Data detected by Multiple QTL Mapping is shown in *Table 5* and *Figure 3*. Two QTLs for days to heading were detected by MQM in field (control) and tunnel (drought stress) trials, on a 2D chromosome, with LOD values 6.93 and 3.14. A major QTL for DPM was found by MQM mapping under control conditions, on 2D chromosome with LOD value 9.39. For SL, a major QTL was found on 4A chromosome under control conditions. For SL, a second QTL was detected on 7A chromosome under water stress with 4.93 LOD value. A LOD value 2.15 was found for TGW under water stress condition. Two QTLs with LOD values 3.98 and 2.41 were found under control and stress conditions on 6A and 1B chromosomes.

Clustering of QTLs for interval mapping

During current study, the different QTLs were found (*Fig. 4*). Two clusters of QTLs were detected on 6A chromosome, which covered almost all part of it. First group contained QTLs for (DH) under field conditions, (DPM) under field conditions, Spike length under field conditions, covered the short arm of chromosome. The second group contained QTLs for (DH) under field conditions and (DPM) under field conditions, which covered the long arm of chromosome. On 2D chromosome, two groups of QTLs were found. First group of QTLs consisted of (DH) under field conditions and DPM under field conditions. The second group consisted of four QTLs for DPM under field conditions and DH under field conditions.

Discussion

These are molecular advances, which made it possible to detect chromosomal regions containing genes for quantitative traits. Bread wheat (*Triticum aestivum* L.) is the staple food of our country and most part of the country is drought prone area so the yield of wheat is badly affected by environmental stress. According to International Water Management Institute (IWMI), wheat production of South Asia will reduce by 50% by 2050 (de Fraiture et al., 2007). The main objective of the study was to trace such lines which are drought tolerant and can produce improved yield in drought prone areas of the country. Hexaploid wheat has complex genome with three types of genome A, B and D. At the time of wheat evoluation three types of plants contribute A, B and D genomes. At that time, *Ae tauschii* is D genome donar and diversity of this plant was very less as compared to two genome contributing plants (Dubcovsky and Dvorak, 2007) limiting its ability for its own evolutionary progress. Few genes of *Ae tauschii* were found for the development of new wheat cultivars, which forced the breeders to collect the accession of *Ae. tauschii* from different parts of the world and used these accessions to produce genetic diversity in wheat genome (Sohail et al., 2011). *Ae. tauschii* is the specie which contributes characteristics of biotic and abiotic to wheat genome. *Ae. tauschii* accessions have D-genome diversity. CIMMYT (International Center for Maize and Wheat improvement) incorporated this diversity of *Ae. tauschii* in elite durum lines and resynthesized the wheat by crossing the *Ae. tauschii* and durum lines (Trethowan and Mujeeb-Kazi, 2008). Synthetic wheat lines are stress tolerant so these lines have ability to overcome stress and better yield under drought stress conditions. During field and tunnel experiments, drought-mapping populations presented extensive segregation as compared to the SH 349 and Opata for most traits under consideration. Recombination events were evidenced by improved offspring as compared to their parents (Zhuang et al., 1997). The mapping population displayed a usual dissemination for drought tolerance of maximum yield components with a great extent of transgressive segregation (*Fig. 1*). All traits showed Normal distribution during the experiment. Transgressive segregation was displayed by all traits in both directions during the analysis of frequency distribution. Polygenic inheritance was observed as the individual lines showed lower and higher values as compare to the parental lines (Kearsey and Pooni, 1996). Transgressive segregation and continuous variation are the two evident attributes of polygenic inheritance (Poehlman and Sleper, 1995). From *Figure 1,* it is cleared that DH and DPM are polygenic inheritance traits and showed normal distribution with transgressive segregation. It is necessary to detect QTLs that the parents should be of contrasting characters under consideration so parents were selected on contrasting characters of interest. For determination of QTLs, it is necessary that major variation exist between the descendant lines.

Table 3 shows the exact parental positions and ranges. Two-factor factorial analysis of variance was used to identify the interaction between the genotypes and treatments. Significant interactions occurred among all genotypes and treatments (*Table 4*). The Pearson coefficient was used to find out significant correlation between traits of interest. They showed different increasing or decreasing values according to control and stress conditions (*Table 4*). The major interaction may be because of environment and genotype interaction, which results in obvious alterations. Significant interactions were observed in genotypes and treatments at α 0.05. Supporting results were found during the El-Feki (2010) experiment, who found out significant ($P \leq 0.05$) correlations in four environmental conditions over two years between grain yield and plant height and

DOI: http://dx.doi.org/10.15666/aeer/1604_44314453

average kernel weight. A research also carried out by Narasimhamoorthy et al. (2006) who found a significant ($P \leq 0.05$) correlation between plant height, average kernel weight and test weight under two environmental conditions. Same results were also found during the experiment of Butler et al. (2005) for correlations of these traits under two environmental conditions. During the recent study, few yield components showed significant correlation with each other and rest of traits showed non-significant results.

For the growth and development of plants, climatic factors play a very important role. Under stress conditions, morphological, physiological and biochemical changes occurred in plants, which ultimately affect growth and yield of plants. QTLs detected by Interval Mapping are mentioned in *Table 5*. Days to heading, is a very crucial stage in wheat growth and development as it is a complex trait and is controlled by many genes at one time. There is variation in day to heading time, which enables plants to grow under diverse environmental conditions. Four QTLs that affected days to heading were detected under field experiment with LOD values 7.69, 3.89, 1.91 and 2.00 on 2D and 6A chromosome respectively. Alleles for two QTLs contributed by Opata and alleles for two QTLs contributed by SH349. First two QTLs were very important, having values 7.69 and 3.89, which were major QTLs. Narasimhamoorthy et al. (2006) reported a QTL for DH on 2D chromosome, while recent findings were also supported by the study and QTLs for DH were reported on 2D and 6A chromosome and results for 6A were supported by Huang et al. (2003).

Table 5. *QTLs detected by multiple QTL mapping of a DH population Opata × SH349. QTL were identified by interval mapping and significance was recognized at an LOD threshold following* 1,000 *permutations (in brackets) (different threshold for each trait). Size of the effect and phenotypic variation explained (R^2) are also presented*

a: Marker interval where the QTL has been detected. b: Chr Chromosome. c: Effects on the examined characters of the alleles from the 'Opata'. d: R2 (%) is the quantity of phenotypic variation clarified by the QTL

The duration of maturity of any crop is decreased by drought stress and differs with genotype, because of their inherent nature. A QTL on chromosomes 1B affected days to physiological maturity having LOD value 3.06, which was a major QTL, and the allele for this QTL was contributed by SH349 and 80.4% R^2 values. Results found during the previous study by Peleg et al. (2009) were in agreement with the present study as QTL for DPM was reported on 1B chromosome. Two QTLs for G/S were found by interval mapping under control conditions having values 2.31 and 2.43 on 6A and 7B chromosomes respectively. A QTL was found on 6A chromosome by Peleg et al. (2011). No supporting reference was found for QTL discovered on 7B, therefore, it is a novel QTL found during our research. The allele for this QTL was contributed by SH349 with 13.1 R^2 value. Under drought conditions, a minor QTL was found on 5A

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_44314453

chromosome with a LOD value 2.03 for thousand-grain weight by interval mapping. Peleg et al. (2011) and Dashti et al. (2007) found same results for thousand-grain weight on 5A chromosome under stress conditions. A QTL was found on 6A chromosome under control conditions having a LOD value 2.02. No supporting reference was found for QTL found for Spike length so it is also a novel QTL.

Multiple QTL Mapping (MQM) was used to get more refine results for QTLs obtained by Interval mapping. Two QTLs were found on 2D chromosome under control and stress conditions for days to heading. These two QTLs were more reliable and consistent as these were found under control and stress conditions and peak marker and chromosome were same. A very little work has been done on yield and yield components of wheat, as wheat genome is very complex and mainly under water stress conditions (Quarrie et al., 2005). They reported QTLs for days to heading on 2D chromosome. A major QTL for days to physiological maturity was detected on 2D chromosome with LOD 9.39 value during the recent study by MQM mapping. Same results were found during the previous study by Huang et al. (2006). Wheat spike grows from the axils of main shoot leaves. The number and length of spike differs from genotype to genotype and mainly depends on ecological situations. For spike length, a major QTL was found on 4A chromosome under control conditions with 3.45 LOD value. A second QTL for spike length was found under stress conditions on 7A chromosome with a LOD value 4.93. Previous results of Chu et al. (2008) and Jantasuriyarat et al. (2004) were in agreement with the recent study.

The main aim of the present study is to improve the existing high yielding drought sensitive wheat cultivars. During the last twenty years, QTL analysis largely used to detect QTLs associated with complex traits, such as yield and yield components under drought stress (Ain et al., 2015). These traits are polygenic traits and are controlled by many genes at a time so it is very difficult to clone such QTL of the traits under drought stress. Only a few QTLs have been utilized in plant molecular breeding for wheat and none QTL is clone yet (Fleury et al., 2010). As discussed above, the major QTLs found during the study can be used for molecular breeding. Such lines can be grown under water stress conditions. Two major QTLs for DH were found by interval mapping under control conditions having LOD values 7.69 and 3.89 respectively. These QTLs are of great importance as these were located on 2D chromosome as it is difficult to find polymorphism for D genome so we can use these QTLs in marker-assisted selection. Additive effect showed that the allele for the second QTL for DH was contributed by SH349 (drought tolerant parent) with 21.4% phenotypic variation. Again, drought tolerant parent (SH349) contributed alleles for third major QTL with 3.06 LOD value and 80.4 % phenotypic variation. QTLs found by the MQM are more reliable and precise as these were obtained after the interval mapping. Eight QTLs were found during the present study and out of which six were major QTLs. Highest LOD value 9.39 was noted for DPM with 79.4 % phenotypic variation under control conditions on 2D chromosome. After that, second major QTL was reported on 2D chromosome for DH with 6.93 LOD value with 35.7% phenotypic variation. Third major QTL was found on 7A chromosome with 4.93 LOD value and allele for this QTL was contributed by SH349. 7A chromosome is considered as important chromosome for yield and yield component (Quarrie et al., 2006). Fourth QTL was found on 6A chromosome with 3.98 LOD value for G/S and again allele for this QTL was contributed by SH349. Same results were found during previous study by Peleg et al. (2011) who reported QTL for G/S on 6A chromosome. Last two major QTLs were found on 4A and 2D chromosomes

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_44314453

with 3.45 and 3.14 LOD values respectively. These QTLs are very important as we can exploit in future for molecular breeding especially the QTLs, which were located on 2D chromosome with high LOD value. A minor QTL for thousand-grain weight was found during the study on 5A chromosome with 2.15 LOD values. QTL for TGW on 5A chromosome was reported during the previous study by Wang et al. (2009) and Peleg et al. (2011). Another minor QTL for G/S was found on 1B chromosome with 2.41 LOD value and additive effect -5.99, means alleles contributed by SH349. In previous study, QTL was reported on 1B chromosome by Dashti et al. (2007). Five drought tolerant wheat lines were identified based on a thousand-grain weight, ranging from 49 to 62 g (*Table 6*).

Table 6. *Drought tolerant lines*

Sr no	Line	Thousand Grain Weight (gm)	Grain per spike (n)
1	54	62.0	26
2	56	62.0	45

4	59	55.6	55
5	18	49.0	26
Parent 1	Opata	22.0	31
Parent 2	SH349	45.0	23

Conclusion

The present study was targeted to dissect the complex quantitative inheritance of yield component of wheat under control and drought stress conditions. Genotyping was executed using SSR markers. Major and minor QTLs were recognized for different yield components. One QTL for thousand-grain weight was found by interval mapping on 5A chromosome while four QTLs were found by multiple QTL mapping under drought stress conditions on 2D, 7A, 5A and 1B chromosome. These identified QTLs are of primary importance for high resolution mapping in synthetic hexaploid wheat. These identified genomic loci were considered auxiliary as they were saturated with molecular markers for accurate localization of QTLs leading to the inheritance of these polygenic traits. Further, genetic and transcriptome characterization of this mapping population could be supportive for the identification of genomic regions closely associated with drought stress resistance. Introgression of these resistant regions into adapted genetic backgrounds through marker-assisted selection is a promising tool for plant evolution, gene cloning and transgenic crop improvement.

(Received 22nd Mar 2018; accepted 27th Jun 2018)

Abstract. The study aimed to assess the genuine impact of phosphogypsum on the growth, feeding, respiration and regeneration of earthworm *Eisenia fetida*. In laboratory condition the earthworms were cultured under 0% (control), 4%, 8% and 10% concentration of phosphogypsum for 30 days. After completion of every 10 day changes in the above parameters were observed to track the impact of phosphogypsum. With increasing exposure duration and concentration of phosphogypsum lower growth rate, declined feeding habit, maximum respiration rate and deprived regeneration power were noticed. The highest and lowest growths were 1.39 gm at 0% and 0.05 gm at 10%, respectively. Maximum feeding rate was 32.65 with a minimum rate 16.20 g g^{-1} live tissue. Respiration rate was highest at 10% i.e. 0.0578 g^{-1} live worm tissue hr^{-1} kg^{-1} soil, as most of the energy used to respire to sustain in such diverse condition and 0.575 g^{-1} live worm tissue hr^{-1} kg^{-1} soil recorded as lowest in 0%. The rate of regeneration was deeply hampered and there was no viable worms left at 8% and 10% concentration to assess. Regeneration was only observed at 0% and 4%.
Keywords: *growth, feeding, respiration, regeneration, earthworm, concentration*

Introduction

Anthropogenic activity and environmental changes are the major sources which directly affect the integrity of terrestrial ecosystems. Industrial activities, waste disposal and agricultural practices are sources of soil pollution. Soils are complex associations containing living organisms, mineral particles and organic matter. The clay fractions of the minerals and the humus of organic matter are colloids of a very small size with a large surface area to volume ratios, and consequently with a high binding capacity to inorganic and organic molecules. The binding of pollutants to soil colloids reduces their mobility and their bioavailability and modulates their biological effects. Deposition of different contaminants on soil through anthropogenic sources are very much prone to alter the basic composition and this might be hazardous to inhabiting organisms. The macrofaunal groups of soil are the integral part of the soil ecosystem and have a significant role in soil fertility and functioning. Earthworms are the one of the macrofaunal inhabitant of the soil and hold the key role in soil formation, alternation and function.

The casts of earthworms boost soil fertility and help various organisms to inhabit the soil and to complete their life cycle. Macro- and micro nutrients and their cycling process solely depend upon earthworms and it has been shown that macronutrients are abundant around earthworm casts and burrows which supports root growth (Edwards and Bater, 1992). Earthworm casts have been found to contain elevated amounts of NH:, NO;, Mg, K and P relative to the surrounding soil (Lunt and Jacobson, 1944;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_44554476

Parle, 1963; Gupta and Sakal, 1967; Syers et al., 1979; Syers and Springett, 1984; Tiwari et al., 1989). Earthworms influence the soil structure by forming macropores, which allow oxygen to enter the soil, whereas micropores between the aggregates give a good water-holding capacity (Lavelle, 1988; Willems et al., 1996). In addition to forming macropores and increasing water infiltration, earthworms have been shown to increase soil the aggregate stability (Li and Ghodrati, 1995) and the water-holding capacity (Stockdill, 1982).

Generally organisms are known to avoid areas polluted with contaminants above tolerable levels (Amorim et al., 2005; Fenoglio et al., 2007). Earthworms serve as indicators of soil status such as the level of pollutants e.g. agrochemicals, heavy metals, toxic substances, industrial effluents and human-induced activities e.g. land-management practices and forest degradation (Radha and Natchimuthu, 2010). Any changes in soil properties have great impact on earthworms and hence they serve as indicator organisms for ecotoxicological studies (OECD, 1984).

The human impact on the environment can be scaled by the measurements of heavy metals in the soil, in plants and in animals because metal pollution adversely affects the density and diversity of biotic communities including humans (Bengtsson et al., 1981; Mountouris et al., 2002). the abundance and distribution of earthworm species (*Pontoscolex corethrurus, Perionex excavatus, Dichogaster modigliani* and *Polypheretima elongate*) (Ching et al., 2006), is primarily based on soil the type, soil moisture, texture and the soil constituent. Usually, the abundance and distribution of earthworms in undisturbed soil are greater than those, that soils that have been cultivated, burnt or undergone various crop practices like the use of fertilizers, fallowing etc. Some researchers have focused on the role of earthworm species in their tolerance and absorption of metals, petroleum hydrocarbons and polynuclear aromatic hydrocarbons (PAHs) (Zachary and Reid, 2008; Owojori et al., 2009).

Generally, the potential hazards of various environmental toxicants to soil invertebrates are assessed by bioassays with the keystone species - earthworm. Earthworms are one of the first receptors affected by soil contamination. They are more susceptible to metal pollution than any other groups of soil invertebrates and toxicity data on earthworms are important in determining “Safe levels” for metals and other contaminants in soil.

Heavy metals have been shown to cause lysosomal membrane instability, changes in gene expression, oxidative stress (Spurgeon et al., 2004a; Berthelot et al., 2008; van Gestel et al., 2009), reduced growth (Spurgeon et al., 1994), slower sexual development (Spurgeon and Hopkin, 1996; Spurgeon et al., 2004b), depleted cocoon production, hatchability (Reinecke et al., 2001; Davies et al., 2003; Spurgeon et al., 2004a) and juvenile viability (Bengtsson et al., 1986; van Gestel et al., 1992), increased mortality (Neuhauser et al., 1985; Spurgeon et al., 1994; Davies et al., 2003) and also they affect the population size, abundance and species diversity of earthworms (Spurgeon et al., 2005).

Earthworms, especially the compost worm *Eisenia fetida*, are model organisms for assessing the effects of various chemicals on terrestrial invertebrates (Spurgeon et al., 2003; Nahmani et al., 2007). *Eisenia fetida* (*andrei*), which is a manure species living in organic matter-rich substratum is recommended by the international guidelines (OECD, 1984; ISO, 1998) as a test species and has been mainly used in genotoxicity studies. It has a short life cycle, hatching from cocoons in 3 to 4 weeks, and reaching maturity in seven to eight weeks. It is a prolific species and its rearing in laboratory is

DOI: http://dx.doi.org/10.15666/aeer/1604_44554476

simple. It is a representative component of the terrestrial fauna, but is mostly used as a compost worm because of its great potential towards decomposing waste. It is an epigeic species and is sensitivity to soil pollutants compared to other field earthworms.

Leachate is a liquid formed from the percolation of rain water through the disposed wastes. The dissolution of contaminants such as heavy metals in the leachate can pose serious pollution problems. Species richness may be reduced due to metal pollution (Nahmani et al., 2003) and this indirectly alters species interaction (Grzes, 2009). From ecotoxicity point of view, earthworms are likely to be sensitive to tillage, inputs of organic matter and the application of chemicals (Edwards et al., 1995 and Smith et al., 2008). Due to their beneficial role in terrestrial ecosystems, earthworms are often used as an indicator species in ecotoxicological evaluation (Abdul Rida and Bouche, 1995). Previously few attempts have been made to study the effect of industrial discharge on earthworms (Goats and Edwards, 1982; Mishra and Sahu, 1989, 1997; Callahan et al., 1991).

Heavy metal can be defined as any metal with a specific gravity higher than 4.00 and which is toxic and poisonous even at a low concentration (Agbaire and Emoyan, 2012). Heavy metal concentrations in the soil are associated with biological and geochemical activities and are influenced by anthropogenic activities (Agbaire and Emoyan, 2012). Heavy metals are considered serious pollutants because they are toxic and non-degradable (Agbaire and Emoyan, 2012). The accumulation of heavy metals in the soil poses many risks to humans and the ecosystems (Odoh et al., 2011). Most importantly pollution by heavy metals in terrestrial ecosystems is a serious environmental concern due to their non-biodegradability and tendency to accumulate in plants and animal tissues (Otitoloju et al., 2009).

As a by-product phosphogypsum is produced in phosphoric acid plants. Phosphogypsum is generated through a filtration process in phosphoric acid plants where insoluble gypsum is separated from the product i.e. phosphoric acid as efficiently as possible. About 4.5 -5 tons of phosphogypsum as by-product is being generated per ton of phosphoric acid recovered. Phosphogypsum generation in India is about 11 million tons per annum and primarily consists of calcium sulphate dihydrate with small amounts of silica, usually as quartz and un-reacted phosphate rock, radioactive material (like radium, uranium) and heavy metals namely arsenic, cadmium, chromium, mercury, nickel, lead and zinc (HAZWAMS/2012-2013). There was very considerable volume of work and research regarding the positive roles of earthworms in agroecosystems, environmental monitoring and sustainability (Dada et al., 2013) but the concern here is to evaluate the influence of phosphogypsum over various physiological parameters of *Eisenia fetida* under laboratory conditions.

Review of literature

Lee et al. (2009) determined the effect of alkalized phosphogypsum on soil chemical and biological properties. Their study came into the conclusion that by mixing alkalizing phosphogypsum with an alkaline material such as Ca(OH)2 can turn it into a useful material for agricultural utilization. Pure phosphogypsum could damage the soil biological properties.

Mishra et al. (2011) assessed the impact of phosphogypsum amendment on soil physic-chemical properties, microbial load and enzyme activities. They carried out

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_44554476

their experiment with 0, 5, 10 and 15% of Phosphogypsum to track the impact and found that the optimal results were recorded in 10%. The experiment summarized with a conclusion that Phosphogypsum amendment will be fruitful at a particular range and can be fatal for the microbial and soil enzyme activities if it exceeded its threshold range.

Chen et al. (2014) investigated the effects of gypsum on trace metals in soil and earthworms. For the study they used FGD (Flue Gas Desulfurization) gypsum which was produced by the removal of SO2 from flue gas streams. The application rates of gypsum ranged from 2.2 Mg ha^{-1} to 20 Mg ha^{-1}. These rates were 2 to 10 times higher than typically recommended. It was observed that the earthworm numbers and biomass were decreased significantly and with the higher rates of gypsum application was found to be hazardous to earthworms and soil integrity.

Rakhimova et al. (2017) evaluated the impact of coal ash and phosphogypsum on soil fertility of Chernozem soils of north Kazakhstan. Soil samples were collected (three times a year) and the initial content of humus, pH, plant nutrient elements and heavy metal content of the soil were tested in laboratory and recorded. The application of Phosphogypsym and coal ashes for fertilization of the soils influenced the growth of soil nutrient elements such as nitrogen, phosphorous, copper and zinc. It also impacted the on neutralization of the soil environment and further investigation is needed to find out actual content of heavy metals (Cu, Zn, Cd and Pb).

Materials and methods

Material

Phosphogypsum

Phosphogypsum was collected from Paradeep Phosphate Limited (PPL), Paradeep, Jgatsinghpur, Odisha, India.

Earthworm used

Eisenia fetida used as experimental organisms. For regeneration adult earthworms with prominent clitellum were used.

Soil

Soil was sieved using 2 mm sieve and packets were made containing 0 g%, 4 g%, 8 g% and 10 g% gypsum with 25 g% water.

Method

500 gm 2 mm sieved, air dried soil was taken in polythene packets with moisture maintained at 25 g % by addition of distilled water in all packets. The control consisted of 500 g soil only and PG was added to soil in experimental sets i.e. 4%, 8% and 10%. Ten replicates of each concentration were taken for each parameter (growth, feeding, respiration and regeneration). After moisture addition the packets were left for five days for stabilization. Culture was maintained with 25 g% moisture and 25 °C temperature (Initially we went for 25 g%, 50 g% and 75 g% concentration of phosphogypsum with 25 g% water for the experiment but it was found that worms unable to tolerate such high amount of phosphogypsum percentage and found dead).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_44554476

Experimental set up for growth

After five days of moisture addition and stabilization of soil, up to 1.70 g of earthworms were inoculated to each packet. Weight of earthworms in each packet was determined and change in weight over initial weight was observed after on 10^{th}, 20th and 30th days. Percentage change in weight of earthworms over zero day culture was estimated.

Experimental set up for feeding

2.5 g of earthworms were inoculated to each packet and estimation of stable aggregates was done at an interval of 10 days by sieving culture sets with water. Carbon content of stable aggregate formed was estimated by Walkley and Black titration method (Walkley and Black, 1934). Then the amount of carbon was converted to energy according to available standard values energy conversion for carbon is 41.44 kJ g^{-1} dry wt. (Remmert, 1980).

Experimental set up for respiration

Out of 10 replica of each concentration, 5 were maintained without earthworms which accounted for microbial respiration. To each packet, an average of 1.5 g of earthworms were added. The respiratory metabolism was estimated on 10th, 20th and 30th day by Alkali Absorption Method (Witkamp, 1966). Carbon dioxide evolution was measured and expressed as mg of $CO_{2.}$ g^{-1} live worm tissue hr^{1} kg^{1} soil.

Experimental set up for regeneration

For regeneration, the guts of the matured earthworm were cleaned and about 50% of post clitellar region was cut with sharp blade. Five earthworms were inoculated into each packet after amputation. Thus twenty five earthworms each were cultured in control, 4%, 8% and 10% of phosphogypsum. The amputed earthworms could not survive in 8% and 10% phosphogypsum. So the regeneration experiment was performed with 4% PG only.

Statistical analysis

Statistical analysis were performed to infer the results (Microsoft excel version 2007). For growth, feeding and respiration, ANOVA test was performed. T-test was performed for regeneration. Comparisons of values were made and values at $p \leq 0.01$ are said to be significant.

Results

Growth

Table 1 and *Figure 1* indicate the changes in the growth i.e. changes in weight pattern of *Eisenia fetida* earthworm under the impact of phosphogypsum in laboratory cultures. In the first phase of estimation (initial 10 days), a positive increase of about 1.53% in weight in control set ups was observed in comparison to experimental set ups. On exposure to 4%, 8%, and 10% phosphogypsum, there was significant decrease (at 0.01 level) of about 23.07%, 23.07% and 75% respectively over zero day. At 20 days,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_44554476

the weight percentage reached up to 5.03 over zero day in control but a continuous decrease in weight by 33.84%, 68.46% and 93.84% was observed when exposed to 4%, 8% and 10% of phosphogypsum. After the end of final phase (last 10 days), 96.40% decrease in weight over initial weight at 10% phosphogypsum. In at 4% and 8%, weight was decreased by 30.93 and 74.82% over initial weight respectively. But in Control sets, there was a remarkable growth noticed (21.53%). Analysis of variance showed significant impact of phosphogypsum treatment on earthworm weight at 0.01 level of significance.

Table 1. *Weight of Eisenia fetida earthworm under impact of phosphogypsum in laboratory culture*

Culture in days	Parameter analysed	Conc. of phosphogypsum in %

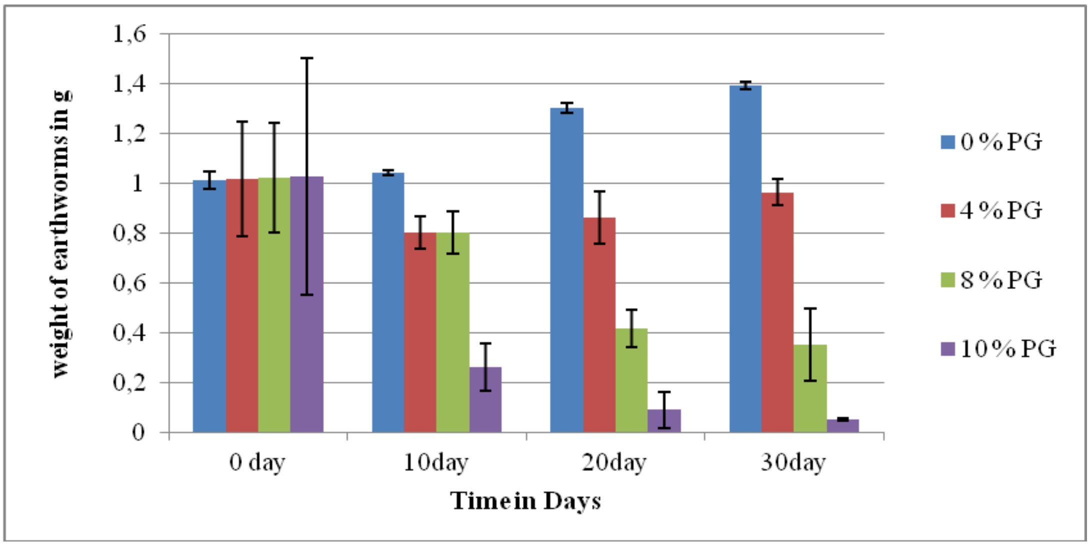

Figure 1. *Change in weight of Eisenia fetida earthworm under the impact of phosphogypsum in laboratory culture. (Mean ± standard deviation)*

Feeding

After 10 days of exposure to 0, 4, 8, 10% of phosphogypsum, the weight of stable aggregates formed was 12.67, 11.72, 12.40 and 9.42 g g^{-1} live tissue (*Fig. 2; Table 2*) and a visible decrease of about 0.009%, 97.66% and 99.20% in stable aggregate formation as comparison to zero day in 4, 8 and 10% of phosphogypsum respectively (*Fig. 3*). On completion of 30 days there was decrease of about 99.7%, 99.8% and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_44554476

99.93% respectively was observed (*Table 2*). When it comes to the matter of carbon content of stable aggregate formed by the earthworms, a consistent and significant decline was noticed by the increase of concentration dose and exposure duration (*Fig. 4*). Highest energy content of stable aggregate formed was 784.74 kJ kg^{-1} soil g^{-1} live tissue at 0% and lowest was 349.09 kJ, kg^{-1} soil, g^{-1} live tissue at 10% on 30th day. A remarkable significance difference noticed in stable aggregate formed at the end of 30 days in comparison to 10th day. After 30 days at 0%, the weight of stable aggregate formed by the earthworms was 32.65 g g^{-1} live tissue which was much higher when it compared to 4, 8 and 10% (22.45, 18.16 and 16.20 g g^{-1} live tissue respectively). Analysis of variance showed significant decrease in the stable aggregate formation by the worms (at 0.01 level of significance) on application of phosphogypsum. Significant decrease in energy content of stable aggregate was also found at 0.01 level of significance.

Respiration

The rate of respiration was found to increase with duration and treatment. After 10 days of exposure the rate of respiration was found to be 0.0564, 0.0565, 0.0567 and 0.0568 mg of CO_2 evolved, g^{-1} live worm tissue hr^{-1} kg^{-1} soil at 0%, 4%, 8% and 10% of phophogypsum, respectively (*Fig. 5; Table 3*). At the end of the last phase (30 days), there was increase of about 0.17%, 0.34% and 0.52% in rate of respiration on exposure to 4%, 8% and 10% phosphogypsum over control respectively. The mg of CO_2 i.e. evolved, g^{-1} live tissue hr^{-1} kg^{-1} soil increased from lower concentrations to higher

Mean ± standard deviation

Regeneration

The amputated earthworms could not survive beyond two days in 8% and 10% phosphogypsum. So the experiment was continued with control and 4% phosphogypsum. On completion of 10 days of exposure to 0% and 4% of phosphogypsum, the percentage increase in regenerated segments was found to be 6.28% and 2.68% respectively (*Figs. 6* and *Table 4*). After 20 days of exposure to 0% and 4%, the percentage of regenerated segments was found to be 10.64 and 5.72% respectively. At the end of 30 days, the percentage increase in regenerated segments was found to be 13.4% in 0% and 8.4% in 4%. The regenerated parts of the worm grown in 4 % phosphogypsum can be marked in the *Fig. 7* after the completion of 30 days. T-test reveals that impact of phosphogypsum has a significant effect on *Eisenia fetida* at 0.01 level of significance.

Discussion

Earthworms ingest organic matter of the soil particle and excrete this in the form of casts, which get deposited on the soil surface and this cast acts as a natural fertiliser for the soil and boosts the soil fertility. Loss of fertility is directly proportional to stable aggregate formed by earthworms. Heavy metallic factor present in the soil directly affects the various physiological activities of *E. fetida*. Majority of heavy metals are toxic to living organisms when retained in the soil and interfere with the biochemical processes and alter the ecological balance (Nwuche and Ugoji, 2008). These heavy metals do not biodegrade rather they bioaccumulate and this may have adverse effects on the biodiversity of the area if the organisms do not develop a mechanism of adaptation to it. Nickel and lead accumulated significantly in worm bodies during the 3-weeks exposure whereas zinc accumulation was efficiently regulated. Nevertheless zinc exposure significantly inhibited the weight gain. Inhibition of weight gain in zinc-exposed worms may be putatively explained by the high energetic costs of efficient zinc regulation (Podolak et al., 2011).

In many other case studies, *D. veneta* (Kwadrans et al., 2008) and *Aporrectodea caliginosa* (Dutkiewicz et al., 2009) were maintained for 4 and 8 weeks, respectively, in soil samples soaked with Cd, Cu, Pb, or Ni chlorides. Body weights of *D. veneta* were unaffected by 4-weeks metal exposure. In a study by Spurgeon et al. (1992), control worms and those on the lowest concentration of metals had slightly increased in weight after 1 week. However, in subsequent weeks their weight declined. Malecki et al. (1982) tested the effect of Cd, Cu, Pb, Ni and Zn on the physiological activity of *Eisenia fetida* in laboratory cultures. They concluded that cadmium was the most toxic metal, as significant decreases in growth noticed. Here it is important to mention that Cadmium is one of the heavy metal present in the phosphogypsum beyond the recommended range. It was observed (Khalil, 2013) that earthworms *Allolobophora caliginosa* feed less and *Pheretima hawayana* escaped into their burrows when exposed to arsenate. Miguel et al. (2012) revealed in a study that weight and mortality of the worms were significantly affected by high levels of heavy metals.

Metal exposure can imbalance the host-bacteria relationship, as evidenced in *D. veneta* after 3-days exposure to filter paper soaked with water (controls) or metal (Zn, Cu, or Cd) chlorides (Podolak et al., 2011). It may assumed that effects of metal exposure on immunity are rather associated with the disrupted balance between the worm immune system and microbial impact from surrounding metal-polluted soil (Salice and Roesijadi, 2002; Wieczorek-Olchawa et al., 2003; Olchawa et al., 2006). Various results indicated that earthworm activity increases the mobility and bioavailability of heavy metals in soil (Wen et al., 2004; Sizmur and Hodson, 2009). But the matter is how far and how much worms can accumulate and able to rotate the mobility of heavy metals. Although concentrated heavy metals in the earthworm's body demonstrate the ability of *E. fetida* to accumulate the heavy metals in their body still it needs to reveal the limit or range which is non-deleterious.

Fordsmand et al. (1998) investigated the toxic effects of nickel on survival, growth, and reproduction of *Eisenia veneta* for 4 weeks of exposure to a nickel chloride spiked loamy sand soil. Nickel caused a significant toxic effect on *E. veneta* at soil concentrations above 85 mg Ni/kg. Survival of adults was only reduced at concentrations above 245 mg Ni/kg, while adult and cocoon wet weight were not affected by soil nickel concentrations up to 700 mg Ni/kg. The results of our study are in close agreement with Ma (1983), Neuhauser et al. (1985), Bengtsson et al. (1986),

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_44554476

Gestel and Dis (1988), Gestel et al. (1989, 1991, 1992). The results of the present study clearly correlate with the work of Zaltauskaite (2010) who reported that *E. fetida* exposed to different concentrations of lead in the soil tended to lose more weight than those in control.

Single metal such as Cu can affect the physiology and growth of *E. fetida* may hampered due to increased tissue concentration of Cu., while the cocoon hatchability and number of juveniles increased as the tissue Cu concentration increased (Leduc et al., 2008). So it was a combine impact of heavy metals which might be more hazardous and has more pronounced toxicity than the individual metals (Olaniya et al., 1991). In some situations *E. fetida* can allocate more energy to growth than reproduction, delaying other physiological development (Leduc et al., 2008). A combination of As, Cr and Cu can impair growth, affect reproduction and cause death also (Leduc et al., 2008).

Sivakumar and Subbhuraam (2005) evaluated the toxic effects of chromium exposure on *E. fetida* and found 14-day LC50 values ranging from 1656 to 1902 mg kg^{-1} for Cr (III) and from 222 to 257 mg kg^{-1} for Cr (VI) in ten soils. Cocoon production by *E. fetida* was reduced by 50% after exposure to a range between 679 and 1110 mg Cr (III) kg^{-1} (Lock and Janssen, 2002b). In a contradictory study Shahmansowri et al. (2005) revealed that though heavy metals such as Cr, Cd, Pb, Cu and Zn were bioaccumulated by *E. fetida,* but a significant reduction of body weight only marked when exposed to higher concentration. Similarly pattern of findings also observed in weight *Pheretima guillelmi* at high concentration of lead in (Rongquan and Canyang, 2009). Among *E. albidus, E. crypticus* and *E. fetida* the most sensitive species towards industrial waste material was *E. fetida* (Kobeticova et al., 2010). The weight of worms was significantly affected by high levels of heavy metals in the study of Miguel et al. (2012).

Impact can vary due to the different contact times during which the earthworm exposed to contaminants (Haghparast; 2013; Golchin et al., 2013). Concentration of the metals in the body of earthworms can reach the toxic level if the contact time of earthworm is a prolonged duration (Hagparast et al., 2013). Jamshidi and Golchin (2013) also confirmed same. Thus, the potential effects of metals may be overlooked or underestimated in short term experiments (Bengtsson et al., 1986), which may explain the truth that sometimes despite the high levels of metal contamination in the soil, no significant impact may not noticed like Kennett et al. (2002). In a such kind of study, Honsi et al. (2003) reported no effect of heavy metals (Cu, Zn, Cd and Pb) on survival of earthworm *E. fetida* exposed to contaminated soils in Norway despite the fact that the concentrations of metals were high (max Pb – 8750 μg g^{-1}, Cd – 110 μg g^{-1} soil). Kaur and Hundal (2016) observed a very sound impact of heavy metals in the body weight of earthworms. Berthelot et al. (2008), Matuseviciute et al. (2005) and van Gestel et al. (2009) findings also support our results. Spurgeon and Hopkin (1996) also argued that the worms living in metal polluted soils reached the lower weight or needed more time to reach the maximum weight than in non-polluted sites.

Trace elements added to the soil with gypsum or any soil amendment may be concentrated in food chains as the elements are consumed and passed from one trophic (feeding) level to another level (Duffy and Gulledge, 2011). Garg et al. (2009) found a pattern of heavy metals accumulation in *E. fetida* after 45 days i.e. Cr>Cd>Pb>Zn and Cd had the greatest detrimental effect on cocoon production and matter of concern is these heavy metals are one of the major part of phosphogypsum.

DOI: http://dx.doi.org/10.15666/aeer/1604_44554476

During their study, Avila et al. (2009) identified that increasing the organic material can reduce the toxicity of heavy metals in the body of earthworms. Irizar et al. (2015) concluded during their study that, if the organic material in the soil is low, earthworms are not able to digest the soil and, as a result, the toxicity of cadmium increases in them, and the mortality and disorder in reproduction rise. Haghparast et al. (2013) showed that organic material is a source of energy for *Eisnia Fetida* earthworms and increases the percentage of their survival. Avila et al. (2009) showed that adding 5% of organic matter to soil contaminated with chromium at a concentration of 0.06 mg/g after 21 days gave no bioremediation, but after 42 days the efficiency of bioremediation (18.33%) increased. At the concentration of 0.1 mg/g the bioremediation efficiency of 30% after 21 days reached 53% after 42 days.

Heavy metallic cations are said to be more mobile or dynamic under acid conditions (Alloway, 1996) as the correlation between soil pH and micronutrients availability has been one of the major aspect of soil (Brady, 1990; Joshi et al., 1983, Sharma et al., 2003; Akinrinde et al., 2005). Although organisms like earthworm can accumulate a high concentration of heavy metals in the body (Shahmansouri et al., 2005; Li et al., 2010; Brewer and Barrett, 1995; Bamgbose et al., 2000) but mineralization of dead earthworms releases accumulated heavy metals back to the soil (Morgan and Morgan, 1988a). The amount of metals accumulated within earthworm tissues is partly dependent on the absolute concentration of metal within a given soil and physiochemical interactions (Ma et al., 1983). When a contaminant is not in equilibrium with the soil, it becomes more bioavailable to living organisms (Davies et al., 2003). Phosphogypsum is one of the industrial waste materials which is acidic in nature and contains various heavy metals. Another major concern here is *E. fetida* has already been reported as very sensitive species towards industrial waste material exposure by Kobeticova et al. (2010).

Earthworms are well capable of regenerating lost segments, but different species have different regeneration ability. After studying regeneration in different kinds of species for 20 years, Gates (1949) published some of his findings that show for certain species there is a possibility of growing into two intact ones from a bisected specimen. *Eisenia fetida* with head regeneration, in an anterior direction, possible at each inter-segmental level back to and including 23/24, while tails were regenerated at any levels behind 20/21, i.e., two worms may grow from one.

Three potential pathways exist for the removal of chemicals from tissues; elements can be regulated by excretion from the body, bound within the matrix of inorganic granules and attached to proteins or other ligands (Tessier et al., 1994). If metals are detoxified primarily by excretion, body concentrations should decrease when previously exposed individuals were transferred to a clean environment. However, if an element is bound in an inorganic matrix or to organic ligands, metal levels may remain constant, even after the exposure has ceased (Spurgeon and Hopkin, 1999). Animals exposed to high concentrations of metals over a long period, the storage capacity of the hepatopancreas may become saturated, allowing metals to pass into the haemolymph and interfere with sensitive biochemical processes (Spurgeon and Hopkin, 1999).

Heavy metals are strongly bound to soils rich in organic matter or clay (Sauve, 2002) and simultaneously earthworm developed specific trafficking, storage pathways and redistribution capacity to regulate the heavy metals, especially essential trace metals such as Cu and Zn, in their bodies that may lead to balance between uptake and excretion (Dallinger, 1993; Morgan and Morgan, 1999). The regulatory capacity of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_44554476

metals can partly explain the ability of some earthworm species, like *D. octaedra*, to live even in a highly metal contaminated areas. Thus, the metal regulation may also have contributed to the development of metal resistance observed in some of the earthworm populations (Bengtsson et al., 1992; Langdon et al., 2001a, b; Reinecke et al., 1999). One additional factor that may reduce harmful effects of metals on the earthworms and also increase intraspecific variation in body burdens is heterogeneous distribution of metals in the soil (Lukkari et al., 2004).

Conclusion

Earthworms form the base of various food chains because they are preyed on by many species of snakes, mammals, and invertebrates (Edwards and Bohlen, 1996) and could increase biomagnification in various trophic levels of the food chain. This whole concept can upset the food chain as well as the food web. Increasing pollution and spontaneous addition of pollutant to soil through anthropogenic sources can alter growth, feeding, regeneration and respiration of *E. fetida* by both direct and indirect effects. These physiological activities of worm can be impaired by direct toxic effects of metals or by bringing changes in the energy budget as an individual attempts to prevent accumulation in sensitive tissues. In earthworms, cadmium, lead, and some zinc are detoxified by binding in granules (chloragocytes) or metallothionein like proteins in the chloragogenous tissue (Morgan and Morgan, 1988b; Morgan et al., 1989). In contrast, copper and the remaining zinc are eliminated by an excretion mechanism (Morgan and Morgan, 1990, 1991). The mechanisms of metal sequestration and elimination have metabolic costs in both development of the system and for the maintenance and repair. This increased the requirement for maintenance energy will ultimately result in a reduction in the energy available for growth and development (Donker et al., 1993a). If there is an increased energy demand for metal sequestration and elimination, this will decrease the energy available for other physiological activity and ultimately affects the organism. Present findings very much evident and transparent about the sensitivity of the worm *E. fetida* towards metallic contamination and indicates juvenile *E. fetida* is more sensitive to metal-contaminated soils than that of mature worms (Spurgeon and Hopkin, 1996). After 4-5 weeks of culture significant reduction was marked in the weight, feeding activity and regeneration capacity of the worm. In contradiction, rate of respiration clearly increases by the increasing of exposure duration with concentration dose. Number of studies on other soil dwelling invertebrates also suggests a clear reduction in growth on exposure to metal-contaminated diets due to avoidance of contaminated food (Drobne and Hopkin, 1995; Laskowski and Hopkin, 1996). In contradiction to our study Podolak et al. (2011) stated that metals may be either regulated (Zn) or accumulated (Ni, Pb) in worm bodies, with or without deleterious effects on body weights, immune competent cells and physiological activity putatively due to their differential impact on soil and coelom-inhabiting microbes. For last few years, phosphogypsum is being used in agricultural soil as a calcium supplement to enhance the crop production (Nayak et al., 2011). Mullino and Mitchell (1990) have reported the use of phosphogypsum to increase yield and quality of forages in Florida. But respiration of soil was deeply affected by phosphogypsum application (Delaune et al., 2006) which directly hampers the physiological activities of soil dwelling organisms including earthworms. However, the chemical and biological response of soil to the waste amendment needs to be thoroughly investigated before recommending its large

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_44554476

scale field application. When it comes to statistical part to verify the significance of phosphogypsum on *Eisenia fetida* (at 0.01 significance level), it was clearly significant. All the physiological activity of the earthworm was significantly hampered due to phosphogypsum and it was almost lethal. The heavy metallic constituents of phosphogypsum adversely affect the growth, feeding, respiration and regeneration activity of the worm.

Nevertheless earthworm based assessment is complicated by the fact that earthworms can develop tolerance to various pollutants, as documented in several studies of populations that have been in contact with high polluting sources over long periods (Bengtsson et al., 1992; Morgan and Morgan, 1992). The direct measurement of heavy metal concentrations in earthworm tissues could provide a means of assessing environmental pollution levels, given the demonstrated correlation between soil contamination and earthworm metal bioaccumulation (Motalib et al., 1997). But here the matter of concern is to generalize these vital facts regarding impact of heavy metals upon soil macrofauna in particular earthworms and standardize the accumulation range. How much and how far earthworms are able to tolerate such wide range and hazardous impact of heavy metals with varying composition of soil. This is a big question to answer. It becomes more necessary to generalize these facts and must be much more aware and watchful towards soil contamination.

Abstract. This study was conducted to investigate the effect of bed planting on the quantity and quality of forage yield of vetch and barley in different crop mixing ratios. The field experiment was conducted in 2014-2015 and 2015-2016 on the paddy fields of the North of Iran (Rasht, Guilan Province) as a factorial analysis in randomized complete block design (RCBD) with three replications. The experimental treatments included bed planting at 2 levels (1. rice bran with bed planting and 2. without bed planting as control) and crop mixing at 6 levels (1. Sole vetch, 2. Sole barley, 3. 20% vetch to 80% of barley, 4. 40% vetch to 60% of barley, 5. 60% vetch to 40 % of barley, 6.25% vetch to75% barley as replacement ratio of crop mixing). The recorded data were the followings: forage yield, crude protein yield and quality traits like crude protein (CP), dry matter digestibility (DMD), and acid detergent fiber (ADF), neutral detergent fiber (NDF). Mixed cropping indices were calculated by means of land equivalent ratio (LER) and Money advantages index (MAI). Results showed that rice bran with bed planting affects some quantity and quality traits of forage. Among mixing ratios, planting of 40% barley and 60% additive vetch had highest forage yield. Additive mixing ratios had the highest crude protein yield among mixing ratios. According to the results, in the North of Iran the highest LER and forage yield was obtained from rice bran with bed planting and 40% additive of vetch to barley.
Keywords: *forage yield, crude protein yield, money advantage index, dry matter digestibility, land equivalent ratio*

Introduction

During the post rainy season (October–March) in the sub-humid region of northern Iran, average cumulative evapotranspiration and runoff are high. Therefore, the low status of soil moisture in the root zone usually limits productivity of rainfed winter crops in this region. Conserving moisture that has accumulated in the root zone during the previous rainy season can increase productivity of rainfed winter crops in the dry season. Soil management practices can influence conservation and efficiency of stored water (Sarkar and Singh, 2007). Applying mulch on the soil surface to reduce evaporation rate and discourage weeds is another water conservation practice in India (Sarkar and Singh, 2007).

Mixed cropping as method crop intensification is commonly practiced in densely populated countries to provide more food. Mixed cropping of annual cereals and pulse crop is commonly practiced in humid topic regions because total seed production generally enhanced compared with sole cropping (Ciftci and Ulker, 2005). The legume-grass combination has been used in several mixed cropping systems including forage

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_44774490

and cover crops (Ramos et al., 2011). Generally, grasses in mixed cropping with legumes take more N than in sole cropping, because of transfer from rhizodeposit-N of legume to the associated grass (Rasmussen et al., 2007).

Vetch is one of popular pulse crops of Iran and is an annual leguminous crop which produces high-quality forage and can be cultivated in most climates as rainfed or irrigated, but grows best in temperate and cold-temperate conditions. In recent years, vetch and grass pea cultivation has drawn much attention as a crop well-adapted to harsh conditions and arid and semi-arid regions, with high protein content (Habibi et al., 2010). The different *Vicia* species are used as direct grazing and also for their green forage, hay and seed (Lanyasunya et al., 2007). In studies of Lanyasunya et al. (2007), the CP, Ca and P contents of common vetch (*Vicia sativa* L.) has shown to be 18.4, 0.132 and 0.34% on a dry weight basis, respectively, with 59% total digestible nutrients. In north of Iran, farmers prefer planting of vetch with cereals like barley over pure planting of them. Their mixture can be considered as feed for animals during winter or early spring.

Sowing a forage crop in rotation with cereals, is a highly effective method for, for example, soil properties reclamation (MeVay et al., 1989) and increasing rainwater infiltration in soils (Daniel et al., 2006). The high ability of forage legumes for nitrogen fixation is among their most important characters that can reduce need for applying chemical nitrogen fertilizers with implementing them in farming rotations (Rao et al., 2005). Kusmiyati et al. (2013) reported that application of 3 and 6 ton/ha mulch increased plant growth, forage yield and nutritional quality of *guinea grass* but Plant growth, forage yield and nutritional quality of *guinea grass* were not affected by monoculture or mixed cropping with *Sesbania*, however the highest yield was obtained from 6 ton/ha mulch and mix cropping.

Forage grass quality is affected by many factors such as the species, cutting interval, phase of plant development, soil fertility, fertilizer, disease and climatic conditions. It is usually found that the most important factor affecting protein content in herbage dry matter is phase of plant development. Forage quality will decrease, in term of decreasing crude protein and increasing levels of cell wall constituents, with advancing maturity (Kusmiyati et al., 2013).

Various indices such as land equivalent ratio (LER) and monetary advantage index (MAI), have been developed to describe the competition and possible economic advantage in intercropping (Banik et al., 2000; Ghosh, 2004). Mathematical indices can help researchers summarize, interpret, and display the results from plant competition trials (Weigelt and Jolliffe, 2003). Indices can express various attributes of competition in plant communities, including competition intensity, competitive effects, and the outcome of competition. They help in the interpretation of complex data and allow comparison of results from different studies with the use of the same index. Among indices being used for assessing competition between intercrops, land equivalent ratio is the most commonly used for intercrop versus sole crop comparisons (Agegnehu et al., 2006).

One the most important reason for mixed cropping is increasing production per area (Ghosh, 2004). Land Equivalent Ratio (LER) and monetary advantage index (MAI) is used by researchers as an indicator to assess effect of intercropping on land productivity (Mead and Willey, 1980).

In this study we aim to quantify the effects of different bed planting and mixing ratio treatments on the quantity and quality yield of barley and vetch under rainfed conditions.

Material and methods

This study was conducted as a factorial experiment in a randomized complete block design with 3 replications in Rice Research Institute of Iran (RRII), located in Rasht (Guilan Province), Iran, during two years, 2014-2015 and 2015-2016. The area is N 37° 16’ and E 041° 36’ and -7 m above sea level.

Experimental factors included bed planting at 2 levels (1. Rice bran as bed planting and 2. Without bed planting as control) and mix cropping at 6 levels (1. Sole vetch, 2. Sole barley, 3. 20% Additive of vetch to barley, 4. 40% Additive of vetch to barley, 5. 60% Additive of vetch to barley, 6. 25% vetch and 75% barley as substitutive ratio of mix cropping).

The experimental site was ploughed, harrowed and a basal dose of 100 kg NPK ha^{-1} was broadcast. Seed planting of an Iranian native cultivar of barley (cv. Behrokh) and annual common vetch (cv. Lameie), were evaluated in an intercropping system. Plots consisted of various row numbers depending on intercropping ratios. Planting rows were 0.2 m wide for both barley and vetch and 5.5 m long. Plots were seeded on October by hand and two extra rows on the border of each cropping pattern were considered as guard rows. Four meters of all rows within each plot were hand-harvested on 4th of May. Rice bran as bed planting was applied by hand-spreading at the rate of 50 kg per hectare to form an approximately 20 mm thick layer between crop rows. Bed planting treatments were imposed before sowing.

After oven drying at 72° for 48 h, herbage dry yield was determined. To determine the influences of N and seeding rate on forage quality, a 200-g sample was taken and grounded to pass through a 1-mm sieve. Near-infrared spectroscopy (NIR) (Inframatic 8600, Perten Instruments) was used to determine forage quality indices, including crude protein (CP), dry matter digestibility (DMD), and acid detergent fiber (ADF) neutral detergent fiber (NDF). Before using NIR, forage quality indices of one replication (using three subsamples) of each treatment was determined using wet chemistry methods as described below. These were further used to calibrate NIR (Jafari et al., 2003).

