and 100% water requirement (*Fig. 25*). The highest Water productivity in 2016 and 2017 was observed in common bean, 100% water requirement and 60 kg N ha^{-1} fertilizer (*Table 6*).

Discussion

Beans are sensitive to soil condition and drought damage and their water consumption increases with age. Irrigation is very important in water stress and showed direct effect on yield (Korir et al., 2006). Increase amount of Nitrogen to a determined level resulted in increase of yield (Singh, 2007). The results showed that moisture stress resulted in decrease of seed weight. Nitrogen influenced all elements of seeds such as number and weight. Shortage of Nitrogen in plants resulted in decrease of efficiency (Lawlor, 2001). According to Marschner (1995), high amount of Nitrogen in crops made them more sensitive to diseases.

Beans were sensitive to water shortage before and during flowering stage. In this step, shortage of water prevented the evolution of inflorescence and decreased the number of young pods and seeds (Singh, 2007; Lizana et al., 2006). High level of Nitrogen had no effect on number of pods. Authors reported the loss of legume yield in drought related to decrease of pods in crops (Singh, 2007). Long term water stress decreases the crop height. Availability of nitrogen influenced cell division and enlarged leaves (Singh, 2007). Water shortage is the most limiting factor in bean and Cowpea production, and improving agricultural Water productivity is essential for the increased leguminous demand. Conventional irrigation cannot be sustained in arid and semi-arid areas because of the rapid depletion of water resources. It is believed that conventional irrigation is a luxury use of water and can be reduced without much effect on economic yield. Methods that may cut down irrigation are of considerable interest and should be explored. Physiological water-saving irrigation strategies especially temporal and spatial deficit irrigation have great potential to practice in Leguminous production in arid and semiarid areas. It is well established that plant Seed production depends on the amount of water used for growth as well as on water productivity. The estimation of water productivity suggests that the amount of seed produced is equal to the water used during growth multiplied by Water productivity, which thus implies that the amount of Seed increases with increasing water productivity for constant water use. Therefore,

© 2018, ALÖKI Kft., Budapest, Hungary

Water productivity would be of particular interest in situations where growth is affected as a result of limiting water availability. The increased water productivity of bean and cowpea under water stress is attributed to seed production being reduced less by drought than water use.

Conclusion

The results showed that water shortage has negative influence on crop yield. The highest seed yield required 100% water and the lowest value was 40% in two varieties. The highest loss of seed yield in drought showed that supplying enough water is necessary to ensure photosynthetic elements to seeds by producing leaves and green coverage. The efficiency of water in common bean was more proper than in Cowpea. Finally based on results, it is suggested that normal beans are in priority of cultivation in studied region.

(Received 29th Dec 2017; accepted 1st May 2018)

Abstract. In this study, the existing drip irrigation systems of 20 cherry (*Prunus avium* L.) orchards in Isparta-Uluborlu (Turkey) region where cherry production is done intensively were evaluated with selected by purposive sampling method; were examined in terms of design and operation; problems related to the subject were determined. For this reason, drip and under tree micro sprinkler irrigation system was re-projected for each enterprise, elements of both irrigation systems compared with the present applications, and suggestions for both irrigation systems and irrigation scheduling are developed. As a result, it has been found that the system elements generally had not been designed properly, and the system layouts and operations were insufficient in all of the existing drip irrigation systems considered. Suggestions for both irrigation systems and irrigation scheduling are developed.
Keywords: *cherry orchard, Prunus avium L., drip irrigation, under tree micro sprinkler irrigation, irrigation scheduling*

Introduction

Almost all new cherry orchards established in Turkey for export are established by the 0900 Agricultural variety of saplings. In general, the harvest of the export grade of 0900 Agricultural variety begins in the first week of May in Izmir province the early season and ends in the last days of July in Konya-Hadim and Nigde-Ulukisla districts as the late season (Taner, 2001). Parallel to the developments in cherry exports, cherry production, in many cities begun to increase, in recent years; though leading provinces in cherry production are Izmir, Manisa, Afyon, Bursa, Konya, Amasya, Isparta, and Denizli in Turkey (*Table 1;* Anonymous, 2016a). Denizli and Izmir are early; other provinces are mid-season cherry production regions.

Isparta province is an important cherry production region for export with high-quality mid-season production. It is in the 6th rank in mid-season production regions in terms of yield. In 2016, cherry production was 55657 tons, the total number of trees was 1197822, and average yield per tree was 46 kg. The major cherry producing areas are the districts of Senirkent and Uluborlu (*Table 2;* Anonymous, 2016b). Fresh cherries are the leading agricultural product that provides export income for the Isparta province. 60% of agricultural products in 2007 were provided by cherries. The value of cherry exports was $5.7 million in 2005, $7.9 million in 2006, and amounted to $10.14 million in 2007 (Anonymous, 2009a).

It is expected that the climate changes expected to occur as a result of global warming will have adverse effects on water resources as well as agricultural production. Depending on the expected changes in climate, such as temperature, precipitation, relative humidity and wind, the water consumption of the plant, which is important in terms of irrigation, and the feeding of the groundwater also change, and those affect the water resources negatively (Anonymous, 1995). In addition to the problems of climate change and drought that may be experienced in relation to this, rapid population

increase, increase in demand for water resources, the tendency of water usage to change gradually according to sectors, decrease in the water quality, and so on increase the importance of the utilization of water resources. According to the results of the assessment made by the World Meteorological Organization (WMO) among 87 member countries, Turkey is among the 74 countries affected by drought (WMO, 1992).

It is possible to predict the pressure over water resources occurred by the impacts of factors such as current growth rate and change of water consumption habits. Therefore, it is necessary to use water resources rationally to leave for healthy and sufficient water to the future generations of Turkey. This means the utilization of water should be planned and in the most efficient way.

In Turkey, both the consciousness and education levels of producers and excessive irregularity of irrigation studies and extreme and faulty water use due to the problems in transferring the results of those studies to the producers have negative effects on soil, environment, plants and water resources in particular. It was found in a study conducted in Sanlıurfa-Harran irrigation that about 5 to 7 times of the needed water was supplied to irrigation and that the groundwater levels were higher than 150 cm, which is considered as the threshold of danger (Tekinel et al., 2001).

Turkey is the first sweet cherry producer cherry production with 494000 tons of sweet cherry a year (Anonymous, 2009b). Isparta-Uluborlu region has an important place in our country in terms of production quantity and product quality. In recent years cherry producers have started to prefer drip irrigation instead of surface irrigation methods. However, these orchards, which are established on the basis of traditional farming, are experiencing problems in designing and operating drip irrigation systems which are subsequently constructed.

In studies conducted to monitor and evaluate the existing drip irrigation systems. It was observed that farmers had generally preferred the drip irrigation system with low initial capital cost, thus planning, layout and operation of a system had been unsuitable and water distribution had not been uniform required. It was also found that drippers had rapidly clogged due to inconvenient filtration and poor water quality (Pitchford, 1979; Fry, 1985). In a few research to evaluate some drip irrigation systems in Turkey (Turkey), the system elements had not been designed properly, the filtration of irrigation water to prevent emitter clogging had not been supplied by installing an adequate control head, and the system layouts and operations were insufficient in all drip irrigation systems considered nine farms in the Antalya region (Yildirim and Orta, 1993), and it also found that drip irrigation systems were not projected as suitable according to project criteria, sufficient control unity was not established, excessive irrigation water was applied and planning and managing of the systems were not done as suitable with regard to current conditions in Sultanhisar and Eskisehir region (Ayran, 2009; Harman, 2013).

In this study, the existing drip irrigation systems of 20 cherry (*Prunus avium* L.) orchards in Isparta-Uluborlu (Turkey) region where cherry production is done intensively were evaluated with selected by purposive sampling method; were examined in terms of design and operation; problems related to the subject were determined. For this reason, drip and under tree micro sprinkler irrigation system was re-projected for each enterprise. Elements of both irrigation systems compared with the present applications. And suggestions for both irrigation systems and irrigation scheduling are developed.

Materials and methods

The research was carried out in 20 cherry (*Prunus avium* L.) orchards in Isparta-Uluborlu (Turkey) region (*Fig. 1*), selected by purposive sampling method, among the enterprises where drip irrigation method is applied.

Figure 1. *The placement of Isparta and Uluborlu in Turkey*

During the research, a survey study was conducted primarily to determine the existing irrigation application skills and levels of the selected producers. The characteristics of the existing irrigation systems in all enterprises (dripper flow and distance, lateral pipe diameter and length, number of lateral pipes running in a row and to be supplied water at the same time, manifold pipe diameter and length, main pipe diameter and length, pipe materials) and control unit factors (filter system, gravel filters, hydro cyclone, sieve-disc filter, pressure regulator, fertilizer tank volume, manometer, valve etc.), were determined according to the measurements and observations conducted.

However, for all enterprises, the data that is essential for project design of the drip and micro sprinkler irrigation method has been obtained. For this purpose, some important characteristics of the enterprise's soil (texture class, field capacity, wilting point and volume weights) for irrigation was determined according to Demiralay (1993) and Tuzuner (1990). Deteriorated and intact soil samples were taken from different layers (0-30, 30-60, 60-90 and 90-120 cm) from the test site. The infiltration rates of the soil of the test area were determined according to the principles given by Gungor and Yildirim (1989) with double cylinder infiltrometer measurements. The dimensions of the enterprise areas were measured by steel tape meters and slopes with the aid of a leveling instrument. The flow rate of the water source was measured by the volume-time method and the sufficiency for cultivation was examined.

In order to determine the irrigation water needs of the cherry plants cultivated in the examined enterprises, firstly the values of the plant water consumption are determined. Climate data of the region where the enterprises are located were taken from Isparta Meteorology Directorate and the values of plant water consumption were determined by the Penman-Monteith method for the process in plant vegetation period. For this, ten-day-long average values of the climate data between 1990 and 2010 were taken into account (*Table 3;* Anonymous, 2011), the reference plant water consumption was calculated, and actual plant water consumption values are obtained by correcting the obtained values with the plant coefficient. Plant coefficients were calculated according to a previous study (Evans et al., 1996).

For each enterprise, a re-drip and under micro sprinkler irrigation system has been designed. In determining the engineering characteristics of the system, the principles given in Yildirim (2008) were utilized. The equations used for the under tree micro sprinkler irrigation system's project design are summarized below.

Wetted area (P)

$$P = \frac{\alpha^{\circ}}{360^{\circ}} \frac{\pi D^2}{4 S_a S_s} \quad \text{(Eq.1)}$$

Heading wetting diameter (D)

$$D = \sqrt{\frac{360\ 4\ S_a S_s\ 0{,}30}{\alpha \pi}} \quad \text{for P = 0.30} \quad \text{(Eq.2)}$$

$$D = \sqrt{\frac{360\ 4\ S_a S_s\ 0{,}50}{\alpha \pi}} \quad \text{for P = 0.50} \quad \text{(Eq.3)}$$

Precipitating rate (Pr_y)

$$Pr_y = \frac{360^{\circ}}{\alpha} \frac{4\ q}{\pi D^2} \quad \text{(Eq.4)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_31313143
© 2018, ALÖKI Kft., Budapest, Hungary

Evapotranspiration for micro irrigation methods (T)

$$T = ET \frac{Ps}{95} \quad \text{(Eq.5)}$$

Amount of maximum net irrigation water ($d_n max$)

$$d_n max = d_k \; Ry \; D \; \frac{p}{100} \quad \text{(Eq.6)}$$

Amount of total irrigation water (d_t)

$$d_t = \frac{d_n}{E_a} \quad \text{(Eq.7)}$$

Maximum irrigation interval (SA_{max})

$$SA_{max} = \frac{dn_{max}}{T} \quad \text{(Eq.8)}$$

Amount of net irrigation water (d_n)

$$d_n = T\,(SA) \quad \text{(Eq.9)}$$

Irrigation duration (Ta)

$$T_a = \frac{1000\; d_t}{q\; N_d} \quad \text{(Eq.10)}$$

Maximum number of operating units (N_{max})

$$N_{max} = \left(\frac{T_g}{T_a}\right)(SA) \quad \text{(Eq.11)}$$

Reference evapotranspiration for Penman-Monteith method

$$ET_0 = \delta/(\delta + \gamma^*)(Rn - G)\; \frac{1}{\lambda} + \gamma/(\delta + \gamma)u^2 \left(\frac{900}{t + 275}\right)(e_a - e_d) \quad \text{(Eq.12)}$$

where P is wetted area (%), D is head wetting diameter (m), S_a is tree spacing (m), S_s is row spacing (m), Pr_y is precipitating rate (mm h^{-1}), α is wetting angle, q is head flow (l h^{-1}), T is evapotranspiration for micro sprinkler irrigation method (mm day^{-1}), ET is evapotranspiration (mm day^{-1}), Ps is ratio of the area shaded by the plant to the total area (%), $d_n max$ is amount of maximum net irrigation water (mm), d_k is available water holding capacity (mm/m), Ry is allowable part of d_k, D is watering soil depth (mm), Ea is water application efficiency (%), SA_{max} is maximum water application interval (days), SA is irrigation interval (days), T_a is irrigation duration (h), d_t is amount of total

irrigation water (mm), N_d is number of head in a decare area (pieces da^{-1}), N_{max} is maximum number of operating units, T_g is daily irrigation duration (h day^{-1}), ET_o is reference evapotranspiration (mm day^{-1}), δ is slope of the vapor pressure curve (kPa $°C^{-1}$), γ* is modified psychometric constant (kPa/°C), Rn is net radiation on the plant surface (MJ m^{-2} day^{-1}), G is heat flow in the ground (MJ m^{-2} day^{-1}), λ is evaporation latent heat (MJ /kg^{-1}), u^2 is equivalent of wind speed at 2 m height (m s^{-1}), t is average temperature (°C), e_a is saturated vapor pressure at average air temperature (kPa) and e_d is actual vapor pressure at average air temperature (kPa) in *Equations 1-12*.

Results and discussion

The average values of soil texture, field capacity, wilting point, volume weight and available water holding capacity of the soil samples taken from the enterprises obtained from the physical analyzes and the values of infiltration rate measured by the double cylinder infiltrometer are given in *Table 4*. The soil texture class was generally clayey, loamy and sandy-loamy and the infiltration rate values of the enterprise's soil ranged from 6.5 mm/h to 18.1 mm/h.

Table 4. *Some physical properties of the enterprise's soil*

As can be seen from *Table 5*, the enterprises participated in the research have a size ranging from 0.23 to 4.8 ha. Eleven of the enterprises (55%) are small (<1.0 ha) family businesses. Operation flows in almost all of the enterprises are sufficient to allow the irrigation systems work efficiently.

It has been determined that the diameters of the main pipes used in the twelve enterprises (60%) in the research (1, 2, 7, 8, 9, 10, 13, 14, 15, 16, 18 and 19) are oversized. This situation increases the initial installation costs of the systems. In addition, in three enterprises (15%) (3, 5 and 11) the employed main pipe diameters were less than the required value. Side pipe diameters are larger than the required values in twelve enterprises (60%) (1, 2, 7, 8, 12, 13, 15, 16, 17, 18 and 20) and smaller in seven enterprises (35%).

It was stated that if the wetted area percentage (p) is less than 30%, in the case of using two laterals for each tree row in the irrigation of the fruit trees according to the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_31313143
© 2018, ALÖKI Kft., Budapest, Hungary

drafting criteria of the drip irrigation system project, a micro-sprinkler system for this area will be more suitable (Anonymous, 2011). Seven of the farms (35%) surveyed in the research had two lateral laid along each plant row, but the wetted areas did not reach the desired level in any of them. In the other thirteen enterprises (65%), irrigation is carried out by 4-5 laterals laid along each tree row. In this case, the cost of the first installation of the irrigation system increases, as well as problems in terms of management occurs. However, in the nineteenth of the enterprises (95%) (except for the operation of 15) the lateral pipe diameters are in required ranges.

Besides, there is no problem in the operation of the irrigation system except for the 3rd enterprise. However, there is a problem in the operation of the irrigation system in the 3rd enterprise. Sufficient amount of irrigation water in sufficient time to apply the appropriate irrigation program to the enterprises located in the area where this enterprise is also located, cannot be supplied by the legal entity with the duty of operating the water mains. The infrastructure of the irrigation system has not been set up properly to provide enough water for agricultural land. It is not believed that the dispute between the company, which established the irrigation system that is located here, and the legal entity of the village can be resolved by the courts, either.

In the examined cherry orchards, the plant row spacing ranges from 5 to 8 m. Dripper spacing ranges from 0.2 to 0.5 m between the laterals used in existing irrigation systems. Therefore, 4-5 laterals in each plant row should be laid in order to obtain a sufficient level of wetting in the root area of the plant. a sufficient wetting zone in the plant root area cannot be established in 50% of the enterprises surveyed. The irrigation interval is longer than necessary for all enterprises except the 5th and 20th (90%). In other words, irrigation practices are not done in the form required by the drip irrigation. As is known, the plant root area is kept moist at the appropriate level by giving a little water at short intervals by drip irrigation method. In addition to this, although the irrigation duration is favorable in four enterprises (20%) (1, 4, 12 and 13), more irrigation periods are being implemented in ten enterprises (50%) (2, 3, 6, 7, 8, 14, 15, 17, 19 and 20), which in turn, causes excess irrigation water to be used in the mentioned enterprises. In the other six enterprises (30%) (5, 9, 10, 11, 16 and 18), less irrigation water is given to the plants because of the less irrigation time applied.

Similar to this research findings, in a few research to evaluate some drip irrigation systems in Turkey (Turkey), the system elements had not been designed properly according to project criteria (Ayran, 2009; Harman, 2013), the filtration of irrigation water to prevent emitter clogging had not been supplied by installing an adequate control head, and the system layouts and operations were insufficient in all considered drip irrigation systems (Yildirim and Orta, 1993).

While *Table 6* gives information on irrigation systems that are re-projected, considering the characteristics of soil, plant and water resources for each enterprise examined whereas the recommended irrigation scheduling at the meetings held with the producer is summarized in *Table 7*. Moreover, the hypothetical irrigation scheduling to be applied if the irrigation was continued with the existing irrigation system in the enterprises is given in *Table 8*.

It was suggested that in the pressurized system; the main pipeline should be constructed from PVC pipes and the manifold pipelines from PE pipes while the T pipelines should be installed as buried in the ground (Kekec, 2006; Yilmaz, 2011). And it was concluded that it would be more appropriate to place the control unit at a single point and at the start of the main pipeline for easier operation in micro irrigation

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_31313143
© 2018, ALÖKI Kft., Budapest, Hungary

systems and it would be more appropriate to place the required sand separator and sand-gravel filter tank at the beginning of the water distribution network in the case of collective micro-irrigation systems. Also, the control unit elements in individual irrigation systems in each operation should be formed of the fertilizer tank, sieve filter, and pressure regulator, if necessary (Yildirim, 2008). In the project of the reconstructed irrigation system for the surveyed enterprises, the main and manifold pipelines were designed according to the principles proposed by Kekec (2006) and Yilmaz (2011) whereas mass irrigation system and selected control unit elements (except pressure regulator) for individual gardens were made according to the principles recommended by Yildirim (2008). The possibility of applying drip irrigation method for each enterprise unit in the survey was examined by taking the principles given in Yildirim (2008) into account. Since the plant and soil characteristics of the enterprises do not allow the installation of the drip irrigation system by laying two laterals along each plant row, it is decided that the more suitable irrigation method for the operators is under tree micro-sprinkler irrigation and the proposed irrigation system is designed accordingly.

Conclusion

As a result, if it is desired to receive the expected benefits and an increase in the irrigation application efficiency from irrigation systems in the enterprise; the importance of assigning the design and construction of the drip irrigation systems, which require knowledge and experience, to professionals, and to firms with the required expertise has been stated.

During the design of the irrigation systems projects, the soil characteristics of the enterprise (texture, field capacity, wilting point, volume weight, available water holding capacity texture, infiltration rate etc); plant characteristics (characteristics of rootstocks and root systems used, planting distances, development and yield of trees, etc.), and characteristics of water resources (flow, quality etc) should be taken into account; designing the project for each enterprise must be done individually, and specific to the enterprise.

After the irrigation system in the enterprises has been designed and installed in accordance with the criteria mentioned above; training of the operators on the operation of the irrigation system to by experts, and the necessity to apply the appropriate irrigation program considering the climate values of the regions where the enterprises are located, should be provided.

(Received 13th Jan 2018; accepted 26th Mar 2018)

Abstract. Zinc oxide nanoparticles (ZnO-NPs) can potentially cause adverse health effects because they are highly soluble and widely used. We evaluated the effect of ZnO-NPs in rat lung. ZnO-NPs were administered via intratracheal instillation to Sprague Dawley rats at three different dosages (1, 5, and 10 mg/kg body weight). Macrophage numbers, total cell count, and total protein concentrations in bronchoalveolar lavage fluid (BALF) highly increased at day 1 in a dose-dependent manner relative to those in the control. Macrophage numbers and total protein concentrations were still elevated at day 14 relative to baseline, whereas total cell number continued to increase. These results indicate that inflammation had not fully resolved by day 14 in rat lungs. Furthermore, a significant increase in IL-6 (but not TNF-α) was observed in 5 and 10 mg/kg dose groups at day 1, which was likely caused by a ZnO-NP-treatment-induced increase in polymorphonuclear leukocytes. Histological examination indicated that multifocal acute inflammation occurred in the ZnO-NP-treated groups and progressed to chronic inflammation by day 14. A partial recovery of lung injury was observed within 14 days after exposure. In conclusion, the results of this study were consistent with those of previous sub-chronic exposure studies.

Introduction

Nanotechnology, as defined by the International Standards Organization (ISO), is a technology incorporating materials which must be less than 100 nm in size in at least one axis. As it is cutting edge technology, many industries have striven to innovate in the nanotechnology field in order to overcome physical limitations and improve economic efficiency (Mousavi and Rezaei, 2011, Wetzel et al., 2003). Therefore, nanotechnology has been widely applied in medicines, electronics, and fabrics, and has rapidly spread in consumer products, including cosmetics and personal care goods (McKiernan et al., 2013, Sawhney et al., 2008, Kaur and Agrawal, 2007). Given this, the safety of nanoparticle products must been properly assessed (Nohynek et al., 2010). Metal nanoparticles such as silver, titanium, zinc, and aluminum are widely used. For

© 2018, ALÖKI Kft., Budapest, Hungary

example, zinc nanoparticles (Zn-NPs) and titanium nanoparticles (Ti-NPs) are currently used in sunscreen cosmetics for the prevention of ultraviolet (UV) radiation-induced dermal diseases, including carcinoma and burns (Monteiro-Riviere et al., 2011, Smijs and Pavel, 2011, Nohynek and Dufour, 2012). However, previous studies have shown that metal nanoparticles induced DNA damage and oxidative stress in keratinocytes (Shukla et al., 2011), hepatoma cells (Kim et al., 2009) and lung epithelial cells (Limbach et al., 2007).

Zinc is an essential mineral with important physiological roles in the human body, and many diseases such as diarrhea (Hambidge, 2000), anorexia (Hambidge et al., 1972), and pneumonia (Bhutta et al., 1999) have been associated with zinc deficiency. It has been reported that zinc oxide nanoparticles (ZnO-NPs) are distinct from other metal oxide NPs as they have high solubility (Zhang et al., 2012). The increased production and use of ZnO-NPs enhances the probability of exposure, causing elevated concerns regarding their potential for unintended adverse health effects. Due to their extremely small size, NPs have a very high probability of cellular uptake and interactions with biological molecules and tissues. Indeed, exposure to NPs is not only providing advantageous opportunities, but also potential risks (Zhang et al., 2014).

Therefore, it is imperative to characterize the environmental health and safety aspects of exposure to ZnO-NPs. However, research investigating the toxicity of ZnO-NPs is far behind nanotechnology advances. In vivo results indicate ZnO-NP exposure via inhalation poses the most important hazard. However, risk assessments, such as exposure assessments and dose-response relationships of ZnO-NP exposure, are relatively scarce. In a previous study, a single intratracheal instillation of rats with 50-70 nm ZnO-NPs and 1000 nm ZnO microparticles (1 and 5 mg/kg Body Weight (BW) respectively) resulted in potent inflammation (Sayes et al., 2007).

Although studies on Zn nanoparticles have been conducted for several decades (Fosmire, 1990, Xia et al., 2008, Buerki-Thurnherr et al., 2013), information about the effects of ZnO-NPs exposure in the rat lung and its recovery have not been reported in detail. Therefore, the objective of this study was to evaluate the recovery at 14 days from acute lung injury induced by intratracheal instillation of ZnO-NPs in 3 different doses (1, 5, and 10 mg/kg BW). We performed intratracheal instillations of ZnO-NPs in Sprague-Dawley rats, and the rats were autopsied at 1 or 14 days after installation. Inflammation responses, Zn burden, and histopathological observations were examined in the collected rat lungs. This study was carried out to examine recovery after intratracheal instillation of ZnO-NPs in the rat lung.

Materials and Methods

Preparation of Zn-NPs

ZnO-NPs used in this study were purchased from Sigma-Aldrich (Sigma-Aldrich, St Louis, MO, USA). ZnO-NPs were dispersed in sterile saline and prepared via 10 min sonication before starting the experiment. Particle size was measured by transmission electron microscopy (TEM). To investigate the state of dispersion of ZnO-NPs when placed into saline as vehicles, samples were analyzed by Dynamic light scattering (DLS).

Animals and Animal Experimental Design

Pathogen-free male Sprague-Dawley (SD) rats aged 7 weeks were purchased from Orient Bio Inc (Seongnam, Korea). Animals were acclimatized for at least 1 week prior to starting the study. Rats were randomized into 4 groups (n = 10 individuals per group) with a vehicle control group (treated with sterile saline). The doses for intratracheal instillation were selected based on a previous study by Warheit et al (Warheit et al., 2009). The treatment procedures for each group were as follows: animals were exposed to 1 (low exposure group), 5 (middle exposure group), or 10 mg/kg body weight (high exposure group) doses of ZnO-NPs by intratracheal instillation. The control group was exposed to saline. Rats were sacrificed at 1 or 14 days after instillation. All animal experiments were performed according to the Guidelines for Care and Use of the National Institute of Environmental Research.

Acute Pulmonary Analysis

To investigate acute lung injury, bronchoalveolar lavage fluid (BALF) was obtained by lavaging the lungs five separate times with 3 ml of calcium- and magnesium-free phosphate buffer solution (PBS, pH 7.4) with the rat deeply anesthetized by isoflurane. The samples were centrifuged at 1,500 rpm for 10 min. The cell-free supernatant of the first lavage was kept separate from other samples for biochemical analysis. The recovered cells from all lavages were resuspended in PBS. The total number of cells (TC) in the BALF were counted with a Vi-Cell ® XR analyzer (Beckman Coulter, Brea, CA, USA), and cell differential tests were performed using cytospin preparations (Shandon, Pittsburgh, PA, USA) stained with Diff-Quick staining solution (Fisher Scientific, Swedesboro, NJ, USA). BALF cells (300/rat) were differentially counted as polymorphonuclear leukocytes (PMN) using light microscopy. The total protein (TP) in the BALF supernatant was quantified using a BCA protein assay kit (iNtRON Biotechnology, Seoul, Korea), and the activity of lactate acid dehydrogenase (LDH) in the BALF was measured by using a QuantiChrom Lactate Dehydrogenase Kit (BioAssay Systems, Hayward, CA, USA). The levels of tumor necrosis factor-alpha (TNF-α) and interleukin-6 (IL-6) in the BALF were estimated by commercially available enzyme linked immunosorbent assay (ELISA) kits (R&D Systems, Minneapolis, MN, USA), which were performed based on the manufacturer's instructions.

Zinc Burden in Lungs

Lungs were collected under anesthesia and frozen at -20°C overnight. Then, the samples were weighed, and the zinc burdens in the lungs were quantified with inductively coupled plasma mass spectrometry (ICP-MS, Varian 820-MS, Australia) after microwave-assisted digestion of the samples with HNO_3 using a microwave digestion system.

Histopathological Examination

For histopathological analysis, lungs were collected and fixed in 10% neutral buffered formalin. Then, the tissues were embedded in paraffin, sectioned (3-5 μm in thickness), and stained with hematoxilin and eosin (H&E). Stained sections were examined by two toxicological pathologists. If there was a discrepancy in diagnosis

between the pathologists, the final consensus would be made by discussing the disagreements under dual microscopy (Olympus Co., Tokyo, Japan).

Statistical Analysis

Analysis of variance (ANOVA) tests and Student's t-tests (GraphPad, San Diego, CA, USA) were used to compare test groups with the control group.

Results and Discussion

Characterization of ZnO-NPs

The average primary sizes of ZnO-NPs were measured by TEM, demonstrating a variety of nanoparticle shapes approximately 200 nm in size, including aggregations (*Fig. 1A*). DLS analysis showed that ZnO-NPs were agglomerated, and the dispersion of ZnO-NPs in saline was observed over a range of 100 to 500 nm in a dose-dependent manner (*Fig. 1B*). In the present study, the DLS results were broader in range than the TEM observations regarding primary particle size. This could be explained by the results of a previous study, which showed higher surface absorbed protein concentrations when zinc oxide was diluted in water rather than in PBS (Wells et al., 2012). The above findings illustrate that when surface-absorbed protein concentrations increase, ZnO-NPs preferentially form agglomerations. This likely indicates why particle sizes measured using DLS were increased compared to TEM.

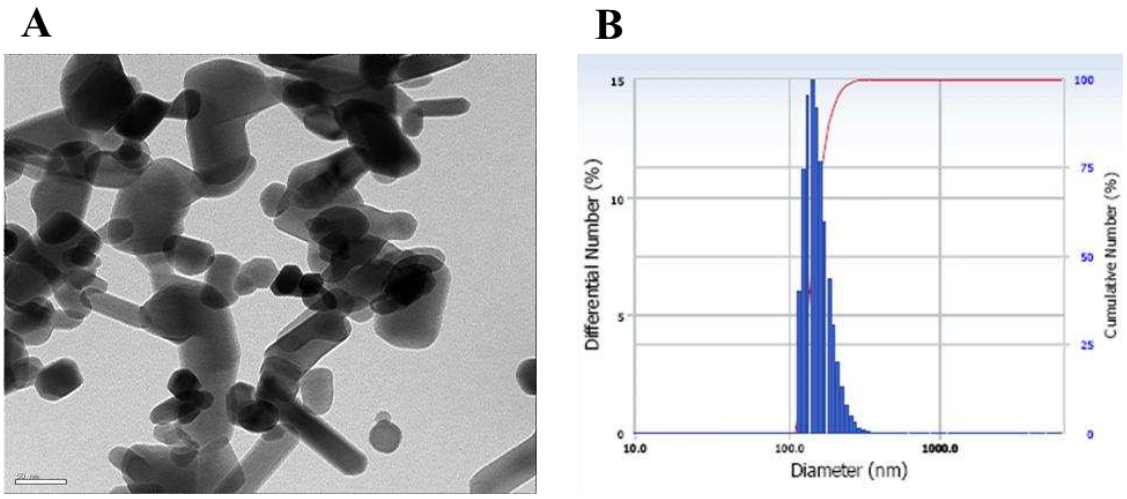

Figure 1. *Characterization of exposure conditions. (A) TEM image of Zn-NPs. Scale bar: 50 nm. (B) DLS analysis of Zn-NPs in saline.*

Body and Lung Weight

The body weights of the rats were measured from the ZnO-NP exposure day until 14 days after exposure. Body weights increased steadily after treatment in all groups, and no statistical differences between the treatment groups and the control group were observed (*Fig. 2A*). The relative lung weights of the rats were also measured to identify

the effect of ZnO-NPs, and no significant differences were found between treatment groups or between days after exposure (*Fig. 2B*).

ZnO-NP Exposure Effects on BALF Cytology

Cell morphology changes were observed in a dose-dependent manner when intratracheal instillation of ZnO-NPs was performed in rats (*Fig. 3A*). 1 day after ZnO-NPs instillation, BALF macrophage presence was increased in a dose-dependent manner. This increase persisted until day 14, although the number of macrophages present at day 14 was lower than that of day 1, suggesting that ZnO-NP effects still exist after 2 weeks of non-exposure. Likewise, the total number of cells in BALF increased in a dose-dependent manner after ZnO-NP instillation, and persisted even at day 14 after treatment. Indeed, total cells at day 14 were even higher than at day 1 (*Fig. 3B*). PMNs also increased at day 1 after ZnO-NP instillation in a dose-dependent manner, but no difference was detected by day 14 (*Fig. 3C*). By comparing the ZnO-NP-exposed groups with the control group results in both day 1 and day 14 rats, we can say that recovery after 14 days did occur. In a previous report, rats were exposed to 1 or 5 mg/kg of ZnO particles, and lung samples were collected after 1 day, 1 week, 1 month, and 3 months after intratracheal instillation (Sayes et al., 2007). We were able to confirm the increase reported by Sayes et al. in total cell numbers at the dose of 5 mg/kg at 1 day after instillation. In our study, an additional dosage of instillation was held for 10 mg/kg. In this dosage treated group, the cell number remained increased even after 14 days of recovery. Regarding the proportion of PMNs in total BALF cells, an increase was observed at 1 day after instillation at a dose of 5 mg/kg, but a return to baseline was observed after 14 days. However, an increase in the proportion of PMNs has been reported to be induced by the same dosage at 1 week after instillation (Sayes et al., 2007). Therefore, by combining the previous study and the present report, we were able to identify that intratracheal instillation at a dose of 5 mg/kg was performed in rats, the proportion of PMNs recovered between 1 and 2 weeks after treatment.

Effect of ZnO-NPs on BALF Biochemical Parameters

BALF was collected and analyzed to assess pulmonary inflammation at days 1 and 14 after exposure to ZnO-NPs. The total protein concentration in BALF increased after treatment in a dose-dependent manner (*Fig. 4A*). The magnitude of increase was higher on day 1 than day 14, although a slight increase was still present at day 14. This result indicates that inflammation was not fully resolved by 14 days after treatment in rat lung cells.

LDH is a cytoplasmic enzyme which is present in essentially all major organ systems. LDH levels in BALF were measured in the control and treatment groups, and no differences were observed, except in the 10 mg/kg dose treatment group at day 1 after instillation (*Fig. 4B*). Increases in extracellular LDH concentrations, which may be caused by cell lysis or cell membrane damage, is used to detect cell damage or cell death (Lott et al., 1986, Click, 1969). Therefore, analysis of BALF LDH concentrations is a potentially useful tool for evaluating lung tissue damage. The increase in LDH caused by high dose (10 mg/kg) ZnO-NP intratracheal instillation observed after day 1 indicated significant cytotoxicity. However, after 14 days, the LDH level had decreased to that detected in the control group. In a previous report, LDH levels were also found to be recovered at 1 week after ZnO-NP exposure at the doses of 1 and 5 mg/kg (Fukui et al, 2015). In our study, this phenomenon was not only observed in these two dosages,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_31453157
© 2018, ALÖKI Kft., Budapest, Hungary

but also at a higher dose (10 mg/kg). Therefore, the recovery of LDH levels appears to occur between day 1 and day 14 in rat lungs.

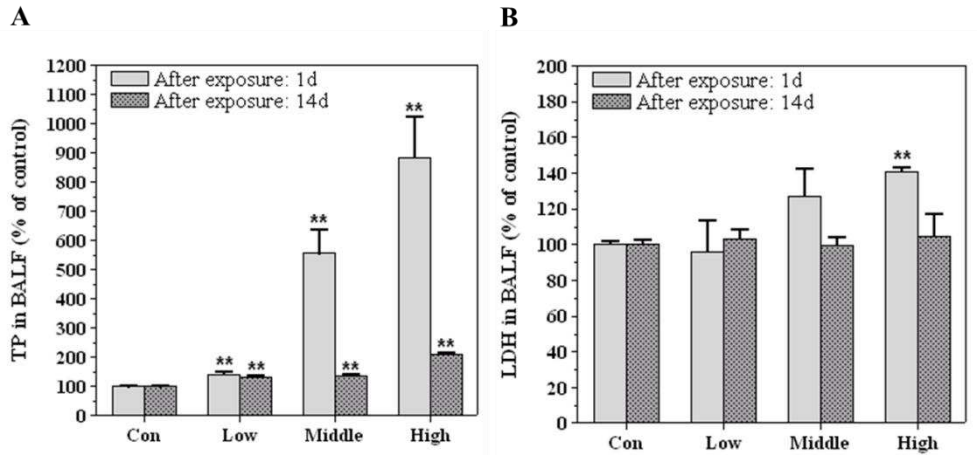

Figure 4. *Analysis of biochemical markers in BALF. (A) Change of total protein concentration in BALF. (B) Level of lactate dehydrogenase (LDH) in BALF. Data was presented as mean ± S.E.M. * = P < 0.05 and ** = P < 0.01 vs. control.*

IL-6 is a second wave cytokine, and it has been reported that serum levels of IL-6 increased in lung cancer patients in relation to the intensity of the acute phase response (Yanagawa et al., 1995). Previous studies showed that TNF-α and IL-6 were produced in the airway or BALF during mycoplasmal infection in pigs, and lung inflammation was observed when the production of these cytokines was increased (Asai et al., 1993, Thacker et al., 2000). Therefore, in this study, the levels of inflammatory cytokines, including IL-6 and TNF-α, were determined in BALF to examine the inflammatory response to ZnO-NP exposure (*Fig. 5*). IL-6 levels were increased in middle and high dose treatment groups at day 1 (*Fig. 5A*). However, IL-6 levels in treated rats were the same as control rats at day 14 after instillation. This result indicates that the rat lung was able to recover IL-6 production during the 14 days after treatment. IL-6 enhances endothelial cell expression of leukocyte adhesion molecules and thereby causes leukocyte accumulation in the lung (Gabay, 2006, Barnes et al., 2011). In a previous study reported by Cicco et al investigated the ability of PMN to secrete IL-6 (Cicco et al., 1990). Thus, the increase of IL-6 in the middle and high-dose treated groups at day 1 may be caused by the increase of PMNs in ZnO-NP-treated animals, as PMNs showed the same trend as IL-6. Although IL-6 is mostly produced by macrophages, PMNs have also been reported as predominant sources of IL-6 in lung inflammation (Zhou et al., 1994). Therefore, we were able to confirm that the increase in PMN seems to be related to the observed increase in inflammatory cytokine levels in the BALF.

TNF-α is a cell signaling protein involved in systemic inflammation, and is one of the cytokines that make up the acute phase reaction (Koj, 1996). It is well known that the dysregulation of TNF production is implicated in various diseases, such as Alzheimer's disease (Swardfager et al., 2010), and inflammatory bowel disease (Brynskov et al., 1994). Therefore, we measured the concentration of TNF-α in the BALF. No significant differences between ZnO-NP-treated and control groups were detected at either day 1 or day 14 after exposure (*Fig. 5B*). A previous study examining IL-6 and TNF-α level in BALF after sub-acute or sub-chronic ZnO-NP exposure had

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_31453157
© 2018, ALÖKI Kft., Budapest, Hungary

noted that lower concentrations of IL-6 and TNF-α were found in the sub-chronic study compared to the sub-acute study (Lampinen et al., 2004). Furthermore, they also found that IL-6 and TNF-α increased immediately after acute exposure (day 1) and progressively decreased with time (day 14), which was similar to the result observed as in the chronic exposure. Therefore, the IL-6 levels found at day 14 in this study showed a similar pattern to the sub-chronic exposure.

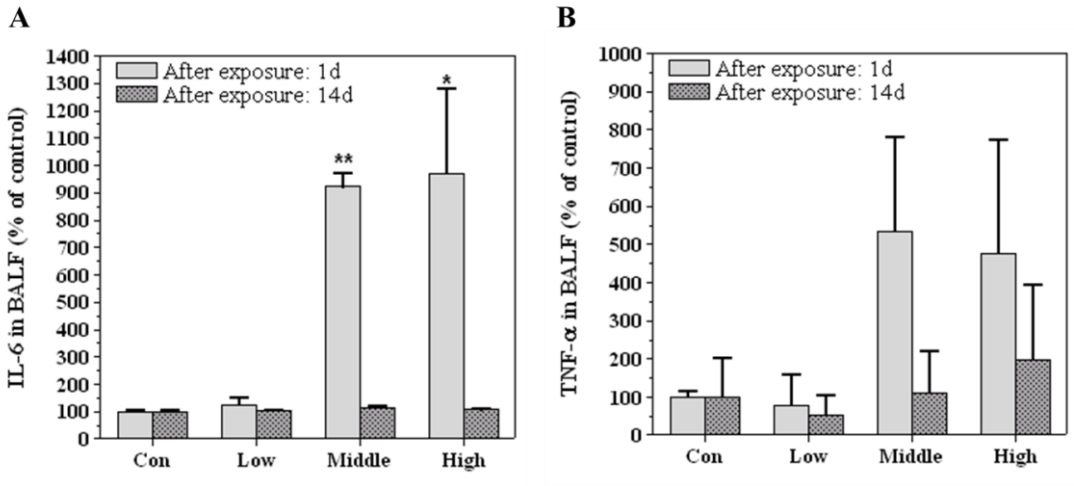

Figure 5. *Effect on secretion of cytokine in BALF after exposure of ZnO-NPs. (A) Level of IL-6 in BALF. (B) Concentration of TNF-α in BALF. Data was presented as mean ± S.E.M. * = P < 0.05 and ** = P < 0.01 vs. control.*

Zinc Burden

Zn content in the lung showed different results in relation to the treatment dosage (*Fig. 6*). Rats sacrificed after day 1 showed a significant increase in all the treatment groups (P < 0.05 for low and middle dose treated groups, P < 0.01 for the high dose treated group). However, by day 14, a significant increase in lung zinc burden was only observed in rats treated with a 5 mg/kg dose. These results indicate that Zn burden was dependent on ZnO-NP exposure quantities, and that Zn burden decreases with time.

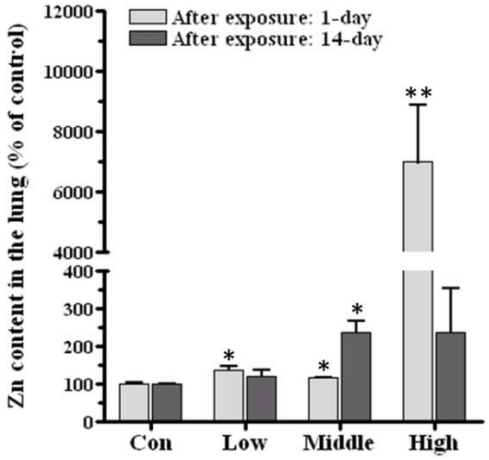

Figure 6. *The burden of zinc in the lung after intratracheal instillation of Zn-NPs. Data was presented as mean ± S.E.M. * = P < 0.05 and ** = P < 0.01 vs. control.*

Histopathological Findings

Histopathological changes were observed in the lungs of rats from the control and treatment groups at day 1 after ZnO-NP exposure (*Fig. 7*). At this timepoint, multifocal acute inflammation was observed near the terminal bronchioles and alveolar ducts in all ZnO-NP exposed groups, however no inflammatory lesion was observed in the control group.The inflammation was particularly severe in the high dose group. In the high dose group, pulmonary edema was also often observed. Pervascular infiltration of inflammatory cells was detected in the ZnO-NP exposed groups in a dose dependent manner, showing 20%, 40%, and 60% incidence rate in the low dose, middle dose, and high dose exposure groups respectively. Inflammatory cell infiltration near the bronchiole was also observed when inflammatory foci were detected, suggesting that they were related to ZnO-NP exposure.

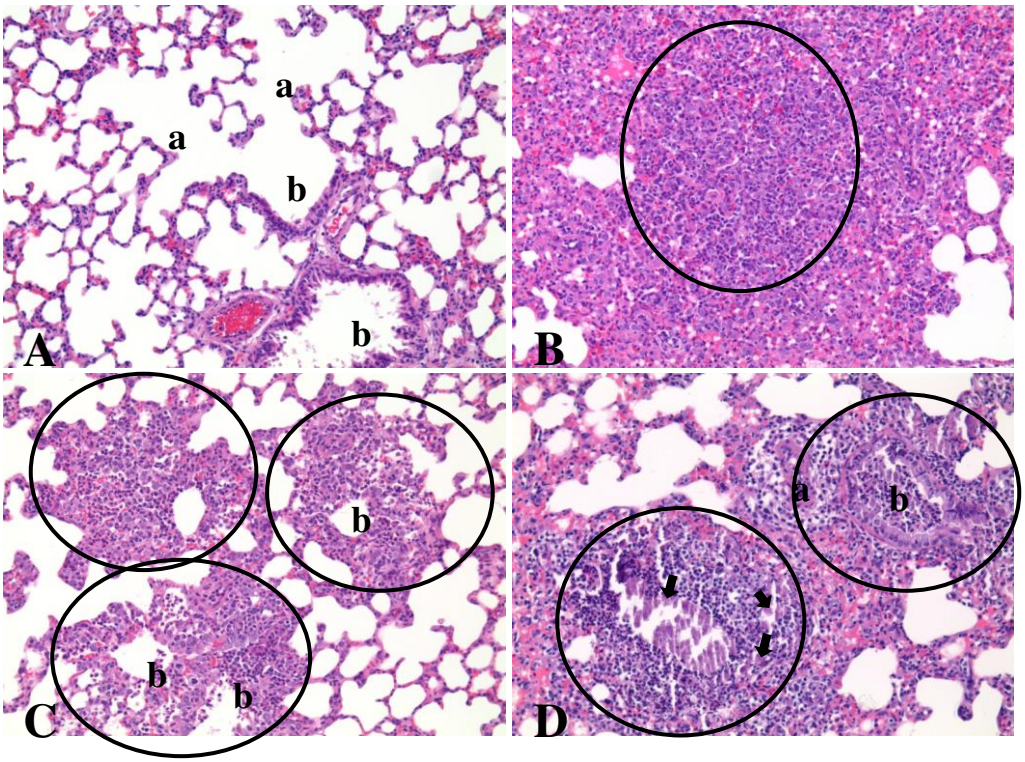

Figure 7. *Histopathology of lungs from rats treated with intratracheal ZnO-NPs at day 1 after treatment. Presence of acute bronchopneumonia, as characterized by neutrophil infiltration around the terminal bronchioles with type II alveolar cell hyperplasia, is marked with circles (B, C, and D). Dark brown foreign materials were often present in the lesion and bronchiolar lymina (arrows in D). a, arteriole; b, terminal bronchioles; ad, alveolar ducts. A = Control; B = Low Dose; C = Middle Dose; D = High Dose. H&E. Magnification=X200 for all.*

Histopathological changes were also observed in the lungs of rats from the ZnO-NP treatment groups at day 14 after the exposure (Fig. 8). Chronic histiocytic alveolitis, at the terminal bronchioles and alveolar ducts, was observed at rates of 40%, 60%, and 40% in low, middle, and high dose treatment groups respectively (Fig. 8). The presence of inflammatory cells may be explained as a chronic inflammatory mechanism, where the acute purulent alveolitis observed at day 1 has become chronic due to the passing of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

time. In contrast with the results from day 1, we were not able to observe purulent inflammation or pulmonary edema at the bronchiole at day 14, and this could be considered as a recovery. In low, middle, and high dose of ZnO-NP exposure groups, lymphocyte infiltration near the blood vessels were observed as 40%, 80%, and 80% respectively, showing a trend to dosage, although statistically significant difference among the groups were not observed.

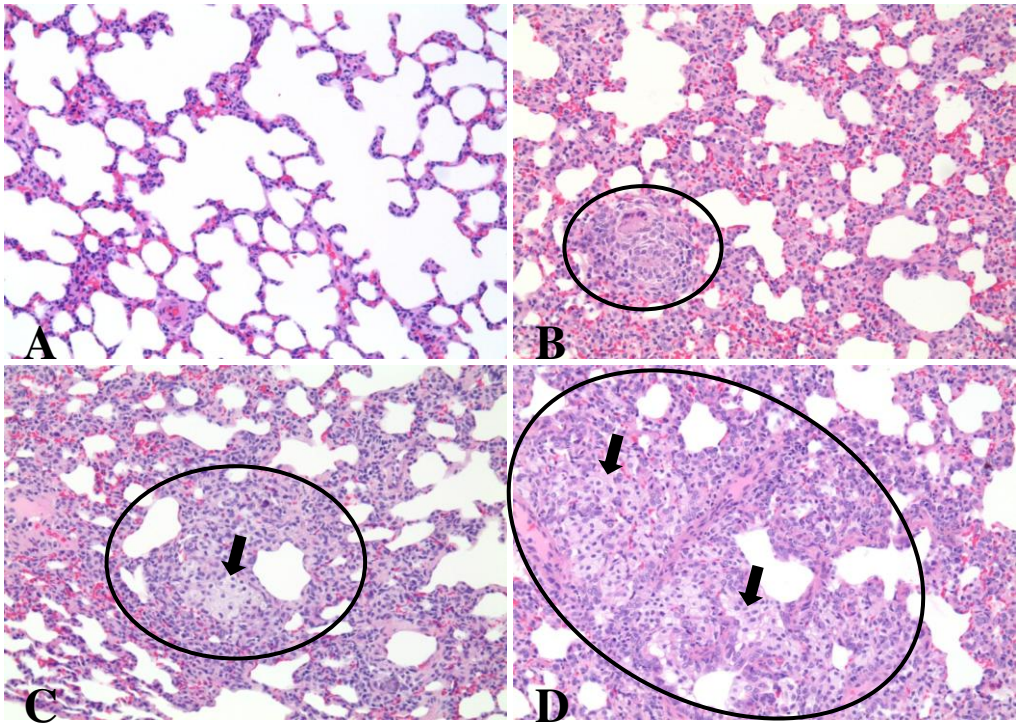

Figure 8. *Histopathology of lungs from rats treated with intratracheal ZnO-NPs at day 14 after treatment. Multifocal histiocytic pneumonitis, as characterized by massive infiltration of foamy macrophages(arrows), in the lungs of low, middle and high dose groups are marked with circles (B,C and D). a, arteriole; b, terminal bronchioles; ad, alveolar ducts. A = Control; B = Low Dose; C = Middle Dose; D = High Dose. H&E. Magnification=X200 for all.*

In previous studies, histopathological observations revealed serious pulmonary inflammation and alveolar wall thickening in the lungs of treated mice (Chang et al., 2012, Saptarshi et al., 2015). Although the experimental animal used was different, similar results were observed in our ZnO-NP exposure experiments. In this study, we observed histopathological differences between day 1 and day 14 after treatment, which suggests some recovery after exposure. Acute bronchopneumonia, as characterized by neutrophil infiltration around the terminal bronchioles with type II alveolar cell hyperplasia, was observed in the ZnO-NP treated groups at acute phase (marked with circles in Fig. 7). Multifocal histiocytic pneumonitis was identified at day 14 (Fig. 8), showing that full recovery had not yet occurred by this timepoint, and suggesting that acute inflammation had shifted to chronic infilammation. In the lesions, infiltration of foamy macrophages was frequently detected (arrow in Fig. 8), and macrophage size increased dose-dependently.

Conclusion

In the present study, we investigated pulmonary toxicity and histopathology of the lungs of rats exposed to ZnO-NPs by intratracheal instillation. The number of macrophages were decreased at day 14 compared to day 1, although they were still higher than baseline levels, suggesting that the effect of ZnO-NPs still existed at 2 weeks after exposure. The total number of BALF cells increased in a dose-dependent manner after treatment, and continued to increase to day 14 after treatment. However, proportion of PMNs returned to baseline levels between 1 and 2 weeks after treatment with 5 mg/kg of ZnO-NPs. LDH levels did recover between day 1 and day 14. Levels of IL-6 increased significantly in rats given 5 or 10 mg/kg doses at day 1, while IL-6 levels were stable by day 14. Based on these results, we can say that recovery was present at day 14 after exposure, which was observed in previous sub-chronic exposure studies. Furthermore, we noted that intratracheal instillation of ZnO-NPs caused multifocal acute purulent inflammation in pulmonary parenchyma. The findings of this study suggest that acute exposure to ZnO-NPs may have deleterious effects in cells, which may lead to tissue damage and possible chronicization of pathological conditions. For further research, examination held after more than 14 days may be required to determine the long-term effects which may be caused by ZnO-NPs through ITI.

Abstract. The aim of this study was to assess effects of prior cultivation in combination with bio-fertilizers and the use of combined fertilizers and on corn (*Zea mays* L.) yield and soil efficacy. A strip-plot randomized complete block design with three replications was used in 2015 at the research farm of Payam-e Nour University in Arak, Iran. Treatments included the pre-cultivation with chickpeas and lying fallow. The fertilizer treatments were no organic fertilizer (control); manure containing 60 kg N per ha [FYM]; vermicompost containing 60 kg N per ha [VC]; FYM + 3000 kg chickpea waste/ha [M]; VM+M; FYM+M+ bio-fertilizer (Celolitec Kalchero) and phosphate-solubilizing bacteria [B] + azetobacter; vermicompost containing 60 kg N/ha + 3000 kg chickpea waste/ha + Celolitec Kalchero and; VC+M+B). The results showed that the effect of pre-cultivation with chickpeas on plant height, fresh forage yield, leaf phosphorus, leaf protein, organic carbon, available soil nitrogen and available soil phosphorus were significant. The effect of fertilizer type on all traits (except grain width) was significant. The highest phosphorus (5.53 mg/g), grain protein (10.57%), length of corncob (17.17 cm), grain width (2.18 mm), grain length (9.48 mm), fresh forage yield (22436.7 kg/h) and raw ash (6.60 mg/g) were obtained with the VC+M+B treatments. Leaf phosphorus and fresh forage yield after pre-cultivation with chickpeas were higher than for the fallow pre-treatment.

Introduction

Corn is the world's third most important dual-purpose crop (grain and forage). It plays an important role in human and animal nutrition. Corn forage used for livestock feed provides a high amount of energy, is not harmful and is free of substances such as prussic acid and oxalic acid which are found in plants such as sorghum. It also can be consumed by livestock at all stages of growth (Dahmardeh et al., 2009; Hollander et al., 2007).

Recent attention has focused on the quality and health of the soil in order to produce sustainable crops. Many countries have encouraged the use of natural inputs out of growing concern for the safety of food products (Hollander et al., 2007). The frequent use of chemical fertilizers and lack of soil conservation in ways that are destructive to soil organisms eventually leads to loss of vitamins and other beneficial compounds in plants which are essential to their production (Hiltbrunner et al., 2007).

Currently, the fertilization system focuses on the supply of a few macronutrients, although plants need at least 13 types of mineral nutrients which come from the soil. This is another reason for the imbalance in plants that are fed mineral fertilizers (Atiyeh et al., 2000).

Manure and vermicompost are widely used organic fertilizers. In addition to the usual benefits of compost, vermicompost is a source of organic substances, improves the water-holding capacity of the soil, increases absorption of nutrients and has a hormone-like effect on the plant (Bachman and Metzger, 2008; Campitelli and Ceppi, 2008). Vermicompost is finer and better in texture than compost and has nutrient forms that are easily absorbed by plants (Roy et al., 2010). Studies have shown that the presence of plant growth regulators in vermicompost improves plant growth (Atiyeh et al., 2000). A study on chickpeas showed that the application of three tons of vermicompost per hectare significantly increased the biomass over that of the control (Kapoor et al., 2002). Zaller (2007) showed that vermicompost significantly increased the biomass of tomato varieties.

Biological fertilizer is organic fertilizer derived from animals, plants and other types of waste that includes microorganisms that act in relation to the fixation of nitrogen, phosphorus and other nutrients in the soil (Kumar et al., 2014). One way to achieve sustainable agriculture is the use of microorganisms, which play an important role in the nutrition of plants (Abdel-Aziez et al., 2016).

Currently, phosphate-solubilizing microorganisms (PSMs) are used as biological fertilizer to increase yield and maintain soil health (Khan et al., 2010). Studies have shown that PSMs dissolve phosphorus that is fixed in the soil and improves plant yield (Gull et al., 2004). Research also showed that PSMs increase the germination, absorption of nutrients, plant height and number of branches, nodules, biomass and chickpea yield over that of the control (Rudresh et al., 2005).

One element that limits crop yield is nitrogen. Product waste, especially from legumes, which have a symbiotic relationship with the bacteria of the rhizobium family can improve soil nitrogen. The aim of this study was to investigate the effect of pre-cultivation with chickpeas and the application of phosphorus and nitrogen dissolvent and chickpea waste to increase the efficiency of vermicompost and manure for corn and soil efficacy.

Materials and methods

This experiment was done in 2015 on the research farm of Payam-e Nour University in Arak, Iran (34° N and 50° E at 1757 m in elevation). This experiment was a strip-plot randomized complete block design with three replications. The region has a cold steppe climate, an average rainfall of 250-350 mm, a maximum temperature of 40 °C and a minimum temperature of -7 °C (for more detail, see *Table 1*).

The pre-cultivation treatments were 1- chickpeas and 2- lying fallow. The organic fertilizers were as follows: 1- control (without fertilizer); 2- manure containing 60 kg N/ha (FYM); 3- vermicompost containing 60 kg N/ha (VC); 4- manure containing 60 kg N/ha + 3000 kg chickpea waste/ha (FYM+M); 5- vermicompost containing 60 kg N/ha + 3000 kg chickpea waste/ha (M+VM); 6- manure containing 60 kg N/ha + 3000 kg chickpea waste/ha + bio-fertilizer (Celolitec Kalchero) + phosphate-solubilizing bacteria + azotobacter (B+M+FYM); 7- vermicompost

containing 60 kg N/ha + 3000 kg chickpea waste/ha + Celolitec Kalchero + phosphate-solubilizing bacteria (Barvar 2) + azotobacter (VC+M+B).

Table 1. *Soil physical and chemical properties of field*

EC (dS/m)	pH	Saturation Percentage	Available P (ppm)	Available K (ppm)	Total N (%)	Total C (%)	Soil texture
1.73	7.9	27.05	12.1	302	0.052	0.52	Sandy loam

Each plot consisted of four rows 6 m in length. The distance between rows was 35 cm and the plant spacing was 10 cm. The density of the plants was 28.5 plants/m^2. Before applying the treatments, soil sampling was done from different parts of the farm and the results are shown in *Table 2*.

In order to prepare the field for planting, fertilizer was added to the soil in the amount required for each treatment. It was mixed with the soil using a disc to a depth of 30 cm. The corn variety used in this experiment was the single-cross 704. Barvar 2 is a phosphate-solubilizing fertilizer containing *Pantoea agglomerans* strain (P5) and *Pseudomonas putida* strain (P13) that was used in some treatments. The date of planting was 6 June, which is the usual time for the region. During the growth season, irrigation was carried out as needed and weed control was done manually. The protein content of grain was determined by Kjeldahl method (N × 6.25, wet basis) (Wang et al., 2016).

Phosphorus contents of corn leaf and soil were determined using spectrophotometer (UVD 2960). Dried material was burned in a muffle furnace at 550°C and used to determine the raw ash content (Theuretzbacher et al., 2014).

At the early dent, after removing the half-a-meter margins from both sides of the planting lines and two lateral lines, harvesting was carried out near the soil surface. In each plot, six plants were selected. After measuring the growth characteristics of plant height, length, width and grain thickness, diameter and ear length and fresh yield, the plants were transferred to the laboratory and the amount of plant nutrients in them was determined. The protein content was determined as by Kjeldahl at N = 6.25. Phosphorus was estimated using a spectrophotometer. SAS (ver. 11) software was used to analyze the variance of data. LSD 0.05 values were used for comparison of means.

Results

The results showed that the effects of prior cultivation on plant height, fresh forage yield, leaf phosphorus, leaf protein, organic carbon, available soil nitrogen and available soil phosphorus were significant at the 1% level. The effect of fertilizer type on grain length, ear length, plant height, fresh forage yield, phosphorus, leaf and seed protein content, organic carbon, available soil nitrogen and available soil phosphorus were significant at the 1% level and on grain thickness, corncob diameter, crude fiber and crude ash content at the 5% level. The interactions of prior cultivation and fertilizer type with plant height, organic carbon, available soil nitrogen and available soil phosphorus were significant at the 1% level (*Tables 3* and *4*).

Grain characteristics

The largest values for grain length and grain thickness were obtained from the treatments containing three fertilizers. Then next largest values were for the two-fertilizer treatment followed by a single fertilizer. The lowest amount was observed in the control treatment (without fertilizer). The length and thickness of the grains, respectively, were 14% and 12% for VC+M+B, 12% and 11% for FYM+M+B, 11% and 11% for VC+M, 11% and 9% for FYM+M, 8% and 7% for VC, 10% and 6% higher for FYM greater than for the control without fertilizer. In general, grain yield and grain thickness were higher in the compost treatments than in the manure treatments, but the difference between these was not significant.

Ear characteristics

The greatest lengths and diameters of corncobs were found in the three-fertilizer treatments and the lowest in the control treatment (without fertilizer). The length of the corncob in both the three-fertilizer treatments (VC+M+B and FYM+M+B) increased by 6% and in the FYM+M, VC+M, FYM and VC treatments by 5% when compared to the control (*Table 4*). The treatments containing compost resulted in greater corncob lengths than those with manure at all levels of fertilization, but the difference was not significant. All fertilizer treatments increased the corncob diameter over that of the control (*Table 5*).

Table 5. *Mean comparisons of corn traits under different fertilizer*

Treatments	Mean			
	Grain length (mm)	**Grain width (mm)**	**Corncob length (cm)**	**Corncob diameter (mm)**
CO	8.31^{e}	1.92c	16.12^{d}	20.24^{b}

VC+M	9.26^{bc}	2.12^{ab}	17.02^{bc}	21.52^{a}
FYM+M+B	9.33^{ab}	2.15^{ab}	17.10^{ab}	21.70^{a}
VC+M+B	9.48^{a}	2.18^{a}	17.17^{a}	21.67^{a}

CO: control; FYM: manure containing 60 kg N/ha; VC: vermicompost containing 60 kg N/ha; M: 3000 kg chickpea waste/ha; N: bio-fertilizer (Celolitec Kalchero) + phosphate-solubilizing bacteria + azotobacter

Plant height

The plant height at all levels of fertilization except for VC+M, was higher with chickpea pre-cultivation than with no pre-treatment (6% increase in plant height over the control). The greatest plant height with and without cultivation was observed for VC+M+B and the lowest was for the control (*Table 8*).

Yield of fresh forage

The highest fresh forage yield was obtained for VC+M+B and FYM+M+B (15% and 14% increase over the control, respectively). The VC+M and FYM+M combinations

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

increased 13% and 11%, respectively, over the control and the VC and FYM treatments increased 9% and 4%, respectively, over the control (*Table 6*). The use of vermicompost in all fertilizer treatments increased the yield over that of the manure treatment. The prior cultivation treatment significantly increased the yield of forage by 361 kg over the fallow treatment (*Table 6*).

Table 6. *Mean comparisons of corn traits under different fertilizer*

Treatments	Mean			
	Fresh forage yield (kg/ha)	**Leaf phosphorus (mg/g)**	**Grain protein (%)**	**Raw ash (mg/g)**
CO	19473.3^{f}	1.96^{g}	5.17^{e}	6.08^{e}
FYM	20220.0^{e}	2.52^{f}	7.01^{d}	6.23^{de}

FYM+M+B	22163.3^{b}	4.95^{b}	10.16^{a}	6.52^{ab}
VC+M+B	22436.7^{a}	5.53^{a}	10.57^{a}	6.60^{a}

CO: control; FYM: manure containing 60 kg N/ha; VC: vermicompost containing 60 kg N/ha; M: 3000 kg chickpea waste/ha; N: bio-fertilizer (Celolitec Kalchero) + phosphate-solubilizing bacteria + azotobacter
Within columns, means followed by the same letter do not differ significantly ($p \leq 0.05$)

Leaf phosphorus

This trait was strongly influenced by the type of fertilizer used. The amount of phosphorus of in the leaves of the VC+M+B and FYM+M+B treatments increased by 182% and 152%, respectively. For the VC+M and FYM+M treatments, respectively, it increased by 98% and 86% and in the VC and FYM treatments by 38% and 28%, respectively (*Table 6*). Fertilizer treatments containing vermicompost showed significantly higher levels of phosphorus over treatments containing manure (*Table 6*). The difference between the fallow and pre-cultivation with chickpeas was significant in terms of leaf phosphorus content. The chickpea treatment showed an 11% increase in leaf phosphorus over the fallow treatment (*Table 7*).

Table 7. *Mean comparisons of corn traits under different prior cultivation treatments*

Treatments	Mean	
	Fresh forage yield (kg/ha)	**Leaf phosphorus(mg/g)**
Fallow	21291.81^{b}	3.39^{b}
Pre-pea cultivation	21553.18^{a}	3.80^{a}

Within columns, means followed by the same letter do not differ significantly ($p \leq 0.05$)

Grain protein

The highest protein content in the seeds was observed in the three-fertilizer treatments. The lowest protein content was observed in the non-fertilized (control) treatment. Grain protein content in the VC+M+B and FYM+M+B increased by 104%

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_31593169
© 2018, ALÖKI Kft., Budapest, Hungary

and 97%, respectively. In the VC+M and FYM+M treatments, it increased 80% and 67%, respectively, and in the VC and FYM treatments, it increased 46% and 36%, respectively, over the control (*Table 6*). There was no significant difference in this trait between the vermicompost and manure treatments.

Raw ash

The highest raw ash content was observed in the three-fertilizer treatment of VC+M+B (9% increase compared to control); however, the difference was not significant from the FYM+M+B (7% increase compared to control) and VC+M (6% increase compared to control). The lowest ash content was observed in the control treatment (*Table 6*).

Soil properties

The traits of soil organic carbon, available soil nitrogen and available soil phosphorus were strongly influenced by the simple effects of fertilizer type and pre-cultivation and the interaction of these treatments was also significant ($p < 0.01$; *Table 4*). Pre-cultivation with chickpeas at almost all levels of fertilizer increased the levels of organic carbon, available soil nitrogen and phosphorus because of the effects of chickpea cultivation that remained in the soil. Soil organic carbon is one of the most important factors for soil and production capacity and is a major reason for the higher values of most traits in the pre-cultivation with chickpea treatment over the fallow treatment. Fertilizers contained higher amounts of organic carbon compared to the control. The highest available soil nitrogen levels were 0.887% and 0.844% in the VC+M+B and FYM+M+B treatments, respectively, in the pre-cultivation with chickpea treatment (*Table 8*).

Table 8. *Interaction effect of fertilizer and prior cultivation on corn height and soil properties*

Pre-cultivation	Fertilizer treatment	Plant height (cm)	Organic carbon (%)	Available soil N (%)	Available soil P (ppm)
Fallow	CO	85.6 ^{j}	0.503 ^{e}	0.524 ^{h}	12.4 ^{g}

The highest available soil phosphorous was found in the three-fertilizer combination under pre-cultivation (16.5 and 16.3 ppm. respectively), dual fertilizer (15.9 ppm) and VC+M+B under fallow conditions (15.3 ppm). These results show how the strong synergistic effects of various fertilizers in the soil to improve its physical and nutritional status. Other researchers have reported vermicompost as a soil organic modifier for increased nitrogen and phosphorus absorption (Sekar and Karmegan, 2010).

Discussion

Based on the results of this experiment, the combination of fertilizers that included organic fertilizer, corn residue and biofertilizer achieved the high yield. It appears that the increase in absorption of nutrition by the plant in this type of treatment and subsequent improvement in growth conditions led to the increased yields.

Manure and vermicompost alone managed to improve the nutritional status of the plant and, subsequently, increased the relative yield compared to the control, but this increase was lower than for the combined fertilizer treatments. Darzi and Haj-Sihedadi (2012) reported that the use of high levels of vermicompost in dill cultivation significantly increased the yield and plant height. Other researchers reported an increase in the physical, chemical and biological properties of soil and improved plant nutritional conditions that were attributed to the increase in the duration of vegetative and reproductive growth, the better use of growth resources and an increase in yield components and grain yield (Arankon et al., 2004). Roesti et al. (2006 improvement of the soil fertility, prevention of the leaching of nitrogen, an increase of biological activity and improvement of the soil structure as resulting from the use of vermicompost. Vermicompost application has been found to stimulate soil microorganisms, maintained the supply of nutrients to the plant and increase yield (Roy and Singh, 2006). The use of vermicompost, in addition to supplying nutrients from worm residue, improves the soil biological conditions and increases the microorganism activity in the soil (Anwar et al., 2005). An increase in phosphorus uptake in the soil was found to increase soil nitrogen efficiency and ultimately result in better plant growth (Zubigala et al., 2002).

Simultaneous use of organic fertilizers, plant residue and biofertilizer increased the absorption of elements from the soil, proper growth of the plant and produced the highest biological yield and seed yield in corn. In many other studies, PSMs have also increased the phosphorus concentration in the soil and plant and ultimately improved yield (Gull et al., 2004). Research has also shown that the use of these microorganisms increased and improved the germination ability, absorption of elements, plant height, number of branches, biomass and yield of chickpeas compared to the control treatment (Rodrish et al., 2005).

These biofertilizers increase nutrient availability and produce growth hormones by increasing nitrogen efficiency. Gull et al. (2004) observed that phosphate-solubilizing bacteria increased the number of nodules in chickpeas by 50% and increased N fixation and concentration in the plant. The application of phosphorus solubilizing bacteria increased the phosphorus concentration, which increased nitrogen efficiency, which increased development of the plant shoot, root and leaf area and, ultimately, the yield (Soltani et al., 2010). Mokhtari and Besharati (2013) also showed that the use of phosphorus-soluble bacteria significantly increased the concentration of nitrogen, phosphorus, potassium, iron, and zinc compared to the control, which significantly increased the yield over that for the absence of bacteria.

In the current study, pre-cultivation with chickpeas had positive effects on phosphorus soil availability and absorption, which increased the corn forage yield. Other studies have also found a positive effect of the adding of plant residue, especially legumes either by reversing the residue of the previous crop or adding residue to the field on soil characteristics, nutrient reserves in the soil and plant tissues and yield (Wilhelm et al., 2004). Fischer et al. (2002) showed that the return of plant residue is effective in providing more nitrogen and increasing the yield of corn and wheat, especially in the long-term, along with a more gradual decrease in soil fertility and degradation of yield. This makes the procedure economically advantageous.

Conclusion

As a conclusion the effect of pre-cultivation with chickpeas on more plant traits were higher than fallow. The highest phosphorus, grain protein, length of corncob, grain width, grain length, fresh forage yield and raw ash were obtained with the VC+M+B treatments. In more traits there were a synergistic effects of pre-cultivation with fertilizers compared with fallow plots.

(Received 2nd Feb 2018; accepted 2nd May 2018)

Abstract. This study was selected to assemble the current information in order to establish a mass-balanced ecosystem model within the resettled maritime limit zone of the Bay of Bengal, Bangladesh through ECOPATH approach covering over 90000 km^2. A total of 19 functional groups were considered demonstrating all trophic levels in the food web where the estimated trophic interactions between the groups were varied from 1 (primary producers and detritus) to 3.45 (sharks). The ecotrophic efficiency (EE) of most of the consumers was >0.80; indicating a largely exploited ecosystem and high energy transfer from lower to higher trophic levels. Moreover, the gross efficiency (0.0018) and transfer efficiency (11.12%) of the whole system symbolize the 'developing systems' with somewhat maturity. Ecosystem's overhead (64.6) and ascendancy (35.4) also designate the ecosystem's stability. Thus, this study concludes that the resettled maritime area of BoB reserves significant backup strength to face stress situations having capacity to rapid restoration to the original states.
Keywords: *Ecopath with Ecosim (EwE), Bay of Bengal (BoB), ecological groups, maritime ecosystem, mass balance*

Introduction

Ecosystems are superbly balanced although they are reasonably complex, non-linear and their structures are composed by the interconnection of living and non-living bodies with their habitat. In every portion of an ecosystem, has a significant role to play and if any alteration is occurred to any portion of a particular ecosystem, the whole ecosystem of that area can also be altered. This is not only dynamic but also hierarchically ascended. Ecosystems structures and processes are associated across the spatial and temporal balances. Due to their complication and the array of negative and positive response across balances, the predictability of these structures is inadequate (Gunderson, 1999). Sustainable usage of ecosystem components is unlikely in absence of a better understanding of balancing ecosystem dynamics that foster ecosystem capability (Bengtsson et al., 2003). Coastal and marine ecosystems are among the largest aquatic ecosystems of the world, covering 71% of the earth and fish populations are one of the most vital parts of these systems (BOBLME, 2011). Therefore, management approach that is based on fisheries ecosystem has reaped consideration for maintaining long-term sustainability to balance ecosystems (ICES, 2000). In recent, the ability of marine ecosystems to produce fish for supporting human interest is extremely degraded by

overfishing, excessive trawling, and loss of spawning and nursing grounds (McGlade et al., 2002). Noticeable limitation exists between single and multispecies fisheries management, which does not consider a comprehensive assessment of changes in ecosystem arrangement, and functions linked with the interactions of individuals (Mace, 2001; Pikitch et al., 2004). The concept of ecosystem-based fishery management needs the improvement of tools to gain perceptions in ecosystem functioning and the effect of fishing on ecosystem structure. Some of the critical issues like interspecies interactions within an ecosystem, effects of the enormous environmental and climatic alterations along with the fishing impacts should be incorporated to formulate an ecosystem based management strategy in any habitat (Browman et al., 2004; Pikitch et al., 2004).

Recent improvements in constructing multispecific ecosystem based modeling approach of aquatic ecosystems named "Ecopath with Ecosim (EwE)" are successfully used to evaluate the structure and ecosystem effects of fishing (Polovina, 1984; Christensen and Pauly, 1992). This approach provides a base for feasible and applied simulation model having actual predictive power that can be performed more rapidly and rigorously than ever before (Christensen and Pauly, 1993; Walters et al., 1997; Christensen and Walters, 2004). The construction of such mass-balance models of ecosystems are based mainly on food consumption, diet composition, biomass and mortality estimates. The ECOPATH packages of software have now been improved (Walters et al., 1997, 1999) through including ECOSIM (simulation module) and ECOSPACE (spatial module). These new modules have not only upgraded the quantitative command of the approach but also permitted qualitatively new inquiries.

Recently, Bangladesh has been settled maritime boundary with neighboring states Myanmar and India up to 200 nautical miles from the coastline comprising about 121110 km^2 (MoFA, 2014), whereas coastal and shallow shelf waters constitute about 20% and 35% respectively, the rest covers deeper waters (Khan et al., 1997). The entire shelf area of Bangladesh (up to 200 m depth contour) covers about 66440 km^2 and from the coastline to 10 m (0-10 m) depth zone comprises 24000 km^2 (*Table 1*). Nevertheless, in the context of fisheries resources, from the coastline to 200 m depth zone plays a significant role as it almost covers four major fishing grounds of Bangladeshi waters and also produces most of the marine catch (Lamboeuf, 1987; Khan et al., 1997). The declared areas of four major fishing grounds (*Fig. 1b*) are 'South Patches' and 'South of South Patches' covering an area about 6200 km^2. In addition, 'Middle Fishing Ground' contains 4600 km^2 area (*Table 1*) and 'Swatch of No Ground' covers 3800 km^2 (Khan et al., 1997). Among them 'Middle ground' and 'South patches' have been declared as 'Fish sanctuaries' in the Bay of Bengal. Still, the detailed ecological and oceanographic data of these areas are limited to determine the suitability of these areas as fish sanctuary.

In the context of the recent settlement of the maritime boundary, 'Blue Economy' recently turned into a buzzword for sustainable development, particularly in highlighting the vision of SDG (Sustainable Development Goals) for Bangladesh. The Government of Bangladesh emphasized those marine and coastal fisheries resources based blue economy might act as a driver for sustainable development, designating development not only for today but also for the upcoming years (Shamsuddoha and Islam, 2016). Moreover, this new relocated vast area could not be accessible to fishing due to the lack of vessel capability and suitable fishing technology (Hossain et al., 2014). The Bay of Bengal (BoB) defined as a temperately productive ecosystem among the world's 64 Large Marine Ecosystems (Hussain and Hoq, 2010) has great potential

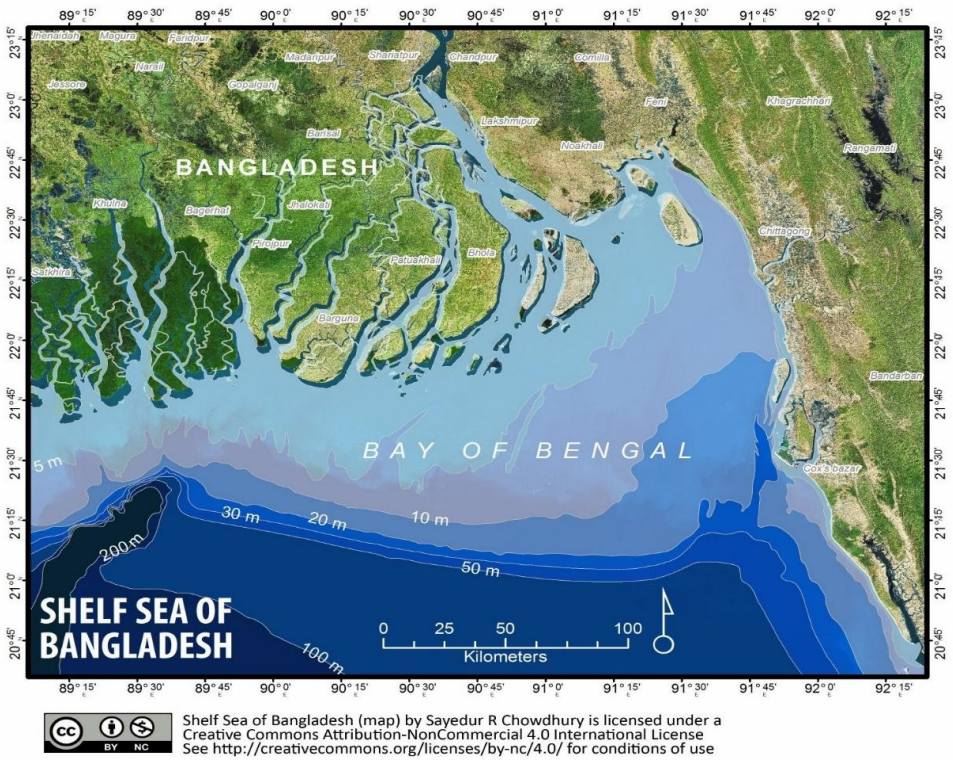
for fisheries because of the enormous nutrient input from the river flow of the Ganges and Brahmaputra (ESCAP,1988). A total of 475 species of finfish, 36 of shrimps, 15 types of crabs, 5 varieties of lobster, and over 300 species of mollusks were recorded (FRSS, DoF). The fishes which are presently exploited consist mainly of the shallow water estuarine species and some mid-water species. The average total marine industrial catch over the last decade (*Table 1*) was 540592 Mt (DoF, 2016). Functionally, marine fisheries are sub-divided into industrial and artisanal fisheries. The average production of the last ten years shows that the industrial fishery based on trawl fishery (shrimp and fish trawl) contributes only 5% of the total marine captures and the artisanal fisheries (mainly based on Set bag net and Gillnet fisheries) contributes 95%.

Table 1. *The geographic location and covered areas of the major fishing grounds of the EEZ of the Bay of Bengal, Bangladesh (Khan et al., 1997)*

Depth zone (m)	Area (km^2)	Fishing grounds	Location	Depth
≤ 10	2400	South Patches	(Lat. 20°50'N to 21°40'N;	10-40 m (depth)
10-24	8,400	(3400 km^2)	Long. 91°00'E to 91°50'E)	
25-49	4,800	South of South Patches	(Lat. 20°50'N to 21°40'N;	10-100 m (depth)
50-74	5,580	(2800 km^2)	Long. 91°00'E to 91°50'E)	
75-99	13,410	Middle Ground	(Lat. 20°50'N to 21°20'N;	10-100 m (depth)
100-199	10,250	(4600 km^2)	Long. 90°00'E to 91°00'E)	
All shelf	66,440	Swatch of No Ground	(Lat. 21°00'N to 21°25'N;	10-100 m (depth)
		(3800 km^2)	Long. 89°00'E to 90°00'E)	



Several surveys and studies have been piloted to assess and estimate the potentialities of marine fisheries resources of Bangladesh since 1970 to 1980 by the collaboration of National and International agencies, but no fresh assessment is available. Limited reports are found focusing on biological, environmental and resource management concerns of the Bay of Bengal (BoB) (Hossain, 2003; Huntington et al., 2007; Hussain and Hoq, 2010), but such pieces of evidences are insufficient to consider and manage of our marine resources systematically. Conversely, in the near future, there is a possibility of dropped off the fisheries role on people's livelihoods as the stocks of various fish and shrimps are showing diminishing trends due to effects of climatic change, water pollution and fishing pressure (BOBLME, 2011). In recent, Mustafa (2003) made an attempt to describe the ecosystem features of BoB based on trawl catch data but overlooked the most important artisanal fishing areas and Ullah et al. (2012) described the shallow coastal areas not exceeding the 10 m in depth. Therefore, the maritime waters of the BoB, Bangladesh remain to be one of the most unfocused areas in the world, thus limiting the exploitation, exploration, conservation and management of its marine, though this zone is recognized as one of the world's ample and diversified ecosystems considered by greater productivity (Islam, 2003). All of these studies considered only short-term available data that not elucidate long-term outputs properly. Hence, attempts are made by authors to drive a new study concerning management of the maritime resources of the BoB, Bangladesh using the ecosystem scheme. The EwE (ECOPATH with ECOSIM; version 6.5) routine package was used in the current study to develop the mass-balance ecosystem model. The aim of this study is to illustrate the interaction between the diverse ecological groups and to define the flow of energy in the maritime area of Bay of Bengal, Bangladesh. In addition, another aim of this study is to measure the existing capability of the maritime ecosystem of BoB, Bangladesh to cope with the emerging "blue economy" pressure.

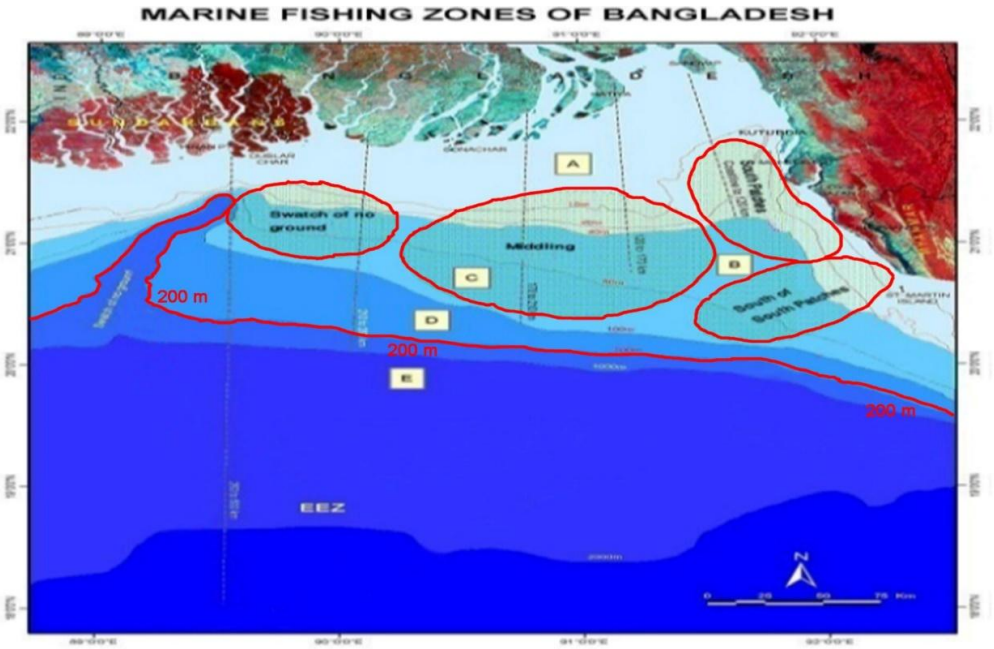
Materials and methods



Study areas

The Bangladesh part of the Bay of Bengal is located between 20° N and 22°30' N latitude, and 89◦ E and 92°30' E longitudes (*Fig. 1a*). The current study mainly focuses on the ecosystem structures of the major fishing grounds of the BoB, which lies from the baseline to 200 m depth zone (*Table 1*) occupying about 90000 km^2 that covers not only 24000 km^2 of inshore area but also 66440 km^2 of all shelf areas. The demarcation line is used to illustrate the depth zone and fishing grounds in the current study (*Fig. 1a, b*). Nevertheless, this area of both offshore and inshore water covers more than 90% of fishing activities in the country (DoF, 2015a) and thus, this model can be designated as 'resettled maritime ecosystem of Bay of Bengal, Bangladesh'. The bottom topography of the shelf sea is usually coarse sandy and muddy with some rocky blotches, but the shallow inshore areas are dominated by muddy bottom. Moreover, the shelf zone down to about 150 m seems to be quite smooth with very limited obstacles to bottom trawling whereas due to existence of precipitous slope trawling is not possible into the waters deeper than 180 m (Khan et al., 1997). The oceanographic features in BoB mainly depend on three key factors: (i) precipitation, (ii) wind direction; and (iii) mass siltation from the river discharges (Lamboeuf, 1987) that have a strong influence on the abundance and distribution of fishes too. The annual average temperature is about 26°C and the yearly average rainfall of the BoB, Bangladesh is approximately 3800 mm where over 80% precipitation is received from June to September (DoEF, 2015). Hence, these areas are treated as a sole homogenous area as they cover a wide range of marine habitats. However, this zone has been carefully chosen for the present study because of the availability of fisheries landing data.

Overview of ECOPATH model (version 6.5)

The software 'ECOPATH' was designed for analyzing trophic dynamic interactions within the fisheries resources systems (Christensen and Pauly, 1992, 1995). This scheme is based on the previous work, which was first demonstrated by Polovina (1984), and it has been widely applied to aquatic systems after successive improvements (Christensen and Pauly, 1993; Pauly et al., 2000). Ecopath is basically a large spreadsheet that is instantaneously keeping track of all the individuals or species and entire feeding interactions occurring within the ecosystem (Christensen and Pauly, 1993). This approach designates an ecosystem at steady-state for a certain period and assumes mass balance in production of any specified prey that is equivalent to the biomass consumed by predators in combination with the estimated captured biomass (e.g. in fisheries) and any other exports from the system, i.e. (*Eq. 1*):

$$B_i \left(P / B\right)_i EE_i = Y_i + \sum\left(B_j\right) \left(Q / B\right)_j DC_{ij} + EX_i \qquad \text{(Eq.1)}$$

B_i represents the biomass of prey i group; P/B_i is the production/biomass ratio of that group; EE_i is the ecotrophic efficiency. Y_i symbolizes the yield (or catch rate of fisheries) of i groups; B_j is the biomass of predator j group and Q/B_j is the food export or consumption per unit biomass of j, DC_{ji} is the fraction of prey i in the diet of j and EX_i is the export of i. When the input values of the parameters of the model are delivered, ECOPATH assesses the missing parameters for each group within the model, e.g. the annual biomass production, the annual biomass consumption or ecotrophic efficiency for each functional groups of the ecosystem.

Model construction

Fisheries landing data

Existing marine capture fisheries of BoB are categorized into two major sub-divisions, i.e. industrial trawl captures and artisanal captures which put up about 95% of the total marine landings. The term 'industrial captures' indicate 'large-scale' which mainly focus on demersal fish and penaeid shrimps in the offshore waters. Artisanal consist of a number of diverse categories of traditional fishing gears and crafts i.e. gillnets, set bag nets (SBN), longline, trammel net, purse seine etc (*Table 2*).

Table 2. *Gear wise landed total marine catches (metric ton) since 2005-06 to 2014-15 (10 years) of Bangladesh*

Year	Fishing types (fleets/gears)						Total marine catch (MT)
	Industrial trawl catch	*Gillnet	*Set bag net (SBN)	*Longline	*Trammel net	*Others (Purse seine)	
2005-06	34084	264627	153687	16224	7399	3789	479810
2006-07	35391	265668	154736	15325	12883	3435	487438
2007-08	34159	274526	159043	13856	12466	3523	497573
2008-09	35429	296634	154164	16724	9680	2013	514644
2009-10	34182	297332	149142	18373	12608	5645	517282

*Fishing gears that used for large-scale commercial catch having different net mesh size (Gillnet, Trammel net and Purse seine consist of fine twin nylon net while Longline consist of hooks and rope lines and Set bag net having sack like bag at it's cod end)

Annual catch data of the last 10 years (from 2005-06 to 2014-15) from the Fisheries Resource Survey System (FRSS) of Department of Fisheries (DoF) of Bangladesh were considered in this study (*Table 2*). Due to the scarcity of an efficient data collecting and recording system, it is not possible to find the total species-wise annual landing data but group-wise data in FRSS. In addition, some of the reference reports (Mustafa, 1999; Nabi, 2007) and reports from the NGO organizations (eg. FAO country data) were also considered for this study.

Ecological or functional groups

Functional groups were characterized based on similarities in feeding habits, bulk body mass, life history parameters, physiological behavior and spatial distributions to keep homogeneous characteristics throughout the species within a group (Yodzis and Winemiller, 1999). More than 82 fish species and 20 types of shrimps and crustaceans are regularly collected by FRSS (DoF, 2015b), thus, over 77 taxonomic families of fish, shrimps, crustaceans, mollusks were included in this study. Representative species were selected based on their significance to fisheries and available information in the statistics (*Table 3*).

Greater preference was given to collect data from those pieces of literatures having local and regional data for every group when life history parameters, diet composition, food consumption, habitat and other information were considered for the modelling (*Table 4*). Where diet data were not available, information from similar ecosystems was

considered. Fishbase (www.fishbase.org; Fröese and Pauly, 2006) has also been applied to link up the gaps whenever possible. Data sources of non-fish groups are given in *Table 5*.

Table 3. *Ecological or functional groups used in ECOPATH model including estimated total catch and percent composition of the maritime ecosystem of BoB, Bangladesh*

Ecological or functional group	Major families or species	Total catch (MT)	Catch composition (%)	Explanation (habitat/fishing type)
1. Sharks	Carcharihinidae Squalidae Sphyrnidae Rajidae	3245	0.97	Down to 30 m depth Mostly Longline, SBN and Gillnet
2. Rays	Rhinobatidae Dasyatidae	2005	0.001	Down to 30 m depth Mostly Longline, SBN
3. Diadromous (Pelagic)	*Tenualosa ilisha* *Tenualosa toli*	215500	39.8	0-100 m depth, mostly by Gillnet
4. Minor Pelagics	Muglidae Gobidae *Setipinna spp* *Coilia dusumieri* *Gudusia chapra* Other Clupeids (Sardines) Engraulidae (Anchovies) Exocoetidae (Flying fish)	17530	3.2	Down to 10 m depth Mostly SBN, Gillnet and few catch by trawls and purse seines
5. Medium Pelagics	Scombridae *Scomberomurus guttatus* *Rastrelliger kanagurta* Other Mackerals *Euthunnus affinis* *Parastromateus niger* *Megalaspis cordyla* *Pterotolithus maculatus* *Decapterus spp.*	29352	5.4	10-100 m depth Mostly Gillnet and few catch by trawls
6. Minor Mesopelagics	Leiognathidae	6240	1.15	10-100 m depth Mostly Gillnet catch
7. Medium Mesopelagics	*Lepturacanthus savala* *Pampus chinensis* *Pampus argenteus* Trichiuridae	27843	5.15	10-100 m depth Mostly SBN and Gillnet, slightly by trawls
8. Medium Demersal	*Lates calcarifer* Lutjanidae (Snappers) Synodontidae (Bombay duck) Sciaenidae (Jew fish)* Pomadasidae	141434	27.7	0-100 m depth Mostly SBN and Gillnet, slightly by trawls and trammel net *Longline also used in fishing

Basic parameters of fish

Estimation of biomss (B): The biomass of each ecological group per unit area in the habitat area (i.e. t/km^2) was estimated in average by using Gulland (1971) formula of $B = Y/F$, where Y represents the annual yield of each group and F symbolizes the coefficient of fishing mortality. Biomass of sharks and other unexploited groups, i.e. benthos, aquatic invertebrates, zooplankton, phytoplankton, and detritus were obtained from various reference data (*Table 5*). In addition, biomass of other crustacean, gastropod and cephalopod groups were obtained from Arreguin-Sanchez et al. (1993) and Christensen and Pauly (1993).

Estimation of production/biomass (P/B): Estimation of this ratio is equivalent to the total mortality (Z) (Pauly et al., 2000) as it was really hard to assess directly. Consequently, this parameter was calculated by obtaining the sum of the fishing (F) and natural (M) mortalities while the entry of *P/B* ratios is optional. The estimated *P/B* values and other population parameters are given in *Table 4*.

Table 4. *Life history parameters of the functional fish groups that were selected for ECOPATH model in the maritime ecosystem of BoB, Bangladesh*

Representative species	L_{inf} (cm)	K (/yr)	Z (/yr)	F (/yr)	M (/yr)	E	References

Phytoplankton	Computed by ECOPATH	-	Fixed Value

Estimation of relative food consumption (Q/B): Consumption/biomass (*Q/B*) ratio of each group was calculated through the following empirical relationship suggested by Palomares and Pauly (1999):

$$log\ Q/B = 7.964 - 0.204\ log\ W_{inf} - 1.965.T + 0.083.A + 0.532.h + 0.398.d$$

where, W_{inf} represents the asymptotic weight that can be calculated from the asymptotic length L_{inf} (one of the VBGF parameter found from ELEFAN routine of FiSAT II package) and length–weight relationships (LWR) of the representative species derived

from various sources (*Table 4*). *T* symbolizes the average annual temperature of that habitat which is expressed as 1000/(*Tc* + 273.1). Here *Tc* represents the annual average temperature of sea surface (26°C) (DoEF, 2015). *A* signifies the ratio of the square of the caudal fin height and its surface area, and *h* and *d* are binary variables demonstrating the feeding class of the fish species, i.e. for detritivore ($h = 0$, $d = 1$) and herbivore ($h = 1$, $d = 0$) and for carnivore ($h = 0$, $d = 0$). The aspect ratio of the caudal fin (*A*), which is the indication of metabolic activity, was collected mostly from the FishBase (Fröese and Pauly, 2006) and also from the laboratory works that were conducted in the Population Dynamics laboratory of Bangladesh Fisheries Research Institute (BFRI) during the data collection period. For other functional groups, *Q/B* was assembled from various literatures (*Table 5*).

Diet composition of every group

Still today, there are no complete investigations about trophic interactions of the coastal and marine ecosystem of Bangladesh. Only limited works have been done on diet composition of fishes in this area (Mustafa and Mansura, 1994; Mazid, 1998). Most of the studies are qualitative in nature where diet items of fish are frequently lumped together. Due to the deficiency of available data on diet composition of functional groups considered, Mustafa (2003), Fishbase (www.fishbase.org) data (Fröese and Pauly, 2006) and the study of Mohamed (2010) were used to complete the diet matrix of this study (*Appendix 1*).

Ecotrophic efficiency (EE)

It provides the fraction of the yield of a group that is consumed within the system (i.e. transported through the trophic web) or caught by any fishery. In most cases, maintenance of the input values that provide the output fraction of EE between 0 and 1 are not possible as EE by definition, its fraction lies between 0 and 1. The EE is used to be computed from additional parameters in the Ecopath model since there is no field calculation to assess this parameter (Christensen et al., 2000).

Estimation of pedigree index

It categorizes the given input sources of an Ecopath through computing the type of source data on which it is based and specifying the probable uncertainty associated with the input. The main principles used here is that input estimated from native data (i.e. from the area covered by the model in question) as a rule is better than the data from elsewhere, be it a guesstimate, derived from other models or derived from empirical relationships. Three scales meet the above principles here, firstly for biomass assessing, second one for the estimating of *P/B* and *Q/B* and the rest for diet composition that are varied between 0 to 1. When the score is close to 0 that indicates the used input data is not rooted within local data, whereas value close to 1 means that are fully rooted within local data. The measure of fit (t^*) is also computed to define how well rooted the given model is in local data.

Evaluating the model through mass balancing method

The parametrization of Ecopath is based on its master equation (*Eq. 1*) which requires mass-balancing states of the functional groups. For this reason, the input

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_31713196
© 2018, ALÖKI Kft., Budapest, Hungary

parameters need to be adjusted in a style to maintain the ecotrophic efficiency (EE) values less than 1. This practice depends on the understanding of which adjustments need to be done (Kavanagh et al., 2004). Primarily, input parameters like biomass, production-consumption rate, food consumption and fishing catch records were set into the basic input tools sheet of the package. Biomass accumulation value was taken as zero as the model was considered to describe an average for one year. Initial running of the routine provided the *P/Q* ratio and EE, but some of them were not balanced as EE values were greater than 1 which pointed out their higher demand in relation with sustainability. Initially EE values were found in case of diadromous pelagic (0.86), minor pelagic (0.96), medium mesopelagic (0.89), minor demersal (0.98), medium demersal (0.99), Gastropods (0.68) and benthos (1.26). On the other hand, some groups showed the exceeded value (one) of respiration/assimilation, which is not possible because respiration value cannot be exceeded from assimilation (Christensen et al., 2000). Thus, new run continues with the revised entries of biomass and diet composition values of the previous run, till to the achievement of mass balance. New run was also performed to obtain EE and gross efficiency values of all groups as it should be less than one. In order to get mass-balance, diet matrix needs to be adjusted because of its variation and instability of food sources and feeding habits throughout the groups. The foremost output of Ecopath modeling is the assessment of trophic levels which sometimes may be beyond expectation. In this case, one must check the diet matrix of the input data and also compare the data with the trophic levels of the same or similar species data of FishBase.

Results

The basic estimates of the mass-balanced models of maritime eosystem of BoB, Bangladesh are given in *Table 6*. Life-history parameters and production-consumption data of non-fish groups are also presented in the *Tables 4* and *5*. Moreover, pre-balancing diagnostics of the maritime ecosystem BoB, Bangladesh model are presented in *Figure 2*.

TL = trophic level, B = biomass, P/B = production rate, Q/B = consumption rate, EE = ecotrophic efficiency, R/A = respiration-assimilation ratio, NE = net efficiency and OI = omnivory index

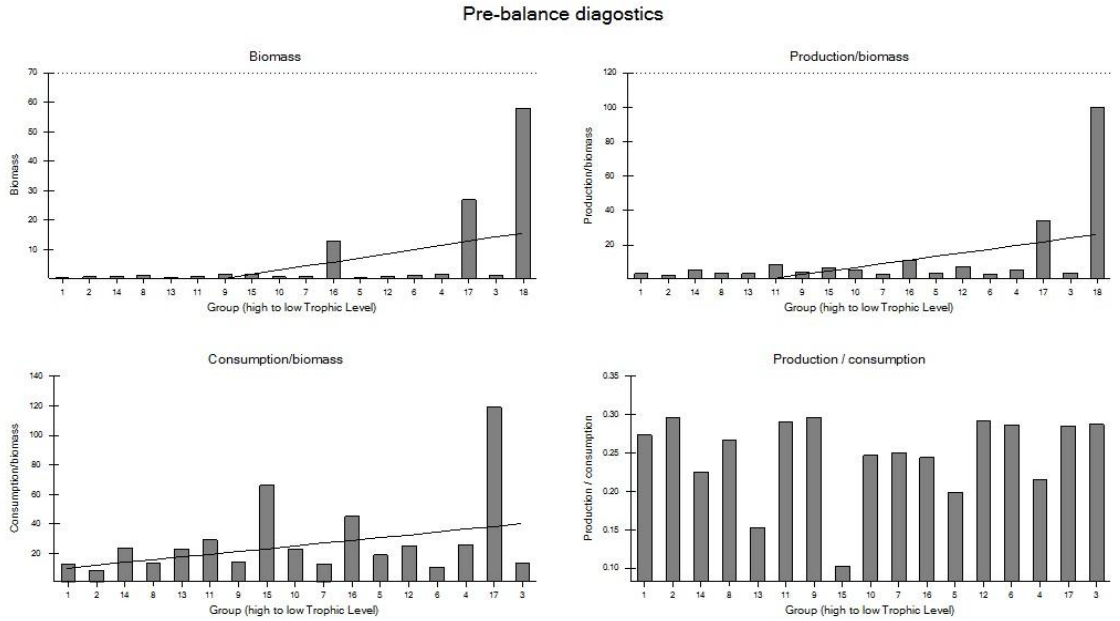

Figure 2. *The figure represents the pre-balancing diagnostics of basic inputs for construction of mass-balanced marine ecosystem model of Bay of Bengal, Bangladesh*

Mean trophic level was found 2.53, with the highest value obtained from sharks (3.45) and rays (3.04) groups followed by medium demersal (2.80) and gastropods (2.85), while the lowest value was obtained from phytoplankton (*Table 6*). In case of estimating ecotrophic efficiency, penaeid shrimps showed the higher EE value (0.99) followed by cephapods (0.98) while diadromous pelagic showed lower value (0.202) and except minor pelagics and demersal all fish groups showed higher EE values (EE > 0.8). Benthos showed the highest rate of respiration–assimilation ratio (0.87) whereas shrimps and crustaceans showed lower. In this model, the maximum omnivory index was found in the apex predators like rays group (0.61) followed by sharks (0.49). The highest *P/Q* values was found in minor demersal group (0.296) while net efficiency was obtained from the rays and minor demersal groups (0.37). Most of the fish groups showed the lower fishing mortality rate over the predation mortalities. In addition,

The resource biomass assembly of the BoB, Bangladesh maritime ecosystem model points out that it is predominantly a low trophic level driven ecosystem. However, the assessed pedigree index of the BoB maritime ecosystem was found 0.631 (*Table 9*) that conformed the developing stage of overall quality of an Ecopath approach as discussed by Christensen et al. (2005). In this study, Shanon diversity index of the maritime ecosystem of BoB was found 1.55 that was also within a satisfactory level (*Table 9*).

Table 9. *The overall system statistics of the maritime ecosystem of BoB (no unit for indices and ratios)*

Parameter	Value	Units
Sum of all consumption	4149.14	t/km^2/year
Sum of all exports	3613.73	t/km^2/year
Sum of all respiratory flows	2186.27	t/km^2/year
Sum of all flows into detritus	3803.94	t/km^2/year
Total system throughput	13753.08	t/km^2/year
Sum of all production	6933.04	t/km^2/year
Mean trophic level of the catch	2.53	
Gross efficiency (catch/net p.p.)	0.0018	
Calculated total net primary production	5800	t/km^2/year
Total primary production/total respiration	2.65	
Net system production	3613.73	t/km^2/year
Total primary production/total biomass	51.24	
Total biomass/total throughput	0.008	/year
Total biomass (excluding detritus)	113.2	t/km^2
Total catch	10.5	t/km^2/year
Connectance Index	0.325	
System Omnivory Index	0.285	
Ascendancy	35.4	
Overhead	64.61	
Ecopath pedigree index	0.631	
Measure of fit, t*	3.25	
Shannon diversity index	1.56	
Throughput cycled (excluding detritus)	328.2	t/km²/year
Predatory cycling index	5.34	% of throughput without detritus
Throughput cycled (including detritus)	403	t/km²/year
Finn's cycling index	2.93	% of total throughput
Finn's mean path length	2.47	

In addition, in the flow diagram of the systems, the greatest flows were observed from phytoplankton to zooplankton and from detritus to aquatic invertebrates, benthos, and others that are presented in *Figure 3*. The direct and indirect impacts throughout the groups including their exploiting gears are also shown in *Figure 4*.

Discussion

The relative biomass of the ecological groups of this study initially estimated from the Ecopath model that revealed considerable differences due to three issues. Firstly, all groups were not equally captured through all the gears and same catchability was not found in every gear types. Therefore, some may be under or over-exploited in the survey. Secondly, Ecopath computes the biomass by the data of given catch. So, the larger the catch, the greater the biomass estimate. Lastly, the estimated catch data was mostly on group-wise rather than species-wise which may led to comparatively diverge catch value for different species. The estimated biomass of the BoB maritime ecosystem varied from 0.42 to 1.65 mainly for targeted catch groups i.e. demersal fishery and lowest for the shark groups due to absence of large predators.

Diet matrix preparation for this ECOPATH model was the most difficult task due to lack of earlier studies on feeding ecology. In order to make the study realistic some stomach content studies and diet isolations have been done. But most of the qualitative data provided by external studies were converted into a quantitative form for preparing the diet matrix. Although this model contains many groups (19 groups), the diet matrix

© 2018, ALÖKI Kft., Budapest, Hungary

comprises some low proportions. In fact, these values are hard to determine from field data. This nature might be significantly influenced the ultimate result.

Production-consumption (*P/Q*) rate of less than 0.3 may assist as a diagnostic feature in a balanced model. In most cases, the *P/Q* values of all possible functional groups range from 0.05 to 0.3, but some exceptions may happen in case of coral reefs, fish larvae, nauplii, bacteria and other minute, fast-growing organisms. The present study supports this concept for all groups which was 0.103 to 0.296. Demersal groups showed higher *P/Q* ratio than most of the pelagic groups (*Table 6*), this may be due to higher consumption rate of benthic communities and some predatory behavior of few demersal species. Nevertheless, pelagic species are typically herbivores and generally dependent on phytoplankton and detritus.

One of the most significant feature of an ecosystem is to assess ecotrophic efficiency (EE) (Christensen et al., 2000) which is mainly the fraction of production consumed by predators. In the BoB model, the EE values varied extensively from 0.24 to 0.99 (*Table 6*). Normally, just over the zero value points out the 'group' was not consumed until now by any other groups throughout the system while close or equal to 1 designates a heavily preyed group, where there are no individuals left to die of old age. Only sharks (0.16) showed lower EE value which was realistic and expected as for the top predators (Christensen et al., 2000). In addition, in both cases of phytoplankton and detritus, the EE values were less than 1.0 that was settled with the systems proposed by Christensen and Pauly (1992) that indicates more producers would have entered than left. However, the estimated EE value of detritus (0.15) was the lowest among the groups probably due to absence of typical primary consumers in the ecosystem. Out of all targeted groups, the estimated EE value of penaeid shrimps and cephalopods were shown the highest values over 0.9 (*Table 6*) that were likely the consequence of greater fishing pressure and predation. Similar reports were found from Islam et al. (1993) that penaeid shrimps were highly exploited throughout the maritime waters of BoB.

Mean trophic level (TL) is the vital index of the complete exploitation level of fisheries groups low in the food web and its effect on predator and prey species. Fishing down the marine food web, in which fishing fleets gradually target species minimum in the food web, may or may not be the reason for decline in global mean trophic levels of catches. The BoB maritime ecosystem had a mean trophic level of 2.53, with the highest 3.45 (sharks) and lowest being 1 (phytoplankton and detritus) (*Fig. 3*). Except the predators' maximum group biomass and ecological production occupied the place at around TLIII (*Table 6*). Ecopath generally computes trophic levels higher than IV (Ulanowicz, 1995). A total of 9 TLs were counted in this study (*Table 8*), which may be due to the cannibalistic characters of the peak trophic levels (Haputhantri et al., 2008). Therefore, the trophic accumulation routine in Ecopath gathered the 19 groups in a normal food chain with ten trophic levels where primary producers (TLI) comprised detritus and phytoplankton (*Table 7*). The result displayed that the maximum flow of the system was transferred from secondary consumers mainly composed of zooplankton group followed by TLI where phytoplankton was the single contributor. This output reveals the significance of zooplankton for the activation of trophic level of the BoB maritime ecosystem which is dominated by lower trophic level of fisheries resources as reported by Hossain (2003). For each group, the flow to the detritus contains non-absorption rate of diet and those components of the group that die of old age, diseases, etc. The detritus flow indicates that almost every functional group of the BoB maritime

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_31713196
© 2018, ALÖKI Kft., Budapest, Hungary

ecosystem are severely exploited by either excessive fishing pressure or predation along with other mortalities, i.e. cannibalism (*Table 7*).

Gross efficiency of the system was 0.0018 indicates less crowd of target fisheries in the food chain. Actually increasing trend of gross efficiency index represents the fisheries 'development' which is generally much lesser than 1.0 as globally it is about 0.0002. This results is almost similar with the by Mohamed et al. (2005) and Ullah et al. (2012). In addition, the average transfer efficiency (TE) was 11.02% where flows from phytoplankton were demonstrated more essential than flows from detritus demonstrating a significant planktonic food chain throughout the maritime ecosystem of BoB (*Table 8*). Actually, transfer efficiency acts as an index of the significance of detritus in a system. The TEs for TLII, as suggested by Ryther (1969), are 15% for marine areas, but the most common range is 10–20% (Odum, 1971; Barnes and Hughes, 1988). However, the accounted of all flows was 11.89% (*Table 8*) which covers the above range demonstrating ecosystem maturity (Odum, 1971). In addition, estimated TEs of the trophic levels III, IV and V of this study were within the standardize range of 10–20% for coastal zones (Odum, 1971; Barnes and Hughes, 1988). Hence, the existence of some dominating fish groups having higher EE value around TL III may be the basis of the higher TE in TLIII.

Mixed trophic impacts may be direct or indirect i.e. as for a prey; a group causes a positive impact on others while as a direct predator, impact is negative. In the current observation, zooplankton, phytoplankton, and detritus were showed to have a positive impact on most other groups. The impact was greater on their direct consumers, i.e. most of the pelagic fishes depend on either phytoplankton or detritus or both. Negative impacts were due to benthos or zooplankton as a consumer of aquatic invertebrates, phytoplankton, and detritus or as a competitor for the same food source. Phytoplankton and detritus were shown a significant positive impact on pelagic groups and moderately positive on some of the demersal groups whereas barely any impact was found on penaeid shrimps and cephalopods (*Fig. 4*). The system package designated that the impact on detritus would be negative since detritus normally accompanied by phytoplankton in the regimes of several primary consumers. Thus, upsurge of phytoplankton would stimulate primary consumers to forage more detritus. Zooplankton had significant negative impact on themselves due to the existence of greater quantity of carnivorous zooplankton and relatively low negative impact on phytoplankton, which also indicates the existence of herbivory zooplankton in that ecosystem. Remarkable positive impact of detritus was observed on most of the functional groups whereas detritus had neither positive nor negative impact on itself in that ecosystem. Comparable results are also observed in other ecosystems (Christensen and Pauly, 1993). Fishing fleets also negatively affected several groups i.e. pelagic groups were negatively impacted by Gill net whereas demersal by SBN operations. Thus, it can be concluded that increased fishing pressure by gillnet and SBN in the BoB maritime ecosystem would have generated more negative impacts on fish groups, especially on the demersal and predators.

Total system throughput (*TST*) is the sum of all flows (e.g. total consumption, total respiration, total export and total flows to detritus) in a system which represents the 'size' of the entire system in relation to flow (Ulanowicz, 1986). The estimated *TST* for BoB was relatively higher 13753 t/km^2/year (*Table 9*) but consistent with tropical marine ecosystems with much turnover. This result was also similar (*Table 10*) with the

© 2018, ALÖKI Kft., Budapest, Hungary

studies of San-Pedro Bay, Phillipines by Campos (2003) and Karnataka, India by Mohamed et al. (2005).

The ratio of total primary production and total respiration (*PP/R*) is considered by Odum (1971) to be a significant ratio to describe the 'maturity' of an ecosystem. Previously, a system needs to be developed for being balanced as the production is expected to exceed respiration that provides a ratio greater than 1. Finally, in 'mature' systems, the *PP/R* ratio should be 1; when energy is constant that is roughly balanced by maintenance (Odum, 1971). The *PP/R* value was found 2.65 which was higher than 1, thus, it is concluded that the BoB marine ecosystem is not so developed or still in developing stage. The net system production value of 3613.7 t/km²/year was assessed for the BoB maritime ecosystem, which again points out the BoB is still developing but also little bit matured comparing with the other studies. Generally, system production is greater in immature systems and nearby zero in maturity stages. The net system production value of British Columbia shelf ecosystem were also provided 4106 t/km^2/year (*Table 10*) which was greater than the current value. This may be happened due to absence of large predators as well as lower trophic level as this system completely based on TLII to TLIII. Moreover, the ratio between a system's primary production (*PP*) and total biomass (*B*) was 51.24, which was higher and also indicates some sorts of immaturity. Production exceeds respiration largely in immature systems and therefore it will influence the system's *PP/B* ratio which dimension is per unit time, and it can take any positive value.

The available ecosystem energy flow directly supports the total system biomass which can be expected to rise maximum for the utmost maturity stages of a system (Odum, 1971). The ratio of *B/TST* is directly proportional to the system maturity, where the estimated value tends to be low during the ecosystem development stage and increases as a purpose of maturity (Christensen, 1995). From the present study, system biomass/throughput ratio was found 0.008 being lower compared with those given by Ullah et al. (2012); Mohamed et al. (2005); Garces et al. (2003), which showed the status of comparative maturity of the ecosystem (*Table 10*). The yield of a group throughout a system is size-specific that has been revealed that the inverse of a group's production/biomass ratio is a degree of size (Christensen and Pauly, 1993). However, the estimated total biomass (excluding detritus) 113.2 t/km^2 was higher than the study of Ullah et al. (2012) but lower than the value of Mohamed et al. (2005), as their study based on the adjacent area of BoB. But the total catch (10.5) was comparatively higher than the above studies which may be due to excessive artisanal fishing pressure in Bangladeshi waters.

The trophic flows to detritus were observed highest for zooplankton and smallest for top predators. For each group, the flow to the detritus contains non-absorption rate of diet and those components of the group that die of old age, diseases, etc. The detritus flow indicates that almost every functional group of the BoB maritime ecosystem are severely exploited by either excessive fishing pressure or predation along with other mortalities, i.e. cannibalism (*Table 7*). The cycling matter and energy flow is considered as a vital process of any active natural ecosystems (Odum, 1969). The percentage of 'cycling index' is the fraction of an ecosystem's throughput that was developed by Finn (1976). It was basically intended to calculate Odum's (1969) system maturity. However, its explanation was not as simple as originally conceived that intensify recycling as a system matures. Detritus played a supreme role in all flows (cycled) in the BoB model where the total cycled flow was 328.2 t/km^2/year. The Finn's cycling index was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_31713196
© 2018, ALÖKI Kft., Budapest, Hungary

obtained 2.93%, which was lower compared with the study by Mohamed et al. (2005) for Karnataka, India and Ullah et al. (2012) for coastal ecosystem of BoB. Similar close output was reported by Christensen and Pauly (1993) for Yacatan and Northern Gulf of Mexico. Actually, Finn's cycling index gives the proportion of flow in a system that is recycled compared with total system throughput and immature systems give lower value while matured provide higher. Finn's mean path length is the measurement of the mean quantity of groups that a unit of flux will experience from its entry into the system until it leaves the system. Over-all 680 pathways was obtained from the BoB maritime ecosystem and the mean length of pathways was computed as 6.33, was found a little bit higher when compared with the range (2.86–4.95) reported by Baird and Ulanowicz (1993) for the four estuaries. Nevertheless, the lower number of pathways proves the simplified feature of that ecosystem and it is cycled through detrital pathways.

The connectance (CI) and system omnivory index (SOI) of the BoB maritime ecosystem was 0.322 and 0.285 respectively. In fact, the CI can be predictable and associated with maturity, which can be define by the ratio of 'the quantity of actual links with the number of possible links'. The connectance index is mostly determined by the level of taxonomic aspect used to characterize prey groups. On the other hand, the system omnivory index is proposed as a substitute which is defined as the mean omnivory index of all consumer's weight-mass by the logarithm of each consumer's consumption. The SOI is a measurement of how the diet interactions are scattered between trophic levels. The SOI is stimulated by apparent drawbacks of the CI. In the development stage of an ecosystem, CI would be close to 1 in most systems and increase maturity reduce the value of connectance. Moreover, a prey having the same 'score' in case of connectance index whether it supports 1, 10 or 100% of its higher trophic's diet.

Another important fact is ascendancy, which is a measurement of system growth, and development of network links whereas proportion of a system's capacity not considered. When the system's capacity is considered, it is known as system's overhead, which was the reserved energy of an ecosystem (Ulanowicz and Norden, 1990). The relative values of ascendancy (35.4) and system's overhead (64.6) of the maritime ecosystem of BoB indicated the ecosystem's stability and some sorts of maturity. This proved that maritime ecosystem of BoB have significant backup strength also have the capacity to control any pressure situations through fast reformation to the original stages.

Conclusion

The software outputs indicate that the maritime ecosystem of BoB is steadily reaching maturity, although it is still considered to be in a developing phase. Excessive artisanal fishing pressure is the main hindrance to develop ecosystem quality. One of the major challenges for this multispecies ecological modelling was the scarce of studies on the feeding ecology of the various functional groups. Therefore, further studies should be required in order to get more specific estimations for a multispecies approach to improve basic inputs of the system and also improve the catch landing statistics of the national record.

(Received 10th Feb 2018; accepted 9th May 2018)

Abstract. Land use change (LUC) particularly the conversion of forest to other land uses, determines the scale of forest carbon shifts. Here, remotely sensed data Multispectral Satellite Images (MSI) of the study area for the year 1990, 2000, 2010, 2017 and geographic information system (GIS) tools were used to analyze the land use change patterns. For biomass calculation and related forest carbon losses in the Margallah Hills National Park of Pakistan the field inventory data were collected by random forest sampling from 1990 to 2017 . Our results showed that during the period from 1990 to 2017, the area under dense forest decreased by 11.14% (0.41% yr^{-1}), while the area under open forests increased by 4.28% (0.15% yr^{-1}). Similarly, agricultural land and settlements increased by 53.17% (1.96% yr^{-1}) and 67.78% (2.51% yr^{-1}) respectively, during the same period. The conversion of forests into other land uses resulted in the reduction of carbon value. In 1990, carbon loss is estimated at 5531.5 $MgC \cdot yr^{-1}$ (7.22%) of the total carbon pool. Overall, land use change released 154 GgC (5.70 $GgC \cdot yr^{-1}$), highlighting that land use change significantly alters carbon dynamics of the Park. Land use change and related carbon losses indicating the magnitude of anthropogenic disturbances in the Park. The preservation and rehabilitation of degraded forest as well as reforestation of the converted forests are necessary for forest carbon conservation meeting emissions reduction obligations of the Kyoto Protocol.

Keywords: *remote sensing, forest loss, satellite images, land use change, carbon loss*

Introduction

Land Use Change (LUC) is the modification of the earth's surface due to human activities which result in the disturbance of the Earth's natural ecosystem and environmental processes (Lambin, 1997). The availability of LUC data has had an important role in advancing research and providing long-lasting solutions to environmental and ecological policymakers (Zhao et al., 2004; Ullah et al., 2016; Mukete et al., 2017). For instance, LUC has become the key issue in many disciplines like forestry, agriculture, environmental sciences, geology and hydrology (Weng, 2001). Additionally, LUC has been greatly applied in studies relating to soil degradation, cropland loss, urban expansion, desertification and deforestation within the past three decades. LUC has been known to cause long-term effects on forest

ecosystem functions such as a net decrease in forest area globally from 31.6% to 30.6% since 1990 (FAO, 2015).

The application of MSI in LUC studies has gained precedence in detecting and estimating both spatial and temporal dynamics of forest cover changes. In our study remote sensing data at periodic intervals and Geographic Information System (GIS) provide information for land use change analysis, modeling, and management (Sudhakar Reddy et al., 2008; Kennedy et al., 2009). For instance, using LANDSAT data and digital analysis the detection of land degradation due to waterlogging and soil salinization occurring over a 10-year period in China was enabled(Gao and Liu, 2010). Similarly, Rembold et al. (2000) used LANDSAT TM data between 1972 and 1994 to estimate land cover changes in central Ethiopia. This is because monitoring through satellite images is not only cost-effective and fast but also provides reliable land use and land cover change detection information (Martin and Tracy, 2007). Within the past three decades, various change detection techniques using satellite imagery have been developed including post-classification comparison (PCC), image differentiation, principal component analysis (PCA) and vegetation index differencing (Lu et al., 2004). Among these, many studies have found the post-classification comparison to be the most accurate procedure especially as it represents the nature of changes as they occur. This method is also thought to reduce problems associated with multi-temporal images recorded under different atmospheric and environmental conditions (Yuan et al., 1999).

Forests are the largest sources of global terrestrial carbon sink, while LUC is the key factor which determines the extent of carbon sink over time (Pan et al., 2011). Forests have a key role in carbon sequestration which is distorted by LUC and land management activities (Abatzoglou et al., 2017). From 1985 to 1990 LUC and land management activities released over 156 PgC into the atmosphere, particularly in tropical areas where deforestation was observed to have caused approximately 60% of these emissions (Houghton, 2003). Since the 1980s, LUC in Forest land and grassland has been responsible for forest carbon sink in North America and Europe (Nabuurs, 2013). LUC associated with deforestation and land degradation emits CO_2 and other greenhouse gases and therefore it emerged as a burning issue in the scientific community (Thompson et al., 2011). However, in a recent economic survey, LUC would affect over 36% of the United States land area. This is attributed to increased urban land and where urban developmental factors such as culture and socio-economic would be major contributors (Radeloff et al., 2012). In addition, there are also chances and risks of forest conversion into new land uses including agriculture and settlements (Searchinger et al., 2008). Furthermore, concerns about climate change have forced many countries to monitor terrestrial carbon. The Inter-Governmental Panel on Climate Change (IPCC) guidelines for national greenhouse gases strictly requires monitoring of carbon pool through the effect of land-use change and wood removal (IPCC, 2006).

LUC and their associated impacts on forest cover have been widely addressed by the United Nations Framework Convention on Climate Change (UNFCCC). The UNFCCC has also developed guidelines for member countries to measure LUC and related activities. Pakistan as a member of the UNFCCC and IPCC has to follow the proposed greenhouse gas emissions and removal related guidelines. Only about 4% of Pakistan's total land area is under forest which is under threat from deforestation (Cochard and Dar, 2014).

In Pakistan, most studies focused on sequestered carbon in different forest types such as in subtropical forests (Nizami, 2012) and in forest plantations (Ahmad and Nizami, 2015; Ahmad et al., 2015; Saeed et al., 2016). Similarly, studies were conducted about the carbon stock in Oak Scrub Forest of Sheringal Valley Dir Kohistan (Khan et al., 2015), and the carbon stock in Chichawatni irrigated plantation in Pakistan (Muhammad et al., 2017). Most of these studies evaluated carbon stocks in particular land use types (Ahmad and Nizami, 2015), while others focus on land use change and deforestation patterns (Hassan et al., 2016). However, none of these studies has been carried out on LUC and their related carbon losses in protected areas. In order to determine LUC and carbon induced emissions in a protected area in Pakistan, the present study in Margallah Hills National Park (MHNP) of North West of Islamabad aims to determine LUC and carbon induced emissions in a protected area in Pakistan.

MHNP has subtropical broad-leaved evergreen, subtropical chir pine forests and rich in flora and fauna. It is one of the best-protected areas in Pakistan providing medicinal plants, economic and aesthetic values to surrounding communities and the country. However, in the past three decades, land use change and deforestation have ultimately released considerable amounts of carbon into the atmosphere. This study, therefore, presents a comparative analysis of the temporal LUC and forest carbon-loss estimation in MHNP. The main objectives of the study includes the pattern of LUC in the MHNP during the period 1990, 2000, 2010 and 2017, their impacts on carbon dynamics and to analyze the major drivers of LUC in the MHNP.

Materials and methods

Study area

The study area is located at the foothills of the Himalaya Mountains around the north east of Islamabad, the MHNP (73°7'3.32"E, 33°41'59.61"N and 73°1'34.07"E, 33°45'2.87"N) (WWF, 2009) covers an estimated area of 17,386 hectares (ha) and composed of diverse ecological resources MHNP is dominated by *Acacia modesta, Quercus incana, Pinus roxburghii, Dodonea viscosa, Olea ferruginea* and *ziziphus mauritiana* and also have plant spp having medicinal value like *Lantana camara* (Asma et al., 2009). This park has about 1700 flowering species, more than 50 species of grasses 53 species of ferns and it is also rich in wildlife having common leopard, jackal, rhesus monkey, barking deer, porcupine, foxes and wild boars (WWF, 2009). The MHNP with the altitude of 469-1560 m, as shown in *Figure 1,* is made up of rugged slopes and gullies and the soil are characteristically composed of limestone (Butt et al., 2015). Temperature ranges between -3.9 °C in January to 41.6 °C in June and average annual rainfall ranges between 245 and 1142 mm (PMD, 2015).

Data acquisition

Satellite images (LANDSAT) were obtained from United States geological survey (USGS) (http:// glovis.usgs.gov), for March 1990, 2000, 2010 and 2017. The images were selected based on quality and minimum cloud cover, see *Table 1.* In addition to using satellite images, ancillary data were collected which included topographic maps, aerial photographs, and ground truth data. In March 2017 using GPS, ground truth data in the form of reference points were collected which was used for image analysis and accuracy assessment.

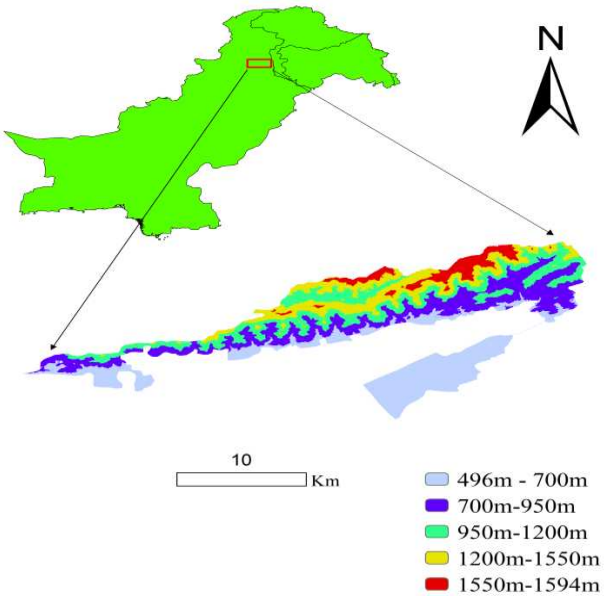

Figure 1. *Map of Pakistan and elevation map of Margallah Hills National Park (MHNP)*

Table 1. *Satellite sensors specification*

Sensor	Year	Band/color	Resolution	Source
Landsat 8 OIL imagery	2017	Multispectral	30 m	USGS, glovis
Landsat 5 TM imagery	2010	Multispectral	30 m	USGS, glovis
Landsat 7 ETM imagery	2000	Multispectral	30 m	USGS, glovis
Landsat 5 TM imagery	1990	Multispectral	30 m	USGS, glovis

Preprocessing of satellite imagery

Image pre-processing was preceded by the acquisition of topographic maps at the scale of (1:50,000) for the study area, obtained from a survey of Pakistan. The map was first scanned and exported into the processing software ArcGIS 10.2 and ENVI 5.1. Image pre-processing was necessary before the classification and change detection, for establishing a relationship between acquired data and biophysical processes (Abd El-Kawy et al., 2011). To correct the geometric distortion of the satellite image geometric correction was performed from the topographic sheet as well as from the GPS by selecting 20 Ground Control Points (GCP's) around the study area. Then the geometrically corrected image was used to clip the region of interest (ROI). After that, the image was classified into five different classes such as dense forest (DF), open forest (OF), agricultural land (AL), settlements (SM), and water bodies (WB) with corresponding classes by assigning per-pixel signatures. On the bases of different digital number (DN), different colours were assigned to each landscape to differentiate them. Later on, Atmospheric, radiometric and topographic corrections were performed using ArcGIS 10.2 and ENVI 5.1. Training samples for each predetermined class were selected by delimiting polygons and spectral signatures for each land cover type derived from satellite imagery. Supervised classification was performed by using a maximum likelihood algorithm. To improve the quality of classification and to classify the un-classed pixels, post classification smoothing was performed.

Accuracy assessment

The accuracy of the classified maps was crosschecked by 200 random GCPs. GCPs were randomly selected after which the user and producer accuracy were calculated for each LUC. Finally, the Kappa statistics were calculated by the observed and expected using *Equation 1* (Chandra and Ghosh, 2006).

$$k = \frac{\text{Observed} - \text{Expected}}{1 - \text{Expected}} \quad \text{(Eq.1)}$$

Kappa statistics for 1990, 2000, 2010, and 2017 were 0.90, 0.91, 0.87, and 0.91 respectively.

Land-use change detection map

Post-classification change detection technique was performed by using ENVI 5.1. LUC detection map was developed by using the classified map of 1990 and 2017; the map of 1990 was used as the base map (*Fig. 5*). In an urban environment, the post classification has been used by various researchers effectively due to its efficiency in location, nature, and rate of change detection (Hardin et al., 2007). The annual rate of change in each land use type was measured according to Puyravaud (2003; *Eq. 2*):

$$r = \{\frac{1}{(t_2 - t_1)}\} x \ln(\frac{A_2}{A_1}) \quad \text{(Eq.2)}$$

where, A_1 and A_2 are the areas of land use type at different time t_1 and t_2

Carbon inventory

Biomass carbon was assessed by field inventory in dense forest (DF) and open forest (OF). A total 150 sample plots of 20 × 30 m were taken randomly in the study area (75 plots in DF and 75 in OF). In each sample plot, the diameter of all trees greater than 4 cm was measured at breast height (DBH). The height of 20 trees per species was recorded, sufficient to construct DBH/height function of a specific plot. Abney's level was used to measure the height of the trees. The volume of all trees present in the sampling sites was measured using *Equation 3* (Newbery, 2009), and total biomass $kg \cdot ha^{-1}$ was calculated by multiplying biomass with the wood density kg m^{-3} of particular species using IPCC (2006) proposed guidelines.

$$\text{Volume of tree } (m^3) = (\frac{\pi}{4}) \times d^2 \times h \times f \quad \text{(Eq.3)}$$

where d^2 is the square of DBH, *h* is height and *f* is the form factor. Biomass of tree was calculated by using stem volume (m^3) and multiplying it by the wood density kg m^{-3}. The wood density values were confirmed by previous research and reports. Biomass expansion factor (BEF) for subtropical forests of Pakistan was used to determine the biomass of entire forests (*Eq. 4;* Haripriya, 2002; IPCC, 2006).

$$\text{Biomass } (kg) = \text{Volume}(m^3) \times \text{Wood density } (kg \cdot m^{-3}) \quad \text{(Eq.4)}$$

For determining the biomass, carbon values of understory vegetation (USV) sub-plot of 4 × 4 m was established in each sample plot. First, the vegetation in each plot was harvested, their fresh weight was recorded, and all the harvested materials were put into the labeled bags for further analysis. Then, the samples were dried in an oven at 72 °C for 48 h and their dried weights were measured for biomass. Similarly, litter, dead wood and cones present in the sub-plot were also collected, and followed the procedure mentioned above for USV for biomass carbon assessment. The soil samples were collected from the selected plots at the depth of 0-15 cm and 15-30 cm with the help of soil auger and core sampler in three replications. Each soil sample was weighed and labelled in the field. Core sampler of 0.0001256 m^3 (diameter = 4 cm, height = 10 cm) was used to measure the bulk density of each soil sample. The soil samples were brought to the laboratory for further analysis. To measure the soil organic content the method of soil oxidizable organic carbon given by Walkley (1934) and Rayment (1992) was used. Carbon was determined by using total plant biomass convertible factor that is the representative of average biomass content of the plant. According to this convertible factor, the carbon content is 50% of the total plant biomass, this factor is used worldwide (Brown and Lugo, 1982; Saugier et al., 2001). The carbon values in the soil were (MgC ha^{-1}) measured by multiplying the bulk density, carbon concentration and the thickness of the layer (Ahmad and Nizami, 2015).

Carbon loss assessment

The deforestation resulted in the conversion of forestland into AL and SM. Similarly it also resulted in the conversion of DF to OF. We assess the net loss of carbon value associated with deforestation. Change in carbon is determined by *Equation 5* (Zheng et al., 2011)

$$\Delta C = TFC_{t2} - TFC_{t1} \quad \text{(Eq.5)}$$

The annual rate of carbon loss is determined by *Equation 6:*

$$\Delta C = \frac{(TFC_{t2} - TFC_{t1})}{(t_2 - t_1)} \quad \text{(Eq.6)}$$

ΔC = Carbon loss or gain
TFC_{t2} = Total forest carbon at time t2
TFC_{t1} = Total forest carbon at time t1

Results

Land uses and Land use change

Our image analysis results showed that in 1990 the major land uses in the study area were a dense forest (DF), open forest (OF), agricultural land (AL), settlements (SM), and water bodies (WB). The land-use change statistics (*Table 2*) showed that from 1990 to 2017, the area under DF and WB were decreased, while we saw increase in the area under OF, AL, and SM as shown in *Figures 2, 3, 4* and *5,* respectively. In 1990, the area under DF was 55.87% and it was reduced to 49.55% in 2017. The conversion of DF to other land uses resulted in a 6.32% decrease in the area under DF. Our results of LUC

SM	662.5	3.8	760.5	4.37	940.3	5.4	1111.6	6.39
WB	544.2	3.1	534.9	3.07	528	3.03	520	2.99
Total	17387	99.97	100	17286	99.02	17386	100.32	17386

Table 3. *Periodic/annual pattern and trend of land uses and LUC*

Land use categories	1990-2000 change (%)	Annual change (%)	2000-2010 change (%)	Annual change (%)	2010-2017 change (%)	Annual change (%)
Dense vegetation	-4.54	**-0.453**	-2.88	**-0.288**	-4.14	**-0.591**
Open forest	+3.15	**+0.315**	+0.257	**+0.025**	+0.831	**+0.118**
Agricultural land	+9.21	**+0.92**	+21.22	**+2.12**	+15.69	**+2.22**
Settlements	+14.79	**+1.47**	+23.64	**+2.36**	+18.21	**+2.2**
Water body	-1.7	**-0.17**	-1.2	**-0.12**	-1.5	**-0.12**

The results showed that during the period 1990-2000, DF decrease by 4.54% (0.453% yr^{-1}), during 2000-2010, DF reduced by 2.88 (0.288% yr^{-1},) and 4.14% (0.591% yr^{-1}), respectively as shown in *Table 3*. Apart from a decrease in area under DF, major changes were also observed for WB, OF, AL and SM (*Table 4* and *Fig. 6*). Our results showed that a total of 1268.78 ha forest land (DF, OF) has been converted into other land uses from 1990 to 2017 and Indicating the increasing scale of anthropogenic pressure on forest resources of the Park as shown in *Figure 7*.