Relative feed value (RFV) was identified and formulated by Van Dyke and Anderson (2002). All formulas are indicated below:

$$DDM = 88.9 - (0.77 \times ADF\%)$$

$$DMI = (120 / NDF\%)$$

$$RFV = DDM\% \times DMI\% \times 0.775$$

$$NE1 = ((1.044 - (0.0119) \times ADF\%)) \times 2.205$$

where DDM was digestible dry matter as percentage (%) of dry matter, and DMI was dry matter intake as percentage (%) of body weight.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_44774490

The measure used to estimate effectiveness and profitability of inter-or mixed cropping is Land Equivalent Ratio (LER), which is calculated as (Mead and Willey, 1980):

$$LER = Y_{ij} / Y_{ii} + Y_{ji} / Y_{jj}$$

where:

Yii and Yjj = Yields of i and j species in their sole cropping,

Yij and Yji = Their yield in mixed cropping.

When LER measures 1.0, it indicates that the mixed cropping and sole cropping have yield equivalence, LERs above 1.0 indicate advantages of mixed cropping and LERs below 1.0 show no real yield advantages from mixed cropping.

The Monetary Advantage Index (MAI) which gives an indication of the economic advantage of the intercropping system was calculated according to Ghosh (2004) as follows:

$$MAI = (\text{monetary value of combined intercrops})\ (LER - 1) / LER.$$

Economic values of grain and stover produced were estimated based on the average forage yield of barley (70$ per ton) and vetch (110$ per ton).

Data analysis for two years was done using SAS (*Ver* 9.1). For collation of additive and substitutive mixed cropping we used orthogonal analysis. Analysis of combined experiments was done at the end of two years and means were compared using LSD test at 0.05 probability level. Before statistical analysis.

Results and discussion

Ash

There is no difference between additive and replacement of treatment (*Table 1*). Results showed that without bed planting and 60% additive to barley (7.65%) had higher ash and sole vetch on without bed planting (6.64%) had lowest ash (*Table 2*). Among mixtures, the highest Ash values obtained from 25% vetch and 75% barley treatment with 7.48% and sole barley with 7.09% had lowest ash (*Table 2*). Alizadeh and Teixeira da silva (2013) reported that pure vetch obtained the lowest ash values and they did not find any differences between of mixture ratios.

Water soluble carbohydrates (WSC)

There were no significant differences in the two-year and orthogonal average values of WSC (*Table 2*). The results showed that bed planting and mixing ratios had significant effect on WSC and without rice bran treatment had higher amount of WSC. Among mixing ratios, sole vetch had higher WSC and sole barley had the lowest WSC (*Table 2*). Dahmardeh et al (2009) noted that WSC concentration increased in intercrops compared with in the sole cowpea.

Neutral detergent fiber (NDF) and acid detergent fiber (ADF)

Other important quality characteristics for forages are the concentrations of NDF and ADF (Assefa and Ledin, 2001). In this experiment a similar trend to that of CP content

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_44774490

was observed for NDF, it increased as the common vetch seeding proportion increased in mixtures (*Table 2*). The 25% vetch and 75% barley (33.49%) as well as vetch monoculture (32.90%) had the lowest value of NDF, whereas the highest value was observed in monoculture barley (36.97%). This result like most other studies (Caballero et al., 1995; Assefa and Ledin, 2001).

Error	44	0.14	1.27	1.67	4.79	2.27	2.78
CV (%)		5.12	6.48	3.11	6.23	2.66	3.50

** and *, respectively, significant in 1% and 5% level

The concentrations of acid detergent fibers were not affected by year and orthogonal (*Table 1*). Among mixing ratio treatments, 60% additive vetch to barley produced statistically maximum ADF (42.23 g.kg^{-1}) and the minimum ADF values obtained from 25% vetch to 75% barley with average of 40.54 g.kg^{-1} (*Table 2*).

Kocer and Albayrak (2012) noted that sole pea had lowest ADF and NDF concentration. Aasen et al (2004) reported that increasing the legume proportion resulted in decreased ADF and NDF concentrations for the legume-grass mixtures. Carr et al. (2004) found that pea, barley, oat, pea-barley and pea-oat mixtures of ADF values 38.2%, 38.5%, 34.4% and 36.5%, respectively. Strydhorst et al. (2008) reported that barley and pea-barley mixtures of NDF values were 55.2% and 41.8%, respectively. Van Soest (1996) indicated that under similar growth conditions, legumes have low NDF values whereas cereals have high values which are in agreement with the present study.

Dry matter digestibility (DMD)

There were no significant differences in DMD among the Bed planting factors. However, there were significant differences between orthogonal and mixture ratios (*Table 1*). Without bed planting had higher DMD (*Table 2*). Among mixture ratios, the highest DMD was obtained from sole vetch (58.49 g.kg^{-1}) and lower DMD was shown from monoculture barley (55.16 g.kg^{-1}). Sadeghpour et al. (2014) reported that annual medic sole culture had higher DMD than barley and mixture of barley with annual medic therefore decreased DMD of the mixed forage.

Total digestible nutrients (TDN)

The TDN refers to the nutrients that are available for livestock and are related to the ADF concentration of the forage and, as percentage of ADF increases, TDN declines (Albayrak et al., 2011). The results showed that mixing ratios and interaction of mixing

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_44774490

ratios and bed planting had effects on TDN. Among mixing ratios, 75% barley and 25% vetch (49.06 $g.kg^{-1}$) and 20% additive vetch to barley (46.94 $g.kg^{-1}$) had the highest and lowest TDN values respectively. Kocer and Albayrak (2012) reported that Pea-oat and pea-barley mixtures ratios had more TDN values than monoculture oat and barley monoculture. They noted that the TDN refers to the nutrients that are available for livestock and are related to the ADF concentration of the forage.

Relative feed value (RFV)

Forage nutritive value, as indicated by the RFV, was improved in all legume–barley mix cropping relative to the sole barley crop (*Table 3*). The lower barley sole crop RFV was attributed to the higher NDF and ADF concentrations in the sole crop barley. Carr et al (2004) reported higher NDF concentrations in sole crop barley relative to pea–barley intercrops of the legume–barley intercrops, Sole vetch had the highest RFV (168.7%), while sole barley had the lowest RFV (139.3%). Differences in RFV of legume and barley were attributed to differences in NDF, as ADF was similar between legume and barley.

CV (%)		6.84	3.37	14.26	11.47	20.91

** and *, respectively, significant in 1% and 5% level

As expected, RFV values are positively correlated with NDF and ADF contents since they are functions of each other. The highest RFV was determined in the pure stand of common vetch while the lowest RFV was observed in the pure stand of barley (*Table 4*).

Van Soest (1996) reported that the RFV is not a direct measure of the nutritional content of forage, but that it is important for estimating the value of the forage. The RFV is an index that is used to predict the intake and energy value of the forages and it is derived from the DDM and DMI. Forage with an RFV value >151 is considered prime (Horrocks and Vallentine, 1999). In the present experiments, the RFV values of most treatments was higher than 151 and it showed high quality of forage production in north of Iran.

Net energy for lactation (NE_l)

Our results showed that orthogonal, year and mixing ratios had significant effect on NE_l (*Table 2*). Additive mixing ratios had more NE_l than substitutive mixing ratio. Among mixture ratios, the highest NE_l was obtained from sole vetch averaged 8.02 mgcal.ha^{-1} (*Table 4*). These results are similar to the results of other researchers who reported that sole common vetch had highest NE_l (Yilmaz et al., 2015). On the other hand, Lauriault and Kirksey (2004) found that mixtures of pea with rye and barley had no effect on NE_l.

Crude protein (CP)

Crude protein content of produced forage is one of the most important criteria to measure forage quality (Assefa and Ledin, 2001). Therefore, concerning the relative low protein content of cereals (Mpairwe et al., 2002) and animal requirements for balanced feed, the importance of mixed cereal-legume cropping would increasingly appear to supply a nutritional diet (Lanyasunya et al., 2007). The results evidently showed that the mixture ratios had effect on crude protein and Monoculture common vetch had the highest CP content (average of 20.97%) and sole barley had the lowest CP content (*Table 4*). In our results in all mixtures, the CP content increased as common vetch seeding proportion increased (*Table 4*). These results are in agreement with those reported by Giacomini et al. (2003). Also, Lithourgidis et al. (2006) reported that crude protein values of mixed of cereals with common vetch (*Vicia sativa* L.) had higher amount than the cereal monocultures. Similar to our results, Osman and Osman (1982) also found the highest and the lowest crude protein percentage in legume and cereal sole cropping, respectively and as legume ratio increased in mixture, protein`s percentage of mixture forage was improved.

Forage yield

Application of bed planting significantly increased ($P < 0.05$) forage yield. Rice bran as bed planting treatments (BP2) had higher forage yield than without rice bran (BP1). Kusmiyati et al (2015) reported that the effect of bed planting significantly increased plant growth and forage yield of guinea grass.

According to the results, among mixing ratios, the highest forage yield was obtained from 40% additive vetch to barley with the average value of 1844 kg ha^{-1} that it was not significantly other mixture ratio treatments (*Table 4*). Also, the lowest forage production was harvested from sole vetch with the average value of 1075 kg ha^{-1} (*Table 4*). In average of two years, Forage yield showed significant difference among mixing ratios. The highest yield was obtained with 40% additive vetch to barley and sole cropping of vetch produced the lowest yield. Agegnehu et al. (2008) reported that additive mix cropping increased forage yield between 3% to 22% over sole cropping.

Crude protein yield (CPY)

Crude protein yield is a measure that relates CP concentration to the dry matter yield per unit area and gives a better estimate of total CP available in the season. One of the main advantages of legume–cereal forage intercrops has been increased protein yield, relative to cereal sole crops (Aasen et al., 2004; Carr et al., 2004). There was a significant effect for protein yield by years (*Table 3*) from 40% additive vetch to barley with the average value of 1844 kg ha^{-1} that it was not significantly other mixture ratio treatments (*Table 4*). Also, the lowest forage production was harvested from sole vetch with the average value of 1075 kg ha^{-1} (*Table 4*). The maximum crude protein yields of 2078.5 kg ha^{-1} were obtained from rice bran as bed planting and 40% additive vetch to barley and the minimum of protein yield of forage obtained from sole vetch with both of BP1 and BP2 (*Table 4*). These results suggest that relying on sole vetch as a source of on-farm protein is not sufficient to satisfy the farmers’ need. It could be concluded that planting of sole vetch might reduce the total forage yield but will increase the overall crude protein yield of the forage which is a more desirable feed for animals.

DOI: http://dx.doi.org/10.15666/aeer/1604_44774490

Carr et al (1998) noted that increasing intercrop protein yield required a significant proportion of legume DM in the intercrop mixture. Crude protein yield of forage is one of the main criteria for forage quality. In all mixtures, an increase in the rate of vetch resulted in higher crude protein yield (Karagic et al., 2011). This was expected since legume establishment was greatly enhanced by the barley support, resulting in a higher protein-rich legume proportion in the mixture. An increase in the rate of dry matter and crude protein content apparently resulted to the increase in the rate of vetch in the mixtures. Strydhorst et al (2008) reported that barley intercrops with legumes improve forage quality compared to pure stand barley. Furthermore, lupin–barley, faba bean–barley, and pea–barley intercroppings had higher protein yield compared to pure barley.

Land equivalent ratio (LER)

The LERs in all mixed treatments were more than one (*Table 5*). Between additive and replacement ratios, the highest LER was belonged to additive ratio (*Table 5*). Results, showed that rice bran as bed planting, had better LER than without rice bran treatments (*Table 5*).

Table 5. *LER and MAI measured for mixing ratios and bed planting of vetch and barley in two years*

Orthogonal	LER	MAI
Additive ratio	1.62	340.6
Replacement ratio	1.52	281.2
Bed planting (BP)		
Without rice bran (control) (BP1)	1.57	291.2
Rice bran bed planting (BP2)	1.67	369.8
Mixing ratios (MR)		
20% (MR1)	1.54	280.6
40% (MR2)	1.66	362.2
60% (MR3)	1.66	378.9
25 vetch and 75% barley (MR4)	1.52	281.2
BP * MR		
BP1 * MR1	1.51	256.0
BP1 * MR2	1.57	305.5
BP1 * MR3	1.66	369.3
BP1 * MR4	1.44	233.9
BP2 * MR1	1.58	305.4
BP2 * MR2	1.75	419.4
BP2 * MR3	1.66	422.5
BP2 * MR4	1.60	332.0

The highest LERs of dry forage production were obtained with mixed cropping 40% and 60% additive vetch to barley, which means 66% more land were needed in sole cropping. The lowest yield-LER and was belonged to 25:75 vetch-barley ratio.

Land Equivalent Ratio (LER) was used to assess profitability of mixtures relative to sole cropping of two crops in respect of dry forage). LERs of >1 were obtained in all

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_44774490

mixed treatments, showing higher advantage and land use efficiency in mixed compared with sole cropping. For most mixtures, the LER values of vetch were below 0.5, indicating that vetch has disadvantages in terms of land use efficiency (Rakeih et al., 2010). In our study, land use efficiency appeared to be higher in common vetch. This could be explained by the fact that Hungarian vetch is more sensitive to warm climate conditions, which affects its competitiveness with barley in terms of land use efficiency. Similar results were reported for legume–cereal intercropping (Hauggaard-Nielsen et al., 2006; Dhima et al., 2007; Yılmaz et al., 2015). These results again confirm that mixed cropping generally produce more yield per area than its related pure stands (Park et al., 2002). Similar reports on yield enhancement from intercropping of legume-nonlegume crops have been reported (Banik et al., 2006; Ghosh, 2006; Agegnehu et al., 2006; Vasilakoglu and Dhima, 2008).

Monetary advantage index (MAI)

Results showed that additive ratios had higher MAI (*Table 5*). The highest MAI (422.5) was obtained in the BP2:MR3, which implied that the planting pattern was highly economical and advantageous for the mixtures. Dhima et al (2007) reported that if LER value was higher, then there was an economic benefit expressed with MAI values such as obtained in the present study.

Conclusions

Mix cropping is an important practice in the North of Iran and is considered as part of the subsistence farming designed to meet increase domestic food requirements and investigations to finding a better bed planting that is important to find better production. The results of this study clearly indicate that mixing vetch with barley and bed planting affected on the forage yield and quality. The greater benefit for forage quality was found when common vetch was grown in a monoculture or in mixtures with barley. The results indicated that usage of rice bran as bed planting had better effect on some quantity and quality of hay and mixture of common vetch with barley at the 40 and 60% additive vetch to barley gave higher forage yield and crude protein yield of all mixtures is higher than monoculture and can recommended in the North of Iran. Moreover, further studies are required to validate the positive role of other legumes in mixture with barley and to more comprehensively elucidate the effects of other bed planting on plants and their nutritional quality.

Abstract. Within measurement model from the perspective of strong disposability, the paper measures the Chinese agricultural water environmental efficiency in 2013, by using the spatial econometric model to analyze spatial effect and influencing factors of agricultural water environmental efficiency in China. The results showed that: (1) Agricultural water environmental efficiency of thirty-one provinces in China is spatially correlated, and its distribution characteristics are: on the one hand, agricultural water environmental efficiency is unevenly distributed in space, which characteristics that gradually reduces from east to west; on the other hand, agricultural water environmental efficiency varies in regions, characteristics—the eastern coastal region is high-value agglomeration area, and the central and western regions are low-value agglomeration areas. (2) Agricultural water environmental efficiency can be influenced by many factors, such as high development level of the rural economy, reasonable changes of agricultural structure, good agricultural environment infrastructure, pertinence environmental regulation. However, the extensive mode of rural industrial growth has reduced agricultural water environmental efficiency.
Keywords: *water pollution, directional distance function, spatial autocorrelation, strong disposability, spatial econometric model*

Introduction

"UN-Water Global Analysis and Assessment of Sanitation and Drinking-Water (GLAAS) 2017 report" points out that nearly 2 billion people around the world are still using faecal contaminated sources of drinking water and are therefore at risk of contracting cholera, dysentery, typhoid and polio. It is estimated that contaminated drinking water causes more than 500,000 deaths per year due to diarrhoea. With the rapid development of rural economy, the problems of agricultural water environment in China gradually appear. "China's environmental state bulletin in 2014" shows that agricultural ammonia and nitrogen emissions accounted for 31.4% of total emissions in the national wastewater discharge in 2014, while agriculture chemical oxygen demand (COD) emission accounted for 48%. In order to control the environmental pollution of rural water, the relevant laws, regulations and policies of the central government and the local government all involve issues relating to rural water environmental governance.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_44914504

The initial stage of rural water environment management is mainly focused on the formulation of relevant standards and the implementation of regulatory responsibilities. With the continuous intensification of rural water pollution, the source governance strategy that integrates environmental protection policies with industrial policies has been proposed. Due to the randomness and decentralization of rural non-point source pollution, comprehensive environmental supervision is difficult to achieve. It is also more difficult for farmers and township enterprises to afford taxes and penalties for water pollution. Therefore, more effective governance measures are to strengthen publicity, education, and guidance so that farmers can understand the damages of water environmental pollution, master clean production technologies, and participate in water environment management. On the one hand, the rapid growth in the number of policies reflects the increasing importance of our country's water environment issues. On the other hand, policy measures have been constantly changing from "command control type" to "voluntary participation type"; policy objectives have also gradually changed from macroscopic guidance to microcosmic operations. To achieve the goal of coordinated development of economic growth and water environmental protection, more and more people pay attention to the improvement of the efficiency of resources and environment. On this basis, many scholars began to study environmental efficiency and proved the existence of spatial agglomeration effect of agricultural water resources in China (Li et al., 2008; Sun and Liu, 2009; Sun et al., 2010). Due to agricultural water pollution along with the rainfall and runoff in space migration, does agricultural water environmental efficiency have the effect of spatial agglomeration as well as agricultural water resources efficiency? What are the factors that influence agricultural water environmental efficiency? Through the study of the question above, the agricultural water environmental efficiency can be better improved. Thus the coordinated development of economy and environment can be ensured. Therefore, many scholars have researched agricultural water environmental improvement from the perspective of environmental efficiency.

Literature review

For better coordination of economic development and environmental protection, the World Business Council on Sustainable Development (WBCSD) put forward the concept of environmental efficiency to measure the environmental cost during economic development process, and thus to estimate the sustainability of the economy. According to the WBCSD definition, environmental efficiency is achieved through the delivery of "competitively priced goods and services that satisfy human needs and bring quality of life while progressively reducing environmental impacts of goods and resource intensity throughout the entire life-cycle to a level at least in line with the Earth's estimated carrying capacity". Based on this concept, many scholars began to do research in the field of agriculture environment efficiency. Fulginiti et al. (1998) used the Malmquist Production Index and the Cobb-Douglas Production Function to study the agricultural environmental productivity in 25 developing countries over 25 years. The results showed that the production efficiency of the agricultural environment in the least developed countries decreased most significantly to more than half. Countries have experienced a decline in agricultural production efficiency. Regardless of the environment, Ruttan (2002) found that the world's agricultural productivity had dramatically increased in the past half-century. Galanopoulos (2004) used DEA-based

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_44914504

Malmquist Productivity Index method to evaluate the agricultural environmental efficiency of EU countries and 13 other candidate countries. The results showed that European countries generally have low agricultural environmental efficiency. Nanere et al. (2007) revised the efficiency of agricultural production and considered that the level of environmental damage has a significant impact on the efficiency measurement model. Restuccia et al. (2008) compared agricultural production efficiency and total factor productivity in different countries and regions and found that the correlation between agricultural environmental productivity and labor productivity was not significant in the same period. but compared to agricultural total factor productivity in developed and developing countries, the gap continues to grow. Barnes et al. (2009) believes that measuring the environmental efficiency can achieve a win-win situation, which can not only reduce the investment of farmers but also reduce the environmental externalities. Li (2014), Li et al. (2011) and Min et al. (2012) made an empirical analysis of agricultural environment efficiency of several provinces in China from the perspective of agricultural economic development, resource utilization and environmental coordinated development. Yang and Chen (2011) measured the growth of agricultural environmental technical efficiency of several provinces in China, and the empirical results show that the agricultural environment efficiency in the east is significantly higher than that in the central and western regions. The difference between the central region and the western region is very small. Ignoring environmental factors will overestimate China's agricultural productivity growth. Pan and Ying (2013a) investigated agricultural productivity under the restriction on resources and environment in China. The results show that without consideration of environmental pollution constraints, China's overall agricultural productivity level will be overestimated, and the state of agricultural productivity diversification in each province will continue. Zhang and Feng (2016) studied measurement model of agricultural environment efficiency in China and its dynamic evolution under the strong disposable perspective. The above research on environmental efficiency measurement laid the foundation for follow-up study.

In addition, scholars at home and abroad have further studied the influencing factors of environmental efficiency. Monchuk (2010) studied the influencing factors of agricultural environment efficiency in China. It proved that agricultural structure changes and agricultural economic development level significantly improved the efficiency of the agricultural environment while the industrialization lowered the efficiency of agricultural environment. Through the research on the influencing factors of Spanish agriculture ecological efficiency, Picazo-Tadeo (2011) found out that environmental regulation, education level, and agricultural training can improve the efficiency of agricultural ecological while agricultural economic development level had the opposite effect. According to the study of Gadanakis (2015), the British agricultural technical efficiency was mainly influenced by farm scale, farmers' level of education and experience, agricultural environmental payment, and cost, environmental regulation, etc. Liang et al. (2012) found that agricultural environmental technology efficiency could be better promoted by improving the level of economic development and agricultural infrastructure investment while the agricultural environment management policy affected little on it. Through empirical research, Li (2014) concluded that China's agricultural green productivity was influenced by factors such as the household contract responsibility system, agricultural price system reform, rural industrialization, public agricultural investment, agricultural taxes and fees reform and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_44914504

agricultural openness variables, etc. Yang and Liu (2015) found that high abundance of water resource, farmland water conservancy construction and environment regulation could be obviously beneficial to agricultural water resources efficiency.

In conclusion, the existing research has made abundant achievements in measurement and influencing factors of environmental efficiency, which provides a reference for the rural water environment management and relevant policy making. However, the spatial effect of agricultural water environmental efficiency was taken little consideration.

Moreover, the current efficiency measurement model and agricultural water environmental characteristics at present stage have some differences. Therefore, a more reasonable efficiency measurement model should be used to study the spatial heterogeneity of agricultural water environmental efficiency in China, and to analyze the influencing factors of these spatial differences.

Research method

Efficiency measurement model

The existing efficiency measurement models are mainly based on foreign agricultural environmental efficiency and the domestic industrial environmental efficiency such as joint weak disposable distance function and the SBM model. However, agricultural water environmental efficiency in China now could not meet the demand for pollution (undesirable outputs) characteristics including null associatively and joint weak disposability. First, in regards to characteristics of agricultural pollution, the agricultural environmental pollution in China at this stage is not inevitable, and the agricultural environmental governance can increase production to some extent. Therefore, it does not meet the requirements for combined weak disposal and zero integration. Second, as for the pollution control costs, agricultural environmental pollution control yields benefits to economy to some degree and does not satisfy the economic significance of the joint weak disposition. Third, from the perspective of environmental regulation, the existing agricultural environmental regulation is not sufficient to achieve the transformation of agricultural environmental pollution from strong disposability to joint weak disposability. Based on the above analysis, the pollution characteristics of China's agricultural environment are different from those of industrial environmental pollution and agricultural pollution in developed countries. The combination of zero-integration and weak disposal is still unsatisfactory. Therefore, another way must be found to measure the agricultural environmental efficiency in China. The strong disposability thought provides a solution for measuring China's agricultural environmental efficiency (Zhang and Feng, 2016). Here is the definition (*Eq. 1*):

$$AWEE=\frac{1}{1+\vec{D}\left(x,y,b;g\right)} \tag{Eq.1}$$

where x is input variable; y is the expected output variable; b is the unexpected output variable;

$$D\left(x,y,b;g\right)=\sup\left\{\beta:\left(y,b\right)+\beta g\in p^{s}\left(x\right)\ \right\}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_44914504

$$p^{s}\left(x\right)=\left\{\left(y,b\right)\middle|\sum_{j=1}^{n}z_{j}x_{j}\leq x,\sum_{j=1}^{n}z_{j}y_{j}\geq y,\sum_{j=1}^{n}z_{j}b_{j}\leq b,z_{j}\geq 0\right\}$$

Spatial econometric model

(1) Spatial autocorrelation model

Global Moran's *I* index describes the cluster state of the distribution of regional economic activities from the whole regional space view. Here is the definition (*Eq. 2*):

$$I=\frac{\sum_{i=1}^{n}\sum_{j\neq i}^{n}W_{ij}z_{i}z_{j}}{\sigma^{2}\sum_{i=1}^{n}\sum_{j\neq i}^{n}W_{ij}} \tag{Eq.2}$$

Where n is the number of observations; X_i is the observation in position i; Z_i is the standardized transformation of X_i;

$$z_{i}=\frac{x_{i}-\bar{x}}{\sigma},\bar{x}=\frac{1}{n}\sum_{i=1}^{n}x_{i},\sigma^{2}=\frac{1}{n}\sum_{i=1}^{n}\left(x_{i}-\bar{x}\right)^{2}$$

Global Moran's *I* index involves only the whole regional space, whereas the spatial association patterns of separate regions in the global geographic range are not included. Here we use the local Moran's *I* index to analyze local characteristics of spatial association. Here is the definition of local Moran's *I* index (*Eq. 3*):

$$I=\frac{I_{i}-E\left(I_{i}\right)}{\sqrt{Var\left(I_{i}\right)}} \tag{Eq.3}$$

where $I_{i}=\sum_{j=1}^{n}w_{ij}\left(x_{i}-\bar{x}\right)\left(x_{j}-\bar{x}\right)$.

(2) Spatial lag model

Spatial lag model (SLM) is used to study whether the variables have a spillover effect in the space aspect. The mathematical expression of SLM is as follows (*Eq. 4*):

$$y=\rho Wy+X\beta+\varepsilon \tag{Eq.4}$$

Where x is independent variable; y is dependent variable; β reflects the effect of x on y; ρ is the spatial autoregressive coefficient; Wy is endogenous variable.

(3) Spatial error model

Spatial error model (SEM) can be used to determine whether an error term is dependent on space level. The definition of SEM is as follows (*Eq. 5*):

$$\begin{aligned}y&=X\beta+\varepsilon\\ \varepsilon&=\lambda W\varepsilon+\mu\end{aligned} \tag{Eq.5}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_44914504

where x is independent variable; y is dependent variable; β reflects the effect of x on y; ε represents the random error term vector; λ is autoregressive parameters; μ is random error vector of standard normal distribution; W is spatial weight matrix; λ stands for the error impact degree which adjacent area has in the local area.

Efficiency measure and its spatial characteristics

Variable definition and data processing

After full consideration of the existing research achievements and the characteristics of agricultural water environment (Li et al., 2014; Han, 2013; Pan and Ying, 2013b; Liang et al., 2012), the indexes in this paper are selected as listed in *Table 1.*

Table 1. *Measurement index of agricultural water environmental efficiency*

First-grade indexes	Second-grade indexes	Variables interpretation
Input	Land input	Cultivated land area
	Irrigation investment	Effective irrigation area
	Fertilizer input	The net amount of fertilizer applied in agricultural production, including nitrogen, phosphorus, potassium and compound fertilizer
	Agricultural machinery investment	Agricultural machinery total power
	Labor input	Gross labor in agriculture, forestry, animal husbandry and fishery
Output	Expected output	Total output value in agriculture, forestry, animal husbandry and fishery (economic benefit) Grain yield (social benefit)
	Unexpected output	Emission of COD Emission of nitrogen and phosphorus

The sources of nitrogen and phosphorus emissions, as well as COD emissions, come from two periods. The first period is after 2012, and the data can be found in “China Environmental Statistics Yearbook”. The second period is between 1990 and 2012, and the statistics can be measured by the way of unit investigation and evaluation of related literature (Chen et al., 2006; Lai et al., 2004). The formula is as follows (*Eq. 6*):

$$E = \sum_i SU_i \times \rho_i \times LC_i \qquad \text{(Eq.6)}$$

where E is agricultural pollutant emission; SU_i is pollutant production base; ρ_i is intensity coefficient of pollutants; LC_i is pollutant discharge coefficient.

Due to the difficulty of obtaining data on water environmental pollution, the research only uses the data before 2013 for analysis. This study will examine the agricultural water environmental efficiency of 31 provinces in mainland China. Based on China’s development and policy factors, these provinces and autonomous regions are divided into three areas: east, central, and west China. The data above are from the annual “China Statistical Yearbook”, “China Rural Statistical Yearbook”, “Handbook of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_44914504

Agricultural Pollution Fertilizer Loss Coefficient” and “Poultry Breeding Industry Pollution Discharge Coefficient Handbook”, etc.

Measurement result

The measurement result of China’s agricultural water environmental efficiency in 2013 can be obtained through *Equation 1* and *Figure 1* is the sub-bitmap. The sub-bitmap shows that the spatial distribution characteristics of agricultural water environmental efficiency in China is uneven and the distribution pattern can be described to be gradually decreased from east to west. The average efficiency values of eastern, middle and western regions are 0.89, 0.80 and 0.75.

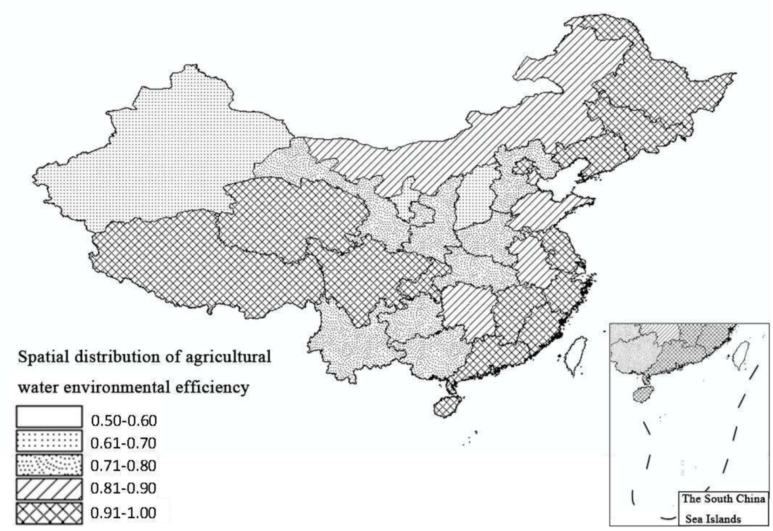

Figure 1. *Spatial distribution of agricultural water environmental efficiency*

Spatial autocorrelation test

By using global Moran’s *I* method to test the measurement results of agricultural water environmental efficiency of China in 2013, the research showed that all the results managed to pass the test under 5% confidence level. The result of this test can support the conclusion that the agricultural water environmental efficiency of thirty-one provinces in China is spatially correlated and its distribution has certain accumulation characteristics, and therefore it is easy to form neighborhood imitation effect of agricultural water environmental efficiency.

To further study the spatial dependence situation of agricultural water environmental efficiency in different regions, the local Moran’s *I* test and Local indicators of spatial association (LISA) was carried out in 2013 (*Fig. 2*). LISA is used to test whether there is agglomeration in the local area. The LISA agglomeration area reflects the closeness of the observation values in adjacent areas to characterize regional differences. From *Figure 2* it turns out that most of the eastern coastal provinces present a High-High accumulation model while some of the mid-western regions still carry a Low-Low accumulation pattern. The former area usually holds high agricultural water environmental efficiency value and is more prone to cooperate with each other to improve that efficiency. The regional economic development level can partly explain

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_44914504

this phenomenon. The natural characteristics of the more developed river system and more intertwined river network also play an important role. On the contrary, poorer water resources sharing system and a rather slow economic development level have formed a less cooperated environment in the mid-western area, and this has caused low agricultural water environmental efficiency value.

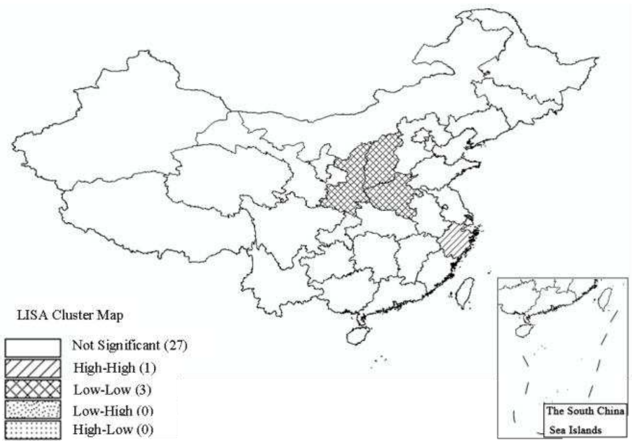

Figure 2. *Local spatial auto-correlated LISA cluster map of agricultural water environmental efficiency in China*

Analysis of the factors influencing spatial heterogeneity of agricultural water environment

Variable selection and data sources

The efficiency of agricultural water environment is influenced by many factors, such as the economy, resources, environment, etc. The influence factors here were chose out of two considerations. The existing research papers listed in *Table 2* and the characteristics of agricultural water environment itself. Based on this, the following influence indexes are selected.

(1) Rural Economy Development Level (REDL). This index is based on per capita net income, which defines the year 2000 as the base year, in rural areas to exclude the impact of price change.

(2) Agricultural structure change (ASCP&ASCG). ASCP represents the proportion of poultry industry output in total agriculture output value, and ASCG shows the proportion of grain crops and economic crops.

(3) Rural industrialization (RI). The total output value of township enterprises which make up the gross rural output value is the measure of this indicator.

(4) Agricultural environmental infrastructure level (AEIL). The investment quota of agricultural infrastructure is the standard.

(5) Environmental regulation (ERCOD&ERNH). Environmental regulation can be reflected in concrete measures like environmental policy making, environmental law enforcement and environmental governance Investment, etc. Considering this, the indexes measuring environmental regulation could relatively be the quantity of environmental policy, the number of pollution control law enforcement and pollution control costs, etc. However, these indexes have their limitations on both index attributes and data sources which might cause deviant results. Therefore, in this paper, the effect

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_44914504

of pollutant control is used to measure environmental regulation precisely. For example, Cole and Elliott (2003) used pollutant emission density as an indicator to measure environmental regulation intensity. Changes in pollutant emissions and pollution emission intensity coefficient were respectively used as the indicator by Fu and Li (2010) and Li and Tao (2012) to measure environmental regulation better. Based on this idea, agricultural COD and ammonia nitrogen emission intensity were chosen as the proxy variable of environmental regulation in this research. The relationship between environmental regulation strength and pollutant emissions intensity is that the former is directly proportional to the latter.

The data above are drawn from "China Statistical Yearbook", "China Rural Statistical Yearbook" and "China Environmental Statistics Yearbook".

Table 2. *Influence factors of representative researches*

Author	Year	Research contents	Selection of influence factors

Interpretation of estimated results

The estimated results of OLS, SLM, and SEM are summarized in *Table 3*. According to the values in *Table 3,* the R-squared value of each respectively is 0.6606, 0.6683 and 0.7468. The value of SEM, as well as SLM, is higher than that of OLS, which means that the assumption of the agricultural water environmental efficiency is independent of provinces in the least squares regression analysis. Thus the conclusion that the agricultural water environmental efficiency of thirty-one provinces in China is spatially related in section 3.3 is proved.

Comparing the LogL, AIC and SC values between SLM and SEM, it proves that SEM model is better than SLM model. This result shows that the efficiency of agricultural water environment in China is not only affected by the agricultural water environmental efficiency of neighboring provinces but also affected by the structural differences between regions. The differences include development level of the rural

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_44914504

economy, agricultural structure change, rural industrialization, agricultural environmental infrastructure, environmental regulation and other factors not included in the model. Since the spatial error coefficient of SEM has passed the 1% significance level test, the existence of significant spatial dependence of agricultural water environmental efficiency in different provinces is tested.

Table 3. *Regression results of the model*

Notes: ***, **, *, respectively, stands for the significant level of 1%, 5%, and 10%. The values below OLS are T-Statistics, and the values below SLM & SEM are Z-Statistics

It can be seen from the above results that the efficiency of agricultural water environment influenced by the structural errors impact shows as follows:

(1) The positive estimated coefficient of rural economy development level (REDL) means that the improvement of rural economic development level can increase the efficiency of the agricultural water environment. With the improvement of rural economic development level, people's demand for water environment quality has also improved. Both farmers and government are paying more attention to the agricultural water environment, and this can improve the pollution problem thus can help to improve the efficiency of the agricultural water environment. Besides, agricultural environment-friendly production technology has been improved; and the resource

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_44914504

consumption, as well as pollution generation, have been decreased. All these efforts promote the efficiency of the agricultural water environment.

(2) Agricultural structure change causes two kinds of influence on the efficiency of the agricultural water environment. On the one hand, the positive estimated coefficient of ASCP shows that the proportion of animal husbandry in agricultural output helps to the proportion of animal husbandry in agricultural output. The high added value of animal husbandry explains for that. On the other hand, the estimated coefficient of ASCG is also positive. It means that the proportion of grain crops in planting also counts. Rather stable fertilizing amount of grain crops and increasing fertilizing amount of cash crops can help to solve water environment problem because the fertilizer using does great harm to the water environment.

(3) The negative estimated coefficient of rural industrialization (RI) means that rural industrialization decreases the efficiency of the agricultural water environment. Firstly, the overdevelopment and overuse of resources in the process of rural industrialization pollute the rural water environment. Secondly, urban and rural industrial pollution transfer, unreasonable rural industrial distribution, as well as the extensive growth of the rural industry, also influence rural water environment efficiency.

(4) Positive agricultural environmental infrastructure level (AEIL) shows that the improvement of agricultural environmental infrastructure level has an impact on rural water environment efficiency, but with insignificant effect. Projects like irrigation and water conservancy, ecological engineering, water saving irrigation improve comprehensive agricultural production capacity and output level while decreasing pollution discharge and ecological destruction. However, problems like insufficient investment, unreasonable investment project and unmanned management after completion decrease the influence AEIL on rural water environment efficiency.

(5) The influence of environmental regulation on the efficiency of agricultural water environment can be divided into two parts. For the first part, the negative estimated coefficient of ERCOD shows that environmental regulation decreases the agricultural water environmental efficiency on the agricultural COD emission reduction side. The possible explanation is that the livestock and poultry breeding industry, which accounts for 90% of agricultural COD emission, is too dispersed for the specialized management system to be made. Moreover, the randomly caused pollution also adds to the difficulty. For the second part, if the estimated coefficient of ERCOD is positive, it means that the environmental regulation increases the agricultural water environmental efficiency on the agricultural ammonia and nitrogen emission side. This can be attributed to the fertilizer and pesticide management system since these two are the main sources of ammonia and nitrogen emission, and a series of such regulations have been released in China recently. Regulations like “Water Pollution Prevention and Control Law”, “Pesticide Management Regulations” and “Regulations on the Protection of Basic Farmland” are among these effective measures.

Conclusions and policy implications

The strong disposable direction distance function was applied to measure the efficiency of agricultural water environment in 2013, and the spatial econometric model was further used to analyze the spatial effect of agricultural water environmental efficiency as well as its influencing factors. As a result, two main conclusions were drawn from the research. Firstly, agricultural water environmental efficiency in thirty-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_44914504

one provinces of China is spatially related. The two spatial distribution features are an unbalanced spatial distribution which presents gradually reduced distribution pattern from east to west and spatial aggregation where eastern coastal areas are mostly high with agricultural water environmental efficiency while the majority of mid-western regions stay in the low part. Secondly, regional structural differences among neighboring provinces also influence the agricultural water environmental efficiency apart from the mutual impact factor. Regional structural differences behave in many aspects such as economic development level of the rural area, agricultural structure changes, industrialization in the rural region, agricultural environmental infrastructure, environmental regulation, etc. These spatial influence factors perform their influences to agricultural water environmental efficiency in their way. For instance, the coordination of the above elements can be a benefit to the improvement of agricultural water environmental efficiency while the extensive rural industrial growth feature will do otherwise.

Based on the conclusions above, the following policy recommendations are drawn:(1) In treatment of agricultural water environment pollution, inter-regional cooperation in economic and environmental protection, spatial linkage of policy measures, cross-regional agricultural water ecological compensation fund and coordination of water environment management among different provinces (municipalities and autonomous regions) are all essential and should be taken into consideration. Specifically, the eastern area should set an example for and cooperate with the mid-western area in agricultural water environment management. For the mid-western area, the “scientific guidance, point to an area” principle should be followed and the detailed steps should be implemented gradually. In this process, the mid-western area should not just imitate from eastern area, adjustment of the policies are necessary when facing problems with specific characteristics of their own. (2) Here are some points every region should follow: Firstly, Improvement of their own economy level and cooperation with other parts should be important tasks, and integration of regional economy should be the target. Secondly, cleaner production and environmentally friendly technology should be advocated to optimize the agricultural structure. Thirdly, rural industrialization should be promoted to more intensive growth mode instead of the existing extensive growth mode. The fourth point suggests that investment in agricultural infrastructure should be increased to form a complete agricultural infrastructure system. Last but not least, policy tools like prevention and control measures, industrial adjustment, and financial support should be comprehensively applied as the inspiriting mechanism to help to improve the agricultural water environmental policy system.

The countries participating in the “Belt and Road” initiative, represented by China, mostly use agriculture as the main industry. There are problems in measuring and improving agricultural water environmental efficiency in these countries. Studying on the evaluation and influencing factors of China’s agricultural water environmental efficiency has certain reference significance for the countries participating in the “Belt and Road” initiative.

This study only compares agricultural water environmental efficiency among the Chinese provinces. If the data includes other advanced countries, for instance, countries participating in the “Belt and Road” initiative, it may provide more information on the level of China’s agricultural sector. Also, this research can be combined with

(Received 22nd May 2018; accepted 5th Jul 2018)

Abstract. In this study, bird species of Hoynat Island, which is one of the two biggest islands on and around the Black Sea coast, and population trends of these species in a year and nesting site selection of breeding bird species, were examined. Hoynat Island is also the largest know area to show breeding behaviour for European shag in Turkey. Observations were conducted between 2011 and 2017 years. It was found three bird species preferred for nesting Hoynat Island throughout the year. These species are great cormorant (*Phalacrocorax carbo* Linnaeus 1758), European shag (*Phalacrocorax aristotelis* Linnaeus 1761) and yellow-legged gull (*Larus michahellis* J. F. Naumann 1840). These species show breeding and incubation behaviours on the island and surrounding rocks. While *P. aristotelis* uses the island as a short-term stopover when it first comes to the area, it stays in the rocks on the tunnel then and during the incubation process. *P. carbo* and *L. michahellis* do not use the rocks on the tunnel and only *P. carbo* stays for a while on the top of trees in the upper part of the tunnel. *P. carbo* and *L. michahellis* use the island as a stopover and incubation area. Using the island and surrounding as a nesting site, *P. aristotelis*, *P. carbo* and *L. michahellis* have reached the highest population in June. During this month, 170 *P. aristotelis*, 670 *P. carbo* and 475 *L. michahellis* were counted. It was found that breeding preparations of the birds in the study area started in February and hatching continues until June.
Keywords: *habitat use, great cormorant, European shag, yellow-legged gull, Hoynat Island, Turkey*

Introduction

Turkey is between two continents (Europe and Asia); therefore, it is a wealthy country in terms of fauna, flora and habitat diversity thanks to its location. Habitat loss and degradation on islands are key processes leading to population decline of birds. Habitat generalism is an important attribute in determining the ability to persist in heterogeneous and human-perturbed landscapes (Sol et al., 1997; Marvier, et al., 2004; Vergara and Armesto, 2009). Habitat generalist species have broad habitat amplitudes (occupying several habitat types) and usually they behave as opportunistic species, preferring the habitats offering more resources (Medel and Jaksic, 1988; Magura et al., 2003). Unlike specialist species, which are constrained to use a small habitat spectrum, habitat generalists may switch their habitat selection pattern over time as expected from habitat selection theory (Fretwell and Lucas, 1970; Rosenzweig, 1985; Latta and Faaborg, 2002; Chen et al., 2008). Consequently, changes in population size and in the spatial distribution of their resources over time may result in a wide temporal variability in habitat use by generalist species (Diamond, 1975; Holt, 1993; Mobæk et al., 2009; Hahn et al., 2011).

Great cormorant, European shag and yellow-legged gull are nested in Hoynat Island. In North America, great cormorants are strongly associated with marine coastlines, in contrast to their smaller cousins, double-crested cormorants. In Europe, great cormorants are also found in inland, freshwater areas and in coastal estuaries. Nesting habits may vary among subspecies. North American great cormorants (*P. c. carbo*) nest mainly along coasts. Eurasian subspecies (*P. c. sinensis*) nest in inland areas, but the two subspecies sometimes occur in nesting colonies together in areas of recent overlap (British Isles) (Hatch et al., 2000).

European shags are found throughout western Europe, from Iceland, the British Isles, Portugal, Gibraltar, and northern Africa east to Greece and north into the Ukraine and as far north as Norway. European shags are found along rocky, marine coastlines and islands and are never found very far from land or very far inland. Preferred foraging grounds are in clear, protected waters over sand or rocky substrates, such as in bays or coastal channels. They avoid fresh, brackish, or muddy water (Birdlife International, 2009; Del Hoyo et al., 1992). European shags build nests of sticks, seaweed, and other marine debris on rocky ledges, cliffs, or stacks. Nests have been found from just above the high water level to 100 m above the sea. Nesting areas host large concentrations of these birds, who nest in close proximity. Breeding season varies regionally, Black Sea populations breeding from January to March. (Del Hoyo et al., 1992; Snow, 2008; RSPB, 2009; Birdlife International, 2009; Arkive, 2018).

Yellow-legged Gull can be found in Europe, the Middle East and north Africa. It is resident in much of southern Europe, on the coasts of the Mediterranean, Black Sea and Caspian Sea, on the Azores and Madeira, Portugal, and on the Canary Islands, Spain. The nest is constructed of nearby vegetation, feathers, debris and old carcasses, and is preferably positioned close to or under bushes, or on rocky and sandy islands, beaches, spits, sea cliffs, grassy or shrubby river islands, and occasionally on high ground hundreds of meters from water (Del Hoyo et al., 2013).

Turkey, which is highly important for especially birds, hosts various bird species that are threatened with extinction worldwide. Hoynat Island is one of the 305 Key Biodiversity Areas (KBA) and 184 Important Bird Areas (IBA) of Turkey (Kılıç and Eken, 2004). The island is one of the two biggest islands of Black Sea. Hoynat Island is also the only area to show breeding behavior for European shag in Turkey. There is not any other comprehensive scientific study conducted for bird species in the study area. Only midwinter water bird count was observed during some years. But no data on the island has been revealed during these counts.

Materials and methods

Study area

Eastern Black Sea Region, where Hoynat Island is located, is situated in Caucasus which is one of the most important regions of the world in terms of nature conservation (*Fig. 1*). Caucasus Ecological Region, which is located between Black Sea and Caspian Sea and which covers lands of Azerbaijan, Armenia and Georgia and some parts of Russia, Iran and Turkey, is acknowledged as one of the wealthiest places of the world concerning biodiversity. Eastern Black Sea coasts located in this region host many bird species. The island is 100 meter away from the coast. There is not any settlement area on Hoynat Island. It is estimated that Hoynat Island was once used by sailors as a storage and shelter.

Hoynat (Akkuş) Island and its surroundings selected as study area in this project are located in Bolaman-Efirli route in Ordu province which constitutes the only natural coast line out of the highway influence area of 542 km Black Sea coast road completed

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45054514

in 2007. Therefore, this area is also one of the last natural habitats of the bird species in the Black Sea. There is not any other comprehensive study conducted for bird species in the study area. Depending on the observations carried out in different dates, Nature Association of Turkey identified Akkuş Island in the Eastern Black Sea as an Important Bird Area (IBA) (Kılıç and Eken, 2004). So, Akkuş Island IBA was registered as IBA with the code of DKD001-TR059 because of 'island under full protection and necessary to be monitored, area including important populations of bird species threatened with extinction' status, and the island located in 18 km west of Ordu and 100 m off the coast of land and region surrounded by high cliffs that are perpendicular to the sea are identified as 'necessary to be monitored' status. Under this study, *Phalacrocorax aristotelis* and *Larus michahellis* are the bird species determined in the area. Especially the island and its surroundings determined as breeding area of *P. aristotelis* which is threatened with extinction were acknowledged as important bird area with their natural and undisturbed structure. The project area was also identified as 'Culture and Tourism Protection and Development Region' by the Ministry of Culture and Tourism in 2009. Accordingly, Hoynat (Akkuş) Island was accepted by the Ministry of Culture and Tourism as an area necessary to be monitored under the categories of B1(i) and B3 with its 90 double *P. aristotelis* population in the Eastern Black Sea and Çoruh Basin.

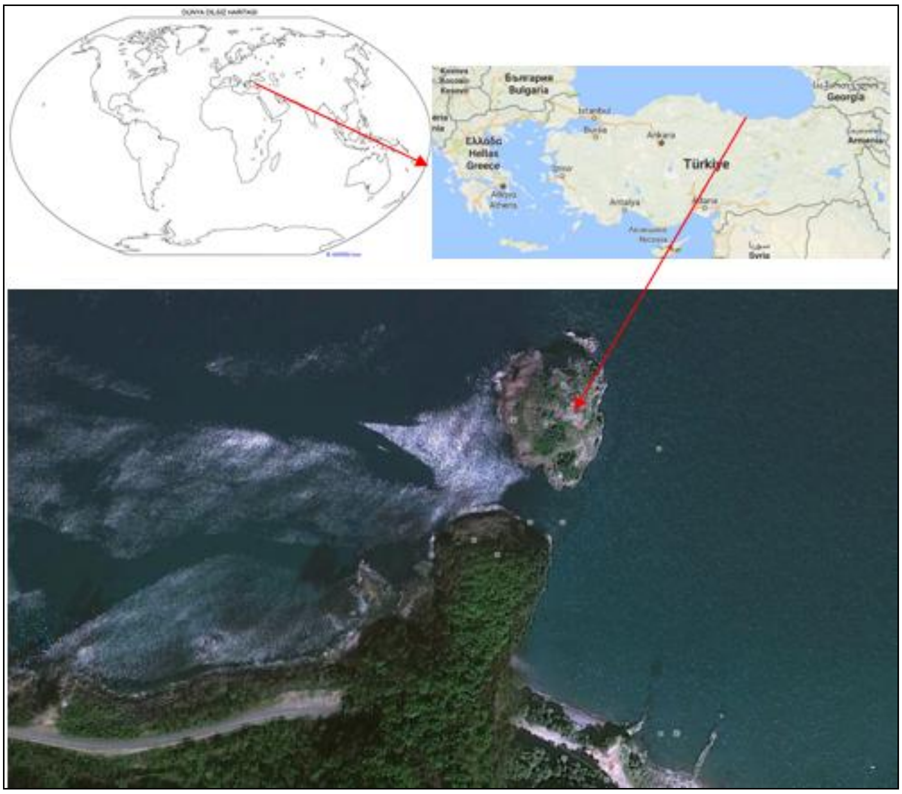

Figure 1. *Location of study area (Google Earth)*

Bird sampling

Direct observations were carried out to the study area every month periodically between June 2011 and January 2013 under the project (Bibby et al., 1992; Oğurlu, 2003). Observations continued from 2013 to 2017 after project during breeding seasons.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45054514

Bird species which have high population spreading the area, habitat use and breeding situation of the species were tried to be identified by benefiting from Kiziroğlu (1989); Heinzel et al. (1992); Kasparek (1992); Jonsson (1993); Roselaar (1995); Kirwan et al. (1998) resources.

Habitat classification

We used the criteria of Hahn et al. (2005, 2010) as a guide for grouping vegetation units (hereafter called "habitat types"). This habitat classification is focused on habitat features important for birds, such as vegetation structure and dominant plant species, as well as geographical factors like altitude, exposition and incline. Three habitats, i.e. bushes on the island, meadows and tunnel bluffs, were classified as breeding habitats in the area.

Results and discussion

As a result of the studies carried out during the project, It was found three bird species preferred for nesting Hoynat Island throughout the year. These species are great cormorant, European shag and yellow-legged gull and showed breeding behaviours on the island and surrounding cliffs (*Fig. 2; Table 1*). Additionally, 1-3 individuals from *Ardea cinerea, Egretta alba, Egretta garzetta, Larus canus, Larus ridibundus, Podiceps cristatus* and *Corvus corone* species were also observed in Hoynat Island. Observations continued from 2013 to 2017 and no significant changes were observed in population numbers. Among these species, there is no endangered species on global scale. But Hoynat Island is the largest known area to show breeding behaviour for European shag in Turkey.