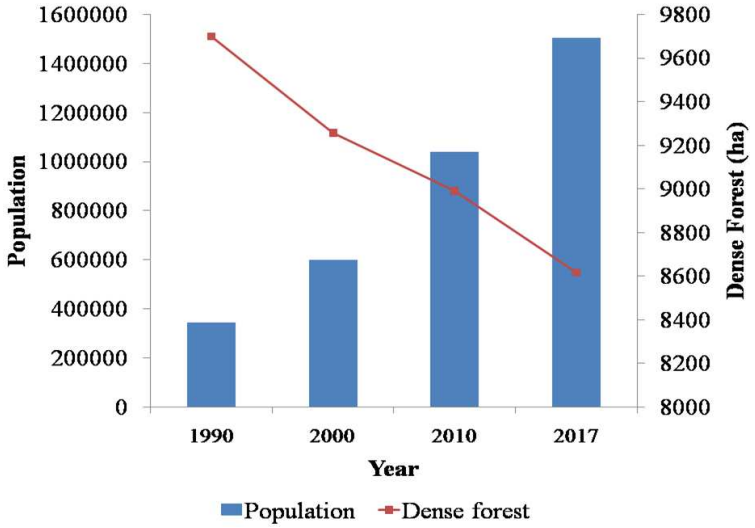

Figure 7. *Increase in population of Islamabad city*

Carbon dynamics and carbon losses

The estimated carbon value recorded in DF is 164.14 ± 8.96 MgC ha^{-1}, whereas it is in 94.62 ± 8.75 MgC ha^{-1} in OF (*Table 5*). In each forest, the higher value of carbon is recorded for upper storey vegetation (UPSV) followed by soil, understorey vegetation and litter dead wood. The results of the total carbon stock (*Table 6*) showed that in 1990 the total forest carbon stock was 2131 GgC. Similarly, the total forest carbon stock was reduced in 2000, 2010 and 2017 i.e. 2076 GgC, 2034 GgC, and 1987 GgC respectively. These findings revealed the decreasing trend in carbon value associated with LUC. Taken together as a whole the present results indicated that LUC accounted for 154 GgC loss from 1990 to 2017.

Table 5. *Carbon pool comparison*

Carbon pool	Dense forest (MgC·ha^{-1})	Open forest (MgC·ha^{-1})
Upper storey	105.69 ±22.58	40.78 ±24.55
Understorey	2.3 ±0.27	1.81 ±0.41
Litter/dead wood	1.13 ±0.32	0.96 ±0.22
Soil	54.97 ±12.67	51.06 ±9.81
Total carbon	164.14 ±8.96	94.62 ±8.75

Discussion

Land use and land cover change

Natural forests are mostly located in the temperate and subtropical regions of Pakistan where LUC and deforestation are continuous processes. The increase in SM and AL from 1990-2017, indicate the scale of LUC in the park. We found that in the last 27 years SM has increased by 67.78% as compared to our base year 1990. Between 1990 and 2017 SM for Islamabad increased from 16,281 to 51,039 ha as shown in *Figure 8*. This increase is attributed to the migration of people from villages to cities for better health facilities, education, and job opportunities. Also, settlement expansion (built-up areas) around Rawal Lake, have caused an increase in SM in and around the park (Hassan et al., 2016). Similarly, due to unsustainable agriculture practiced by local villagers, AL expanded from 770.9 ha in 1990 to 1180.8 ha in 2017.

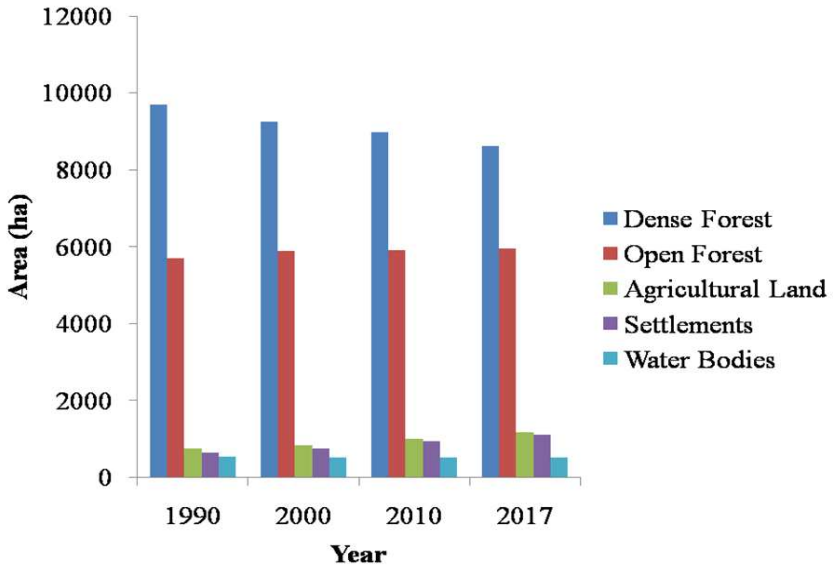

Figure 8. *Temporal change in classes*

Increase in settlements from 10 villages in 1990 to over 20 villages in 2017 may have induced AL expansion in the MHNP due to population pressures (Khalid et al., 2015). Related studies also show settlements to have increased by 23% in the MHNP between 1992 and 2012 (Hassan et al., 2016). The periodic and annual rates of increase in the OF, AL, and SM were notably higher between 2010 and 2017. This may be due to an increase in population between 2010 and 2017 per km^2 of Islamabad (PBS, 2017). This increase in population around the park causes major shifts in LUC. Overall, an average annual loss in DF for MHNP is 0.42% which is much higher than the 0.21% average annual deforestation from terrestrial protected areas of the Philippines (Apan et al., 2017).

For instance, the DF in the base year 1990 was 9697.1 ha and decreased to 8616.69 ha in 2017, as shown in normalized difference vegetation index (NDVI) map (*Fig. 9*). This decreasing trend in DF is similar to that reported by Malik and Husain (2003) which was 59.4% in 1990 and decreased to 56.3% in 1998. The conversion of DF into OF in and around the park could be attributed to unregulated and illegal logging

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_31973214
© 2018, ALÖKI Kft., Budapest, Hungary

by local villagers for fuelwood, livestock grazing, and forest fires. As elsewhere around the globe, forest fires are a regular part of MHNP especially during the drier months of summer (Chanthalath et al., 2017). These fires usually damage the DF more severely as compared to OF. The continuous reduction in the area under DF and increase in areas under OF, AL, and SM showed DF to have been mainly converted into OF, AL, and SM.

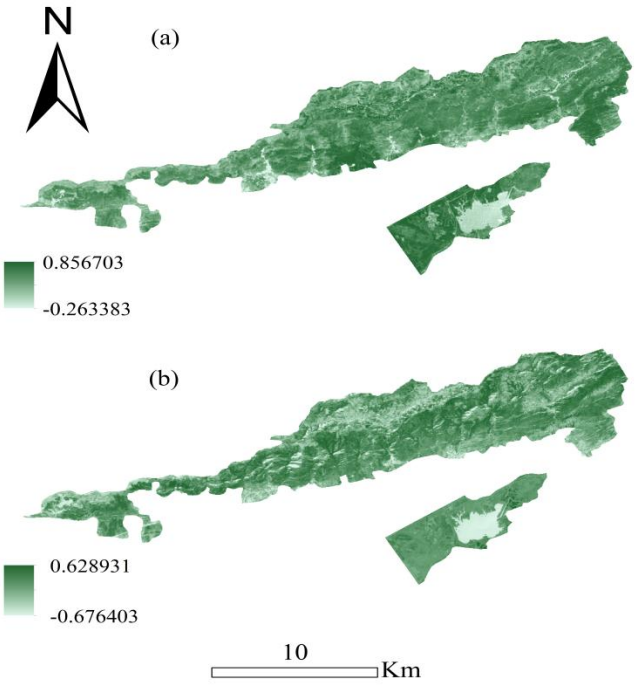

Figure 9. a. *Normalized difference vegetation index (NDVI) for(a) 1990 and (b) 2017*

Carbon dynamics and carbon losses

The calculated value of carbon varied between 94.62 ± 8.75 $MgCha^{-1}$ in OF to 164.14 ± 8.96 MgC ha^{-1} in DF with average carbon stored in forestland being 129 ± 8.85 MgC ha^{-1}. Similar results were reported for carbon stock in Ghoragali, Pakistan (subtropical/chir pine) (Nizami, 2012). Similarly, our present estimates are also inconsistent with the reported value by Rana et al. (1989) from the Himalayan region of India.

The conversion of forestland to other land uses resulted in carbon loss from 2131 GgC for 1990 to 1977 GgC in 2017. Same results were previously reported which showed loss of 32.7 PgC from the protected areas of Brazil Amazonia in 2014 (Nogueira et al., 2018). Similarly, in the protected areas of US from 1700-2005 more than 3 million km^2 of forest land, grassland and shrub land were converted to agricultural land that caused 10,607 TgC loss (Lu et al., 2018). This reduction in carbon supports the fact that the transformation of forestland to other land uses reduces the carbon storage potential of forestland. Deforestation, agricultural and settlement expansion attributed to population growth, resulted in forest conversion, hence decrease in carbon stock. Over these different periods, the highest rate of carbon losses was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_31973214
© 2018, ALÖKI Kft., Budapest, Hungary

recorded for the period 2010-2017 as shown in *Table 7*. This period also coincided with the maximum of population growth and human migration within the study area. According to the population statistics data (PBS, 2017) between 2010 and 2017, 0.422 million people migrated to Islamabad as compared to 0.245 million during 1990-2000. The expansion in AL and SM usually occurred near the old settlements, where local people grow crops. Although this LUC affects carbon loss, the intensity is much higher where DF is converted into SM, AL, or OF (Zheng et al., 2011). Within the past seven years (2010-2017) the rate of annual DF loss calculated was -0.59% much higher than in the first and in the second decade. This is due to an increase in hiking trails, roads, and recreational spots in and around the park thus directly affecting natural forest cover and carbon storage.

Table 7. *Carbon loss*

	Total carbon loss/gain (MgC)		**Net carbon loss (MgC)**	**Net annual carbon loss ($MgC \cdot yr^{-1}$)**
	DF	**OF**		
1990-2000	-72386.71	+17071.13	-55315.57	-5531.55
2000-2010	-43783.21	+1438.36	-42344.84	-4234.48
2010-2017	-61145.52	+4646.30	-56499.22	-8071.31

The population of Islamabad increased from 343,000 to over 1,502,000 from 1990 to 2017. These demographic factors in conjunction with other environmental and socioeconomic factors constitute major driving forces of LUC in and around MHNP (PBS, 2017). Additionally, in 1990 the population living in villages around Margallah Hills was estimated at about 20,000 but this increased to over 90,000 in 2017 distributed across 20 villages (Khalid et al., 2015). This demographic pressure is also a major threat to the sustainability of these natural ecosystems (Khan and Khan, 2009; Ali and Nyborg, 2010; Cochard and Dar, 2014). This demographic pressure also drives the expansion of built-up areas and agricultural land, as well as wood extraction (fuelwood, artisanal and commercial logging), which are drivers of forest cover change and degradation of natural ecosystems (Moffat et al., 1998; Agudelo-Vera et al., 2011). Other studies have also shown that anthropogenic activities are major threats to global forest cover (Rokityanskiy et al., 2007; Zomer et al., 2008; Ahmad and Nizami, 2015; Saeed et al., 2016). Historically, this increase in population and other underlying factors particularly in developing countries have been observed to be the most important driving force of LUC (Rosero-Bixby and Palloni, 1998). According to (Lambin et al., 2003), these underlying drivers of LUC are poverty, population growth, and socio-economic situation. Increased population often results in the migration of people in search of farmlands and open forests are easier to convert to agricultural land (Meli and Meli, 2015). Rural communities around the MHNP have witnessed an unregulated and uncontrolled urban expansion which has pushed these communities into forested lands of the area. Stone quarrying for cement making is also a contributor to carbon loss because Margallah hills have a high quality of limestone, shale, and sandstone used for cement production (Muhammad et al., 2013). There are over 700 stone quarries around the MHNP with dire consequences for the surrounding vegetation, plant and animal species, namely 38 species of mammals and over 600 plant species in the MHNP (Dawn News, August 23, 2010). In a related study, Ali et al. (2006) observed wood harvesting

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_31973214
© 2018, ALÖKI Kft., Budapest, Hungary

for commercial and household consumption, forest disease, and unregulated harvesting to be main drivers of deforestation in the watershed area of the MHNP.

Forest fires regularly occur in the MHNP due to fallen dry needles of chir pine in summer and dry season around May. According to de Groot et al. (2009), about 40.9% to 53.9% of carbon is lost annually due to forest fires depending on the intensity of forest fire. Most of the forest fires that occurred in subtropical forests of Pakistan are accidental due to recreational activities and negligence. Increasing trends of forest surface fires have been observed in subtropical forests of Pakistan (Nafees and Asghar, 2009). Forest fires are known to reduce soil carbon, soil erosion, reduction in understory vegetation and soil bareness (Jaiswal et al., 2002). The grazing and trampling of livestock severely affect vegetation regeneration thus also contributing towards LUC. Khalid et al. (2015) found that MHNP has to bear the pressure of 12,000 and 13,000 domestic livestock grazing.

Conclusion

The knowledge obtained from this study may serve as an input into the rehabilitation and management of degraded forest ecosystems in Pakistan and in the world. Furthermore, the MHNP is located in Islamabad and near Rawalpindi, which are Pakistan's most important twin cities with high demographic pressures. The present Study highlighted the temporal loss of forest carbon sink with the land use change in MHNP. The study also discussed the major drivers of land use change and carbon loss in MHNP i.e. stone crushing for cement making, fuel wood for commercial, population pressure, AL and SM expansion with detrimental effects on the ecosystem of the park. Moreover, the building of new infrastructures in the twin cities has resulted in a decrease in the forest area. These factors coupled with weak governmental policies, and inadequate land use management plans, facilitate a reduction in forest biomass and ultimately carbon sequestered in the MHNP. Deforestation control through improved forest management, appropriate forest conservation policies, development of land use management plans and urbanization regulations will help curtail, curb and reverse this deforestation process. This study provides results and recommendations to researchers for future studies focusing on especially the effects of land use change on wildlife habitat of MHNP and the effects of carbon loss on the local environment of MHNP. Additionally, an improvement in the national forest monitoring capacity and the implementation of REDD+ arrangement and sustainable land and forest management approaches can control the current forest cover loss, and carbon loss resulting from LUC.

(Received 10th Feb 2018; accepted 10th May 2018)

Abstract. *Angklung paglak* is a traditional musical instrument made of bamboo of *Using* (an ethnic community of Banyuwangi). This study was conducted to reveal the Local Ecological Knowledge (LEK) in *angklung paglak* manufacturing and its correlation to bamboo conservation. The data collecting was done through documentation, participant observations, and interviews. For ensuring the validity and reliability of the data, cross-referenced and repeated information methods were used. The local knowledge in *angklung* making includes selecting *benel* (*Gigantochloa atter*) and *ori* (*Bambusa arundinacea*) as *angklung* materials, the age of the bamboo (more than three years old), the best month for logging since August to October, and the air drying the bamboo without exposing it to the direct sunlight in upright position. The belief includes logging on a particular day and a taboo for logging in December to February (sprouting period). Meanwhile, the local practice is reflected in the selective felling. The LEK found in the study- knowledge, belief and practice, contributes to the bamboo preservation. The whole process of *angklung* making teaches people to preserve and to live with nature, which reflects an ecological human characteristic. The perseverance and the ecological awareness are the keys to make a high-quality *angklung paglak*.
Keywords: *ethnoecology, musical instrument, bamboo conservation, local wisdom, bamboo management*

Introduction

Local people play an important role in conserving and managing natural resources as well as environment (Chaiphar, et al., 2013). Their interaction with nature has influenced the way of thinking, behaving, expressing and appreciating their culture (Keraf, 2002). Local people develop a system of local knowledge as a representative of the adaptation processes to their environment, including knowledge, belief, tradition, practices, and view of life (Vandebroek et al., 2011). Local knowledge can be unique because it differs in each community or country (Jasmine et al., 2016). The accumulation of knowledge, practices, and belief in the relationship of living things (including human) and environment is defined as Local Ecological Knowledge (LEK) (Berkes et al., 2000). LEK itself has contributed to the biodiversity conservation through ecosystem management and sustainable biodiversity which are experienced by local people. The persistent practices of natural resources by the local people are the basic knowledge of a complex ecological system (Gadgil et al., 1993).

Most *Using* (also *Osing,* an ethnic community of Banyuwangi in East Java Indonesia) are farmers for which the rice fields are their main resource and valuable property. The agricultural tradition that has been created by them is then passed to the next generation and is still being practiced by today's *Using* people. Anthropologically,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_32153228
© 2018, ALÖKI Kft., Budapest, Hungary

culture is defined as human's creations which are obtained by acquiring or learning (Koentjaraningrat, 2015). One of the agricultural cultures of the *Using* people is a musical instrument called *Angklung Paglak*. This instrument is made of bamboo and played at the harvest time. The aim of playing it is to tell people that one's rice is about to be harvested. It also motivates the workers. The term *paglak* is derived from the name of a hut used by *Using* farmers to rest and oversee the field. People usually play the *angklung* in this *paglak* (Saputro et al., 2015); its height is 5-10 meters so that the sound can be heard by people around. The *angklung* players stand on the *paglak* and they will climb to it through the stairs of a single bamboo culm in which each internode is equipped with a bar for footing.

The *angklung* manufacture requires special knowledge and skill to produce a set of a melodious one. A set of *angklung paglak* consists of two pieces, each is made of 13-15 bamboo tubes (13-15 tones). The makers exceptionally pay attention to the quality; even they select the bamboo culm carefully. The tubes must be unbreakable and the tone must be stable. The belief in specific days and months to log bamboo trees also becomes the consideration in manufacturing to this day.

LEK can be learnt through holistic approach by using ethnoecology study. This approach analyzes how LEK, the history, the social and ecological function, as well as the relation to other dominant cultures are obtained in the local society (Ruiz-Mallén et al., 2012). Ethnoecology is a study of knowledge and management of the local people which is related to the ecological interactions (Martin, 2001). The purpose of the present study was to reveal the LEK of *Using* people in making *angklung paglak* through an ethnoecology study. The LEK covers knowledge, belief, practices of managing bamboo during the process of *angklung* manufacture which leads to bamboo conservation.

Methodology

Banyuwangi is a region in East Java Province, Indonesia. It is located at 7°43'- 8°46' South latitude and 113°53'- 14°38 East longitude (Badan Pusat Statistik Kabupaten Banyuwangi, 2015). Banyuwangi is a province located in the eastern area of East Java (*Fig.1*). This study was conducted in Glagah, Banyuwangi, specifically in three villages, namely Kemiren, Glagah, and Tamansuruh. In these three villages, there are *angklung* makers and musicians, and the people who are still playing it during their field ritual. *Using* community of Kemiren often present *angklung* art performances for tourists. Of all *Using* communities, only those living in Kemiren hold still strongly to the culture of *Using*, thus Kemiren was declared as an *Using* tourism village by the government of East Java Province in 1995 (Indiarti, 2015).

This study employed descriptive qualitative approach and based on the standard method of anthropology research (wide-ranged individual interviews, deep discussions, and participants observations) (Ripunjoy & Indira, 2012; Choudhary et al., 2008). Data collecting was done through documentation, participant observations, and interviews (Bungin, 2012; Albuquerque et al., 2014a). The researcher acted as the instrument and the data collector. The documentation technique was conducted through reviewing literature of researches, journals, and books related to *Using* culture, especially *angklung paglak*. The participant observation was done by involving the researcher into the whole manufacturing process of *angklung paglak*, beginning from the bamboos logging until the harmonizing. The interview was done through direct communication

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_32153228
© 2018, ALÖKI Kft., Budapest, Hungary

with some informants. The interview was in the form of semi-structured individually and Focus Group Discussions (FGDs) (Choudhary et al., 2008).

Individual dept-interview was conducted through three stages namely preliminary, primary, and closing. The preliminary interview was carried out by introducing the researchers to the informants, explaining the research description generally, asking the informants' willingness or ensuring the importance of that informant's role in research that would be undertaken. In the primary interview, the research data collecting was done by semi-structured interview and directly observing the informant's activity; this interview was averagely conducted three times. In the close interview, the validity and reliability were conducted using cross-referenced and repeated information methods. Focus Group Discussion was executed twice by involving the main informant and recommendation-informant. The interview was conducted using interview guideline. There was an open discussion in every interview and it was recorded using a recorder as permitted by the informant and then the field journal was made.

The informants consist of main and recommended informants who were obtained through purposive and snowball sampling techniques (Bungin, 2012; Albuquerque et al., 2014b) . The purposive sampling technique was used to choose the main informants, while the snowball sampling technique was used to choose the recommended informants. The main informants were 61 and 57 years old-elders of *Using* in Kemiren Village. The recommendation-informants were the maker as well as the player of *angklung paglak* (local expert) and *Using* society. Based on the recommendation from both elders, the local experts are chosen from two people living in Kemiren Village and Tamansuruh Village and four people from *Using* society in Kemiren Village. According to the local expert from Tamansuruh Village, two other local experts were found namely one person is from Glagah Village, Glagah Sub-District and another one is from Mangir Village, Rogojampi Sub-District. The recommendation informants are 37-74 years old. All informants are the original residents of their village (they were born and still live in those villages). Based on the observation and preliminary interview results, the selected *angklung* makers are from Tamansuruh and Glagah Villages. The data analysis was done qualitatively. The data validity and reliability tests were done by using cross-referenced and repeated informations (Albuquerque et al., 2014b).

Results

Angklung paglak is played to amuse and motivate people who are harvesting their rice. Unluckily, the *Using* people now rarely play it when harvesting their rice. The *angklungs* were played instrumentally following the pentatonic *slendro* of Banyuwangi; it is different from the *Sundanese angklung* whose notes refer to the Western diatonic (Syaiful, 2015). The *Using* people call one piece of *angklung* as *ancak angklung*. One *ancak* contains 13-15 tones (13-15 bamboo tubes) which are connected using a strap and attached to a wooden bar (*Fig. 2*). The *angklung* set consists of two pieces, so that it needs two people to play; one as the main player and another one is the backing player (*Fig. 3*). Mostly, the *angklung* performance is followed by two *kendang* players; they use small size *kendang*. The most played songs are *Lemar-lemir, Sekar Gadhung, Tetho Lelung, Gondoriyo, Kembang Jeruk, Lebak-lebak* which are considered as old songs, while the new songs are *Hoya-hoya, Jaran Ucul, Ojo Cilik Ati* (Syaiful, 2015).

Based on the participant's observation and interview, it is known that there were several stages in the process of *angklung paglak* manufacture, among others (1) bamboo culm selection, (2) bamboo logging, (3) drying, and (4) *angklung* harmonizing. The principle in its manufacture is to produce a quality *angklung* that has melodious and stable tone and unbreakable bamboo tubes. This principle is inherited by the ancestors.

Bamboo culm selection

Using people used *benel* (*Gigantochloa atter*) and *ori* (*Bambusa arundinacea*) bamboos to make *angklung*. The knowledge of both types of bamboo is originated by their ancestors hereditarily. The *benel* bamboo is used more frequently than the ori one due to the gentle sounds produced and the durable tone stability. Meanwhile, *ori* is used because of its high tone sound. However, there are some people also make a set of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_32153228
© 2018, ALÖKI Kft., Budapest, Hungary

angklung from both *benel* and *ori*, in which tones 1-10 are from *benel* for producing bass sound, while the higher pitch tones 11-15 are from *ori*. The difference in selecting the type of bamboo used is related to everybody's interest in the resulted tone. Nevertheless, generally, people recognize that the sound of *benel* bamboo is the most tunable for *angklung*.

Angklung makers buy bamboo from bamboo clump owners and do not take the wild one. The bamboo is selected by the makers them selves since it is only they who know the characteristics of potential bamboos (*Fig. 4a*). The makers use bamboos of more than three years old with the erect culm. In this selection stage, there are two methods used to choose the culm; the first includes a bamboo that is more than three years old but still alive and the second includes a dead (dry) which they call the *glagaran.* The alive bamboo is characterized by its yellowish culm and over grown lichen, and is still leafy, coloured mostly yellow. While bamboo *glagaran* is characterized by the yellow and leafless culm. The maker who uses *glagaran* claims that based on his experience, it will not any further shrink making the sound stable (does not need to be harmonized frequently). Meanwhile, those who choose the alive culm also claim that the *angklung* tube does not easily break. Until today, both ways to select the culm are still utilized by the *angklung* makers that finally become the special characteristic of *angklung.* However, they should maintain the principle of producing a high-quality *angklung* (the sound is tunable and the tube does not easily break.

Bamboo logging

Using people believe that *Pahing* (one of the Javanese days) in August, September, and October is the best day to log a bamboo tree. However, the maker who uses *glagaran* may log in June up to October. *Using* people mark December up to February as a time when a shoot bamboo sprouts or rainy season comes. They believe that during the rainy days the bamboo "breastfeeds", this time the shoot bamboo sprouts, so *Using* people will not log the bamboo during those times. Based on the *Using* people's experience, the bamboo logged during the rainy days will be easily powdered due to the insects, the culm will get softer and cannot be used to make an *angklung*. Thus, the sound will be less melodious, unstable, and they need more time to dry the culm. The *angklung* makers are very selective in logging the bamboo and never choose the wild ones. There is a belief that bamboo growing near a river will need a longer time to dry, so they do not use such kind of bamboo. Bamboo that grows near a river produces less melodious sound, thus the tones tend to be unstable. Generally, they will test the potential tone of the culm by hitting it and listening to the sound produced.

Bamboo drying

Angklung makers who use live bamboo need to dry the bamboo before cutting it into pieces. After logging the bamboo culms, they will air dry the culm for about three months, without exposing it to the direct sunlight. Culm drying is done upright with the base position of the culm is below (*Fig. 4b*). Whenever they think that the culms are dry enough, the culms are then cut at every two nodes. *Glagaran* needs not drying. After logging *glagaran* culms, the maker cuts them at every two nodes and immediately continues with the harmonizing process.

The ancestors of *Using* people used to store the bamboo tubes on *pogo* (a rack made of a small sized bamboo which are arranged well). The *Pogo* is placed under the roof of their kitchen and above the stove, so that the bamboos were exposed to smoke.

DOI: http://dx.doi.org/10.15666/aeer/1603_32153228
© 2018, ALÖKI Kft., Budapest, Hungary

However, today's *angklung* makers prefer not doing so because the bamboo will turn black and it might influence the aesthetic. Based on their experience, there is no difference between bamboo stored on *pogo* or elsewhere.

Harmonizing bamboo tones

One of the bamboo tube sides is firstly cut with certain length using a *buding* (a type of a big knife). The bamboo tube is harmonized by shaving it with a knife to get the right tone according to its potential (*Fig. 4c*). *Using* people call the knife as *ladeng lanang* because it is usually used by men (*Fig. 4d*). This is the most difficult stage of all because they need to concentrate and be meticulous in listening to the tone produced. The setting of the first tone (the third low note) is the most important step in this stage. The meticulousness in listening to the tones is believed to be related to the art talent of the makers so that they can produce a melodious set of *angklung* (*Fig. 4e*). The bamboo tubes that have formed an *angklung* (13-15 tone) are perforated for the holes of strap. The fault position of the hole may affect the tone generated by the bamboo tubes. The strap used to tie and arrange *angklung* tubes is a plastic rope (*Fig. 4f*), but the *Using* ancestors used a rattan rope in the past. The simple form of the wood buttress without additional ornament eases the angklung players to bring it to the *paglak*. Nowadays, the shape of the wood buttress is made by request.

Figure 4. *The angklung paglak manufacturing: Bamboo logging, done by the maker using saw and* buding *(a); Bamboo drying, the culm (alive bamboo) is air dried without being exposed to direct sunlight in upright position (b); Harmonizing angklung tones use ladeng lanang (a knife usually use by Using men), done by shaving the bamboo tube to get the right tone according to its potential (c); traditional tool used to manufacture angklung (ladeng lanang to shave the bamboo tube,* buding *to cut bamboo's branch, saw to log and cut the bamboo into pieces) (d); a set of angklung paglak tubes as the result of angklung harmonizing (e); and the arrangement of angklung tubes using plastic rope at the wood buttress (f)*

Discussion

The art of angklung paglak

Nowadays, *Using* farmers who play *angklung paglak* or invite the musicians during harvest time are farmers who get a testament (*weluri*) from their ancestors. *Weluri* in *Using* can be assumed as messages or attitude inherited by the ancestors to their descendants. Now, *angklung paglak* is mostly played during art performances for tourism, traditional ritual such as *Ider Bumi* and *Tumpeng Sewu* in Kemiren, welcoming guests, and at event of *Using* family. Some musicians are often invited to perform in some international art performances. *Angklung paglak* is also sold and purchased by various buyers with different social background such as academicians, musicians, art lovers, and *Using* community outside of Banyuwangi. This is one of the reasons why *angklung* makers do not want to dry the bamboo on the *pogo*. *Angklung* selling also stimulates the makers to modify the wooden buttress to beautify the *angklung*, including the shape of buttress, added curvings and other ornaments.

LEK in angklung paglak manufacture

The ancestors of an ethnic community have proven to have done a local knowledge-based conservation (Tamalene and Al Muhdhar, 2017). The *angklung* manufacture is still based on *weluri* from ancestors. The principle of manufacturing a good *angklung* is still preserved. The *angklungs* are made carefully even though it takes time. Such *weluri* is considered as LEK of *Using* people since it includes belief, knowledge, and practices that are in line with the principle of natural resources management or conservation. Local practices are the result of experiment and observation among generation (Turner et al., 2000). The experience in managing bamboo has created a specific interaction pattern between *Using* people and the environment. This experience is descended from generation to generation. There is a small difference in the practice of *angklung* manufacture by the ancestors. Local practices are considered as a dynamic creativity and innovation mechanism (Slathia et al., 2016). The *angklung* makers available today have the descendant of the *angklung* makers. They said that since they were a child they often see their grandfathers/grandmothers play and make *angklung* so that they like *angklung* and are interested in making it as well. Their ancestors give *weluri* to make *angklung* in the form of belief, advice, guidance, taboo, knowledge, and practice to make *angklung* through oral transmission. The makers then learn to their ancestors (*Fig. 5*).

Their beliefs on logging bamboo culm on *Pahing* day and between August up to October are guidance for *angklung* maker. The time of collecting or harvesting a certain plant has a conservation value (Agize et al., 2013). *Pahing* in Indonesian means bitter, so bamboo which is logged on *Pahing* day is believed to be durable because insects will not gnaw it due to its bitter taste. They also mean that it will be their prayers. The belief has been proven through experiences since bamboo culms which are logged in other than August up to October will be easily powdered (gnawed by insect). Borer is pests of harvested bamboo so they will harm the bamboo. The borer species are including *Dinoderus ocellaris, D. minutes,* and *D. brevis* (Dransfield and Widjaja, 1995; DIJPEN, 2011). The starch content in the bamboo culm is the lowest during the dry season, thus, logging a bamboo culm during dry season will make the bamboo durable since the borer will not gnaw it because of the low starch inside (Razal et al., 2013). *Using* people will not log bamboo culm in December up to February because there is a taboo to log bamboo tree during the rainy season. They believe it will distort the "breastfeeding time"

© 2018, ALÖKI Kft., Budapest, Hungary

(sprouting process). This belief helps preserve the bamboo regeneration. Local belief in something taboo plays a role in environmental preservation because it makes people beware in resources utilization (Tamalene et al., 2014), and has preserved various kinds of species (Gavali and Sharma, 2004). Bamboo logging during a shoot sprout will destroy the shoot itself and influence the bamboo regeneration (Razal et al., 2013).

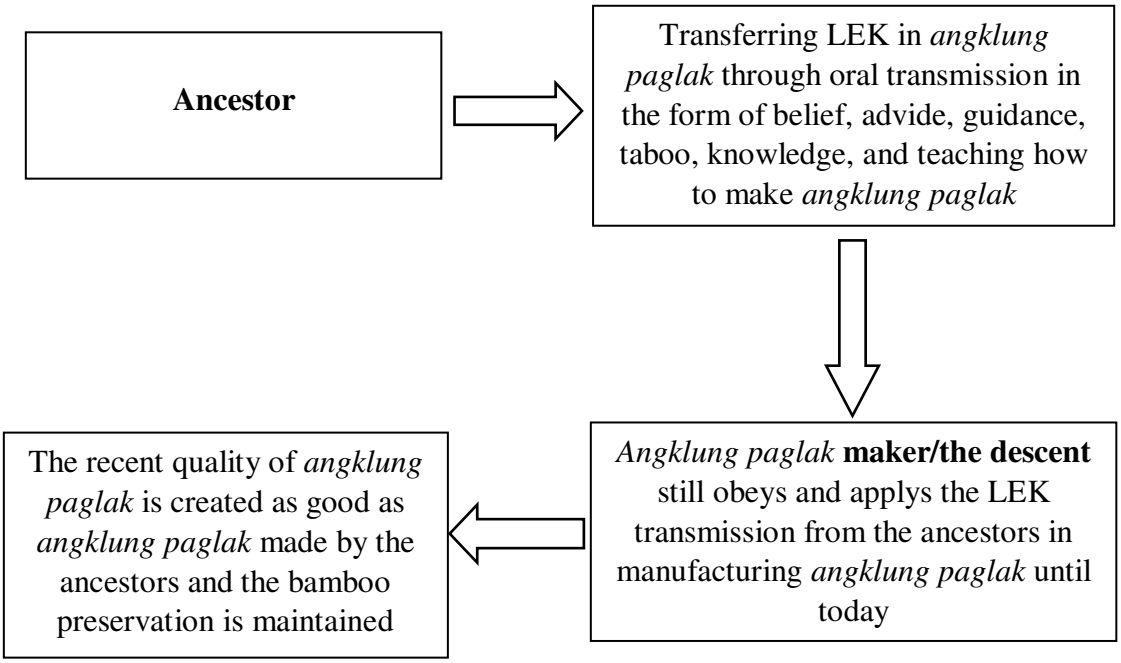

Figure 5. *Process of LEK transmission in angklung paglak making*

The knowledge of bamboo species (*benel* and *ori*) and criteria of suitable culm as the *angklung* material are precious knowledge, so as the process of its manufacture. Local knowledge about *benel* and *ori* as angklung materials will lead to the preservation of these bamboo varieties. The difference between the former and today's *angklung* manufacture becomes the reflection of LEK evolutionary in which new knowledge may exist replacing the previous knowledge based on experiences or trial of a generation (Sunaryo and Joshi, 2003). Such difference in knowledge includes the difference in selecting the bamboo age, drying process, and the variation of bamboo in one *ancak angklung*. The most important thing is the consistency in making melodious *angklung*, stable tones, and durable or unbreakable bamboo tubes.

The high demand of *angklung* makes the bamboo stock dropped. Therefore, the local practice and wisdom which is possible to be done by the makers is to log as many bamboo culms as possible in August up to October for stocks. Yet, selective logging is still practiced by *Using* people. They only log the potential bamboo, with appropriate age (more than three years old) and erected culm. The makers, who choose *glagaran* bamboo, will not make *angklung* of carelessly chosen bamboo to fulfill the demand. They sometimes stock the *angklung* which are ready to be sold. If there is a request and they run out of bamboo, they will ask the customer to wait. They do not want to disappoint their customers because of its quality.

The bamboo conservation practices can be seen during the whole process of *angklung* manufacturing, beginning from the bamboo selection, bamboo drying, and

© 2018, ALÖKI Kft., Budapest, Hungary

angklung harmonizing. The logging day and the selective felling which are not done when shoot bamboos are sprouting are the practice of bamboo management by considering the bamboo preservation. The selective felling can conserve the bamboo and its reproduction (Dransfield and Widjaja, 1995), while clear felling of bamboo clumps will affect the number of sprouts and the height of bamboo (Nath et al., 2009). The selective felling which is done by logging only a potential bamboo is a practice of showing respect to the nature, i.e. the right of bamboo to live and grow naturally. Meanwhile, drying the bamboo culm is done by for a particular period without additional substances. *Angklung* makers do not manipulate the bamboo culm and only manage it naturally. The culm is only cut into several tubes, which are harmonized regarding to the potential tones until get melodious tones. Briefly, the procedure to make *angklung* includes four stages (*Table 1*).

Table 1. *Stages of Angklung making*

No.	Stages of Angklung Making	Activities
1	Bamboo culm selection	• The type of bamboo used: (1) *Benel* (*Gigantochloa atter*): produced gentle sounds (2) *Ori* (*Bambusa arundinacea*): produced high tone sound • The type of *benel* is the most frequently used bamboo • The age of bamboo: more than three years old bamboos with the erect culm. Two methods used (1) alive bamboo: it needs a drying process firstly (2) dead (dry) bamboo: it does not need the drying process; it can be directly harmonized
2	Bamboo logging	• A belief that *Pahing* (one of the Javanese days) in August, September, and October is the best day to log bamboo for *angklung* • Do not log bamboo during sprouting time in rainy season (a taboo) • Dead bamboo (*glagaran*) can be logged since June to October
3	Bamboo drying	• Alive bamboo is air-dried at the upright position where the base part is in the bottom for about three months
4	*Angklung* harmonizing	• One of the bamboo tube sides is partly cut • That part is shaved with a knife (*ladeng lanang*) to get a right tone • Every tube is perforated for the rope hole • Arranging the the bamboo tube at the wood buttress is started from the low to the high tones using plastic rope

The *angklung* maker does not log wild bamboo at a riverside or forest. Whereas, logging the wild one will not be as costly as when logging the clumps from the bamboo farmers. One *ancak angklung* needs 6-8 bamboo culms since each culm might produce

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_32153228
© 2018, ALÖKI Kft., Budapest, Hungary

different potential tones. The *angklung* makers mostly buy bamboo from clumps at farmer's field or garden. Meanwhile, the bamboo management done by the bamboo farmers in Kemiren Village includes two things namely planting and preserving the bamboo (*Table 2*). Home gardens play an important role in conservation and management of the sustaining natural resources species (Agize, 2013). The decision to buy bamboo culm is considered as a conservation practice for it preserves the wild bamboo life.

Table 2. *Bamboo management*

No	Type of Management	Technique of Management
1.	Bamboo planting	• The 1-2 years old bamboo is cut with the height about 1 meter from the ground • The bamboo with its rhizome (*Using* people call it *bongkotan*) are taken; it is then planted in the place they want • The new sprouts (different from the shoot) will grow close to the stem base or rhizome while the stem is weathered over time
2.	Preservation	• People apply selective felling to preserve the bamboo to keep the productivity • The three years-bamboo will be cut/harvested • The harvesting is undertaken out of rainy season (out of sprouting period)

Unfortunately, there is a belief in *Using* community that *angklung* makers must be the descendant of the previous *angklung* makers. *Using* people believe that only those who descent the blood of *angklung* makers or those who have art talent are capable to make melodious *angklungs*. These people are considered to have diligence and capability in listening to tones, and they must inherit this ability from their ancestors. This ability causes other people who want to learn to make an *angklung* less confident. Besides, the instructor or the *angklung* maker will also doubt the students' perseverance in manufacturing *angklung*, since they have to be very patient in listening and finding the correct tone.

Angklung paglak is a symbol of cooperation in farming of *Using* community. This art is disappearing within the decreasing cooperation tradition (*ngrasah*) in field, even though it is not reducing the social interaction between *Using* people. The cooperation in harvesting time no longer exists since they harvest the rice by using a sickle and a rice mill. The rice is directly sold in field, so the process of harvesting runs quickly. It is different from the past, where people used traditional finger-bladed knife (*ani-ani/gampung*) therefore the harvest time took several days. *Angklung paglak* performance which was done formerly in harvest time is no longer practiced today. A local tradition has an important role in conserving biodiversity. A local tradition that is still done by a community may preserve the conservation practices related to that tradition (Tamalene and Al Muhdhar, 2017). The biodiversity conservation is appropriate when it applies cultural value and religion approach compared to constitution and law regulation (Hongmao et al., 2002).

Conclusion

In brief, *angklung paglak* is one of the cultural products of *Using* community as the expression of farming culture. The process of *angklung* manufacturing consists of several stages: bamboo selection, logging, drying, and *angklung* harmonizing. Each process is considered as a system of local knowledge or LEK which includes belief, knowledge, and practices of managing bamboo. Local knowledge in *angklung* making including selecting *benel* (*Gigantochloa atter*) and *ori* (*Bambusa arundinacea*) as *angklung* materials, age of bamboo (more than three years old), best month for logging in August up to October, and air drying the bamboo without exposing it to the direct sunlight in upright position. The belief on a particular day that is on *Pahing* day and a taboo for logging in December up to February may affect to the time of bamboo logging. The selective felling practice by choosing only potential bamboo, buying it rather than logging the wild one also contribute to the bamboo preservation. The bamboo drying, which is done in order to prevent borer to gnaw the bamboo starch, is also done without any manipulation and chemical substances addition. This reflects ecological human characteristics. *Angklung* making teaches people to preserve and live in harmony with the nature. The perseverance in harmonizing *angklung* also contains value respect to the nature, for what it has given to humans.

Acknowledgements. The authors greatly appreciate all informants, especially Mr. Andori and Mr. Ardi (the *angklung* makers). The deep gratitude is also dedicated to Mr. Purwadi and Mr. Suhaemi as the elders of *Using* community in Kemiren Village, Banyuwangi.

(Received 12th Feb 2018; accepted 17th May 2018)

Abstract. The farming-pastoral zones in semi-arid regions of China are known to be typically ecologically vulnerable areas. It is required to research the agricultural and pastoral area ecological pattern that can guarantee ecological safety, and put forward the reasonable ratio for plough and grassland. This study selected the West Liaohe River Plain as the research area, and utilized a remote sensing interpretation and field visit method to analyze the land use situation during different periods of time. Also, the distribution scope of the natural grassland was identified, and the ecological security patterns of the agriculture and animal husbandry in the West Liaohe River Plain were adjusted based on the basic principle of natural grassland expansion. Then, the distribution of groundwater flow field in the research area was simulated, and the rationality of the ecological security pattern supported by the groundwater conditions was analyzed. The grassland areas after the adjustments measured 28,760.7 km^2, and accounted for 43.87% of the total area of the West Liaohe River Plain. The grassland area will be recovered to the level of 1990 following the adjustment of this ecological pattern.
Keywords: *land use, natural grassland, expansion, critical water levels, groundwater*

Introduction

The breadth and depth of the influences of human activities on global ecosystems have been expanding continuously with the rapid progress of urbanization. Therefore, the structures and functions of natural ecosystems have significantly changed. The ecological environmental problems caused by the degradation of the ecological systems have become a bottleneck, and have restricted social and economic development. In the early 1980s, ecological security had become a research hotspot in the field of nascent international ecological systems (Naveh, 1994; Yu, 1996; Steffen et al., 2015), and as a result the ecological security pattern theory came into being at the right moment. On the basis of the mutual feedback between patterns and processes, it achieved effective control of the ecological process through the construction of regional ecological security patterns, in order to give full play to the ecological function; realize the effective and reasonable allocations of regional natural resources and green infrastructures; guarantee the necessary ecological natural resources and material welfare; and ultimately achieve ecological security (Dabelko, 1995; Peng et al., 2017). Ecological security patterns have become one of the important spatial methods used to alleviate the contradictions between ecological protection and economic development (Yu, 1996; Meng et al., 2012; Ou et al., 2015; Zhao and Xu, 2015). The majority of the hot spots include the farming-pastoral zones (Li and Cao, 2014), arid/semi-arid areas (Meng et al., 2017), scenic areas (Zhang et al., 2008). These types of areas are potentially strongly disturbed by human activities, resulting in the ecological safety problems becoming outstanding in these

DOI: http://dx.doi.org/10.15666/aeer/1603_32293244
© 2018, ALÖKI Kft., Budapest, Hungary

areas. Previously, many researchers have identified ecological sources based on a "source-sink" theory (Chen et al., 2006) of landscape ecologies, and established the resistance surfaces of the expansions of the landscape elements using minimum cumulative resistance models. The security patterns were then determined with different elements and classes according to the expansion trends (Pan and Liu, 2015), in order to effectively control the landscape space structure. In addition, cellular automata models (Zhu and Liu, 2013), scenario analyses (Mao et al., 2013), GAP analyses (Liu et al., 2009) were used for the establishment of the land ecological security patterns.

However, at the present time, the majority of the research studies conducted on the construction of the ecological security patterns have been analyzed from the perspective of landscape ecologies, without identifying the driving factors which had led to the changes of the regional ecological patterns. Also, the previous related studies also lacked evaluations of the effectiveness or rationality of the construction of the ecological security patterns based on the driving factors (Xu et al., 2017; Zhang et al., 2018). The natural attributes of the regional hydrological cycles determine the basic patterns of an ecosystem (Chen, 2007). For example, for semi-arid areas, the natural ecosystems are grassland vegetation supported by groundwater. The spatial patterns and landscape changes of ecosystems reflect the pattern evolution of the groundwater spatial distribution, and the realization of the ecological safety patterns must be supported by the groundwater conditions. For a long time, the agricultural structure in the farming-pastoral zones in semi-arid regions is unbalanced, with over-developed water sources, and the unsustainable problem in development is more and more serious. In part of the region, the development intensity of water source has approached extremity, with increasingly serious land desertification, grassland degradation and weakening ecological functions. Unbalance even reversal in ratio of plough and grassland has been a comparatively common phenomenon in farming-pastoral zones in semi-arid regions, which obviously does not conform to the national policy for ecological civilization construction, and it is required to research the agricultural and pastoral area ecological pattern that can guarantee ecological safety, and put forward the reasonable ratio for plough and grassland, which is an important ecological safety problem with far-reaching influence. In this research study, by regarding the West Liaohe River Plain as the research area and based on a "source-sink" theory, a minimum cumulative resistance model was used to establish the landscape ecological security patterns. Also, the rationality of the ecological security pattern supported by the groundwater conditions was analyzed, in order to provide references for the ecological protection in semi-arid areas.

Materials and methods

In this research study, by taking the West Liaohe River Plain as an example, with the aim of protecting the natural attributes of the ecological system, a method was established for evaluating the ecological structure in the farming-pastoral zone, and a reasonable natural and human ecosystem was constructed. First, the remote sensing information and field visit data were used to analyze the changes in land usages in the West Liaohe River Plain, along with the distribution scope of the natural grassland. Second, the critical groundwater level of the vegetation community in the West Liaohe River Plain was calculated in combination with the data obtained from the field visit and historical investigations. Third, the existing natural grassland vegetation was found

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_32293244
© 2018, ALÖKI Kft., Budapest, Hungary

to have a good protection of biological diversity, and could be used as the gene pool for the ecological restoration of the grassland. Therefore, the outward expansion was based on the natural grassland in order to adjust and merge the grassland scope. Finally, the critical burying depth of the groundwater recharged vegetation was regarded as the constraint condition, in order to analyze the rationality of the ecological pattern supported by the groundwater subsurface flow field.

Study areas

In China, the semi-arid area is a strip zone between the arid area of the northwestern inland river, and the semi-humid area in the north and northeastern regions of China. This includes the west section of the Songliao River Basin; northwestern section of the Haihe-Luanhe River Basin; upper and middle reaches of the Yellow River Basin, and so on. Among these areas, the West Liaohe River was determined to be a relatively complete basin, and was therefore selected as the research area for this study (*Fig. 1*).

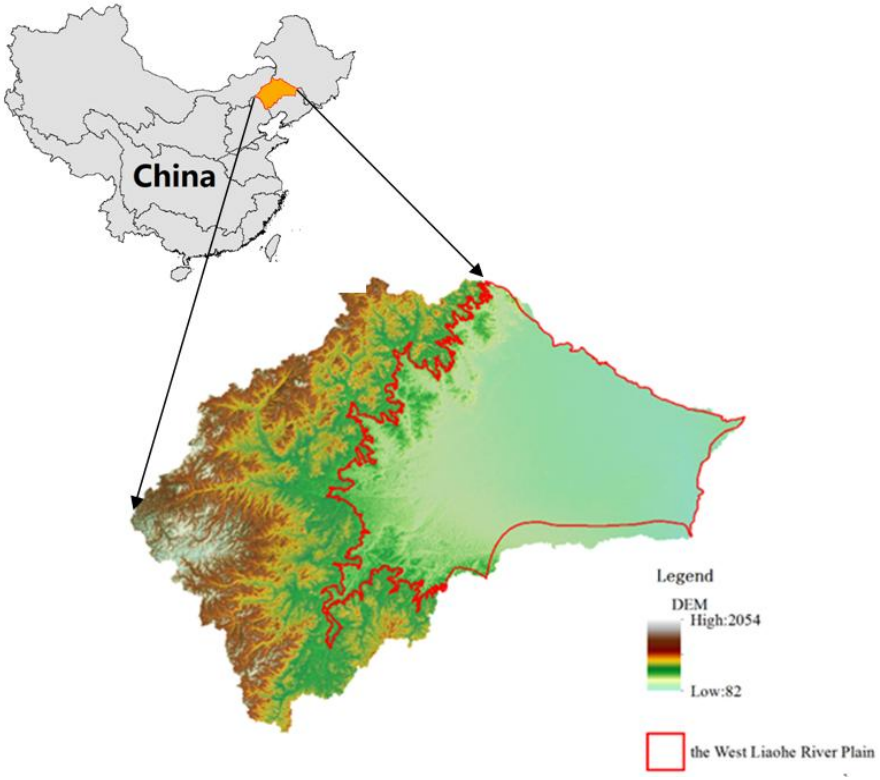

Figure 1. *Study areas*

The West Liaohe River Plain is located east of the West Liaohe River Basin. Its main section is located in Tongliao City, within 41°05′ to 45°13′N and 116°10′ to 123°35′E, with a land area of approximately 65,000 km^2. The West Liaohe River Plain is a typical farming-pastoral zone in the semi-arid region of China. The regional average annual precipitation is less than 380 mm, and the annual average water evaporation is more than 1,000 mm. Also, this area has obvious semi-arid characteristics. The rainfall in this area does not directly generate surface runoff, and the precipitation has a significant vertical infiltration. The groundwater is abundant, and the vertical recharge is stable.

The vegetation in the pasturing area includes mainly typical herbaceous steppe vegetation communities, as well as arbor, shrub, and sub-shrub steppe vegetation and meadow vegetation communities. The natural ecology in a semi-arid area is a steppe vegetation supported by groundwater. The changes in the spatial patterns and landscapes of ecosystems are known to reflect the pattern evolution of the spatial distributions of the groundwater. The grassland ecologies represent the natural attributes of the ecosystems in semi-arid areas, and are the ecological foundations which support these areas. The grassland ecological security is not only related to the pasture itself, but also greatly affects the ecological quality, safety, and stability of the entire region.

Changes in the land usages

This study selected four periods for the interpretation of the land usage and analyzed the dynamic changes of the ecological patterns of the West Liaohe River Plain, in order to identify the distribution scope of the natural grassland in the West Liaohe River Plain, in combination with the field visit. The remote sensing interpretation results are shown in *Figure 2*.

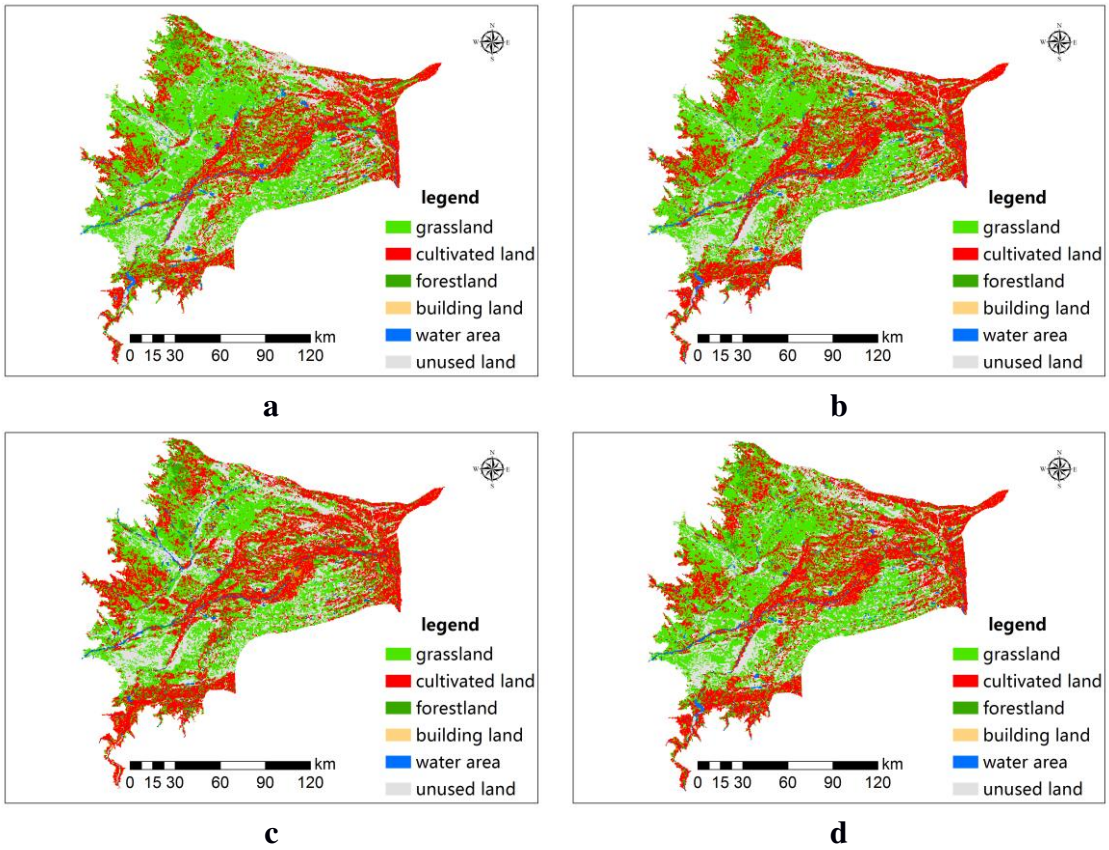

Figure 2. *Distribution of the land use types in the West Liaohe River Plain between 1990 and 2016:* ***a*** *1990,* ***b*** *2000,* ***c*** *2010 and* ***d*** *2016*

It was determined that, in the land use types of each region, the grassland and cultivated land areas occupied a larger proportion, while the water and construction land areas occupied a smaller proportion. The southwest, northeast, and middle areas were

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_32293244
© 2018, ALÖKI Kft., Budapest, Hungary

basically covered by cultivated land, while the grassland areas were mainly distributed in the Jarud Banner in the northwest, and Horqin Left Back Banner in the south. According to the comparison of the grassland and cultivated land areas during the different periods, the grassland area in the West Liaohe River Plain was found to have been sharply decreased, from 29,092 km^2 in 1990 to 21,428 km^2 in 2010. Also, the grassland areas were increased after 2010, with the grassland areas reaching 22,439 km^2 in 2016. The changes in the cultivated land areas showed an opposite trend. For example, the cultivated land areas increased from 18,251 km^2 in 1990 to 26511 km^2 in 2010. Moreover, the cultivated land areas had decreased after 2010, and were 23,372 km^2 in 2016. It was found that the proportion of the agriculture and animal husbandry land usages in the West Liaohe River Plain had already been reversed by 2010.

Grassland vegetation investigation

The author carried out grassland vegetation investigation in grassland of West Liaohe River Plain for three times in July to August, 2016, and July to August, 2017 (*Fig. 3*), with vegetation investigation area of 6,702.89 km^2, and 306 sampling points are selected in all. 94.1% of sampling points are concentrated in natural grassland, with 297 sampling points distributed in all; and 9 sampling points are spread in other regions. It can reflect the vegetation distribution condition of grassland in the West Liaohe River Plain basically, with good representativeness and comprehensiveness. Longitude and latitude positioning can be done for all the sampling points with handheld GPS, and the phytology professionals carry out statistics and record for the plant category and species name, perform photograph and description for the surrounding ecological environment of the sampling point, screen out the dominant species, and determine the community name and species composition of the sampling point.

Calculation method for critical buried depth of groundwater recharge vegetation

In regard to grassland plants in semi-arid areas, the ability of plants to absorb water is the most important condition for their competitive survival. Previously, many research studies have examined the adaptability rates of different plants under drought stress conditions (Zhou, 1999;Jin, 2010; Zhang, 2011). The author puts forward a kind of calculation method for critical buried depth of groundwater recharge vegetation (Chen et al., 2016). The analysis and calculation are composed of two parts: one is the vegetation root system active layer connected to ground, the other is the underwater diving active layer connected to groundwater surface. Under certain climate and soil condition, the root system layer thickness is related to vegetation type, which can be acquired according to the field investigation and the existing vegetation ecology research result. The forming of underwater diving active layer is the result of capillary force action, and the maximum lifting height of capillary water can be used as the thickness index of underwater diving active layer. Calculation formula for maximum lifting height H of capillary water is as follows:

$$H = 2\gamma / \rho gR$$

ρ is liquid density, g is gravity acceleration, R is effective aperture.

Natural grassland expansion based on a source-sink theory

In order to minimize the grassland degradation, the grain for green and closing measures have been widely applied in the farming-pastoral zones in recent years. The natural restorations of rehabilitated land areas are very slow processes. The formation of a stable vegetation community usually takes between 15 and 20 years. Moreover, the formations of such vegetation communities are relatively singular and do not contain rich species. Natural grasslands basically maintain the natural attributes of grassland areas due to good groundwater conditions, and less human interference. Natural grasslands have abundant plant species, and provide gene pools for grassland ecological restorations. Therefore, the adjustments in the ecological patterns in the farming-pastoral zone of the West Liaohe River Plain should include the expansion of the natural grassland as the basic principle, which will potentially increase the connectivity of the habitat patches and increase the mobility of the species among the patches. It will promote inter-plate gene exchanges and species mobility, as well as enhance the opportunities for species re-immigration. At the same time, the species in the isolated patches will be able to survive and continue, which will then provide a continuous network of habitats for the species which lack space diffusion capabilities. Therefore, the natural grassland areas will be continuously enlarged, and the natural nature of the natural grasslands can be maintained.

A “source-sink” theory is a basic theory which is used in the study of landscape ecology. The “source” landscape refers to the landscape type which can promote the development of the ecological processes in the study of the patterns and processes of an area. The “sink” landscape is the landscape type which can stop and delay the development of the ecological processes. The positive significance of the application of this theory was to couple the static landscape pattern with the dynamic ecological process. This assisted in the understanding of the relationship between the ecological pattern and the process, and provided a scientific basis for putting forward effective

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_32293244
© 2018, ALÖKI Kft., Budapest, Hungary

ecological spatial regulation and management methods. At the present time, this theory has been effectively applied on a large scale in the field of biodiversity conservation. Therefore, by taking the natural grassland expansion as the basic principle, this study used a "source-sink" theory method in the landscape ecology in order to adjust and optimize the ecological pattern of the agriculture and animal husbandry land usages in the West Liaohe River Plain. The natural grassland, as a gene pool for the grassland ecological restoration, played a key role in the safety of the entire plain ecosystem. Therefore, it was used as a "source" in this study, while the farmland and unused land were regarded as a "sink". In order to avoid direct conflicts among the different landscape functions (such as the grassland, farmland, and so on) from the aspect of a spatial pattern, a buffer zone was arranged in the contact zone between the grassland and large irrigation zone (including the closed grassland or artificial green belt) which eliminated the impact of the irrigation zone on the grassland, and facilitated the conservation and restoration of the natural attributes of the natural grassland areas.

In order to reflect the process in which the "source" landscape experienced different media in order to overcome resistance, it was necessary to evaluate the landscape resistance based on the dynamic characteristics of the "source" landscape in the study area. Therefore, with the help of GIS technology, this study used a minimum cumulative resistance model to express the influence of the landscape media on the spatial diffusion of the landscape "source", and thereby established a landscape resistance surface. The minimum cumulative resistance model considered the landscape "source", distance, and landscape interface characteristics, as shown in *Equation 1:*

$$MCR = f_{min} \sum (D_{ij} \times R_i)(i = 1,2,3,\ldots m;\ j = 1,2,3,\ldots,\ n) \quad \text{(Eq.1)}$$

where D_{ij} refers to the field distance from the landscape "source" j to a landscape unit i in the space; and R_i denotes to the resistance coefficient of a certain landscape unit i in the space, and represents the difficulty level of the movement passing. The minimum cumulative resistance model used in this study was essentially the measurement and evaluation on the accessibility of a path from the "source" landscape to a point in the space. The smaller the resistance value, the higher the accessibility to this point. Therefore, the resistance model was able to reflect the potential possibility and tendency of the landscape unit movement, and was a type of abstract expression of the landscape changes. This provided an analysis basis for the landscape function characteristics. As far as the protection and utilization of the municipal ecosystem were concerned, the areas with stable municipal ecosystem structures were favorable to the migration and diffusion of the landscape unit, and the resistance to migration and diffusion were smaller. In contrast, there was a higher resistance to the unit movement and diffusion.

Different landscapes suffer different resistances during the processes of movement and migration, which are dependent on the suitability degree of the landscape interface to the survival, reproduction, and migration of the elements. However, the resistance coefficient is also relative, and can be used to calculate the cost distance since it can relatively reflect the differences in the different resistance factors. This research study set 1 as the minimum resistance coefficient, which represented the fact that a certain landscape unit could move freely, and its area was the most suitable space. Also, this study set 100 as the maximum resistance coefficient, which assumed that the landscape unit could not move, and its area was the most unsuitable space. As far as the research area was concerned, the areas which could not be adjusted involved urban development

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_32293244
© 2018, ALÖKI Kft., Budapest, Hungary

planning (such as urban construction land, large irrigation areas, and so), which were determined to have the largest resistance value (100). The farmland areas had a smaller resistance value of 70; unused land had a resistance value of 50; and the deteriorated grassland areas were given a resistance value of 10.

The classified statistical measurements were made for the cumulative resistance values by using a 1/2 standard derivation in GIS. The critical threshold was determined to divide the corresponding resistance intervals according to the frequency discontinuity and spatial distribution characteristics of the resistance value. Therefore, the influence degree of the natural grassland on the entire expandable area was divided into the expansion core area, expansion connection area, and expansion buffer area.

Analysis of the rationality of the groundwater supported ecological pattern

The natural grassland expansion areas had been adjusted to the different types of landscapes only from the perspective of landscape ecology. However, whether or not the groundwater conditions supported these adjustments of the ecological pattern still required verification. This study used a distributed type water cycle simulation model MODCYCLE as the tool (Lu et al., 2012), and simulated the groundwater flow field in the West Liaohe River Plain through establishing a water cycle simulation model for the West Liaohe River Basin. The period ranging from 2001 to 2014 was used as the base year period for the study of the West Liaohe River Basin. The hydrometeorological and water consumption data during the corresponding period were used as the basis to conduct the water cycle simulation construction, parameter calibration, and model validation in the base year of the West Liaohe River Plain area. The input data which were involved in the MODCYCLE model included the fundamental spatial data and the water cycle driving data. The spatial data included the basic region/basin information, such as the elevation, soil distribution, and so on, while the water cycle data included the meteorological driving data, water for human activities, and so on. This research study collected the meteorological data from 22 National Meteorological Stations in the West Liaohe River Plain, along with the precipitation data from 89 local rainfall stations (*Fig. 4*).

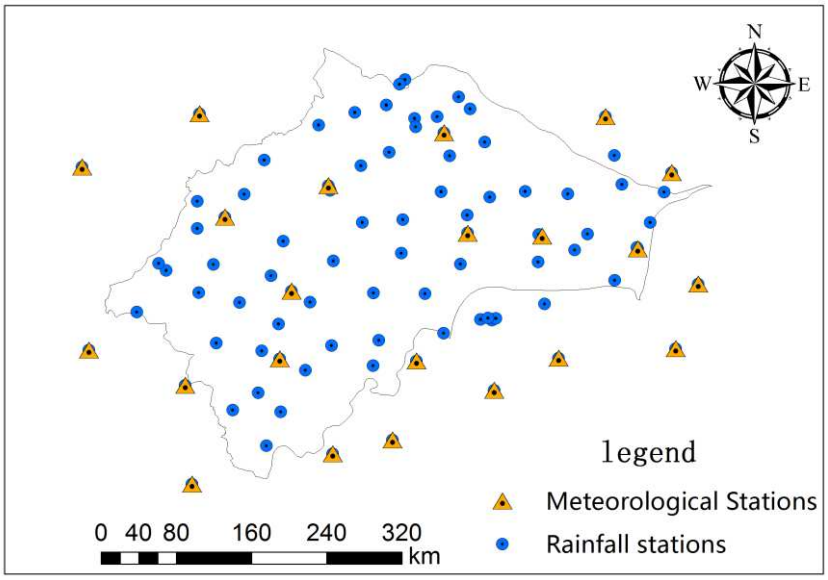

Figure 4. *Distribution of national meteorological stations and rainfall stations*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_32293244
© 2018, ALÖKI Kft., Budapest, Hungary

The water intake and usage processes for human activities utilized the 2001 to 2014 statistical data from the water resources bulletin for the West Liaohe River Basin. Contour map for the groundwater depths in the West Liaohe River Plain in 2014 is shown in *Figure 5*.

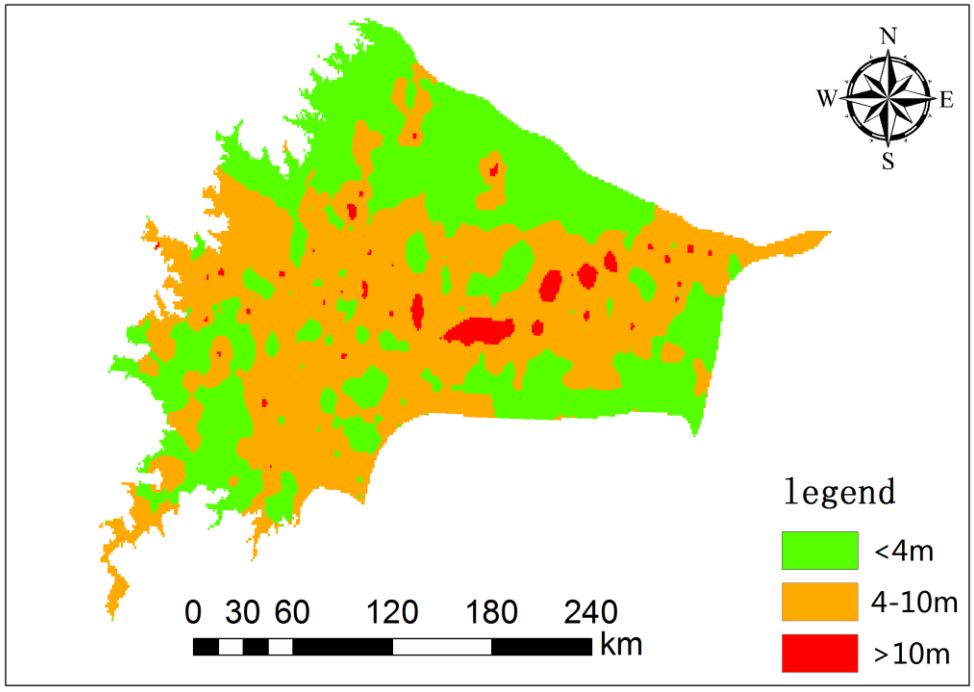

Figure 5. *Contour map for the groundwater depths in the West Liaohe River Plain in 2014*

The contour maps of the groundwater levels in the natural grassland expansion areas and the West Xiliao River Plain could be superposed. Then, the rationality of the ecological pattern of the farming and pastoral areas supported by the groundwater flow field were analyzed. The groundwater conditions in the expansion areas were divided into the supporting, basically supporting, and non-supporting areas according to the groundwater level values of ≤ 3 m, 3 to 4 m, and > 4 m.

Results and discussion

Distribution scope of natural grassland

Through carrying out vegetation investigation of the West Liaohe River Plain, 306 valid sampling points are obtained, with 258 species of plants found in total, divided into 52 families and 169 categories. Grassland of the West Liaohe River Plain includes three types: natural grassland, sown pasture and deteriorated grassland (*Fig. 6*). Wherein, the natural grassland is influenced slightly by man-made interference, with rich vegetation species diversity and high vegetation coverage, and the grassland with natural property is the gene pool for grassland ecology restoration. The sown pastures in the West Liaohe River Plain are mainly planted with the commercial crop alfalfa, with high vegetation coverage but single composition. The deteriorated grassland is influenced by man-made interference intensely, and the vegetation composition is mainly successive

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_32293244
© 2018, ALÖKI Kft., Budapest, Hungary

vegetation, with low vegetation coverage. The grassland degraded seriously may be degraded to mobile sandy land, with exposed sand head and scare vegetation, and only the pioneer plants such as Agriphyllum arenariun Bieb. can grow here, which has lost the natural property of grassland basically. This paper interpreted the distribution condition and field vegetation investigation result of grassland with different coverages by using remote sensing, and recognized the distribution scope of grassland influenced by man-made interference slightly with natural property. The area of natural grassland is 6,702.89 km^2, which is mainly distributed in Jarud Banner in northern part and Kezuohou Banner in southern part. Wherein, the natural grassland area of Jarud Banner is 3,932.43 km^2, and that of the Kezuohou Banner is 2,770.46 km^2.

Critical water levels of the groundwater recharged vegetation

Through the examination of the research data and vegetation investigation, and in accordance with the different water conditions, the steppe vegetation community in the West Liaohe River Plain was roughly divided into seven types and 22 communities. The critical burial depths of the groundwater of the different vegetation communities in the West Liaohe River Plain were obtained through calculation. The calculation results are shown in *Table 1* as follows: the critical burial depths of the majority of the vegetation communities were within 4 m. Meanwhile, the agriophyllum squarrosum community,

Distribution of the natural grassland expansion

As detailed in *Figure 7,* The expansion core area of the natural grassland was determined to be 7,922 km^2. It is distributed around the natural grassland, and suffered a lower level of resistance. Also, it played a key role in protecting the natural grassland from the interferences of human activities, thereby maintaining its natural attributes. It was considered to be the most direct area for the expansion of the natural grassland. The patches of farmland and unused land areas in this area were all completely adjusted to grassland. The farmland to grassland areas were implanted to the dominant and common associated species of the adjacent natural grassland plant communities through artificial cultivation or introduction processes.

The expansion connection areas of the natural grassland were determined to be 3,799.85 km^2. With the outward expansion of the natural grassland along the expansion core area, it had suffered from major influences of human activities. This area showed a landscape pattern in which large sheets of deteriorated grasslands were staggered with patches of farmland and unused land. The differences between this area and the expansion core area were that the dominant species from the vegetation communities in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_32293244
© 2018, ALÖKI Kft., Budapest, Hungary

the adjacent expansion core area had difficulties adapting when only the attributes of the patches were changed to those of closed grassland or further artificial planting. Therefore, in this study it was necessary to adjust the vegetation communities in the connected areas in combination with the aforementioned factors.

The expansion buffer areas of the natural grassland were determined to be 1859.51 km^2. The larger the distance to the natural grassland resulted in higher resistance. The existing landscapes mainly included large irrigation areas, highly fragmented farmland areas near towns, unused land, and degraded grassland interlacing areas. These areas had a very low possibility of recovering the natural attributes of the natural grassland due to the limits imposed by urban development planning. This easily led to the loss of the natural attributes of the grassland under enhanced artificial interference conditions. Therefore, it was determined to be necessary to protect the patches in these areas and maintain stability by taking such measures as returning farmland to grassland, limiting land reclamation, closing degraded grassland, and so on. These measures provided security boundary conditions for the restoration of the grassland ecosystems within the core and connected regions of the study area.

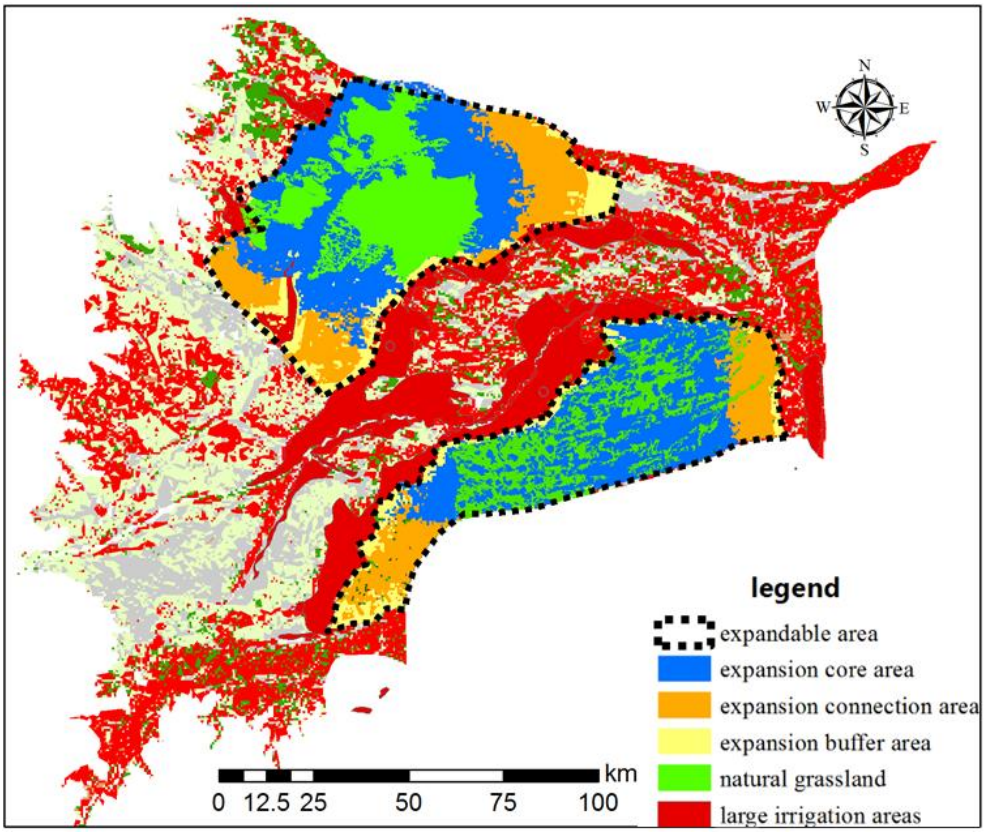

Figure 7. *Distribution of the natural grassland expansion in the West Xiliao River Plain*

Ecological pattern

As detailed in *Figure 8,* in the natural grassland expansion areas, the areas with groundwater levels within 3 m consisted of 5,258.96 km^2. The groundwater conditions in these areas met the requirements to recharge water for the critical burial depths of the vegetation. Also, the adjustments of the ecological patterns in this area could be

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_32293244
© 2018, ALÖKI Kft., Budapest, Hungary

supported. The areas with groundwater levels within 3 to 4 m measured 4,565.86 km^2, and the groundwater conditions in these areas had the ability to recharge water for the growth of fruticeta with long root systems, such as the dominant species Caragana microphylla Lam. The areas with ground water levels above 4 m accounted for 3,896.51 km^2, and the ground water conditions in these areas were determined not to meet the recharging requirements of the critical burial depths of the vegetation. It was therefore concluded that the expansions of the natural grassland in these areas would be meaningless if the conditions of the groundwater were not improved. Therefore, the expansions of the natural grassland should first be transformed in the ecological pattern adjustment areas which were supported by the groundwater conditions. Second, shrub communities with long root systems, such as Caragana microphylla Lam, could be planted in the ecological pattern adjustment areas which were basically supported by the groundwater conditions. Finally, the ecological pattern adjustment areas which were not supported by the relative groundwater conditions could be eliminated.

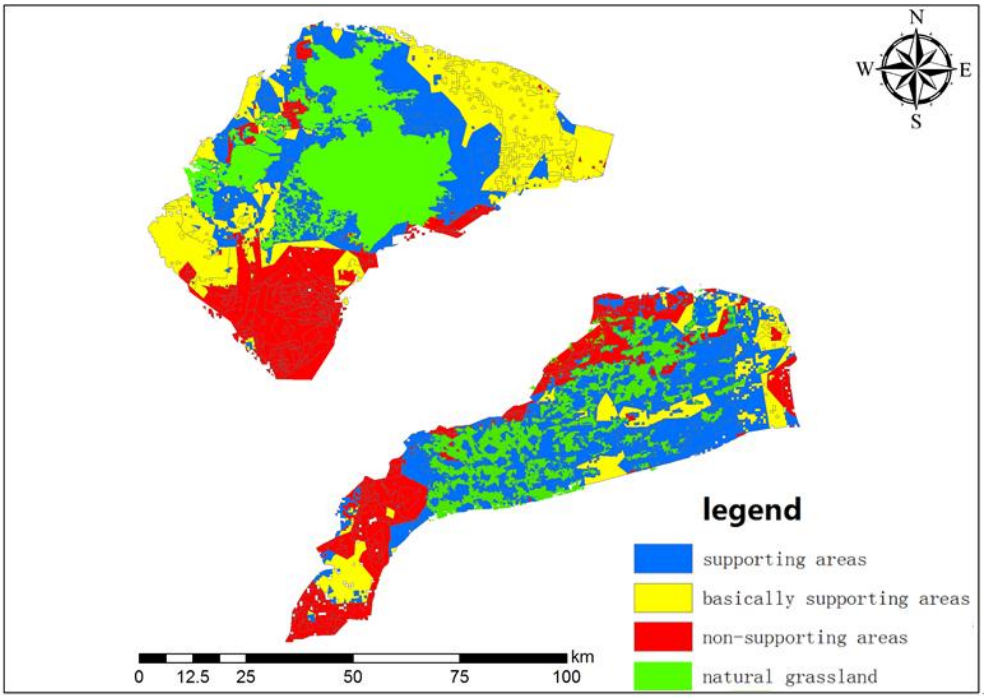

Figure 8. *Distribution of the rationality of the ecological patterns supported by the groundwater subsurface flow field*

The adjustments to the reasonable ecological patterns in the farming-pastoral zone of the West Liaohe River Plain were based on the basic principle of the natural grassland expansion. The optimization and adjustments of the ecological patterns were conducted using a landscape ecology method, and the demands of urban planning and social-economic development were also considered. Moreover, the groundwater conditions were used to analyze the rationality of the adjustments, and the results are shown in *Figure 9*. The grassland areas after the adjustments measured 28,760.7 km^2, and accounted for 43.87% of the total area of the West Liaohe River Plain. Among the grassland areas, the natural grassland areas had been expanded by 8,909.24 km^2, which increases from the original 6,702.89 km^2 to 15,612.13 km^2, which accounted for

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

23.87% of the total area of the West Liaohe River Plain. The farmland areas were determined to be 20,932.4 km^2, which accounted for 31.93% of the total area of the West Liaohe River Plain. Among the farmland areas, the large irrigation areas were 7,729.58 km^2, and accounted for 11.81% of the total area of the West Liaohe River Plain.

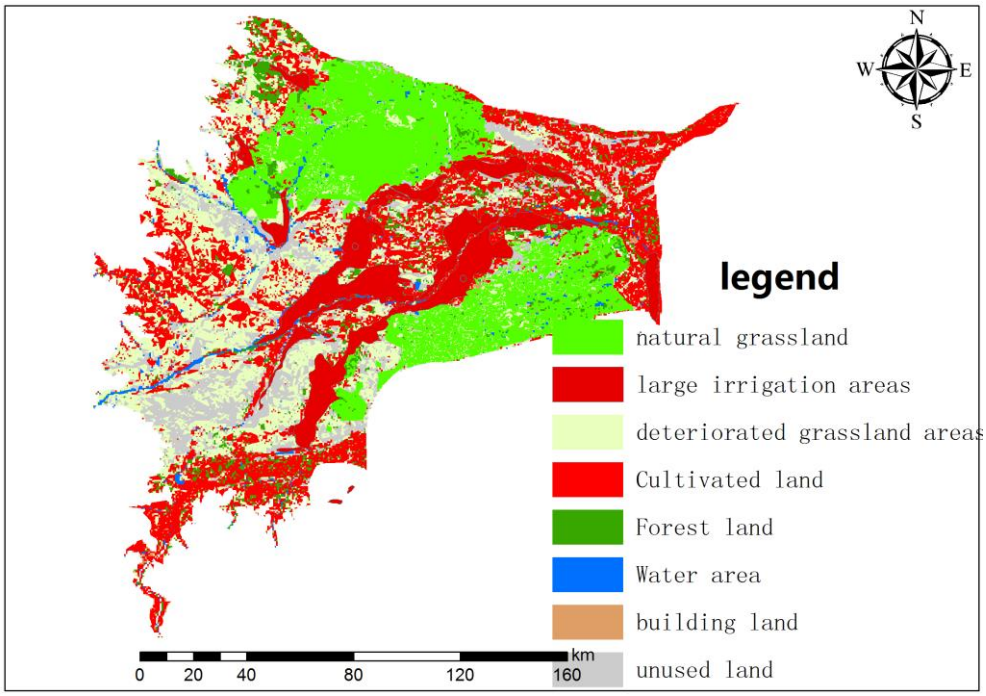

Figure 9. *Ecological patterns of the farming-pastoral zone in the West Liaohe River Plain*

Table 2 details the statistics of the land usage situations in the West Liaohe River Plain since 1990. Through this adjustment of the ecological pattern, the grassland areas have been basically recovered to the level of 1990, which has provided conditions for the ecological restoration of the grassland areas.

Table 2. *Land usage situations in the West Liaohe River Plain during the different periods*

Land usage	1990 (km^2)	2000 (km^2)	2010 (km^2)	2016 (km^2)	Ecological pattern (km^2)

Conclusion

The farming-pastoral zones in semi-arid regions are typically ecologically fragile zones, as well as important ecological barriers. The ecological environments are not only the basis and guarantee of regional economic development, they are also barriers relating to the ecological security of the Yellow River Basin, Haihe River Basin, and Beijing-Tianjin-Hebei Regions. In this research study, by taking the West Liaohe River Plain as the research area, and the natural grassland expansion as the basic principle, adjustments were made to the ecological security patterns of the agriculture and animal husbandry in the West Liaohe River Plain. Then, the rationality of the ecological security patterns supported by the groundwater conditions was analyzed. The grassland areas were expanded through the adjustments of the ecological patterns, which provided the conditions and foundation for the ecological restoration of grassland. The natural attributes of the regional hydrological cycles determine the basic patterns of an ecosystem, it was necessary to recognize the decisive influences of the regulation and management of the groundwater level on the grassland vegetation community pattern. In future research, we should focus on how to improve the biodiversity of grassland and how to control the water level of the groundwater.

Acknowledgements. The research was supported by the ministry of water resources' special funds for scientific research on public (No.201501031) and the National Science Foundation for Distinguished Young Scholars of China (Grant No.51409271).

(Received 13th Feb 2018; accepted 9th May 2018)

Abstract. Aqueous extract of *Pongamia pinnata* (PALE) was accessed to alleviate mercuric chloride ($HgCl_2$) induced stress on seed germination and early seedling growth of *Zea mays* L. Maize seeds were soaked in 5 and 2.5% PALE prior to sowing in the pots and $HgCl_2$ was applied at rate of 1 and 0.5 mg kg^{-1} to the soil to induce an artificial stress for the germination and seedling growth. The results showed that seed germination (%), root dry weight and photosynthetic pigments were significantly reduced by $HgCl_2$ at 1 mg kg^{-1}, which resulted in accumulation of phenolic compounds in maize leaves. It was found that the total soluble phenolic content was negatively correlated with shoot dry weight ($r = -0.656$, $p = 0.001$). On the other hand, seed soaked with PALE significantly alleviated adverse effects of $HgCl_2$ stress on seed germination and growth attributes of maize, thus it was found to be effective to protect maize plants from adverse effects of mercury and can be recommended for application in mercury contaminated areas of farmer's field.

Keywords: *mercury stress, phenolic, Pongamia pinnata, phytoremidiation, PALE, Zea mays, $HgCl_2$*

Introduction

The term 'heavy metal' is often used to cover a diverse range of elements, which are considered to be toxic to human health as being an important class of pollutants. Although heavy metals are naturally present in the soil (Zakir et al., 2014), but the geologic and anthropogenic activities have caused them to increase to the toxic level that are harmful to both plants and animals (Alyemeni and Almohisen, 2014). Heavy metals adversely affect the development of both vegetative and generative parts of the plants (Jeliazkova and Craker, 2003) leading to losses in yield (Chatterjee and Chatterjee, 2000). Therefore, the remediation of heavy metal polluted soils cannot be over emphasized (Chibuike and Obiora, 2014).

Heavy metals block functional groups of metabolically important molecules, alter hormonal balance, reduce nutrient assimilation, protein synthesis, and DNA replication (Nagajyoti et al., 2010). They inhibit chlorophyll synthesis by substitution of magnesium in chlorophyll and also water uptake (Boening, 2000). Among the various types of heavy metals, mercury accumulates in all parts of the plant but mostly in roots indicating that roots serve as a barrier to mercury uptake (Bibi et al., 2016).

To reclaim the soils contaminated with heavy metals, various physical and chemical approaches have been adopted but these are expensive and make the soil unsuitable for plant growth (Marques et al., 2009). Biological approach (bioremediation) on other hand is the best for establishment / reestablishment of plants on polluted soils. Being a natural process, it is an environment friendly method. Phytoremediation is a part of bioremediation in which plants are used for the treatment of polluted soils (Cuypers et

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_32453253
© 2018, ALÖKI Kft., Budapest, Hungary

al., 2010). The different mechanisms used for phytoremediation are phytostabilization, phytovolatilization and phytoextraction (Chaney et al., 1997). The amount of phytochemicals such as plant phenolics are reported to increase under the stress of heavy metals. This increase of phenolic content is correlated with increased activity of enzymes involved in biosynthesis of phenols under heavy metal stress (Winkel-Shirley, 2002; Rizvi, 2006; Bibi et al., 2016).

Pongamia (*Millettia pinnata*), formerly known as *Pongamia pinnata*, is a tree/shrub widely cultivated in Pakistan. It can tolerate a wide range of soil types including saline, alkaline, sandy, heavy clay and rocky soils and waterlogged soils. Pongamia is used in land reclamation and as a soil stabilizer (Shirbhate and Malode, 2012). Keeping in view the harmful effects of heavy metals on plants and the role of phytochemicals in heavy metal stress tolerance of plants, the present investigation was carried out to alleviate mercury induced stress on maize plants by *Pongamia pinnata* leaf extract.

Material and methods

The healthy and fully expended leaves of *Pongamia pinnata* (200 g) were collected (20 gm per tree) from the campus of the University of Science and Technology, Bannu, mixed together to form a composite sample, dried under shade for 2 to 3 weeks and finely ground in an electric grinder. The elemental composition of *Pongamia Pinnata* leaf was analysed following the method described by Rashid (1986). The powdered leaf material was digested in a solution of nitric acid and perchloric acid (2:1) and heated at 150 °C. After cooling it to room temperature, the volume was raised to 50 ml using deionized water and filtered. Elemental analyses were carried out using an Atomic Absorption Spectrophotometer (Model: Perkin Elmer Analyst-200, USA).

Preparation of Pongamia pinnata leaf extract

Formal maceration techniques were used in the preparation of extracts. The *Pongamia pinnata* leaf powder (20 g) was soaked in 200 mL of distilled water and was kept there for 48 h. It was filtered first with fine porous cloth and then with a Whatman No. 1 filter paper. The aqueous extract obtained was designated as a 10% (w/v) stock solution. This stock solution was further diluted to 5 and 2.5% (w/v) in distilled water and were denoted as PALE.

Bioassay

The seeds of maize (*Zea mays* L., variety Azam) were obtained from the Agriculture Research Centre Sara-e- Nourang, Lakki Marwat, KP, Pakistan. Finely ground uniformed soil (sand and clay 1:1) was filled in plastic pots (8×12 cm^2) for sowing of maize seeds in order to facilitate easy penetration of roots and uprooting of plants at the time of harvest. The soil used as culture medium was analyzed for pH, content of available nitrogen and phosphorous using standard protocols. Determination of soil pH was carried out by the method of McLean (1982). For electrical conductivity (EC) determination, the saturated paste of soil was prepared by suspending soil into water and thoroughly mixed by using magnetic stirrer for 30 min. After settling, the EC was noted by using conductivity meter (Page et al., 1982). Phosphorous content of the soil was determined according to the method of Olsen and Sommers (1982). For determination of total nitrogen content 10 g of soil was digested in micro-Kjeldahl flask

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

with 20 mL of concentrated H_2SO_4 and 10 g digestion mixture. After digestion, the flasks were allowed to cool. The contents were transferred to a 50 mL flask and distilled. The distillation was carried out in the presence of 20 mL of 40% NaOH and collected in 5 mL boric acid. The distillate was titrated against 0.1 N H_2SO_4 using $KMNO_4$ as indicator. The particle size of the soil was determined at Agriculture Research Station Sari Naurang Lakki Marwat, Pakistan. The physico-chemical properties of the soil are shown in *Table 1*.

Table 1. *Physico-chemical properties of the soil used in the experiment*

Parameters	Values
pH	7.5
E.C.	3.10 dS m^{-1}
Total nitrogen content	0.41% dry weight
Total phosphorous content	29 mg kg^{-1}
Clay (<0.002 mm)	34%
Fine silt (0.002–0.02 mm)	13%
Fine sand (0.05–0.2 mm)	23%
Coarse sand (0.2–2 mm)	30%

To impose artificial stress of mercury, $HgCl_2$ was added at 1 and 0.5 mg kg^{-1} soil. The experiment was carried out statistically in completely randomized design (CRD) with three replications for each treatment (various levels of mercury and PALE) in a glass house in the Department of Botany, University of Science and Technology, Bannu, KP Province, Pakistan. Maize seeds were soaked in various treatment levels of PALE for three hours before sowing them in pots. The following samples were examined: Control pots where seeds soaked in distilled water were sown, Pots with soil contaminated with $HgCl_2$ at 1 mg kg^{-1} soil, Pots with soil contaminated with $HgCl_2$ at 0.5 mg kg^{-1} soil, Pots with soil contaminated with $HgCl_2$ at 1 mg kg^{-1} soil where seeds soaked in 5% PALE were sown, Pots with soil contaminated with $HgCl_2$ at 1 mg kg^{-1} soil where seeds soaked in 2.5% PALE were sown, Pots with soil contaminated with $HgCl_2$ at 0.5 mg kg^{-1} soil, where seeds soaked in 5% PALE were sown, Pots with soil contaminated with $HgCl_2$ at 0.5 mg kg^{-1} soil, where seeds soaked in 2.5% PALE were sown.

When 90% of the seeds were germinated in control pots, the seeds germination (%) was calculated according to the following formula:

$$\text{Seed germination } (\%) = (\text{Seeds germination / Total number of seeds grown}) \times 100$$

The plants were harvested 28 days after sowing and were analyzed for the following morphological, physiological and biochemical growth attributes. The shoot and root weight were determined using electronic balance. Root length was determined using a measuring tape. The leaf photosynthetic pigments were analysed according to the method described by Arnon (1949). The total soluble phenolic content of the maize leaves were determined by the Folin-Ciocalteau method (Wolfe et al., 2003). The extract (200 µL) was mixed with the Folin-Ciocalteau reagent (Sigma-Aldritch, Cat # F9252-100ML) and incubated for five minutes at room temperature in dark. The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_32453253
© 2018, ALÖKI Kft., Budapest, Hungary

mixture was added to a 1.5 mL sodium carbonate (7%, w/v) solution and incubated in dark for 90 min. The optical density of the mixture was determined at 760 nm using a spectrophotometer (Hitachi's U-5100 Tokyo, Japan). Standard curve made of various concentrations of gallic acid solutions was matched with the sample measurements. The concentration of total phenolic content was expressed as μg gallic acid equivalents g^{-1} sample.

Statistical analyses

Analysis of variance technique (ANOVA) was used for the analysis of data and the Least Significant Difference (LSD) test (Steel and Torrie, 1980) was used for the comparison of treatment means. Student Statistix (version 8.1 USA) software package was used for the determination of coefficient of correlation.

Results and discussion

The Pongamia leaf was analysed for elemental composition and total soluble phenolic content (*Table 2*). Among macronutrients, Na (204 μg g^{-1}), K (197 μg g^{-1}), Ca (67 μg g^{-1}) and Mg (89 μg g^{-1}) were determined. Among micronutrients Fe (42 μg/g), Mn (22 μg/g) and Zn (35.22 μg/g) were analysed. The total soluble phenolic content of Pongamia leaf was 139 mg gallic acid g^{-1} d.w. Plant extracts were characterized by the presence of natural phenolics and various types of nutrients having beneficial effect on plant growth (Ullah et al., 2014; Khattak et al., 2015).

Table 2. *Nutrient composition of Pongamia pinnata leaf*

Parameter studied	Value (μg g^{-1} d.w)
Na^+	204
K^+	197
Mg^{2+}	67
Ca^{2+}	80
Fe^{2+}	42
Mn^{2+}	22
Zn^{2+}	35
Total soluble phenolic content (μg gallic acid g^{-1} d.w)	139000

The data depicted that soil contamination with higher concentration of $HgCl_2$ (1 mg kg^{-1} soil) significantly reduced the seed germination compared to control (*Table 3*). On the other hand, seeds soaked with PALE significantly ameliorated adverse effects of $HgCl_2$ on seed germination (%). A negative impact of $HgCl_2$ stress on shoot fresh and dry weights was observed (*Table 3*). However, the exogenous application of PALE minimized adverse effects of $HgCl_2$ on shoot fresh and dry weights. Root length was also significantly reduced by $HgCl_2$ at 1 mg kg^{-1} soil as compared to untreated control (*Table 3*). The application of PALE (5%) exhibited stimulatory effects and minimized adverse effects of $HgCl_2$ on root length. The soil contamination with $HgCl_2$ significantly decreased root fresh weight as compared to control ($p < 0.05$). The PALE effectively protected fresh weight of roots from adverse effects of $HgCl_2$ induced stress. At higher concentration of $HgCl_2$ (1 mg kg^{-1} soil), the beneficial effect of PALE on root fresh

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_32453253

weight was also found to be stronger. The $HgCl_2$ has no significant effect on root dry weight (*Table 3*).

Mercury stress results in abnormal seed germination with a significant reduction in germination indices (Patra and Sharma, 2000). Mercury reduces mitotic activity in plant organs, therefore results in lower biomass production (Patra et al., 2004). The beneficial effect of PALE on seed germination and morphological growth characters of maize under $HgCl_2$ could be attributed to its phytochemical composition. Previous studies have shown that the aqueous leaf extract of *Moringaoleifera* was highly effective and protected maize plants from adverse effect of $HgCl_2$ (Bibi et al., 2016).

Results showed that $HgCl_2$ at 1 mg kg^{-1} soil significantly reduced chlorophyll *a* content as compared to control (*Table 4*). The application of PALE at 5% concentration significantly ameliorated adverse effects of $HgCl_2$ stress on chlorophyll *a* content. All the treatments showed non-significant effect on chlorophyll *b* content (*Table 4*). The reduction of chlorophyll content under mercury stress has been reported in *Marrabiumvulgare* (Moreno-Jiménez et al., 2007). Mercury disrupts the photosynthetic machinery by inactivating the magnesium ion of the chlorophyll molecule (Patra et al., 2004).

In the present investigation, it was found that $HgCl_2$ induced stress caused accumulation of phenolic compounds in the leaves of maize (*Table 4*). Total soluble phenolic content was found to be higher when $HgCl_2$ was applied at 1 mg kg^{-1} soil. However, soaking seeds in PALE resulted in further augmented accumulation of phenolics in maize leaves. The most effective concentration of PALE was 5%. Plants accumulate phenolic compounds when exposed to heavy metal stress (Klepacka et al., 2011). Accumulation of phenolic under heavy metal stress has also been reported in *Phaseolus vulgaris* (Hamid et al., 2010), *Boerhavia diffusa* (Abdussalam et al., 2015) and *Trigonellafoenum-graecum* (Askari and Azmat, 2013). Phenolic compounds protect cell biomolecules from oxidative damage by scavenging reactive oxygen species and prevent lipid peroxidation. This is achieved by the reduced forms of phenolic compounds whereas in oxidized state, these may function as prooxidants (Sakihama et al., 2000). Antioxidant activity of Pongamia extract was correlated with its flavonoid and phenol content (Behera et al., 2012). The higher increase in phenolic compounds by seed soaked with PALE under $HgCl_2$ stress indicates the possible role of bioactive compounds present in the extract which contributed to the mercury stress tolerance of maize.

It was observed that Hg stress resulted in the accumulation of phenolic compounds with a reduction in the content of photosynthetic pigments. On the other hand PALE not only caused accumulation of phenolic compounds but also improved the content of photosynthetic pigments. This suggested that exogenous application of PALE reduced chlorophyllase activity responsible for chlorophyll degradation. Phenolic compounds

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_32453253
© 2018, ALÖKI Kft., Budapest, Hungary

either stimulate or inhibit the content of photosynthetic pigments that is why phenolics are considered as compounds with bifunctional role, one of stimulation and another of inhibition (Yang et al., 2004). This may be attributed to the fact that phytochemicals present in PALE have stimulatory effect on photosynthetic pigments in maize.

The correlation of chlorophyll *a* was found to be positive with chlorophyll *b* ($r = 0.691$, $p = 0.000$), germination (%) ($r = 0.581$, $p = 0.005$), root fresh weight ($r = 0486$, $p = 0.025$) and shoot fresh weight ($r = 0.571$, $p = 0.006$). The total soluble phenolic content was negatively correlated with shoot dry weight ($r = -0.656$, $p = 0.001$). The correlation of root fresh weight was also positive with shoot fresh weight ($r = 0.491$, $p = 0.023$).

Conclusion

The growth of maize was inhibited when grown on $HgCl_2$ contaminated soil due to the toxicity of mercury. This mercury stress was associated with the accumulation of phenolic compounds. It was found in the present studies that exogenous application of PALE was effective in alleviating the adverse effects of $HgCl_2$ on maize plants grown under $HgCl_2$ contaminated areas, thus, PALE can be used in bioremediation of contaminated soils for better plant growth. *Pongamia pinnata* is a drought tolerant and nitrogen fixing plant species. Its oil has potential for use as a feedstock for biodiesel production and can survive under harsh environmental conditions. Therefore, it is a more suitable tree species for exploitation as a source of future bioregulators for improving growth and productivity of crop plants.

(Received 17th Feb 2018; accepted 30th May 2018)

Abstract. In this study, the vegetation of 63 sabkha and sewage canals in central region of Saudi Arabia was analyzed. A total of 109 plant species belonging to 83 different genera and 34 different plant families were collected. The most common plant families were *Chenopodiaceae* (18 species), *Poaceae* (16 species) and *Asteraceae* (10 species). Vegetation in the study area was classified into 6 groups; two of them were found in sabkhas only, one was found in sewage canals only and the other three were found in both habitats. The main factors controlling the plant presence and vigour in the studied wetlands were soil salinity, pH, EC, soil texture and content of organic matter.
Keywords: *wetlands, vegetation, DECORANA, TWINSPAN*

Introduction

Wetlands are defined as the areas that are inundated or saturated by surface or groundwater at a frequency and duration sufficient to support a prevalence of vegetation typically adapted for life in saturated soil conditions (LePage, 2011). They include, for example, salt marshes (sabkhas), shallow ponds and sewage canals. Wetlands are identified by unique soils (hydric soils), plants adapted to life in wet environments (hydrophytes) and the presence of water (hydrology) during the growing season. From an ecological perspective, wetlands are simply a particular slice of the continuum between the wettest ecosystem types (rivers, lakes, estuaries, and the marine environment) and the driest environments within a physiographic (broad-scale subdivisions of the Earth's surface based on terrain texture, rock type, geologic structure, and history) region (Brinson, 2011).

Wetlands in the central region of Saudi Arabia are considered among the main diverse habitats. However, there have been no studies of their vegetation diversity until now. In Saudi Arabia, wetlands are located in a hot and dry region that is experiencing major climate changes. They are generally characterized by high biodiversity in terms of both animals and plants. With their hydrologic characteristics, wetlands have a great ecological importance. They have plants with high productivity and provide habitats for many wild fishes and birds (LePage, 2011). Saudi Arabia has several natural and industrial wetlands including lakes, sabkhas and wadis. Beside their importance to various animals especially amphibians, wetland habitats have a great potential to conserve biodiversity of plants (Flinn et al., 2008). Al-Obaid et al. (2017) stated that wetlands are also of great economic importance in agriculture and grazing. Nevertheless, the plant communities of different wetlands in Saudi Arabia has not been fully described. The aim of this study was to characterize the vegetation of different wetlands in central region of Saudi Arabia.

Materials and methods

Study area

The central "Najd" region is the large central plateau in Saudi Arabia; it is divided into two parts: the higher Najd in the west (located on the Arabian Shield region) and the lower Najd in the east. The altitude in this area ranges from 500 - 1000 m above sea level. The higher Najd is characterized by an extensive system of large wadis. Wadis in general flow from west to east, following the slope of the land, from the higher mountains in the west to the lower plains of Najd.

Qassim is located in the northern central region of Saudi Arabia with an area of 80.000 km^2. It has two different geological regions; one is located on the Arabian Shield region and the other is located in the sedimentary sector (the Arabian Shelf). Qassim has many sabkhas and wadis in addition to several mountains. Riyadh is located at 24° 38' N lat. and 46° 43' E long. in the central region of Saudi Arabia occupying a large area of Najd plateau with an average altitude of 600 m above sea level. Riyadh is characterized by several mountains (e.g. the Tuwaiq Mountains) and sand dunes. Similar to Qassim, Riyadh is divided into two geological sectors; the western part is the Arabian Shield sector and the eastern is the sedimentary sector (*Fig. 1*).

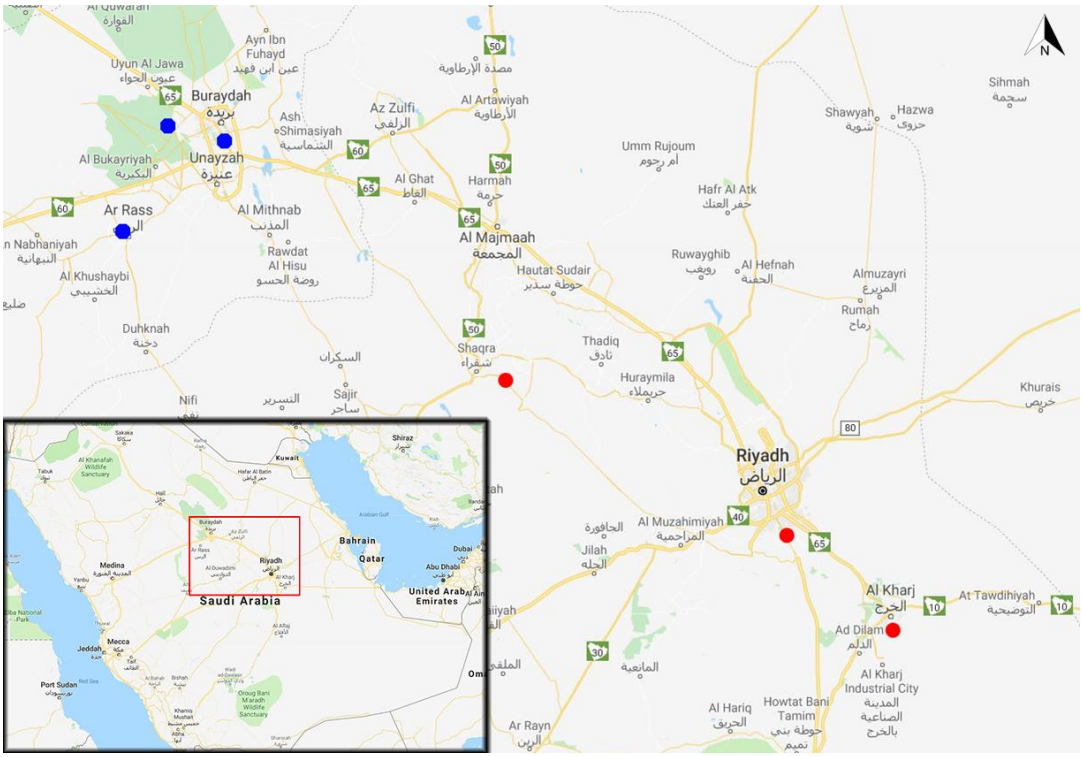

Figure 1. *A map showing the different studied sites*

The study area is characterized by high temperatures especially from June to August when the temperature can exceed 45 °C. The general climate in the study area is hot summer and mild to cold winter. The rainfall is very low with an average of less than 200 mm/ month, and most of the rain falls during spring with almost no rain in the summer. The wind is usually laden with dust from upwind desert areas. *Table 1* summarizes the climate characteristics of the two studied areas; Riyadh and Qassim.

Table 1. *Average of climate records for 10 years (2005 – 2014) in Riyadh and Qassim areas (Source: Saudi General Authority of Meteorology and Environmental Protection)*

Climate variable	Riyadh		Qassim	
	Range	Mean	Range	Mean
Max air temperature (°C)	20.95 – 43.93	32.44	20.43 – 44.72	32.58
Min air temperature (°C)	7.48 – 27.66	17.57	6.74 – 27.33	17.00
Rainfall (mm/ month)	0.00 – 320.91	160.46	0.00 – 320.00	160.00
Relative humidity (%)	8.30 – 94.30	51.30	4.20 – 99.80	52.00
Wind speed (km/ h)	4.10 – 7.10	5.6	4.90 – 7.40	6.15

Sample stands

In the present study, 63 different stands were selected to represent the two main studied habitats (sabkhas and sewage canals) that exist in different wetlands in the central region of Saudi Arabia. GPS coordinates for all the studied stands were recorded (*Appendix 1*) and in every stand, an area of 50 m × 50 m was sampled. Sampling was carried out during the spring season 2016 in order to ascertain the maximum presence of the different plant species. Plant samples collected from each stand were identified according to Collenette (1999) and Chaudhary (2001) and presented at the herbarium of King Saud University, Riyadh, Saudi Arabia. Plants were classified into annual herbs, annual grasses, perennial herbs, perennial grasses and shrubs (*Appendix 2*). The pattern of geographical distribution (chorotype) of each species were studied following Chaudhary (2001). The total and mean cover and presence of each species were calculated for each stand following the method described by Kent (2012).

Soil analysis

Three soil samples were collected from each stand at a depth of 50 cm and mixed together to form a composite sample. Soil physical and chemical characteristics were assessed. The hydrometer method was used to determine the soil texture (Day, 1965). The "Loss on Ignition" method (combustion at 550 °C) was used to calculate the total organic matter present in the soil samples. Soil pH and electrical conductivity (EC) was calculated in soil suspension 1: 5 w: v. Nitrogen content in soil samples was determined using the micro Kjeldahl method (AOAC, 1990). Phosphorus content was determined following the method of APHA (2005). Concentrations of various nutrients (Ca, K, Mg, Fe, Na) were measured following the methods described by Allen (1989).

Water analysis

One water sample from each stand was collected (where applicable) and chemical analyses were performed. Samples were collected at a depth of 1 m above surface that is around the middle of each water body. Water pH and EC were examined according to Allen (1989). Phosphorus content was determined following the method of APHA (2005). In addition, levels of Ca, K, Mg, Fe and Na in the water samples were investigated (Allen, 1989).

Statistical analysis

Canonical correspondence analysis (CCA) and detrended correspondence analysis (DCA) using DECORANA software (Hill, 1979a) and multivariate analysis using

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_32553269
© 2018, ALÖKI Kft., Budapest, Hungary

TWINSPAN software (Hill, 1979b) were performed to calculate the estimates of cover for 109 plant species collected from the 63 stands. Species richness (α-diversity) was defined as the average number of species present in each individual stand. Gamma diversity (γ-diversity) was determined based on the total number of species for each stand. The relative cover (p_i) of each stand was used to calculate the relative evenness using the Shannon-Wiener index $\widehat{H} = -\sum_{i=1}^{s} p_i \log p_i$ and the relative dominance concentration using the Simpson index $C = \sum_{i=1}^{s} p_i^2$ where s is the total number of species collected (Pielou, 1975; Magurran, 1988).

Results

The total number of plants collected from the different wetlands studied in the Riyadh and Qassim areas was 109 plant species belonging to 83 different genera and 34 different plant families, with a species richness factor of 1.31 (109 species / 83 genera). The most abundant plant families were Chenopodiaceae with 18 different plant species (16.5%), Poaceae represented by 16 different plant species (14.7%), Asteraceae with 10 different plant species (9.2%) and Fabaceae with 7 different plant species (6.4%). The least abundant families were Aizoaceae, Amaranthaceae, Apocynaceae, Asphodelaceae, Cistaceae, Cucurbitaceae, Ephedraceae, Frankeniaceae, Juncaceae, Lamiaceae, Malvaceae, Molluginaceae, Neuradaceae, Orobanchaceae, Portulacaceae and Ruppiaceae, with each family being represented by only one plant species (*Fig. 2a*, bar chart). *Fig. 2b* (pie chart) shows that the predominant life forms were annual herbs with 40 different plant species (36.7%) and perennial herbs with 34 different plant species (31.2%). The total number of different annual species was 45 (41.3%), while the perennial species were represented by 64 different species (58.7%). In terms of the global geographical distribution of the plants collected, the most represented regions were the Saharo-Arabian region with 39 (35.10%) different plant species followed by the bi-regional Saharo Arabian-Somalia Masai with 10 (9.2) different plant species and the Tropical and Saharo Arabian-Irano Turanian regions with 8 (7.3%) different plant species for each. Generally, the most abundant species were those typically found in a single region (52 species, 46.9%) and the bi-regional species (30 species, 28.4%) while the multi-regional and cosmopolitan species were the least abundant with 12 species (11.0%) and 1 species (0.9%), respectively. The most abundant plant species in all the habitats studied were *Phragmites australis* (with a relative presence 'P' = 41.3%, a relative coverage 'C' = 15.4%), *Tamarix nilotica* (P = 39.4%, C = 5.71%), *Salosola imbricate* (P = 34.9%, C = 1.32%), *Zygophyllum propinquum* ssp. *migahidii* (P = 25.4%, C = 16.0%) and *Tamarix aucheriana* (P = 25.4%, C = 16.0%). In contrast, the rarest plants (≤ 1) in the habitats studied included (for example) *Aizoon canariense*, *Chenopodium album*, *Plantago amplexicaulis* and *Salvia spinosa*.

In the present study, two forms of wetlands in Saudi Arabia were studied, namely sabkhas (natural) and sewage canals (industrial). Seventy-nine different plant species belonging to 69 genera and 28 families were found in sabkhal habitats. Chenopodiaceae, Poaceae and Asteraceae were the most highly represented plant families with 14, 14 and 7 plant species, respectively. Most of the plant species in sabkhas were annual herbs (34 species, 43%) and perennial herbs (20 species, 25.3%). The most abundant plant species were *Tamarix aucheriana* (P = 39.47%, C = 13.16%) and *Zygophyllum propinquumm* ssp.*migahidii* (P = 34.21%, C=4.03%), while the rarest plant species were *Chenopodium album* and *Salvia spinosa*. In contrast, in sewage canal habitats, 58 different plant

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

species belonging to 50 genera and 26 families were found. The most abundant families there were members of the Poaceae (9 species, 15.5%) and Chenopodiaceae (8 species, 13.8%). Perennial herbs twenty different species (34.5%) were the most represented group followed by annual herbs with 16 species (27.6%). *Phragmites australis* was the most abundant plant species (P=57.69%, C=24.04%) followed by *Tamarix nilotica* (P=50.00%, C=8.85%), *Calotropis procera* (P=38.46%, C=8.31%) and *Pulicaria undulata* (P=38.46%, C=6.92%). In contrast, *Aeluropus lagopoides* and *Amaranthus viridis* were the rarest plants (*Appendix 1*).

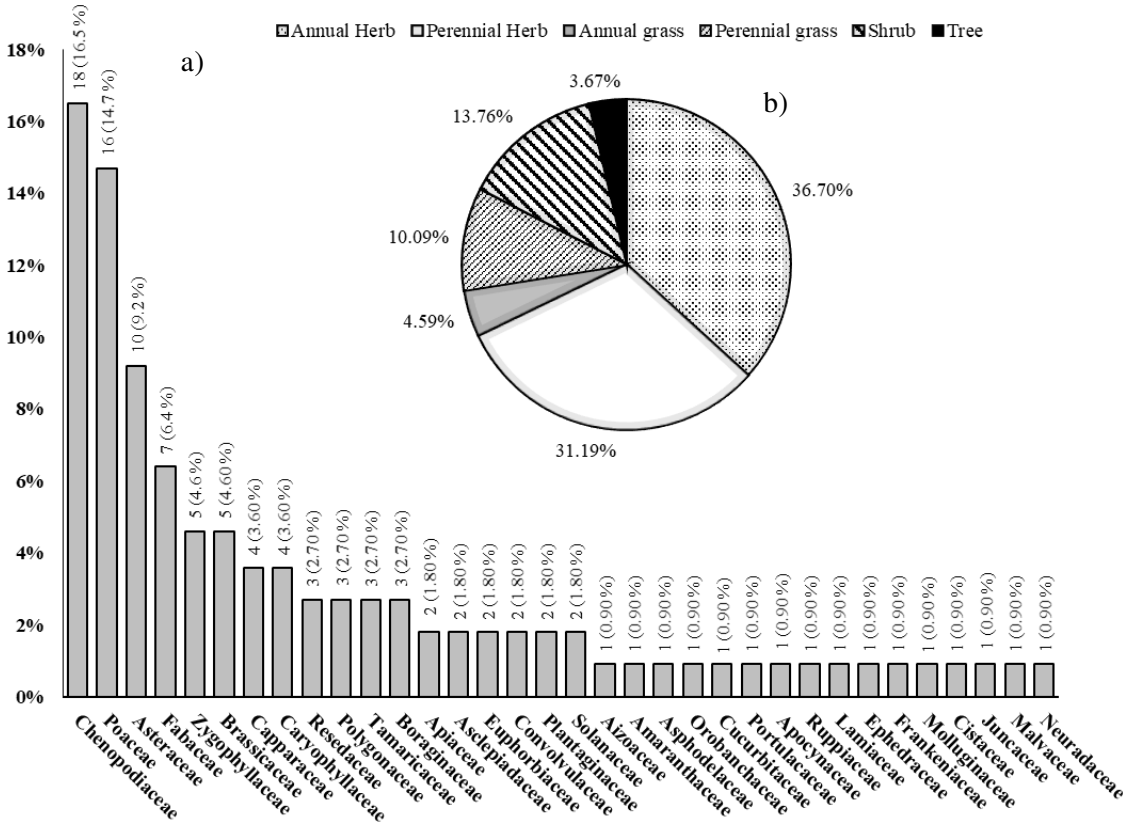

Figure 2. *(a) Number and percentages of different represented families (bar chart) and (b) lifeforms (pie chart) in the studied stands.*

Cover estimates for 109 plants collected from 63 different stands using TWINSPAN software generated 6 different vegetation groups at the third level of classification (*Fig. 3a, Table 2*). Of these groups, only two groups only occupied sabkhas habitats; a) that characterized by *Tamarix aucheriana – Phragmites australis* and b) that characterized by *Centropodium forsskalii – Emex spinosa*. One group occupied sewage canals only (*Calotropis procera – Citrullus colocynthis*), two groups mainly occupied sabkhas; a) *Suaeda vermiculata – Seidletzia rosmarinus – Zygophyllum propinquum* ssp. *Migahidii* and b) *Haloxylon salicornicum – Suaeda aegyptiaca*. One group mainly occupied sewage canals (*Tamarix nilotica – Salsola imbricata*). Further analysis of the same data set using DECORANA software showed a reasonable segregation between the groups that had been generated (*Fig. 3b*).

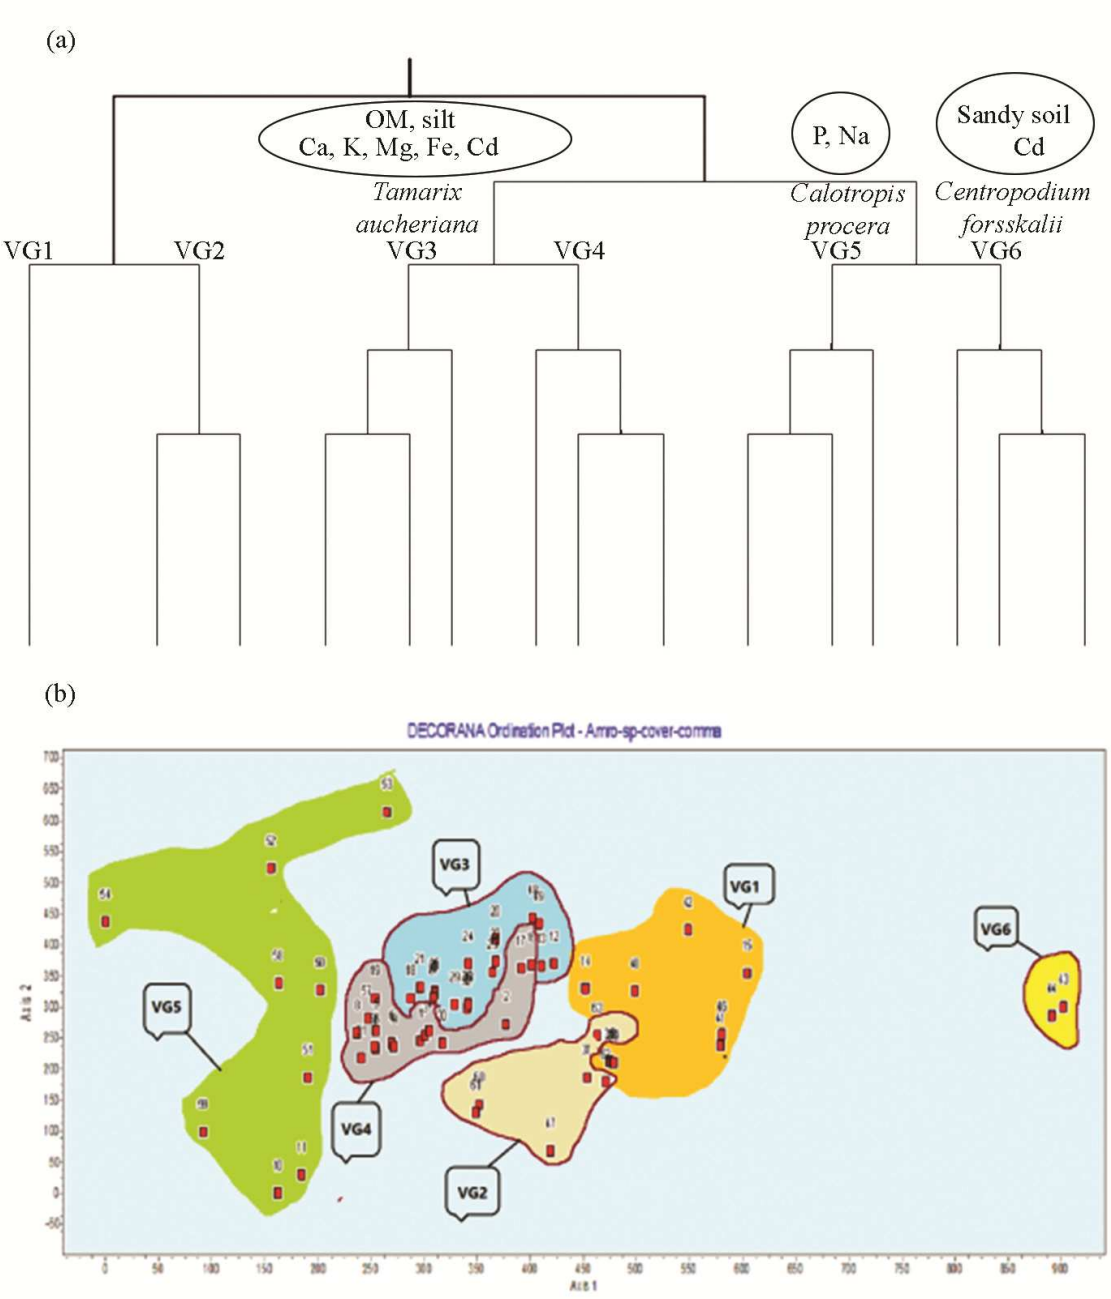

Figure 3. *(a) Dendogram showing the relationship between 6 different vegetation groups generated by TWINSPAN and (b) Segregation of different vegetation groups after applying DECORANA analysis.*

CCA analysis showed that different environmental factors related to soil affect the species distribution on the two axes. There was a positive correlation between the Simpson index value and the first axis and a negative correlation between the same axis and EC, Ca, Mg, Cr and Cd. Meantime, the second axis correlated negatively with silt percentage in soil, organic matter, Ca, K, Mg, and Cd (*Fig. 4a*). Plant species recognized as psammophytic (associated with sandy soils) occupied the positive upper left and right sides of the CCA plot (*Fig. 4b*) and showed a positive correlation with the

Discussion

Wetlands are considered a very significant habitat for diverse group of animals, plants and even microbes. In addition to their important role in the water cycle, and in removing excess nutrients and other contaminants from polluted water, they are one of the most biodiverse sites around the world. Wetlands contribute significantly in keeping the ecological balance between different plant species. In Saudi Arabia, wetlands are the richest habitats from the point of view of plant diversity because of the availability of moisture, in contrast to the many dry places around the kingdom. In this study of the vegetation of 63 different sites, it was found that perennial plants were the most abundant life forms. Our earlier (unpublished) studied on wetlands in Saudi Arabia have also shown that perennial plants are more abundant than annual plants in valley habitats in the Riyadh area. In contrast, we found that annual plants were more abundant in Sabkha habitat in the Qassim area (unpublished data). Levels of species richness (1.31) in this study indicated the high plant diversity at the region. Members of the Chenopodiaceae family were the most abundant family in the stands studied. This may be due to the high tolerance of drought and salinity typical of the members of this family. Stebbins (1974) pointed out that the Chenopodiaceae plants were typically able to grow in saline sandy soils such as sabkhas. It could, also, be due to the fact that members of the Chenopodiaceae disperse readily due to their lightweight seeds (El-Sheikh, 2013). In the present study, where the Chenopodiaceae were most abundant, they were followed by Poaceae and Asteraceae. In contrast, at the level of Saudi Arabia as a whole, Chaudhary (2001) found that the most abundant families were first, the Poaceae followed by the Chenopodiaceae and the Zygophyllaceae.

In the present study, perennial plants were more represented than annuals. Wetlands habitats such as sabkhas and sewage treatment areas are very different from the dryland areas, in that they provide the moisture required by plants, and do so year-round. In addition, soils in wetlands have higher concentrations of various nutrients that promote the growth of various perennial species. The dominant plants in wetlands are trees as they can tolerate drought stress for longer periods, and they can draw water from surface and deep soil via their extensive root systems (Al-Rowaily et al., 2012). Chorotype analysis showed that mono-regional plants were the most abundant and were represented by the Saharo Arabian, Tropical and Irano-Turanian groups, respectively. The study stands are located, mainly, in the Arab Sahara Region located between the Tropical and Irano-Turanian regions (Alatar et al., 2012). The central region of Saudi Arabia is a part of the Arab Sahara Region and their plants are mainly mono-regional belonging to the Saharo Arabian group (Al-Nafie, 2008). The presence of plants normally associated with Saharo Arabian-Somalia Masai, Saharo Arabian-Irano Turanian and Mediterranean-Irano Turanian floras indicate that the central region of Saudi Arabia is a transitional area with some of the characteristics of surrounding regions. This supports earlier vegetation studies of the central region (Alatar et al., 2012; Alatar et al., 2015) and studies of Kuwait (El-Sheikh et al., 2012).

TWINSPAN analysis showed that there were 6 different vegetation groups in the study sites. Shaltout et al. (1997) studied the vegetation of coastal lowland of eastern Saudi Arabia. In their analysis, they found 12 different vegetation groups include *Tamarix aucheriana* and *Phragmites australis* communities. In addition, *Phragmites australis* was found in the Hail region in northern Saudi Arabia (El-Ghanim et al., 2010). In the present study, it was found that salinity, soil texture and nutrient levels were the main environmental factors affecting the distribution of plants in each stand.

Our results are supported by other studies of similar habitats (Alatar et al., 2012; El-Sheikh et al., 2012). The Shannon index showed a positive correlation with sand content in soil because soils with more sandy texture provide soil aeration in wetlands such as sabkhas and sewage canals. Furthermore, percentage of cover was positively correlated with organic matter content and potassium levels. Shrubs and trees benefit from the presence of high organic matter which as it decomposes provides nutrients for growth, allowing development of significant biomass (Alatar et al., 2015). Other macronutrients especially K, Mg and Ca also play a critical role in maintaining plant osmotic pressure in a saline environment, adjusting the pH of the plant cell, protecting cells from toxicity and serving as co-factors for several enzymes (Shiel, 2001).

Psammophytic plants were the most abundant lifeform in the stands studied followed by halophytes and shrubs. This pattern reflects characteristics of the whole flora of Saudi Arabia (Chaudhary, 2001). Psammophytic plants were correlated with Shannon index, species evenness, species richness and number of species in each stand. Increased plant cover may promote higher chlorophyll content in plants as a result of competition and shading. Abou-Sitta and Al-Taisan (1995) found that desert plant growing in shade had higher chlorophyll content than plants growing in sunny areas. Higher chlorophyll content enhancing plant's ability to photosynthesize and produce the carbohydrates essential for growth. There was a clear correlation between halophytes and the EC of the soil. Clearly, we could expect halophytic plants to be the most abundant group of plants under high salinity conditions (Alatar et al., 2012; El-Sheikh et al., 2012). In the present study, the third and sixth vegetation groups which dominated by *Tamarix aucheriana* and *Centropodium forsskalii*, respectively, were found only in sabkha habitats. This could be attributed to the high salinity levels in these habitats. Halophytes are, also, able to hyperaccumulate some of the heavy metals including Cr, Pb, Fe, Mn, Cu and Cd. Heavy metals hyperaccumulators can remediate contaminated soil by sorting such metals in inert forms in their vacuoles using a mechanism similar to the one that halophytes use to cope with salinity (Van Oosten and Maggio, 2015). In the present investigation, the fifth vegetation group dominated by *Calotropis procera* was found only in sewage canals habitats. These habitats were characterized by high levels of heavy metals. This could be an explanation for the high presence of *Calotropis procera* in these habitats because its high ability to accumulate heavy metals (Galal et al., 2016).

The vegetation of the sabkhas and sewage canals in this study fell into 6 different vegetation groups. The third vegetation group, dominated by *Tamarix aucheriana* and *Phragmites australis*, showed high values of percentage of cover and a high Shannon index associated with high soil organic matter, silt percentage in the soil and concentrations of Ca, K, Mg, Fe and Cd. In contrast, the fifth vegetation group, dominated by *Calotropis procera* and *Citrullus colocynthis*, was associated with high soil concentrations of Na and P. This could be due to the role of Na in maintaining pH and ionic balance in plant cells and tissues, and the essential role of P as a macronutrient required for the biosynthesis of amino acids and nuclear proteins (Shiel, 2001). The sixth vegetation group, dominated by *Centropodium forsskalii* and *Emex spinosa*, was associated with high values of species richness and a high Simpson index. This vegetation group was mainly found in sand habitats with good soil conditions. Sandy soils are particularly suitable for growth of various annual herbs and grasses. The distribution of such plants is related to salinity.

(Received 19th Feb 2018; accepted 18th May 2018)

Abstract. In the summer of 2007 an enormous wild fire occurred on Vidlič Mt. (Southeast Serbia), which burned down more than 2500 ha of vegetation. Our aim was to study the short-term patterns of diversity changes and vegetation dynamics in the grasslands and rocky ground vegetation affected by the fire. Plots of vegetation were observed according to Braun-Blanquet phytosociological methods. Species richness and Simpson's diversity index were calculated per quadrant for each of three seasons. ANOVA, Unequal HSD *post hoc* test and Linear Regression were performed in order to follow the post-fire vegetation dynamics and diversity. The species richness and diversity of the fire-affected sites were highest in the zone of thermophilous oak forests, slightly lower in the transitional belt, and lowest in the belt of beech forests. With increasing altitude, the values of richness and diversity decreased. Considering life-forms composition, the most important influence of wildfire was the relationship between two most represented categories, hemicryptophytes and therophytes. It was concluded that the cover values of 13 species show comparatively high levels of statistically significant differences between the stages of vegetation formed in the post-fire period. Limestone grasslands and rocky ground vegetation showed quick recovery after the fire, which indicates that these habitats show comparatively high resilience to fire.
Keywords: *wildfire, fire-affected, community composition, floristic similarities, burned plots, species richness, life-forms changes, vegetation recovery*

Introduction

Over the last few years, an increasing number of fires have occurred in natural areas. Worldwide, more than 50,000 forest fires occur annually (Aleksić et al., 2009), on average destroying more than 40 million ha of forest (Lukić et al., 2017). There are "fire climate regions" in which fires have a greater frequency and intensity on substrate with good drainage, and this, combined with the flammability of the dead combustible materials results in any fire having a greater surface area (Dimitrov, 1999). Jurjević et al. (2007) point out that there are three areas that are seriously endangered by fires on Earth: the Mediterranean, the North American area of pine forests and the area of African savannas because of their climate, weather conditions and the character of the substrate. In Europe alone 30,000–40,000 forest fires a year take place and the fire-affected area amounts to over 500,000 ha annually (Jurjević et al., 2007). Damage in

North America is significantly higher. In Europe, most fires take place in the in ecosystems of the Mediterranean: Italy, France, Greece, Spain, Portugal and Croatia (Margaletić and Margaletić, 2003; Türkmen and Düzenli, 2011). In humid regions there are not as many forest fires and the consequences are not nearly as disastrous (Vukelić and Rauš, 1998).

Between 2004 and 2013, 3800 ha (2250 ha categorized as forests) were destroyed by fire in Serbia (Nikolov, 2015). In just five years (2003-2007) 580 fires were counted and most of them (64%) were in 2007 (Tabaković-Tošić et al., 2009).

The comparative fire ecology of plant communities on serpentinite and sandstone substrates, especially the degree to which species diversity depends on fire, has been underlined by Safford and Harrison (2004). In addition, Pausas and Ribeiro (2017) provided insights into several positive effects of fire on grasslands formed on rocky areas, emphasizing its role in increasing the landscape variability, creating new ecological niches, thereby ensuring the improvement of general plant diversity.

Although several studies on the effects of fire on vegetation in Serbia and its surroundings have been reported (Čolić, 1960, 1966; Vukićević, 1965; Dinić et al., 2003; Janković, 2003; Marković et al., 2015a, 2016), only a few of them consider long-term post fire regeneration patterns in forests focusing on species richness and diversity (Vukićević, 1965; Čolić, 1966). The short-term patterns of dry grasslands and rocky outcrop vegetation over the limestone formations have not yet been investigated in the central Balkans. Furthermore, no studies have yet evaluated the effects of fire on grasslands growing over limestone derived soils, which is one of the most highly represented types of vegetation in the mountain regions of the northeastern, eastern and southeastern parts of Serbia. The carbonate substrate predominant on Vidlič Mountain contributes to the faster and greater warming and drying of terrestrial vegetation (Margaletić and Margaletić, 2003) and it is more sensitive to the occurrence of fire.

The wildfire on Vidlič Mountain happened in 2007 and burned over 2500 ha of grasslands, shrubbery and forest vegetation, considerably changing the landscape of the mountain (Ministry of the Environment and Spatial Planing, 2008), and a forest area of 1000 ha was impacted by uncontrolled wildfire (Panić, 2007). Subsequently, a large area of open grassy and dwarf shrubbery semi-opened vegetation of approximately 1000-1500 ha was also engulfed by fire. The wildfire crossed the skeletal slopes rapidly. The repercussions of the fire on these habitats were neither recorded nor repaired by any governmental organization, as they were in the case of forests, whereby the State Forestry Enterprise was fully engaged.

Several fundamental studies of xeric vegetation in Serbia have already been performed by Jovanović-Dunjić (1955, 1956), Danon (1960), Diklić (1962), Diklić and Nikolić (1964). This vegetation plays an important role in stopping further denudation in limestone areas. During the previous century, a well-developed area of forest on Vidlič Mountain was largely destroyed, remaining mainly on the northern and eastern slopes. Deciduous forest of Hungarian and Turkish oak (*Quercetum frainetto-cerris* Rudski 1949), one of the most widespread types of forest is considered to be climax in the region (Mišić et al., 1978). Different stages of degradation of this community are present on the mountain. The fragments with oriental hornbeam (*Carpinus orientalis*) are one of them. The upper region of the mountain is covered by moesian beech forests (*Fagetum montanum moesiacum*), considered to be a climate-regional community. After woodcutting, and the period of subsequent grazing, many types of meadows, xeric pastures and shrub-like vegetation native to rocky slopes were formed over the vast area

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_32713288
© 2018, ALÖKI Kft., Budapest, Hungary

of eroded slopes. Thus, xeric vegetation in the region is secondary by origin, representing the plagioclimax in the habitat of well-developed deciduous woodland. Its origin, floristic composition and structure are also determined by the warm climate, and particularly by edaphic factors (Diklić and Nikolić, 1964). Bearing steppe characteristics, which is indicated by presence of numerous sub-Mediterranean species, this vegetation is important for many reasons. It plays an important role in stopping further denudation not only regionally, but also in the wider limestone areas of the Peninsula. Different varieties of xeric pastures are traditionally used for grazing, which was particularly popular in previous centuries. This vegetation is also important as a source of medicinal (Marković et al., 2010) and especially aromatic plants (Marković et al., 2009). Finally, in spite of the barren and shallow soils, the xeric vegetation of this region is rich in plant species, especially endemic, endangered and steppe relict representatives (e.g. *Adonis vernalis*, *Paeonia tenuifolia, Ranunculus illyricus, Sternbergia colchiciflora, Hyacinthella leucophaea*).

Our general hypothesis was that the effects of wildfire on plant communities and their diversity would be weaker on more fertile limestone soils and soils with frequent rocky outcrops. We assumed that well represented rocky fraction, typical for the limestone areas, could play an important role in following phenomena:

1) Limestone soils have higher ratios of herbaceous to woody fuels, thus increasing fire spread rates, decreasing fire intensity, and reducing soil heating - fire move faster, and therefore, its impact could be less severe.

2) Soil layer could be only shallowly affected, so the seed bank in the ground would be better preserved.

3) Limestone soils have frequent rocky outcrops which can provide safe sites for plants to avoid burning, saving unburned “patches” of initial vegetation.

The short-term patterns of post-fire diversity for the open and semi-opened, herbaceous to shrubby vegetation on the Vidlič Mt. calcareous plateau in the central Balkan Peninsula were chosen as the object of the present study. To the best of our knowledge, this is the first significant contribution to the post-fire ecology of limestone areas across the Peninsula.

Material and methods

Study area

The study was conducted in fire-affected areas of Vidlič Mt., including surfaces covered by dry grasslands and rocky ground vegetation (*Fig. 1*). Vidlič Mt. is an extension of the Stara Planina (Balkan Mt.) mountain chain, which is a large calcareous plateau located in eastern Serbia (Vidanović, 1955). Its ridge stretches in a prevailing northwest-southeast direction between Serbia and Bulgaria (Petrović, 1999). In geological terms the mountain is mostly built of limestone and dolomite formations, with well-represented cretaceous, jurassic and triassic layers (Vidanović, 1960; Petrović, 1999). Smaller areas are covered with marlstone and sandstone (Andjelković, 1977). Dry skeletal and barren land covers the mighty rocky deposits over the whole area. The prevailing soil types are rendzina and calcomelanosol, which achieve different evolutionary forming phases (Antonović and Mrvić, 2008). Rendzina is nutrient-poor soil formed on soft limestone, as well as on carbonate and silicate substrates like marlstone and sandstone. Calcomelanosol is shallow, humus rich soil formed on limestone and dolomite containing a high percentage of calcium and magnesium

carbonate (Miljković, 1996). The climate is temperate continental, with hot summers and prominent drought periods. Climate steppe and mediterranean influences are represented across the large base, while the upper part of the mountain has features of a mountain climate (Vidanović, 1960). The mountain is characterized by dynamic relief, inclined slopes, and vast deforested areas exposed to extensive erosion.

The main focus in our previous study (Marković et al., 2015b) was on grasslands belonging to the already familiar alliances *Festucion valesiacae* (Festuco-Brometea) and *Seslerion rigidae* (Festuco-Seslerietea). *Carici humilis-Stipetum pulcherrimae, Potentillo-Caricetum humilis* and *Sanguisorbo-Festucetum vallesiacae* are the most commonly represented associations in the investigated area. Great attention was also dedicated to the fire-affected vegetation of extremely eroded areas, in particular *Euphorbio myrsiniti-Bothriochloetum* (Chrysopogoni-Satureion), that represents final degradation stage of termophilous forests, as one of the most common associations on rocky ground.

In our previous study we investigated the vegetation of 10 unburned plots on Vidlič Mt. in detail (Marković et al., 2015b). The phytocoenoses investigated from unburned areas were found to be similar to those that cover other limestone areas in this region. In the present study, unburned areas were compared with burned ones.

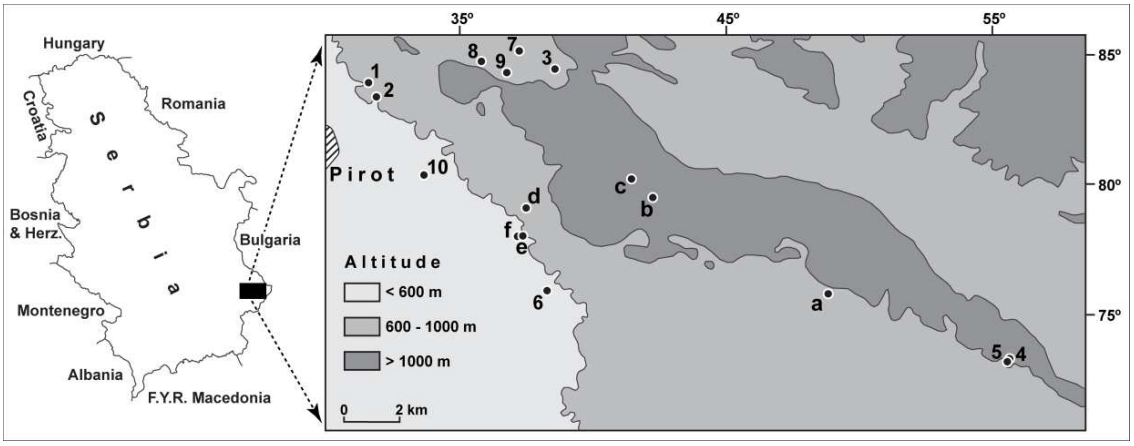

Figure 1. *The area of Vidlič Mt. investigated and location of the plots analyzed: the spatial position of the plots referring to fire non-affected vegetation (1-10) and plots referring to the vegetation of fire-affected localities (a-f). (1, 2 – Mali Vrh; 3 – Basara; 4, 5 – Vlkovija; 6 – Vučje; 7, 8, 9 – Crni vrh;10 – Izvor; a – Visočki Odorovci; b, c – Basarski kamik; d, e, f – Vučje)*

Data collection procedures

The vegetation dynamic of burned xeric grasslands in three consecutive seasons (2008-2010) was followed, and a comparison between the stages of vegetation established at the burned sites with the vegetation of similar, unburned habitats was carried out. In order to track changes in the vegetation at the burned and unburned plots, six phytocoenological plots (a-f) were made in the first, second and third years after the fire. Plots from unburned areas were chosen randomly, and plots from burned areas were then taken from the same vegetational belt. In the beech forests belt unburned plots for comparison were found at greater distances from the burned plots (*Fig. 1*). Plot data for the fire non-affected vegetation as well as for fire affected vegetation are

The Braun-Blanquet method (1964) was applied for phytocoenological analysis. The 10 plots per fire affected site (quadrants 100 m^2) were analysed. Phytocoenological analysis included data on the locality, altitude, exposure, terrain inclination, plot area, abundance, cover, plot code, floristic composition and degree of presence. The plant material collected was identified according to Josifović (1970-1977) and Velchev (1982-1989) and the nomenclature was adjusted according to Tutin et al. (1964-1980, 1993). The plant material was collected during the summers of 2008-2010 (June, July and August) and deposited in the "Herbarium Moesiacum Niš", University of Niš (HMN).

Data analysis

The combined values were transformed into a numerical scale as proposed by Westhoff and Van der Maarel (1973) to enable comparison of the floristic composition of the plots in different seasons. Simpson's diversity of species in the community, within the minimum range, was performed in the Flora software package (Karadžić et al., 1998). The species richness (the total number of species), and Simpson's diversity index (Whitaker, 1972) that includes species evenness, were calculated per quadrant (100 m^2) for each of three seasons. The mean values of richness and diversity for the plots were presented.

DOI: http://dx.doi.org/10.15666/aeer/1603_32713288
© 2018, ALÖKI Kft., Budapest, Hungary

Descriptive statistics (Means, Standard Deviations) of richness and diversity were calculated. The influence of fire damage and elevation on the values of richness and diversity were tested using one way and two way analysis of variance (ANOVA) and the 95% LSD test was used to analyze the differences between the fire-affected and non-affected plots and different altitudes. Linear regression was performed in order to estimate the correlations between the richness/diversity and altitude, exposure and slope. The analysis of variance (ANOVA) was also used to determine whether there were differences in the floristic composition of the main stages of vegetation in the post-fire period. The unequal HSD *post-hoc* procedure was used to identify the exact seasons (I-III) that show differences in the mean values of significant species. The univariate analysis of species cover values was performed on taxa with highest presence in the plots (60-80% and 80-100%) per year, resulting in the descriptive statistics presented in *Table 4*. All of the statistical analyses quoted here were performed using the STATGRAPHICS Plus 5.0 software.

A comparison of the floristic similarities between the burned and unburned plots in the second and third year were made using Sorensen's coefficient of similarity (Sc) based on presence vs. absence (Smith and Killeen, 1995).

The system proposed by Mueller-Dombois and Ellenberg (1974) modified by Stevanović (1992) is used for the identification of plant life-forms as follows: phanerophytes (P), chamaephytes (Ch), hemicryptophytes (H), geophytes (G) and therophytes (T). In order to find out how the life-form composition changed, the percent of the basic groups was observed during the first, second and third year of post-fire period and compared with the components of fire non-affected vegetation.

Results

Species richness and diversity

In the first year after the fire (*Fig. 2A, B*) the species richness and diversity of the fire-affected sites was the highest in plots e and f, located in the zone of degraded thermophilous oak forests (*Quercetum frainetto-cerris* subass. *carpinetosum orientalis*) formed at low altitudes (500-600 m) (*Fig. 3A, B*). Slightly lower richness and diversity were noted in localities (a and d) from the transitional belt between the oak (*Quercetum montanum*) and beech forests at upper altitudes (700-900 m). On the plots (b and c) located in the belt of beech forests (*Fagetum moesiacae montanum*) over 1000 m above sea level, the poorest values of richness and diversity were recorded. As expected, in the second and third year after the fire (2009 and 2010) an increasing trend of richness and diversity was registered in almost all plots (*Fig. 2A, B*).

By calculating the average values of diversity, it was noticed that the richness and diversity of the burned vegetation were generally reduced in comparison to the unburned areas (*Fig. 4A, B*). After an initial fall, richness and diversity generally had an increasing trend, but did not reach the values of unburned vegetation in the third year (*Table 2*). However, over time, richness (expressed as extreme range and standard deviation values) exerted an upward trend, while for diversity the opposite was true. Fire damage and elevation caused statistically significant differences in both richness and diversity but no interaction between them was found (Two-way ANOVA) (*Table 3*). Furthermore, differences between burned (a-f) and unburned areas (1-10) as well as differences between altitude belts (up to 600 m, 600-1000 m and over 1000 m)

were also confirmed (homogenous groups - A and B, obtained by LSD tests, denoted differences in 95% of the cases) (*Table 2*).

Correlations with environmental variables

Richness and diversity had a strong positive correlation (r = 0.98; ANOVA *p*-value = 0.0001) (see also *Fig. 3A, B*). With increasing altitude, the values of richness and diversity decreased (r = -0.80 and -0.78, resp.; *p*-values = 0.0001). But richness and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_32713288
© 2018, ALÖKI Kft., Budapest, Hungary

diversity increased towards E-WS showing moderate positive correlations (r = 0.69 and 0.68, resp.; *p*-values = 0.0001). The correlation between diversity and richness and the slope of the terrain were weak and without statistically significant differences (r = 0.10 and 0.05, resp.; ANOVA *p*-values > 0.01). But richness and diversity have significant strong negative correlations with the vegetation belt (from oak, through transitional to beech forest) (r = -0.85 and -0.85, resp.; *p*-values = 0.0001).

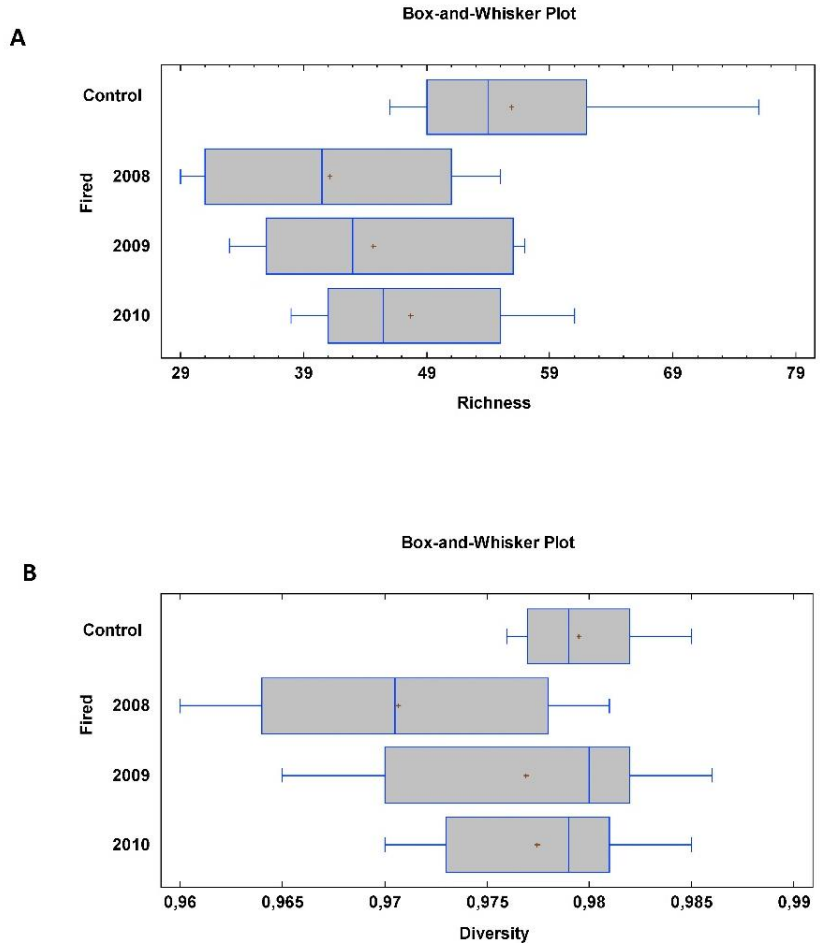

Figure 4. *Mean values of richness and diversity of fire non-affected plots (control) and fire-affected plots in three consecutive years*

Life-forms dynamics in post-fire period

The life-form composition of the vegetation of fire non-affected plots (1-10) could be described by the dominance of herbs (H), including forbs and grasses, represented with 54%, but also large percent of annual plants (T), represented with 32% of all registered species. The group of generally low plants, with semifruticose sprouts (Ch) was presented with 7% in this vegetation. The plants that survived thanks to solid subterranean organs (G) were represented with 5%, while the percent of shrub species (P) was approximately 2%. The composition of life-forms in the vegetation of fire-affected plots (a-i) is considerably different due to the fire influence and became unstable, especially in the first period of post fire recovery. The most important consequence of wildfire is the relationship between two best represented growth-form

categories, hemicryptophytes and therophytes. The percent of annual representatives in the vegetation of the fire-affected plots (a-i) rapidly increased in the first stage of its revitalization. Under the new conditions, the presence of therophytes (44%) almost exceeds percentages of herbaceous perennial plants, represented with 46% in the first year. Other functional groups, chamaephytes (8%), geophytes (7%) and phanerophytes (1%) were lesser represented in that phase. In the second year of post-fire period, the proportion of therophytes gradually decreased compared to hemicryptophytes (36% *vs.* 47%) while percentage of chamaephytes (11%) began to be more significant. As expected, during the third year of observation, the percent of hemicryptophytes increased (49%) while of therophytes decreased to 32%. The contribution of other vegetation components in the final year of observation was as follows: chamaephytes 12%, geophytes 5% and phanerophytes 2%. Considering life-form of taxa with higher phytocoenological importance, a significant role could be assigned to perennial grass species *Festuca valesiaca* that was dominant in vegetation of all studied post-fire stages. However, significant abundance and coverage were also achieved by some annual species, e.g. *Bromus squarrosus, Filago montana* (firs year) and *Sideritis montana* (first and second year), which easily inhabited burned plots in the initial stages. During the middle post-fire period the vegetation was characterized by higher cover values of *F. valesiaca* and perennial species *Teucrium chamaedrys*, as well as comparatively low cover values of annual species. Increasing cover values of other herbaceous perennial plants beside *F. valesiaca* (e.g. *Euphorbia cyparissias, Medicago falcata* and *Galium purpureum*), along with almost insignificant coverage of therophytes, which was recorded in the final year of observation.

Univariate analysis of species cover values in relation to vegetation dynamics

According to the results of the ANOVA test it was concluded that the values of 13 out of the 21 species compared possess comparatively high levels of statistically significant differences between groups of taxa based on their phytocoenological importance in the post-fire period (*Table 4*). The following species stand out because of their high F values: 1) *Centaurea stoebe* and 2) *Sanguisorba minor*. These species can have an extremely significant role in floristic as well as phytocoenological differentiation between the stages in the early post-fire period of restoration. Among the other species, *Bromus squarrosus, Filago montana, Hieracium bauhinii, Rosa canina, Koeleria splendens, Eryngium campestre, Medicago falcata* and *Fragaria vesca* could also play an important role in the post-fire dynamics of the vegetation.

The unequal HSD *post hoc* test confirmed that all 13 species represent important indicators of post-fire dynamics in calcareous grassland and bedrock vegetation. There were especially significant differences in the cover values of *C. stoebe*, *S. minor* and *R. canina* in the third year, while *B. squarrosus* and *F. montana* were more represented during the first year after the fire (*Table 4*).

Floristic similarity between the unburned and burned vegetation

The floristic similarity between the unburned and burned vegetation in the first three years after the fire was lower than 50% according to Sorensen's coefficient of similarity. The unburned and burned plots in the oak forest belt at lower altitudes showed the highest values (*Table 5*). The lowest similarity was recorded between the unburned and burned plots in the beech forest belt at higher altitudes (20–27%).

Discussion

The specific patterns of succession of calcareous grasslands in different conditions and regions in Europe have been the subject of several recent studies (Alard et al., 2005; Schrautzer et al., 2009). Rutherford et al. (2011) have studied post-fire plant succession immediately after disturbance. The majority of the conclusions suggest that there is still much to be learned about how the conditions following a fire are reflected in the interactions between species in the early stages after a fire, and what impact they may have on later successional development.

Plants respond in two different ways to fire: some species survive fire and then resprout, while others are killed by fire, but germinate from fire-resistant seeds (Oliveira et al., 2015). The survivorship of plants after fire is dependent on their characteristics, the meteorological conditions and other disturbances such as grazing (Robberecht and Defossé, 1995; Peláez et al., 2009).

A previous study has shown that the highest values of diversity, exactly referring the most diverse vegetation in the highest zone, were followed by plots from the transitional zone at medium altitudes (Marković et al., 2015b). As the altitude increased, the diversity of fire non-affected vegetation increased. In the present study this trend was not noticed in the first year after the fire. In contrast, the greatest diversity was recorded at lower altitudes, while on plots at higher altitudes the diversity was lower. These findings are in accordance with the fact that more fertile soils have a stronger response to disturbance than other soils, which has been confirmed in previous investigations (Harrison et al., 2003; Grime, 2006). Limestone plots at lower altitudes have a deeper layer of soil than plots at higher altitudes. Short-term patterns of post-fire succession in the vegetation investigated were also dependent on exposure and slope, but to a much lesser extent in comparison to altitude.

The effects of the fire on plant communities were weaker in rockier habitats at higher altitudes where the fire moved faster and therefore lost its severity, giving a better chance to some of the plant forms to resist or to their seeds to survive in the sheltered places between the larger rocks of the fire impacted area.

In the study, the first post-fire year was characterized by moderately low diversity and more important role of annual species, in contrast to the wildfire non-affected vegetation. This was confirmed in a study of fire on limestone grasslands communities in Derbyshire (England) where the representation of short-lived species was higher in the burned plots than in those which were unburned (Lloyd, 1968). In the second year after the fire, a quantitative increase in the species richness and Simpson's index was recorded. The growth of species richness reflects a more intense process of species immigration from the surrounding preserved vegetation toward the burned plots. Hence, during the second year, the diversity of fire affected xeric vegetation on the mountain was improved, being more stable in most cases. The second post-fire year was characterized by an increase in the number of perennial plants. This trend continued in the third year after the fire when bunch grasses and other perennial species became dominant. According to Bennett et al. (2003) and Zedler (2007) grasses usually have capability to recover their full coenological and biological functionality, including reproduction, within one or few years after fire. As some recent studies have shown (Figueira et al., 2016; Wright and Fensham, 2018), the effects of fire on habitats can stimulates the production of inflorescences in some grass species, and hence support their faster spreading.

The field surveys and observations show that the calcareous grassland vegetation in the study was very sensitive to the fire. Because of the removal of competition in burned areas, the importance of easy spreading plant species with short life cycles generally increased during the first period after the fire. Similar results were found by Ghermandi et al. (2004) and Papanastasis et al. (2002). According to our results the cover values of annual and biennial representatives increased due to the effects of the fire during the first two years. Consequently, the dominant species during the very first stage of vegetation formed after the fire were annual plants (*Bromus squarrosus, Filago montana*), and they were recorded in most of the plots, reaching high cover values in the overall vegetation. From the same group of plants, the annual (or sometimes biennial) species *Sideritis montana* was considerably important in the first, and especially second year after the fire, but was almost completely suppressed during the third year. This was plant especially abundant in waste, highly eroded and nutrient-poor, burned surfaces at higher altitudes. Since the cover value of the overall vegetation declines (caused by fire), annual species respond more rapidly and achieve greater cover values than perennial species in the first phase of its restoration. The same results were obtained in limestone Mediterranean mountain ecosystems in Greece (Papanastasis et al., 2002). At the same time, their further existence and cover values are strongly dependent on the degree of perennial species restoration. Namely, several perennial species were less affected by the fast-moving flame, and survived due to the presence of rhizomes, bulbs and similar subterranean organs or semifruticose aboveground sprouts. The production of a high number of new tillers in the early post-fire stages is one characteristic which increased the capability of restoring the perennial grass species (Ghermandi et al., 2004; Gittins et al., 2011; Gonzalez et al., 2015). As expected, sparse members of phanerophytes, as *Crataegus monogyna*, remained fire non-affected; while some of them (*Rosa canina*) additionally increased in the later period. Hence, perennial species like *Festuca valesiaca, Asperula cynanchica, Euphorbia cyparissias, Galium purpureum, Petrorhagia saxifraga, Teucrium chamaedrys* and *Satureja kitaibelii* were also important in the first stages, as they were minimally damaged by the fire. What's more, the cover values of dense caespitose grasses and semi-shrubs were high and stable all across the post-fire period. Their role in the stabilization of the floristic composition and restoration of the coenological relationships toward the initial communities in the period following the fire could be taken as important, as they were recorded in every season after the fire. Perennials rapidly achieved greater cover values, invading the destroyed habitats from the remnant patches of vegetation sheltered by the rocks, or by dispersion from the fire non-affected vegetation. During the final year of this study, they generally reached high phytocoenological importance, while annual species lost their role in the overall cover. A considerable number of perennials kept their cover values stable in the final two years, while some of them (e.g. *Festuca valesiaca, Euphorbia cyparissias, Teucrium chamaedrys, Centaurea stoebe, Sanguisorba minor*) increased their coverage. In that way the recovery stage of vegetation formed over the three years after the fire became more similar to the initial vegetation of calcareous grasslands on the mountain, which has been confirmed in other studies (Kucera and Enrenreich, 1962; Kucera and Koelling, 1964). This very quick floristic recovery after fire is also a characteristic of Mediterranean habitats (Caturla et al., 2000; Trabaud, 2003). In a wider sense, the limestone grasslands and rocky ground habitats on Vidlič Mountain have similar ecological characteristics to Mediterranean

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

habitats as evidenced by the presence of large number of species with sub-Mediterranean, or even Mediterranean chorological character (Marković et al., 2015b).

In contrast, our results of Sorensen's coefficient of similarity indicate that the floristic composition of the unburned plots is not very similar to the floristic composition of the burned plots. The biggest differences were shown by plots at the highest altitudes, whereby the coefficient of floristic similarity was 20-27% in the first three years.

Such low floristic similarity can be explained by the geographic distance between the unburned plots and the burned ones. The species composition in grasslands depends much more on the surrounding vegetation than some other habitats such as scrubland (Chust et al., 2006). Community composition was enriched by new fugitive species which increased diversity in a quantitative sense but the floristic composition lost the quality it had before the fire. Similar results were obtained by Mitchell et al. (2009).

Conclusion

Having in mind species diversity, calcareous grasslands are of great importance for the conservation of biodiversity in Europe. The results for species richness and diversity after large fires in southeastern Serbia confirm that limestone grasses and rocky ground habitats have high resilience to fire. The trend was noticed that species richness and diversity are higher on lower altitudes. On the other hand, the result of Sorensen's coefficient of similarity indicates that the floristic composition of limestone grasses and rocky ground vegetation was changed and showed slow recovery in the stage after burning. The analyses of life form dynamics showed that the percent of annual plants rapidly increased in the first stage of revitalization. In the second and further stages the proportion of therophytes gradually decreased compared to hemicryptophytes. Additional studies in the future should be carried out on the changes in community composition.

Dry grasslands and other types of vegetation formed on limestone, rocky ground areas in Serbia and Balkan Peninsula are important habitats for endemic and some medicinal, especially aromatic plants. Therefore, results on the impact of uncontrolled wildfire on xeric vegetation on limestone terrains would have general application in wildfire management, as well as in nature conservation.

Abstract. Phrygana is a widespread vegetat type in the eastern Mediterranean, mainly represented by *Sarcopoteriwn spinosum* dominated formations in the Aegean islands and Crete. The effects of overgrazing and frequent burnings on phrygana are relatively known by scientists, but limited attention has been paid to the functioning of these communities when grazing and fires are suppressed. The aim of this study is to investigate post-fire vegetation and fuel dynamics in an ungrazed *S. spinosium* dominated phrygana in northwestern Crete. Fuel was first analyzed according to shrub, herb, litter, and total load; then live and dead materials; and finally, 0-0.5 cm and 0.6-2.5 cm of leaf diameter classes. Vegetation was analyzed based on cover and life form composition and dynamics. Also, species richness, diversity, and dynamics were investigated. One-way ANOVA was used to test for fuel and vegetation differences among sites, and Shannon-Wiener and Equitability indices were used to assess both diversity and evenness. Results showed a rapid reestablishment of both the vegetation (cover, life form, species richness and diversity) and fuel, as early as the 3rd and the 6th post-fire year, respectively. Fuel and vegetation were tremendously dominated by unpalatable and highly flammable dwarf shrubs, which smothered herbaceous plants. Species diversity was relatively low, indicating that few species crushingly structured the community by their high cover, while the remaining species were poorly abundant. The implications of the results in the context of a rational management planning of phryganic ecosystems are discussed.
Keywords: *biomass, Phrygana, post-fire dynamics, species diversity, species richness, vegetation Cover*

Introduction

Many, if not all, ecosystems of the world are known to undergo cyclic processes of disturbances and recovery, occurring at specific spatiotemporal scales. These natural phenomena allow ecosystems to maintain their ecological processes as well as their biological and ecological diversity in space and time (Naveh, 1994).

At least since the Jurassic geological time, fires had always been a natural selective force which affected plant community structure, productivity, and species composition (Le Houerou, 1974; Trabaud, 1994, 2000). In addition, fires have been associated with species diversity maintenance (Christensen, 1985), have contributed to stands rejuvenation (Trabaud, 2000), and have allowed species coexistence in space and time, by interrupting competitive advantage of dominant species (Malanson, 1987).

Mediterranean forests and shrublands exemplify the abovementioned ecological systems that cope with natural disturbances such as natural fires' and grazing by wildlife.

As far as post-fire plant demography in phrygana is concerned, documented a great deal of dwarf shrubs' seed germination and seedling recruitment during the first post-fire year, contrasting with the unburned phrygana (Arianoutsou, 1998). By far, the dominant seedlings were made up of *Cistus* spp. and *Sarcopoterium spinosum* (with numbers multiplied by 10 and 20 times). On the contrary, a low seed germination level portrayed dwarf shrub in the 2nd post-fire year; 10 seeds per m^2 for *Cistus* spp. and 3 seeds per m^2 for *S. spinosum* were counted in winter. A similar demographic trend has also been reported for other phryganic communities by Naveh (1974), Papanastasis (1977), and Arianoutsou (1998), that is, a decrease in a number of dwarf shrubs' seedlings during the first post-fire year, and no conspicuous seed germination during the 2nd post-fire year. It is worthwhile referring that two main hypotheses have been suggested to explain the decrease in seedling density. The negative effects of the hot and dry Mediterranean summer on dwarf shrub seedlings' survival (Ferran et al., 1998) or the strong inhibiting competition exerted by the massive herbaceous plants on the young dwarf shrubs' recruits (Henkin et al., 1999; Seligman and Henkin, 2000).

Regarding to the post-fire fuel/biomass dynamics, there is insufficient research has been devoted to ecosystem structure and post-fire fuel dynamics in phryganic ecosystems. In Greece, the little literature available on the subject focused mainly on aboveground net primary production, whereas fuel and fire hazard-oriented studies are almost lacking. It is worthwhile mentioning that Christensen (1985) also highlighted the substantial contribution of herbaceous plants to shrubland production in immediate post-fire years.

To our knowledge, Papanastasis (1980) have provided the scanty, but useful, information available on fuel characteristics in Greek phrygana in relation to fire hazard. Thereby, the latter author mentioned that phryganic ecosystem are inclined to accumulate dead material as they age; thus, becoming decadent if unburned. This characteristic coupled with small sized material featuring phryganic dwarf shrubs contribute to render the older communities highly flammable (Papanastasis, 1977). However, as reported by Papanastasis (1980) in an experimental study, *Sarcopoterium spinosum* plants did not bum easily unless enough dead fuel had existed on them. This latter fuel required, at least, three post-fire years to be accumulated. Additionally, it has been indicated that herbaceous plants occurring in phryganic formations are also fire-adapted. Indeed, some species, such as *Andropogon hirtus*, a perennial grass that retains its old growth, contribute to the flammability of the phrygana (Papanastasis, 1977). Finally, fuel distribution has been documented to be uniform only on old and thick phrygana with no or few herbaceous plants. Most often, fuel is discontinuously distributed in grazed communities, made up of dwarf shrubs and herbaceous plants fairly intermingled (Papanastasis, 1977, 2000).

Studies have reported that both high ecosystem diversity and landscape maintenance in the Mediterranean have been promoted and ensured by the cyclic disturbances properly induced by humans and their livestock (Naveh, 1994; Naveh and Whittaker, 1980, 2007). However, improper land use such as wildfires and overgrazing for decades has significantly altered the ecosystems, and more particularly rangelands, such as phrygana in the eastern Mediterranean. Therefore, the objectives of the current research are to investigate post-fire fuel and vegetation dynamics in an ungrazed *Sarcopoterium*

spinosum dominated phryganic community in northwestern Crete (Greece) for a relatively short period; that is, between 3 and 12 years.

Materials and Method

Study area general description

The study area is represented by the hills of Malaxa situated in northwestern Crete (*Figure 1*). This part of the island is administratively managed by the Prefecture of Chania, and more specifically by the municipality of Souda. The climate of Chania is typically the Mediterranean, characterized by a long dry summer season with a monotone wind regime, and precipitations ranging from September to May (Elhag and Bahrawi, 2016). The recent climatic data of Chania, for the last 20-year-period, indicated an annual precipitation averaging 690.4 mm. The Bagnouls-Gaussen ombrothermic diagram, drawn from the abovementioned data displays a longer dry summer period than mentioned by Elhag and Bahrawi (2016), beginning in April and ending in mid-September. The rainy period, ranging from October to March is characterized by an average precipitation of 615.65 mm, and the xerothermic period, extending from April to September, reaches 74.75 mm only. It is worth noting that January and February are the coldest months, with an average temperature of 10.6 °C, and July the hottest month with an average of 24.7 °C. Based on Emberger's pluviothermic quotient value (Q=86) calculated for Chania, Elhag and Bahrawi (2018) classified this region in the subhumid Mediterranean bioclimate. The differences among the designated study sites were evaluated based on its soil chemical properties (*Table 1*).

Sampling techniques and procedures

Fuel sampling and procedural steps

Sampling location was randomly selected in the central part of a physiognomically homogeneous vegetation, and line-transects were run in four directions from a central point. Each line-transect was 15 m long and one plot was taken at the end. The total number of plots per site was four. In each 1 m^2-plot, all the aboveground biomass was clipped and put in a plastic bag. As regards the laboratory work, the first step consisted in fuel separation to shrub, herb, and litter. Shrub was then divided to live and dead parts. It is noteworthy that live material included green leaves and fresh twigs, whereas dead material all the parts devoid of living tissues. Afterward, live and dead materials were separated into two leaf diameter classes: 0-0.5 cm and 0.6-2.5 cm. Finally, the fuel was oven dried at a temperature of 105° C for 24 hours, then weighted with a digital balance according to the categories.

Vegetation sampling and procedural steps

Vegetation sampling was carried out in the central part of a physiognomically homogeneous vegetation to ensure samples' representativeness and to avoid any edge effects. In each sampling location, four line-transects were run from a central point. Following the scheme used in fuel sampling, but transect length was 20 m. Cover values of plants, litter, and bare ground were then recorded using Line Transect and Point Intercept methods combined (Bonham, 1995); a 20 m measuring tape was stretched between two stakes along the line-transect, and a pin was dropped perpendicularly to the tape each 20 cm interval. Observations were recorded by reading the hits. The laboratory work was conducted in a herbarium: plant specimens were identified with the help of a stereoscope and the descriptive keys of Flora Europaea referential volumes (Tutin et al., 1980).

Analytical procedures and statistical treatments

Fuel analysis

Fuel was analyzed according to the several categorizations based on the fuel separation to shrub, herb, and litter, fuel separation to live, dead materials, and fuel separation to diameter classes. Post-fire changes in fuel composition and dynamics were investigated at the abovementioned three category levels. Analysis of variance (one-way ANOVA) was used to test for fuel load differences among sites, and Duncan multiple range tests for mean pair's comparisons.

Vegetation composition

Vegetation composition was analyzed based on shrub and herbaceous covers. In each site, both percent cover and percent cover composition were calculated according to the following two formulae of Bonham (1995):

1. Percent cover = (number of point intercepts / total points) x 100.
2. Percent cover composition = (number of point intercepts / total point intercepts of vegetation) x 100.

© 2018, ALÖKI Kft., Budapest, Hungary

Floristic composition

Floristic composition was analyzed based on life form richness. Following are the different life form groups (Kent, 2011):

- Phanerophytes: species with perennating buds emerging from aerial parts of the plant.
- Chamaephytes: species with perennating buds borne on aerial parts close to the ground (below 2 m).
- Geophytes: species with buds or shoot apices, which survive the unfavorable period below ground.
- Hemicryptophytes: all aboveground parts of the plant die back in unfavorable conditions, and buds are borne at ground level.
- Therophytes: plants that survive the unfavorable period as seeds. Species are annuals and complete their life cycle from seed to seed in the favorable summer months.

Species richness

Post-fire species richness dynamics was described using the following two ecological parameters (Blondel and Aronson, 1995; Magurran, 2013):

- A number of species per site, which combines the four lines-transects.
- Species richness per site, which is the sum of the total richness recorded in each line-transect of that site divided by the total number of line-transects (n = 4).

Species diversity

Post-fire species diversity dynamics was investigated using both heterogeneity and equitability (also referred as evenness) indices. Species diversity was calculated using the Shannon-Wiener heterogeneity index (H') which is based on the Information Theory (Naveh and Whittaker, 1980, 2007; Magurran, 2013). The formula is the following:

$$H' = -\sum_{i=1}^{s}(P_i)(log_e P_i) \quad \text{(Eq.1)}$$

where:
H' = the Information content of sample (nits/individual),
s = Number of species,
Pi = Abundance of the i^{th} species expressed as a proportion of total cover.

Equitability which refers to the pattern of distribution of individuals among species was calculated using the following index proposed by (Kent, 2011) based on Shannon-Wiener diversity index:

$$J = H'/H'_{max} \quad \text{(Eq.2)}$$

where:
J = the Equitability index,
H' = Shannon-Wiener diversity index,
$H'_{max} = \log_e (s)$ = Maximum possible value of H',
s = Number of species.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_32893303
© 2018, ALÖKI Kft., Budapest, Hungary

The equitability index ranges from 0 to 1. It tends towards 0 when almost all abundances correspond to one species of the community, and towards 1 when each species is represented by the same abundance.

Species dynamics

Species dynamics was analyzed because of their cover changes throughout the different post-fire stages. The following community's characteristics were particularly brought out:

- The dominant species structuring the vegetation by its abundant cover.
- The diagnostic species of the community by their constant presence whatever fire interval considered.

Results

Post-fire fuel dynamics

In all sites, both shrub and litter accounted for about 97% of the total fuel composition. By far, shrub's contribution was the most important (about 80%). The herbaceous vegetation (about 3%) represented the remaining fuel. In addition, shrub, litter, and total fuel loads differed significantly (p=0.003, p=0.034, and p=0.002, respectively) among the sites, while herbaceous load did not (p=0.508) as it shown in *Table 2*.

Table 2. *Shrub, herb, litter, and total fuel loads (oven-dry weight) measured at four sites with different fire intervals (kg/ha)*

Site N [Fire interval]	Shrub			Herb	Litter	Total fuel
	Live	Dead	Total			
Site 1 [3 years]	3092.3^{a}	835.1^{a}	3927.4^{a} (84.0%)	209.2 (4.5%)	537.3^{a} (11.5%)	4673.9^{a} (100%)
Site 2 [6 years]	6097.5^{C}	6191.l^{b}	12288.6^{b} (83.7%)	459.7 (3.1%)	1928.7^{ab} (13.2%)	14677.0^{b} (100%)
Site 3 [9 years]	5044.3^{bc}	7284.9^{b}	12329.2^{b} (77.2%)	360.6 (2.2%)	3286.0^{b} (20.6%)	15975.8^{b} (100%)
Site 4 [12 years]	3986.4^{ab}	7380.6^{b}	11367.0^{b} (76.5%)	502.9 (3.4%)	2979.2^{b} (20.1%)	14849.l^{b} (100%)

Percentage of total fuel load between parentheses. Comparisons among sites performed by conducting one-way ANOVA and Duncan's Multiple Range Test, both at the p=0.05 level of significance. Values followed by the same letter are not statistically different

The results showed that shrub composed the bulk of the fuel between 3 and 12 years after fire. It is worth noting that a substantial amount of litter was accumulated as early as the 3rd post-fire year, whereas herbaceous biomass was lowly produced. Furthermore, a threefold amount of both shrubs and total fuel (about 12000 kg/ha and 15000 kg/ha, respectively) were noticed six years after fire, and a six-fold amount of litter (about 3000 kg/ha) nine years after fire, as compared to the amounts produced at the 3rd post-fire year. On the other hand, the statistical analyses suggested a stabilization of shrub, litter, and total fuel loads since the 6th post-fire year onwards.

Live and dead shrub fuel loads measured at the four sites with different fire intervals are presented in *Table 3*. The highest live material's contribution (about 80% of shrub

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_32893303
© 2018, ALÖKI Kft., Budapest, Hungary

fuel composition) was noted in the 3rd post-fire year. On the contrary, the dead material was found highly accumulated (about 65% of shrub fuel composition) in the 12nd post-fire year. One must notice the similar proportions of both live and dead materials in the 6th post-fire year. Additionally, both live and dead fuel loads were found differing significantly (p=0.038 and p=0.002, respectively) among the sites and the following differences were highlighted in the multiple comparison tests (Elhag et al., 2017):

- Site 1 had significantly lower live fuel load (3092.3 kg/ha) than site 2, characterized by almost double biomass (6097.5 kg/ha). Otherwise, similar loads characterized the three oldest sites.
- Site 1 had significantly lower dead fuel load (835.1 kg/ha) than site 2, site 3, and site 4, characterized by similar high loads (about 7000 kg/ha).

Table 3. *Live and dead shrub fuel loads (oven-dry weight) measured at the four sites with different fire intervals (kg/ha)*

Site N [Fire interval]	Live fuel	Dead fuel	Total fuel
Site 1 [3 years]	3092.3^{a} (78.7%)	835.1^{a} (21.3%)	3927.4^{a} (100%)
Site 2 [6 years]	6097.5^{c} (49.6%)	6191.1^{b} (50.4%)	12288.6^{b} (100%)
Site 3 [9 years]	5044.3b^{c} (40.9%)	7284.9^{b} (59.1%)	12329.2^{b} (100%)
Site 4 [12 years]	3986.4^{ab} (35.1%)	7380.6^{b} (64.9%)	11367.0^{b} (100%)

Percentage of live and dead fuel load between parentheses. Comparisons among sites performed by conducting one-way ANOVA and Duncan's Multiple Range Test, both at the p=0.05 level of significance. Values followed by the same letter are not statistically different

The results show that live material overwhelmingly dominated shrub fuel composition in the 3rd post-fire year, while the dead material was not substantially accumulated yet. On the other hand, a dead material composed the fuel bulk in the oldest post-fire stage (Elhag et al., 2017). Furthermore, the statistical analyses suggested that both live and dead fuel loads stabilized since the 6th post-fire year onwards, even though the following dynamic trends were noted:

- Live fuel load decrease since the 6th post-fire year onwards.
- Dead fuel load increase as early as the 3rd post-fire year onwards.

In all the sites, live fuel was almost entirely made up of material in the 0-0.5 cm diameter class. The latter size class material also dominated dead fuel composition (about 89%), while larger fuel in the 0.6-2.5 cm diameter class was poorly represented (about 11%). Additionally, live and dead fuel loads in the 0-0.5 cm diameter class differed significantly (p=0.046 and p=0.001, respectively) among the sites. On the contrary, dead fuel load in the 0.6-2.5 cm diameter class did not (p=0.143) as it shown in *Table 4*. Multiple comparison tests showed the following differences among the sites:

- Site 1 had significantly lower live fuel load in the 0-0.5 cm diameter class (3092.3 kg/ha) than site 2 characterized by a nearly twofold production (5832.5 kg/ha). Otherwise, similar loads characterized the three oldest sites.
- Site 1 had significantly lower dead fuel load in the 0-0.5 cm diameter class (796.9 kg/ha) than site 2, site 3, and site 4, characterized by similar high loads (about 6000 kg/ha).

Post-fire vegetation dynamics

In all sites, shrubs composed about 73% of the vegetation cover, whereas herbs and grasses contributed to about 27% only. With respect to the herbaceous component, it is worth noting that the most contributing species to total vegetation was the perennial grass *Brachypodium retusum* with an average cover amounting to about 3%. Additionally, both shrub and herbaceous covers did not differ significantly (p=0.269 and p=0.087, respectively) among the sites. The above results show that shrubs overwhelmingly structured the vegetation, whereas herbaceous contribution was not substantial. Overall vegetation cover stabilization was also detected as early as the 3rd post-fire year onwards (Elhag et al., 2017).

114 species belonging to 23 families were recorded in the community using the line transect and point intercept methods combined. The floristic composition based on life form richness in the four sites with different fire intervals is summarized in *Table 5*.

Table 5. *Life form richness of the four sites with different fire intervals*

Life forms	Site 1 [3 years]	Site 2 [6 years]	Site 3 [9 years]	Site 4 [12 years]
Phanerophytes	4 (9.8%)	3 (5.4%)	4 (6.6%)	4 (5.9%)
Chamaephytes	5 (12.2%)	7 (12.5%)	8 (13.1%)	7 (10.3%)
Geophytes	3 (7.3%)	2 (3.6%)	3 (4.9%)	2 (2.9%)
Hemicryptophytes	11 (26.8%)	19 (33.9%)	14 (22.9%)	17 (25.0%)
Therophytes	18 (43.9%)	25 (44.6%)	32 (52.5%)	38 (55.9%)
Total	41 (100%)	56 (100%)	61 (100%)	68 (100%)

Percentage of total life form groups for each site is given between parentheses

In all the sites, therophytes and hemicryptophytes were the most dominant life forms, both contributing to about 76% of the floristic composition. It is worthwhile mentioning that therophytes were, by far, the most represented life form (about 49%), followed by hemicryptophytes (about 27%). The remaining forms, in decreasing richness, were the chamaephytes (about 12%), phanerophytes (about 7%), and geophytes (about 5%).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_32893303
© 2018, ALÖKI Kft., Budapest, Hungary

The hemicryptophyte richness differed significantly (p=0.002) among the sites, whereas the other life forms did not (p=0.208, p=0.144, p=0.554, and p=0.255 for phanerophytes, chamaephytes, geophytes, and therophytes, respectively.

Multiple comparison tests showed the following differences among sites as regards hemicryptophyte richness:

- Site 2 had significantly higher mean richness than site 1, site 3, and site 4.
- Site 3 and site 4 were characterized by similar mean richness, lower than site 2.

In other respects, the statistical analyses revealed that species richness of phanerophytes, chamaephytes, geophytes, and therophytes did not differ significantly in all the studied post-fire stages, suggesting a stabilization process as early as the 3rd post-fire year onwards. On the other hand, it was noted a substantial increase of hemicryptophyte richness until the 6th post-fire year, and a decrease thereafter. The similar richness values obtained for the latter life form in the two oldest post-fire stages seemed to indicate a stabilization process since the 9th post-fire-year onwards. However, the study of a longer chronosequence is needed to confirm this latter suggestion (Elhag et al., 2017).

In *Table 6*, the number of species increased from site 1 (S=44) to site 4 (S=74). On the contrary, species richness was similar (s comprised between 16.75 and 22.75): no significant differences were detected among sites (p=0.075). Based on the latter ecological parameter which allows a subtle appreciation of the differences among sites, the results indicated that in all sites, an average of 21 species was collected in the covered transects. This average species number can be considered as representative of the community in each site (Blondel and Aronson, 1995; Magurran, 2013). Moreover, the species richness assigns to each species a weight that is proportional to its appearance probability along the sequence of transects; consequently, the less abundant species will be attributed a small weight (Blondel and Aronson, 1995; Magurran, 2013). On the other hand, it was noted that 70.4%, 70.2%, 85.1%, and 85.1% of the species occurring in site l, site 2, site 3, and site 4, respectively, were recorded in one transect only and with a minimal cover value.

Table 6. *A number of species and richness in the four sites with different fire intervals*

Site N [Fire interval]	**Site 1 [3 years]**	**Site 2 [6 years]**	**Site 3 [9 years]**	**Site 4 [12 years**
Number of species	44	57	67	74
Species richness	16.75 (±1.25)	21.50 (±0.29)	22.75 (±1.25)	22.50 (±2.72)

Standard error between parentheses

The values of heterogeneity index which were relatively low (less than 2.5) as compared to those usually obtained in more diversified communities (3.5). (Washington, 1984; Kent, 2011), suggested that in the four post-fire stages, the study phrygana was characterized by a relatively low diversity (*Table 7*). In other words, the environmental conditions prevailing in the community tended to be slightly unfavorable, allowing the settlement of a small number of species which were relatively abundant (Cowling et al., 1996). On the other hand, the values of mean equitability index (which did not exceed 0.7) suggested that in the covered transects, an appreciable number of species had a more or less similar importance, but few others were more abundant (Cowling et al., 1996).

The description of plant species dynamics suggests that three main characteristics portray the ungrazed phryganic community between 3 and 12 years after fire:

- One overwhelmingly dominant dwarf shrub species, *Sarcopoterium spinosum*, chiefly structuring the vegetation by its abundant cover.
- Less represented species competing actively to occupy a position and coexisting with other species in the community. Their covers increase, decrease, or stabilize, depending on the ecological conditions prevailing in each post-fire dynamic stage.
- Several species present with a minimal cover, in all likelihood due to the strong competition pressures they undergo from the dominant taxa.

Table 7. *Shannon-Wiener heterogeneity and equitability indices in the four sites with different fire intervals*

Site N [Fire interval]	Site 1 [3 years]	Site 2 [6 years]	Site 3 [9 years]	Site 4 [12 years
Heterogeneity	1.867 (±0.21)	1.843 (±0.10)	2.177 (±0.06)	1.963 (±0.12)
Equitability	0.660 (±0.06)	0.601 (±0.03)	0.698 (±0.01)	0.634 (±0.02)

Standard error between parentheses

Within the frame of the studied chronosequence, *Table 8* outlines the plant species dynamics as follow:

Discussion

During the post-fire dynamic process, the fuel accumulated in the community was chiefly issued from shrubs, mainly made up of *Sarcopoterium spinosum* and *Cistus creticus*, and litter. Litter was enough accumulated as early as the 3rd post- fire year. In comparison with the results of Arianoutsou-Faraggitaki (1984) in a phrygana of Attica, there is an agreement about shrub dominance as soon as the 3rd post-fire year onwards. However, the community of Malaxa had almost double the shrub fuel load (3927.4 kg/ha vs. 1950.0 kg/ha) three years after the fire. Additionally, a total fuel load of the Malaxa phrygana in comparison with a *Sarcopoterium spinosum* dominated phrygana in Thessaloniki showed that the former had almost double fuel load (4673.9 kg/ha) than the latter (2800.0 kg/ha). Thus, the Malaxa phryganic community is characterized by a higher fuel production than the two other communities. These differences in biomass production may be attributed to differences in the prevailing environmental conditions or to the management practices (e.g., grazing), or even both.

It is important to highlight that the fuel characteristics favor particularly the high flammability of the vegetation. It seems clear that the high contributions of shrub and litter to the total fuel facilitate the spreading of any potential fire. The statement is based on (Specht et al., 2012) who reported that in shrub-dominated vegetation, the primary carrier of the fire is either shrubs or litter. Additionally, dead material accumulation with the age of the community is the expressed by an increase of the dead-to-live fuel ratio, leading inevitably to an increase of the likelihood of fire and its potential intensity (Henkin et al., 1999; Seligman and Henkin, 2000; Paula et al., 2009). On the other hand, small sized fuel featuring phryganic dwarf shrubs, like *Sarcopoterium spinosum* and *Cistus creticus*, and its substantial accumulation with the age since the last fire, increase the vegetation flammability. According to Specht et al. (2012), small diameter fuel dries out and ignites more rapidly than larger fuel because of its large surface area compared to its volume. Consequently, fire most often starts and spreads in fine fuel.

Regarding the vegetation composition, it was noted that in Malaxa community shrubs contributed the bulk of the vegetation cover, while herbaceous plants were not abundant. This confirms previous observations about the encroachment potential of shrubs after a transitional competition by herbaceous plants during the first two post-fire years (Le Houerou, 1974; Naveh, 1974; Papanastasis, 1977; Arianoutsou-Faraggitaki, 1984; Keeley and Babr-Keeley, 1999). Shrub cover dominance in other Mediterranean-type shrublands has been exemplified by Ferran et al. (1998) who reported 76% of the total cover chiefly dominated by *Quercus coccifera* in garrigues of Valencia, three-and-a-half years after fire passage.

As far as the floristic composition is concerned, it was remarked that therophytes and hemicryptophytes were the dominant life forms (in terms of species number) in the studied community, with a noticeable advantage of the therophytes. Within the mentioned life form groups, by far, herbs prevailed over grasses. The comparison between the biological spectra of the studied phrygana and the grazed *Sarcopoterium spinosum* dominated batha of Ariel investigated by Ish-Shalom-Gordon (1993) shows that therophytes are, by far, the most represented life form with 49% and 56%, respectively. However, the two communities differed regarding the second highest represented life form; hemicryptophytes (27%) in Malaxa as against chamaephytes (15%; referred as bush by Ish-Shalom-Gordon) in Ariel. Geophytes were better represented in Ariel (12%) than in Malaxa (5%).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_32893303
© 2018, ALÖKI Kft., Budapest, Hungary

Furthermore, therophytes have been reported to be the most represented life form in other phryganic communities, but covering small areas (Bergmeier and Matthäs, 1996; Böhling and Gerold, 1995; Bergmeier, 1998; Ish-Shalom-Gordon, 1993) raised the possibility that the high annual therophytes richness portraying phryganic communities is favored by the occurrence of relatively predictable seasonal rainfall, but (Chilton and Turland, 2004) contended that the mentioned richness is the result of relatively rapid evolution under stress induced by drought, fire, and grazing. One has to note that due to their shallow-rooted system, therophytes depend on water supply in the upper soil layer to carry out their germination, growth, and reproduction (Bergmeier and Matthäs, 1996).

With respect to the floristic composition, the results obtained in Malaxa community are in agreement with those of Ish-Shalom-Gordon (1993) who recorded the same three dominant families in Ariel hatha: that is, Asteraceae, Fabaceae, and Poaceae. However, the two communities differed as regards the relative importance of the families: in Malaxa, the most represented family was the Fabaceae (22.8%), followed by the Poaceae (21.9%) and the Asteraceae (14.9%). On the contrary, in Ariel, the dominant family was the Asteraceae (16.6%), followed by the Fabaceae (14.6%) and the Poaceae (8.0%). The lower representation of Poaceae and Fabaceae in Ariel batha might be the fact of the higher grazing pressure (by goats and deers).

The richness values recorded in the studied phrygana cannot be fairly compared with the results obtained by other authors like Ish-Shalom-Gordon (1993) and (Bergmeier, 1997) who also investigated species richness in phrygana owing to the different methods used for data collection, and the management- types. For information, Ish-Shalom-Gordon (1993) found a total of 199 species in a grazed community of Ariel (Israel), using a 100 x 100 m plot; and Bergmeier (1997) counted a total of 91 and 86 species (and an average species number of 15.3 and 19.5) in grazed and non-grazed 20 x 30 microplots, respectively, in a phrygana of Sfakia (Crete). Nonetheless, the use of species richness as well as diversity indices provided a good insight into the organization of the community and the number of the more representative species at each post-fire stage.

The final interesting finding of the study is the similar stable species richness, heterogeneity, and equitability characterizing the community of Malaxa as early as the 3rd post-fire year onwards. These results are in line with other studies which indicated, that burned Mediterranean plant communities reestablish rapidly by auto succession process (Naveh, 1974; Trabaud and Lepart, 1980; Christensen, 1985; Trabaud, 1994; Arianoutsou, 1998; Henkin et al., 1999; Allen, 2014). Similar conclusions have also been drawn for Califomian chaparrals (Trabaud and Lepart, 1980). However, the relatively low diversity characterizing the community of Malaxa, as compared to other more diversified phrygana, is in all likelihood due to both fire suppression and non-grazing.

Conclusions

The unburned and ungrazed phrygana is characterized by a rapid reestablishment of both vegetation cover and overall aboveground biomass. These two latter's are overwhelmingly dominated by highly flammable dwarf shrubs, chiefly *Sarcopoterium spinosum*, in the case at hand. The cover tends to close and stabilize as early as the 3rd post-fire year with little or no risk of soil erosion, whereas the overall aboveground

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_32893303
© 2018, ALÖKI Kft., Budapest, Hungary

biomass needs a bit longer time to do so: that is, at the 6th post-fire year. In such a community, the herbaceous component is not substantially represented with respect to cover and aerial biomass (excepting during the first two post-fire years). This may be ascribed to the combination of both the high inhibiting competition pressure exerted by shrubs and the accumulation of litter, which restrict the spreading and the development of herbaceous plants to few openings which are temporarily free from competition.

Furthermore, the rapid reestablishment and stabilization of the representative species as well as the overall plant diversity as early as the 3rd post-fire year is in keeping with the general pattern of auto-succession and resilience characterizing Mediterranean-type communities which undergo cyclic fires. Phryganic communities recover faster than more advanced Mediterranean type shrublands. However, when the phrygana is ungrazed and unburned for a period, say 12 years as the community of Malaxa exemplifies it, the overall plant diversity becomes relatively low, probably after reaching its highest values during the first two post-fire years. Such a community may be characterized by a "dictatorial-type" organization (in which few species (chiefly dwarf shrubs in the present case), dominate by their abundances and broaden their niches to the detriment of the remaining species which are poorly represented.

In other respects, the conservation of the traditional practices, such as rotational burning and grazing, respectful of the diversity and the functioning of phryganic ecosystems may have positive socioeconomic repercussions. As previously, seen, a non-grazing situation associated with fire suppression for a period, both favor a rough encroachment of unpalatable dwarf shrubs such as *Sarcopoterium spinosum* and *Cistus creticus*, which heavily smother the herbaceous plants.

These are mainly annual legumes and grasses of high palatability and nutritive values. Consequently, the amount of pasture is reduced, and livestock production is lessened, affecting negatively the economy at both local and national levels. To optimize the benefits that can be gained from phryganic communities, both grazing and fire should be incorporated in the management plan, as pointed out by. To be beneficial, grazing management should observe a stocking rate equivalent to the grazing capacity of the rangeland, combine grazer and browser animals for a better control of plants, and respect the season and duration of grazing. Also, prescribed or controlled fires improve the grazing capacity of phryganic communities.

Tourism, as an additional source of income, can also be promoted by maintaining the biological and landscape diversity and attractiveness made up of mosaics of phrygana, maquis, and forests.

Post fire disturbances within the four study sites led to unpalatable and highly flammable dwarf shrubs, which smothered herbaceous plants. Species diversity was relatively low, indicating that few species crushingly structured the community by their high cover, while the remaining species were poorly abundant.

(Received 21st Feb 2018; accepted 21st May 2018)

Abstract. In this study, some biochemical parameters (glucose, urea, calcium, triglyceride, cholesterol, creatinine, uric acid, total protein, iron, albumin, phosphorus, H.D.L., magnesium) hemoglobin and hematocrit depending on the pre-reproductive and reproductive periods and sex were determined in a total of 20 *Testudo graeca* specimens in the Çanakkale (Turkey). For the biochemical parameters, 0,5 ml of blood was collected from the scale in the lateral ligament of the neck with a 5-ml aspirating syringe. The blood was transferred into the biochemical tubes and centrifuged; the plasma part was separated and was measured by spectrophotometer. In conclusion, plasma biochemistry parameters were determined on sex-related pre-reproduction and reproduction periods in *T. graeca*. When comparing the pre-reproductive and the reproductive period in terms of glucose, uric acid and iron values, statistical differences were found in the females. It was determined that cholesterol values of males were significantly different between periods. In the females, glucose value was found high in the pre-reproductive period and uric acid and iron values were high in the reproductive period. Cholesterol values of males were found high in the pre-reproductive period. Iron levels in the pre-reproductive period were significantly different between males and females.

Keywords: *Testudo graeca, plasma biochemistry, hematology, reproductive period, Turkey*

Introduction

Reptiles have different adaptations to terrestrial life that are not usually found in other animal species. The turtle group, which includes species living on land, in freshwater, and in marine ecosystems and also has varying morphological and physiological characteristics is one of the important groups among reptiles (Godfrey and Campbell, 2002). Plasma biochemistry studies have been used to support and extend the results of studies in the field of hematology, as animal populations, physiology, guide the determination of the environmental status of the habitat in which they live (Jacobson et al., 1991; Raphael et al., 1994; Lopez-Olvera et al., 2003).

For all these reasons, biochemical analyses of blood plasma are an important method for finalizing the health of many animal species and in recent years, reptile-related hematology and plasma biochemistry studies have been increasing rapidly.

There are many studies on blood cells and clinical hematology (Marks and Citino, 1990; Dickinson et al., 2002; Lopez-Olvera et al., 2003; Tosunoğlu et al., 2005; Hamooda et al., 2014; Bielli et al., 2015) and plasma biochemistry associated with *Testudo* species (Gilles-Baillien, 1969, Lopez-Olvera et al., 2003, Dickinson et al., 2002, Marks and Citino, 1990, Scope et al., 2013, Hamooda et al., 2014; Özdamar, 2014, Hetenyi et al., 2016). Mediterranean Spurred Tortoise, *T. graeca* is classified in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

the vulnerable species category according to IUCN (Red list) criteria. It is spread in all suitable habitats (areas with less vegetation) in Çanakkale province (Tosunoğlu et al., 2017). Since *T. graeca* is an endothermic species, it may be affected by environmental conditions and external factors, as well as many internal and external factors affecting its blood parameters. Studies on hematology (Tosunoğlu et al., 2005), and plasma biochemistry (Hamooda et al., 2014) are very limited in *T. graeca* species. Tosunoğlu et al. (2005) have established reference intervals for blood cell measurements and clinical hematology parameters in *Testudo hermanni* and *T. graeca* species. Hamooda et al. (2014) conducted a study to determine sexually and seasonally related changes in plasma biochemical values of *T. graeca* species, which are spread in Libya.

There is no study about plasma biochemistry related to sex and different periods on *T. graeca* species which can be found around our country.

The purpose of this study is the determination of parameters of plasma biochemistry (glucose, urea, creatinine, calcium, albumin, cholesterol, total protein, uric acid, phosphorus triglycerides, magnesium, iron, HDL-cholesterol, hemoglobin and hematocrit) related to the sex (female-male) and different periods (pre-reproduction and reproduction period) of *T. graeca,* and the determination of reference intervals. It is also aimed to determine whether all parameters differ between pre-reproduction and reproduction period and between male and female individuals.

Materials and Methods

Çanakkale region is located in northwestern Turkey, and *T. graeca* samples used in this study were collected from mountainous areas around Bayramiç (39° 46' 33.2" K, 26° 46' 24.4" D, Altitude: 239 m), Lapseki (40° 14' 50.8" N, 26° 47' 13.9" E, Altitude: 315m), Ezine (39° 47' 15.30" N, 26° 14' 53.45" E, Altitude: 140m), Çan (40° 07' 31.8" N, 26° 31' 22.9" E, Altitude: 60m) and city center (40° 06' 55.0" N, 26° 25' 28.4" E, Altitude: 117m) (*Fig. 1*). In all of these localities, species were observed in open areas with low vegetation.

A total of 20 specimens were collected manually in two different periods; 11 (7 ♂♂, 4 ♀♀) in the pre-reproduction period (March and April 2016) and 9 (5 ♂♂, 4 ♀♀) in reproduction period (June and July 2016) in forested areas, through the bushes and the open areas. All the procedures on the samples were made with the permission of Çanakkale Onsekiz Mart University, Animal Experiments Ethics Committee with the decision numbered 2015/108. Morphological measurements were made with digital caliper and tortometer. After the samples were brought to the laboratory and the necessary blood samples were taken, the tortoises were left behind in the habitats from which they were collected.

For plasma biochemistry analysis, 0.5 ml blood was taken with a 5 ml scaled syringe on the right or left side of the ligament in the jugular vein on the neck (Wright, 2008). Blood samples were transferred to biochemical tubes containing lithium heparin (BD Vacutainer, Becton Dickinson, Plymouth, UK). The blood was centrifuged at 4000 rpm for 10 minutes in a centrifuge, and the plasma part was separated. Biochemical parameters (glucose, urea, calcium, cholesterol, triglyceride, creatinine, uric acid, total protein, iron, albumin, phosphorus, H.D.L. and magnesium) to be studied were obtained by measuring with ELIMAT brand auto analyzer using commercial kit in the obtained plasma. For hematocrit analysis, blood was taken into micro hematocrit tubes and centrifuged at 1000 rpm for 5 minutes in a micro hematocrit centrifuge and micro hematocrit tubes were calculated with hematocrit paper and the result was found as %. Total hemoglobin concentration was measured colorimetrically with a sahli hemoglobinometer (Tanyer, 1985).

Descriptive statistics of plasma biochemistry parameters were evaluated using SPSS (20.0 for Windows Student Version) statistical program. Statistical comparison was made using the Mann Whitney U test in the SPSS program.

Results

In this study, morphological measurements were taken from the samples and similar sized samples were used. The carapace lengths of specimens were measured as about 16.14 cm in male individuals and about 20.37 cm in female individuals. In this study, plasma biochemical values were examined separately in female and male individuals in pre-reproduction and reproduction period, and the data pertaining to a total of 15 parameters are given in *Table 1*.

* P value of less than 0.05 indicates significant difference between the compared means.

When comparing the pre-reproductive period and the reproductive period in terms of glucose, uric acid and iron values, statistical differences were found in the females. It was determined that cholesterol values of males were significantly different between periods. In the females, glucose value was found high in the pre-reproductive period and uric acid and iron values were high in the reproductive period. Cholesterol values of males were found high in the pre-reproductive period. In addition, there was statistical difference between iron values of males and females in the pre-reproductive period.

Discussion

Glucose

In our glucose values, when females were compared, it was found that there was a statistically significant difference in glucose between pre-reproduction period and reproduction period (P: 0.034; U: 0.000; Z: -2.121). When male and female individuals were evaluated together, there were significant differences between the two periods (P: 0.007; U: 12.00; Z: -2.694). In both sexes, glucose levels were found to be higher in the pre-reproduction period than in the reproduction period. It is thought that there is an increase after hibernation because the animal that is wakened from winter sleep fed too much to be prepared for the reproduction period. Hamooda et al. (2014) found that glucose values in the *T. graeca* specimens were close to each other in females and males.

Urea

In our urea values, no statistically significant difference was found between the sexes in the periods. Gilles-Baillien (1969) determined the urea value of *T. hermanni* as 2.46 mg/dL and found that the urea concentration increased when preparing for winter sleep.

Cholesterol

In our cholesterol values for males, when pre-reproduction and reproduction period were compared, it was determined that there is a significant difference (P: 0.006; U: 0.000; Z: -2.739). When male and female individuals are evaluated together, there are significant differences between the two periods (P: 0.007; U: 12.00; Z: -2.694). The cholesterol values obtained in both genders in the pre-reproduction period are higher than in the reproduction period. Hamooda et al. (2014) reported that cholesterol in *T. graeca* was significantly higher in females during the season in which they were active, and varied by season. These observations and analyzes have shown that there is a close relationship between egg development and vitellogenesis (Christopher et al., 1999, Hidalgo-Vila et al., 2007). And they have shown that testosterone hormone has a negative correlation with cholesterol.

Albumin

In our albumin values, there were no significant differences in pre-reproduction period and reproduction period, and similar values were determined. Dickinson et al. (2002) found that sex, location, and period cause significant differences in hematology and blood biochemistry in the desert turtle *Gopherus agassizii*, they found that there was no difference between the male and female individuals in albumin values. In our values, no statistically significant difference was found between the sexes in both periods.

Calcium

There was no statistic difference between the sex and periods in terms of the calcium parameter. Marks and Citino (1990) found that plasma vitelline causes an increase in the amount of calcium present during the reproduction period in the *Testudo radiata* specimens. And they found that calcium levels were not significantly different between males and females.

Creatinine

In our creatinine values, there were no significant differences in pre-reproduction period and reproduction period, and close values were determined. There was no difference between the sexes in both periods. Hamooda et al. (2014) reported that creatinine values of *T. graeca* were found close to each other in males and females. There was no statistically significant difference in the creatinine values of *T. hermanni*, periodically in both sexes (Özdamar, 2014).

Total protein

There was no significant difference in pre-reproduction period and reproduction period, and close values were determined. There was no statistic difference between the sexes in both periods. In *G. polyphemus*, serum total protein levels were found to be higher in females compared to males (Taylor and Jacobson, 1982). Özdamar (2014) reported that the pre-reproduction period in *T. hermanni* species was shorter in females than in males.

Uric acid

There was no statistic difference between the sexes in both periods. It was determined that uric acid value in females was statistically different when pre-reproduction period and reproduction period were compared (P: 0.034; U: 0.000; Z: -2.121). When male and female individuals were evaluated together, there were significant differences between the two periods (P: 0.007; U: 8.000; Z: -2.694). It was determined that the uric acid levels in both sexes were lower in the pre-reproduction period than in the reproductive period. Scope et al. (2013) found that the concentration of uric acid in the *T. hermanni* specimens was the highest after winter hibernation. The lowest values were found to be 0.9 mg / dL in October and the highest value was found to be 5.4 mg / dL after winter sleep.

Phosphorus

In our phosphorus values, there were no significant statistical differences in the pre-reproduction period and reproduction period, but they were observed to be lower in reproduction period. Phosphorus was found to have no effect on sex. By Scope et al. (2013), phosphorus values of *T. hermanni* were found to be higher in females than in males and the maximum value for phosphorus was seen at the earliest in June.

Magnesium

There were no statistical differences between the sexes and the periods. Hamooda et al. (2014) found magnesium in *T. graeca* as 5.33 mg/dL in females and 5.64 mg/dL in males.

Triglycerides

In our triglyceride values, there was no statistical difference. Hamooda et al. (2014) observed that the concentration of triglycerides in female *T. graeca* showed a significant increase when compared to males.

DOI: http://dx.doi.org/10.15666/aeer/1603_33053313
© 2018, ALÖKI Kft., Budapest, Hungary

Iron

In our iron values, a significant difference was found between males and females in pre-reproduction period (P: 0.019; U: 1.000; Z: -2.345). When the female individuals were compared between the pre-reproduction and the reproduction period, the statistical difference was observed (P: 0.021; U: 0.000; Z: -2.309). A detailed study on the reference intervals of the iron values of tortoises has not been found.

HDL cholesterol

There was no statistical difference between the sexes and the periods. Sex and size were found to influence the biochemical parameters of HDL-cholesterol (Whiting et al., 2007; Anderson et al., 2011). Mader and Divers (2013) reported that in reptiles; females had high cholesterol during active laying period.

Hematocrit

In our hematocrit values, there was no statistical difference between the two periods and sexes. Hamooda et al. (2014) suggested that low levels of hematocrit in the *T. graeca* species are related to sexual affect. Tosunoğlu et al. (2005) found hematocrit values between 21-34% for *T. hermanni* and 24-36% for *T. graeca* species. They noted that hematocrit value is potentially informative about the state and physiology of the tortoises.

Hemoglobin

In our hemoglobin parameters, there was no statistical difference between the two periods and sexes. Tosunoğlu et al. (2005) reported hemoglobin levels of 4.9-7.4 g/dL for *T. hermanni* and 5.2-9.7 g/dL for *T. graeca*. Hamooda et al. (2014) found that the concentration of hemoglobin in the *T. graeca* species was characterized by low average values in both males and females, which have a significant effect in favor of male tortoises.

Conclusion

Biochemical analyses of blood plasma are an important method for assessing the health of many animal species. For this reason, comparative hematological results of *T. graeca*, which is on the Red List of the IUCN in the Vulnerable category, are given in this study. The data of this study will be useful for evaluating future health problems and for species conservation studies.

METEOROLOGICAL DROUGHT ANALYSIS USING ARTIFICIAL NEURAL NETWORKS FOR BURSA CITY, TURKEY

KATIP, A.

Department of Environmental Engineering, Faculty of Engineering, Uludag University
Görükle Campus, 16059 Bursa, Turkey
e-mail: aballi@uludag.edu.tr

(Received 21st Feb 2018; accepted 24th May 2018)

Abstract. Climate change is one of the most important environmental events of recent years. Floods and droughts may occur more frequently with climate change. Droughts could be classified as meteorological, hydrological or agricultural. When meteorological drought appears in a region, agricultural and hydrological droughts follow. In this study, the standardized precipitation index (SPI) was applied for meteorological drought analysis in Bursa City-Turkey. Analyses were performed on 3-, 6-, 9- and 12-month-long data sets. According to the analyses most of the percentages (67-72%) for all SPI values (3, 6, 9, 12 months) was in the near normal class close to Marmara Region-Turkey. Also meteorological variables and SPI-12 values were simulated with ANN models and had different structures. It was found that R and MSE values calculated were in the acceptable ranges and rising of hidden layers and input numbers in the model structures was ensured for more efficient model run. Modelling the precipitation from the meteorological parameters (Model 2) was possible with some error. Therefore simulations of SPI-12 and soil temperatures were indicative to meteorological and agricultural droughts. Comparison of the observed values and the modelling results showed a better agreement with SPI-12 and soil temperature parameters. Drought predictions made by ANN models would be useful for local administrations and water resources planners and would be extremely important for drought risk management.
Keywords: *aridness, standardized precipitation index (spi), modelling*

Introduction

In an increasing and demanding society with the development of industrial technology, mineral and energy resources are needed for fossil fuels. Besides the obvious benefits (rising of the living standards for most people) the exploitation of the natural resources of the Earth has not been without a cost. This cost is climate change. Climate change refers to both the rise in global temperatures because of human activities and the many consequential impacts such as more intense and frequent droughts and storms, melting glaciers and ice sheets, rising sea levels, warming seas (NOAA, 2017).

Droughts naturally occur in almost all climatic zones, and are a result of the reduction of precipitation from normal amounts for an extended period of time (Belayneh et al., 2016). Precipitation is not the only factor determining the development of drought. Hot weather, low soil moisture, wind, increasing demand of water due to population growth, irregular usage of water resources and human activities in the regions influence the drought events. Extended periods of drought can lead to several adverse consequences, which include a disruption of the water supply, low agricultural yields, and reduced flows for ecosystems (Belayneh et al., 2016). As the result of the long meteorological drought, agricultural and hydrological drought occurs. Drought may cause famine, hunger, and death and so it affects a community socially, economically and psychologically. Water shortages will become one of the most important environmental and social problems in some countries around the world in the near future (IPCC, 2014).

Annual water amount per capita in Turkey is expected to decline (700-1910 m^3). Increasing evaporation because of global climate change will cause occurrence of more severe and prolonged droughts in Turkey (Kurnaz, 2014). Variation in the hydrological cycle will conduce to irrigation and water supply problems as well as increase in sudden flood events (Wen et al., 2013). Therefore, drought analysis is important in water resource management and planning, and for long-term economic and social planning (Buttafuoco and Caloiero, 2014; Ibrahimi and Baali, 2017).

Forecasting and analyzing meteorological drought characteristics specifically their initiation, time, frequency, severity and involved area are important. Because time, duration and severity of drought are not known it is analyzed with probability and statistical methods in any region (Belayneh et al., 2016; Deo et al., 2015; Ibrahimi and Baali, 2017; Buttafuoco and Caloiero, 2014). Precautions could be taken to minimize the drought with drought analysis and measures. Drought can be examined spatially and temporally. When the temporal analyses were made, duration, amplitude and intensity of drought might be calculated.

A drought period starts when the Precipitation Index falls below zero. When the drought period finishes the Precipitation Index rises above this level. Number of drought periods are denoted as "m"; duration of drought periods are showed as L_1, L_2, …….L_m; total of lacks lower from each drought level-magnitude demonstrated as "M_1 , M_2 , …….M_m".

The ratio of magnitude to duration of drought periods is identified as "drought intensity" (McKee, et al., 1993). It is formulated as *Equation 1:*

$$I_n = \frac{M_n}{L_n} \qquad \text{(Eq.1)}$$

The sum of the lack of n^{th} along a series M_n (Magnitude) is calculated as *Equation 2:*

$$M_n = \sum_{i=1}^{m} \left| X_0 - X_i \right| \qquad \text{(Eq.2)}$$

In this equation:
X_0: SPI cutoff level is zero for each drought,
X_i: It is a standardized series,
m: Number of drought periods for the cutoff level (X_0).

Maximum and minimum values of drought features (L_{max}, L_{min} ,M_{max} , M_{min} , I_{max} and I_{min}) are calculated for each cutoff level. Also, some basic statistical parameters as mean, standard deviation, median, skewness, kurtosis values are determined. These values inform about the statistical properties of the M, L and I values of data set (McKee et al., 1993).

A common tool utilized to monitor current drought conditions is a drought index. Drought indices are expressed by a numeric number, which is believed to be far more functional than raw data during decision-making (Pedro-Monzonís et al., 2015). Several drought indices have been developed around the world in the past based on rainfall as the single variable, including the widely used Deciles. There are some indices as Standardized Precipitation Index (SPI) (McKee et al., 1993) and Effective Drought Index (EDI) (Deo et al., 2015) and also the well-known Palmer Drought Severity Index

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_33153332
© 2018, ALÖKI Kft., Budapest, Hungary

(PDSI) which considers temperature along with rainfall (Belayneh et al., 2016). In temporal and spatial drought analysis, standard precipitation index and kriging methods are generally used respectively. SPI (*Eq. 3*) obtained by precipitation (mm) at a given time is subtracted from the mean precipitation and in the sequel divided by standard deviation value (Anonymous, 2014a, 2016a).

$$SPI = \frac{X_i - X_i^{mean}}{\sigma} \quad \text{(Eq.3)}$$

In this equation:
SPI: Standard Precipitation Index
X_i: precipitation (mm)
X_i^{mean}: mean Precipitation (mm)
σ: Standard deviation

The SPI drought index was chosen to forecast drought in this study due to its simplicity, its ability to represent droughts on multiple time scales, and because it is a probabilistic drought index. In addition, the study by Gürler (2017) determined that the SPI is the most appropriate index for monitoring the variability of droughts in Turkey because it is easily adapted to local climate, has modest data requirements, and can be computed at almost any time scale.

Application of statistical models has a long history in drought forecasting. Development of ANN (Artifical Neural Network) approaches with high precision of estimation was considered to be effective in eliminating the arduous task of field works and development of complex models that involve partial differential equations.

An application of ANN to solve civil and environmental engineering problems began in the late 1980s (Ibrahimi and Baali, 2017). ANN has recently been applied in hydrological forecasting to examine the rainfall-runoff relationship in watershed, to characterize daily stream flow and monthly reservoir inflow, to evaluate rainfall-runoff models, to forecast river flow, to forecast future precipitation values and for the purposes of drought forecasting (Daliakopoulos and Tsanis, 2016; Lima, et al., 2016; Pedro-Monzonís, et al., 2015; Belayneh et al., 2016). Also it could be used easily in climate models of catchment area (Salami and Ehteshami, 2016), forecasting for ecology, water quality and quantity (Sinha and Das, 2015; Lallahem and Hani, 2017; Chen et al., 2017)

In this paper, Standardized Precipitation Index-SPI (3, 6, 9, 12 months) were calculated based on monthly mean precipitation values, to determine drought categories and then total of 6 model structures were tested and validated with ANN model structures. The first aim of this paper was to develop suitable ANN models by considering the feed-forward back-propagation learning algorithm in the estimation of total monthly precipitation (mm), the average monthly minimum and surface soil temperatures (10 cm, °C) and SPI-12 values. The second aim was providing information from modeled parameters to meteorological and agricultural drought. Also the suitability of soil temperatures modelling for drought forecasting was investigated when the precipitation data was absent. For this purposes meteorological drought analysis was performed for the Bursa Centrum Station. In the drought analysis, it was determined that whether precipitation values were fitting gamma distribution and SPI method was used. Drought was investigated in SPI-12 and the obtained drought categories given by

McKee et al. (1993) were modeled by ANN. Importance of this study lies in the risk management in countries around the world fighting with drought.

Materials and methods

Study area and data

Bursa is a large city in Turkey, located in Northwestern Anatolia, within the Marmara Region. It is the fourth most populous city in Turkey and one of the most industrialized metropolitan centers in the country. According to the 2013 general population determination results Bursa Province had 2,787,539 inhabitants (Anonymous, 2014b). Bursa between 28-30 degrees latitude and 40 degrees longitude circle is located in the southeast of the Marmara Sea (*Fig. 1*).

Figure 1. *Location of Bursa City and Meteorology Station*

It is 155 m above sea level and its total area is 10 819 km^2. The climate type of Marmara is dominant in Bursa. Marmara climate is known as a Terrestrial to Mediterranean transitional climate. Characteristics of the Marmara climate are as follows: annual precipitation is between 500-1000 mm, annual average temperature values are 14-16 °C, warmest month average: 23-25 °C, coldest month average: 5-6 °C. The most rain falls in winter, December, January, February. The arid months are June, July and August. Percent of precipitations are 38.3% of winter, 9.4% summer, 26.8% autumn and 25.5% in spring (Anonymous, 2014c). According to the long-term (1984-2013) averages, highest monthly average temperature was in July with 25.1 °C, the lowest monthly average temperature was in January with 5.6 °C and monthly average of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_33153332
© 2018, ALÖKI Kft., Budapest, Hungary

the most rainfall was in December with 93.8 l/m² (Boz, 2015). There are 16 meteorological stations in districts of Bursa City. There are no stations in Yıldırım and Gürsu districts but two stations in the Osmangazi District. In this study, meteorological data (years of 1984–2013) from the 16 stations in Bursa was taken from Ministry of Forestry and Water Affairs, Meteorological Department Station 17116 (Bursa-Center) and meteorological drought was investigated. Between 12 and 40 station numbers were used for meteorological and agricultural drought analyses in many studies (Milanović et al., 2014; Sun et al., 2017; Łabędzki and Bak, 2017; Pablos et al., 2017). The stations are not located in district centers but in areas close to agricultural land. Therefore urban heat island could not cause significant difference between surface temperature in stations and in arable lands (Yang et al., 2016). The data collection was synoptic (3 hourly) and daily (Anonymous, 2014c). Reporting periods for long-term averages according to climatological standard were either 1971-2000, or 1981-2010. But the climatological values between different date ranges in the international reports were presented and evaluated (NOAA, 2017). Regular data recording for Bursa stations had started in 1984. Thus, the values between 1984 and 2013 were evaluated in this study. The parameters for statistical calculations were monthly total precipitation (mm), average air and soil temperature, pressure, vapor pressure, insolation intensity, wind speed, relative humidity were given in *Table 1*. Also long time averages of air temperature and monthly total precipitation are shown in *Figures 2* and *3,* respectively.

Table 1. *Statistical values of used parameters (1984-2013)*

Parameters	Max	Min	Average	Standard deviation	Total*	%*
Monthly average air temperature (°C)	27.90	1.10	14.70	7.27	3	0.80
Monthly average maximum air temperature (°C)	31.90	6.20	21.58	5.79	2	0.55
Monthly average minimum air temperature (°C)	24.50	-8.80	8.81	8.08	3	0.83
Monthly average minimum surface soil temperature (°C)	20.80	-5.50	7.47	5.89	17	4.72
Monthly average 10 cm soil temperature (°C)	33.30	2.20	16.56	8.93	9	2.50
Monthly total precipitation (mm)	396.60	0.00	58.26	48.26	3	0.83
Monthly average pressure (hPa)	1017.00	997.50	1004.31	3.72	5	1.39
Monthly average vapor pressure (hPa)	51.80	4.60	11.64	4.87	19	5.28
Monthly average-daily total global insolation intensity (cal/cm²)	644.70	86.20	312.67	149.29	9	2.50
Monthly total global insolution intensity (cal/cm²)	19341.60	2585.25	9484.77	4578.44	9	2.50
Monthly average wind speed (m/s)	3.50	0.80	1.95	0.44	11	3.06
Monthly average relative humidity (%)	84.50	46.30	66.68	7.64	4	1.11

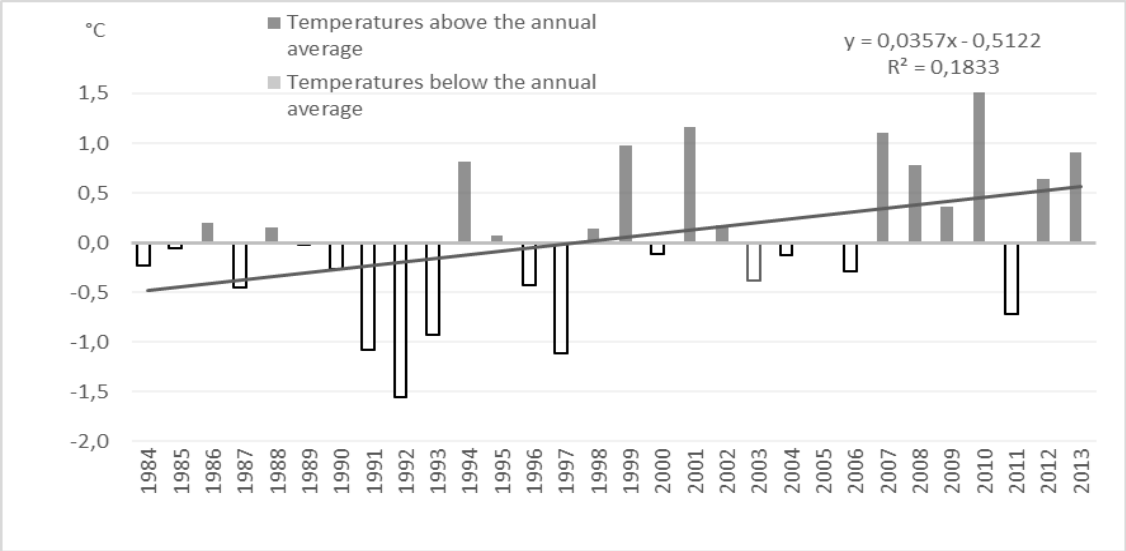

Figure 2. *Long-time averages of air temperature*

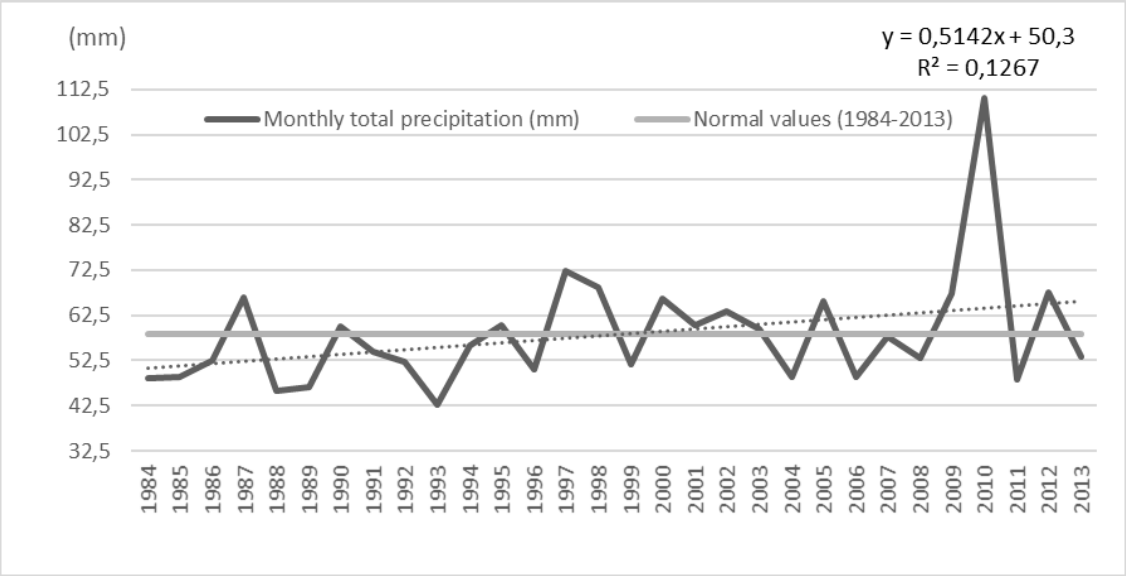

Figure 3. *Long-time averages of monthly total precipitation*

SPI calculation

The SPI is based on the probability of precipitation at any time scale (at least 30 years). The probability of observed precipitation is then transformed into an index. This long-term precipitation time series is then fitted to a gamma distribution, which is then transformed through an equal probability transformation into a normal distribution. Positive SPI values indicate wet conditions with greater than median precipitation and negative SPI values indicate dry conditions with lower than median precipitation. McKee and others (1993) originally calculated the SPI for 3-, 6-,12-, 24- and 48-month timescales (Buttafuoco and Caloiero, 2014; Belayneh et al., 2016; Anonymous, 2016a). *Table 2* presents SPI drought classes.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_33153332
© 2018, ALÖKI Kft., Budapest, Hungary

Table 2. *SPI drought classification (Anonymous, 2016a)*

SPI Values	Class
>2	Extremely wet
1.5–1.99	Very wet
1.0–1.49	Moderately wet
−0.99 to 0.99	Near normal
−1 to −1.49	Moderately dry
−1.5 to −1.99	Very dry
<−2	Extremely dry

In order to calculate the SPI, a probability density function that adequately describes the precipitation data must be determined. The gamma distribution function was selected to fit the raw rainfall data in this study. The SPI is a *z*-score and represents an event departure from the mean, expressed in standard deviation units. The SPI is a normalized index in time. SPI values can be categorized according to the classes.

In this study, the SPI_SL_6.exe (Standardized Precipitation Index Program) was compiled in C++ for PC developed by the National Drought Mitigation Centre, University of Nebraska-Lincoln, and it was used to compute time series of drought indices (SPI) for the station in the Bursa and for each month of the year at different time scales (Anonymous, 2016a). The input file was set up to analyse the 1-, 3-, 6-, 9- and 12-month SPIs and output file of the months was constituted.

In this study, input and output data for the simulations were normalized SPI values depending on precipitation. Before the training SPI values were demeaned 0 to 1. So variables were made dimensionless and similarity selected at random has been removed.

The formulation for dimensionless (normalization) values was determined with *Equation 4:*

$$F = (F_i - F_{min}) / (F_{max} - F_{min}) \quad \text{(Eq.4)}$$

In this equation, F was any dimensionless value; F_i was i^{th} value in measurements; F_{max} and F_{min} were maximum and minimum measurements (Ibrahimi and Baali, 2017; Deo et al., 2015).

ANN model and training algorithm

Artificial neural networks are formed of a set of simple elements, the alleged artificial neurons. These elements are inspired by biological nervous systems. Models of neural networks are separated into two categories: feed forward neural networks and recurrent neural networks. Feed forward neural networks deliver data linearly from input to output and they are the most popular and most widely used models in many practical applications (Daliakopoulos and Tsanis, 2016). The feed forward neural network (FNN) with as few as a single hidden layer and arbitrary bounded and smooth activation functions can approximate a continuous nonlinear function. The model of a neuron and multi-layer FNN is represented in *Figure 4* (Chen et al., 2014; Yonar and Yalılı, 2014).

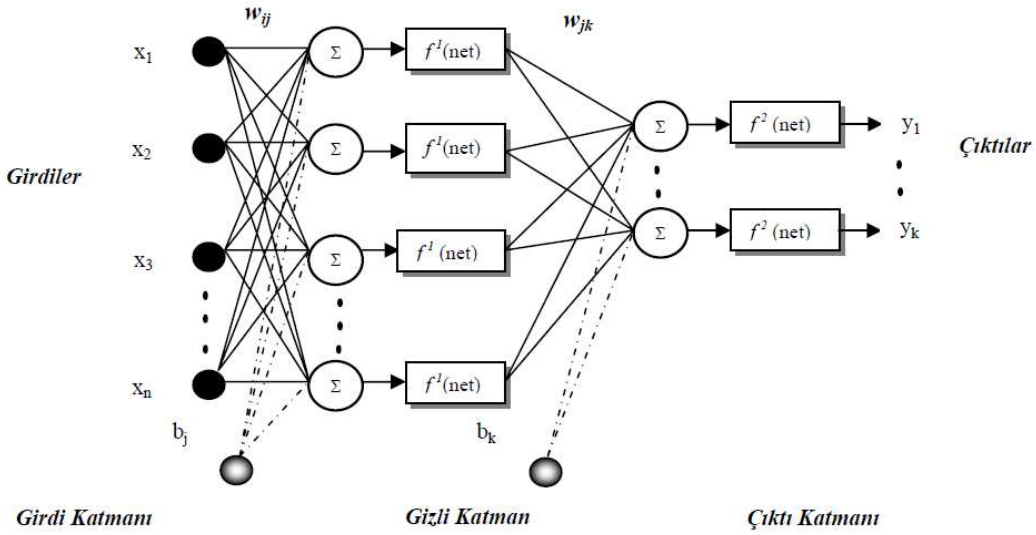

Figure 4. *Multi-layer feed forward neural network*

As shown in *Figure 4,* the elements constituting ANN are input layers, hidden layers (number of hidden layers are one or might be more}, output layer linkages between the layers and linkage weights.

The data of the problem is in the input and output layers. Productivity and importance of information in the input layer are provided with the weights. Net (basis) function expresses that effectiveness of input data to neuron. For an analytical study, the connection networks are mathematically represented by a basis function u (w, x). The net value is a linear combination of the inputs and the output of a neuron can be expressed as *Equation 5:*

$$out = f(n)$$

where

$$n = \sum_{j=1}^{R} w_j x_J + b \qquad \text{(Eq.5)}$$

x_1, x_2, … ,x_R are the input signals; ω_1,ω_2, . . .,ω_R are the weights of neuron; b is bias value; and f(·) is the activation function.

Activation function is a function determining the neuron output with processing the net inputs obtained from net function. The linear and sigmoid are common used activation functions in the construction of artificial neural networks.

An example of the sigmoid is the logistic function, defined by *Equation 6:*

$$f(n) = \frac{1}{1+e^{-n}} \qquad \text{(Eq.6)}$$

As sigmoid function (*Eq. 7*) can also be used as hyperbolic tangent function and it gives the outputs range between [0-1] (Cömert and Kocamaz, 2017):

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_33153332
© 2018, ALÖKI Kft., Budapest, Hungary

$$f(n) = \frac{1-e^{-n}}{1+e^{-n}} \quad \text{(Eq.7)}$$

The inputs x_1, x_2, . . ., x_R are multiplied by weights $\omega_i,j_{(1)}$ and summed at each hidden neuron i.
Then the summed signal would be calculated as *Equation 8*:

$$n_{i(1)} = \sum_{j=1}^{R} w_{i,j(1)} x_J + b_{i(1)} \quad \text{(Eq.8)}$$

The output y at a linear output node can be calculated as *Equation 9:*

$$y = \sum_{i=1}^{z} w_{1,i(2)} \frac{1-e^{-(\sum_{i=1}^{R} x_j w_{i,j(1)} + b_{i(1)})}}{1-e^{-(\sum_{i=1}^{R} x_j w_{i,j(1)} + b_{i(1)})}} + b_{1(2)} \quad \text{(Eq.9)}$$

where R is the number of inputs, z is the number of hidden neurons, ωi.j(1) is the first layer weight between the input j and the i^{th} hidden neuron, ω1,i(2) is the second layer weight between the i^{th} hidden neuron and output neuron, bi(1) is a biased weight for the ith hidden neuron and b1(2) is a biased weight for the output neuron (Chen et al., 2014)

The learning algorithms using in ANN are heuristics, partial Newton methods, matched gradient methods and Levenberg Marquardt methods. In this study feed forward neural network structure was used and Levenberg Marquardt training algorithm supervised training algorithms was preferred for training. Levenberg Marquardt algorithm is the least squares calculation method based on maximum neighborly idea (Chen et al., 2017). The sum of squared errors of any one of the element in the training set (N number of elements) could be calculated as *Equation 10:*

$$E(w) = \frac{1}{2}\sum_{i=1}^{N} (y_{mi} - y_i)^2 = \frac{1}{2}(y_m - y)^T (y_m - y) \quad \text{(Eq.10)}$$

Symbol *(w)* in *Equation 10* would be defined as *Equation 11:*

$$w = [w_{1,1(1)}, w_{1,2(1)}, \ldots, w_{z,R(1)}, b_{1(1)}, b_{2(1)}, \ldots, b_{z(1)}, w_{1,1(2)}, w_{1,2(2)}, \ldots, w_{1,z(2)}, b_{1(2} \quad \text{(Eq.11)}$$

Two number of different hidden layer neuron for each input neurons was tested in this study. This was because; in the recent study were two different approaches used in determining the number of hidden layer neurons. The first was (N+1)/2 and the second one was (2*N+1) (Chen et al., 2017). “N” was the number of neuron in the input layer (Chen et al., 2017).

Performance and sensitivity analysis of ANN

The performance of the forecasts from the data-driven models was evaluated. The Pearson correlation coefficient is one of the most commonly used performance in selecting proper inputs for the ANN (Chen et al., 2014). Correlation coefficient is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_33153332
© 2018, ALÖKI Kft., Budapest, Hungary

described as the degree of correlation between the empirical and modeled values (*Eq. 12*):

$$r = \frac{\sum_{i=1}^{N_o}(y_i - \bar{y})(y_{mi} - \bar{y}_m)}{\sqrt{\sum_{i=1}^{N_o}(y_i - \bar{y})^2 \sum_{i=1}^{N_o}(y_{mi} - \bar{y}_r}} \quad \text{(Eq.12)}$$

where y_i and y_{mi} enounce the network output and measured value from the i^{th} element; $\bar{y}$ and $\bar{y}_m$ conceive their average respectively, and N_o describes the number of measurements.

Another performance computation is mean absolute error (MAE). The MAE is used to measure how close forecasted values are to the observed values. It is the average of the absolute errors. The smaller values of MAE and MSE (mean square error) provide the better performance (Belayneh et al., 2016). MAE and MSE are estimated with *Equations 13* and *14:*

$$MAE = \frac{1}{N_0}\sum_{i=1}^{N_0}|y_{mi} - y_i|^2 \quad \text{(Eq.13)}$$

$$MSE = \frac{1}{N_0}\sum_{i=1}^{N_0}(y_{mi} - y_i)^2 \quad \text{(Eq.14)}$$

ANN application

In this study, all the ANN models were created with the MATLAB ANN toolbox (Matlab, 2015). The tangent sigmoid transfer function was the activation function for the hidden layer, while the activation function for the output layer was a linear function. All the ANN models in this study were trained using the Levenberg Marquardt (LM) back propagation algorithm. The LM back propagation algorithm was chosen because of its efficiency (Nawi et al., 2016; Cömert and Kocamaz, 2017).

All the ANN models the cross validation technique was used to partition the data sets; 80% of the data was used to train the models, while the remaining 20% of the data was used to test and validate the models, with 10% used for testing and 10% used for validation (Berhan et al., 2015; Belayneh et al., 2016). The training set was used to compute the error gradient and to update the network weights and biases. The error from the validation set was used to monitor the training process. If the network over fits the data the error in the validation set will begin rising. The testing data set is an independent data set and is used to verify the performance of the model.

Total number of 359 data based on monthly average values was used in this study and 6 model structures were tried. In the first model 6 parameters associated with air temperature, global insolation and precipitation parameters were used as inputs, the parameters of monthly average of 10 cm soil depth temperature and monthly average of surface soil minimum temperature were outputs. In the second model, 3 numbers of air temperature, 2 of soil temperature, 2 number of global insolation and monthly average of humidity parameters were used as inputs (total of the 8 parameters) and monthly total precipitation parameter was identified as output. 3 and 9 month SPI values in 3rd and 4th models and 3, 9 and 12 month SPI values in 5th and 6th models were used as input

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_33153332
© 2018, ALÖKI Kft., Budapest, Hungary

parameters. 12 month SPI was defined as output in3rd, 4th, 5th and 6th models. In the 1st and 2nd models, only meteorological parameters were modeled. SPI parameters were modeled in the other 4 models. The results related to ANN modelling experiments with a different number of hidden layers were defined in a comparative way.

Results and discussion

Assessment of SPI Values

3, 6, 9 and 12 month SPIs were calculated with SPI_SL_6.exe program. If the Standard Precipitation Index falls below zero a drought period start, number of drought periods "m", duration of drought periods L_1, L_2, …….L_m and total of lack from each drought level-Magnitude "M_1, M_2, …….M_m" and the ratio of magnitude to duration of drought periods identified as "drought intensity" parameters were calculated with Microsoft Office Excel (Windows 7 Home Premium) computer program. In addition to this cutting levels were decided as class intervals for SPI. According to the cutting levels M, L and I values were obtained for mild, moderate, severe and extreme drought conditions. The calculated statistical parameters of drought were given in *Table 3*.

Table 3. *The statistical parameters of drought*

Drought parameters		Number of events	Max	Min	Median	Most of repetition	Std	Skewness	Kurtosis	Average
M	3 Month	50	13	1	3	1.00	2.64	1.46	2.40	3.460
	6 Month	33	21	1	4.00	1.00	5.23	1.63	2.57	5.485
	9 Month	27	24	1	4.00	1.00	6.42	1.35	1.47	6.481
	12 Month	20	33.0	1	4.5	1.00	10.32	1.34	0.60	8.850
L	3 Month	50	13.41	0.02	2.065	0.05	2.80	1.54	3.30	2.861
	6 Month	33	24.59	0.01	2.07	-	5.73	2.05	4.41	4.395
	9 Month	27	25.86	0.07	2.04	1.42	6.90	1.63	2.15	5.322
	12 Month	20	30.87	0.09	1.7	-	10.35	1.59	1.27	7.065
I	3 Month	50	2.094	0.02	0.68	0.05	0.50	0.84	0.49	0.741
	6 Month	33	1.17	0.01	0.58	-	0.36	0.02	-0.97	0.567
	9 Month	27	1.21	0.07	0.53	-	0.35	0.19	-1.12	0.565
	12 Month	20	1.08	0.09	0.46	0.12	0.33	0.30	-1.45	0.507

As shown in *Table 3,* when the duration of drought becomes longer (3 Month to Month 12), number of events and median values of drought intensity were reduced but averages of drought intensities were found in same drought class "near normal". The calculated percentages of event number and drought classes (McKee et al., 1995) were given in *Table 4*.

Regarding the percent of event number it was seen that the most of the percentages (67%-72%) for all SPI values were in the near normal class. In the previous studies drought intensity of Marmara Region was found as maximum "1" (Sırdaş, 2002). Drought intensities of Bursa were determined close to Marmara Region in this study.

<−2	Extremely dry	3.014	1.381	1.950	1.685

The effect of neural network structure on performance function (MSE) and model estimation power (R)

The effect of neural network structure by changing of inputs, outputs and number of hidden neurons (layer) on model performance was investigated. Mean Square Error (MSE) has been adopted as a measure of performance (as performance function) for comparing the effectiveness of tested structures (Belayneh et al., 2016; Lalahem and Hani, 2017). The performance function (MSE) values and correlation coefficients (R) obtained for training, validation, testing and whole data sets. The model structures and their performance functions (MSE) values and correlation coefficients (R) of the data sets are presented in *Table 5*.

In the first model, air temperatures (3 parameters), global insolutions (2 parameters) and total precipitation were chosen as inputs also twin soil temperature parameters were chosen as outputs. This model was run quite efficiently.

In the second model air temperatures (3 parameters), soil temperatures (2 parameters), global insolations (2 parameters) and monthly average relative humidity (%) were inputs and monthly total precipitation (mm) was the output parameter. The calculation of MSE values of model 2 resulted in large numbers while correlation coefficients (R) were found little higher than in the other models. Therefore, modelling the precipitation from the meteorological parameters was possible with some error and this model run was not quite efficient.

In model 3 and model 4, modelling the SPI 12 from SPI 3 and SPI 9 was very efficient and also with increasing of hidden layer number in model 4 the model worked better than model 3. In model 4 MSE values of training and validation stages were decreased and correlation coefficient (R) of whole data was increased.

Increasing of input numbers in model 5 and model 6 (3, 6 and 9 months SPI) led to more efficient modelling than model 3 and model 4. R values were increased and MSE values were decreased in model 5 and 6. When model 5 compared to model 6, rising of hidden layer in model 6 was ensured more efficiently than in model 5.

As a result, it was found that all of the 5 models were successfully except model 2. R and MSE values calculated were in the acceptable range (Sinha and Das, 2015; Yonar and Yalili Kilic, 2014). MSE values in this study were found smaller than some water quality studies (Chen et al., 2014). This showed that hydrological and meteorological parameters were modeled well with ANN (Daliakopoulos and Tsanis, 2016; Sušanj et al., 2016; Sayagavi and Charhate, 2017). But in some water pollution and quality studies when number of data and tests were increased MSE values were calculated

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_33153332
© 2018, ALÖKI Kft., Budapest, Hungary

smaller (Sinha and Das, 2015; Yonar and Yalili Kilic, 2014). It was revealed in this study that precipitations in connection with meteorological drought were modeled better with SPI values. In the other studies SPI values were modeled well with neural network and Neural-based Fuzzy Inference System too (Ibrahimi and Baali, 2017; Belayneh et al., 2016). Also some modelling studies about the other drought indices (e.g. Effective Drought Index -EDI) gave good results (Pedro-Monzonís et al., 2015). *Figures 5* and *6* display the observed time series and forecasted values with the model structures. In addition, the corresponding scatter plots were also presented.

Conclusion

Drought is a climate element that has devastating consequences on national economy and public life and Turkey is located in the semi-arid region. Therefore, monitoring and precautions for drought species are crucial.

In this study, time series of the Standardized Precipitation Index (SPI) are constructed for different periods based on monthly mean precipitation values, to determine drought categories. It was determined that the most of the percentages (67-72%) for all SPI values (3, 6, 9, 12 months) was in the near normal class close to Marmara Region-Turkey.

Not only benefiting from the precipitation series, other meteorological variables were also used for examination of drought. If precipitation data is absent, it is not possible to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_33153332
© 2018, ALÖKI Kft., Budapest, Hungary

account for the drought index. Therefore, soil temperatures in Bursa City-Turkey as an indicator of agricultural and meteorological droughts were simulated with ANN model in this study. In addition, total precipitation and 12 month Standard Precipitation Index (SPI-12) parameters were also simulated with Artificial Neural Network Model had different structures.

Table 5. *The model structures and their performance functions (MSE) values and correlation coefficients (R) of the data sets*

Model No	Inputs	Outputs	ANN	MSE			R			
				Training	Validation	Testing	Training	Validation	Testing	Whole data set
Model 1	Monthly average air temperature (°C) Monthly average maximum air temperature (°C) Monthly average minimum air temperature (°C) Monthly total global insolation intensity (cal/cm²) Monthly average-Daily total global insolation intensity (cal/cm²) Monthly total precipitation (mm)	a) Monthly average minimum surface soil temperature (°C) b) Monthly average 10 cm soil temperature (°C)	6-1-2	1.3091	1.0263	0.8606	0.9917	0.9928	0.9945	0.99204
Model 2	Monthly average air temperature (°C) Monthly average maximum air temperature (°C) Monthly average minimum air temperature (°C) Monthly average minimum surface soil temperature (°C) Monthly average 10 cm soil temperature (°C) Monthly total global insolation intensity (cal/cm²) Monthly average-Daily total global insolation intensity (cal/cm²) Monthly average relative humidity (%)	Monthly total precipitation (mm)	8-1-1	1192.0973	741.9998	1142.2332	0.6761	0.8199	0.7924	0.71032

It was confirmed that 5 models of the 6 models were successful except for model 2. It was found that R and MSE values calculated were acceptable and rising of hidden

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_33153332
© 2018, ALÖKI Kft., Budapest, Hungary

layers and input numbers in the model structures were ensured efficiently. Modelling the precipitation from the meteorological parameters (Model 2) was possible with some error. For this reason, it was found that simulations of SPI-12 and soil temperatures were indicative to meteorological and agricultural droughts. Also this study showed that ANN was effective in forecasting the SPI and was effective tool for drought forecasting.

Finally, the developed ANN models were found to be suitable to make effective extreme point predictions. Drought predictions made by ANN models would be useful for local administrations and water resources planners. Hence, this paper presented an applicable approximation to this planning stage by means of the ANN modelling approach.

Acknowledgments. I would like to thank Environmental Engineer Tuncay BOZ for computer aids and his valuable research to improve the manuscript.

(Received 26th Feb 2018; accepted 24th May 2018)

Abstract. This study was conducted in a greenhouse in Izmir/Turkey during the winter-early spring of 2016-2017, on spinach grown in the floating water culture system. Cultivation was carried out in aerated nutrient solutions on seedling trays, and peat was used as germination and rooting medium. Each seed was inserted to each hole (17 cc) in trays with 210 cells (957 plant m^{-2}). Following germination in the germination chamber, trays were moved to climate controlled greenhouse. After emergence, the seedlings were transferred to water culture on 07.12.2016 and 10.03.2017 for the 1st and 2nd period, respectively. The nutrient solution was applied as "full dose" (mg L^{-1}: N 150, P 50, K 150, Ca 150, Mg 50, Fe 5.0, Mn 0.50, Zn 0.05, B 0.50, Cu 0.03, Mo 0.02), "half dose" (with macro elements reduced by 50%) and "without nutrients" (water). Plants as baby leaves were harvested 3 times in both periods. Results showed that plant growth, yield, quality, and water consumption vary depending on the concentration of nutrient solution as well as the temperature during the growing season. Especially in the 2nd period when the temperatures were higher, plant water consumption and yield increase and earliness were achieved. It was observed that as the concentration of nutrient solution decreased, vitamin C, leaf Ca content and pH value of the nutrient solution increased while leaf N, P, K and Fe contents, EC value of the nutrient solution, leaf nitrate content, yield and plant biomass decreased. There was no statistical difference between full and half dose applications in many measured parameters. It is concluded that spinach can be grown as a baby leaf in a floating water culture and that in addition to reducing nitrate content, half-dose application may be preferred in terms of yield and water consumption, and production should be done during early spring season in greenhouse conditions for high yield and quality.
Keywords: *water culture, growing period, dose, yield, nitrate, vitamin C*

Introduction

In world markets, the demand and interest in clean and minimal processed food stuffs is continuously increasing with each passing day. Life styles of people on the other hand have evolved into a practical and a swift style. Employed or working women are able to spend less time in kitchens; therefore, they mostly prefer freshly consumed, instant, practical and healthy foods. Edible leaf vegetables are quite rich in vitamins and antioxidants (Yadav et al., 2013) and they are commonly used in salads and several other dishes. Thus, they are quite preferred by the consumers. These vegetables should be cleaned right after the harvest and such a cleaning process results in serious waste of time and water. In recent years, soilless culture, especially hydroponic culture, have become popular to facilitate the cleaning of edible leaf vegetables and to serve them for consumption with a minimum processing (Nicola et al., 2007).

Among the hydroponic culture systems, static solution culture is the oldest and easiest soilless culture technique. In today's modified version of the technique, plants

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_33333350
© 2018, ALÖKI Kft., Budapest, Hungary

are placed over styrofoam platforms freely floating over the nutrient solution and thus the method is called as "floating water culture" (Morgan, 1999; Gül, 2008). The system is composed of a basin containing nutrient solution, a light-weight material able to float over the nutrient solution to hold the seeds or seedlings and an air pump for aeration of the system.

Floating water culture was designed and developed by Arizona University in 1980; couple years later, was used in vegetable culture commercially in Florida (Resh, 1998). The method is commonly used in seedling production (Carrasco et al., 2003; Bilalis et al., 2010) and regular or miniature vegetable production (Fontana et al., 2010; Carrasco et al., 2011). The system today is widely used in unheated greenhouses of Mediterranean countries with minimum control of climate parameters for the same purposes (Duyar and Kılıç, 2016).

The advantages of floating hydroponic systems are specified as: easy system construction, economic production, low labor costs because of automation systems, rapid plant growth, homogeneous products, high and quality yields, clean products, greater number of plants per unit area, easy harvest, optimized fertilizer and water use, minimum evaporative losses, environment-friendly production and easy adaptation to small production areas (Fernandez et al., 2008; Franco et al., 2011; Tomasi et al., 2015). On the other hand, aeration demands of nutrient solution and resultant electricity requirement, changes (increase or decrease) in temperature of nutrient solution based on seasons are considered as potential disadvantages of the floating systems (Nicola et al., 2005; Rodriguez Hidalgo et al., 2010). Despite all these disadvantages, floating systems are largely preferred for production of various vegetable species since in soil plants are exposed to several soil-borne diseases, leaves are contaminated with soils resulting in leaf losses. The vegetables produced in soil cultures should also be cleaned and washed through before to serve them to the markets. When the leaves are washed and served to markets, leaf heat ups and resultant losses are experienced. On the other hand in floating hydroponic cultures, contamination with soil is totally eliminated, thus significant savings achieved in labor and water since post-harvest washing is not required.

Besides clean production, low nitrate contents are desired in directly consumed edible leaf vegetables. Excessive nitrogen uptake (excessive fertilization) or inhibition of nitrogen transformation into protein by some environmental factors result in nitrogen accumulation throughout the plant growth stages (Kara, 1993). A small part of nitrogen taken through nutrition is reduced to nitrite by the mouth bacteria and conveyed to the stomach. When the pH level of the stomach got above 5.5, nitrate is converted into hazardous nitrite ions through bacterial nitrate reductase activity. Nitrite then interacts with hemoglobin and result is methemoglobin formation; hemoglobin Fe^{+2} then oxidized to Fe^{+3} and ultimately blood oxygen carrying function is reduced or inhibited. Then the case is evolved into a hazardous disease for kids (methemoglobinaemia, blue-baby syndrome, cyanotic, cyanosis). Nitrite has various other negative impacts on human health, for instance it reacts with secondary amines and result in formation of carcinogen, mutagen and teratogen nitrosamines (Tannenbaum and Correa, 1985; Kara, 1993; Özdestan and Üren, 2010).

Existence of nitrate problems in leaf edible vegetables let the researchers mostly focus on nitrate in these species. Hydroponic researches revealed that micro element concentrations of the nutrient solution could be reduced (Cocetta et al., 2007; Duyar and Kılıç, 2016), nutrient solution could be diluted (Vernieri et al., 2005), plants could be stayed in water for couple days before the harvest (Gonnella et al., 2004; Jakse et al.,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_33333350
© 2018, ALÖKI Kft., Budapest, Hungary

2013), NO_3-N could be withdrawn/replaced with Cl, SO_4 and NH_4 (Van Der Boon et al., 1990) all to reduce nitrate contents of the vegetables. These researches also revealed that floating culture could be used as an economic and environment-friendly culture technique.

Hoagland nutrient solution (Hogland and Arnon, 1950) is commonly used in floating culture researches undertaken for leaf edible vegetables (Vernieri et al., 2005; Cocetta et al., 2007; Alberici et al., 2008; Duyar and Kılıç, 2016). Although Hoagland nutrient solution supply quite quality nutrition for leaf edible vegetables harvested in short periods, it is known that this nutrient solution was primarily developed for tomato to get high yield in long growing periods. Thus in this case, potential use and efficiency of Hoagland nutrient solution in leaf edible vegetables are arguable issues. It was also considered that element contents of Hoagland prescription was higher than the prescriptions adapted for leaf edible vegetables and had quite much nutrient contents in post-harvest residues with potential environmental pollution (Alberici et al., 2008).

Spinach could be an alternative crop in greenhouses since it allows for multiple short-duration production cycles and a much faster economic return (Brandenberger et al., 2007). Besides, spinach is a vegetable with a high nutritional value (Ko et al., 2014) The present study was conducted to investigate the potential use of floating hydroponic culture for spinach production in unheated greenhouses in winter-early spring periods (1). Since there are not any species-specific nutrient solution prescription, availability of a nutrient solution other than Hoagland nutrient solution (winter nutrient solution prepared for lettuce) for spinach culture was also investigated in this study (2). Effects of dilution of macro element concentrations of the nutrient solution on plant growth and development, yield, quality and water consumption were also investigated in this study (3). In this way, high yield and quality spinach culture with floating hydroponic culture and proper nutrient prescription in proper periods in unheated greenhouses under Mediterranean climate conditions was assessed.

Materials and Methods

Experiments were conducted in vegetable greenhouse of Horticulture Department of Ege University Agricultural Faculty (Bornova-İzmir/Turkey, 38°27'17.03''N, 27°14'17.71''E) in winter-early spring growing periods of 2016-2017.

'Aletta F_1' (Küçükçiftlik Seed Co., Balıkesir/Turkey) spinach (*Spinacia oleracea* L.*)* cultivar was used as the plant material of the experiments. Styrofoam seedling trays (66.5 x 33.5 x 4.9 cm, with 17 cc, 210 cells) were used as the growing place. Peat (Klassman TS1) was used as the substrate for seed germination.

Seeds were sown in two successive periods on 24.11.2016 in the 1st period (winter) and on 21.02.2017 in the 2nd period (early spring) into the peat-filled seedling trays as to have one seed per cell (1.5 g seed per m^2). Excess plantlets were thinned after emergence. There were 957 plants per m^2. Following the seed sowing, growing medium were moistened, covered with stretch films and placed into germination chambers. Seedling trays were kept in germination chamber (dark, day/night 18-20°C, 80% humidity) for 4 days. They were then placed into seedling adaptation greenhouse and kept there until they had 1-2 true leaves. During this period, seedlings were irrigated with boom irrigation system of the greenhouse.

Hydroponic cultures were formed in 80×44×19 cm (52 liters) plastic basins (*Fig. 1*). PE-transparent air hoses were used to aerate nutrient solution. One end of the hose was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_33333350
© 2018, ALÖKI Kft., Budapest, Hungary

connected to air compressor and the end was closed. The hose passed through culture basins and outlets with air stones were placed for each basin. Mini valves were used to adjust aeration rates (8.0-8.5 mg L^{-1}). Compressor electricity was supplied with a timer; the timer was set as 30:30 minutes start:stop mode for 24 hours.

Figure 1. *View of floating cultures in plastic basins*

The plant nutrient solution proposed by Gül (2008) for winter lettuce (mg L^{-1}: N 150, P 50, K 150, Ca 150, Mg 50, Fe 5.0, Mn 0.50, Zn 0.05, B 0.50, Cu 0.03, Mo 0.02) was used in this study. The recommended prescription was accepted as "**full dose**" (complete nutrient solution) and this full dose was compared with **"half dose"** with 50% reduced macro nutrients. Electrical conductivity (EC) of prepared nutrient solution was 1.6-1.8 dS m^{-1} in full dose; 1.2-1.3 dS m^{-1} in half dose while pH was 5.5-6.0 and 6.3-6.5, respectively. **"Water"** without any fertilizers was another treatment in order to test if irrigation water alone could be used due to short crop cycle. The content of irrigation water was as follows: N 7, P 1.10, K 1.19, Ca 127.4, Mg 45.8, Na 29.8, Cl 52.0, Fe 1.43, Mn 0.88, Zn 0.38, Cu 0.11 mg L^{-1}; EC 0.93 dS m^{-1}; pH 7.35. Each basin was filled with nutrient solution treatments or water (40 L). Seedlings were transplanted to water culture on 07.12.2016 for the 1st period and on 10.03.2017 for the 2nd period when they had 2 true leaves. Plants were kept in hydroponic culture for 59 days in the 1st period and for 38 days in the 2nd period. Throughout these periods, depleted nutrient solution or water was resupplied weekly and EC and pH adjustments were made in each time. Productions were terminated on 07.02.2017 for the 1st period and on 17.04.2017 for the 2nd period.

Greenhouse indoor temperature, relative humidity and solar radiation values were measured with sensors (Delta-T Devices) and recorded with data loggers (Delta-T Devices; GP1 and DL3000). Manual thermometers were used to measure the temperature of nutrient solution. Temperatures (°C) of the nutrient solutions and water treatments were measured in the morning, noon and evening of each day.

Harvests were performed when the outer, older leaves reached to a length of 10-15 cm. When the plants reached to harvest maturity, 10 homogeneous plants were selected from each replication and plant growth parameters were measured. Root lengths (from top to bottom) were measured with a tape meter and average root length was expressed in cm. The distance between the starting place of the roots and the tip of plant leaves was measured again with a tape meter (cm) and the values were used as plant height. Leaf fresh weight of the plants was measured with a precise balance. Leaves were dried

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_33333350
© 2018, ALÖKI Kft., Budapest, Hungary

at 65 ºC until a constant weight and weighted again to get leaf dry weights. The values were used as fresh (FW) and dry (DW) weights (g) and dry matter (%).

The first harvest was performed 33 days after transplantation to hydroponic culture in the 1st period and 20 days after transplantation in the 2nd period. A total of three harvests were performed on 10.01.2017, 27.01.2017 and 07.02.2017 in the 1st period and on 30.03.2017, 07.04.2017 and 17.04.2017 in the 2nd period. In each harvest, plants were cut above the growing tip to allow plants to regrow new leaves. Harvests were terminated after the 3rd harvest because of the losses in leaf quality. From the first to last harvest, plants harvested from each replication were weighted separately and yields per harvest (g) and total yields (g m^{-2}) were calculated.

From each replicates, 10 plants were randomly selected to determine leaf total chlorophyll content (mg g^{-1}) (Arnon, 1949), nitrate content (mg kg^{-1}) (Cataldo et al., 1975) and vitamin C content (mg 100 g^{-1} FW) (Pearson, 1970) spectrophotometrically.

Plant samples taken from the first harvest were separated as roots and upper sections and dried at 65°C. Dried samples were than ground and passed to sieves and subjected to N, P, K, Ca, Mg and Fe element analyses. P content of wet digested samples was determined colorimetrically with Vanadomolibdophosphoric yellow color method; K and Ca contents were determined with a flame photometer; Mg and Fe readings were performed in an atomic absorption spectrophotometer. Total N was determined with modified Kjeldahl method. Results were expressed as % dry matter and mg kg^{-1} DW (Kacar and İnal, 2008).

Plant water consumption (L $plant^{-1}$) was calculated using the following *Equation 1:*

$$Plant\ water\ consumption = \frac{applied\ nutrient\ solution - drainage\ solution}{number\ of\ plant} \quad \text{(Eq.1)}$$

Nutrient solution and water samples were taken from the basins twice a week and EC and pH of the samples were measured with a portable EC and pH meter.

In the present research, 105 plants were used per replicate. Experiments were conducted in randomized plots experimental design with 4 replications and two factors (periods - 1st and 2nd period; nutrient solution concentrations - full dose, half dose and water without fertilizer). Resultant data were subjected to variance analysis with JMP (version 5.0.1) statistical software. Tukey's test was used to compare treatment means. F test was used to specify significance levels (ns: nonsignificant, *: significant at $0.01<P\leq 0.05$ and **: significant at $P\leq 0.01$).

Results

Climate data

Average greenhouse indoor temperatures and relative humidity values were 11.3°C and 72.5% in the 1st period, 19.8°C and 71.1% in the 2nd period, respectively. Solar radiation value was 5.55 MJ m^{-2} day^{-1} in the 1st period and 10.64 MJ m^{-2} day^{-1} in the 2nd period.

Nutrient solution temperatures varied between 3.5 and 32.0ºC (average 10.7 ºC) in the 1st period and between 9.2 and 37.5 ºC (average 20.0 ºC) in the 2nd period.

Plant growth and biomass values

The effects of growing periods on plant height, root length, leaf fresh and dry weights and dry matter contents, root dry weight and dry matter contents were found significant. All these parameters had greater values in the 2nd period than in the 1st period. In the 2nd period, plant heights increased by 27.1%, root lengths increased by 17.5%. As compared to the 1st period, plant fresh and dry weights increased respectively by 1.9 and 2.6 folds in the 2nd period (*Table 1*).

Nutrient solution concentration had significant effects on plant heights, root lengths, leaf fresh and dry weights and leaf dry matter. There were not significant differences in these measured parameters of full and half doses but water-treated plants had the lowest values. However, the greatest root length was obtained from water treatments (*Table 1*).

Period x nutrient solution concentration interaction had significant effects on plant height, root length, leaf biomass and root dry matter. The highest plant heights, leaf fresh and dry weights and leaf and root dry matters were higher in the 2nd period (early spring) in full and half dose treatments. The lowest measurements were obtained from water treatment excluding root lengths (*Table 1*).

Table 1. *Effects of different season and nutrient solution concentration on plant growth and biomass*

Period	Nutrient solution concentration	Plant height (cm)	Root length (cm)	Leaf			Root

Yield

Effects of the period, nutrient solution concentration and period x concentration interaction on yields values were found to be significant (*Table 2*, *Fig. 2*). The highest yield values were obtained from the 1st harvest. As compared to the 1st harvest, yield values in the 2nd and 3rd harvests respectively decreased by 41.5% and 50.3% in the 1st period and by 72.1% and 52.3% in the 2nd period.

In all three harvests, full dose-treated plants had the highest yield values, but they were placed in the same statistical group with the half dose-treated plants. As compared to the full dose, yields in half dose and water treatments increase respectively by 18.7% and 71.8% in the 1st harvest, by 10.0% and 70.8% in the 2nd harvest and by 18.8% and

84.0% in the 3rd harvest. With regard to yield values under interactions, the greatest yields in the 1st and 3rd harvests were obtained from 2nd period x full dose treatments and the greatest yields in the 2nd harvests were obtained from 2nd period x full dose treatments. Yields decreased in water treatments and the lowest yield values were obtained from water treatments in both periods (*Table 2*).

Table 2. *Effects of different growing periods and nutrient solution concentrations on yield of harvests*

compared to full dose, 17.0% decrease was observed in half dose and 74.8% decrease was observed in water treatments. The greatest total yield was obtained from the 2nd period x full dose interaction and it was followed by the 2nd period x half dose which was placed in the same statistical group (*Fig. 2*). Of the total yield, 53.2% was obtained from the 1st harvest, 21.1% from the 2nd harvest and 25.7% from the 3rd harvest.

Quality parameters

Total chlorophyll contents were significantly influenced by the period, nutrient solution concentration and period x concentration interaction. While the total chlorophyll content was 1.18 mg g^{-1} in the 1st period, the value reached to 1.64 mg g^{-1} with 38.9% increase in the 2nd period. Total chlorophyll contents did not significantly change in full dose and half dose treatments, but decreased by 12.5% in water treatments. The greatest chlorophyll content was obtained from the 2nd period x full dose interaction and it was followed by the 2nd period x half dose interaction which was also placed in the same statistical group (*Fig. 3*).

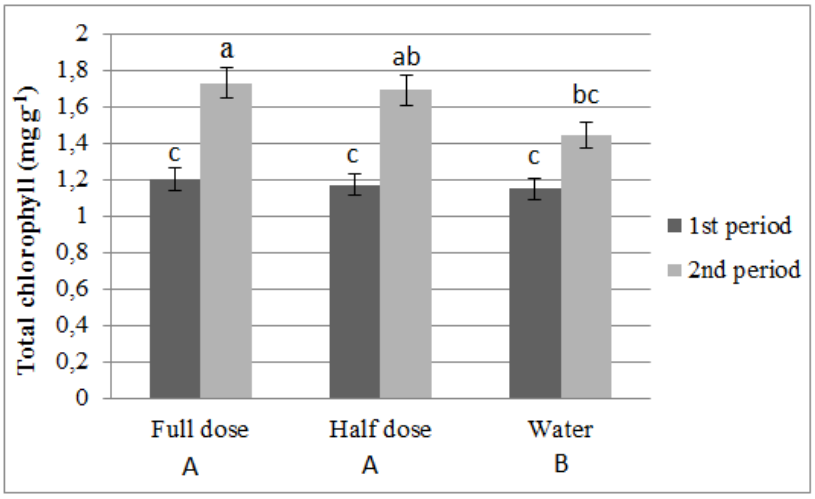

Figure 3. *Effects of treatments on total chlorophyll content*

Capital letters indicate main effects of nutrient solution concentration; small letters show interaction effects of period and concentration.

While periods did not have significant effects on leaf nitrate content, nutrient solution concentration had significant effects on nitrate contents. Leaf nitrate contents decreased with reduced nutrient solution concentration, but the differences between full dose and half dose treatments were not significant. As compared to half dose, leaf nutrient contents decreased by 9.1% in half dose treatments. The lowest leaf nitrate content was obtained from water treatments. Considering the interactions, the lowest leaf nitrate contents were obtained from water-treated plants of both periods. Significant differences were not observed in leaf nitrate contents of the other treatments (*Fig. 4*).

Capital letters indicate main effects of nutrient solution concentration; small letters show interaction effects of period and concentration.

Vitamin C contents were also significantly influenced by the period, nutrient solution concentration and period x concentration interaction. As compared to the 1st period, vitamin C content reached to 47.5 mg 100 g^{-1} with 43.5% increase. Leaf vitamin C contents increased with decreasing nutrient solution concentration. Leaf vitamin C contents of full dose, half dose and water treatments were respectively measured as 29.8, 41.8 and 58.2 mg 100 g^{-1}. Under interaction, the greatest vitamin C content was obtained from the 1st period x water and the 2nd period x water treatments (*Fig. 5*).

Leaf nutrient contents

Growing period had significant effects on P and Fe contents and the values were greater in the 1st period than in the 2nd period. The effects of growing period on N, K, Ca and Mg contents were not found to be significant (*Table 3*).

Table 3. *Effects of different growing periods and nutrient solution concentrations on leaf nutrient content*

Period	Nutrient solution concentration	N (%)	P (%)	K (%)	Ca (%)	Mg (%)	Fe (mg kg^{-1})

ns, * and **: nonsignificant, significant at $0.01 < P \leq 0.05$ and $P \leq 0.01$, respectively.

Except for Mg, nutrient solution concentration and period x concentration interaction had significant effects on all nutrients. P, Ca and Fe contents of full and half dose treatments were not significantly different, but water treatments had significantly different values. N, P, K and Fe contents decreased, Ca contents increased with decreasing nutrient solution concentration. A similar case was also observed under interaction (*Table 3*).

Plant water consumption

Depending on seasonal temperature differences and length of growth periods, amount of water applied to treatments varied between 0.316-0.361 L plant^{-1} in the 1st period and between 0.387-0.434 L plant^{-1} in the 2nd period. About 23.7% more water was applied to plants in the 2nd period. Removed water quantity was greater in this period and plant water consumption was also 52.7% more as compared to the 1st period. Effects of period and period x concentration interaction on plant water consumptions were significant, but nutrient solution concentrations did not have significant effects on water consumptions. Plant water consumption was 0.163 L plant^{-1} in the 1st period and 0.249 L plant^{-1} in the 2nd period. Plant water consumptions of full dose, half dose and water treatments were respectively measured as 0.205, 0.215 and 0.197 L plant^{-1}. Considering the interactions, the greatest plant water consumption was obtained from the 2nd period x half and full dose treatments (*Fig. 6*).

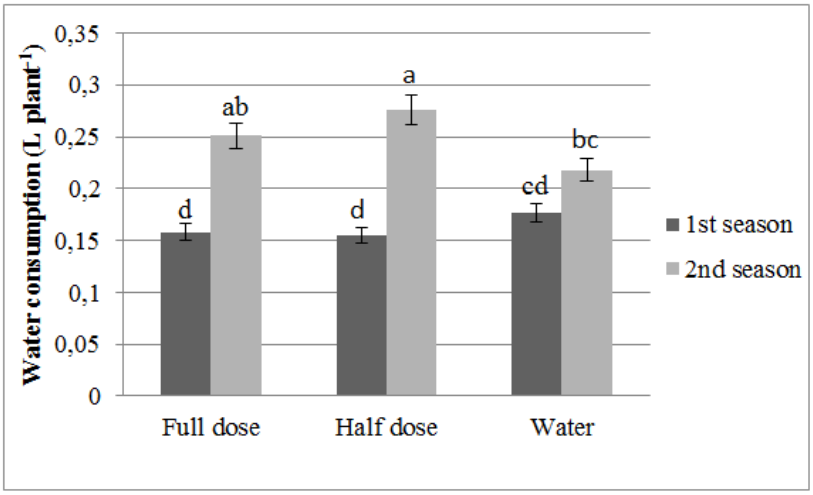

Figure 6. *Plant water consumption under interaction effects of treatments*
Period: P≤0.01, Concentration: nonsignificant, Period x Concentration: P≤0.01
Small letters show interaction effects of period and concentration.

Nutrient solution EC and pH values

Nutrient solution EC values of the 1st period varied between 0.75-0.90 dS m^{-1} in water treatments, between 1.16-1.40 dS m^{-1} in half dose treatments and between 1.56-1.75 dS m^{-1} in full dose treatments. The values were 0.8-1.0 unit higher in the 2nd period. Average EC of nutrient solution in full and half doses were 1.65 and 1.28 dS m^{-1} in the 1st period and 2.51 and 2.0 dS m^{-1} in the 2nd period, respectively.

Nutrient solution pH values were tried to be kept between 5.5 and 6.5 however, pH values of the 1st period varied between 6.62-7.89 in water treatments, between 6.38-7.35 in half dose treatments and between 5.59-7.23 in full dose treatments. In the 2nd period, pH values increased by 0.8-1.05.

Discussion

Plant development and biomass values of both periods revealed that plant development decreased with decreasing nutrient solution concentration. Similar findings were also reported in previous studies carried out on spinach (Cocetta et al., 2007) and rocket (D'Anna et al., 2003). In present study, there were not significant differences between the full and half dose treatments, but full dose treatments had better plant growth and development because of higher nutrient content of solution provided to the plants however water-treated plants had the least development due to lack of nutrients sufficient for plant growth.

Plant development data also revealed that besides nutrient solution concentrations, indoor temperatures of the growing periods influenced plant growth and development (Alberici et al., 2008). High temperatures of the 2nd period (average 19.8°C) stimulated plant development (Alberici et al., 2008; Eşiyok, 2012).

In present study, root lengths exhibited a different trend from the other plant development parameters. Water-treated plants had longer root lengths and this may be result from plant instincts to release their roots to deeper portions of the growth medium to get plant nutrients under nutritional stress conditions (Taiz and Zeiger, 2008).

However root dry matter was the highest in full dose in the 2nd period which could be attributed either the nutrient concentration of solution or higher temperatures.