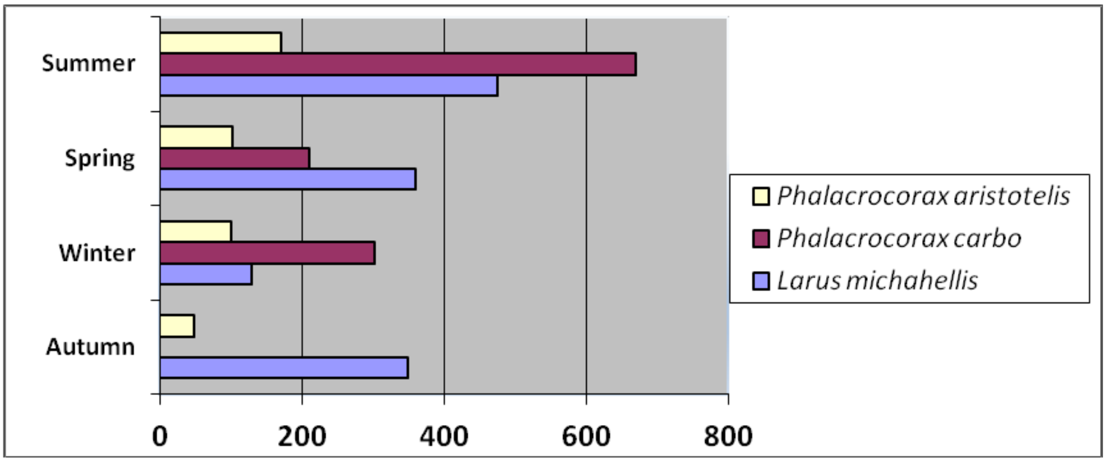

Figure 2. *Seasonal numbers of the breeding bird species (P. aristotelis, P. carbo and L. michahellis) in Hoynat Island*

It was found in the project area that breeding behaviors started in February and hatching continued until June. At the end of January, *P. aristotelis* and *P. carbo* started preparations for nesting at the end of February. Eggs started to open and hatching started in April. Therefore, *P. aristotelis* and *P. carbo* were observed as fully covered with their breeding coverage. On the other hand, *L. michahellis* incubated one month

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45054514

later and young birds exited from eggs around at the end of May or the beginning of June.

Table 1. *The breeding bird species in the island and surrounding*

Observation date	Species	Habitat use			Total number of individuals
		Rock balconies on the tunnel	Grassland on the island	Bushland on the island	
6 June 2011	*Phalacrocorax aristotelis*	155		15	170

28 October 2012	*Phalacrocorax aristotelis*	18			18
	Larus michahellis		225		225
30 November 2012	*Phalacrocorax aristotelis*	49			49
	Larus michahellis		320		320
04 February 2013	*Phalacrocorax aristotelis*	48			48
	Phalacrocorax carbo			302	302
	Larus michahellis		130		130

During breeding period, bird species were found in the different habitat types. *P. aristotelis* used rock balconies on the tunnel, *P. carbo* used bushland and *L. michahellis* used grassland on the Hoynat Island. However, none of the species has interfered with each other’s breeding areas during the breeding season (*Table 2*; *Fig. 3*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

Table 2. *Habitat types for breeding birds in Hoynat Island and surrounding*

Bird species	Habitat types	Area (m^2)
Phalacrocorax aristotelis	Rocky area	7565
Phalacrocorax carbo	Grassland	7294
Larus michahellis	Bushland	1840

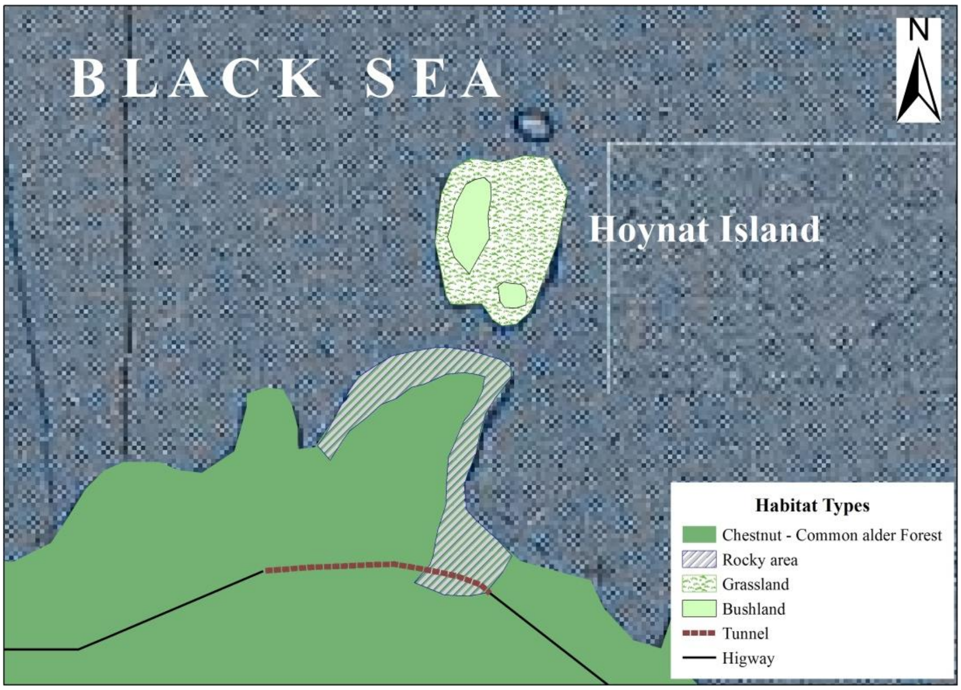

Figure 3. *Habitat types for breeding birds in Hoynat Island and surrounding*

It was also observed that there were differences between the nesting site selections of the identified bird species. Thus, rocks on the island and rocks on the tunnel were addressed as two habitats in terms of area usage of the birds. The island defines the area on which rocks, bushes and small trees exist and which does not have any connection with the land; on the other hand, rocks on the tunnel cover the top of the tunnel on the highway located in 200 meter of the island and cliffs located between tunnel and the island and including some balconies. While *P. aristotelis* uses the island as a short-term stopover when it first comes to the area, it stays in the rocks on the tunnel then and during the incubation process. *P. carbo* and *L. michahellis* do not use the rocks on the tunnel and only *P. carbo* stays for a while on the top of trees in the upper part of the tunnel. *P. carbo* and *L. michahellis* use the island as a stopover and incubation area. Using the island as a temporary stopover, *A. cinerea* never prefers the rocks on the tunnel (*Fig. 4*).

P. aristotelis makes a nest on the rock balconies on the tunnel and rock region near the tunnel by using brushwood; *P. carbo* makes a nest on the top of the bushes in the island or on the high grasses on the ground by using brushwood; *L. michahellis* makes a nest within the grasses in the island or on the ground and stone. In case of *P. aristotelis* and *P. carbo* 3-5 young birds hatch, whereas 2-3 young birds hatch in case of *L. michahellis* (*Fig. 5*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

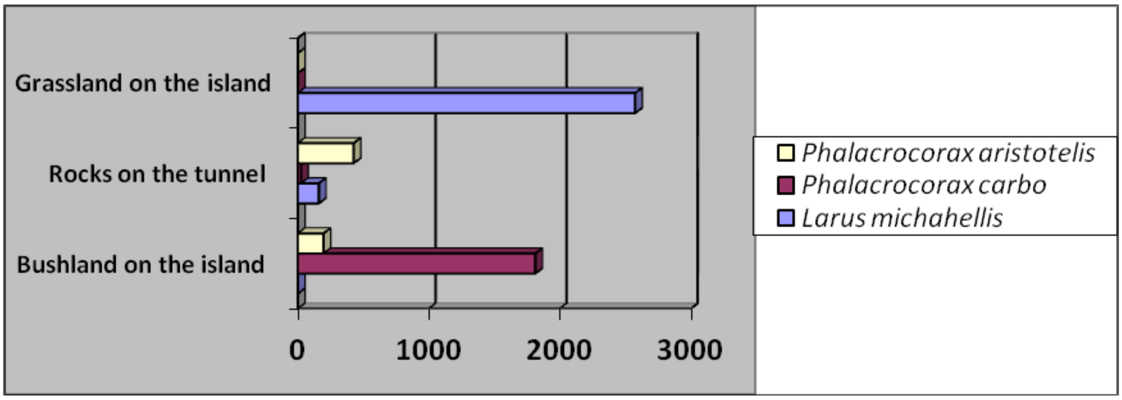

Figure 4. *Nesting site selection of breeding birds in Hoynat Island and surrounding*

Phalacrocorax aristotelis

Phalocrocorax carbo

Phalacrocorax carbo

Larus michahellis

Figure 5. *Nesting sites of the birds in Hoynat Island*

Breeding habitat usage findings obtained in the study are consistent with the literature data. *P. aristotelis* prefers cliffs as nest; *P. carbo* prefers on the top of the bushes and *L. michahellis* prefers meadows. Therefore, rocks on the tunnel are also areas that should be protected as much as the island. That's why, it is recommended to give a 'Natural conservation area' status to the island and rocky area covering the area from the tunnel-top which is the most important area for *P. aristotelis* to the island in order to protect this area and hand down the next generations.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45054514

Many different names are used for the area. For example, in the IBA book it is named as Akkuş Island; however, on the highway signs it is written as Hoynat Island. Local people use Hoynat Island and also Çaka Island. Therefore, it is important to use a single name for resources.

Conclusions

As a result of the studies carried out to date, the occurrences of three nesting bird species in Hoynat Island have been determined. Considering the number of bird populations observed in Hoynat Island, it can be seen how an important nesting area it is for the region and Turkey. Measurements must be taken against threat risks to protect the important bird nesting area. Further urbanization towards Hoynat Island must be stopped, and new buildings must not be allowed in this direction anymore. Study area is not within the scope of hunting ban. The field should immediately be registered into the hunting-ban areas.

Provincial Directorate of Culture and Tourism put a sign with the name of 'Hoynat Bird Paradise' in the project area and opened it ecotourism partly. However, no supportive activity has been implemented in the area. During the field work, many tourist groups who came to the island to make an observation during the summertime were encountered. So, it will be useful to build 'Birdwatching Terraces' in the appropriate places on the west and east exit of the tunnel across the island in order to attract attention and facilitate birdwatching. Hoynat Island should be closed to national and international tourism activities during breeding seasons.

Construction work should not be conducted between February - June which are the breeding months of the birds, and rocks on the tunnel and near the tunnel should not be damaged during the work.

(Received 22nd May 2018; accepted 5th Jul 2018)

Abstract. Orf virus occurs where sheep and goats are raised, and it also infects a broad range of wild artiodactyls. The rates of morbidity and mortality are higher, particularly in lambs and kids experiencing the disease for the first time. Orf virus has been reported in domestic animals and humans in Turkey, so far. In this study, findings on the presence of Orf virus on wild goats were researched for the first time. Field studies were carried out between 2016 and 2017 years. Direct observation methods were used in field studies. In this study, a dead six months of age male wild goat (*Capra aegagrus*) and 3 diseased individuals in poor condition with bloody lesions covering the muzzle area were examined in Sarıçiçek Mountain in Eastern Black Sea Region, Turkey. The gross and microscopic lesions confirmed the diagnosis of contagious ecthyma (CE). This is the first documented report of CE in wild goat from Turkey.
Keywords: *contagious ecthyma, bezoar goat, skin lesions, disease, Turkey*

Introduction

Contagious ecthyma is a parapox virus which affects domestic sheep and goats around the world (Samuel et al., 1975; Yirrell et al., 1989; Wilson and McFarlane, 2012; Peralta et al., 2018; Tedla et al., 2018). It is characterized to have a benign nature, and it can cause a large tumor like vascularized lesions which can be treated using antiviral drugs or removed surgically. It is transmitted through direct contact with infected animals and environmental contamination (Tedla et al., 2018). CE is also a zoonosis of global distribution that affects humans, particularly animal workers, like slaughtermen, veterinarians, farmers, and animal caretakers, after direct or indirect contact with infected animals (Peralta et al., 2018). It has a linear double-stranded DNA genome, of ~135 kbp in size and exhibits an unusually high GC content (~64%). The central region of the genome contains 88 genes which are present in the subfamily *Chordopoxvirinae* and mostly occur in a common order and orientation. The terminal regions of the genome are variable and there are genes associated with virulence, pathogenesis, tropism, and/or immune response modulators (Fleming and Mercer, 2007; Lateef et al., 2010; Peralta et al., 2018). Clinical CE is generally named as contagious pustular dermatitis, orf, soremouth, or scabby mouth. The illness leads to pustules followed by scabbing on the muzzle, face, and lips of ruminants (Wilson and McFarlane, 2012; Tedla et al., 2018). Mortality and morbidity is changeable (Housawi et al., 1992; Elzein and Hausawi, 1997; Haig and Mercer, 1998; Nandi et al., 2011; McInnes, 2014). The reason of CE is Orf virus which is type species of the genus *Parapoxvirus* (Webster, 1958; Delhon et al., 2004; Mercer et al., 2006; McGuire et al., 2012; Li et al., 2012). The virus in dried scabs survived from 8 months to more than a

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45154521

year at room temperature (Manley, 1934; Newsom and Cross, 1934). Crusts exposed to external conditions lost their infectivity quickly during summer, but infectivity persisted for at least 6 months during winter (Boughton and Hardy, 1935). The disease may be caused by direct or indirect contact with the infected animals especially with dried crusts fallen on the pastures during grazing (Harriss, 1948; Kummeneje and Krogsrud, 1979). The disease was also transmitted from wild to domestic goats when infected herds had prolonged contact with salt blocks in the mutual habitat. The disease from infected sheep and goats has been transmitted to other species of animals by feeding them raw sheep carcasses (Wilkinson et al., 1970). Contagious pustular dermatitis of sheep and goats was reported initially by Zellor in 1920 from South West Africa. Since then, it has been reported from almost all parts of world involving not only sheep and goats but cattle, dogs, camel and both free living wild and captive animals also. Lesions can also form inside the mouth, on the coronary band above the hooves, on the udder, or on the genitalia. The incubation period from exposure to the virus until development of clinical signs is 1 to 2 weeks (Merck Veterinary Manual, 2016). CE is not usually lethal, and lesions typically disappear within 2 to 4 weeks, but death may occur if secondary complications, such as bacterial infections or myiasis, develop. Additionally, lesions can be quite painful and hinder feeding in adults or nursing in lambs and kids, leading to emaciation and death, depending on the severity of the infection (Davis et al., 1970). CE is infectious to humans and is considered an occupational hazard for shepherds, with lesions typically found on the hands as a result of direct contact with animal lesions (Uzel et al., 2005; CDCP, 2006). However, not all CE cases in humans are confined to those in contact with sheep or goats (Ballanger, 2006). CE viruses spread from one region to other region which has been occurred by free movements of animals (Mayenga, 2015). The diagnosis of CPD is mainly based on benign nature of the disease and characteristic skin lesions (Rodrignez et al., 1983; Coates and Hoff, 1990). Vaccination coupled with biosecurity measures is an effective method in the prevention and control of CE. Suspected CE can be diagnosed based on the characteristic clinical signs, followed by laboratory tests such as electron microscopy, serum neutralization tests (SNT), histopathology of affected tissues and nucleic acid assay like polymerase chain reaction (PCR) (Nandi et al., 2011; Adeleji et al., 2018).

Materials and methods

Sarıçiçek Mountain is located within the borders of Şebinkarahisar and Çamoluk districts (40°19’50.18” N 38°29’55.53” E) in Giresun province part of Eastern Black Sea Region (*Fig. 1*). The study area is 21765 ha and between 1000 and 1800 m elevations on average. On majority of lands of Sarıçiçek Mountain, the dominant climate is continental. Winters are long and harsh, and summers short and hot. Annual mean temperature is between -15 and +32 °C. Annual mean precipitation is between 500 and 700 mm. Pine (*Pinus sylvestris*) and oak (*Quercus* sp.) forests and alpine steppes have a wide spread in the study area. The study area is one of the most important habitats of about 1500 wild goat in the Eastern Black Sea Region.

This study started as a result of reporting the Orf virus symptoms in wild goat individual by wildlife officers in Sarıçiçek Mountain, on February, 2016. Field studies were carried out between 2016 and 2017 years. Direct observation methods were used in the field studies. Camera traps, binoculars and spotting scopes were utilized along with direct observation. Camera trapping was applied to the wild goat population

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45154521

density areas during the study period in order to determine diseased wild goats. Also, we investigated the carcasses of wild goats perished due to CE in the study area.

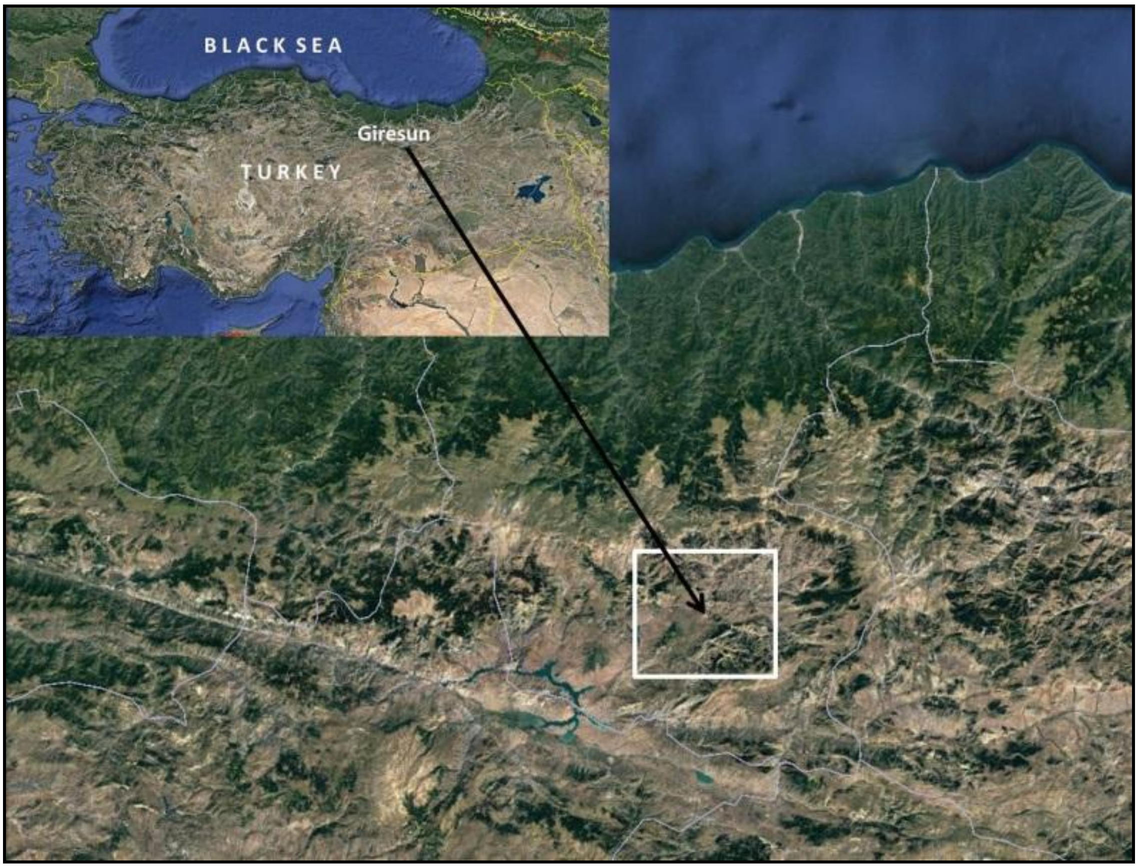

Figure 1. *Location of the study area (GoogleEarth, 2018)*

Results and discussion

As a result of this study, one wild goat individual observed ulcerated papular lesions, including frank red blood on the lips and muzzle with marked swelling and crusting around all edges of the lesions (*Fig. 2*). Histopathological sections were made of the junction between normal skin and the lesions on the lips and muzzle. The remainders of the carcasses were removed from the research area and were buried.

At the end of the study, 442 camera-trap photos belonging to wild goats were obtained and on two wild goat individuals were observed with ulcerated papular lesions, including frank red blood on the lips and muzzle with marked swelling and crusting around all edges of the lesions. Also a dead wild goat was found. This carcass were removed from the research area and were buried (Fig. 2).

Skin lesions of the dead lambs were determined as characteristic CE lesions (poor body condition with bloody lesions covering the muzzle area and warts in the mouth periphery) in our observations. Typical CE viral particles were seen by electron microscopy. Sections of haired skin from the sample had diffuse acanthosis and hyperkeratosis, with numerous intracorneal vesicles and pustules. Moderate numbers of bacterial colonies were observed among superficial keratinized epithelial cells. There was multifocal intracellular edema of keratinocytes of the stratum spinosum. The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45154521

superficial dermis was infiltrated with numerous lymphocytes, plasma cells, neutrophils, and macrophages. The history, gross lesions, and microscopic lesions histopathologically confirmed the diagnosis of CE. The lesions were considered pathognomonic, based on the findings reported literature (Ishii, 1953; Merwin and Brundige, 1982; Housawi et al., 2012).

Figure 2. *Orf virus infection is evident on the muzzle of wild goat in Sarıçiçek Mountain*

It has been reported that lambs may suffer the most from CE infections (Blood, 1971; Samuel et al., 1975; Lance et al., 1981; Merwin and Brundige, 1982; Zarnke et al., 1983) and no signs of CE were reported in previous observations and counts of lambs in Sarıçiçek Mountain. Because this report represents the first documented case of CE about wild goat in Turkey, it is unknown whether the previous low lamb production in this population may have been associated with CE. It is unlikely that the original population was the source of this outbreak of CE, given the short incubation period of 1 to 2 weeks for orf (Merck Veterinary Manual, 2006) and that no diagnoses of CE were made and no clinical signs of orf were reported by wildlife officers or the public for 30 years. It also has been reported that CE may be an important factor for mountain goat

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45154521

known to be infected with high numbers of helminths, bacterial infections, or to be in states of poor nutrition (Samuel et al., 1975).

Conclusion

The studies on CE in Turkey are mainly case reports in the form of single or small groups reported in humans and domestic animals. There is no information about the presence of Orf virus in wild goats due to limited studies about wild animal diseases in Turkey.

The Orf virus is an important contagious disease that can lead to outbreaks and deaths, especially in young and low-immune wild goats. For this reason, detection, isolation, vaccination and separation of wild goats, which are the source of infection, will prevent both new cases and economic losses.

The study area is one of the most important wild goat hunting tourism areas in Turkey. The area is also used extensively by the villagers and shepherds. As the disease is transmitted from infected animals, products or contaminating materials, people who are in contact with these animals or products should be informed about the personal preventive measures. Also, identifying infectious diseases and vaccinations of diseased animals will prevent the spread of the disease.

Acknowledgements. As authors, we would like to thank Giresun, Şebinkarahisar wildlife officers (General Directorate of Nature Conservation and National Parks) for their information and assistance.

(Received 29th May 2018; accepted 11th Jul 2018)

Abstract. The aim of this research is to determinate diversity of mulberries grown in North Anatolia between or within species by ISSR markers. In the study, 38 different mulberry genotypes collected from Tokat region in Turkey were used. ISSR-PCR analyses were carried out on the DNA of genotypes isolated using mini-CTAB extraction method. The levels of polymorphism between genotypes were determined using the UBC-ISSR primers. A total of 96 bands were obtained from 15 UBC ISSR primers. Out of 96 bands, 80 bands were polymorphic. The number of bands obtained per primer ranged between 4 and 11, the average number of bands were determined as 6.4. The average number of polymorphic bands per primer was 5.33. Similarities and differences between genotypes have been studied at the molecular level. The data used for statistical analysis were obtained by the evaluation of ISSR bands. Similarity coefficient and UPGMA dendrogram were built using the Basic Coordinates Analysis. According to the dendrogram, the genotypes have been divided in two main groups, one small and one large group. While the small group was only comprised of black mulberry genotypes, the large group included white mulberry, weeping mulberry and wild white mulberry genotypes. Different mulberry species have been divided into different subgroups within the large group. The polimorfism level within the species was lowest in black mulberry genotypes, and this was followed by weeping mulberry, white mulberry and wild white mulberry genotypes, respectively.
Keywords: *similarity, diversity, dendrogram, North Anatolia, mulberry*

Introduction

Mulberry is a perennial fruit species belonging to the genus *Morus* of the family Moraceae (Datta, 2002; Anonymous, 2006). *Morus*, a genus of flowering plants in the family Moraceae, deciduous trees commonly known as mulberries, grow wild and under cultivation in many temperate world regions. The origin of mulberry is Asia (Awasthi et al., 2004). Over 150 species names have been published, and although differing sources may cite different selections of accepted names, only 10–16 are generally cited as being accepted by the vast majority of botanical authorities. *Morus* classification is even further complicated by widespread hybridisation, wherein the hybrids are fertile. Mulberry trees are either dioecious or monoecious and sometimes will transform from one sex to another. The flowers are held on short, green, pendulous, nondescript catkins that emerge in the axils of the current season's growth and on spurs on older wood. They are wind pollinated and some cultivars will set fruit without any pollination (Anonymous, 2009).

Black, red, and white mulberry are widespread in southern Europe, the Middle East, northern Africa and Indian subcontinent, where the tree and the fruit have names under regional dialects. The most important mulberry species are *Morus alba* (white

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45234530

mulberry), *Morus australis* (Chinese mulberry), *Morus indica* (Indian mulberry), *Morus microphylla* (Texas mulberry), *Morus nigra* (Black mulberry), *Morus rubra* (Red-purple mulberry) and *Morus serrata* (Himalian mulberry) (Tutin, 1996; Vijayan et al., 2004). It is sometimes difficult to distinguish mulberry species morphologically and pomologically from each other, especially the fruits of *Morus nigra, Morus rubra* and *Morus pendula* species, those with black fruits. In fact, cheaper black fruits are sometimes sold in markets instead of *Morus nigra* fruits in high prices (Günes and Cekic, 2004; Erdogan and Pirlak, 2005). Therefore, determining the difference in the species and between species at the molecular level is important in terms of consumers as well as in terms of scientific literature.

The mulberry plants are deciduous and are produced for their fruit and leaves in all parts of Turkey (Anonymous, 2009). The species *M. alba*, *M. nigra* and *M. rubra* are common in Turkey (Ercisli, 2004; Ercisli and Orhan, 2007; Özgen et al., 2009). The main mulberry production areas of Turkey are Black Sea Region and Eastern and Central Anatolian Regions. Turkey has very old mulberry cultivation, and mulberries are one of the main fruits grown by Turkish farmers. The four mulberry species (*Morus alba, Morus nigra, Morus rubra*, *Morus laevigata*) can be seen in different agro-climatic regions in Turkey. There is no registered mulberry cultivar in Turkey but each region has its own local genotypes which are propagated by budding or grafting over many years (Ercisli and Orhan, 2007).

Tokat Province of Turkey, at the mid Black Sea region of Anatolia, has a hot-summer Mediterranean climate with considerable maritime and continental influences. Most parts of province are suitable for mulberry production, and some species of mulberry spread over the province. Although there is no intensive mulberry production by producers, one or two mulberry trees can be seen almost in every orchard, especially near by homes.

The aim of this research is to determinate diversity of mulberries grown in North Anatolia (Tokat Province) between or within species by ISSR markers.

Material and methods

Plant material

For research purposes, a total of 38 different mulberry genotypes from Tokat region in Turkey were used (*Table 1; Fig. 1*). Out of total number 15 belongs to black (*Morus nigra*), 13 to white (*Morus alba*), 5 to pendulous (*Morus pendula*), 2 to everbearing mulberry (*Morus alba*) and 3 to wild mulberry (*Morus alba*).

DNA extraction

Total genomic DNA was extracted according to the CTAB method (Doyle and Doyle, 1987). DNA sample concentration was determined using a fluorometer employing a Hoechst dye (Hoefer Inc., San Francisco, CA, USA), and the DNA

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45234530

samples were diluted to a final concentration of 10 ng/µl with 1 × TE buffer and stored at −20 °C prior to polymerase chain reaction (PCR) amplification.

ISSR amplification

15 primers that produced clear and reproducible fragments were selected out of a hundred UBC primers, which were previously tested for further analyses (*Table 2*). ISSR amplification was performed in a 20 µl volume containing 20 ng genome DNA, 1 × Taq buffer, 2.0 mM $MgCl_2$, 0.2 mM dNTPs, 0.75 µM primer, 0.5 units of Taq DNA polymerase. The amplification reaction consisted of an initial denaturation step at 94 °C for 5 min, followed by 45 cycles of 45 s at 94 °C, annealing at 50–56 °C for 45 s, extension at 72 °C for 90 s, and ended with extension at 72 °C for 7 min. The amplified products were resolved electrophoretically on 2.0% agarose gels run at 100 V in 1.0 × TBE buffer, visualized by staining with ethidium bromide (0.5 µg/ml), and photographed under ultraviolet light (Charters et al., 1996; Rafalski et al., 1996; Cekic et al., 2001) The amplifications were repeated twice and only clear repetitive bands were used in data analysis, and molecular weights were estimated using a 100 bp DNA marker (Vivantis).

Data analysis

The amplified fragments were scored for band presence (1) or absence (0) with all the accessions studied. Similarities and differences between genotypes have been studied at the molecular level. The data used for statistical analysis were obtained by the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45234530

evaluation of ISSR bands. Similarity coefficient and UPGMA dendrogram were built using the Basic Coordinates Analysis (Rolf, 1992).

Results and discussion

On the basis of the number, intensity and reproducibility of ISSR bands 15 primers were selected out of a hundred UBC primers, which were previously tested (Cekic et al., 2001). Bands with the same mobility were treated as identical fragments. Weak bands with negligible intensity and smear bands were both excluded from final analysis. Each primer was evaluated for total band number (TBN), polymorphic band number (PBN) and the ratio of polymorphism (PR= PBN/TBN X 100).

The number of scored bands varied from four to eleven with an average of 6.4 bands per primer and an average of 5.33 polymorphic bands per primer. In total, 80 bands out of 96 derived from 15 primers were polymorphic (*Table 2; Fig. 2*).

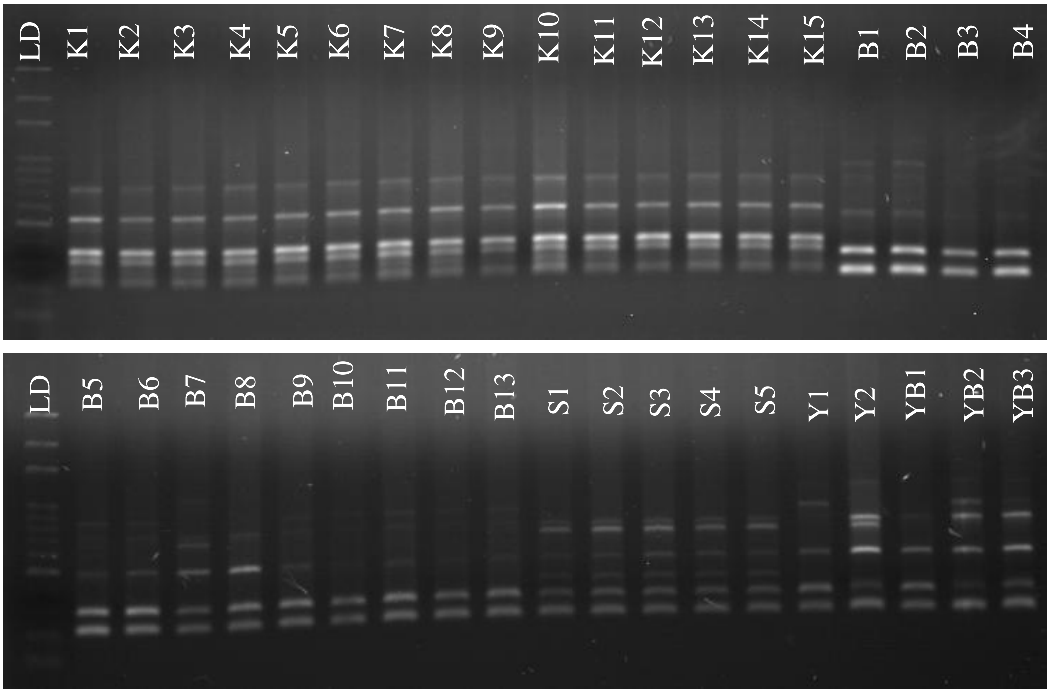

Figure 2. *Agarose gel of polymorphic DNA amplification profiles of different mulberry genotypes (K: Black mulberry, B: White mulberry, S: Pendulous mulberry, Y: Everbearing mulberry (long season harvesting), YB: Wild mulberry) obtained with UBC ISSR primer 811. (LD: 100 bp LADDER -Vivantis)*

Cluster analysis

Genetic similarity among varieties was estimated using dissimilarity coefficient matrix based on ISSR bands scored. Pairwise values of dissimilarity coefficients ranged from 0.27 for genotypes with the same scored bands to 1.00 for the most similar genotypes. The dendrogram was constructed based on the similarity matrix, using UPGMA method (Rohlf, 1992). The 38 mulberry genotypes were divided into two main clusters (*Fig. 3*), in which black mulberry genotypes in one group and the rest of the genotypes falling under the other group. While the first major group contained only

APPLIED ECOLOGY AND ENVIRONMENTAL RESEARCH 16(4):4523-4530.
http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45234530

black mulberries, the second major cluster was further separated into subgroups. The first subgroup contained black mulberry genotypes, respectively which showed very close ISSR profile exhibited the highest genetic similarity ranges (0.95-1.00). On the other hand, the similarity of the second varied 0.75 to 0.96, in which different mulberry species (White mulberry, Pendulous mulberry, Everbearing mulberry, Wild mulberry) separated in different clusters at various stages (*Fig. 2*).

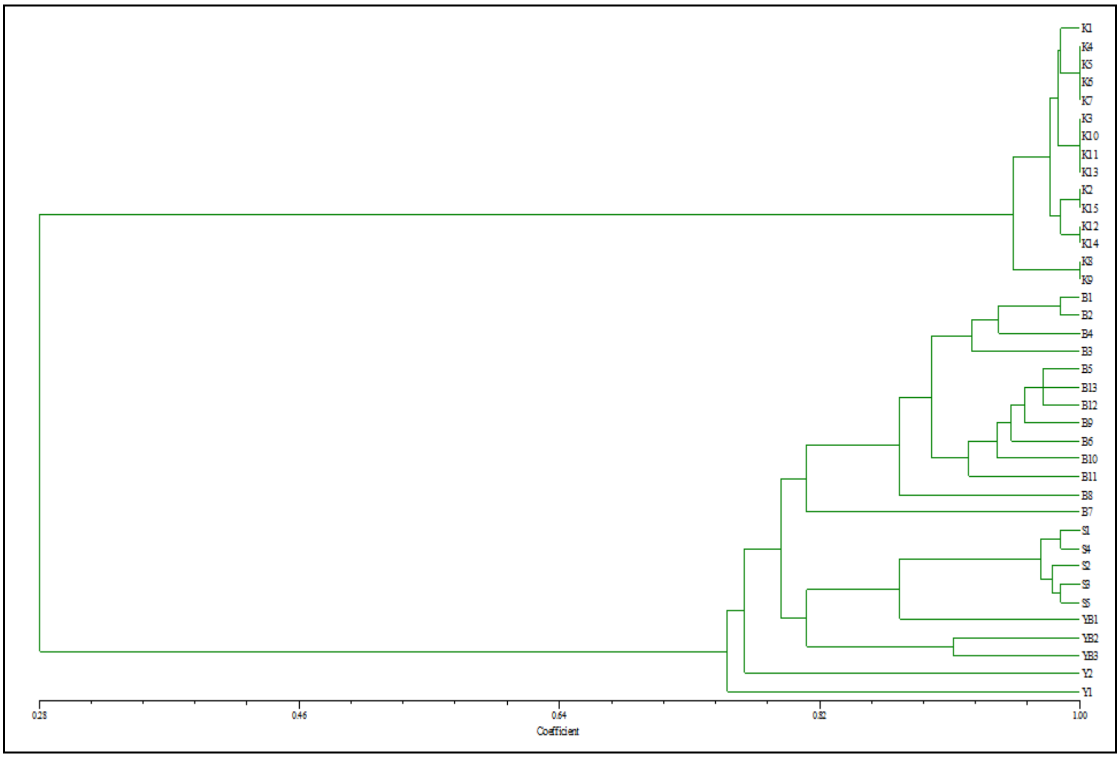

Figure 3. *Dendrogram showing genetic relationships among value of ISSR markers for mulberry genotypes (K: Black mulberry, B: White mulberry, S: Weeping (Pendulous) mulberry, Y: Everbearing mulberry (long season harvesting), YB: Wild mulberry)*

While the small main group in the dendrogram only consists of black mulberry genotypes, the major groups include white mulberry, weeping mulberry, everbearing and wild white mulberry genotypes. However, in the major group, mulberry genotypes belonging to different species constituted their subgroups. The level of polymorphism between black mulberry genotypes was very low. While no polymorphism was observed in the great majority of 15 genotypes of black mulberry genotypes, the lowest similarity level in this species is 94% in dendrogram. The lowest level of similarity within the other species were 96% in the weeping mulberry, 80% in the white and wild white mulberry and 75% in the everbearing mulberry genotypes.

The wild and everbearing white mulberry genotypes were most likely grown from seed. Therefore, these mulberry genotypes showed the least similarities and the greatest polymorphism was obtained from these genotypes. Although 100% similarities were not obtained within the group, polymorphism was low in weeping mulberry genotypes. Significant differences were determined within the group in white mulberry genotypes, and 100% similarities were not observed. The majority of black mulberry genotypes were similar to each other, most of which can be caused by vegetative propagation from

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45234530

a single source by grafting, cutting or dipping. As a matter of fact, previous studies indicate that seeds of black mulberry genotypes hardly germinate without any pre-treatment (Güneş and Çekiç, 2004). In addition, this example is true because the sample area is narrow and there is only one or two black mulberry trees in producer gardens. The results of this study will then shed light on the work to be done for vegetative propagation in this area. Also, the principle component analysis generally put the genotypes into different clusters as parallel to morphological differences of the mulberry species (*Fig. 4*).

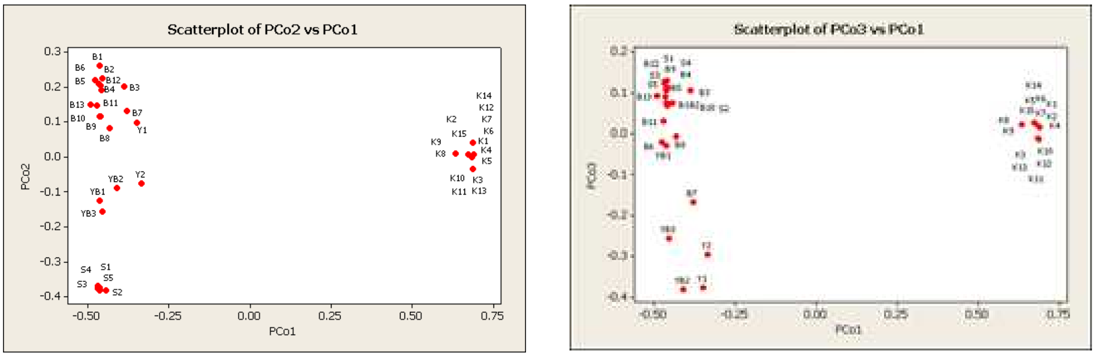

Figure 4. *The principle component analysis of mulberry genotypes according to 15 ISSR primers*

Conclusion

The results of the study mean that molecular tools are more reliable than the phenotypic observations as the well-known fact. Screening of the 38 genotypes of different mulberry species revealed that banding profiles obtained with fifteen ISSR primers were enough to distinguish the diversity between species or within the species. The results indicated that the ISSR technique is effective to develop genotype-specific banding patterns valuable for genotype identification. Since ISSR-PCR technique does not require previous DNA sequence information and uses very small quantity of DNA, it is considered as one of the most widely used techniques for genotype identification and genetic diversity studies. These results mean that molecular tools are more reliable than the phenotypic observations for evaluating variations and monitoring genetic stability.

The wide variation in genetic distance among the different mulberry species revealed by ISSR techniques reflected a high level of polymorphism at the DNA level. The genetic similarity of different mulberry species is low as indicated ISSR analyses. The variability in black mulberry genotypes within the species has been characterized as quite low. We can conclude that the saplings of black mulberry were mostly obtained by budding or cutting from local sources. There are some flows in other mulberry species from outside the province as we can see wide variation within the species.

Abstract. Soil contaminated with phenol poses a serious threat to the groundwater and soil organisms. In this paper, column transport experiments were used to investigate the retention and the mobility of phenol in three types of natural soils from northern Algeria. The effect of methanol, as an organic solvent, on migration of phenol through soil columns was also investigated. Transport parameters such as the retardation factor and the partition coefficient were calculated using "Laboratory Flow-Through". The use of "Laboratory Flow-Through" method showed that phenol was more retained in Corso: a soil with higher organic matter content (7.22%) than Chorfa and Maâtkas (2.72 and 1.87%, respectively) and the retention increased with soil depth. The retardation of the transport of phenol was reduced in the presence of methanol which increased remarkably the mobility of phenol and its retention was much reduced especially at a depth of 5 cm by 25.55% in Corso, 19.05% in Chorfa and 9.18% in Maâtkas.

Introduction

Phenolic compounds are persistent organic pollutants which have been widely used in chemical plants, metallurgical plants and petroleum refineries (Comninellis and Pulgarin,1991; Li et al., 2005; Zhang et al., 2011), with a great variety of functions, in the production of many and different products: plastics, explosives, medicines, paints, detergents, pesticides, anti-oxidants, among others; in fact, phenol is considered among the most serious environmental contaminant which can affect air, groundwater, surface water and soil. It is very harmful even at low concentrations (Din et al., 2009; Pal et al., 2011), since it is toxic, carcinogenic, teratogenic and mutagenic to humans (Zhang et al., 2011).

Phenol is a colourless to light pink crystalline solid liquefies upon contact with water. It is moderately volatile at room temperature and has an acrid odour (Earl et al., 2003). Generally phenol is soluble in most organic solvents and it has a high solubility within water (from 67 g L^{-1} at 16 °C to 84 g L^{-1} at 20 °C) (Earl et al., 2003). Phenol in the aqueous phase is subject to chemical oxidation and adsorption (Sivasubramanian et al., 2012) and it is readily biodegraded under aerobic conditions in all environmental media, including soil and sediment; however, phenol degradation is slower under anaerobic conditions than under aerobic conditions and acclimation times are longer (Earl et al., 2003). A review of biodegradation studies in groundwater indicates that phenol is degraded under methanogenic, sulphate-reducing, iron-reducing and nitrate reducing conditions, with a half-life range of 22 to 533 days (Earl et al., 2003). As a result and based on its low adsorptivity to soil, phenol trickles down through different strata and migrates along with groundwater flow due to tortuosity and favourable

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45314540

hydraulic conductivity of soil (Pal et al., 2014); however, information on levels of phenol in soil is limited (Earl et al., 2003).

Natural soil means soil from the ground (without further modification in the composition), which is distinguished from commercial potting soil. It is composed of mineral component and organic material or humus. Scientists usually test disturbed natural soil samples for soil texture and type and contaminant analysis, among other evaluations; it is easier to collect.

Phenol migration through natural soil has already been experimentally studied by researchers using laboratory batch adsorption test and vertical soil column tests. Smith et al. (1999) showed that phenol was relatively mobile in loamy sand and organic carbon content was found to be the most important soil component controlling retention potential of soils followed by clay mineral content (Khan and Anjaneyulu, 2005; Pal et al., 2014). Different studies showed that addition of other compounds may have an effect on phenol mobility. It is anticipated that the addition of Heavy metals may substantially alter pollutants mobility (Smith et al., 1999); however, compounds such as organic solvents, which were widely used to extract organic contaminants from contaminated soils (Osman and Saim, 2013), may have the opposite effect by increasing the mobility of phenol in soil. Nevertheless, experimental studies of the effect of methanol on the phenol vertical migration through soil media are lacking.

This paper aims to study retention and migration of phenol in three types of natural soils from northern Algeria. For this study, column experiments were used. “Laboratory Flow-Through” (LFT) method (United States, 1999) was used to determine the important parameters governing phenol migration. The effect on phenol mobility of the use of methanol, as an organic solvent, was also established.

Materials and methods

Sampling and soil characterization

Three types of soil were taken from three different regions of northern Algeria, namely, Chorfa (CH) situated in the province of Bouira (SE Algiers), Corso (CO) situated in the province of Boumerdès (E Algiers) and Maâtkas (MA) situated in the province of Tizi Ouzou (E Algiers). These three regions are representative of northern Algeria, as 90% of the population living in northern regions which are most likely to be polluted by phenol used in industrial and agricultural activities especially pesticides. Fifteen (15) soil samples were collected, few hours before the characterization, from multiples spots of each site, by using an Edelman hand auger and then mixed. Only the top 0-20 cm soil layer was sampled. In the laboratory, soil was air dried at ambient temperature, pre-treated by removing any large pieces of debris (e.g. Gravel, plant residues, etc.), gently crushed to break aggregates, homogenized and then screened through a 2 mm stainless steel sieve prior to analysis. These analyzes do not lead to any changes in the composition of the soil sample; therefore, it is still natural. The particle size distribution of soil was measured by laser diffraction (Malvern Mastersizer 2000 instrument). Soil textures were determined according to USDA textural classes (United States, 1993). Organic matter content (OM) was measured by calcination at 550 °C. Organic carbon content (OC) was estimated by dividing the organic matter content by assumed constant conversion factor 1.724; in addition porosity and bulk density (ρ) were also determined.

Chemicals

Phenol, C_6H_6O was obtained in crystal form (99% purity) from Merck Co. (Darmstadt, Germany). Its solubility in water is 76.04 g L^{-1}. Two stock solutions of phenol were prepared by dissolving 70 mg of phenol in 1000 ml of distilled water for the first one and 70 mg of phenol in 1000 ml of a mixture of methanol/distilled water (50:50, v/v) for the second to examine the effect of methanol, as an organic solvent, on transport of phenol. 100 mg of Mercury (II) Chloride ($HgCl_2$) was added to each stock solution as biocide to avoid phenol degradation. As phenol degrades when in contact with air and sunlight, care was taken to keep the stock solutions away from both. $NO3^-$ [KNO3] is used as inorganic non-reactive tracer, prior to each non-conservative phenol transport experiment to test columns performance and to determine retardation factor (R) of phenol within soil columns. Nitrate is widely used as tracer to study solute mobility and transport process (Braun et al., 2015; Zhen et al., 2015). A solution of KNO3 (100 mg L^{-1}) was prepared using distilled water.

Column leaching experiments

Column leaching experiments were carried out in eighteen vertical propylene columns (1.3 cm inner diameter × 6.5 cm length), containing CH-soil for six of them, CO-soil for six others and MA-soil for the last six ones. Nine of these columns were used to study the transport of phenol dissolved in distilled water and the last nine ones were used to study the transport of phenol dissolved in a mixture of methanol/distilled water (50:50, v/v). A 2 mm thick polystyrene filter was inserted in the base of each column. This filter also served as support for the soil at the bottom of the column. Negligible adsorption of phenol onto the column material was observed in phenol tracer test of the empty system. The columns were packed with soil in layers and were shaken to insure uniform mixing between layers. The soil was approximately 1.7, 3.3 and 5 cm thick for each type of soil (*Fig. 1*).

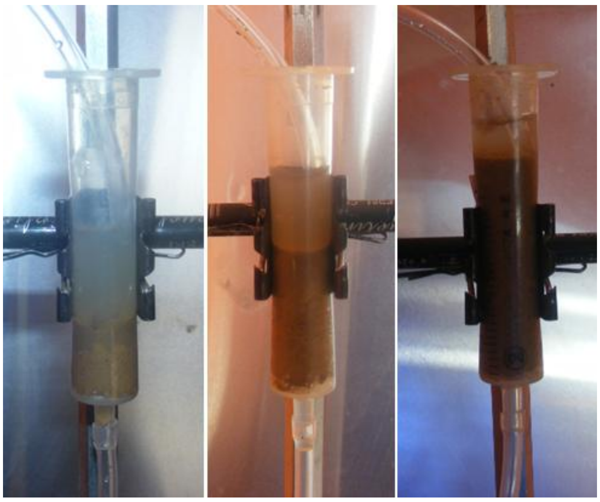

Figure 1. *Soil columns: 1.7 cm thick (left), 3.3 cm thick (middle) and 5 cm thick (right)*

The tracer solution containing $NO3^-$[KNO3] (100 mg L^{-1}) was applied on the top of each first nine soil columns at a constant pressure head under steady state flow conditions, allowing the influents to flow through the soil under positive pressure head

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45314540

(Rodriguez-Liebana et al., 2014). The transport of phenol dissolved in distilled water (70 mg L^{-1}) was performed in the same way as the transport of tracer and in the same soil columns. Transport of phenol dissolved in a mixture of methanol/distilled water (50:50, v/v) (70 mg L^{-1}) was performed in the last nine soil columns in the same way as the transport of the two first solutions to investigate the effect of methanol on phenol transport. Leachate samples were collected and analyzed for $NO3^-$ and phenol concentrations by UV-VIS spectrophotometer at wavelength of 220 nm and 510 nm, respectively. The pore volume (PV) or V_0 of the packed columns was estimated as follows: V_0 = column total porosity× column volume. The breakthrough curves (BTCs) of $NO3^-$ and phenol from the packed columns were generated by plotting the relative concentration (concentration of effluent/ concentration of influent: C/C_0) in the leachate versus the relative pore volume (V/V_0) (*Fig. 2*).

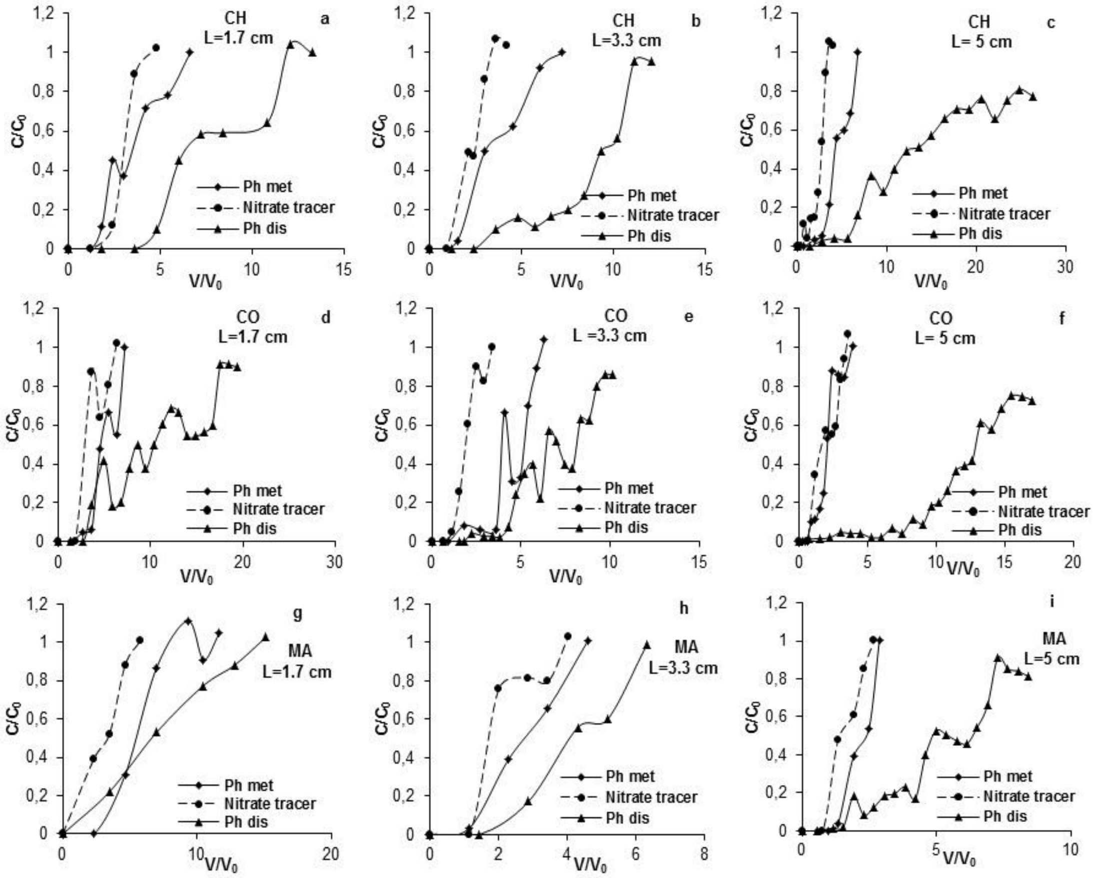

Figure 2. *Measured breakthrough curves of phenol and tracer for various soil columns at different depths: CH at L = 1.7 cm (a); CH at L = 3.3 cm (b); CH at L = 5 cm (c); CO at L = 1.7 cm (d); CO at L = 3.3 cm (e); CO at L = 5 cm (f); MA at L = 1.7 cm (g); MA at L = 3.3 cm (h); MA at L = 5 cm (i). Ph_{dis} and Ph_{met} refer to phenol dissolved in distilled water and phenol dissolved in a mixture of methanol/ distilled water (50:50, v/v), respectively*

Mathematical modelling

The solute transport model, which is considered the dominant mechanism of pollutant transport in porous media, was used in our study. This model is based on the one-dimensional convection-dispersion Richards equation (*Eq. 1*):

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45314540

$$R\frac{\partial C}{\partial t} = D\frac{\partial^2 C}{\partial x^2} - v\frac{\partial C}{\partial x} \quad \text{(Eq.1)}$$

C is the solute concentration in the aqueous phase [ML^{-3}], t is the time [T], D is the hydrodynamic dispersion coefficient [L^2T^{-1}], X is the spatial coordinate [L], and v is the average pore water velocity [$L\ T^{-1}$].

The retardation factor (R) can be defined as (*Eq. 2*):

$$R = 1 + \frac{\rho}{\theta} K_d \quad \text{(Eq.2)}$$

where θ is the volumetric water content [$L^3\ L^{-3}$], ρ is the bulk density of soil [ML^{-3}] and k_d is the partition coefficient [L^3M^{-1}] describing the partitioning of aqueous phase constituents to a solid phase.

For a solute transport without adsorption: $k_d = 0$ then R = 1. R can be calculated from the breakthrough curves using “Laboratory Flow-Through” (LFT) method (*Eq. 3*):

$$R = \frac{V_2}{V_1} \quad \text{(Eq.3)}$$

where V_2 is the volume of the eluted phenol solution when C/C_0 (phenol) = 0.5 and V_1 is the volume of the eluted tracer solution when C/C_0 (tracer) = 0.5 (United States, 1999); therefore, k_d is determined using *Equation 2*.

Results

Soils properties

The measured soils properties are summarized in *Table 1*. Based on texture, CH is loamy sand soil and CO and MA are sandy soils.

Table 1. *Properties of the natural soils (CH, CO and MA) used in study*

Soil	Sand (%)	Silt (%)	Clay (%)	Texture	OM (%)	OC (%)	Porosity (%)	ρ (g cm^{-3})
CH	73.31	24.69	1.98	Loamy sand	1.87	1.08	37.64	0.97
CO	90.49	8.88	0.62	Sand	7.22	4.18	50.21	0.91
MA	91.15	8.84	0.008	Sand	2.72	1.57	39.39	1.03

CH, CO and MA, refer to soils collected from Chorfa, Corso and Maâtkas, respectively; OM, OC and ρ refer to organic matter content, organic carbon content and bulk density, respectively

Transport of phenol in soil columns using “Laboratory Flow-Through Method”

Phenol and tracer breakthrough curves (BTCs) for the soil columns are presented in *Figure 2* and transport parameters calculated using “Laboratory Flow Through” (LFT) method are listed in *Table 2*. The same parameters of columns are considered for the transport of both phenol dissolved in distilled water and phenol dissolved in a mixture of methanol/distilled water (50:50, v/v). The recovery rates of tracer were approach 100% in almost all soil columns, which can be considered ideal (Gibert et al., 2014).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45314540

Transport of phenol dissolved in distilled water

The transport of phenol dissolved in distilled water was retarded in almost all soil columns with late breakthrough curves (BTCs) especially at a depth of 5 cm and in all CO-soil columns (*Fig. 2*). The transport of phenol in the sandy soil MA was the greatest with recovery rates (RR) ranging from 90.97 to 102.77%; however, the recovery rates (RR) of phenol were poor in the sandy soil CO especially at a depth of 5 cm with 75.07% and in the loamy sand soil CH at a depth of 5 cm with 80.80% (*Table 2*).

Transport of phenol dissolved in a mixture of methanol/distilled water (50:50, v/v)

The (BTCs) showed nearly conservative transport behaviour especially at a depth of 5 cm in CO-soil and in MA-soil, where they were slightly delayed relative to the (BTCs) of the tracer (*Fig. 2*).

Table 2. *Retention and transport parameters of phenol in natural soils calculated using column experiments*

Phenol	Soil	Column number	L (cm)	Transport parameters calculated using LFT method		Recovery rate (RR, %)
				k_d (L kg^{-1})	R [-]	
$Phenol_{dis}$	CH	1	1.7	0.38	2	99.90
		2	3.3	1.3	4.42	95.64
		3	5	1.46	4.85	80.80
	CO	4	1.7	1.33	3.43	91.25
		5	3.3	1.25	3.29	85.84
		6	5	3.63	7.62	75.07
	MA	7	1.7	0.37	2	102.77
		8	3.3	0.46	2.23	98.94
		9	5	0.88	3.33	90.97
$Phenol_{met}$	CH	1	1.7	0.08	1.23	99.90
		2	3.3	0.16	1.42	99.92
		3	5	0.21	1.57	99.85
	CO	4	1.7	0.31	1.57	100.01
		5	3.3	0.60	2.11	104.05
		6	5	0.06	1.12	100.62
	MA	7	1.7	0.24	1.66	104.64
		8	3.3	0.24	1.66	100.74
		9	5	0.24	1.66	100.15

Subscripts $_{dis}$ and $_{met}$ refer to phenol dissolved in distilled water and phenol dissolved in a mixture of methanol/distilled water (50:50, v/v), respectively. CH, CO and MA, refer to soils collected from Chorfa, Corso and Maâtkas, respectively. L, k_d, R and LFT refer to soil depth, partition coefficient, retardation factor and 'laboratory flow-through' method, respectively

The recovery rate increased to reach approximately 100% in almost all soil columns (*Table 2*) and the highest reductions in the retention of phenol were observed at a depth of 5 cm and reached 19.05, 25.55 and 9.18% in CH, CO and MA, respectively (*Fig. 3*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45314540

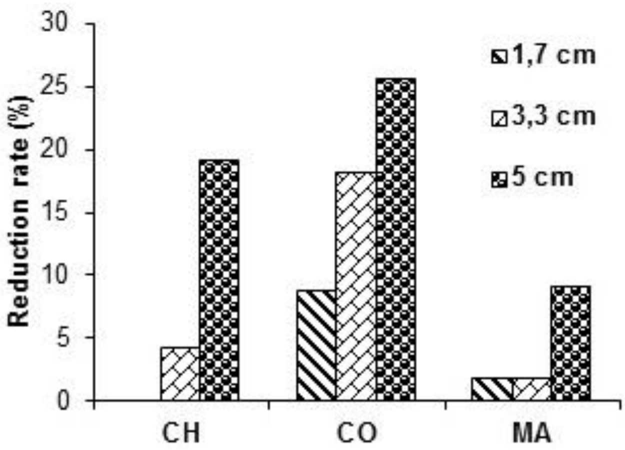

Figure 3. *The reduction rate of the retention of phenol in various soil columns at different depths. Reduction rate is the difference between recovery rate of phenol dissolved in distilled water and recovery rate of phenol dissolved in a mixture of methanol/ distilled water (50:50, v/v)*

Variation of the retardation factor with soil depth

As shown in *Figure 4,* the changes in the retardation factor values (R) measured using (LFT) method were found to be positively correlated with soil depth, for transport of phenol dissolved in distilled water (a), and followed the linear equations $R = 0.857\ L + 0.899$ ($r^2 = 0.847$), $R = 1.283\ L + 0.503$ ($r^2 = 0.740$) and $R = 0.405\ L + 1.168$ ($r^2 = 0.886$) for CH, CO and MA, respectively, which suggested that the retardation of the transport of phenol increased with soil depth.

However, for transport of phenol dissolved in in a mixture of methanol/distilled water (50:50, v/v) (b), there is no significant correlations between retardation factor values (R) and soil depth, except for CH, where the retardation factor value (R) increased with soil depth and followed the linear equation $R = 0.102\ L + 1.063$ ($r^2 = 0.992$). Therefore the retardation of the migration of phenol through CH increased with soil depth.

Discussion

Effect of soil composition on retention and migration of phenol

For transport of phenol dissolved in distilled water, the calculated values of k_d (*Table 2*) denote that retention of phenol was higher in CO-soil (1.33, 1.25 and 3.63 L kg^{-1} at a depth of 1.7, 3.3 and 5 cm, respectively) than in MA-soil (0.37, 0.46 and 0.88 L kg^{-1} at a depth of 1.7, 3.3 and 5 cm, respectively), which were both sandy soils, and it was even higher in CO-soil (1.33, and 3.63 L kg^{-1} at a depth of 1.7 and 5 cm, respectively) than in CH-soil (0.38 and 1.46 L kg^{-1} at a depth of 1.7 and 5 cm, respectively): soil which has the greatest clay content (*Table 1*), except at a depth of 3.3 cm (1.3 L kg^{-1} for CH and 1.25 L kg^{-1} for CO); it is well known that natural clays have good capacity for the adsorption of organic molecules (Djebbar et al., 2012). This fact is supported by high organic matter content (OM) of CO-soil (7.22%) compared to the two other soils (1.87% for CH and 2.72% for MA; *Table 1*); it is well known that, once in soil, organic pollutants bound to organic matter (OM) have reduced mobility due to their low solubility (Valentín et al., 2013). In spite of the high solubility of phenol compared to the other organic pollutants which are less hydrophilic, OM may be of great importance for adsorption of polar organic compounds like phenol (Delle Site, 2001). Based on retardation factor values (R), the soils can be presented in the following orders of retardation of phenol migration: CO> CH > MA at a depth of 5 cm, CH > CO > MA at a depth of 3.3 cm and CO > CH = MA at a depth of 1.7 cm (*Table 2*).

Effect of methanol on retention and migration of phenol in natural soils

The retention of phenol was very low with values of k_d ranging from 0.06 to 0.6 L kg^{-1}, which were much lower than those obtained from transport of phenol dissolved in distilled water. Therefore, the retardation factor values (R) were

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45314540

remarkably lower than those observed from transport of phenol dissolved in distilled water (*Table 2*). It is well known that organic solvents such as methanol are often used to extract phenols from environmental samples (Afghan and Chau, 1989) and types of environmental matrices such as soils (Mahugo Santana et al., 2009); in addition, methanol, as one of the most polar organic solvent, was used by Osman and Saim (2013) to extract phenol, as one of the most polar contaminant, from soil. As a conclusion, our results confirm the opposite effect of methanol on the retention of phenol in our soils. In our case of study, this caracteristic of methonol accelerated phenol vertical migration process through soil.

Conclusion

LFT method based on the one-dimensional convection-dispersion equation (*Eq. 1*) was used to investigate migration and retention of phenol in three types of natural soils. Our results confirm that organic matter can decrease the risk of groundwater contamination (Rodriguez-Liebana et al., 2014). The use of LFT method indicates that phenol was more retained in sandy soil “CO” rich in organic matter than in sandy soil “MA” and in loamy sand soil “CH” both poor in organic matter. The mobility of phenol decreased with increasing soil depth. The effect of methanol, as an organic solvent, on transport of phenol was also investigated. Results indicate that methanol increased remarkably the mobility of phenol through soil columns and decreased its retention. As a negative effect, methanol can increase the risk of groundwater contamination, but it can also be used for cleaning up soils contaminated with phenol, as a positive effect. These results can be generalized and utilized in practice to estimate migration of phenol at large scales in the northern regions of Algeria to predict the gravity of the risk of contamination of groundwater and soil. Further research can be conducted with undisturbed soil samples. In addition, other factors that may influence phenol migration in natural soil, such as pH, should also be considered for future studies.

Abstract. In the years 2007-2009 the differentiation of flora on the area of balks of different length was assessed. The studies of flora were carried out in the area of 7772 ha of Ińsko Lakeland in Poland. For the detailed studies 72 balks were chosen, formed from roadsides and divided into two groups according to the length. Topographic maps in the scale 1:10 000 were used for the assessment of earlier functions of the studied objects. It was shown that in the areas of an arable surface characteristic of average farms as regards their size in the European Union, the size of arable land and the length of balks related with it had an influence on phytodiversity. Despite the fact that the number of phytocoenoses was larger on shorter balks, their specific poverty did not affect biodiversity significantly. The presence of a large number of melliferous species influenced not only phytodiversity of balks, but it also resulted in the improvement of nutritive conditions, among others, for bees. A larger number of plant species on long balks, including also melliferous and therapeutic species, proves correct management of the production space in a long time period.
Keywords: *fields, flora, Ińsko Lakeland, phytocoenoses, bees, melliferous and therapeutic plants*

Introduction

In the middle of the 19th century a change of the production space started leading to its rationalization and intensification (introduction of mineral fertilization, soil reclamation, simplified crop rotation, land integration). These changes resulted in the reduction of species diversity in the cultural landscape (Kędziora et al., 2012; Pe'er et al., 2014; Horta et al., 2015). Cultivation of old species of wheat (einkorn wheat, emmer wheat, spelt, Polish wheat and club wheat), wild rye, bristle oat, millet, buckwheat and multispecies crops: flax, hemp, tobacco and hop was discontinued in favour of monocultures: wheat, maize, rye. There was a change in the density of boundary nature objects such as balks and midfield roads and other forms of environmental islands. The term "environmental islands" was coined in 1967 by McArthur and Wilson. It describes surface objects, such as: groups of trees, water ponds, water-free pits and grasslands. Polish researchers have extended the scope of this definition to cover the linear forms as well: drainage ditches, roadsides and farmbounds (Loster, 1991; Ratyńska, 2002; Karg, 2003, 2005; Symonides, 2010). Balks, i.e. narrow, uncultivated strips of grass

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45414558

vegetation participate, due to their location, in maintaining biological diversity of agricultural landscape, constituting valuable habitats for plants (Štefanová and Šálek, 2014).

In order to maintain biodiversity in monoculture cultivation it is important not to apply chemical plant protective agents on the fringes of the fields. Dobrzański (2009) shows that on large plantations the width of individual fields should not exceed 100 m, and that of balks 1 m, which inclines towards maintaining areas of increased fragmentation. A positive aspect of land consolidation is reduction of the cost of the performed cultivation and limitation of potential neighborhood conflicts. However, land fragmentation makes it possible to lower the risk related to spatial variability of meteorological conditions and natural catastrophes (Penov, 2004; Di Falco et al., 2010). According to Kazlauskaite-Jadzevice et al. (2016), for the purpose of preserving biodiversity, the traditional Lithuanian landscape should be maintained and even further developed, particularly on highly undulating areas (Feiza et al., 2008; Kinderiene and Karcauskiene, 2016).

The quality of soils in the European Union is strongly differentiated, from quite fertile brown soils in the west to weak podsol soils in the central part (Directive, 2004**).** In the countries of the "old" EU, the process of food production is strongly mechanized and is of an intensive character. For example, in Great Britain 95% of agricultural acreage belongs to the farms of the surface exceeding 20 ha. Larger fragmentation is observed in the south of Europe, e.g. in Greece, Portugal and Italy. The differentiation of the surface of plots depends on the size of a farm, the degree to which the field works were mechanized (Noga, 2005). An average size of arable land in the EU changed depending on the number of membership countries (for example the EU -15: 23 ha, and currently the EU - 27: 13.8 ha).

Taking into consideration the diversity of economic and social conditions in the European Union, the arable land in the North-West Poland was taken for the study. In the area set for the study, the most dominant were brown soils with farms of an average size of 21 ha. In the EU agricultural and environmental programs according to package 9 (of the buffer zone), the emphasis was laid on the protection of land against pollution of agricultural origin. Such function is played, among other things, by midfield balks which also results in maintaining biodiversity. Considering these regularities it was assumed that fragmentation of arable land will affect the diversity of balks. In view of the above, the aim of the study was to assess the differentiation of flora in the area of balks of different length. The usability of flora as bee nutrients was also studied and the presence of therapeutic species was determined.

Material and methods

Study object

In the years 2007-2009 the studies of flora were carried out in the area of 7772 ha of Ińsko Lakeland in Poland. This mesoregion is characterised by a diversified terrain relief with moraine hills of steep slopes and of considerable relative heights. Wet dells occur there as well as numerous lakes and rivers. This mosaic of diversified habitats is additionally enriched by an irregular course of boundaries between fields and forests (Borzyszkowski et al., 2016). The arable land in the studied area constituted above 60% of the surface and is dominated mainly by soils of complex 4 and 5, i.e. by very good and good rye soils, determined as leached brown and acid ones. In the structure of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45414558

surface layer of soils, light loamy and heavy loamy sand prevailed (Gamrat, 2012). An average surface of arable land in this area amounted to 21 ha, which reflects approximate conditions in the European Union.

Analysis of flora

For the detailed studies 72 balks were chosen, formed from roadsides and divided into two groups (36 objects in each group) according to the length: I - up to 500 m, II - >500 m (*Fig. 1*). The width of the balks varied from 50 to 70 cm. Topographic maps in the scale 1:10 000 were used for the assessment of earlier functions of the studied objects.

According to the description prepared by Dzwonko (2007), 72 phytosociological releves were taken and used for the identification of 11 vegetation communities determined in the synthetic table which refers to shorter and longer balks. The surface of releves varied from 10 (0.5 m × 20 m) to 14 m^2 (0.7 m × 20 m). The species composition of the plans was also analysed with reference to their usability as bee nutrients (along with defining their melliferous potential and length of flowering), additionally the occurrence of therapeutic species was also assessed (including ornamental, cosmetic and edible ones).

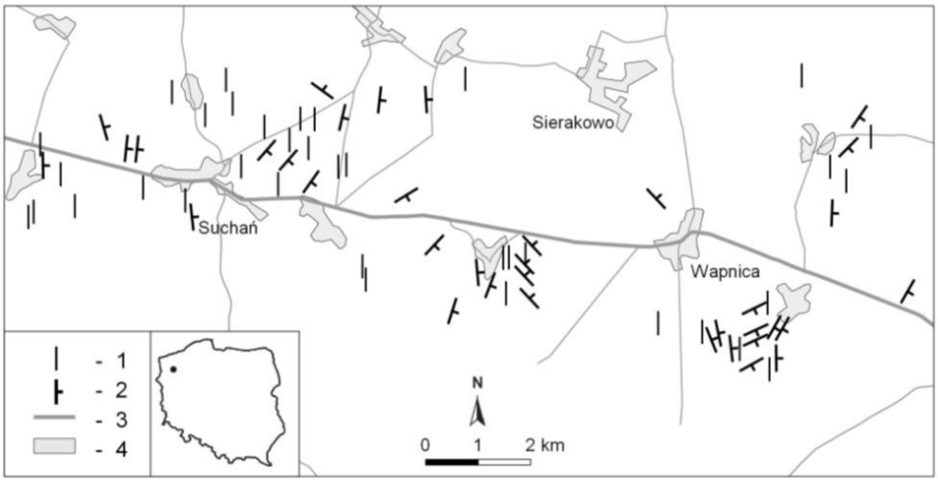

Figure 1. *A schematic map showing studied balks on the Ińsko Lakeland. (1 - short balks, 2 - long balks, 3 - roads, 4 - buildings)*

Analysis of melliferous plants

The species of plants found at the balks were classified according to Lipiński (2010) and Pogorzelec (2018) as a food base for bees, i.e. giving their values of honey yield [kg/ha or kg/tree or bush] and the time of flowering. Floristic observations were made during floristic studies. The frequency of bees on melliferous plants was determined: 3 - frequent, 2 - weak, 1 - sporadic or presence of other pollinators, x - no insects were observed (*Table 3*).

Statistical analysis

The results concerning the number of plant species occurring on the balks were developed on the basis of the univariate analysis of variance. Additionally, such factors

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45414558

as the complex, type of soil and surface layer were tested. The significance of differences was evaluated using the Tuckey's test at the significance level α = 0.05. For the isolated groups of balks the linear relationship was determined between the number of all the species of plants and the number of plant species according to their sociological belonging. All statistical analyses were performed with Statistica 12 PL software (Statsoft).

Results

In the studied area 102 species of plants were observed, of which balks from group II (of the length of the object amounting to 916 m) were characterised by higher phytodiversity (89 species). Shorter balks showed a 1.5 times decreased number of plant species (59).

Out of the species isolated according to their sociological belonging, ruderal species dominated (53 species). There was a smaller number of meadow species (39 species). *Triticum aestivum* L. was shown as an agricultural species. Trees and shrubs occurred rarely, there were individual specimens*: Alnus glutinosa* Gaertn., *Betula pendula* Roth., *Crataegus monogyna* Jacq., *Prunus domestica* L., *P. padus* L., *Rubus caesius* L., *R. idaeus* L., *Salix alba* L., except for *Sambucus nigra* L. which formed a vegetation patch in the area of one object.

Large diversity of the number of species at 72 isolated research objects resulted in the observation of statistically significant differences between the average number of species on the balks of group I (8) and group II (11). Such diversity was not recorded as regards agricultural and ruderal trees and shrubs. In the case of meadow species - their larger number occurred on the long balks (*Fig. 2*).

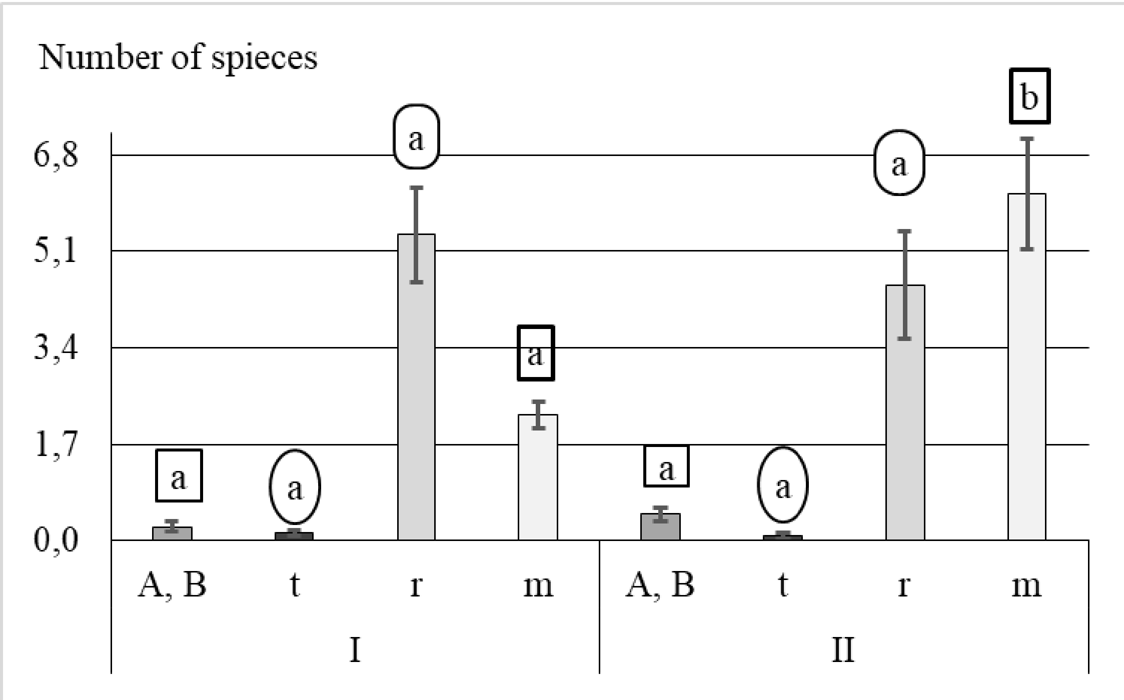

***Figure 2.** The number of plants on the balks. (I - group of balks (short), II - group of balks (long), A, B - trees, shrubs, t - tillage species, r - ruderal, m - meadow)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45414558

Arable land of good agricultural quality constitutes about 2/3 of the studied area. However, considerable diversity of the terrain both in the period when PGRs (State Agricultural Farms) functioned to the year 1989 and at present were not conducive to a large consolidation of arable land. This fact had an influence on the diversity of this landscape.

The largest number of ruderal species according to sociological groups (*Table 1*) was characteristic of the very weak rye-lupine complex (complex 7).

Table 1. *The mean number of plant species according to their nationality sociological*

Group	Soil complexes				Soil type		Mechanical composition of the soil	
	2	4	5	7	lb	ab	lls	lss
G	11.0[a]	8.2[a]	9.8[a]	21.0[a]	9.0[a]	11.0[a]	11.0[a]	8.0[a]
A, B	0.3[a]	0.3[a]	0.5[a]	1.0[a]	0.3[a]	0.6[a]	0.5[a]	0.2[a]
t	0.1[a]	0.1[a]	0.2[a]	0.0[a]	0.1[a]	0.3[b]	0.1[a]	0.1[a]
r	4.8[a]	5.0[a]	4.2[a]	15.5[b]	4.7[a]	5.7[a]	5.0[a]	5.0[a]
m	5.8[a]	2.9[a]	5.0[a]	4.5[a]	4.1[a]	4.4[a]	5.2[a]	3.0[b]

Group: G - General, A, B - trees, shrubs, t - tillage species, r - ruderal, m – meadow
Soil type: lb - leached brown soil, ab - acid brown soil
Mechanical composition of the soil: lls - light loamy sand, lss - loamy sand strong

In the studied area leached brown soils dominated (74%) in the surface layer with light loamy sands (54%). The diversity of the type of soils and their mechanical composition in the surface layer did not influence the number of species: trees and shrubs and green species from ruderal habitats. The type of soil influenced the number of agricultural species and the mechanical composition of soils had an influence on the number of meadow habitats.

In both groups of balks a statistically significant correlation was observed between the general number of plant species and the number of those from ruderal habitats (*Figs. 3* and *4*). A stronger relation occurred for the area of balks from group I (0.96) than from II (0.70).

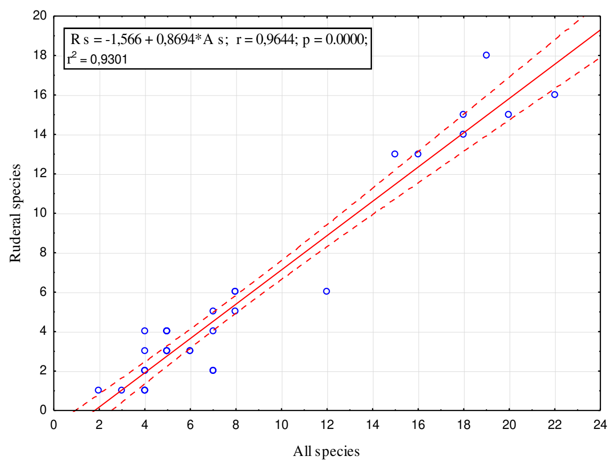

Figure 3. *Relationship between number of all species and ruderal species (balks I)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45414558

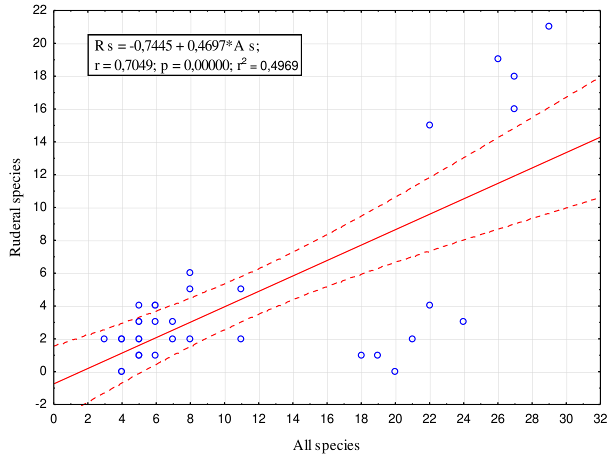

Figure 4. *Relationship between number of all species and ruderal species (balks II)*

In the case of longer balks (group II) additionally a significant linear dependence was observed between the number of plant species and the number of those from meadow (*Fig. 5*). In regression, the r^2 coefficient of determination is a statistical measure of how well the regression line approximates the real data points. It should be noted that in the case of longer baulks only slightly below 50% was explained by the positive correlation between the number of all species and ruderal species or between the number of all species and meadow species (coefficient of determination was from 50 to 46%).

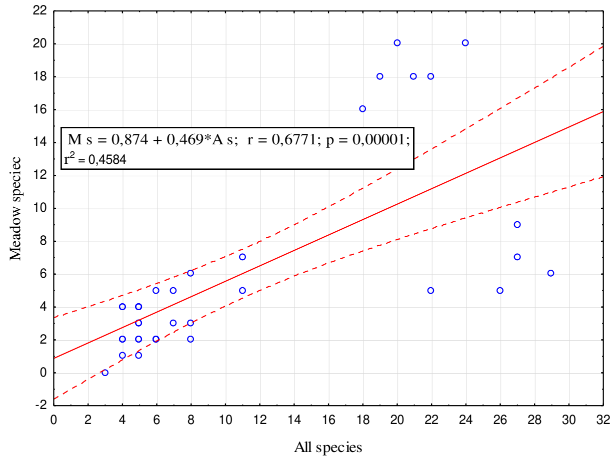

Figure 5. *Relationship between number of all species and meadow species (balks II)*

In the area of all the objects analysed from the phytosociological angle, 11 communities were found, including 10 in the area of shorter balks.

Out of phytocoenoses (marked with a grey colour) the most frequent were phytocoenoses of the grasses: community *Lolium perenne* (25 objects) and association *Agropyretum repentis* (18 objects). Other gramineous phytocoenoses were not so numerous: community with *Dactylis glomerata* (7 objects), with *Apera spicae-venti* (6 objects) and with *Agrostis capillaris* and *Arrhenatheretum elatioris* (4 objects – *Table 2*).

Cl. - class, O. - order; constancy, Ch. - characteristic species, I-V - order number, S: I - proportional participation of species < 20%, II - 40-20%, III - 60-40%, IV - 80-60%, V - 100-80%; D - the coefficients of cover (from 1 to 8 750) were estimated for 36 phytosociological releve's; . not present

The indicated species belonged to 10 phytosociological classes, 2 subclasses, 17 orders. The most numerous were the species of meadow and ruderal habitats (respectively *Molinio-Arrhenatheretea* class - 33 and *Artemisietea vulgaris* - 25 species) and segetal ones (*Stellarietea mediae* class - 16 species). The species of ruderal habitats that formed numerous patches were, among others: *Artemisia vulgaris* L. (D-3056), *Urtica dioica* L. (D-1944), *Picris hieracioides* L., *Verbascum thapsus* L., *Fallopia dumetorum* (D-1750), *Galeopsis pubescens* Willd., *Rumex obtusifolius* L. (D-1507). As to the meadow species, the following were presenrt in large numbers: *Dactylis glomerata* L. (D-2604), *Lolium perenne* L. (D-3244, 2701), *Arrhenatherum elatius* (L.) P. Beauv. ex J. & C. Presl (D-1000, 1944), *Achillea millefolium* L. (D-1611). At present, numerous species from segetal habitats were, among others: *Lactuca serriola* L., *Linaria vulgaris* Mill. (D-1507), *Capsella bursa-pastoris* (L.) Medik. (D-1264), *Tripleurospermum inodorum* (L.) Sch. Bip. (D-1076). Less numerous, as far as species are concerned, however often present, were: *Agropyretea intermedio-repentis* class, *Koelerio glaucae-Corynephoretea canescentis* and *Epilobietea angustifolii* in a form of the following species: *Elymus repens* (L.) Gould (D-1903, 3604) and *Convolvulus*

DOI: http://dx.doi.org/10.15666/aeer/1604_45414558

arvensis L. (D-1507). Species belonging to other phytosociological classes (*Festuco-Brometea*, *Rhamno-Prunetea*, *Salicetea purpureae*, *Trifolio-Geranietea sanguinei*) occurred in small numbers (from 1 to 3 species).

Herbal plants were classified according to the way of their use as: food base for bees (67), therapeutic (64 species), ornamental (22 species), cosmetic (15 species), and seasoning herbs (22 species). Despite the domination of grass communities, there were also numerous dicotyledonous species with a melliferous function (*Table 3*).

[3] - frequent, [2] - weak, [1] - sporadic or presence of other pollinators, [x] - no insects were observed, * - values of honey yield *yield* [kg/ha or kg/tree or bush]

This species on the fields are a valuable food base for bees, especially when the cultivated species are no longer flowering, i.e. in spring and late summer. The flora of the balks are numerous species on which bees forage for a long time, for example from March to September or October, and are also characterized by high honey yield values. They are the so-called common “weeds” (grasshopperdead-nettles, shepherd’s purse and sorrel). In summer, the main species begin to flower, including those that bloom from June to October (including: *Erigeron canadensis* (L.) Cronquist, *Galeopsis pubescens* Willd., *Hieracium umbellatum* L., *Malva sylvestris* L., *Fallopia convolvulus* (L.) Á. Löve, *Urtica dioica* L.). High value of honey yield of autumnal melliferous plants is a caloric food just before the wintering of bees. The diversity of plant species on the balks, through a different flower structure, can provide a food base for numerous (other than bees) pollinating insects, for which balks are not only a place of feeding but also nesting. The plants weakly covered by honeybees, and many other pollinators are, among others: *Fallopia dumetorum* (L.) Holub, *Lathyrus pratensis* L., *Matricaria discoidea* DC., *Papaver rhoeas* L., *Silene latifolia* Poir.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45414558

Many of therapeutic species show an influence on at least three systems of the human body (for example: digestive system, respiratory system, excretory system, immune system, nervous system and also on dermal layers of the skin). Among others, these are: *Artemisia absinthium* L., *Ballota nigra* L., *Berteroa incana* (L.) DC.), *Centaurea cyanus* L., *C. scabiosa* L., *Chamomilla recutita* (L.) Rauschert, *Ch. suaveolens* (Pursh) Rydb., *Chenopodium album* L., *Cichorium intybus* L., *Cirsium arvense* (L.) Scop., *C. oleraceum* (L.) Scop. and *Equisetum arvense* L. Out of cosmetic species there were, among others: *Aegopodium podagraria* L., *Erigeron canadensis* (L.) Cronquist, *Papaver rhoeas* L., *Potentilla anserina* L., *Urtica dioica* L. Seasoning herb species are, among others: *Achillea millefolium* L., *Artemisia absinthium* L., *A. vulgaris* L., *Capsella bursa-pastoris* (L.) Medik., *Chamomilla recutita* (L.) Rauschert, *Cirsium oleraceum* (L.) Scop., *Crataegus monogyna* Jacq., *Elymus repens* L., *Heracleum sphondylium* L., *Lactuca serriola* L., *Pastinaca sativa* L. Decorative herb species are, among others: *Lysimachia nummularia* L., *Malva sylvestris* L., *Plantago lanceolata* L., *Oenothera biennis* L. and *Solidago canadensis* L.

On the terrain of balks it was shown that 31% of the species belong to the group of very burdensome weeds. These species are resistant to breaking (e.g. they possess long rhizomes or a strong taproot system) and they spread quickly, which is connected with the number of yielded seeds. These are, among others: *Achillea millefolium* L., *Aegopodium podagraria* L., *Anagalis arvensis* L., *Apera spica-venti* (L.) P. Beauv, *Capsella bursa-pastoris* (L.) Medik., *Centaurea cyanus* L., *Chenopodium album* L., *Consolida regalis* S. F. Gray, *Equisetum arvense* L. The presence of dicotyledonous plants, strongly rooted, i.e. 32 species of weeds and 12 species of grasses (such as, for example: *Cynosurus cristatus* L., *Dactylis glomerata* L., *Deschampsia cespitosa* (L.) P. B., *Elymus repens* (L.) Gould, *Lolium perenne* L., *Phleum pratense* L.) conducive to strong sodding of subsoil, was related to the earlier use of the balk as a field track.

Discussion

Diversity of the species occurring in the agricultural landscape is caused by the presence of constructive elements such as areas used agriculturally, grassland and unused areas, to which belong drainage ditches, water canals, hedges and balks, but also biotopes of a high degree of naturalness such as fragments of forest ecosystems or afforestation. In the space-time system of the agricultural landscape it is important that there occur anthropogenic species strongly related with a given form of the object or with historical kind of the use of land (Harrach and Sauer, 2002). The studied area of the Lake District is characterized by a varied landscape structure composed between numerous hills (> 150 m above sea level). Fields are separated by narrow areas of forest ecosystems, large and small lakes with a long shape (Wapnica Lake, Wapnica Południowa, Sierakowskie, At Poplar, Sicko) and water ponds. The richness of so many natural elements of the landscape is conducive to the presence of various forms of environmental islands, and the diversity of sculpture facilitates the existence of numerous midfield balks. Aavik and Lira (2010) determined the main factors of plant species richness and composition in field boundaries. They surveyed the vegetation of field boundaries in organic and non-organic farms, and recorded the field boundary type and width. It was found that field boundary type and landscape structure described most of the variation in species composition of these boundaries, while organic farming had little effect. Boundary type had a specific impact on species diversity ditches enhanced

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45414558

the richness of nature-value species and suppressed agrotolerants; woody boundaries hosted only a few agrotolerant species and road verges increased the species richness of both species groups. The richness of nature-value species benefited from wider open boundaries, while narrow boundaries hosted more agrotolerant species.

A large number of fragmented plots significantly influences farmers' unwillingness to implement new technologies and innovations which could improve efficiency of agricultural production. The owners of larger rural areas consent to technological novelties and modern solution much more willingly than the owners of smaller and fragmented plots. However, in Bulgaria, the case of land fragmentation caused abandonment of the use of irrigation systems, which turned out to be unprofitable in such small areas (Penov, 2004). In the 1950s and 1960s, water conditions were regulated in the studied area, with numerous ditches and drainage channels present. The nearest surroundings of the ditches are grasslands, usually of a long shape, separating the individual areas of the fields. The undulating terrain of the research (close distance between the contours within 50-70 m) and the extensive network of drainage ditches, despite the use of intensive mechanical and chemical treatments, enabled the presence of numerous balks. Fragmentation of arable land is more and more frequently regarded as the main cause of difficulties with undertaking agricultural activity, particularly in well developed countries. Therefore, the best economic effect was achieved due to specialization and intensification of plant production. Despite many negative effects of land fragmentation, some positive features can be found in this situation in the agricultural space. It is obvious that fragmentation of the plots increases the costs of production, but lowers its risk (Dudzińska, 2012). The studied area in its north-eastern part adjoins the natural area of Ostoja Ińska (PLB 320008), and in the southern part, on a considerable length it borders with another natural area - the Ina Valley near Recz (PLH320004). Such a neighborhood between two such valuable protected areas, i.e. an area of special protection of birds and of significance for the community, makes it a cover area. Its proper functioning in the landscape is a buffer for negative external factors. At large fragmentation and dispersion of arable fields it is possible to avoid negative effects of weather anomalies such as droughts, floods, fires, hailstorms and other unexpected spatial factors (pest infestation).

As a result of large-area economy and, in considerable areas, monoculture economy significant floristic impoverishment of arable land took place, both in a direct way (field areas - segetal plants) and in an indirect way (areas of marginal habitats - seminatural way), both in a thought over way (application of agrotechnical treatments) and in a thoughtless way (devastating activities accepted). At present, the agricultural landscape undergoes treatment aiming at restoring the previous - natural gene pool (Bauer and Wing, 2010; Paudel et al., 2015). Increased biodiversity is favored by the proximity of other forms of environmental islands. 83% of the studied area was connected to field roads. A few balks neighbored with another object (for example small ponds, grasslands or excavations) or they were located nearby (up to 20-30 m).

Intensification of agricultural production leads to a threat to the habitat and biological diversity. Up to the 1990s, farmers' efforts were directed towards the elimination of weeds (Horta et al., 2015). This study also confirmed Skrajnej on the Kałuszyńska Upland (2010). Through "rapaciousness" of seeds, seedlings and cuttings, as well as increased survival of seedlings in the periods of environmental stress, weeds are treated as nutritive competitors of farm plants. Therefore, some species have been completely eradicated. The share of common and very common species amounted to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45414558

only 8%, although some were characterized by a significant degree of coverage. In the studied area, among the species with a wide range of occurrences the following were recorded: *Equisetum arvense* L., *Elymus repens* (L.) Gould, *Convolvulus arvensis* L., *Capsella bursa-pastoris* (L.) Medik. and *Stellaria media* (L.) Vill.). However, among these cosmopolitan species, only the couch-grass occupied larger areas.

At present, larger and larger significance is attached to diversity. Therefore, the approach to the problem of weed control changes. From the point of view of the amount of crop yields, complete elimination of weeds is not necessary in all conditions. If weed infestation is reduced to the level not threatening farm plants and economic factors are taken into consideration, the effect of diversity protection can be achieved (Gerowitt et al., 2003). In the studied area among the species threatened by extinction to various degrees only one species was observed - *Consolida regalis* S. F. Gray - as sporadic in association with *Agropyretum repentis*, and out of plants constituting the place of living and reproduction of animals, there were, among others: *Chenopodium album* L., *Cirsium arvense* (L.) Scop., *Stellaria media* (L.) Vill., *Galium aparine* L., *Polygonum aviculare* L., *Rumex obtusifolius* L., *Sonchus arvensis* L., *Tripleurospermum inodorum* (L.) Sch. Bip., *Urtica dioica* L. Van Acker (2009) noticed that many plant species can survive in the soil even up to a few years. If weeds did not cause loss to crop yields, they could be treated as “a good and indispensable neighbor” of the cultivated plants. Weed control and creation of the conditions limiting their reproduction and formation of seeds is conducive to farm plants. However, a negative influence of the liquidation of weeds on the functioning of the ecosystem through the disturbance of soil processes and nutritive dependences between plants, microflora and fauna cannot be avoided. However, in the studied area of the balks, the so-called weeds form communites with *Apera spica-venti* and *Chenopodium album*.

Areas classified as wasteland, including midfield balks, are a valuable habitat as a food base for bees. Mačukanović-Jocić and Jarić (2016) in their research on the role of phytocoenoses in maintaining the diversity of melliferous species, showed their greatest share (over 80%) in the *Consolido-Polygonetum avicularis*. In earlier studies Jarić et al. (2013) as phytocoenoses with the highest share of melliferous species they pointed to *Petasitetum hybridi* (70%). Among the species found in the analyzed areas, species constituting the core of the phytocenosis *Consolido-Polygonetum avicularis*, i.e. larkspur and knotgrass, have been demonstrated. However, *Consolida regalis* S. F. Gray appeared as sporadic species, and *Polygonum aviculare* L. occupied slightly larger areas, mainly in contact with the roadside. Among the listed communities, the most melliferous species (64%) were demonstrated in one of the *Lolium perenne* community.

The studies by Denisow and Wrzesień (2007) on the vegetation of balks in the areas of communes near Lublin showed the presence of 214 plant species, 80% of which constituted bee nutrient taxa. The definite majority of melliferous species was connected with meadow, nitrophilous and ruderal communities. Of the species found in the midfield studied balks 67 plants showed melliferous properties. Bee nutrients of high melliferousness and the coefficients of cover (D) were, among others: *Ballota nigra* L. (values of honey yield 368 kg/ha, D-1215), *Melilotus officinalis* (L.) Pallas (200, 1458), *Medicago lupulina* L. (200, 1264), *Salix alba* L. (150, 292), *Trifolium repens* L. (90, 104). Considering the production of pollen, the most valuable melliferous plants commonly found in most communities were: *Taraxacum officinale* F. H. Wiggers coll. and *Cirsium arvense* (L.) Scop., occupying larger areas and already less numerous: *Cichorium intybus* L., *Daucus carota* L., *Medicago lupulina* L., *Rubus caesius* L. In the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45414558

studied area, grass species predominated on the surface, such as: *Apera spica-venti* (L.) P. Beauv, *Arrhenatherum elatius* (L.) P. Beauv. ex. J. & C. Presl, *Dactylis glomerata* L., *Elymus repens* L., *Lolium perenne* L. These species are valuable for bee-keeping due to the heavily occupied areas. This is confirmed by Ceglińska's (2008) study, which has recorded the presence of pollen grains in all honey samples. Among all taxa pollen grains present in one sample, *Poaceae* pollen has reached the highest frequency (70%). The study by Link (2007) of long and narrow belts of balks in the extensively developed fields (each research area amounted to 4.1 ha) in the vicinity of Bronowice, lists 153 plant species, whereas in the intensively managed areas only 59 species. He emphasized the role of balks in the middle of intensively managed agricultural landscapes. The ecological function of these objects is not to be overestimated, even if they constitute 0.8% of the whole surface. In the analysed research area 45% of the observed flora of the balks showed melliferous properties, and these were species characterised by high melliferousness (over 300 kg/ha). Maintenance of a natural habitat or natural habitat elements in a farm is important for behaviour of bees in functionally differentiated communities of agroecosystems (Forrest et al., 2015). This study examined how the quality of a field boundary habitat and farming system (organic or conventional) affect species richness and abundance of diurnal lepidopterans and bumblebees in boreal agricultural landscapes. The results showed positive effects of field boundary area on lepidopteran diversity, as well as positive effects of nectar flower abundance on lepidopterans and bumblebee abundance. The results suggested that a successful conservation strategy for lepidopterans present in boreal agroecosystems depends on proper management of field boundaries, irrespective of farming regime. The results concord with a general hypothesis that the effects of organic farming might be overpowered by the effects of landscape structure in heterogeneous landscapes (Ekroos et al., 2008).

Apart from bee nutrient properties flora of the balks provides raw materials for the production of pharmaceuticals. It was proved that 75% human population benefits from therapeutic properties of herbs. Particularly precious are those gathered in the areas of high sanitary values and which are subject to the protection of biological diversity and such is the area of balks (Abbas et al., 2015). In the studied terrain 63% of plants possessed therapeutic properties affecting at least three human ailments. They were meadows species: yarrow (with carminative, antispasmodic, anti-haemorrhagic, antiallergic properties), hogweed (shows anti-diarrheal properties, regulates digestion, is used in laryngitis and physical exhaustion) or curly dock (astringent, antidiarrheal, antibacterial, anti-anemic, detoxifying effects). Only a few of them are helpful in treating one condition. Therapeutic species that are helpful in treating many diseases predominate.

The results indicated a positive influence of integrated farming on biodiversity of herbal and bird communities in the conditions of agricultural landscape. Especially noteworthy was the positive importance of integrated meadows as the type of farmland with the highest species diversity, due to the interconnectedness of all components of the ecosystem (Štefanová and Šálek, 2014). The flora of the balks of the studied area is structurally diverse also in terms of heights. Thus, it enables convenient conditions for the creation of ecological niches for animals staying temporarily or permanently in the fields. The highest layer, although only in few boughs, is trees. Mainly it was a white willow with the height (on non-topped specimens) of up to 16 m. Single specimens of shrub were found more often for example (up to 5 m in height) - elder. In local

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45414558

depressions of the studied area, herbaceous plants grew up to 1.5 m (mugwort or nettle). The remaining sward was definitely lower, except for inflorescences of some grasses (oat-grass, tufted hair grass) or dicotyledons (common chicory, evening primrose, melilot, mallow).

Halada et al. (2011) identified the habitat types listed in the Habitats Directive Annex I that require low-intensity agricultural management for their existence. They discussed that habitat types for which either doubts remain on their dependence on agricultural management, or the relation to extensive farming practices exists only in part of their area of distribution in Europe or under certain site conditions, respectively. Assessments of the conservation status of habitats of European Importance by 25 EU Member States in 2007 showed that habitats identified in the study as depending on agricultural practices had a worse status than non-agricultural habitats.

Plant communities in the area of balks constitute poor phytocoenoses dominated mainly by grasses (for example *Convolvulo arvensis-Agropyretum repentis*), the participation of which is linked with a high level of fertilization in in the neighbouring fields. In the studied area 14 species of grasses were observed, out of which 6 constituted communities. These were: communities with *Apera spicae-venti* from *Stellarietea mediae* class (crop fields communities), association *Agropyretum repentis* from *Agropyretea intermedio-repentis* class (semi-perilous pioneer communities), association *Arrhenatheretum elatioris* from *Molinio-Arrhenatheretea* class, communities with *Dactylis glomerata*, communities with *Lolium perenne,* communities with *Agrostis capillaris* (semi-natural and anthropogenic turf meadow and pasture communities). Literature data also prove that on edge belts there is a slight number of segetal species from class *Stellarietea mediae* (Denisow and Wrzesień, 2007). However, Gargała and Trąba (2014) conducted studies in the south of Poland (Podkarpacie - Subcarpathia) and showed higher participation of such species (to 50%). In the research area of balks in Ińsko Lakeland (Pojezierze Ińskie) segetal species from class *Stellarietea mediae* constituted 14%. Among them two species: *Apera spica-venti* (L.) P. Beauv and *Chenopodium album* L. dominated in communities.

Balks are treated as linear elements in the strongly changed landscape which particularly refers to the area of arable fields. They are under strong pressure due to their small surface in relation to a very long line of adjacency, which results in poverty of plant species (Ratyńska, 2011). The width of the examined balks in the Ińsko Lakeland ranged from 50 to 70 m. The average length of short/long balks was 246 m and 916 m respectively, at a minimum of 76 m and 522 m respectively, and a maximum of 421 m and 2552 m. No relationship was observed between the increase in the width of the balks and the increase in the number of plants present there. In order to sustain biodiversity and maintain species, propositions difficult to accept can be met, such as undersowing weeds and sowing worse cleaned seeds and leaving some weeds in the field. Such a situation takes place in Western Europe countries of higher intensification of agriculture. In relation to this, the choice of undersown segetal plants becomes significant. An important criterion of the selection of these plants will be high reliability and therapeutic properties. Fast urbanization, habitat destruction, over-grazing and over-harvesting of medicinal plants has resulted in a loss of native species and traditional knowledge among the local communities. Efforts are required to conserve habitat as well as indigenous knowledge of the study area (Abbas et al., 2015).

The clearly significant effect of study by Tuomisto et al. (2012) is somewhat in contrast with the contradictory findings obtained in some areas of Western and Eastern

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45414558

Europe. In Western Europe, such studies could probably have led to ambiguous results because the landscape devastation there had reached a much higher level, and thus regeneration of communities of organisms is a long-term matter and requires synergistic interaction of multiple positive factors. The studied area of the lake district is characterized by average soil quality, strongly undulating terrain and locally diversified humidity conditions, which do not induce farmers to significantly increase the anthropogenic pressure associated with the cultivation of these fields.

Losses of biological diversity which result from the land use can lower their ecological role (Hooper et al., 2012). Bee reactions are not equally negative (Winfree et al., 2009) because the mosaic of seminatural and arable habitats which differ as regards vegetation, soil and water conditions compensates transformations in the economic production space, which illustrates that these habitats are richer as regards biodiversity by 10.5% (Julier and Roulston, 2009). The selection of therapeutic species should take into account their place of origin (the areas under protection) and local soil-weather conditions. Plant undersowing can be regarded as highly beneficial in the case of species particularly threatened by extinction in a given area. For this reason it is possible to sustain the natural state of vegetation and propagation of useful organisms. This is important from the point of view of environmental protection and can be of larger significance if the plants are grown in large areas. Relatively well maintained balks characterised by significant biodiversity in the area of Ińsko Lakeland can constitute a good point of reference to determine a beneficial specific composition on soils representing average soil conditions for cultivation in Europe.

Conclusions

1. It was shown that in the areas of an arable surface characteristic of average farms as regards their size in the European Union, the size of arable land and the length of balks related with it had an influence on phytodiversity. Despite the fact that the number of phytocoenoses was larger on shorter balks, their specific poverty did not affect biodiversity significantly.
2. The presence of a large number of melliferous species influenced not only phytodiversity of balks (102 species), but it resulted in the improvement of nutritive conditions, among others, for bees. Variety of plant structure (trees, shrubs, herbs), considerable flowering length (from March to October) and various flower construction of the so-called field weeds can provide a food base for many pollinators, including honeybees.
3. A larger number of plant species on long balks, including also melliferous (67) and therapeutic species (64), proves correct management of the production space in a long time period.
4. More and more climatic changes are pushing us to undertake further, more detailed studies of the physical factors and flora of the balks that shape the surrounding biodiversity.

Acknowledgements. Authors thanks Marek Pogorzelec for valuable comments in assessing the frequency of bees flying on selected plant species.

(Received 7th Feb 2018; accepted 24th May 2018)

Abstract. The objective of the present study is to investigate the physiological responses of three soil strains of cyanobacteria (collected from areas contaminated with oil in southern Iran and from paddy-fields in north of Iran) to crude oil concentrations in limited salinity (NaCl) and irradiance conditions. Three cyanobacteria species of *Fischerella* sp. ISC107, *Nostoc* sp. ISC101, *Phormidium* sp. ISC108 were assayed. After purification, samples were grown in BG11 and $BG11_0$ media. The results showed that the efficiency of hydrocarbon source utilization of *Phormidium* sp. ISC108 was higher than in other cyanobacteria in crude oil treatment. The highest growth rate was observed at 3% crude oil concentration in *Phormidium* sp. ISC108. Also, the highest levels of allophycocyanin, phycocyanin, phycoerythrin, chlorophyll, carbohydrate, protein and phycobiliprotein were obtained from cyanobacteria *Phormidium* sp. ISC108 had larger phycobilisomes than the other strains (3.99 µg/gdw). The highest ratio of PSII/PSI was observed in *Fischerella* sp. ISC107. The highest levels of photosynthetic indices were assigned to 3% crude oil. In fact, reducing photosynthetic efficiency in higher levels of crude oil could be related to the toxic effect of organic hydrocarbons on algae growth. It can be concluded that the cyanobacteria can be used as a bioremediation for decomposing crude oil especially in the coastal area of the Persian Gulf and the Caspian Sea. The results of this research can be valuable for reducing the contamination which affects the fauna and flora of the marine ecosystems in Iran.
Keywords: *crude oil, cyanobacteria, allophycocyanin, chlorophyll, carbohydrate, phycobiliprotein*

Abbreviations: APC: Allophycocyanin; Chl: Chlorophyll; PE: Phycoerythrin; PC: Phycocyanin; PBP: Phycobiliproteins; PSI, PSII: Photosystem I, II; PBP/Chl: PSII/PSI ratio; Phycobilisome size: PC+PE/APC

Introduction

In tropical and temperate crude oil production sites, cyanobacterial mats often develop on petroleum contaminated zones in surface soils and water environments. Cyanobacterial mats are microbial combinations composed of photosynthetic and non-photosynthetic bacteria and fungi embedded in cyanobacteria mucilage (Shruthi and Rajashekhar, 2014). Factors that influence the uptake, bioconcentration and degradation of many chemical pollutants include extremely limited light, the structure and concentration of the chemical substances, pH, temperature and nutrient availability of the medium, cell size, number and physiological capabilities of microorganisms (Amirlatifi, 2011). Crude oil is a highly toxic mixture of more than 10000 different hydrocarbons. Accidental spills of crude oil in environment cause severe contamination of marine and continental ecosystems. Contamination is an important problem in waters

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45594573

due to spill of processed petroleum derivates especially diesel and fuel (Liu et al., 2009). These pollutants can potentially be degraded by a great variety of soil and aquatic microorganisms. Bacteria, filamentous fungi, yeasts, and cyanobacteria are known to be important hydrocarbon degraders (Prince et al., 2010; Das and Chandran, 2011).