Hydroponic culture of miniature-leaf vegetables largely depends on environmental factors and species, but 3-6 weeks earliness is usually achieved with hydroponic culture compared with open field culture (Gonella et al., 2003 & 2004; Cocetta et al., 2007; Conte et al., 2008). Harvest was performed in present study 4 weeks after seeding and 20 days after transplantation to water culture in the 2nd period. In other word, an earliness was achieved with hydroponic culture (Eşiyok, 2012; Iannotti, 2017) due to higher temperatures, however in the 1st period lower temperatures delayed harvests up to 8 weeks after the seeding (Alberici et al., 2008; Eşiyok, 2012).

In hydroponic cultures yield varies according to plant species and cultivars, growth period temperatures, number of plants per unit area (plant m^{-2}), plant harvest lengths, growing periods, nutrient solution concentrations and number of harvests (D'Anna et al., 2003; Alberici et al., 2008; Jakse et al., 2013). For instance spinach yields for 1150 plant m^{-2} plant density and 10-15 cm harvest lengths was reported between 1130-1500 g m^{-2} (Cocetta et al., 2007) or between 832-1748 g m^{-2} with 12 cm harvest lengths (Alberici et al., 2008). In present study, plant density was 957 plant m^{-2} and harvests were performed at plant heights of 10-15 cm and 3 harvests were performed in each treatment. As the average of two periods, the 1st harvest yields at full dose, half dose and water treatments were respectively measured as 2083.1, 1692.7 and 585.8 g m^{-2}. Total yields were respectively calculated as 3912.9, 3247.7 and 982.2 g m^{-2} which were greater than the earlier results reported for spinach in hydroponic culture (D'Anna et al., 2003; Vernieri et al., 2005; Cocetta et al., 2007; Alberici et al., 2008; Rodriguez-Hidalgo et al., 2010; Duyar and Kılıç, 2016). Present findings revealed that spinach yields of hydroponic culture were also greater than the yield of soil-culture (Eşiyok, 2012). Water-treated plants had lower yield values than nutrient solution-treated (fertilized) plants. Such a finding indicated that very low amount of nutrients in the tap water and nitrogen coming from the nitric acid added to adjust element content and pH was not sufficient for plant growth and development particularly if the harvest period is extended.

In present study, yields decreased with decreasing nutrient solution concentrations. In previous studies, 20-50% decrease were reported with decreasing nutrient solution concentrations in rocket (Vernieri et al., 2005; Alberici et al., 2008; Duyar and Kılıç, 2016), spinach (Cocetta et al., 2007; Alberici et al., 2008) and lettuce (Alberici et al., 2008). Alberici et al. (2008) experimented 50% and 25% reduced macro elements as compared to control (100%) and reported varying decreases in yields of spinach, rocket and lettuce and recommended 25% reduction in micro nutrients. However, in our study full dose and half dose treatments were placed in the same statistical group. Thus, it was concluded that 50% reduction in macro element contents did not resulted in significant decreases in yields, thus could reliably be used in hydroponic spinach culture and provide significant savings in fertilizers and system costs.

Total chlorophyll contents varied between 1.15-1.73 mg g^{-1} and present values comply with the earlier findings (Cocetta et al., 2007; Franco et al., 2011). Total chlorophyll contents were not influenced by nutrient solution concentrations (Cocetta et al., 2007; Alberici et al., 2008), but influenced by growth periods (Fallovo et al., 2009). Present chlorophyll contents were higher in the 2nd period which could be attributed to higher temperatures (Popescu and Buruleanu, 2017).

Leaf nitrate contents decreased with decreasing nutrient solution concentrations (Cocetta et al., 2007; Alberici et al., 2008; Fallovo et al., 2009; Duyar and Kılıç, 2016). Such a case can be explained with the decreased nitrate concentration of the plant tissues through using the nitrate already stored in vacuole in case of lower nitrate concentrations than the plant requirement (Okamoto et al., 2006; Tsay et al., 2006; Antonacci et al., 2007; Alberici et al., 2008). Besides genetic characteristics, growth period, light, temperature, growing conditions, fertilization and storage have also significant effects on plant nitrate accumulations (Premuzic et al., 2001; Frezza et al., 2005; Magnani et al., 2007; Kim and Ishii, 2007). In present study, leaf nitrate contents (1177.2-1811.9 mg kg^{-1}) also varied with the periods and nutrient solution concentrations which were in a harmony with previous research results (Cocetta et al., 2007; Alberici et al., 2008). European Commission Regulation No: 1258/2001 specify the maximum threshold value as 3500 mg kg^{-1} for spinach and lettuce (EUR-LEX, 2017). Present values were below this threshold value, thus did not exert any risks on human health.

Majority of leaf edible vegetables is a great source of vitamin C (Burrell and Ebright, 1940) and plant vitamin C contents may vary with the growing period and cultural conditions (Eşiyok et al., 2006). Spinach vitamin C contents were reported as 19.4 mg 100 g^{-1} by Cocetta et al. (2014), as between 25.0-71.0 mg 100 g^{-1} by Bergquist et al. (2007) and Çıtak et al. (2010), as 48 mg 100 g^{-1} by Bangash et al. (2011) and as 120.0 mg 100 g^{-1} by Fujiwara et al. (2005). Present values (22.42-68.60 mg 100 g^{-1}) comply with those earlier ones. Nutrient solution concentration influenced vitamin C contents and increasing vitamin C contents were observed with decreasing nutrient solution concentrations (Duyar and Kılıç, 2016). Vitamin C content of full and half dose treatments were not significantly different. Higher vitamin C contents of water-treated plants were resulted from nutrient stress conditions since plants increase vitamin C contents under stress conditions (Munzuroğlu et al., 2000). Zhang et al. (2016) related such a case with increasing mioinocytol oxygenize enzyme activity in ascorbic acid biosynthesis and recycle and decreasing ascorbate oxidase and glutathione reductase enzyme activities. Ascorbic acid accumulation increases with decreasing N concentrations.

Leaf nutrient contents vary based on plant species and cultivars, growing period, production system, fertilization program, plant tissue and sampling time (Kacar and Inal, 2008). In present study leaf N contents varied between 3.76-5.27%, P contents between 0.19-0.99%, K contents between 1.66-8.13%, Ca contents between 0.36-3.55%, Mg contents between 0.95-1.125 and Fe contents between 33.7-84.0 mg kg^{-1}. In both periods, leaf N, P, K and Fe contents decreased, but Ca contents increased with decreasing nutrient solution concentration. In IFA (1992) records, N, P, K, Ca, Mg and Fe contents of young spinach leaves harvested 40 days after plantation were respectively specified as 2.6%, 0.3%, 4.7%, 1.0%, 1.0% and 189 mg kg^{-1}. Barlas et al. (2011) reported N contents of rocket leaves as between 2.94-5.23% (average 4.32%), P contents as between 0.12-0.27% (average 0.25%), K contents between 3.99-5.98% (average 5.13%), Ca contents between 2.20-3.55% (average 2.95%), Mg contents between 0.33-0.79% (average 0.58%) and Fe contents between 183.3-776.9 mg kg^{-1} (average 350 mg kg^{-1}). Present N, Ca and Fe values of floating culture system were lower, but P, K and Mg contents were higher than those earlier findings. High nutrient contents may be related to sink effect of young leaves under existence of high nutrient concentrations (Gonnella et al., 2004).

The amount of water applied to plants was greater in the 2nd growing period because of higher temperatures of the period. Since the system is a closed system, only the nutrient solution left at the end of the period was removed. Nutrient solution concentrations did not influence amount of water applied. Plant water consumption was the greatest in half dose treatments and the least in water treatments. However, the differences in water consumptions were not significant. Similar with the present findings, Duyar and Kılıç (2016) also reported higher water consumptions for half dose treatments in rocket and parsley grown in floating water culture in autumn and spring seasons and researchers indicated higher water consumption values in spring season.

Since plants are cultured in closed soilless systems, pH, EC and dissolved oxygen levels of the system should be carefully adjusted (Gonella et al., 2003). Potential EC and pH problems can be eliminated with a proper nutrient solution and dissolved oxygen problems can be eliminated through proper aeration of the system (Tesi et al., 2003; Lenzi et al., 2011).

Conclusion

Recent researches about floating hydroponic cultures mostly focused on practices to reduce system costs (seed bed ambient, ambient quantity). It is quite significant to find cheap and easily supplied seed germination media. In present study, peat (Klassman TS1) with quite high germination performance and can be easily supplied from the markets was used (Rodriguez-Hidalgo et al., 2010; Jakse et al., 2013) and a successful culture was achieved. Cocetta et al. (2007) used perlite in hydroponic study and reported yields as between 1.1-1.5 kg m^{-2}. Such values were lower than the value obtained from peat. Researches are still going on about different substrate materials. Amount of growing medium per seedling tray is also an important factor in reducing system costs. Jakse et al. (2013) achieved better outcomes from rocket hydroponic study with small-size cells, thus with greater plant density (160 cell seedling trays, 2000 seed m^{-2}). Further research is needed about optimum cell sizes for different species. In present study, 17 cc seedling trays with 210 cells (957 plant m^{-2}) were used and a successful culture was achieved. However, there is still a need for further research on seedling tray shapes (lined-trays), trays cell sizes and plant densities.

Considering entire results of the present study, it was concluded that (1) winter lettuce prescription (mg L^{-1}: N 150, P 50, K 150, Ca 150, Mg 50, Fe 5.0, Mn 0.50, Zn 0.05, B 0.50, Cu 0.03, Mo 0.02) could reliably be used for hydroponic spinach culture without any losses in yield and quality; (2) 50% macro nutrients reduced half dose (mg L^{-1}: N 75, P 25, K 75, Ca 75, Mg 25, Fe 5.0, Mn 0.50, Zn 0.05, B 0.50, Cu 0.03, Mo 0.02) could be used successfully in hydroponic spinach culture since the yields of half dose treatments were not significant different from the full dose treatments and half dose reduced leaf nitrate contents. In this way, significant savings could be achieved in fertilizer costs; (3) spinach culture should be performed under optimum climate conditions for high yield, quality and earliness since temperature is a limiting factor for growth and development of vegetables, yields are significantly influenced by low temperatures. However further researches are needed optimization for fast and continuous production at larger scale.

HOW WELL DOES BORDERING FOREST COMPOSITION PREDICT TREE ESTABLISHMENT IN UTILITY CORRIDORS?

(Received 26th Feb 2018; accepted 21st May 2018)

Abstract. The relation between bordering tree forest composition, seed rain and tree seedling establishment was estimated in a powerline corridor of southern Quebec (Canada). Red maple was the most important tree species in the bordering forests, accounting for nearly half of the 18 tree species found, in terms of basal area. Seeds from 10 tree species were found in the seed traps, the large majority of which being from gray birch, followed by red maple, paper birch, and white ash. A good proportion of seeds from gray birch and eastern hemlock were dispersed in winter. Seedlings from 14 tree species were sampled in the right-of-way, the large majority being from red maple and gray birch. The relation between nearby bordering tree, seed and seedling abundances varied among tree species. Seed abundance collected within a single year appeared to be poorly related to tree representation and seedling abundance, suggesting high interannual variation in seed production. Distance to seed source was weakly related to seedling establishment for some species such as gray birch. However, for many species, tree composition in the neighboring forest was a good predictor of nearby seedling establishment, implying that dispersal limitation may be an important factor in determining tree composition.
Keywords: *seed dispersal, seedling establishment, tree composition, Acer rubrum, Betula populifolia*

Introduction

Tree establishment in open sites may be viewed as beneficial or detrimental depending on management purposes. On sites assigned to forest production, natural establishment contributes to reforestation, and cutting practices frequently include protection of seeding trees or forest patches in order to insure sufficient seed sources (Solarik et al., 2010). Lack of natural tree establishment may necessitate direct seeding (St-Denis et al., 2013) or planting (Corbin and Holl, 2012). In powerline corridors, on the other hand, tree establishment is often a nuisance and costly cutting operations are needed to keep a low vegetation cover that does not interfere with operation and safety (de Blois et al., 2004), Understanding the factors that influence seedling establishment in open sites can therefore contribute to better planning and vegetation management for a variety of purposes.

Because they act as seed sources, trees bordering an opening should be the best predictor of recolonization pressure (Martínez-Orea et al., 2014). However, bordering forest composition and seedling composition in the opening may not always be closely related. First, annual seed production, germination rate, and interannual variation vary depending on species and tree size (Hill et al., 1995). Also, seed rain at a particular location further depends on proximity to seeding trees and seed dispersion. Finally,

seedling establishment varies between species depending on biotic and abiotic factors such as seed size, seed predation, soil requirement, herbaceous cover, predation, or climatic condition (Gill and Marks, 1991). All these factors interact to determine recolonization or tree invasion pressure.

How accurately can we therefore predict tree establishment potential from bordering tree composition alone? This question is important especially in the context of integrated vegetation management (IVM), where the goal is to minimize environmental damages and costs. IVM practices require adapting management strategies to the local ecological context (Nowak and Ballard, 2005). If the goal is to prevent or reduce tree invasion as in many utility rights-of-way, a sound assessment of tree invasion pressure is crucial to design efficient interventions. A situation where there is high invasion potential from a fast growing but little competitive tree species, for example, may require active prevention with the sowing of a competitive herbaceous cover to control invasion (de Blois et al., 2004), while sites with low invasion pressure may be best treated by targeting specific invaders as needed.

The objective of this study is to assess the relation between bordering tree forest composition, seed rain, and seedling establishment in a powerline right-of-way of southern Quebec, Canada. The work presented here is part of an ongoing long-term project that aims to design and implement efficient integrated vegetation management practices in powerline rights-of-way corridors.

Study site

The study site is located in Roxton County (45° 54'N, 73° 49'W), in the Montérégie Region of southern Quebec, Canada (*Fig. 1*).

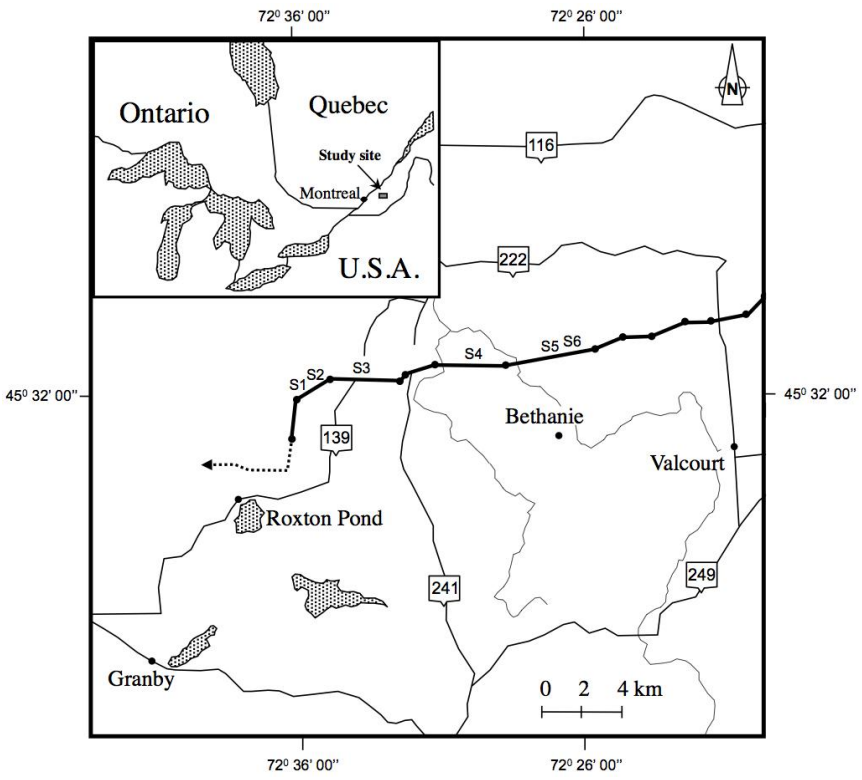

Figure 1. *Study site*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_33513361

This region has a humid continental climate with hot summers and cold winters. The mean annual temperature and total precipitation are, respectively, 6.3 °C and 1215 mm for the years 1981 to 2010 (Granby meteorological station). Mean maximal temperature is 25.2°C in July and –14.2°C in January (Environment Canada, 2015).

The sampling sites are distributed along a 14.6 km portion of a powerline right-of-way (*Fig. 1*). In this portion, the topography is slightly rugged, with a 79 m altitude difference between the first and last sampling site. A surficial deposit of sandy to gravel till lies over the bedrock made of calcareous shale and sandstone of the Sillery Formation (Prichonnet, 1984).

The Montérégie region is part of the Maple – Basswood Bioclimatic Domain (Ministère des Ressources naturelles du Québec, 2003) and the St. Lawrence Lowlands Ecoregion (Ecoregions Working Group, 1989). The studied powerline portion is mostly bordered by forests interspersed with cultivated fields and pastures. Mesic sites are mostly occupied by submature woodlands dominated by sugar maple (*Acer saccharum*) accompanied by red maple (*Acer rubrum*), yellow birch (*Betula alleghaniensis*), American beech (*Fagus grandifolia*), Ironwood (*Ostrya virginiana*) and eastern hemlock (*Tsuga canadensis*). These woodlands are often managed for maple sugar production. In the moderately drained sites, most of which are partially to severely disturbed by partial cutting, trembling aspen (*Populus tremuloides*), large-toothed aspen (*Populus grandidentata*), pin cherry (*Prunus pensylvanica*), paper birch (*Betula papyrifera*), white ash (*Fraxinus americana*) or gray birch (*Betula populifolia*) accompany red maple. Poorly drained sites are colonized by gray birch, balsam fir (*Abies balsamea*), willows (*Salix* sp), black ash (*Fraxinus nigra*) and white elm (*Ulmus americana*). Other common tree species found in the area include black cherry (*Prunus serotina*), eastern white cedar (*Thuya occidentalis*), tamarack (Larix laricina), balsam poplar (*Populus balsamifera*), red elm (*Ulmus rubra*) and eastern cottonwood (*Populus deltoides*) (Boivin et al., 2004).

The right-of-way is an 80m-wide corridor that has been deforested during a period going from September 1998 to February 1999, followed by the construction of the powerline. A portion of the right-of-way was grubbed and sown with an herbaceous mix while the rest was simply left as is.

Methods

Six sampling locations were selected in the right-of-way based on the following criteria: there had to be a forest border on each side of the right-of-way; the types of forest bordering the sampling sites had to cover a wide range of composition (*Table 1*). Data were collected in three phases over a period of 16 months (from April 2003 to August 2004) in order to characterize 1) forest border composition, 2) seed rain in the right-of-way, and 3) seedling establishment.

Bordering forest composition was sampled on July 2004 in two 80m x 20m plots adjacent to the right-of-way, one on each side, with the long axis perpendicular to the right-of-way (*Fig. 2*). We identified and measured the diameter at breast height (DBH) of every tree (DBH > 10 cm) in each plot. For gray birch, for which significant seed production starts when the trees are still small, we also counted the number of individuals in each of two small size-classes (sapling 1: 1-5 cm DBH; and sapling 2: 5-10 cm DBH). Because tree size for a particular species is generally correlated to seed production, we measured tree importance in terms of basal area.

Table 1. *Characteristics of the sampled sites S1 to S6*

Name	Bordering vegetation: dominant [2] / co-dominant (forest age) [3]		Distance from S1 (km)
	North border	**South border**	
S1	Rma / Sma (young)	Rma / Las (young)	0
S2	Rma / Sma (young)	Rma / Tas (young)	0.4
S3	Sma / Rma (mature)	Rma / Sma (sub-mature)	3.8
S4	Rma / Gbi (sub-mature)	Rma / Tas (sub-mature)	8.6
S5	Rma / Ael (young)	Bfi / Tas (sub-mature)	13.7
S6	Gbi / Rma (young)	Rma / Wil (young)	14.0

1: Sowing was done with an herbaceous seeding mix (*Phleum pratense; Trifolium reprens; Trifolium pratense*) for revegetation purposes
2: Ael = American elm; Bfi = Balsam fir; Gbi = Gray birch; Las = Large-toothed aspen; Rma = Red maple; Sma = Sugar maple; Tas = Trembling aspen; Wil = willows
3: young (20-40 years); sub-mature (41-60 years) and mature (61-80 years). Estimations based on photointerpretation and field validation, reported on ecoforest maps of the Ministère des forêts (Québec, 1994).

Because certain types of seeds – notably birch seeds – are known to disperse on snow in winter, we used two types of seed traps to fully evaluate tree seed rain in the right-of-way. For summer seed rain, we used seed traps made of funnels of 30 cm of diameter (opening surface: 0.09 m^2), with a nylon mesh fastened at the small end to receive and store the seeds. The traps were fixed on a metal pole so that the opening end of the funnel was at 1 m above ground level in order to avoid the effect of the dense surrounding herbaceous vegetation. In April 2004, before seed fall of the earliest seed producer (red maple, starting seed fall in mid-May), 23 traps were installed in each sampling site, within a 10m-wide transect crossing the right-of-way (*Fig. 2*). Every month until late November, the nylon mesh were collected and replaced with new ones.

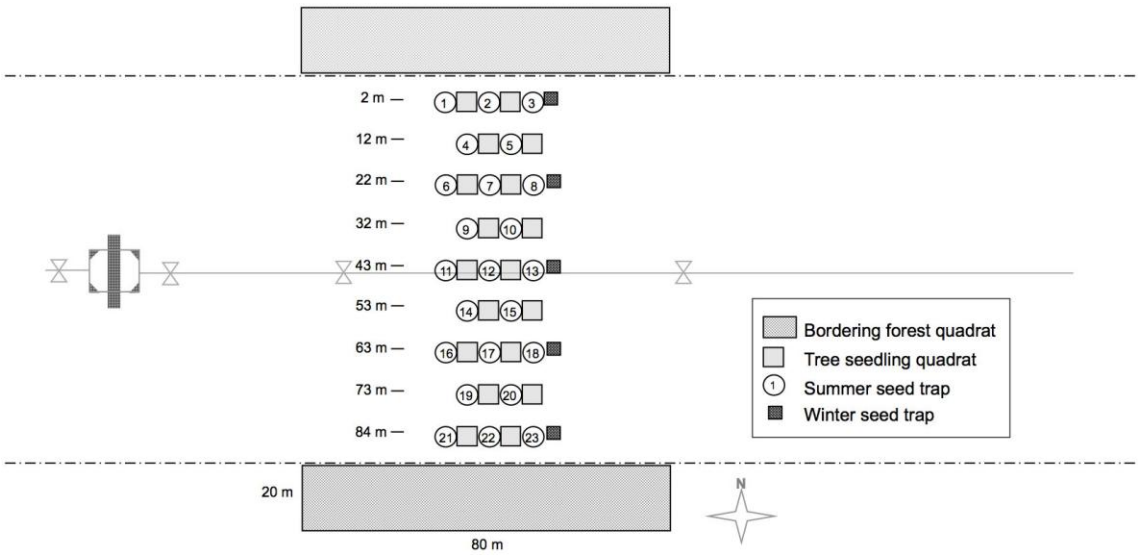

Figure 2. *Sampling design in a sampling site of the powerline right-of-way*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_33513361

Winter seed dispersion was evaluated using 1 m^2 nylon cloth pinned to the ground and covered with a screen of the same size to assure an adhesive surface for seed collection. Five of these winter seed traps were uniformly located along a transect crossing the right-of-way in each of the six sampling sites in fall 2013, before the first snowfall (*Fig. 2*). The traps were collected in the following spring, during snowmelt, in March 2004, in order to collect all seeds deposited over the $1m^2$ surface during winter. The snow remaining on the traps was melted and the organic material was filtered and added to those accumulated on the traps, and all tree seeds were sorted, dried, identified and counted. Birch seeds were identified using Kenneth and Brinkman (1974).

Tree seedlings were identified and counted in 18 $1m^2$ plots uniformly located in a transect crossing the right-of-way in each sampling sites of the same year. Information about the height and age were noted (*Fig. 2*). The number of seeds and seedlings counted in the plots along a transect were pooled in order to examine the relation between bordering tree, seed and seedling abundances between sites. For red maple and gray birch, the large number of seeds and seedlings allowed the study of their distribution along each transect, thus further allowing to study their spatial relation within sites.

Correlations using non-parametric Spearman tests were determined between 1) the distance to the nearest border and the abundances of seeds or seedlings (for red maple and gray birch only) and 2) seed abundance in summer and winter (for gray birch). Statistical tests were done using JMP statistical software version 6.

Results and discussion

All 6 sampling locations combined, 18 tree species were present in the forest plots bordering the rights-of-way (*Table 2*). Red maple was by far the most important tree species, accounting for nearly half of the total basal area for all trees, followed by sugar maple, trembling aspen, balsam fir, large-toothed poplar and gray birch. All the other tree species had a relative basal area lower than 3%. We found seeds from 10 tree species in the winter and summer seed traps, the large majority of which being from gray birch (80.7%), followed by red maple, paper birch, white ash, and yellow birch (*Table 2*). Note that there were no paper birch trees in the bordering forest plots despite the fact that it represented more than 5% of the seeds in the seed traps, suggesting long-distance dispersal. A good proportion of seeds from gray birch, eastern hemlock, and yellow birch were dispersed in winter (*Table 2*). This was particularly notable for yellow birch, which had almost half of its seeds dispersed in winter, confirming the necessity of sampling winter-dispersed seeds for a complete assessment of seed rain at a particular location (Matlack, 1989).

We found no seeds for several tree species that are otherwise represented in the adjacent bordering forest plots, including species known to produce large number of wind-dispersed seeds such as trembling aspen and large-toothed poplar. This absence may be due to a large interannual difference in seed production, with low production the year of our sampling.

Seedlings from 14 tree species were sampled in the right-of-way, the large majority being from red maple and gray birch (*Table 2*). There is generally little correspondence for species relative abundance between the tree – seed – seedling datasets, but there is a close relation for the relative rank of a species between the tree and seedling datasets: of the 6 most abundant trees in the bordering forests, 5 are also the most represented in the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

seedling sets, with both red maple and trembling aspen keeping the same rank (*Table 2*). There is little relation, both in terms of relative abundance or rank, between seed abundance and either tree abundance in the bordering forest or seedling abundance in the right-of-way. Again, this may be due to large interannual difference in seed production (Houle 1999).

Table 2. *Abundance and ranking of bordering trees, seeds and seedlings of the tree species in the right-of-way*

If we exclude species with little representation in the 3 data sets, we find that the relation between tree, seed, and seedling abundance in a particular sampling site varies largely among species (*Fig. 3*). The combined tree abundance of both borders is a good indicator of seedling presence within the right-of-way for red maple, sugar maple, balsam fir, white ash, and northern white cedar. Gardescu and Marks (2004) also found a close relationship between seedling emergence and seed source in red maple and white ash. The primary reason for this spatial relation is more likely attributed to a short distance dispersal than to local suitable habitat conditions since the absence of trees in a particular sampling site often results in a low number or in the absence of seeds (see sugar maple, balsam fir, white ash and eastern white cedar). For red maple, with trees

present in all borders, there was a close relation between tree, seed and seedling abundances. For these species, seed dispersal is thus an important factor in explaining seedling establishment. In general, these species are also those that have the largest seeds, representing another example of the relation between dispersal limitation and seed size (Battaglia et al., 2008).

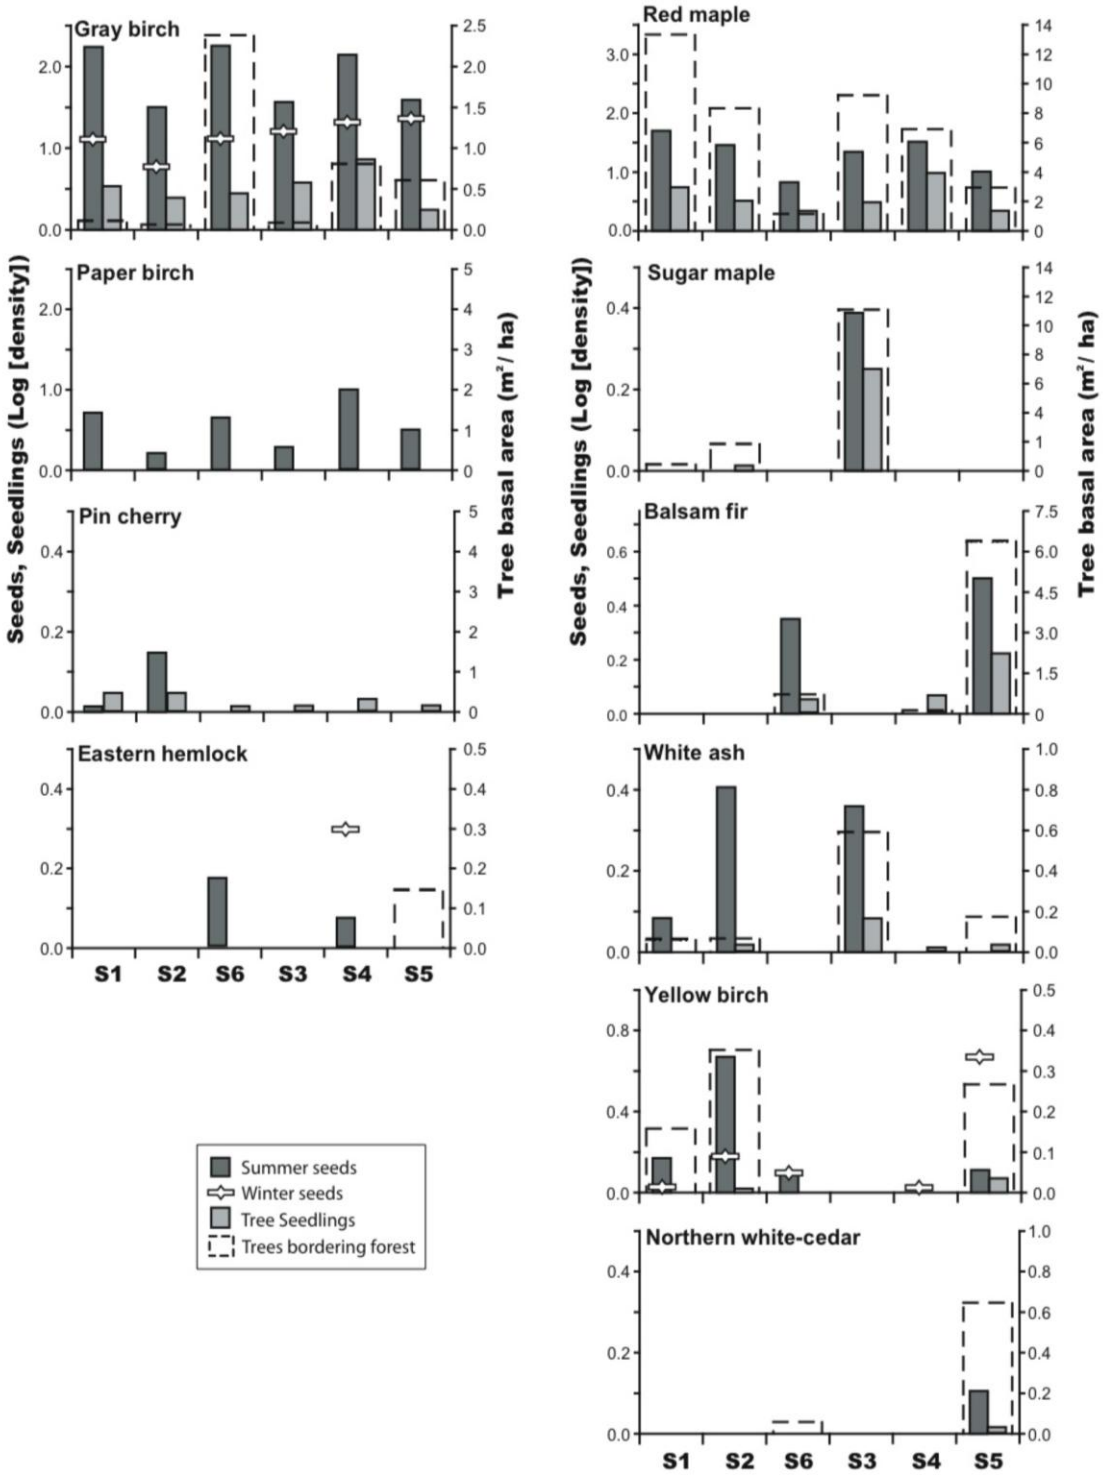

Figure 3. *Abundance of trees (in the bordering forest), seeds, and seedlings in each sampling site of the powerline right-of-way for the most common tree species*

Other tree species showed little relation between tree and seed abundance within a sampling site. Gray birch seeds, both summer and winter dispersed, were present in great numbers in all sampling sites, irrespective of the abundance of seeding trees in the nearby border, suggesting a predominance of long-distance dispersal processes (Caughlin et al., 2014). Dispersal mechanisms in winter and summer did not create changes in dispersal patterns since the relative abundance in winter and summer appears to vary similarly. Paper birch seeds, present in all sites, also originated from more distant trees since they were absent in all borders. The large number of widely dispersed seeds combined with the total absence of seedlings suggest that paper birch does not find suitable conditions for seedling establishment in the right-of-way.

Dispersal of pin cherry seeds is known to be predominantly achieved by birds (Marks, 1974). While pin cherry trees are almost absent from the borders, seeds were found in all sites, although most often in small numbers. The two sites with the most pin cherry seeds were also the ones with the presence of seedlings. There was apparently no relation between the presence of eastern hemlock trees and the abundance of seeds (no seedlings were found), but the overall low tree and seed numbers in our sampling forces caution in interpreting this pattern.

Red maple and gray birch were sufficiently abundant in all sampling sites, both in terms of seeds and seedlings, to allow the study of their spatial patterns at the scale of a single sampling site. These two species are known to be aggressive colonizers (Lavoie, 1999, Abrams, 1998), and they both represent management problems in powerline rights-of-way (Boivin et al., 2004, Mercier et al., 2001). For red maple, there were often a decreasing number of seeds from the edge to the center of the right-of-way in several sampling sites (particularly apparent in S1, S2, S4, and S5) (*Fig. 4*). The same pattern occurred for seedlings in S5.

Overall, there was a significant negative correlation between the abundance of seeds and seedlings at a particular location in the rights-of-way and the distance from the nearest border ($r=-0.65$ and -0.42 respectively, $p<0.001$ in both cases). Both of these patterns indicate that the lower establishment in the center of the right-of-way is at least partly due to low seed dispersal distance at the scale of the transect. A greater tree seedling establishment at the edge of another powerline right-of-way was also related to the proximity of seeding trees and low seed dispersal distance by Brisson et al. (1997).

For gray birch, there was no relation between seed and seedling abundances and the distance to the nearest border ($r=-0.16$ and -0.02 respectively). Although spatial patterns of seed distribution for gray birch results from long-distance seed dispersion, the pattern along transects crossing the right-of-way implies smaller-scale dispersion processes, as shown by the apparent spatial autocorrelation in seed distribution within most sampling locations (*Fig. 4*). This may be due to local wind patterns within the rights-of-way.

Conclusion

Seed abundance collected within a single year appeared to be poorly related to tree representation in the bordering forest and seedling abundance in the right-of-way, most likely due to interannual variation in seed production (Wesołowski et al. 2015). We found that the relation between nearby bordering tree, seed and seedling abundances varies among tree species. Distance to seed source was not so important for natural seedling establishment for some species such as gray birch. Winter seed dispersal may contribute to its long-distance dispersal. However, for many species, tree composition was an overall good predictor of nearby seedling establishment in terms of ranking. While this may be partially related to local suitable conditions, it also suggests that dispersal limitation may be an important factor in determining tree composition (Abiyu et al. 2016). These results may better inform powerline rights-of-way managers about corridor portions that may need greater plant control operations, but they are also relevant to other applications such as forest restoration and forestry.

Abstract. After peat extraction cut-over surface usually consists of moderately to highly humified peat which undergoes secondary transformation due to severely disturbed water conditions. The study was carried out within a mountain bog (Polish Carpathian) located in Orava-Nowy Targ Basin, southern Poland. The objectives of the study was to determine physical, hydrophysical and chemical properties of the upper layer of soil on two post-extracted areas of different age and to identify correlations between hydrophysical parameters and re-vegetation pattern. Vegetation was analysed in two groups: bog forming (*Sphagnum*, others) and non-bog forming (true mosses, trees, others). Secondary transformation of peat was quantitatively described by water-holding capacity index W_1. It correlated with thickness of residual peat and a range of properties of cut-over peat (e.g. porosity, bulk density, soil moisture content, ash content). The Principal Component Analysis (PCA) demonstrated the key importance of water table depth, residual peat thickness and hydrophysical conditions of the cut-over peat, especially water-holding capacity index W_1, soil moisture content and macropore volume on re-vegetation by typical bog species. Correlation of W_1 index with soil properties and *Sphagnum* occurrence indicates that it can be a useful indicator in evaluation of secondary transformation of cut-over bogs and therefore the potential for spontaneous regeneration of typical bog vegetation.
Keywords: *secondary transformation of peat, peat soil properties, water retention, cut-over peatland, peat quality*

Introduction

The European continent experienced the greatest loss of global resources of mires and peatlands, which is estimated at about 52% of their area (Joosten and Clarke, 2002). Management of peatland has a long tradition in Europe. Peatlands were drained and used mainly as farmlands and forests. Peat has also been extracted for fuel for centuries. In Western Europe its exploitation was the most intense in the 19th century, when mechanized peat extraction was introduced. Since the second half of the 20th century, peat has become an increasingly popular growing media in horticulture, and the most suitable substrate is poorly decomposed raised peat (Ilnicki, 2002). Rapid rate of degradation and disappearance of peatland ecosystems, particularly in Western Europe, encouraged development of a preservation and protection strategy for peatlands of Central Europe where losses have been less severe (Bragg and Lindsey, 2003).

In 2016 in Poland there were 290 peat deposits documented as suitable for peat extraction, of which 83 were still actively extracted and 78 were post-extracted sites (Szuflicki et al., 2017).

Peat extraction requires drainage and removal of acrotelm, which severely alters natural functions of peatlands e.g. maintaining stable water level (Van Seters and Price, 2001). Peat soil after drainage experience transformation in aerobic conditions which is termed as secondary transformation (e.g. Kalisz et al., 2015). To quantitatively evaluate its state a water-holding capacity index W_1 may be used (e.g. Gawlik, 1992). This index expresses as a ratio of the lowest and the highest water-holding capacity of the soil and reflects changes in the physical, hydrophysical and chemical properties of peat soil subject to drying (Gawlik, 2000; Sokołowska et al., 2005).

When the cut-over sites are abandoned without any further treatment, the peat mass undergoes shrinkage, compression, and oxidation collectively known as peat subsidence (e.g. Eggelsmann, 1986). Those processes alter morphology of the soil profile as well as physical, hydrophysical and chemical properties of peat (Ilnicki and Zeit, 2003). As shown in other research (e.g. Schlotzhauer and Price, 1999; Price et al., 2003) increase in soil density after drainage results in pore size reduction, decrease of hydraulic conductivity and specific yield (the capacity of saturated soil to release water from storage by gravity drainage). This, in turn, further causes greater fluctuation of water table (e.g. Schouwenaars, 1993; Whittington and Price, 2006). Changes in pore size distribution trigger alterations in water storage that depends on the size of pores in the zone of water table fluctuation and the corresponding specific yield (Verry et al., 2011). Chemical transformation, mainly mineralization of nitrogen and carbon containing compounds, and composition of organic and inorganic material may change nutrient status of the soil as well as ground water quality (e.g. Wind-Mulder and Vitt, 2000; Laine et al., 2013). Peat oxidation leads to relative enrichment of ash content and to lowering of C:N ratio due to a preferential loss of C over N resulting from microbial decomposition (Krüger et al., 2015). It also causes substantial emissions of greenhouse gases (CO_2, N_2O), which is a considerable challenge in the context of climatic changes (e.g. Couwenberg, 2011; Hufnagel and Garamvölgyi, 2014).

Considering irreversible changes in peat structure and properties as well as greenhouse gases emission, restoration of post-extracted peatlands should begin right after the cutting is finished (Waddington et al., 2001). The only way to delay these processes is by complete inundation or by re-establishment of peat forming vegetation (Joosten, 1992). Regeneration of typical bog vegetation with *Sphagum* as a dominant component depends primarily on the hydrophysical conditions of the uppermost peat layer, as they are considered the main factors affecting water table fluctuations and the occurrence of water stress (Schouwenaars and Gosen, 2007).

Due to the history of peatland management in Europe and Poland, many studies on degradation of organic soils concern drained and agriculturally used (grasslands, arable lands) peatlands, especially fens (see Parent and Ilnicki, 2003). There have not been many research on the secondary transformation of soils of post-extracted bogs in Poland. This topic should be definitely focused on, especially in the context of numerous activities aimed at the conservation and restoration of peatlands (e.g. Herbichowa et al., 2007; Okruszko et al., 2011; Glińska-Lewczuk et al., 2014). Currently, degraded peatlands are often near or within various nature protection areas as in the case of the cut-over bog investigated in this study. That is why the assessment of regeneration potential of such sites is particularly important.

The objectives of the presented study were as follows: a) to determine physical, hydrophysical and chemical properties of the upper layer of peat soil on post-extracted areas of different age, b) to identify correlations between hydrophysical parameters of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

cut-over peat surface and re-vegetation pattern. This will expand our knowledge on changes in bog peat undergoing degradation in post-extraction areas. It would be also helpful in selecting soil parameters most strongly affecting the potential of cut-over bogs for restoration of typical bog peat-forming vegetation.

Materials and methods

Study area

The study was carried out within a raised bog Bór za Lasem which is located in Orava-Nowy Targ Basin, southern Poland (*Fig. 1*). It is one of 27 sites that form a complex of mountain peatlands belonging to the European Ecological Network Natura 2000 (PLH120016, PLB120007). Northern and southern borders of the Orava-Nowy Targ Basin are flanked by mountain ranges. It is located within moderately warm climate zone with local peculiarities (Kondracki, 2011). Mean annual air temperature is 5.5 °C (max: July 16 °C; min: February -6 °C), and annual total precipitation ranges from 750 mm to 825 mm (Olszewski, 1988). Basic weather characteristics were also recorded in 2016. Between June and August mean air temperature was 15.4 °C, with a maximum of 37.0 °C and minimum of -2.9 °C. Mean precipitation for that period was 375 mm.

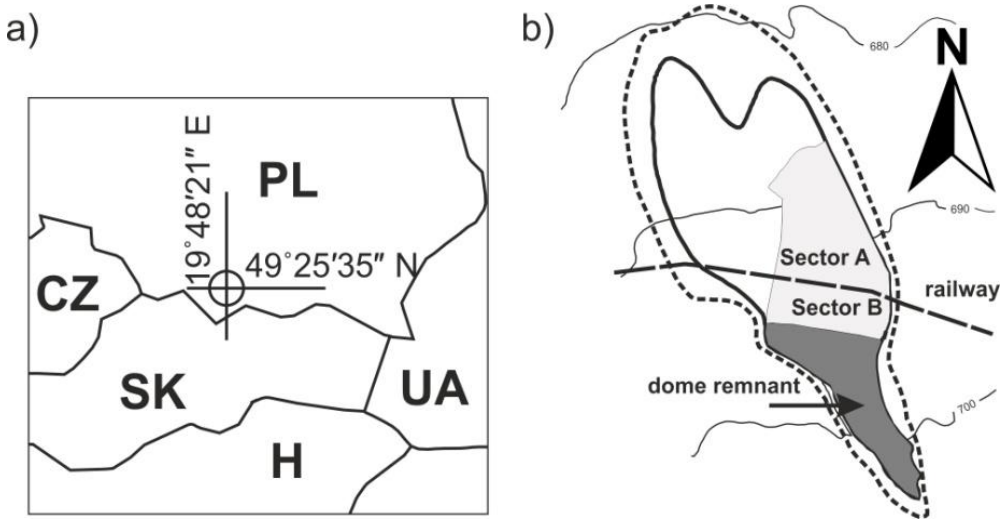

Figure 1. *Location of Bór za Lasem peat bog (a) and investigated post-extraction sectors (adapted from Łajczak, 2006) (b)*

Bór za Lasem bog was formed as a result of paludification of poorly permeable clay substrate. It is a raised bog but the supply of shallow groundwater was important at the initial stage of its formation. The site is dominated by ombrogenic peats, cotton-grass-*Sphagnum* (*Eriophoro-Sphagneti*) and hummock *Sphagnum* (*Eusphagneti*), and locally with poor-fen *Sphagnum*-sedge (*Sphagno-Cariceti*) peat and sapric peat at the base. The bog area is 55 ha, and mean peat thickness is ca. 1.80 m (max 3.65 m). Mean degree of peat decomposition (determined with microscopic method) in the remaining bog dome is 30%, and mean ash content is 2.2% (Lipka and Zając, 2014).

After the Second World War, the bog was extracted within two sectors (*Fig. 1*), with block-cutting method using heavy machinery. Sector A (ca. 16 ha) was cut-over from the beginning of 1960s until the beginning of 1980s. Then the extraction continued on Sector B (ca. 8 ha) until the beginning of 1990s (personal communication). When the extraction was finished the sites were abandoned (*Fig. 2*). Both sectors are crossed with a network of secondary drainage ditches spaced at about 20 m that remove water to main ditches. Most of the secondary ditches are currently filled in and overgrown with vegetation and primary ditches remove water mainly during major floods after precipitation and spring snowmelt.

a

b

Figure 2. *General view of the investigated post-extraction Sectors A (a) and B (b) of Bór za Lasem peat bog*

Measurements of water level carried out from June to August 2016 in both post-extracted sectors in piezometers showed that if the residual peat was ca. 40 cm and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_33633380
© 2018, ALÖKI Kft., Budapest, Hungary

less thick the water table dropped 13–22 cm below the peat layer (recorded for 58% and 17% of the plots on Sectors A and B respectively). If peat layer was thicker, mean water level was 25.4 cm for Sector A and 16.1 cm for Sector B. Control measurements of groundwater quality were performed twice in the summer in two piezometers from each sector. Mean water pH were 2.86 and 3.07 and electric conductivity 41 μS cm^{-1} and 50 μS cm^{-1} for Sectors A and B respectively.

Soil analysis

The study on post-extracted area of Bór za Lasem bog was conducted in the years 2015–2016. Twenty study plots (5 m × 5 m each) were laid out on each of the two sectors and they were arranged in W-shaped transects. At each study plot peat thickness was measured with a soil probe and samples for laboratory analysis were taken from two layers: 0–10 cm (after removing of litter) and 10–20 cm. Soil samples were collected in metal rings (160 rings, 250 cm^3) and into plastic bags (80 samples). Additionally, to determine peat type exposed after extraction, peat matrix samples were collected from eight randomly selected plots from different areas on both sectors (four locations from each sector). All the analyses were performed in duplicate.

The degree of peat decomposition was determined according to Von Post (1924), and peat type with microscopic method based on plant macrofossils composition (Kac et al., 1977; Tobolski, 2000).

The state of secondary transformation of peat was assessed based on physical, hydrophysical and chemical properties comprising: water-holding capacity index (W_1), dry bulk density (ρ_b), specific density (ρ), total porosity (n), volumetric moisture content (θ_v), saturated moisture content (θ_s), volumetric shrinkage (S_v), maximum hygroscopic moisture content (MH), water retention curve (pF), ash content (A), pH, electric conductivity (EC), total carbon (C), total nitrogen (N), mineral nitrogen forms (NO_3^-, NH_4^+), and available phosphorus (P).

Bulk density, soil moisture content and volumetric shrinkage were measured in samples of undisturbed structure following sample drying at 105 °C for to a constant weight. To determine saturated moisture content, soil samples were soaked with water for three weeks before drying. Bulk density and soil moisture content were then calculated with routinely used formulas. Volumetric shrinkage was estimated as a difference in sample volume in saturated and dry state (105 °C) to its volume in saturated state. Specific density was calculated with the formula by Okruszko (1971) based on ash content (see *Eq. 1*), and total porosity was worked out using specific density and bulk density.

$$\rho = 0.011 \cdot A + 1.451 \quad \text{(Eq.1)}$$

Water-holding capacity index was determined according to the method provided by Gawlik (1992). Each soil sample was divided into two parts. One part at field-moisture state was saturated in distilled water for 7 days. The second part was first dried to an absolutely dry weight (105 °C), and then saturated in distilled water (7 days). Water content was determined by a gravimetric method after centrifuging the samples at 1000 *g* for 1 h at 10 °C in a laboratory centrifuge with a cooling unit. The results were recalculated to 100 g of absolutely dry weight. Water holding capacity index was calculated as a ratio of water content in a sample dried up to 105 °C and in a sample of field-moisture. The state of secondary transformation of peat was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_33633380
© 2018, ALÖKI Kft., Budapest, Hungary

evaluated according to the classification by Gawlik (2000): I – initially secondary transformed (W_1: 0.36–0.45); II – weakly secondary transformed (W_1: 0.46–0.60); III – moderately secondary transformed (W_1: 0.61–0.75); IV – strongly secondary transformed (W_1: 0.76–0.90); V – completely degraded ($W_1 > 0.90$).

Water retention characteristics of the soil were determined using the equilibrium centrifuging method (Smagin and Prusak, 2008). Then, laboratory data were fitted with Van Genuchten model using the RETC computer program (Van Genuchten et al., 1991). These data were used to find out water retention capacity and differential porosity of the peat soil assuming that field water capacity (FWC) corresponded to θ_v at pF 2.0, available water retention (AWR) to θ_v between pF 2.0 and pF 4.2, easily available water retention (EAWR) to θ_v between pF 2.0 and pF 2.7 and small pore retention (SPR) to θ_v between pF 2.7 and pF 4.2. Macropore volume was calculated as a difference between total porosity and volumetric moisture content at pF 2.0, mesopore volume was defined in the same way as AWR and micropore as volumetric moisture content at pF 4.2. Maximum hygroscopic moisture content was determined in a vacuum drying oven in the presence of saturated solution of K_2SO_4 (Mocek and Drzymała, 2010).

Soil ash content and pH analysis was performed in air dry samples as described by Sapek and Sapek (1997). Ash content was determined by a loss on ignition method where a peat sample (2 g) was incinerated in a muffle furnace at 550 °C, and then calculated as difference between weight of the sample dried up at 105 °C and its weight after incineration. Soil pH and electric conductivity were determined in 1:10 (soil:solution) ratio. Soil pH was measured by a potentiometer in distilled water and in 1 M KCl. The resulting values of electric conductivity were corrected for H^+ ions (Sjörs, 1950). Total carbon and nitrogen were determined on a CNS elemental analyzer. The samples were devoid of carbonates (inorganic carbon), and thus total carbon content corresponded to organic carbon content. These data were used to work out C:N ratio. The content of ammonium nitrogen (NH_4^+) and nitrate nitrogen (NO_3^-) was measured with a flow injection analysis method, and available phosphorus (P) was determined by Egner-Riehm method based on soil extraction with calcium lactate solution acidified with hydrochloric acid (Lityński et al., 1976).

Vegetation

At each study plot the percentage of cover by vascular plants and mosses was assessed. The bryophytes were determined to the genus level. Statistical analysis was based either on individual taxa or groups of species with similar habitat preferences. An analysis of effects of environmental factors on plant species occurrence (paper under review) demonstrated key importance of water level. Therefore, this paper analysed the vegetation pattern with regards only to chosen parameters affecting hydrological conditions of the soil surface. For the analyses vegetation was subdivided into groups: a) bog forming vegetation: *Sphagnum*, other bog species, b) non-bog forming vegetation: true mosses, trees (higher than 1.5 m), other non-bog species.

Statistical analysis

Distribution of the determined soil parameters was verified with Shapiro-Wilk test ($p > 0.05$). As some variables did not follow a normal distribution, and the data

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

transformation was ineffective, the non-parametric Spearman rank correlation coefficient was used to assess the interdependencies between them. Significance of differences in the analysed parameters of the two soil layers between both sectors was assessed using a parametric t test for normal distribution variables, and nonparametric U-Mann Whitney test for non-normal distribution variables. The statistical analysis was performed in Statistica 12.

To compare the soil samples in terms of all investigated parameters and to estimate their relation to vegetation and environmental factors a multivariate statistical analysis method, i.e. Principal Component Analysis (PCA) was employed. It is a useful technique for identifying common patterns in data distribution that reduces the initial dimension of data sets and facilitates data interpretation. Ordination of all samples from 0–10 cm and 10–20 cm layers was based on eleven soil parameters (samples with negligible effect because of intercorrelations were excluded). The impact on vegetation was assessed with selected soil parameters (water-holding capacity index, volumetric moisture content, saturated moisture content, maximum hygroscopic moisture content, differential porosity) affecting hydrological conditions of the uppermost soil layer (0–10 cm). Since the soil parameters (variables) had different units, the data were centred and standardized to zero mean and unit variance before subjecting the data set to PCA. Residual peat thickness, water level and cover of vegetation were treated as passive variables not affecting the results of the ordination. Multivariate analysis was performed with Canoco software (ter Braak and Smilauer, 2002).

Results

When exploitation ceased on the younger Sector B, the site was covered with bog peat of cotton grass-*Sphagnum* (*Eripohorum-Sphagnum*) type with decomposition degree H4-6 as per Von Post scale. On Sector A harvesting exposed pine-*Sphagnum* peat (*Pinus-Sphagnum*) and sapric peat in which remains of pine wood were identified. One third of the study plots on this sector had a ca. 5 cm thick layer of compressed moss of decomposition degree H4 at a depth of approximately 5–6 cm. On other study plots peat decomposition ranged from H5 to H8.

Sectors statistically differed mainly in physical and hydrophysical properties and some chemical properties. On Sector B there were more significant differences in parameters between the two investigated layers than on Sector A. The largest with-in site variability was noticed for chemical properties, such as ash content (especially in 10–20 cm layer), mineral nitrogen forms and corrected EC. The most variable physical and hydrophysical parameters included thickness of residual peat (Sector B) and volumetric water content (Sector A, 0–10 cm). Low to moderate variability with a coefficient of variation usually below 30% was noticed for the other variables (*Tables 1* and *2*).

The soil water potential (pF)-moisture contents characteristic (*Fig. 3*) featured higher moisture content at FWC on older Sector A. Also, on this sector the volume of macropores was significantly lower (nearly two times) and that of micropores clearly higher, especially in 10–20 cm layer than on younger Sector B. In consequence, EAWR was higher on Sector B, while on Sector A more water was retained in smaller pores (SPR) (*Table 3*). In the layer 0–10 cm SPR represented 83% and 68% of AWR on Sectors A and B, respectively.

Explanations: FWC – field water capacity; AWR – available water retention = mesopores; EAWR – easily available water retention; SPR – smaller pores retention; SD – standard deviation; V – variability coefficient
[1]Statistically significant difference ($p < 0.05$) in the layer 0–10 cm between Sectors A and B
[2]Statistically significant difference ($p < 0.05$) in the layer 10–20 cm between Sectors A and B
[3]Statistically significant difference ($p < 0.05$) between the layers 0–10 cm and 10–20 cm on Sector B

Water-holding capacity index W_1 for the majority, i.e. 57% of analysed samples ranged between 0.46 and 0.60 (weakly secondary transformed), for 22% of samples it was 0.61–0.75 (moderately secondary transformed), and for 17% of samples between 0.36 and 0.45 (initially secondary transformed). Mean values of W_1 in the layers 0–10 cm and 10–20 cm (*Table 1*) indicated moderate to weak secondary transformation of peat mass on Sector A, while on Sector B it was weak to initial. There was a strong positive correlation of the W_1 index with bulk density and ash content (consequently with specific density), and a negative correlation with total porosity, volumetric shrinkage and soil moisture content. Moderate correlation was observed with thickness

[1]0–10 cm layer only

In PCA of all soil samples (both sectors and layers) (*Fig. 4*), the first PCA axis explained 45.3% and the second 12.4% of total variance. Water level and residual peat thickness most strongly correlated with the first PCA axis. Dispersion of soil samples was higher on Sector A than on Sector B. The samples were arranged from those from the older Sector A, layer 0–10 cm (left-hand part of the diagram), to those from the younger Sector B, layer 10–20 cm (right-hand part of the diagram). The samples from Sector A, layer 10–20 cm and Sector B layer 0–10 cm occupied a common central area of the diagram. Single samples deviated from this trend. There was a significant ($p < 0.05$) negative correlation ($r=-0.771$) between residual peat thickness and water level. In general, an increase of peat thickness and water table level was associated with a decrease in bulk density, water-holding capacity index W_1, maximum hygroscopic moisture content and total N and an increase in total porosity, macropore volume, soil moisture content, volumetric shrinkage, pH, total C and C:N ratio. Contrary to that, micropore volume, ash content and corrected EC were increasing with depth on the older Sector A but decreasing on the younger one.

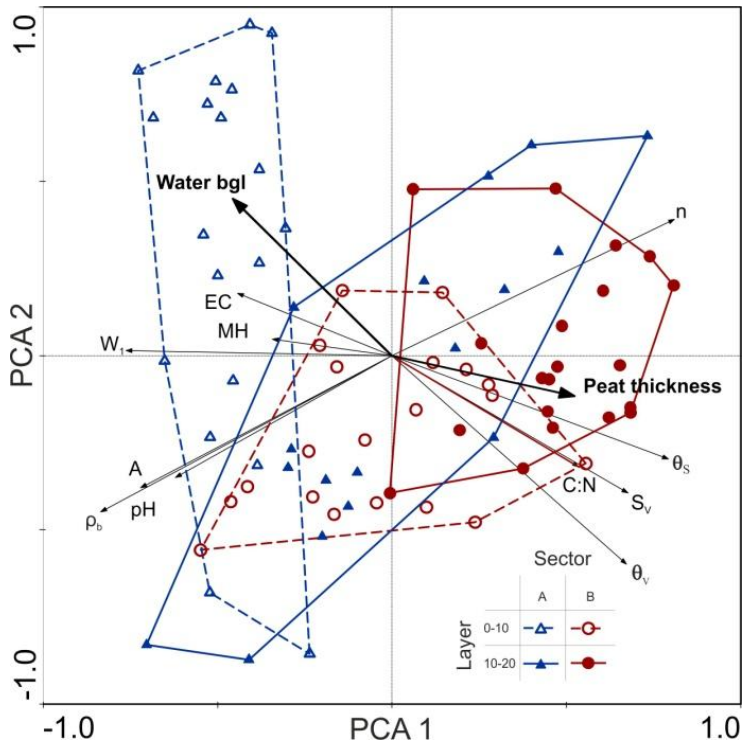

Figure 4. *Result of PCA ordination conducted on soil parameters of all samples. Abbreviations: W_1 – water-holding capacity index, MH – maximum hygroscopic moisture content, θ_v – volumetric moisture content, θ_s – saturated moisture content, ρ_b – bulk density, n – total porosity, S_v – volumetric shrinkage, A – ash content, C:N – total nitrogen and total carbon ratio, EC – corrected electric conductivity, Water bgl – mean water level below ground. Environmental factors (Peat thickness, Water bgl) are displayed as passive variables*

Typical bog-forming species occurred on all plots (*Table 5*). Mosses of the *Sphagnum* genus, which are the main bog forming plants, were found only on 44% of the plots and did not achieve a large coverage. Among the bog forming vascular plants the most frequent (97%) and of the largest cover (on average 36%) was *Eriophorum vaginatum*. Trees exceeding 1.5 m were found on the majority of the plots (82%), sometimes reaching high cover (up to 60%), especially on the older Sector A (*Fig. 5*). These were mainly *Betula pendula* and *Pinus sylvestris*. Small trees (up to 1.5 m) appeared with a relatively high frequency. However their share in the area cover was small. *Calluna vulgaris*, *Vaccinium myrtillus* and *V. vitis-idea* were among the most common other non-bog forming species. Very few minerotrophic species were recorded more than once (*Empetrum nigrum*, *Juncus effusus*, *Sorbus aucuparia*, *Carex nigra*, *Eriophorum angustifolium*, *Dryopteris carthusiana*). The most frequent was *Dryopteris carthusiana* with frequency 11%.

In PCA ordination based on the parameters affecting hydrological conditions (*Fig. 5*) the first axis explained 34.7%, and the second 30.1% of total variance. Water level, residual peat thickness and vegetation most strongly correlated with the second axis. Typical bog forming vegetation was clearly concentrated in the lower part of the diagram, opposite to the non-bog forming vegetation. Especially cover of *Sphagnum* was associated with studied plots showing lower W_1 index, higher water level, peat thickness, soil moisture content and macropores volume.

Discussion

Post-extracted areas of peatlands are divers mainly in terms of characteristics of the exposed peat (type, degree of decomposition, thickness), drainage intensity, climatic conditions, as well as the re-vegetation pattern. That is why making direct comparisons of hydrological conditions and soil properties of cut-over peat with other sites is difficult. However, there are some distinct trends in secondary transformations of analysed peat soil. The study indicated that the changes in a bog peat were similar to that observed in minerotrophic fens (e.g. Ilnicki and Zeitz, 2003).

The longer time after abandonment of post-extracted areas without any treatments e.g. drainage blocking, the more advanced secondary transformation of peat, reaching deeper layers. Differences in physical and hydrophysical soil properties of examined sites were essential as compared with fibric material (e.g. Boelter, 1969) of the uppermost (acrotelm) layer of a natural bog. An increase in pH, electric conductivity and mineral forms of nitrogen (NO_3^-, NH_4^+) at peat surface was recorded, as on other post-extracted areas (Wind-Mulder et al., 1996), but overall it remained acidic and poor in nutrients. We used water holding capacity index W_1 as a quantitative indicator of secondary transformation of cut-over bog. The correlations stated between W_1 index and the range of analysed soil properties were similar to those reported in other studies, mainly for fens (Gawlik, 1993, 1996; Szajdak et al., 2000; Boguta and Sokołowska, 2014; Glina et al., 2016). This suggests that water-holding capacity index W_1 can be a valuable measure reflecting the degree of peat soil degradation on post-extracted areas, which is manifested primarily in changes of soil hydrophysical conditions.

We observed strong correlation between parameters affecting water conditions of surface peat, i.e. water level, residual peat thickness, soil moisture, pore sizes and water-holding capacity index W_1 and establishment of different vegetation groups (bog forming and non-bog forming). In time, peat substrate quality created more unfavourable hydrophysical conditions for re-vegetation by typical bog species, especially *Sphagnum* what was evidenced in multivariate analysis (older vs. younger sector). However, to be more specific the state of secondary transformation of peat depends more on soil water conditions after drainage than the time that elapsed since drainage (Gawlik, 1996).

Hydrophysical conditions of the peatland surface are considered the main variable affecting *Sphagnum* growth (e.g. Price and Whitehead, 2001). Peat (catotelm) that was exposed after ceasing peat extraction on investigated site maintained high water retention capacity but water was retained with high pressure. Similar results were reported for other post-extracted sites (Schlotzhauer and Price, 1999; Mustamo et al., 2016). High water retention capacity results from the moderate to high decomposition degree of the peat matrix, hence high fraction of small pores (e.g. Boelter, 1969). Increase in bulk density due to peat consolidation and further decay in drainage conditions subsequently alter size of pore spaces (e.g. Whittington and Price, 2006). Hence increased peat decomposition and soil compaction result in a decrease in easily available water retention and a rise in smaller pores retention (Gawlik, 1992).

Macropore volume in analysed soil was comparable with specific yield reported by Price (1996) or Mustamo et al. (2016) on post-extracted sites, as well as with the water yield coefficient (which represents the same area on pF curve as macropores and is an equivalent of specific yield) given by Boelter (1969) for sapric peat. Their percentage was very low compared to slightly decomposed *Sphagnum* peat (Verry et al., 2011). Low macropores volume and specific yield may seriously inhibit *Sphagnum*

development as unlike vascular plants it is unable to uptake water from the substrate when pore-water pressure is lower than –100 mb (Hayward and Clymo, 1982 after Price, 1997). According to Price and Whitehead (2001), hydrological conditions suitable for *Sphagnum* recovery require high water table level (24.9 ± 14.3 cm), volumetric moisture content above 50%, and pore-water pressure above –100 mb. However, if volume of small pores is high, water is held at such low pressure that it cannot be drawn by *Sphagnum* through capillary suction (Price et al., 2003). Furthermore, Dixon et al. (2017), who studied moss water availability demonstrated that both factors, deeper profile and shallower starting water table, delayed the beginning of very high surface tension and that peat deposits shallower than 0.5 m showed the lowest capability of equalizing prolonged periods of evaporative stress.

The cited studies are consistent with our results that indicated better conditions for establishment of bog forming vegetation, especially *Sphagnum* on areas with thicker residual peat layer, shallower water table, higher soil moisture content and macropore volume. On such areas surface peat layer was less secondary transformed. This was expressed in lower W_1 index, which indirectly denoted lower density of peat, hence higher porosity. Hydrophysical properties of the uppermost layer of cut-over peat are particularly important to *Sphagnum* as they lack roots and vascular channels (Schouwenaars and Gosen, 2007) and unlike vascular plants they cannot take up water from deeper layers of soil. On the contrary, non-bog forming vegetation (mainly true mosses and trees) developed better on drier conditions, when peat layer was thin and secondary transformation of peat expressed as W_1 index, more advanced. Increased share of true mosses, like *Polytrichum* associated with lowered water level was described by Potvin et al. (2015). Dry conditions also facilitate tree seedling establishment, as *Sphagnum* growth is then impeded (Limpens et al., 2014). In humid climatic conditions of Central Europe woodland is a typical potential vegetation (Ellenberg and Leuschner, 2010), so trees occupy abandoned post-extracted peatlands over time. Trees strongly affect peatland ecosystems through changes in the structure and species composition, availability of light and soil physical and chemical properties (Mitchell et al., 2007). Trees (Van Seters and Price, 2001) and also ericaceaous shrubs (Farrick and Price, 2009) increase peat drying by interception of precipitation water and transpiration, which especially in birch is high (Fay and Lavoie, 2009). Therefore, they may further exacerbate secondary transformation of peat.

It is important that restoration should begin directly after extracted area is abandoned (Price, 1997). Only then it can be possible to mitigate effects of drainage and consequently changes in peat structure and properties as well as to inhibit establishment of trees.

Conclusions

The properties of the peat surface deteriorate on abandoned cut-over bogs, where peat dries up over time. The process can be also exacerbated by vascular vegetation, especially trees. Secondary transformation of peat may be comprehensively described by water-holding capacity index W_1. It correlates with thickness of residual peat and a range of properties of cut-over peat (e.g. porosity, bulk density, soil moisture content, ash content), that change as the degradation advances. Identification of these correlations means that W_1 index may be used in evaluation of secondary transformation of peat mass on cut-over bogs.

The study demonstrated the key importance of water table depth, residual peat thickness and hydrophysical conditions of the cut-over peat surface, especially water-holding capacity index W_1, soil moisture content and macropore volume on re-vegetation of *Sphagnum.* Negative correlation of W_1 index with *Sphagnum* occurrence indicates that it may also be a useful measure in evaluation of the potential of cut-over bogs for spontaneous regeneration of typical bog vegetation, mainly *Sphagnum* species. Implementation of such approach into practice requires further research on other degraded bogs for verification.

Our study suggests that prospective restoration strategy of post-extracted areas should consider implications of unfavourable physical properties of the cut-over peat surface on hydrological conditions. However, any solutions aimed at providing appropriate hydrological conditions must be site-specific due to huge diversity of local conditions (e.g. Gorham and Rochefort, 2003; Price et al., 2003; Shantz and Price, 2006).

Acknowledgments. We thank to the authorities of Gmina Czarny Duanjec, especially Michał Jarończyk and Bogusław Sroka from Peat Production Plant "Bór za Lasem" in Czarny Dunajec for help and permission to conduct the research. We also thank to Ewa Zagrodzka and Marek Turschmid for assistance in the field and laboratory work. This research was carried out within Projects DS-3331/KMIKŚ and DS-3337/KEKiOP financed from a research grant allocated by the Polish Ministry of Science and Higher Education.

EXAMINATION OF ANATOMICAL FEATURES OF TOMATO (*LYCOPERSICON ESCULENTUM* MILL.) VARIETIES CULTIVATED UNDER HYDROPONIC SYSTEM

TUYLU, M.

Department of Biology, Institute of Science, University of Süleyman Demirel, Isparta, Turkey
e-mail: meltemtuylu@hotmail.com

(Received 27th Feb 2018; accepted 21st May 2018)

Abstract. In the study it was aimed to examine and determine some anatomical features of *Lycopersicon esculentum* Mill. cv. Ceren and *Lycopersicon esculentum* Mill. cv. Panda varieties cultivated under hydroponic condition in greenhouse in Şanlıurfa, Turkey. Cross sections were cut from the root, stem and leaf by microtome and examined by light microscopy. The results were photographed. Biometric measurements of some tissues were performed. The roots of the plants are surrounded by 1 layered epidermis formed by big and small cells. Vascular bundle gathered in the centre. Stems are formed 1 layered epidermis, 1-2 layered chlorenchyma, 3-4, 4-5 layered collenchyma and 3-4, 4-5 layered parenchymatic tissues. Vascular bundles are bicollateral. Pith is parenchymatic. Stomate, epidermal hair and glandular hair are observed. Leaves are bifacial and amphistomatic. Mesophyll is formed by 1 layered palisade parenchyma and 2-3 layered spongy parenchyma. Big vascular bundle is bicollateral and small vascular bundle is collateral. They have epidermal and glandular hairs. As a result, some basic anatomical features examined showed that cv. Ceren and cv. Panda are convenient for cultivation under hydroponic system.The data obtained will contribute to soilless agricultural cultivation in the province and will pave the way for similar scientific studies.
Keywords: *light microscopy, plant histology, soilless agriculture, water stress*

Introduction

Greenhouse cultivation has developed related to negative developments such as climate changes and agricultural fields' abuse. In greenhouse soil and soilless agriculture can be applied depending on available irrigation and cultivation technologies. In soilless agriculture aggregate and nonaggregate (hydroponic) cultivation conditions can be used (Alan, 1990). Soilless agriculture is more productive than soil agriculture and its production cost is half of soil agriculture (Özkan, 2014).

Plant cultivation in soilless conditions is particularly developed in horticulture. It is mostly used for the cultivation of vegetable and ornamental plants. Yield can differ according to the variety of plants in cultivation using soilless agriculture techniques. For instance, while 1.25-2.5 ton da^{-1} tomato is cultivated in soil agriculture, 15-75 ton da^{-1} tomato is cultivated in soilless agriculture. 1.625 ton da^{-1} cabbage is cultivated in soil agriculture while 2.25 ton da^{-1} cabbage is cultivated in soilless agriculture (Alan, 2010).

Plants grow in biotic and abiotic conditions depending on their needs. These conditions may cause stress in plants. As stated in Korkmaz and Durmaz (2017) plants undergo changes in terms of quality of stress factor and genetical and ontogenic features of plants. Thus, plants adapt to factors of their environment by developing stress reactions. Stress reactions of plants exposed to stress effects can be observed when the general features of plants which are original to species are compared.

In this case not only morphological reactions of plants but also their physiological and anatomical reactions and etc. should be considered as a whole. When all these features are considered together, it can be seen if plants complete their developments and adapt to the conditions of their habitat.

Tomato has been conventionally cultivated by using soil culture techniques. In the study, it was aimed to anatomically examine root, stem and leaf of the two varieties of tomato cultivated by using hydroponic system and to histologically specify their adaptations to the condition. Two different varieties of tomato (*Lycopersicon esculentum* Mill.) were randomly chosen from among varieties which are preferred cultivating in greenhouse by farmers in Turkey and were examined.

Materials and methods

The research was carried out in Şanlıurfa in Southeastern Anatolia. The study area is 465 m above sea level and located between 37°08'N latitude and 38°46'E longitude (Demirok and Tuylu, 2017). *Lycopersicon esculentum* Mill. cv. Ceren (offspring F1) and cv. Panda (offspring F1) which are hybrid varieties of tomato were cultivated by using aerated deep water culture in polycarbonate covered greenhouse in Harran University, Şanlıurfa, Turkey in spring in 2016 *(Fig. 1).* Anatomical studies were carried out in the laboratories in Ankara University, Ankara, Turkey. The data of climate belonging to 2016 and 1985-2016 long years (LY) in the province of cultivation (Anonymous, 2016) is given in *Table 1,* some climate values measured in the greenhouse in 2016 when the research was carried out are shown in *Table 2*.

Figure 1. *An appearance of hydroponic culture in greenhouse*

The treatment was created as with 3 replications according to the random parcels plant pattern. Seedlings were transplanted to the hydroponic system at primary stage. 8 plants were cultivated in each basin. 2 of 8 plants cultivated were separated as border effect. Samples were taken at random from the remaining 6 plants and were observed. The basins which were made of galvanized sheet in the size of 50x200x30 cm were used for hydroponics. Nutrient solution was modified by using Arnon and Hoagland (Tuylu et al., 2018). Stock A and Stock B solutions were separately prepared (*Table 3*). Electrical conductivity (EC) of nutrient solution was measured as 2.5 dS m^{-1} by EC meter and pH of nutrient solution was set to 5.8-6.5 by using nitric acid. In soilless agriculture EC of nutrient solution has to be kept at optimum level. While high electrical conductivity (EC) reduces the yield affecting number of fruit, diameter of fruit and thickness of pericarp negatively, it causes increase of parameters of quality such as titratable acidity, amount of dry substance which is easily soluble in water, reducing glucose and lycopene (Söylemez ve Pakyürek, 2017). Air compressors were used to aerate nutrient solution used in hydroponics and nutrient solution was changed once a week. The plants were cultivated as a single stem by pruning. They were applied pesticide against diseases and pests if necessary.

Table 3. *The content of element in nutrient solution (mg l^{-1})*

The samples of plants vegetatively and generatively grown were kept in alcohol 70% for anatomical studies. The samples of 3rd harvest root, stem and leaf were anatomically examined from period of production including 5 harvests. Small pieces taken from lower, middle and upper parts of root, stem and leaf were dehydrated by putting them in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

different concentration series of ethanol. Then, they were saturated by paraffin. The samples were embedded in paraffin blocks to take cross sections. 8-10 µm thick cross sections from root and leaf and 20-30 µm thick cross sections from stem were taken by microtom (Leica SM 2000 R). The cross sections were stained by safranin-fast green (Algan, 1981; Tuylu et al., 2017). They were examined by light microscope (Leica 1000) and the results were photographed by digital camera (Leica EC3). The photos are completely original. Biometric measurements were performed in some tissues by using Las v4.3 program.

In the anatomical study 3 groups in itself for each replication were created. The total number of cross sections taken from the plants and examined is 90 on 9 preparats for each replication and total 270 values of measurement were obtained by taking 3 from each section. The arithmetic mean of the values of measurements and mean standard deviation were calculated by using Excel computer software and the results were commented.

Results

Some anatomical features of root, stem and leaf of cv. Ceren and cv. Panda varieties

Roots

It is observed that the general shape of cv. Ceren's root is curved. It is surrounded by one sequenced epidermis formed by large and small cells. Parenchymatic cells (cortex) between epidermis and vascular bundles have such a very thin wall that the area between epidermis and bundles looks like a large air space. It is observed that xylem vessels are big and clear and phloems are generally smaller and less than xylem vessels (*Fig. 2a, b* and *c*).

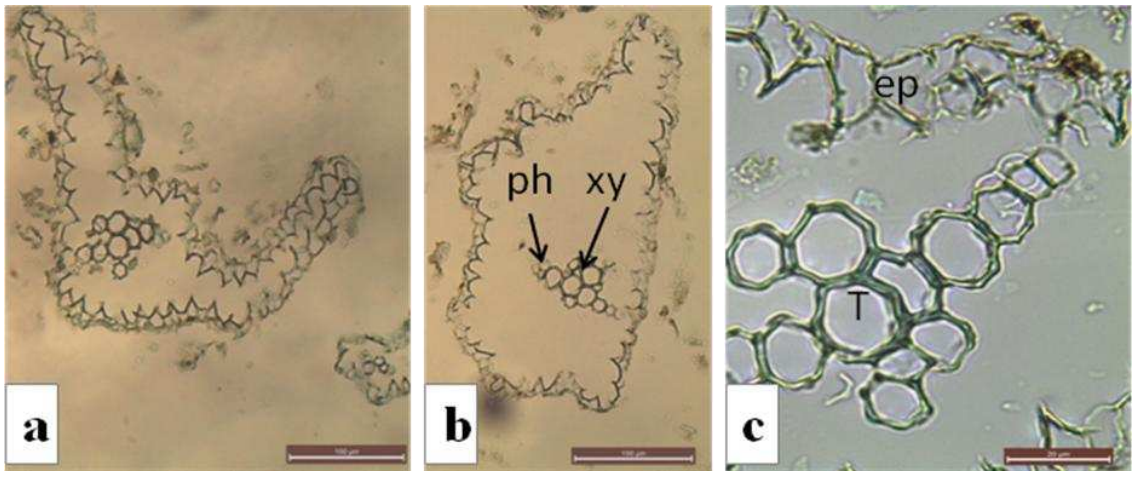

Figure 2. *Root cross section in cv. Ceren. a. general shape of root, bar = 100 µm, b. xylem (xy), phloem (ph), bar = 100 µm, c. epidermis (ep), trachea (T), air space (as), bar = 20 µm*

cv. Panda's root is surrounded by one layered epidermis formed by large and small cells. Endodermis and pericycle are not clearly observed. Vascular bundle is gathered in the centre (*Fig. 3a* and *b*). Parenchymatic cells (cortex) are observed between the epidermis and the vascular bundles (*Fig. 3c*).

Biometric measurements were performed in xylem vessels in roots of two varieties. For these measurements, it was statistically determined that cv. Ceren's xylem vessels are slightly bigger than cv. Panda's xylem vessels (*Table 4).*

Table 4. *Results of xylem vessels diameter in roots (µm) ($p < 0.05$)*

Plants	Mean diameter of xylem vessels ± std deviation
cv. Ceren	9.982 ± 3.980
cv. Panda	8.059 ± 1.721

Stems

Stomate, epidermal hair and glandular hair are observed in stem of cv. Ceren which is surrounded by one layered epidermis (*Fig. 4a, b, g, h* and *i*). There are 1-2 layered chlorenchyma, 4-5 layered collenchyma and 4-5 layered parenchymatic tissue (*Fig. 4a* and *b*). Bicollateral vascular bundles surround the stem like a ring (*Fig. 4c* and *d*). 1-2 layered sclerenchyma around pholem facing in the direction of epidermis and 1-2, sometimes 3 sclerenchyma cells around phloem facing in the direction of pith are observed (*Fig. 4a, c* and *e*). Pith is parenchymatic. Crystal-sands are observed in parenchymatic cells (*Fig. 4f*).

One layered epidermis, stomate, epidermal hair and glandular hair are observed in stem of cv. Panda (*Fig. 5b, g, h* and *i*). There are 1-2 layered chlorenchyma, 3-4 layered collenchyma and 3-4 layered parenchymatic cortex (*Fig. 5a*). Vascular bundles surround the stem like a ring and they are bicollateral (*Fig. 5a* and *c*). 1-2 layered sclerenchyma around phloem facing in the direction of epidermis and 1-2 sclerenchyma cells around phloem facing in the direction of pith are observed (*Fig. 5a, d* and *f)*. Pith is parenchymatic (*Fig. 5e*). Crystal-sands are rarely observed in parenchymatic cells.

Biometric measurements were performed in some tissues in stems of two varieties. For these measurements, there is no clear difference between thickness of cuticle and diameter of xylem vessels of two varieties statistically. It was determined that the

Leaves

cv. Ceren' s leaf is bifacial (*Fig. 6a*). Mesophyll is formed by one layered palisade parenchyma with spaces between the cells and 2-3 layered spongy parenchyma with spaces between the cells (*Fig. 6b*). Big vascular bundle is bicollateral (*Fig. 6c*). Collateral small vascular bundles are embedded into mesophyll and surrounded by bundle sheath (*Fig. 6d* and *e*). It is amphistomatic. They have glandular and epidermal hairs (*Fig. 6f* and *g*). Crystal-sands are observed (*Figure 6e*).

cv. Panda's leaf is bifacial. Mesophyll is formed by one layered generally short-celled palisade parenchyma with spaces between the cells and 2-3 layered spongy parenchyma with spaces between the cells (*Fig. 7a*). Big vascular bundle is bicollateral (*Fig. 7d*). Collateral small vascular bundles are embedded into mesophyll and surrounded by bundle sheath (*Fig. 7b*). It is amphistomatic (*Fig. 7a*). They have glandular and epidermal hairs (*Fig. 7e* and *f*). Crystal-sands are observed (*Fig. 7c*).

Biometric measurements were performed in some tissues in leaves of two varieties. These measurements showed no clear difference between mean thickness of cuticle, lower epidermis and diameter of xylem vessel of two varieties statistically.

Upper epidermis is thicker in cv. Ceren than in cv. Panda. It is determined that cv. Ceren's mesophyll is wider, and its big vascular bundle is longer than those in cv. Panda. Width of big vascular bundle in cv. Ceren is smaller than the one in cv. Panda (*Table 6*).

Discussion

The root of cv. Ceren is formed by very thin-walled parenchymatic cells between epidermis and vascular bundles and these cells could not be clearly observed. Parenchymatic cells in cv. Panda are more thick-walled than in cv. Ceren. Endodermis and pericycle could not be observed in cv. Panda either. According to Sam et al. (2000) structure and functions of all plant organs are affected by water stress. The diameters of root xylem vessels are different from each other in cv. Ceren and cv. Panda. In Tuylu et al., (2018), Malatya Kurucaova variety of tomato was examined and stated that cortex is thicker in the root cultivated in hydroponic culture and the diameters of root xylem vessels are narrower than those in the root cultivated in perlit. Regarding the two studies it is clear that cortex and xylem vessels in the root were affected by water stress.

The anatomical features in the stems and leaves examined are similar to the general anatomical features of Solanaceae family and *Lycopersicon esculentum* Mill. mentioned in Metcalfe and Chalk (1950) and Rost (1996). The fact that both plants have some features such as palisade parenchyma cells with spaces is the result of adaptation which they developed under water stress conditions. According to the results of mean biometric measurements in stems and leaves of cv. Ceren and cv. Panda, they adapted to the condition with histologically different sizes. The mean thickness of epidermis and mean thickness of cortex and collenchyma in stem of cv. Ceren are more than the ones in cv. Panda. Significant differences between thickness of cuticle and diameter of xylem vessel of the two varieties were not observed. In Tuylu et al. (2018) it was determined that cuticle and epidermis are thicker and cortex and xylem vessel are narrower as a

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_33813391
© 2018, ALÖKI Kft., Budapest, Hungary

result of water stress in the stem cultivated under hydroponic system than those cultivated in perlit condition.

According to the results of mean biometric measurements in leaves, significant differences between thickness of cuticle, lower epidermis and diameter of xylem vessels of the two varieties were not observed. The fact that in cv. Ceren upper epidermis is thicker than in cv. Panda is the result of different adaptation of the two varieties to water stress. Sam et al. (2000) studied the effects of water deficit on epidermis of leaf at preflowering stage in *Lycopersicon esculentum* Mill. cv. INCA9 and stated that water stress have slight effects on width and lenght of epidermis cells. Thus, it is understood that the plant also shows epidermal change under water stress as it shows under water deficit. The width of mesophyll in cv. Ceren increases more clearly than the one in cv. Panda. In parallel with this, the length of big vascular bundle in midrib region increases and its width reduces. Tuylu et al. (2018) figured out that midrib region is wider due to water stress in leaf of tomato cultivated in hydroponic system and big vascular bundles are larger than the ones cultivated in perlit condition. They stated that no clear change was measured in other tissues of leaf.

Conclusion

Considering the histological changes and biometric measurements it is understood that adaptation of cv. Ceren and cv. Panda have some differences from each other under the same cultivation conditions. According to the results it is figured out that some anatomical features such as parenchymatic cells, endodermis, pericycle, xylem vessel in root, epidermis, cortex and collenchyma in stem, upper epidermis, mesophyll, big vascular bundle in midrib region in leaf can vary from each other in terms of histologically thickness, width, length, arrangement of cells and etc. in the two different varieties belonging to the same genus cultivated at the same time and under the same condition.

In the study, the two varieties could grow in alternative condition which is out of their natural cultivation condition and it was observed that they could complete their developments in some basic tissues. In this cultivation the roots of plants were exposed to excess water, but both plants adapted to water stress condition and developed by means of some anatomical changes. In both plants no clear anomaly was observed. cv. Ceren and cv. Panda are convenient for cultivation under hydroponic culture mentioned in terms of some basic anatomical features examined. However; features of fruit of the plants should be evaluated in terms of parameters of yield and quality before recommending the producers to cultivate the two varieties under hydroponics. In addition, in the study the anatomical features of the two varieties determined will contribute to other studies.

(Received 28th Feb 2018; accepted 21st May 2018)

Abstract. This study presented the distribution of the largest forest fires in the area of Sanming, Fujian province of China from 2000 to 2009 and focused on the spatial and temporal dynamics of forest fire occurrences. The fire location distribution, occurrence causes, and daily, monthly and annual distribution of fires influenced by weather were examined. The weather data was analyzed using the software FWI Calc. v.10.3.1.106. There were a total of 818 forest fires occurred in the period 2000-2009 that burned 87 million m^2 of forests; the fires have been detected during the fieldwork. The time distribution of forest fire occurrence had a regular pattern daily, and most forest fires occurred between 9 a.m. and 5 p.m., accounting for 92.42% of total fires. It was found that drier and warmer weathers provided favorable conditions for forest fire occurrences, and the majority of serious fires were occurred between 2008 and 2009, which was a period with relatively dry and warm weather. Significant relationships between forest fire occurrence and weather were determined in the study. Because of human activities and more combustible species in Youxi and Datian counties in the Sanming area, the two counties had the highest fire risks.

Keywords: *fire dynamics, forest meteorology, weather parameters, Fire Weather Index (FWI), Canadian Forest Fire Danger Rating System (CFFDRS), Sanming*

Introduction

Over the last decades, scientists and forest managers have begun to explore the emulation of forest fire disturbance in managing forest landscape (Seymour et al., 2002; Cleland et al., 2004; Nitschke, 2005; Ekoungoulou et al., 2017) because forest fire is a key process in regulating vegetation succession, plant regeneration, and maintaining biodiversity in many forest ecosystems (Rollins et al., 2004; Ekoungoulou et al., 2018b). Trees, the major components of forests (Ekoungoulou et al., 2014a and 2014b), absorb large amounts of atmospheric carbon dioxide by photosynthesis (Ekoungoulou et al., 2015), and forests return an almost equal amount to the atmosphere (Ekoungoulou et al., 2018c) by auto-and heterotrophic respiration (Ekoungoulou et al., 2014b and 2014c). Understanding the spatial and temporal variation of forest fire provides a long-term perspective of dynamics of ecosystem processes and vegetation patterns (Gonzalez, 2005; Nonaka and Spies, 2005). Use of forest fire statistics, including records of ignition sources, number of forest fire occurrences, and burnt area, is an effectual method to understand the spatial and temporal characteristics of forest fire (Kasischke et al., 2002; Liu et al., 2015). Variability of climate and fire weather also influences forest fire behaviors and the fire severity at various time scales (Liu et al., 2010).

Different geographical, topographical, and climatic characteristics exist across the vast landmass of China; as a result, forest fire regimes would vary spatially in the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_33933406
© 2018, ALÖKI Kft., Budapest, Hungary

country. Forest fire has been a serious issue in China's forest management; in the period 1950-2000, there were 13,600 fire occurrences per year in China. The yearly average of burned area in the period was approximately 758,000 ha, according to the official report from the China's forestry bureau (Zhang and Qingwen, 2008). Because of climatic differences across China, fire season varies in major forest regions. In the Northeastern China and Inner Mongolia, fire season lasts from spring to autumn. Fire season is from winter to spring in the southern and southwestern China and from summer to autumn in the northwestern China. In China, wildland fires are not distributed uniformly over the country; most of the fires occurred in approximately 100 key counties from 16 main forestry regions (Guo and Fu, 2007). Also, the number of forest fires in China and the burnt area fluctuated largely annually, and the burnt area was over 1 million ha in years 1951, 1955, 1956, 1961, 1962, 1972, 1977, 1987 and 1996 (Zhong et al., 2003).

The increase of human population and human activities has resulted in an increase in forest fire frequency (Guo and Fu, 2007). As modern society has encroached on forests and thereby forest fires threaten the regional economy and the safety of residents, forest fires have become an important issue socially as well as scientifically (Kalabokidis et al., 2002). From the statistical data reported by the Ministry of Forestry, China in 1999, most wildland fires are caused by non-productive fire utilizations such as smoking (accounting for 40.6%). The rest were caused by productive fire utilizations such as prescribed fires for land reclamation (30.9%), lightning and other natural disasters (0.38%), arson (1.52%), and others (21.18%) (Anon, 1999). There is no doubt that much progress has been achieved in forest fire prevention and protection in China since the foundation of the new China (Lifu et al., 2003). However, with the fast growing economy in China, the present situation of forest fire protection is becoming even more urgent. Therefore, the forest fire study in Sanming becomes important. The study focused on spatial and temporal fire distribution, ignition causes, and the influence of temperature, humidity, precipitation and wind speed on forest fire occurrence. The study can help develop local fire management and forest fire prevention projects.

Materials and Methods

Study site

Sanming is located in the northwest of Fujian Province, between 116.22 to 118.39 °E and 25.30 to 27.07 °N, with ~230 km from east to west and ~180 km from south to north (*Fig. 1*). The total area of Sanming is approximately 22,900 km^2, including the urban area of 1,178 km^2. Mountainous area farm land, river and others account for 82%, 7.3%, 8.7%, and 2% of Sanming city, excluding the urban area. Sanming belongs to a sub-tropical climate of monsoon with considerable precipitation and clear presence of four seasons. Annual mean temperature is between 17-19.4°C; average annual precipitation is from 1,565 to 1,795 mm with the maximum annual precipitation 2,255 mm and the minimum annual precipitation 1,131 mm, and average relative humidity is between 79 to 94%.

The forest cover of the city is around 28.26 million hm^2, and by the year of 2000, the forested area in the city had already reached its upper limit with 71% of available lands being forested (Guo and Fu, 2007). Chinese fire (*Cunninghamia lanceolata* (Lamb.) Hook) and Masson pine (*Pinus massoniana* D. Don) account for 76% of the forested area. The dominance of the two species resulted in an overall lack of bio-diversity and

an increasing challenge to the ecological health of the forest in the city (Huang, 2009; Song et al., 2004).

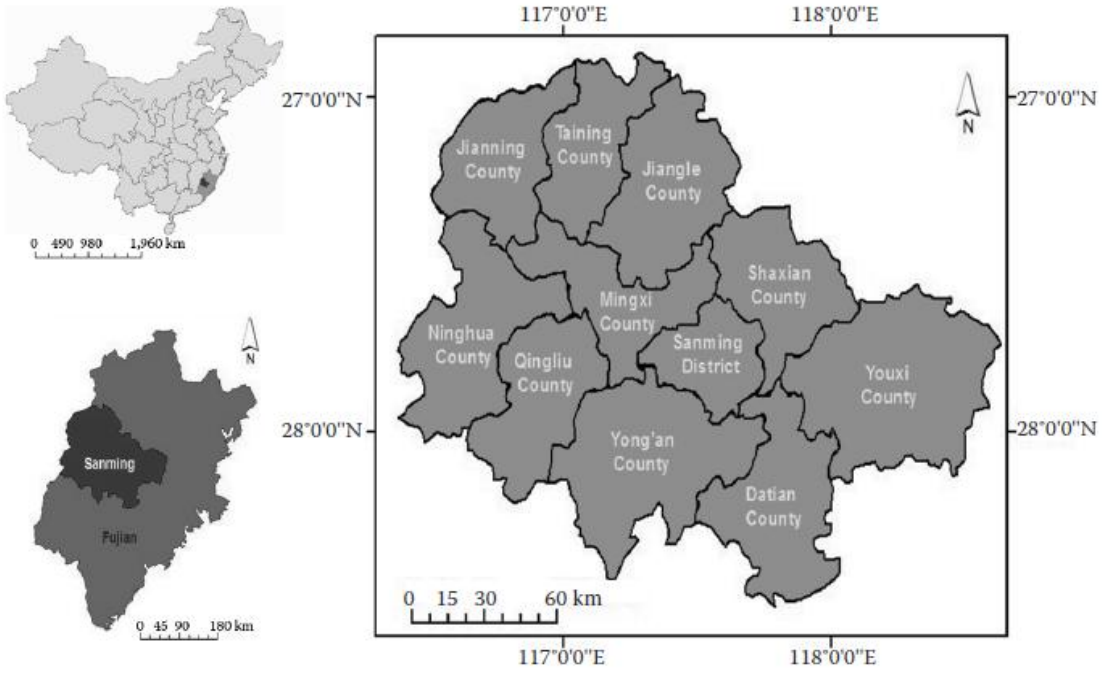

Figure 1. *Location of Sanming city and Fujian Province in Southeast China*

Data collection

In this study we used fire occurrence records provided by the Administrative Divisions of Fujian Province from 2000 - 2009. Each record consists of fire information such as fire locations, fire severity classes, ignition causes and the date of fires. Weather data of temperature, relative humidity, precipitation and wind speed were collected from the Yong'an Meteorological Station, which is located at 117.21 °E longitude and 25.58 °N latitude with the elevation of 206 m. Both fire dandy weather data were analyzed using statistical software Minitab 2002 to find out relationship between forest fire occurrence and weather conditions. The spatial and temporal analyses were conducted using the software FWI Calculator v.10.3.1.106 and the graphic results were prepared using the software SigmaPlot v.10.0.

Data analysis

The Fire Weather Index (FWI) system is the first part of Canadian Forest Fire Danger Rating System (CFFDRS) introduced into New Zealand in 1980. It has proved to be a suitable fire danger rating system for the country. The FWI was evaluated for several seasons before it was introduced for the 1980-81 fire season. FWI is based on weather readings taken at noon standard time and it rates fire danger at the midafternoon peak from 2:00 - 4:00pm. Weather readings required include the air temperature in the shade, relative humidity in the shade, wind speed at 10 meters aboveground level for a mean over 10 minutes; rainfall for the previous 24 hours. FWI calculator v.10.3.1.106 can read the weather input file every 15 minutes after the initial midday reading. If the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

weather station software keep updating this file (e.g., every 10-15 min), FWI Calculator will record the peak temperature and other relevant weather values. The FWI System outputs three moisture codes: the Fine Fuel Moisture Code (FFMC), the Duff Moisture Code (DMC), and the Drought Code (DC), with higher values indicating drier conditions and greater fire danger. The FWI System also generates four fire behaviour outputs based on the above indices: the Initial Spread Index (ISI), the Build-Up Index (BUI), the Fire Weather Index (FWI), and the Daily Severity Rating (DSR), with higher values indicating elevated fire danger. A fire danger rating system should act as a tool on tracking the day-to-day susceptibility of forests to fire, or the system should enable fire managers to properly assess the levels of preparedness and the suppression resources needed to keep fire losses to a minimum. The system should be capable of measuring weather variations that cause the day to day changes in fire danger. The fire danger information provided through the system can be used to define the fire season (Liu et al., 2015), determine appropriate fire prevention measures, assess the likelihood of fire occurrence, determine fire suppression response and resources deployment, inform public, make decisions to close areas at high risk, issue or cancel burn permits, plan and conduct controlled burns.

The graphic results have been prepared using the SigmaPlot v.10.0 (Ekoungoulou et al., 2018a) software. Analysis of Variance (ANOVA) was used (Ekoungoulou, 2014) to test possible differences between fire occurrence among different months and years. Fire ignition causes and their spatial distribution were showed as topographic maps using the version 9.3 of ArcGIS software.

Results and Discussion

Spatial distribution of three classes of forest fire

Spatial distribution of forest fires in Sanming was showed in *Table 1*, and the fires were categorized into three classes. Class 1 means fire warning, Class 2 means ordinary fire, and Class 3 indicates serious fire. According to this classification scheme, the fires that burn less than 1 hm^2 are classified as Class 1 fire; the fires that burn between 1 hm^2 and 100 hm^2 are Class 2 fires, and Class 3 fires are the ones burn more than 100 hm^2. There were 133 Class 1 fires, 674 Class 2 fires and 11 Class 3 fires occurred in Sanming between 2000 and 2009, respectively, and total fire area and total burnt areas in this period were 11,730.27 hm^2 and 8,721.16 hm^2, respectively. In the southeastern Youxi and Datian counties, Class 3 fires occurs more frequently than in other counties, and burnt areas in the two counties were relatively large compared to other counties (*Fig. 2*). There were 172 and 146 fires, and burnt areas were 1,703.70 and 2,350.50 hm^2, respectively in Youxi and Datian counties from 2000 to 2009. So, Datian counties was considered the highest vulnerable to forest fire in Sanming city during the study period. The results revealed that Classes 1 and 2fires distributed in all countries, but only Class 1 fires occurred in the Sanming district from 2000 - 2009.

Ignition causes

According to the statistical data of forest fire occurrences in the last 10 years in Sanming, a substantial number of forest fires were caused by human. *Fig. 3* indicates that 64.97% of fires were caused by waste-land-burning, followed by 9.41 of careless smoking, 4.48% of fire from outside, 3.47% of children-playing-fire, and lightning of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_33933406
© 2018, ALÖKI Kft., Budapest, Hungary

0.82%. Clearly, most forest fires in Sanming are caused by human activities, whereas lightning only cause a small number of forest fires. Waste land burning is the major causes of forest fire in Sanming, and such caused fires were unevenly distributed in the study area. A total of 462 fires were caused by waste-land-burning; among these fires, 60 were Class 1 fires; 398 were Class 2 fires, and only four Class 3 fires, respectively. *Fig. 4* indicates that most of waste-land-burning fires were n Youxi (172 cases) and Ninghua (95 cases) counties, and in the two counties human disturbance was mainly cause for forest fires. The spatial and temporal changes of forest fires in the study are studies in the following aspects: daily changes, monthly and seasonal variations, and annual changes.

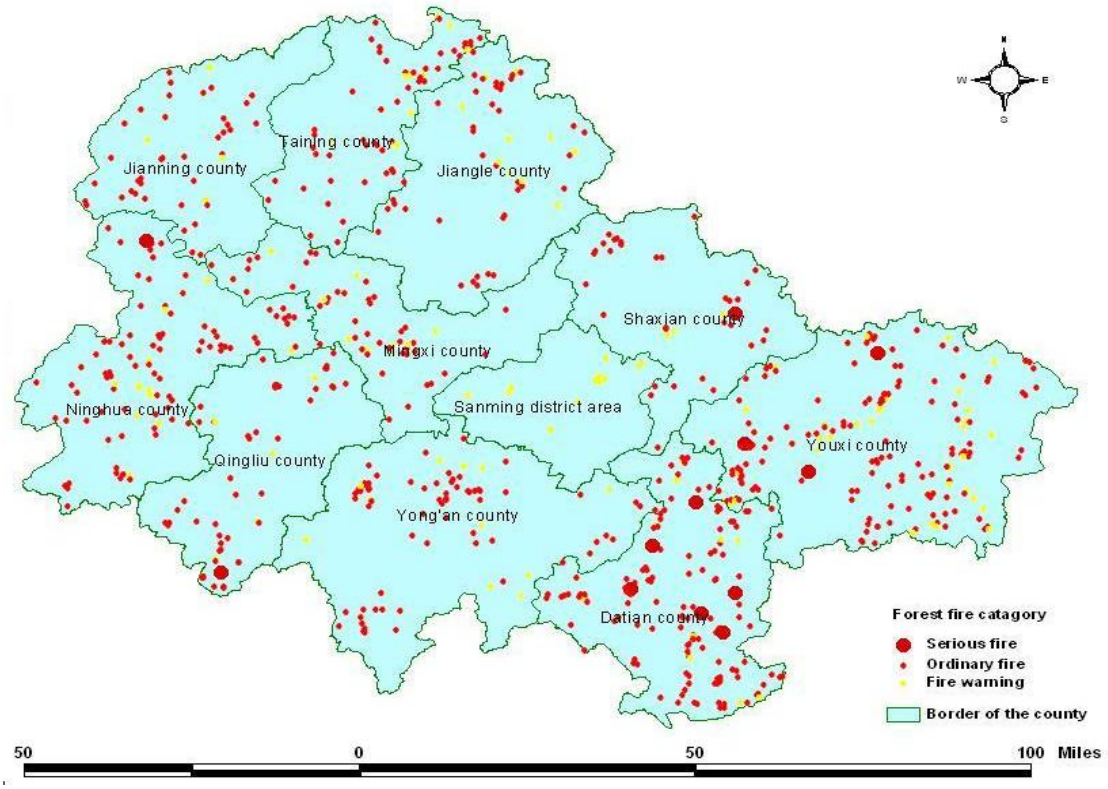

Figure 2. *Spatial distribution of three classes of forest fire the study area*

The daily variation of forest fires

In the *Fig. 5a*, it was found that most of the forest fires occurred in Sanming between 9 a.m. to 5 p.m., and during this time period 92.42 % of the total fires, or 161 fires, occurred at 2 p.m with a burnt forest area 2,271.10 hm^2 (*Fig. 5b*). No fire has ever occurred from 1:00 am to 5:00 am, and only nine fires occurred between 5:00am to 6:00am. This is because there were almost no human activities in such time period daily and weather at such times were relatively cool.

Fig. 5c and *Fig. 5d* showed the temporal distributions of fire frequency and burnt area along the day time from 1:00am to 11:00pm. The fires caused by waste land burning peaked mainly from noon to 3 p.m., with a total of 308 fires burnt 5,213.90 hm^2 areas. The fires with unknown causes occurred from 9 a.m. to 9 p.m. with a total of 108 fires and a burnt area of 1,207.70 hm^2, which were comparatively lower than those of

the waste land burning fires. Lightning-caused fires mainly occurred from noon to 5 p.m., and the total burnt area was 120.10 hm^2.

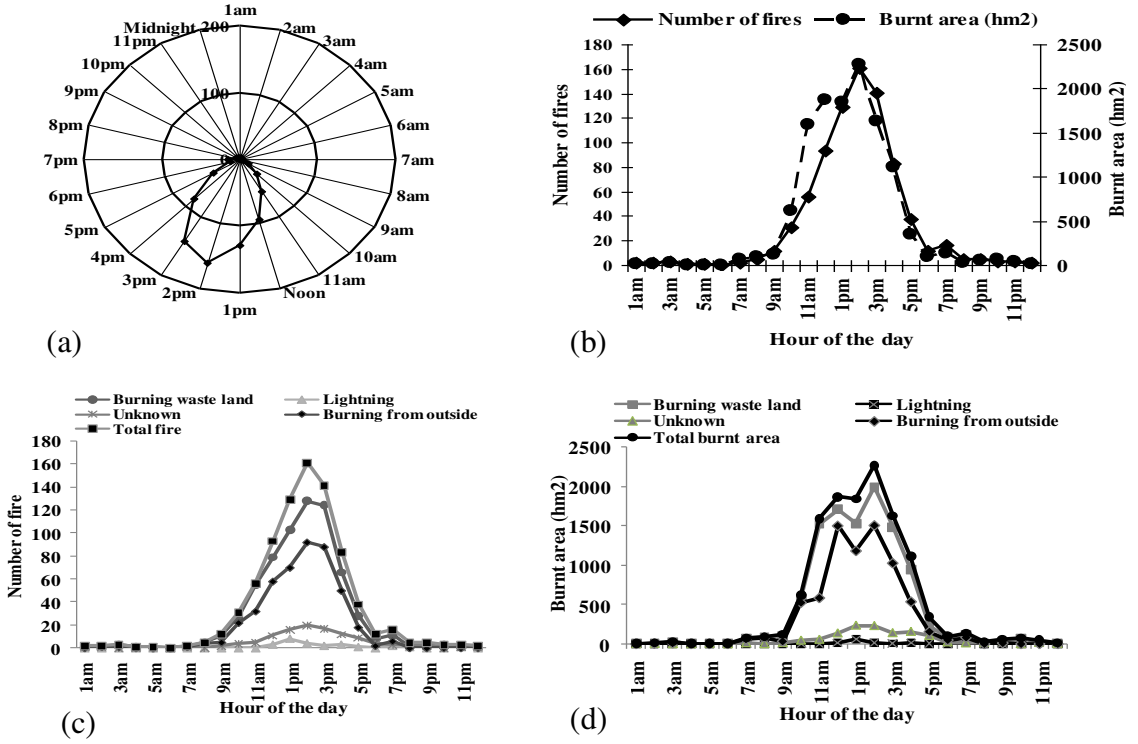

Figure 5. *Forest fire and burnt area distributions in a day time*

Monthly change of forest fire

As *Fig. 6a* indicates, over the 10-year period 2000- 2009, fire frequency was higher in spring (January-March) than in other seasons., because during the period of January-March weather are relatively dry and relative humidity are low (*Fig. 6b*). March is the month with most forest fires occurred and large areas burned, followed by February and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_33933406
© 2018, ALÖKI Kft., Budapest, Hungary

January. During the period 2000-2009, there were 269 fires occurred in March that burned 4,976.40 hm^2, which accounted for 33% of fire occurrences and 41% of total area burnt, respectively. February and January were ranked as the second and third in terms of fire frequency and areas burned; there were 179 fires in February with an area burned of 3,730.50 hm2, which accounted for 22% of total fire occurrences and 31% of areas burned. The same figures for January were 87 and 1,170 hm^2, which were 11% of total occurrences and 10% of areas burned.

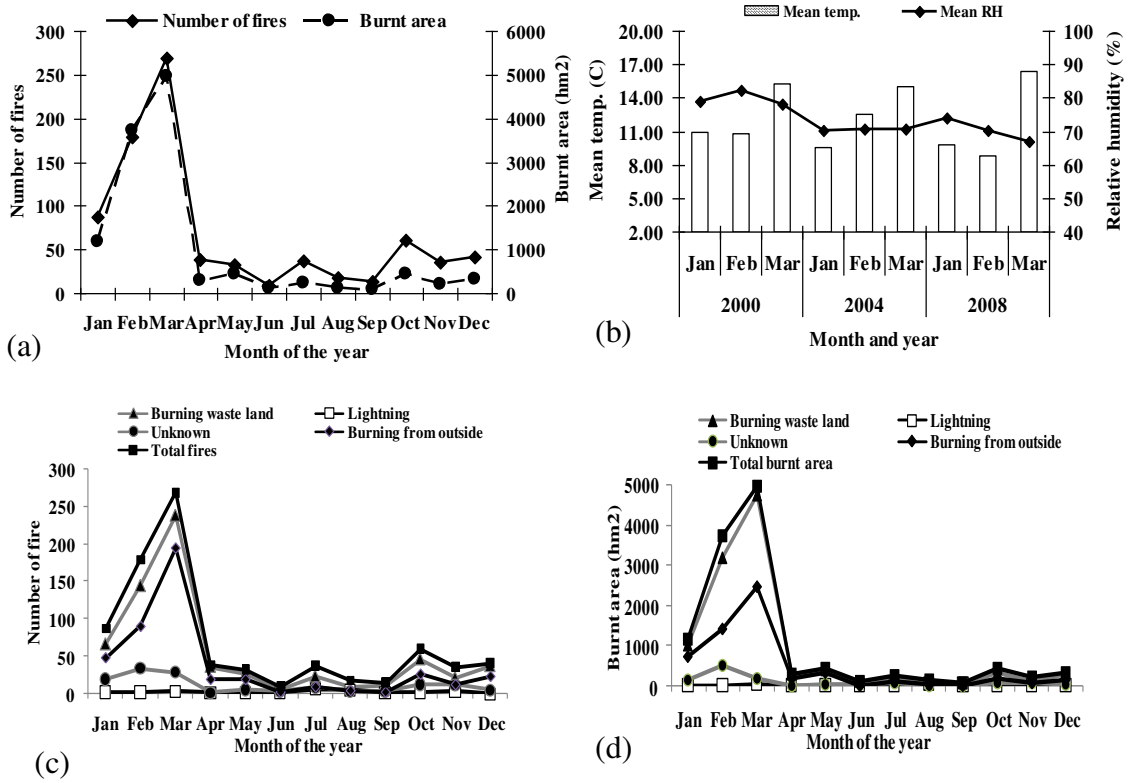

Figure 6. *Forest fire and burnt area distribution in the month of the year*

Fig. 6c and *Fig. 6d* contain the monthly distributions of fire frequency and areas burned by different ignition causes. Waste land burning for crop production and burning from outside sources were major ignition causes that accounted for about 70% of total fire occurrences 84% of all area burnt in three months from January to March. The period of May to December appeared to be the time least prone to forest fires. The fires of unknown causes were most likely to occur in the beginning months of a year and the frequency of such fires was highest in February. Lightning-caused fires were the least serious in the study area.

Forest fire annual distributions

Fire situations varied from year to year in the period 2000-2009, and the statistics showed in *Fig. 7a* and *Fig. 7b* suggested that the years with more than 100 forest fires and an area more than 1,500 hm^2 were 2000, 2004, 2008 and 2009. Other years suffered less forest fires. Waste land burning, burning from outside sources, and unknown causes were the three major ignition causes. The severity of such fires was raising from 2007,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_33933406
© 2018, ALÖKI Kft., Budapest, Hungary

and in 2009 the total forest occurrences and areas burned by such fires were 165 and 3,861.30 hm^2, respectively.

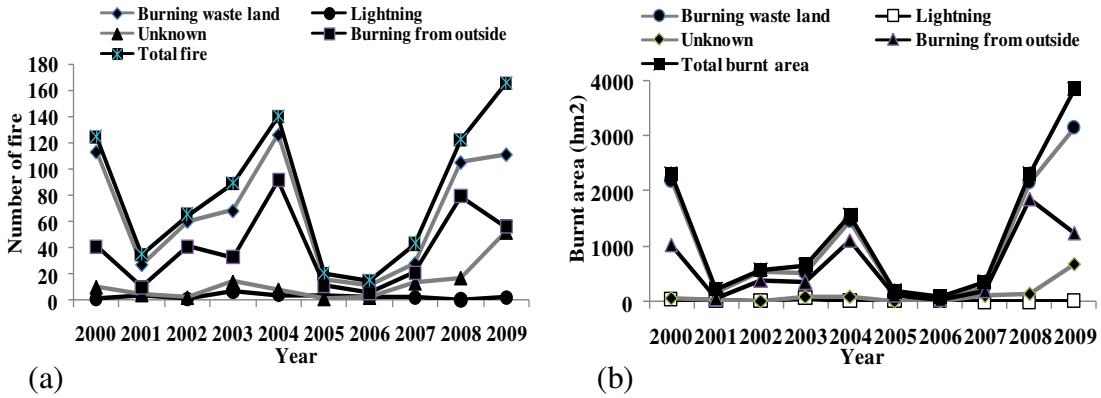

Figure 7. *Forest fire annual distributions in Sanming*

Influence of forest fire by weather parameters

Forest fires are more likely to occur when it is dry and less likely to occur when it is wet and with low temperature. *Fig. 8a* and *Fig. 8b* depicted decreasing trends of rainfall and relative humidity caused by increasing trends of temperature and wind speed. Such weather change patterns lead to a dry weather condition that favors more forest fire occurrences. All serious fires occurred in the day time between 10:30 and 16:15 hours because of dry and warm weather during this time period of the day. In Sanming, most of serious fire occurred in 2008 and 2009 in the early noon when temperature is maximum (> 29 °C), wind speed reaches > 3 m/s, and relative humidity is low with no precipitation (*Table 2*).

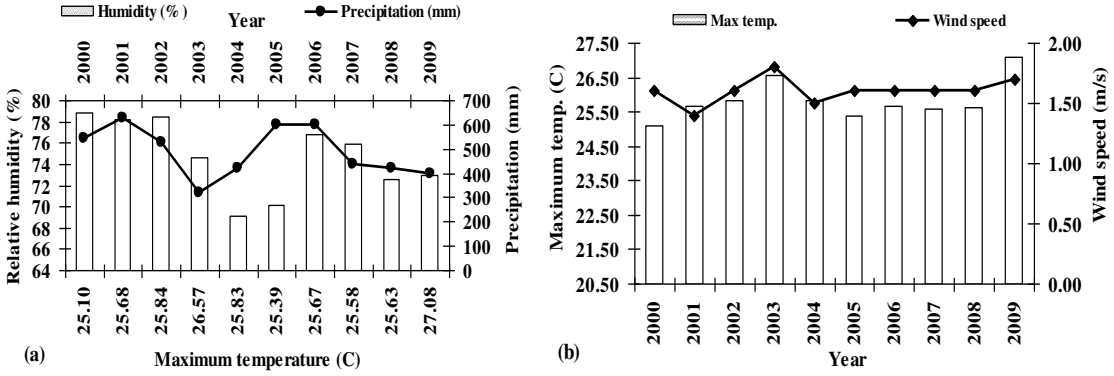

Figure 8. *Weather parameters change trend in Sanming between 2000 - 2009*

Table 3 consisted of the F-test results on annual and monthly forest fire distributions. Have significant relationship with changes of temperature, precipitation, relative humidity and wind speed, and such atmospheric movement prone to highest forest fires in Sanming.

Sanming zoning map based on fire proneness

Sanming can be divided into three zones based on fire proneness, i.e., the high risk zone, the reasonable risk zone, and the low risk zone (*Fig. 9*). The southeasttern Youxi and Datian counties are delineated as the high fire risk zone (Class I fire danger area) because of high human disturbance and concentrated distribution of more combustible Masson pine forests. The reasonable risk zone (Class II fire danger area) includes the northwestern Jianning, Mingxi, Ninghua, Qingliu, and South Yong'an counties; the human disturbance in these counties is minimal and the area has been covered by less flammable Chinese fire forest. Taining, Jiangle, Shaxian counties and Sanming district belong to the low risk zone (Class III fire danger area) where only few fires occurred in small. The vegetation cover in the zone is less combustible species of eucalyptus and bamboo. The map provides a useful tool for local forest managers for planning and executing their fire prevention and suppression exercise.

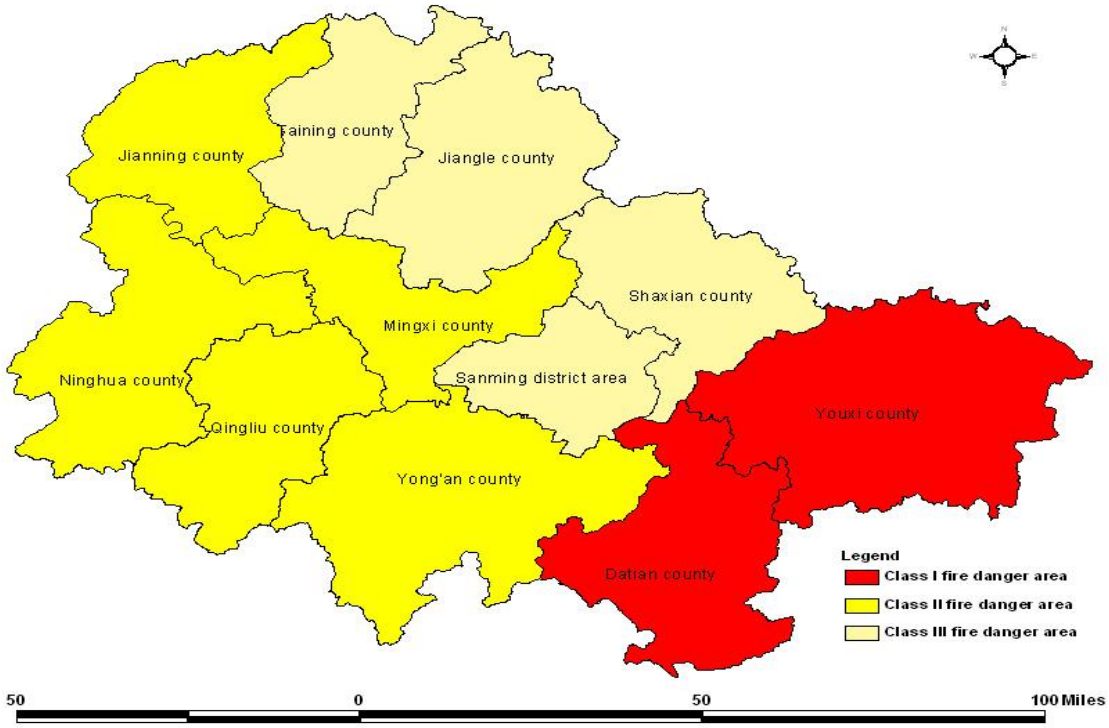

Figure 9. *Sanming zoning map based on forest fire proneness*

In Sanming city, most forest fires are caused by human-being, and lightning and arson fires only make up a small portion of all fires in the period 2000-2009. Our results are similar to the finding by (Zhong et al., 2003) that most forest fires in China are human-caused. Temporal and spatial analyses of forest fires are important for successful forest fire management (Keane et al., 2003). In the current study, we analyzed the temporal and spatial patterns forest fires based on forest fire statistics between 2000 and 2009 in the city. The highest numbers of fires occurred in Sanming around 2 p.m., and there are similar studies in other localities in China that forest fires are more likely to occur at 2:00 p.m in Beijing, Wuyishan Mountain and Hangzhou city (Huang, 2009; Liu et al., 2009). A study conducted Toronto, Canada illustrated that the fires incident density changes over time (in hour), the period between after-lunch time and the beginning of evening time seems to have the densest patterns of forest fire appearance (Asgary et al., 2010). The study also found the important number of occurs of forest fire in the spring and the feeble number of fire damage occurs in the autumn. The time-series processing of monthly forest fire occurrences and zone burned did show a strong seasonal pattern. Spring season was highly incident of fire of forest occurrences in Sanming and feeble fire of forest distributed in other seasons of year. Dry weather, heavy sunshine, low humidity and high wind speed from January to March explains this district difference among seasonal and monthly forest fire characteristics.

Forest fire occurrences goes upward over time especially the ascending trend after the year 2007 and in 2009 the highest number of fire (165 cases) and areas burned (3,861.30 hm^2) was found there. Weather and climate influence forest fire comportment and account for the variability in fire harshness at different time scales. Valdiya (2006) asserted that the accretion in temperature increment the chance of fire appearance

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_33933406
© 2018, ALÖKI Kft., Budapest, Hungary

whereas precipitation and humidity have the different relation with fire. The data of weathers processed regarding this study have also strong relationship with forest fire occurrence. The counties throughout all of Sanming were classified into three group based on fires of forest proneness to examine the spatial assessment of fires of forest. In Sanming, many fires of forest were occurred in spring from January to March and a little forest fires can be registered in others seasons of the year. Dynamic of the wildland fires were clearly and detected in Youxi County and Sanming District, respectively. Southeast areas had larger forest fire appearances compare to other areas because of heavy forest use by human and more combustible species, a well-developed firefighting system with rapid suppression prevented large forest fires about the fire risk zone.

Conclusion

Fujian is a green province in China with forest coverage of 65.95%, and Sanming is one of the green cities in the provinces with forest coverage of 71%. Forest fires are recurrent disturbance events in Sanming because the city is dominated by over-matured, more combustible and flammable species. In this study, we found that the temporal and spatial patterns of forest fires exhibited considerable variations along time and by changing weather characteristics. The new insights into the temporal and spatial dynamics of forest fires in Daming could be applied to help allocate firefighting resources in fire season for immediate fire suppression in the southeastern China. Also, our results can be used to verify and readjust the fire precautionary period. During the 1960s, a wide range of people migrated to Sanming from other parts of Fujian and the increased urbanization and human activities increased opportunities for fire ignition. The results from this study can be used to help closely monitor fire danger conditions in the city. For example, population can be notified that January-March is the period most venerable to fire through some education programs, such that people would be more careful in their life and production activities in the period. Also, our results can be incorporated into legislation such that some practices in forest areas that are conducible to fire could be banned legally. According to this research's results, it's recommended to set and slopes, and to collect weather and forest fire data daily in Fujian area. These findings indicate that either the frequency or the mean length of prolonged weather, alone, cannot fully describe the short-term climate influence of an area.

(Received 5th Mar 2018; accepted 21st May 2018)

Abstract. Plankton is the basis of many food webs and is the main food of aquatic trophic chains. The primary productivity achieved by phytoplankton depends on the availability of nutriments. Phytoplankton biodiversity of two natural connecting lakes (Lella Fatma and Zerzaim) in the region of Megarine in South East of Algeria was studied during the period from January 2016 to December 2016. The relationships between the biomass of phytoplankton and the physicochemical properties of water were assessed in 28 genera of phytoplankton belonging to five classes (Mediophyceae, Coscinodiscophyceae, Bacillariophyceae, Euglenophyceae and Cyanophyceae). The statistical analysis performed during this study clearly shows that there is a strong correlation between differing physicochemical water parameters of the studied lakes and the influence on the phytoplankton population diversity.
Keywords: *phytoplankton, Megarine, lakes, diversity, nutriments*

Introduction

Natural lakes in arid areas constitute an important source to both ecological equilibrium and economical uses and in this ecosystem, biotic and abiotic components interact with them and determine the ecological statue of ecosystem (Awah, 2008). Population growth and the economic development are responsible for major modifications of water and the aquatic cycles are often perturbed by the excessive contributions in nourishing elements (Flandroy et al., 2018).

In addition to enriched nutrient content, these inputs induce an enhanced vegetation growth leading to an anarchic algal development, which propagate the unsightly appearance of water plans, emanation of unpleasant odors, death of aquatic species (Benredjeb and Romdhane, 2002; Brient et al., 2001). This has a detrimental effect on valuable ecosystem services, such as water supply, production, recreation, aesthetics, and more importantly the availability in sufficient quantity and quality that contributes to the maintenance of health. Enhanced anthropogenic activities deteriorate water quality (Chukwu et al., 2008) and impair their basic use through the process of pollution (Hur and Jung., 2009; Wu et al., 2005; Zhang et al., 2009).

Algae are widely present in environments, such as streams, lakes and rivers and although relatively inconspicuous, they have a major importance, in terms of ecology and in relation to human use of natural resources. The maximum production of phytoplankton is obtained when the physicochemical factors are at optimum level (Muhammad et al., 2005).

The relation between the biodiversity and the functioning of the ecosystems is a fundamental ecological question and it is essential to know the potential effect of various abiotic and biotic elements (Zhang et al., 2018).

Phytoplanktons are highly diverse group of photoautotrophic organisms with unicellular reproductive structures, which are important for aquatic habitats (Ariyadej et al., 2004; Welker, 2008). They are important primary producers in the base of the food chain, constitute a vital link and an important biological indicator of the water quality (Laskar and Gupta, 2009). Maintenance of a healthy aquatic ecosystem depends on the biotic properties of water and the biological diversity of the ecosystem (Hillebrand et al., 2017).

In order to visualize the state of lakes in the Saharan region of Algeria, we have studied the spatiotemporal distribution of phytoplankton of two Saharan lakes during the year 2016, to determine the phytoplankton diversity and the abiotic factors responsible for their distribution.

The main objectives of the present study were (i) to measure the physicochemical factors of both lakes, (ii) to establish the inventories of phytoplanktons and (iii) to determine the spatiotemporal variations.

Material and methods

Study site

Megarine (Arabic: المقارين) is a town and commune in Ouargla province Algeria, it is located just North of Touggourt city. The region is made up of a large area of palm plantations surrounding an oasis network that extends from Sidi Slimane beyond Touggourt through to Balidat Ameur. Beyond the oases is the arid and barren landscape of the Sahara, featuring areas of sand dunes (ergs) and flat rocky plains (regs). The region of Megarine is approximately 285 km² (Dubost, 2002) in area and is located in the center of Touggourt region which is limited to the North by Sidi Slimane, to the South by Meggar and on the West by el Alia. The approximate meteorological conditions of the area are a mean annual precipitation 35.05 mm, temperature 23.3 °C, relative humidity 42.8%, visibility 12 km and wind speed is 12.4 km/h (ONMT, 2016) and the climate is hyper-arid, with a long dry season.

The lake of Megarine is divided into two small lakes namely Lella Fatma and Zerzaim (*Fig. 1*). Lella Fatma is located at latitude 33°12′21″ North and longitude 06°05′54″ East and Zerzaim lake is located at latitude 33°12′12″ North and longitude 06°05′50″ East. The two lakes are connected to each other by a natural trench but still distinct during the rainy period. The lakes are covered with *Juncus* and other macrophytes like *Phragmites*, *Tamaricaceae*, etc…

Sampling sites and physicochemical analysis

Sample capturing used 0.5 l PVC bottles and were rinsed with distilled water and rinsed with sample water pre-sample collection. Samples were taken from a depth of 20 cm each month for one year (2016), at the five previously mentioned points of each lake (*Fig*. 2, *Table 1*).

Some parameters are measured in situ, such as: temperature, electrical conductivity, pH and dissolved oxygen, using a multi-field parameter (Multi 350; SET5, Germany), while other parameters such as: nutrients (nitrogen compounds (NO_2^-, NO_3^-, NH_4^+) and PO_4^{3-} phosphates), were determined by using the standardized methods of Rodier (1996) using a spectrophotometer (60310) at the laboratory of the Scientific and Technical Research Centre for Arid Areas (CRSTRA), Biophysical Station, Touggourt, Algeria.

Simultaneously, to the abiotic data, phytoplankton samples were taken at the same points using a conical net ending with a collector and the collected phytoplankton samples were preserved in small plastic containers in 4% formalin (Anderson et al., 2002; Cemagref, 2007). Water samples containing the algae were collected from between 20 and 40 cm depth, away from the shore in order to have all the ecological types of algae and several techniques have been used, pressing plants and other submerged substrates and scraping from submerged or simply wet stones, branches or debris (Bourrely, 1966; Iltis, 1980). The harvested samples were placed in opaque glass jars previously washed and labeled (date of harvest, name of the study station and sampling point).

The determination of the different taxa that we concentrated by a net, was made in the laboratory under a microscope; for the systematic study, a series of specialized books of determination were consulted (Germain, 1981; Komàrek and Anagnostidis, 1994, 1997; Krammer and Lange-Bertalot, 1991, 1986).

Statistical analyses

Relative abundance and frequency were realized in order to evaluate the importance, the place and influence of species within a stand. Statistical analysis (correlation and correspondence analysis) was performed using Statistica 10 software, to remove the effects between the abiotic and biotic components.

Results

Physicochemical characteristics

During the study period, the region was characterized by: an air temperature average of 23.3°C (max = 33.5 °C in July and min = 12.7 °C in January), the annual rainfall of 49.6 mm with highest value in January (20.55 mm) and lowest in July (0 mm), and the average annual wind speed of 12.4 km/h (O.N.M.T., 2016).

Physicochemical characteristics of our lakes showed that: water temperature average ranged from 22.86 °C in Lella Fatma lake and 22.37 °C in Zerzaim lake. The temperature of water trace a seasonal evolution (*Fig. 3a*) relatively related to air temperature, which increases in summer (El Haouati et al., 2015). The minimum values are found in the winter with typical 16 °C in January for two lakes, and the maximum during August with 30 °C in Lella Fatma Lake and 29 °C to the Zerzaim Lake. The temperature augmentation is due to the absorption of the Sun's rays (Zheng et al., 2015).

In general the change in pH in the two lakes has a trend that varies between 7.46 and 8.6. For both lakes, these values are close to neutral (over 7). This deviation in the alkalinity was due to a good photosynthetic activity and also to the nature of the ground (Parinet et al., 2004). Aquatic plants consume dissolved CO_2 (by respiration) and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

displace the calcium-carbon balance, this tends to decrease the concentration of H^+ ions caused by the increase in pH, which is a good indicator of photosynthesis (Nagaraju et al., 2018). The pH value indicates the trophic state of a lake: an acidic water surface is oligotrophic, a neutral water surface is mesotrophic and an alkaline water surface is eutrophic (Stager et al., 2018).

The electric conductivity average value was 43.8 mS/cm in Lella Fatma Lake and 38.86 mS/cm in Zerzaim Lake, these results obtained showed a fluctuation in the interval of 11.4 and 76.8 mS/cm, which is higher in summer (*Fig. 3b*). The electrical conductivity is proportional to the amount of dissolved ionisable salts, it is a good indicator of the degree of mineralization of water, in our case the mineralization was high (S.E.E.E., 1996).

Dissolved oxygen variation is related to several factors, mainly temperature and salinity (Franco, 2017). The mean values of dissolved oxygen during the study period were 2.56% (min: 0.13%, max: 13.84%) for Lella Fatma Lake and 2.63% (min: 0.12%, max: 11.07 mg/l) for Lake Zerzaim. The high values of dissolved oxygen were found in the month of May and the autumn season; this elevation was due to the air movement (wind) (*Fig. 3c*).

Phosphorus and nitrogen are the two main nutrients essential for plant growth and are naturally present in soil, rock and vegetation. An accelerated load of phosphorus and nitrogen from anthropogenic sources can cause harmful algal blooms and is one of the biggest problems facing many countries around the world.

Nutrients observed during the study had an average of nitrogen components of 7.97 mg/l in total within Lella Fatma lake and 9.85 mg/l in Zerzaim lake (*Fig. 3d*).

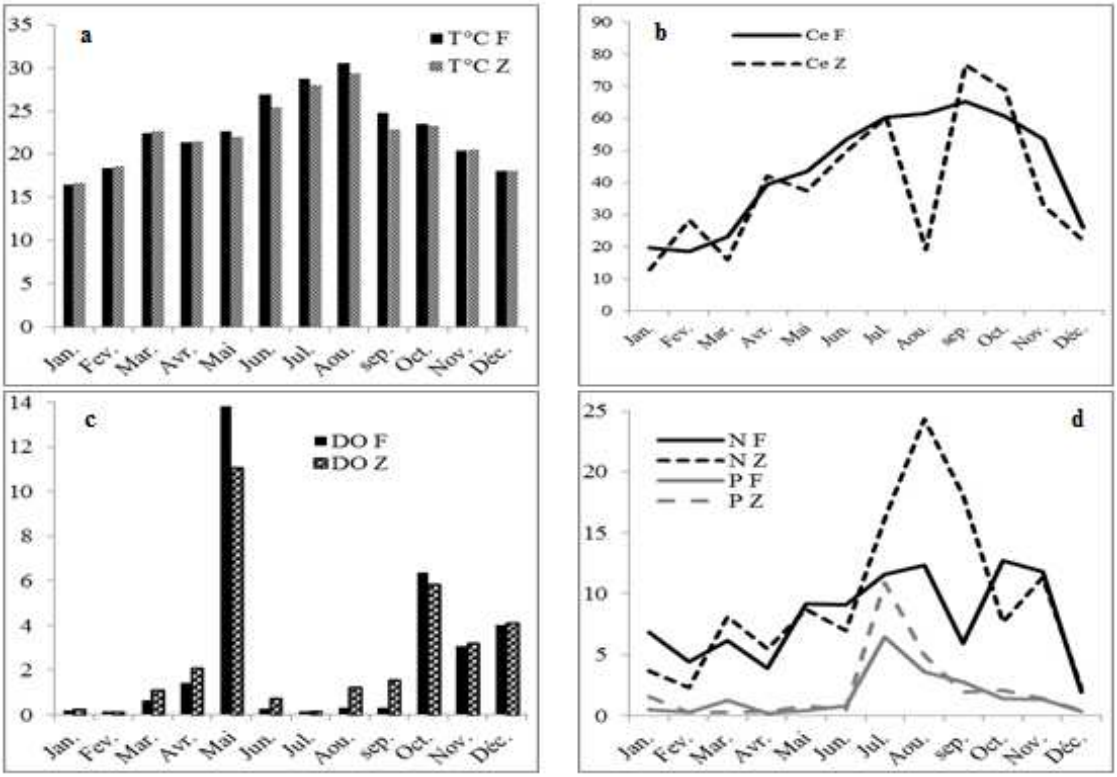

Figure 3. *Annual variation of the physicochemical parameters of the two lakes.* ***a.*** *Water temperature,* ***b****. electrical behavior,* ***c.*** *dissolved oxygen,* ***d.*** *nutriments N & P*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

The N/P ratio (Redfield, 1963) of ambient concentrations may indicate the limiting nutrient. N/P ratio < 16/1 indicates nitrogen limitation, while phosphorus limitation occurs when N/P 16/1 (Goman et al., 2017).

The graphs in *Figure 3d* demonstrate that the values of nitrogen in totality are higher than phosphorus' values.

To determine whether it is phosphorus or nitrogen that limits the development of algal biomass, the most frequently used method is to compare the value of the total nitrogen/total phosphorus (N/P) ratio measured in water with that measured in a non-deficient algal population. If results show that an N/P ratio is above 7.2 it indicates a phosphorus limitation and an N/P ratio of less than 7.2 is due to nitrogen limitation (Goman et al., 2017). The application of this criterion indicates that phosphorus is the limiting factor in the lakes, where it was found that the N/P ratio averaged at 4.98 for Lella Fatma lake and 4.58 for Zerzaim lake.

Phytoplankton biodiversity

Diversity, abundance and dominance of phytoplankton community of lakes were studied during January 2015 to December 2015 with a total of 58 spices belonging to 20 family, 14 orders, 5 classes and to 3 phylums (Bcillariophyta, Euglenophyta and Cyanobacteria) being observed. A total of 23 species of Cyanophyceae, 21 species of Bacillariophyceae, 12 species of Mediophyceae, 1 species of Coscinodiscophyceae, and 1 species of Euglenophyceae (*Table 2*).