In fact, toxicity and transformation of pollutants may change by cyanobacteria or microalgae depending on the species. The strains of microalgae (*Stichococcus* sp., *Chlorella* sp. and *Scenedesmus quadricauda*) and cyanaobacteria (*Nostoc* sp., and *Phormidium* sp.) are capable to grow without any apparent toxic effect in medium containing 1% black oil and bacterial protectants. The bacteria protect the algae from the toxic effect of the oil, while the cyanobacteria provide the bacteria with oxygen (O_2) and other extracellular carbon-rich exudates (Stal, 1995). For example, El-Sheekh et al. (2013) revealed that the growth of *Scenedesmus obliquus* was increased in the presence of high concentrations of crude oil as compared with *Chlorella vulgaris* and the highest growth of *Scenedesmus obliquus* was obtained at 0.5% crude oil, whereas, in *C. vulgaris*, the highest rate of growth was obtained at 2% crude oil. Some metabolic pathways are inhibited or abolished and some others are enhanced or induced when a change in the environment exceeds a certain threshold level. There are certain reports on the responses of cyanobacteria to oil pollution (Abed et al., 2015; Shruthi and Rajashekhar, 2014; Tamkini et al., 2015) regarding the metabolic versatility of cyanobacteria in different strains. For example, Iranian Stigonema strain Fischerella sp. FS 18, showed the best growth at 0.5% salinity (Soltani et al., 2011) but this may have changed and reached to 1% at different alkalinity (Amirlatifi et al., unpublished data) and Irradiance (Soltani et al., 2007).

Despite of this high potential of microalgae, there is not much attention to the physiological activities of these microorganisms under petroleum contamination. Recent works are changing and some preconceived notions concerning the adaptation of microalgae to extreme environments. As might be expected, physiological acclimatization is enough to achieve adaptation under slightly stressful conditions (Costas et al., 2008). It seems logical to believe that these versatile organisms may have powerful acclimation and adaptation mechanisms to help them stay in extreme habitats, such as oil-polluted soils for a long time. Crude oil rapidly inhibits photosynthesis and growth of microalgae, but little is known about the mechanisms that allow the adaptation of microalgae to extreme environments.

In order to enhance the knowledge on the adaptation of microalgae, including Cyanobacteria to extreme petroleum contamination (Carrera-Martinez et al., 2011), investigating the ecophysiological behaviors of native organisms under field and laboratory conditions is of priority. Southern and northern epidaphic and endaphic cyanobacteria are unexplored. Despite the fact that the southern provinces are oil-rich regions and oil is strategic for Iran, and given that cyanobacteria have been found to have significant potential in the biotechnology of medicine, industry, fisheries presently, little is known about the ecophysiology of the epidaphic and endaphic cyanobacteria of the oil and gas fields in the south and north of Iran (Soltani et al., 2006).

In this way, the demonstration of these organisms could be the reason for future exploitation from various aspects, including physiology and ecophysiology. As it was noted, given that oil and agriculture are of particular importance in the Iranian economy such studies are considered strategic and also the problem of survival and growth under

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45594573

various stress conditions could be useful for applied dimensions considering the necessity of using soil reformers in the future (Soltani et al., 2006).

Combined review of three concentrations of oil; the intensity of limited light can be considered as innovative work in the present study. The microbial stacks and shells should be able to deal with these three factors simultaneously both in flood conditions (rice cultivation) and under the conditions of the underlying layer of oil, and in combination condition. In most studies performed, one or two factors have taken under consideration (Rajendran et al., 2007). However, due to the lack of data for comparison with other indigenous specimens in the country and elsewhere in the world, it is necessary to use reports than detailed scientific analysis (Shokravi et al., 2002).

The objective of present work was to investigate physiological responses of three soil strains of cyanobacteria (collected from areas contaminated with oil in southern Iran and from paddy-fields in north of Iran) to crude oil concentrations in limited salinity and irradiance conditions. The authors hope that, the present work would be an attempt for better understanding of potential native cyanobacteria for both agricultural biotechnological and oil bioremediation projects.

Materials and methods

Isolation of strains

Fischerella sp. ISC107, *Nostoc* SP. ISC101, *Phormidium* sp. ISC108 were collected from north (paddy-fields of Golestan province, near the Caspian Sea) and south (petroleum contaminated soils near the Persian Gulf) (*Fig. 1*). The collected samples were cultured by ordinary methods (Lowry et al., 1971). Purification and liquid cultures were performed by solid agar and routine procedures with BG11 and $BG11_0$ media (Andersen, 2005). $BG10_0$ was used that included the following ingredients: $MgSO_4{\cdot}7H_2O$, 0.3 mM; $CaCl_2{\cdot}2H_2O$, 0.25 mM; $K_2HPO_4{\cdot}3H_2O$, 0.18 mM; $Na_2MgEDTA$, 0.003 mM, citrate ferric 0.02 mM; citric acid, 0.029 mM; Na_2CO_3 0.188 mM; microelements 1 $ml{\cdot}L^{-1}$. All chemical materials were purchased from Merck Company (Germany) and used without further purification.

Culture conditions

Stock cultures were grown in the $BG11_0$, and BG11 culture media. Each cyanobacterium was pre-cultured in Erlenmeyer flasks at pH~7 and at temperature of 25 °C. Cells were collected from stock cultures in logarithmic phase of growth and were used as inoculate for experiments. Cells from stock culture were inoculated in 300 ml of $BG11_0$ medium in 500 ml Erlenmeyer flasks stoppered with cotton plugs. The following treatments were used: 0 (control), 1, 2, 3, 4, 5, 6, 7, 8, 9 and 10% crude oil and limited irradiation (5 $\mu Em^{-2} s^{-1}$) and limited salt (17 mM NaCl) for incubation period of 14 days.

Analytical methods

Growth measurements and pigment composition

Cell growth was checked by evaluation of algal dry weight, every 2 days in duplicate (Kaushik, 1987; Shruthi and Rajashekhar, 2014). Chlorophyll *a* (Chl. *a*) concentration was evaluated performing overnight extractions with methanol. Centrifuged extracts were measured at 665 nm and calculated by the extinction coefficient (Lowry et al.,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45594573

1951). Phycobiliproteins were extracted after osmotic shock and evaluated spectrophotometrically at 750, 652, 615 and 562 nm. Oxygen (O_2) evolution was measured using a Clark-type sensors measuring oxygen partial pressure from Hach Chemical Company (Shruthi and Rajashekhar, 2014). The total carbohydrates were measured using the anthrone-thiourea method (Herbert et al., 2010), and soluble proteins were estimated using bovine serum albumin as the standard (Liu et al., 2009).

Statistical analysis

Statistical differences were examined using the General linear multivariate model test by SPSS software version 16.0.

Figure 1. *The sampling location: a) North of Iran (paddy-fields of Golestan province, near the Caspian Sea) and b) South of Iran (petroleum contaminated soils near the Persian Gulf*

Result and discussion

Cyanobacteria isolated from northern paddy-fields and southern oil fields of Iran include *Fischerella* sp. ISC107, *Nostoc* sp. ISC101, *Phormidium* sp. ISC108. The results of the physiological responses of isolated samples to the increase of crude oil in limited light and limited salinity conditions were 5 $\mu E \cdot m^{-2} \cdot s^{-1}$ and 17 mM, respectively ($p < 0.01$).

Table 1 shows the growth rate (μ), the doubling time (G) in the three samples under oil treatments from zero to 10%. As it is shown, growth rate and doubling time was positive for all three samples. Investigating the doubling time indicated that the highest amount of time to be doubled was observed in the control concentrations for *Phormidium* sp. ISC108, 1 and 6% for *Fischerella* sp. ISC107 and 4% for *Nostoc* sp. ISC101. On the other hand, the growth rate in *Fischerella* sp. ISC107 and *Nostoc* sp. ISC101 showed an increasing trend from zero to 10% of crude oil, while a different process was observed in *Phormidium* sp. ISC108, so that the highest rate of growth increased to 3% concentration, and with increasing concentrations up to 4%, where reduction in growth rates was observed ($p < 0.01$). Sample survival in oil treatments indicates that the sample could not increase the biomass in the treatments and only retained itself from death, and again, increasing trend was observed to 6% concentration, then, a decreasing trend was observed with increasing concentrations up to 10% (*Table 1*) ($p < 0.01$). Kiayi et al. (2013) found that the time of cell division, and hence, the doubling time was decreased with the increase in growth, the results are consistent with the obtained results in this paper (Kaushik, 1987).

	μ	0.52	0.39	0.73	0.61	0.67	0.5	0.39	0.44	0.48	0.76	0.75
Nostoc SP. ISC101	G	1.37	0.82	0.94	0.99	1.18	1.06	1.02	0.79	0.82	0.95	0.66
	μ	0.5	0.83	0.73	0.69	0.58	0.65	0.67	0.86	0.83	0.72	1.03

Figure 2 presents the growth curve of three samples under crude oil treatment. As it is the logarithmic phase of *Phormidium* sp. ISC108 an increasing trend ($p < 0.01$) was observed. This trend was observed in all treatments in this sample. The samples showed a decrease in growth after the ninth day until the thirteenth day ($p < 0.01$). In addition, the absorption rate in this curve was higher than those of the other two samples.

The results indicated the survival of the *Phormidium* sp. ISC108 in all oil treatments. Also an upward trend was observed in the study of the logarithmic phase of *Fischerella* sp. ISC107 and *Nostoc* sp. ISC101 strains. So, in different concentrations of crude oil treatment, they first encountered a decline in growth rate and again showed an increasing trend ($p < 0.01$). Generally, the productivity of the hydrocarbon resource of *Phormidium* sp. ISC108 was higher than those of other strains in crude oil treatment (*Fig. 2a, b, c*). Amirlatifi et al. (2013) reported that biomass amounts was 3.88, 4.35 and 4.60 mg/ml^{-1} on the 12th day of inoculation at control, 1 and 7% concentrations, respectively. This increasing trend was consistent with the results of this study.

DOI: http://dx.doi.org/10.15666/aeer/1604_45594573

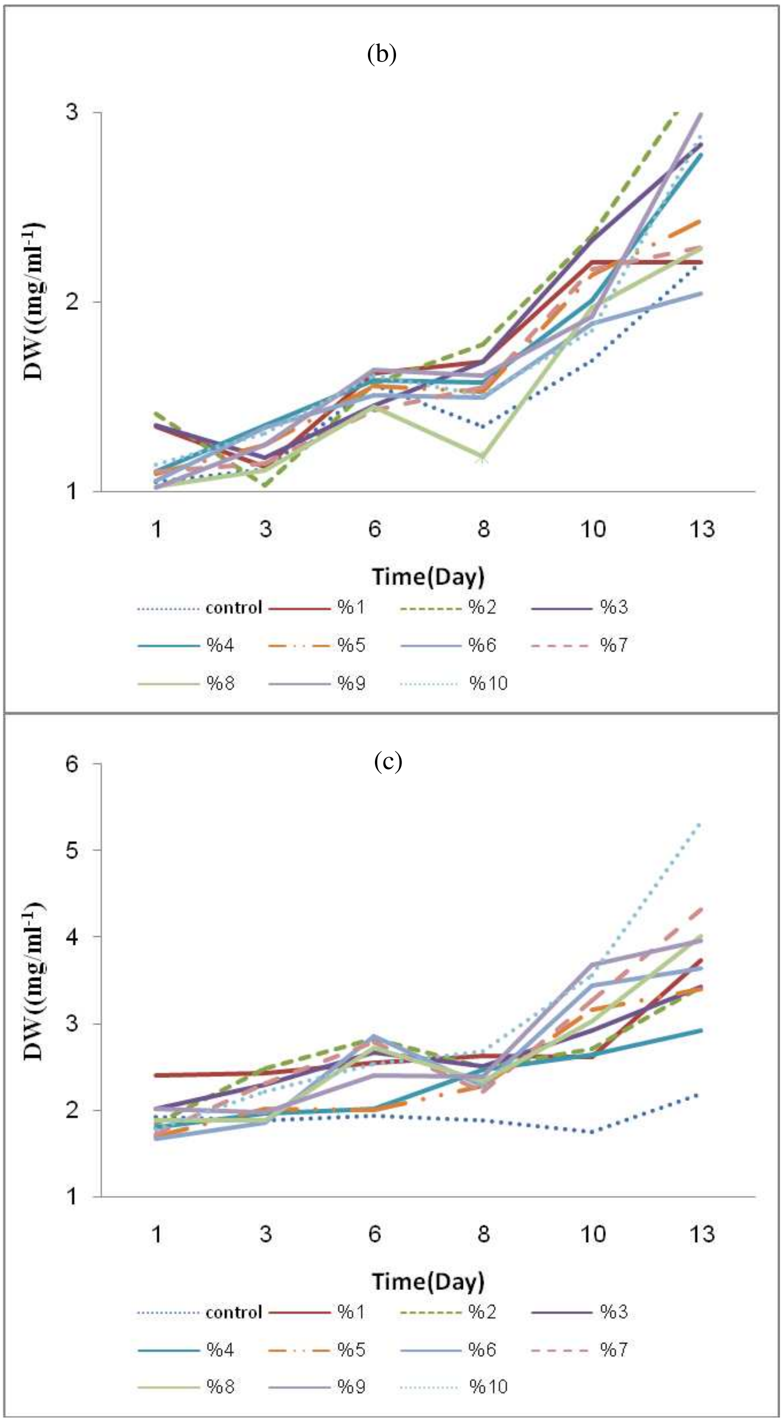

Figure 2. *Dry weight (DW) in different crude oil concentrations. limited light and limited salinity conditions were 5 $\mu E{\cdot}m^{-2}{\cdot}s^{-1}$ and 17 mM. (a) Phormidium SP. ISC108; (b) Fischerella SP. ISC107; (c) Nostoc SP. ISC101*

Figure 2 shows that in cyanobacteria *Phormidium* sp. ISC108; lag phase is not observed throughout the treatments with different oil levels. The progressive phase with a roughly identical gradient was observed in the first days after inoculation, which results from the rapid adhesion of the sample to the environment. On the third day, and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45594573

after the seventh day of inoculation, the growth rate changes and the effect of oil treatments could be observed.

Growth up to 1.04 mg/ml^{-1} is due to the high uptake of this sample (in general) with high concentrations of crude oil. This growth is reduced in two other cyanobacteria (*Fig. 2a, c*). In *Fischerella* sp. ISC107, although a decline was observed in growth rate, generally due to habituation to oil change conditions was more sensible in the first days after inoculation (*Fig. 2b*). The pattern of behavior in this cyanobacterium is due to the absence of a negative growth phase until the third day at a concentration of 3% of the specific crude oil. However, a sample under the influence of time could be adapted to this concentration (*Fig. 2b*). The existence of a long-term delayed phase in salinity of 3% in cyanobacterium *Nostoc* sp. ISC101 is remarkable, which continues even as negative growth until the eighth day.

In addition, in this sample, the lower level was observed in the treatments except at 10% with high growth slope as the same as *Phormidium*, but latent and negative phase is more remarkable, which generally is due to the incapability to habituate in short time (less than 72 h) to high concentrations of oil (*Fig. 2c*). The shorter lag phase and the same trends of growth curves that can be observed in other samples showed that *Phormidium* is not sensitive to higher concentration of oil through the more growth and will not be affected in the short time.

On the contrast, the growth rate in *Table 1* indicates that the amount of produced biomass in such a situation is higher than those of other treatments (*Table 1*). The effect of oil concentration on all three samples is considerable and the amount of biomass production in cyanobacteria is affected by combination of oil concentrations, irradiation and salinity stresses (*Table 1*). The results of mean comparisons using Tukey's test shows that dry weight in different genera under crude oil was classified into three groups and the genus *Phormidium* sp. ISC108 and *Fischerella* sp. ISC107 had the highest and the lowest amount (*Table 2*).

Table 2. *Dry weight (DW) in three strains of cyanobacteria under limited light and limited salinity conditions were 5 $\mu E \cdot m^{-2} \cdot s^{-1}$ and 17 mM. Data shows X ± SE*

SP	**DW (mg/ml^{-1})**
Phormidium SP. ISC108	3.23 ± 1.628^{a}
Fischerella SP. ISC107	$1.67 \pm .543^{c}$
Nostoc SP. ISC101	$2.58 \pm .737^{b}$

The amounts of dry weight in different days also shows a significant difference, so that the values were classified into 5 categories, the highest and the lowest amounts of dry weights were observed on day 13 and the first day, respectively (*Table 3*). On the other hand, the dry weight contents at different concentrations of crude oil were classified into three categories, which showed a significant difference, so that the control concentration had the lowest value and concentrations of 1-5% crude oil shows the highest amount (*Table 4*). Dhull et al. (2014) found that by increasing the concentration of carbon in the medium, the biomass production rate increases in some microalgae species, which is consistent with the results of this study.

Lack of salinity or salinity of 17 mM, could affect the results. The same amount of salinity and the lack of involvement in such surveys is a defect for any process with a biotechnological approach. Gu et al. (2012) shows that the growth and production of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45594573

pigments in *Nannochloropsis oculata* under pond conditions and using *in vitro* photo-bioreactor is affected by salinity. The salinity range was from 15 to 55 g/l^{-1} in the form of five treatments. Reducing salinity from 55 to 15 g/l leads to increasing growth and chlorophyll content. Lack of lag phase in the presence of high concentrations of oil, could be considered. In the studies of Amirlatifi et al. (2011) and Abed et al. (2015), the absence of lag phase has been evaluated from the viewpoint of the outflow of wall-forming compounds and nitrogen metabolism.

10	2.42±1.039^{b}

A sample that can be adapted to the new conditions at the first days after inoculation will not have problem with wall-forming compounds and subsequent reproduction for entry into the log phase (Soltani et al., 2011). Under laboratory conditions, cyanobacteria have shown a delayed phase or a negative growth phase depending on the acidity and alkalinity conditions (Amirlatifi, 2011).

Shokravi et al. (2002) reported that the *Fischerella* sp., *Nostoc* sp. and *Oscillatorian* cyanobacteria have shown a lag phase when they enter the natural environment due to their incompatibility with the environment in the first days. It should not be said which factors have contributed to the difference in growth behavior, but this difference has always been existed.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45594573

Compared with the laboratory conditions employed in the present work, as well as studies by Amirlatifi et al. (2011), Pakzad et al. (2011) and Badeli et al. (2012), although neither of the three environments has shown significant differences in terms of growth on the twelfth day, under laboratory conditions, this behavior is not observed at least within the first few days. It was not possible to follow the growth curve in the days following the twelfth day, and it is possible that the cyanobacteria would be retrieved, but it cannot be commented on this due to the lack of investigation on this issue.

Under laboratory conditions, the behavior of samples is different, and the progressive and stagnant phase continues until the 12^{th} day. This indicates the difference between the behaviors of the natural, and, the laboratory environments. In the studies of Chekigar et al. (2012) and Marvizade (2012) on cyanobacterium *Microchaete* sp. it has been shown that cyanobacteria changes trend in carbon dioxide and salinity treatments in the last days and shows a pattern similar to that in the natural conditions in this study.

In this study, such a pattern was related to the change in photosynthetic mechanism (Marker, 1972) and the carbon dioxide condensation mechanism (Chekigar, 2012) under laboratory conditions. It is likely that such a situation exists in the natural environment, as well. Particularly, under the natural environment, there was no carbon dioxide inoculation. However, it is definitely not possible to comment because the condensation-inhibiting compounds were not used in this study.

Table 5 deals with the effect of oil concentrations on the ability of cyanobacteria to habituate with limited light. Regarding the severity of extreme limited light, surveys conducted in Iran have been limited to surveys devoted to paddy-field of Northern Province in Iran.

Table 5. *Photosynthetic pigments amount in different cyanobacteria grown under limited light and limited salinity conditions were 5 $\mu E \cdot m^{-2} \cdot s^{-1}$ and 17 mM. Data shows X ± SE*

APC: Allophycocyanin, PE: Phycoerythrin, PC: Phycocyanin, Carbo: Carbohydrate, Pro: Protein,Chl: Chlorophyll, PBP: Phycobiliproteins

The results of the mean comparisons obtained from the physiological traits with Tukey's test shows that PC (Phycocyanin), PE (Phycoerythrin), Chl (Chlorophyll), Carbo (Carbohydrate), Pro (Protein) and PBP (Phycobiliproteins) traits were classified into three groups in different genus, so that the genus *Phormidium* sp. ISC108 had the highest and *Fischerella* sp. ISC107 had the lowest amount. Also, evaluation APC (Allophycocyanin) values showed that the genus *Fischerella* sp. ISC107 showed the lowest amount but other genus show the highest amount.

The study of PBP/Chl and PC+PE/APC values showed that the concentration of 10% crude oil was the highest value (*Table 6*). In fact, the ratio of PBP/Chl shows the relationship between the photosystem II and the photosystem I. It should be noted that these results were precisely the same as that found for the comparison of the mean values of PBP / Chl (PSII/PSI ratio). Also, the results of the measurement of phycobilisome (PC+PE/APC) showed that the *Phormidium* sp. ISC108 strain had the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45594573

highest value (3.99; $P \leq 0.01$). On the other hand, PBP values were classified into three categories, as *Fischerella* sp. ISC107 showed the minimum amount but *Phormidium* sp. ISC108 showed the maximum amount (*Table 5*).

Table 6. *Photosynthetic pigments amount in different crude oil concentrations under limited light and limited salinity conditions were 5 $\mu E \cdot m^{-2} \cdot s^{-1}$ and 17 mM. Data shows X±SE*

APC: Allophycocyanin, PE: Phycoerythrin, PC: Phycocyanin, Carbo: Carbohydrate, Pro: Protein, Chl: Chlorophyll, PBP: Phycobiliproteins

Shokravi and Soltani (2011) studied the simultaneous effect of extremely limited light of 2 micromoles quanta per square meter per second and pH was studied on cyanobacteria *Hapalosiphon* sp. FS56. Soltani et al. (2006) studies on *Fischerella* sp. FS 18 showed that this species not only has the ability to survive in this intensity, but also has high photosynthetic and high nitrogen activity. The studies by Amirlatifi et al. (2013) has confirmed the same result for the *Nostoc* sp. FS 76 and *Anabaena* sp. FS 77.

The results of the mean comparison of physiological traits using Tukey's test showed in different concentrations of crude oil that the various amounts of APC in different concentrations of oil (0 to 10%) were classified in 3 groups. Moreover, the lowest amount of APC was observed in 3% crude oil and the highest amount was obtained in 2, 9 and 10% concentration of crude oil. While in PC amounts, the lowest values were observed at 2% crude oil concentration and the highest values were at 3% crude oil, which were classified in four separate categories. The study of PE values also showed that a sample of 9% and 3% oil content had the lowest and the highest value, respectively.

In a study by Hamouda et al. (2016), it was recorded that with the increase in crude oil content, the amount of carotenoides was increased in *Calothrix. kesseleri* and *Anabaena oryzae*, while according to Liu et al. (2009), the amount of carotenoids was decreased in mixotrophic cells than photo-autotrophic cells, which may be due to the toxic effect of organic hydrocarbons on the growth of algae, which is consistent with the results of this study and with the results of Liu et al. (2009). Also, the results of Chl values in various oil concentrations show that concentrations of 9 and 10% were the lowest and the concentrations of 3% were the highest amounts and the data were categorized in five separate categories.

DOI: http://dx.doi.org/10.15666/aeer/1604_45594573

El-Sheekh et al. (2013) reported that the highest amount of chlorophyll (6.13 µg ml^{-1}) was obtained in *Chlorella vulgaris* fifteen days after inoculation with 1.5% concentration of crude oil, while in the samples examined in the present study, the highest amount (3.58 µg/gdw; $P \leq 0.01$) was obtained at a concentration of 3% crude oil.

The obtained results from Carbo values indicated that the values were classified into 7 categories, so that a concentration of 10% crude oil and a concentration of 3% crude oil had the lowest and the highest values, respectively. In the following, the physiological traits showed that the protein traits were classified into 7 groups, as the concentration of 10% and 3% showed the lowest and the highest values, respectively.

By investigating PBP values, it was concluded that the concentration of 3% crude oil was the highest and the concentrations of 2, 9 and 10% crude oil contained the lowest values, so that the data were categorized into five categories. Amirlatifi et al. (2013) found that the concentration of photosynthetic pigments depends on the concentration of crude oil that by increasing crude oil concentration, phycobiliproteins concentration was reduced. The results of the present study are also consistent with the mentioned study.

It seems that the reason for the reduction of phycobiliproteins in algae under conditions of environmental stress is resulted from the induction of biosynthesis of certain proteins. It can also affect the stability of the protein and its re-rotation by the protein proteolytic rate.

Pittmanet al. (2010) reported that the optical intensity limited to 10 µm quanta per square meter per second has been used on the cyanobacteria *Nostoc* sp. UAM206 and has reduced the growth and photosynthesis activity in comparison with 60 µM Quanta per square meter per second and 300 µM quanta per square meter per second, respectively.

Studies by Marvizade (2012) and Chekigar et al. (2012) have shown that the two species studied in this article retain their survival and have high photosynthetic and nitrogen activity in extreme conditions of 2 µM Em^{-2} s^{-1} in the presence of white light, which is far lower than other tested species such as *Nostocsp* FS 76 and *Anabaena* sp. FS 77 (Amirlatifi, 2011; Badeli et al., 2012).

Table 5 and the results table of photosynthesis (*Table 6*) show that the application of oil concentration not only does not entail tension on the photosynthetic apparatus, but also significantly increased the efficiency of this apparatus ($p < 0.01$). The maximum rate of photosynthesis increases significantly in these conditions ($p < 0.01$). This issue is in full compliance with the increase in sample growth rate under the above conditions.

Measurements of photosynthetic pigments (*Tables 5* and *6*) are due to phycobilisome system. It seems that in addition to the main pigments, the rode sections and the core sections of the phycobilisome is oscillated under the influence of oil concentrations.

It seems that the increase in oil concentration has significant effect on the increase of light absorption power ($p < 0.01$). In addition, salinity not only does not damage the phycobilisome system, but also adds to the length and power of its optical absorption. This is a major biotechnological achievement that could be particularly used in the process of inoculation of algae, for agricultural and for other purposes. Whether non-aeration (although it reduces the activity of the phycobilisome system a little) increases the limited light absorption efficiency and amplifies it through the phycobilisomes is another biotechnological achievement that can be useful in intensive culture through eliminating of carbon dioxide induction (Montagnolli et al., 2015; Prince et al., 2010).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45594573

Significant increase in total sugar and total protein content (*Tables 5* and *6*) is remarkable from two perspectives ($p < 0.01$). Coordination with the potential of photosynthesis and nitrogen activation on the one hand, and the efficiency of the phycobilisome system on the other, is shown to be capable of generating total carbohydrate and protein. In other words, salinity not only does not reduce the level of carbohydrate pool and protein, but also significantly increases it ($p < 0.01$).

Relative absorption studies under in vivo conditions could be considered as evidence of the situation of the pigmentation of the reaction center structures, the light collector complex and phycobilisome antennas (qualitatively).

It seems that the phycocyanin level is interacted with the growth rate observed in both cyanobacteria, as the main and permanent barrier of phycobilisome in both cyanobacteria, under the influence of extreme limited light and salinity, although the absorption peaks in cyanobacteria are moved a little affected by combined stresses.

Soltani et al (2007) stated that cyanobacteria *Fischerella* sp. FS 18 loses its central allophycocyanin under acidity and alkalinity treatments and changes in light intensity.

Shokravi et al. (2011) in their research declared that Cyanobacteria *Hapalosiphon* sp.FS56 loses its allophycocyanin part under combined treatments of limited extreme light, acidity and alkalinity, in extreme alkaline conditions. Both samples contain phycoerythrin parts. Ahmadi Livani et al. (2009) reported that salinity and limited irradiation treatments in cyanobacterium *Hapalosiphon* sp. FS56 have not removed the allophycocyanin.

However, the results of this study indicate that the content of phycobilisome is completely preserved in extreme light stress conditions (2 micromoles quanta per square meter/second) and salinity in both cyanobacteria. In the studies of Tamkini et al. (2015), it has been shown for the first time that short-term irradiation and carbon dioxide treatments could lead to the displacement of pigments. This finding was also used in this study. It appears that the physiological fluidity of the sample in short periods of time (in shock) at very low light intensities can be as high as 2 $\mu M\ Em^{-2}\ s^{-1}$. The results of Tamkini et al. (2015) showed that optical shock and carbon dioxide could lead to extreme reactions.

In addition to this, the combination of crude oil, light and carbon dioxide shocks can change the color of the pigment and, of course, the size of the phycobilisome, even in the five to ten minute period. This is also compatible in other light intensities.It is appeared that light and carbon dioxide, combined with salinity affect the state of light-absorbing pigments. Interestingly, in this case, there are microsporine-like amino acids (MAAs) that have been considered as anti-ultraviolet treads. It was found in the studies by Badeli et al. (2012) and Amirlatifi et al. (2011) that the species of *Nostoc* sp. FS 101 and *Anaphana* contain more. This significant photosynthesis continues to 7% oil values (ANOVA, $p < 0.05$).

About *Microcheate* sp. FS13*,* photosynthesis is similar but its value is less (approximately 44 micromoles oxygen per dry weight unit), which is equivalent to the ones have been obtained from *Nostoc* sp. FS 101 and *Annapana* by Amirlatifi et al. (2013) and Badeli et al. (2012).

Absorption spectra in vivo in the first days after inoculation and comparison with the days after inoculation in different concentrations indicate the effect of a time factor on the behavior of the phycobilisome system of the sample in different oil conditions at different times. In the first hours after inoculation, both samples have high-density

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45594573

spectra, in which phycobilisome system has its pigments fully, especially phycocyanin that is detectable. But then, the sample behavior changes under the influence of salinity.

The change in the behavior of the phycobilisome system is natural and is due to the metabolic fluidity of the sample, but the important issue is the time problem. In the short and medium term studies, the problem of the effect of short time (shock) on the process of changing the phycobilisome system has been evaluated.

Conclusion

The marine environment is highly susceptible to pollution by petroleum, and so, it is important to understand how the microorganisms degrade hydrocarbons. In this research, the effects of crude oil under limited light and limited salinity on physiological characterization of the cyanobacteria *Fischerella* sp. ISC107, *Nostoc* SP. ISC101, *Phormidium* sp. ISC108 were investigated. This study showed that growth rate and doubling time was positive for all three samples, but *Phormidium* sp. ISC108 had the highest rate of growth in elevated oil concentration. Photosynthetic pigments amount in different cyanobacteria grown under the limited light and limited salinity conditions showed that *Phormidium* sp. ISC108 had the highest amount of APC, PC, PE, Chl, Carbo and Protein. In this research salinity significantly increased the levels of carbohydrate pool and protein and photosynthetic pigments amount ($p < 0.01$). Limited light eliminated induction of carbon dioxide concentration systems. Increasing oil concentrations up to 3% are significantly enhanced photosynthetic pigments amount, carbohydrate and under limited light and limited salinity but it decreased towards high concentrations ($p < 0.01$). It can be concluded that the cyanobacteria can be used as a bioremediation for decomposing crude oil especially in the coastal area of the Persian Gulf and the Caspian Sea. The results of this research can be valuable for reducing the contamination which affects the fauna and flora of the marine ecosystems in our country.

Abstract. This study was carried out to investigate the effects of different cyclanilide (Cyc) and Perlan (Pr) doses on formation of lateral branches on apple [Golden Delicious (GD) and Starking Delicious (SD)] and pear (Deveci and Williams) nursery trees grafted on seedling rootstocks. Except for 5 mg L^{-1} Cyc in Deveci pears, all Cyc concentrations applied in this study increased significantly the number of lateral branches on both apple and pear trees in nursery. In GD apple, while control trees had 2.5 lateral branches, the trees treated 100 mg L^{-1} Cyc had 12.7 lateral branches per trees. Except for 250 mg L^{-1} in GD apple, all other Pr treatments did not cause a significant increase in the number of lateral branches on apple and pear trees. Crotch angles of SD apples decreased significantly with 750 mg L^{-1} Pr treatments. The 250 and 500 mg L^{-1} Pr treatments significantly reduced number of lateral branches of Williams pears. It was concluded based on present findings that entire Cyc doses could be used as an efficient tool to increase the number of lateral branches in apples and pears; high Cyc doses could also be used to reduce the first branch height in both apple cultivars and Deveci pears.

Introduction

For a profitable fruit growing, there are many factors to consider when establishing an orchard. These factors include rootstock, cultivar, tree density, training system, pruning methods and support systems. The primary target of the systems developed for the orchards is to maintain high yield levels through early and late yields and to get exceptional fruit quality (Robinson, 2003). The basic factor for early production is to get fruits from the initial years. Therefore, branched trees are used while establishing orchards (Coşkun, 2011). Number of lateral branches, crotch angle and the first branch height are significant factors in having early and high yields (Barritt, 1992; Hrotko et al., 1996; Kviklys, 2006; Koyuncu and Yıldırım, 2008; Magyar et al., 2008).

The formation of lateral branches can be controlled through external applications of growth regulators effective in apical dormancy. Cytokinins are known to inhibit apical. Previous researches indicated that benzyladenine (BA), a synthetic cytokinin, stimulated lateral branch formation (Faust, 1989; Atay and Koyuncu, 2016; Ipek et al., 2017). Perlan (Pr) or Promolin ($BA+GA_{4+7}$) have an active ingredient of cytokinins and gibberellin and these commercial products were also reported to stimulate lateral branch formation in different fruit species (Cody et al., 1985; Elfving, 1985; Yıldırım et al., 2010). Another approach to stimulate lateral branch formation is to inhibit transport of auxins which stimulate apical dormancy. It was reported in previous studies that 2,3,5-triiodobenzoic acid and n-propyl-3-t-butylphenoxyacetate and similar chemicals inhibited polar auxin transport and increased the number of lateral branches (Jacyna and Dodds, 2001). Cyclanilide (Cyc) has emerged as a bio-regulator inhibiting auxin transport and it was

reported in previous studied that Cyc stimulated shooting of lateral buds in different fruit species (Tamas, 1995; Mickelbart, 2011). On the other hand, effects of such chemicals usually vary based on species and cultivars (Wustenberghs and Keulemans, 1999). Previous studies were mostly carried out over the trees grafted on clonal dwarfing rootstocks. On the other hand, in Turkey, nursery trees grafted on seedling rootstocks are still used at considerable rates in apples and pears. These trees generally yield late because of strong vegetative growth. Therefore, in nursery trees grafted on strong rootstocks, breaking apical dormancy and stimulating lateral-branch formation are even more important. This study was conducted to investigate the effects of Cyc and Pr treatments at different doses on lateral branch formation in Golden Delicious and Starking Delicious apple cultivars and Williams and Deveci pear cultivars grafted on seedling rootstocks.

Materials and methods

Plant material

This study was conducted in a commercial nursery orchard in Tokat (Turkey) located between 40° 18’ north latitude and 36° 13’ east longitude in 2015. Experimental site has a loamy soil texture with moderate lime, low organic matter, sufficient P_2O_5 and K_2O levels. Annual average temperature (based on 55-years data) is 12.6 °C, average relative humidity is 62.8% and average precipitation is 432.1 mm (Tokat Meteoroloji Station). In the study years average temperature, average relative humidity and average precipitation are measured as in 13.1 °C, 62.7% and 318.1 mm, respectively. Fertilization was performed in all experimental plots in accordance with the results of soil analyses. Irrigations were performed with drip irrigation. Golden Delicious (GD) and Starking Delicious (SD) apple cultivars were grafted on apple seedling rootstocks *(Malus domestica* L), Williams and Deveci pear cultivars were grafted on pear seedling rootstocks *(Pyrus communis* L.*)* with T-budding.

Treatment

Concentration

Apple nursery trees were subjected to 250, 500, 750 and 1000 mg L^{-1} Perlan (18.8% 6-benzyladenine (BA) and 18.5% GA4+7) and 25, 50, 75 and 100 mg L^{-1} Cyclanilide (Cyc) treatments; pear trees were subjected to 250 and 500 mg L^{-1} Perlan and 5, 10, 15 and 20 mg L^{-1} Cyclanilide treatments. All experimental solutions were applied with 0.1% surfactant. Control trees were subjected to only distilled water treatments with surfactant.

Experimental design

Nursery trees were planted with 80 cm plant spacing and 15 cm row spacing. Standard cultural practices were performed regularly. All treatments were performed in the first week of July when the trees reached to a height of 70-80 cm from the soil surface. Treatments were sprayed about 15-20 cm above the canopy.

Investigated parameters

At the end of growth season, tree trunk diameter, tree height, lateral branch length, height of the first branch, crotch angle, number of lateral branches were determined.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45754583

Trunk diameter was measured with a caliper from 5 cm above the graft union. Tree height was measured as the height from the graft union to tip of the tree. Lateral branches longer than 10 cm were counted in each tree to get number of lateral branches per tree. Their lengths were measured to get average lateral branch length. The crotch angle was measured with a protractor. The height of first branch was taken as the distance from the bud union to the first induced feather longer than 10 cm.

Statistical analysis

Experiments were conducted in randomized block design with 3 replications with 10 trees in each replicate. The normality of the data was confirmed by the Kolmogorov-Smirnov test and the homogeneity of variances by the Levene's test. Except for number of lateral branches, resultant data were subjected to variance analysis. Means were separated by Duncan's multiple range test. Since the number of lateral branches did not have a normal distribution, they were analyzed with Friedman test.

Results

As compared to control treatment, neither Cyc nor Pr treatment resulted in significant changes in trunk diameters of either apple cultivars (*Table 1*). A similar response was observed in tree heights. Relative to control treatment, decreases in tree height were observed only with 100 mg L^{-1} Cyc and 750 mg L^{-1} Pr treatments of SD cultivar. Experimental treatments did not result in significant differences in lateral branch lengths of GD. Although some treatments created differences in lateral branch lengths of SD cultivar, both Cyc and Pr treatments did not result in significant changes in lateral branch lengths as compared to control treatments.

Low Cyc doses did not have significant effects on the first lateral branch height. However, higher doses (75 and 100 mg L^{-1}) result in significant decreases in both cultivars (*Table 2*). All Pr doses did not cause a significant change in the first lateral branch height of GD apples. In the SD apple tree, while 1000 mg L^{-1} Pr treatment decreased the first lateral branch height, effects of the other doses were not significant when compared to control treatment. Crotch angles of SD cultivar significantly decreased only with 750 mg L^{-1} Pr treatment. Effects of the other treatments were not found to be significant.

Entire Cyc treatments remarkably increased the number of lateral branches in both apple cultivars. While the number of lateral branches was 2.5 in control treatment of GD cultivar, the value increased to 12.7 with 100 mg L^{-1} Cyc treatment. In GD cultivar, significant differences were observed in number of lateral branches the among the Cyc application concentrations. Number of lateral branches in 50, 75 and 100 mg L^{-1} Cyc treatments was remarkably higher than both the control and 25 mg L^{-1} Cyc treatment. Similarly, Cyc treatments increased number of lateral branches also in SD cultivar, but the differences between Cyc doses were not found to be significant. On the other hand, effects of Pr doses on number of lateral branches varied based on the cultivar and treatment dose. Relative to control treatment, only 250 mg L^{-1} Pr treatment significantly increased number of lateral branches in GD cultivar (*Fig. 1*).

No treatment was significantly different from each other and control with respect to trunk diameters and tree heights in Deveci and Williams pear cultivars. The differences in lateral branch lengths of the treatments were not found to be significant in Williams cultivar. In Deveci cultivar, 250 mg L^{-1} Pr-treated trees had significantly higher tree

The first branch height and crotch angle of Williams cultivar under Cyc and Pr treatments were similar to the control treatments. In Deveci cultivar, on the other hand, Pr treatments yielded similar values with the control saplings, but Cyc treatments (except for 5 mg L^{-1} Cyc) significantly reduced the first branch heights. Although the crotch angles of 15 mg L^{-1} Cyc-treated trees were significantly higher than the crotch angles of 5 mg L^{-1} Cyc-treated trees, both treatment did not differ from control treatment respect to crotch angle (*Table 4*).

The experimental treatments had significant effects on number of lateral branches in both pear cultivars. Except for 5 mg L^{-1} Cyc treatment, other Cyc treatments significantly increased number of lateral branches in Deveci cultivar. In this pear cultivar, while the number of lateral branches per tree was 0.93 in control treatment, the value increased to 5.68 with 15 mg L^{-1} Cyc treatment. Number of lateral branches in Pr-treated trees of Deveci cultivar was similar with the control treatment. In Williams cultivar, all Cyc treatments significantly increased number of lateral branches. However, both Pr doses significantly reduced the number of lateral branches. As compared to 5 mg L^{-1} Cyc treatment, 10 and 15 mg L^{-1} Cyc treatments were significantly more effective on increasing number of lateral branches (*Fig. 2*).

Discussion

Cropping is usually delayed in orchards established with trees with less number of lateral branches (Elfving, 2010). Therefore, some plant growth regulators are used to reduce the effects of apical dormancy and thus to stimulate lateral branch development. It was reported in previous studies that benzyladenine (BA) applied either alone or together with gibberellic acid (GA_{4+7}) increased number of lateral branches in apple and pear saplings (Neri et al., 2004; Koyuncu and Yıldırım, 2008; Yıldırım et al., 2010). In present study, the effects of Pr treatments varied based on species and cultivars. More efficient and stable outcomes were achieved from Cyc treatments. Even remarkable at higher doses, all Cyc treatments distinctively increased number of lateral branches both in apples and pears. A similar case was reported by Elfving and Visser (2006a) for cherry saplings. Previous researchers also indicated that Cyc treatments yielded better outcomes for lateral branch development than Promalin ($BA+GA_{4+7}$). Researchers also indicated that the effects of Promalin varied based on species, but Cyc had more stable outcomes for different species (Elfving and Visser, 2006a, b; Ipek et al., 2017; Lordan et al., 2017).

Previous researchers indicated that the effects of both Pr and Cyc on trunk diameter and tree height varied depending on species, cultivars, rootstocks and treatment doses (Gastol and Poniedzialek, 2003; Rossi et al., 2004; Elfving and Visser, 2006a, b; Kalyoncu et al., 2011; Sazo and Robinson, 2011; Moghadam and Zamanipour, 2013; Lordan et al., 2017). However, none of these studies mentioned about a negative impact of those treatments on nursery tree quality parameters. In present study, both Pr and Cyc treatments generally did not have any negative effects on trunk diameter and tree height of apple (GD and SD) and pear (Deveci and Williams) cultivars.

Some researchers reported that BA and Promalin treatments increase lateral branch lengths of apple saplings (Greene et al., 1990; Kalyoncu et al., 2011). Gastol and Poniedzialek (2003) carried out a study with 3 different apple cultivars and indicated that effects of Promalin treatments on lateral branch lengths varied with the years and climate conditions. Elfving and Visser (2005) reported that different Cyc doses did not result in significant changes in lateral branch lengths of Cameo apples grafted on M26 rootstocks, but significantly reduced lateral branch lengths of Fuji apples. Despite the differences in lateral branch lengths of treatments in Deveci pear and Starking Delicious apple cultivar, none of the treatments resulted in significant changes in lateral branch lengths of apples and pears as compared to the control treatments. Such findings revealed that response of nursery trees to Pr and Cyc treatments with regard to lateral branch length might vary based on the rootstocks and cultivars.

Although being changed based on intended market, the first branch height is a significant criterion for all markets. Contradictory outcomes were reported in previous studies about the effects of Pr and Cyc treatments on the first branch heights (Elfving and Visser, 2005, 2006b; Yıldırım et al., 2010; Sazo and Robinson, 2011). Except for Williams cultivar, Cyc treatments decreased the first branch height of the nursery trees, on the other hand Pr treatments generally did not have significant effects on the first branch heights. In previous studies, positive effects of Promalin and Cyc-like growth regulators on crotch angles were reported (Gürz, 2005; Yıldırım et al., 2010). However in this study, no results were obtained to support that both Pr and Cyc could have a beneficial effect on crotch angles of nursery trees of apple and pear cultivars.

DOI: http://dx.doi.org/10.15666/aeer/1604_45754583

Conclusion

Although there are several studies indicating that external application of growth regulators effective in apical dormancy may stimulate lateral branch formation in fruit trees, effects of such growth regulators usually vary based on the rootstock and cultivars. Present findings revealed that all Cyc doses could be used to increase number of lateral branches in apple (Golden Delicious and Starking Delicious) and pear (Deveci and Williams) cultivars grafted on seedling rootstocks; Cyc doses could be used as an efficient tool to reduce the first branch height in two apple cultivars and Deveci pear cultivar. Also, these growth regulators stimulated shooting of lateral buds through inhibiting apical dormancy and did not have any negative impacts on tree heights.

(Received 21st May 2018; accepted 11th Jul 2018)

Abstract. Scolytinae subfamily (Coleoptera: Curculionidae) is represented by 135 species in Turkey including 8 species of the genus *Hylastes* Ericson and 7 species of the genus *Crypturgus* Ericson. A total of 79 adult individuals of *Hylastes opacus* Erichson and 6 adult individuals of *Crypturgus hispidulus* Thomson, C. G. were obtained from log and pheromone traps in pine stands at twelve localities during 2014. *H. opacus* and *C. hispidulus* were recorded for the first time in Turkey. *H. opacus* were obtained from trap logs of *Pinus brutia* and *Pinus nigra* and also pheromone traps in *P. brutia* stands. Adult individuals of *C. hispidulus* were observed in association with *Orthotomicus erosus* and *Pityogenes pennidens* on *P. brutia* and *P. nigra* log traps.
Keywords: *Hylastes opacus, European bark beetle, Crypturgus hispidulus, Pinus brutia, Pinus nigra, Marmara, Turkey*

Introduction

The Scolytinae subfamily (Coleoptera: Curculionidae) is one of the largest groups of Coleoptera and it is represented by 135 species in Turkey (Wood and Bright, 1992a, b; Knížek, 1998; Selmi, 1998; Sarıkaya and Avcı, 2011; Sarıkaya 2013; Sarıkaya and Knížek, 2013; Cognato, 2015; Lieutier et al., 2016). The majority of species feed on dead or dying tissues and are not normally considered to be of an economic importance. However, such species can become economically important if their galleries create holes in timber used for furniture or veneer, or if they transport pathogenic fungi to living trees during the feeding period by young adults to mature the gonads. The relatively small number of species that attack living trees, saplings or seedlings, or the seeds of commercial crops are sometimes of major economic importance, causing damage estimated in millions of dollars (Knížek and Beaver, 2007).

Species of the genus *Hylastes* Ericson primarily colonize subterranean stem parts of various conifers, predominantly, *Pinus*, *Picea* and *Abies* genera. The genus *Hylastes* has 21 species in conifers throughout the Holarctic region (Webber and Gibbs, 1989; Bright, 2014). It is presented with eight species in Turkey; *H. angustatus* (Herbst,), *H. ater* (Paykull), *H. attenuatus* Erichson, *H. batnensis anatolicus* Knížek & Pfeffer, H. *brunneus* Erichson, *H. cunicularius* Erichson, *H. linearis* Erichson and *H. substriatus* Strohmeyer (Selmi, 1987; Wood and Bright, 1992a; Lieutier et al., 2016; Alonso-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45854591

Zarazaga et al., 2017). Their adults feed on the tender bark near the root collars of seedlings and transplants, often girdling them, the species is frequently considered a noxious pest of nurseries and pine plantations, not only killing small plants but exposing older trees to infestation by wound parasites such as *Fomes* (Basidiomycetes, Polyporales: Polyporaceae) (Hoebeke, 1994). *Hylastes* species are also the vector of black stain root diseases and some of them have been reported as serious pests in forestry (Webber and Gibbs, 1989).

The genus *Crypturgus* Erichson breed in conifers throughout the Holarctic region and fifteen species are currently recognized (Wood and Bright, 1992a; Jordal and Knížek, 2007). It is represented with 7 species in Turkey; *C. cinereus* (Herbst), *C. cylindricollis* Eggers, *C. dubius* Eichhoff, *C. mediterraneus* Eichhoff, *C. numidicus* Ferrari *C. parallelocollis* Eichhoff and *C. pusillus* (Gyllenhal) (Wood and Bright, 1992a; Selmi, 1998; Lieutier et al., 2016; Alonso-Zarazaga et al., 2017). Species of the genus *Crypturgus* have very small body size (0.9–1.5 mm) and inhabit bark of the trees. The species are very abundant throughout the whole Mediterranean basin, but largely secondary, infesting only trees heavily stressed or already infested by more aggressive species. They have no economic relevance; high population density of this species may interfere with the development of associated more aggressive species (Lieutier et al., 2016).

In the current study *Hylastes opacus* Erichson and *Crypturgus hispidulus* Thomson, C. G. were reported for the first time to Turkish fauna.

Material and methods

Specimens of *H. opacus* and *C. hispidulus* were collected from trap logs and pheromone traps in stands of *Pinus brutia* Ten. and *P. nigra* J. F. Arnold in Marmara Region, Turkey (*Fig. 1*).

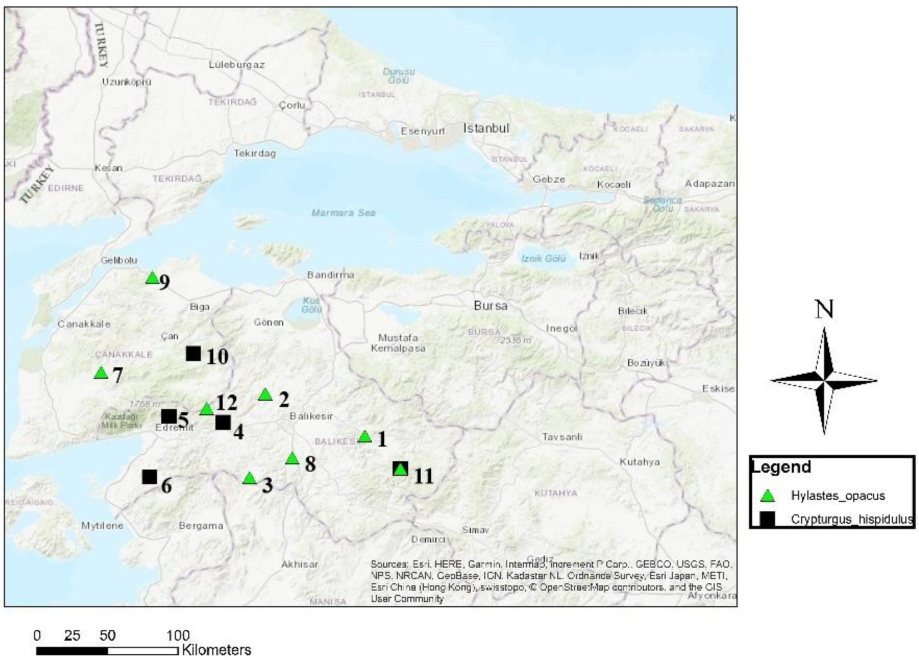

***Figure 1.** Collection sites*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45854591

Pheromone traps baited with the pheromone of *Orthotomicus erosus* Wollaston and trap logs were set up in February 2014 in 12 sites. Coordinates of the collection sites and trap types are presented in *Table 1*. Traps were checked for the presence of beetles at regular intervals. Insects were collected and identified on the basis of characteristic morphological features of the elytra and elytral declivity by using a LEICA S8APO stereomicroscope. Taxonomic keys in (Grüne, 1979; Wood, 1982; Hoebeke, 1994; Jordal and Knížek, 2007) were used to determine the specimens. Color photographs of specimens were prepared by using the stereomicroscope with a LEICA DFC295 digital video camera. Voucher specimens of *H. opacus* and *C. hispidulus* were prepared appropriate methods and preserved at Istanbul University-Cerrahpaşa, Faculty of Forestry, Department of Forest Entomology and Protection.

Result and discussion

A total of 79 adult individuals of *H. opacus* and 6 adult individuals of *C. hispidulus* were collected during 2014 from eight localities in Turkey at various altitudes between 93 and 1164 m (*Table 1*). The number, locality and date of captured *H. opacus* and *C. hispidulus* are given in (*Table 2*).

H. opacus can be distinguished from other Turkish species of the genus *Hylastes* by frons without longitudinal ridge (Grüne, 1979; Freude et al., 1981). Its adults were 2.5-3 mm long and were recognized by the following combination of characters: frons and vertex closely and coarsely punctured; pronotum as long as wide and constricted anteriorly; interstriae flat, wider than striae; elytral declivity with filiform setae; and body black with antennae and legs reddish brown and elytra dull (*Fig. 2*).