Frequency and spatiotemporal distribution of phytoplankton species

According to the calculation of the relative abundance that is based on the number of individuals observed under the microscope, phytoplankton populations exhibit fluctuations in abundance as a function of time and space. This spatiotemporal variation (*Fig. 4*) differs from one species to another, and in this study was as follows:

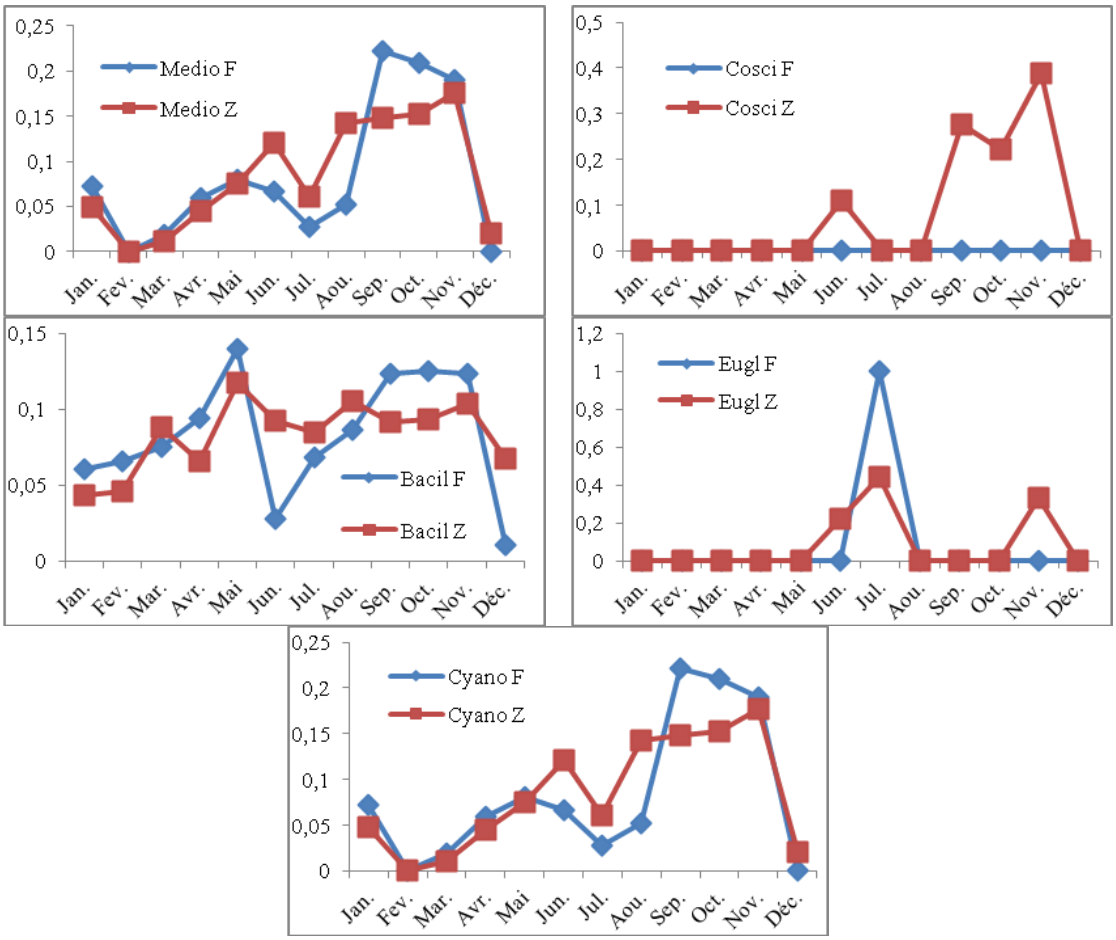

Figure 4. *Spatiotemporal variation in relative abundance of phytoplankton in lakes (Lella Fatma & Zerzaim) (2016). (Cyano: Cyanophyceae, Bacil: Bacillariophyceae, Medio: Mediophyceae, Cosci: Coscinodiscophyceae, Eugl: Euglenophyceae)*

Cyanophyceae forms the most dominant group with 23 species, or 39.7% of the total phytoplankton community andare represented in the majority by the genus Chroococcus.

Bacillariophyceae forms the most diverse group, with 21 taxa, or 36.2% of the entire population, the representative species of the group are: *Achnanthes minutissima*, *Fragilaria, Mastogloia and Nitzschia.*

Mediophyceae, this class contains 12 species, with a proportion of 20.7%, dominated by genre *Amphora* and species *Cocconeis placentula*.

The two final groups **Coscinodiscophyceae** and **Euglenophyceae** are represented by only one species respectively: *Melosira dickiei* in Zerzaim Lake only and *Phacus orbicularis*in both lakes.

© 2018, ALÖKI Kft., Budapest, Hungary

The influence of environmental variables on the distribution of phytoplankton groups in the Megarine lakes' was assessed using PCA analysis (*Fig. 5*).

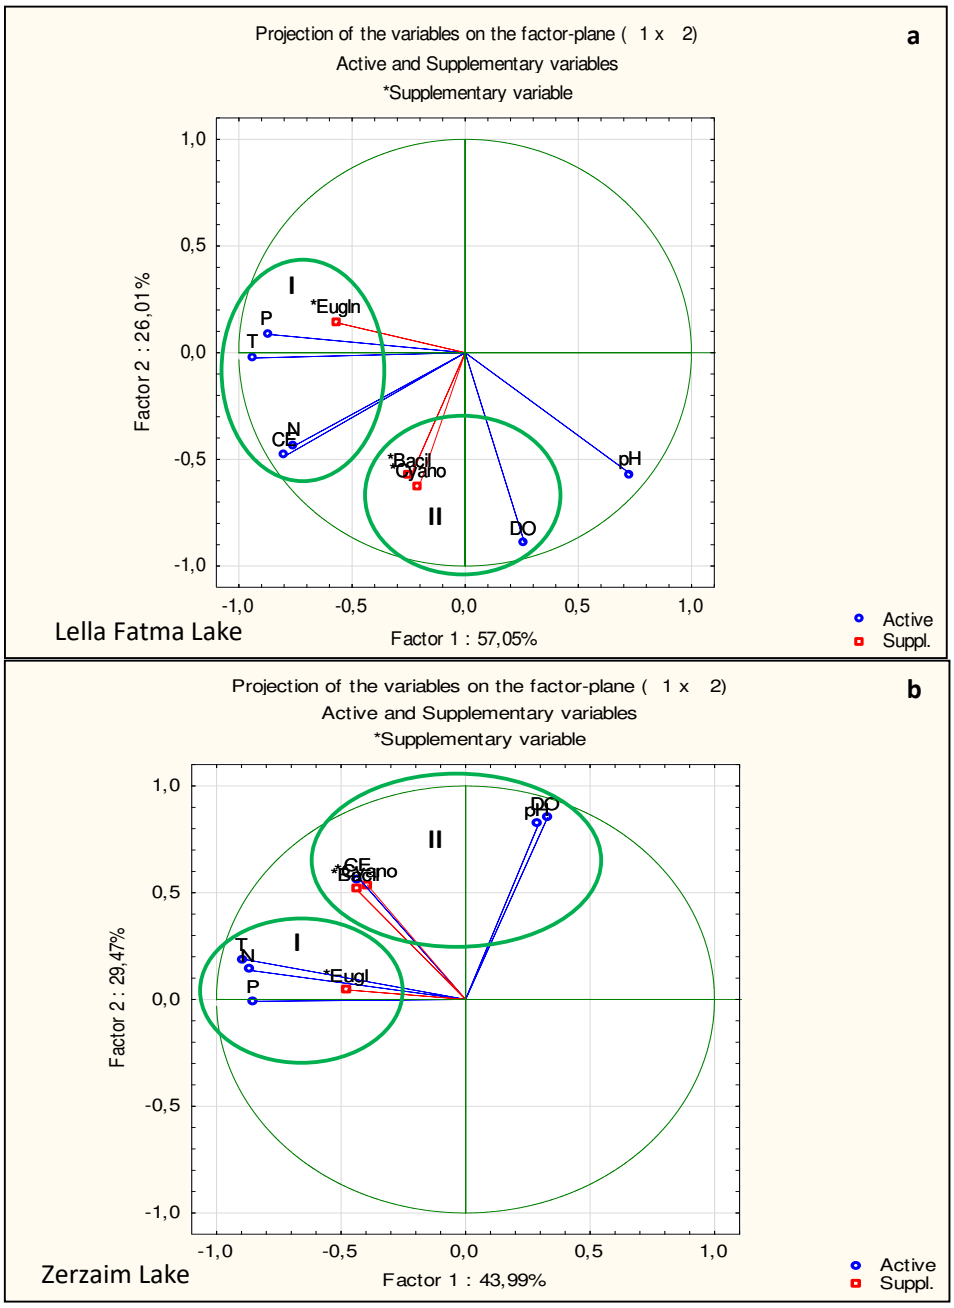

Figure 5. *Principal components and Classification Analysis diagram of environmental variables and phytoplankton groups in lakes (Lella Fatma & Zezeim) during period study (2016). (T: water temperature, pH: hydrogen potential, CE: Electric conductivity, DO: Dissolved Oxygen, P: Phosphate, N: nitrogen elements, Bacil: Class Bacillariophyta, Eugle: Euglenophyta, Cyano: Cyanobacteria)*

The PCA of the biotic and abiotic parameters, in the two studied lakes, showed that the first two axes F1 and F2 contain most of the data since they present 83.06% of the total inertia for the Lake Lella Fatma and 73.46% for Lake Zerzaim. Examining the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_34073419
© 2018, ALÖKI Kft., Budapest, Hungary

correlations between the axes and the different components makes it possible to explain the meaning of each axis in the structured distribution of the variables clouds.

"Lella Fatma" Lake: The F1 axis (57.05% of total inertia) is mainly correlated with temperature, electrical conductivity and nutrients (nitrogen and phosphorus), as long as the F2 axis (26.01% total inertia) is mainly bound with dissolved oxygen (*Fig. 5a*). The PCA allows for discrimination of the two groups:

Group I contains the Euglenophyta, directly proportional to the presence of nutrients, water temperature and electrical conductivity and from this a conclusion can be made that the axis represents organic matter mineralization phenomenon.

Group II, the Bacillariophyta and Cyanobacteria prefer well-oxygenated waters, therefore this axis relates to eutrophication.

"Zerzaim" Lake: The F1 axis (43.99% of total inertia) is correlated in particular with temperature and nutrients (nitrogen and phosphorus), as long as the axis F2 (29.47% of total inertia) is bound with dissolved oxygen (*Fig. 5b*).

Group I contains the Euglenophyta, always remains directly proportional to the presence of nutrients and the temperature of the water, it is therefore the mineralization of organic matter that takes place at this level.

Group II, Bacillariophyta and Cyanobacteria have a relationship proportional to the oxygen level, the potential of hydrogen and the electrical conductivity, so the presence of the phenomenon of eutrophication is noted

Discussion

An annual evolution in phytoplankton community with regard to physicochemical properties was evident in this study, and monitoring of the phytoplankton compartment in both lakes highlights that it is directly influenced by the fluctuation of abiotic parameters (Wetzel, 2001).

The phytoplankton populations in Lake Zerzaim were denser and more diversified in relation to the environmental parameters and more favorable than in Lake Lella Fatma, especially with the contribution of nitrogen and phosphorus.

Cyanobacteria perform photosynthesis with release of oxygen, and it is beneficial to find them in abundance within the lakes.

Cyanobacteria were also known to produce a variety of bioactive compounds of which some have toxic effects and are called cyanotoxins**.** The effects of some harmful algal blooms were not related to toxin production, but they were involved in depletion of dissolved oxygen concentration caused by algal proliferation, death and decay or night respiration (Shaista, 2008)**.**

Several freshwater, brackish water and marine cyanobacterial produce hepatotoxins (Welker, 2008) and in this study, it highlights: the genera of Microcystis that may produce linear and cyclic peptide (Ploutno et al., 2005), Oscillatoriamay produce toxins, aplysiatoxins which may cause skin problems in swimmers (Shaista, 2008).

Phytoplankton require nitrogen as a basic element in protein anabolism (Forsberg, 1977), and the nutritional role of phosphorus is assumed to be responsible for the rapid eutrophication of water bodies (Griffith et al., 2009), which was the case for the study.

Finally in the Megarine region lakes the development of phytoplankton populations was obviously caused by nutrients (nitrogen and phosphorus); and has caused a migration of micro-algae towards the deeper depths of lakes (Serizawa H et al., 2008).

The remarkable difference between the two lakes in terms of phytoplankton density was due to human activity, because the road to the Lake Lella Fatma is accessible and easy for people and even vehicles. For this reason, the lake is a place of tourist events in each summer. Unlike the Zerzaim lake, which characterized by the absence of clear pathways and surrounded only by palm trees and other plants on each side.

Physicochemical and phytoplankton data obtained in this study could be used as a baseline and reference point when assessing further changes caused by nature or man, since there has not been published information or data on these lakes.

Subsequent studies should allow a more precise approach to the interactions existing between the phytoplankton compartment and the adjacent levels of the food web and the impact of the abiotic parameters of the lakes. The rapid evolution of phytoplankton communities in response to environmental changes reinforces the importance of their ecological monitoring because of the importance of these lakes.

Conclusion

The study of some physicochemical parameters of Megarine lakes made it possible to characterize the general state of water during the year 2016. The results obtained showed that the lakes suffer from an agricultural pollution and shows that these lakes were favorable ecosystems to microalgae proliferation. The succession of phytoplankton populations was therefore conditioned by abiotic parameters. Phytoplankton represents a remarkable compartment by the role it plays, not only in the aquatic environment but also in all areas of our life: environmental quality (oxygen), food (fish and seafood), well-being (health, beauty), industrial resource, therefore it is imperative to monitor them in the global ecosystems.

(Received 3rd Mar 2018; accepted 21st May 2018)

Abstract. Okra (*Abelmoschus esculentus* L.) regeneration frequency to a large extent depends on its genetic structure and its recalcitricity. In present study, the influence of silver nitrate ($AgNO_3$) in combination with cytokinins such as 6-benzyl amino purine (BAP) and kinetin (KIN) to regenerate multiple shoots from cotyledonary node explants of *A. esculentus* were optimized. Cotyledonary node explants were excited from 10-days old okra *in vitro* seedlings and incubated on Murishage and Skoog (MS) medium supplemented with different concentration and the combination of BAP alone and in combination with KIN. The highest percentage of shoot bud regeneration (75%) was achieved on MS medium supplemented with 2.0 mgL^{-1} BAP. Highest percentage of shoot multiplication and proliferation (85%) with 6.75 shoots per explant having 3.75 cm length was obtained on MS medium containing 1.5 mgL^{-1} BAP + 1.5 mgL^{-1} KIN + 3.0 mgL^{-1} $AgNO_3$. On the other hand, non-containing $AgNO_3$, the combination of 1.5 mgL^{-1} BAP + 1.5 mgL^{-1} KIN, a maximum of 53% shoot multiplication with 2.3 shoots per explant having 3.75 cm length was recorded. Individual shoots were elongated on MS medium supplemented with 1.5 mgL^{-1} BAP + 1.5 mgL^{-1} GA_3 (Gibberellic acid) (shoot length 5.60 ± 0.70^a cm) and rooted on half strength MS medium + 1.0 mgL^{-1} IBA (Indole 3-butiric acid) + 200 mgL^{-1} AC (Activated charcoal), with highest root formation 83% with 5.20 roots per shoot having 4.8 cm length was achieved. The current protocol will be useful for the development of okra transgenic plant as a result of genetic transformation.

Keywords: *growth regulators, shoot multiplication, organogenesis, cytokinins and auxins*

Abbreviations: $AgNO_3$ – silver nitrate, MS – Murishage and Skoog, ddH_2O – double distilled water, $HgCl_2$ – mercuric chloride, NaOH – sodium hydroxide, HCL – hydrochloric acid, PGRs – plant growth regulators, AC – activated charcoal, 2,4-D- 2,4 – dicholorophenoxyacetic acid, BAP – 6-benzyl aminopurine, KIN – kinetin, GA_3 – gibberellic acid, IBA – indole-3-butyric acid, NAA – α-naphthyl acetic acid, μmol m^{-2} s^{-1}– micromoles per meter square per second

Introduction

Okra (*Abelmoschus esculentus* L.) is a member of Malvaceae family, which is mostly known as lady's finger. It is an important vegetable crop owing to its palatability for human consumption. It is cultivated in sub-tropical and tropical areas throughout the world (Dhande et al., 2012). India is the leading country followed by Nigeria, Sudan, Mali and Pakistan with the production of 5.5 million tons and covers an areas of 0.48 million hectares in the world (FAOSTAT, 2016). It is tremendous source of balanced human food containing protein, vitamins, and minerals which provides important compounds for medical (Gemede et al., 2015; Düzyaman and Vural, 2001). Moreover, its regular consumption could prevents hepatitis, cancer, ulcers and diabetes (Kumar et al., 2009a). Plants from the Malvaceae family such as okra are particularly susceptible to various

© 2018, ALÖKI Kft., Budapest, Hungary

environmental stresses such as abiotic and biotic stresses which reduce crop growth, yield and cause economic loss (Venkataravanappa et al., 2015).

Development of plant transformation and genetic engineering made it capable to isolate different disease and pest's resistant genes from bacteria and plants. Then transfer these resistant genes into economically valuable crops which can be grown under stressed conditions (Manickavasagam et al., 2015). Effective regeneration system is the pre-requirement for transgenic plants (Michel et al., 2008). In addition, *in vitro* reproduction technique offers a powerful tool to protect genetic resources and mass-multiplication of endangered plant species (Choffe et al., 2000). However, okra is one of the most recalcitrant crops for genetic modification with the lack of an efficient *in vitro* regeneration system amongst the leading reasons. It is widely reported that okra regeneration protocol using different explants such as hypocotyl, cotyledon, shoot tips, cotyledonary nodes, cotyledonary axis and plumule from zygotic embryo (Mangat and Roy, 1986; Roy and Mangat, 1989; Irshad et al., 2017; Narendran et al., 2013; Dhande et al., 2012; Manickavasagam et al., 2015; Daniel et al., 2018). However, available okra regeneration protocols are not well-organized for the development of transgenic plants. The main reasons for poor regeneration protocols of okra are due to its recalcitrant nature which takes longer time and requires skills (Manickavasagam et al., 2015).

Shoot multiplication through direct organogenesis is a good alternative way of regeneration, which takes less time, has lower soma clonal variability and higher efficiency index than indirect regeneration system (Juturu et al., 2015). Additionally, it has the ability to overcome the limitation of genotype requirement in transformation system. Several efforts have been made for getting an efficient regeneration system of okra by using different protocols (Anisuzzaman et al., 2008; Dhande et al., 2012; Kumar et al., 2009a; Mangat and Roy, 1986; Narendran et al., 2013; Irshad et al., 2017; Kumar et al., 2015). Various factors including media composition, explants, culture conditions, carbon sources, browning of callus, phenolic secretion, culture vessels and slow *in vitro* response have been shown to influence *in vitro* regeneration of okra (Irshad et al., 2017; Kumar et al., 2015). Media composition plays an important role in the regeneration efficiency. Kumar et al. (1998) reported that the development and growth of cells cultured *in vitro* rely on existence of ethylene and phytohormones in culture environment. Different evidence's showed that the morphogenic response of adventitious bud induction can be improved by inhibition of ethylene biosynthesis and gaseous environment in the culture medium (Pua, 1999). Inhibition of ethylene biosynthesis is a good alternative to improve the adventitious bud induction.

Silver Nitrate ($AgNO_3$) has been reported a potential ethylene inhibitor in various economically important plant species (Zhang et al., 2001; Jakubowicz et al., 2010; Kumar et al., 2016; Mookkan and Andy, 2014; Venkatachalam et al., 2017; Aylin Ozudogru et al., 2005). Addition of regeneration enhancer such as silver nitrate ($AgNO_3$) in growth medium plays a vital role in shoot multiplication and stated in various economically important plants such as *Vigna mungo* (Mookkan and Andy, 2014), *Gossypium hirsutum* (Kumar et al., 2016), *Arachis hypogaea* (Aylin Ozudogru et al., 2005), *Cucumis sativus* (Venkatachalam et al., 2018), *Catharanthus roseus* (Panigrahi et al., 2017) and *Prosopis cineraria* (Venkatachalam et al., 2017).

In this study, we reported an effective *in vitro* regeneration system to induce multiple shoots through cotyledonary node explants of *A. esculentus* by using various plant growth regulators with different combination, concentration and growth promoter e.g. silver nitrate ($AgNO_3$). The basic objectives of this study were (a) to improve direct regeneration

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_34213435

protocol for okra by using cotyledonary node as explant (b) to examine the impact of cytokinins and auxins by using alone or in combination with $AgNO_3$ on shoot multiplication through *in vitro* seedling derived cotyledonary node explants. This alternative method will be beneficial for attaining transgenic plants of commercial okra genotypes.

Materials and methods

Silver nitrate ($AgNO_3$) stock solution preparation

For the preparation of stock solutions, chemicals were purchased from Solarbio® (China). A Stock solution of $AgNO_3$ (0.5 mgL^{-1}) was prepared with sterilized distilled water and stored in screw-capped bottles. The stock solution was kept at 4 °C until further use.

Plant material and seed germination

Abelmoschus esculentus "Xiang Fu" cultivar was used in the experiment. Seeds purchased from vegetable seed market (P. R. China, Fuzhou), were surface sterilized by washing with sterilized double distilled (ddH_2O) water 3-5 times and then treated by immersion in 0.1% weight per volume (w/v) $HgCl_2$ (mercuric chloride) for 3 minutes, following the 5 rinses with ddH_2O to remove the residual of $HgCl_2$, then treated with 70% ethanol for 30 seconds and washed 3-5 times with ddH_2O and immersed overnight in ddH_2O. The sterilized seeds were inoculated in half-strength Murishage and Skoog (1962) (MS) basal solid medium without addition of plant growth regulators in sterilized baby food jars (5×9 cm), 5-8 seeds per jar and was kept in dark condition.

Culture medium and conditions

The cotyledonary node explants were cultured on MS medium fortified with different concentration and combination of BAP, KIN, thidiazuron (TDZ), silver nitrate ($AgNO_3$), gibberellic acid (GA_3), indole 3-butiric acid (IBA), α-naphthalene acetic acid (NAA) and activated charcoal (AC). For the whole experiment, MS basal medium containing 2.5% sucrose (w/v), 0.8% agar (w/v) and pH was adjusted to 5.8 by the use of 0.5 N NaOH or HCl prior to autoclaving at 121 °C for 20 min. The culture conditions were maintained at 25 $\pm$ 2 °C with 70% relative humidity and 16:8 h light/dark photoperiod supplied by cool white fluorescent lamps (Philips, Beijing, China) at an intensity of 60 $\mu mol\ m^{-2}\ s^{-1}$.

Explant preparation and shoot induction

Cotyledonary node explants were excised aseptically from 2-week old *in vitro* raised seedlings (*Fig. 1A*) and cultured on MS medium augmented with different concentration of BAP (0.5, 1.0, 2.0, 2.5 mgL^{-1}) alone or in combination with KIN (0.5, 1.0, 2.0, 2.5 mgL^{-1}) for shoot bud induction. Consequently, the shoot buds were sub-cultured into same fresh MS medium for two weeks intervals to enhance the shoot bud development. Data on shoot proliferation percentage (%) and number of shoots per explant were measured after two weeks intervals.

Multiple shoots induction

To investigate the effect of $AgNO_3$ on shoot multiplication, two experiments were carried out containing $AgNO_3$ and non-containing $AgNO_3$. In the first experiment (containing $AgNO_3$), *in vitro* derived shoot buds were cultured on MS medium containing

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_34213435
© 2018, ALÖKI Kft., Budapest, Hungary

various concentration of BAP (0.5, 1.0, 2.0, 2.5 mgL^{-1}), KIN (0.5, 1.0, 2.0, 2.5 mgL^{-1}) and TDZ (0.5, 1.0, 2.0, 2.5 mgL^{-1}) in combination with $AgNO_3$ (0.5, 1.0, 2.0, 2.5 mgl^{-1}), as growth enhancer. In second experiment (non-containing $AgNO_3$), shoot buds were cultured on MS medium supplemented with BAP, KIN and TDZ at equimolar concentration. The shoot bunches were sub-cultured on same fresh shoot multiplication medium at every two weeks intervals for fast shoot growth with more number of shoot buds. Shoot initiation and growth characteristics were noticed per week, while data for shoot multiplication responses, mean number of shoot per explant and shoot length was noted after four weeks of inoculation.

Shoot elongation

In order to obtained healthy shoots with appropriate length for rooting, well developed shoots (1-1.5 cm) in length were isolated from shoot bunches and cultured on MS medium containing different combination and concentration of BAP (1.0, 1.5, 2.0 mgL^{-1}) and GA_3 (1.0, 1.5, 2.0 mgL^{-1}) alone or in combination. The shoot length (cm) and shoot elongation frequency (%) were noticed after three weeks of culture.

Rooting of regenerated shoots and acclimatization

Elongated shoots (2.0-5.0 cm in length) were excised aseptically and cultured on half strength MS medium containing (100, 200 mgL^{-1}) AC with various concentration (0.5, 1.0, 1.5 mgL^{-1}) of IBA and NAA. Root formation frequency, root length and number of roots per shoot were recorded after four weeks of cultured. The plantlets with roots were cautiously detached from the culture medium and distilled water was used to remove the agar traces and rooting medium. Plantlets were shifted into plastic cups comprising of vermiculite and garden soil (1:1) and watered every second day. The plastic cups were covered with polyethylene bags for 5 days and kept in the growth chamber at 25 ± 2 °C with relative humidity (70%) and 16/8-h of light/dark photoperiod having light intensity of 80 µmol m^{-2} s^{-1} supplied by cool white fluorescent tubes. These plantlets were then transferred to greenhouse under natural conditions for further growth and development.

Statistical analysis

The experiments were carried out based on a CRD (complete randomized design) with n = 10, and each experiment was performed three times. MS medium without plant growth regulators was used as a control treatment at every step of experiment. One-way analysis of variance (ANOVA) was performed using SPSS version 17.0 version (SPSS Inc., Chicago, IL, USA) for all statistical analysis and difference among mean values were analyzed by using Tukey's test, p-value ≤ 0.05.

Results

Effects of plant growth regulators on shoot bud induction

Morphogenetic responses of cotyledonary node explants (*Fig.1B*) with various concentrations of BAP and KIN were given in *Table 1*. Cotyledonary nodal explants cultured on MS medium without PGRs (control) gave no response. However the response was quicker in the presence of cytokinins including BAP and KIN (*Fig.1C*). Various results were observed on medium supplemented with different type and concentration of

© 2018, ALÖKI Kft., Budapest, Hungary

cytokinins. Among the tested concentration of BAP and KIN, shoot induction percentage (75%), with 4.5 numbers of shoots, was observed on MS medium supplemented with 2.0 mgL^{-1} BAP alone was higher as compare to the combination of 2.0 mgL^{-1} BAP + 2.0 mgL^{-1} KIN, (4.15 number of shoots) with 70% response.

Table 1. *Effects of different concentration of plant growth regulators (PGRs) on shoot bud differentiation from cotyledonary node explants of okra.*

Culture media	Plant growth regulator (mgL^{-1})		Shoot proliferation %	No. of shoots/explant
	BAP	KIN

The labels M1-M13 (M1- Controlled) presents PGRs combination, values represented mean ± standard error; data were recorded after four weeks of culture on MS medium supplemented with BAP and KIN. Best results are indicated in bold, mean followed by the same letter within a column are not significantly different according to Tukey's test with p-value ≤ 0.05

Shoot multiplication and proliferation

Multiple shoot induction was not observed in medium without PGRs (control). Among the tested combinations medium containing $AgNO_3$, maximum shoot multiplication percentage (85%) was noticed on a medium fortified with 1.5 mgL^{-1} BAP + 1.5 mgL^{-1} KIN + 3.0 mgL^{-1} $AgNO_3$ with maximum number of shoots (6.75 shoots/ explants, 3.90 cm in length) followed by the other combination (1.75 shoots/ explants, 1.0 cm in length), with lowest multiple shoot percentage (37%), on a medium containing 2.0 mgL^{-1} TDZ + 4.5 mgL^{-1} $AgNO_3$ was recorded (*Table 2A*). Whereas highest percentage of shoot multiplication (51%) with maximum shoot numbers (3.80 shoots/explants, 2.30 cm in length) was observed on MS medium having the combination of 1.5 mgL^{-1} BAP + 1.5 mgL^{-1} KIN with non-containing $AgNO_3$ (*Table 2B*) (*Fig. 1D, 1E*).

Shoot elongation

Well-proliferated shoots were isolated from the shoot bunches and transferred to the MS medium supplemented with different concentration of BAP and GA_3 for shoot elongation. Media without PGRs showed a negligible result of shoot length (0.5 cm) with 10% shoot elongation. On the other hand, Media containing GA_3 and BAP showed significantly effects on plant height with maximum shoot length (5.6 cm) and highest shoot elongation percentage (80%) in medium supplemented with 1.5 mgL^{-1} BAP + 1.5 mgL^{-1} GA_3 following the lowest shoot length (2.50 cm) was measured on MS medium comprising 2.0 mgL^{-1} GA_3 alone. Among the tested PGRs, medium supplemented with GA3 alone was not effective for shoot elongation (*Table 3, Fig. 1F& 1G*).

Table 3. *Effects of MS medium supplemented with GA_3 and BAP on elongation of isolated shoots of okra*

Culture media	Plant growth regulator (mgL^{-1})		Shoot length (cm)	Shoot elongation %

The labels M1-M10 represent PGRs combination, values represented mean ± standard error; data were noted after four weeks of inoculation on MS medium containing GA_3 and BAP. Best results are indicated in bold, mean followed by the same letters within a column are not significantly different according to Tukey's test with p-value ≤ 0.05

In vitro rooting and acclimatization

Well-developed, elongated shoots were excised from the *in vitro* regenerated shoots and cultured on half strength MS medium supplemented with different concentration of IBA, NAA along with AC for root induction. Highest rooting frequency (83%) as well as normal roots production (5.20 roots/shoot, 4.80 cm in length) was observed on MS medium supplemented with 1.0 mgL^{-1} IBA + 200 mgL^{-1} AC combination. While lowest rooting response (38%) was observed on medium fortified with 0.5 mgL^{-1} IBA alone (*Table 4, Fig. 1H*). Before transferring to the green house, plantlets with well-developed root system were transferred to the plastic cups having vermiculite and garden soil (1:1) and they were raised in the growth chamber for two weeks at 25 ± 2 °C with 70% relative humidity and consequently grown in the field with an of 87% survival rate (*Fig. 1I*).

The labels M1-M19 represent PGRs combination, values represented mean ± standard error; data were recorded afterward the culture of four weeks on half strength MS medium composition with auxins IBA and NAA in combination with AC. Best results are indicated in bold, mean followed by the same letter within a column are not significantly different according to Tukey's test with p-value ≤ 0.05

Discussion

Direct *in vitro* regeneration system has the potential to improve the phyto-pharming genetics under the influence of internal and external factors, used for genetic transformation. In present study, our main purpose was to establish, an efficient regeneration system in okra through shoot multiplication by cotyledonary node as explant. Shoot multiplication was enhanced from cotyledonary node explants which varied with the type of growth regulator, concentration, and combination used. In general, cotyledonary nodes was found more effective for shoot initiation and multiplication explants source. Till date, regeneration through cotyledonary node explants have been found in various plant species including *Abelmoschus esculentus* (Irshad et al., 2018), *Pisum sativum* (Jackson and Hobbs, 1990), *Punica granatum* (Naik et al., 2000), *Gossypium hirsutum* ((Kumar et al., 2016), *Vigna mungo* (Mookkan and

© 2018, ALÖKI Kft., Budapest, Hungary

Andy, 2014), *Lathyrus sativus* (Tesfaye et al., 2017), *Prosopis cineraria* (Venkatachalam et al., 2017) and *Cucumis sativus* (Venkatachalam et al., 2018).

Cytokinins play a key role in shoot organogenesis. BAP and KIN used alone or in combination showed different responses. When BAP was used alone, at low level of 0.5 mgL^{-1} BAP showed only (43%) shoot induction with an average of (1.33) number of shoots, but highest shoot induction (75%), with (4.5) number of shoots was observed at 2.0 mgL^{-1} BAP. Similar observation was reported previously in *Prosopis cineraria* (Venkatachalam et al., 2017; Sangeetha and Venkatachalam, 2014), *Dendrocalamus strictus* (Goyal et al., 2015) and *Tinospora cordifolia* (Panwar et al., 2018). Whereas shoot induction slightly decreased (60%, 3.80 number of shoots) with increasing of BAP concentration up to 2.5 mgL^{-1} (*Table 1*). Increased concentration of cytokinins suppressed the initiation of shoot buds. Similar results have been reported in various plant species *Enicostema axillare* (Sasidharan and Jayachitra, 2017) and *Prosopis cineraria* (Venkatachalam et al., 2017).

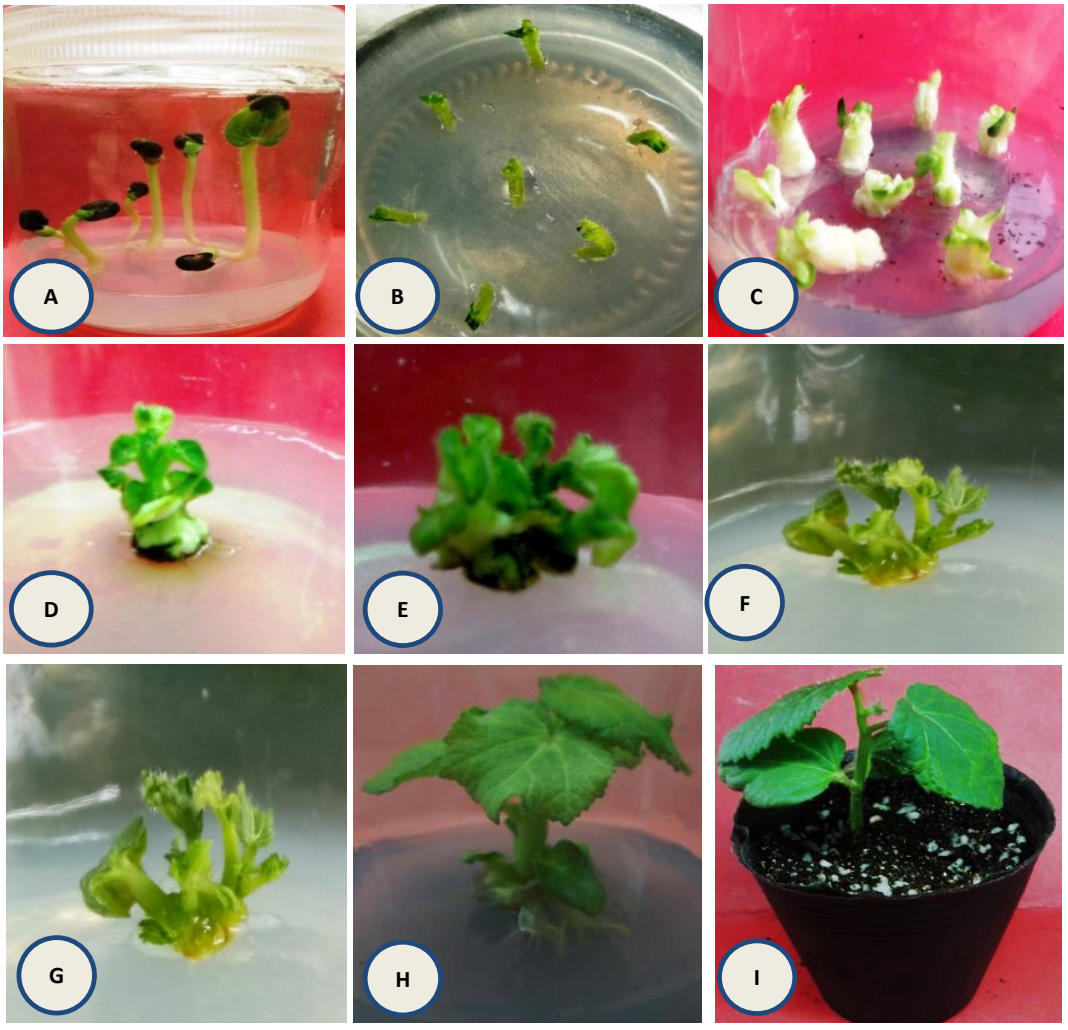

Figure 1. *Direct in vitro regeneration of okra (Abelmoschus esculentus L.) through cotyledonary node explant and the effect of $AgNO_3$ on multiple shoot formation. (A) 10-days old okra seedling. (B) Cotyledonary node explants. (C) Vigorous cultures after two weeks in culture media. (D) Multiple shoots inductions from nodal regions. (E) Multiple shoots formation and development. (F, G) Proliferation and elongation of multiple shoot. (H) Rooting of elongated shoots. (I) Regenerated plant*

KIN showed less potential to shoot initiation then BAP. At lowest concentration of 0.5mgL^{-1}, it showed 58% with 1.68 shoots/explant and 65% with 3.50 shoots/explant at 2.0 mgL^{-1} BAP respectively. But the number of shoots per explant were significantly decreased at 2.5 mgL^{-1} BAP producing only 2.90 number of shoots with 38% response. Our results are in contrast with (Sivakumar et al., 2014). Rathore et al. (2016) also reported that KIN showed fewer shoot induction results in *Withania coagulans*. Fewer responses were observed at the lowest and highest plant growth regulator concentrations then intermediate level. Bakrudeen et al. (2011) in *Catharanthus roseus* preferred the use of BAP and KIN alone but not in combination. Our finding matches with the earlier reports of *Colocynthis citrullus* (Ntui et al., 2009), *Catharanthus roseus* (Bakrudeen et al., 2011) and *Prosopis cineraria* (Venkatachalam et al., 2017) in which BAP demonstrated positive influences on regeneration of shoot bud than to KIN.

Ethylene produced in culture medium, is known as an inhibitor of plant development and morphogenesis relying on the species and culture stage (Mohiuddin et al., 1997). $AgNO_3$ can induce variable responses *in vitro* by the inhibition of ethylene action. Kumar et al. (2009b) and Zhang et al. (2001) reported that the shoot multiplication is owing to the action of silver ions as a competitive ethylene inhibitor level by the crosstalk of ethylene and hormones rather than the ethylene biosynthesis inhibition. Use of regeneration enhancer in culture medium has been reported to be useful for shoot multiplication. Among the various compounds that have been widely used, $AgNO_3$ showed a positive effect on plant tissue cultures (Zhang et al., 2001). At 1.0 mgL^{-1} and 4.5 mgL^{-1} $AgNO_3$ induced 3.8 and 3.33 shoots/explant with 38 and 50% responses. But highest number of shoots/explant (4.0) was recorded at 3.0 mgL^{-1} $AgNO_3$ with 75% response. At 1.5 mgL^{-1} BAP + 3.0 mgL^{-1} $AgNO_3$ induced highest number of shoots 5.5 shoots/explant with 77% response but response decreased (68%) with increasing the concentration and produced 4.75 number of shoots/explant at 2.0 mgL^{-1} BAP + 4.5 mgL^{-1} $AgNO_3$, our results are similar with the finding of (Mookkan and Andy, 2014; Balkhande et al., 2013).

In case of 1.0 mgL^{-1} KIN + 1.5 mgL^{-1} $AgNO_3$ showed 50% response with 2.90 number of shoots per explant, which slightly increase with increasing the concentrations of 1.5 mgL^{-1} KIN + 3.0 mgL^{-1} $AgNO_3$ 50% response, 3.83 shoots/explants and at 2.0 mgL^{-1} KIN + 4.5 mgL^{-1} $AgNO_3$ highest response 67% with decreasing number of shoots (3.60 shoots/explant) was recorded. Our findings are in line with (Mookkan and Andy, 2014). Whereas in comparison, at lowest concentration of 1.0 mgL^{-1} TDZ + 1.5 mgL^{-1} $AgNO_3$ showed higher response 60% with 2.75 shoots/explants, but at higher dose of 2.0 mgL^{-1} TDZ + 4.5 mgL^{-1} $AgNO_3$ presented lowest response 37% with 1.75 shoots /explants (*Table 2A*). Results clearly indicate that TDZ and $AgNO_3$ at low concentration favored multiple shoot induction while higher dose shows negative results. Same findings were observed by Ouma et al. (2004) in cotton. Among the combinations evaluated, maximum number of shoot percentage (85%) was observed at a medium 3.0 mgL^{-1} $AgNO_3$ + 1.5 mgL^{-1} BAP + 1.5 mgL^{-1} KIN by inducing (6.75 shoots/explant) which was comparatively higher than earlier reports but at higher dose of 4.5 mgL^{-1} $AgNO_3$ + 2.0 mgL^{-1} BAP + 2.0 mgL^{-1} TDZ, consequently decreased the number of shoots (4.33 shoots/explant), with (49%) shoot induction response (*Table 2A*). Whereas, lower number of shoots (2.90 shoots/explant) were observed at a medium containing 3.0 mgL^{-1} $AgNO_3$ + 1.5 mgL^{-1} BAP + 1.5 mgL^{-1} TDZ having 48% response with (2.90 shoots/explant) followed by the lowest response 37% with 1.75 shoots/explant was observed at 4.5 mgL^{-1} $AgNO_3$ + 2.0 mgL^{-1} BAP (*Table 2A, Fig. 1E*). In general BAP

was found to be most efficient cytokinins in comparison to TDZ and KIN, similar phenomenon was reported by (Venkatachalam et al., 2018) and the addition of $AgNO_3$ along with other cytokinins enhanced the multiple shoot induction was also previously reported by (Venkatachalam et al., 2017; Mookkan and Andy, 2014; Naik et al., 2000).

The results achieved from our study suggests that $AgNO_3$ could be used as a worthy improver or regeneration enhancer for *in vitro* regeneration of okra through shoots multiplication, meanwhile the responses may vary with the plant species. Fasolo et al. (1989) reported that cytokinins have the feature to stimulate the shoot proliferation but inhibit the elongation. Whereas, shoot elongation is important in plant tissue culture, which varies with the medium type, concentration and combination of PGRs used in different plants. Highest response of shoot elongation (80%) was achieved with 5.60 cm shoot length on optimal concentration of 1.5 mgL^{-1} BAP + 1.5 mgL^{-1} GA_3 (*Fig. 1F, 1G*) followed by the lowest shoot length (2.50 cm) which was recorded at a medium containing 2.0 mgL^{-1} GA_3 (*Table 3*). Our results indicated that use of BAP and GA_3 enhance the shoot elongation. Similar results of BAP and GA_3 combinations were reported by (Selvaraj et al., 2006) in *Cucumis sativus,* (Gonbad et al., 2014) in *Camellia sinensis* and (Kumar et al., 2016) in *Gossypium hirsutum*.

Well-developed rooting is essential for successful *in vitro* regeneration in many plants and the use of half strength MS medium promotes the rooting (Rahman et al., 1992; Oakes et al., 2016). The addition of AC enhances the root formation due to the large surface area which can adsorb many types of substances leadings to improve the cell growth and development (Ghazzawy et al., 2017). IBA at 1.0 mgL^{-1} produced the 2.70 roots/shoot with 43% response, which varies on higher and lower concentration. While in combination with 100.0 mgL^{-1} AC + 1.5 mgL^{-1} IBA produced 4.80 roots/shoot with 68.50% response, which increases with increasing the concentration of AC and showed the highest response 83% with 5.20 roots/shoot on medium containing 200.0 mgL^{-1} AC + 1.0 mgL^{-1} IBA. In case of NAA, the highest responses 70% with 4.88 roots/shoots on a medium containing 200.0 mgL^{-1} AC + 1.0 mgL^{-1} NAA were observed. Our results are in agreement with previous reports of (Şan et al., 2015; Irshad et al., 2017; Kumar et al., 2016). The rooted plantlets were hardened by transferring into plastic cups containing vermiculite and garden soil (1:1) mixture. They were then kept in a growth chamber for two weeks at 25 ± 2 °C with 70% relative humidity and consequently established in the field condition with 87% survival rate. This protocol will be useful for multiple shoot induction, direct plant regeneration, shoot elongation, rooting and hardening of other relevant plant species.

Conclusion

In this study, an efficient *in vitro* plant regeneration protocol was established using cotyledonary node explants of *A. esculents* "Xiang Fu" cultivar. BAP at 2.0 mgL^{-1} was found to be most effective for shoot bud initiation from cotyledonary nodal explants. Shoot multiplication frequency was enhanced by the addition of silver nitrate ($AgNO_3$) in the medium and the highest shoot multiplication frequency was achieved on MS medium fortified with 1.5 mgL^{-1} BAP + 1.5 mgL^{-1} KIN + 3.0 mgL^{-1} $AgNO_3$ with maximum number of shoots (6.75 shoots/explants, 3.90 cm in length). Highest shoot elongation (80%) was observed in a medium containing 1.5 mgL^{-1} BAP + 1.5 mgL^{-1} GA_3 with maximum shoot length 5.6 cm. Highest rooting frequency (83%) with (5.20 roots/shoot, 4.80 cm in length) was observed in MS medium supplemented with 1.0

mgL^{-1} IBA + 200 mgL^{-1} AC. Furthermore, the whole protocol from seedling establishing to regenerated plants was completed in only 3.5 to 4.0 months. This efficient protocol for high-frequency plant regeneration through shoot multiplication in okra (*Abelmoschus esculentus* L.) will be a valuable tool for further genetic transformation.

Acknowledgements. This experiment was conducted in the Key laboratory of Plant Tissue Culture, College of Horticulture, Fujian Agriculture and Forestry University Fuzhou, Fujian, 350002, China. This achievement was completed by the financial support of "Fujian Agriculture and Forestry University" China and FAFU scholarship program are gratefully acknowledged. We would like to express our appreciation to all lab mates, Abdul Waheed and Muhammad Tayyab for their valuable suggestions.

DETERMINATION OF OPTIMUM MANAGEMENT STRATEGY FOR HONEY PRODUCTION FOREST LANDS USING A'WOT AND CONJOINT ANALYSIS: A CASE STUDY IN TURKEY

GÜNGÖR, E.

Bartın University, Faculty of Forestry, 74100 Bartın, Turkey
e-mail: egungor@bartin.edu.tr; phone: +90-5-326-283-318; fax: +90-3-782-235-069

(Received 11th Mar 2018; accepted 21st May 2018)

Abstract. In this study, it was aimed to develop alternative management strategies for Honey Production Forest (HPF) lands, which are planned to be set up in Bartin, and to select the optimum one. For this, a model (A'WOT-CJA), in which A'WOT (SWOT-Analytical Hierarchy Process) and Conjoint Analysis (CJA) are used together, was developed within the framework of ecological, social and economic criteria based on the participation principle. Within the scope of A'WOT-CJA, the honey status of Bartin was determined by SWOT in the first step and it was prioritized using AHP by digitizing in the second step. The highest SWOT values found as a result of AHP are "honey type" with 0.245 in terms of strength, "honey production season length" with 0.202 in terms of weakness, "bee product type" with 0.224 in terms of opportunity and "beekeeping type" with 0.147 in terms of threat. However, in order to improve the effectiveness and comprehensiveness of the strategies, 81 strategies with four factors, each consisting of three levels, were developed and evaluated by CJA in the third step. However, since it was difficult and time consuming to prioritise these 81 strategies, these strategies were reduced to 9 through orthogonal rotation and were arranged to be 110 participants among those related to the subject (50 people from the local population, 10 people from public institutions, and 50 people from NGOs). According to the A'WOT-C results, HPF optimum management strategy of Bartin Province was formed as follows; *"In the establishment of honey forests, giving priority to the chestnut species with high economic return, putting the lands, where the honey production season will last at least six months, forward in land selection, preparing the lands especially to increase the honey and royal jelly yield and the lands being in such form to support migratory beekeeping."*
Keywords: *forest management, beekeeping, participation, multi-criteria decision-makings, rural development*

Introduction

The necessity of using the natural resources effectively and efficiently in consideration of increasing population, needs and expectations refers to a precise equation in today's world and human being is the basis of this equation. Planners and implementers endeavour to meet the ever-changing and evolving needs. This process also increases the expectations for natural resources.

Although the fuel wood and timber are the most known among the resources obtained from the forests, the non-wood forest products (NWFP) are the most common products obtained from forest resources. Within the scope of plant-derived non-wood forest products in Turkey, apicultural products and honey have important roles as well as wild food plants, medical and aromatic plants, bulbous plants, dye plants and mushrooms (HFAP, 2013). Forest resources also provide an important input to apicultural products with their rich biodiversity and gene resources.

Forests are important resources for the production of quality honey (HFAP, 2013). Furthermore, while forests provide a low investment environment for beekeeping activities, they create high income opportunity with the labour force input and constitute an important source of income for forest villagers (Yilmaz, 2006; Gungor and Ayhan,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_34373459
© 2018, ALÖKI Kft., Budapest, Hungary

2016). In addition, they make significant contributions to reduce the rural-urban migration and ensure community stability with the influence of income (Yilmaz, 2006). When viewed from this aspect, it can be stated that beekeeping is one of the most important rural development instruments (Korkmaz et al., 2015). On the other hand, while forests contribute to honey production, they also help pollination and soil conservation and they fulfill an important function at the point of conservation and development of biodiversity (HFAP, 2013).

Honey and apicultural products produced together with honey such as propolis, royal jelly, pollen and beeswax have an important place in world trade. Today, there are around 59 million bee hives in the world and around 1 million 250 thousand tonnes of honey is produced from them. India is the country with the highest number of hive assets in the world (12 million hives). Nevertheless, China, which has 9 million hives, is the country that produces the biggest amount of honey (466.6 thousand tonnes) in the world. After China, Turkey (94.7 thousand tonnes), Iran (74.6 thousand tonnes), Ukraine (73.7 thousand tonnes) and Russian Federation (68.4 thousand tonnes) come respectively in terms of honey production (*Figure 1*) (FAO, 2018). As can be understood from these statistics, Turkey is the second most important honey producer of the world.

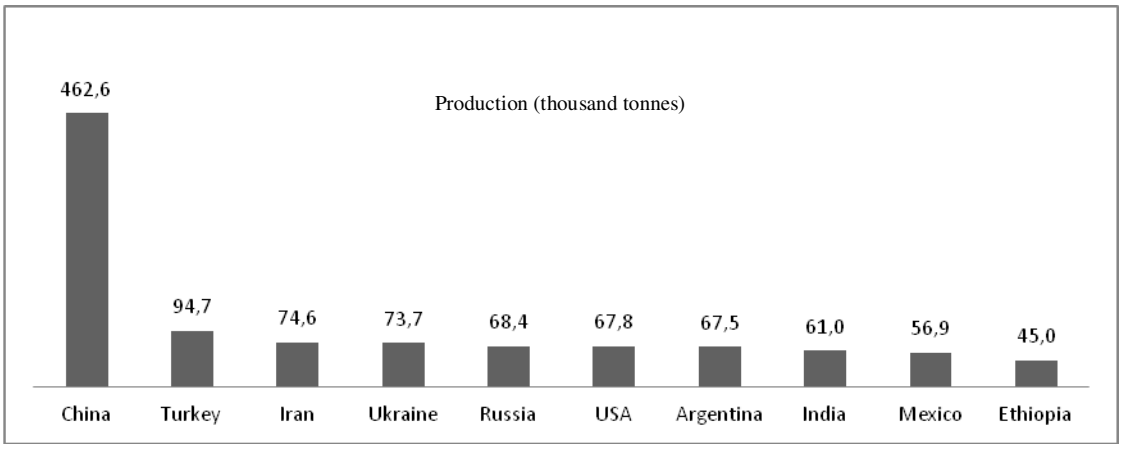

Figure 1.*World's 10 largest honey producers (FAO, 2003)*

The average honey production per hive is around 22 kg in the world. Canada (56 kg/hive), China (52 kg/hive), Mexico (39 kg/hive), Argentina (27 kg/hive) and the USA (26 kg/hive) are the countries that carry out honey production above the world average. Turkey is considerably lower than the world average with the production value of 15 kg/hive (ranks number 12) (FAO, 2009, 2018). Although 75% of honey plant species and varieties, which are available in the world, are available in Turkey (HFAP, 2013), Turkey does not yet have a sufficient role in the world honey trade, as the honey yield per hive is below the world average (OCEP, 2013).

On the other hand, forest areas in Turkey cover the 27.6% (21.678.134 ha) of the area of the country (*Table 1*). The areas, where there are forest trees and shrubs such as chestnut, tilia, acacia and rhododendron, which can be used as honey forests, form about 4% of the forest areas (GDF, 2015). When forest gap inside the forests are added to these areas, it is understood that Turkish forest areas have sufficient potential for Honey Production Forests (HPF).

In order to increase honey production yield and to establish sustainable honey forests, the areas, where forests are to be established, should be determined with a participatory approach by taking the social demands and resource constraints into consideration. For this reason, interest groups should be included in the planning process during the process of determining the optimal management strategy of HPF. Through the HPFs to be planned in this way, the forests will be capable of providing many ecological-environmental, economic and socio-cultural benefits as well as the yield increase.

Effective strategies should be developed and implemented at the determination, management and planning stages of HPF lands in forests due to the contributions of beekeeping and apicultural products. There are number of examples of forest products and services in the world that are integrated into management strategies (Leuschner, 1992; Clutter et al., 1992; Duerr, 1993; Klempeer, 1996; Martell et al., 1998; Carsjeans and Vanderknaap, 2002; Eastman et al., 1998; Yilmaz, 2004; Gungor, 2005; Sen and Gungor, 2018).

Food safety, which has become even more important with the increase in world population, and the production of honey and other apicultural products within this context (FAO, 2009), have become one of the ultimate goals that should be achieved for Turkish forestry (GDF, 2015). However, the studies conducted to increase honey production are not carried out by scientific methods but by the initiatives of decision makers. Within this scope, it was aimed to develop alternative management strategies for the planning of HPF sites using multi-criteria decision making methods and to select the most suitable HPF site by prioritising the alternatives.

Study area

Bartin Province, which is the study area, is located in the Western Black Sea region of Turkey between 41°53' northern latitude and 32°45' eastern longitude (*Figure 2*). Its surface area is 2,143 km^2. In Bartin, mild marine climate (Black Sea Climate) with warm (26 °C and over) summers and cooler winters (-2 °C and below) prevail (BMST, 2017). The fact that it is close to the sea and that the mountain ranges, which are not very high, are parallel to the shore causes the temperature differences on the coastline to decrease and humidity to increase (BG, 2017). For this reason, Bartin Province has an important potential of honey production in terms of its geographic location and climate. The general area of Bartin Province is 228,576 ha. The forest area is 135,437 ha and the forest area ratio of the province is 59.3%. This value is above the average of Western Black Sea (50%) and the country (28%) (GDF, 2015). Bartin Province has an important potential of honey production in terms of its forest area values.

Bartin is one of the significant regions in terms of potential honey production areas due to its rich biodiversity in the Black Sea region, its edaphic and climatic conditions, for having tree species with high nectar yield such as chestnut, tilia and false locust etc. (GDF, 2011; WWF, 2003, 2010; Gungor and Ayhan, 2016).

On the other hand, in terms of honey production, forest area, general area, number of forest villages, population, general population and number of hives of Bartin Province and region and country values are given in *Table 1* (Gungor and Ayhan, 2016).

Figure 2. *Geographical location of Bartin Province*

.

Bartin Province, which has a high portion of forest assets, is also well above the country average in terms of forest villager density. Therefore, Bartin Province, which has an important potential for honey production, is well below the country and the region average in terms of honey yield level (*Table 1*). As can be understood from these statistics, Bartin Province could not tip the scales in its own favour in honey production.

Table 1. *Comparison of forest area, general area, number of forest villages, population, general population and number of hives of Bartin Province with region and country values*

Materials

Data necessary to realize the study aim is obtained from various public institutions, non-profit organizations and literature. Within this scope, Management Plans by the Forestry Operation Directorate of Bartin (FODB) (FODB, 2005), Honey Forest Action Plan (HFAP) by the General Directorate of Forestry (GDF) (HFAP, 2013) and Bartin Honey Forest Project (BHFP) (BHFP, 2013) were utilized. Moreover, the statistical data of the state institutions and organizations (TBMM, 2010; BAKKA, 2011, FAO, 2018, TUIK, 2017) and the Honey Forest Projects (GDF, 2012a; 2012b; 2014) conducted in various provinces and scientific research studies conducted in the region (Genc, 2003; Tutkun, and Bosgelmez, 2003; Misir, 2011; Dogaroglu, 2017; Bekar and Acar, 2017; Gungor and Sen, 2018; Sen and Gungor, 2018) were also utilized within the scope of this study. In addition, the records of Turkish Association of Beekeepers (TAB) (TAB, 2017) and Beekeepers Association of Bartin (BAB) (BAB, 2017), which is connected to this centre, were also used within the scope of the study together with the employers of association and the local public talks.

Methods

In the development of alternative management strategies for HPF sites and in the selection of the optimum one, the evaluation of the ecological, social and economic criteria together and the opinion of the interest groups (local community, public institution representatives, NGO representatives) will also increase the likelihood of making the right selection. There are many pure and hybrid Multi-Criteria Decision-Making (MCDM) techniques that can be used for this purpose in the literature such as AHP (Analytic Hierarchy Process), ANP (Analytic Network Process), A'WOT (SWOT-AHP), CJA (Conjoint Analysis), TOPSIS (Technique for Order of Preference by Similarity to Ideal Solution), TOPSIS-G (Technique for Order of Preference by Similarity to Ideal Solution with grey numbers), VIKOR (Multi-Criteria Optimization and Compromise Solution), ELECTRE (Elimination and Choice Expressing Reality), PROMETHEE (Preference Ranking Organization Method for Enrichment of Evaluations), SAW (Simple Additive Weighting), DEMATEL (Decision-Making Trial and Evaluation Laboratory) and DANP (DEMATEL-based ANP).

Considering the aim of the research, the most appropriate MCDM hybridization was decided to be A'WOT (SWOT-Analytic Hierarchy Process) and Conjoint Analysis (CJA) combination (A'WOT-CJA). Because within the scope of A'WOT-CJA, the honey status of Bartin Province was determined by SWOT and the obtained SWOT criteria were prioritized by digitizing by AHP. Thus, the factors standing out in each SWOT group formed the basis of HPF management strategies. Sub-levels should also be defined for the factors developed for more comprehensive strategies. In this way, the participants can better interpret and analyse the strategies. In this direction, a total of 81 strategies were developed by adding sub-levels to each SWOT factor. However, the strategies were reduced to 9 through orthogonal rotation in CJA, since it was difficult and time consuming to prioritise these 81 strategies. By this means, more consistent results were obtained. These 9 strategies were ranked by the 110 participants in the direction of CJA, and thus HPF optimum management strategy for Bartin Province was determined. The MCDM techniques used within the scope of the study are explained below.

A'WOT technique

In the study, a hybrid technique A'WOT (SWOT Analysis and Analytical Hierarchy Process (AHP) combination) was used. A'WOT is a hybrid method developed by Kurttila et al. (2000) and Pesonen et al. (2001a). This method provides a structure combining the AHP method of Saaty (1980) with SWOT. The purpose of utilizing AHP in SWOT analysis is to evaluate the SWOT factors systematically. While SWOT analysis provides a frame for the decision status analysis, AHP supports more analytical application of SWOT (Kurttila et al., 2000; Kangas et al., 2001; Kajanus et al., 2004).

SWOT (Strengths, Weaknesses, Opportunities and Threats) is a commonly applied tool in the analysis of internal and external environment in order to provide a systematic approach and support to the cases of strategic decision making (Wheelen and Hunger, 1995, Hill and Westbrook, 1997). The purpose of SWOT implementation in the process of strategic planning is to develop and adopt a strategy that is generally adaptable between internal and external factors. SWOT can also be used, when alternative strategies emerge (McDonald, 1993). SWOT analysis is not capable of assessing the case of strategic decision making in a comprehensive way. It remains at the level of detecting the factors only. In addition to this, the expression of individual factors is often very general and short. Moreover, SWOT does not include tools for determining the significance of factors analytically or evaluating decision alternatives according to the factors. Therefore, the more use of SWOT is mainly based on the qualitative analysis carried out during the planning process and the skills and expertise of the people involved in the process. In summary, SWOT analysis is a list of internal and external factors or an incomplete qualitative examination. For this reason, it is sometimes called as "SoWOT" (Hill and Westbrook, 1997). General structure of SWOT Analysis realized within the scope of A'WOT is given in *Table 2*.

Table 2. *Structure of SWOT analysis*

SWOT ANALYSIS		
	POSITIVE FACTORS	NEGATIVE FACTORS
Internal factors	STRENGTH (How can we utilize the Strength)	WEAKNESS How can we convert these to Strength
External factors	OPPORTUNITY (How can we convert these to Strength)	THREAT (How can we convert these to Opportunity)

When the operation strategy is required to be determined by using SWOT analysis only, the internal and external factors, which are effective on the strategy, are listed roughly, indefinitely and superficially and evaluated as qualitatively insufficient (Hill and Westbrook, 1997). That is to say, in the traditional SWOT analysis, effect of each factor on the proposed plan or strategy is not determined. This problem is overcome by using AHP. In the AHP, each factor is assigned relative priorities in the direction of binary comparisons (Masozera et al., 2006). Therefore, the missing aspects of the SWOT analysis in terms of measurement and evaluation are eliminated by AHP. Thus, SWOT groups and their factors become measurable and their priorities are quantified.

The idea of using AHP within the framework of a SWOT is to assess the SWOT factors systematically and to balance them according to their intensity (Saaty, 1980;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_34373459
© 2018, ALÖKI Kft., Budapest, Hungary

Kurttila et al., 2000). When AHP is included in the SWOT analysis, it analyses the factors of SWOT analysis by comparing them with each other. AHP helps to conduct SWOT in a more analytical way and the AHP – SWOT combination is a hybrid model that is referred to as A'WOT. The range of application of A'WOT technique is quite extensive and there are many studies available since it is mostly used in the field of forestry (Leskinen and Kangas, 1998, Kurttilla et al., 2000, Leskinen 2000, Pesonen et al., 2000, Pesonen et al., 2001b, Kajanus et al., 2004; Yilmaz, 2007; Leskinen et al., 2008; Gungor, 2011; Gungor and Sen, 2018). A'WOT decision hierarchy benefiting from the AHP is given in *Figure 3*.

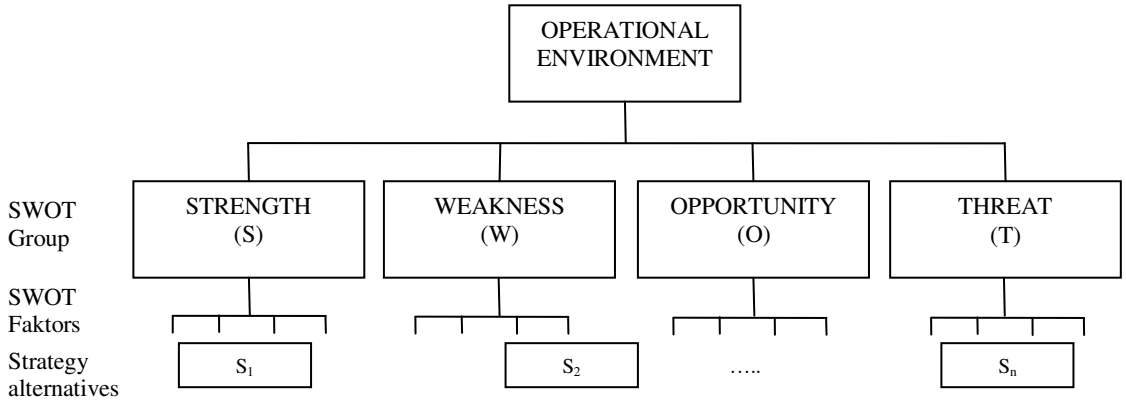

Figure 3. *Hierarchical representation of A'WOT analysis (Kangas et al., 2001)*

In the first step of the A'WOT technique, SWOT analyses are carried out. For this, firstly SWOT groups consisting of Strengths, Weaknesses, Opportunities and Threats are formed (*Figure 3*). Subsequently, the SWOT factors for each SWOT group are ranked as neutrally as possible. Thus, the internal and external equity factors obtained are included in the SWOT analysis. However, considering the fact that the human brain can compare up to 7 ± 2 elements at the same time (Schomoldt et al., 1995), the number of factors in each SWOT group should not be more than nine.

Later in the A'WOT technique, binary comparison operations are performed between the SWOT factors in each SWOT group. While these binary comparisons are being made, the one, who is performing the comparison is asked to state ordinance by asking questions such as "which factor is more preferred (important) when factor 1 is compared to factor 2?" and "how much more the factor, which is preferred more after that, is preferred than the other factor?" According to the information obtained from these comparisons, the relative significance (priorities) of the SWOT factors are calculated using the eigenvalue approach within the AHP technique. Then, the binary comparisons are made between the four SWOT groups. For this, a SWOT factor with the highest priority value is selected from each group to represent the group. Thus, by using these four SWOT factors selected from each group, the priority values of the SWOT groups are calculated using binary comparisons and eigenvalue approach, as in the previous step. In the next stage, the relative priority value of each SWOT group and the relative priority value of each of the SWOT factors in this group are multiplied separately. Thus, the overall priority value of each SWOT factor included in the relevant SWOT group is obtained. This operation is carried out separately for each of the four SWOT groups. As

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_34373459
© 2018, ALÖKI Kft., Budapest, Hungary

a result, the overall priority values of all SWOT factors, of which the total value is equal to one, are obtained (Kurttila et al., 2000; Pesonen et al., 2001a).

After making the comparisons in A'WOT, useful quantitative information about decision-making can be obtained (Kurttila et al., 2000). In addition, the use of A'WOT ensures the selection of alternatives according to each SWOT factor and each SWOT group (Pesonen et al., 2000). When the significance of different SWOT groups are identified, the selection alternatives can be prioritized as a whole in terms of strategic selection.

By including the AHP technique in SWOT analyses, SWOT groups and their factors become measurable and their priorities are set forth numerically. The weights of each calculated SWOT group and factors constitutes the basis of the strategies to be developed in the next step.

After the hierarchical structure model is created, matrices are created by making binary comparisons. Binary comparison is the comparison of two factors or criteria and is based on the judgment of the decision maker. By binary comparison, it is aimed to determine the relative significance of the elements in the hierarchy comparing to the element at the top level (Kurttila et al., 2000). In order to determine the significance levels of SWOT groups and factors among themselves in the AHS, (n×n) binary comparison matrices, which are shown in the formula given in equation 1, are created (Saaty, 1995) and the criteria or alternatives are compared binarily.

$$A=\begin{bmatrix} 1 & a_{21} & a_{31} & \cdots & a_{n1} \\ 1/a_{21} & 1 & a_{32} & \cdots & a_{n2} \\ 1/a_{31} & 1/a_{32} & 1 & \cdots & a_{n3} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 1/a_{n1} & 1/a_{n2} & 1/a_{n3} & \cdots & 1 \end{bmatrix}_{nxn} \quad \text{(Eq. 1)}$$

The relative significance of contribution to the purpose of each criteria given in Equation 1 and the superiority of each target are determined in a binary comparison of judgments (Saaty, 1980). The 1-9 significance scale developed by Saaty (1980) is used in order to assign value in the comparisons. The meanings expressed by the significance levels are shown in *Table 3*.

Table 3. *Scale of relative significance (according to Saaty, 1980)*

Intensity of importance	Definition	Explanation
1	Equal importance	Two factors contribute equally to the objective.
3	Weak importance of one over another	Experience and judgement slightly favor one over the other.
5	Essential or strong importance	Experience and judgement strongly favor one over the another
7	Very strong or demonstrated importance	Experience and judgement very strongly favor one over the other.
9	Absolute importance	The evidence favoring one over the other is of the highest possible validity
2,4,6,8	Intermediate values	When compromise is needed.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_34373459
© 2018, ALÖKI Kft., Budapest, Hungary

Following the formation of the binary comparison matrices the eigenvector of each item is calculated showing that an item is more important than the other items (Kurttila et al., 2000). The eigenvector of the matrix in dimension of n×1 is determined as follows (equation 2):

$$i = 1,2,3, \ldots., n \; ve \; j = 1,2,3, \ldots, n$$

$$b_{ij} = \frac{a_{ij}}{\sum_{i=1}^{n} a_{ij}} \quad \text{(Eq. 2)}$$

In order to determine the significance distributions of the criteria, it is necessary to calculate the W = [w_i] nx1 column vectors. W column vector is obtained from the arithmetic mean of the row elements of the matrix, which is the value of the b_y values given in the formula given in Equation 2.

The consistency ratio (CR) for each of the binary comparison matrices is calculated (equation 3). For this ratio, an upper limit of 0.10 is required. The ratio being over 0.10, means that there is inconsistency in decision making. In this case, improvement is necessary in judgement. The largest eigenvector of the matrix A (λ_max) is calculated and the CR value is obtained (equation 4).

$$i = 1,2,3, \ldots., n \; ve \; j = 1,2,3, \ldots, n$$

$$D = [a_{ij}]_{nxn} \times [W_i]_{nx1} = [d_i]_{nx1} \quad \text{(Eq. 3)}$$

$$\lambda_{max} = \frac{\sum_{i=1}^{n} \frac{d_i}{w_i}}{n} \quad \text{(Eq. 4)}$$

The randomness index (RI) is another value needed for calculating the consistency ratio. *Table 4* contains the RI values which are determined from constant numbers and determined according to n value (Kurttila et al., 2000). The CR value is calculated according to the formula given in Equation 5.

$$\boldsymbol{CR} = \frac{\boldsymbol{\lambda - n}}{\boldsymbol{(n-1).RI}} \quad \text{(Eq. 5)}$$

Table 4. *Randomness index*

n	1	2	3	4	5	6	7	8	9	10
RI	0.00	0.00	0.58	0.90	1.12	1.24	1.32	1.41	1.45	1.49

Later, the factors taking the highest values as a result of A'WOT calculations are detailed to make the strategies more effective. In this stage, Conjoint Analyses were utilized and more detailed strategies were developed in this way by adding criteria to the factors found in A'WOT results in the Conjoint Analysis.

Conjoint analysis

The word Conjoint is a combination of the words CONside and JOINT. Conjoint Analysis (CJA) was developed in the 1970s (Orme, 2009). CJA is a market research method determining the consumer preferences of multi-featured goods or services that are effective in demand determination. By using this analysis, it is assumed that the value given to any product by a person corresponds to the total utility deriving from all of the determined qualities of that product and then, the likelihood of purchasing that product is in proportion to the benefit they obtain from that product. CJA determines the most customer satisfactory combination of the factors related to the product or service that they consider during the purchasing stage and at the same time ensures the determination of the most preferred factor levels for that product or service.

The measurement of tools is one of the most basic concepts in CJA which is designed as factors and sub-levels. A utility gives a subjective decision of preference of each participant. It also forms the conceptual basis for the measurement value which is a very important concept for this research (Anderson et al., 2010).

In case the number of factors and their levels are high in CJA, an extra burden will be added on the participants and the time speared for the research by participants will increase. Many participants may not want to participate in the survey since it will take too much time or even they do participate, they may give up they may quibble in order to save time (Louviere, 1988; Marshall and Bradlow, 2002). For this reason, there is no need to include a factor, which does not make any difference in the study to be carried out (Hair et. al, 1995). The number of factors to be used in CJA is usually between 4 and 7 and this number can increase up to 10 to 15. The number of levels is determined to be between 2 and 5 (Scholl et. al, 2005).

A simple model of CJA, which is generally used to understand consumers' reactions or preferences to a product or service, is given in equation 6 (Malhotra, 1996; Raghavarao et. al, 2010):

$$y_k = \sum_{j=1}^{J} \sum_{m=1}^{M_j} \beta_{jm} x_{jm} \qquad \text{(Eq. 6)}$$

Here:

y_k : Total utility of an alternative,

β_{jm} : Utility value of factor j at level m,

x_{jm} : The dummy variable, which takes the value of 1 for level m of the factor j and 0 for the other cases, 1 if incentive k has value m of factor j 0 else.

CJA, which includes statistical analysis such as correlation and regression and uses qualitative and quantitative data, analyses the effects of many independent variables by using the (utility) function as a dependent variable. In this way, the effect of each variable on consumer preference is determined.

CJA was used in many researches such as Irish consumer preferences for honey (Murphy et al., 2000), in the preference of local food producers (Darby et. al, 2008): in the preference stage of honey consumers in Czech Republic (Sanova et. al, 2017).

In this research, the strategies found as a result of A'WOT were ranked by CJA. For this, the significance of each factor and sub-level influencing the preferences were

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_34373459
© 2018, ALÖKI Kft., Budapest, Hungary

determined by CJA (utility, weight) and their combinations were presented to the participants. By this means, the optimum management strategy of HPF was determined.

Preparation and implementation of survey forms

SPSS (Statistical Package for Social Science) 21.0 package program was used for A'WOT and CJA. Surveys conducted under the context of A'WOT and CJA were implemented through face-to-face interviewing method in place. The surveys were made in the Central District, Amasra District and Kozcagiz District of Bartin.

The number of participants was determined according to the simple random sampling method. In this method, the sub-groups/layers are represented in the sample at the proportion of their weights in an environment of which the boundaries are set. In order to be able to make the sampling, the number of units to be selected from each sub-population is determined by the share of that sub-population within the entire population (Kurant et al., 2011). Thus, the sample to be formed is guaranteed to represent the population with all its sub-units (Fuller, 2009). Participants in the study were assessed in three interest groups (in the sub-layer) as local residents, public institutions and NGOs in order to increase the precision of A'WOT and CJA analyses. Later, the number of participants, who were subject to the survey in each interest group, was calculated using the formula given in equation 7 (Daniel, 1999):

$$n = \frac{NZ^2pq}{d^2(N-1)Z^2pq} \quad \text{(Eq. 7)}$$

Where:

N : Population size (102 people from the local population, 20 people from public institutions, and 98 people from NGOs),

n : Sample size (50 people from the local population, 10 people from public institutions, and 50 people from NGOs),

Z : Z statistic for a level of confidence. Confidence level 95% (1.96),

p : Probability of the presence of the aspect aimed to be measured within the main group (taken 50% due to the multi-purpose nature of this study),

q : 1-p,

d : Sampling error considered 10% (0.1).

As a result of the calculations made, surveys were made within the context of both A'WOT and CJA with a total of 110 people, 50 from local residents, 10 from public institutions and 50 from NGOs.

Results and Discussion

SWOT findings and A'WOT calculations

Evaluation of Bartin Province in terms of honey production is given in *Table 5*. SWOT outputs were evaluated by AHP under the scope of A'WOT and the values of SWOT groups and factors, which were considered to be effective in the development of HPF management strategies in Bartin, were obtained.

When *Table 5* is examined, Strengths group has the highest score in the SWOT group with 0.352. This is followed by Opportunities with 0.324. Weaknesses with 0.172 ranks third and Threats with 0.151 is the last. According to these results, it is understood that in the development of the HPF management strategies for Bartin Province, a structure, which emphasizes Strengths and Opportunities and dismisses Weaknesses and Threats, should be adopted. Moreover, "S4" in the Strengths group has the highest score among the SWOT factors with 0.245 (0.086 in the total average). "O3" with 0.224 (0.,073 in the total average) from Opportunities group ranks second. "W2" with 0.202 (0.035 in the total average) from the Weaknesses group ranks third and "T5" with 0.147 (0.022 in the total average) from the Threats group is the last one. In addition, showing the values obtained on the figure is given in *Figure 4*.

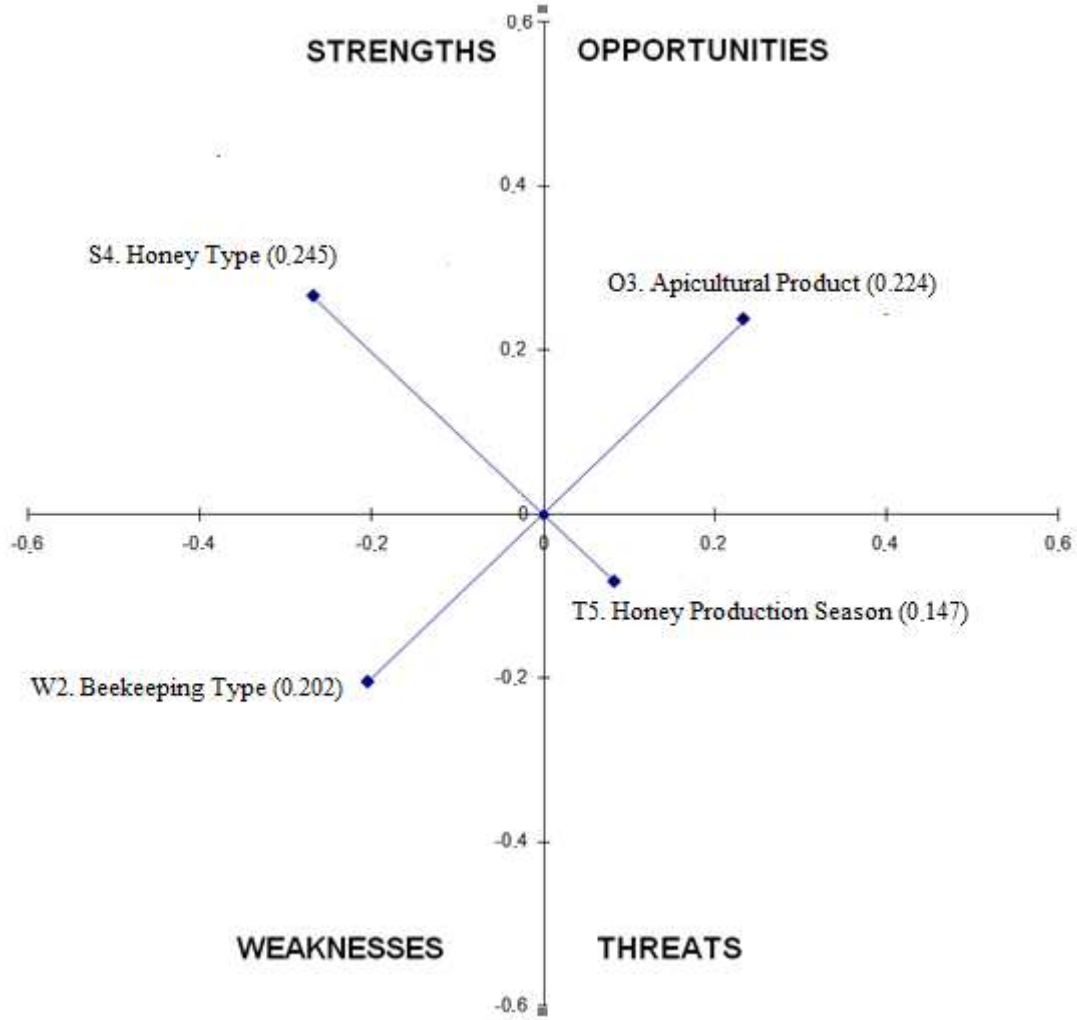

Figure 4. *An illustration of the relative significance of SWOT factors in an A'WOT application to HPF optimum management strategy*

CJA calculations

CJA was used in determining the sub-criteria of the factors determined by A'WOT. In the CJA calculations made according to the formula given in Equation 1, "*preference score and order of priority for alternative HPF management strategies"* was taken as the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_34373459
© 2018, ALÖKI Kft., Budapest, Hungary

dependent variable. Dependent variable was measured by ordering and 9 strategies were used in ordering. In the development of the strategies, there were four independent factors (variables) determined by A'WOT and three levels developed under CJA (*Table 6*).

Table 6. *A'WOT factors and CJA levels*

1st Step: Factors determined under A'WOT			2nd Step: Levels developed under CJA
SWOT groups	**SWOT factors**	**Factor Name**	**Factor Level**
Strengths	S4	Honey Type	1. Tilia + False Locust Honey 2. Chestnut Honey 3. Rhododendron Honey
Weaknesses	W2	Beekeeping Type	1. Stationary beekeeping on the same land 2. Migratory beekeeping on the same land 3. Migratory beekeeping on different lands
Opportunities	O3	Apicultural Product	1. Honey + Royal Jelly 2. Propolis + Bee Venom 3. Pollen + Beeswax
Threats	T5	Honey Production Season	1. Maximum 3 months 2. Approximately 6 months 3. 9 months and longer

By taking the factors and sub-levels in *Table 4*, it is possible to develop a total of 3^4=81 combinations (strategies) on the basis of full design (full profile) (Green and Sirinavasan, 1978; Malhotra, 1996, Gungor, 2005). However, in this case it is difficult and time consuming for participants to prioritise 81 strategies. For this reason, management strategies have been developed in which each factor and sub-levels are independent (as an orthogonal design) (Hair et al., 1995; Smith, 1999). In the development of these strategies, in accordance with the CJA and for the purpose, the most negative level of each factor was taken as a reference (*rhododendron honey* for the factor of honey type, *pollen+beeswax* for apicultural product factor, *maximum 3 months* for honey production season, for the type of beekeeping *stationary on the same land*). For the remaining levels, 8 dummy variables with the values of 0 or 1 were defined. Based on this dummy variable defined, 9 alternative management strategies were developed based on orthogonal design (*Table 7*).

Table 7. *HPF management strategies formed on the basis of orthogonal design in CJA*

Strategy No	Factors and Levels			
	Honey Type	**Apicultural Product**	**Honey Production Season**	**Beekeeping Type**
1	Tilia + False Locust Honey	Pollen + Beeswax	Approximately 6 months	Stationary beekeeping on the same land
2	Tilia + False Locust Honey	Propolis + Bee Venom	Maximum 3 months	Migratory beekeeping on the same land
3	Chestnut Honey	Honey + Royal Jelly	Approximately 6 months	Migratory beekeeping on the same land
4	Tilia + False Locust Honey	Honey + Royal Jelly	9 months and longer	Migratory beekeeping on different lands

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_34373459
© 2018, ALÖKI Kft., Budapest, Hungary

5	Rhododendron Honey	Pollen + Beeswax	9 months and longer	Migratory beekeeping on the same land
6	Rhododendron Honey	Propolis + Bee Venom	Approximately 6 months	Migratory beekeeping on different lands
7	Chestnut Honey	Propolis + Bee Venom	9 months and longer	Stationary beekeeping on the same land
8	Chestnut Honey	Pollen + Beeswax	Maximum 3 months	Migratory beekeeping on different lands
9	Rhododendron Honey	Honey + Royal Jelly	Maximum 3 months	Stationary beekeeping on the same land

Later on, special cards were prepared for the strategies in *Table 7* and presented through personal interviews. The interviews were held in Bartin in 2016 with representatives of local residents and state institutions and non-governmental organizations. The number of persons interviewed was found using the formula (Equation 7) that gives sample size in limited communities.

Determination of optimum management strategy

As required by CJA, the participants were asked to rank the strategies, which are formed according to *Table 7*, from the best to the worst. The optimum management strategy for the HPF in Bartin was determined as the result of the analysis of the linear regression model, in which the average of the priorities given by 110 participant to each strategy is considered the dependent variable and the dummy variable levels of the factors as independent variable, using CJA.

According to the CJA results, in the strategies developed during the establishment process of honey forest, "*Honey Production Season* "with 34.44% ranks first, "*Beekeeping Type*" with 28.15% ranks second, "*Honey Season*" with 22.66% ranks third and "*Apicultural Product*" factor with 14.75% ranks last (*Table 8*).

Table 8. *CJA results*

Factor Name	**Factor Levels**	**Utility Coefficient**	**Significance Level (%)**
1. Honey Type	1.1. Tilia + False Locust Honey	-0.151	22.66
	1.2. Chestnut Honey	0.572	
	1.3. Rhododendron Honey	-0.421	
2. Apicultural Product	2.1. Honey + Royal Jelly	0.507	14.75
	2.2. Propolis + Bee Venom	-0.363	
	2.3. Pollen + Beeswax	-0.144	
3. Honey Production Season	3.1. Maximum 3 months	-0.748	34.44
	3.2. Approximately 6 months	0.421	
	3.3. 9 months and longer	0.327	
4. Beekeeping Type	4.1. Stationary beekeeping on the same land	-0.993	28.15
	4.2. Migratory beekeeping on the same land	0.565	
	4.3. Migratory beekeeping on different lands	0.428	

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_34373459
© 2018, ALÖKI Kft., Budapest, Hungary

For the most preferred and most important "Honey Production Season" factor, the "*Honey production season being approximately 6 months*" level with a utility coefficient of 0.421 ranked first, the "*Honey production season being 9 months and longer*" level with the utility coefficient of 0.327 ranked second, the "*Honey production season being maximum of 3 months*" level with the utility coefficient of -0.748 ranked third.

According to these results, participants want the honey production season to be approximately 6 months. Bartin Province (770 mm), which in fact has a rainfall average above the Turkey's rainfall average (573 mm), (BMST, 2017) is also above the country average (17%) in terms of honey plant rate (the average of Bartin Province is 23%) (GDF, 2011). This situation provides an advantage to Bartin Province in terms of honey production. However, when the yield level statistics per hive are examined (*Table 1*), it is understood that the hive yield is below the country average.

The honey production season shorter than three months means a low income for the beekeeper and it causes them to spend the rest of the year actively and makes it necessary for them to deal with other works. This prevents the desired specialization in beekeeping and causes people to consider beekeeping as a hobby (Korkmaz at all, 2015). It is possible to find the same result in other countries as well. For example, according to data of 2010, around 76% of beekeepers in Europe see this work as a hobby. However, around 10% does beekeeping professionally. However, in Kosovo and Hungary, 20% or less of the beekeepers were hobbyists. In Romania, about half of all beekeepers were hobbyists. Except for Kosovo, Greece, Romania and Spain, professional beekeepers represented less than 10% of the total population of beekeepers (Chauzat et al., 2013).

Although the beekeepers react positively to the fact that the honey production season is 9 months or longer, the latter statements indicates that this will not be possible in Bartin and its surrounding regions. Likewise, experienced beekeepers and institutional officials stated that honey yield has decreased after the extension of season (6 months and more), especially in the production of chestnut honey (Gungor and Ayhan, 2016).

For the "*Beekeeping Type*" factor, which has the second important place in the strategy, the "*Migratory beekeeping on the same land*" level is the most preferred one with a utility coefficient of 0.565. This was followed by "*Migratory beekeeping on different lands*" with a coefficient of 0.428. The least preferred is the "*Stationary beekeeping on the same land*" with the coefficient of -0.993. According to these results, it is understood that the participants are more interested in migratory beekeeping than stationary beekeeping. When the literature related to the subject is examined (GDF, 2011, 2012a, 2012b; BAKKA, 2011; BHFP, 2013; HFAP, 2013; Gungor and Ayhan, 2016; Gungor and Sen, 2018) it is understood that for the success of beekeeping, it is a must to shift from stationary beekeeping to migratory beekeeping.

The point to be considered here is the performance of "migratory beekeeping on the same land" activity instead of "migratory beekeeping on different lands", which is a more comprehensive beekeeping activity, due to limited capital and labour in shifting from stationary beekeeping to migratory beekeeping. Likewise, when considering the rough structure of the Bartin Province and its surrounding topography (BHFP, 2013), and the honey plant richness (Genc, 2003; Misir, 2011), different vegetation periods can be observed even in the case of a single honey forest in the same year. For this reason, a certain amount of accumulated capital and labour should be ensured in beekeeping first

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_34373459
© 2018, ALÖKI Kft., Budapest, Hungary

and in the next stage, migratory beekeeping, which is the way of professional beekeeping that should be adopted.

For the "Honey Type" factor, which has the third important place, the level of "Chestnut Honey" is the most preferred one with a utility coefficient of 0.572, while the other levels are less preferred. When looking at the market sales prices of the region for honey, it is understood that the highest return belongs to chestnut honey (BAKKA, 2011; FAO, 2009, 2018; Gungor and Ayhan, 2016; TUIK, 2017; BAB, 2017; Gungor and Sen, 2018). This, naturally draws the attention of the beekeepers and the community to chestnut honey. Just like the honeydew honey in Mugla and Anzer honey in Rize, the chestnut honey draws the attention of honey consumers and producers in Bartin. The obtained results of the survey are also corroborative regarding the interest in chestnut honey in Bartin. The interest for the chestnut honey in Bartin Province was also observed in another province of Turkey. In other words, it was determined that the consumers from Izmir knew the chestnut honey with 33.3%, citrus honey with 9.4%, thyme honey with 21.6%, hayit honey with 11.8% and French Lavender honey with 3.9% (Baki et al., 2017). However, due to climatic conditions, the production values of chestnut honey in the region change from year to year (TUIK, 2017). Likewise, the average rainfall of the last 5 years (690 mm) is lower than the average of the last 50 years (770 mm) (BMST, 2017). For this reason, during the last 5 years, there have been significant decreases in the production of chestnut honey in Bartin Province (TUIK, 2017) and many beekeepers have suffered from this (BAB, 2017). In order to avoid experiencing this suffering, beekeepers need to enrich the honey variety taking into account the climatic conditions and to take preventive and protective measures against fluctuations in honey prices such as the diversity of the portfolio in the economy. Based on what has been told, it will be appropriate to take other types of honey (linden honey, false locust honey and rhododendron honey) into consideration in addition to chestnut honey.

For the “Apicultural Product” factor, which ranks the last meaning the least important one, the "Honey + Royal Jelly" level was the most preferred one and the "Propolis + Bee Venom" level was least preferred one with a utility coefficient of 0.507. The obtained results show that level of interest and knowledge of beekeepers and people of the region on apicultural products is inadequate.

In another study conducted in this subject (Baki et al., 2017), it was understood that 60% of the consumers consumed pollen, 36% consumed propolis and 4% consumed the royal jelly. However, it was determined that they did not use cream containing bee venom for therapeutic purposes. While the consumption of cream honey, organic honey and royal jelly was not encountered in studies conducted in previous years (Saner et al., 2011), in this study the consumer, who consumed these products, were encountered despite the low rate and number. Based on the formation of required consumer awareness, increased consumption of such apicultural products depends on ensuring healthy production and accessibility to these products in Turkey (Baki et al., 2017).

When it comes to beekeeping, the most common product coming to mind is honey. In fact, since honey is the most profitable product among the apicultural products, the result of this survey can be considered as natural. However, both for the sustainability of production and in order to increase the income generated from apicultural products and to reduce the risks, other apicultural products such as propolis and royal jelly should also be produced and consumed in the region (Baki et al., 2017).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_34373459
© 2018, ALÖKI Kft., Budapest, Hungary

In order to ensure diversity in apicultural products, some progress has to be made in beekeeping as well. For example, the approach of regarding beekeeping as a second occupation or even as a hobby should be put up, specialized and qualified beekeeping activities should be performed and the capital allocated by the beekeepers for this work in this context should be increased (Park ve Youn, 2012). In addition, it is a must to have extensive knowledge on beekeeping in order to obtain all of the apicultural products. In a study conducted in Japan and South Korea (Kohsaka et al., 2017) on this subject, it was emphasized that the combination of traditional methods of beekeeping with modern methods would be important for beekeepers.

When the honey yield values of the World, Turkey and Bartin Province are compared, the average annual honey yield of our country (15 kg) is considerably lower than the world average (22 kg) (FAO, 2018). Bartin's honey yield value (14 kg), which is already below the world average, is also lower than the country's average (TUIK, 2017). Hive presence of Bartin and Turkey, which is in good state when compared in terms of the hive presence of the world, does not comply with the values obtained in honey production and honey yield (Gungor and Ayhan, 2016). In a comparison made for European countries, it was reported that honey yield levels and hive numbers of EU countries are also below the world average (Chauzat et al., 2013).

On the other hand, it should also be known that the increase in crop yields of plants provided by bees through pollination is 10-12 times (Yakovleva, 1975), even 20 times (Crane, 1972; 1975) of the monetary value gained from apicultural products. Also, there are many studies regarding the benefits of bees on pollination (EFSA, 2013; Goulson, 2013; IUCN, 2013, etc.). When including the economic values to be obtained indirectly through positive externalities in the light of this information, the honey production quantities and economic return of the HPF in Bartin Province will rise to higher levels.

Conclusions

In the research, a structure, which takes the ecological, social and economic values into consideration and acts according to the participation principle, was taken into consideration and A'WOT-CJA calculations were made within this scope. In the establishment phase of HPF, the current situation is set forth by SWOT analysis, prioritized with AHP (according to A'WOT technique) and arranged by CJA. For this reason, the research is the first forestry study in Turkey where A'WOT-CJA are used together.

According to the A'WOT findings obtained, Strengths (0.352) ranks first, Opportunities (0.324) ranks second, Weaknesses (0.172) ranks third, and Threats (0.151) ranks fourth in SWOT groups. In the development of management strategies in the direction of A'WOT, a structure, which emphasizes Strengths and Opportunities and dismisses Weaknesses and Threats, was adopted. According to this, the presence of natural forests and honey plants increasing the honey yield in A'WOT, the fact that the chestnut honey, which has a high market price and is in demand, is produced in the region, the long honey season and the existence of production potential of apicultural products such as pollen, beeswax and propolis including honey are the factors standing out.

In the research, sub-levels were added to the factors found in the A'WOT result *(honey type, apicultural product, honey production season, beekeeping type)* in CJA and optimum management strategy was determined to be *"In the province of Bartin,*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_34373459
© 2018, ALÖKI Kft., Budapest, Hungary

chestnut type with high yield of honey should be given priority, the lands, where the flora is rich in terms of honey plants, should be selected as honey forest areas, these lands should be prepared especially in the way of increasing honey and royal jelly yield, the lands, where the honey production lasts approximately six months, should be highlighted in land selection and the honey forest lands should be constructed in a way to support migratory beekeeping." as a result of CJA calculations.

A'WOT-CJ model used under the scope of the research can be used in the prioritization stage of HPF lands, which are planned to be set up in Turkey, and in the decision making stage. By using A'WOT-CJA, which has an analytical structure, including the HPF management plans will have a more dynamic structure and potential conflicts between beneficiaries, local residents and management can be avoided as the opinions of the interest groups, meaning participants, were taken into consideration at the planning stage. Besides, the HPFs to be established in line with the developed strategy will contribute to the formation of a sustainable structure, to local beekeeping and to rural development. The HPFs, which have an important position in terms of food security, should be one of the priority issues in the strategies to be developed in order to support the rural population in Turkey.

In the study, a hybrid MCDM method was applied in determining the HPF management strategies. In this method, A'WOT and CJA techniques are used together. From this aspect, it is possible to state that it is a case study in the field of prioritizing natural sciences, forestry and management strategies. In addition, A'WOT-CJA followed in this study will be a role model for future research projects.

Acknowledgments. This research did not receive any specific grant from funding agencies in the public, commercial, or not-for-profit sectors.

Abstract. Research on the effect of gabions (wire mattresses filled by stones) on stream biota was conducted on the regulated and natural reference reaches of the Oščadnica stream in northern Slovakia. The fish community reacts sensitively not only to overall sets of changes but also to the shape and material of a riverbed. Therefore, the assessment of the impact of the gabions on the stream biota was realized by the bioindication of the ichthyofauna. Based on a comparison of the quantitative indicators in the regulated and natural reference reaches of the Oščadnica stream, we can say that gabions do not have any negative effects on the ichthyofauna, which is mainly represented by brown trout. Brown trout is the species that reacts most sensitively to morphological stream changes. The results of the research show that gabions do not have any negative effects on the stream biota.
Keywords: *bioindication, ichthyofauna, river regulation, armouring of the river channel, abundance, ichthyomass*

Introduction

River regulation changes a river´s basic morphological and flow characteristics, for example, by alternating riffle zones with calm pool areas and introducing variable riparian borders with a wide range of cover places for fish. This type of activity has a negative impact on river biota and results in decreased biodiversity (Cianfrani et al., 2009; Palmer et al., 2010). Modifications resulting from regulations are very noticeable in assessments of the availability of specific habitats that are necessary for a river´s restoration (Mažeika et al., 2006). It has been shown that the negative impacts of river regulation are mainly restricted to a river´s upper reaches or rhitral streams (Macura, 2012). The variability of a riverbed decreases in the upper part of a stream, which has a significant impact on the ichthyofauna. Therefore, any morphological changes are reflected by the fish (Macura et al., 2012).

The research shows that freshwater fish are good indicators of morphological changes in the river channel and biotic integrity in freshwater ecosystems (Pont et al., 2006, Cheek et al., 2016, Roni et al., 2014, Schmutz and Jungwirth, 1999). They also respond sensitively to changes in temperature and flow (Avery-Gomm et al., 2014, Schlosser, 1987, 1990; Cowx and Welcomme, 1998). Due to their longevity, mobility and sensitivity to biotope changes, they are suitable for assessing the ecological river

integrity (Keeley et al., 2015, Aarts and Nienhuis, 2003, Chovanec et al., 2003, Welcomme et al., 2006).

The Water Framework Directive (2000/60/EU) requires information about morphological changes and other characteristics of the quality of a stream that affect the presence of macrophytes and macroinvertebrates (Artemiadou et al., 2005; Friberg et al., 2005).

A river restoration scheme that preserves the high variability of a riverbed does not have any negative impact on an overall ecosystem. The design parameters of covers, pools and other structures that create a variable morphology in a regulated channel are therefore important components of restoration proposals of rivers (Koščo et al., 2010) and water reservoirs (Augustinková et al., 2017). Biological and hydrological relations have been studied in many streams, and authors have drawn attention to specific flow patterns that are specific to individual regions. However, these relations are better described by biological responses to alterations in flow regimes (Snelder and Lamouroux, 2010).

Therefore, it is necessary to focus on the factors that affect the living conditions of aquatic organisms and their life processes. Therefore, fish are suitable bioindicators for a water environment because their lives are closely connected to their environment. Individual species always occupy a certain kind of habitat, so that each change in the environment can cause changes in its fish community. Species that are able to adapt can survive; others recede into more suitable conditions or are completely eliminated. Other species that can survive in these conditions come to that location, which changes not only the whole original fish community but also the ecological nature of the flow. The fish community reacts sensitively not only to a whole set of changes but also to the shape of and the material constituting the riverbed.

Intensive discussions are ongoing among water managers, ichthyologists and hydrobiologists. Nowadays, these specialists believe that the success or failure of any restoration project depends on understanding of river biotopes (Zhang et al., 2016) and continuous stream monitoring. The aim of current research is to quantify the design characteristics of appropriate habitats for river restorations (Döll et al., 2010; Pastuchová et al., 2008). Taking this trend into account, the results in this article are focused on the impact of the objectification of gabions on the aquatic habitats of streams.

The characteristics of gabions

The basic philosophy of a gabion´s structure is its fusion with a natural environment. After decades, the whole gabion´s construction is overgrown by vegetation and is thereby perfectly stabilized. The system is ecological; the materials used have a natural character, except for the use of wires that are covered by a PVC protective layer. This type of gabion is only used when the wiring construction is expected to have a long life and is located in an aggressive environment. Based on the type of construction for which the structure is designed, several basic types of products, such as baskets, mattresses and sacks, are available. These elements can be combined. To stabilize a slope, a combination of a basket with a rod that forms a mesh of different lengths is also often used.

An important area in gabion constructions is their use in water management structures. It is even possible to say that we find gabion constructions the most

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_34613472
© 2018, ALÖKI Kft., Budapest, Hungary

important constructions in the field of water management structures. As in other types of constructions, different systems and materials can be used. In water management structures, wire mattresses are the most suitable construction elements due to their elasticity. Because a flexible construction can copy a terrain and carry large deformations without any destruction, wire mattresses can be recommended for fragmented riverbanks in river restorations.

Materials and methods

The Oščadnica stream in northern Slovakia (*Fig. 1*), where the two reference reaches were chosen, was selected to determine the impact of wire mattresses in a regulated stream channel. The natural reference reach (49.4193° N 18.8417° E) is 150m above the regulated stream channel (49.4198° N 18.8388° E). The stream channel is structured, and the riverbanks are stabilized by the root system of the riverbank vegetation (*Fig. 2*).

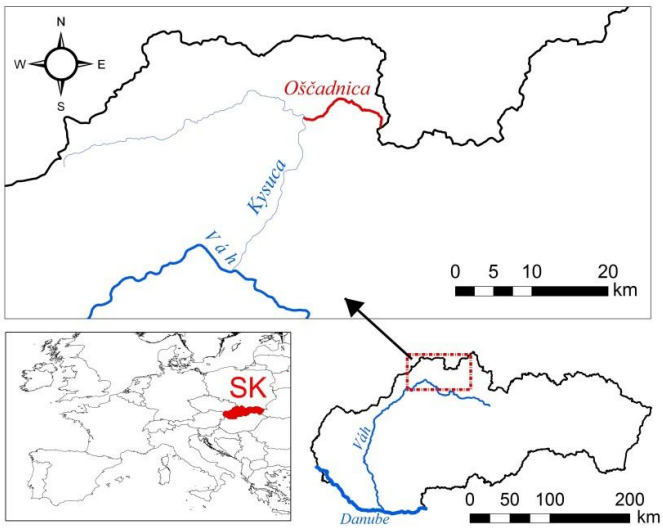

Figure 1. *Location of the Oščadnica stream within Europe*

Figure 2. *Natural reference reach of the Oščadnica stream*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_34613472
© 2018, ALÖKI Kft., Budapest, Hungary

In the regulated reference reach, the stream channel has a simple trapeziodal profile with slopes on a gradient of 1:1.5. The slopes and the base are stabilised by wire mattresses. The reference reach lacks riverbank vegetation (*Fig. 3*).

Figure 3. *Regulated reference reach of the Oščadnica stream; the riverbanks are stabilized by wire mattresses*

The water quality

The data about the water quality in the Oščadnica stream were taken from the hydroecological projects of the Váh catchment. The oxygen content was determined by direct measurements by an oxygen searcher (Hana Instruments) during the ichthyological research. The saturation of the water by oxygen ranged from 95.2% to 98.8%.

Topographic measurements in the reference reaches

The topography of the reference reaches is represented by cross sections that are related to the polygonal traction. The polygonal traction is created by points located between 20 - 25 m apart. The cross section was measured by nivelation from each point. The polygonal traction points were fixed with wooden pins. Properly measured polygonal traction allows for the changing of any fixed points in case of their damage. Longitudinal and cross sections were implemented for the hydraulical model.

Ichthyological research

The research on the Oščadnica stream was realised five times between 2015 and 2016. The selected reference reaches of the stream were covered by 10 x 10 mm mesh barriers at both ends after hydrometric measurements. The fish were pursued by an electrical aggregate. After the fish were caught, they were placed in a relay located below the lower barrier in the stream and outside the electric field. In each reference reach obstructed by mesh, three hunts were undertaken at an average interval of 45 minutes. After each hunt, the fish were counted, measured, weighed and released back to the stream below the mesh.

The abundance was evaluated from the measured data, according to the Leslie and Davis method (1939).These values, in combination with the average weight of each species, were used to calculate the biomass of each species and the total ichthyomass. „Abundance“ refers to the frequency rate of each species, whereas the biomass is its total weight. The total abundance means the entire frequency rate of all the individual species in the community in the selected stream, and the ichthyomass means the total weight of the community. The abundance, biomass and ichthyomass values are presented per hectare of the water surface.

“Occurrence constancy” is evaluated according to the presence of individual species in a given reference reach depending on the time. This “occurrence constancy” expresses the persistence of the generic composition of the ichtyocenosis.

The relevant calculations are:

$$K = \frac{n_i}{s} \quad \text{(Eq.1)}$$

where K is the “Occurrence constancy”, n_i is the amount of samplings of the occurrence of the species i, and s is the number of all the samplings. The occurrence constancy is expressed in the following categories:

I uncommon species: 0-20%
II rarely occurring species: 20-40%
III species often occurring: 40-60%
IV species predominantly occurring: 60-80%
V species almost always occurring: 80-100%

Other characteristics of the ichthyofauna are shown by the species diversity index and equitability index. The diversity index represents the ratio of the number of species and the number of individuals in the population. The diversity index is a structurally quantitative expression of the characteristics of each community, in this case, ichthyocenoses. The relevant calculation is:

$$H' = \sum_{i=1}^{s} \left(\frac{n_i}{N}\right) \cdot \ln\left(\frac{n_i}{N}\right) \quad \text{(Eq.2)}$$

where S = total number of species, n_i = number of individuals for “i” species, and N = total number of individuals of all the species.

Equitability (equanimity) relates to diversity and expresses the relative distribution of all the individuals in the community of the species present. The relevant calculations are:

$$K = \frac{H'}{\ln S} \quad \text{(Eq.3)}$$

where H'= diversity index, and S = the total number of species detected.

Schedule of the field measurements

From the perspective of the determining the impact of the stream regulation, the impact of climate change or the conservation of fishery resources, it is important to focus on the summer period (Carlson et al., 2015, Murchie et al., 2008). Summer period at the minimum discharge can be considered as a design condition, because it creates

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_34613472
© 2018, ALÖKI Kft., Budapest, Hungary

the highest load on the biota of the stream. High discharges do not have any significant negative impact on the biota of the stream. Hence, the dates of ichthyological, topographic and hydrological measurements were scheduled during the summer period at low water levels. To accentuate the impact of higher temperatures, ichthyological measurements have started at 11 am and ended after 4 pm. After all, the discharge was determined by hydrometry and the water level in the individual cross sections was marked. The topography of the riverbed was always measured the following day, after ichthyological and hydrometric measurements. Specific dates for ichthyological and hydrometric surveys were: 4.6.2015, 27.10.2015, 12.6.2016, 24.7.2016 and 2.9.2016.

Results

In the natural reference reach of the Oščadnica stream, there are demonstrably higher abundance values but small differences in the biomass (*Fig. 4* and *Table 1*). From the data, it is clear that fewer fish were present in the regulated stream reference reach but that their weight was higher. The hydrobiological research also confirmed that the wire mattresses did not have any negative impact on the macrozoobenthos. An evaluation of the macrozoobenthos on both reference reaches indicated that no significant difference was found in the structure of the species and in the amount of the bottom fauna in the regulated and natural reference reaches. The amount of organisms was only lower in the sampling in 2015 in the regulated reference reach, but the species diversity was higher in the regulated reference reach. There were no differences in the number of taxa found (the measurements were taken twice, i.e., in May and September).

The results obtained indicate that even in a prismatic stream channel that is not suitable for fish, there are the same ichtyomass and macrozoobenthos. This confirms the assumption that wire mattresses have a similar influence on the biota as rockfill or as a natural riverbank.

Explanations: BT = brown trout, EM = Eurasian minnow, AB = Alpine bullhead, SL = stone loach, CH = chub, G = grayling

There are six species of fish (*Table 2*) in the monitored reference reaches of the Oščadnica stream. While all six species were present in the regulated reference reach, only four species were detected in the natural reference reach. Grayling and chub are not found in this reference reach. The "constantly occurring" species in both reference reaches are Eurasian minnow, brown trout and Alpine bullhead; the regulated reference reach also contains stone loach. The grayling and chub in this reference reach belong to category I, uncommon species. The stone loach in the regulated reference reach belongs to category II, species that rarely occur.

The state of these indexes of the diversity and equitability of the species in the regulated reference reach is statistically higher than in the natural reference reach (*Table* 3).

The abundance and biomass of brown trout in the natural part of the Oščadnica stream is significantly higher than in the regulated part, with the exception of the regulated part, where the autumn biomass is lower. The average weight does not show any significant differences between the natural and regulated streams; however, the spring values are higher than the autumn values.

Discussion

There is enough information about the impact of the stream restoration on ichthyofauna (Bovee, 1982, 1986, Booker and Dunbar, 2004, Parasiewicz and Walker, 2007). Most fish species prefer certain combinations of water depths, velocity rates, bedding material and hiding possibilities. Information about the influence of velocity rate and depth of the water on habitat preferences is also sufficient, for example in Macura et al. (2016). However, there is a lack of information on the impact of the environment material, especially on the impact of the stabilisation material. Therefore, the basic aim was to compare the impact of the gabions armouring of the riverbed on the quality of the aquatic habitat. It would be ideal, if the gabion armouring was used for a natural flow for a sufficient length. Such a regulation does not exist in Slovakia, neither in the Czech Republic. Therefore, the Oščadnica stream, where the river channel is armoured by gabions on both sides and the regulation is long enough to reflect the fish habitat preferences, was selected for this study. This regulation is directly linked to the natural stream.

If there would be a significant negative effect of the regulated stream on the ichthyofauna, the research would continue by modelling the quality of the aquatic habitat by the IFIM methodology, specifically the SEFA model. This would allow a partial selection of the impact on the morphological changes in the regulated stream and the impact of the armouring material. Therefore, the reference reach was topographically measured in detail and a hydraulic model for the SEFA program was prepared. The measured results of the abundance and ichthyomass did not confirm any negative state of the restored stream compared to the natural one.

Several authors report that a suitable bioindicator of the environment is brown trout, because it responds sensitively to the changes in flow velocity and depths of the stream (Hooper, 1973; Shirvell and Dungey, 1983; Reiser and Wechse, 1976; Macura, 2016). Alpine bullhead and the stone loach are less sensitive to morphological changes. If we evaluate the trout independently, the abundance and the ichthyomass is higher in the natural stream; except the measurements in June 2015, where the parameters of regulated flow are slightly predominated. If we consider the trout together with minnow, which also sensitively responds to morphological changes, then the parameters will be again higher for the regulated stream, except for the ichthyomass in the measurements from October 2015. For the brown trout, the Wilcoxon signed-rank test has been performed, resulting in 6% significance of the abundance only. This value indicates the difference between the regulated and the natural stream, but it is not statistically significant. However, it is important to note that the number of measurements is relatively small for a good statistical evaluation. Therefore, the statistical data provided in the article is necessary to comprehend as additional data only. Based on the obtained data it cannot be clearly stated that there is a negative impact of the regulation of the Rajčianka stream as well as influence of the riverbank armouring by gabions is not pronounced.

Conclusion

Ambiguous differences in the abundance and ichthyomass values between the regulated and the natural reach confirm that the regulated reach with gabion armouring has no proven (negative or positive) effect on the ichthyofauna, that indicates the biota quality in the stream. Similarly, small differences in zoobenthos were observed. Regarding to the mentioned facts it can be said that there is no significant impact of the gabions on biota in the stream. The aim of the article was to highlight the results of the research and the description of those properties that may affect the use of gabions. The specific properties of this armouring material allow a wide range of uses in the stream regulations and restorations.

Abstract. The type and the management have strong effect on the composition and activity of microbial community and therefore on fertility of the soil. In this study ecological and conventional managements were compared in a sandy area of the Nyírség (North-Eastern) region, Hungary. Soil samples were collected twice from the upper and lower part of the sloping study sites, in autumn 2012 and in spring 2013, from the 0-30 cm and 30-60 cm depth intervals. Beside the main physical and chemical soil properties, the community structure (phospholipid fatty acid characterization) and activity (invertase and catalase enzymes) of microbes were investigated. The recycled plant residues can buffering the negative environmental/human effects, decreases the differences between the chemical and microbiological results of two elevation positions, and results favourable conditions to the soil microbes. Higher pH, total and organic C content, total and nitrite-nitrate-N content, furthermore higher enzymatic activities were measured in the ecological than in conventional site. Our results showed that ecological management had positive effect on the quality and fertility of the sandy soils in the Nyírség region by improving the chemical soil parameters and increasing the community size and the activity of microbes. Most of the measured parameters were more favourable in the 0-30 cm than the lower sampled layer.

Introduction

The global human population is 7.5 billion and it is expected to reach 9.7 billion by 2050 (UN, 2015). Thus, applying the rules of sustainable management is essential to meet the growing demand for food. Organic production is a management system based on best environmental practices, a high level of biodiversity, the preservation of natural resources and the application of high animal welfare standards. In contrast, conventional management system focuses firstly on high crop yield, however the demand for healthy foods has been started to emerge.

In ecological management mineral fertilizers could be replaced with green manure, manure, recycled crop residues. In Hungary, the ecological management is carried out in accordance with the 834/2007 and 889/2008 EU Commission Regulations. Pesticides and mineral fertilizers are allowed only in conventional management based on different regulations of the countries. The European Union is divided into three zones concerning

the authorisation of a Plant Protection Products and Hungary belongs to the zone "B", with Belgium, Czech Republic, Germany, Ireland, Luxembourg, Netherlands, Austria, Poland, Romania, Slovenia, Slovakia and the United Kingdom. Furthermore in Hungary a list of the currently authorized plant protection products and enhancing substances is published yearly. The dose of applied nitrogen fertilizers is regulated by the Nitrates Directive (1991).

Nowadays, the negative effects of used chemicals on the biodiversity and human health are known (EASAC, 2015; Kim et al., 2017; Kidd et al., 2017), moreover there are several reports on qualitative and quantitative differences of soil microbial community in ecological and conventional managements (Romaniuk et al., 2011; Ge et al., 2013). Beside sustainability, there is growing demand for healthy food and plant production and ecological management opens this door.

The soil microbial community has important role in the soil fertility, because of its influence on the dynamics of organic matter and nutrient cycles (Bowles et al., 2014).

Phospholipid fatty acids (PLFAs) are the main component of the membrane of all living microbial cells, where special PLFA patterns characterise different microbial groups (Gude et al., 2012; Zogg et al., 1997; Zelles et al., 1992; Bossio et al., 1998). Thus, the application of PLFA techniques results in direct information for the group-level identification, classification and quantification of microbial community composition (Wu et al., 2009). Properly selected and applied soil cultivation method results in higher soil organic carbon content, hereby provides available nutrients for the soil microbes (Prasad et al., 2016). The microbial activity and biodegradation as well as the organic carbon and total nitrogen content also are more pronounced in the ecological management than in conventional management system (Ge et al., 2013).

The objective of the present study was to give a complex characterization of the studied ecological and conventional sites in a topographically heterogenous area. We hypothesized, that the ecological management had favourable influence on the soil physical and chemical properties as well as on the community structure and microbial activity of soil, hereby contributing to sustainable plant production.

Materials and methods

Sampling sites and management

The studied fields belong to the Research Institute of Nyíregyháza, University of Debrecen, in the North-Eastern part of Hungary. The region has a moderately cold-dry continental climate with 10.5 °C annual mean temperature and 500-750 mm annual mean precipitation. The soil type is acidic sandy soil (Dystric Arenosols) with diverse forms of dunes (Michéli et al., 2006). The selected areas were close to each other (about 400 m, *Fig. 1*) however, soils varied according to the topographical position (*Fig. 2a,b*). Soil samples were collected from two representative upper and lower parts of the slope of both ecological and conventional management sites, so we distinguished four sample types: EU: ecological upper part of slope (475849°17'N to 475849°72'N, and 214036°82'E to 214037°35'E, 156 m above the sea level); EL: ecological lower part of slope (475848°81'N to 475849°57'N and 214031°48'E to 214031°97'E, 151 m above the sea level); CU: conventional upper part of slope (475841°35'N to 475841°91'N and 214051°10'E to 214051°55'E, 158 m above the sea level); CL: conventional lower part of slope (475842° 43'N to 475842°99'N and 214054°64'E to 214054°96'E, 153 m

above the sea level). The difference in elevation between the upper and lower part of the slope is 5 m in both site. We used for the measure of GPS coordinates an Trimble NOMAD 900 G device.

Ecological crop production has been maintained since 1997. In the studied sampling period, cereal crops (rye with hairy vetch and oat) were cultivated in the ecological and conventional fields, respectively. In both managements soils were ploughed upto 30 cm depth every year. Furthermore, in the conventional management fertilizers and pesticides were applied according to the needs of the plants. In the ecological management the loss of organic and mineral matters were compensated with farmyard and green manure (at least once in 5 years, respectively) and regular incorporation of the crop residues.

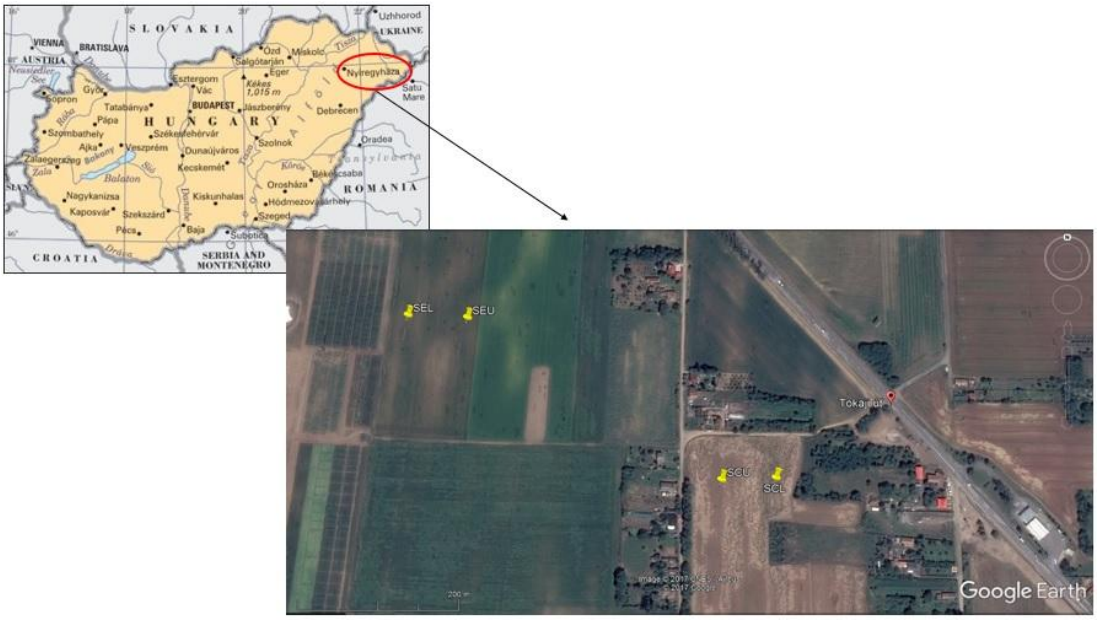

Figure 1. *Location of the investigated areas*

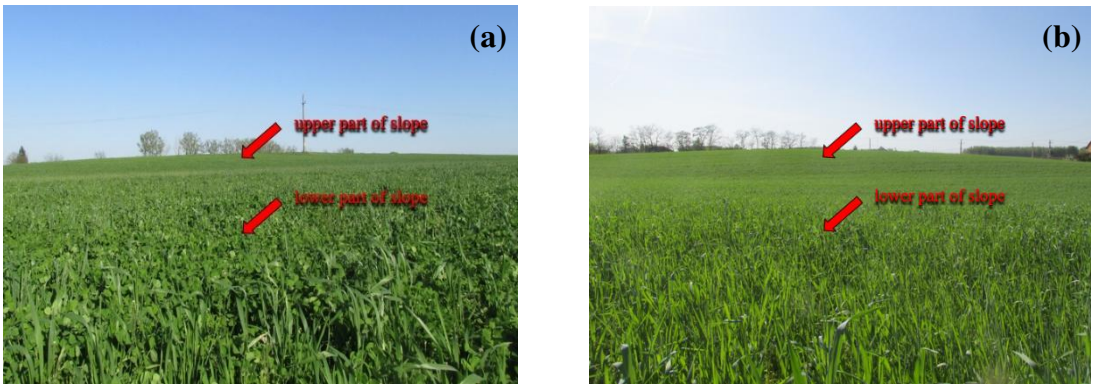

Figure 2. *Topographical differencies in ecological (a) and conventional (b) sites*

The physical properties indicated the heterogeneity of sandy soils in Nyírség region (*Table 1*). These parameters were determined with dry sieving and sedimentary method

from the upper 30 cm depth interval in autumn 2012 (Buzás, 1993), from the same samples than chemical properties. Although the two investigated sites were located within a few hundred meters, the textures of these soils were different. The soil moisture was significantly higher in the ecological site.

The cultivated plants in ecological field were rye with hairy vetch (the previous crop was buckwheat), and in the conventional site oat was cultivated and rye with hairy vetch was cultivated in 2012 year.

Sampling time and method

Samples were collected in two different seasons. The first sampling was completed in autumn 2012 (25-26 October), and the second sampling was done on 25 April 2013. The observed anomalies of weather are shown in *Fig. 3*, based on the data of the meteorological station of the Research Institute of Nyíregyháza.

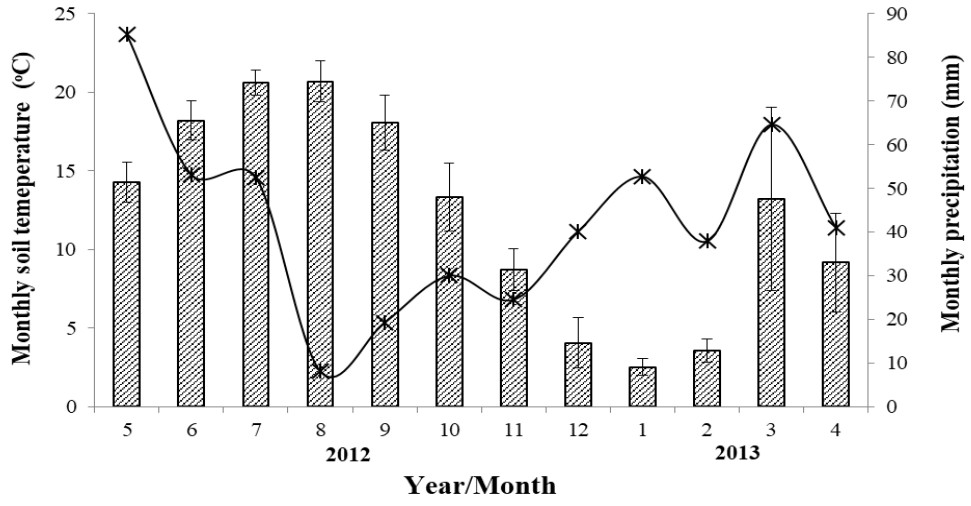

Figure 3. *Soil temperature and precipitation of the investigated areas measured by the Research Institute of Nyíregyháza, from May 2012 until April 2013. Data were provided by a μ-Metos meteorological station (Pessl Instruments GmbH.,Weiz, Austria), which recorded the data in every 2 minutes in the area of the Research Intstitute*

Soil samples were collected from two depth intervals, 0-30 cm (ploughed) and 30-60 cm, in four repetitions. One repetition is a composite of four drilled subsamples. Samples for microbial analysis were put into a cooler bag in the field, and were frozen immediately after being carried to the laboratory. The samples for chemical analysis were stored air-dried until the analysis.

Determination of chemical soil properties

These properties were measured in the samples collected from the 0-30 cm soil depth. The larger plant roots were removed and the air-dried samples were sieved (2 mm mesh size) before the chemical analyses. Soil pH was measured with a Hach-Lange, HQ411D type digital pH meter (Hach-Lange, Loveland, Colorado, USA) in a 1:2.5 soil:KCl suspension (MSZ-08-0206-2 Hungarian Standard Method, 1978). Total carbon (C) and nitrogen (N) content were measured with varioMax CNS elemental analyser (Elementar Analysensysteme GmbH, Hanau, Germany). The organic carbon content was measured spectrophotometrically (UNICAM UV2 spectrophotometer, Thermo Scientific, Waltham, Massachusetts, USA) after acidic digestion (potassium dichromate and cc. sulphuric acid; MSZ-08-0452 Hungarian Standard Method, 1980). The KCl extracted nitrite-nitrate-N concentration was measured with an autoanalyzer FIA Star 5000 (Foss, Hilleroed, Denmark; MSZ 20135 Hungarian Standard Method, 1999).

Phospholipid fatty acid (PLFA) analysis

For PLFA analysis the samples were chosen based on the results of enzyme activities measurements. PLFAs were extracted, fractionated and methylated as described by White et al. (1979) with minor modifications. Methyl nonadecanoate was used as internal standard after the methylation step. The prepared samples were stored at -20 °C until the analysis. The PLFAs were separated and identified using a gas chromatograph-mass spectrometer system (GC 6890N with MS 5975, Agilent, Santa Clara, CA, USA) with a 100 m Supelco SP-2560 column, in selected ion mode and scan mode as well (50-350 amu).

Detected PLFAs were expressed in nmol PLFA g^{-1} dry soil unit (the results were corrected with the soil moisture content), and these data were used to represent the different microbial groups of soil. The unbranched, saturated PLFAs 14:0, 15:0, 16:0 and 18:0 represented the general bacterial biomass (Gude et al., 2012). The branched, saturated PLFAs iC15:0, aC15:0, iC16:0, iC17:0, aC17:0 indicated the G-positive (G^+) (Zogg et al., 1997), as well as the monoenoic and cyclopropane unsaturated C16:1n7c, C16:1n5c, C18:1n9c, cyC19:0 indicated the G-negative (G^-) bacteria (Zelles et al., 1992). The 10MeC16:0 and 10MeC17:0 represented the Actinobacteria (Bossio et al., 1998), and C18:2n6 was used as a fungi marker (White et al., 1979). Sum of these measured PLFAs were used to calculate the total PLFA concentration of the soil microbial community.

Soil enzyme activities

Samples were stored at -20 °C and were incubated for one day at 4 °C before the analysis. Before sieving (Ø = 2 mm), larger plant roots were removed in the laboratory. Invertase activity was measured photometrically at 508 nm, with 3,5-dinitrosalicylic acid (Mikanová et al., 2001). Catalase activity was determined with potassium

© 2018, ALÖKI Kft., Budapest, Hungary

permanganate titration from air-dried soil samples (MSZ-08-1721/4-86 Hungarian Standard Method, 1986).

Statistical analysis

All measurements were reported as mean values with standard error (SE). Statistical analysis was done using three internal repetitions respectively (n = 12) for the more accurate statistical result except in case of PLFA analyses, where internal repetitions were not measured (n = 4). All statistical analyses were carried out with the IBM SPSS Statistics 22.0 software package (IBM Inc., USA), applied a significance level of $P < 0.05$ was applied. One-way analysis of variance (ANOVA) followed by Tukey's-b and Games-Howell tests (depending on to results of the test of homogeneity of variences) were used to compare the means of different sampling sites. Correlations between abiotic and biotic soil parameters were determined using Pearson's correlation. Principal Component Analyis (PCA) was used to compare PLFA profiles between two management systems and soil layers. For PCA the two enzyme activities and the PLFA results, furthermore the total C and N content were used as variables, because the total C, N content significantly influenced these parameters.

Results

Chemical soil properties

The soils in the Nyírség region generally have acidic pH in accordance with the measured low pH_{KCl} (3.89-5.98) of the sampling sites (*Table 2*). The pH_{KCl} was more favourable in ecologically managed sites than in conventional sites. Chemical parameters were better on the lower part of slopes, but topography had reverse effect on pH_{KCl} because it was higher in the samples originated from the upper part of slopes (EU: 5.98; CU: 3.94) than samples from the lower part of slopes (EL: 5.02; CL: 3.89).

Table 2. *The main chemical parameters of investigated soils*

Sampling site	pH_{KCl}	total C *	organic C *	total N *	NO_2^- NO_3^- - N *	C:N ratio
EU	5.98±0.13^{c}	0.573±0.005^{b}	0.462±0.008^{b}	0.063±0.000^{b}	0.012±0.003^{ab}	9.13±0.05^{c}
EL	5.02±0.04^{b}	0.727±0.033^{d}	0.711±0.013^{d}	0.085±0.004^{d}	0.020±0.001^{b}	8.52±0.09^{b}

[3]EU, ecological upper part of the slope; EL, ecological lower part of the slope; CU, conventional upper part of the slope; CL, conventional lower part of the slope

Generally, comparing the two managements, favourable values were found in ecological management, where all the measured chemical parameters were better. The most significant differences were in cases of available-N and organic-C content. The values measured in the conventional management on the upper part of slopes are only 58.3% and 51.1% of values measured in ecological site, respectively, while on the lower

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_34733488
© 2018, ALÖKI Kft., Budapest, Hungary

part of slopes these portions are 50.0% and 78.2%, respectively. However the differences in total-N and total-C content between the managements were less, 63.5% and 54.6% on the upper part of slopes, respectively, while 85.9% and 88.7% on the lower part of slopes, respectively. According to the elevation positions, the C:N ratio was higher on the upper part of the slope in ecological site, while in the conventional management higher ratio was measured on the lower part of the slope.

Microbial community structure

The actual structure of microbial community was identified by PLFA markers. Lower concentrations of the individual PLFA markers were measured in spring 2013 (*Table 4*) than in the previous sampling time (*Table 3*). Microbial biomass, estimated as total PLFA showed significant differences ($P < 0.05$) between the management systems, reliefs and depths. The highest value was measured in EU upper soil depth interval (23.736±1.05 nmol PLFA g^{-1}) in autumn 2012. In the first sampling time the highest G^+:G^- ratio was measured in samples from EU 0-30 cm depth interval (1.623±0.07). Fungi:general bacteria ratio was the highest in CU in upper soil depth interval (0.186±0.01). In contrast to the other data, actinobacteria:general bacteria ratio was higher in the 30-60 cm soil depth interval (except in CU), and was significantly higher in ecological fields (0.291±0.01 in EU; 0.162±0.00 in EL). There is a large difference in this ratio between the two soil depth intervals in the ecological field while it is similar in both studied depth intervals of conventional field.

[3]EU, ecological upper part of the slope; EL, ecological lower part of the slope; CU, conventional upper part of the slope; CL, conventional lower part of the slope

In spring 2013 (*Table 4*) the G^+:G^- bacteria ratio was also higher in the ecological samples on the upper part of the slope (1.386±0.05 in EU), but this ratio was close to each other on the top and the bottom of the hill. Fungi:general bacteria ratio was higher on the upper part of the slope in the upper soil depth interval (0.160±0.01 in EU, 0.223±0.01 in CU). In contrast to the other PLFAs, the actinobacteria:general bacteria ratio was higher in the 30-60 cm depth interval in both managements(except of CL).

Comparing the managements, significantly higher ratios were found in ecological fields (0.202±0.01 in EU, 0.209±0.01 in EL). The calculated ratios show similar trend to the previous sampling time.

Soil enzyme activities

Both measured enzyme activities showed similar trends to the main chemical parameters with higher values in the ecological field and in the upper depth interval. In case of invertase enzyme (*Fig. 4a,b*), a large decrease in activity was observed in spring 2013 in both sampling sites and depth intervals, with most pronounced changes in the upper 30 cm of EU site (-13.92 mg glucose * g^{-1} dry soil * 4 h^{-1}). However this decrease was more significant, than in the case of PLFAs. In both managements and depth intervals the intensity of decrease was similar, about hundredth.

The invertase activity was effected in different ways by the elevation position. Generally, higher activity was measured in the upper depth interval on the upper part of slopes, while in the 30-60 cm depth interval higher activity was found on the lower part of slopes. The only exception was in the upper depth interval in autumn under conventional management, where the activity was higher on the lower part of the slope.

On the contrary, a slight increase (0.09-0.83 mg O_2 * g^{-1} * h^{-1}) of catalase activity was observed in spring 2013 (*Table 5*), but the ratios of ecological:conventional sites in different elevation positions were similar to the results of autumn 2012. In most cases, the activity was higher on ecological sites and on the lower part of slopes. Our results suggest the higher stability and independence of catalase enzyme from the environmental factors comparing to the invertase activity.

Principal component analysis

Results of principal component analysis (PCA) indicated that the sampling sites under different managements, elevation positions and depth intervals were separated (*Figs. 5-6*). In autumn 2012 the first component contained the bacterial PLFA groups and total PLFAs while fungal PLFA belonged to this component just in the upper depth interval. The second component represented C and N content, invertase and catalase enzymes in every cases while fungi and actinobacteria PLFAs in the below depth interval. Ratios of individual microbial groups usually were weak indicators of soil properties. In spring 2013 similar trend was observed.

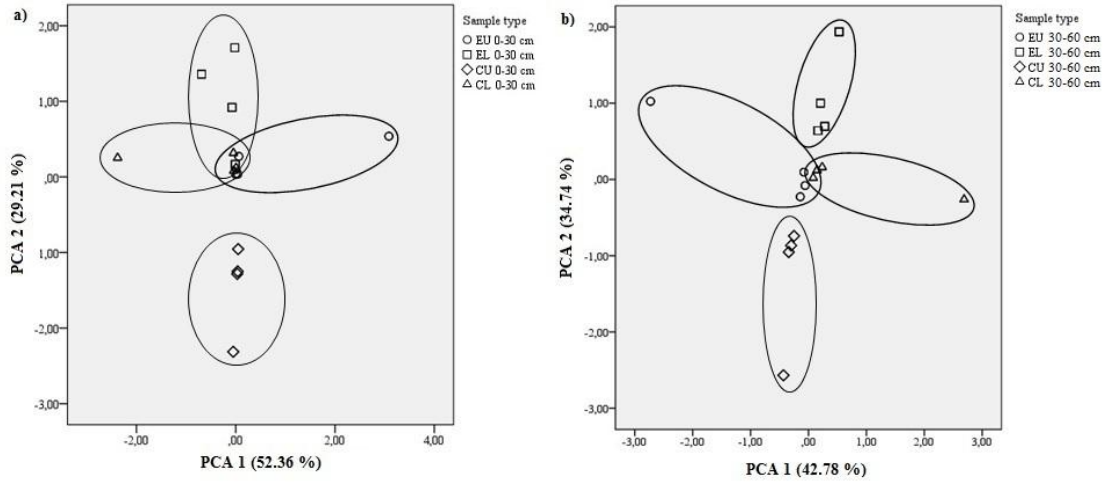

Figure 5. *Results of principal component analysis in autumn 2012 from the 0-30 cm (a) and the 30-60 cm soil layer (b). EU, ecological upper part of the slope; EL, ecological lower part of the slope; CU, conventional upper part of the slope; CL, conventional lower part of the slope*

Discussion

Chemical soil properties

Our results excellently presented the heterogeneity of sandy soils in Nyírség region. Earlier results (Yan-Jun et al., 2014; Wang et al., 2013) showed that the nutrient content was more favourable in those sites, where organic manure/crop residues were used as fertiliser, and the higher proportion of larger aggregates (> 2 mm) were observed. This probably resulted in increased microbial biomass and activity with increased extracellular polysaccharides providing good cementing agent to soil aggregation process (Liu, 2007). These are in accordance with our measured enzyme activities and PLFA results. The favourable effect of ecological management is indicated by the smaller difference between the two topographical sites than in conventional field. Furthermore the lower soil moisture in the conventional sites also may be responsible in the lower enzymatic activities (Stark and Firestone, 1995).

The different microorganisms are located in different parts of soil. While bacteria live in the smaller pores, fungi are located in the larger pores and on the surface of aggregates therefore fungi are more sensitive to different environmental effects (Gordon et al., 2008). Nevertheless our sampling sites on hills were not affected by topographical exposure which is proved by the higher microbial activity and PLFA values on the upper part of slopes.

In this study higher soil pH on ecological site was observed which suggests that organic manure apply and/or lack of fertilizer could, to some extent, alleviate soil acidification. Furthermore, the measured lower values of pH_{KCl} in conventional site probable were caused by the acidifying effect of the applied fertilizers (Pais and Horváth, 1990). The pH seems to be a chemical soil factor with high importance on microbial properties (Bååth and Anderson, 2003; Wang et al., 2013), which is also confirmed the results of our correlation studies (*Table 6*).

Table 6. *Relationships of biotic and abiotic variable pairs in autumn 2012*

Among others pH has strong effect on substrate availability of enzymes (Voroney, 2007) which play the basic role in energy and nutrient supply of microbial communities. Usually the PLFA content increases with increasing pH (Bååth and Anderson, 2003)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_34733488
© 2018, ALÖKI Kft., Budapest, Hungary

which was proved by the 0.884 correlation coefficient between total PLFA and pH_{KCl}. That means 2-6 times higher concentrations of different PLFAs in the samples with higher pH.

The organic matter and nutrient pool is more stable where organic nutrient inputs are applied, rather than in case of other nutrient supplying techniques (Nardi et al., 2004). The quality and quantity of plant residues input into the soil can affect the organic matter content of soils (Chen et al., 2000; Edmeades, 2003). Greater than 100 kDa SOM fraction, which improves the soil structure and increases the plant and microbial nutrient uptake, was observed at the highest percentage in case of organic manure application (Dell'Angola et al., 1964). Furthermore, application of animal manure in organic management could increase the microelement content of soil (Bíró et al., 2005). The increasing organic C and PLFA content of ecological field indicated the possible presence of this SOM fraction. The increase of total and organic carbon, total nitrogen and the carbon:nitrogen ratio in our ecologically managed sampling sites resulted in higher available N content for plants. Based our results acidic pH in conventional sites could inhibit the availability of these nutrients.

Soil community structure and microbial activity

The different organic matter content and the value of available substrates resulted in the structural changes of microbes, because the nutrient supply method had strong effect on the community structure (Hartman et al., 2006). When the easily available, unstable carbon forms are present in the soil, the increase of G^- bacteria markers can be observed (Peacock et al., 2001), but less easily available carbon source increases the value of G^+ bacteria in the soil (Keynan and Sandler, 1983). The higher G^+:G^- bacteria ratio in an ecological site indicates the presence of more stable carbon forms.

Higher rate of fungi in the ecological management than in the conventional one has already observed (Esperschütz et al., 2007; Marschner et al., 2004). The increasing organic matter input resulted in an increase of fungi, thereby the increase of fungi:bacteria ratio (Frostegård and Bååth, 1996). However, our results showed that fungi:general bacteria ratio was depended on the climate conditions and can varied seasonally. In case of easily available fertilizer application the ratio of bacteria increased, because the fungi are primarily responsible for breakdown of the persistent materials (Grayston et al., 2004). This was confirmed by our results, where the values of fungi markers were higher in the ecological samples from the upper 30 cm soil layer because of the presence of recyclable but not easily available plant residues.

The main difference of the two management systems was found in the upper soil layer. While in this layer the conditions were more favourable for the microbes especially in case of substrates sources (Prasad et al., 2016), the number and activity of microbes were higher and the differences between the two cultivated systems were stronger.

When the values of easily available nutrients decreased, the decomposition process of actinobacteria became dominant (Bastida et al., 2013). The found negative correlation between actinobacteria markers and organic C ($r = -0.379$) indicated that the degradation processes started in autumn after the harvest and recycling of plant residues, but this relationship was not statistically significant.

Seasonal variation had strong effect on the microbial status of soils in both management systems (*Fig. 4* and *Table 5*). In spring 2013 the results were not significantly different probably due to the reduced microbial activity and the inactive

© 2018, ALÖKI Kft., Budapest, Hungary

microorganisms because of the combined effect of autumn soil cultivation and the extremely cold spring weather.

Our study revealed that the land use impact on soil enzyme activities vary under different management and environmental conditions. The recycled plant residues could increase the essential substrates' concentrations of enzymes (e.g. cellulose, hemicellulose) (Wick et al., 1998) which could result in higher enzyme activities. The organic matter, increased by the recycling of plant residues, can protect the extracellular enzymes against destroying them (Martens et al., 1992) and provide their substrates which could increase the enzymes activities in ecological field. However, the acidic pH usually inhibits the microbial activity (Sahoo et al., 2010). Differences are significant also in the lower soil layer which indicate the positive effect of long-term ecological management on the whole soil profile.

Invertase enzyme can break down some carbohydrate polymers at the end of the C cycle therefore its activity depends on other enzymes using higher organic matter as a substrate. Catalase protected cells against the oxidative damage. Invertase activity usually positively correlated with soil organic carbon and total nitrogen content (Frankenberger and Johanson, 1983). Catalase activity usually was stable in the soil, and showed significant correlation with organic carbon content and reduced with depth (Alef and Nannipieri, 1995). Close vertical connection of different soil layers is represented by the results of invertase activity. The unfavourable climate in spring 2013 decreased the enzyme activity not only in the upper, but also in the lower soil depth interval. Although both measured enzymes are extracellular but their climate-sensitivity seems to be rather different. Similar decreasing of invertase activity and PLFA values suggested the closer connection of invertase activity with the living microbial cells. However, the differences between the PLFA values in two sampling time were not so high than in case of invertase activity. This fact indicated a metabolically inactive microbial biomass (Šnajdr et al., 2008).

Locations of enzymes and PLFAs (living cells) in soil are different: our results suggest that living microbial cells are connected rather to the higher soil particles while enzymes, especially the catalase, are connected rather to the medium sized particles. The soil temperature and moisture, the available substrates are the most dominant factors having combined effects on the seasonal dynamic of microbial activity (Bing-Cheng and Dong-Xia, 2012).

Conclusions

Beside altered microbial activity, structural changes in microbial biomass were observed between the ecological and conventional managements but the differences were less in unfavourable climate conditions.

We confirmed that as low as 5 m differences in the topography can result in different physical, chemical and microbiological properties in different soil depth of the upper and lower parts of the slope. These differences due to the elevation positions are less in the ecological field, indicating stronger soil protecting management.

The relationships between living cells and enzyme activities were different at the four studied sites. Our results proved the strong correlation between invertase activity and microorganisms while catalase activity was found more stable and independent from living cell number. The bacterial and fungal microbe groups showed different

sensitivity to the environmental factors (temperature, moisture, pH), and their seasonal variability was also observed.

Ecological management enhanced the microbial activity of acidic sandy soil compared to the conventional one. Positive effects of recycled crop residues were observed in ecological site, but more investigations are required on the relationships between the quality and quantity of recycled crop residues and the different chemical and microbial properties on the upper and lower part of slopes.

Abstract. In their natural habitats and application environments, lactic acid bacteria are often exposed to osmotic changes. At metabolic level, bacteria are able to *de novo* synthesize or uptake specific solutes from environment to maintain constant turgor pressure. In the work, the [1]H nuclear magnetic resonance (NMR) spectroscopy based on intracellular metabolites profiles of *Lactobacillus salivarius* under hyper-osmotic growth conditions was characterized. New characteristic peaks of compatible compounds, such as betaine, carnitine, choline and/or their derivatives were detected. Especially, the cytoplasmic concentrations of proline increased dramatically when the osmolarity was raised from about 0.40 to 1.84 osmol/kg by adding 0.8 mol/l NaCl to the medium. Comparative analysis of the metabolites of *L. salivarius* FDB89 grown under aerobic and anaerobic conditions with NaCl stress revealed an overlap of up-regulated compounds of more than 50%. 2-aminobutyrate, pyruvate, glycine, trimethylamine-*N*-oxide, and acetylcholine were detected only under anaerobic condition, and 2-oxoglutarate, tyrosine, glutamine and glutamate were detected only under aerobic condition, which suggested oxygen also has a non-negligible effect on osmotic response in *L. salivarius* FDB89.
Keywords: *Lactobacillus salivarius*, metabolomics, hyper-osmotic stress, quantitative [1]H NMR spectroscopy, principal component analysis

Introduction

Lactobacillus is a genus of gram-positive facultative anaerobic or micro-aerophilic bacteria that produce lactic acid as the predominant end-product during the sugar fermentation. *Lactobacillus* is normally isolated from oral cavity, intestinal tract, vagina and fermented products, and generally recognized as safe (GRAS). As a major part of lactic acid bacteria (LAB) group, they especially have an important role in the development of the organoleptic, nutritional and/or hygienic quality of fermented foods, and are extensively exploited for the health-promoting properties (Machado et al., 2004; Shellhammer et al., 2017). *Lactobacillus salivarius* FDB89 used in this study, was isolated from the healthy centenarian's fecal samples from the volunteers inhabited in Bama longevity villages in China (the fifth longevity area in the world), and was

© 2018, ALÖKI Kft., Budapest, Hungary

confirmed to be able to convert the carcinogen 4-nitroquinoline-*N*-oxide to a less toxic compound and its geno-toxicity is significantly inhibited in previous study (Zhao et al., 2013), which highlights its potential probiotic use.

As we know, microorganisms are often exposed to hyper-osmotic environments generally produced by high concentrations of common salt or sugar used in food processing, which has been accepted as a desired and effective preservation method to suppress spoilage of microbes (Tsakalidou et al., 2011). However, high-osmolarity might initially result in plasmolysis, loss of turgor, shrinkage of the cell, and further elevate reactive oxygen species (ROS), cause cytoskeleton rearrangement, which increases DNA strand breaks and oxidation of proteins and DNA bases. It is interesting that cells could accommodate by accumulating osmoprotectants or increasing the expression of relative shock proteins, and the failure to adapt usually results in cell apoptosis (Burg et al., 2007). Osmotic stress response of some microorganisms (e.g., *Escherichia coli*, *Salmonella typhimurium*, *Lactococcus lactis*, and *Lactobacillus plantarum*) have been studied intensively by genetic, proteinic, physiological, and biochemical methods (Glaasker et al., 1996; Hoffmann et al., 2013; Meadows and Wargo, 2015; Métris et al., 2016; Rep et al., 1999; Teo et al., 2009). But the osmotic response studies at metabolic level are limited. And it was found that different microorganisms may have different response mechanisms. Bacteria reduced the deleterious osmotic effects by uptake or synthesis of some compatible solutes including amino acids (glutamine, glutamate and proline) and their derivatives (peptides, glycine-betaines and *N*-acetylated amino acids), polyols (glycerol) and/or sugars (trehalose and sucrose), which are not inhibitory to most cellular processes, but rather stabilize the biological structure and function of macromolecules (Hoffmann et al., 2013; León et al., 2018).

Nuclear magnetic resonance (NMR), as an important non-targeted analytical techniques, enables to rapidly produce reliable, reproducible, and unbiased metabolite profiles of each sample, and has been widely applied in analyzing metabolic networks and distinguishing biopolymers (Pinto et al., 2014; Tomita et al., 2018).

In this work, we aimed at employing ^{1}H NMR technique combined with principal component analysis (PCA) approach to evaluate the metabolic response of *L. salivarius* to osmotic stress (under aerobic and anaerobic condition) and indicate potential biomarkers that may provide comprehensive information of osmo-adaptation on the microbial fermentative behavior.

Materils and methods

Bacterial strain and growth conditions

L. salivarius FDB89 (*L. salivarius* subsp. *salivarius*) was provided by culture collection of MOE Key Laboratory of Functional Dairy (China Agriculture University, China). Two kinds of culture mediums incluing control (MRS medium) and hyper-osmotic medium obtained by adding NaCl (final concentration 0.8 mol/l) to the basal MRS were used. The changes of physiochemical characteristics in aerobic and anaerobic condition for hyper-osmotic medium was compared with control (only aerobic condition). The strain was sub-cultured twice in deMan-Rogosa-Sharpe (MRS) medium for 12 h at 37°C prior to experimental use, 20 ml of cell suspensions in 100 ml flasks were incubated at 120 rpm under aerobic conditions as control. For typical anaerobic growth condition in hyper-osmotic medium, cells were cultivated in Hungate

tube previously excluding oxygen with high purity nitrogen at 37°C without shaking. For each treatment, the assay was repeated at least three times.

Growth and pH assays

Samples were taken at two-hourly intervals for 24 h. The absorbance at 600 nm (OD_{600}) was determined for growth curve of *L. salivarius* FDB89 (Michael et al., 2010). And the pH was measured after calibration of the pH meter (Sartorius, Goettingen, Germany) with standardized pH buffer solutions 4.01 and 7.00 (Hamilton, Switzerland) prior to the analysis.

Preparation of intracellular extract

Stationary phase cells were carefully micro-filtrated to avoid lysis and washed for twice with physiological saline solution to remove any remaining nutrient solution. The sediment was quickly transferred to a clean Eppendorf tube and quenched immediately into liquid nitrogen. The whole process should be accomplished within 2 min (De Angelis and Gobbetti, 2011).

A biphasic system was performed to extract the intracellular metabolites with some modifications (Aliferis and Jabaji, 2010; Tomita et al., 2017). Briefly, 2.0 ml of cold methanol/chloroform (1:1, v/v) was added to the tube containing the cells and fully vortexed for 60 s, then 1.0 ml of Milli-Q water (0°C) was added, sonicated for 2 min and centrifuged at 8944 × *g* for 5 min at -20ºC. And 1.5 ml of the aqueous layer was carefully pipetted into a new tube and immediately frozen. The extraction was lyophilized and stored at -80ºC for analysis.

^{1}H NMR data acquisition and processing

Lyophilized extraction were dissolved in 650 µl of 0.1 mol/l phosphate buffer (pH 7.0), in deuterium oxide (D_2O, Norell Inc., USA), containing 0.5 mmol sodium 3-(trimethylsilyl) propionate-2,2,3,3-d_4 (TSP, Sigma-Aldrich, UK)(chemical shift and reference indicator). Additionally, sodium azide (0.2% w/v) was added to preserve the samples for longer storage. Insoluble material was removed by centrifugation at 8944 × *g* for 2 min at 4°C, 600 µl of the supernatant was transferred into a 5-mm diameter NMR tube for determination (Galafassi et al., 2013; Graham et al., 2010).

NMR spectra were acquired at 300 K using a DRX-600 NMR spectrometer (Bruker, Germany, proton frequency 600.13 MHz, 14.1 T) equipped with a 5-mm PATXI probe. One-dimensional solution ^{1}H NMR experiments were done with the following parameters (Galafassi et al., 2013; Li et al., 2018; Nieva-Echevarría et al., 2017): pulse program for water suppression; relaxation delay, 4 s; mixing time (for noesy), 1 s; acquisition time, 2.28 s; number of steady states transients (dummy scans) is 4; number of transients, 256; solvent suppression, pre-saturation with spoil gradient; spectral width is 12 ppm; time domain size of 32 k. Peak-width at half height of TSP was less than 1.50 ± 0.15 Hz (mean ± SD).

All NMR spectra were zero filled to 65, 536 points and applied with an exponential line broadening factor of 0.3 before Fourier transformation, manually phased, baseline corrected and calibrated by the TSP signal at 0 ppm using TOPSPIN 2.1 (Bruker Topspin GMBH, Rheinstetten, Germany). Selected peaks were assigned and quantified using the 600 MHz library from Chenomx NMR suite 6.0 (Chenomx Inc., Edmonton, Canada).

Principal component analysis

The spectral region between 0.20 and 10.00 ppm of each spectrum was divided into equally sized buckets with a width of 0.04 ppm. The regions of water (between 4.75 and 5.00 ppm), methanol (between 3.35 and 3.37 ppm) and chloroform (between 7.67 and 7.70 ppm) were excluded. Scaled to the total spectrum area of the residual regions, each bucket area was integrated and each spectrum was transferred into a 1 × 238 vector. Principal component analysis (PCA) was performed on processed ^{1}H NMR data with AMIX 3.7.10 (Bruker BioSpin, Rheinstetten, Germany).

Results

Growth of L. salivarius FDB89 under different conditions

The growth rate and final pH were similar for *L. salivarius* FDB89 at NaCl stress with or without oxygen (*Figs. 1* and *2*). The absence of NaCl stress in the growth media resulted in about 1.4-fold increased maximum absorbance of *L. salivarius* FDB89. The result was in agreement with previous study (data not shown) and supported by other reports (Arsenijevic et al., 2013; Varelas et al., 2017). Based on the results, the cell culture in stationary phase was sampled at 12 h for NMR measurement.

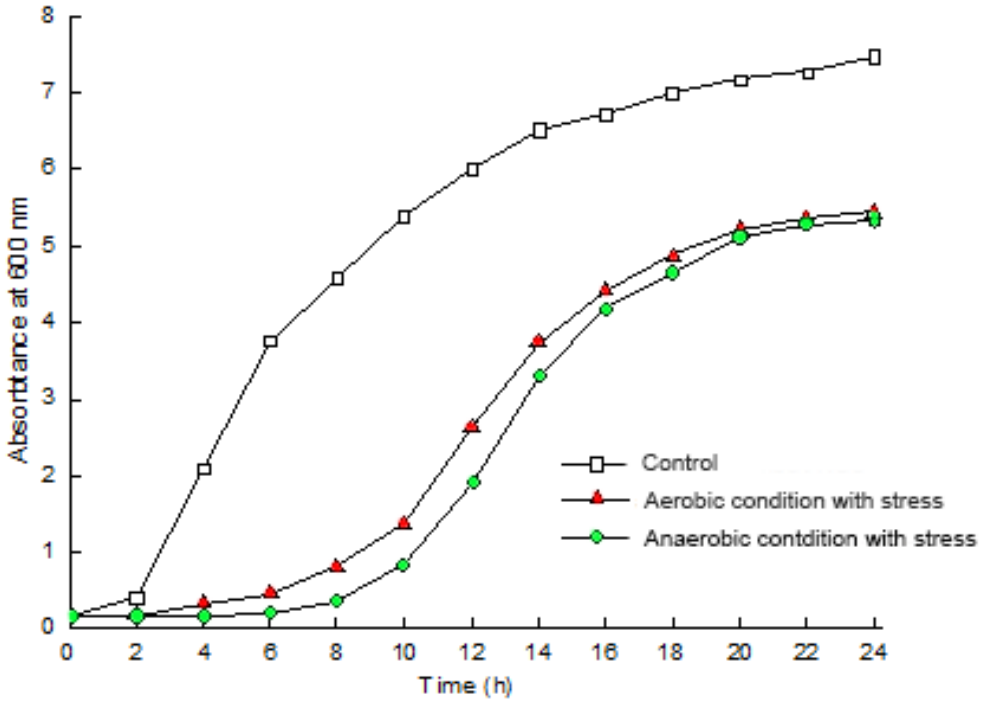

Figure 1. *Growth curves of L. salivarius FDB89 cultivated under different growth conditions*

Visual inspection of ^{1}H NMR spectra and assignment of compounds

Representative ^{1}H NMR spectra are presented in *Fig. 3*, which shows the metabolic profiles of *L. salivarius* FDB89 stationary phase cultivated under normal and NaCl (aerobic and anaerobic) stress conditions. About 44 metabolites were presumptively identified by Chenomx software (*Table 1* in Supplemental Data).

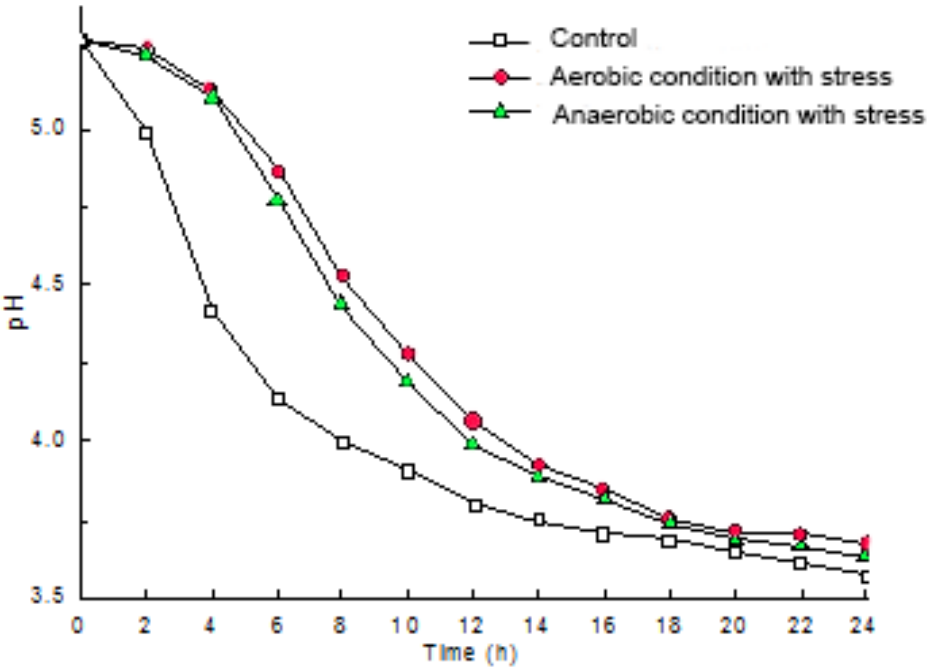

Figure 2. *Changes in pH when L. salivarius FDB89 grown under different culture conditions*

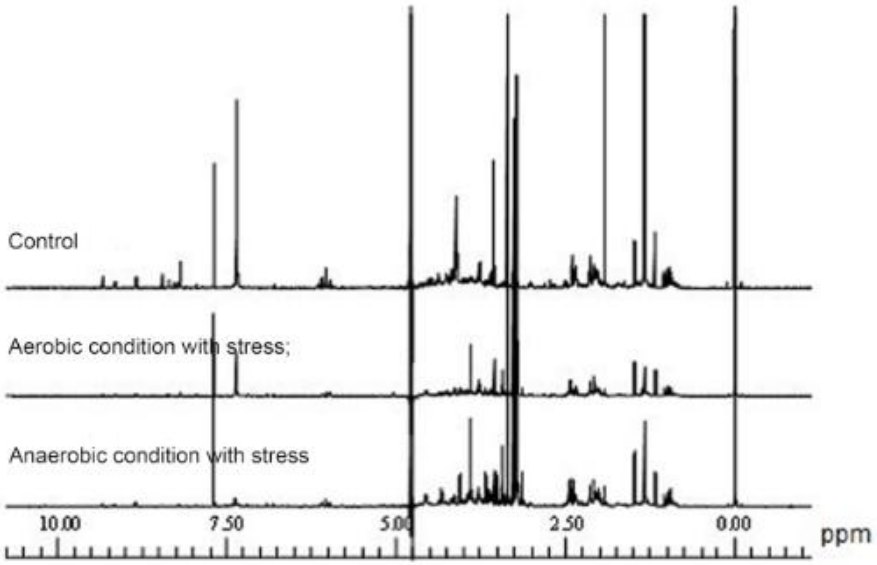

Figure 3. *Representative 600 MHz [1]H NMR spectra of intracellular extracts of L. salivarius FDB89 under different growth conditions*

It was difficult to discern the individual peaks with certainty in the [1]H NMR spectra between approximately δ 1.9-2.5 and δ 3.0-4.5 ppm due to overlapping amino acid and sugar resonances. However, conspicuous differences were observed among the three spectra patterns and peak intensities. In the osmotic spectrum, new peaks of betaine, carnitine, choline and its derivatives (e.g., sn-glycero-3-phosphocholine, phosphocholine, and acetylcholine), and isoleucine, phenylalanine, pyrimidine and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_34893500
© 2018, ALÖKI Kft., Budapest, Hungary

cyclopentanecarboxylic acid were also observed. Higher peaks of methionine, proline, malonate, and aspartate have been discerned compared to control one. In the spectrum without NaCl stress, the characteristic peaks of isocitrate, arginine, kynurenine, propionate, UDP-glucose and succinate were identified, and the peak intensity of 2-hydroxybutyrate, alanine, glycine, valine, glutamine, acetate, lactate, pyroglutamate, threonine and NAD^+ increased.

2-Aminobutyrate, pyruvate, acetylcholine and trimethylamine oxidexide were only observed in hyper-osmotic and anaerobic condition. In contrast, tyrosine, glutamine and glutamate were the particular compounds in aerobic condition regardless of NaCl stress. The peak intensity of methanol at δ 3.30 in anaerobic condition is 1.5-fold greater than those of aerobic ones. The results showed different metabolic pathways of *L. salivarius* FDB89 under anaerobic and aerobic conditions. Being a major part in one carbon metabolism, more methanol was observed in anaerobic condition, it might be used as energy and carbon skeleton in this condition.

As a rapid and non-targeted method, NMR technique provides information about a very wide range of different compounds, in spite of its deficiency in the database system. In this work, many unknown peaks in NMR spectra could not be assigned.

Principal component analysis

When visual inspections of ^{1}H NMR spectra of different growth conditions are compared, only marginal variations at metabolite levels are obvious. Both the peak overlapping and low intensities between the signals also affect the full interpretation, and it is difficult to accurately assess statistical differences between datasets and comprehend the individual variability in each sample. So PCA was performed to reduce and analyze the acquired NMR data for discrimination. The corresponding points from one sample group occur close together on score plot, but far from other ones (*Fig. 4*). The values of PC1 and PC2 cumulatively accounted for 99.59% of the total variability (*Fig. 4A*), so the preparation of intracellular extraction in this study was reproducible and reliable.

Score plots well define the notable separations between PCA comparisons with the PC1 of 99.50% (*Fig. 4B*) and 90.68% (*Fig. 4C*), respectively, illustrating significant differences in the metabolic profiles of *L. salivarius* FDB89 cultured under different growth conditions. The loading plots indicate the metabolites that are contributed significantly to the individual variables in terms of magnitude and direction to PCs, and permit the potential biomarkers to be identified.

Fig. 4B shows oxygen also has an important influence on the stress response of *L. salivarius* FDB89. For aerobic condition, higher levels of glycylproline, oxoglutarate, glutamine, tyrosine and lysine were characterized. Whereas trimethylamine-*N*-oxide, pyruvate, 2-aminobutyrate and glycine were the major metabolites accumulated in anaerobic condition. With betaine, carnitine, choline, alanine, leucine, proline, phenylalanine, valine, actate, lactate, malonate, pyroglutamate, serine, and isopropanol were all identified in the both salt stress conditions. But their contents in anaerobic condition are much lower than those in aerobic one except acetate and pyroglutamate. Those metabolites were regarded as the representative metabolites or biomarkers, respectively, for aerobic and anaerobic condition with osmotic stress.

Fig. 4C shows higher levels of betaine, carnitine, choline and its derivatives, sn-glycero-3-phosphocholine, proline, glycylproline, isoleucine, phyenylalanine, malonate, isopropanol, cyclopentanecarboxylic acid and taurine, which were identified as

important metabolites for *L. salivarius* FDB89 under osmotic stress. And arginine, propionate, lactate, acetate, proglutamate, and succinate were shown to be important contributors in control condition.

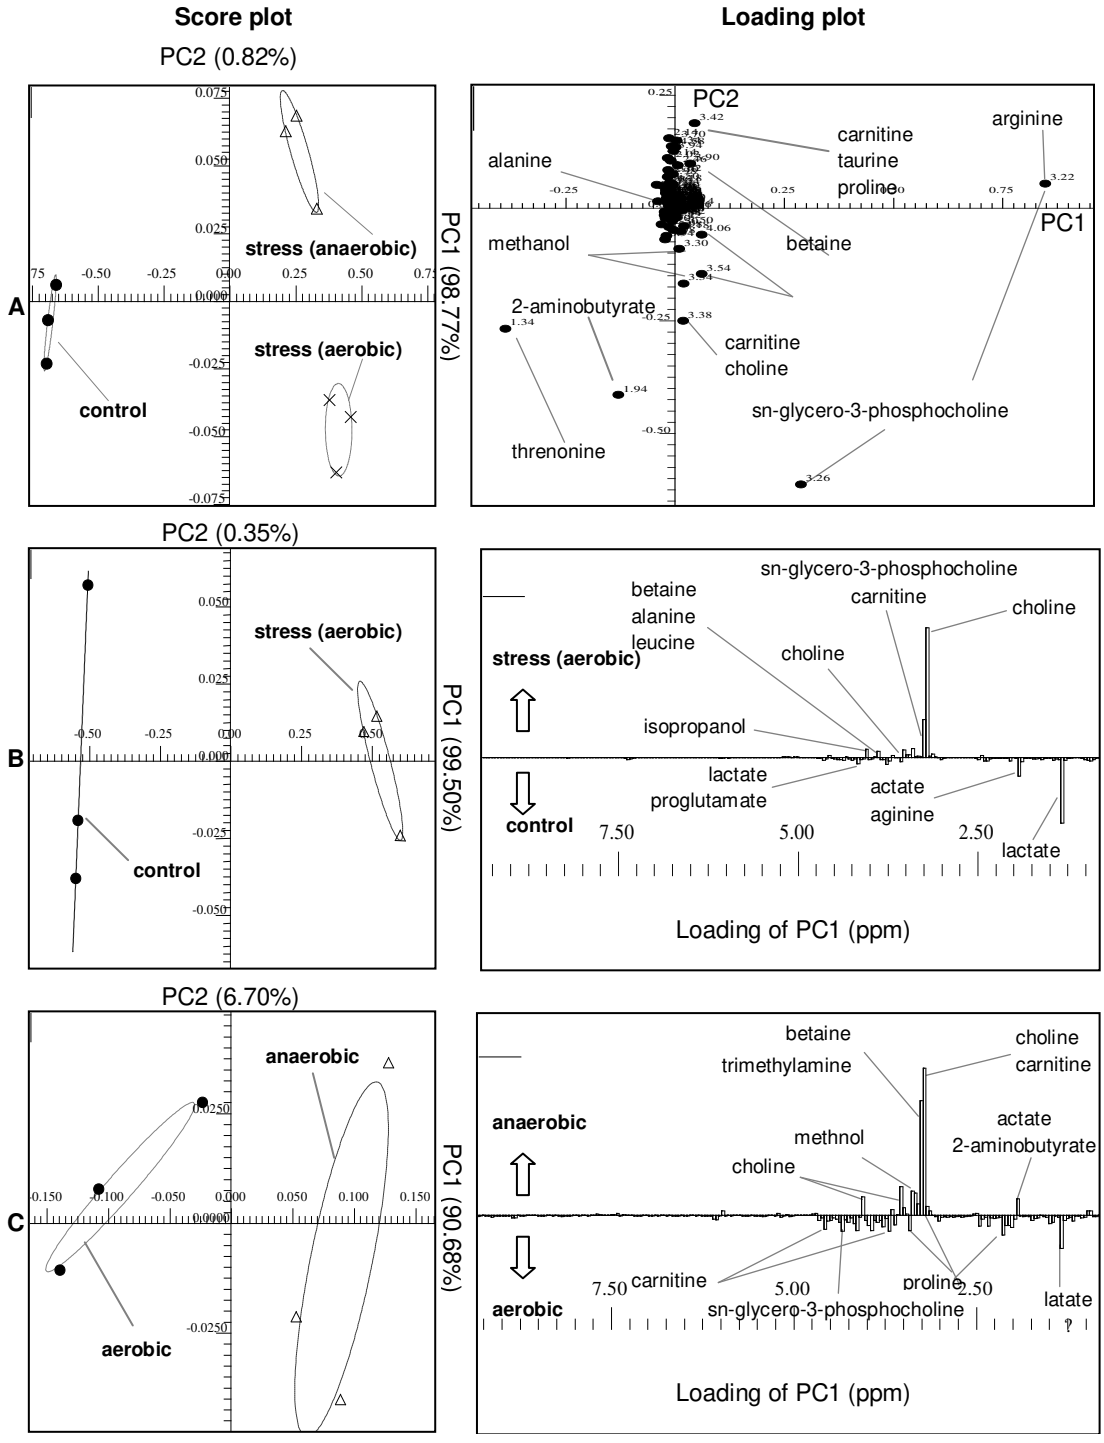

Figure 4. *PCA of intracellular extracts of L. salivarius FDB89 under different growth conditions: (A) PCA of control and aerobic and anaerobic conditions with stress; (B) control versus anaerobic condition with stress; (C) aerobic condition with stress versus anaerobic condition with stress*

Biomarker identification by direct comparison of their peak intensities

The biomarkers identified by PCA could be identified directly by their increased metabolite resonances among the three types of growth models. In this study, PCA of ^{1}H NMR spectra indicated that betaine, carnitine, choline and its derivatives (mainly including sn-glycero-3-phosphocholine, phosphocholine, and acetylcholine), proline, malonate, aspartate, cyclopentanecarboxylic acid, and to a much lesser extent isoleucine, and phenylalanine were potential biomarkers of *L. salivarius* FDB89 when exposed to osmotic stress.

Discussion

Cellular responses induced by stress are essential for the survival of cells under adverse conditions. These responses, resulting in cell adaptation to the stress, are accomplished by a variety of processes at the molecular or metabolic level. Initial adaptive responses to high-osmolarity is a large increase in the uptake rate and the amount of cytosolic potassium, which normalizes cell turgor, and followed by a slower accumulation of different intracellular organic osmolytes at metabolic level, mainly including polyhydric alcohols, free amino acids and their derivatives. They are able to additionally normalize intracellular ionic strength, and enhance their osmotic tolerance and survival. These responses have presumably occurred in cells chronically adapted to osmotic stress (Hoffmann et al., 2017). In this study, the intracellular metabolic profiles of *L. salivarius* FDB89 cells under NaCl stress has been investigated using ^{1}H NMR method, and the effect of oxygen on osmotic response was evaluated (*Fig. 4*). Our results indicated that *L. salivarius* FDB89 grown under osmotic stress, compared to control condition, consistently accumulated abundant betaine, carnitine, choline and its derivatives (e.g., sn-glycero-3-phosphocholine, acetylcholine and phosphocholine), regardless of the presence of oxygen, while none of them are observed in the cells without stress (*Table 1* in Supplemental Data). These compounds are presumed to play a dominating adaptive role in mediating osmotic adjustment and protecting macromolecular structures and function at high and variable concentrations in osmotic stressed cells, which was also in accordance with previous studies (Hoffmann et al., 2017; Meadows and Wargo, 2015; Sheehan et al., 2006; Li et al., 2013).

Proline, and to a lesser extent, isoleucine, phenylalanine and methionine as the most important amino acids increased in *L. salivarius* FDB89 when exposed to NaCl stress. However, it could not be considered that all these amino acids except proline are biomarkers due to an opposite result obtained using gas chromatography mass spectrometry (GC/MS) (data not shown). For example, aspartic acid was identified as an observably increased amino acid to defend against NaCl stress in GC/MS analysis. Moreover, cells grown in anaerobic condition with osmotic stress clearly face energy limitation, resulting in the differences of their osmotic response ways. In this work, more than 50% of the overlapping peaks down-regulated except methanol and pyroglutamate. 2-aminobutyrate, pyruvate, glycine, trimethylamine-*N*-oxide and acetylcholine were detected only under anaerobic high-osmolarity condition, which suggested oxygen also has a non-negligible effect on the selection of osmolytes for *L. salivarius* FDB89 under osmotic stress. In contrast to conventional methods, which most often focus on the analysis of few specific metabolites as markers, NMR technique combined with PCA approach enables to rapidly screen large quantities of metabolites and identify potential biomarkers easily using pattern recognition techniques in a single

© 2018, ALÖKI Kft., Budapest, Hungary

experiment (Li et al., 2013; Miller et al., 2007). But there are some unknown peaks with higher abundance and much lower abundance in the complex matrices have not distinguished, additional verification using other methods is often necessary to confirm that the biomarkers identified by NMR-based screening are reproducible and reliable (McKelvie et al., 2009).

Conclusion

In their natural habitats and application environments, microorganism is usually exposed to osmotic changes. At metabolic level, bacteria are able to de *novo* synthesize or uptake specific solutes from environment to maintain constant turgor pressure. In the present study, the ^{1}H NMR and GC/MS metabolomics of *L. salivarius* FDB89 subjected to hyper-osmotic culture conditions was analyzed. Results indicate that nitrogen compounds (mainly amino acids and amines) including proline, isoleucine, phenylalanine and methionine may serve as potential biomarkers. However, not all organisms accumulate the same organic osmolytes, and the selection of osmolytes depends on the duration of the osmotic stress and the availability of substrates and osmolytes in the surroundings. The analysis of the metabolic profiles exposed to iso-osmotic concentrations of ionic and/or non-ionic (e.g., sucrose, lactose, trehalose, and sorbitol) compounds is also needed in furtuher metabolomics studies.

Abstract. The method of asynchronous cultivation was used to cultivate surplus sludge in sewage treatment plant under anaerobic environment. The best anaerobic treatment scheme was determined by the single factor and orthogonal experiments, and the degradation kinetics of organic matter in pickle washing wastewater was studied. The characteristics of organic matter removal were studied by Excitation-Emission-Matrix Spectra (3D-EEM) and parallel factor analysis (PARAFAC). The experimental results show that when the influent salinity is 11.98 g/L, chemical oxygen demand (COD) is 3500 mg/L and pH is 7, the removal rate of COD can reach more than 80% after anaerobic static 24 h. The order of importance of each factor is: substrate concentration > salinity > pH > residence time. The kinetics of anaerobic degradation of pickle washing wastewater shows that when the salt content in water samples is 0-30.22 g/L, the degradation reaction type of inhibitor salt is anti-competitive inhibition. When salt content was 36 g/L, the inhibition type is a mixed type. 3D-EEM shows that after anaerobic treatment, tryptophan substances in water decreased, humus increased, anaerobic biodegradation transformed most of the macromolecular proteins into humus substances, and the anaerobic ammonification reaction has occurred, which made COD lower while NH_3-N increased.
Keywords: *orthogonal experiment, salinity, kinetic study, inhibition type, three-dimensional fluorescence spectroscopy (3D-EEM), parallel factor analysis (PARAFAC), tryptophan, humus*

Introduction

Kimchi wastewater is a kind of typical high salt wastewater, including salt water and cleaning wastewater. It has the characteristics of weak acid and high organic content (Sichuan, 2012). It is difficult to treat, and the quality of water varies greatly with season and the type of pickled vegetables (Li et al., 2012). Kimchi wastewater has great harm. Its rich organic matter, ammonia nitrogen, and phosphorus nutrients can lead to eutrophication of the water body. High salt content will also cause serious salinization of the soil (Sichuan, 2010; Chang et al., 2014). At the same time, because of its weak acidity and high organic content, it can cause odor and breed mosquitoes and flies, Therefore, in order to reduce its impact on the water environment, the pickle wastewater must be concentrated and timely treated (Yang et al., 2017). Therefore, reducing the content of organic pollutants in kimchi wastewater is not only the necessary work to respond to the environmental protection policy but also the necessary work to reduce or even eliminate the threat to the environment and ecological balance (Zhao et al., 2011).

The treatment methods of high salt wastewater mainly include physicochemical method (Wu, 2017; Zhen et al., 2017; Von, 2016), biological method (Li et al., 2013; Du et al., 2014) and biological physicochemical combined technology. The biological

© 2018, ALÖKI Kft., Budapest, Hungary

method has always been a common and efficient treatment method (Sima, 2013) in wastewater treatment. At present, from the domestic and foreign research status of pickle wastewater, there are many studies on pickle salinized wastewater, and most of them are concentrated on the optimization of the bioreactor and the culture of salt - eating bacteria. For example, Li et al. (2013) have studied the treatment effect of ASBBR process to the wastewater of pickled vegetable. The results show that the effluent COD can be reduced to 375 mg/L when the system runs to 79 d, the removal rate is 92.86%. Du et al. (2014) studied the effect of MBR technology on the treatment of salty pickled mustard wastewater. The results showed that the ammonia nitrogen, SS, COD, and phosphate were greatly removed under the intermittent aeration condition. Ali et al. (2011) studied the effect of COD/N ratio and salinity on the performance of the batch reactor. The experiment showed that high salinity inhibited nitrification, and high COD/N ratio was beneficial to nitrogen removal (> 90%).

However, little research has been done on pickle cleaning wastewater, and little research has been done on organic composition in pickle wastewater. Compared with saline wastewater, the washing wastewater also has high salinity, and the amount of wastewater is larger, and the water quality fluctuates more. Therefore, this paper takes the pickle cleaning wastewater as the research object, uses the method of domestication of sludge to reduce the inhibitory effect of high salinity on the microorganism, and establishes a stable and efficient anaerobic biological treatment system (Yu, 2009). While seeking the best anaerobic treatment conditions and exploring the inhibition mechanism, 3D-EEM and PARAFAC analysis methods are used to further understand the bubble. The feasibility of anaerobic degradation of organic compounds in vegetable cleaning wastewater was verified and provided a theoretical basis for the practical treatment of pickle wastewater. This study not only improved the stability and degradation efficiency of the anaerobic treatment system of pickle wastewater by using the domesticated sludge, but also deeply explored the inhibition mechanism of the salinity on the anaerobic treatment, undertook the task of reducing most of the organic matter, and filled the blank of the organic matter analysis of the pickle wastewater by using 3D-EEM technology.

Experimental materials and methods

Experimental materials, reagents and instruments

Wastewater: the pickled vegetable wastewater is taken from pickle plant in Xin Fan Town and be treated by flocculation. The wastewater is light yellow, low turbidity and good transparency. The main index of wastewater is shown in *Table 1*.

Table 1. *Quality indexes of pickle wastewater*

Project	Content
COD/(mg/L)	2000~3500
pH	6.5~7.5
Turbidity	10~30
Salt content (calculate by NaCl)/(g/L)	10~15
SS/(mg/L)	50~100
NH_3-N/(mg/L)	30~80
TP/(mg/L)	10~15

Anaerobic initial culture sludge: The surplus sludge comes from the sewage treatment plant of hi-tech west district. The concentration of mixed liquor suspended solids (MLSS) is 10.42 g/L, and the concentration of mixed liquor volatile suspended solids (MLVSS) is 6.42 g/L.

Experimental reagents: glucose (water), urea, potassium dihydrogen phosphate, two sodium hydroxide, sulfuric acid and silver sulfate, potassium dichromate, mercury sulfate, ammonium ferrous sulfate, potassium sodium tartrate, potassium iodide, mercuric iodide, sodium hydroxide, ammonium chloride, potassium sulfate, ammonium molybdate, potassium antimony tartrate acid, ascorbic acid, potassium dihydrogen phosphate, chloride sodium, silver nitrate, potassium chromate etc..

Experimental instruments: DZKW type electric thermostatic water bath, BS-124-S electronic balance, vacuum suction device, WXJ-III type microwave digestion device, 722s spectrophotometer, JSM280G-18 type portable pressure steam sterilizer.

Experimental device: The anaerobic reactor is a self-made reaction device. The anaerobic bottle adopts a 1.5-L filter bottle as an anaerobic reactor, and the gas is collected by drainage method. The experimental device diagram is shown in *Figure 1*.

Figure 1. *Solid diagram of anaerobic experimental device*

Method of experiment and analysis

Acclimatization of anaerobic activated sludge

Rinsing the excess sludge with water, and then settle for half an hour later and discard the upper layer of cloudy liquid for so many times. An appropriate amount of sludge was placed in a 1.5-L closed glass reactor, which accounted for about 1/3 of the total volume of the container. Then the culture medium with a nutrient ratio of CODcr:N:P = 200:5:1 (CODcr at about 4000 mg/L, composed of glucose, urea, and two

© 2018, ALÖKI Kft., Budapest, Hungary

potassium hydrogen phosphate) was added for continuous culture. Changing the water every two days, and stirring properly, and controlling the temperature at 37 °C. After a period of time, it was observed that the sludge became darker and darker, and the acidity of the effluent weakened. A large number of bubbles appeared on the surface, indicating that sludge could start domestication. A certain concentration of NaOH solution was used to adjust the influent pH to keep it between 6.8 and 7.5. The adaptability of sludge to wastewater water quality is improved by continuous cultivation and acclimatization with flocculating effluent and nutrient solution, and the proportion of flocculated effluent in the influent is gradually increased. COD was measured every 4 days in the domestication period, and COD was measured every 2 days once the acclimation became stable.

Anaerobic experimental process

After domestication for a month or so, the influent is completely replaced by flocculation effluent, and the anaerobic effluent is basically stable. The best experimental scheme was determined by studying the effects of different influent pH, salinity, substrate concentration, residence time and temperature on COD removal. By changing the salinity of influent, the Monod fitting equation of anaerobic biodegradation kinetics under different salinity conditions was investigated, and the kinetic equation of anti-competitive inhibition was deduced by the steady-state method, which has a further understanding of biodegradation process.

Analysis method of 3D-EEM

Preparation of water sample: In order to analyze the composition and change characteristics of dissolved organic matter in water samples. First, the original water, anaerobic stable effluent sample and the same batch of water samples were collected in 50 ml plastic sample tube; Then, the water system membrane with a diameter of 50 mm and 0.45 m pores was installed in the sand core filter device (Yang et al., 2014). The water samples taken from the previous step were poured into the filter device, the vacuum pump was opened and filtered, and the 50-ml filtrate was collected in the Tetrafluoroethylene bottle, and the water samples were frozen in the icebox at 4 °C to slow down the metamorphic (Zhu et al., 2014); Finally, the water samples after treatment are sent to the fluorescence spectrophotometer for testing.

The measurement method of water sample: Using deionized water as the blank water sample, the three-dimensional fluorescence characteristics of water samples were scanned by Hitachi F-7000 fluorescence spectrophotometer (Produced by Hitachi high-tech company), its parameters were shown in *Table 2*.

Table 2. *Parameter meter of the fluorescence spectrophotometer*

Project	Parameter setting

Analysis method of 3D-EEM: The FL Solutions software is used to extract the fluorescence intensity data matrix within the wavelength range, and the matrix is introduced into the drawing software Origin 8.5 to get the three-dimensional contour map of the water sample, at the same time the data is introduced into the Matlab R2014b data processing software platform which is pre-installed with the N-way320 and parafacmodeling VER2.0 Toolbox toolkit. After deducting the Raman peak value of the blank water sample, the parallel factor analysis method is used to analyze the parallel factor. Finally, the three-dimensional fluorescence spectrum and the number of parallel factors, the fluorescence peak position and the fluorescence intensity of each parallel component are obtained, and the weakening amplitude is calculated.

Experimental results and discussion

The degradation of COD during domestication

As can be seen from *Figure 2,* 0-30 d is a period of domestication. During this period, with the increasing of raw water in the entering water, the concentration of chlorine ion is also increasing, and the removal rate of COD is decreasing. The removal rate of COD is reduced to 27.9% when the entering water is all the raw water; 32-50 d is a continuous domestication period, and the water entry conditions are consistent. With the prolongation of the culture period, the removal rate of COD increased gradually and reached more than 60% in the 44 d. At the end of continuous domestication, the removal rate of COD reached more than 65%; 50-68 d is the stable period of effluent. It can be seen that under the influent water quality, the water quality of the effluent can reach COD below 700 mg/L, and the removal rate of COD is above 70%. Thus, it can be seen that anaerobic sludge acclimation is completed.

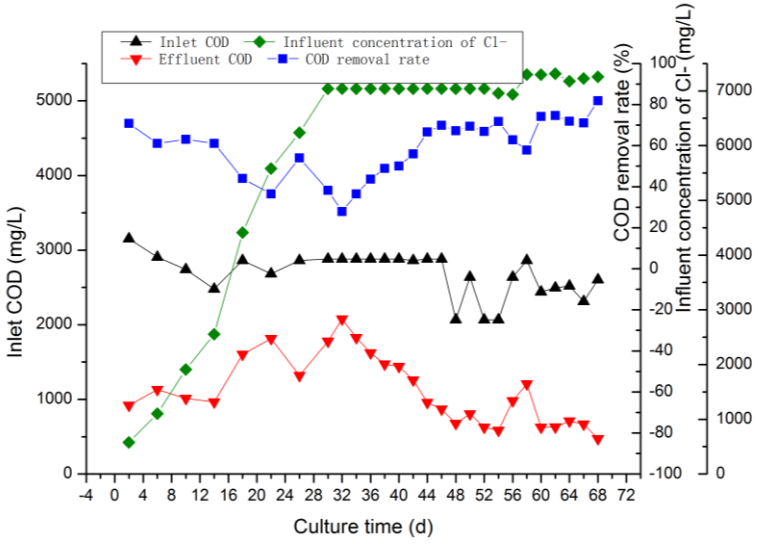

Figure 2. *Changes in each index during acclimatization*

The effect of pH on the removal of COD

The reaction temperature was 38 °C, the coagulation effluent was added to the anaerobic device to 1.5 L, and the water was changed every 24 h. The COD degradation

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

of the residence time HRT = 24h under different pH influent conditions was investigated, such as *Figure 3*. The pH range is 5-9, shaking the reactor manually several times a day, and ensuring that every pH influent condition stays 4 d in the anaerobic plant.

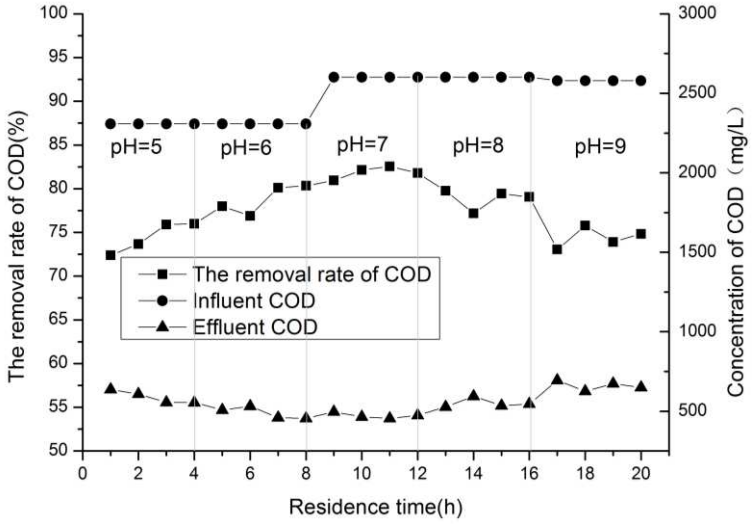

Figure 3. *pH effect on COD removal*

As can be seen from *Figure 3,* in the 5-7 range, with the increase of pH value, the COD removal rate gradually increased, while the pH value continued to rise, the removal rate began to decline. The best effect was achieved at pH = 7, the COD removal rate reached 81.8%, and the COD effluent concentration was 474 mg/L. The degradation effect of COD in the acid environment is better than that of COD in the alkaline environment. This is due to the hydrolysis acidification reaction under acidic conditions, which makes a large number of macromolecule carbon chains in the wastewater break into small molecular carbon chains and decompose organic matter into small molecular substances such as CO_2, CH_4 and H_2O under anaerobic digestion, causing the whole environment to be under the weak acid condition (Hu and Yan, 2009; Liu, 2011), so the best pH is 6-7.

Effect of substrate concentration on the removal of COD

The reaction temperature was 38 °C, the coagulation effluent was added to the anaerobic device to 1.5 L, and the water was changed every 24 h. The removal of COD under different COD concentration of influent was investigated, as shown in *Figure 4*. COD changes in the range of 1000-5500 mg/L, gently swaying several times a day and ensuring a stable operation of each concentration for 4 days.

As can be seen from *Figure 4,* when HRT = 24 h, in the range of 1000-3500 mg/L COD increased with the concentration of substrate removal rate increased gradually, but when the concentration continues to rise, the removal rate began to decline, so the best effect in COD is 3500 mg/L, the removal rate of COD reached 85.6%, the effluent COD concentration is 466 mg/L. The low substrate concentration will cause the low organic load of activated sludge and increase the operating cost, while too high substrate concentration will cause the excessive organic load to cause the excessive acid

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

production of sludge to make the reactor acidosis and affect the effect of effluent. Therefore, it is necessary to control the COD concentration at the appropriate level (Liu, 2011).

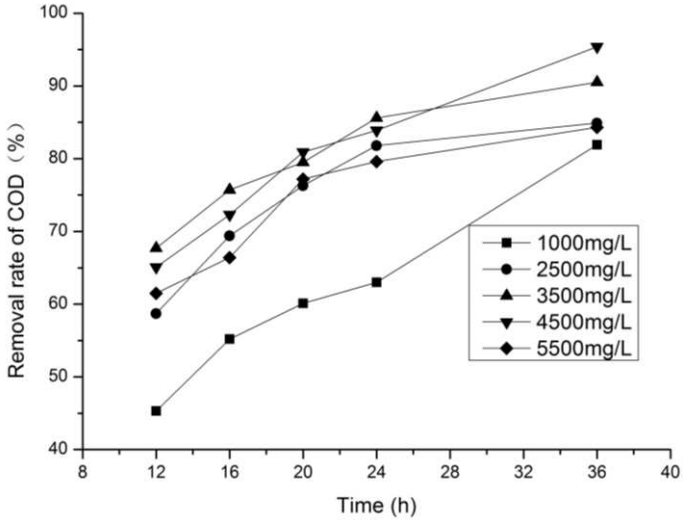

Figure 4. *The effect of substrate concentration on the removal of COD*

Influence of residence time on the removal efficiency of COD

The reaction temperature was 38 °C, the coagulation effluent was added to the anaerobic device to 1.5 L, and the water was changed every 24 h. The influent COD concentration is 2602 mg/L, pH = 7 and salinity is 11.98 g/L, The removal of COD under different residence time was investigated, as shown in *Figure 5.*

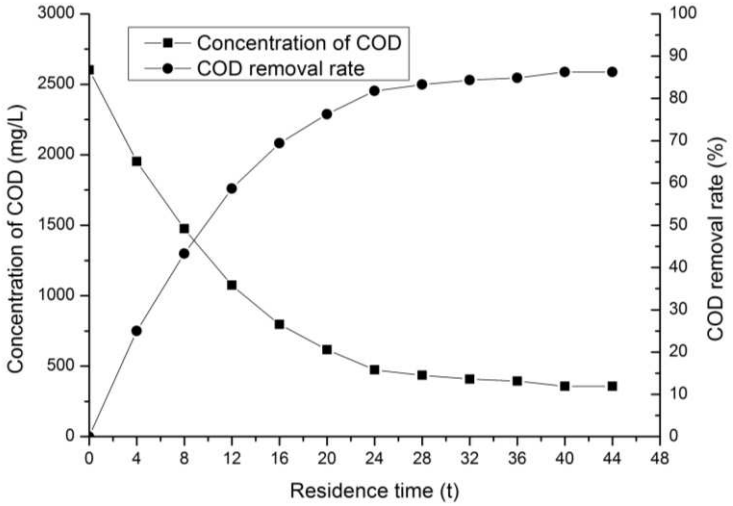

Figure 5. *The effect of residence time on the removal of COD*

As can be seen from *Figure 5,* with the prolongation of residence time, the effluent concentration of COD decreases gradually, and the COD removal rate increases gradually, and tends to balance at HRT = 24h. Therefore, the best residence time is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_35013516
© 2018, ALÖKI Kft., Budapest, Hungary

24 h, the COD removal rate reaches 81.8%, and COD effluent concentration is 474 mg/L.

Study on the effect of salinity on the anaerobic degradation of pickle cleaning wastewater and its kinetics

The reaction temperature was 38 °C, the coagulation effluent was added to the anaerobic device to 1.5 L, and the water was changed every 24 h. The removal of COD under the different salt concentration of influent was investigated, as shown in *Figure 6.* Salt changes in the range of 0-36 g/L, gently swaying several times a day and ensuring a stable operation of each concentration for 4 days.

From *Figure 6* we can see that the removal rate of pickle cleaning wastewater increases with the increase of HRT, and it can be seen that at the same HRT, the removal rate of COD decreases with the increase of salt concentration. When the salinity was maintained at 11.98 g/L, the removal rate is 81.8%; when the salinity was reduced to 0 g/L and 6.5 g/L, the removal rate of COD increased to 90.3%, 82.6%; when the salinity was increased to 17.93 g/L, 24.16 g/L, 30.22 g/L, 36 g/L, the removal rate decreased to 79.3%, 68.9%, 67.4%, 64.1% respectively. It can be seen that the acclimated anaerobic sludge can achieve good results in the treatment of pickles cleaning wastewater in the 0-24 g/L salinity range.

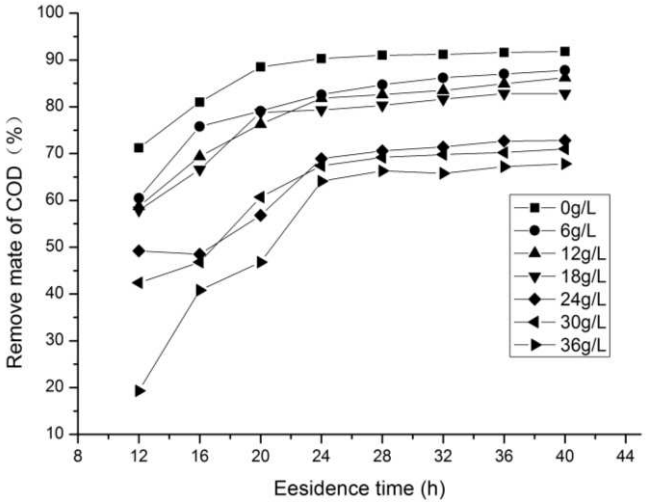

Figure 6. *Effect of different salinity at different residence time on COD removal*

As can be seen from *Figure 6,* different amount of salt in the anaerobic digestion process has an inhibition on microbial metabolism at different levels, the relationship between the specific growth rate and the matrix concentration is no longer consistent with the Monod relationship. Therefore, it is necessary to modify the kinetic formula of Monod specific growth rate according to the characteristics of wastewater and inhibitor.

The anaerobic biological removal rate of the usual matrix is described by the Monod equation (*Eq. 1;* Liu, 2011):

$$V = \frac{V \max S}{Ks + S} \quad \text{(Eq.1)}$$

Comparing the value of K, K_0, Ks, and K_{S0}, according to the following formula A-D in *Table 4* can infer the type of inhibition.

Table 4. *Inhibition type table*

Formula number	Inhibition type	Inhibition condition
A	Competitive	$K = K_0, K_s \rangle K_{S0}$ and $K^* = 1.0, K_s^* \rangle 1.0$
B	Non-competitive	$K \langle K_0, K_s = K_{S0}$ and $K^* \langle 1.0, K_s^* = 1.0$
C	Anti-competitive	$K \langle K_0, K_s \langle K_{S0}$ and $K^* \langle 1.0, K_s^* \langle 1.0$
D	Mixed	$K \langle K_0, K_s \rangle K_{S0}$ and $K^* \langle 1.0, K_s^* \rangle 1.0$

Note: V, V_{max} – to the removal rate and the maximum ratio of removal (d^{-1}); S_0, S, S_e – influent, reactor and water matrix concentration (mg/L); X – microbial concentration (mg/L); t – eaction time (h); K^* and K_s^* – inhibition constants; K – The maximum ratio of substrate removal in the absence of inhibitor (d^{-1}); K_{S0} – The saturation constant in the absence of a suppressing substance; K_I – The dissociation equilibrium constant of an inhibitor and an enzyme (microorganism) complex, also known as the inhibitor constant

According to the inhibition types determined by the above methods, the inhibition mechanism can be analyzed. Further, the inhibition kinetic constant K_I of substrate anaerobic biodegradation can be obtained by dynamic steady-state treatment.

It can be seen from *Table 3* and *Figure 7a-g* that the substrate V_{max} of the organic compounds in the anaerobic degradation wastewater is lower than the acclimated salt concentration when the content of salt is below 11.98 g/L and higher than 11.98 g/L. This shows that the change of salt content in the wastewater has a certain inhibitory effect on the anaerobic microorganism which has been adapted to the high salt concentration. At the same time, it can be seen from *Table 4* that when the concentration of salt is 0-30.22 g/L, $K^* < 1$ and $Ks^* < 1$, it is known that the type of degradation reaction is anti- competitive inhibition, that is, the sodium chloride in wastewater cannot combine with the enzyme directly, NaCl can only combine with

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_35013516
© 2018, ALÖKI Kft., Budapest, Hungary

enzyme-substrate complex to form an intermediate complex, enzyme-substrate-inhibitor.

$1/V_{max}$ is used to make a straight line of salt concentration I, its longitudinal intercept is $1/V_{max}$, the slope is $1/V_{max}K_I$, the fitting line equation is y = 1.10392x + 24.75291, and KI = 22423 mg/L can be calculated. The greater the K_I value, the less inhibition of anaerobic degradation of organic matter. Anti-competitive inhibition kinetic fitting curve sees *Figure 8*.

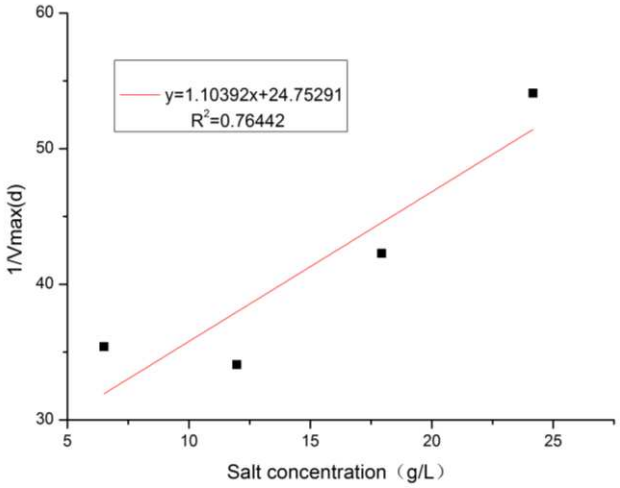

Figure 8. *Anti-competitive inhibition kinetic curve fitting curve*

Therefore, when the salt content in the water sample is ≦ 30.22 g/L, the anti-competitive inhibition kinetic equation of the salt concentration to the anaerobic COD degradation reaction is as follows (*Eq. 2*):

$$V = \frac{V_{max}S/\left(1+\frac{i}{K_I}\right)}{K_s/\left(1+\frac{i}{K_I}\right)+S} = \frac{V_{max}S}{K_s+S/\left(1+\frac{i}{K_I}\right)} = \frac{0.02934S}{3.68\left[1+\frac{i}{22423}\right]} \quad \text{(Eq.2)}$$

When the salt content is 36 g/L, K^* < 1 and Ks^* > 1, the type of NaCl's inhibition of wastewater is mixed type, the reaction process is relatively complex.

Optimization of anaerobic activated sludge for COD degradation

Formulation of the orthogonal experiment

Through the above single factor experiments, 4 factors were determined in this experiment, the concentration of A: the substrate, B: salinity, C: pH, and D: residence time. Each factor was selected in three levels. The level table of the experimental factors was shown in the lower *Table 5,* and the orthogonal experiment was carried out by the L9 (3^4) orthogonal table.

The result and analysis of the orthogonal experiment

The results of the orthogonal experiment are shown in *Table 6*. From the result of *Table 6,* the order of importance of each factor is B > C > A > D. The main influence factor in the experimental range is B substrate concentration, followed by C salinity, and then CpH, factor D residence time is the smallest. It is determined that the best scheme of anaerobic biodegradation to the pickle cleaning wastewater is A2B2C1D1, that is, when COD concentration is 2500 mg/L, the salt content is 6 g/L, pH is 7, residence time is 20 h, the effluent is the best.

Table 5. *Experimental factor level table for anaerobic treatment*

Level	**Factor**

Removal of fluorescent organic matter

Measurement results of 3D-EEM

The three-dimensional fluorescence spectrum and contour map of water intake and anaerobic effluent were shown in *Figures 9* and *10*. Before and after treatment, COD decreased from 2068 mg/L to 584 mg/L, and the removal rate was 71.8%. NH_3-N increased from 52.8 mg/L to 135.3 mg/L and increased by 156.3%. The spectrogram of the contour clearly expresses the excitation of the peak intensity of the spectral peak

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

intensity of the influent and the effluent, and the position and relative intensity of the emission wavelength. You can see from *Figure 9,* the water has a strong peak excitation/emission band at 270 ~ 295 nm/340 ~ 360 nm; can be seen from *Figure 10,* the anaerobic effluent has 4 fluorescence peak excitation / emission bands are located at 270 ~ 295 nm/340 ~ 360 nm, 245 ~ 285 nm/420 ~ 450 nm, 295 ~ 310 nm/420 ~ 450 nm. 345 ~ 370 nm/420 ~ 450 nm. Because of the large changes in the front and back-fluorescence peaks, it can be found that the species of soluble organic matter in water has changed greatly before and after the anaerobic treatment. At the same time, it can be seen from the contour map that the spectral map overlaps to a certain extent.

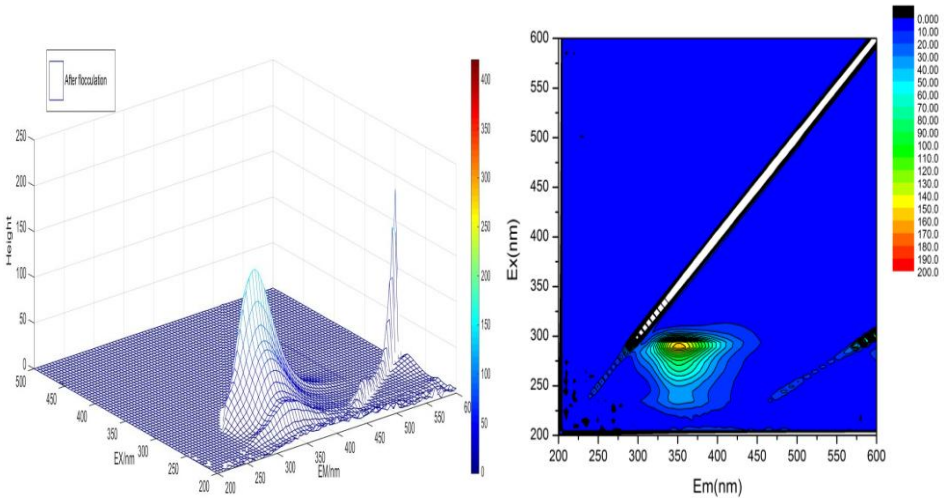

Figure 9. *Influent fluorescence spectrum and contour map*

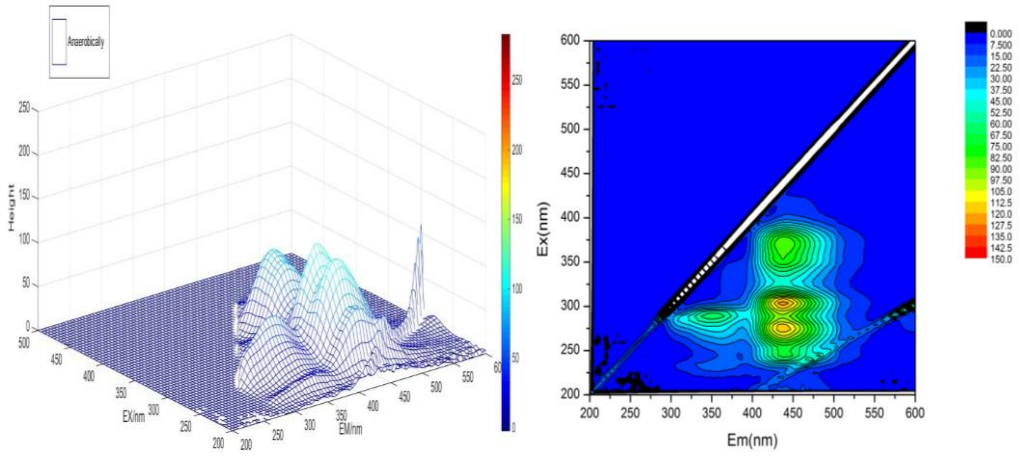

Figure 10. *Fluorescence spectra and contour maps of anaerobic effluent*

Results of parallel factor analysis

For the same batch of 5 samples, the original data matrix (5 * 82 * 82) was measured by PARAFAC parallel factor analysis. 3 parallel factors in the water sample were obtained by the parallel factor analysis model, and the core consistency map is shown in *Figure 11*. Parallel factor decision rule: when the kernel consistency is greater than or

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_35013516
© 2018, ALÖKI Kft., Budapest, Hungary

equal to 80% or in the vicinity, show that this factor is reliable and that 50-80% is not stable, then, < 50% for the problem. The choice of factor number is to select the maximum number of factors before the kernel conformance is rapidly falling (Ma, 2014).

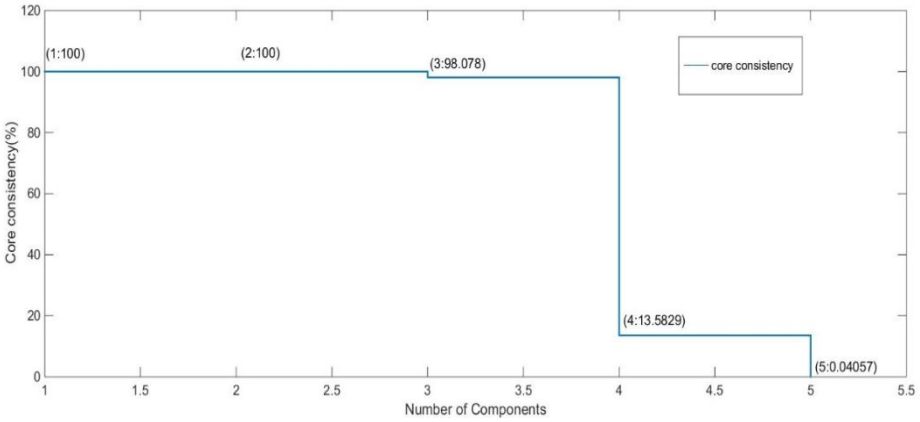

Figure 11. *Core consistency diagram*

The 3-factor excitation and emission spectral profiles obtained by using the parallel factor model are shown in *Figure 12*.

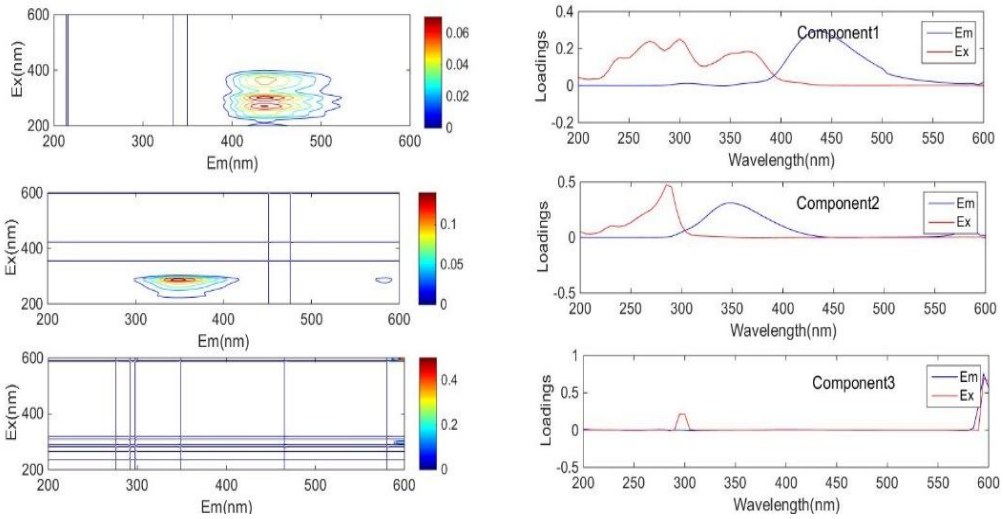

Figure 12. *Parallel factor excitation and emission spectrogram*

As can be seen from *Figure 12,* factor 1 has 4 optimal excitation wavelength, were 250 nm, 270 nm, 300 nm, 360 nm, optimal emission wavelength is 435 nm, respectively characterizing that UVA humus produced by terrestrial plants or soil organic matter, the unknown humus produced by microbiological processes, UVA humic substances produced by terrestrial plants, endogenous microorganism processes, and UVC humic substances produced by terrestrial plants or soil organic matter, belonging to visible fulvic acid. Therefore, factor 1 indicates a kind of humus-like substance (Zhu et al., 2014; Ma, 2014; Hao et al., 2007; Liu et al., 2012). The optimal excitation and emission wavelength of factor 2 is 285/350 nm, characterizing that highly excited luminescent

© 2018, ALÖKI Kft., Budapest, Hungary

tryptophan produced by terrestrial plants, endogenous generation and microbial processes, which is amino acids that are free or bound to proteins and the fluorescence characteristics are similar to those of free tryptophan, indicating a complete protein or less degraded peptide (Hao et al., 2007; Liu et al., 2012). While factor 3 did not find the full fluorescence peak and the best emission wavelength. The inference is that it should be caused by scattering and cannot indicate organic matter in water. From *Figure 9* and *10* can be seen that after anaerobic treatment factor 2 fluorescence peaks decreased, that is, the fluorescence peak intensity of tryptophan is reduced by 58.7%. While factor 1 fluorescence peaks increased, the fluorescence peak intensity of the humus is increased by 11.5 times. Protein reduced and humic substances in water increased after anaerobic treatment, we can indicate that anaerobic biodegradation has converted most of the macromolecular proteins into humus, and the anaerobic ammonification reaction has been taken, which made COD lower while NH_3-N increased.

Conclusion and prospect

(1) The concentration and impact of salinity will inhibit the anaerobic microorganism's degradation ability. In this study, the adaptability of anaerobic microorganisms to high salt wastewater was improved by acclimation of anaerobic sludge. After domestication, the removal rate of COD increased from 27.9% to over 70%. The single factor optimization results showed that the removal rate of COD could be raised to more than 80% again under the condition of pH = 7 and the residence time for 24 h. It is indicated that the water quality is the most significant factor affecting the anaerobic effect. Try to ensure that the influent water quality is stable at COD concentration of 2500 mg/L, the salinity of 6 g/L and pH of 7, so as to achieve the best effect of effluent. Therefore, the anaerobic treatment system in this study is feasible for treating pickle cleaning wastewater.

(2) According to the results of 3D-EEM research, there are a lot of tryptophan (protein) in the pickle cleaning wastewater. The anaerobic biodegradation can convert most of the large molecular protein into humus, and the anaerobic ammonification reaction has occurred, which made COD lower while NH_3-N increased. Therefore, anaerobic treatment in this study has a significant contribution to the removal of organic matter from Pickles wastewater.

(3) Follow up studies can focus on the following aspects: First of all, biological or physicochemical methods should be combined for further treatment of anaerobic effluent to ensure effluent quality. Secondly, in the future research, we need to further optimize the methods of cultivation and domestication of anaerobic sludge, further shorten the cycle of acclimation and put into operation at an early date. Finally, it is necessary to expand the scale of the anaerobic reactor and investigate the treatment effect in the actual engineering application.

(Received 17th Mar 2018; accepted 21st May 2018)

Abstract. Ground beetles (fam. Carabidae) as beneficial insects are valuable organisms to study whether any of the new implemented agricultural measures in fruit production is beneficial. The aim of our study was to analyze impact of different types of exclusion nets on ground beetle species composition and abundance in an apple orchard. The study was conducted in an IPM apple orchard, situated in the north-west part of Croatia. The treatments for the study were four types of exclusion (colored) nets (Agritenax white, Agritenax yellow and Agritenax red all with photo selective properties and Stop Drosophila Normal net - pearl color) and non-covered trees acted as a control. Ground beetles were collected during the summer and autumn (from July 1st until October 15th in 2015) with pitfall traps. During the study, a total of 1559 specimens of ground beetles were identified and sorted into 28 species. Significant differences in the captures under nets were observed for species: *Anchomenus (Anchomenus) dorsalis* (Pontoppidan 1763), *Microlestes minutulus* (Goeze 1777), and *Pterostichus (Feronidius) melas melas* (Creutzer 1799). The most of the ground beetles (413) were recorded under the Agritenax yellow nets and the least (184) in the control. Our study showed the positive effect of exclusion nets on ground beetle species composition and diversity in IPM apple orchard thus confirming their value in assessing the introduction of new agricultural measures into practice.
Keywords: *Agritenax and Stop Drosophila Normal net, Croatia, IPM fruit production, pitfall traps, soil dwelling fauna*

Introduction

Ground beetles (Coleoptera: Carabidae) are beneficial organisms as predators of various pests in different developmental stages in agricultural production (Lövei and Sunderland, 1996; Kromp, 1999). Their communities are not bound to a certain crop type, but shift in dominance according to the crop-specific rhythm of cultivation and changes in crop phenology and microclimate (Kromp, 1999). Any change in agricultural practices, especially novel practices, can directly affect ground beetles. Because they are highly sensitive to anthropogenic impacts, ground beetles can be considered as bioindicators of environmental impacts from cultivation practices (Kromp, 1999). The composition and richness of Croatian ground beetle fauna have been studied in a variety of arable crops represented in different agricultural practices (e.g. alfalfa and red clover, winter wheat and barley, maize, sugar beet and vegetable gardens) (detail described in: Kovačević and Balarin, 1960; Sekulić et al., 1973; Bažok et al., 2007; Stančić, et al., 2010; Kos et al., 201 201 2013; Lemić et al., 201 2017; Drmić et al., 2016; Virić et al.,

© 2018, ALÖKI Kft., Budapest, Hungary

2017). Clearly there have been few studies of changes in ground beetle communities in response to orchard production, and particularly to those agricultural and crop protection practices that are now standard in apple production.

The standard method for crop protection in Croatian apple orchards is Integrated Pest Management (IPM), which is a suite of environmentally and toxicologically acceptable procedures to control pest populations. Those measures could affect activity, density and species richness of apple orchard ground beetle communities. A new approach of applying colored photo selective shade nets (exclusion nets; anti-hail nets) for improving the utilization of solar radiation by fruit trees was introduced in practice recently (Shahak et al., 2004). The photo selective netting in apple orchard has a positive effect on flowering, fruit-set, fruit size, color and internal quality, in addition to non-specific reduction of water stress, superficial damage and sunburn (Shahak et al., 2004). The main reason to set up the exclusion nets during this study in IPM Croatian orchards was to test their effectiveness in preventing codling moth to apple fruits (Pajač Živković et al., 2016). This experiment resulted in a highly significant reduction of codling moth in IPM orchards (Pajač Živković et al., 2016). The main consequence of applying exclusion nets is the change in the microclimate beneath the trees, accordingly any change of this kind could lead to a disturbance and towards affect orchard ground beetle communities. Therefore, we hypothesized that exclusion nets could have a negative impact on ground beetles in IPM orchards.

The main objective of this study was to define and analyze what type of exclusion net has the least negative impact on ground beetle abundance and diversity in an IPM Croatian apple orchard.

Materials and methods

Study area

The study was conducted in an IPM apple orchard (46°9’47”N, 15°52’52”E), situated in north-west Croatia (Krapina County; *Fig. 1*).

Figure 1. *Experimental site in Croatia (Krapina County)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_35173528

Beetle collection was carried out during the growing season in 2015. The study area is characterized by a continental-humid climate of warm, rainy summers and cold winters (Penzar and Penzar, 2000). The average annual precipitation in this region is 850 mm and the average annual temperature is 11 °C (MHS, 2017). The soil in the study area is typical pseudogley (IUSS Working Group WRB, 2015). The orchard elevation is 282 a.s.l. Apple cultivars of 'Braeburn', 'Idared', 'Golden Delicious', 'Granny Smith' and 'Jonagold' are grown on a surface of 600 m^2. During the study period, insecticide treatments were not applied on the experimental site in order to exclude their impact on orchard entomofauna. Fungicides were applied by standard IPM principles in order to maximize apple health and minimize the risk of economic and ecological threats for the environment. Weeds are managed by mulching treatments between rows several times in the season, and vegetation in the row was not treated with herbicides. The orchard is surrounded by agricultural fields (arable crops and grasslands).

Experimental design

Experimental design was a random block arrangement with four treatments in three repetitions. The treatments were four types of exclusion nets (Agritenax white, Agritenax yellow, Agritenax red – photo selective ones and Stop Drosophila Normal net - pearl color) and non-covered trees as a control. Agritenax nets produced by Tenax S.r.l., Italy were of the same density (2.4 × 4.8 mm) while Stop Drosophila Normal net, produced by Artes Politecnica, Italy was of 0.9 × 1 mm in density. Each treatment was placed on three neighboring trees, while in three cases neighboring trees were uncovered with exclusion nets what represented a control plot (*Fig. 2*).

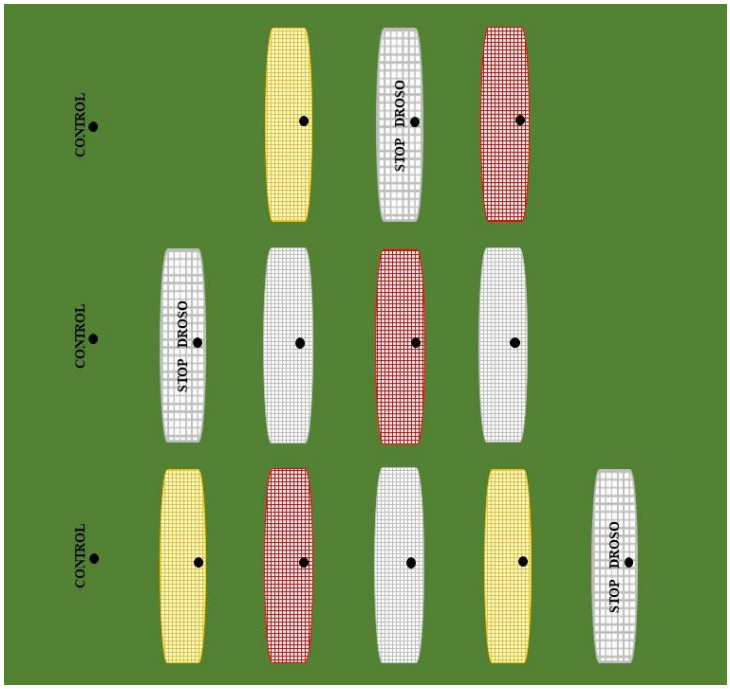

Figure 2. *Schematic representation of experimental design*

The study occurred in the center of the IPM apple orchard planted with the variety 'Braeburn'. Trees were completely covered with nets and fixed to the ground with metal

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

pegs at the petal fall and the nets were removed after the harvest of apple fruits. Before setting up nets, existing arthropod fauna on apple trees were eliminated by applying neonicotinoid insecticide thiacloprid (Calypso® 480 SC, Bayer CropScience). One pitfall trap was placed in each treatment in the soil beneath the trees.

Beetle sampling and data analysis

Ground beetles were collected during summer and autumn (from July 1st until October 15th in 2015) (week 28 till week 42 of the year) with pitfall traps. Traps were a metal cylinder covered with a metal lid (Ø = 10 cm wide and h = 20 cm). The cylinder was buried in the soil and a round edge plastic southpaw was fitted above. A polythene pot was placed at the bottom of the cylinder. The plastic pot was half filled with saline water (20% solution) for preservation. For transportation purposes the pots had lids. Traps were inspected on a weekly basis and beetles were preserved in 70% EtOH until identification. The identification of the collected ground beetles was based on the works of: Auber (1965), Bechyne (1974), Harde and Severa (1984) and Freude et al. (2006).

The abundance of captured beetles on a weekly base was used as the response variable, and both week and net type, were used as fixed predictor variables in a two-factor analysis of variance, performed separately for each identified beetle taxon. The Tukey honestly significant difference test was used for post-hoc comparisons among means within levels of the two fixed factors (R Core Team, 2017).

Results

During the study, a total of 1559 specimens of ground beetles were identified and sorted into 28 species represented in *Table 1*.

The maximum number of specimens, 98 belonged to *Pterostichus (Feronidius) melas melas* (Creutzer 1799), which is five times the number of specimens of *Carabus (Procrustes) coriaceus* (Linne 1758), with a total of 196 individuals. In addition to these two species, among the most abundant was *Microlestes minutulus* (Goeze 1777) with a total of 81 specimens (*Table 1*).

Table 1. *Identified species, captures of species under different net treatments and total capture of species during collection in IPM apple orchard, Krapina, Croatia, 2015 (*p < 0.05; **p < 0.001)*

Abbreviations: A.R. – Agritenax red; A.W. – Agritenax white; A.Y. – Agritenax yellow; S.D.N. – Stop Drosophila Normal; CONT. – No net, control
Different letters indicate significantly different treatment levels

The population dynamics of the most abundant species under different exclusion nets and on the control is shown in *Figures 3*, *4* and *5*. Significant captures of species *P. melas melas* started on all treatments from August 13th and lasted till the end of monitoring period. During September two stresses for the population were detected, the first lasted from August 27th to September 3rd while the second lasted from 17th to 24th September. The trend of captures under all nets as well as on the control during the study period was more or less uniform (*Fig. 3*).

The first significant increase in captures of *C. coriaceus* started on all treatments in the first half of September and the most ground beetles were collected at the beginning of October. A significant number of adults have been captured till the end of monitoring period (*Fig. 4*).

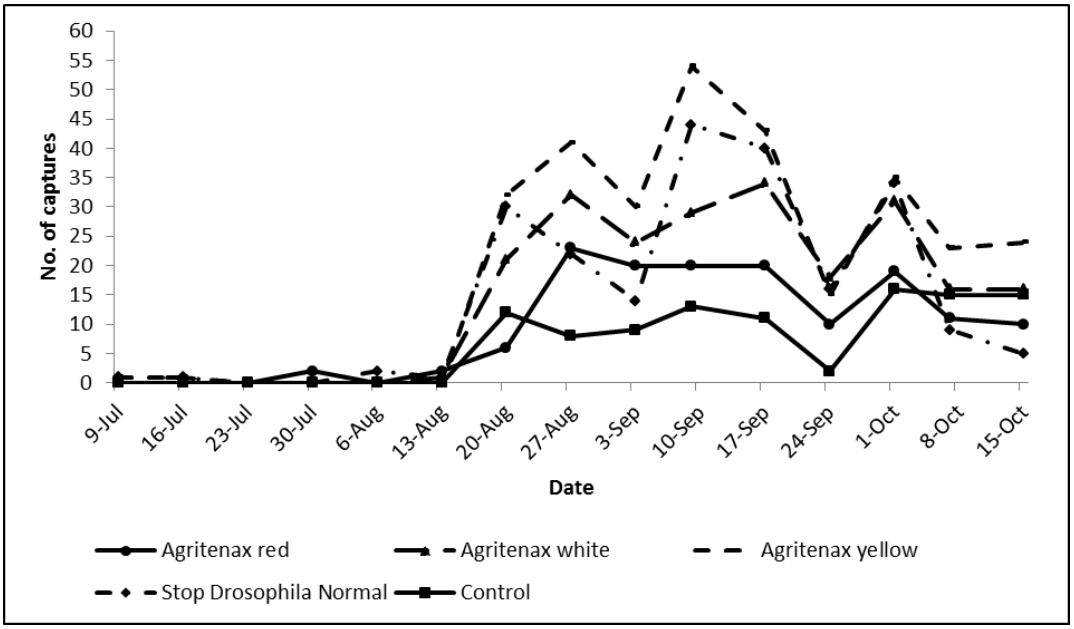

Figure 3. *Population dynamic of species Pterostichus melas melas in IPM apple orchard under different exclusion nets and on the control*

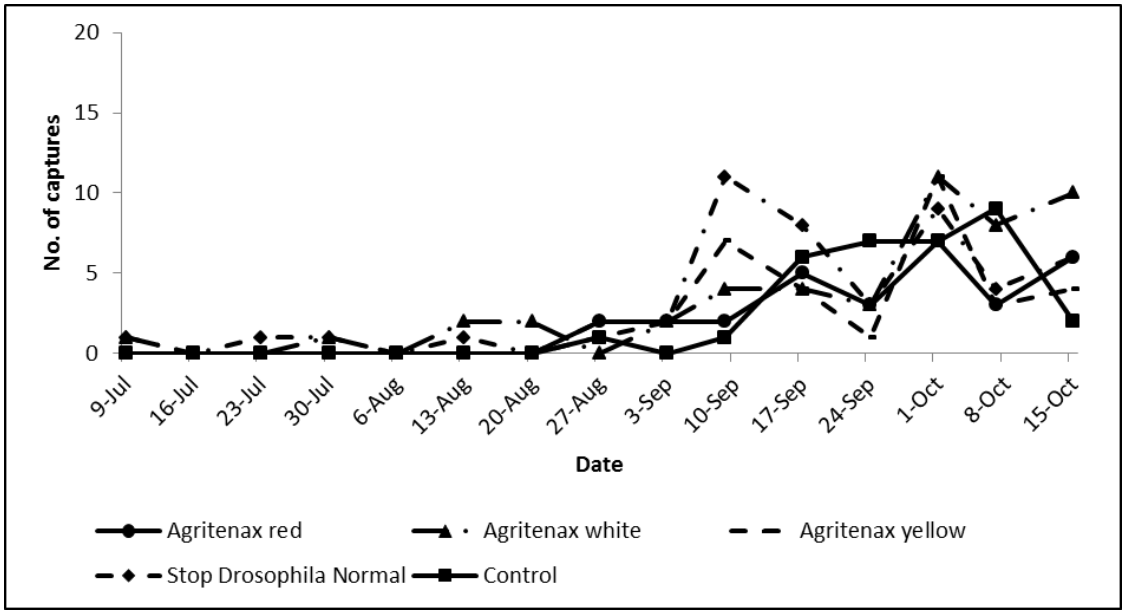

Figure 4. *Population dynamic of species Carabus coriaceus in IPM apple orchard under different exclusion nets and on the control*

The captures of species *M. minutullus* started on all treatments at the end of July and lasted until the beginning of October. Greater stress for the population of this species occurred from 3rd to 10th of September when the capture fell suddenly on all traps. Under Agritenax white nets captures were higher in September than in August, while the captures under the Agritenax red nets as well as on the control were higher at the beginning of August compared to September (*Fig. 5*).

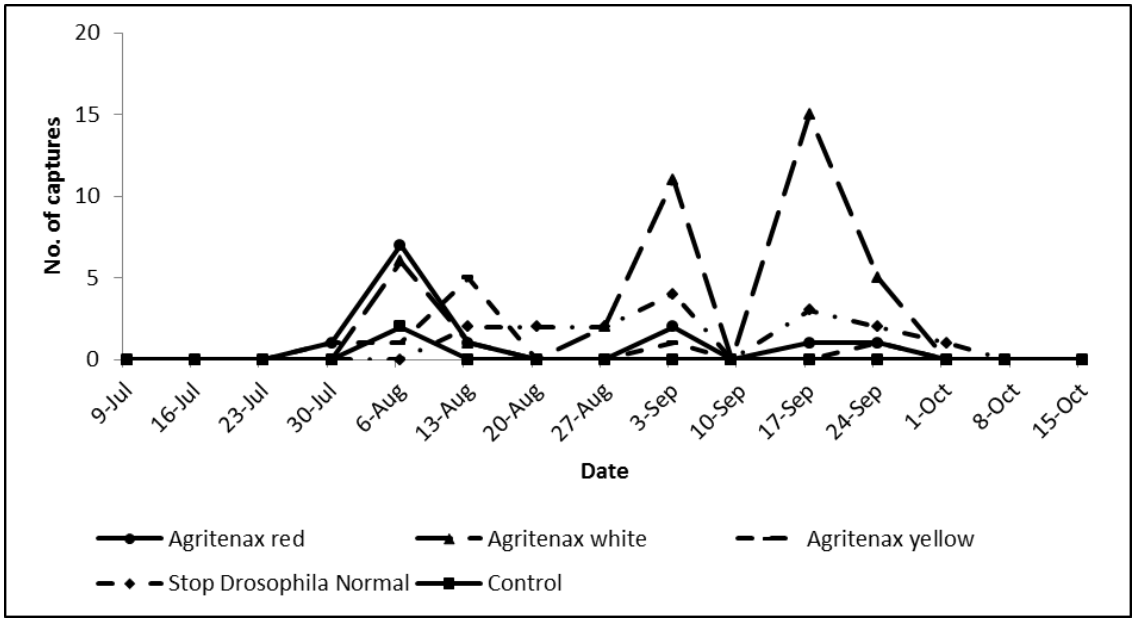

Figure 5. *Population dynamic of species Microlestes minutulus in IPM apple orchard under different exclusion nets and on the control*

The biggest catch of one species of ground beetles under one type of exclusion nets was 299 and belonged to *P. melas melas* under Agritenax yellow nets. During the study just one individual of *Anchomenus (Anchomenus) dorsalis* (Pontoppidan 1763) and *Nebria (Nebria) brevicollis* (Fabricius 1792) were captured.

The most ground beetles (413) were recorded under the Agritenax yellow nets and the least (184) on the control (*Table 1*). Significant effects of time of capture were observed generally for more abundant species. Extremely high ($p < 0.001$) and high ($p < 0.01$) differences between the week of the capture were established on seven species (*Table 1*). The effect of net type was observed for only four species. A significant interaction between net and time of sampling was observed only for *Harpalus (Harpalus) rubripes* (Duftschmid 1812). This species was caught in low numbers; therefore because of its rarity further conclusions about it will not be made.

Significant differences in the captures under nets were observed for species *A. dorsalis*, *Microlestes minutulus* (Goeze 1777), and *P. melas melas* (*Table 2*). This study shows that there are significantly more captures of the species *A. dorsalis* under the Stop Normal Drosophila nets in relation to Agritenax red, white and yellow nets. On the other hand, for the same species, there is a lack of captures on the control. For *M. minutullus* the highest capture was established under Agritenax white nets in relation to Agritenax red and yellow where the captures were significantly lower (*Table 2*). For this species, captures on the control were the lowest. Captures of adult specimens of the species *P. melas melas* were the highest under the Agritenax yellow nets (*Table 2*). While captures under Agritenax red and white nets, also as for the Stop Normal Drosophila nets, did not defer statistically. Captures for *P. m. melas*, were similar to those of the other two species, and were the lowest on the control (*Table 2*).

There was no difference in captures between closely observed species beneath Agritenax red nets and control. *P. melas melas* had higher rates of captures under the Agritenax yellow nets than other two species in relation to the control. Species of *P.*

melas melas and *M. minutulus* were captured more beneath the Agritenax white nets, and *P. melas melas* and *A. dorsalis* beneath the Stop Normal Drosophila nets in relation to the control.

Discussion

Various authors have developed different kinds of experiments or have gathered knowledge to prove that the presence of ground beetle, as wide spread beneficial organism, could be an indicator for habitat quality (Bourassa et al., 2008; Avgın and Luff, 2010; Koivula, 2011). Our investigation showed a similar importance for the bio-indicative value of this family and their presence in our apple orchard habitat with 28 species found. These results are in a similar range as that of studies in apple orchards from Hungary (Kutasi et al., 2004), Spain (Miñarro et al., 2008), Italy (Paoletti et al., 1995), Canada (Smith et al., 2004) and Japan (Funayama, 2011). Various total captures of ground beetles in our study can suggest that several species should be closely considered for their indicator value because of their abundance, such as *P. m. melas*; *C. coriaceus*; *M. minutulus*; *Harpalus (Harpalus) dimidiatus* (P. Rossi 1790) and *A. dorsalis*. According to Miñarro and Dapena (2003) the three most common beetles, *Pterostichus (Steropus) gallega* (Fairmaire 1859), *Pseudoophonus (Pseudoophonus) rufipes* (De Geer 1774) and *Poecilus (Poecilus) cupreus* (Linne 1758) represented more than 98% of the total captures. Those species were not present in our study, but on the other hand our three most abundant species represented more than 75% of the total captures. Similar results were found in a study from Miñarro et al. (2008) where 83.76% of all captures were for three of the most abundant species *P. rufipes* (55.84%), *P. cupreus* (17.62%) and *Carabus (Tachypus) cancellatus subsp. cancellatus* Illiger 1798 (10.30%), respectively. The most abundant species, which basically determined the composition of orchard carabid assemblages in study from Markó and Kádár (2005), were *Harpalus (Harpalus) froelichii* Sturm 181 *Harpalus (Acardystus) flavescens* (Piller & Mitterpacher 1783), *Calathus (Neocalathus) ambiguus subsp. ambiguus* (Paykull 1790), and *Harpalus (Harpalus) hirtipes* (Panzer 1796). Every agronomic

practice may influence the environmental variables such as the substrate temperature or humidity, the availability of organic matter, food or shelter, and consequently carabid captures may fluctuate in accordance with their own needs (Miñarro et al., 2008). The exclusion nets also change microclimate conditions (e.g. temperature, relative humidity, light) (Brkljača et al., 2016; Fruk et al., 2016) beneath the net as well as on the soil surface beneath the trees. This practice could influence the richness and diversity of ground beetles. Applying exclusion nets for improving the utilization of solar radiation by fruit trees (Shahak et al., 2004) influences the total capture rate of some ground beetle species. The Agritenax yellow nets had the highest total ground beetle captures among all other nets and the control. Captures varied most likely due to solar radiation, as nets influenced the cover of ground plants or soil humidity beneath the trees, or due to an altered abundance of pests or other fauna. In the study of Miñarro and Dapena (2003) and Miñarro et al. (2008), it was found that ground beetles were captured in the greatest abundance in tilled and herbicide plots compared to mulched plots. In our study, the exclusion nets clearly attracted some ground beetles from the surrounding areas, though the whole orchard was mulched and no herbicides were applied. We observed water condensation on each type of net over the sampling period which implicates that water loss is lower than on the control plots, which is also corroborated by some authors (Wachsmann et al., 2014). Although soil moisture negatively affected carabid catches in cultivated fields (Cárcamo, 1995), in our study exclusion nets might have had the opposite impact. Our sampling period was summer and the beginning of autumn when water loss from the soil is the greatest and ground beetles might be seeking a humid microclimate. It is clear that exclusion nets change the microclimate, which can impact other organisms, such as weeds, which can improve the water balance beneath the apple trees. This could influence prey species richness for ground beetles. Exclusion nets influenced capture rates of three species (*A. dorsalis*, *M. minutullus* and *P. m. melas*). Species of *A. dorsalis* occur in open meadows and grasslands, usually on soil rich in gravel or clay, and often limestone soil. The species also inhabits arable land, particularly winter crops on heavy soil (Merivee et al., 2012). It is a spring breeder, meaning the species is the most numerous between May and June (Lindroth, 1986). The influence of exclusion nets could be explained mainly by their increase of the preferred (aphid) prey of this species, which is a known aphid predator of cereal crops (Thiele, 1977; Bilde and Toft, 1997). The second important species for this study was the eurytopic *M. minutulus.* It is predominately found at sites with pioneer vegetation or grasses (Brändle et al., 2000) as a typical predator, fully winged. The species is a spring breeder and in this study it was also influenced by exclusion nets. The presence of this species in this study was mostly under Agritenax yellow nets during September. The reason for this could be their preference for prey (aphids) and prolonged vegetation of weeds (grass) under this type of net. The capture of species *P. melas melas* as a predatory, autumn breeder species, that inhabits forests, forest edges, meadows and agricultural land, was also influenced by exclusion nets. Reasons for this, besides prey preference for aphids, might be humidity that attracted another prey, slugs, of the genus *Pterostichus* (Oberholzer et al., 2003). Slugs were observed in high abundance under exclusion nets. Funayama (2011) considered that only *Amara chalcites* Dejean 1828 adults can be used as bioindicators for pesticide use pressure in apple orchards in northern Japan, whereas the main diet of this species is probably C3 plants. The results of our study showed that, the selected omnivorous and predatory species of ground beetles are influenced by the exclusion nets, so that they have the potential as

bioindicators for evaluating the use of netting for improving agricultural habitat. Furthermore, Miñarro et al. (2008) stated that in orchards, groundcover management affected the density and diversity of ground beetles, which is consistent with our study in which exclusion nets have influenced microclimate (humidity) and ground beetle prey attraction.

Conclusion

The main conclusions of the study are: a) one species of ground beetle could not be considered for bio-indicative value of cultivation impacts and b) most of the captures were for the several most abundant ground beetle species. Considering all of the above, the main hypothesis about the negative impact of the exclusion nets on ground beetles could be rejected as this study indicates a positive effect from exclusion nets on ground beetle abundance in an IPM apple orchard planted with different varieties of apples in north-west Croatia.

Abstract. In this study, the seasonal succession of the diatoms on *Phragmites australis* community was investigated in Lake Mogan (Turkey), and the epiphytic diatom community was used to estimate the ecological condition of the lake. Five stations were chosen in the littoral region of the lake, and diatom samples were taken from the *P. australis* monthly between January and November 2013. Two stations were selected in the pelagial region and chlorophyll *a* concentrations were determined. Lake water temperature, pH, dissolved oxygen concentration, conductivity and Secchi depths were measured, and total nitrogen, total phosphorus and silicate were analyzed. A total of 61 epiphytic diatom species were identified in Lake Mogan. The dominant species were those with tolerance to α–β mesosaprobic conditions. According to the mean Secchi depth, chlorophyll and total phosphorus concentrations, the lake was eutrophic. The IDG, IPS, DESCY, WAT, IDP and TDI indices, calculated according to epiphytic diatoms, indicated an ecological quality between medium and poor (classes III-IV). Among them, IDG and IPS are recommended for monitoring of ecological status in the lake because these indices also integrated all diatom taxa within the samples. The occurrence of pollution-tolerant species and the fact that most indices showed an ecological quality of medium or poor indicated an increase of organic matter and eutrophication in Lake Mogan.
Keywords: *epiphyton, reed, shallow lake, water quality, chlorophyll*

Introduction

The most widespread algae, diatoms, can be found in all water resources, from small streams to sea, and from clean to polluted water. Diatoms include many different forms and can be found on all types of substrates; and they can easily be sampled in great numbers from small surfaces in aqueous environments. They can also be sampled from artificial surfaces, so that their rapid response to changes in water quality, together with a fast access to results by means of diatom indices, make them advantageous for use in monitoring water quality. Among their disadvantages are the need for taxonomic knowledge in identifying them, and the difficulty in separating dead and live cells. Diatoms have been used as an indicator of water quality since 1949, and for this reason many species have been classified according to their tolerance and sensitivity to pollution. The cells do not break up easily because they contain silica, and are indicators of long term as well as short term changes (Cox, 1991; Round, 1991; Smol and Stoermer, 2010). Diatoms are particularly used as indicators of pH, conductivity, salinity and trophic level (Cox, 1991).

The Water Framework Directive, adopted by and implemented in the European Union in the year 2000, classifies water resources by their ecological qualities and aims to bring water to a good ecological quality. Phytobenthos, according to Water Framework Directive, is one of the indicators used to determine the ecological quality of standing and flowing waters (Anonymous, 2000). The use of epiphytic diatoms, which are a component of lake phytobenthos, is important to estimate the ecological quality of shallow lakes.

Because diatoms form a large proportion (90-95%) of benthic habitats of water ecosystems, they have become an important part of water quality monitoring studies (Ács et al., 2004). The occurrence of a particular diatom species in different bodies of water, from clean to polluted waters, enables the use of indices of diatom variety. Diatom indices are based on tolerance and/or sensivity of taxa (genus or species) and allow the assessment of water quality using the structure of diatom communities.

Although there have been many studies of the use of diatoms in determining water quality and/or ecological quality in flowing water (Atıcı, 1997; Eloranta and Soinien, 2002; Blanco et al., 2004; Johnson et al., 2006; Kalyoncu et al., 2009; Salomoni et al., 2011; Gün, 2011; Solak and Ács, 2011; Kıvrak et al., 2012; Tokatlı, 2012; Kalyoncu and Şerbetçi, 2013; Taş et al., 2015; Demir et al., 2017; Toudjani et al., 2017;), a limited number of such studies have been conducted on lakes (Poulíčková et al., 2004; Ács et al., 2005; Kovács et al., 2007; Lirika et al., 2013; Tokatlı, 2013; Kavya and Ulavi, 2014; Szabo et al., 2017). For this reason, studies of the use of diatoms to determine ecological quality in lakes are of great importance. Tokatlı (2013) reported that the TDI index had been calculated in Porsuk Reservoir using epipelic diatoms, and that according to this index it was mesotrophic.

Several studies have been conducted in limnology, water quality or phytoplankton in Lake Mogan (Akbulut and Akbulut, 2002; Fakıoğlu and Pulatsü, 2005; Atıcı et al., 2010; Yerli et al., 2012; Atıcı and Tokatlı, 2014; Şanal et al., 2015). Demir et al., (2014) researched the possibility of using Q index in assessing the ecological quality class of Lake Mogan. Estimates of the ecological quality made in connection with phytoplankton community structure in the lake were compared with the nutrient status. The results showed that Q index could be used in monitoring ecological quality in Lake Mogan. It is a shallow lake surrounded by a belt of reed *Phragmites australis* (Cavanilles) Trinius *et* Steudel on its shores. According to King et al., (2006), *P. australis* is recommended as an ideal plant for sampling epiphytic diatoms when determining ecological quality in lakes.

The aim of the present study was to determine the ecological quality of Lake Mogan, which is an important example of a shallow lake under anthropogenic pressure, using epiphytic diatoms found on *Phragmites australis*, and to determine the diatom composition in the lake.

Materials and Methods

Study Site

Lake Mogan is situated in Sakarya Basin, 20 km south of Ankara in Turkey, between 39˚44'45" and 39˚47'45" north, 32˚46'30" and 32˚49'30" east, at an altitude of 973 m above sea level. It has an area of 5.7 km², and an average depth of 2.4 m. The maximum depth is 4.25 m. The lake is 5.4 km long and approximately 1.7 km wide. Its shore length is approximately 16 km (Demir et al., 2014).

Because they have ecological and recreational importance, the wetland-marsh areas around Lakes Mogan and Eymir have been designated as the Gölbaşı Special Environmental Protection Area (Anonymous, 2015). Lake has been heavily influenced by human actions ranging from agricultural and domestic to semi-industrial pollution sources. The lake under the pression of anthropogenic pollution due to the external phosphorus load resulting from detergents in waste water effluents and fertilizers in agricultural run-off from nearby areas (Fakıoğlu and Pulatsü, 2005; Topçu and Pulatsü, 2017).

Analysis

In this study, samples were taken once a month from Lake Mogan between January and November 2013. Samples of water and epiphytic diatoms were taken at five stations chosen in the littoral region of the lake (stations 1, 2, 3, 4 and 5), and other water samples were taken at two stations in the pelagial region (stations 7 selected at the deepest point of the lake and station 6 close to the entry) in order to determine the concentration of chlorophyll *a* (*Figure 1*). In December, samples could not be taken because the lake was frozen.

Two independent parallel water samples were collected from below the lake surface with a 2 l Ruttner water sampler. At each station in the littoral region, five reeds (*Phragmites australis* (Cavanilles) Trinius *et* Steudel) were collected, and 20-cm sections were taken from below the water surface (King et al., 2006). The sections of reeds were placed in a container and agitated with 70% ethanol to separate the epiphytic algae from the plants and to bring them to a homogeneous state (TS EN 15708, 2010). The diatoms were treated with H_2O_2 to remove organic material, and triplicate stable preparations were made using Naphrax (CEN, 2004).

Identification of the diatoms was performed by measuring them with an imaging system using a Leica DFC295 camera and the LAS vs 4.8 program, and referring to the relevant taxonomic literature (Krammer and Lange-Bertalot, 1985, 1986, 1988, 1991a, 1991b; Cox, 1996; Lange-Bertalot, 2013). Also, all of the taxonomic data was updated in accordance with algae databases (Guiry and Guiry, 2018). Triplicate preparats were counted for each station. At least 400 cells were counted in each preparat, and SLA, DESCY, IDSE, SHE, TDI, CEE, IPS, IBD, IDAP, EPI-D, DI-CH, IDP, SID, TID, WAT, %PT, IDG, LOBO and TDIL diatom indices were calculated using the OMNIDIA vs 6.06 package (Lecointe et al., 1993). Most of the indices are modified from the weighted average equation of Zelinka and Marvan's index (Bellinger and Sigee, 2010). In addition, ecological characteristics were determined according to Denys (1991), Håkansson (1993), Hofmann (1994) and Van Dam et al., (1994). In the chlorophyll *a* analysis, spectrophotometric method was used. Dublicate water samples of 500 ml taken from below the surface at two stations were filtered with Whatman GF/C filter paper and extracted with acetone, after which the optical density of the extract was read on a spectrophotometer (Shimadzu UV 1240) at wavelengths of 630, 645 and 665 nm (Strickland and Parsons, 1972; APHA, 1998).

Measurements were made at the stations of Secchi depth using a 20 cm diameter Secchi disc, of dissolved oxygen, pH and electrical conductivity, using a YSI ProPlus Multiparameter. Total phosphorus, total nitrogen and silica were analyzed by standard methods (APHA, 1998).

Statistical analyses

The monthly and station-to-station variations in water temperature, Secchi depth, dissolved oxygen, pH, electrical conductivity, total phosphorus, total nitrogen and silicate values in Lake Mogan were analysed using a one-way variance analysis (ANOVA). In addition, the correlations between diatom indices and physico-chemical parameters were examined with Spearman correlation analysis using SPSS vs17 package. All statistical calculations and checks were conducted according to Kesici and Kocabaş (2007).

Results

The monthly variations in water temperature, Secchi depth, dissolved oxygen, pH, EC, total nitrogen and silicate in the lake were found to be significant ($p<0.05$), but the variations in these parameters between stations were found not to have statistical significance. An evaluation was made according to the average of the results of the monthly measurements in the lake and according to the Surface Water Quality Directive and trophic status criteria (Anonymous, 2016) (*Table 1*).

In the samples taken from Lake Mogan, 58 species from the class Bacillariophyceae were identified, two species from Coscinodiscophyceae, and one from Mediophyceae, totaling 61 species. The composition of the species of diatoms in the lake is given in *Table 2*.

It was found that *Achnanthidium minutissimum, Navicula cryptonella, Ulnaria acus, Encyonopsis microcephala, Rhopalodia gibba* and *Nitzschia dissipata* were dominant in the epiphytic diatom community of the lake. When percentage distribution of the epiphytic diatom species was considered, it was found that *A. minutissimum* was predominant with an average of 17%, followed by *N. cryptonella* with 8.5% and *U. acus* with 7.3% (*Table 2*).

Table 2. *Composition of epiphytic diatom species in the research period in Lake Mogan*

Species	**Composition %**
Achnanthidium minutissimum (Kützing) Czarnecki	17.00

Table 3 shows the ecological evaluation of the diatom community in Lake Mogan. The diatom community in the lake was classified by its pH as alkaliphilic. Oxygen requirement was found to be high. There was a slight salinity, and in terms of nitrogen uptake, autotrophic nitrogen tolerance was found. The saprobity level was estimated as β-mesosaprobic and α-β mesosaprobic. The trophic condition was found to be eutrophic, as having numerous eutrophication-tolerant species (*Table 3*).

Results were made of the variations by station of diatom indices in Lake Mogan (*Table 4*). In calculation of diatom indices, 100% of the species identified were used for IDG, 97-100% for IPS, 88-96% for EPI-D, 81-89% for IBD, 76-85% for TDI, 64-67 % for TDIL, 74-85% for TID, 70-83% for CEE, 63-73% for SID, 61-73% for IDSE, 60-73% for SLA, 58-70% for SHE, 53-67% for DI-CH, 44-57% for IDP, 38-50% for DESCY, 35-51% for LOBO, 27-43% for IDAP, and 20-33% for WAT.

Table 4. *The variation of diatom indices according to stations in Lake Mogan*

Station	**DESCY 1-5**	**WAT 0-100**	**TDI 0-100**	**IDG 1-5**	**IPS 1-5**	**IDP 0-4**	**IDP**
1	3.84	68.74	52.56	3.73	3.61	1.63	III
2	3.87	71.72	48.50	3.80	3.66	1.52	III
3	3.96	66.85	52.5	3.68	3.42	1.68	III
4	3.66	69.07	48.15	3.74	3.57	1.67	III
5	3.74	68.74	52.34	3.72	3.56	1.67	III

The correlation between diatom indices and the physical and chemical parameters measured in the lake was examined, and it was found that most of the diatom indices were correlated with the physical and chemical parameters (*Table 5*).

Discussion

In this study on Lake Mogan, the ecological quality of the lake was estimated in relation to epiphytic diatoms and various parameters of water quality. Considering the composition of species identified in the study, it was found that most were alkaliphilic species with high oxygen requirements according to Håkansson (1993) and Van Dam et al. (1994). This is supported by the pH and oxygen values of the lake. The saprobity level was estimated as β-mesosaprobic according to Van Dam et al. (1994), and α-β mesosaprobic according to Hofmann (1994). In addition, it was found to contain fresh and saltwater species which prefer water rich in electrolytes. Most species were found in β-mesosaprobic and α-mesosaprobic environments in terms of organic pollution, and in terms of trophic level, most species were eutrophic and organic pollution tolerant. The trophic condition was found to be eutrophic according to Van Dam et al. (1994), and according to Hofmann (1994) as having numerous eutrophication-tolerant species.

The mean IBD, EPI-D, DI-CH, SID, CEE, IDAP and IDSE indices calculated according to the epiphytic diatoms identified in the lake indicated that the water quality of the lake was in class II, and the mean TID index showed a water quality of class II-III. Lake Mogan showed class III (α-mesosaprobic) water quality according to WAT index. Values of 3 and 4 according to DESCY index and of 1.5 and 2.0 according to IDP index indicated medium nutrient-rich waters (Descy, 1979; Gómez and Licursi, 2001). Averages of 3.81 for DESCY index and 1.63 for IDP index were estimated. IDG, IPS, IDP, WAT, DESCY and TDI indices calculated according to epiphytic diatoms indicated class III water quality. According to these values, Lake Mogan is in class III of water quality (critic level pollution and eutrophication). TDIL, developed with the investigation of epiphytic diatoms on *P. australis* in shallow lakes in Hungary, was applied in Lake Mogan, and the proportion of the species used in the index was found to be 64-67%. The indices used in different countries have been developed for water sources in different typologies. It was determined that the greatest number of species was used by IDG. This is because in this index, taxonomy is at the genus level, and this greatly eases its application to many bodies of water. According to chlorophyll *a* and total phosphorus concentration, Lake Mogan is eutrophic. The occurrence of eutrophic and pollution-tolerant species and ecological quality varying from medium to poor on most indices indicated an increase in organic material and eutrophication in Lake Mogan.

According to SLA and SHE indices, Lake Mogan showed class I water quality, while according to the average LOBO index, the lake showed class V water quality. The results of SLA, SHE and LOBO index were not in accordance with water quality parameters and other diatom indices. Therefore, SLA, SHE and LOBO indices are not suitable for use in future water quality monitoring studies in Lake Mogan.

According to the results obtained in this study, it could be said that IDG, IPS, IDP, DESCY, WAT and TDI indices reflected water quality of lake. Various researchers have shown that diatom indices calculated with diatom compositions found in the littoral regions of lakes can be used to reflect their trophic conditions. Blanco et al. (2004) monitored the water quality of six lakes in Spain, and reported that there was a significant correlation between the total nitrogen concentration and IBD and IPS indices, and that this correlation was lower than with phosphorus concentration. Acs et al. (2005) calculated IBD, IPS and IDG indices in monitoring the water quality of Lake Velence in Hungary, and concluded that IBD index could be the most suitable. Lirika et al. (2013) used Trophic Diatom Index (TI_{DIA}) and Saprobic Index (SI) to determine the

© 2018, ALÖKI Kft., Budapest, Hungary

water quality of Lake Ohrid. Kavya and Ulavi (2014) used Louis Leclercq IDSE index in Lakes Karanji and Kukkarahalli in India. Blanco et al. (2004) found IPS suitable in six lakes in Spain, Acs et al. (2005) found IPS and IDG suitable in Lake Velence. In Turkey, Tokatlı (2013) used TDI index in calculating the water quality of Porsuk Reservoir, and reported that the water quality of the lake was mesotrophic.

A significant correlation was found in this study between total phosphorus and total nitrogen concentrations and WAT index. In studies conducted in Turkey on epilithic diatoms in running water, Solak et al. (2007) reported that in Muğla-Akçay (Great Meander river) SLA, DESCY, IDP**,** LMA, WAT, CEE and IDAP indices showed high correlation with chemical variables. Solak (2009), working on Felent river in Kütahya, and Akbulut et al., (2010) on Kızılırmak river, found that IDAP, WAT, CEE and IPS indices had the highest correlations with physical and chemical parameters. Kıvrak et al., (2012) calculated EPI-D, SID, TDI and IDP indices in Akarçay river in Afyonkarahisar, and reported that these four indices, used in Akarçay and sensitive to organic pollution, could be successfully used in evaluating water quality in running waters in Turkey. Gün (2011), used SLA, DESCY, IDSE, SHE, TDI, GENRE, IPS, IBD, EPI-D, DI-CH, IDP, SID and TID indices in the Değirmendere river. It was concluded that the indices which showed the most deviation from physical and chemical parameters were TDI and DESCY. Tokatlı (2012) reported the water quality of the Upper Basin of the Gürleyik river as meso-eutrophic according to TDI index, and as mesotrophic according to IBD index.

In Turkey, apart from a study by Tokatlı (2013) to determine the water quality of Porsuk Reservoir using Trophic Diatom Index (TDI), no study was found monitoring the water quality of a lake using diatom indices. As a result, IDG and IPS are the most suitable for use in future studies of Lake Mogan. IDG, IPS, IDP, DESCY, WAT and TDI indices reflected water quality of lake but IDG and IPS also integrated all diatom taxa within the samples.

Conclusion

In conclusion, epiphytic diatoms can be used to monitor ecological quality in shallow lakes such as Lake Mogan, which are rich in aquatic macrophytes and surrounded by reed belts. Lake Mogan is an important example of a shallow lake which is under threat from pollution even though it has a protected status. Biological monitoring studies must continue concerning the sustainable use of the lake, and steps must be taken to prevent its pollution. It is predicted that the research conducted will contribute to the pool of knowledge for the protection and restoration of the lake.

(Received 22nd Mar 2018; accepted 25th May 2018)

Abstract. The challenges accompanying socio-ecological and demographic transformations in the urban areas necessitate for coordinated efforts to ensure urban ecological resilience. Trans-disciplinary analytical construct of urban ecosystem services (UES) empowers the policy makers and urban planners to synchronize the orientations of human impacts and resilience of ecological resources in urban areas. The current study provides a systematic overview about the research orientations, approaches and techniques used in the recent studies regarding UES. The study examined: what types of evaluation methods were adopted in the recent UES research? What is their spatial and temporal pattern? What types of UES were focused and environmental components relied upon for the assessment? To address these questions, 116 relevant publications were scrutinized by using a set of assessment criteria. The findings indicated a lesser focus in research towards UES in developing countries as compared to the volume and increasing share of their urban population. The study also establishes that an overwhelming proportion of the UES research was carried out in the industrialized countries of the northern hemisphere but rather skewed towards studying regulatory ecosystem services. The recommendations for improving the relevancy of contemporary research for stakeholders were made.
Keywords: *urban ecosystem services, ecosystem disservices, urbanization, socio-ecological systems, urban environment, resilience, urban ecology*

Introduction

The contributions of natural resources to social and economic systems are referred to as ecosystem services (ES) defined as the benefits humans draw from the functioning and processes of ecological systems (Costanza et al., 1997; Daily et al., 1997; De Groot et al., 2002). It is acknowledged that the life on the planet Earth is a product of and

DOI: http://dx.doi.org/10.15666/aeer/1603_35453581
© 2018, ALÖKI Kft., Budapest, Hungary

dependent upon the constant support and productivity of ecosystems and services arising thereby (De Groot et al., 2002). These benefits from the ecological resources are classified into four major groups or categories i.e. regulatory, cultural, provisioning and supporting services (De Groot et al., 2002; Millennium Ecosystem Assessment, 2005a).

The birth of new urban settlements and/or the increase in the size of existing urban centers at the cost of non-urban land usages pose(s) new social and environmental challenges (Haase et al., 2014b). The increase in the proportion of global urban population (Heilig, 2012; Haase et al., 2014b), transformations in the urban based economic activities and concomitant life style changes in the urban centers have their visible impacts on the natural environment. The conjectured estimations suggest that the process of urbanization will accelerate in the future (Cohen, 2004; United-Nations, 2014; Graça et al., 2017). The promising technological advancements are sometimes misconstrued as a replacement for the natural ecosystems of urban areas. These advancements can supplement the contributions of natural ecological systems in an urban area but are incapable of substituting their role (Honey-Rosés et al., 2014).

The term "ecosystem services", initially appeared in Ehrlich and Ehrlich's work in 1981 (Liu et al., 2010; Chaudhary et al., 2015) while highlighting the contribution of ecological systems for human life. Now the term ES is frequently used for assessing the material contribution of natural resources in human wellbeing. The concept provides a common vocabulary for evaluating tripartite linkages between ecological, social and economic systems to ensure their integrated management. The concept of ES has proven useful, firstly, to synthesize the efforts for linking human and ecological systems for coherence and sustainability (Costanza and Daly, 1987; Daily et al., 2009). Secondly, scientists and policy makers rely on the concept while evaluating economic and political tradeoffs between landscape development and conservation alternatives (De Groot et al., 2010; Mcshane et al., 2011; Bürgi et al., 2015).

The analytical construct of Urban Ecosystem Services (UES) is relied upon for the assessment, management and conservation of the urban ecological resources and their correlation with human life. The paradigm of UES seems to be a more pragmatic strategy to ensure that the impacts of urbanization, climate change and socio-ecological transformations on the urban environment are addressed.

The first studies on UES date back to the mid-1990s (Cairns Jr and Palmer, 1995) but the interest in this sphere had spread worldwide by the end of the last century (Bolund and Hunhammar, 1999). The researchers such as Alavipanah et al. (2017), supported the previous findings of (Gómez-Baggethun et al., 2010; Kronenberg and Hubacek, 2013; Haase et al., 2014b) that less than 10% of ES research in scientific publications was investigated in urban areas and also depicted a decline in the publication concerning UES after 2015.

It transpires from scholarly efforts that the demands for UES are mounting but paradoxically the efforts are less focused to address the challenges associated with the urban environment (Millennium Ecosystem Assessment, 2005b; Haase et al., 2014b). The situation demands a systematic review of UES studies based upon an innovative framework for postulating pragmatic measures to improve the orientations, trends and techniques in research regarding UES.

Keeping in view these expectations, the current study was designed to decipher various dimensions of UES research in recent years. In this connection, the present review was carried out on the basis of selected research publications to analyze: 1) The current spatial-temporal trends in UES research 2) To weigh research orientations,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

approaches, and techniques adopted in the recent studies 3) to evaluate the components of urban environment used for assessments in the reviewed publications. The outcomes of the current study will provide insights and innovative options for integrating efforts to ensure the sustainable provision of UES.

Material and method

The current review is a meta-analysis and is based upon the bibliographic information obtained from ISI web of Knowledge (www.webofknowledge.com). The study considered the articles published in English during the period (May 2007 - May 2017) against the search term "urban ecosystem services'. The search returned a total of 127 records. Out of these, only those records were considered for further scrutiny, where, the search term UES was included in either the Title, Abstract or Keywords of a publication. On these criteria, 116 records were identified for further processing and content analysis (*Appendix-1*).

The content analysis of selected papers, based upon a list of assessment criteria with the predetermined choices (*Table 1*), was carried out to determine the current orientations of or in the UES studies, techniques and measures (monetary/non-monetary) relied upon in the research for assessments and inferences. The information pertaining to environmental components used for evaluating UES was also extracted from the reviewed publications. A component was only included in this study, provided, it was used as a parameter for assessment to publish the article. The components with different appellations, used to assess analogous goals (such as Hedonic Pricing or Property Value; carbon absorption or storage etc.) amalgamated into a single category for brevity and analysis. In this way 10 classes were formulated to interpret trends to select component(s) for assessing UES. The quantitative findings of this analysis were cartographically displayed in *Figures 1-7* for estimations and inferences.

Table 1. *Selection and assessment criteria adopted for the review of selected research publicatons*

Criterion (question)	**Possible entries**
Which type(s) of ES were analysed?	i. Regulating Services ii. Provisioning Services iii. Cultural Services iv. Supporting Services v. Cumulative Assessment of ES vi. Ecosystem Disservices
From which country (city) empirical data/ contextual information were obtained? If required for assessments.	The name of country/city in which the site/situation of study is located.
What is the location of Principal/corresponding author of the study?	The location of author

© 2018, ALÖKI Kft., Budapest, Hungary

What kinds of evaluation methods/indicators were relied upon for assessments in these studies?	i. Monetary ii. Non-Monetary iii. Both (Monetary and Non-Monetary) iv. Not Applicable
What was the principal objective of the study?	The objectives of these publications were grouped into eight categories on the basis of homogeneity in focus: i. Planning and Management ii. Assessment study iii. Governance and Policy iv. Assessment of Method v. Climate Adaption vi. Landuse Planning vii. Urban Ecology viii. Environmental Justice
Which specific component(S) of urban environment was/ were assessed?	The name of component(s) assessed in a publication: i. Aesthetics ii. Biodiversity iii. Carbon Sequestration/Storage iv. Climate Regulation v. Energy vi. Food Fuel vii. Hedonic Pricing viii. Others ix. Socioecological x. Water Management
What type of enquiry technique was used in the study?	i. Assessment (technique)study ii. Experimental (technique)study iii. Exploratory (technique) method iv. Conceptual Framework
What was the principal consideration of the study?	The content analysis revealed that reviewed studies were inherently designed to address the impacts of the following challenge (s): i. urbanization, ii. climate change iii. Loss of urban biodiversity

Results

Spatio-temporal trends

The temporal analysis of these publications in *Figure 1* reflected an upward trend to use the term UES in title, abstract or keywords in the initial years of the selected timeframe. However, a decline in tendency to use the term UES in publications was noticed in the last two years of the selected period.

The *Figure 2* illustrates that a leading share of UES research was carried out in European (62.71%) and North American (23.73%) contextual surroundings. The contributions in UES research from other continents were found disproportionately less as compared to the proportion of people residing in the urban areas of these continents (*Figure 2*).

The spatial analysis of these selected publications revealed (*Figure 3*) that a predominant proportion of UES research (99%) was carried out in the contextual settings of the northern hemisphere while the share from the southern hemisphere was found to be the less than (1%).The significant intra-continental inequalities in the publications regarding UES were also observed (*Figure 3*). In this connection, the

contributions from Germany (20) are significantly higher than those from other European countries; China (4) is at the forefront from Asia while the USA (24) is the leading country in North America. The city of Berlin (Germany) was most frequently assessed in (9) studies from different perspectives of UES and followed by New York (USA) in (7) and Stockholm (Sweden) in (6) studies (*Appendix-2*).

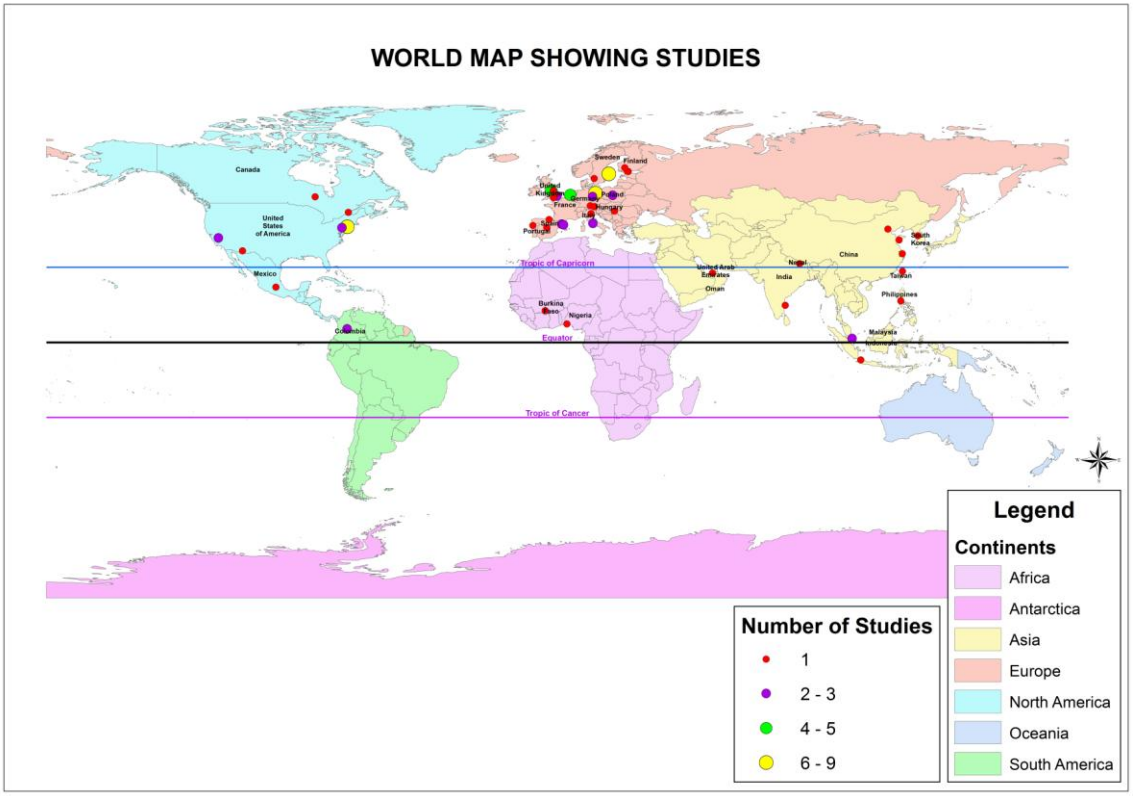

Figure 3. *World map showing locations and the numbers of UES studies*

The use of term UES in the title, abstract or keyword of a publication provides a measure to assess how much importance is given in research on highlighting the contributions of green infrastructure in urban social life. The *Figure 4* explicitly describes the frequency with which the term UES was used in the title, abstract and keywords of reviewed publications. The term urban ecosystem services was most frequently used in the abstracts (70), followed by keywords (56) and titles of (41) the reviewed publications.

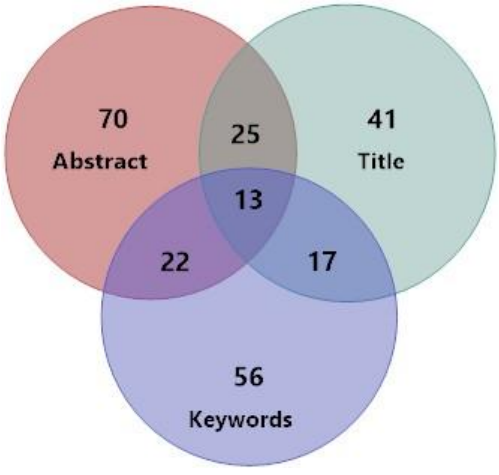

Figure 4. *Showing the use of the term UES in abstract, title and keywords*

Types of UES and research trends

The intertwined and overlapping nature of contributions from UES makes it more intricate to catalogue a study into a specific category of services. As a pragmatic measure to overcome the problem, a specific study was simultaneously catalogued into different categories of ecosystem services provided these services were tested/evaluated in the publication. In the majority of publications, the focus of research was observed on the cumulative assessment of UES. It was followed by the deliberations on Regulatory services, cultural services and provisioning services. While the supporting services were assessed the least. However, urban ecosystem disservices (UESD) were also focused in (13) publications (*Figure 5*).

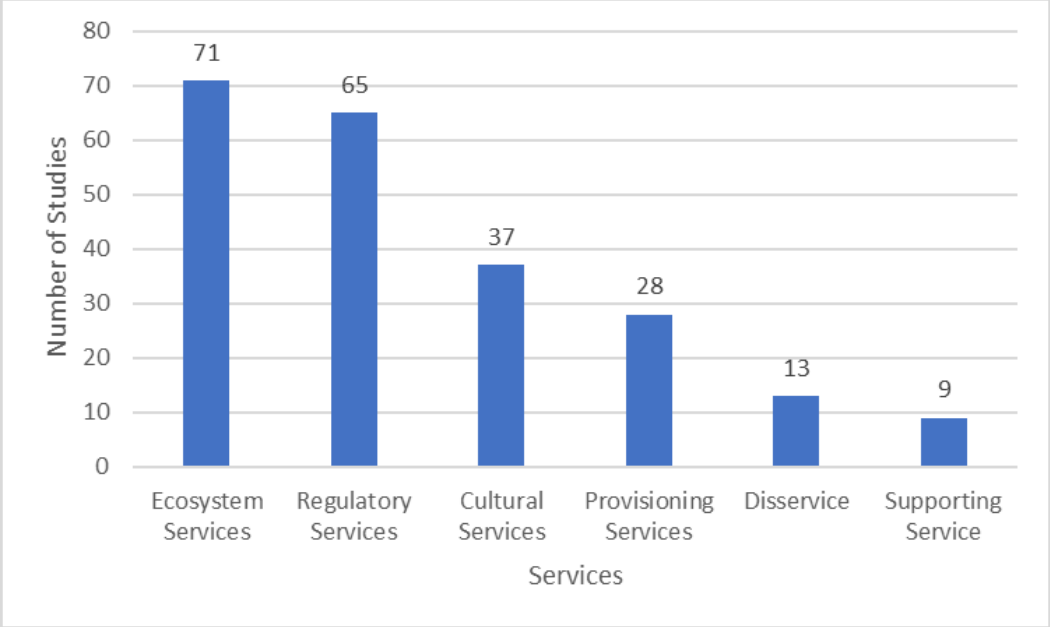

Figure 5. *Graph showing number of studies designed to focus the types of ecosystem services and disservices*

Study paradigms and UES

The impacts of urbanization, ecological degradations in urban areas and threats from global climatic changes are the potential stressors for UES. The content analysis of selected publications was carried out for assessing how much emphasis is being given to these stressors in UES studies. The findings in *Figure 6* revealed an intersecting nature of research inclinations. It also enumerates the number of studies designed to scrutinize the role of these stressors on the resilience of UES.