The distribution area of *H. opacus* includes; Austria, Belgium, Bulgaria, China, Denmark, England, Estonia, Finland, France, Germany, Greece, Hungary, Ireland, Italia, Japan, Korea, Latvia, Lithuania, Macedonia, Norway, Poland, Russia, Slovakia, Slovenia, Sweden, Switzerland, North America and Canada (Wood and Bright, 1992a; GBIF, 2017; Fauna Europaea, 2018).

	Total		**6**

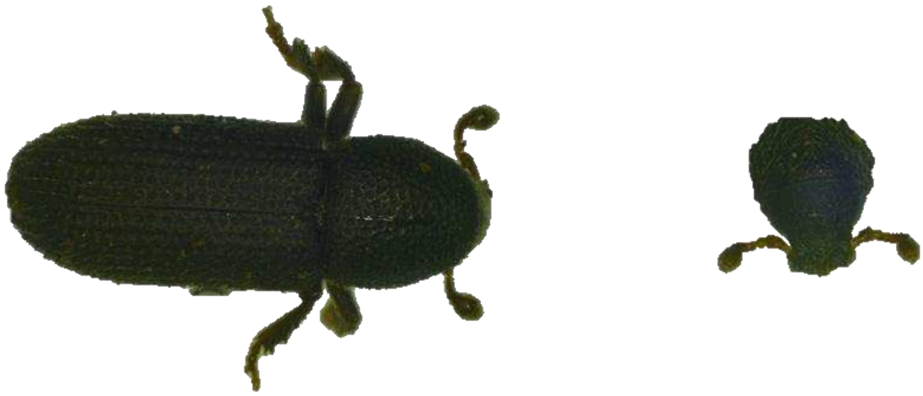

Figure 2. *Hylastes opacus Erichson*

We obtained only six adult of *C. hispidulus* individuals from log traps in Balıkesir and Çanakkale province in 2014. *C. hispidulus* can be differentiated from other Turkish species of the genus *Crypturgus* (except *C. pusillus, C. cylindricollis* and *C. parallelocollis*) by shiny elytra and with round punctures of striae and elytral declivity with individually placed setae. It can be distinguished from *C. pusillus* by fine pronotum with sparsely punctured and elytral discs and sides with erect and long setae. It differs from *C. cylindricollis* and *C. parallelocollis* in terms of sizes (Grüne, 1979; Freude et al., 1981; Lompe, 2002; Jordal and Knížek, 2007). Its adults are 1.2-1.3 mm long and have the following features: interstriae with rows of white to light brown, short, thick and filiform setae; body black (*Fig. 3*).

The distribution area of *C. hispidulus* includes; Austria, Belarus, Bulgaria, Central and North European Russia, Czech Republic, Denmark, England, Estonia, Finland,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

Germany, Hungary, Italia, Latvia, Lithuania, Norway, Poland, Slovakia, Slovenia, Sweden, Switzerland, and Ukraine (GBIF, 2017; Fauna Europaea, 2018).

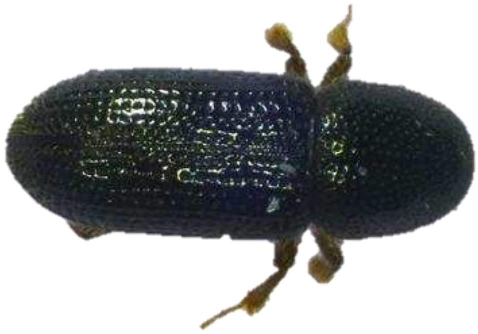

***Figure 3.** Crypturgus hispidulus Thomson, C. G.*

There were records from Greece and Bulgaria of *H. opacus*. Likewise, *C. hispidulus* was reported from Bulgaria (Doychev and Ovcharov, 2006). Although both of them were recorded in the neighbouring countries, *Hylastes opacus* and *Crypturgus hispidulus* were recorded for the first time in Turkey. As mentioned above, the Scolytinae subfamily is represented by 135 species in Turkey. Five of those species are known only in the country. We have contributed 2 species to Scolytinae of Turkey by current article.

H. opacus breeds in the bark of stumps or at the bases of unhealthy *Pinus* spp., chiefly Scotch pine (*P. sylvestris*). It occasionally infests the bark of other conifers for example *Picea* spp. and *Larix* spp. (Freude et al., 1981; Wood and Bright, 1992a; Hoebeke, 1994). We obtained *H. opacus* from trap logs of *P. brutia* and *P. nigra* and also pheromone traps in *P. brutia* stands. *C. hispidulus* lives under the bark of *Picea, Pinus* and less often on larch species. It also occurs in the galleria of other larger bark beetles for example; *Xylechinus pilosus*, *Hylurgops palliatus*, *Polygraphus poligraphus*, *P. subopacus*, *Tomicus minor*, *Pityogenes chalcographus* etc. (Freude et al., 1981). We observed that their adult individuals were associated with *Orthotomicus erosus* and *Pityogenes pennidens* on *P. brutia* and *P. nigra* log traps. Our findings are consistent with previous studies regarding the presence of adult individuals under the bark of pine species (*P. brutia* and *P. nigra*), and the association of *C. hispidulus* with other Scolytine species.

Conclusion

Bark beetles are important disturbance agents in forestry. They can colonize weak or recently killed trees, however a few species are capable of killing healthy trees. One of the most important characteristics of bark beetles is their association with fungi. In this study, where we present two new species for Turkish fauna, our main goal was to examine the association of bark beetles-fungi. Due to the experimental design we are not able to give more detailed information for these two new species. Additional work, including their life cycle should be conducted to determine their impact on forest ecosystem.

(Received 25th May 2018; accepted 5th Jul 2018)

Abstract. The aim of this study was to research the morphology and to make ready a hair identification key for common mammals in Turkey and also to make up a comprehensive method for the preparation of hair identification key for Turkey's mammals. Despite the wide application of this technique in the determination of diet composition in large carnivores, it has not been used in Turkey up to this point, thus this paper is the first study and an appropriate guide for using this technique in ecological studies and management of many species and populations in Turkey. In this research, hair structures of eighteen species representing four mammalian orders including Artiodactyla such as wild goat, chamois, red deer; Carnivora such as leopard, eurasian lynx, gray wolf, brown bear; Lagomorpha and Rodentia were investigated. The studied large carnivore species constitute the main predator species and the others are important prey sources. The microscopic structure of the hair was studied using the hair medulla and cuticle scale patterns. Afterwards, the structural features of hair for each species were comparatively used in order to prepare a descriptive and photographic hair identification key.
Keywords: *microscopic structure, photographic key, medulla, cuticle, wildlife*

Introduction

Hair identification of mammalian species has efficient practices in wildlife, biology, ecology and forensic medicine in particular the study of food habits of carnivores using investigation of prey hair in scats is widely utilized. The purpose of morphological identification of animal hairs is to classify the animal species from an unknown hair pattern to a special taxon based on well-defined, genetically based features (Tridicio et al., 2014). Knowledge of diet of carnivores is an important and essential factor for management and conservation of endangered species (Klare et al., 2011). Several techniques have been suggested to study species diet (Karanth and Sunquist, 1995; Ciucci et al., 1996). Despite these methods, scat analysis has been extensively used because this method is a non–harmful way and scat collections can be easily done throughout the year (Boitani and Powell, 2012). Various hair identification key atlases have been published on European mammal hairs (Day, 1966; Dziurdzik, 1978; Keller, 1978; Faliu et al., 1980; Debrot et al., 1982; Teerink, 1991; Meyer et al., 2002; Cornally and Lawton, 2016). Dietary habits of species are critical for the study of sustainable wildlife conservation and management (Treves and Karanth, 2003). Knowing the answer of question "Who eats what?" is essential for recognizing predator-prey relationships and a healthy ecosystem (Symondson, 2002; Sheppard and Harwood, 2005). Diet is basic principle in animal ecology but is specifically critical in the study of large carnivore species (Gese, 2001; Treves and Karanth, 2003). Scat analysis method is the most widely used to examine carnivore diet preferences (Leopold and Krausman, 1986; Gamberg and Atkinson, 1988). Knowledge of predators' diet is very important

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45934603

for sustainable wildlife conservation and management (Anwar et al., 2012). Scat analysis is based on morphological identification of indigestible prey remains such as bone and hair (Symondson, 2002; Sheppard and Harwood, 2005). Carnivore food habits studies from the prey hairs in scats has been widely accepted and used for describing the diet of mammalian predators, because of non-destructiveness of hairs and easily available scats at all times (De-Marinis and Asprea, 2005). The research of hair has been used in wildlife study in order to gather information such as species distribution, population density, species' dietary habits and translocation studies (Waters and Lawton, 2011).

Guard hairs have the ability to be used for identification, as a result, in this study only guard hairs were used to prepare the identification key. Hair structure is made of three layers: the medulla, the cortex and an outermost layer, the cuticle (Oli, 1993). The cortex is the middle layer of hair. It is composed of longitudinal and shriveled cells, which appears under the light microscope as a homogeneous mass without any details. This layer is of limited value for identification (Teerink, 1991). The medulla is composed shriveled dead cells but unlike the cortex they are clearly visible (Teerink, 1991; Hausman, 1920). Hair scale patterns formed by the cuticle and hair cross-sectional patterns formed by the cortex and medulla are the two main characteristics used in species recognition (Moyo, 2005). In identifying hair species it is necessary to compare the scales and medulla from the same parts of the hairs (Hausman, 1920).

The use of hair identification key could be helpful to distinguish hair structures of many related and unrelated species. Methods of direct comparison by microscopy have also been used but they are all time consuming (Oli, 1993). Photographic reference key has been proved the best and easy method for the comparison of characteristics of hairs recovered from the scats of carnivores (Oli, 1993).

In this study, a photographic hair identification key of common mammals of Turkey was developed. In this paper, hair structures of eighteen mammalian species have been investigated. This study is also important for all wildlife studies as important for Turkey. The aim of this study is to present a descriptive and photographic identification key and to provide a descriptive and simple method for the preparation of hair identification keys for other mammals in future studies.

Materials and methods

The structure of guard hair was examined in eighteen different mammal species found throughout Turkey. We investigated the hair structures of eighteen species representing four mammalian orders and nine families including Bovidae, Cervidae, Suidae, Canidae, Felidae, Mustelidae, Ursidae, Leporidae, and Sciuridae (*Table 1*). We collected hair tufts from taxidermied animals housed in Karadeniz Technical University, Wildlife Museum of Department of Wildlife Ecology and Management. All of the samples were dorsal guard hair from mature adult animals. Guard hairs are important in species identification as they exhibit diagnostically reliable features (Eunok et al., 2014). The hair samples were collected from at least five spots in the dorsolateral body region of each specimen (Wallis, 1993). The hairs samples were taken from the dorsal region of the body. De Marinis and Asprea (2005) noted that hairs from other body regions show similar characteristics to dorsal hair, but are often less distinct making identification more problematic.

Table 1. *Studied mammal species in this research*

Order	Family	Scientific Name	English Name
Artiodactyla	Bovidae	*Capra aegagrus*	Wild goat
		Gazella subgutturosa	Goitered gazelle
		Rupicapra rupicapra	Chamois
	Cervidae	*Capreolus capreolus*	Roe deer
		Cervus elaphus	Red deer
		Dama dama	Fallow deer
	Suidae	*Sus scrofa*	Wild boar
Carnivora	Canidae	*Canis aureus*	Golden jackal
		Canis lupus	Gray wolf
		Vulpes vulpes	Red fox
	Felidae	*Lynx lynx*	Eurasian lynx
		Panthera pardus	Leopard
	Mustelidae	*Martes foina*	Stone marten
		Meles meles	European badger
		Lutra lutra	European otter
	Ursidae	*Ursus arctos*	Brown bear
Lagomorpha	Leporidae	*Lepus europaeus*	European hare
Rodentia	Sciuridae	*Sciurus anomalus*	Caucasian squirrel

Medulla structure

Dead cell and the gaps between them create several patterns of medulla that are good indicators for identification (Teerink, 1991). If hair samples are not prepared for observation under light microscope, in most cases, medulla seems so dark that its structure can hardly be observed. Accordingly, the hair is placed into the mixture solution of 70% hydrogen peroxide and 30% ammonia for about 20 to 60 minutes so that hair colour is washed and the hair becomes transparent (De Marinis and Agnelli, 1993; Rezaie et al., 2012). Then, samples were placed in the water to be thoroughly washed and then a number of samples were placed on gelatine-treated solution and some were placed on liquid paraffin. Comparison between paraffin and gelatine slide displayed a more precise structure of the medulla (Teerink, 1991). Hair samples impregnated with paraffin and gelatine were placed on slides. Then, these slides were studied under a light microscope with a magnification of 100 and 400.

In this study, we have used the hair classification system that was proposed by De Marinis and Asprea (2005) and Teerink (1991). This classification has been based on cellular composition, cellular structure and pattern, medulla margins and width of cortex (Teerink, 1991) (*Fig. 1*).

Cuticle scales pattern

The outermost layer, the cuticle, is made up of a large number of overlapping transparent scales of keratin. Observation placement of scales pattern is usually impossible or can hardly be seen with a light microscope without special preparation (Teerink, 1991; Rezaie et al., 2012). Therefore, it is essential to make a gelatine impression of the hair or to use an electronic microscope (Homan and Genoways,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45934603

1978). Although the electronic microscope showed more detail of cuticular scale pattern, gelatine impressions were more practical (Perrin and Campbell, 1980). For this reason, the mixture of gelatine solution was placed on a slide, consequently hairs were placed on it. After drying for about 20 to 40 minutes, the gelatine will be solid and the hairs can be removed. As a consequence, the scales of hairs remaining on the gelatine can be seen under the light microscope with a magnification of 100 and 400 (Teerink, 1991; Oli, 1993). In this study, scale patterns of hairs are classified according to longitudinal axis of the hair, the structure of scale margins and the distance between scale margins (Teerink, 1991) (*Fig. 1*).

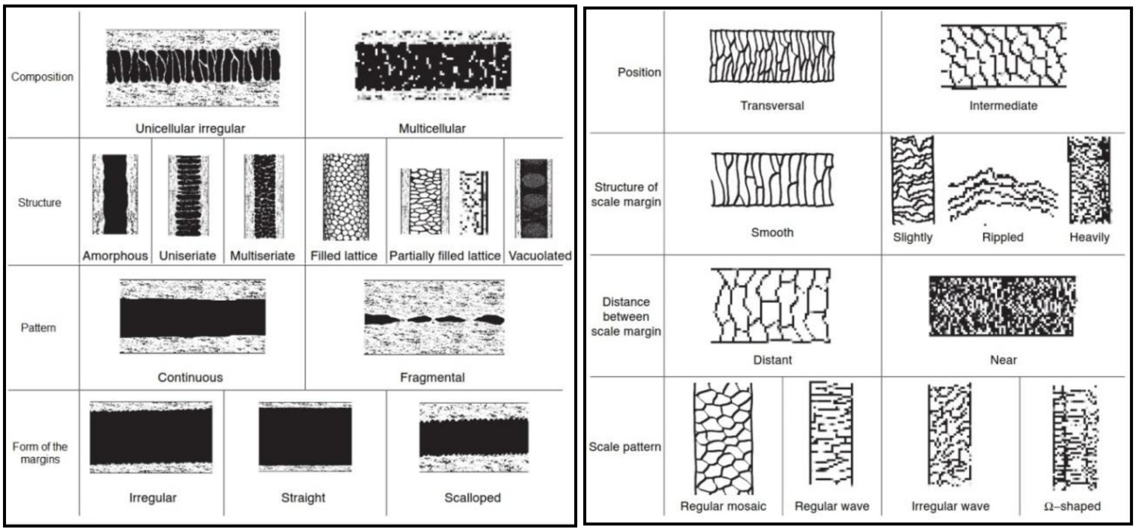

Figure 1. *Medulla (left) and Cuticle (right) classification system used in our hair key to identify common mammals of Turkey (Teerink, 1991)*

Results and discussion

In all species, the medulla structure of the hairs is an important key for the identification of species at the family level and the medulla structure per species is constant throughout the hair length (Homan and Genoways, 1978; Toth, 2002; De Marinis and Asprea, 2005). But at lower levels, such as subfamily and genus, for instance the wild goat and goitered gazelle, the medulla structure does not give the correct results in species identification, due to its high resemblance, so the cuticle pattern was used for identification of both species. The cuticle pattern shows more changes in hair length at family and subfamily levels. The cuticle is a useful tool used to distinguish species among wild ungulates. (De Marinis and Asprea, 2005). Therefore, firstly, in an attempt for microscopic identification, we investigated the medulla structure up to order and family levels and in order to identify at genus and species levels, it is recommended to use the cuticle pattern. As a result, in microscopic morphology the use of medulla structure has priority over the cuticle pattern and the use of the cuticle pattern individually, will cause confusion (De Marinis and Agnelli, 1993).

Keller (1981) separated Cervidae, which have similar medulla structure, from Bovidae on the basis of cross-sections. But hair cross-sectioning is a sophisticated and time consuming process in laboratory. So, we distinguished these taxa by the cuticle of hairs without cross-sectioning. The methods applied in this research can be easily, quickly and economically used in wildlife researches like previous studies (Toth, 2002;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45934603

Chernova, 2003; Eunok et al., 2014). For a wildlife researcher who knows the worked habitat well, these simply obtainable data are very important resources at identifying for species.

Among all studied mammals species, european badger, wild boar and brown bear hairs can be identified without the help of microscopic studies. The hairs of these species can be easily identified by the naked eye based on the general view of the hair, which are hard and thick. However, they have bristly hairs which can be distinguished from those of other species even if the researcher is not highly skilled in hair identification (De Marinis and Asprea, 2005). Medulla and cuticle features of these species are not clearly displayed due to amorphous cellular structure and morphological structures of their hairs. The hair of those animals should be classified by macroscopic view for hair profile and hair general appearance (Eunok et al., 2014).

Medulla features

All investigated Leporidae, Sciuridae family and wild ungulates, except wild boar, showed a multicellular composition. The predator mammals studied, except european badger and brown bear, showed an unicellular composition. European badger and brown bear showed a multicellular composition. The reason of differences medulla composition of these species is their hair structures which have amorphous cellular structure. All studied mammal species' medullary features are listed in *Table 2*.

Table 2. *Medullary features of 18 mammal species from Turkey*

Species	Composition	Structure	Pattern	Form of the margin	Cortex width
Capra aegagrus	Multicellular	Partially filled lattice	Continuous	Scalloped	Narrow
Gazella subgutturosa	Multicellular	Partially filled lattice	Continuous	Scalloped	Narrow
Rupicapra rupicapra	Multicellular	Partially filled lattice	Continuous	Scalloped	Narrow
Capreolus capreolus	Multicellular	Partially filled lattice	Continuous	Scalloped	Narrow
Cervus elaphus	Multicellular	Partially filled lattice	Continuous	Scalloped	Narrow
Dama dama	Multicellular	Partially filled lattice	Continuous	Scalloped	Narrow
Sus scrofa	Multicellular	Amorphous	Continuous	Irregular	Width
Canis aureus	Unicellular	Vacuolated	Continuous	Irregular	Medium
Canis lupus	Unicellular	Vacuolated	Continuous	Irregular	Medium
Vulpes vulpes	Unicellular	Multiseriate	Continuous	Irregular	Medium
Lynx lynx	Unicellular	Uniseriate	Continuous	Scalloped	Medium
Panthera pardus	Unicellular	Uniseriate	Continuous	Scalloped	Medium
Martes foina	Unicellular	Uniseriate	Continuous	Scalloped	Medium
Meles meles	Multicellular	Amorphous	Continuous	Irregular	Medium
Lutra lutra	Unicellular	Uniseriate	Continuous	Scalloped	Medium
Ursus arctos	Multicellular	Amorphous	Continuous	Straight	Width
Lepus europaeus	Multicellular	Multiseriate	Continuous	Scalloped	Narrow
Sciurus anomalus	Unicellular	Uniseriate	Continuous	Scalloped	Medium

Studied Bovidae and Cervidae family species have a partially filled lattice hair structure. Canidae family species except red fox have vacuolated hair structure. Red fox has multiseriate hair structure. Felidae family species have uniseriate hair structure.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45934603

European hare has multiseriate hair structure. Mustelidae family species except european badger have uniseriate hair structure. European badger has amorphous hair structure. Caucasian squirrel has uniseriate hair structure. Faliu et al. (1980) and Keller (1981) found the medullary lattice structure in wild boar. But, we found the medullary amorphous hair structure in wild boar and brown bear. We did not find in brown bear, as previously reported by Debelica and Thies (2009) found the medullary hair structure vacuolated in brown bear. All investigated mammals, showed a continous pattern. Studied Bovidae, Cervidae, Felidae, Leporidae, Mustelidae (except european badger) and Scirudae family species have form of the scalloped hair margin. Canidae family species, european badger and wild boar have form of the irregular hair margin.

Cuticle features

Among the mammals studied, except the leopard, position is transverse. The leopard has the most diverse pattern of cuticle hair so that from the base to the tip of the hair has intermediate structure. All mammals studied, except european badger due to amorphous cellular structure and morphological structures of hair have smooth scale margin. Irregular rippled scale pattern can be observed in all studied species except Bovidae family and wild boar. The pattern of cuticle in the entire hair length of the Bovidae family and wild boar is regularly waved. De Marinis and Asprea (2005) found regularly waved pattern of cuticle in all Cervidae species. But we found them irregularly waved. Eunok et al. (2014) found irregularly waved pattern of cuticle in wild boar. But we found it regularly waved. The pattern of cuticle in european badger is not visible due to morphological structures of hair. All studied mammal species' cuticle features are listed in *Table 3*.

Table 3. *Cuticle features of 18 mammal species from Turkey*

Species	Position	Scale margin	Scale pattern	Distant between scale margin
Capra aegagrus	Transversal	Smooth	Regular wave	Distant
Gazella subgutturosa	Transversal	Smooth	Regular wave	Distant
Rupicapra rupicapra	Transversal	Smooth	Regular wave	Distant
Capreolus capreolus	Transversal	Smooth	Irregular wave	Distant
Cervus elaphus	Transversal	Smooth	Irregular wave	Distant
Dama dama	Transversal	Smooth	Irregular wave	Distant
Sus scrofa	Transversal	Smooth	Regular wave	Distant
Canis aureus	Transversal	Smooth	Irregular wave	Near
Canis lupus	Transversal	Smooth	Irregular wave	Near
Vulpes vulpes	Transversal	Smooth	Irregular wave	Near
Lynx lynx	Transversal	Smooth	Irregular wave	Near
Panthera pardus	Intermediate	Smooth	Irregular wave	Near
Martes foina	Transversal	Smooth	Irregular wave	Near
Meles meles	Transversal	Not visible	Not visible	Near
Lutra lutra	Transversal	Smooth	Irregular wave	Near

We studied the hair structures of eighteen species representing four mammalian orders and nine families including Bovidae, Cervidae, Suidae, Canidae, Felidae, Mustelidae, Ursidae, Leporidae, and Sciuridae. The identification key was developed by using Turkey's 18 mammal species' hairs medulla and cuticle patterns (*Fig. 2*).

Order	Family	Medulla	Cuticle
Artiodactyla	Bovidae				Wild goat (*Capra aegagrus*)	
					Goitered gazelle (*Gazella subgutturosa*)	
					Chamois (*Rupicapra rupicapra*)	
	Cervidae				Roe deer (*Capreolus capreolus*)	
					Red deer (*Cervus elaphus*)	
					Fallow deer (*Dama dama*)	
	Suidae				Wild boar (*Sus scrofa*)

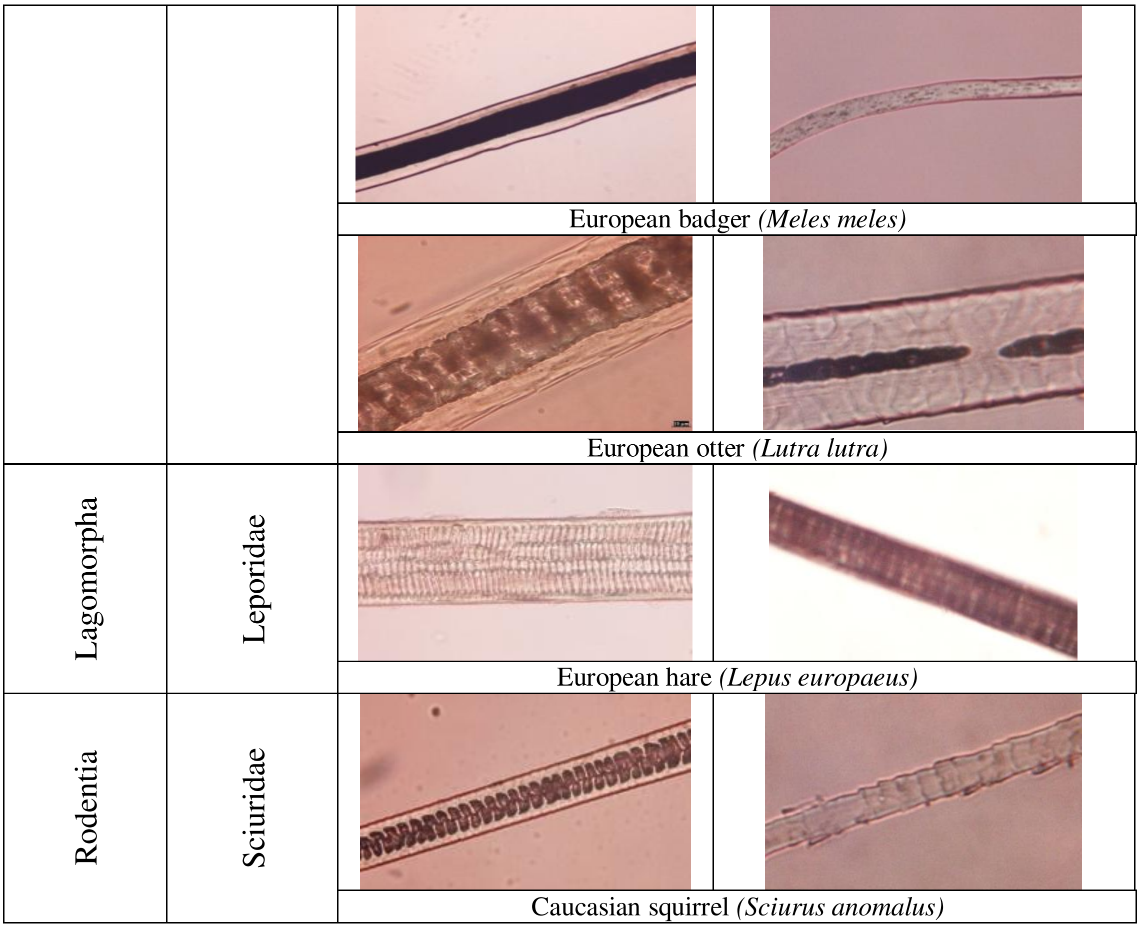

Figure 2. *Medulla (left) and Cuticle (right) patterns used in our hair key to identify common mammal species of Turkey*

Conclusions

No studies have constructed identification keys of mammal hair until this time in Turkey. Mammalian species formed by hair identification key occur in major ecosystems of Turkey such as forests, steppe, grasslands, meadows, alpine, high mountains and rivers and experience a wide range of threats. However, ecology, taxonomy, distribution, population sizes and statutes of those species are uncertain due to limited research. With this study, mammalian species can be easily identified by looking at the hair samples in the scats obtained from field studies, and they will be able to get information about their ecologies.

Our hair key allows hair identification based on morphological structures which are clearly recognizable, considering the hair medulla and cuticle. The present research provided a basic guide for wildlife researchers in ecological studies and population management of prey and predators. The techniques employed in this study are relatively simple and can be easily, quickly and economically applied in routine investigations making it suitable for wildlife studies. It is difficult to determine the species from the hair in the scats with the naked eye except for some species which have hard and thick due to variations considerably hair structures between species. Use of hair identification key will be helped to determine the species.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_45934603

In Turkey, wildlife studies on mammalian species are still not enough. Therefore, our hair identification key will be helped to provide basic ecological information for sustainable wildlife conservation and management. The present research provided a basic hair identification key for further research in wildlife studies.

(Received 18th Jan 2018; accepted 25th Apr 2018)

Abstract. Knowledge about weed density and composition plays an important role in weed management decision making. Surveys were carried out to study the weed flora composition in rice fields of Guilan Province in Iran. 481 fields from 16 regions were selected for survey. Weed samples were taken with a W-shaped sampling pattern. Weed species were identified and the plant density, percentage frequency, uniformity, and abundance indices were determined. Biodiversity was calculated using Shannon-Weiner (H′) and Simpson (D) diversity indices. A total of 66 species, belonging to 43 genera and 29 families were identified. The highest number of weeds belonged to the two families Cyperaceae and Poaceae with 15 and 8 species, respectively. The most frequent weed species were *Echinochloa crus-galli* (89.8%), and *Paspalum distichum* (79.4%), *Echinochloa oryzoides* (60.3%), *Cyperus difformis* (56.5%), *Ecliptal prostrate* (49.5%), *Cyperus serotinus* (34.7%), *Azolla filiculoides* (34.5%), *Sagittaria trifolia* (31.6%), *Cyperus esculentus* (31.6%) and *Alisma plantago-aquatica* (28.7%). Relative abundance index indicated that the annual weed species were more dominant than the perennial ones. Based on Shannon-Weiner and Simpson's diversity indices Talesh area had the highest weed diversity (H′ = 2.85; D = 0.916) and Rudbar showed the lowest diversity values (H′ = 1.97; D = 0.749).
Keywords: *abundance index, density, dominance, rice fields, sustainable agriculture*

Introduction

Rice is the primary staple food for more than half of the world's population and provides 20% of the total calorie intake of people in the world (Dass et al., 2016). More than half of the world's rice is produced in Asia (Awan et al., 2015). In Iran also rice is the main staple food in most parts of the country. There are almost 600,000 hectares of rice plantation in Iran with a total production of 2,540,000 tons (FAO, 2016). More than 75% of the rice crop is grown in the Provinces of Mazandaran and Guilan, north of Iran. Weeds are considered as the most important challenge to rice production in Iran (Yaghoubi et al., 2010; Tshewang et al., 2016). The mean reduction in rice yield caused by weeds competition is 40-60%, which may reach 94-96% if weeds are not properly controlled (Chauhan et al., 2011). Rice yield reduction resulting from weed competition may vary depending on rice planting methods, type of weed, degree of importance of the weed, agricultural operations, and weather conditions (Jabran and Chauhan, 2015). Information regarding spatial variation of weeds plays an important role in increasing efficiencies of weed management methods. The four main pillars of management suitable for the location of interest are collection of information, its analysis, adoption

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_46054617

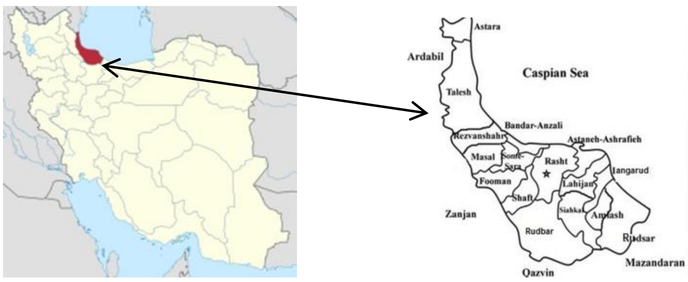
of suitable decisions, and applying management practices based on obtained information (Mohammaddoust Chamanabad, 2011).

Weed community and its distribution in rice fields are determined by the planting method, moisture regime, land preparation, and crop management (Matloob et al., 2015). Weed succession and distribution patterns in rice fields are dynamic in nature, and weed flora composition may be region-dependent (Begum et al., 2008; Uddin et al., 2010). Information concerning presence or absence of weeds, their composition, abundance, importance, and rank depends on weed management strategies and mean rice yield (Begum et al., 2006). Poggio et al. (2004) believe that structures of weed communities and their diversity are determined by environmental and management factors and by interspecific competition between weeds and crop plants and intraspecific competition between plants of the same weed species. Rao et al. (2007) stated that there was a broader spectrum of variation and diversity in rice weeds in direct seeding areas compared to transplanted areas. Weed flora composition in agricultural systems results from seasonal changes, crop rotation, and long-term environmental changes such as soil erosion and climate change. Agricultural operations such as plowing, the crop plant species growth, weed control methods, and fertilizer application changes the natural distribution pattern and availability of resources and, hence, change the structure and composition of plant species (Ahmadvand, 2005; Kraehmer et al., 2016; Lal et al., 2014 Noroz zade et al., 2008). Accurate determination of weed distribution pattern and density at each location is of great importance. Therefore, before any action is taken, the necessary maps of weed distribution pattern and density must be prepared (Lass et al., 1993).

However, detailed information on the presence, composition, abundance, importance and ranking of weed species especially in Guilan province with around 230000 hectare rice fields is rare. Understanding the sociological structure of weeds in rice fields is a pre- requisite for its effective management. Weed management can be an effective step in increasing production and hence in preserving the actual potential yields of crop plants thus increasing production. The objective of this study is to investigate rice weed community richness and composition in the Guilan province, Iran during 2014 and 2016 and their relationships with management.

Materials and methods

The study was conducted in Guilan province, Iran, which is situated in the north of Iran, South of the Caspian Sea and occupies about 14,044 km by area. Guilan Province is located between 36° 34' to 38° 27' latitudes and 48° 53' to 50° 34' longitudes *(Fig. 1)*.



Iran

Guilan

Figure 1. *Geographic map of Guilan province*

DOI: http://dx.doi.org/10.15666/aeer/1604_46054617

Guilan province has the best type of weather and soil with moderate and humid climate typically known as the moderate Caspian climate. The annual average rainfall is 1356 mm, the annual average temperature is 16.1 °C. During the springs and summers of 2014, 2015 and 2016, when the current study was being done, temperature ranged from 16 to 29.4 °C, monthly average rainfall recorded 213 to 853 mm, average sunshine hours 3320, and relative humidity averaged 45-87%.

The chemical and physical attributes of the soil at the study sites are given in (*Table 1*).

Table 1. *Physico-chemical properties of soil in regions of Gilan province*

Based on the area under rice cultivation in each site of this province, 481 fields were selected from 5 days after transplantation to the end of panicle formation. Weeds in rice fields include annuals and perennials. In each growing season, seeds were sown in the seedling nursery and 21- day-old seedlings were transplanted with 2-3 seedlings per hill. Taking the area of each field into consideration, 0.25 m^2 quadrats were done to take samples using a W-shaped sampling pattern. The weeds in each quadrat were counted and their genera and species were identified. The frequency, field uniformity over all fields, density of the weeds in each field, the mean weed density of the visited fields, and relative abundance of the various species in each County were calculated using the following equations (Thomas, 1985):

Frequency (F) indicates the ratio of the number of fields having a specific weed species to the total number of the fields, and is expressed in terms of percentage. Frequency is concerned with the presence or absence of a species in a quadrat, a field, or a region, and does not refer to the number or quantity of the species (*Eq. 1*):

$$F_k = \sum (Y_i/n) \times 100 \qquad \text{(Eq.1)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_46054617

In above equation, F_k represents the frequency of the species, Yi the presence or absence of the species, and "n" the number of visited fields.

Uniformity (U) expresses the percentage infestation of the field by the species of interest and shows the surface area occupied by the weed (*Eq. 2*):

$$U_k = (\Sigma\Sigma X_{ij}/m_i) \quad \text{(Eq.2)}$$

In *Equation 2,* U_k is the uniformity of the field for the species k, X_{ij} the presence or absence of species k in quadrat "j" and in field "i".

Density refers to the counted individuals of each species m^2 in the field of interest (*Eq. 3*):

$$D_{ki} = \left(\frac{\Sigma Z_j}{m_i}\right) \times 4 \quad \text{(Eq.3)}$$

In *Equation 3,* Dki stands for the density of species k in field i and Z_j the number of plants in quadrat j.

Mean density indicates the average number of plants belonging to each species m^2 of the visited fields (*Eq. 4*):

$$MD_{ki} = \left(\frac{\Sigma D_{ki}}{n}\right) \quad \text{(Eq.4)}$$

In the above relation, D_{ki} represents density in each field and "n" the total number of visited fields.

The coverage value indicates the coverage of plants m^{-2} for floating and submerged species averaged over fields sampled (*Eq. 5*):

$$MC_{ki} = \left(\frac{\Sigma C_{ki}}{n}\right) \quad \text{(Eq.5)}$$

In *Equation 5,* C_{ki} represents the coverage of plants m^{-2} for floating and submerged species and "n" the total number of visited fields.

Relative abundance (RA) was used to rank the weed species in the survey and it was assumed that the frequency, field uniformity, and mean field density measures were of equal importance in describing the relative importance of a weed species (*Eq. 9*). This value has no units but the value for one species in comparison to another indicates the relative abundance of the species (Hakim et al., 2013). The relative frequency (RF), relative field uniformity (RFU), and relative mean field density (RMFD) were calculated (*Eqs. 6-8*) by dividing the parameter by the sum of the values for the parameter for all species and multiplying by 100 (Nagaraju et al., 2014).

$$RFk = \frac{\text{Frequency value of species}}{\text{Sum of frequency values for all species}} \times 100 \quad \text{(Eq.6)}$$

$$RFUk = \frac{\text{Field uniformity value of species k}}{\text{Sum of field uniformity values for all species}} \times 100 \quad \text{(Eq.7)}$$

DOI: http://dx.doi.org/10.15666/aeer/1604_46054617

$$\text{RMFDk}=\frac{\text{Mean field density value of species k}}{\text{Sum of mean field density values for all species}}\times 100 \qquad \text{(Eq.8)}$$

$$\text{RA}_k = \text{RFk} + \text{RFUk} + \text{RMFDk} \qquad \text{(Eq.9)}$$

One of the common methods for studying diversity of plant communities in the ecology of weeds and species uniformity and richness in agricultural ecosystems is to using the Simpson index and the Shannon-Wiener index. Species richness (S) was measured by the mean number of species per treatment (Magurran, 1988). The Simpson index (D) gives more importance to the common species, but the Shannon-Wiener index (H') puts greater importance on rare species and is calculated by *Equations 10* and *11* (Poggio et al., 2004).

$$H' = -\sum_{i=1}^{s}\left(Pi\ Ln(Pi)\right) \qquad \text{(Eq.10)}$$

$$D = 1 - \sum_{i=1}^{s}(Pi)^2 \qquad \text{(Eq.11)}$$

In these equations, Pi represents the relative abundance of a specific species (the i^{th} species) that is calculated as –Pi = ni/N, and Ln is the natural logarithm. In the values obtained for the Shannon-Wiener index, the larger values indicate greater diversity in the weed communities (of the related County). After calculating the Shannon-Wiener index for every County, the Pielou index (E) has been used to determine the uniformity of the community (*Eq. 12*) (Booth et al., 2003).

$$E = \frac{H'}{ln\ S} \qquad \text{(Eq.12)}$$

H' represents the Shannon-Wiener index and S the number of weed species observed in each community (County), and logarithm of S is used in this relation (Magurran et al., 1988). As for the uniformity of the weed community in each County, the closer the obtained value gets to zero the more non-uniform the community is (one weed species is dominant in the community). However, the closer the obtained values are to 1, the more uniform the community will be (we witness the highest species diversity and lack of dominance of a specific weed species) (Mesdaghi et al., 2005; Tang et al., 2014).

After collecting the data and making the calculations required for determining the population indices, this information created the main layer in the project, and was then designed in the format of a databank.

Results

In the present research, a total of 66 species, belonging to 43 genera and 29 families were collected from the 16 representative sites (*Tables 2* and *3*). Thirty- four of the identified species were annuals and 22 perennial species. Moreover, 11 species were

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_46054617

grass weeds, 17 sedges, 30 broad-leaved species, 4 ferns, 2 vascular gymnosperms, and 2 algae (*Tables 2* and *3*). With respect to life cycle, annual weeds with 34 species were the most diverse. Cyperaceae were the largest family representing with 15 species, followed by Poaceae with 7 species, Lythraceae with 5, Polygonaceae with 4, Asteraceae and Salviniaceae with 3 species and others families with 2 or 1 species (*Tables 2* and *3*). Weeds have non-uniformly distributed in various families including Cyperaceae, Poaceae, Lythraceae, Polygonaceae, Asteraceae, and Salviniaceae that accounted for 36 species (54.5%).

Species with higher abundances had greater uniformity. Among the grass weeds, the most frequent weed species is *E. crus-galli* (89.8%) (*Table 2*), followed by *P. distichum, E. oryzoides* with frequency higher than 50%. *Echinochloa spp* are of the weeds that appear immediately after rice sowing or transplanting (Yaghoubi and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_46054617

Farahpour, 2013). And may compete heavily with the rice for nutrients, space, light and water. The most frequent observed species among the sedges were *C. difformis* with 56.5%, *C. serotinus* and *C. esculentus* with frequency of 34.5 and 31.6%, respectively. Among broad-leaved weeds *E. prostrata*, *S. trifolia*, and *A. plantago-aquatica* respectively with 49.5, 31.6, and 28.7%, frequency, were the most abundant weeds (*Table 2*). Among the floating and submerged species, *A. filiculoides*, *L. minor*, and *P. nodosus* with frequently of 34.1, 28.3, and 19.33%, respectively, were the most frequent observed species (*Table 3*).

C. difformis and *P. distichum* were the most abundant species with 9 and 8 plants m^{-2}, respectively. *E. crus-galli* and *C. esculentus* with a density of 5 plants m^{-2}. *E. prostrate* and *Monochoria vaginalis* were the other weed species with more than 2 plant m^{-2}. While other weed species varied from 0.003 to 1.91 plants m^{-2}. Weeds density was very variable for different species (*Table 2*) and it is an important factor for adoption any decision for weed control. Uniformity refers to quantitative measurement of weed distribution in fields and relative abundance values quantify the predominance of a given weed species in a environment by calculating the frequency, field uniformity, and density of a particular weed species relative to all over species observed. *E. crus-gall, P. distichum, C. difformis, A. filiculoides, E. prostrata, E. oryzoides, L. minor, C. esculentus, C. serotinus, S. trifolia, M. vaginalis*, respectively, had the highest uniformity in rice fields of Guilan (*Tables 2* and *3*). Among the grass weeds, uniformity and relative abundance for *E. crus-galli* were 34.7% and 31.18, *C. difformis* with 22.8% and 24.56, respectively, had the highest uniformity and relative abundance among the sedges (*Table 2*), and *A. filiculoides* was present with the highest uniformity and relative plant coverage of 18.5 and 24.3%, respectively, among the floating and submerged weeds (*Table 3*). The most important weeds with high RA value in rice fields were *E. crus-galli* (31.18), *P. distichum* (29.28), *C. difformis* (25.56), *E. prostrate* (13.7), *E. oryzoides* (13.28), and, *C. esculentus* (13.25) (*Fig. 2*).

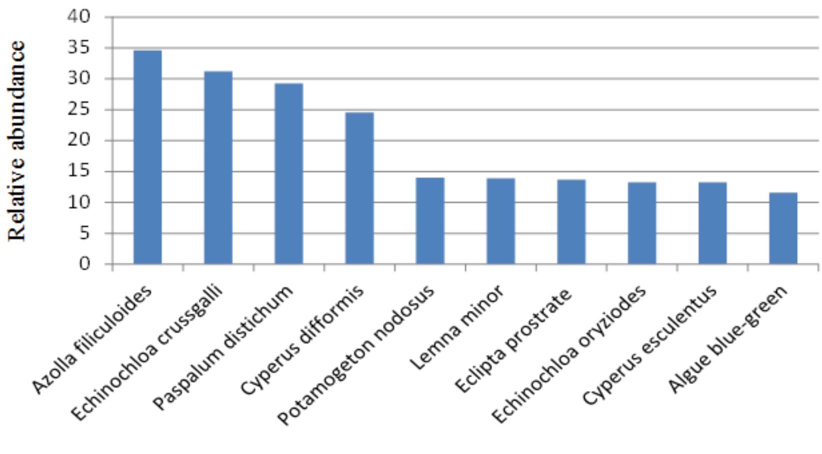

Figure 2. *Top 10 important weed species in rice fields of Guilan Province, Iran*

Rudsar and Langarud regions were the most dominant site registering a total of 47 weed species followed by Rasht and Lahijan (46 sp.), Astaneh-ye Ashrafiyeh (42 sp.), Amlash (37 sp.), Talesh (36 sp.), Foman and Siahkal (34 sp.), Rudbar (32 sp.), Rezvanshahr and Sowme'eh Sara (30 sp.), Masal (28 sp.), Astara (27 sp.) and Shaft and Anzali (25 sp.). The Simpson and the Shannon-Wiener distribution indices had the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_46054617

highest values in Talesh and the lowest in Rudbar regions (*Table 4*). It shows that weed diversity was the highest and the lowest in these regions. The Shannon-Wiener index gives greater importance to rare species, and the smaller the value of this index for the relative abundance of a species the rarer the species will be *E. arvense*, *G. aparine*, *S. valerandi*, and *Ch. vulgaris* were among the most rarely found species.

Table 4. *Quantitative indices of weed distribution in various regions of Guilan Province*

Item	Area	Shannon-Wiener index	Simpson index	Pielou index	Species richness
1	Talesh	2.850	0.916	0.795	36
2	Rezvanshahr	2.740	0.909	0.806	30
3	Foman	2.590	0.896	0.734	34
4	Rudsar	2.640	0.892	0.686	47
5	Siahkal	2.530	0.885	0.717	34
6	Langarud	2.450	0.877	0.640	47
7	Astaneh-ye Ashrafiyeh	2.580	0.874	0.690	42
8	Amlash	2.360	0.865	0.654	37
9	Astara	2.230	0.863	0.677	27
10	Rasht	2.420	0.858	0.632	46
11	Lahijan	2.420	0.843	0.632	46
12	Sowme'eh Sara	2.340	0.834	0.688	30
13	Masal	2.645	0.904	0.792	28
14	Shaft	2.050	0.815	0.637	25
15	Anzali	1.990	0.787	0.618	25
16	Rudbar	1.970	0.749	0.568	32

In the present research, *Echinochloa spp* was the most common weed in rice fields of Guilan province, and Langarud and Rudsar Counties each with 47 species and Anzali and Shaft with 25 species (with 71.2 and 37.9%, respectively) had the highest and lowest species diversities. Rezvanshahr city was 0.806 and Rudbar city with 0.568 highest and lowest levels of Pielou index (*Table 4*). As for the Simpson index, any species that is more dominant has a greater relative abundance. This index gives greater importance to the more common species.

Discussion

During the last century, more than 1,800 species were identified in rice fields (Kamoshita et al., 2014). Tshewang et al. (2016) reported weeds in fields in Bhutan included 27 species (13 annual and 14 perennial species) belonging to 10 families. In a study conducted in rice fields of Egypt, 71 weed species were identified, and it was reported that the largest percentages belonged to the Poaceae, Asteraceae and Cyperaceae families with 28, 9, and 7%, respectively. It founded that various factors including the environment, soil, and biological factors such as soil structure, pH, nutrients, and moisture, type of crop, and history of grown crops influenced weed diversity (Hakim et al., 2010; Turki et al., 2002). *E. colona* constituted about 60% of the weed population 60 days after transplantation. In the research by Matloob et al. (2015),

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_46054617

D. aegypticum, E. colona, and *E. crus-galli* were more common than other grass weeds. In our study, the most common grass weeds were *E. crus-galli, P. distichum* and *E. oryzoides. C. serotinus*, which has also been reported from some Asian countries and from Italy, is apparently confined to transplanted rice. Yakup (2007) reported 70 weed species from rice fields in western Java, with the broad-leaved, Cyperaceae, and grass weeds having the largest number of species. Dominance and relative population of broad-leaved weeds increased by about 62% more than grass weeds and sedges 30 days after rice was transplanted (Singh et al., 2008). In Malaysia, grass weeds formed more than 80% of weed communities in direct seeding of rice. Broad-leaved weeds are more dominant than grass weeds and sedges in direct rice-sowing (Matloob et al., 2015). Scirpus species play an important role among weeds in rice fields (Schaedler et al., 2015), and Begum et al. (2006) reported that *F. miliacea* and *Scirpus grossus* were the most common weeds among the sedges emerged by the change from transplanting to direct rice-sowing in some regions of Malaysia. Singh et al. (2008) observed that most common weeds in rice fields were of annual types that were able to survive even under unfavorable conditions and complete their life cycle from seed to seed during one growing season. All weed species are not identically present in crop plants. *Echinochloa spp* and weedy rice are the most common weeds in rice fields of the world (Kraehmer et al., 2016). In the present study, *E. crus-galli* and *E. oryzoides* were the most dominant weeds. It seems that weedy rice cannot survive in transplanted rice mainly because of handweeding. Kraehmer et al (2016) stated that *C. rotundus, C. iria, and C. difformis* were the most frequent observed Cyperus species in rice fields. In another report submitted by Kraehmer et al. (2016), it was stated that the genera Alisma, Heteranthera, Monochoria, and Sagittaria constituted the most frequent found broad-leaved weeds in rice fields. In our study, the weeds of *E. crus-galli, P. distichum, E. oryzoides, C. difformis, A. filiculoides, A. plantago-aquatica, E. prostrate, C. esculentus, C. serotinus, Xanthium strumarium, Lemna minor* were dominant species. Nithya and Ramamoorthy (2015) identified 23 weed families in rice fields among which nut-grass (*C. rotundus*) was the most dominant because of its biological and physiological characteristics. Despite presence many sedges in our study, *C. rotundus* is not listed here probably because of not being able to survive in flooded rice. Rabbani et al. (2011) collected 20 weed species from five locations in the Punjab region of India and noticed that *C. difformis, E. colona, Euphyllia glabrescens, Cynodon dactylon*, and *P. paspaloides* had the highest abundances in at least 60% of the fields. The following weeds are economically important in India: *E. crus-galli*, *E. colon*, *Cyperus spp*., *Alternanthera spp*., *C. rotundus, Commelina benghalensis, Caesulia axillaris, Ammania spp., Dnebra spp., E. prostrata, F. miliacea,* and *Dactyloctenium aegypticum* (Rao et al., 2015). Begum et al. (2006) reported that *Oryza sativa* L. (weedy rice), *E. crus-galli*, *Leptochloa chinensis*, *L. hyssopifolia*, and *F. miliacea* were the most frequent found species with abundances higher than 30%. *Wolffia globosa* was the most abundant weed in rice fields of North Costal Andhra Pradesh (Nagaraju et al., 2014). Wicks et al. (2003) reported that mean densities of weeds were less than 9 plants m^{-2}, but some species had a higher mean density than the average. Uddin et al. (2009) stated that densities of most species were higher compared to the total weed density. Uddin et al. (2009) stated that *C. compressus* and *C. aromaticus* with 16.7 and 43.6%, respectively, had the highest uniformity. Most of the weeds that had the highest frequencies, uniformity, and mean density in the field are hard to control (Hakim et al., 2013). This is confirmed by the problematic weeds in terms of relative abundance in the rice agro-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_46054617

ecosystems. Kandibane et al. (2007) identified 17 weed species in rice fields with *E. colona*, *C. rotundus*, *C. iria*, *C. difformis*, *Panicum repens*, and *Brachiaria mutica* the more dominant ones. Considering the dominance of several weed species in rice fields of Guilan Province and the low values of the index, we can consider unsuitable management of weeds and consecutive rice growing one of the reasons why these species have become dominant. Rezvanshahr and Rudbar had the lowest values of the Pielou index (E = 0.806 and E = 0.568, respectively) (*Table 4*). In Kashmir, the Bandipora and Anantang districts had the highest and the lowest values of the Shannon-Wiener index (H' = 3.755 and H' = 3.271), respectively (Bahaar and Baht, 2012). A study in the greenhouse conducted, floristic diversity was greater *ex situ* (H'= 2.66) than *in situ* (H'=2.53). The high number of weed species found *ex situ* contributed to the great floristic diversity in this area (Mesquita et al., 2013).

The Simpson index had the values of 7.82, 6.82, 6.56, and 6.12 in Kiliyanur, Thailapuram, Thensiruvallur, Aadhanapattu, and Konthamur, respectively, whereas the highest value of the Shannon index (2.46) was that of Kiliyanur. Of the 56 identified species belonging to 23 plant families, 37 species were present in Kiliyanur, 45 in Thensiruvallur, 30 in Thailapuram, 28 in Konthamur, and 32 in Aadhanapattu. Nithya and Ramamoorthy (2015) stated that the Simpson index allowed better comparison between various areas compared to the Shannon-Wiener index. In the present study, *C. difformis*, *P. distichum, E. crus-galli, A. filiculoides* and *C. esculentus* had the highest values of the Simpson index among the 66 weed species identified in the rice fields.

Conclusion

Weed flora composition in rice fields of 16 counties in Guilan Province includes 66 species belonging to 29 families. Eleven species, three grass (narrowleaf) species (*E. crus-galli*, *P. distichum*, and *E. oryzoides*), three sedge species (*C. difformis*, *C. serotinus*, and *C. esculentus*), four broad-leaved species (*E. prostrata*, *S. trifolia*, *A. plantago-aquatica*, and *P. nodosus*), and one fern species (*A. filiculoides*) were the most widespread and of the highest abundances. Depending on weed management, weed growth in transplanted rice begins around 5 days after pulling or transplanting. Perennial weeds such as *P. distichum, P. nodosus, A. filiculoides,* and *B. umbellatus* new species with high density and tolerance to flooding the main tool for weed control in transplanting rice cause numerous problems like using more herbicides and repeating the handweeding in rice fields Every year, due to lack of awareness of the identification and effective factors on weed control of farms, their population is increasing. Therefore, the study of the role of management in the restructuring of communities and species diversity of weeds can be useful in developing strategies and management of weeds.

(Received 27th Feb 2018; accepted 11th Jul 2018)

Abstract. Penang Island has witnessed rapid urban development and economic growth in recent years. With the ambitious vision to become a developed country by 2020, planners and policy-makers need to know the most likely direction of future urban development without compromising on the forest landscape. In this study, remotely sensed data combined with cellular automata models were used to predict the land use land cover change in Penang Island, Malaysia. Cellular Automata (CA)-Markov models were applied in 1990 and 2006 to predict the land cover in 2016. Land use land cover maps for the study area were derived from 1990, 2006, and 2016 Landsat Images (MSS, TM, and OLI). The accuracy of models is above 80%. A Markov model was applied in 2006 and 2016 to predict the land cover in 2042. The results indicate that the built-up area had expanded more in the east towards the north and south, and also towards the centre of the island and moving upwards to the north. The models suggest limiting urban development in the centre of the island to protect forest landscapes. This study serves as guidelines for other studies which attempt to project land use land cover change in forest landscape while experiencing similar land use changes.
Keywords: *Penang Island, CA-Markov, land use land cover change, accuracy, future land use*

Introduction

Environmentalists and landscape planners who are knowledgeable about land use and land cover (LULC) change are concerned that LULC can affect the global environment (Guan et al., 2011). Majority of the causes leading to biodiversity loss is due to changes in land use which are associated with habitat loss and fragmentation (Sala et al., 2000). Deforestation, urbanisation, agriculture intensification, as well as overgrazing and subsequent land degradation are all classified as land use changes in anthropogenic origin. The existence of nature, viz: slope and elevation are also involved in the change (Lambin, 1997), thus making the dynamics of land use a complex process. This complication which caused the LULC dynamics to change originates from economics, politics, culture and society as well as other legal aspects (Lambin, 1997). However, the main causes of land and forest degradation are severe changes made to urbanisation and agriculture. Such decline in natural resources which affects the environment quality through air pollution (Wu et al., 2012), water pollution (Hua, 2017), and can influence the climate are man-made changes (Angelsen and Kaimowitz, 1999). Therefore, having a good knowledge of land use land cover will be useful in providing information when decision making for using and managing the land use resources (Lu et al., 2004).

A sudden growth in distant senses data in temporal, spatial and spectral resolutions appears to be beneficial as it provides essential tools for identifying changes on the Earth's surface at different scales (Wu et al., 2006; Rogan and Chen, 2004). Several suitable approaches that have been used to model the land use land cover changes by

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_46194635

using remotely senses data are; statistical models (regression and structure equation model), mathematical models (linear and static), systems model (stock and flow), agent based models cellular models (Cellular Automata (CA) and Markov Chains), and evolutionary models (neural networks) (Parker et al., 2003; Agarwal et al., 2002). Roger and Chen (2004) cited that digital change detection is defined as the process of determining and describing the changes in land use characteristic based on co-registered multi-temporal remote sensing data. These techniques used for assessing change are numerous including both statistical and rule-based methods (Coppin et al., 2004; Rogen and Chen, 2004; Lu et al., 2004).

Modeling LULC change

To detect changes that have happened or are about to take place, LULC change models are used (Veldkamp and Lambin, 2001). These change models involve analysing historical land use data where the past land transformation and transition are evaluated. The transition trend which has been identified is amalgamated with environmental variables to provide an estimate of future land use (Eastman, 2009; Pijanowski et al., 2002). Having an understanding of the factors of change (i.e population growth, soil type, distance to road or other facilities), the models have the ability to provide a probabilistic prediction of where the changes may happen (Overmars et al., 2003). LULC model which was designed to evaluate the cumulative impact of land use change and develop future activities (Veldkamp and Lambin, 2001) which are essential in helping and supporting decision making of land use planning (Guan et al., 2011). In particular, LULC change have been forecasted to be important for understanding and highlighting of potential modifications and alterations that might happen over landscapes in the future. LULC changes have been applied in different situations viz; rural development and urban growth (Kityuttachai et al., 2013), selecting conservation priority areas and setting alternative conservation measures (Adhikari and Southworth, 2012) and simulating rangeland dynamics under different climate change scenarios (Halmy et al., 2015; Freier et al., 2011).

To understand better the dynamics of land use change at different angles, the Markov chain analysis has been extensively used (Baker, 1989; Muller and Middleton, 1994). This chain analysis works on the probability of a system being in a certain state at a certain time can be determined, if the state at an earlier time is known (Bell and Hinojosa, 1977). To put it simply, this method develops a transition probability matrix of land use change between two different dates by providing an estimation of probability that each pixel of certain LULC class will be transformed to another or remains in the class (Eastman, 2009). This method has an added advantage in modeling land use change especially on a large scale (Weng, 2002). Although different from logistic regression, Markov chain analysis cannot assume statistical independence data (Overmars et al., 2003) but is suited for spatial dependent land use data but has the ability to forecast all multidirectional land use changes among all classes land use available (Pontius and Malanson, 2005). One problem that can arise when using Markov chain models is that this method is more suitable for short term projections (Sinha and Kimar, 2013) and not spatially explicit especially not providing the spatial distribution of the changes (Sklar and Costanza, 1991). However, this problem can be overcome by integrating with other different dynamic empirical models e.g. cellular automata models (Guan et al., 2011; Weng, 2002). The CA- Markov is regarded as a spatial transition model as it contains the stochastic aspatial Markov techniques with the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_46194635

stochastic spatial cellular automata method (Eastman, 2009) which is capable of predicting the two-way transitions among the available LULC classes (Pontius and Malanson, 2005). Therefore, the main purpose of this study is to demonstrate the ability of CA-Markov models to predict the LULC changes for year 2042 with special attention on the ecologically impaired forest land in Penang Island, Malaysia.

Materials and methods

Study area

Penang Island is located in the northern part of Malaysia which lies within a latitude of 5°12'N to 5°30'N and longitude of 100°09'E to 100°26'E (*Fig. 1*). The total area of Penang Island is approximately 295 km^2, and is also the most populated island in the country with an estimated population of 720 000 (Tan et al., 2011, 2010). George Town is the main capital city which is located in the east region of Penang Island. Generally, Penang Island enjoys an equatorial climate with hot and humid conditions throughout the entire year. In other words, the average mean of daily temperature is about 27 °C, with a maximum and minimum average mean of daily temperature at 31.4 °C and 23.5 °C respectively. Specifically, the average annual temperature varies between 27 to 30 °C (Tan et al., 2011, 2010). Meanwhile, the average humidity is between 70 to 90%, and having the daily mean humidity between 60.9 and 96.8% (Tan et al., 2011, 2010). The average annual rainfall is 267 cm, and the annual total can reach up to a maximum of 624 cm (Ahmad et al., 2006). When the monsoon winds arrive, the population of Penang Island experienced sunshine during the day and rainfall in the evenings.

Figure 1. *Study area of Penang Island*

Since George Town constitutes a unique architectural and cultural townscape in the country, the island received recognition from UNESCO World Heritage Site as one of the tourism centres in Malaysia. This recognition will help to increase the number of visitor arrivals to Penang Island. Nevertheless, an increase in population will increase in the built up area and decline in forest land. Generally, the total area of forest land is approximately 154 km^2 with a population density of 132 persons per km^2. Forest land (41%) was the predominant land use in Penang Island, followed by urban area (18%), agriculture area (8%) and water bodies (33%) in 1990. Urbanisation and agricultural practices indirectly had a negative impact on the fate of ecology and biodiversity of the forestry land. The main reasons for choosing Penang Island for LULC change prediction are the rapid population growth, availability of data sets with zero cost, and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_46194635

ecological of forest land impaired (Tan et al., 2011, 2010). According to Tan et al. (2011, 2010), the growing population rate between the year 2000-2010 was higher than the years from 1990-2000 and will continue to increase in the coming future as well as the infrastructure of development. Therefore, identifying the potential areas that are likely to be converted into other land use classes would benefit the decision makers and landscape planners as references and guidelines for the policies to be designed in a better way for sustaining the ecology integrity of forest land.

Data sources

Three LULC vector data sets for Penang Island for 1990, 2006 and 2016 (*Table 1*) were taken from USGS Earth Explorer. But the land use was grouped into four classes, namely built-up area, agriculture area, forest land, and water bodies while the road vector data was used to generate the land change suitability maps. Generally, images for classification were chosen between the months of February to April because of clear sky or cloud free during this period. All the dataset was rectified to Universal Transverse Mercator (UTM) coordinate system, Malaysian Cassini State Plane zone 03, and WGS 1984 Datum and clipped to the island boundaries. For this particular study, different software packages were applied as each one has its strength in certain operations needed for analysis. ENVI v4.7 was used for the classification of images and accuracy assessment; IDRISI Selva v.17 was used for CA-Markov modeling (Eastman, 2009); and ArcGIS v10.1 was used to produce suitable maps and final map. The steps of the research study are shown in *Figure 2*.

Table 1. *Specific of remotely sensed data used for the study*

Sensors	Month/day	Year	Spatial resolution (m)	Path/row	Band combination
Landsat MSS	03/04	1990	60	128/56	1,2,3
Landsat TM	02/21	2006	30	128/56	1,2,3
Landsat OLI	03/20	2016	15	128/56	2,3,4

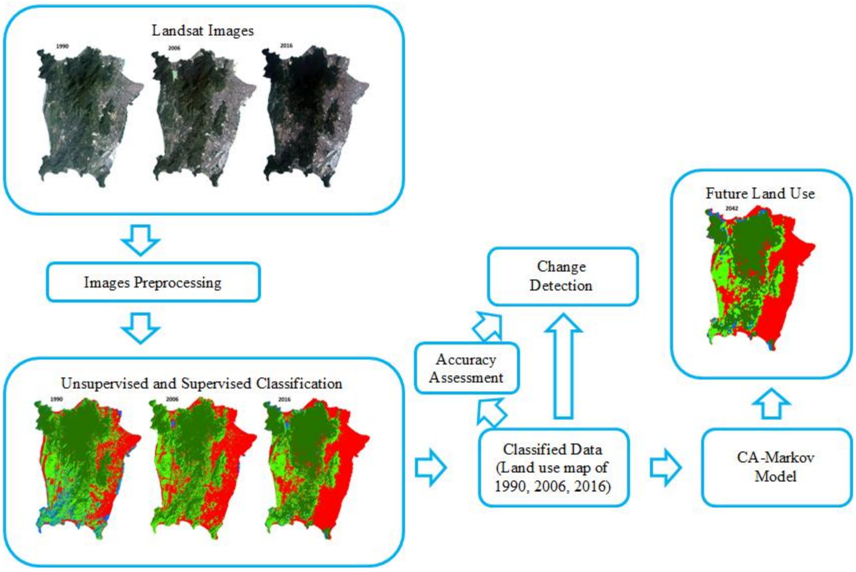

Figure 2. *Demonstration of research methodology as a flowchart*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

Data preprocessing, LULC classification and change detection

To set up a direct link between data and the biophysical phenomena it represents, it is essential to preprocess the satellite images (Parsa et al., 2016). Pre-processing can be achieved by using ArcGIS version 10.1 for geo-referencing, mosaicking and sub setting of the image for the Area of Interest (AOI). The Landsat OLI has experienced spatial sharpening using the panchromatic bands which caused a 15 m resolution. The Landsat MSS and TM images for 1990 and 2006 were originally in 30 m resolution. However, further image processing analysis was carried out using ENVI 4.7. The image appeared in a composite of natural colours using a combination of 3,2,1 for Landsat MSS and TM, and 4,3,2 for Landsat 8. The maximum likelihood supervised and unsupervised classification was performed using several selected regions, and Regions of Interest (ROI) were based on delineated classes of agriculture area, forest land, built up area and water bodies (*Table 2*).

Table 2. *Description of the LULC classes mapped in the study area*

Class name	Description
Vegetation area	Includes all agricultural lands
Forest land	Includes all forest fields
Built up area	Includes all residential, industrial area, commercial, administration, cemetery and transportation, as well as sewage treatment plant (include individual septic tank)
Water bodies	Includes all water bodies (river, lakes, gravels, stream, canals, and reservoirs)

To carry out the LULC change detection, it is proposed to apply the post classification detection method in the ENVI 4.0, for purpose of comparison, by using two classified images to produce change information on a pixel basis. In simple words, the interpretation between the two images will provide changes “from- to” information. All the data were geo-rectified and resampled to ground resolution of 15*15 m for Landsat OLI and 30*30 m for Landsat MSS and TM which was projected toWGS84 UTM with a RMSE of less than 0.5 pixels. Subsequently, the classified images from two different data sets are compared using a cross-tabulation in determining the qualitative and quantitative aspects of changes for the periods from 1990 to 2016. The extent of change and percentage of change can be expressed in a simple formula (*Eqs. 1* and *2*) as follows:

$$K = F - I \qquad \text{(Eq.1)}$$

$$A = \frac{(F-I)}{I}\ x\ 100 \qquad \text{(Eq.2)}$$

where K is the magnitude of changes, A is percentage of changes, F is first data, and I is reference data (Mahmud and Achide, 2012). This research study uses LULC techniques to decide on the differences and to explain the percentage of land use changes with the period of time. Furthermore, the prediction of LULC changes for 2042 will involve IDRISI Selva which will be further explained in CA-Markov model analysis.

DOI: http://dx.doi.org/10.15666/aeer/1604_46194635

Accuracy assessment

To find out the quality of information provided from the classification process, an accuracy assessment for 1990, 2006 and 2016 images was carried out to establish the quality of information taken from the classification process. It is important to conduct an accuracy assessment for individual classification before the change detection analysis (Behera et al., 2012). Kappa tests are used to measure the accuracy of classification as the test is able to account for all elements in confusion matrix including diagonal elements (Halmy et al., 2015). Kappa test measures predefined producer rating and user assigned rating and are expressed in *Equation 3:*

$$K = \frac{P(A)-P(E)}{1-P(E)} \quad \text{(Eq.3)}$$

where *P(A)* is the number of time the *k* raters agree, and *P(E)* is the number of time the *k* raters are expected to agree only by chance (El-Kawy et al., 2011; Pontius and Millones, 2011). Meanwhile, user accuracy is defined as the probability of a pixel on the image actually representing a class on the ground. The producer's accuracy will show the probability a pixel being correctly classified and is mainly used to determine how well an area can be classified (Pontius and Millones, 2011). As mentioned earlier, 4 categories of classes were delineated. Each category have a minimum of 50 points to increase the percentage of accuracy assessment (El-Kawy et al., 2011). Therefore, the accuracies of classification for 1990, 2006 and 2016 are 87.31%, 88.49% and 91.62 with a kappa statistic of 0.86, 0.85, and 0.90 respectively. According to Weng (2010) the lowest level for accuracy assessment in identification of LULC categories in remote sensing should be at least 85%. Then, the data will be imported into IDRISI Selva v.14.0 as an ASCHII text file for further analysis.

Markov model

The Markov model is capable of calculating past conditions and predict on how a particular variable changes over time. This model has been extensively used in ecological modeling (Adhikari and Southworth, 2012; Behera et al., 2012). The uses of the Markov model in LULC change modeling is promising due to its ability to quantify the states of conversion between land use types as well as the rate of conversion among the land use type (Pontius and Malanson, 2005). A homogenous of the Markov model for predicting land use change can be represented mathematically as *Equations 4* and *5* (Sinha and Kumar, 2013);

$$L_{(t+1)} = P_{ij} * L_{(t)} \quad \text{(Eq.4)}$$

and

$$P_{ij} = \begin{bmatrix} P_{11} & P_{12} & \cdots & P_{1m} \\ P_{21} & P_{22} & \cdots & P_{2m} \\ \vdots & \vdots & \vdots & \vdots \\ P_{m1} & P_{m2} & \cdots & P_{mm} \end{bmatrix} \quad \text{(Eq.5)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_46194635

where, $L_{(t+1)}$ and $L_{(t)}$ are the land use status at time t + 1 and t respectively. $0 \leq P_{ij} < 1$ and $\sum_{j=1}^{m} P_{ij} = 1 \ (i, j = 1,2,3 \ldots .m)$ is the transition probability matric in a state.

Cellular automata (CA) model

The cellular automata (CA) model, is an area spatially dynamic model, which is frequently used for LULC change studies. In this model, the transition of a cell from one land-cover to another depends on the state of the neighbourhood cells (Verburg et al., 2004). Generally, a cell has a high probability to change to land-cover class ‘A’ than to a land-cover class ‘B’ if the cell is closer proximity to land-cover class ‘A’. Similar to the Markov Model, the CA applies previous state information of a land-cover as well as the state of neighbourhood cells for its transition rules. Since CA models have been extensively used in LULC changes analysis especially in forest cover change analysis (Verburg et al., 2004; Messina and Walsh, 2001), it has the ability to integrate with the Markov model and make it a dynamic spatial model.

CA-Markov model

The CA-Markov model is a combination between cellular automata, Markov chain, multi-criteria, and multi-objective land allocation to predict land cover change over time (Parsa et al., 2016; Behera et al., 2012). The Markov model is not only spatial contiguity but is also the probable spatial transitions occur in a particular area over a time. Markov and CA-Markov modules in IDRISI Selva were used to create transition probability and transition area matrix (Eastman, 2009). Transition probability matrix is formed by cross tabulation of two images of different time and determines the probability of a pixel in a land use class to change into another class during that time (Parsa et al., 2016; Eastman, 2009). Transition area matrix contains the number of pixels that are expected to change to a land use class from another class during a time period (Parsa et al., 2016; Behera et al., 2012; Eastman, 2009). Land use map dated 1990 and 2006 were used to create transition probability matrix in order to project land use map for the year 2016. In creation transition probability matrix, Markov module in IDRISI Selva was used and the proportional error was set to be 15% (Eastman, 2009).

IDRISI Selva uses CA-Markov model that repeatedly produce the land use allocation until areas that are predicted by the Markov model are identified. The number of times it is repeated depends on the number of years a projection is made. Here in this study, the number of repeated process performed was 9 because the land use map of 2006 was taken as a base map for projecting the land use in 2016. A contiguity filter of a kernel size of 5*5 pixels that accounts the neighbourhood pixels was used to create spatially explicit continuous weighting factors so that the pixels that are far from the existing land use class have a lower suitability than the pixels that are near. In this study, the filter used was for analysis:

0	0	1	0	0
0	1	1	1	0
1	1	1	1	1
0	1	1	1	0
0	0	1	0	0

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_46194635

After a predictive data has been built, the model is then validated to test the accuracy of the model. The process of gauging the accuracy of the model will be illustrated in the validation prediction model section. Then, the techniques of CA-Markov for producing the transition probability matrix and transition area matrix is repeated by using land use map dated 2006 and 2016 to cross tabulate to produce the land use map of the year 2042 (*Table 8*). In other words, the actual land use map of 2016 are used as based map to produce simulated 2042 map of LULC at the study area.

Validation LULC prediction model

For purpose of evaluating and to avoid any miscalculation of the model, it is necessary to investigate between the actual map and simulated map and to compare the output from the model with the actual land use map. The evaluation model is based on the Kappa Index of Agreement (KIA) approach, which is widely used in validation of LULC change predictions (Parsa et al., 2016; Halmy et al., 2015; Behera et al., 2012). Whereas the accuracy assessment process was done using the VALIDATE module in IDRISI Selva. For this study, a simulated land use map of 2016 will be used to compare with the actual land use map of 2016. The results of the comparison between the simulated and actual map for year 2016 can be shown in *Table 3* as well as *Figure 3a* and *b*.

Table 3. *Comparison of actual and projected LULC types in 2016*

Category	2016A (ha)	2016S (ha)
Forest land	110 854	109 350
Built-up area	88 183	83 742

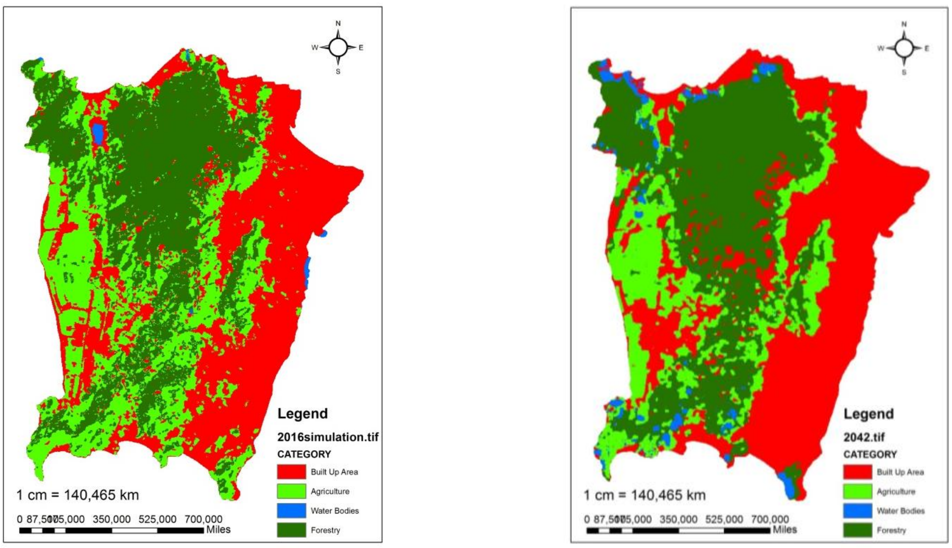
Water bodies	41 971	39 291
Total	295 000	295 000

2016A = 2016 actual map, 2016S = 2016 simulated map



a b

Figure 3. *LULC simulated map of 2016 (**a**) and 2042 (**b**)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_46194635

A Kappa value of 0 illustrates the agreement between actual and reference map (equals chance agreement), the upper and lower limit of kappa is +100 (it occurs when in total agreement) and -1.00 (it happens when agreement is less chance) (Sinha and Kumar, 2013). In this study, the validation indicates K values (Kno = 0.823, Klocation = 0.851; KlocationStrate = 0.851; Kstandard = 0.831) above 0.8 showing satisfactory level of accuracy. According to Pontius and Millones (2011), if the results are greater than 0.8 for each kappa index agreement, then the K statistics are considered accurate. Hence, CA-Markov modeling is suitable for accurate prediction of future LULC's.

Results and discussion

Land use land cover (LULC) changes

According to *Table 4,* the results indicate the forest land, built-up area, agriculture area, and water bodies for 1990, 2006, 2016 and 2042 (*Figs. 3a, b* and *4a, b, c*). In other words, the LULC changes between 1990 to 2006 showed the built-up area and agriculture area have increased by 19 633 ha and 44 302 ha, while the forest land and water bodies have decreased by -7 218 ha and -56 717 ha, respectively (*Table 4; Fig. 4a* and *b*. This situation has occurred because the forest land and water bodies were converted into built-up area and agriculture area. Specifically, forest land and water bodies are likely to transform into agriculture area, before these activities are transformed again into built-up area (*Table 5*).

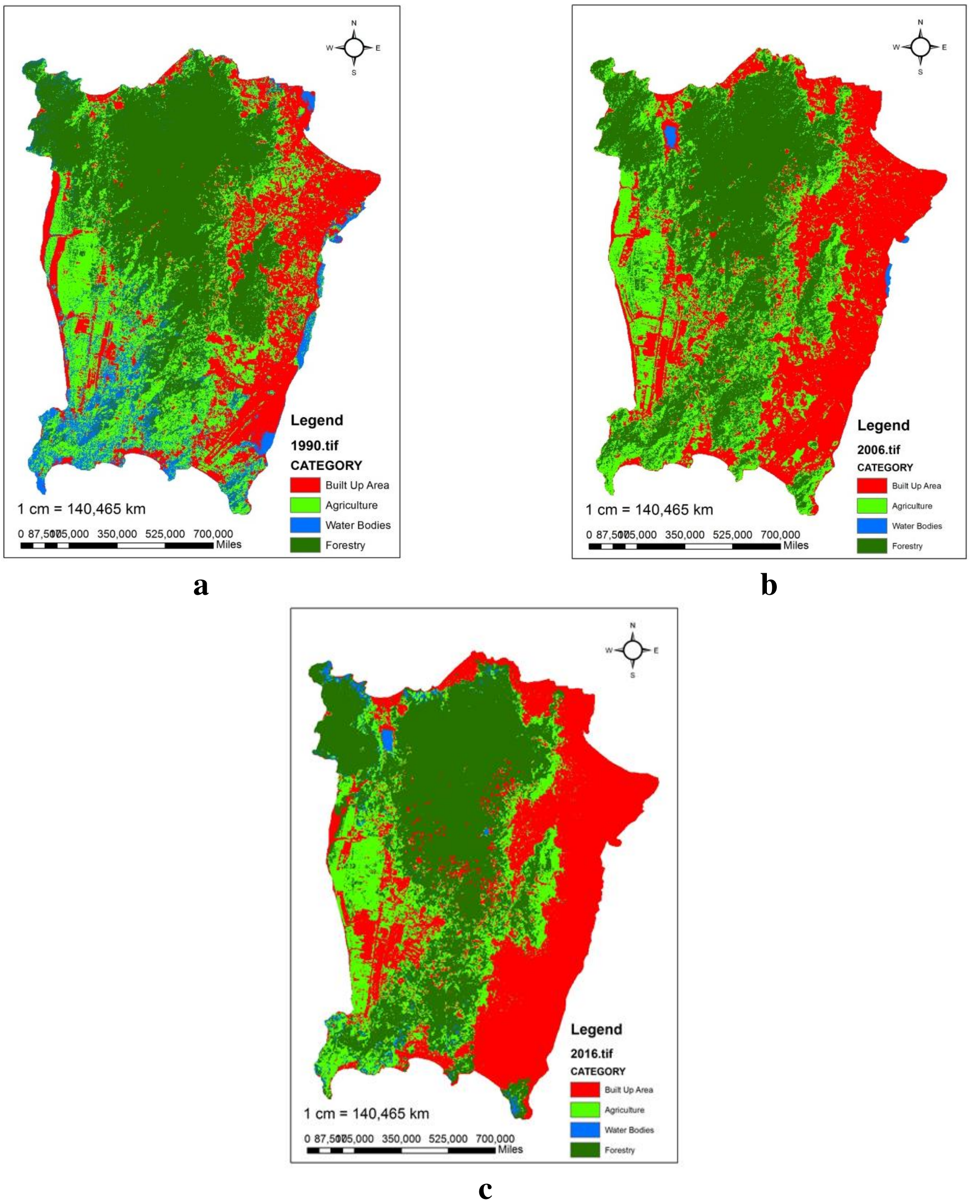

Figure 4. *LULC actual map of 1990 (**a**), 2006 (**b**), 2016 (**c**)*

Sufficient water supply with fertile soil leads to the agriculture activities to be carried out, while abandoned forest land would be in demand for built-up and agriculture activities. In addition, with the country's vision of 2020 to be a developed country, the rapid development becomes prioritised and these encouraged the attraction of local and non-local residents to concentrate on Penang Island. Due to the population growth and rapid urbanisation, the demand for shelter and job opportunities could also increase. Indirectly, this situation will raise the pressure on forest land and water bodies to negatively affect in the quality and quantity, which could bring harm to living species and cause extinction.

Nevertheless, the LULC change for the next 10 years indicated that forest land continued to donate to the coverage area for agriculture activities for 31.22% before its transformation into a built-up area for 29.72% (*Table 6*). Meanwhile, only the built-up

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_46194635

area will continue to increase especially in the north, south and centre of the island; while others in east, northeast, and southeast show a high cluster of built-up area in Penang (*Fig. 4c*). Besides that, water bodies also showed positive development, where the minority coverage area of forest land and agricultural activities are being converted into water bodies for 6.70% and 10.66%, respectively (*Table 6*). Generally, the recognition of Penang Island as a tourist centre from World Heritage Site in 2008 had raised the economic value of the country, and indirectly increased the tourists' arrival in the island. As a result, the built-up area is detected to have enlarged the area to fulfil the demand for commercial activities such as hotels, restaurants, shopping malls, hypermarkets, etc. As a proof, several residential activities are suspected to concentrate on the surroundings of Penang Hill (which was highlighted as one of the historical heritage attraction as well as for its flora and fauna). Indirectly, this area is exposed to the danger of landslide and rock falls. Simultaneously, although the water especially from the river is not supplied as drinkable sources, but the awareness of the need for quality and quantity of water supply for agriculture activities and aquatic species had been extended and were detected scattered in the north and the south of Penang Island. Hence, these situations will continue to decline from the forest land into built-up area, agriculture activities, and water bodies. Therefore, the natural biodiversity especially living animals on the island will become extinct due to the rampant deforestation for the human activities.

Table 6. *Transition probability of area and matric calculated using land use maps of 2006-2016*

Category		2006–2016			
		Forest land	**Built-up area**	**Agriculture area**	**Water bodies**

	P	0.86	5.62	1.18	92.34

F = frequency in hectare, P = percentage

Overall, LULC changes for 26 years from 1990 showing only the built-up area and agriculture area are having an increment steadily for more than 20%; while forest land are having a positive effect for approximately 15% and water bodies are less than 5% (*Table 7*). Increase in built-up area proved that population growth and rapid urbanisation have succeeded in archiving the country's vision of 2020 as a developed country. Indirectly, these results will enhance the demand towards agricultural activities as well as decline in the forest land and water bodies. When the water quantity decreases through the coverage area and evaporation process during droughts season, plus with drastic climate change and water pollution through anthropogenic activities, this resulted to pressuring the supply of water as a whole. So, this situation shows that the water bodies should paid attention to avoid excessive negative impact that may affect the aquatic species and reduce the food supply through agricultural activities.

Simultaneously, forest land provides various benefits in terms of climate regulation, human health, recreation, refuge, fresh water supply, etc. In other words, declining forest land will reduce the possibility of accessible freshwater supply resources. Hence, forest land should be protected from deforestation on a large scale. This is because forest land not only links to the water bodies, but also consists of various species of flora and fauna which exist indigenously or naturally. Therefore, destruction towards forest land and water bodies will bring negative impact and will decline the human quality life.

Prediction of future LULC changes

Simulated future LULC change is extended for the next 26 year from 2016, which has been interpreted in *Table 8*.

Table 8. *Transition probability of area and matric calculated using land use maps of 2016-2042*

Category		**2016–2042**			
		Forest land	**Built-up area**	**Agriculture area**	**Water bodies**
Forest land	F	35 795.37	32 849.16	21 204.65	10 361.82
	P	35.72	32.78	21.16	10.34
Built-up area	F	2 170.74	83 063.12	7 532.64	0
	P	2.34	89.54	8.12	0.00
Agriculture area	F	10 317.12	13 986.96	27 662.34	5 735.58
	P	17.88	24.24	47.94	9.94
Water bodies	F	1 979.60	8 694.17	3 174.49	30 737.24
	P	4.44	19.50	7.12	68.94

F = frequency in hectare, P = percentage

The result indicates that the built-up area, agriculture area, water bodies, and forest land are detected to continue to 'grow' in the coverage area of about 18 510 ha (26%), 10 637 ha (12%), 5 365.8 ha (7%), and 4 822 ha (8%), respectively. In other words, the future LULC map only shows the built-up area and water bodies are having an increment in the coverage area, while agricultural activities and forest land are

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_46194635

suspected to decline. Generally, water provides food and water sources, recreation activities, sustaining the ecosystem, maintaining the humidity of land surface from overheating and the climate changes, etc. The benefits and importance of water resources had increased the awareness of local residents to sustain the quality and quantity from 'disappearance' and be concerned with environmental issues. Nevertheless, LULC map in 2042 resulted to an increase in built-up area showing a sign of warning that the population growth has increased and urbanisation could be achieved in making Penang Island as one of the developed states. Indirectly, the built-up area will increase the demand for water and food sources, shelter, employment, recreations, etc.; as well as creating various numbers of environmental problems such as pollution, the cause of extinction towards living and non-living being. This situation also signalled that 'confiscation' of other class area in fulfillment of the quantity of the population will happen.

As a proof that confiscation could happen, the CA-Markov analysis has shown that forest land and agricultural activities is declining in the coverage area to contribute to the built-up area. To be more specific, future LULC map in 2042 indicated that several areas of forest land in the centre of Penang Island especially surrounding the high hills. This was transformed into built-up area, as well as the north and the west of agriculture area had been converted into water bodies. As explained previously, the forest land plays an important role in providing the sustainability of water resources, food resources, land resources, and air source (which was also referred to as the climatic matter) to provide the comfort continuance of living overall. However, pressured in fulfilling the demand of humans on the 'greedy' attitude had caused the forest land to become a 'victim' of deforestation, which can be shown in *Figure 3b*. There are only several areas that remained as forested land especially the high hills like Batu Feringghi, Bukit Bendera, Bukit Ayer Hitam, and Bukit Relau; including several forested areas at ground land like Teluk Bahang, Pantai Acheh, and Balik Pulau (*Fig. 3b*). Therefore, these areas should be preserved and conserved so that nature can be maintained for its originality and avoid from being damaged or destructed. As a summary, LULC change for 1990 to 2016 shows that the built-up area and agriculture area experienced a gain more than a loss by 29% and 21% (*Fig. 5a*); while forest land and water bodies have a loss more than a gain by -33% and -17% (*Fig. 5a*). Furthermore, the next 26 years of LULC change will indicate that the built-up area, agriculture area, and water bodies are having a gain more than a loss (*Fig. 5b*) by 46%, 2% and 2% (*Fig. 6b*), respectively; while only the forest land are having a loss more than a gain (*Fig. 5b*) by -50% (*Fig. 6b*). Therefore, forest land should be given attention and priority from deforestation on a large scale through various methods of laws, policies, moral and ethical value, religion, and awareness, which are important to prevent it from being constantly taken advantage of by other classes.

Conclusion

This study utilised satellite images (1990, 2006, and 2016) to analyse the land use land cover of Penang Island, Malaysia. Two classified images (1990 and 2006) were used as an input to the CA-Markov model to predict the 2016 land use land cover. The model output is validated with an actual image of 2016. Based on the results, the model is used to predict land use land cover for 2042. The overall results showed a predominant increase in built-up areas from 18% of total land use in 1990 to 77% by

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_46194635

2042. The increase is found mainly at the expense of forest land, where these areas are reduced from 41% in 1990 to 25% in 2042. Based on the environmental framework of Penang Island in 2042 as planned by City Council of Penang Island, it is noted that Penang Island is planned to expand more to the east towards north and south. Nevertheless, the result of CA-Markov model in this study complied with the 2042 Master Plan, where the built-up areas are expected to encounter an expansion not only from the east to the north and south, but also towards the centre of the island and moving upwards to the north. In this model, it could suggest to limit urban development in the centre of the island to protect forest landscapes. To understand how the changes in the landscapes may influence the distribution of the important species will help guide conservation planning in the area. This study can serve as guidelines for other studies which attempt to project land use land cover change in forest landscape experiencing similar land use changes.

Abstract. Through laws, policies and plans, governments manage natural ecosystems, including rangelands. According to the political and economic approaches, scientific achievements and the ecological and social developments, the mentioned laws and policies must be developed and updated. Investigation of the effects of these measures can play an important role in the improvement of management processes and updating laws and policies. Reduced level and trend of destruction affirms that the government's actions of Iran in rangeland management are not effective enough and need to be reassessed. The present research was carried out aiming at investigating the effectiveness of laws, policies and plans on rangeland management based on a survey of rangeland management specialists. In this research, results and data have been collected based on questionnaire from experts in executive department (Forest, Rangeland and Watershed Organization), Natural resources research specialist and university faculties. Given the facts that a large number of contestants were available and based on the type of this research, the non-probability sampling method (judgment sampling) has been used. Data were analyzed through using SPSS software, descriptive and inferential statics of (X^2) and Kruskal-Wallis test. The total number of specialist rangers in this study was 268 people. The results show that A significant part of the experts participating in this research believe that the nationalization of rangelands has had profound effects on rangeland management systems. In addition, a large number of respondents believe that government policies in relation to rangeland need to be revised and redevelopment plans should also be prepared and implemented in accordance with ecological and social conditions.
Keywords: *laws, land reform, nationalization of rangelands, rangeland survey, grazing permit, rangeland management plan, rangeland management policy, effectiveness, Iran*

Introduction

In the Middle East, livestock breeding and rangeland management flourished thousands of years ago, and rich indigenous knowledge has existed along with deep cultural roots in relation to rangelands in various areas. Based on investigation of historical documents, Javanshir (1999) states that the terms related to the pastoralism are seen in the life of the ancient Persian societies; all of which confirms the importance and development of livestock and range management in the ancient history of this part of the world. This is despite the fact that the science of rangeland management has a relatively short history and only dates back to the early twentieth century. What is currently known as the science of range management first appeared in the US. Holechek et al. (2004) state that in the United States, livestock grazing and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_46374654

its impacts on the degradation of pastures were brought into attention back at late 19th century.

Anyway, during the past century, due to population growth, agricultural land development and the expansion of residential areas, the pressure on rangelands has increased dramatically and in many parts of the world the pastures have been degraded and reduced in size. Therefore, many governments have tried to reduce the degradation of pastures and control the grazing process. Through laws, policies and plans, governments manage natural ecosystems and try to improve them during time based on political and economic approaches, scientific achievements, ecological transformations and social changes. Therefore, studying the effectiveness of policies used in rangelands management can play a very important role in guiding governments to improve management processes and update the rules and regulations. Considering the decrease in the area and quality of rangelands, it can be concluded that the government's programs in rangeland management have not been effective enough. So, in order to investigate this issue, some of the laws, policies and plans of rangeland management have been investigated in this research and analyzed based on the experts opinions.

Rangeland areas of Iran

The area and quality of rangelands can be an appropriate indicator in the assessment of the success or failure of management programs and measures. Considering the rangeland areas, Squires et al. (2017) state that more than 85 percent of Iran's surface area is arid and semi-arid, and from the total land area, 84.8 million ha, equivalent to 51.4 percent, consists of pastures. It argued by Farahpour and Marshall (2001) that only 9.3 million ha of pastures (10.3%) are in good conditions and 37.3 million ha are in moderate conditions (41.4%), and the remaining, 43.4 million ha, have poor condition (48.3%). Eskandari et al. (2009) provide the following estimates for the rangeland areas. Their report is important because Eskandari was, at the time, the Director General of the Forests, Rangelands and Watershed Management Organization (FRWO). This rangeland Technical Bureau, which is the main provider of rangelands management and implementer of government policies of Iran, is part of the FRWO, which is also one of the deputies of the Ministry of Agriculture Jihad. Therefore, the above-mentioned report can be considered as a formal report by the government.

1. Niknam (1968) reports the rangeland areas to be 100 million ha.
2. The American FMC Company (1974) reported the rangeland areas to be 90 million ha.
3. The rangeland technical Bureau (FRWO) in 1996, the rangeland area is 90 million ha.
4. Based on digital satellite images, land maps, and vegetations of Iran, FRWO reported the rangeland areas to be 86.1 million ha in 2005 and 84.7 million ha in 2008.

Among the most important causes of the decline in rangeland areas we may refer to increase in population and demand for food, the grazing pressure of livestock, change of use, drought, desertification and government policies. Karimi and Karami Zahkardi (2016) stated that regarding the changes in rangeland areas, despite the importance of rangelands, studies have shown that in the past years, the quality and grading

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_46374654

rangelands have undergone changes that were due to inappropriate human activities and most of these degradations included rangelands of good and moderate quality. Therefore, these changes can confirm the failure of government policies and programs in the management and conservation of rangelands.

Rules and regulations related to rangeland management

Araghi et al. (1998) state that after the Constitutional Movement, conservation of forests was considered important by legislators. Added was the concern for maintaining the rangelands. In 1960, the issue of rangelands was directly and clearly observed along the forests in the law of forests and rangelands for the first time. The approval of the nationalization of forests and rangelands (in 1963) declared the rangeland as public property belonging to the state. Shamekhi (2009) stated that Islamic jurisprudence is the main legislative basis, and that the Islamic Revolution of 1979 created a new stage in legislation. Also, the Islamic jurisprudence had a great influence on current laws. Motamedi et al. (2007) state that in 1967, after the enactment of "the Law on the Conservation and Use of Forests and Rangelands", and in concordance with the provisions of the Note 1 of the Article 3 of this Law, *"the use of rangelands for which a plan has not been prepared and approved in relation to livestock feeding requires acquiring a grazing permit from the Ministry of Natural Resources and also observance of terms and conditions that are notified by the Ministry*." In fact, according to this law, the rangeland management policy is determined by the government. According to Zohdi (2018), established in recent decades, the rules and regulations related to rangelands and rangeland management in Iran have an impact on rangelands and how they are used, and, on the other hand, they are the basis of the policies governing the management and government organization concerned and have a profound effect on the rangeland management system. Moeenedin (1994) states that since 1963 rangeland have been nationalized and individual ownership have been abandoned to the government and thus management evolves in the rangeland. This was taken on an immediate basis and did take into account the facilities and personnel or the creation of the necessary underlying culture. Ahmadi et al. (2011) state that "the law of the nationalization of forests and rangelands" is a major legal regulation and in which various issues have been referred to such as grazing of livestock in natural resources, requiring the stakeholders to obtain grazing permit from the FRWO during a one –year period, and the issue of excess number of livestock. Due to ambiguities, some legal provisions have an impact on the factors affecting the rangelands negatively and have led to increased degradation. Usefi et al. (2016) asserted that Article 3 of "the Conservation and Use of Forests and Rangelands Act" (adopted in 1967) is the first legal step in rangeland surveys and the issuance of permits, the first grazing conditions for livestock in rangelands were approved and on this basis in 1970 and notified by the government. Moeenedin (1997) states that the rangeland survey that was performed under specific social and political conditions in the 1980s, played a very important role in distorting the balance of livestock and rangelands. Abolhassani et al. (2013) indicated that since the adoption of "the Land Reform Act" and "the Nationalization Act of Natural Resources" in 1964, many reports have been published on intensifying the degradation of rangelands. In order to prevent further degradation of the rangelands, the government set some criteria for the systematic and careful use; however, these

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_46374654

criteria were not properly implemented and accompanied the sudden increase in the number of livestock at the time.

Rangeland management policies

Baker and Eckerberg (2013) said that in general, a public policy may be defined as "a series of measures approved and followed by the state to solve a problem". In addition, the term "policy" can refer to a proposal or a set of specific measures that the government devotes to addressing a general problem. More precisely, the term "policy" means a formal proposal or operational plan that can be thought of as a centralized and executable tool that requires resource allocation. Zohdi (2018) state that it is not clear whether laws come before policies or they are adopted based on policies. However, what is certain is that they both affect each other. By signing the technical cooperation agreement in the framework of the Point Four Program between Iran and the United States on October 19, 1950, and taking into account the presence of experts from the US and some European countries for these programs, significant events occurred in relation to Iranian rangelands that were the basis of future developments or natural resources, especially the rangelands, of Iran. Since 1953, experts from the Point Four Program Organization have carried out extensive studies of agricultural systems, rangelands and rangeland management in Iran, which resulted in a widespread policy or plan for the Mohammad Reza Shah, called "the Shah and People Revolution", or "the White Revolution". The land reform policies, which include the nationalization of forests and rangelands in 1963, is one of the most important parts of this policy package, had a profound and significant impact on Iran's agricultural and rangeland management systems. Etemadi (1996) says "Despite numerous transient and local laws adopted about forests and rangelands over the past seventy years, the law of forests (adopted in 1943), the law of forests and rangelands (adopted in 1950), Act of Protection and Use of Forests and Rangelands (adopted in 1967) are recognized as milestones among the adopted laws. But the interesting point is that at every stage, a kind of political decision has been the basis for the preparation and adoption of a law. The law of Protection and Use of Forests and Rangelands, approved in 1967, was approved by the Cabinet of Ministers on the basis of a political decision approving the nationalization of forests and rangelands on January 17, 1963. The nationalization of forests and rangelands is the second out of the six principles of the political-economic and social developments of the 1960s. Four months after the final adoption of the Conservation and Exploitation Act, the Ministry of Natural Resources was formed with the merger of forestry, wildlife management, and aquaculture and fishery organizations. Fisher (2015) showed that in the years 1962 to 1966, Mohammad Reza Shah and the Council of Ministers adopted laws aiming at reforming Iran's social, political and economic structure. These reforms are generally known as "Six Point Reforms" or "Shah Revolution". The most important measures in this program were agricultural reforms and land management systems. As a result of these measures, large agricultural lands owned by a small numbers of Khans and landowners were divided among farmers and this was the reason for changing the lifestyle and social patterns of the country. In the following years, other policies were adopted by the government that directly or indirectly affected rangelands. Mashayekhi (1990) states that a major policy that was pursued in Iran was import increase of alfalfa to feed livestock and reduce the pressure on rangelands. Studies have shown that, from 1973 to 1984, alfalfa imports increased about ten times and this has been one of the reasons for the degradation of rangelands, because, with the increase in imports of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_46374654

alfalfa, the total supply of feed increased and livestock breeders increased the number of livestock. Then, the large population of livestock, especially in droughts, increased the pressure on rangelands. It was shown by the results that the total area of agricultural land increased by 50%, from 6 to 9 million ha, after 1988. Under these conditions, despite the increase in total agricultural land, the amount of land allocated to forage production has decreased. Also, under the same conditions, the demand for food production in agricultural lands has been increasing, farmers moved their livestock to the rangelands and used extra lands for food production. Therefore, the pressure on the rangelands is increased. Eskandari et al. (2009) stated that, in order to reduce the pressure on the rangelands and increase the production of proteins, the most important policy adopted by the Ministry of Agriculture Jihad was the production of red meat in closed and industrial feedlots and changing the livelihood of rangeland owners. In addition, reforming the cropping pattern and increasing forage production, financial support, government facilities and land allocation have been other policies adopted by this ministry. On the other hand, some of the FRWO's policies for the systematic management of rangelands based on observance of criteria and terms included attraction of capital and knowledge in rangeland management, the provision of rangeland managers with their customary rights in order to reduce the number of small stockbreeders, increase of scientific and technical capacities of rangeland keepers and their role in rangeland management, land use systematization, conversion of low-productivity farms into producers of forage, reduction of population exploiting the rangelands, balancing the number of livestock and rangelands, proper management in droughts, rangeland surveys, identification of common rights of livestock breeders, migration systematization, preparation and implementation of rangeland management plans, precipitation management, collection and production of seeds of quality crops, restoration and improvement of rangelands, insurance plans for rangeland management etc.

Rangeland management plans

Salmasi (1994) declares that the first scientific and technical measure in Iran in terms of rangeland management included the idea of reformation and use of rangelands based on Article 3 of "the Conservation and Use of Forests and Rangelands" (1967) which was the only legal tool for long-term exploitation of rangelands. In these plans, the main purpose was to reform, rehabilitate and properly utilize the rangeland. The first attempt at rangeland plans was made in 1969 with the preparation of extensive rangeland management plans. Since 1977, in the second attempt, experts focused on smaller units of operation, or in other words, the rangeland allotment. FRWO (2009) reported that despite the fact that scientific standards were followed in the establishment of large rangeland management projects, because of the large extent and lack of attention to customary areas and social issues, none of these plans were implemented. These plans were under focus till 1976. Large rangeland management plans were not successful for various reasons. Therefore, small projects were considered by the rangeland Technical Bureau (Government). Since 1976, the preparation and implementation of range plans were made in a new way and began with the emphasis on cooperation between the government and the stakeholders. Several rangeland plans were prepared from 1977 to 1979; however, out of 407 drafted designs, only 87 were approved, and only 30 were implemented, which indicates the failure and un-acceptance of such plans. The rangeland plans faced with a serious ignorance after the Islamic Revolution and they

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_46374654

were nearly forgotten between 1980 and 1984, but in the years 1982 to 1984, a new attempt was made on large plans. During these years, plans such as forage crops were considered more seriously. In 1984, changes were made in the rangeland exploitation by changing the rangeland survey guidelines and the taking into account the livestock instead of humans (rangeland managers), in such a way that the growth of the stakeholder populations was observed from this year onwards. Since 1987, rangeland projects became part of FRWO's policies and were included as the main administrative program of the government for rangeland management. Also in this year, the duration of rangeland management projects increased from 15 to 30 years in order to increase the share of stakeholders. Composition of rangeland projects was gradually accepted as the main policy of rangeland management and is still the main policy of the state in managing rangelands. Zohdi (2018) state that the early rangeland management plans, prepared based on American schemes, and known as "large rangeland projects", continued until 1976, during which time, 24 projects were established on two million and five hundred thousand hectares and a huge attempt was made to rehabilitate the rangelands and strengthen the vegetation in the framework of these projects. Since 1977, rangeland projects became the main policy of managing rangelands in the framework of rangeland allotments known as "small projects". According to the latest report of FRWO, by August 2017, 14,651 range management projects have been prepared at 34,051,703 ha; of which, 13302 have been approved (31,804,989 ha), 8193 were outsourced and agreements were made with stakeholders as administrators (19,781,615) and 5488 RMP (14,671,245) are under construction. For every specific area, known as the rangeland allotment, these projects are prepared by consultant companies under the supervision of the government and implemented by the stakeholders as the administrators. Rangeland allotment contains a specific area of rangelands that has historically been exploited by an individual or a group of pastoralists, and its boundaries were determined by the surveying boards of the rangelands based on the documents provided by stakeholders and approved by the survey boards.

Materials and methods

The present study was conducted based on evaluation of rangeland management history in Iran and its effective factors. For this purpose, the principles of the subject were investigated by library studies and a review of scientific records and related documents. Based on the results of library studies, a questionnaire was prepared for attaining the expert opinions. Given the large number of rangeland experts were available and taking into account the type of the study, a non-probabilistic and judgment sampling method was used. Data from the survey via questionnaire were analyzed using SPSS software and the descriptive and inferential statistics of Chi square (X2) and Kruskal-Wallis test. The statistical population was divided into three main groups: 1. Rangeland management experts in the administrative area (experts from FRWO and Headquarters of the Natural Resources Departments of the Provinces); 2. Rangeland management experts in the research area; 3. Specialists, faculty members and PhD students in the area of rangeland management. The structure of the questionnaire was based on the results of library studies. This questionnaire is divided into three main sections: questions related to the personal profile of the respondent, questions related to the rules and regulations, and questions related to rangelands. In the rangeland and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_46374654

rangeland management section of the questionnaire, items related to government policies and plans are provided. A total of 268 questionnaires were completed and gathered in the present study. To verify the authenticity, validity and reliability of the items, the questionnaire was first distributed among a number of experts for a pilot test, and after revising its defects, the final questionnaire was designed. Finally, the validity of the questionnaire was verified by the Cronbach test.

Results

In order to study the results of this research, the items of the questionnaire were divided into 4 sections based on the assumptions of the research and the responses were analyzed using the statistical methods described above. The results are presented below.

Respondents profiles

From among 268 respondents, 233 were male and 35 were female. The highest number of females belonged to the provincial experts in the administrative area. Among the administrative experts, experts from 28 provinces participated in the study. The average age of retired experts of the rangeland office was 65.9 (oldest group) and the average age of the PhD student group was 34.1 years (youngest group). 71% of respondents aged 27 to 49 years old. Among the 268 respondents, 2 had diploma degree, 32 were undergraduates, 177 were graduates and 57 had doctoral degree (PhD). In terms of academic rank, 177 (66%) were experts, 34 PhD students, 9 research instructor, 24 assistant professors, 16 associate professors, and 8 were faculty members and professors (*Table 1*).

Evaluation of the results of the components of the rules and regulations

Thirty one closed, multiple choice items are related to laws and regulations. The results analysis showed that among respondent groups, there is a significant difference in the order of 1% for responses given to the 31 studied variables. This is despite that there was less significant difference between the three main groups of respondents (academics and experts from the research section of FRWO), and that it is at the error level of 5% and confidence level of 95%. In terms of gender, the difference in the responses was significant for only four items at the 5% error level. The results of statistical analysis indicate that the effect of the respondents’ education on the responses was significant at the error level of 5% for the 11 items (*Table 2*).