The trends in UES assessments

The findings of content analysis have been condensed in *Figure 7* to illustrate the numbers and proportion of studies focusing on a particular type of ES: nature of methods/indicators opted for evaluation, types of techniques relied upon for investigations, research or study objective(s) in contemporary research and selection of environmental component(S) for measurements (*Appendix-3*). These findings are indispensable for interpreting contemporary trends in UES studies.

Discussion

Trends and techniques used in UES evaluation

The contingent valuation techniques proposed by Ciriacy-Wantrup in 1947, laid the foundations of Ecosystem Valuation (ESV) in modern times (Ciriacy-Wantrup, 1947; Spash, 2011; Mitchell and Carson, 2013) and a subsequent fervor for environmentalism in the 1960s, providing the much needed impetus to ESV (Liu et al., 2010; Salzman, 2011).

The findings in *Figure 5* indicated that Regulatory services (RS) are more in focus of the contemporary UES research compared to the other three types of ES or ESDS. It is followed by the focus of researchers on studying cultural services (CS) and Provisioning services (PS). In this connection, supporting services (SS) were observed as a lesser priority area of investigation. These dissimilarities in focus towards different types of UES are due to the nature of urban economic activities and socio-cultural life style of urban areas. Besides this, a recent surge in reported incidents of "urban heat island effect" and exacerbating climatic and environmental settings of urban areas are other plausible explanations for this skewedness in favor of RS and CS. Whereas, it is pertinent to mention that the societal acknowledgement of ecological resources meaningfully enhanced by the tangible contribution of PS. Besides this, the resilience of an ecological system is significantly determined by the performance of SS. Therefore more focus in UES research is required on assessing the contribution/role of SS and PS for ensuring sustainable provisions of UES in the face of mounting challenges to urban environment.

A marked emphasis in the majority of the reviewed publications (*Figure 6*) was observed on either 1) to measure the socio-ecological impacts of urbanization and concomitant behavioral changes on provision of UES for informed decision making 2) to assess the potentials of urban ecology for ensuring human wellbeing and urban environmental resilience or 3) to decipher the consequences of global warming and climate change on the supply of UES and socio-ecological sustainability of the urban areas. These propensities in research reflect the growing consciousness for ensuring urban ecological resilience in the face of imminent social, psychological, climatic and environmental vulnerabilities of urban areas.

The assessment or evaluations of an urban phenomenon, situation, policy or problem appeared a preferred technique of enquiry (49.14%) in the recent research (*Figure 7*). This analytical approach was adopted from different perspectives such as assessing the validity of a technological innovation/method (Lakes and Kim, 2012; La Rosa and Wiesmann, 2013; Schreyer and Lakes, 2016; Tigges et al., 2017), the effectiveness of a policy or planning instrument (Kaczorowska et al., 2016; Larondelle et al., 2016), or to estimate the impacts of socio-cultural factors on urban environment in studies (Kremer et al., 2013; Buchel and Frantzeskaki, 2015; Escobedo et al., 2015; Sutton and Anderson, 2016). As compared to this, the Experimental mode of enquiry was observed in a few studies (11.21%) for estimating the potentials of green infrastructure in the given urban context (Taylor et al., 2014; Cameron et al., 2015; Coma et al., 2017) and for assessing sthe role of building material (Capener and Sikander, 2015) in regulating the climate of urban areas. Experimentations with the help of Remote Sensing (RS) and Geographic Information System (GIS) were also made in studies (Tigges et al., 2013; Schreyer and Lakes, 2014) to evaluate their effectiveness for integrated planning of urban ecological resources. The experimentations with new options and opportunities

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_35453581
© 2018, ALÖKI Kft., Budapest, Hungary

are incumbent but resource dependent (financial and technological resources) however, the use of GIS and RS is gaining acceptance among the research communities (Kolanuvada et al., 2016) in the developing countries and in the less developed regions (Thapa, 2012) as well. These findings corroborate the notions that application and acknowledgement of RS and GIS as a research tool for integrated urban environmental managements will increase in the future.

The exploratory style of investigation was observed in (22.41%) studies. The method was specifically adopted in studies to understand patterns of urban land use changes (Haase et al., 2014a; Kain et al., 2016) or to explore nature based solution for the resilience of urban environment (Pataki et al., 2011; Kuittinen et al., 2016; Santiago Fink, 2016). This technique of investigation was also observed in the reviwed publications such as (Ernstson et al., 2008; Connolly et al., 2014; Kronenberg, 2015; Dennis and James, 2016b). These studies were designed to improve the environmental governance and management of urban areas.

The (17.24%) studies based their conclusions on conceptual discourses for postulating measures to ensure the resilience of urban ecosystems. This sort of orientation in UES research was specifically observed in the studies which were conceived to address the challenges of land use changes (Stott et al., 2015; Kain et al., 2016) and socio-cultural transformations in urban areas (Ernstson et al., 2010; Andersson et al., 2014). The researchers also contributed their scholarships through conceptual framework in the studies (Rozos et al., 2013; Wu, 2014; Mcphearson et al., 2015; Haas and Ban, 2017) to improve the precision and practicability of research regarding UES.

Monetary vs. non-monetary parameters for evaluating UES

The publications were assessed to study prevailing inclinations in UES research regarding the use of monetary and/or non-monetary parameters.

The monetary assessments of cost and benefits linked with UES are vital for informed decision making (Aevermann and Schmude, 2015). After the publication of The Economics of Ecosystems and Biodiversity (TEEB) in 2011 the use of monetary parameters in ES research are gaining more recognition. The use of monetary parameters for corroborating findings was found limited (3.45%) and restricted to the assessment mode of investigation. These findings are in line with the assertions of Sutton and Anderson (2016) that the monetary valuations of UES are more intricate and complex as compared to non-monetary valuations of ES. The overlapping nature of the benefits from UES: contestations over classification between benefits and/or services, controversies over methodology used for data acquisition and differences over spatial-temporal scale used for study are the conceivable explanations for less reliance on monetary parameters in the research concerning UES. However, the findings in monetary terms are readily and unambiguously understood in the present age of market economy and, thus, offer an effective technique for disseminating awareness about the contributions of ecological resources. Therefore, further investigations are needed to address the methodological/operational ambiguities responsible for discouraging the use of monetary parameters in UES research.

However, the majority of studies (66.38%), irrespective of their study design or orientation, preferred non-monetary parameters for evaluations of benefits arising from the ecological infrastructure of urban areas (Alam et al., 2016; Dennis and James, 2016b; Grafius et al., 2016; Kain et al., 2016; Kolanuvada et al., 2016; Kuittinen et al.,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_35453581
© 2018, ALÖKI Kft., Budapest, Hungary

2016). As compared to this a substantial proportion of (18.97%) publications based their conclusions on the cumulative outcomes of monetary and non-monetary parameters (Elmqvist et al., 2015; Kiss et al., 2015; Langemeyer et al., 2015; Czembrowski et al., 2016). The added focus towards the cumulative assessments of UES is needed for holistic appraisal regarding the contributions of natural capital. The outcomes of such a research will ensure more support from social institutions and scientific communities for integrated ecological management of urban areas. Whereas, a number of publications (11.21%) extended their assertions through scholastic discourses or conceptual understandings rather than relying on either monetary or non-monetary measurements such as (Wu, 2014; Frantzeskaki and Kabisch, 2016; Corburn, 2017). These orientations, in the contemporary research, are indispensable for postulating out of the box strategies for uninterrupted supply of UES in the face of accelerating urbanization, ecological degradation and looming threats from climate change.

Study components and UES evaluation

The environmental component(s), relied upon for assessments in UES studies also reflect the inclinations of contemporary research. The findings in *Figure 7* indicate the proportion of studies which focused on a particular component of urban environment for assessment.

The anthropocentric orientations in UES research are stressed (Alberti et al., 2003; Graça et al., 2017) for integrated urban environmental management. In line with these demands a substantial number of studies (n=69) relied on the cumulative outcomes of socio-ecological parameters for drawing inferences and estimations regarding UES from diversified contextual settings such as (Ernstson et al., 2008; Buchel and Frantzeskaki, 2015; Escobedo et al., 2015; Vollmer et al., 2015; Graça et al., 2017).

It was followed by the selection of components related to urban biodiversity (n=64). The assessments about different forms of urban green infrastructures such as street trees (Kiss et al., 2015; Mcpherson et al., 2016), urban forests (Baró et al., 2014; Fusaro et al., 2015), parks (Sutton and Anderson, 2016) and impacts of urban vegetative diversity (Wang et al., 2015; Calderón-Contreras and Quiroz-Rosas, 2017) were made for different purposes ranging from the assessments of services and disservices of urban ecological infrastructure to urban planning.

A significant number of studies (n=57) in the 3rd category based their findings on atmospheric components of the urban environment. The measurements and quantifications of atmospheric temperature (Taylor et al., 2014; Di Leo et al., 2016) humidity (Capener and Sikander, 2015) and gaseous components (Manes et al., 2012) were made in these studies from various aspects while evaluating their impacts on the urban environment. The acquisition of accurate, cost effective and time efficient data related to atmospheric components at different spatial scale have become possible and easier due to advancements in the atmospheric and remote sciences (Larondelle and Lauf, 2016). In this connection a growing reliance on remotely sensed data for evaluating different components of urban climate was also observed.

The component of water was analyzed in the 4th category (n=42) from diversified perspectives for efficient use and management of urban blue infrastructure. The dominant orientations in the urban water studies were found towards accurate measurement of urban water resources (Larondelle and Lauf, 2016), to illustrate the importance of the rivers for urban residents (Vollmer et al., 2015; Weber and Ringold, 2015) and to postulate measures to ensure the efficient use of available water (Mccarthy

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_35453581
© 2018, ALÖKI Kft., Budapest, Hungary

et al., 2011). A growing interest to evaluate the impacts and complementing ability of technological innovations on urban water supply was also observed in studies (Rozos et al., 2013; Honey-Rosés et al., 2014). The components relied upon for assessment of cultural/aesthetic services such as the availability, role and importance of parks and urban green spaces were adjudged in the 5th category (n=42).

Urban climatic anomalies such as the urban heat island effect, smog, haze and resultant global warming are attributed to imbalance in the atmospheric carbon emanating from industrial, vehicular and domestic sources which are mostly located in the urban areas (Rosenfeld et al., 1998; Di Leo et al., 2016). These unwarranted climatic incidents induce researchers to strive for 'green oriented' solutions to control carbon emissions and concentration in the urban areas. In response to these challenges the focus of (n=35) studies in the 6th category was observed for finding plausible solutions to control and mitigate the adverse impacts of carbon concentrations in urban areas (Kuittinen et al., 2016; Tigges et al., 2017).

The assessments were made in (n=18) studies to evaluate the contribution of the urban ecological resources in providing food and fuel to urban residents and to weigh their contributions in managing the energy requirements of the urban areas in (n=14) studies. The market price of dwellings was also used as a proxy variable in (n=9) studies to assess the interrelationship between urban environments and worth of the property.

Besides these, a large number of other components (n=100) of urban environments from diversified settings were also used as parameters to evaluate the role and significance of UES for the urban areas.

Focus of research in UES

The studies in this review were designed to achieve multiple and diverse objectives, ranging from resolution of local environmental concerns to philosophical discourses for improved performance and resilience of urban ecological capital. The objectives found in the selected publications reflect the focus of these studies.The objectives set to achieve identical targets by using different linguistic expressions were condensed into eight groups for brevity and analysis (*Table 1*).The findings in *Figure 7* reflect the proportion of studies designed to achieve a specific target.

The sustainable planning and management of UES was observed as the most common objective of (28.45%) publications such as (Kronenberg, 2015; Stott et al., 2015; Vollmer et al., 2015; Alam et al., 2016; Dennis and James, 2016b). A closer scrutiny of the data indicates that such orientations in the research are closely associated with the industrialized nations. The appraisal of governance and policy associations with UES in (17.24%) studies appeared as the next important stream of investigation. The studies such as (Ernstson et al., 2010; Connolly et al., 2013; Connolly et al., 2014; Kronenberg, 2015; Frantzeskaki and Kabisch, 2016) were carried out to decipher the effects of environmental governance and policy framework on their contextual urban environment.

The assessments of context specific phenomena and practices are also stressed in the recent literature (Schreyer and Lakes, 2016) to get insights for optimal utilization and resilience of urban ecological resources. The focus of (20.69%) publications such as (Honey-Rosés et al., 2014; Youngsteadt et al., 2015; Dennis and James, 2016a; Kain et al., 2016) were found to estimate the impacts of contextual occurrences on the provisions of UES.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_35453581
© 2018, ALÖKI Kft., Budapest, Hungary

To test the viability/application of new methods, techniques and approaches in the research are needed and validated in (13.79%) research initiatives regarding UES such as (Lundy and Wade, 2011; Lakes and Kim, 2012; Pincetl, 2012; Tigges et al., 2013). The use of GIS and RS for measuring, evaluating and planning of urban ecological resources is gaining acceptance. The researchers preferred to rely on the data retrieved through RS and GIS for detecting Urban Land use changes (Thapa, 2012; La Rosa and Wiesmann, 2013), estimating carbon storage/ sequestration (Baró et al., 2014; Tigges et al., 2017), assessing water availability (Yao et al., 2015) and for the measurements of urban vegetative cover (Banzhaf and Kollai, 2015; Schreyer and Lakes, 2015; Kolanuvada et al., 2016; Schreyer, 2016; Schreyer and Lakes, 2016). Besides this, a growing trend of computer-aided modelling for better utility and conservation of urban ecological resources was observed in this review (Grêt-Regamey et al., 2013). The scholastic efforts of (Huang et al., 2011; Inostroza, 2014; Martinico et al., 2014) for improvements in methodologies, techniques and approaches for better assessments of potentials and pressures on UES were also observed in this review.

The focus in studies were also observed on postulating measures to mitigate the consequences of creeping global warming for urban areas. The orientations of (8.62%) publications such as (Geneletti and Zardo, 2016) were found towards conjecturing on adaptive measures for the sustainability of urban environmental health, to address the challenges associated with global warming and consequential climate change. The researchers like (Mcwilliam et al., 2014; Estoque and Murayama, 2015; Grafius et al., 2016; Kaczorowska et al., 2016) tried to decipher the imprints of Urban Land use changes (5.17%) on sustainable provision of UES and highlighted the importance of land use planning for urban environmental resilience in their studies. The content analysis also indicated a growing emphasis in UES research on the accurate assessments of urban ecological resources in (3.45%) studies such as (Wu, 2014; Wang et al., 2015).

Besides, these dominant orientations in UES research a growing propensity in recent studies (2.59%) was also noticed in studies such as (Corburn, 2017) to ensure equitable distribution of UES among urban inhabitants under the influence of Environmental Justice debate.

Conclusions

This study is based on a systematic review protocol applied on a set of 116 scientific publications. It provides an overview of the evolving trends and gaps in UES research. The most obvious finding of this overview is that the concept of urban ecosystem services is gaining recognition as a component of informed decision making in urban planning and as a tool to monitor socio-ecological resilience of the urban areas. This review also establishes the fact that the research regarding UES is more focused in the technologically advanced and economically developed countries which have a really significant exposure to urban based industrial activities. The appearance of environmental externalities due to earlier industrialization, pressures from the society for healthy urban environment and availability of resources to fulfill these demands are the plausible explanations for more determined efforts to ensure resilience of UES in these countries. However, the insights of these studies are also immensely important for the regions where the research regarding UES is still in its embryonic stages.

The majority of publications based their appraisals on non-monetary parameters instead of monetary measurements. However, the evaluation of ecological contributions

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_35453581
© 2018, ALÖKI Kft., Budapest, Hungary

in monetary terms increases the acceptability of scientific findings and encourages policy makers/planners to adopt and utilize these findings.

A greater proportion of studies in this review either relied on assessment or an exploratory mode of investigations. These research techniques are frequently used in the social sciences and are comparatively easier, however an inherent element of subjectivity associated with them may compromise the objectivities in findings. As compared to it, a reliance on experimental mode of enquiry in UES will augment the credibility of findings. However, the conceptual style of investigation is imperative for postulating novice approaches for integrated management of UES in the face of emerging challenges for the urban areas.

The outcomes of this study stress on further investigations for devising standard protocols for the monetary measurements of UES. These initiatives should, hopefully, help to overcome the operational and methodological ambiguities for assessments of UES. The future research collaborations between and among nations based upon interdisciplinary research paradigm seems a viable option to achieve this objective. The trans-national research collaborations between the developed world and the less developed regions are also incumbent for postulating comprehensive strategies. These collaborations will also provide the opportunities to retrieve data from the contextual settings of these less investigated regions for conceptual discourses at the global level. Furthermore, these initiatives will directly and indirectly extend the much needed exposure and technical support to researchers investigating UES in these regions.

It is the considered opinion of the authors of this research contribution that the Sustained focus in research on UES is more needed in the less developed regions of the world. In these geographical regions the poor are the worst victims of urban ecological degradation. Thus, sustainable and equitable provisions of UES in these regions is a question of equity and justice debate and a real challenge for the researchers and urban planners to address.

Abstract. Good data analysis is required for the optimal design of water resources projects. However, data are not regularly collected due to material or technical reasons, which results in incomplete-data problems. Available data and data length are of great importance to solve those problems. Various studies have been conducted on missing data treatment. This study used data from the flow observation stations on Yeşilırmak River in Turkey. In the first part of the study, models were generated and compared in order to complete missing data using Artificial Neural Network Fuzzy Inference Systems (ANFIS), multiple regression and Normal Ratio Method. Thus, it is tried to define the usability besides the other model to complete the missing data. Likewise, in the study. It is aimed to define the minimum number of data necessary for the use age of ANFIS. For this purpose in the second part of the study, the minimum number of data required for ANFIS models was determined using the optimum ANFIS model. Of all methods compared in this study, ANFIS models yielded the most accurate results. A 10-year training set was also found to be sufficient as a data set.
Keywords: *Anfis, missing data, multiple regression, normal ratio method, Yeşilırmak*

Introduction

Both the growing population and the rapidly developing industrialization lead to an increased demand for water. The limited availability of resources results in a number of problems in meeting the demand. Exploitation of unused water resources or using existing water resources in an optimum way can be a solution to these problems. Optimal utilization of available water resources, in particular, requires a good analysis of data. Due to the small number of stations in project areas or insufficient data length, some studies have been undertaken to generate new data using existing measurement stations (Aissia et al., 2017). These hydrological studies have mainly focused on precipitation (Sun et al., 2017), evaporation (Güçlü et al., 2017) and river flows (Shiau and Hsu, 2016).

Studies on missing data treatment generally address data correlation (Bakis and Göncü, 2015; Britoa et al., 2017), back-propagation (BP) neural network using Artificial Intelligence (Gao and Wang, 2017), ANFIS models (Dastorani et al., 2010; Mpallas et al., 2010) and models using artificial neural networks (ANN) (Kim and Pachepsky, 2010; Kim et al., 2015). In addition, Fuzzy studies (Coulibaly and Evora, 2007), in which modeling is based on pure expert knowledge, are also important. Some studies on missing data treatment using ANFIS are the completion of missing flow data of the Middle Euphrates basin (Yilmaz and Muttil, 2014), completion of missing precipitation data in Serbia (Petkovic et al., 2016) and Malaysia (Nawaz et al., 2016),

© 2018, ALÖKI Kft., Budapest, Hungary

and completion of missing flow data and modelling of sediment transport of Terengganu River, Malaysia (Ismail and Zin, 2017) and Gediz River, Turkey (Ulke et al., 2009).

This study investigated the monthly data of the stations of Yeşilirmak River in the North of Turkey. In this study, Normal Ratio Method which is frequently used in literature and of which usability is proven and the Regression methods enable to reach the results by the relationship between the data are chosen to be able to compare the accuracy of affered ANFIS model. In the first part of the study, multiple regression tests based on interstation correlations were performed. In the second part of the study, an optimum data completion model was selected using ANFIS. In the last part of the study, the number of data required for a correct prediction was searched and the minimum number of data required for reliable estimates was discussed.

Material and Method

The first part of this section of the study will present information and statistics on Yeşilırmak River and its stations. The second part will provide information on the classical method, multiple regression method and ANFIS used in the study.

Yeşilırmak River and stations

The Yeşilırmak basin, one of the 25 basins in Turkey, is located between latitudes 39° 30' and 41° 21' and longitudes 34° 40' and 39° 48' (*Figure 1*). The basin is named after Yeşılırmak River. The main river channel of the basin is 519 km in length. The main tributaries of Yeşilırmak River are Kelkit, Çekerek, Çorum, Çat and Tersakan streams. Estimated to be about 3,8 million ha, Yeşilırmak basin is the third largest basin in Turkey (Kurunç et al., 2005).

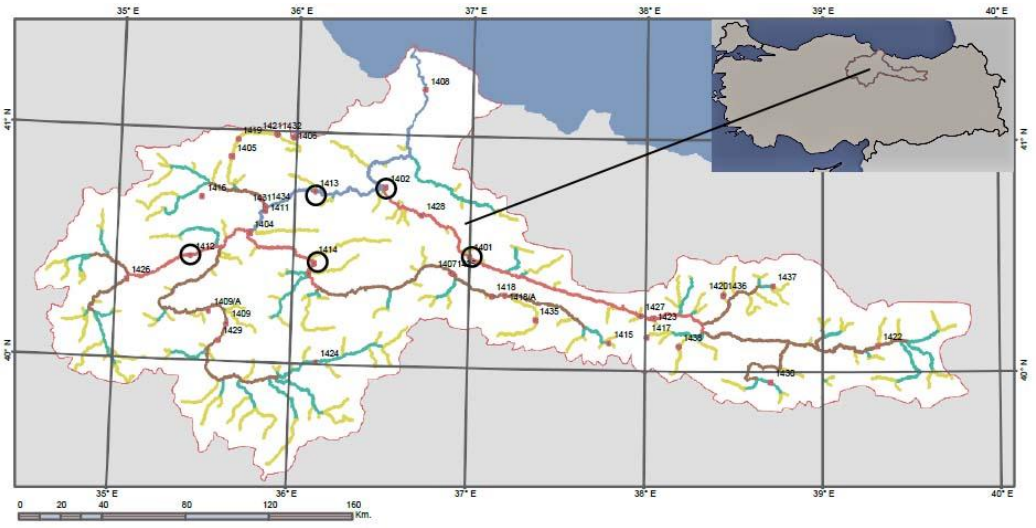

Figure 1. *Site location map of Yeşilırmak Basin*

Stations No 1401, 1402, 1412, 1413 and 1414 of Yeşilırmak River were used in the study. *Table 1* shows the statistics of the stations. *Table 2* summarizes the correlation between the stations.

Methods

Missing data treatment using Normal Ratio Method

In this method, each input data is divided by its annual average value, and these values are multiplied by the average of the station (average of data) whose missing data are to be completed. All input values obtained in the last stage of the calculation are summed, and divided by the number of inputs so that the missing data are completed (Ismail and Zin, 2017).

$$Q_e = (Q_1 * \frac{Q_{e(ort)}}{Q_{1(ort)}} + Q_2 * \frac{Q_{e(ort)}}{Q_{2(ort)}} + \cdots + Q_n * \frac{Q_{e(ort)}}{Q_{n(ort)}})/n \qquad \text{(Eq.1)}$$

where Q is the flow rate and n is the number of input stations.

Multiple regression analysis

Multiple regression analysis is a statistical method for determining the mathematical dimension of the relationship between variables affecting each other. The value to be estimated using the equation formulated based on multiple regression analysis is written in the form of a function of values affecting it (Sun and Trover, 2018).

DOI: http://dx.doi.org/10.15666/aeer/1603_35833594
© 2018, ALÖKI Kft., Budapest, Hungary

$$Y = \beta_1 X_1 + \beta_2 X_2 + \cdots + \beta_k X_k + U \quad \text{(Eq.2)}$$

where Y is the dependent (estimated) variable, X is the independent (explanatory) variable, β is the regression coefficient, k is the number of input parameters and U is the error term.

Multiple linear regression analysis can be used when data are normally distributed, the relationship between independent variables and dependent variable is linear, and error variance for each independent variable is constant (Hair et al., 2009).

ANFIS

Developed by Jang (1993), ANFIS is a modeling method that combines Fuzzy Logic and YSA models. Different from Fuzzy Logic, ANFIS is based on the use of data for the automatic acquisition of rules. ANFIS structure uses artificial neural networks' learning ability and fuzzy logic inference, and therefore, it is more successful than when artificial neural networks model or fuzzy logic is used alone. When input and output values are known, ANFIS determines all possible rules or allows them to be generated using input and output values (*Figure 2*). ANFIS structure consists of five layers: fuzzification layer, rule layer, normalization layer, defuzzification layer and summation layer (*Figure 3*). The first and fourth layers are adaptable (Nayak et al., 2004; Jang, 1993). ANFIS models can be especially used in the conditions if there are lots data and if they are organized.

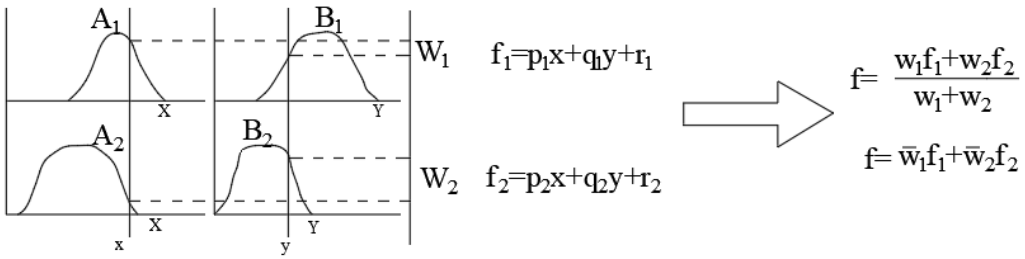

Figure 2. *Fuzzy Inference System*

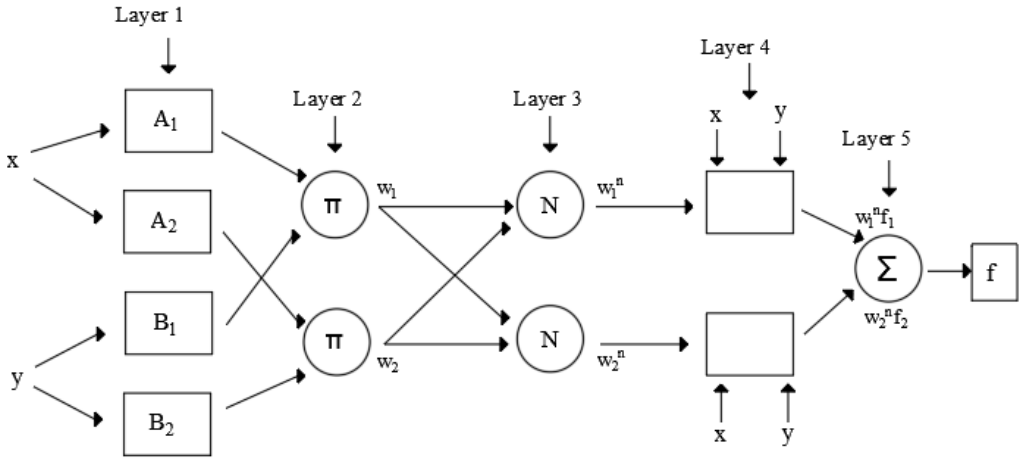

Figure 3. *ANFIS architecture*

Results

Models were developed using Yeşilırmak River data for the estimation of missing data of stations 1402 and 1413. Two-input-one-output models and four-input-one-output models were developed to complete the missing data of station 1402. The two-input-one-output models were used as the output of station 1402. Stations 1413 and 1401 connected to station 1402 on the left- and right-hand sides, respectively, were used to estimate station 1402. In addition to these stations, stations 1412 and 1414 connected to station 1413 on the left-and right-hand sides, respectively, were used to estimate station 1413 in the four-input-one-output models. A two-input-one-output model was developed, and stations 1414 and 1412 were used for the estimation of missing data of station 1413. In the models developed for stations 1402 and 1413, classical and multiple regression models were constructed and compared as well as the ANFIS method. In the last part of the study, the minimum number of data required to reach the correct result using ANFIS models was obtained.

First data set models

The aim of these models was to complete the missing data of station 1402. For this, the data of stations 1413 and 1401 were used. Of 540 data, the first 400 were used for training and the remaining for testing. In addition to ANFIS models generated by changing the number of sets of input parameters, classical method and the multiple regression model were used to compare the results (*Table 3*).

The equation of the classical method is:

$$X_{1402} = (2{,}072 * X_{1401} + 2{,}215 * X_{1413})/2 \quad \text{(Eq.3)}$$

The equation of the multiple regression model is:

$$X_{1402} = 0{,}896 * X_{1401} + 1{,}178 * X_{1413} + 5{,}37 \quad \text{(Eq.4)}$$

Table 3. *Training and testing data results of models developed for the first data set*

Models		Training Data		Testing Data	
		R^2	Mean Squared Error %	R^2	Mean Squared Error %
ANFIS Models	3-3	0.976	11.73	0.977	17.36
	4-4	0.977	11.66	0.978	17.38
	5-5	**0.983**	**10.99**	**0.979**	17.55
	6-6	0.980	11.13	0.978	**16.60**
	7-7	0.979	11.12	0.961	17.00
	8-8	**0.983**	11.09	0.959	17.12
Normal Ratio Method		0,970	11.79	0.955	18.85
Multiple Regression		0,972	13.54	0.960	18.62

The results of this part of the study show that ANFIS models are not superior to the classical and multiple regression models but that all ANFIS models yield better results than the other two methods. The models in which each input has 5 subsets are the optimum models. The speed of the training phase of the model is also noteworthy. The

© 2018, ALÖKI Kft., Budapest, Hungary

comparison of the values obtained from the optimum ANFIS model with the observed values shows that the errors of both the minimum and maximum flow values are very few (*Figure 4*).

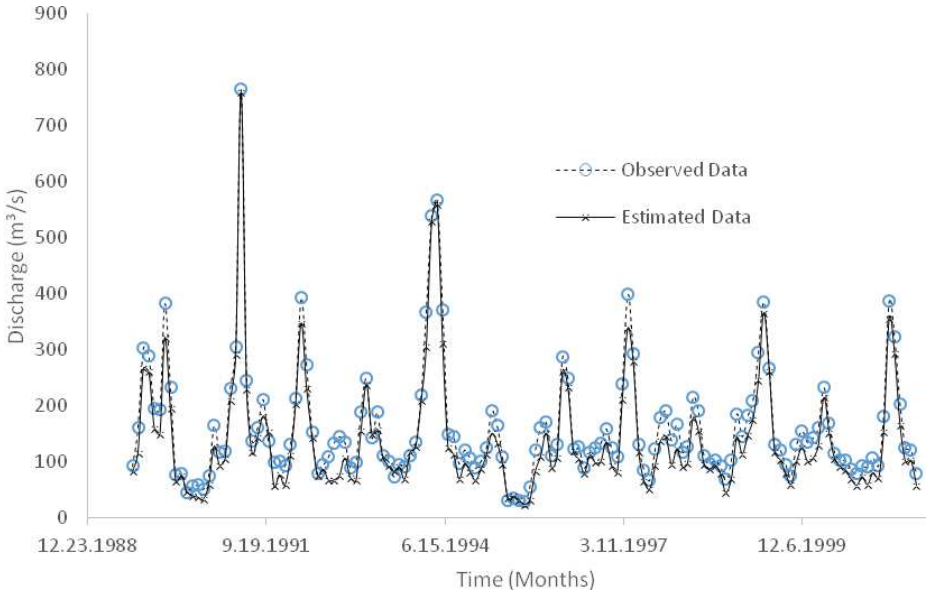

Figure 4. *Comparison of observed data and estimated data of Anfis (5-5) model test data for the first data set*

Second data set models

These models also aimed to complete the missing data of station 1402. To achieve this, the data of stations 1412 and 1414 as well as those of 1413 and 1401 were used. Of 504 data, the first 405 were used for training and the remaining for testing. In addition to ANFIS models generated by changing the number of sets of input parameters, classical method and multiple regression model were used to compare the results (*Table 4*).

The equation of the classical method is:

$$X_{1402} = (2{,}107 * X_{1401} + 19{,}53 * X_{1412} + 2{,}26 * X_{1413} + 5{,}44 * X_{1414})/4 \quad \text{(Eq.5)}$$

The equation of the multiple regression model is:

$$X_{1402} = 0{,}921 * X_{1401} + 1{,}036 * X_{1412} + 1{,}090 * X_{1413} - 0{,}251 * X_{1414} + 11{,}071 \quad \text{(Eq.6)}$$

The results show that ANFIS models provide more accurate results than the classical model and worse results than multiple regression models. The models with 4 inputs are quite slow, especially when the number of subsets of inputs is greater than 5. The models with an increasing number of inputs are much slower than multiple regression models. The comparison of the values of the optimum ANFIS model with the observed values shows that although the largest error is at the minimum flow values, this error is quite small at the maximum flow values (*Figure 5*).

Table 4. *Training and testing data results of models developed for the second data set*

Models		Training Data		Testing Data	
		R^2	Mean Squared Error %	R^2	Mean Squared Error %
ANFIS Models	3-3-3-3	0.933	28.96	0.916	26.92
	4-4-4-4	0.986	11.27	0.919	16.94
	5-5-5-5	**0.991**	10.30	0.918	18.14
	6-6-6-6	**0.991**	**9.85**	0.919	19.09
Normal Ratio Method		0.873	33.79	0.863	28.61
Multiple Regression		0.976	18.26	**0.975**	**16.73**

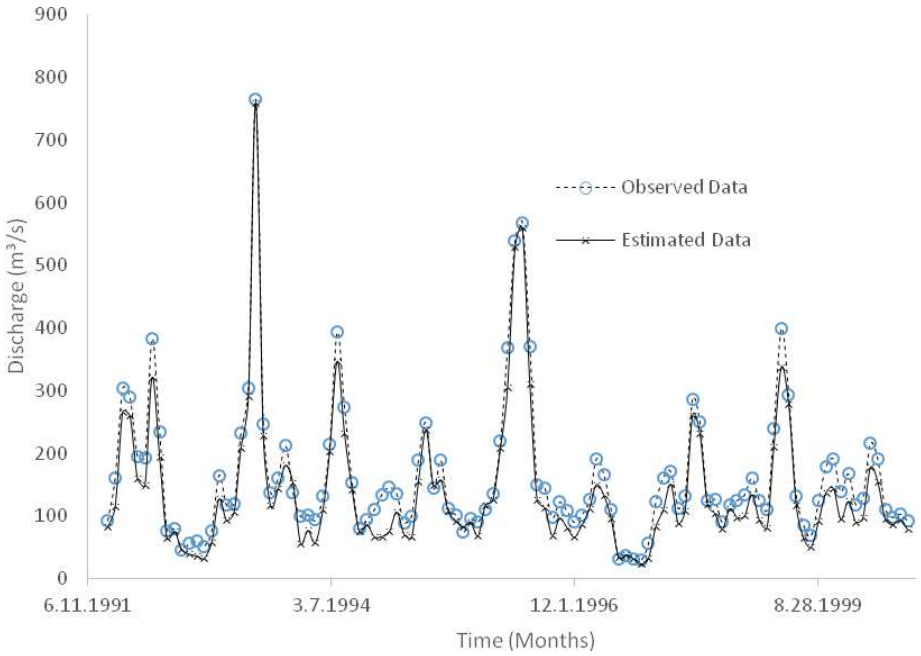

Figure 5. *Comparison of observed data and estimated data of Anfis (5-5) model test data for the second data set*

Third data set models

The aim of these models was to complete the missing data of station 1413. For this, the data of stations 1412 and 1414 were used. Of 504 data, the first 405 were used for training and the remaining for testing. The results were compared using the classical method and multiple regression model as well as ANFIS models generated by changing the number of sets of input parameters (*Table 5*).

The equation of the classical method is:

$$X_{1413} = (2{,}407 * X_{1414} + 8{,}641 * X_{1412})/2 \quad \text{(Eq.7)}$$

The equation of the multiple regression model is:

$$X_{1413} = 0{,}404 * X_{1414} + 4{,}904 * X_{1412} + 17{,}576 \quad \text{(Eq.8)}$$

Table 5. *Training and testing data results of models developed for the third data set*

Models		Training Data		Testing Data	
		R^2	Mean Squared Error %	R^2	Mean Squared Error %
ANFIS Models	3-3	0.890	20.29	0.865	23.24
	4-4	0.892	19.35	0.872	22.93
	5-5	**0.881**	**18.64**	**0.879**	**22.56**
	6-6	0.865	19.88	0.854	23.07
Normal Ratio Method		0.764	27.41	0.694	36.60
Multiple Regression		0.905	34.26	0.757	46.74

The results show that ANFIS models provide more accurate results than the classical and multiple regression models. Although the results are not as good as those in the first data set, they remain within acceptable error limits. The models in which each input has 5 subsets are the optimum models. The comparison of the values of the optimum ANFIS model with the observed values shows that the errors of both the minimum and maximum flow values are very few (*Figure 6*).

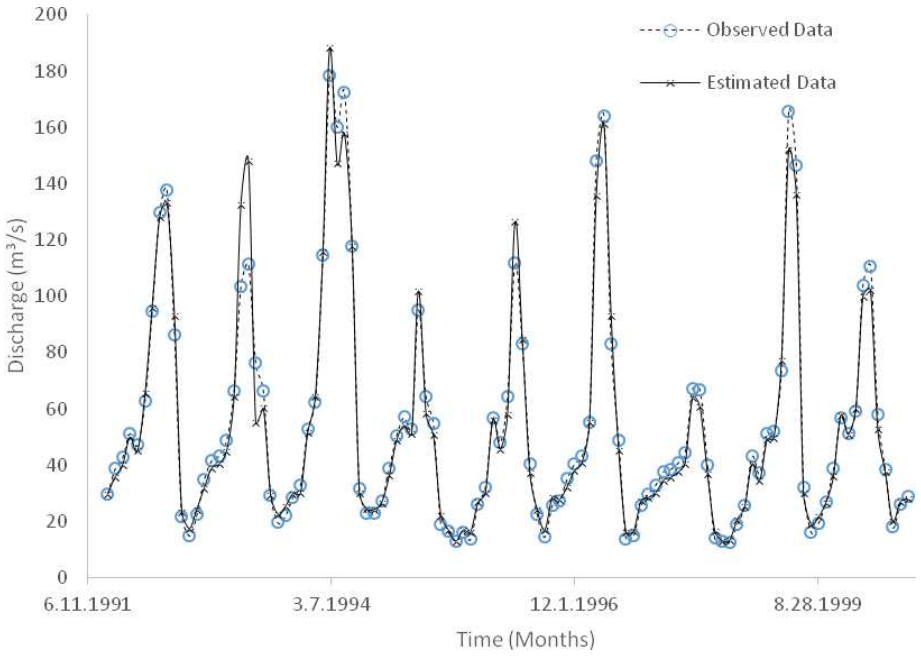

Figure 6. *Comparison of observed data and estimated data of Anfis (5-5) model test data for the third data set*

Determining the Minimum Number of Data for Anfis Model Training

This part of the study attempted to obtain the minimum number of data required for a reliable ANFIS model training. The model with a 5-5 set of the first data set (the optimum modelling) were the model of choice for this purpose. The models were trained using a 10-year data set and the procedure was repeated year by year. The evaluation of the results is summarized in *Table 6*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_35833594
© 2018, ALÖKI Kft., Budapest, Hungary

Table 6. *Regression and error values for the number of data used for ANFIS model training*

Number of Data	Training Data		Testing Data	
	R^2	Mean Squared Error %	R^2	Mean Squared Error %
1- year	0,999	0,74	0,036	169,27
2- year	0,993	13,42	0,071	118,02
3-year	0,992	16,79	0,139	111,06
4- year	0,985	21,38	0,198	36,91
5- year	0,980	22,39	0,628	30,44
6- year	0,981	21,23	0,738	21,92
7- year	0,982	19,77	0,803	20,12
8- year	0,983	18,76	0,844	17,77
9- year	0,984	16,88	0,898	17,74
10- year	0,985	12,27	0,967	17,65
33- year	0,983	10,99	0,979	17,55

The number of data used for ANFIS model training does not affect the regression coefficient of the training data very much (*Table 6*). However, the regression results obtained during the testing of the models show that the results of the 10-year data set and model are very similar to those of the 33-year data and training *(Figure 7*). The error values show that the 8-year data set is sufficient for training (*Figure 8*). In conclusion, a 10-year data set may be sufficient for Anfis model training.

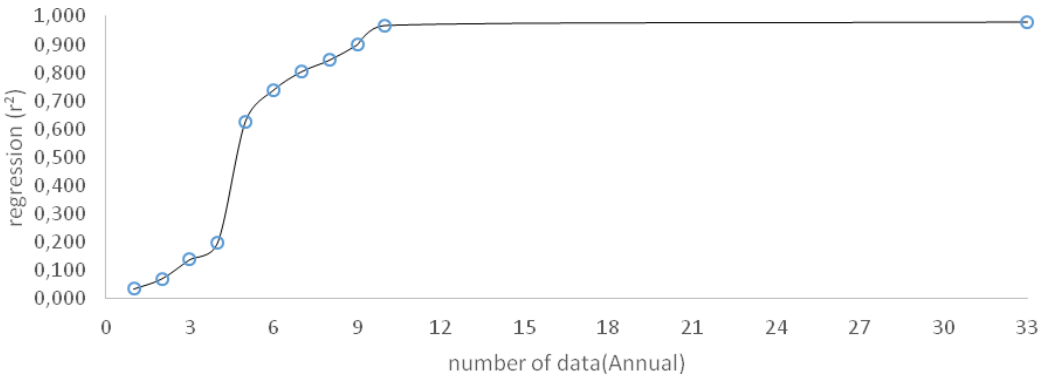

Figure 7. *Regression values for the number of data used for ANFIS model training*

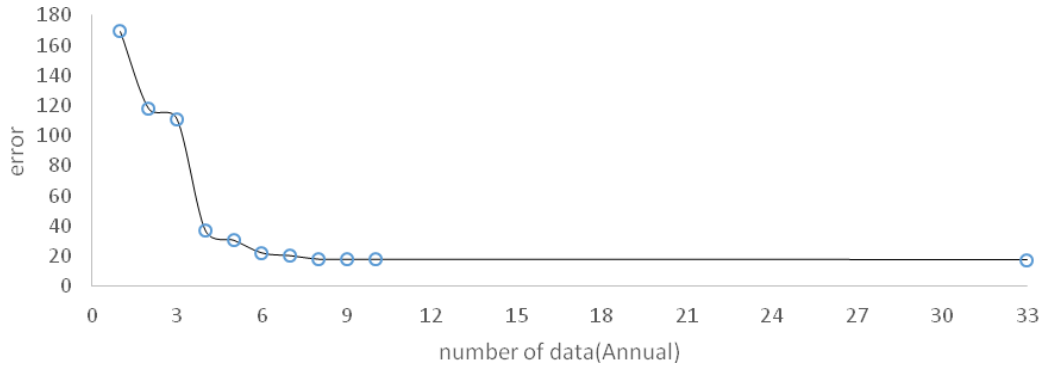

Figure 8. *Error values for the number of data used for ANFIS model training*

Discussion

The study was repeated with 3 different data sets and ANFIS model behaviors is searched in different models. When the obtained results are analyzed it is seen that the increase in the number of the stations affects ANFIS modelsadversely; however, this effect isn't so big as Normal Ratio Method has. In contrast to this, it can be said that the increase in the number of the stations affect Multiple Regression Models in a positive way. While the proportion of error is more in the minimum discharge value, it is much smaller in the maximum discharge value. The changing of error in the maximum values isn't effected so much by the changings in the number of stations. One of the biggest lacknesses of ANFIS models is memorizing during the process of the training. To be able to overcome this lackness, some of the data should be allocated for testing. The accuracy rate which has %99 accuracy proportion during the process of training reaches to much lower degrees for testing date. This is a proof for the model that this model is composed via memorizing instead of learning and it can't be used. The closeness between the results obtained out of training and the test results shows that ANFIS is appropriate to complete missed data.

In the second part of the study, it is focused on the number of data which is necessary for being able to to use ANFIS models. Especially in the situation of having fewer data, the needed number of data is tried to determine to be able to get reliable results. In the study done for this, it is noticed that there is a difference less than % 1 between the models composed with a decade data and 8 composed with 33 years data. When error test data in inspected, it can be said that 8 years datacan be used safely. It is defined that the data is less and 3 years data can't be used. Annual data in the model is the biggest proof for showing tı trust the training results. Although the training results are extremely trustable, the test resultsare weak.

In the stuation of increasing the number of data, the results abtained via ANFIS move away the accuracy and so the time or elevation the results becomes longer. Additionally, every input parameter must be balanced in the number of membership functions. Number of membership functions is important for the accuracy of the model. Having many membership functions may affect the accuracy of the model in the negative way. The operation time of the models increases exponentially at the same time. For example while in a model having 2 inputs and having 5 sets of membership functions for each input, 25 rules composes; in amodel having 4 inputs and 10 sets of membership functions for each 10^4 rules are needed to be composed. However, this affects the model's operation performance adversely.

Conclusion

Sometimes it is not possible to collect long and coordinated data in order to optimally use water resources projects.The aim of this study was to develop ANFIS models for stations on Yeşilırmak River in order to solve this problem and improve the existing methods. Another aim of the study was to investigate how the number of input parameters and amount of data affect ANFIS models. For this purpose, 3 different data sets were analyzed.

Results show that besides classical and regression models, ANFIS models can be used to complete missing flow data. ANFIS models yield very accurate results especially when the number of input parameters is small. However, multiple regression models yield better results than ANFIS models when the number of input parameters is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_35833594
© 2018, ALÖKI Kft., Budapest, Hungary

large. In addition, it takes ANFIS models longer to achieve results when the number of input parameters increases. Lastly, at least a 10-year data is required for a reliable ANFIS model training phase.

In conclusion, the ANFIS modelling yield accurate results and therefore can be used to complete missing data when the number of input parameters is small and data set is older than 10 years.

ANFIS models must be advocated by using the data of past and they can be used to complete the missing data which is going to happen in the future after proving their usage by looking at the test results. In addition, via this, newly opened stations past data can be supplied. In addition to completing the data of streamflow, it is thought that it can be used to complete the data having great importance in the projects of water sources. Such as rainfall, evaparation, water quality and sediment.

(Received 23rd Mar 2018; accepted 30th May 2018)

Abstract. This paper presents a comparative analysis of expert opinions on forest biodiversity indicators for protected areas, using a questionnaire given to forest experts in Turkey and Sweden. Experts were selected according to whether they had studied or worked in areas related to biodiversity, protected areas and sustainable forest management. A Mann-Whitney U test was used to determine the differences between the opinions of Swedish and Turkish experts regarding the indicators. The experts from both countries considered "endemic species" and "naturalness" as the most important indicators, while "overused species", "forest distribution and regeneration", "carrying capacity in terms of important species of area" and "the existence of different conservation status of protected areas" were considered equally as the least important indicators. The most important difference between the two groups was related to the indicators "dead wood" and "hollow trees", which Swedish experts found more important than their Turkish counterparts. Two other large differences were that the Swedish experts found "litter layer" much more important and Turkish experts instead found "plant species composition" much more important. The differences between the two groups reveal different perspectives regarding the planning and management of protected areas in each respective country.
Keywords: *sustainable forest management, dead wood, hollow trees, Turkey, Sweden*

Introduction

First introduced to the forestry literature in the 1990s, sustainable forest management criteria and indicators have been important tools for measuring the sustainability of forests (Mendoza and Prabhu, 2000; Brang et al., 2002). In 1992, the International Tropical Timber Association (ITTO) was the first to propose such criteria and indicators for tropical forests (ITTO, 1992, 2005). Subsequently, the annual Rio Summit highlights the importance of sustainable forest criteria and indicators, along with monitoring and reporting. (Castañeda et al., 2001; Rametsteiner, 2001; Mcdonald and Lane, 2004; Wolfslehner et al., 2005; Mrozek et al., 2006; Steenberg et al., 2013). Recently, the first step was taken towards the development of criteria and indicators for sustainable forest management for nine regional processes in the world. These processes include: the International Tropical Timber Organization (ITTO), Helsinki Process (MCPFE/Pan-European Process), Montreal Process, Tarapoto Proposal, Dry Zone Africa Process, African Timber Organization Process (ATO), Near East Process,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

Lepaterique Process of Central America and Dry Zone Asia Process (Akyol and Tolunay, 2014).

For these regional processes, seven key levels were identified as an overall framework for sustainable forest management. These levels include: the extent of forest resources, biodiversity, health and vitality of forest ecosystems, protective functions of forests, productive functions of forests, socio-economic functions, and legal, political and institutional framework (Castañeda, 2000; Siry et al., 2005; Purnomo et al., 2005; Grainger, 2012).

Among these levels, biodiversity criteria and indicators have been among the most debated since the Rio Summit. Until recently a great deal of effort has been undertaken to further develop the indicators for this criteria (Kotwal et al., 2008) because biodiversity refers to the dynamism, health, sustainability and energy of an ecosystem and its resilience against any kind of disturbance factor (Gülsoy and Özkan, 2008). In short, biodiversity is one of the fundamental bases for the continuity of life. Moreover, there are crucial challenges for ensuring the sustainability of biodiversity (Hagan and Whitman, 2006). These challenges arise because biodiversity is typically defined as the diversity of life measured at the levels of genes, species and ecosystems and the mutual interactions between these levels (Hagan and Whitman, 2006; Gaston, 1996; Claridge et al., 1997). Genetic structure is the primary component of vitality and is the basis of these levels.

The most important factor for the protection and sustainable use of biodiversity is the need to make a quantitative assessment of biodiversity (Duelli and Obrist, 2003). However, due to various challenges, the most practical approach for assessment is to use indicators related to biodiversity (Hagan and Whitman, 2006; Lindermayer et al., 2000). However, it is also difficult to identify and measure indicators for biodiversity (Heink and Kowarik, 2010) because the variables that can be practically surveyed and quantified are quite limited.

The main strategies developed to protect biodiversity and ensure its sustainability primarily include legal protection and the sustainable management of areas (Svancara et al., 2005). Protected areas that cover almost 12% of the Earth's surface are an important component of global protection strategies (Wells and McShane, 2004; Bajracharya et al., 2005). Although there are a broad spectra of indicators related to sustainable forest management, none of the abovementioned processes adequately describe protected areas (Blicharska et al., 2011; Tolunay and Akyol, 2015). This is because sustainable forest management processes utilize indicators that focus mainly on production forests across the world, which differ from protected areas.

Protected areas are of vital importance for biodiversity, and thus it is necessary to develop appropriate criteria and indicators. For example, one of the objectives of the "Integrated Approach to Management of Forests in Turkey, with Demonstration in High Conservation Value Forests in the Mediterranean Region" project implemented by the United Nations Development Programme is to develop biodiversity indicators in Turkey within the scope of sustainable forest management (UNDP, 2017).

The aim of this study was to evaluate biodiversity indicators that can be used for the sustainable management of protected areas, using opinions from experts. This data is then preliminarily presented for further discussion. From a global point of view, different or similar perspectives to various indicators are to be expected. Factors such as climate, geographical location, biodiversity, development level, and cultural features change the perceptions about and perspectives regarding protected areas in terms of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_35953609
© 2018, ALÖKI Kft., Budapest, Hungary

nature conservation. To obtain some diverse perspectives, expert views were solicited about the protected areas in Turkey to represent Mediterranean forestry and from Sweden to represent Nordic forestry. We aimed to contribute to the protection and sustainable management of biodiversity in protected areas, which is of great importance at a global scale.

Materials and methods

The main materials of this study were comprised of indicators related to the protection, development and sustainability of biodiversity, which are among the criteria and indicators for sustainable forest management. The primary data was obtained from a survey conducted online in Turkey and Sweden. The secondary data was composed of information obtained from literature analyses and information, and documents and reports from various public entities and organizations (FAO, CIFOR, etc.).

The questionnaire was composed of multiple choice questions using a 4-point Likert scale (not important, less important, important and very important). The questionnaire contained a total of 27 questions divided into two parts. The first part asked about demographic features of the participating experts. The second part asked the experts to assess a set of biodiversity indicators developed from different sustainable forest management studies across the world (*Table 1*).

Table 1. *The set of indicators[1] prepared for the evaluation by the experts*

Indicators	Definition
Plant species composition	The number and composition of plant species per forest types and other wooded area types
Naturalness	The amount of forest types and other wooded area types divided in natural, semi natural or plantation
Forest distribution and regeneration	The rates of natural regeneration and survival of tree species
Sensitive and rare ecosystems	The amount and distribution of sensitive and rare ecosystems
Dead wood	The volume of standing and downed dead wood in different forest types and other wooded area types
Hollow trees	The number of hollow trees and the proportion of the total amount of trees or wood volume
Litter layer	The litter and decaying condition
Genetic resources	The condition of forest genetic resources in the areas managed for seed production, protected areas and other areas
Ecosystem structure	The spatial structure of forest covers in the ecosystem level
Endangered species	The number of endangered forest species according to Red List classification of International Union for Conservation of Nature (IUCN) in relation to total number of forest species. (Threatened, rare, vulnerable, endangered or extinct, mammals, birds other vertebrates or invertebrates)
Endemic species	The population condition of endemic forest species
Overused species	The population condition for overused forest species
Species whose lives depend on protected areas	The number of individuals and population trend for species dependent of protected forests

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_35953609
© 2018, ALÖKI Kft., Budapest, Hungary

Species whose distribution area is declining and habitat loss	The size of declining species distribution area and the existence and status of forest habitat losses within protected areas
Major distribution areas and population status of the species	The size of distribution area and population status for forest species
Carrying capacity in terms of important species of area	The carrying capacity for important species of protected areas
Water resources and wetland	The quality of water resources and wetlands in forests (Number and area)
Damaged areas	The size and proportion of forest areas damaged by various processes and factors (Pests, disease, fire and flood)
Human use of protected areas	The size and proportion of human uses of land within protected areas (Residential areas, agricultural areas, such as roads, etc.)
Effects of other sectors	The effect on forest from other sectors (Mining, agriculture, livestock, energy and infrastructure etc.)
Existence of contaminants around protected areas	The number, size and type of pollutants around protected forest areas
Differentiated conservation status within protected areas	The existence of areas with different conservation status within the protected forest area (Status, size, cause etc.)
Other issues important for sustainable management	-The availability and capacity of an institutional structure for the management and existence of functional legislation -The existence of economic policy framework and financial instruments -The educational and informational opportunities for implementation of the policy framework -the strengthening of knowledge about endangered species (inventory or research) -The management plans

[1]This set is based on the biodiversity indicators used in International Tropical Timber Organization (ITTO), Helsinki Process (MCPFE/Pan-European Process), Montreal Process, Tarapoto Proposal, Dry Zone Africa Process, African Timber Organization Process (ATO), Near East Process, Lepaterique Process of Central America, Dry Zone Asia Process, Center for International Forestry Research (CIFOR) processes at global level (FAO, 1996, 1997, 2003, 2004, 2010; CIFOR, 1999; ITTO, 2003, 2005; CCFM, 2004; MCPFE, 2006; MPCI, 2017)

In this study, the expert group consisted of specialists from universities and research institutions, experts at ministries of agriculture, forestry and environment related to protected areas, and NGO representatives in both Turkey and Sweden. Experts were selected according to whether they had studied or worked in areas related to biodiversity, protected areas and sustainable forest management. The interest areas and biographies of the experts were reviewed on their web sites.

Three-hundred participants who were assumed to be related to the subject were asked to participate in the study. The survey was submitted to Turkish and Swedish experts simultaneously between September and December 2016. The web link for the questionnaire was sent to Turkish and Swedish experts via email. During the survey, three reminders were given once a month. Ultimately, 122 experts from Turkey and 112 experts from Sweden participated in the survey. Therefore, the response rate was quite high (81.3% for Turkish, 74.6% for Swedish experts), and we assumed that this rate was rather satisfactory (Nulty, 2008). The profile characteristics of the experts participating in the study are demonstrated in *Table 2*. One third of the experts in the study were women and the proportion of women was higher in the Swedish group. The Swedish

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

group had a slightly lower average age than the Turkish group. Nearly 70% of the experts belonged to universities and research institutes. There was a higher proportion of experts from universities and research institutes in the Turkish group. The Swedish group had a higher proportion of experts from governmental institutions, but a lower proportion from NGOs.

Statistical analyses were conducted using Statistical Package Program (SPSS 20.0) and the results were evaluated at a significance level of 5%. Cronbach's alpha coefficient was calculated as 0.856, and was greater than 0.8; thus, the scale had high statistical reliability. The data obtained from the questionnaire had a non-parametrical distribution (Kolmogorov-Smirnov test, $p < 0.05$); therefore, a Mann-Whitney U test (Nachar, 2008) was used to determine the differences between the opinions of Swedish and Turkish experts regarding the indicators. According to the average of the responses given by the experts, the indicators were ranked starting from indicators that were considered the most important

Results

Opinions of experts for biodiversity indicators related to forest species

The opinions about the importance of endangered and endemic species as indicators between the Turkish and Swedish experts did not significantly differ (*Table 3*). In other words, the experts in both groups found these indicators equally important (*Fig. 1*).

The evaluated level of importance for the other five species indicators (*Table 3*) was statistically different ($p < 0.05$) between the two groups. For all of these indicators, the level of importance given by Turkish experts was higher than that of Swedish experts (according to 4-point Likert scale) (*Fig. 1*). The least important species indicator in the evaluation was "overused species". It was also the indicator where the evaluation differed most between the groups. In total, 47% of Swedish experts found this indicator

not and less important, while only 9% of the Turkish experts found this indicator less important.

Table 3. *Mann-Whitney U test results for the importance of forest species indicators*

Indicators	M-Whitney U	Wilcoxon W	Z	p
Endangered species	6325.000	12653.000	-1.798	0.072
Endemic species	6623.000	12951.000	-0.853	0.393
Overused species	4085.000	10413.000	-5.721	**0.000**
Species whose lives depend on protected areas	5889.500	12217.500	-2.494	**0.013**

Opinions of experts for indicators related to conservation of natural heritage, genetic resources and some forest structures

Genetic diversity refers to the diversity of genetic material and is assessed as the genetic difference in a specific species, population, variety, subspecies or race. The Turkish and Swedish experts found the indicators for genetic resources very important (*Fig. 2*), and there were no statistically significant differences found between the two groups (*Table 4*).

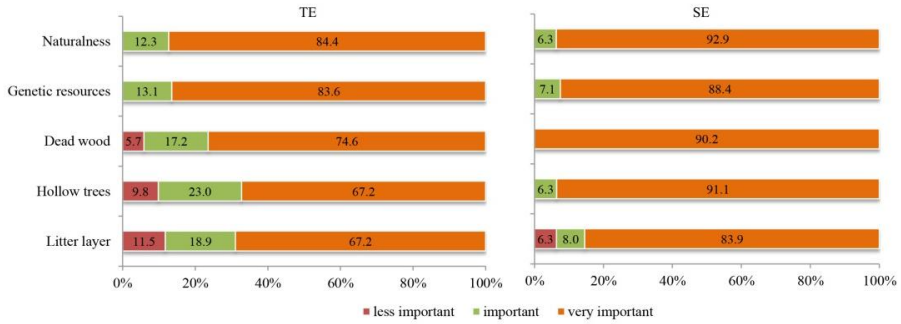

Figure 2. *Differences in given level of importance for the conservation of natural heritage, genetic resources and some forest structures indicators (n_{TE} = 122, n_{SE} = 112, only values > 5%)*

Turkish experts found the indicators for dead wood and hollow trees less important than their Swedish counterparts (*Fig. 2*). The opinion about the importance of the dead wood and hollow trees indicator differed significantly between Turkish and Swedish experts (*Table 4*). Similarly, the "naturalness" indicator was found more important by the Swedish experts (*Fig. 2*). Another significant difference was that the Swedish experts found litter layer more important than did Turkish experts.

Table 4. *Mann-Whitney U test results for the importance of conservation of natural heritage, genetic resources and some important structures in forests indicators*

Indicators	M-Whitney U	Wilcoxon W	Z	p
Naturalness	6249.500	13752.500	-2.033	**0.042**
Genetic resources	6528.500	14031.500	-0.971	0.332
Dead wood	5801.000	13304.000	-2.984	**0.003**
Hollow trees	5202.000	12705.000	-4.411	**0.000**
Litter layer	5720.500	13223.500	-2.843	**0.004**

Opinions of experts for biodiversity indicators related to ecosystem

Regarding biodiversity indicators related to ecosystem, there were different opinions between the two expert groups for "plant species composition" and "forest distribution and regeneration" (*Fig. 3*). These indicators were found relatively more important by the Turkish experts and were statistically different (*Table 5*).

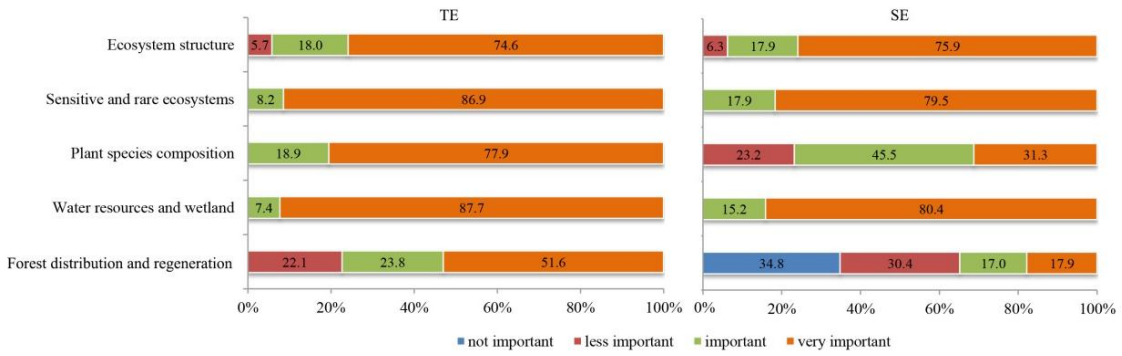

Figure 3. *Differences in given level of importance for ecosystem indicators (n_{TE} = 122, n_{SE} = 112, only values > 5%)*

Table 5. *Mann-Whitney U test results for the importance of ecosystems indicators*

Indicators	M-Whitney U	Wilcoxon W	Z	P
Ecosystem structure	6723.000	14226.000	-0.279	0.780

Turkish and Swedish experts found "sensitive and rare ecosystems" and "ecosystem structure" indicators equally important. The "plant species composition" indicator was found less important by the Swedish experts (*Fig. 3*).

Opinions of experts for biodiversity indicators related to conservation status and external factors

There were no statistically significant differences between the opinions of the Turkish and Swedish experts regarding the importance of forest biodiversity indicators regarding conservation status and external factors (*Table 6*), and most of the experts deemed these indicators as "important" or "very important" (*Fig. 4*).

Table 6. *Mann-Whitney U test results for the importance of conservation status and external factors indicators*

Indicators	M-Whitney U	Wilcoxon W	Z	p
Existence of contaminants around protected areas	6467.500	12795.500	-1.057	0.290
Differentiated conservation status within protected areas	6226.500	12554.500	-1.341	0.180
Effects of other sectors	6788.500	14291.500	-0.110	0.913
Human use of protected areas	6392.500	12720.500	-1.009	0.313
Damaged areas	6650.000	14153.000	-0.450	0.653
Other issues important for sustainable management	6794.500	14297.500	-0.107	0.915

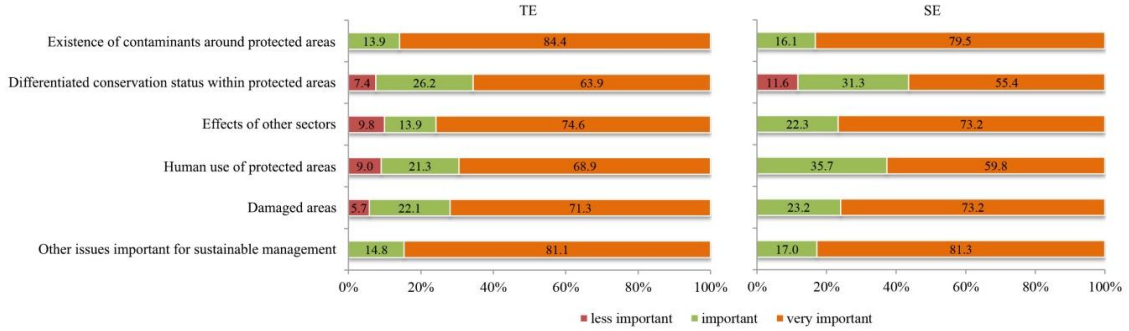

Figure 4. *Differences in given level of importance for forest biodiversity indicators related to conservation status and forest structure (n_{TE} = 122, n_{SE} = 112, only values > 5%)*

Ranking for forest biodiversity indicators

Table 7 presents the ranking of the scores and opinions of the experts for each indicator from the highest score to the lowest according to averages. The averages are calculated from the responses given on a 4-point Likert scale (not important = 1, less important = 2, important = 3 and very important = 4). Accordingly, the top five and last five indicators in the table are indicated with a grey colour. *Table 7* shows that only the indicator "forest distribution and regeneration" out of the 23 indicators had an average value of 2.74. The average value of the remaining 22 indicators was above 3. In general, this indicates that the experts found the indicators appropriate for the study.

The average values of the responses given by the Swedish and Turkish experts regarding the importance level of the indicators reveal that "endemic species" and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_35953609
© 2018, ALÖKI Kft., Budapest, Hungary

"naturalness" were placed at the top amongst all indicators. This means that experts from both groups found endemic species and naturalness indicators equally important. The indicators for which there were the largest differences in opinion between the Swedish and Turkish experts included "dead wood" and "hollow trees". These indicators were ranked third and fourth, respectively, by Swedish experts, while Turkish experts ranked them fourteenth and eighteenth, respectively. The two indicators where both Turkish and Swedish experts gave the lowest rank and found equally less important were "overused species" and "forest distribution and regeneration". Additionally, "carrying capacity in terms of important species of area" and "the existence of different conservation status of protected areas" were found equally less important (*Table 7*).

Table 7. *Mean scores and rank for the evaluated forest biodiversity indicators*

Indicators	Turkish experts		Swedish experts		Total	
	Mean	Rank	Mean	Rank	Mean	Rank
Endemic species	3.90	1	3.88	2	3.89	1
Naturalness	3.81	5	3.92	1	3.86	2
Endangered species	3.89	2	3.83	6	3.86	3
Genetic resources	3.80	6	3.83	5	3.81	4
Water resources and wetland	3.83	3	3.76	9	3.79	5
Existence of contaminants around protected areas	3.83	4	3.74	10	3.79	6
Sensitive and rare ecosystems	3.80	7	3.77	8	3.78	7
Other issues important for the sustainable management	3.76	9	3.79	7	3.78	8
Dead wood	3.64	14	3.84	4	3.74	9
Hollow trees	3.57	18	3.88	3	3.72	10
Species whose lives depend on protected areas	3.76	8	3.61	15	3.69	11
Ecosystem structure	3.66	13	3.70	12	3.68	12
Species whose distribution area is declining and habitat loss	3.75	11	3.60	16	3.68	13
Damaged areas	3.64	15	3.70	13	3.67	14
Effects of other sectors	3.61	16	3.69	14	3.65	15
Major distribution areas and population status of the species	3.68	12	3.57	17	3.63	16
Litter layer	3.51	21	3.74	11	3.62	17
Human use of protected areas	3.58	17	3.55	18	3.57	18
Differentiated conservation status within protected areas	3.52	20	3.40	19	3.46	19
Plant species composition	3.75	10	3.08	21	3.43	20
Carrying capacity in terms of important species of area	3.53	19	3.27	20	3.41	21
Overused species	3.48	22	2.71	22	3.11	22
Forest distribution and regeneration	3.25	23	2.18	23	2.74	23

Other indicators with large differences were "plant species composition," as this was ranked tenth by Turkish experts and only twenty-first by Swedish experts. On the contrary, "litter layer" was ranked eleventh by Swedish experts and twenty-first by Turkish experts and was found less important than other indicators. The sometimes-diverging opinions between the groups are interesting, and can be helpful in defining the most important forest

biodiversity indicators. The dynamic and varying structure of the indicators contribute positively to the identification of the best indicators for a given region.

Discussion

Dead wood and hollow trees represent structures of great importance for biodiversity and ecosystem health in forests. They provide important habitats for many species. Furthermore, they play a crucial role in increasing the resilience of forests and ensuring the continuity of ecological balance. Dead wood is a critical source for forest biodiversity and is commonly used as an indicator for sustainable forest management (Jonsson et al., 2016). Although the importance of dead wood for biodiversity is commonly known, directed strategies for protection of dead wood in forest ecosystems are implemented only in some of the regions across the world (Seibold et al., 2015). The most important difference among indicators is "dead wood" and "hollow trees" according to the experts in this study. Turkish experts found these indicators less important. One reason for this may be because of the common belief in Turkey that the existence of dead wood and hollow trees results in entomological pest species outbreaks (bark beetles, etc.) and may have implications for protected areas, for example by increasing the risk of forest fires. On the contrary, hollow trees have for a long time been known among Swedish foresters and biologists as very important for cavity nesting birds and many saproxylic invertebrates (Ehnström and Waldén, 1986; Nilsson and Baranowski, 1994; Ranius and Jansson, 2000). For Turkish conditions, similar results have been found in recent studies (Jansson and Coskun, 2008; Sama et al., 2011; Bergner et al., 2016), but this knowledge is still new and not commonly acknowledged in Turkish society.

Swedish experts found the "naturalness" indicator more important. This may be because of the opinion in Sweden that a desirable management regime in many protected forest areas is to make them look as "untouched" as possible (Steinwall, 2015). Turkish experts found the indicators for "plant species composition" and "forest distribution and regeneration" more important. One reason for this may be that the question of whether or not silvicultural treatments should be implemented in the protected areas of Turkey is still controversial. This debate exists because the affected areas are impacted to a certain extent by anthropogenic factors that are sometimes from entomological pest species outbreaks and an increased risk of forest fire (Colak, 2001; Alptekin et al., 2010). In Sweden there are lower risks for wild fires, and in some forest habitats wild fires are seen as positive and a part of the natural disturbance regime in the northern taiga forest ecosystem (Drobyshev et al., 2012).

The indicators for "sensitive and rare ecosystems" and "ecosystem structure" are used for monitoring, particularly in protected areas (Akyol and Tolunay, 2014). These ecosystems are jeopardized by the global climate change (Williams et al., 2015). Climate change may have multiple effects such as those related to the dynamics of species within ecosystems and abiotic factors that may have implications for ecosystems, such as forest fire dynamics (Costanza et al., 2016). Turkish and Swedish experts found these indicators equally important. It is also important to monitor "plant species composition" and put this in relation to these effects (Seidl et al., 2014; Pommerening et al., 2016), but in this study the Swedish experts found this less important than Turkish experts.

Regarding biodiversity indicators related to conservation status and external factor, there were same opinions between the two expert groups and these indicators were found important or very important. Similar to most developing countries, a rigid and conservative approach is dominant in Turkey. This is the reason why local people are usually excluded from the planning and management of protected areas in Turkey. This approach is based on the assumption that a natural resource can be protected by prohibiting or restricting its exploitation as a natural resource by law (Rutagarama and Martin, 2006). This approach leads to a conflict between managers and users from the perspective of objectives set for the protected areas, since the aims of the resource managers are to minimize or prevent the utilization of these resources while users try to increase their utilization of the resources or at least maintain the same level of exploitation (Alkan, 2009; Alicia et al., 2018). Ultimately, rigid and passive protection approaches fail because there is dependence by local people on the natural resources in or around protected areas. This is especially the case in developing countries, where use could not be eliminated and alternative sources of income could not be provided to locals who are already in difficult socioeconomic situations. As such, protection often times exists only on paper (Akyol et al., 2017; Alkan et al., 2009; Alkan and Korkmaz, 2009; Thomas and Middleton, 2003; WWF, 2003; Arias et al., 2000).

Conclusions

It is important to monitor and assess biodiversity and sustainability in protected areas. Suitable indicators for protected areas have not been developed from the perspective of biodiversity and sustainable forest management. This study analysed a set of forest biodiversity indicators developed in international processes and solicited opinions from Turkish and Swedish forest experts to compare and analyse the indicators.

Although the overall ranking order differed, the first nine indicators were ranked the same by both expert groups and the top four indicators in total when adding the two groups together were among top six for both groups. These indicators were: “endemic species”, “naturalness” “endangered species” and “genetic resources”. The indicators with the lowest rankings in total and for both expert groups were “overused species” and “forest distribution and regeneration”.

Indicators with significant importance ranking differences were “dead wood” and “hollow trees”. This has important implications. Recent studies have shown very high biodiversity in old hollow oaks in Turkey, and thus these studies should be expanded to also cover other tree species and dead wood in general in Turkish forests. Naturally it takes time before results from scientific studies gains acceptance in society, and as such differences may be in part due to such a time lag in distributing knowledge.

The results also reveal different perceptions on the importance of such structures amongst people from different biogeographical regions, and hence environmental conditions may result in different perspectives on nature management. The differences should be considered an advantage in the process of developing improved biodiversity indicators as both groups could benefit from each other’s experiences in these matters.

There is a need for further studies to evaluate the measurability of these indicators and to identify indicators that are the most cost-effective and reliable for measurement and quantification. It is also preferable if these indicators can be monitored in a standardized manner to ensure non-biased long-term data regarding indicator dynamics

and how they relate to external factors, such as climate change. The set of indicators assessed in this study are a first step in the process of developing appropriate indicators for biodiversity in protected areas. This research provides a solid base and a guideline for the next step in the process.

EVALUATION OF AIR AND SOIL POLLUTION USING THE BIOMARKER *MORINGA OLEIFERA* IN JEDDAH CITY, SAUDI ARABIA

AL KHAZAN, M. M.

Department of Biological Science, Faculty of Science, King Abdulaziz University
21589 Jeddah, Saudi Arabia
e-mail: m.kzanm@gmail.com; phone: +96-650-569-4816

(Received 25th Mar 2018; accepted 25th May 2018)

Abstract. Physiological processes, photosynthesis, carbon and nitrogen metabolism, osmotic adjustment and secondary metabolites are known to be affected by air and soil pollutants. The present study was designed to evaluate the impact of air and soil pollution in Jeddah city, Saudi Arabia, on the physiological processes of *Moringa oleifera*. Four accessions differing in their pollution intensity were selected for this study (S1-S4). Elemental analysis revealed that Pd, Cu, Mn, Cr, Fe and Zn were the main soil pollutants in study accessions and trees growing in S2 have accumulated large quantities of these metals in their leaves. The physiological response to environmental pollution in *M. oleifera* tree was found to be dependent on pollution intensity. The heavily polluted accession showed a different response from the rest of accessions. As an adaptive strategy to environmental stress, this site has shown an increase in some metabolites such as lipids, flavonoids, free amino acids, alkaloids and saponins. However, some metabolites were decreased in response to pollution intensity such as soluble sugars and proteins, ascorbic acid, and terpenoids.
Keywords: *Moringa oleifera, heavy metals, phytotoxicity, physiological response, antioxidant capacity*

Introduction

Moringa (*Moringa oleifera* Lam.) is the most broadly cultivated species within Moringaceae family and is known as a rapidly-growing tree. It is commonly distributed in the sub-Himalayan parts of India, Pakistan, Bangladesh and Afghanistan. It has been introduced and become naturalized in many other parts of the world including Arabian peninsula. *Moringa oleifera* has many common names as the horseradish tree, drumstick tree, benzolive tree, kelor, marango, mlonge, moonga, and many other synonyms (Fahey, 2005). *Moringa oleifera* is widely cultivated for many purposes as efficient food stuff, biofuel production, and other implementations. Traditionally, it is used in therapeutic objectives around the world due to actual manifestations. These advantages have been related to metabolites like phenolics, vitamins and proteins (Health, 2005; Adedapo et al., 2009). *Moringa oleifera* offers a rich and unusual mixture of nutrients in its leaves, pods and seeds, amino acids that possess many therapeutic activities like antioxidant, anti-aging and anti-inflammatory. Moringa is sometimes called "Mother's Best Friend" and "Miracle Tree" as it has been advised as a complementary to treat malnutrition (Sreelatha and Padma, 2009).

In fact, moringa is said to provide 7 times more vitamin C than oranges, 10 times more vitamin A than carrots, 17 times more calcium than milk, 9 times more protein than yoghurt, 15 times more potassium than bananas and 25 times more iron than spinach (Rockwood et al., 2013). The leaves of *M. oleifera* has been established as a rich source of phenolics and glucosinolates (Amaglo et al., 2010), minerals like iron, calcium, phosphorus and copper, (Saini et al., 2014a), tocopherols (Saini et al., 2014b) and antioxidants (Dillard and German, 2000). It also contains high concentrations of

© 2018, ALÖKI Kft., Budapest, Hungary

ascorbic acid, estrogenic substances and beta-sitosterol, vitamins A, B and C, α-tocopherol, riboflavin, nicotinic acid, pyridoxine, β-carotene, protein, and essential amino acids such as methionine, cystine, tryptophan and lysine (Rajput et al., 2017). These components have pharmacological potentials like antimicrobial, anticancer, antihyperlipidemic, antidiabetic, antiulcer, analgesic, antifertility, anticonvulsant and hepatoprotective (Ganatra et al., 2012).

Global awareness of air pollution has been rising due to its massive danger to public health. World Health Organization (WHO) reported that annual concentration of ambient air pollution was increased worldwide by 8% during the recent five years (Nakao et al., 2017). In regard to plants, unrestrained use of fossil fuels in industries and transport sectors has led to the increase in concentrations of gaseous pollutants such as SO_2, NO_2, etc. (Rai et al., 2011). It is a known fact that 60 % of air pollution in city is caused by automobiles only. On sensitive species of both plants and animals, the effect of these pollutants is observed at acute level. Response of plants towards air is being assessed by the air pollution tolerance index (APTI). Some plant species and varieties are so sensitive that they can be easily used as biological indicators or monitors of specific pollutants. They can further assist the planner in managing the urban cities (Horaginamani and Ravichandran, 2010).

With the extension of the urban expansion of the city of Jeddah, Kingdom of Saudi Arabia (KSA), many human requirements led to the accumulation of various wastes containing hazardous and non-hazardous components. The lack of proper disposal of those wastes cause environmental disasters on all surroundings. Solid waste management studies have shown that the amount of solid household waste produced per individual in industrialized and developed countries ranges from 2 to 2.5 kg/ day. The World Health Organization classified the Arab Gulf countries among the rich countries characterized by the rise of solid waste for individuals, which led to the emergence of the problem of open and closed garbage dump sites. Due to the fact that plants play an effective role in purifying the environment of pollutants, *M. oleifera* was selected for this study. It was noted that its fruits and leaves are palatable by the expatriate workers, despite of it was planted in areas close to garbage dumps and in heavy traffic roads. This study provides an overview on the nutritional value, antioxidant capacity, secondary metabolites, as well as heavy metals exclusion capacity from air and soil by *M. oleifera* in four differentially polluted accessions in Jeddah city, KSA.

Materials and methods

Green leaves of *M. oleifera* tree were collected during the summer season of 2017 from four different accessions in Jeddah city, KSA. The first accession (S1) was a double public road passing by cars (21.33.32 N; 39.10.33 E), the second accession (S2) was a polluted area by flaming fires, factories wastes and random waste disposal (21.21.16 N; 39.13.09 E). The third accession (S3) was a narrow bystreet with rare traffic (21.33.29 N; 39.10.32 E) and the fourth accession (S4) was a secondary street with average traffic (21.33.49 N; 39.10.44 E). The map of different experimental sites is provided in *Photo 1*. The mature and fully expanded leaves were collected from the top branches of the trees in the study sites. A total of 250 leaves were collected from 5 trees at each experimental site. Leaf samples were washed with tap water several times and once with distillated water, placed in an air-forced oven at 60 °C for five days. Dried samples were grinded into fine powder by an electrical mixer, sieved through 0.2 mm

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_36113626
© 2018, ALÖKI Kft., Budapest, Hungary

sieve and stored in paper bags for analysis. Soil samples were collected at the time of leaves collections from the study sites. Soil samples were collected from the surface soil layers with a depth of about 0 to 20 cm at the tree rhizosphere. Soil samples were replicated three times per each experimental site. The collected soil samples air dried and sieved for physical and chemical characterization.

Photo 1. *A satellite image of the four experimental sites*

Mineral analysis of plant and soil samples

Plant and soil samples were digested with a mixture of 69% HNO_3 and 30% H_2O_2 (5:2 v/v). The mineral content concentrations in digested solutions were determined using inductively coupled plasma-optical emission spectroscopy (Polyscan 61E, Thermo Jarrell-Ash Corp., Franklin, MA, USA).

Estimation of photosynthetic pigments

Total photosynthetic pigments; Chl a, Chl b and carotenoids, were extracted from moringa leaves by grinding in cold acetone (80%) using pre-chilled mortar and pestle. The extracted pigments were centrifugated at 3000 rpm for 15 min and quantified according to the method prescribed by Metzner et al. (1965). The quantified pigments were expressed as (µg/g dw).

Preparation of methanolic extract

The fine powdered plant tissues (5 g for each sample) were extracted with 50 ml of 95% methanol for 12 h at room temperature in an orbital shaker (Panasonic, MIR-S100, Japan). The extracts were filtered through Whatman No. 1 filter paper. The residues

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_36113626
© 2018, ALÖKI Kft., Budapest, Hungary

were extracted twice again as previously and extracts were combined. The combined extracts were concentrated under reduced pressure at 40 °C using rotary evaporator (Heidolph) and adjusted to 50 ml by methanol. Extracts were stored in glass vials at 4 °C until the time of analysis. All the spectrophotometric measurements were carried out using JENWAY 6315 UV/Visible Spectrophotometer (Japan).

Determination of total soluble carbohydrates

The total soluble carbohydrates content in the methanolic extract of plant powder was measured according to the phenol–sulfuric acid method using glucose as a standard sugar (Dubois et al., 1965) and expressed as mg/g dw.

Determination of total soluble proteins

Total soluble protein content of the extract was measured using bovine serum albumin (BSA) as a protein standard. The extract or the standard protein was mixed with Coomassie brilliant blue G250 reagent, the absorbance was measured at 595 nm and the results were expressed as mg/g dw (Bradford, 1976).

Lipid quantification

Total lipid content of leaf powders was extracted by the method reported by Bligh and Dyer (1959). The samples were stirred in a chloroform and methanol mixture (2:1 v/v) over 48 h, the powder was filtered off and washed with additional chloroform. This was repeated three times. The volatiles were removed under reduced pressure and the lipid content was expressed as mg/g dw.

Determination of flavonoids

Colorimetric aluminum chloride method was used for flavonoid determination (Chang et al., 2002). Leaf extract was mixed with 1.5 ml of methanol, 0.1 ml of 10% $AlCl_3$, 0.1 ml of 1M K-acetate and 2 ml of distilled water. The absorbance of the reaction mixture was measured at 417 nm. Total flavonoids were calculated as quercetin from a calibration curve and expressed as mg/g dw.

Determination of ascorbic acid (AA)

Ascorbic acid was extracted by homogenization in 5% sulfosalicylic acid. The resultant homogenate was centrifugated at 5000 rpm for 15 min and 1 ml of the supernatant was incubated with 2 ml 2% Na-molybdate, 2 ml 0.15 N H_2SO4 and 1 ml 1.5 mM Na_2HPO_4 at 60 °C for 40 min. Absorbance was measured at 660 nm and ascorbic acid content was calculated as mg/g dw using a prepared calibration curve by ascorbic acid (Oser, 1979).

DPPH radical scavenging activity

The antioxidant capacity of the obtained methanolic extracts was measured by bleaching of the purple coloured solution of 1, 1- diphenyl-2-picrylhydrazyl radical (DPPH) according to the method of Sun et al. (1988). Methanolic extracts were added to 0.2 mM DPPH and incubated at room temperature for 30 min, then the absorbance was measured against a blank at 517 nm. DPPH scavenging activity was calculated from the formula: (%) = 100 [(A blank-A sample)/A blank].

DOI: http://dx.doi.org/10.15666/aeer/1603_36113626
© 2018, ALÖKI Kft., Budapest, Hungary

Free amino acids estimation

Amino acids content of the methanolic extracts was estimated by ninhydrin assay using glycine as a standard amino acid (Lee and Takahashi, 1966). Samples were mixed with ninhydrin-citrate buffer-glycerol mixture (0.5 ml 1% ninhydrin solution in 0.5 M citrate buffer pH 5.5, 1.2 ml of 55% glycerol and 0.2 ml of 0.5 M citrate buffer). The mixture was then shaken and boiled in a water bath for 12 min, cooled, shaken well, and the absorbance was measured at 570 nm and the result was calculated as mg/g dw.

Determination of phenolic compounds

The total phenolic content of methanolic extracts was determined using Folin-Ciocalteu's reagent (Jindali and Singh, 1975). Aliquot of extracts was mixed with 0.1 ml Folin-Ciocalteu's reagent and 1 ml 20% Na_2CO_3, then completed up to a known volume with dist. water. Thereafter, the absorbance was measured at 650 nm after 30 min and gallic acid was used as a standard phenol and phenol content was expressed as mg/g dw.

Determination of alkaloids

Alkaloids were determined using the method of Harbourne (1984). Alkaloids were extracted by a mixture of acetic acid and ethanol (1:9 v/v). The mixture filtered and the extract was concentrated on a water bath. Concentrated ammonium hydroxide was added dropwise to the extract until the precipitation was complete. The precipitate was collected, washed with dilute ammonium hydroxide and then filtered. The residue is the alkaloid, which was dried and weighed then expressed as mg/g dw.

Estimation of saponins

Saponin content was estimated quantitatively by the method described by Hiai et al. (1975) in the methanolic extract. Aliquot of 0.5 ml extract was mixed with 0.5 ml of 8% vanilline. The mixture was placed in an ice bath and mixed with 5 ml of 72% H_2SO_4, then heated in a water bath at 60 °C for 10 min followed by cooling in the ice-cold water bath. The content of saponins was calculated as mg/g dw using a standard curve by cholesterol.

Total tannins determination

The tannin contents of methanolic extracts were determined by method of Broadhurst and Jones (1978) using tannic as a standard. Aliquot of 400 µl extract is added to 3 ml of 4% vanillin in methanol and 1.5 ml of concentrated HCl. After 15 min of incubation the absorbance was read at 500 nm. Tannin content was calculated as mg/g dw.

Total terpenoids determination

Aliquot of 1.5 ml chloroform was added to 200 µl extract, the mixture was vortexed well, then 100 µl conc. H_2SO_4 were added and incubated at dark for 2 hs. The supernatant was decanted and 1.5 ml of 95% methanol was added, followed by vortexing until all the precipitate dissolved completely and the absorbance was measured at 538 nm. Total terpenoids were calculated using a standard curve prepared by linalool and expressed as mg/g dw (Ghorai et al., 2012).

Statistical analysis

Results were statistically analyzed by one-way ANOVA using Costat under Windows software. Significant differences among accessions were calculated by Duncan's multiple range test at 0.05%. Results were represented as mean of three replications ± standard deviation (SD).

Results

Table 1 shows the physical properties of soil samples collected from *M. oleifera* various growth habitats (accessions). A highly significant change was observed in electrical conductivity (EC) as a measure of soluble salts in the soil and salinity level. The uppermost EC value was quantified for S4 and S1 soil samples (897 and 860 µS/cm, respectively). Meanwhile, the lowermost values were observed in soil samples of S3 and S2 (335.3 and 345.7 µS/cm, respectively). As for soil reaction, the results showed that S1 soil was slightly acidic (6.9), S2 was exactly neutral (7), however S3 and S4 soils were marginally alkaline (7.2).

Table 1. *Physical properties (EC and pH) of soil samples collected from growth accessions of M. oleifera trees in Jeddah city*

No	EC (µS/cm)	pH
S1	860.0±7.0c	6.9±0.2a
S2	345.7±0.6b	7.0±0.0ab
S3	335.3±0.6a	7.2±0.1c
S4	897.0±1.0d	7.2±0.1bc

The concentrations of various heavy metals (Cr, Pb, Cu, Fe, Mn and Zn), as well as some essential elements (P, Ca, Mg and K) in addition to Na in the soils and leaves of *M. oleifera* collected from four differentially polluted habitats, S1-S4, in Jeddah city, KSA significantly varied (*Table 2*).

Table 2. *Mineral analysis of soil samples and M. oleifera leaves (ppm) exposed to different pollution intensities in Jeddah city*

Metal concentration (ppm)	Soil samples				Leaf samples

Difference in heavy metals transport from soils to leaves of *M. oleifera* was remarkable. The most pronounced concentration of metals in soil samples was recorded for Pb, Cu and Mn in S2 soil (3.63, 1.97 and 26.4 ppm, respectively), Cr and Fe in S1 soil (1.15 and 865.0 ppm respectively) and Zn in S3 soil (3.10 ppm). The results indicated that soil S4 is less contaminated with heavy metals than the rest of the soils under study. For essential elements, it has been proven that S1 soil was the richest with P and Ca (23.14 and 296.0 ppm, respectively) and S4 soil was the richest with Mg and K (726.8 and 116.0 ppm, respectively). However, the highest Na concentration was more remarkable in S3 soil (25.47 ppm).

Estimation of heavy metals and essential minerals in *M. oleifera* leaves distinguished trees grown in S2 accession (heavily polluted by flaming fires, factories waste and random waste disposal) as highly accumulative for these elements. The most prominent concentration in S2 leaves was observed for Pb, Cu, Fe, Mn, Zn, P, Mg and Na (1.95, 0.29, 18.0, 2.3, 6.4, 20.89, 147.30 and 83.73 ppm, respectively). However, the most prominent concentration of Ca and K was observed in S1 and S3, respectively (60.80 and 90.20 ppm). Therefore, *M. oleifera* could be used as a biomarker for air and soil pollution in heavily polluted areas like S2 one.

The ambient air and soil pollution profoundly affected photosynthetic pigments concentration in *M. oleifera* leaves. Chlorophyll a content significantly lowered in S2, S3 and S4 accessions (3.90, 3.31 and 3.65 µg/g dw, respectively) comparable to S1 (4.71 µg/g dw) (*Fig. 1*). The most pronounced reduction in Chl a was observed in leaves of S3. For Chl b, the same result was attained, as S1 was higher than other accessions (1.61 µg/g dw). The least Chl b content was observed in S2 and S4 (1.41 and 1.40 µg/g dw, respectively). In contrast to chlorophyll, carotenoids recorded the highest content in S2 leaves (1.46 µg/g dw).

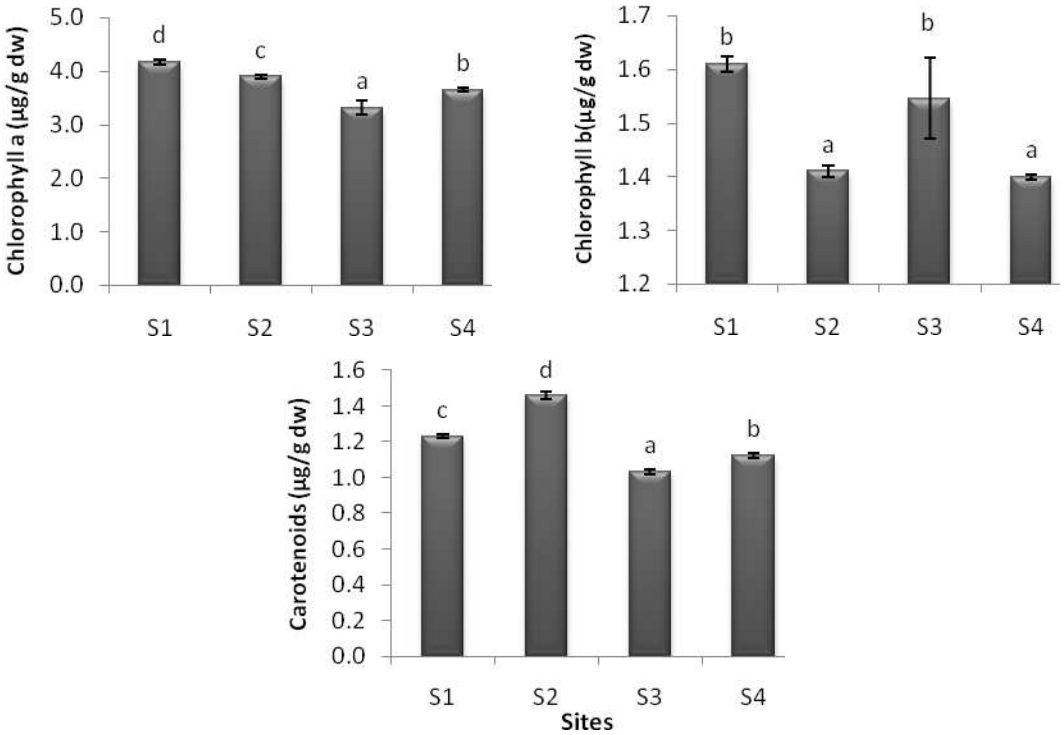

Figure 1. *Photosynthetic pigments of M. oleifera leaves (µg/g dw) exposed to different pollution intensities in Jeddah city*

Total soluble sugars content in *M. oleifera* leaves was profoundly varied with the growth site (*Fig. 2*). The uppermost sugar content was detected in S4 leaves compared to other accessions. However, the least sugar concentration was in leaves of trees growing in S1 (77.6 mg/g dw). The same pattern of sugars concentration was perceived for total soluble proteins in the studied accessions. As for total lipids, the leaves of trees growing in S1 and S4 recorded the least content (58.0 and 61.5 mg/g dw, respectively), whereas those of S2 and S3 recorded higher levels (77.0 mg/g dw).

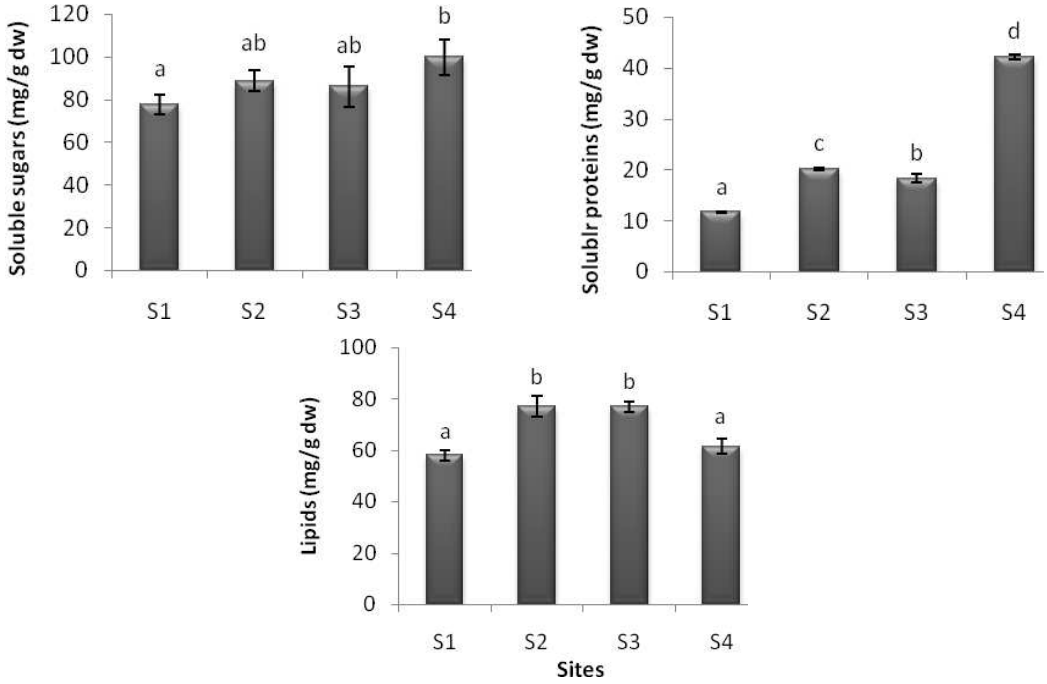

Figure 2. *Total soluble sugars, soluble proteins and total lipids of M. oleifera leaves (mg/g dw) exposed to different pollution intensities in Jeddah city*

Data in *Figure 3* illustrate the non-enzymatic antioxidant activities of *M. oleifera* leaves growing at different accessions in Jeddah city (KSA), represented in flavonoids, ascorbic acid and total free radical scavenging activity (DPPH). The highest flavonoids content (5.76 mg/g dw) was ascertained in S2 leaves, however the least content (2.57 mg/g dw) was in S1. Ascorbic acid level ranged from lower value (19.11 µmol/g dw) in S3 to higher value (23.68 µmol/g dw) in S1 leaves. Free radical scavenging (DPPH) activity differed in plant leaves with the difference in growth position. The most pronounced DPPH activity (35.7%) was detected in S4 leaves, meanwhile the least activity (24.7%) was recorded in S1 leaves.

Accumulation of free amino acids, phenolic compounds and alkaloids in *M. oleifera* leaves in response to pollution intensity in four geographical accessions in Jeddah city is summarized in *Figure 4*. Total content of free amino acids oscillated between 61.9 and 187.0 mg/g dw in the studied plant leaves. Accumulation of free amino acids was more pronounced in S2 (highest value), nevertheless the least content was detected in S1 leaves. Study results revealed a significant difference among study accessions in *M. oleifera* leaves phenolic content. The highest phenolic content was detected in the leaves of S4 and S2 (78.39 and 76.75 mg/g dw, respectively), however the lowermost

© 2018, ALÖKI Kft., Budapest, Hungary

content was in leaves of S1 (39.29 mg/g dw). For alkaloids content, the change with the growth accession was highly significant. Accession S2 recorded the maximum rate of alkaloids accumulation (51.0 mg/g dw) in *M. oleifera* leaves, while accession S3 showed the lowest alkaloids content (25.0 mg/g dw) in *M. oleifera* leaves.

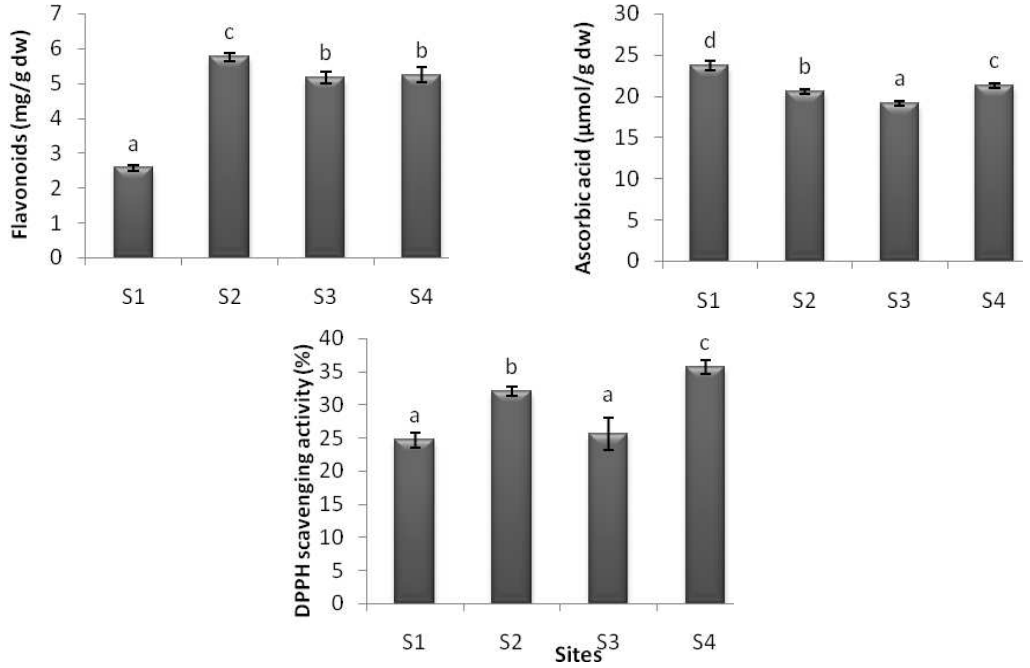

Figure 3. *Non-enzymatic antioxidant activities of M. oleifera leaves (flavonoids, ascorbic acid and DPPH activity) exposed to different pollution intensities in Jeddah city*

Variation in the content of some secondary metabolites (saponins, tannins and terpenoids) in *M. oleifera* leaves with the change in the intensity of air and soil pollution in Jeddah city, KSA, is represented in *Figure 5*. The heavy pollution in S2 by flaming fires, factories wastes and random waste disposal caused the accumulation of saponins in *M. oleifera* leaves with the uppermost value (21.3 mg/g dw) throughout this study. In contrast, the lowermost accumulation of saponins (11.6 mg/g dw) was documented in S2, which is exposed to air pollution by automobile exhaust. Tannins and terpenoids content was significantly varied with growth habitat from lowest value (4.35 and 1.59 mg/g dw, respectively) in S3, to highest one (6.06 and 5.90 mg/g dw, respectively) in S1.

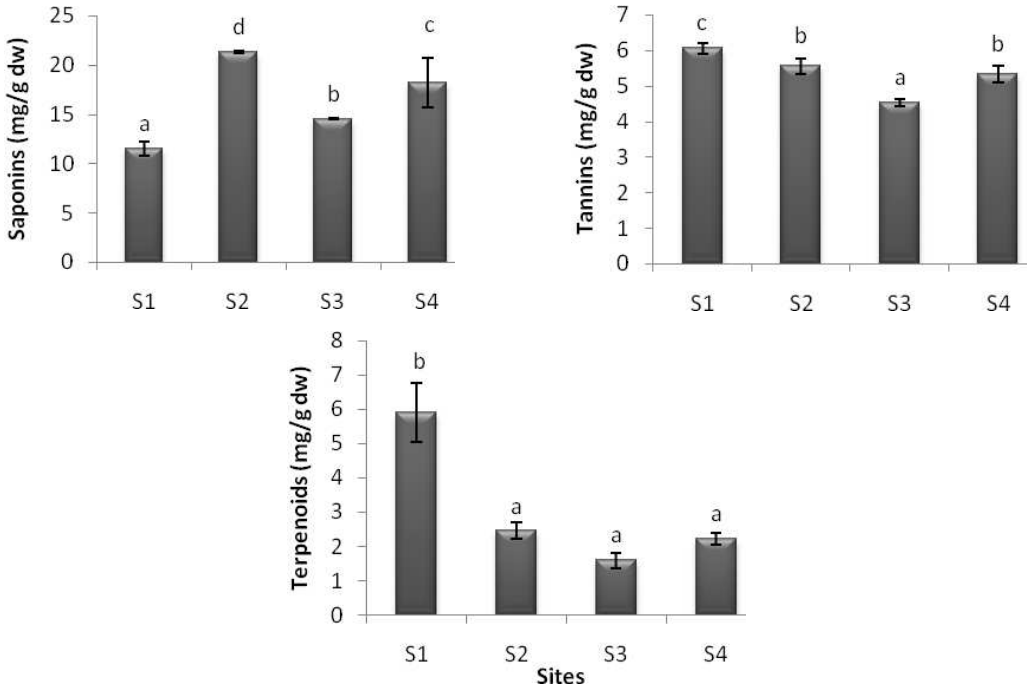

Figure 5. *Variations in secondary metabolites (saponins, tannins and terpenoids) content (mg/g dw) of M. oleifera leaves exposed to different pollution intensities in Jeddah city*

Discussion

The crisis of environmental pollution is one of the most important challenges facing man in our time. After the industrial revolution in the nineteenth century, the sources of water, air and soil pollution increased, which had a profound impact on the biosphere in which humans, animals and plants live. At the end, all sources of pollution affects human health negatively, either directly or indirectly. The plants are considered to be the most important indicators of evidence of pollution occurrence, and also contribute significantly to the removal of some environmental pollutants. In the present study, *Moringa oleifera* tree growing in differentially polluted habitats in Jeddah city, KSA was used as indicator on air and soil pollution. The variation in pollution intensity had significantly affected mineral content, photosynthetic pigments, primary and secondary metabolites and antioxidant status of *M. oleifera* leaves.

The present study showed that S2 soil (the most polluted site due to flaming fires and factories waste disposal) was more polluted with toxic metals as Pb, Cu and Mn. In the

© 2018, ALÖKI Kft., Budapest, Hungary

same time, trees growing in that area accumulated incredible quantities of heavy metals like Pb, Cu, Mn, Fe and Zn in their leaves. Anthropological activities release large amounts of pollutants due to industrial effluents leading to pollution of ground water through the infiltration by soil which is a major issue (Vasanthavigar et al., 2012). Presence of heavy metals in soil and water can cause bioaccumulation affecting the entire ecosystem and pose harmful health consequences to all life forms. The main effects of these metals are inhibition of seed germination, hindering growth and production, affecting the yield of crops and viability of soil microflora (Sethy and Ghosh, 2013).

Photosynthetic pigments of *M. oleifera* leaves were affected by the pollution intensity of the growth site. Chlorophyll a content significantly affected within study accessions, the highest Chl a content was recorded in S1 (double public road exposed to automobile pollutions). Such results are in agreement with those obtained by Giri et al. (2013), who reported that air pollution significantly lowered Chl a content in *Azadirachta indica*, *Mangifera indica*, *Nerium oleander* and *Dalbergia sissoo* leaves. On the other hand, S4 and S2 leaves showed the least Chl b content. This result suggested that Chl b was more sensitive to air pollution than Chl a in *M. oleifera* leaves. Accordingly, the reduction in Chl b content was compatible with the results of Giri et al. (2013) who concluded that polluted sites have less Chl b content than non-polluted ones. Such reduction in Chl b content in air-polluted sites could be attributed to the accumulation of some metals in leaf tissues that increase chlorophyll degrading enzymes activity, inhibit chlorophyll synthesizing activity, or replace Fe and Mn ions in chloroplast proteins reducing their activity. In addition, the non-neutralized heavy metal ions stimulate formation of an excess of free radicals and slow down the turnover of chloroplasts proteins, mostly D1 protein (Lin and Aarts, 2012).

Carotenoids accumulation in plant leaves is a stress marker in most plant species. Carotenoids recorded the highest content in S2 leaves of *M. oleifera*. As a normal consequence of air and soil pollution, generation of free radicals and active oxygen species is stimulated. To prevent the deleterious effects of these oxygen species, plants have developed antioxidative mechanisms to detoxify such molecules. Carotenoids accumulation in response to heavy metals was observed by (Pinto et al., 2011) in *Gracilaria tenuistipitata* macroalga as they play crucial role in membrane stability, specially thilakoid membranes, as well as being natural antioxidants.

Soluble sugars and proteins were significantly lowered in heavily polluted accessions, comparable to those less polluted. Such result is in agreement with those obtained by Tzvetkova and Kolarov (1996), who concluded that decrease in total sugar content of in polluted sites could be attributed to the photosynthetic inhibition or stimulation of respiration rate. Also, decrease of soluble sugars could be an indicator of starch hydrolysis disturbance or altered carbohydrate metabolism in metal and gaseous polluted sites. The reduced carbon and sugar metabolism due to heavy metals and air pollutants might result from their probable interaction with ribulose-bisphosphate carboxilase active centre (Stiborov'a et al., 1987). The reduced protein content in polluted area could be attributed to impairment of pollutants with nitrogen metabolism or disruption in protein synthesizing enzymes. Such findings are in agreement with those of Rai (2016), who attributed that the enhanced rate of protein denaturation and breakdown of existing protein to amino acids are the main causes of protein reduction in response to air pollution. In addition, prolonged exposure to environmental pollutants results in depletion of the antioxidant enzymes as a result of oxidative damage to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

biological molecules, such as protein and DNA (Bebianno et al., 2005). Furthermore, heavy metals disorder protein metabolism either by forming complex with functional side chains or by substituting essential metal ions in metalloproteins (Tamás et al., 2014).

High pollution level in S2 and S3 accession resulted in higher levels of total lipids accumulation in plant leaves comparable to other ones. The same result was obtained by Nouairi et al. (2006) in *Brassica juncea* plants exposed to cadmium stress. They attributed this to the increase in vacuolar area where toxic metals are frequently stored. Previous work of Djebali et al. (2005) revealed variable effects of heavy metals on different fatty acids, as they have negative impact on α-linolenic acid proportion, while other fatty acids were affected positively.

Our results revealed that the highest flavonoids content was found in the heavily polluted (S2) leaves. The results are in accordance with those of Robles et al. (2003) who reported that total flavonoids accumulation was indicator on ozone pollution in *Pinus halepensis* growing at five different polluted areas. Also, *Betula pubescens* leaves in strongly polluted areas significantly accumulated variability of some phenolics which might related to the effect of environmental contamination on shikimate and phenyl-propanoid pathways (Loponen et al., 2001). Such increase in flavonoids content could be associated with its defensive role under conditions of environmental stress.

Variations in ascorbic acid level with growth accession were not effective. Previous work of Zengin and Munzuroglu (2005) showed that metal-treated (lead, copper, cadmium and mercury) bean seedlings showed significant higher ascorbic acid content. Such increase in ascorbic acid in polluted areas could contribute in raising the antioxidant capacity of stressed plants. Heavily polluted areas (S2 and S3) showed moderate DPPH activity, however less polluted areas showed oscillation in DPPH activity. The variation in total antioxidant activity between growth accessions could be attributed to the variable response of plant leaves to pollution intensity, in addition to the selective impact of contaminant kind on the antioxidant molecules.

The highest leaf free amino acids content was accounted for *M. oleifera* growing in S2 accession (most polluted). The increased accumulation of amino acids under metal toxicity might be due to its role in detoxifying heavy metal through making complexes with it, consequently assisting in the protection of the leaf and photosynthetic machinery from heavy metal injury (Rascio and Navari-Izzo, 2011). A leading mechanism in metal detoxification is the chelation of metals by metabolites rich in -SH groups. Hence, the content of non-protein thiols, which include thiol-rich peptides, glutathione, or other -SH rich compounds. A recent work of Nadgórska–Socha et al. (2017) demonstrated that thiol-containing amino acids content in *Robinia pseudoacacia* and *Taraxacum officinale* leaves were higher in the high traffic and emission regions.

Phenolic content in the leaves of *M. oleifera* only slightly differed between the various contaminated study sites. The uppermost phenolic content was detected in the leaves of S4 and S2. Mir et al. (2009) reported that total flavonoids and phenolics in *Catharanthus roseus* and *Ocimum sanctum* may serve as biomarkers of urban auto pollution as they showed a positive relationship with the vehicular pollution load. Rai et al. (2007) have also reported significant increase in total phenol contents in wheat under air pollution stress. Increase in phenolics under environmental stresses was monitored in many plant species as they play a crucial role in defense mechanisms against ROS damage.

With respect to alkaloids accumulation, accession S2 recorded the maximum rate in *M. oleifera* leaves. These results are consistent with those obtained by Singh et al. (2000), who reported that alkaloid content of *Datura innoxia* was considerably accumulated in various plant organs in response to coal-smoke pollution. They attributed the increase in alkaloid content to a chemical adaptation or a defensive/protective strategy under stress. Alkaloids accumulation under stress conditions was reported in various plant species as *Senecio longilobus* (Briske and Camp, 1982), *Lupinus angustifolius* (Jansen et al., 2009) and *Achnatherum inebrians* (Zhang et al., 2011).

On the same pattern, the heavy pollution in S2 caused the accumulation of saponins in *M. oleifera* leaves comparable to other study sites. Szakiel et al. (2011) reviewed that plants belonging to the same species in different geographical zones may differ significantly in their content of secondary metabolites. This phenomenon was observed in many saponin-containing plants, including *Panax ginseng*, *Panax quinquefolius* and *Panax notoginseng*. The accumulation of saponins and other secondary metabolites in response to environmental factors is a part of an adaptive strategy leading to enhanced tolerance (Ramakrishna and Ravishankar, 2011). Nevertheless, tannins and terpenoids along this study showed variable accumulation in response to pollution intensity.

Conclusion

Trees and plants in the surrounding environment are considered the lungs of our life, on which most other organisms rely to obtain oxygen and energy. Civilization and urban life have become a major burden on the environment as a result of pollution of water, air and soil. In this study, *Moringa oleifera* trees growing in differentially polluted accessions in Jeddah city, KSA, showed that the intense pollution has a deleterious impact on the metabolic machinery and the physiological processes of the trees. As a responsive mechanism in heavily polluted accession, *M. oleifera* showed a diminution in chlorophyll, soluble sugars, soluble proteins, ascorbic acid, and terpenoid contents. On the other hand, lipids, flavonoids, amino acids, alkaloids and saponins were accumulated in the tree leaves.

(Received 26th Mar 2018; accepted 25th May 2018)

Abstract. Agricultural production seems to hold the key to economic growth and development in the developing nations of the world. The study focused on the socioeconomic determinants of rural household's arable crop production in Ogun State, Nigeria. The specific objectives of this study were to estimate the gross margin of the farmers and determine the effect of their gender resource on food crop production in the study area. Multistage sampling technique was employed to select 210 respondents as population of the study. Budgetary analysis was used to determine their profit margin while Tobit regression analysis was modeled to determine the effect of household's gender resource(s) on food crop output. The result shows that 54.30% of the respondents have no formal education, 66.7% male and an average household size of 7 persons. Also, a mean age of 51 years and an average farm size of 9 hectares were derived in the study. Furthermore, the budgetary result revealed that food crop production is profitable with Gross margin of ₦205107.20/ha ($564.457/ha). Tobit regression result shows among others that gender of the household's head has a significant influence on output of the farm ($P < 0.05$). The study therefore recommended the provision of labour saving techniques to encourage female farmers in agricultural production in the study area.
Keywords: *gender resource, gross margin, socioeconomics, Tobit regression*

Introduction

The improvement in agricultural production is a result of more efficient use of the factors or production, viz physical, socio-economic, institutional and technological. The role of agriculture in economic development of most countries can hardly be overemphasized, the contribution of agricultural growth to overall poverty reduction has been documented (Sarris, 2005). A retrospective look into the Nigerian economy and its development reveals that agriculture was both the main stay of the Nigerian economy and the chief foreign exchange earner (Nwaiwu et al., 2017). In the 1960s, agriculture accounted for well over 80% of the export earnings and employment; about 65% of the GDP (gross domestic product) and about 50% of the government revenue (FRN, 2000). This contribution to the Nigerian economic growth has however declined over the years.

The contribution of agriculture to the GDP was about 50% in 1970 and 34% in 2003 (CBN, 2003). Although agriculture no longer serves as the leading contributor to

Nigeria's gross national product and leading foreign exchange earner due to phenomenal growth in the petroleum sector of the economy, agriculture is still the dominant economic activity in terms of employment and linkages with the rest of the economy (Adebile and Amusan, 2011). The principal constraint to the growth of the agricultural sector is the fact that the structure and method of production have remained the same since independence more than four decades ago (Ukeje, 2005). The United Nations Food and Agriculture Organization rate the productivity of Nigeria's farmland as low to medium— but with medium to good productivity if properly managed (Parukayo and Umaru, 2012). To be effective, and attain higher level of productivity and growth in the agricultural sector there is a need to identify the major factors that determine its growth.

Agricultural production thus seems to hold the key to economic growth and development in developing countries. It is expected to stimulate increased crop production and growth into marketable surpluses, improve income earnings and employment opportunities, and enhance nutritional status, health care and household welfare in general. It is also expected to create changes in gender roles, imbalances within the household and a shift in the allocation of the resources available within the household. These changes will affect males and females differently in terms of costs and benefits generated and the efficient utilization of the household Resources. This necessitates the need for the incorporation of gender perspectives into development programmes. This is because gender related differences are expected to influence activity diversification and income generation in the household.

Problem statement

Farming activities in tropical Africa has always been dominated by rural women who grow a substantial amount of the staple foods, yet, they still have much less access to knowledge, technology, credit and land than their male counterpart (Adewumi and Omotesho, 2002). African women on small scale rain-fed farms produce up to 70-80% of the domestic food supply in most sub-Saharan African societies (WHO, 2003). On average, they also provide 46% of the agricultural labour. However, women's yields are too low by Green Revolution Standards (3 to 4 tonnes per hectare for food grains), and much lower than men's yields in societies where a comparison can be made (for example, where men grow the same crops on different fields or where yields of female headed households can be compared to those of male headed households).

Gender differences in productivity have been shown to be due to differences in the intensity of use of productive inputs (such as fertilizer, manure, land and labour, credit, extension training, and education) rather than in differences in the efficiency or management styles of men and women (Ganiyu and Omotayo, 2017). Because rural farmers faced problem of cash and/or credit to acquire modern yield-increasing inputs of production, they tend to produce less, and more of their crops are consumed within the family (Rahji, 2007). In Nigeria, the Structural Adjustment Programme (SAP) also tended to disproportionately burden women. The removal of subsidies, which have caused a rise in input prices, and liberalization measures, which have resulted in a flood of cheap imports, have further harmed local food producers, especially women farmers (Rahji, 2007).

Estimates by (Ukeje, 2005), show that if productive inputs like fertilizer, manure and labour could only be reallocated within the African household in some societies the results could mean an increase in the value of household output in the range of 10-20%.

In response to the widespread gender disparity in terms of access to farm credit and technical logistics in rice production, the government of Nigeria has introduced pro-gender special crop interventions like block farms. In view of the above problems, this research will try to find answer to the following research questions such as how do we measure the gender impact of household resource allocation on agricultural production and what is the gross margin of food crop farmers in the study area?

Objective of the study

The general objective of the study is socioeconomic determinant of household food crop production in Ogun State, Nigeria. The specific objectives of the study are to:

1. Describe socio-economic characteristics of food crop farmers in Ogun State, Nigeria
2. Estimate profitability of food crop farmers in the study area
3. Determine the effect of household gender resource on food crop production

Hypothesis of the study

The hypothesis of the study stated in null form:

HO_1: There is no significant difference between female farming hour and male farming hour in agricultural production in Ogun state.

Materials and methods

Methodology

The study was carried out in Ogun State in South Western Nigeria because of her agricultural production pedigree. Ogun state is located in the south-west corner of Nigeria and was created in 1976 by the then Federal Military Government from the old western region (*Fig. 1*). It is neighboured by Oyo, Ondo, Lagos, Edo and Delta States. It is situated within the tropics and derives its name from the big "River Ogun". The state lies between 7°01' and 7°18' N and between 2°2'and 3°55' E. It has a tropical climate with rainforest vegetation on its southern part and a derived savannah on its northern end. It has an estimated land area of 16,409.26 km^2. The estimated human population is 3,751,140 (2006 population census) and it is characterized commercially by a dual economic focus, the bourgeoning industrial sector and a dominant agricultural sector. The study populations were mainly rural farming households who engaged in food crop production in the study area.

Sampling procedure and sample size

Sampling technique for this study was based on the four Agricultural zones by the Ogun state Agricultural Development Programme (OGADEP). These are Abeokuta, Ikenne, Ilaro and ijebu zones. Multistage random sampling technique was employed to select a total of 210 farming household in the study area. First stage involved the random selection of two zones which are Abeokuta and Ilaro. Second stage involved random selection of three (3) and two (2) blocks from each of the two ADP zones respectively. Stage three involved a random selection of four (4) cells from each of the blocks. While the last stage involved random selection of eleven (11) farming households from each of the cells. But a total of 210 sampled data were used for this

study. Primary data were collected in 2014 from food crop farmers using structured questionnaire and interview schedule. Data were analysed by frequency count, percentage, mean, budgetary and Tobit regression analysis using Stata 11.

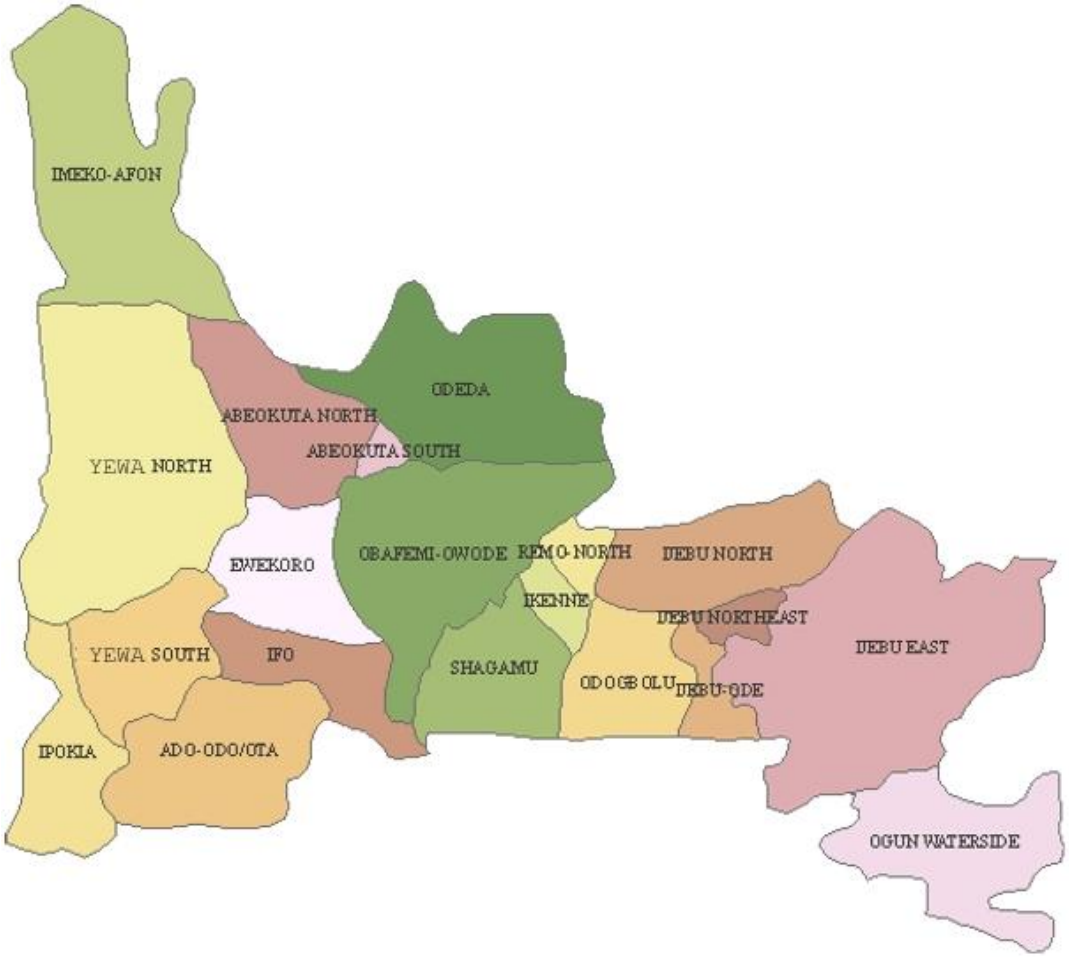

Figure 1. *Map of Ogun State showing local government areas*

Results and discussion

Socioeconomic characteristics of respondents

Socioeconomic factors of the respondents comprise of personal attributes of the respondents are presented in *Table 1*. Majorities (66.7%) of the respondents are male and 33.3% are female. In addition, majority (55.2%) of the respondents were married, this indicates that the respondents are adults and people who have mature orientation of life. Also, 4.8% of the respondents were single and about 30.0% of them had no formal education. This is quite a large proportion in this century as the implication of these results could be that higher number educational year is known to have a positive influence on the ability of the farmers (Omotayo, 2016). The household size as shown in *Table 1* revealed that 1.0% have household size that is less than 3, 46.6% of the respondents have household size that is less than 7, 49.5% of the rural farmers have household size that is greater than 6 and 2.9% of the rural farmers have household that is greater than 10. This is support of the findings of (Adelekan and Omotayo, 2017).

Also, the duration of years spent on farming indicated that 22.9% have spent between 1-10 years in farming with mean farming experience of 23 years. Majority (54.3%) of the respondents rural reported that their spouse had no formal education, 31.4% had primary education and 11.4% had secondary education while 2.9% of them had tertiary education with mean farm size of 9 hectares.

Budgetary analysis of farming households

The budgetary result for farming system of the farming household in the study area was presented in *Table 2*. The Total Variable Cost per hectare (TVC/ha) for food crop production such as maize, cassava, vegetable and pepper was estimated at ₦77131.80/ha ($212.268). Furthermore, Labour cost, Transportation cost, cost of planting materials, cost of herbicides, cost of fertilizer and cost of tractor service was accounted for 41.5%, 2.1%, 5.6%, 5.8%, 11% and 34% of the Total Variable Cost of production, respectively. This implies that labour constituted the larger proportion (42.0%) of Total Variable Cost of production of food crop farmers in the study area. Furthermore, Total Revenue (TR), Gross Margin (GM) for food crop production were estimated at ₦282239.00/ha ($ 789.114) and ₦205107.20/ha ($564.460) respectively in the study area. This implies that food crop farmers perform better in terms of margin between total revenue and total variable cost of food crop production.

Table 2. *Cost-return structure of food crop farmers in the study area. (Source: Field Survey, 2014)*

Variables	Value (N)	% of total variable cost
Revenue		
Value of maize	122255.00 ($336.447)	
Value of cassava	104654.00 ($288.009)	
Value of other	55330.00 ($154.697)	
Total revenue	**282239.00** ($789.114)	
Variable cost items		
Labour cost (N)	32037.00($89.5724)	41.535
Transportation cost	1639.80($4.51275)	2.126
Cost of planting materials	4290.00($11.8061)	5.562
Cost of herbicides	4454.00($12.4530)	5.775
Cost of fertilizer	8511.00($3,044,090)	11.034
Cost of tractor service	26200.00($9,370,840)	33.968
Total variable cost	**77131.80($215.653)**	
Gross margin	**205107.20 ($573.460)**

Parameter estimates of the Tobit regression

Table 3 below showed the result of Tobit regression to determine the effect of explanatory variable on the output of food crop farmers in Ibarapa Central Local Government Area of Oyo State. The Marginal effects of the independent Variables were estimated because they are very important for decision making. Among 14 variables considered in the model, Ten (10) were found to be statistically significant which includes gender, farm size, farm, fertilizer, planting materials and herbicide. All the coefficients have the expected sign. The parameters estimates of the Tobit regression of food crop farmers showed that farm size, fertilizer, hired labour, gender were positively significant at 1% respectively while male labour hour was positively significant at 5% confidence level. This implies that 1% increment in these variables will increase the farmers output by 15.7, 2.8, 0.01, 2.3 and 1.5 respectively. Also, herbicide, female off time and female labour hours were negatively significant to farmers output in the study area at 1%. The implication is that the herbicide was over utilized and female does not really contribute significantly to agricultural production in the study area.

Table 3. *Parameter estimates of the Tobit regression. (Source: Field Survey, 2014)*

Measurement of mean difference between male labour hour and female labour hour in agricultural production

The measurement of mean differences between female labour hours and male labour hours was accomplished with the use of t-test of difference of mean and the result is presented in the *Table 4*. It was based on the hypothesis that there is no significant difference between male labour hours and female labour hours contributing to farming

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_36273635
© 2018, ALÖKI Kft., Budapest, Hungary

output in the study area. The results of the t-test showed that there is a significant difference between the male labour hour and female labour hours. This implies that male contribute more to farming output than their female counterpart in the study area. Therefore, the null hypothesis was rejected. This implies that there exist a variation in their respective contribution to farming output in the study area which was also buttressed by the result of Tobit regression.

Table 4. *Mean difference of between male and female farmer's labour hours. (Source: Field Survey, 2014)*

Category	Mean hour	Standard deviation	Number	t-value	Decision
Male labour hours	6.304541	0.9423509	105	7.6096	Reject H_O
Female labour hours	7.647619	1.990268	105		

Discussion

Various empirical works on household contribution on agriculture such as (Omotayo and Oladejo, 2016; Dipeolu et al., 2009; Ukeje, 2005): reported that male respondents are more involved in agricultural production than their female counterpart. This could be due to the nature of the job as well as the laborious nature of the rural agriculture in the study areas. Furthermore, labour constituted the larger proportion (42.0%) of Total Variable Cost of production of food crop farmers in the study with Total Revenue (TR), Gross Margin (GM) estimated at ₦282239.00/ha ($789.114) and ₦205107.20/ha ($573.460) respectively in the study area. Also, parameters estimates of the Tobit regression of food crop farmers showed that farm size, fertilizer, hired labour, gender were positively significant at 1% respectively while male labour hour was positively significant at 5% confidence level. Also, herbicide, female off time and female labour hours were negatively significant to farmers output in the study area at 1%. Ukeje (2005) was in the opinion that food crop output is proportional to gender of the household head, farm size, agrochemical used and labour cost.

Conclusion

The findings of this study revealed that majority of the farmers are still in their active age, married and are therefore expected to be productive for available resources. Also, food crop production is profitable in the study area. Furthermore, the Tobit regression shows that male contributes more to agricultural production than female in the study area because majority of the female in the study area venture most of their time on household core and agricultural marketing than food crop production. Based on the study findings and conclusions, the following recommendations are made:

1. The research on labour saving techniques for agriculture in the study area should be initiated to as to improve their production.
2. There should be incentive to encourage female farmers in agriculture.
3. Farm expansion policy that will make agricultural land available to households should be made and this will impact positively on food crop production in the study in Ogun state and Nigeria in whole.

(Received 24th Feb 2018; accepted 21st May 2018)

Abstract. Organic wastes are utilized as source of nutrients to grow vegetables and reduce environmental degradation. This research aimed to study influence of different concentrations of organic waste extracts (Goat Manure Extract, GME; Banana Peel Extract, BPE) as T_o: 0% GME and BPE (control: irrigation water), T_1:1% GME, T_2: 2% GME, T_3: 3% GME, T_4: 3% GME + 1% BPE, T_5: 3% GME + 2% BPE on morphological and nutritional traits of loose-leaf Lettuce through hydroponic experiment at Gilgit city in Pakistan. The number of leaves, fresh weight, dry weight, carbohydrates, fat, fiber, calcium, phosphorus, sodium, potassium, chromium, thiamine, niacin, and energy were higher by 74, 7, 72, 13, 157, 100, 6, 15, 9, 4, 33, 150, 68, 53 and 52%, respectively, under T_5, whereas protein, ash, iron and riboflavin were greater by 86, 200, 105 and 292%, respectively, under T_4 compared to T_o treatment except moisture contents. Number of leaves, leaf fresh weight, leaf dry weight, and leaf moisture are strongly related to and are good predictors (R^2 = 0.67-0.97) of energy production from Lettuce. Integrated utilization of organic waste extracts (T_4-T_5) increased Lettuce leaf yield components and its nutritional value for human consumption.
Keywords: *banana peel, goat manure, minerals, nutrients, organic extracts, vitamins*

Introduction

Organic hydroponic production of leafy vegetables under controlled environment is one of the most appropriate technologies to accomplish human food requirements in soilless mountainous and urban areas. This production technology is economically viable to curb food insecurity in urban and rural hardship locations (Croft et al., 2017). Organic productions are preferred owing to inherent health benefits and lack of side effects for human body. Agricultural wastes (farmyard and fruits) are abundantly produced worldwide. Improper management and utilization of these wastes result in environmental degradation and the spreading of diseases (Manahan, 2005). These organic wastes especially manures and fruit peels (banana) serve as potential sources of macro- and micronutrients for crop production (Golabi et al., 2004; Kowalska et al., 2017). Under conventional soil based methods of vegetable production, success of accepted organic

© 2018, ALÖKI Kft., Budapest, Hungary

fertilizer component is dependent on soil decomposer which convert these wastes into useable form of nutrients which are absorbed by plants (Clark et al., 1998). Hydroponic production technology provides an opportunity to grow diverse type of leafy and fruity vegetables using organic sources of plant nutrients (El-Kazzaz and El-Kazzaz, 2017).

Leafy vegetable like Lettuce (*Lactuca sativa* L.) is an annual crop having fibrous root system that survives under diverse temperature situations (Manolopoulou and Varzakas, 2016) and respond to nitrogen levels positively (Gonzalez et al., 2016). It is a rich source of nutrients, minerals and vitamins for human body (Roy and Chakrabarti, 2003; Orech et al., 2007). The vegetable is being grown hydroponically in greenhouses using both salt based fertilizers and organic extracts (Rosik-Dulewska and Grabda, 2002). Though, greenhouse vegetable production is an intensive system mainly used in commercial farming (Kittas et al., 2013). This cultivation is achieved through modifying nutrient medium to optimum levels through testing and comparing different manure extracts. In hydroponics, nutrients which are required for plant growth are provided directly while eliminating needs for soil and soil organisms completely. Direct nutrition results have been noted in the form of higher growth rates and yields compared to soil cultivation (Raviv and Lieth, 2008). But consumers want to buy produce which is not tainted with hazardous chemicals or poisons as result of inorganic methods of nutrition.

Merits and demerits are associated with both organic and salt-based fertilizers. In salt-based fertilizers, nutrient concentration per unit weight is higher, availability is uniform and immediate, and precision of nutrient analysis is rapid compared to organic fertilizer. Mineral nitrogen is productive three-fold more than an organic nitrogen source (Masclaux-Daubresse et al., 2010). Yields were not different for a range of vegetables produced with organic N fertilizers compared to inorganic N fertilizers (Fabio et al., 2007). Gradual diminishing resources of world shows concerns about disadvantages of salt-based fertilizers. This includes excessive energy needs for formation, pollution due to mining and processing, and potential dwindling of finite resources of phosphorous and potassium (Fischer, 1986). The main disadvantage to salt-based fertilizers is that these are synthetically prepared which means the composition of material is chemically or genetically changed by combining, extracting or refining through human activity. Comparatively, organic fertilizers derived from animal or plant wastes are utilizable and recyclable (Elamin and Elagib, 2001). Moreover, organic produce has greater sale price compared to conventional produce (Sgroi et al., 2015). The nutritional value of organic foods compared to traditional ones is twofold the elemental composition on fresh weight basis (Matt et al., 2011; Orman and Kaplan, 2017). Hence the objective of this research was to explore and evaluate prospect of utilization of organic wastes of banana peel and goat manure as source of nutrients for hydroponic production of loose leaf Lettuce vegetable in food insecure soilless mountainous and urban areas.

Material and methods

Experimental site and layout

Research was conducted from March 25 to June 10, 2016 inside a greenhouse (GH) of 16 ft width (bottom), 8 ft height and 40 ft length located at Karakoram International University, Gilgit, Pakistan, having coordinates of 35.91 Latitude and 74.31 Longitude (*Fig. 1*). Temperature remained inside GH was between 20 and 30 °C and was greater by a few degrees compared to outside. Average relative humanity was remained around 65%. Inside GH structure, eighteen sets each made of PVC pipe (3 ft) fitted on an iron

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_36373648
© 2018, ALÖKI Kft., Budapest, Hungary

stand and were arranged to accommodate six treatments with three replications. Within each set, pipe was connected with water inflow pipe and a drainage pipe using connection pipes. Each pipe is closed on both ends with cups and had inlet on one end and an outlet on the other end. Each treatment set was connected with main pipes for supply of water at top and with a drainage pipe at bottom. Main water supply pipe was connected to water storage tank where water supply was controlled with a valve, while drainage pipe served as an outlet from the GH. Each small piece of pipe within a treatment set had five holes to accommodate a gutter containing growth medium (perlite) to anchor a Lettuce plant. Water flow from the tank was maintained to each set (treatment) at the rate of 0.5 L per minute (*Fig. 2*).

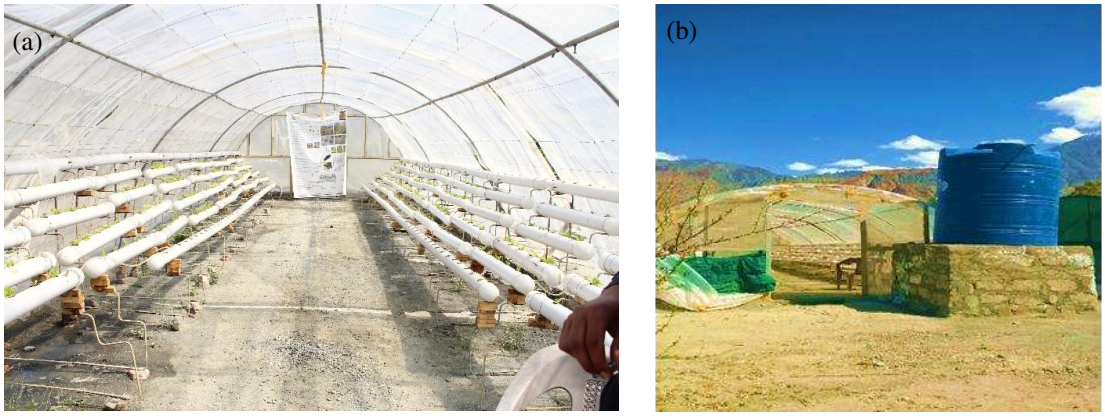

Figure 1. *Experimental site (a: inside; b: outside) for hydroponic production of loose leaf lettuce under greenhouse condition*

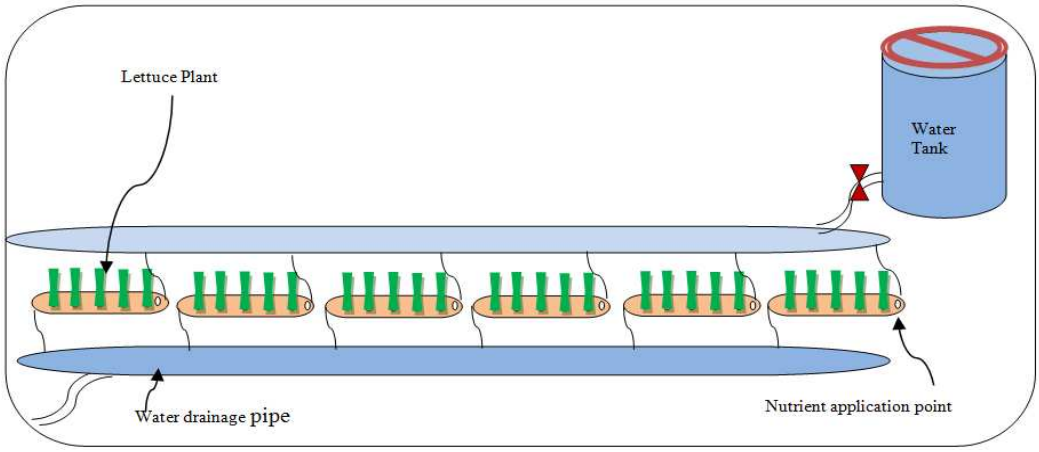

Figure 2. *Schematic diagram of hydroponic system for lettuce production*

Pre-experiment nutrient solution preparation

Two types of extracts were prepared one from goat manure (GM) and the second from Banana peel (BP). Banana peel of fully matured fruit (yellow colored with black spots) was procured from market and goat manure was obtained from a goat farmer in composted condition. Five kilograms of each organic material was boiled into 20 L of

© 2018, ALÖKI Kft., Budapest, Hungary

water in a container over a gas stove till a concentrated solution of 5 L after filtration was obtained.

Experimental organization and management

Experimental plant loose-leaf Lettuce (*Lactuca sativa* var. crispa) of family Asteraceae was seeded in five pots placed in five holes of a pipe of 3 ft long. Six concentrations prepared from concentrated extracts of GM and BP (T_o: 0% GME/BPE, T_1: 1% GME, T_2: 2% GME, T_3: 3% GME, T_4: 3% GME + 1% BPE, T_5: 3% GME + 2% BPE) in total volume of 0.5 L. These treatments/ concentrations were assigned to eighteen sets randomly on the basis of CRD statistical design. The nutrient formulations (diluted) were applied to assigned treatment sets on alternate days. Treatment concentrations were analyzed for major and some minor plant nutrients i.e., Nitrogen, Phosphorus, Potassium, Calcium, Sodium, Chromium, Iron, pH, and EC using standard methods (*Table 1*).

Morpho-nutritional measurement and analysis

After sixty-five days of seeding, leaves of three plants of Lettuce were harvested from each replicate leaving behind the root portion. Number of leaves was counted and fresh weight of leaves was taken. Thereafter, harvested leaves were kept in an oven to dry at 105 °C till constant weight. Dry weight of the leaves was measured using an electronic balance and moisture contents were computed. The dried samples from each replicate were ground and sieved. Powdered triplicate samples were analyzed for proximate and mineral composition for nutritional evaluation of food material in accordance with AOAC (2000). Further, the samples were examined for vitamins, i.e., Thiamin, Riboflavin, Niacin, and Ascorbic acid. Thiamine and riboflavin were found by quantitative analysis as described by Hucker et al. (2011), Niacin was investigated by colorimetric method (Kawila, 2011) and Ascorbic acid (Vitamin C) was found through dichlorophenol Indophenol dye reduction method (Smirnoff, 2000). Kjeldhal method was adopted to find crude protein through determining nitrogen contents of food material. Sohxtech was used to determine crude fat through ether extraction process

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_36373648
© 2018, ALÖKI Kft., Budapest, Hungary

(Thiex et al., 2003). Crude fiber contents were found by acid digestion, alkali digestion and fibertech (Busuttil-Griffin et al., 2015). Ashing of samples was performed in a muffle furnace at 550 °C for 6 hours. For all these determinations powdered and oven dried samples were used in triplicate. Food energy of protein and carbohydrates was derived by multiplying with 4.1 and energy from fat was computed by multiplying with 9.3 (Khalil and Saleemullah, 2004; Arshad and Ranamukhaarachchi, 2012). Analysis of macro-minerals i.e., calcium, phosphorus, potassium, and sodium was carried by digestion of samples with $HClO_4$ and HNO_3 as proposed by Khattak and Rahman (2016) whereas for micro-minerals i.e., chromium and iron, dry ash method was adopted for digestion as described by Abbruzzini et al. (2014). Following the digestion, samples were analyzed for selected minerals using U.V. Spectrophotometer (ORION), Atomic Absorption Spectrometer (VARIAN) and Flame Photometer (SHER WOOD).

Statistical analysis

Data pertaining to number of leaves, leaf fresh weight, leaf dry weight, nutritional composition, mineral contents and vitamins were analyzed using statistical program SAS version 9.0 for one-way Analysis of Variance (ANOVA) and Fisher protected Least Significant Difference (LSD) test was performed to compare treatment means (Gelman, 2005). Pearson Correlation and Regression analysis were performed to know relationship among yield parameters and prediction of energy production.

Results and discussion

Growth and yield performance

Lettuce plant produced number of leaves in the range of 10-18 leaves per plant, leaves fresh weight (LFW) as 239-256 g and leaves dry weight (LDW) as 15-25 g. There was a significant influence of different concentrations (T_o: 0% GME and BPE (control), T_1: 1% GME, T_2: 2% GME, T_3: 3% GME, T_4: 3% GME + 1% BPE, T_5: 3% GME + 2% BPE) of organic extract on number of leaves produced, LFW and LDW. The highest number of leaves per plant (18) was produced under T_5 and reduced ($p = 0.001$) in T_4 and rest of the treatments including control (*Fig. 3A*). The LFW (256 g) and LDW (25 g) of Lettuce were higher under T_4 and T_5 and reduced ($p = 0.001$) in T_3, T_2, T_1, and T_o (*Fig. 3B, C*). Compared to control, yield components of Lettuce were increased with increasing quantity of GME and BPE. Increased supply of extracts carried greater quantity of plant nutrients which have enhanced the yield components of Lettuce. The elements required in trace amounts are easily carried in organic extracts. The results are in agreement with Haggag et al. (2014, 2015) and where a manure compost tea was prepared and utilized for olive seedlings growth. Mowa et al. (2017) also noted increased growth and yield performance of tomato grown on goat manure.

Moisture contents

Leaf moisture of Lettuce was in the range of 90-94% and was influenced significantly due to concentration of organic extracts. It was reduced ($p = 0.001$) in T_1, T_2, T_3, T_4, and T_5 compared to T_o (*Fig. 3D*). Under organic nutrition, moisture in Lettuce leaves was reduced and leaves became more hardy and crispy. Higher moisture in Lettuce leaves causes yellowing and reduces shelf life and market quality.

Nutritional evaluation

Protein, fat, carbohydrates, fibers, and ash contents in Lettuce leaves were in the range of 1.5-2.7, 0.3-0.7, 2.9-3.3, 0.7-1.4, and 0.5-1.5 g, respectively, and were varied significantly under different plant nutrition treatments (*Table 2*). The fat contents were increased ($p = 0.001$) in T_3, T_4 and T_5 (0.8 g) compared to that of T_o, T_1 and T_2 (0.3-0.6 g). Leaf carbohydrates increased ($p = 0.001$) under T_5 compared to rest of the treatments including control. Leaf protein, fibers and ash contents were increased ($p = 0.001$) under T_4 and T_5 conditions compared to rest of the treatments.

Food nutrition of Lettuce leaves was enhanced under higher concentrations of GME and BPE owing to greater efficiency of organic culture carrying high nutritional value. Organic extracts have enhanced bioaccumulation of nutrients. This is in congruence with the findings of Bourn and Prescott (2002), Custic et al. (2003) and Uusiku et al. (2010) where greater nutritional value of organic foods was highlighted compared to conventional inorganic production.

Table 2. *Effect of nutrient extracts of goat manure and banana peel on protein, fat, carbohydrates, fiber and ash contents of lettuce leaves*

Extract concentration	Protein, g	Fat, g	Carbohydrate, g	Fiber, g	Ash, g
T_o: Irrigation water (0% GME/BPE) control	$1.5\pm0.2^{e*}$	0.3 ± 0.0^{c}	2.9 ± 0.1^{c}	0.7 ± 0.1^{d}	0.5 ± 0.1^{e}
T_1: 1% GME	1.8 ± 0.1^{d}	0.4 ± 0.1^{bc}	3.1 ± 0.1^{ab}	1.0 ± 0.2^{c}	1.0 ± 0.1^{d}
T_2: 2% GME	2.0 ± 0.1^{c}	0.6 ± 0.2^{b}	3.2 ± 0.1^{ab}	$1.2\pm.01^{b}$	1.3 ± 0.1^{c}
T_3: 3% GME	2.5 ± 0.1^{b}	0.8 ± 0.1^{a}	3.2 ± 0.1^{ab}	1.3 ± 0.1^{ab}	1.4 ± 0.1^{bc}
T_4: 3% GME + 1% BPE	2.7 ± 0.1^{a}	0.8 ± 0.1^{a}	3.1 ± 0.1^{bc}	1.4 ± 0.1^{ab}	1.5 ± 0.0^{a}

LSD ($p \leq 0.05$)	0.16	0.14	0.17	0.17	0.11

*Different lower-case superscript letters with the column indicate significant difference between the mean values at $p \leq 0.05$

Mineral composition

Calcium, phosphorus, sodium, potassium, chromium, and iron in leaves of Lettuce were in the range of 42-45, 32-37, 4.3-4.7, 58.3-60.6, 0.003-0.004, and 0.83-1.7 mg $(100\ g)^{-1}$ on dry weight basis, respectively, and were significantly influenced under varied plant nutrient management conditions. Contents of all these minerals were higher ($p = 0.001$) under T_3, T_4 and T_5 conditions compared to T_o, T_1 and T_2 treatments (*Table 3*). Compared to control, treatments of organic extracts increased the mineral contents in Lettuce leaves. This shows potential of Lettuce for the take up of minerals supplied by the organic extracts. This is in agreement with the findings of Olle and Williams (2012) where mineral contents were increased compared to soil or inorganic nutrient based cultures.

Vitamins production

Thiamin, riboflavin, niacin and ascorbic acid analyzed in Lettuce leaves were noted in the range of 0.04-0.1, 0.12-0.50, 0.4-0.7, and 7.0-10.7 mg $(100\ g)^{-1}$ on dry weight basis, respectively (*Table 4*). Contents of all vitamins in leaves responded differently to treatment concentrations tested. Contents of thiamin and ascorbic acid were greater ($p = 0.001$) under T_4

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_36373648
© 2018, ALÖKI Kft., Budapest, Hungary

and T_5 compared to rest of treatment conditions. Riboflavin and niacin were higher ($p = 0.001$) under T_3 and T_4 treatments compared to rest treatment environments. Increase of vitamins in organically produced vegetables has also been reported by Matt et al. (2011).

Food energy production

Sum of energy supplied by food items is the ultimate goal that keep human body healthy and active for day to day work. It is a good parameter for comparing and evaluating different food products as beneficial for human health. Total energy production of Lettuce leaves computed from its carbohydrates, protein and fats contents was in the range of 20.7-31.4 calories. Energy value was influenced due to different waste extract concentrations (*Table 4*) and was improved ($p = 0.001$) under T_4 and T_5 treatments compared to T_o, T_1, T_2 and T_3 treatments. Food energy was strongly related with number of Lettuce plant leaves ($r^2 = 0.89$), LFW ($r^2 = 0.82$), LDW ($r^2 = 0.98$) and leaf moisture ($r^2 = -0.98$) (*Fig. 4*). Regression analysis ($r^2 = 0.98$) showed that food energy in Lettuce leaves is predictable using number of leaves, LFW, LDW, and leaf moisture content (*Eq. 1*). The higher nutritional quality of Lettuce leaves makes it better source of food energy as also observed

by Iyaka et al. (2014). Crude carbohydrates, protein and fat contents were quite high in the vegetable samples, thus serve as good source of digestible energy. Furthermore, high potassium, sodium and calcium contents make it good food especially for hypertensive patient as potassium decreases high blood pressure. The proximate and mineral analysis indicates that consumption of Lettuce along with cereals in sufficient quantity could contribute immensely towards attainment of human nutritional needs for normal body growth, development and sufficient protection against diseases caused by malnutrition.

Conclusions

The research results indicated the usefulness of organic extracts of goat manure and banana peel for hydroponic production of loose-leaf Lettuce in soilless mountainous and urban conditions. Lettuce grown under organic extracts had value added characteristics that can be marketed at higher prices. Bioaccumulation of food nutrients, minerals and vitamins in Lettuce leaves has been observed that encompass special significance for human nutrition and health benefits. Furthermore, this research suggests utilization of organic wastes especially goat manure and banana peel for the development sophisticated nutrient solutions for onward application in hydroponic systems. Soilless culture coupled with integrated use of evaluated organic waste extracts appears to be quite successful for gardeners and small farmers for intensive production of leafy vegetables or other high value crops for household use and income generation. It is strongly recommended for further research on use of goat manure and banana peel extracts for other leafy vegetables i.e., spinach, and also research studies on preparation and utilization of other animal and fruit wastes for the production of different leafy vegetables under hydroponic conditions.

Abstract. Streambed vertical hydraulic conductivity (K_v) is a key parameter in the analysis of interactions between streams and aquifers, and that of stream ecosystems. However, the relationship between streambed hydraulic conductivity and stream morphologies has remained untouched. An in-situ standpipe permeameter test method was used to determine the spatial variability in streambed K_v measured along 36 km of stream reach in Ziyarat River, Golestan Province, Iran. To triangulate the data and obtain more reliable results, both rising and falling head methods were used. There was great spatial variability in K_v among the six test reaches and three K_v distribution patterns have been accomplished. Test locations in meandering reaches showed a more heterogeneous distribution of vertical hydraulic conductivity than what was observed in straight reaches. The difference in the K_v of data obtained from meandering reaches was greater than that of the straight reaches which is an indication of a change in the morphology of the river in these reaches due to the erosion and deposition. In other words, morphologic changes of the river in meandering reaches caused evident changes in the streambed which, eventually, caused the erosion and deposition of sediments.
Keywords: *erosion and deposition, groundwater/surface-water relations, geomorphology, hypoheic zone, Iran, geomorphology*

Introduction

Precise measurement of streambed hydraulic conductivity (K_v) is crucial in analyzing the magnitude and extent of water exchange and contaminant transfer between surface water and groundwater. It is even important when coping with a number of geotechnical problems involving the management of groundwater and surface water (Cardenas et al., 2004; Chen et al., 2008; Song et al., 2009; Sebok et al., 2014).

In-stream, the slug test, and the seepage meter coupled with hydraulic gradient measurement, have been widely used. The slug test quantifies only the horizontal hydraulic conductivity. However, it could be employed to specify the permeability of the deeper sediment layer (Chen, 2004; Cheng et al., 2011). The streambed vertical hydraulic conductivity (K_v) is known to constantly vary spatially. It has been found by some studies that the K_v varies greatly along a river transect (Chen, 2005; Min et al., 2013).

In the analysis of the hydraulic relationship between streams and aquifers, the channel morphologic features are key considered as important (Sebok et al., 2014). Variable pressure heads control Hyporheic interaction in the streambed sediments as well as its environmental conditions (Koch et al., 2011).

The interaction of streams and aquifers can be improved by means of growth of meander length and can be decreased by a reduction in river sinuosity (Boano et al., 2006). Because of the transport of fine materials, the hydraulic conductivity of shallow alluvial aquifers under condition of sinuosity-driven hyporheic flow is not fixed (Nowinski et al., 2011). A meandering stream is one of the key sedimentological forms that links the regional aquifers to the streams (Dong et al., 2012). Sebok et al. (2014) showed that there are more variable streambed characteristics in the meandering than in the straight section. The existence of several orders of magnitude in the range of streambed anisotropy values has been seen close to stream banks (Sebok et al., 2013). The water exchange in the main channel can move into slower pools by anabranch diversions, and enhances the exchange process into the subsurface (Koch et al., 2011). A study which combined the K_v and erosion and deposition processes of streambed sediments has been conducted by Genereux et al. (2008) and Levy et al. (2011).

(Jiang et al., 2015) A few studies were conducted on the Biloo River in Shanghai, China in four sites and three different morphologies of hydraulic conductivity (K_v). The data were limited to a small area of the river – around 40 to 50 m of the river which were either straight or meandering. In this study, larger reaches were selected to gain more reliable results. For instance, several bends existed in a meandering reach. To better understand the morphologic effects of the river on the hydraulic conductivity (K_v) of the streambed, the reaches were selected from three parts of the river: upstream, midstream, and downstream. This was done in order to investigate reaches that represent all parts of the river.

In another research conducted by Lopez et al. (2015), the scholars have gathered over 50 samples from Wadi Khulays dune field, located in western Saudi Arabia, while they also measured the parameters, including grain size distribution, porosity and hydraulic conductivity. They attempted to modify the Beyer equation by adding a parameter linked to the mud concentration and for quantifying the fitting parameter, an inverse optimization process was applied. The obtained equation was promising in predicting the saturated hydraulic conductivity, as its estimations present the lowest error of any empirical equation.

Previous studies recommended that there are many effects on hydraulic conductivity such as stream morphology and geomorphology attributes, river- bed forms, erosion and deposition process, and the riverbed sediments. The knowledge of the streambed hydraulic conductivity for different stream mmrophologies relatively is, however, scarce. The present study investigates the spatial variability in streambed K_v spanning 36 km of stream reach in the Ziyarat River, Golestan Province, Iran. An in-situ field standpipe permeameter was utilized to collect 189 total measurements using 6 test sites in 2 stream morphologies: one in the straight stream channel and one in meander reach. All sediment samples were collected after the K_v tests and they were used for grain-size analysis.

This study had three objectives: (1) investigating the hydraulic conductivity (K_v) of the streambed from upstream to downstream; (2) finding the morphologic effects of the river, including the meandering and straight forms, on the hydraulic conductivity (K_v) of the river from upstream to downstream; and (3) analyzing the sediment grain size in

© 2018, ALÖKI Kft., Budapest, Hungary

straight and meandering reaches and examining the relationship between sediment grain size and hydraulic conductivity (K_v). (4) Finding the best empirical methods used to estimate hydraulic conductivity based on the grain-size distribution.

Materials and methods

Study area

Ziyarat River, originating from Alborz mountain range, is located in Golestan Province, which is a northeastern area in Iran. It flows to the north and after 36 kms, merges into Gharesoo River. The drainage basin in upstream is about 100 km^2 with dimensions of 19.64 km in length and 5.11 km in width. The mean of water abstraction rate at stream gauge is about 10.5 m^2. The selected six reaches were all covered by these three categories (*Fig. 1*). The study area is located in a temperate climate. The mean of annual precipitation is equal to 601 mm, and mean temperature is 13.4 °C. The variation in seasonal precipitation is distinctive and not uniform. The temperature of stream water ranges from 19.04 to 29.2 °C. Although, the weather is rainier in winter, the majority of floods occur from August to November. The streambed sediments were alluvial coarse, sand-gravel, and clay and silt in downstream. The highest height of Ziyarat stream gauge is 3068 m and the beginning of main river is 2620 m. The length of the river to Naharkhoran is 21 km with the slop average rate of 10.1% and the remainder of river to Ghorbanabad is 15 km with the slop average rate of 4.6%.

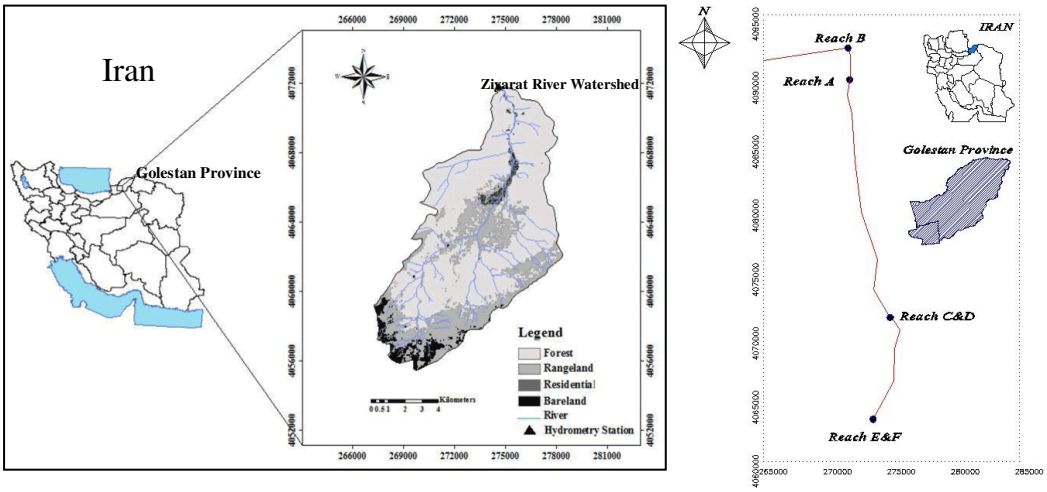

Figure 1. *The location of the study area along the Ziyarat River*

Reach selection

The basis of the triple division follows Leopold and Wolman (1957) which, arbitrarily, identified the rivers with a bend coefficient (sinuosity index) larger than 1.5 as meandering and the ones with a bend coefficient lower than 1.5 as straight rivers. We first explain how reaches were determined in this study and then discuss the way we divided each reach into straight and meandering forms.

For each reach, the following field protocol was used to estimate reach hydraulic conductivity using point measurements (Datry et al., 2014). The length of the reach was around 200 to 220 m and, then, each reach was divided into 10 equal parts using the 11

© 2018, ALÖKI Kft., Budapest, Hungary

transverse sections which had a distance of twice the size of the wetted width from each other. The hydraulic conductivity is obtained from three parts of these 11 sections: the left, center and left sides.

As mentioned above, the straight reach was determined by the sinuosity index which is varied between 1 and 1.5. In addition, the meandering reach was identified by using a sinuosity index of 3 to 4.5 (Gordon et al., 2004). Six reaches were selected in this study: two from the upstream, two from midstream, and two from downstream (*Table 1*). To better investigate the relationship between the hydraulic conductivity and morphology of the river, the selected reaches were straight and meandering. Therefore, in the upstream, one reach is straight and one is meandering. The same can be applied to the reaches in the midstream and downstream.

Vertical hydraulic conductivity

A falling-head test is conducted by rapidly raising the water level in the control well and subsequently measuring the falling water level. Slug-in test is another term for falling-head test. A field permeameter method has been adopted for measuring vertical hydraulic conductivity in previous studies (see e.g. Genereux et al., 2008; Song et al.,

2010; Dong et al., 2012). The purpose of this method is to determine the streambed hydraulic conductivity (K_v), and as it is illustrated in *Figure 2,* it operates by vertically inserting a pipe into the streambed, filling the pipe with water, and calculating the amount of decline of the water level inside the pipe. After repeating this process for a few times, the K_v can be measured using this rate. In the present study, steel standpipe with an inner diameter of 4.8 cm and length of 120 cm was used. The pipe was injected into the sediments of the streambed and ensured that the length of the sediment column was nearly equal to 40 cm. A sensor (Onset HOBO Water Level-U20L-Series) with an accuracy of 1 mm was also employed to measure the water levels. Water was added during the test at the top of the pipe to create a hydraulic head. Then, the head was passed to fall in the pipe. In the current research, a water-level declining interval of 1 cm was used to record the hydraulic head and time. The hydraulic head estimations were obtained more than 3 times.

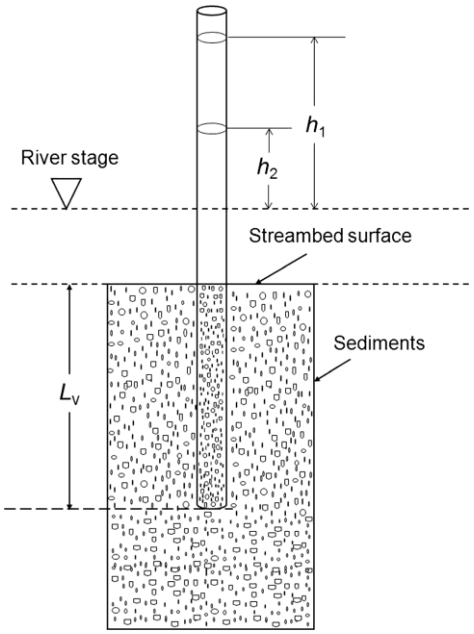

Figure 2. *Schematic diagram showing an in situ permeameter test to determine streambed*

To measure the K_v value using the equation proposed by Hvorslev (1951), all pairs of measured data of hydraulic head and time were used based on *Equation 1.*

$$K_v = \frac{\frac{\pi D}{11m} + L_v}{t_2 - t_1} ln(h_1/h_2) \quad \text{(Eq.1)}$$

where D denotes the inner diameter of the pipe, m denotes the square root of the ratio of the horizontal conductivity K_h represents the vertical conductivity K_v (i.e., $m=\sqrt{\frac{Kh}{Kv}}$), L_v refers to the length of the sediment column, h_1 and h_2 are hydraulic head inside the pipe measured at times t_1 and t_2, respectively. Overall, K_h is greater than K_v. An adapted Hvorslev solution has been proposed by Chen (2004) and Song et al. (2009) in order to specify the K_v when L_v is greater than D:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_36493668
© 2018, ALÖKI Kft., Budapest, Hungary

$$K_v = \frac{L_v}{t_2 - t_1} ln(h_1/h_2) \quad \text{(Eq.2)}$$

However, the error in K_v from the formula provided by the adapted Hvorslev equation (*Eq. 2*) is connected to the ratio (L_v/ D) of the estimated sediment length (L_v) to the inner diameter (D) of the steel pipe. When $1 < m < 5$, if the ratio (L_v/D) is greater than 5, the error of the adapted estimation will be less than 5% (Chen, 2004).

Moreover, to triangulate the data, the rising-head method was used. A rising-head test is initiated by rapidly lowering the water level in the control standpipe and then taking measurements of the rising water level in the standpipe. The Pneumatic Hi-K Slug provides high-quality data for accurate slug testing of hydraulic conductivity (K_v) (*Fig. 3*).

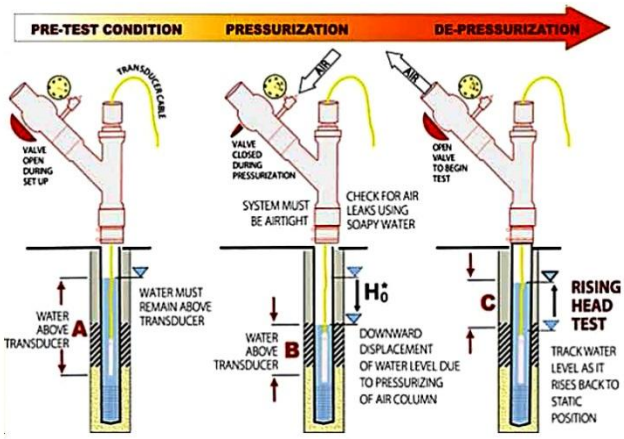

Figure 3. *Anatomy of the pneumatic slug test*

The following instruments were used: Pneumatic 'HI-K' SLUG from Midwest GEOSCIENCES group, Onset HOBO Water Level-U20L-Series, and Universal Optic-USB Base Station.

The experiment was once accomplished using the falling-head method and once using the rising head. Finally, the values of hydraulic conductivity obtained from these two methods were compared and in the cases where there were significant differences, the K_v obtained from the rising-head method was retained. The method of KGS and BOWER was employed particularly for the up and midstream where the K_v was high.

Sediments sampling

Due to limitations in analyzing grain size of sediments for all the 189 data, we decided to delimit the sampling from the streambed for each reach to 9 samples using systematic sampling. In other words, 54 samples from six reached were chosen. Indeed, the nine samples opted (*Table 1*) for sediment sampling were a portion of the 33 points which were measured (*Fig. 4*)

Three points which were selected for each reach were obtained from the middle, right, and left sides (transverse). These three points were located at the beginning, in the middle and at the end of each reach.

Hand Operated Auger instrument was used to sample and transfer undisturbed sediments. Due to sediments resistance and coarseness, common instruments could not properly enter streambed sediments and, particularly, seal. This justifies our employed instrument in this study that was used in hyporheic zone (40-45 cm bellow the river surface). As a result, this led the whole auger to move into streambed sediments. Eventually, the samples were sent to Golestan Province soil mechanic laboratory. Moreover, for measuring hydraulic conductivity based on particle-size distribution (PSD), the 54 sets of soil samples were collected. To estimate particle size distribution (grain size curve), AASHTO-T27 method was applied. The finest sieve size was 0.075 mm and the largest one was 9.5 mm. Particle size < 0.075 mm was grouped into silt and clay, particle size between 0.075–2.0 mm into sand, and particle size > 2.0 mm into gravel (Song et al., 2010).

Figure 4. *Principle of the sediment sampling method*

Normality test

A Kolmogorov-Smirnov test was employed to check whether the distribution of the data was normal or not. This test was conducted using SPSS version 22.0. If $p < .05$, it rejects the null hypothesis that the K_v value does not belong to the normal or lognormal distribution. However, it accepts that the K_v values belong to the normal distribution if $p > .05$.

The results, as displayed in *Table 2*, showed that the values for reach B did not have a normal distribution while the reaches of A, D, and F had a normal distribution. In addition, the reaches of C and E were not normally distributed although their values were close to the significance level for normality. All the 189 data were not normally distributed as indicated by the Kolmogorov-Smirnov test. However, when they were classified into reaches, the results indicated that some of them were normal.

As the extracted data for K_v were in the quantitative form (Ratio Data) and their distribution was approximately normal, while the number of these samples was greater than any other group (33 samples from each group) and only a quantitative variable of six groups was compared with each other, hence we used One-Way ANOVA to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_36493668
© 2018, ALÖKI Kft., Budapest, Hungary

compare the mean of the data at different reaches. First, a comparison was made between the groups in term of variance, so called Test of homogeneity of variance and it was observed that the associated variances were not identical ($P < 0.05$). Therefore, unequal variances tests were used for making a comparison between the mean of six groups; for this purpose, Dunnett tests were utilized. As a result, the obtained significance level was equal to $P < 0.05$, hence the H_0 hypothesis was rejected, while H_1 hypothesis was confirmed with 95% confidence, implying that there is a significant difference between the K_v mean for six reaches level.

Table 2. *Results of the Kolmogorov-Smirnov test for the six reaches*

Test site	Kolmogorov-Smirnov Test Sig.	Number of data
Reach A	0.2	33
Reach B	0.000	33
Reach C	0.047	33
Reach D	0.2	33
Reach E	0.048	33
Reach F	0.102	33

Therefore, the six reaches were analyzed through one-way ANOVA. *Table 3* shows that there was not any significant difference between the reaches of C and D. Similarly, no significant difference was observed between the reaches of E and F. The correlations between the other reaches were, however, significant.

Table 3. *Result of one-way ANOVA for comparing six reaches*

	Reach A	Reach B	Reach C	Reach D	Reach E	Reach F
Reach A	-------	*	*	*	*	*
Reach B		-------	*	*	*	*
Reach C			-------	√	*	*
Reach D				-------	*	*
Reach E					-------	√
Reach F						-------

Results

The values of K_v in the 189 measured data for six reaches of the streambed were between 0.109(m/d) and 152.37(m/d). According to *Table 4*, overall, the highest value of K_v, as expected, was found in the upstream within reach F, which was a meandering type of reach. The least amount of hydraulic conductivity was obtained in downstream in reach B, which is also a meandering type. To better analyze the hydraulic conductivity in these six reaches, K_v was obtained for 11 intervals which had a distance of 20 m. In fact, in each reach, the K_v was measured once in the middle of the streambed, once in the right side, and once in the left side of the streambed. Therefore, from each reach of the streambed in the total 11 intervals, 33 data of hydraulic conductivity were obtained.

Table 4. *Statistics for K_v values from permeameter tests*

	Range (m/d)	Mean (m/d)	Median (m/d)	Std. error of mean	Std deviation
Reach A	0.245-4.860	1.798	1.632	0.235	1.351
Reach B	0.109-5.041	0.687	0.233	0.204	1.172
Reach C	71.48-142.2	104.55	105.68	2.57	14.76
Reach D	63.56-125.56	102.46	103.99	2.604	14.6
Reach E	73.76-146.67	118.56	122.47	3.304	18.98
Reach F	63.01-152.37	118.96	122.25	3.66	21.05

Reach A

Geographical position of reach A is presented in *Table 1* which illustrates that this reach is located in the downstream. This reach has a straight form and since the grains of the sediments in the streambed are tiny, the hydraulic conductivity has been low, within the range of 0.245(m/d) and 4.86(m/d), as shown in *Table 4*. The distribution of the data was normal, and the results also showed that the mean of K_v in the middle of the streambed is more than the right or left sides of it as shown in *Table 5*. In addition, the mean of the data in the middle of the canal is closer to the first quarter.

Table 5. *Mean of K_v values for three sides test reaches*

	K_v (left)	K_v (center)	K_v (right)
Reach A	1.700	2.68	1.01
Reach B	1.098	0.549	0.414
Reach C	97.79	113.75	102.11
Reach D	110.56	103.064	93.76
Reach E	114.89	127.36	113.43
Reach F	128.68	119.40	108.81

Reach B

Reach B which is a meandering type of reach, is located in downstream, as mentioned in *Table 1*. It was previously highlighted that the K_v obtained from this reach did not have a normal distribution. Since this reach was in the lower side of the streambed, its range of K_v was remarkably such low that it was between 0. 109 (m/d) and 5.041 (m/d), and its mean was 0.687 (m/d), as shown in *Table 4*. As it was illustrated in *Figure 5b,* the rate of changes to the hydraulic conductivity in the left side of the streambed was more than the middle and right side of it. The grains of the sediments were mostly made of silt and clay which, in some parts, acted like an impermeable layer.

Reach C

This reach was located in the middle part of the streambed and had a straight form. Its geographical position is described in *Table 1* According to *Table 4,* the range of changes of K_v is between 71.48 (m/d) and 142.2 (m/d) which shows a permeable layer. Moreover, the median and mean of K_v data in the middle of the streambed are more

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_36493668
© 2018, ALÖKI Kft., Budapest, Hungary

than the left and right sides of it (see *Figure 5c*). The mean of K_v, as shown in *Table 4*, is 104.55. Although the data were not normal, its distribution was close to normal (see *Table 2*).

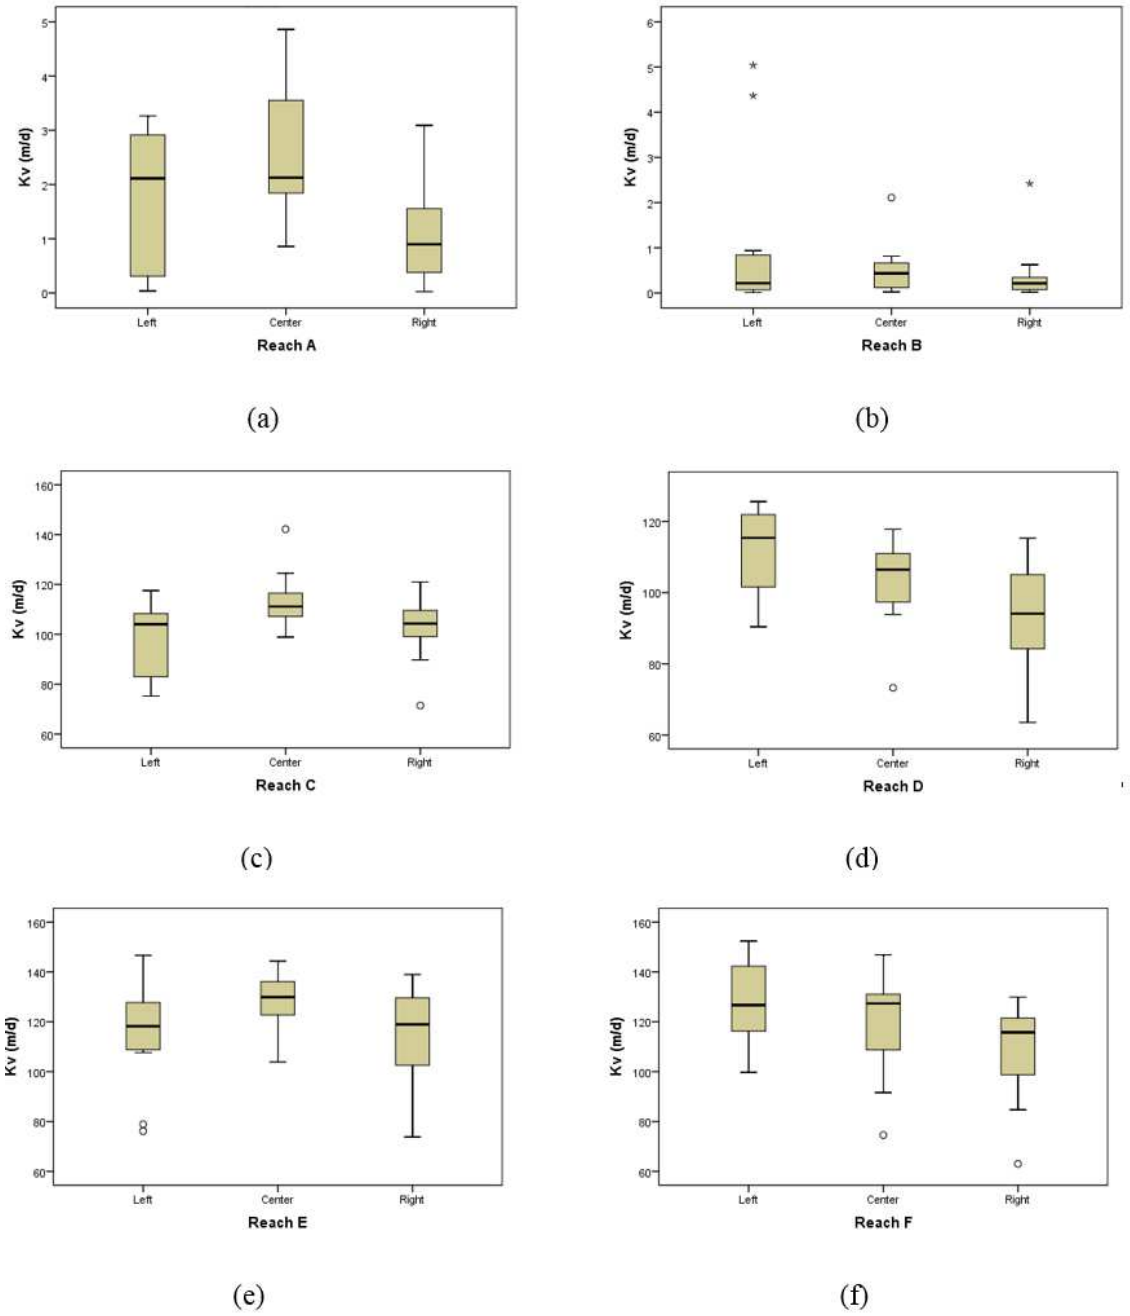

Figure 5. *Box plots of streambed K_v for each test reach*

Reach D

This reach, which has a meandering shape, is located at the geographical position of *Table 1*. The range of K_v, as shown in *Table 4,* is between 63.56 (m/d) and 125.56 (m/d) and the mean of the K_v of the streambed is 102.46 (m/d). In addition, the mean of the K_v in the left side of the streambed is more than the right side. According to what is shown in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_36493668
© 2018, ALÖKI Kft., Budapest, Hungary

the box plot, the range of the changes of the K_v in the right side of the streambed is more than the other two parts. The data were normally distributed, as indicated in *Table 2*.

Reach E

This reach of the river, which has a straight shape, is located in the upper part of the river. The range of the changes of K_v (*Table 4*) is between 73.76 (m/d) and 146.67 (m/d). Moreover, the K_v for the riverbed is equal to 118.56 (m/d). The results indicated that the K_v for the streambed in the middle part of the river is more than the other two parts. The range of the changes in the middle part, however, was less than the other two sides. This range, as displayed in *Fig. 5e*, has decreased the normality of the data, though they were so close to normality. The plot of frequency (*Fig. 6e*) shows the normality of the data.

Reach F

This reach of the river, which has a meandering shape, is located in the upper side of the river and based on *Table 1*, the range of its changes is between 63.01 (m/d) and 152.37 (m/d) (*Table 4*). Also, (*Table 5*)shows that the hydraulic conductivity (K_v) in the left side of the river is more than the other two sides. Similarly, the range of hydraulic conductivity in the left side is higher than the middle and right sides of the river (see *Fig. 5f*). The distribution of the data was also normal, as demonstrated in the frequency plot (see *Fig. 6f*).

Grain size analysis

Grain size is the main controlling factor for streambed hydraulic conductivity (Song et al., 2010). After investigating the six reaches, it became evident that the physical features in the downstream and, in particular, the meandering reach (Reach B), were different from the other reaches, as shown in *Table 6*. The sediments in the bed of these two reaches (A and B) were completely small and consisted of silt and clay (*Table 6*).

The average distributions of grain size in sediments are significantly different at each position of the channel at all the tested reaches (*Fig. 7*).

It becomes evident after comparing the data and distributions of K_v values (*Table 4*) collected from In situ permeameter tests at each position (L/C/R) at all test reaches that a higher average value of cumulative percentage in weight of silt and clay (< 0.075 mm) is correlated with higher hydraulic conductivity.

According to *Table 5*, the process of erosion in the left side of the channel is stronger than in the right side. Erosional areas mainly occur in the left towards the central channel which has caused the mean K_v in the left side of the reach to be more than the right side. Therefore, the mean of the grain size in the left side of the reach is expected to be more than the right side (*Fig. 7b*). In fact, in Reach A, the central area has more erosion than the left or right sides, and it is shown that the erosional process increases from the center bank to the right and left banks. The hydraulic conductivity in the middle part of reach A is more than the other parts and this is directly related to its larger grain size. For better analysis of the 54 sediment samples, obtained from six selected reaches of the entire riverbed, we were obliged to determine the percent of sediments particles size in accordance with *Table 6*. *Table 6* is useful for gaining an insight into the impact of erosion and sedimentation on hydraulic conductivity within

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_36493668

six reaches, resulted from difference between the morphological properties of the reaches, from upstream till downstream.

Table 6. *Sediment grain size distributions for the 54 samples collected*

Particle size	Test reaches					
	Reach A	**Reach B**	**Reach C**	**Reach D**	**Reach E**	**Reach F**
% < 2 mm	58	100	40.8	47	40.8	42.1
Average value of < 0.075 mm cumulative percentage in weight	2.7	18	1.11	2	1.12	1.4
Average media d_{50} (mm)	1.2	0.17	3.1	2.1	3.1	2.9

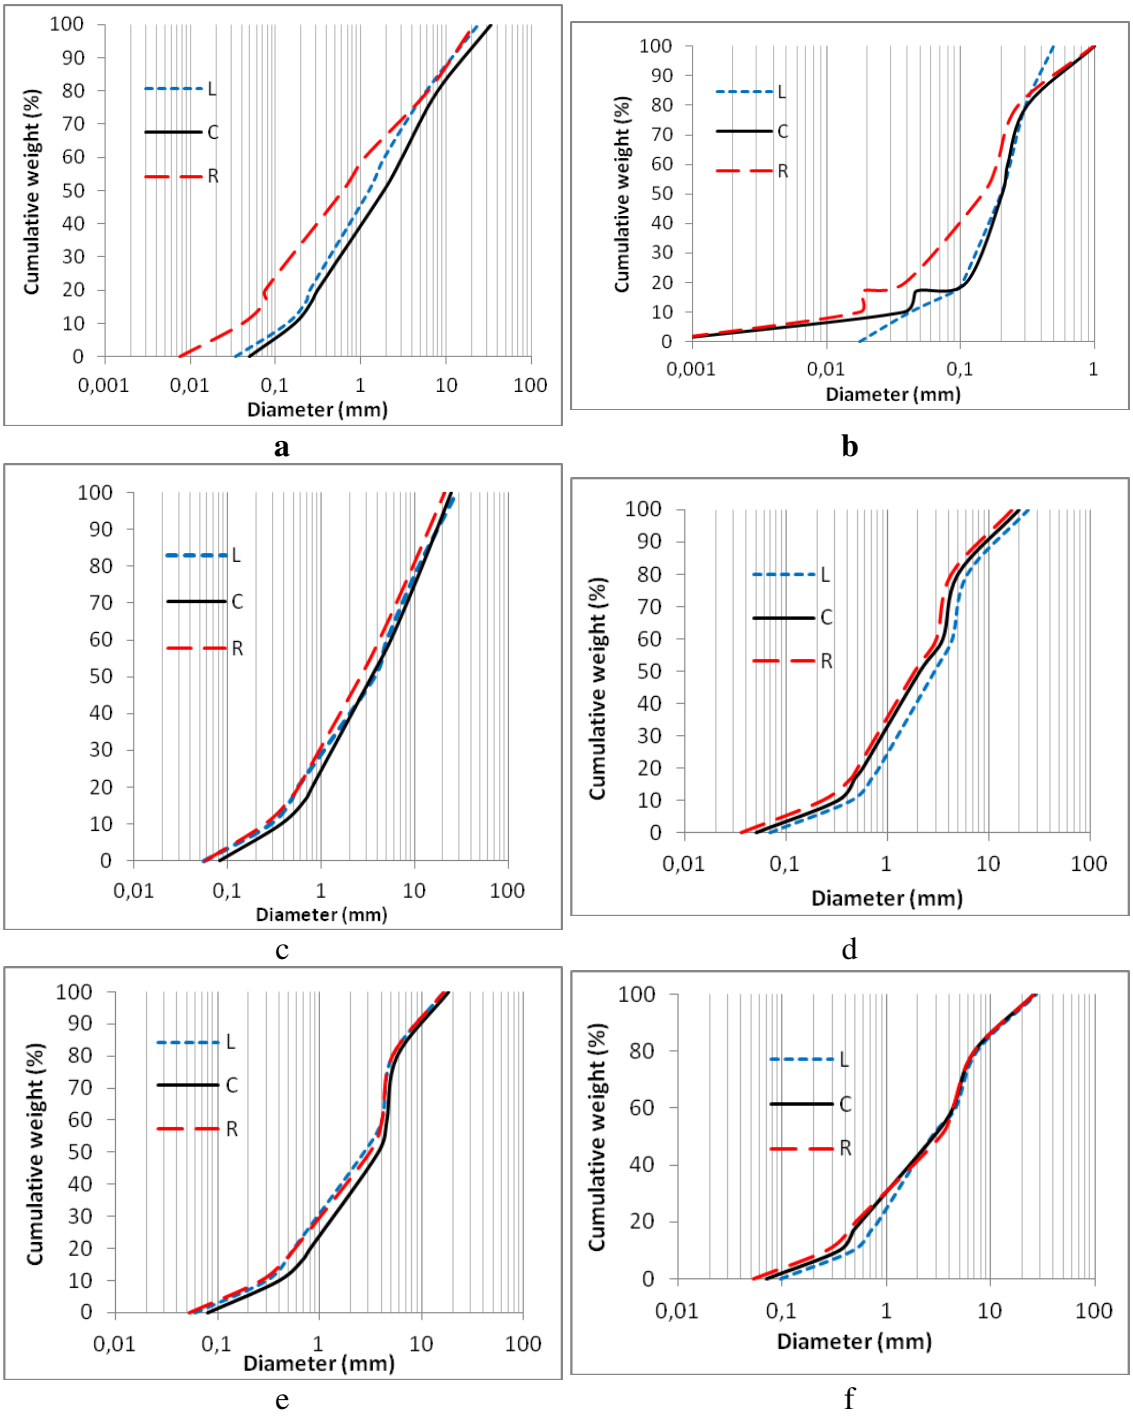

Figure 7. *Average grain size distributions of streambed from each test reach along the Ziyarat River.* ***a.*** *Straight reach A,* ***b.*** *Meandering reach B,* ***c.*** *Straight reach C,* ***d.*** *Meandering reach D,* ***e.*** *Straight reach C,* ***f.*** *Meandering reach F*

This difference can be attributed to the difference between meandering reaches and straight reaches, such that with more erosion in the left parts of the reach due to the curvature of the streambed. This difference affects the grain size of the sediments and, eventually K_v.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

When the particles in the upstream are compared with the ones in the downstream, it becomes evident that the larger grains exist in the upstream and the smaller ones exist in the downstream and even the silt and clay particles (<0.075 mm) cover the whole river in this part. This could be a reason for the high hydraulic conductivity (K_v) in the upstream and a low hydraulic conductivity (K_v) in the downstream as well as the impermeability of the streambed in the downstream. To better understand this issue, the correlation between K_v and d_{10} was investigated. d_{10} is the soil particle diameter (mm) such that 10% of all soil particles are finer (smaller) by weight.

Correlation between K_v and grain size

The statistical analysis of the values of K_v and the grain size of the sediments in the streambed showed that the K_v had the highest correlation with d_{10} and d_{60}.

Where d_{10} and d_{60}, are the soil particle diameter (mm) that 10% and 60% of all soil particles are finer (smaller) by weight.

Pearson correlation analysis was used to verify whether the two normally distributed variables were significantly correlated. However, when all the data from correlation coefficients between grain size and the vertical hydraulic conductivity are taken into account for each test reach. The results showed that the correlation between K_v and d_{10} was higher (r = .906) than the one between K_v and d_{60} (r = .0.748). The results for all the test reaches showed that the correlations were significant at 95% confidence level. The analysis indicated that the significance level was less than 0.05 which is an indication that the two variables were statistically correlated and had a linear correlation.

Empirical methods used to estimate hydraulic conductivity from grain-size distribution

The available soil properties such as particle-size distribution revealed many different relationships. As shown in *Tables 7* and *5* empirical methods; USBR, Shepherd, Hazen, Beyer, Slichter and Kozeny, were selected from Vukovic and Soro (1992) to measure Ks, hydraulic conductivity. The applied parameters are as follow: g denotes the acceleration of gravity; ν denotes the kinematic viscosity for a given temperature; in this study, at 20 °C, $\nu = 1.004 \times 10^{-6}$ m^2/s (Kasenow, 2002).

β represents a dimensionless coefficient, All equations have the porosity (n) function, and d_w refers to the effective grain diameter (mm) at w cumulative weight percentage of smaller grain size. Porosity can be estimated by (Vukovic and Soro, 1992; Kasenow, 2002) $n = 0.255(1 + 0.83^c)$, where c is the coefficient of grain uniformity and is represented by $c = d_{60}/d_{10}$. Here, d_{60} and d_{10} are the particle diameters derived from cumulative distribution curves and represent size fractions at which they are equal to 60% and 10%, respectively, of the sample by weight composed of grains of a smaller size (Ayers et al., 1998).

Results are clearly shown in *Figure 8,* illustrates the mean score between the obtained Hydraulic conductivity data from empirical formulas and permeameter tests in six reaches from upstream to downstream. It is evident that the mean of these five formulas in first and second reaches from downstream are completely near. Therefore, it indicates that empirical formulas are good predictors for estimating the hydraulic conductivity, especially in fine sediments.

K_v			65.47	14.41	78.85

Also shown are the arithmetic mean $\bar{x}_a$, the geometric mean $\bar{x}_g$ and median hydraulic conductivity $(\tilde{x})$ calculated by the methods K values are given in md^{-1}

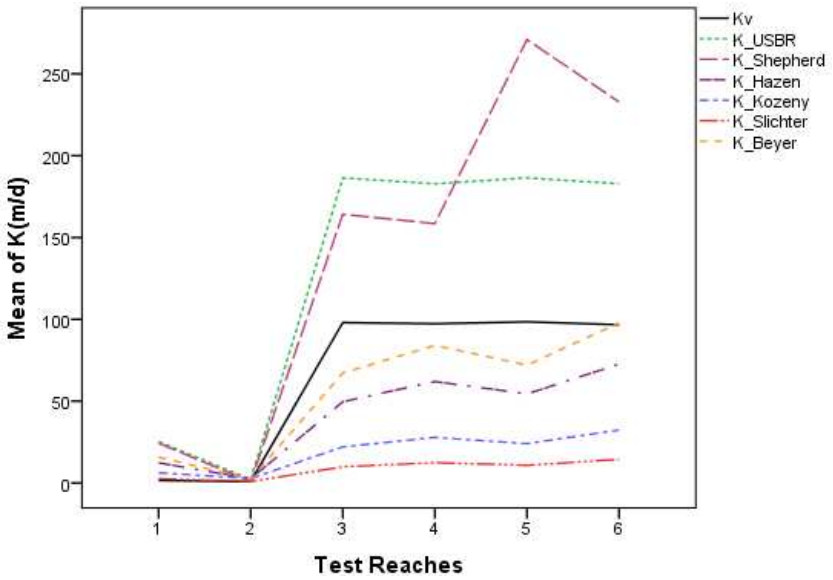

Figure 8. *Mean values of K from each of the five empirical grain size methods for these six reaches*

We should bear in mind that *Table 7* shows the the arithmetic mean $\bar{x}_a$, the geometric mean $\bar{x}_g$ and median hydraulic conductivity $(\tilde{x})$. The obtained medians from USBR formula and permeameter test were closer. Box plot Odong (2007) proved that Kozeny formula is the best estimator. Comparing different formulas, Song et al. (2009) stated that the obtained data from USBR were closer to hydraulic conductivity measured from Falling-Head standpipe method.

Discussion

The amount of K_v in the total 189 samples analyzed in the six reaches was between 0.109 and 152.37. According to *Table 4*, overall, the highest measured K_v in the upstream was obtained for reach F and the lowest range of hydraulic conductivity was measured in downstream in the meandering reach B. In addition, this study shows that in straight reaches, whether in the upstream, midstream, or upstream, the highest K_v was found in the central part of the river.

In the straight-shaped reaches (see *Fig. 7a, c, e*), the curve intersection of the right, middle and left sediments with X axis was close to each other, while in the meandering reaches such difference was evident due to the high potential of the flow in sedimentation, particularly within the left section of the river channel (see *Table 5*) and this fact leads to a relative increase in the hydraulic conductivity of the mentioned section. That is, the impact of meandering reach properties within B, D and F reaches on the sediment particles transfer led to the lack of a uniform distribution for the particles percentage. The interesting aspect of the difference reaches to its peak in the downstream of the river (see *Fig. 7b*), where the relative increase in the sedimentation within the right section of the reach and existence of erosion within the left section not only lead to formation of variable percent of silt and clay fine particles, but also these factors lead to formation of an impermeable layer and mitigation in the hydraulic conductivity, as well as they lead to a high mean difference of K_v between the left and right sections of the river.

The findings of streambed K_v distribution indicated a large spatial variability for each reach test and grain size in streambed sediments (Song et al., 2010). Sebok et al. (2014) found that the streambed attributes in meandering reaches were more different than in straight ones. The variability of K_v values was related to the erosion and deposition of streambed sediments, as found in some other studies (e.g. Genereux et al., 2008; Levy et al., 2011).

The results obtained in this research are in line with the afore-mentioned results, but with the innovation in choosing the reaches throughout the river, the effect of meandering and straight reaches on the hydraulic conductivity has been clarified, so that the morphological variation of the river are more evident in the downstream of the river, so that the variation ranges for K_v are closer at the upstream, even in the meandering reaches, but this case is contrariwise in the downstream section, and changes in the K_v are obvious.

Regional variations in streambed characteristics, including sedimentary texture and sedimentary structure, have been among other attributes (Min et al., 2013). As a result, the grain size of streambed sediment, which can be related to various types of morphologies, bed forms, and erosional and depositional regimes, is correlated with K_v values.

With regard to the investigation applied in the present study, it was observed that each test reach has different stream morphology. Reach B, which is a meandering reach, is composed of silt and clay particles which has caused the hydraulic conductivity to be low and, in other words, it causes an impermeable layer to exist in the bed of the river. Another point is related to the speed of the stream. Since, this reach has the lowest speed of stream compared to other reaches; its steep is close to zero.

Previous studies which have been accomplished by Jiang et al. (2015) and Sebok et al. (2014) have somewhat clarified the role of river morphology in the hydraulic conductivity, but in the present research it was attempted present novelty in the methods

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_36493668
© 2018, ALÖKI Kft., Budapest, Hungary

section, especially a Rising Head test method was added with the advanced instrument, and most importantly, the morphological properties of the river and their impact on the K_v were studied. Moreover, the role of straight and meandering reaches in the entire river along the whole path from upstream and downstream was considered

This study indicates that the special stream morphologies have caused bed forms that relate to erosion and deposition of channel at each test reach. Those different erosion and deposition patterns resulted in different sediment distributions and spatial variability for K_v values at each test reach (*Fig. 7*), while the erosional side can probably have greater grain size contrast due to depositional conditions. These are the reasons for hydraulic conductivity variability and the spatial distribution patterns. In fact, the steep of the streambed can be considered as one of the factors leading to the erosional changes in the sediments of the river.

The consistent distribution of the composing materials of the river in the upstream and due to the fact that they approach to each other in the midstream, but in the downstream, especially in the meandering reach of Ghorbanabad (Reach B), this distribution is not consistent and these changes on the shape of the river have led to irregular changes in K_v. In addition, it has caused the distribution of particles to be mixed with sand, as illustrated in the image. In other words, due to the existence of silt and clay, the streambed has changed into an impermeable bed with a very low K_v. Erosion and deposition in of sediments in the meandering reaches D and F have led to a higher difference in their hydraulic conductivity.

It should be also noted that, this study attempted to cover the whole streambed so upstream, middle stream and downstream samples, which were selected. The result showed Beyer as the best predictor, however, other formulas might have been the best if all streams had not been selected. On other words, if only downstream sampling with its fine sediments (silt and clay) had been selected, slitcher formula might have been the best. Since, this formula is the strongest in fine sediments. Overall, to have better generalization to all such alluvial rivers (starting from mountain then releasing to plain and/or sea), six reaches were selected.

Due to the selected river morphology, being mostly coarse sediments, Beyer and USBR were more successful in predicting Ks. That is, rivers' fine sediments in downstream were fewer than coarse ones in the whole streambed.

The meticulous pints which is obvious in the present research is related to the fact that hydraulic conductivity difference relative to the estimation of experimental formals is located at downstream and upstream of the rover. So, this fact is highly essential due to the special morphology of the riverbed within this range, in which the bed sediments consisted of coarse grains. In the Future studies, the selected ranges considering whether the region is located in downstream or upstream should be scrutinized independently due to the critical role of d_{10} factor for estimating the hydraulic conductivity of the riverbed.

Conclusion

In this study, an in-situ permeameter test method was conducted using both falling and rising-head methods to determine the spatial variability in streambed. The K_v in a 36-km stream reach in Ziyarat River, located in Golestan Province, Iran, was studied. Collectively, the data from 189 measurements at 6 test reaches were analyzed. There were two different stream morphologies: straight reach and meandering reach. The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_36493668
© 2018, ALÖKI Kft., Budapest, Hungary

results showed that the difference in the K_v of meandering reaches was more than the straight reaches, and this difference shows a change in the morphology of the river in these reaches as a result of erosion and deposition. To put it simply, the morphologic changes in the meandering reaches have caused evident changes in the streambed which have, eventually, led to the erosion and deposition of sediments and fluctuations in the values of K_v.

The K_v distributions in the straight reach show that the K_v values are greater in the center of the river. The analysis showed that the significance level was less than 0.05, which is an indication that the two variables are statistically related and have a linear correlation. The distributions of morphologies in streambed from each test reach along the Ziyarat River indicated that the stream morphology is a key variable which affects erosional and depositional conditions and bed forms. The erosional and depositional stream hydrologic processes winnowed the sediments and mobilized the sand and other particles contained in the streambed to form deposits of different grain size.

Streambed hydraulic conductivity may be related to the grain size. The results of grain size analysis showed that the average grain size distribution of streambed sediments in each right, central, and left side of the section in the downstream (Ghorbanabad Reach) have significant differences, especially in the meandering reach of the downstream.

Due to the dynamic sedimentation and scouring processes in the streambed, K_v showed higher temporal variability – 0.5 m below the streambed surface occurred in a relatively stable environment. The significant difference between the K_v of streambed in the upstream and downstream stems from the form of the sediments composing the streambed such that with an increase in the silt and clay in the downstream, a layer with low impermeability is formed. In addition, the K_v obtained from the two straight and meandering reaches in downstream had a significant difference whereas the same corresponding data were different from each other in the upstream and midstream. Therefore, the effect of the river morphology on K_v is evident. This indicates that in a meandering stream, more measurements are necessary for the thorough characterization of hydraulic parameters than in a straight stream.

Indeed, the importance of d_{10} factor relation with hydraulic conductivity cannot be ignored due to the key role of extremely fine particles in the riverbed, including slit and clay. Especially, the afore-mentioned relation is evident within the meandering reaches throughout the river and downstream regions. Moreover, the prediction of hydraulic conductivity using the experimental formulas for data validation was highly affected when the capability of the each experimental formula within upstream to downstream was tested in terms of direct and meandering reaches. The findings obtained for the present article will be useful for other rivers incorporating the similar morphological properties whose bank originates from mountain of steep slope and finally it reaches to see after passing through a plain.

Declarations. There is not any conflict of interest.

(Received 7th Feb 2018; Accepted 9th May 2018)

Abstract. The aim of the present study was to evaluate the impact of management practices on soil biological properties of texturally different soils of Haryana. Surface soil samples were collected from 25 organic farms and their adjoining conventional farms at 11 districts of Haryana and assayed for microbial biomass carbon (MBC), dehydrogenase and phosphatase activities along with total bacterial, actinomycetes and fungi populations in soil. The overall dehydrogenase and phosphatase activities at different locations were found to increase from 35.3 to 56.1 µg TPF g^{-1} soil 24 hr^{-1} and from 275.8 to 364.1 µg PNP g^{-1} soil, respectively under organic farming i.e. an increase of 57.5 and 32.01%. Overall a significantly higher MBC (69.1 %) was observed under organically managed soils (274 mg kg^{-1}) compared to conventional (162 mg kg^{-1}). The total bacterial, fungal and actinomycetes counts increased by 56.9, 55.2 and 49.5%, respectively, in comparison to those in the conventionally managed soils. The study concluded that soils under organic farming were found to be superior in terms of biological properties than conventionally managed soils which are essential for enhancing soil production and other functions in the given ecosystem.
Keywords: *management practices, microbial growth, organic farming, soil quality*

Introduction

Land management practices in present day agriculture are getting more and more important where food grain production and fertilizer use run parallel to meet the food requirements of over increasing population of India and leading to over exploitation of our natural resources like soil and water and therefore, soil is degrading day by day with respect to its fertility and productivity. This may be attributed to the fact that removal of nutrient resources from the soil strata is higher than their replenishment, so soil is becoming deficient in major available macro and micronutrients, which consequently leads to the decline of organic matter in soil and the overuse of chemical fertilizers and pesticides are adversely affecting the ecosystem (Yang et al., 2000). Thus, most soils are far from being ideal in fertility and should therefore be improved only by adopting appropriate management practices which includes amendments, like organic manures for enhancing the activity of "soil life". Enzymes and microorganisms like bacteria, actinomycetes and fungi present in soil are sensitive to changing soil environment and hence are considered to be one of the best soil health indicators. These microbes found to have direct role in sustaining soil fertility and its production by playing a crucial role in transformation of various nutrients and thereby improving the soil functioning in a

DOI: http://dx.doi.org/10.15666/aeer/1603_36693689
© 2018, ALÖKI Kft., Budapest, Hungary

given ecosystem. Thus, the study of the microbes and responses of enzymatic activities to disturbing agricultural activities is vital to understand how management practices contribute to sustaining soil fertility and productivity to improve soil (Wardle et al., 1999). Microbial populations and their activity are of immense importance in maintaining or sustaining soil health. Providing habitat and transformation of nutrients are complex processes brought about by succession of different micro-organisms in the soil which affect the soil fertility and over use of pesticides in conventional farming may inhibit these vital processes (Baum et al. 2003; Jolankai et al., 2006). Moreover, when soil applied pesticides fail to reach the target, they affect adjacent ecosystems through leaching or aerial drift affecting the diversity and abundance of non-targeted microorganisms causing negative effects on ecosystem processes and trophic interactions (Pimentel and Edwards, 1982). Different land management practices and continuous cultivation without any addition to soils are imposing variations in organic matter levels of soils and subsequent loss of soil organic carbon from the fields under intensive agricultural practices and leads to the alteration of microbial biomass (Srivastava and Singh, 1989). Therefore, there is a growing intention among farmers and researchers to adopt alternative farming practices that enhance or improve the biological properties of soils and thereby sustain soil health and productivity. Among different farming systems, organic farming is popular and its adoption level is increasing day by day to achieve the target of sustainability. In India, it has been estimated that cultivated area under certified organic farming has grown almost 17 fold in the last decade (0.042 mha in 2003-04 to 1.49 mha in 2016-17). The State of Haryana, one of the major agriculture based state of the country situated in the NCR region. It has about 4000 ha of land under organic farming (Anonymous, 2016). The key characteristics of organic farming include protecting the long-term fertility of soils by maintaining organic matter, fostering soil biological activity, careful mechanical intervention, providing nitrogen self-sufficiency through the use of legumes and biological nitrogen fixation, effective recycling of organic materials including crop residues, livestock wastes and weed, and diseases and pest control relying primarily on crop rotations, natural predators, diversity and resistant varieties. At present, the most optimistic estimates show that about 25-30 percent of nutrient needs can be met by various organic sources. Many researchers reported that in organically managed fields activity of earth worms is higher than in inorganic field (Edwards and Lofty, 1974; Kotcon, 2011; Rai et al., 2014; Velmourougane, 2016). In the biodegradation process, earthworms and microbes work together and produce vermicompost, which provides macro (N, P, K, Ca, and Mg) and micro nutrients (Fe, Mn, Zn, and Cu) (Amir and Fouzia, 2011). In organic farming, use of manures and crop residues instead of a synthetic fertilizer is reported to reduce groundwater contamination, improve microbial activity, recycle dairy/poultry wastes, and improve soil properties (Poudel et al., 2002). However, the information regarding the long-term effect of organic farming practices on soil biological properties and its feasibility are very scanty. Keeping in view the above concerns, the present study was planned to evaluate the long-term impact of management practices on soil biological properties like microbial biomass carbon (MBC), dehydrogenase and phosphatase activities along with bacterial, actinomycetes and fungi populations in fields particularly of vegetables and horticultural crops with texturally different soils in Haryana.

Materials and Methods

Study area

Organic farms under different cropping systems, vegetables and horticultural crops and their adjoining conventional farms were identified at eleven districts of Haryana, namely, Sirsa, Fatehabad, Hisar, Jind, Kaithal, Karnal, Kurukshetra, Ambala, Panchkula, Yamunanagar and Panipat and their soil properties were studied. Locations of different sampling sites are presented in *Figure 1*. A total of 150 soil samples (three replications) of 0-15 cm depth were collected from the two types of farming systems, which were pooled to make 50 composite samples and analysed for microbial biomass, dehydrogenase and alkaline phosphatase activity, total bacterial, fungal and actinomycetes counts. The texture of soils varied between sand to clay loam, representing almost all the soil types of the State and is presented in *Table 1*.

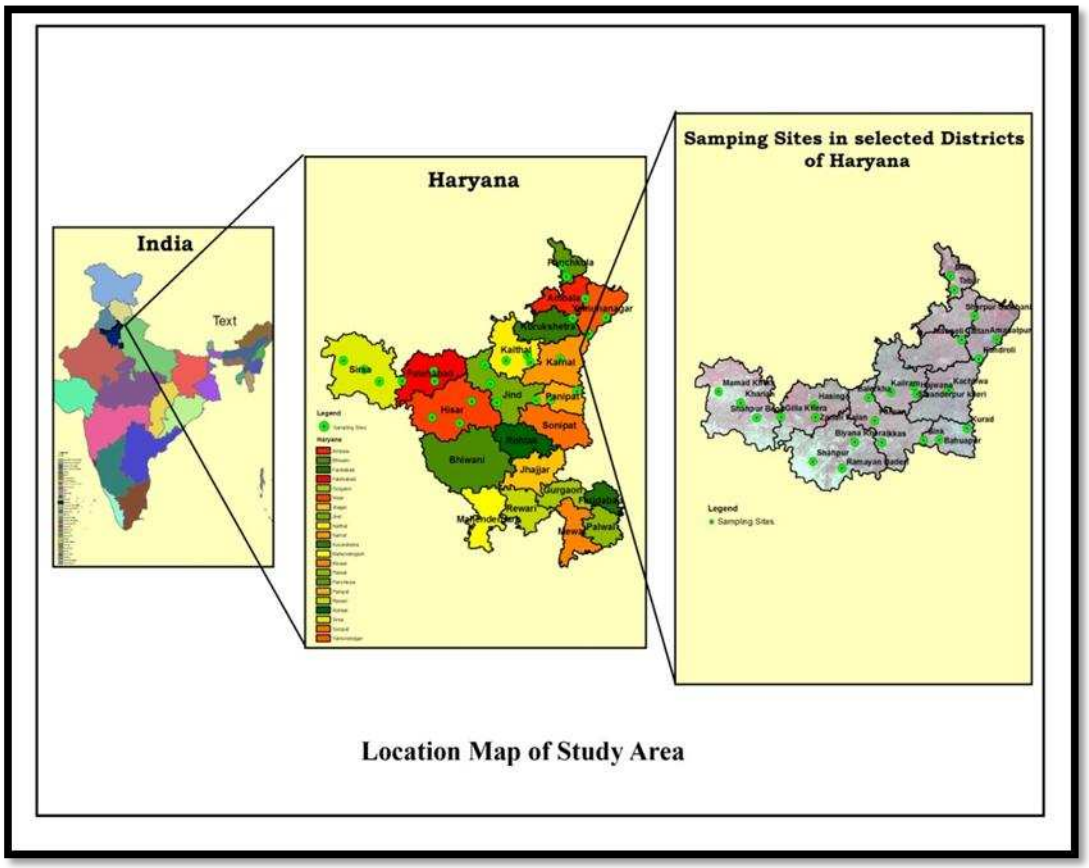

Figure 1. *Sampling sites in selected districts of Haryana*

Collection of soil samples

The soil samples collected were representative of the area sampled. A field was treated as a single sampling and recently fertilized fields, bunds, channels, areas near trees, farm ways, buildings, wells, compost piles or other non-representative locations were avoided during sampling. Three soil samples were taken randomly from field and finally one composite sample was prepared.

Processing of soil samples

After collection soil samples were kept refrigerated at 0°C for analysis of the microbiological properties. Growth media used for the total bacterial, fungal and actinomycetes counts are given in *Table 2*.

Table 2. *Growth media used for microbial analysis*

Sr. No.	Microbe	Medium
1.	Bacteria	Nutrient Agar
2.	Fungi	Potato Dextrose Agar
3.	Actinomycetes	Ken-Knight‘s Medium

Soil enzymatic activities

Dehydrogenase activity

Dehydrogenase activity was determined by using the method of Casida et al. (1964). Five gram soil was taken and mixed with 3% solution of 2,3,5-triphenyl tetrazolium chloride and 2.5 ml of distilled water, and incubated for 24 h at 37°C temperature in an incubator. After incubation, 10 ml methanol was added and shaken for 1 minute and filtered through Whatman No. 1 filter paper. The absorbance was measured at 485 nm by using a spectrophotometer.

DOI: http://dx.doi.org/10.15666/aeer/1603_36693689
© 2018, ALÖKI Kft., Budapest, Hungary

Alkaline phosphatase activity

Alkaline phosphatase activity was determined by using the method of Tabatabai and Bremner (1969). Enzyme activity was measured by taking 1 g of soil in a flask and adding 0.2 ml of toluene, 4 ml of modified universal buffer (MUB), 1 ml of p-nitrophenyl phosphate solution to it. After incubating for 1 hour, 1 ml of 0.5 M $CaCl_2$ and 4 ml of 0.5 M NaOH were added. After stirring for a few seconds, suspension was filtered through Whatman No. 1 filter paper and absorbance of the filtrate was measured at 420 nm using a spectrophotometer.

Microbial biomass carbon (soil fumigation-extraction method)

Microbial biomass carbon (MBC) was determined by soil fumigation-extraction method (Vance et al., 1987). 10 g of soil was fumigated with 20 ml of $CHCL_3$ in vacuum desiccators for 24 hours in dark and another 10 g of the same soil sample was refrigerated, then both samples (fumigated and non-fumigated) were extracted with 0.5 M K_2SO_4 for half an hour and then the extract was treated with H_2SO_4 and orthophosphoric acid, and heated on hot plate at 120 ^oC for 30 minutes. After diluting to 250 ml with distilled water, 2-3 drops of ferroin indicator was added and titrated against 0.05 N FAS (Ferrous Ammonium Sulphate) and MBC was calculated:

$$MBC(\mu g/g\ soil) = \frac{OC_F - OC_{UF}}{K} \quad \text{(Eq.1)}$$

where,

- OC_F = Total amount of EC (Extractable C) in fumigated soil.
- OC_{UF} = Total amount of EC (Extractable C) in non-fumigated soil.
- K = The proportion of microbial C evolved as CO_2= 0.45 for 10 days of incubation at 25°C (Jenkinson and Ladd, 1981).

Microbial counts

Total bacterial, fungal and actinomycetes counts were estimated using serial dilution plate technique. One gram of soil was transferred into 10 ml of sterilized water in 250 ml flask. Sample was mixed by vigorous shaking and now the sample was diluted ten-fold (10^{-1} dilution). From this, 1 ml of soil suspension was transferred to another 9 ml water blank with the help of sterile pipette and hence sample was diluted to 10^{-2}. Similarly, dilutions were made up to 10^{-7}. Different dilutions were made to estimate the different microbial parameters (*Table 3*).

Table 3. *Dilution used for different microbes in the appropriate nutrient media*

Sr. No.	Microbe	Dilution factor
1.	Bacteria	10^{-6} -10^{-7}
2.	Fungi	10^{-3} -10^{-4}
3.	Actinomycetes	10^{-4} -10^{-5}

Now, 1 ml of different diluted samples i.e.10^{-6}-10^{-7} were transferred in appropriate pre-sterilized labeled Petri-plates in front of laminar flow. Then 25-30 ml of appropriate media was poured into each dilution plate and shaken to ensure uniform dispersal of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_36693689
© 2018, ALÖKI Kft., Budapest, Hungary

cells/suspension in the media. These plates were allowed to solidify on working table of the laminar. Further, the plates are incubated in an inverted position (upside down) for 2-5 days at 28 ± 2°C temperature in an incubator and number of colonies on different dilution media plates were recorded and populations per gram soil were enumerated.

Statistical analysis

The significance of treatment effects was analyzed using two factorial RBD analysis with OP Stat, CCS HAU Hisar software (Sheoran et al., 1998). Spatial variability graphs were prepared by using ArcGIS software.

Results and Discussion

Dehydrogenase and phosphatase activity

Data on dehydrogenase activity in soils under the two farming systems given in *Table 4* revealed that organic farming led to significant improvement in dehydrogenase activity over conventional practice. The dehydrogenase activity under organic farming was observed significantly higher than in conventional practice at all the locations with different soil textures. The soil dehydrogenase activity in different locations varied between 18.5 to 46.0 µg TPF g^{-1} soil 24 hr^{-1} in conventional farming while it ranged from 23.8 to 78.6 µg TPF g^{-1} soil 24 hr^{-1} under organic farming. The extent of increase in dehydrogenase activity under organic farming was, however, found to increase with fineness of the texture at different locations. For example, the increase in dehydrogenase activities were 28.6 % in sand (L_1), 55.1 % in loamy sand (L_8), 68.1% in sandy loam (L_{12}), and 76.6% in clay loam soil at location L_{24}. The overall dehydrogenase activity which was 35.3µg TPF g^{-1} soil 24 hr^{-1} under conventional farming at different locations was found to increase to 56.1 µg TPF g^{-1} soil 24 hr^{-1} under organic farming i.e. an increase of 57.5%. The interactive effect of location and farming system on dehydrogenase activity was also found significant. The significant increase in the dehydrogenase activity in texturally different soils of different locations under conventional and organic farming is presented in *Figure 2*.

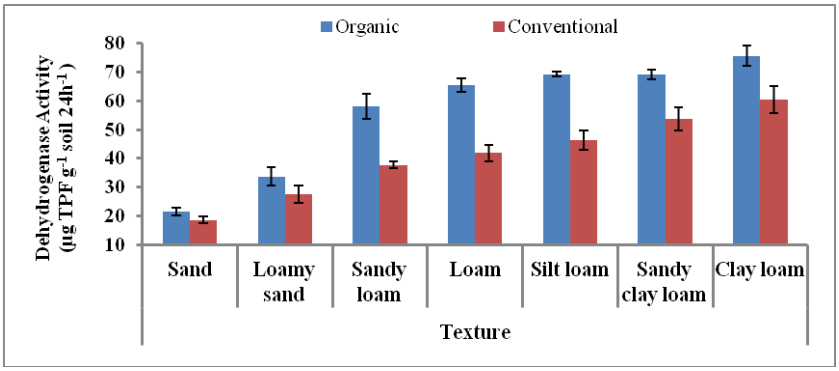

Figure 2. *Dehydrogenase activity in different textured soils under conventional and organic farming*

Moreover, adoption of organic farming showed a significant increase of alkaline phosphatase in different textured soils over the conventional farming. In general, both

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_36693689
© 2018, ALÖKI Kft., Budapest, Hungary

the farming systems were found to enhance the phosphatase activity with increase in clay content of soil but the extent of increase of alkaline phosphatase was greater under organic farming system than in conventional practice .The values of phosphatase activity varies from 132.6 to 453.1 µg PNP g^{-1} soil hr^{-1}among different locations under conventional system of farming while it ranged from 151.8 to 642.8 µg PNP g^{-1} soil hr^{-1} under organic system of farming. The conversion of conventional system of farming to organic farming resulted in a significant increase in phosphatase activity from 275.8 to 364.1 µg PNP g^{-1} soil hr^{-1}. The per cent increase in the phosphatase activity under organic farming over conventional in different textured soils showed an increase of 22.8 % in sand which further increased to 36.8% in clay loam soil. The phosphatase activity in different textured soils of different locations under conventional and organic farming is represented in *Figure 3*.

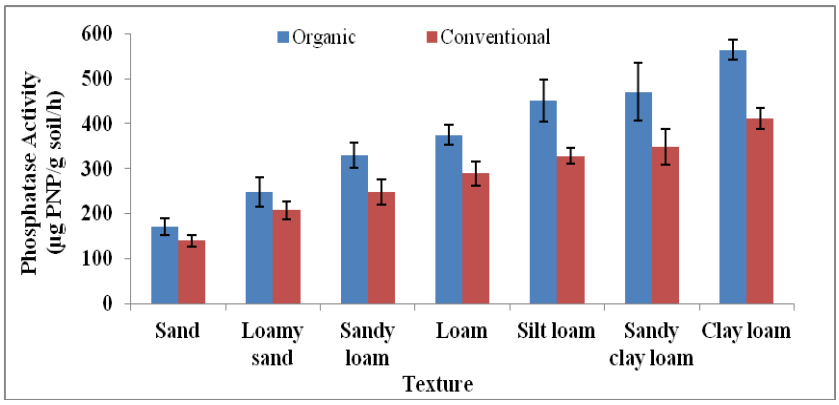

Figure 3. *Phosphatase activity in different textured soils under conventional and organic farming*

The study confirmed the positive influence and higher microbial activity indices of organic farming (higher enzymatic activity, higher soil microbial biomass carbon content) compared to conventional farming system and the higher enzyme activities under organic practices might be attributed to enhanced nutrient availability from added organics, increase in release of root exudates due to improved crop growth and favorable environment for microbial growth (Burns et al., 2013; Tamilselvi et al., 2015).

Farmyard manure and crop residues provide a source of organic matter, and when returned to soil they increase organic C in soil (Banger et al., 2010) and further, the prevalence of organic substrates stimulated soil microorganisms to produce enzymes responsible for the conversion of unavailable nutrients to plant available forms. Most importantly, a closer look at the relationship between physicochemical and biological indicators of soil health evidenced the significance of organic matter to enzyme activities suggesting enhanced nutrient cycling in systems receiving organic amendments (Sihi et al., 2017). Moreover, phosphatase activity in the soils occurs either in response to plant roots exudates or from microbes such as bacteria or fungi (Dinkelaker and Marschner, 1992) and changes in phosphatase activity can indicate changes in the soil phosphoryl substrates (Rao and Tarafdar, 1992).

These findings agree with several research studies (Mader et al., 2002; Dinesh et al., 2010; Lazcano et al., 2013; Sunita, 2016) where higher microbial biomass and enzyme activities were reported even in a single growing season in response to short-term incorporation of organic manures in organics compared to conventional systems.

This indicates that instant increase in soil enzymatic activities which are associated with a rapid increase in availability of organic substrates required for microbial growth.The dehydrogenase (*Figure 4a*) and phosphatase (*Figure 4b*) activities in soils plotted for organic farming against adjoining soils under conventional farming (intercept set at zero) also showed clearly that organic farming is very effective in enhancing dehydrogenase (y = 0.663x) and phosphatase (y = 0.738x) over conventional system in Haryana (*Figure 4*). Moreover, the spatial variability maps for different location are also presented in *Figure 5* and *Figure 6*.

Microbial biomass carbon (MBC)

The MBC is one of the fractions of SOC which constitutes a very small portion but considered as a good indicator of soil health. Organic farming had significant effect on soil microbial biomass carbon in texturally different soils at different locations (*Table 4*). Locations with fine textured soils have significantly higher amount of MBC as compared to locations with light textured soils i.e. L_1 to L_{25}. Under conventional farming, the MBC was lowest (87 mg kg^{-1}) in sand at location L_2, while it was highest in clay loam soil at location L_{25} (271 mg kg^{-1}). Similarly, the values of lowest and highest MBC were found to be 105 and 411 mg kg^{-1} in sand (L_2) and clay loam soil (L_{25}) under organic farming. Overall a significantly higher MBC (69.1 %) was observed under organically managed (274 mg kg^{-1}) as compared to conventional (162 mg kg^{-1}). The interactive effect of location and farming system was also found significant and the highest MBC content (411mg kg^{-1}) was observed at location L_{25} under organic farming. Variations in MBC in different textured soils under conventional and organic farming have also been presented in *Figure 7*. MBC serves as an important reservoir of plant nutrients (Marumoto et al., 1982; Okur et al., 2009) and soil microbial C decrease with decrease in fineness of soil texture due to declining C input but observed to be higher in organically managed soils than in conventionally managed due to the permanent input of organic residues with high C/N ratio (Schjonning et al., 2002; Crecchioa et al., 2004; Melero et al., 2006; Araujo et al., 2009; Amaral et al., 2011). Furthermore, higher soil microbial biomass carbon in organic farming is mainly due to the regular application of farmyard manure and large carbon inputs in the form of organic amendment. Additionally, farmyard manure supplies readily available N, resulting higher plant biomass. Consequently, more crop residues are incorporated in soil and thereby higher organic matter levels are maintained (Roldan et al., 2005). This also provides a favorable environment for microorganisms, contributing to a highly diverse and stable microbial community structure in organic farming systems (Wada and Toyota, 2007).

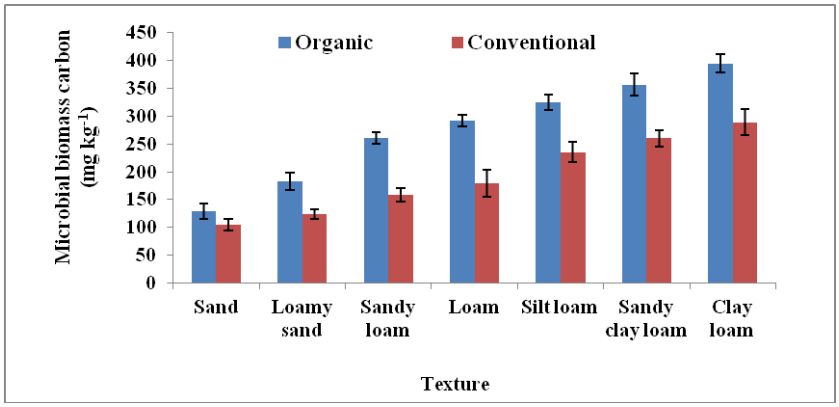

Figure 7. *Microbial biomass carbon in different textured soils under conventional and organic farming*

The plot of the microbial biomass carbon of soils under organic farming against the microbial biomass carbon of the adjoining soils under conventional farming (intercept set at zero) showed that organic farming in general increases microbial biomass carbon (y = 0.638x) of soils (*Figure 8*). The spatial variability maps of MBC for different location are also presented in *Figure 9*.

Total bacterial, fungal and actinomycetes counts

Wide variation of soil microbial populations has been recorded at different locations under organic and conventional farming systems as well (*Table 5*). The consistent increase was noticed in the population of bacteria, fungi and actinomycetes at all the locations under organic farming but the extent of increase was more pronounced in heavy textured soils subjected to organic manures such as FYM, neem cake or vermicompost.

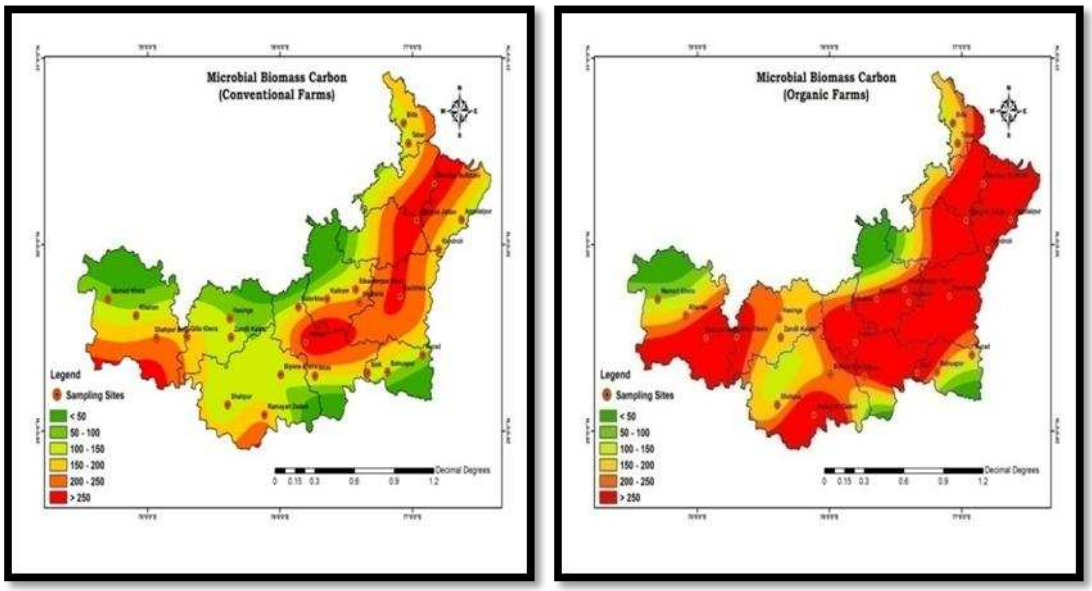

Figure 9. *Spatial variability map of MBC in soils under conventional and organic farming systems at different locations of Haryana*

The mean value of different locations pertaining to population of bacteria was observed to be 14.87×10^6 CFU g^{-1} soil under conventionally managed soils which was significantly increased to 23.34×10^6 CFU g^{-1} soil upon conversion to organic farming. Similarly, fungi population was significantly increased from 12.08×10^3 CFU g^{-1} soil to 18.76×10^3 CFU g^{-1} soil and actinomycetes population from 15.09×10^4 CFU g^{-1} soil to 22.57×10^4 CFU g^{-1} soil under organic farming as compared to conventional farming practices. The average populations of bacteria, fungi and actinomycetes in the soils at different locations under organic farming were 56.9%, 55.2% and 49.5%, respectively, higher than those in the conventionally managed soils. In different textured soils, the bacteria showed variations from 6.25×10^6 in sand to 24.56×10^6 CFU g^{-1} soil in clay loam soil whereas fungal and actinomycetes population varied from 5.17×10^3 in sand to 23.58×10^3 in clay loam soil and 6.86×10^4 in sand to 28.89×10^4 CFU g^{-1} soil in clay loam, respectively, under conventional farming (*Figures 10 to 12*).

Addition of various nutrient inputs through various sources such as FYM, neem cake and vermicompost under organic farming practices exhibited huge variation and resulted in rapid stimulation of microbial growth and subsequently, the increase in bacteria, fungi and actinomycetes population was observed to be 7.75×10^6, 5.96×10^3 and 8.28×10^4 CFU g^{-1} soil in sand to 38.34×10^6, 31.06×10^3 and 35.89×10^4 CFU g^{-1} soil, respectively, in clay loam soil. The significant increase in population of these microorganisms under organic farming, however, observed to be significant only in loamy soils as compared to conventional farming system.

Growth of bacteria, fungi and actinomycetes on different nutrient media has also been shown in *Plates 1 to 3*. The average populations of bacteria, fungi and actinomycetes in the soils at different locations under organic farming were 56.9%, 55.2% and 49.5%, respectively, higher than those in the conventionally managed soils.

The addition of FYM, neem cake, vermicompost and other organic sources of nutrients enhanced growth of microbial populations which may be attributed to the increment in organic matter in soil that serves as a food and energy source for microbes. These results are supported by the findings of Bobulska et al. (2015). In recent years, multiple studies comparing conventional and organic agriculture have reported differences in soil properties, increased microbial activity and diversity in organically managed soils, or distinct microbial profiles between the two systems (Wu et al., 2008; Moeskops et al., 2010; Bobulska et al., 2015). Results from our study clearly indicated that soil texture significantly affected bacteria, fungi and actinomycetes populations, and higher growth of microbial populations was observed in heavy textured soils (clay loam) than light textured soils (sand). Among six textural classes, the highest growth of microbial populations was observed in clay loam and the lowest in sand and there was positive a correlation between soil organic carbon and growth of microbial populations. Several researches documented that fine soils were found to be more suitable for bacteria, fungi and actinomycetes survival because smaller size particles provide a protective habitat for microorganisms through pore size exclusion of predators (Sessitsch et al., 2001 and Zhang et al., 2007). Alternatively, higher microbial population in clay loam soils may be due to a higher organic matter content, water retention characteristics and nutrient availability (Grayston et al., 2004). Microbial activity in soil is strongly influenced by the clays and humates which bind organic chemicals, inorganic ions, and water films to their surfaces (Van et al., 1996).

The bacterial (*Figure 13a*), fungal (*Figure 13b*) and actinomycetes (*Figure 13c*) populations of soils plotted for organic farming against adjoining soils under conventional farming (intercept set at zero) also showed clearly that organic farming had a promising effect in increasing bacterial (y = 0.632x), fungal (y = 0.633x) and actinomycetes populations (y = 0.642x) over conventional system in Haryana (*Figure 13*). The spatial variability maps of bacteria, fungi and actinomycetes at different locations are also presented in *Figures 14 to 16*.

Conclusion

The biological properties of soils in terms of enzymatic activities, microbial biomass carbon and total CFU of bacterial, fungal and actinomycetes populations were studied for the organic and conventional farming practices and they were found to be superior in the case of organic farming practices as compared to their counterparts. Higher organic matter input through application of various organic manures under organic farming practices is the key factor in enhancing the enzymatic activities and soil microbial biomass carbon along with higher growth of microbial populations in soil. The results from the study indicate that the management practices have clear positive and significant effects on various biological properties of soils. Enzymatic and microbial responses to chemical fertilizers and pesticides under conventional farming indicated the resource limitation and substrate availability to these biological communities in soil. Thus, microbiological properties of soil can serve as potential heath indicator of soils as being affected by different management practices.

Abstract. Most of the world's catches of sharks are incidentally taken by tuna fishing gear, constituting bycatches that increase the extinction risk of several species of shark. This not only alters ecosystem functions by removing top predators, but may also hinder the industry production itself due to cutoff measures set by authorities. This paper focuses on the female population abundance of a very important bycatch species, the shortfin mako shark (*Isurus oxyrinchus*), and proposes a stochastic model for quantitative risk assessment under varying harvest regimes and control measures. The proposed model can be applied to any shortfin mako shark population by changing initial conditions and harvest parameters. The flexibility of the model makes it practicable to simulate hundreds of scenarios, analyse and compare the most relevant results such as the risk of extinction caused by a given harvest regime, median time to extinction, expected minimum biomass, risk of low harvest, and risk reduction caused by control measure; these outcomes are useful for rational decisions under uncertainty. We present an application example as a means to demonstrate how the proposed model can be used to drive management decisions for sustainable tuna harvest.
Keywords: *stochastic model, probabilistic systems, sensitivity analysis, monte carlo simulation, ecological modeling*

Introduction

Fishes represent the only major food source still harvested from wild populations (Ryman et al., 1995). In 2014, fish harvested from aquaculture amounted an estimated first-sale value of U$160.2 billion (FAO, 2016). Tunas and tuna-like species are an important food source, used mostly for canning and sashimi, and, because of their high economic value and extensive international trade, are an important global commodity. The total catch of tuna and tuna-like species was about 7.4 million tons, representing 9% of the global catch in 2013. Tuna fishing is undertaken by thousands of vessels in

the Pacific, Indian and Atlantic oceans, using a range of gear types (e.g., longline) (Clarke, 2008; FAO, 2016; Gilman and Lundin, 2008; Hamilton et al., 2011).

Most of the world's catches of sharks are incidentally taken by various types of tuna fishing gear, constituting bycatch that is either discarded at sea (without fins or dead) or landed for sale (Carvalho et al., 2011). Bycatches increase the risk of extinction of several species of shark and alters ecosystem functions by removing top predators (Myers and Baum, 2007). Moreover, bycatches cause economical risk to the industry because of conservation limits set by the International Commission for the Conservation of Atlantic Tunas (ICCAT), i.e., a cutoff threshold at which fishing should stop, often set at 20% of the unfished equilibrium abundance of relevant species such as the mako shark (Smith et al., 1993). In other words, if mako shark population declines more than 80% of its unfished equilibrium abundance, tunas' harvest must be forbidden. Thus, we focus here on a shark species mainly because there has been increasing concern about the status of some shark stocks and the population-level effects caused by their exploitation (Anon, 2009, 2013; Carvalho et al., 2011; FAO, 1999; Myers and Baum, 2007).

The adult shortfin mako shark (SMA) (*Isurus oxyrinchus*) is an apex predator at the top of the marine environment food web and it is not a prey to any marine animal. These sharks are long lived, slow growing, reach sexual maturity late in their life history, and produce few offspring (Levesque, 2007). They have a common total length of 270 cm, maximum total length of 445 cm (Weigmann, 2016), maximum published weight of 50.,8 kgs and maximum reported age of 32 years (Natanson et al., 2006).

This work focuses on the SMA for several reasons (Anon, 2009, 2013; Cosandey-Godin and Morgan, 2011; Levesque, 2007): (i) its relatively high abundance and presence in multiple and widespread fisheries; (ii) it is captured in great numbers in all oceans and ranks as one of the most dominant species caught in pelagic longlines and gillnets; (iii) it is considered an apex predator at the top of the marine environment food web; (iv) female SMAs are being caught below the size of maturity; (v) unlike most shark species, the SMA is economically important due to both its quality of meat and fins; (vi) it is a valuable product of the pelagic longline swordfish and tuna fisheries; (vii) failures in conservation management of SMA can be significant and costly.

Therefore, we propose a stochastic population model for Quantitative Ecological Risk Assessment (QERA) of SMA bycatch that results from the industrial tuna fishing. Our model is a useful tool for both conservation of SMA and the sustainable management of tuna industry. Moreover, it is capable of describing the dynamics of SMA population under varying conditions (harvest regime and control measures), for evaluating the role of such conditions, and for producing meaningful conclusions that can be used to drive conservation and management decisions. The model is thought to be generic so that it can be applied to any SMA population (e.g., South Atlantic, North Atlantic, North Pacific) by making minor changes in parameters and initial conditions.

We exemplify the application of the model for the SMA South Atlantic population and describe means of evaluating risk of extinction and yield associated with alternative decisions about harvest rates and cutoff threshold. The methodology, used for QERA in both the model building and application example, is similar to the approach used in (Duarte et al., 2013, 2014; Duarte and Droguett, 2015), but here it is specifically tailored for solving the SMA case.

The remainder of the paper is organized as follows. First, we provide a brief literature review. Second, we propose a model structure to describe the dynamics of the

DOI: http://dx.doi.org/10.15666/aeer/1603_36913709
© 2018, ALÖKI Kft., Budapest, Hungary

system in any ocean. Next, by means of an application example, we demonstrate how to conduct a QERA of SMA bycatch implied by tuna fishing based on the proposed model. Finally, we conclude remarks by presenting the model benefits and shortcomings.

Materials and Methods

Literature Review

Even though the SMA is physiologically unique, economically important, and exploited in relatively large numbers (Levesque, 2007), there are few population models for this species (Anon, 2009, 2013). These approaches aimed at diagnosing the population status over the last 30 years by quantifying measures such as past and current biomass, and abundance. Conversely, we aim at describing the population dynamics under varying scenarios over time so that the proposed model can be a useful tool for rational decisions under uncertainty.

There are some applications of stochastic models for risk assessment of marine fish (Duarte et al., 2013; Fu et al., 2004; Hart and Cadrin, 2004; Smedbol and Stephenson, 2004) that have the goal of describing the population dynamics over time and under predefined conditions by using past data for estimating the model parameters and setting the initial conditions. They include uncertainty in parameters, and thus results are given in terms of probability. However, at the best of authors' knowledge, there is no such approach tailored for mako shark populations.

Yet, our modelling approach is similar to the two models of herring (Fu et al., 2004; Smedbol and Stephenson, 2004) in the following aspects: (i) it evaluates the risk of extinction caused by harvest; (ii) includes uncertainty in parameters; (iii) has the flexibility to include a cutoff measure; and (iv) includes low-frequency events that may cause recruitment failure, which occurs when individuals at age 0 (pups) have poor survival due to hypothetical events such as pollution, construction or any human impact in breeding areas on the coast; or environmentally induced recruitment failure such as hurricanes, earthquakes, tsunamis. The specific cause of recruitment failure remains a mystery and there is no research about its effects in SMA, but we assume recruitment failure may also occur with SMA as happens with other marine fishes (Payne et al., 2009; Smedbol and Stephenson, 2004).

In spite of the similarities, our approach departs from the abovementioned works in the following aspects: (i) the proposed model describes a population of a shark species, which is the utmost difference because sharks and herrings have remarkably different life histories; (ii) it models females only; (iii) it measures uncertainty about the future harvest regime through a plausible range of scenarios; and (iv) it evaluates the risk caused by conservative scenarios of harvest regime (Levesque, 2007). Then, in the next section, we present the characteristics of the proposed model.

The Proposed Model

The proposed model only considers females because they are a key indicator to control. In fact, females produce new individuals and keep the life cycle on. Thus, keeping track of females is more effective to evaluate extinction risk. Furthermore, most available data are given only for females, probably because of the same aforementioned reason. Thus, hereafter, "population", if not specified, refers to "female population".

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_36913709
© 2018, ALÖKI Kft., Budapest, Hungary

Then, the purpose of the model is to describe the SMA female abundance over 100 years under varying conditions. Indeed, we consider: (i) a benchmark scenario (Scn-0) that simulates the natural population dynamics under no harvest; (ii) varying harvest scenarios with different harvest parameters and (iii) harvest scenarios with and without a cutoff threshold for which no harvest occurs if abundance falls below it.

Now, let $N_i(t)$ be the abundance of females in stage *i*; N the total abundance of female population; s_i the survival rate (per year) of females in stage *i*; p_i the permanence rate (per year) of females in stage *i*; *f* the fecundity rate (pups per year); a_{ij} the transition rate (per year) from stage *j* to stage *i*, where *i* is the line and *j* the column in the matrix; h_i is the harvest rate for stage *i*; N^{cutoff} is the abundance threshold for cutoff; and F^{rf} is the frequency per year that recruitment failure occurs. Note that $a_{10} = s_0$; $p_1 = s_1 - a_{21}$; $p_2 = s_2 - a_{32}$; and $p_3 = s_3$. Then, the algorithm described below constitutes our proposed generic model for SMA female abundance that can be parameterized to describe the dynamics of the system in any ocean. It represents one replication for simulating the population model and involves the following steps:

i)If $N < K$, then make

$$\begin{bmatrix} N_0(t+1) \\ N_1(t+1) \\ N_2(t+1) \\ N_3(t+1) \end{bmatrix} = \begin{bmatrix} 0 & 0 & f & 0 \\ a_{10} & p_1 & 0 & 0 \\ 0 & a_{21} & p_2 & 0 \\ 0 & 0 & a_{32} & p_3 \end{bmatrix} \begin{bmatrix} N_0(t) \\ N_1(t) \\ N_2(t) \\ N_3(t) \end{bmatrix} \quad \text{(Eq.1)}$$

If $N > N^{cutoff}$, then make

$$\begin{bmatrix} N_0(t+1) \\ N_1(t+1) \\ N_2(t+1) \\ N_3(t+1) \end{bmatrix} = \begin{bmatrix} N_0(t+1) \\ N_1(t+1) \\ N_2(t+1) \\ N_3(t+1) \end{bmatrix} * \begin{bmatrix} 1-h_0 \\ 1-h_1 \\ 1-h_2 \\ 1-h_3 \end{bmatrix} \quad \text{(Eq.2)}$$

ii) Otherwise:

$$\begin{bmatrix} N_0(t+1) \\ N_1(t+1) \\ N_2(t+1) \\ N_3(t+1) \end{bmatrix} = [K] \begin{bmatrix} 0.169 \\ 0.678 \\ 0.086 \\ 0.068 \end{bmatrix} \quad \text{(Eq.3)}$$

iii)Generate random number *U* from a uniform distribution.

If U < F^{rf}, then

$$\begin{bmatrix} N_0(t+1) \\ N_1(t+1) \\ N_2(t+1) \\ N_3(t+1) \end{bmatrix} = \begin{bmatrix} N_0(t+1) \\ N_1(t+1) \\ N_2(t+1) \\ N_3(t+1) \end{bmatrix} * \begin{bmatrix} M^{rf} \\ 1 \\ 1 \\ 1 \end{bmatrix} \quad \text{(Eq.4)}$$

Table 1 defines the model variables, parameters and initial conditions. The estimation of parameters and the setting of initial conditions will be explained in next

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

sections. *Eq. 1* is a Lefkovitch matrix (Lefkovitch, 1965), which describes the natural dynamics of the population. We consider a four-stage structure for SMA population: pups, juveniles, mature adults, and post-reproductive adults. *Eq. 2* models the effect of harvest, which was considered in the simulation to reflect stage selectivity by the fishery. Note that harvest strategies do not affect survival rates. Instead, for each scenario, harvest was included by removing a certain proportion of the stage-specific population every year, and a cutoff threshold was included to simulate a control measure in which no harvest occurs if the abundance declines belowthat limit. *Eq. 3* describes the Density Dependence (DD) effect, which represents a change in the influence of any factor that affects population growth as the population density changes (Forbes et al., 2010; Pauwels, 2002). The constants in *Eq. 3* refer to the steady-state population distribution, i.e., the proportion of individuals in each stage (16.9% age 0, 67.8% juveniles, 8.6% mature adults and 6.8% post-reproductive adults) when the population dynamics reach a stationary state, which is based only on the stage matrix for Scn-0 and is a result of eigenvalue analysis. For more details, see references (Akçakaya et al., 1997; Akçakaya and Root, 2013; Burgman et al., 1993). Finally, *Eq. 4* allows to include known and/or suspected variations in vital rates (survival and fecundity) caused by low-frequency, high-consequence events such as recruitment failure. This is modelled via Bernoulli trials (Burgman et al., 2012).

Note that, although the proposed model structure is thought to be generic, it can be tailored to incorporate many realistic and case-specific features such as: (i) a stage-structured SMA population (pups, juveniles, mature adults, and post-reproductive adults); (ii) stage-specific initial abundance; (iii) uncertainty in parameters such as survival and fecundity; (iv) Density Denpendency; (v) low-frequency events that may cause recruitment failure; (vi) stage-specific annual harvest as a proportion of the stage-specific abundance; and (vii) cutoff threshold for which no harvest occurs if abundance is below it.

The four stages (pups, juveniles, mature adults, and post-reproductive adults) considered for female individuals in the population are structured based on characteristics such as weight, survival, fecundity and harvest rate. A summary of the female SMA life history in our model is as follows (*Fig. 1*) (Levesque, 2007). Pups (stage 0) are born at age 0. Those who survive until age 1 become juveniles (stage 1). The juveniles, who survive until the age of 19-21, reach maturity and become mature adults (stage 2). Mature adults who survive produce new pups until the age of 25-27 years, when they reach sexual mortality and become post-reproductive adults (stage 3). Post-reproductive adults naturally die at an average age of 32 years. By doing so, we can project the stage-specific population abundance using a Lefkovitch matrix (also known as Stage matrix) (Lefkovitch, 1965).

The model also considers DD. Authors of fish case studies (Fu et al., 2004; Smedbol and Stephenson, 2004) had reported difficulty for estimating the DD parameters. Most assumed Ceiling-type DD (Akçakaya et al., 1999), according to which, on one hand, vital rates are not affected until the population reaches the carrying capacity K that is the level of abundance above which population tends to decline. On the other hand, other types of DD increase vital rates at low density. Thus, Ceiling-type DD is more conservative to assess extinction because production of new individuals is likely to be underestimated at low density and, hence, the risk of extinction will be overestimated (Burgman et al., 1993).

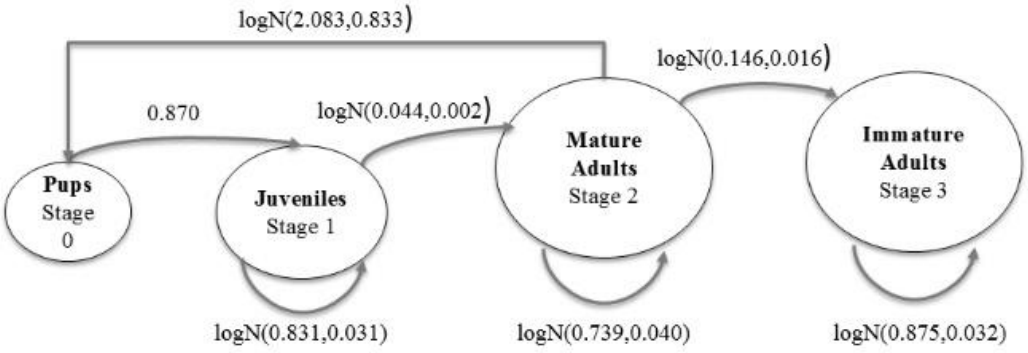

Figure 1. *Female SMA life cycle. The values above the arrows are estimates for transition and permanence rates*

Then, our model also assumes Ceiling-type DD. If the population significantly grows so that it reaches *K*, then it remains at that level until the population decreases below this level. In this case, *K* acts as a population ceiling (Akçakaya et al., 1999). These conditions are modeled in the first and second steps of the algorithm.

The proposed model also includes uncertainty. The effect of parameter uncertainty on outcomes can be bounded by fitting a Probability Distribution Function (PDF) (e.g., Normal or Lognormal) to each parameter chosen from their average, lower and upper values. For a given scenario, one should define initial conditions and fit a PDF to each parameter using data, literature information, and/or expert opinion. After that, a chosen number of replications of the model (say 10,000) can be simulated via Monte Carlo approach (Kalos and Whitlock, 2008). For a given scenario, the result is a dataset of abundances, $N_i(t)$, for each stage *i* and for each time-step *t*. From such dataset, the following summarized outputs can be provided:

- PDFs for the proportion of abundance decline within 100 years.
- Cumulative Distribution Functions (CDFs) for the time to quasi-extinction (i.e., 80% population decline) within 100 years.
- point estimates originated from either the PDFs or CDFs, i.e.:
    - year-specific risk of quasi-extinction (i.e., probability of 80% abundance decline).
    - median time to quasi-extinction.
    - expected minimum abundance (i.e., an estimate of the smallest population size that is expected to occur within 100 years).
    - expected total harvest weight at the end of simulation.
    - year-specific risk of low harvest (i.e., the probability that the annual harvest will be at or below a threshold measure).

For the same population, one can conduct a sensitivity analysis of harvest scenarios and control measures by varying parameters such as h_i and N^{cutoff}, while keeping all other parameters the same. For example, by keeping all other parameters the same as in Scn-0 and varying parameters related to harvest, we aim at evaluating the added/reduced risk caused by each harvest scenario. Likewise, by keeping all other parameters the same and varying the cutoff threshold, we aim to assess the reduced risk caused by this limit that is, in fact, a control measure to satisfy conservation objectives.

Thus, the proposed model provides the following outputs: risk categories and ranking of scenarios for better risk communication to stakeholders; the quantified reduced risk caused by varying control measures; suggest harvest regime that not only reduces conservation concerns, but also achieves maximal benefits by increasing yield over the long term at acceptable risk of low harvest.

Application Example

We conduct an application example and parameterize the proposed model to the South Atlantic Ocean. The next subsections are useful as a guide on how to apply the model and interpret results. The outcomes are useful to validate the model, yet they should not be used to drive real political decisions with regard to conservation of SMA since data are still uncertain. However, in the future, with more accurate SMA catch data available, a new round of scenarios can be simulated and the outcomes may be used for this purpose.

Materials and Data Sources

Data used here are gathered from several public sources. Estimates of parameters related to the harvest distribution of stages and sex were obtained from onboard observer's data provided under request by the Brazilian Ministry of Fisheries and Aquaculture. An onboard observer after each set filled out the logbooks. Data included individual records of 33 vessels in the South Atlantic that registered 241,776 SMAs catches between December/2004 and February/2009. Useful information to this work also considered: the vessel identification, onboard observer identification, date, location of fishing ground (latitude and longitude), effort (number of hooks), fork length (cm) and sex (male, female or not available).

To transform data given in terms of fork length into weight or age and the inverse, we use the length-weight correlation (Kohler and Casey, 1995) (*Eq. 5*) and the 3-parameter Gompertz growth function for SMA, (Natanson, 2002) (*Eq. 6*), which produced the most biologically reasonable estimates for females.

$$WT = 5.2432 \times 10^{-6} \times (L)^{3.1407} \quad \text{(Eq.5)}$$

where: WT = Total weight; L = Fork length (i.e., the length of a fish measured from the tip of the snout to the end of the middle caudal fin rays and is used in fishes in which it is difficult to inform where the vertebral column ends (Froese and Pauly, 2011)).

$$L(t) = L_0 e^{G(1-e^{(-kt)})} \text{ and } G = \ln {}^{L_\infty}/_{L_0} \quad \text{(Eq.6)}$$

where: t is the age (years); L_0 = 88 cm; $L_\infty = 366$ cm; and k = 0.087 $year^{-1}$.

From the female total catches, only 7,359 had their fork length measured so that we transform fork length into age, then into stage, and calculate (respectively for age 0, juvenile, mature adult and post-reproductive adult) the annual catch percentage for each stage i, AC_i, as 5.95%, 92.21%, 0.38% and 1.46% and the average weight in kg of each stage as 6.7, 113.9, 329.5, 417.2. Thus, stage-specific harvest rates are estimated for a specific scenario as follows:

$$h_i = \frac{(population\ harvest\ rate\ per\ year\ for\ the\ specific\ scenario) \times \sum_{\forall i} N_i(0) \times AC_i}{N_i(0)} \quad \text{(Eq.7)}$$

Bycatch of SMAs results in substantial number of SMAs being discarded dead. Quantifying total harvest from bycatch is challenging because comprehensive data on these discards are unavailable (Cosandey-Godin and Morgan, 2011). Then, we assume that mortality of SMAs is greater than catch estimates (Anon, 2013) for two reasons. Indeed, estimates may not include uncertainty about (i) post-release mortality (Cosandey-Godin and Morgan, 2011; Gilman et al., 2008), and (ii) the catches of sharks that were illegally discarded at sea to make space for tunas in the freezers.

Estimates of initial abundance and carrying capacity were obtained from a stock assessment conducted by ICCAT (Anon, 2013) and estimates of parameters related to the ecology and population dynamics (i.e., natural mortality, age and growth, reproduction, stage-specific life span, age at first maturity, age-weight) were gathered from literature. *Table 1* describes the model parameters and their source of information. For the cases, where there is more than one source for the same parameter, we assume the one with widest confidence interval in order to be more conservative. Note that for the Carrying Capacity parameter, to extrapolate data that do not differentiate sex (Anon, 2013) into females only data, we consider the common male:female ratio in the population that is equal to 1 (Garcia-Cortes and Mejuto, 2002).

We adopted software RAMAS Metapop v.6.0 (Akçakaya and Root, 2013). This software is a computational tool for population model construction and probabilistic simulation via Monte Carlo methods (Kalos and Whitlock, 2008).

Parameters, Uncertainty and Error

Table 1 presents the parameters ω governing the dynamics of the system. They were given either as a mean value $\bar{\omega}$ or as a triplet $(\omega_L, \bar{\omega}, \omega_U)$, which represents lower, mean and upper values. For the latter case, we consider the parameters have a truncated normal distribution and that the error $(\max\{\bar{\omega} - \omega_L, \omega_U - \bar{\omega}, 0.5(\omega_U - \omega_L)\})$ corresponds to a 3σ interval; thus, such parameters will be randomly selected to fall between their limits in 99.865% of replications.

It is believed that one can make good use of a Gaussian approach in vital rates because there is a reasonable reason for random values not to be too far away from the average, i.e., there are biological limitations preventing very large deviations and natural forces of equilibrium bringing vital rates back to their average values (Taleb, 2007). For probabilistic simulation, the RAMAS software converts the normal distribution of vital rates into a corresponding lognormal distribution. This conversion avoids bias resulting from truncation because $\omega \geq 0$ (Burgman et al., 1993; Ferson and Akçakaya, 1990).

We assume that the population is exposed each year to a 10% probability of recruitment failure (i.e., $F^{rf} = 0.1/year$ - *Eq. 4*) that decreases stage 0 abundance to 5% of the value expected if such event had not occurred. Carrying capacity (K) was estimated (*Table 1*) based on the population biomass provided by the stock assessment as 956,777 mt (from Scenario-6 in reference (Anon, 2013)) under virgin conditions, i.e., the current population abundance if there was no fishing. Most simulation scenarios included annual harvest that prevented abundance from reaching the ceiling defined by K.

Initial Conditions

First, we estimate the initial population abundance from the stock assessment by ICCAT (Anon, 2013), which simulated 13 scenarios with varying parameters and provided the SMA biomass in 2010 as result of each simulation. We consider the effect of uncertainty in initial biomass by using the result of the scenario with the lowest value, i.e., 885,085 mt from Scenario-6, Table 19 (Anon, 2013). Next, we assume the initial stage distribution is equal to the steady stage distribution in *Eq. 3*; this results in the initial conditions in *Table 1*.

Harvest Scenarios

The real number of SMA catches is uncertain. The landing data only show known catches, but the unknown catches (e.g., illegal discards at sea) may be even greater than the known ones. As suggested by (Taylor et al., 2002), the effect of parameter uncertainty on outcomes can be considered by consolidating scenarios with parameters chosen from the range of plausibility. We interviewed an onboard observer and data monitor that worked in a tuna longline vessel that had capacity to stock 200 tons of fish meat. From that discussion, we deliberated a range of playsibility for real catches, i.e., we assumed real catches are not smaller than Catch Estimates (CE) in 2010 and not greater than thirty-two times CE. We simulated hundreds of harvest scenarios by varying catch paremeters whitin this range of plausibility. For the sake of illustration, *Table 2* only presents the parameters of six scenarios that we thought are the most relevant to present in this work. We selected these scenarios for presentations purpose for the following reasons: Scn-0 is a base scenario that reflects natural population growth without any bycatch; Scn-CE is one extreme in the range of plausability which reflects catch estimates without unknown bycatches; Scn-4 is another extreme that reflects total catches (known and unknown) being thirty-two times greater than CE; and Scn-1. Scn-2, Scn-3 are well spaced intermediate scenarios withint the range of plausibility in which total catches are, respectively, four, seven and twenty-one times greater than CE.

Table 2. *Harvest parameters*

Harvest scenario	**Scn-0**	**Scn-CE**	**Scn-1**	**Scn-2**	**Scn-3**	**Scn-4**
Total harvest per year	0	0.29%	1%	2%	6%	9%
h_0	0	0.10%	0.34%	0.67%	2.02%	3.03%
h_1	0	0.40%	1.39%	2.87%	8.34%	12.51%
h_2	0	0.01%	0.04%	0.08%	0.25%	0.38%
h_3	0	0.06%	0.21%	0.41%	1.24%	1.87%
Number of female catches at first year	0	6,259	21,584	43,168	129,505	194,257
Number of times that simulated catches are greater than catch estimates (Anon, 2013)	0	1	4	7	21	32

By simulating Scn-0, we aim at evaluating the natural population dynamics, quantify its background risk and the added risk caused by all relevant scenarios when compared to it. By simulating Scn-CE, Scn-1, Scn-2, Scn-3 and Scn-4 we aim at propagating the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_36913709
© 2018, ALÖKI Kft., Budapest, Hungary

effect of uncertainty about real catches. We also simulate all harvest scenarios with and without cutoff in order to evaluate the maximum reduced risk caused by this management threshold that is, in fact, a control measure to comply conservation objectives.

Risk Categories

By categorizing risks, results can be better interpreted by risk managers, society, and other interested parties. We use the risk categories proposed by (Duarte et al., 2013, 2014; Duarte and Droguett, 2015). It is important to note that the following categories are more conservative than the International Union for Conservation of Nature (IUCN) categories (IUCN, 2001). The latter are used to classify species affected by a whole range of environmental changes and human disturbance at regional (IUCN, 2003) or global-levels, whereas the former is proposed to classify risks caused by a single stressor (harvest) to a single population, which is our case.

- CRITICALLY ENDANGERED (CR): more than 50% additional probability of quasi-extinction within 3 generations (i.e., median time to quasi-extinction is shorter than 3 generations).
- ENDANGERED (EN): more than 20% additional probability of quasi-extinction within 5 generations.
- VULNERABLE (VU): more than 10% additional probability of quasi-extinction within 5 generations.
- NEGLIGIBLE (NE): less than 10% additional probability of quasi-extinction within 5 generations.

We assume that female SMAs have a generation time of 20 years (Froese and Pauly, 2011) and harvest scenarios that cause NE risks are considered sustainable.

Results and Discussion

Fig. 2 illustrates how female SMA average abundance in the South Atlantic varies over time (100 years) for several harvest scenarios (Scn-0, Scn-CE, Scn-1, Scn-2, Scn-3 and Scn-4, respectively, 0%, 0.29%, 1%, 2%, 6% and 9% of the population removed every year). The Scn-0 curve represents the population dynamics if no fishing occurs. Scn-0 curve is superimposed on Scn-CE, which shows the abundance trajectory if real catches were as described by landing data. The abundance reaches a dynamic equilibrium at the carrying capacity, which is around 2,33E+6.

Note that population growth rate when unfished (Scn-0) is almost nil and the same happens to Scn-CE. Obviously, the population abundance for Scn-CE is overestimated because landing data do not consider unkown bycatches discarded at sea. Catch estimates from landing data is so optimistic that, for practical purposes, the population dynamics under these catch estimates (Scn-CE) is the same as under no fishing (Scn-0). Nonetheless, Scn-CE is a positive scenario that is presented to highlight model accuracy.

Because of the great uncertainty about real catches, we also consider Scn-3 or Scn-4 (6% or 9% annual harvest, respectively), which show overfishing situations in which the population rapidly declines to, respectively, 1,260,764 (258,496 mt) and 519,322 (106,477 mt) females. Scn-3 causes an additional 10.6% risk of quasi-extinction within 5 generations; then, it is classified as VU, whereas Scn-4 causes 56.2% probability of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1603_36913709
© 2018, ALÖKI Kft., Budapest, Hungary

quasi-extinction within 3 generations; thus, it is categorized as CR. These two scenarios simulate more conservative situations, but, given the great importance of SMA to the ecosystem, it is worth dealing with uncertainty in this way. In the case of more accurate SMA catch data being available in the future, interpretation of results may change.

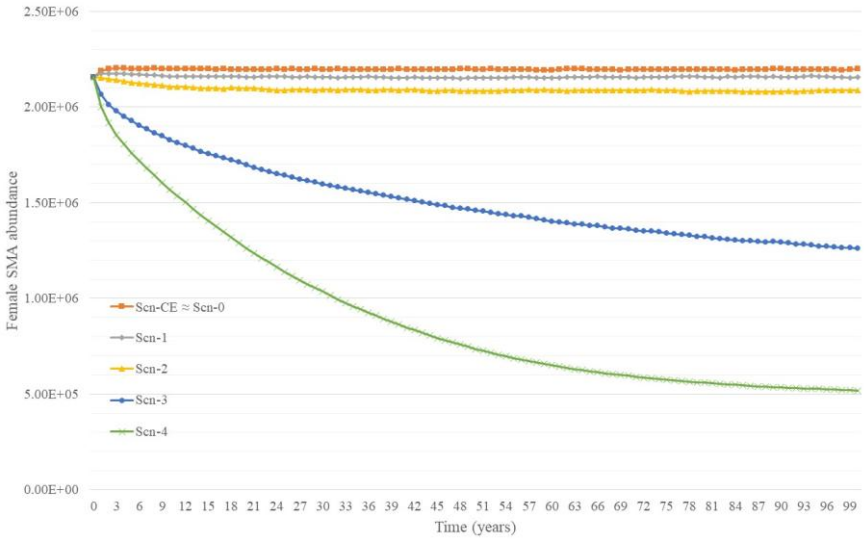

Figure 2. *Female SMA average abundance for relevant scenarios.*

Table 3 summarizes the main results for each harvest scenario. Values with a + or – symbol mean that they are being compared to the benchmark Scn-0, except for the maximum effect of cutoff measure, which is compared against the same scenario without cutoff. The risk of harvest scenarios is indicated both as additional risk of quasi-extinction compared to Scn-0 and as reduced expected minimum abundance also related to Scn-0. The median time to quasi-extinction is calculated from the CDF for the time that the population size will fall below the quasi-extinction threshold. Only Scn-4 had the median of its distribution shorter than 100 years, i.e., 50% probability of quasi-extinction within 56 years. All other scenarios had less than 50% probability of quasi-extinction within 100 years.

Table 2. *Risk results*

Harvest scenario	Scn-0	Scn-CE	Scn-1	Scn-2	Scn-3	Scn-4
Risk of quasi-extinction	0	0	0	0	+0.106	+0.878
Risk category	NE	NE	NE	NE	VU	CR
Median time (years) to quasi-extinction	>100	>100	>100	>100	>100	56
Expected minimum biomass (mt)	332,785	327,778	316,081	297,773	170,477	80,731
Maximum effect of cutoff measure	Not applicable	Not significant	Not significant	Not significant	-0.057 risk of 83% population decline	-0.721 risk of 87% population decline
Expected yield (total harvest weight (mt))	Not applicable	73,660	241,554	469,821	1,000,000	886,045
Risk of low harvest (≤ 250 mt)	Not applicable	0	0	0	0.132	0.887

© 2018, ALÖKI Kft., Budapest, Hungary

The Effect of the Cutoff Threshold Measure

We quantify the maximum effect caused by the cutoff management threshold. The maximum effect of cutoff is measured as the maximum reduced risk for a scenario with and without cutoff. The reported number is the Kolmogorov-Smirnov test statistic D, which is the maximum vertical difference between risk curves, based on a two sample Kolmogorov-Smirnov test (Akçakaya and Root, 2013). The approximate location (point X at which maximum reduced risk occurs, i.e., percentage of decline) is also given.

Thus, we simulate all harvest scenarios with and without cutoff, compare their risk of population decline and measure the maximum reduced risk and the point at which it occurs (*Table 3*). For Scn-4, the cutoff measure reduces 72% the risk of 87% population decline, whereas for Scn-3, it reduces 5.7% the risk of 83% population decline. For all other scenarios, risk reduction is insignificant.

Harvest Results

The yield of SMA is not only important as a secondary product, but also as an indicator for yield of tuna, since SMA are bycatched by various types of tuna and tuna-like fishing gear. Thus, changes in SMA harvest means proportional changes in tuna harvest. The number of SMA catches as a proportion of tuna catches depends on several specific factors such as the vessel fishing gear and fishing grounds. Thus, the vessel interested in how the presented SMA harvest results impact their yield of tuna should make their own estimates.

Fig. 3 shows, for each harvest scenario, the expected total weight of harvest as a function of time. The harvest is calculated based on the average weight of each stage (see Materials and Data Sources section). Scn-0 is not applicable here since it is not a yielding scenario. Total harvest for 100 years of simulation and risk of low harvest are presented in *Table 3*.

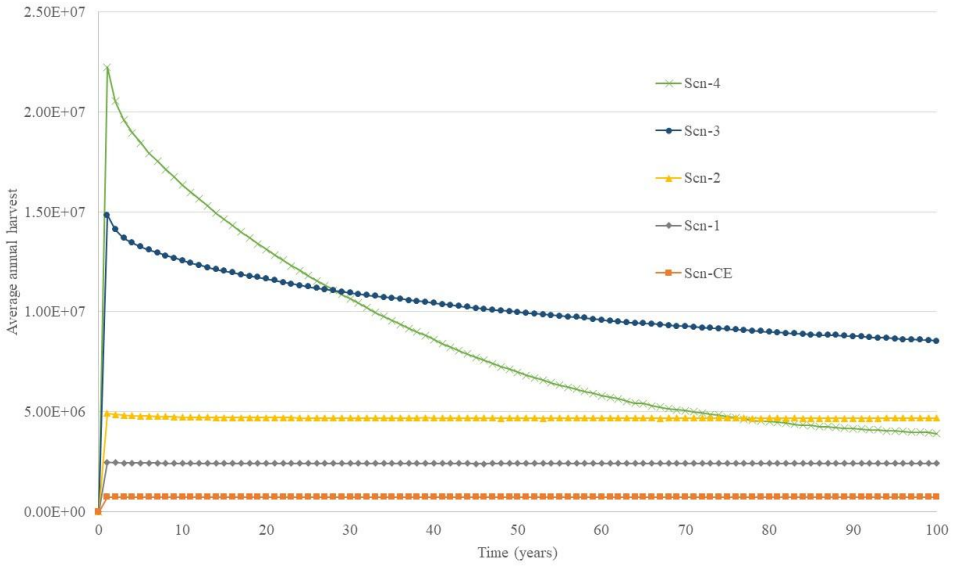

Figure 3. *Average weight of female SMA harvest as a function of time for each harvest scenario (Scn-CE, Scn-1, Scn-2, Scn-3 and Scn-4)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

It is worth focusing on Scn-3 or Scn-4 to deal with uncertainty because of inaccurate SMA catch data. These scenarios are not good for both conservation and production because: (i) they are not sustainable, i.e., Scn-3 is categorized as VE and Scn-4 as CR; (ii) although Scn-3 maximizes yield, it causes a considerable risk of low harvest (13%); and (iii) Scn-4 does not provide maximum yield and risk of low harvest is significantly high (89%).

Conclusions

This paper dealt with a very important bycatch species of worldwide tuna fisheries. Its capture is of major conservation concern, thus this subject is of great interest and relevance for pelagic fisheries and their management. Yet, the methodology to approach the problem is innovative because it is capable of: (i) quantifying the added risk of extinction caused by harvest scenarios and the reduced risk caused by cutoff measures; (ii) dealing with uncertainty; (iii) including low frequency events; and (iv) quantifying risk of low harvest.

The proposed model can be applied to any SMA population by changing initial conditions and harvest parameters. We conducted QERA for the SMA South Atlantic population in order to exemplify the application of the model and consistent results were obtained.

The model is most useful for risk managers as an aid for rational decisions about harvest regimes under uncertainty. The flexibility of the model made it practicable to simulate and evaluate hundreds of scenarios and analyze their results. The risk results of relevant scenarios were transformed into risk categories for easier communication to stakeholders. The model also allowed for update of parameters as new data become available. Companies interested in sustainable production can thus register data of SMA bycatch and use them as an input for the model.

For the application example, great uncertainty on input data also caused great uncertainty in results. Without accurate SMA catch data, which is caused for example by unknown illegal discards, uncertainty about the real scenario is great. Consequently, risk results for SMA quasi-extinction varies from categories NE to CR.In this sense, we recommend future studies that can reduce data uncertanty, e.g.: improving the current methods for data monitoring onboard; new data gathering methods other than the traditional onboard observer (e.g., fin trade data); and new statistical approaches for catch estimates (e.g., bayesian statistics). In this way, our proposed model can be used to simulate less uncertain scenarios in order to aid decision makers. For now, the application example described in this article only works for the sake of illustration.