The rules are well implemented	0.4	3.4	38.1	39.6	18.7	2.27	2.00	0.81	35.68
The rules are consistent with ecological conditions, customary relations, and socio-economic issues	0.0	6.3	19.4	63.8	10.5	2.47	2.00	0.68	27.53
Rental ranges to other ranchers are correct and should be regulated	0.7	9.8	23.9	36.9	28.7	2.40	2.00	0.98	40.83
The rangeland survey agenda is good and effectiveness	0.0	10.1	45.5	35.9	8.5	2.92	3.20	0.76	26.03
Grazing in forests is correct	0.0	8.9	37.7	41.8	11.6	2.72	2.00	0.79	29.04
Guild of livestock breeders can be important role in range management	15.7	56.0	17.1	9.0	2.2	3.85	4.00	0.88	22.86
The rules and regulations concerning rangeland need to be reviewed	20.1	60.5	16.9	1.8	0.7	4.12	4.00	0.65	15.78

St.Ag (Strongly Agree), Ag. (Agree), Ne. (Neutral), Dis. (Disagree), St.Dis (Strongly Disagree), St.D (Standard Deviation), CV (Cofficent of Variation), A.S.R (Average Score of Response)

The analysis of responses has shown that a large number of respondents believe the approval of nationalization of forests and rangelands in 1963 did not have a positive effect on rangeland and rangeland management. Also, more than 50% of the responses consider the implementation of the above-mentioned resolution as weak or very weak. Therefore, based on the results, the research hypothesis regarding the positive effectiveness of the nationalization of forests and rangelands is rejected. In connection with the conservation and use law of forests and rangelands (adopted in 1967), the results show that it had a more positive and better effect on rangelands than the nationalization law. Respondents believe that this is a better and more comprehensive law than the nationalization law of forests and rangelands. However, a significant proportion of experts did not provide their opinion in this regard, but at the same time, a large proportion of respondents still do not take the law of protection and use of forests and rangelands as a comprehensive one. The results of this research show that about 50% of respondents believe that approved laws do not meet the requirements of principal management and the others do not consider the rules deterrence appropriate. More than 58% of participants in the research believe that the rules are not being implemented correctly and completely. A significant proportion of respondents (more than 74%) believe that rules related to rangeland management with ecological condition, Conventional relations and social and economic issues have low consistency. Nowadays, many rural councils and some livestock breeders who do not have livestock equal to the number of livestock in Grazing Permit (GP) or Rangeland Management Plan (RMP), Ranges are rented to maintain their privilege and privilege for the purpose of income from this area. In this regard, more than 65% of the experts oppose the lease and regulation of the rangeland.

Reviewed and notified several times so far, the rangeland survey agenda is one of the most important provisions of rangeland management and is the main basis for rangeland surveys. Examination of the results of this agenda declares that a significant number of experts believe that this agenda does not conform to the common user relations and cannot solve the problems of small stakeholders. Also, about 52% of respondents believe that this agenda cannot establish a balance between livestock and rangeland. In contrast, more than 44% of experts believe that the rangeland survey agenda can pave the way for the participation of stakeholders in the determination of the rights to rangeland management. While nearly 61% of respondents take the role of rangeland survey in rangeland management as a positive role, more than 79% of the experts agree with the revision and updating of the guidelines. The results showed that many experts disagree with the issuance or extension of grazing permits in forests. In total, more than 44 percent of respondents consider the effectiveness of the above guidelines very low and more that 45 percent did not have an opinion about this issue. More than 71% of the experts participating in this research consider the role of Guild of livestock breeders, managing pastures and more useful implementation of positive rules. An important point about rules and regulation related to pastures management is that, over 80% of respondents believe that the rules and regulations need to be reviewed and updated, and only 2.5% oppose this claim.

Evaluation of the analysis results of the components related to government policies and programs for rangelands management

In this section of the research, a total of 35 items were used based on the content and objectives, which is grouped and analyzed according to the content and purpose of *Table 3*.

As the analysis of the result of study in *Table 3* shows, more that 57% of respondents believe that plant coverage and the balance of livestock and pasture have been better in the last 3-4 years, in contrast, only 9.5% have opposed this issue. Also, 66.5% of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_46374654

participants in the study said that the rate of land use change in the past was less than 2017.

Table 3. *Results of the evaluation of the effectiveness of government policies, plans and programs related to rangeland management*

Indicator	Percent of responses					Mean	Mode	St.D	CV
	St.Ag (5)	Ag. (4)	Ne.(3)	Dis.(2)	St. Dis.(1)				
Rangeland vegetation and equilibrium of livestock and rangeland in the past (30 to 40 years ago) have had better health	7.1	50.0	33.7	7.6	1.9	3.88	4.00	0.71	18.30

Range management Plan in the current situation are not a good policy for managing rangelands	22.0	47.8	14.9	13.4	1.9	3.75	4.00	1.01	26.93

St.Ag (Strongly Agree), Ag. (Agree), Ne. (Neutral), Dis. (Disagree), St.Dis (Strongly Disagree), St.D (Standard Deviation), CV (Coefficient of Variation), A.S.R (Average Score of Response)

More than 50% of the respondents did not provide any opinion about the large RMPs that were produced in Iran between 1969 and 1976, and about 30% of them considered the Plans as good ones. More than 88% of rangeland specialists believed that management of different types of rural and non-rural rangelands need different schemes, while 41% opposed to the fact that current RMP are good models for managing rangelands. Anyhow, 33% agree with this statement and 25% did not give any opinion. In contrast, more than 45% of respondents believe that current RMPs provide good models for nomadic rangeland management, to which only 29% opposed. About 82% opposed to the following statement: “the current framework of rangeland management plans is intact and comprehensive”; which indicates the disapproval of the framework for these projects by the respondents of the study. Results regarding the positive effectiveness of RMPs on improving vegetation, livestock and rangeland balance, income of rangers and their further participation show that more than 33% did not evaluate it positively, and only 23% consider positive impact for RMPs. However, more than 43% did not have any point of view regarding this issue. A large number of respondents believe that rangelands under camel grazing have special conditions and require a specific management model. One of the problems encountered in RMPs is that these are one prescription for all different conditions. Over 91% of the respondents believe that “the framework of RMPs should be adapted to ecological and managerial conditions”. Also, a large number of respondents agree with the utilization of medicinal plants and industrial plants in the rangelands, and believe that this may help the economy of rangeland management. Most respondents (over 90%) said that “*the rangeland management policies of the FRWO have to be improved and upgraded according to the changing situations*”. Also, 67% stated that “*as the rangeland management plans are not suitable for the current rangeland management*”, to which only 14% opposed. The results show that only 6% of respondents believe that there is a good quality for the supervision of natural resource departments of the counties and provincial offices on rangelands and RMPs, and this figure declines to 3.3% for the FRWO. Over 70% of the respondents chose the “weak” and “very weak” scales for the FRWO’s supervision. More than 55% of the experts stated that the legal proceeding of natural resource departments against the offenders is “appropriate to some extent” and 7% find these measures “appropriate”. More than 48% believe that the supervision by the Rangeland Issues Bureau is “weak” or “very weak”. Over 62% of the respondents think that the stations producing the grassland seeds are of high importance, but a large number of the respondents (more than 68%) believe that these stations have not been properly managed in recent years. More than 78% of respondents believe that FRWO had “little” or “very little” success in managing rangelands, and 17.5% said that the FRWO has not been successful at all. So the total proportion of specialists who considered the FRWO is unsuccessful in rangeland management was 96%. In this regard, more than 64% of respondents stated that the policies of FRWO were not effective in managing rangelands. The results of Kruskal Wallis test on rangeland management and policymaking data (*Table 3*) show that at an error level of 5%, different groups of respondents (from experts FRWO, Natural resources research specialist and university faculties) made significant differences in 15 items, gender and educational level in 4 items, scientific rank in 8 items, Education in 6 items show that at an error level of 5%, different.

Discussion

Basically, based on their core strategies, governments define executive policies in each sector and, proceed with the implementation of relevant laws in order to regulate these policies and their enforcement. The management of natural resources and lands in each country is influenced by the large-scale policies and the general approach of governments. In Iran, in the late 1950s and early 1960s, important improvements were made in the agricultural and land management fields, nationalization of forests and rangelands. For the management of renewable natural resources, especially rangelands, as major rulings, the Nationalization of Forests and Rangelands (1963) and the Protection and Use Act (1967) are now five decades old. National rangelands were established and the rangeland management structure and related organizations were formed according to these two laws. The results of this research have shown that, for various reasons, a large number of the respondents believe that “the nationalization of forests and rangelands” in 1963 had no positive effects on the rangeland management system due, primarily, to the fact that its implementation mechanisms were not provided or properly implemented. But, In contrast, a large number of audience were in the belief that “the Law on the Conservation and Use of Forests and Rangelands” in relation to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_46374654

rangeland management was better and more complete than “the nationalization of forests and rangelands”. The results showed that, as most respondents indicated, Existing laws and regulations are not concordant with ecological facts, customs, social relations, and social and economic issues. Most of the surveyed statistical population believed that the rules and regulations are weak in implementation. Also, 90% of respondents have emphasized the need to review the relevant laws and regulations. These results are consistent with those of Shamekhi (1992), Salmasi (1994), Azkia (1997), Moeenedin (1994, 1997, 1998), Abdolahpour (2001), Farvar (2005), Eskandari et al. (2009) and Abolhassani et al. (2013). In addition the results indicated that the rangeland survey agenda is not acceptable for the establishment of the balance between the livestock and rangeland and needs to be seriously revised. Moeenedin (1998), Abdolahpour (2001), and Abolhassani et al. (2013) obtained similar results. The above mentioned agenda plays an important role in the determination of the rights of livestock breeders and the establishment of a balance between the livestock and the rangeland; so, it is necessary to be upgraded according to the changes and current conditions. Related to the laws of rangeland management in Turkey, Koc et al. (2014) states that in 1998, the Turkish Parliament approved a rangeland law that empowered the central government to adjust the season of grazing, grazing capacity, to improve the rangelands, and to take other measures to control the use of rangelands. In the present day Turkey, the rangelands of the Republic of Turkey are dedicated to the villages and each village has a right for grazing. Owners of domestic animals in many of these villages still apply the Chergasht (immigration for grazing) method, and in some cases some groups act similar to their predecessors. For the United States, Larson-Praplan (2014) states that one of the first laws approved in relation to rangeland management was the Homestead Act, signed and endorsed by President Abraham Lincoln in 1862. Later, in 1880s, several rules for the management of California rangelands were created. The laws approved in the 1970s have had a great impact on rangeland management. Also, in 1978, the rangeland improvement law was approved and the Clean Water Act was also a part of other related laws that were adopted in this decade. As stated by Holechek (1981), one of the most important events associated with rangeland management was the adoption of the Taylor Grazing Act in 1934, according to which the public land management was assigned to the state-owned grazing service. In response to the pressure of environmental groups, the National Environmental Policy Act was approved by the Congress in 1969. Feller (1998) states that since 1993, significant progress has been made in the field of laws, regulations, standards and guidelines for livestock grazing in public lands of the western US states. Following a two-year attempt, amendments were made to the legislation on grazing and the issuance of permits in 1995. In China, as Peter Ho (2000) indicated, the rangeland law was passed in 1985, through which the rangeland management policy was recognized officially and determined the rights and responsibilities of the government and livestock breeders. According to this law, livestock breeders who were permitted to use grasslands were required to guarantee long-term utilization of the rangelands. In the case of Mongolia, Hannam (2014) states that, according to the law approved in 1992, all lands are state-owned. Mongolia’s environmental law system was supposed to achieve goals of environmental policies based on environmental protection laws in 1995. Mongolia’s environmental law system does not have the ability to effectively manage the major environmental problems in the country. It should be noted, however, that since 2011, the Mongolian government has begun a comprehensive environmental law review. The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_46374654

study of the status of rules related to rangelands management in several countries indicates the evolutionary trend in the implementation and enforcement of the above laws in these countries. In recent decades, many countries have been trying to update natural environment laws in line with changes in ecosystems, exploitation communities, climate change, and international achievements derived from important environmental conventions.

Historically, local breeders used grassland cover on the forest floor in the northern forest (Hirkani) and Zagros forests as pasture. Many experts believed that the presence of livestock in forests is one of the most important factors in destroying and preventing natural regeneration of forests, so they emphasized that permit should not be issued for grazing in forests. Therefore, as rangeland management experts, many respondents in this study oppose the issuance and extension of the permit. In addition, due to poor government supervision and the migration of a large part of the villagers to cities, Islamic councils that are responsible for managing rural rangelands in most villages, rangelands that do not have a local livestock breeders are given to other, which is illegal the rangeland survey agenda. But, many experts believe that, given the high frequency of the phenomenon in many parts of the points of the country, it is necessary for the government to organize it. A significant proportion of research respondents opposed leasing of rangelands, while a large number advocated organization of the phenomenon. Currently, permits for medicinal plants, ecotourism, beekeeping, etc. are issued for a variety of individuals who are not generally administrating the rangeland plans. The results have shown that most experts believe that these permits should be issued in the form of a rangeland management plan and only for the administrator. Another important point is that rangeland plans have a single model in all circumstances, while many respondents stated that there should be different plans for in rural and non-rural, ecologically different and camel rangelands. Many experts think that there are problems in rangeland management framework which should be solved. Iran is a country with a diversity of ecological conditions that require different patterns of management. However, the framework for rangelands is the same for all ecological conditions. The results have shown that more than 90% of the respondents of the questionnaire believe that *"the framework of rangeland projects should be designed according to ecological and managerial conditions."* This is a very important issue to consider in policy making and designing management plans. A total of 90% of the rangeland experts believe that *"FRWO policies on rangeland management must be adapted to the conditions."* Also, the results indicate that many experts believe "*Rangeland management plans as rangeland management policy in the present situation, do not address rangeland management"* and a significant number of the audience said in this study that the FRWO was not successful in rangeland management. These are consistent with the results of Alizadeh and Mahdavi (2007), Mirdeylami and Moradi (2017). Regarding RMPs, Amiri Maleki et al. (2009) stated that in general, the implementation of RMPs in the summer rangelands has been very successful, but it has not been successful – and has been deteriorating sometimes – in winter rangelands due to extended implementation time, early grazing, numerous usages, and being positioned in rural areas. In addition many studies have shown that implementation of RMPs is generally better than lack of any plans for the rangelands. In this regard, Dehdari et al. (2014) state that in rangelands with a plan due to the safety of the land owners regarding the ownership of the rangeland and more control of the governmental systems, are less than conflict between the land owners of one rangeland or nearby ranges. Also, the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_46374654

implementation of rangeland management plans in rangeland allotments has improved the conditions of the rangelands. Based on the obtained results, Eftekhari et al. (2016) state that there is a significant difference at the error level of 1% between the rangelands for which plans have been implemented and others; the major reason being observance of management principles such as the time of arrival and departure of livestock, the optimal distribution of livestock in the rangeland and the relative realization of livestock and rangeland balance in these rangelands.

Depending on the ecological conditions of rangeland ecosystems and the social characteristics of the stakeholders, different countries apply different policies to reduce the degradation of rangelands, each having different advantages and disadvantages. Hannam (2014) states that due to the ecological hazards that have been caused by the unplanned exploitations, a comprehensive plan has been implemented by the Mongolian government since 2011 to update environmental laws and regulations. Due to the degradation of the Turkish rangelands, being aggravated from 1950s and continued until the 1980s, Koc et al. (2014) believe that excessive grazing has caused a major concern for degradation of rangelands and soil erosion. Therefore, in the year 1980, the Turkish government identified about 14 million ha of severely degraded lands and began to amend and rehabilitate these lands by subsequent laws (such as the 1998 rangeland law). YanBo Li et al. (2014) state that in China three major rangeland management policies have brought about major changes in livestock numbers and rangeland ecosystems: Rangeland Household Contract System (RHCS), Ecological construction projects (ECPs) and Herder Settlement Policy (HSP). The implementation of these policies provided major modifications to rangeland management systems. In the mid-1980s, RHCS began in Chinese major herding areas, and is currently used in the six main provinces of northwestern China. By 2011, this policy covered about 79% of China's exploitable rangelands. Gongbuzeren et al. (2015) state that, over the past 30 years, the Chinese government linked three main policies of the Rangeland Household Contract Policy (RHCP), the Nomad Settlement Policy (NSP), and the RAPs (Rangeland Ecological Construction Projects) to manage the rangelands. These policies have caused great changes in rangeland communities as well as rangeland ecosystems. Many studies have shown that RHCP policy has had a significant negative impact on rangeland management and ecosystems. This is despite that the nomadic system for the exploitation of rangelands evolved over time and has been consistent with the unsustainable environmental conditions of the rangelands. It is also true that NSP policy has had a few positive impacts on livelihood, but most studies have shown major negative impacts of this policy on rangeland ecosystems. Also, studies have shown that RECPS policies have had positive effects on the restoration and regeneration of rangeland ecosystems, but have made negative effects on livelihood of rangeland managers. In general, it can be argued that making changes in any of the components of rangeland ecosystems or the stakeholder communities could lead to changes in other components. Therefore, we have to look for a SES (social-ecological systems) system based on which we can balance social and ecological factors. Government policies in the mentioned countries have had a different impact on rangeland ecosystems and stakeholder communities, but the important point is that ongoing studies are examining the effects of these policies in a continuous manner, that can be very effective in improving and reforming policies and management practices.

Conclusion

The study of the above-mentioned sources indicates that rangeland management legislation in Turkey, Mongolia and China has not long been a long history, but a few decades ago, but it has evolved and governments are trying to update it. In the United States, the rules for managing rangelands have a longer history and evolved in an evolutionary process with changes in rangeland ecosystems and utilizable communities. The results of this research have shown that there is no specific rule for rangeland management in Iran, and the legal rules of rangeland have been seen in the general framework of the laws of natural resources management. In the past 50 years, despite the many changes in rangeland ecosystems and utilitarian communities, these rules have not been revised and updated. On the other hand, despite the numerous and parallel rules and the poor implementation of the relevant laws, the effectiveness of the rules related to management and conservation of rangelands has greatly decreased. Therefore, due to the wide variation in the level and quality of the rangeland and the changes that have been made in the exploiting communities and the climate change that has been increasing in the Middle East region, it is necessary to complete and update the laws related to the management of rangeland ecosystems. Also, given the international obligations created, these laws must also be in line with these obligations. Another important point in relation to the rules of rangeland and the effectiveness of existing laws is the low and inadequate studies and studies in this area that show the need for comprehensive and in-depth reviews on this issue.

In conjunction with government policies and programs, the results of this study have shown that policies will come at a time when they are consistent with the ecological, social, and economic realities of the day, and that they can be fully implemented. However, in some cases, due to the lack of a clear strategy in the management of natural resources and the change of government, the government's priorities in the management of natural resources and land changed frequently and the continued implementation of the principled policies with has encountered a problem. The research confirms that rangeland specialists believe that policies, management patterns and plans should be tailored to ecological conditions and social characteristics of operators, which is absolutely necessary in a country with a high ecological and social diversity in Iran. Therefore, based on the accurate and updated data of the strategic plan for management of rangelands, we must prepare and implement the ecological diversity and social features of different areas. On the other hand, the government should regulate and define its macro policies in line with the sustainability of natural ecosystems. To achieve this, it is necessary to carry out extensive and in-depth research into the impacts of policies on rangeland management and other natural ecosystems, as well as comprehensive studies on the updating of ecological, social and economic data. In addition, with the presence and cooperation of international institutions, the experiences of other countries that have succeeded in managing rangelands and legislation for natural ecosystems.

(Received 26th Mar 2018; accepted 3rd Jul 2018)

Abstract. The role of infrastructure in promoting development in Nigeria cannot be overemphasized, given its importance in economic wellbeing of the populace and growth of the economy. This study examined the influence of infrastructure on the profitability of food crop production among rural farming households in Oyo State, Nigeria. Data were collected on six infrastructural facilities (tarred roads, potable water, market, health centre, storage facilities and school). Multi-stage sampling technique was used to select 120 farmers from two Agricultural zones of Oyo state. Data were analyzed using Descriptive statistic, Budgeting Analysis (BA) and Ordinary Least Square regression (OLS). OLS was employed to determine factors affecting profitability of food crop production in the study area and the model was well-fitted. Findings revealed that the majority (70.0%) of the respondents were male with 74.0% of them married and had a mean farm size of 12 ha. Based on the current state of rural infrastructure, 47.5% of the respondents reported that available tarred roads are functioning as against 23.0% of them whom reported that health facilities were not functioning. The study concluded that rural infrastructure is essential to the output of agriculture production in the study area. Rehabilitation of rural roads and the general upgrading of the rural infrastructures which will boost agricultural production across the state is recommended.
Keywords: *budgeting analysis, descriptive statistics, ordinary least square regression, rural infrastructure, Nigeria*

Introduction

In Nigeria, agriculture involves forestry, livestock, fishing as well as farming of food and cash crops such as yams, cassava, maize, cocoa, groundnut and oil palm. The country is largely endowed with natural resources (e.g. abundant land supply, human and forestry) that are necessary for the development of agriculture. The country has a total land area of about 98.3 million ha out of which 71.2 million ha (72.4%) are cultivable but only 34.2 million ha (34.8%) are currently in use (Daramola, 2014). In the country, agriculture faces a number of challenges and the majority of the farmers still depend on subsistence agriculture for their livelihood. More than 64% of people in the rural areas are not able to meet their basic food needs, and well over 50% of women

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_46554665

still engage in subsistence agriculture for survival (Ale, 2004). Other challenges include under-developed land property rights, infrastructural inadequacies, limited irrigation and inadequate storage facilities (Ashok and Balasubramanian, 2006).

Rural infrastructural is basic physical and organisation structures needed for the operation of a society or enterprises, or the services and facilities necessary for an economy, infrastructure is a set of investments that include rural roads, water supply, rural housing, rural electrification, sanitation, energy and telecommunication and agricultural processing (Anija-Obi, 2001). These facilities enhance the standard of living of rural famers (Onwuemenyi, 2008). The improvement of rural infrastructure is highly related to agricultural production in various ways. For instance, it is is one of the several subject of activities that are essential for rural transformation. Thus, the existence of poor quality or inadequate infrastructure will inevitably have a negative impact on agriculture (Patel, 2014).

Poor access to infrastructural facilities such as healthcare centre, educational institutions, communication gadgets and water supply lead to low agricultural production. This status and development of rural people enhance the quality of rural labour (Pinstrup-Andersen and Shimokawa, 2006). Agricultural development is essential for economic growth, rural development and poverty alleviation in low income and developing countries. Productivity increase in agriculture is an effective driver of economic growth and poverty reduction both within and outside agricultural sectors (Onwuemenyi, 2008). Such productivity increase depends on rural infrastructures, well-functional domestic markets, appropriate institutions and access to appropriate technology. While the state of rural infrastructures varies widely among developing countries, lower income countries including Nigeria suffer severe rural infrastructure deficiencies (Ekong, 2003).

Presently, Nigerian food crop production sub-sector is dominated by weak and inefficient producer-market linkages due to poor infrastructure including lack of improved processing facilities, low farm productivity, poor post-harvest handling and storage, expensive and poor access to inputs (high quality seeds, fertilizing and crop protection products), inadequate market information, lack of transparency among players, low capacity to meet quality standards, and limited efficiency distribution networks. This has declined rice productivity and low income for the rice farmers in Nigeria, especially in Oyo State.

Problem statement

Agriculture infrastructure although involves huge initial capital investments, long gestation periods, high incremental capital output ratio, high risks and low rates of returns on investments and increasing crop yields, thereby promoting agricultural growth (Patel, 2014). Government initiatives to improve the quality and quantity of infrastructure in the rural areas through programmes such as the construction of small dams and boreholes for rural water supply and the clearing of feeder roads for the evacuation of agricultural produce and the supply of electricity to rural areas from large irrigation Dams, the establishment of nine River Basin Development Authorities (RBDAs) in addition to the two existing ones (Sokoto and Rima RBDAs); DFRRI, the Poverty Relief and Infrastructure Investment Fund and the Comprehensive Agricultural Support Programme, have registered limited impact on the lives of many rural people (World Bank, 2006). The effort by government to increase productivity of farmers has been fulfill thus has adversely affected the level of agricultural production and socio-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_46554665

economic life of rural farmers because the improvement of these infrastructure are not available in the area of study. Rural infrastructure such as roads, irrigation, transportation, primary markets and weather forecasting services can reduces production cost, transportation cost, storage expenses, dealing cost and operation risk and enhance efficiently. Deficient infrastructures have negative implication on the present state of agriculture.

Agricultural production is still highly dominated by the small holder farming system. The farms are dominated by small scale farmers who are responsible for about 95% of total production (Fasoranti, 2004). This is not unconnected with the unattractiveness of agriculture which is a result of lack of necessary infrastructures in the rural areas which forms the bulk of agricultural zones in the country. In addition, small scale agriculture has in the time past suffered from limited access to credit facilities, modern technology farm inputs and inefficient use of resources. Nevertheless, it is on record that 50% of world's population is dependent on subsistence agriculture. In the words of Akande (2003), food cropping system and the postharvest services in Nigeria encompass a wide range of agricultural activities ranging from land clearing, seed bed preparation, broad casting, fertilizer application, weeding and bird scaring. Others include harvesting, threshing, parboiling, drying, winnowing, bagging and marketing and distribution. These activities are largely executed manually, women and children, the very vulnerable segments of the society are largely involved. Food crop production expansion in Nigeria is therefore bound to reduce drastically the foreign exchange spending on food importation and more importantly it could lead to the transfer to money into hands of the very vulnerable group of the Nigeria economy.

As indicated by Fakayode et al. (2009), the provision of efficient infrastructures is now widely recognize as indispensable to agricultural progress as it is known fact that infrastructure can support economic growth, reduce poverty and make development environmentally sustainable. In any modern society, infrastructure plays a pivotal and often a decisive role in determining the overall productivity and development of a countries economy as well as the quality of life of the citizens. The role of infrastructure such as electricity, transportation networks, safe water, and good health centre in promoting development cannot be overemphasized. The improvement increases the efficiency of production and contributes to standard living (PCU-NFDO, 2005). Rural infrastructure and development have enormous implication on production outcome in agricultural sector and over all significant development of the country. The effort by government to increase productivity of farmers has not been effective, and this has adversely affected the level of agricultural production and socio-economic life of rural farmers because the improvement of these infrastructures is not catered for in the area of study (Fakayode et al., 2009).

Felloni et al. (2001) reported that rural infrastructure such as roads, irrigation, transportation, and primary market and weather forecasting services can decrease production and transportation cost, storage expenses; dealing cost and operation risk and enhance efficiency. Deficient infrastructures have great negative implications on present state of agriculture. The United Nations (2009), estimated that 48.3%t of Nigeria's population live in the urban areas while the majority of the people (51.7%) live in the rural areas and they are largely engaged in agricultural production. Agriculture as the traditional mainstay of Nigeria's economy is a prominent industry in the rural areas, and its development is expected to have positive spill-over effects on food security, rural infrastructural development, and overall rural development. Thus,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_46554665

the immense values of the rural communities in overall national development have prompted both past and present administrations to formulate series of policies and programmes aimed at transforming rural-Nigeria. In order to ameliorate this solution, it is important to know the available infrastructures in the area so that more recommendations can be made to enhance farming operations. It is against this background that the study will provide the answers to the following questions:

1. What are the existing rural infrastructures in the study area?
2. What is the current state of existing rural infrastructures?
3. How do these rural infrastructures affect agricultural productivity in the study area?

Aim of the study

This study focused on the effect of rural infrastructure on profitability of food crop production in rural farming households in Oyo state, Nigeria.

The objectives are to

1. Describe the socio-economic characteristics of the respondents
2. Examine current state of the existing rural infrastructure
3. Determine the effect of these infrastructures on farm productivity
4. Estimate the profitability of crop farmers in the study area.

Materials and methods

Methodology

The study was conducted in Oyo State which has its capital in Ibadan (*Figs. 1* and *2*). The study area covers approximately an area of 28,454 km^2 with an estimated population of 5,591,589 people (NPC, 2006). It is an inland state in South-Western Nigeria. It bounded in the north by Kwara state, in the east by Osun State and the south by Ogun State. The income generating activities in the area includes: trading, farming, hunting, blacksmithing, weaving, tailoring and carpentry. The major crops cultivated in the area include yam, maize, cassava, okra, melon, groundnut and cash crops such as mango, cashew and citrus.

Figure 2. *Map of Oyo State indicating the local government areas and Agricultural Development Programme (ADP) Zones. (Source: Nigerian Muse, 2010)*

Model specification

Ordinary least square regression analysis

$$\text{Ln } y = \beta_1 \text{In } X_1 + \beta_2 \text{In } X_2 + \ldots\ldots.. \beta_n \text{In} X_n + e \qquad \text{(Eq.1)}$$

$$Y = f\,(X_1, X_2, X_3, X_4, X_5 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots X_{14}, U) \qquad \text{(Eq.2)}$$

Y = Gross margin (₦), X_1 = Farm size (hectare), X_2 = cost of hired labour, X_4 = Educational Status, X_5 = Farming Experience (Years), X_6 = Age of household head (Years), X_7 = distance to Potable water (if present, yes = 1, no = 0), X_8 = distance to Tarred Road (if present, yes = 1, no = 0), X_9 = Schools (if present, yes = 1, no = 0), X_{10} = Market (if present, yes = 1, no = 0), X_{11} = Health Centre (if present, yes = 1, no = 0), X_{12} = Storage Facilities (if present, yes = 1, no = 0), e = Error term.

Results and discussion

Demographic characteristics of food crop farmers

The socio-economic distribution of food crop farmers varied for all the parameters evaluated (*Table 1*). For instance, 38.0% of the respondents fall between age group of 20–40 with the mean age of 44 years while about 19.0% of the respondents are above 61 year old. This finding is similar to that of Fasoranti (2004) who reported on cost and return of crop production in Akure, Ondo State, Nigeria. One could infer from this result that crop farmers in the study area are young, active and still in the productive age. Also, the result of socio-economic distributions of the respondents showed that

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_46554665

majorities (70.0%) of the respondents were male while 30.0% were female. This implies that male are actively involved in farming. This could be attributed to the fact that Nigerian cultures do not permit women free access to and control over land (Rahji, 2007).

Table 1. *Socio-economic characteristics of the respondents. (Source: Field Survey, 2014)*

Characteristics	Frequency	Percentage	Mean

In terms of formal educational level of food crop farmers, 45.0% of the respondents has no formal education, those with tertiary education were about 4.0% and about 22.0% of the respondents had secondary education. The percentage of uneducated rural farmers is an indication of the level of infrastructure (school) in the study area. This result was in line with Mundluk et al. (2002) who reported that a large proportion of rural households continue to lack access to basic services. Furthermore, the duration of years spent farming indicated that 33.0% have spent between 1–10 years in farming, 24.1% of the rural farmers have spent 11–20 years in farming. Anijah-Obi (2001) corroborated this findings that longer year of farming experience helps the farmers to make rational choices and decision.

Perceived state of rural infrastructure in the study area

The perceived state of the selected rural infrastructure in the study area was evaluated (*Table 2*). Relative to tarred road, 47.5% of food crop farmers indicated that the road present are still functioning while about 4.0% of them reported that the available road are not functioning due bad state of disrepair. Among the respondents, 8.0% of them of had access to functioning potable water as against 5.0% that reported that the available market are been abandoned. Furthermore, 22.0% of the respondents have access to functioning healthcare service in the study area as against about 13.4% that had no access to storage facilities. According to FAO (2005 rural infrastructure plays a crucial role in poverty reduction, economic growth and empowerment for the Africa poor. Farmers efforts to escape poverty and overcome subsistence agricultural levels are been limited by the present of infrastructure in the study area, poor access to market, poor storage facilities and extension contact.

Table 2. *Perceived state of rural infrastructure in the study area. (Source: Field Survey, 2014. Freq = frequency)*

Infrastructure	Functional		Not functional		Partially functional		Abandoned	
	Freq	%	Freq	%	Freq	%	Freq	%

Budgeting analysis of food crop farmers in Oyo State

Gross margin was used to estimate the cost and return on food crop production in the study area as presented thus: GM = TR – TVC

$$\text{Benefit cost ratio (BCR)} = \frac{TR}{TC}$$

$$TC = TFC + TVC$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_46554665

where TC = total cost, TR = total revenue, TC = total cost, TR = total revenue, TFC = total fixed cost, TVC = total variable cost, GM = gross margin,
TR = ₦233909.5,
TVC = ₦122053.9,
TFC = ₦9200.0,
TC = ₦131253.9,
GM = ₦233909.5 – ₦131253.9 = ₦102655.6

$$BCR = \frac{233909.5}{131253.9} = 1.8$$

Given that the BCR is greater than 1, it shows that the crop production is profitable in the study area. This implies that for every ₦1.00 invested in agriculture in the study area, an expected return of ₦1.80 is certain with all things been equal.
This conformed with the findings of (Omotayo and Oladejo, 2016; Ekpe and Alimba , 2013) on food crop production in Ebonyi State which has positive gross margin as shown by the study because Total Revenue (TR) is far more than Total Variable cost (TVC). The profitability of crop enterprise and farmers income is expected to increase significantly if more land is put under food crop production.

Regression analysis

Result of the determinant of profitability of food crop production in the study area was presented in *Table 3*. The marginal effects of the independent variables were estimated because they are very important for policy and decision making. Parameter estimate of OLS revealed that farm size, potable water, storage facilities and quantity of agrochemicals used are significantly related to the farmers' profitability. Furthermore, total household size, educational level of the respondent, health, market and school are statistically not significant to farmers' production. This may be due to the availability of extension service, their scale of production is low and majority of them used local storage facilities. This is in line with the result of the work done by Okorie et al. (2011), who noted that farmers with increased household size obtained higher yield due to family labour supply. This reduces the cost of production since family labour is not paid for. The educational qualification of rice farmers bore positive signed coefficient and was not statistically significant.

The positive relationship indicates that the higher the level of education of the farmers, the higher their yield in rice production. This is true because educated farmers are intelligent and calculative in utilization of available resources and are able to adopt innovation on rice products. Unlike uneducated farmers who has low adoption level. Furthermore, it also implies that better education and more farming experience in terms of longer years may improve awareness of potential benefits and willingness to participate in local natural resource management and conservation activities. This result was in conformity with Ekong (2003), which explained that the spread of needed infrastructure and introduction of appropriate technology in rural areas would markedly improve rural economy and their output. Adjusted R^2 value of 0.507 implies that 50.7% variability in farmer's profitability is explained by the independent variables while the remaining 49.3% of the variability is accounted for by the error term and the excluded variables.

Conclusion and recommendation

The analysis of the socio-economic characteristics of the respondents showed that majority of the farmers are old and quite experienced in food crop production. Based on the findings from this study, it is evident that male are more involved in farming enterprise than female in the study area. Majority of the respondents are married, under basic education and mean household size of 12 persons. The study further revealed that food crop production is profitable in the study area with BCR of 1.8 which implies that for every ₦1.00 invested in agriculture in the study area, an expected return of ₦1.80 is certain with all things been equal. The result of the regression analysis showed that farm size, state of potable water, storage facilities and quantity of agrochemical used were statistically significant and had influence on farmers' profitability in the study area. Therefore, government and Non-government organization (NGOs) should collaborate with farmers with a view in providing the needed infrastructure in order of their priorities so as to increase their production in the study area.

1. Government should provide the rural farmers with necessary agricultural inputs at a subsidized level as this will equally enhances their productivity.
2. On basic healthcare facilities, both Government and Non-governmental Organizations (NGOs) should help in developing the rural health sector so as to increase labour availability and at the long run improve the productivity.
3. This research calls for general rehabilitation of the infrastructural facilities in the study area with a view of encouraging more people to agriculture and improving their productivity.
4. Government should work with existing social organization and involve them in distribution of necessary inputs for rice production.
5. Timely provision of necessary farm inputs to enhance rice production.

Abstract. The disinfection process is of great importance to the water supply to prevent diseases spread by water. Due to its negative impacts on human health, the number of studies conducted on disinfection systems alternative to chlorination and similar traditional methods has been increased. Successive and hybrid systems that are highly efficient in inactivating the pathogenic microorganisms that may be present in water are being developed. In this study, the disinfection efficiency of the antibacterial filled column, ultrasonic reactor and UV reactor that we developed was increased by the successive and hybrid usage of the methods when *Escherichia coli* bacteria were used to detect the disinfection efficiency of the systems. In single disinfection studies, bacterial inactivation efficiency occurred in UV process was higher than antibacterial column and also, efficiency occurred in antibacterial column was higher than ultrasonic reactor. Triple hybrid usage of these systems resulted in an 8 log microbial inactivation reducing single treatment disadvantages of these systems. Furthermore, the flow speed and temperature effect were examined during the studies, and it was observed that the temperature had a positive effect on the hybrid system.
Keywords: *bacterial inactivation, ultrasound, silver, ultraviolet radiation*

Introduction

Obtaining safe drinking and usage water has been increasingly gaining importance today. The fecal microorganisms that contaminate water generally originate from infected or disease carrying animal and human wastes. When water is contaminated with fecal matter, the disinfection procedure required to remove the microbial load is very important. Chlorination, ozone, ultraviolet radiation (UV), filtration and other methods are widely used for disinfection at the water distribution source. Choosing the right disinfection method is important for achieving the most effective microbial removal in water. The main factors affecting the choice of disinfection method are the efficiency, cost, applicability, pilot study requirement and side effects. The disinfection efficiency is determined by the ability of the method to inactivate the selected microorganisms to the target level. The disinfection method must be practical; and its handling, storage and production/application in the field as well as its monitoring and control must be simple. It must also achieve disinfection targets. The disinfectant should not create a toxic effect on aquatic life, it should not be transported to or bioaccumulate in nutrients, and it should not be transformed into or form carcinogenic, mutagenic or toxic substances (Liviac et al., 2010). Therefore, the side effects of the system used must be researched. When all of these elements come

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_46674680

together, a compelling argument can be made for using methods such as disinfection with ultrasound and metal ions as an alternative to conventional techniques when these new systems are used successively as hybrids.

Metal ions such as Hg, Au, Ag, Pb and Cu affect living organisms as disinfecting substances (Blanc et al., 2005). Metal ions are effective for the inactivation of bacteria (Fauss et al., 2014), fungi (Das et al., 2013) and viruses (De Gusseme et al., 2011), even at low concentrations. Metal ions inhibit the growth of some algae and fungi. A review of the literature (Chang et al., 2008; De Gusseme et al., 2011; Das et al., 2013; Fauss et al., 2014) shows that the Ag ion has often been used in antibacterial material production (Srinivasan et al., 2013) and water disinfection studies because it is nontoxic and effective for human health, even at low concentrations compared to other metal ions.

It is possible to kill the cells of microbial populations through ultrasound. The bactericidal effect of ultrasound is related to cavitation (Declerck et al., 2010). The formation of bubbles during cavitation usually kills the microbial cells (Naddeo et al., 2014). Small, high energy gas filled bubbles are formed during cavitation. The ultrasound process causes the microscopic bubbles to explode and a mechanical shock occurs (Rutala et al., 2007). High temperature (5500^0 C) and pressure (50 Mpa) points are formed when the molecules around the bubbles collide with each other during explosions (Leighton, 2007). Fragmentation occurs after the destruction of structural and functional units in the cell (Skauen, 1976). The cavitation bubbles blow up when the ultrasound is applied, and OH^- and H + reactive radicals are produced in the liquid media (Birkin et al., 2001). H_2O_2 (hydrogen peroxide) is formed when these radicals react with oxygen. The intense bubble formation prevents temperature and pressure alterations and causes DNA lysis, cell membrane disintegration and cell wall damage when the free radicals are formed (Vasilyak, 2010).

Since the 1900s, radiation emitted from an ultraviolet light source has been used for the disinfection of water sources (Choi and Choi, 2010). UV radiation, initially used for high quality water supplies, has gained importance in recent years in the treatment of waste water (Copperwhite et al., 2012; Nelson et al., 2013). It was determined that ultraviolet radiation at sufficient dosages may be used as a bactericide and virucide without forming any toxic compounds (Xu et al., 2009; Oguma et al., 2013). Radiation at a wavelength of 254 nm prevents cell reproduction when it passes through the cell membrane of the microorganism, leading to its death (Rincon and Pulgarin, 2004). The disinfection efficiency of UV radiation depends on the turbidity of the water (Bergmann et al., 2002). Therefore, a pre-distillation process such as filtration is needed when the organic content of the water is high and when it is turbid (Winward et al., 2008; Abd-Elmaksoud et al., 2013).

In the disinfection studies that were conducted using ultraviolet radiation, ultrasound and metal ions, it was possible to increase the bacterial inactivation efficiency and remove its disadvantages when successive and hybrid methods were used (Summerfelt et al., 2009; Wu et al., 2011; Zhu et al., 2014). Amirsardari, Yu and Williams found that trihalomethanes were decreased by 90% and halides were decreased by 98% when ozonation was used as a pre-treatment method along with UV radiation (Amirsardari et al., 2001). Butkus et al. (2005) determined that one more log removal was obtained compared to single UV radiation application in the inactivation of MS-2 coliphage viruses at 10^9 PFU/mL concentration when UV radiation was used. Naddeo et al. (2009) determined that the disinfection efficiency of the US-UV hybrid system was approximately 96% while the disinfection efficiency of the UV system alone was approximately 80% in the total coliform and E. coli disinfection studies that were conducted using pilot-scaled ultrasonic and UV reactors.

This study aims to develop alternative water disinfection systems with the goal of recovering disadvantages present in conventional water disinfection methods and increasing the efficiency of the disinfection. Except for conventional disinfection methods, the bacterial inactivation efficiencies of UV radiation, ultrasound and Ag^+ ion adulterated antibacterial column methods were examined with the goal of achieving optimal water hygiene standards. The disinfection efficiencies of these methods in dual ((Ag+ US, Ag+UV, US+UV) and triple (Ag+US+UV) successive systems were determined. We concluded that the disinfection efficiency was increased when successive systems were applied.

Materials and methods

This research was conducted in Department of Environmental Engineering, Anadolu University, Eskisehir, Turkey.

In this study, the disinfection efficiencies of antibacterial filled columns, ultrasonic (US) reactors and UV reactors were determined under continuous flow conditions. The inactivation of *Escherichia coli* bacteria was examined after single (Ag, US and UV), dual (Ag+US, Ag+UV and US+UV) and triple (Ag+US+UV) system disinfection.

Water disinfection with the antibacterial filled column

Two mm bead-shaped antibacterial filling material was used for water disinfection in the antibacterial filled column. Brick dust was used as the primary body material to which 25% antibacterial powder was added. The filling materials were then baked at 800 °C. Antibacterial powder (ABP) has an antibacterial effect due to the presence of silver. The calcium and phosphate based body releases the silver in a controlled manner. The reactor column that was used in this study had a height of 30 cm and a diameter of 2 cm.

Inductively Coupled Plasma Optical Emission Spectroscopy (ICP-OES, Varian 720) was used to measure the silver concentrations in treated water to control silver released from ABP because hesitation of silver usage in water has increasing for human health recently. In order to show silver concentration released from ABP is under safe limit, measurements were taken after subjecting the study solution through the antibacterial filled column at different flow rates. The study solutions were put through the reactor one time at different continuous flow rates: 5 mL/min, 25 mL/min, 50 mL/min and 100 mL/min.

Water disinfection with the ultrasonic reactor

An ultrasonic reactor that generates sound at a frequency of 40 kHz referred low-frequency ultrasound was used in the ultrasound disinfection procedure. The ultrasonic reactor was designed by us and has a diameter of approximately 60 mm and a width of 40 mm. There were transducers at two sides of the reactor. 100 watts of power was applied to the system. The disinfection studies were conducted at the5 mL/min, 25 mL/min, 50 mL/min and 100 mL/min. flow rates.

Water disinfection with the UV reactor

The UV disinfection column that was used for inactivating the microorganisms in this study had a diameter of 4.6 cm and a length of 25 cm. The UV lamp that was used here (Philips TUV 8 W UVC) had a wavelength of approximately 254 nm. The studies carried out in the continuous system using 1.3 L/min and 2.6 L/min flow rates.

Water disinfection with successive systems

Water disinfection with successive systems was carried out with the goal of removing disadvantages of the disinfection methods and observing the synergetic effects of these methods. The antibacterial filled column, the ultrasonic reactor and the UV reactor were successively used as dual and triple systems in the successive disinfection studies. The triple hybrid disinfection system yielded the best results and was conducted at 40 °C as well as ambient temperature (25 °C). The goal was to determine the temperature effect.

The disinfection studies where the antibacterial filled column and ultrasonic reactor were successively used were conducted at a 5 mL/min flow rate for the antibacterial filled column and a 25 mL/min flow rate for the ultrasonic reactor.

The disinfection studies where the ultrasonic reactor and UV reactor were successively used were conducted at a 5 mL/min flow rate for the ultrasonic reactor and a 2.6 mL/min flow rate for the UV reactor.

The disinfection study where the antibacterial filled column, ultrasonic reactor and UV reactor were used as a triple hybrid system was conducted using a 5×10^8/mL bacterial concentration. The flow rates for the antibacterial filled column and the ultrasonic reactor were 100 mL/min, and the flow rates for the UV reactor were 1.3 L/min and 2.6 L/min. The study was performed at a 2.6 L/min at a flow rate under 40 °C.

Microbiologic studies

The solution to be used for the disinfection studies was prepared by adding *Escherichia coli* bacteria to sterilized distilled water at the desired concentrations. The desired initial bacterial concentrations were obtained by making necessary dilutions from a bacteria culture that was kept for 1 day at 37 °C. The samples were cultivated in plate count agar (PCA, Merck KGgA, Germany) media and were incubated for 1 day at 37 °C. The microbiologic studies were conducted at ambient temperature inside sterile cabinets (Heraeus KSP- 18 Class II). After incubation, the efficiency of the disinfection systems was determined by counting the colonies. It was assumed that bacteria that were alive equaled a colony in solid media.

The bacterial concentration of initial and effluent water was determined with a simple and well-known plate count method during all disinfection studies using serial dilution of the samples. 1 mL aliquot was taken from treated water and un treated water according to desired time interval depending operation parameters (flow rate, hydraulic retention time or disinfection period). The bacterial concentrations of aliquot taken from system were obtained by making necessary dilutions (10×, 100× and 1000× dilutions) transferring 9 mL sterilized water gradually. 150 µL samples taken from each dilution was inoculated on PCA solid media, and the plates were incubated at 37 °C for 18-24 h. The bacterial concentration of each samples was calculated using viable cells grown in PCA plates and 150 µL sampled volume as colony forming unit per sample volume expressed mL (CFU/mL).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_46674680

The results of microbiological studies were expressed as average of three independent experiments with error bar using standard deviation (SD). Each experiment was performed with three parallels. Statistical significance of the difference of the counted bacteria in in plate count agar among each trials was determined by analysis of variance (ANOVA) using one-way post hoc statistical test. In order to show reliability of measurement, p value obtained from one-way ANOVA test was given for each disinfection study.

Results and discussion

The disinfection efficiency with the antibacterial filled column

The disinfection procedure was conducted at a 1×10^5 CFU/mL bacterial concentration using different flow rates with the goal of determining the efficiency of the antibacterial filled column. The experimental results are given in *Figure 1*.

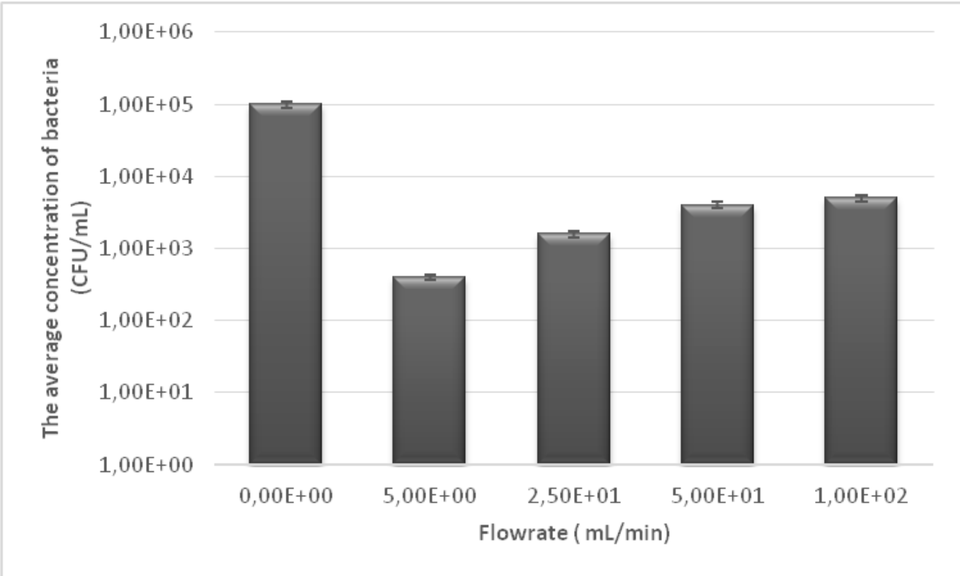

Figure 1. *The effect of different flow rates on bacteria removal at a 1×10^5 CFU/mL initial bacterial concentration in the antibacterial filled column (p value was calculated as 0.0000000003 using one-way ANOVA test. This value showed that there is no significant difference of each measurements among each three disinfection experiment because $p < 0.01$)*

The best bacteria removal was achieved at the 5 mL/min flow rate. As the contact time with the active matter increases with a decrease in flow rate, it is expected that the bacterial inactivation rate also increases. These results are seen in *Figure 1*. 2 log bacterial inactivation was achieved for the 5 mL/min flow rate. The silver concentrations of the study solutions subjected through the antibacterial filled column in a continuous system at different flow rates are given in *Figure 2*.

It was observed that the amount of silver present in the samples at the 5 mL/min flow rate was greater than that at other flow rates, however 5 mL/min was the lowest flow rate used in the study. The silver concentration at 5 mL/min was determined to be 74 µg/L.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_46674680

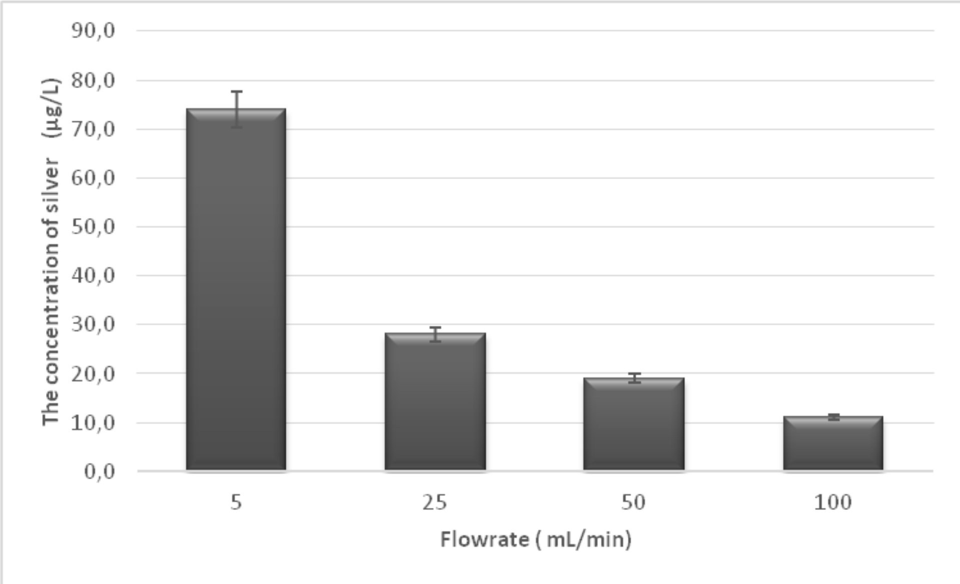

Figure 2. *The silver amounts that are released to study the solution of different flow rates in the antibacterial filled column disinfection procedure (DL: 0.35 µg/L, RSD: 5% and R^2: 0,9967 of ICP-OES calibration)*

Silver ions have the highest level of antimicrobial activity of all the heavy metals and its bacterial inactivation mechanism is well known in the literature. Our study demonstrated that disinfection process conducted with antibacterial filled column achieved sufficient inactivation ratio using silver ions released to water from filling materials surface.

Although, there is no unique or rigid safe limit of silver ion concentration allowed in water according to health and environmental organization, number of studies focused on silver toxicity has been increasing in literature to find out safe limit of silver used in potential implications for human health and the environment (Marambio-Jones and Hoek, 2010). These studies have showed that silver can be present in metallic silver, silver salts (generally silver sulphate), silver complexes and nano-sized silver. Also, researcher has reported silver nano particle is more toxic to fish, algae, some plants, fungi and mammalian cells due to nanosized effect than silver salts compounds (Panyala et al., 2008). Marambio-Jones and Hoek reported toxiccity concentraions of silver between 50 µg/mL-100 µg/mL among rewied reserchs depending toxicity organisms and silver form presented in water.

The results of disinfection studies and ICP-OES analyses showed that increasing hydraulic retention time affected directly disinfection efficiency because silver ion amount released to water increased with lowering water flow rate. ICP-OES measurement showed that silver concentration released from ABT to water was under toxicity level reported in previous studies and released silver concentration could be controlled increasing flowrate. In order to achieve powerful bacterial disinfection in antibacterial column, silver ion concentration should be increased in water according to water and health regulation for silver amount of water to avoid its environmental risks. However, there are two possible problems in the case of demanding more silver concentration to achieve adequate disinfection efficiency for strength microorganisms. These are the increasing cost of silver added to system and increasing silver amount in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_46674680

the human bodies consuming the water disinfected with silver due to bioaccumulation. Our study indicates that innovative successive and hybrid disinfection process conducted with ultrasound and UV can be used in order to escape these problems.

The disinfection efficiency of the ultrasonic reactor

The disinfection procedure was conducted using a 1×10^5 CFU/mL bacterial concentration subjected to a 40 kHz ultrasonic frequency with the goal of determining the efficiency of the ultrasonic reactor. The results obtained using different flow rates through the ultrasonic reactor are given in *Figure 3*.

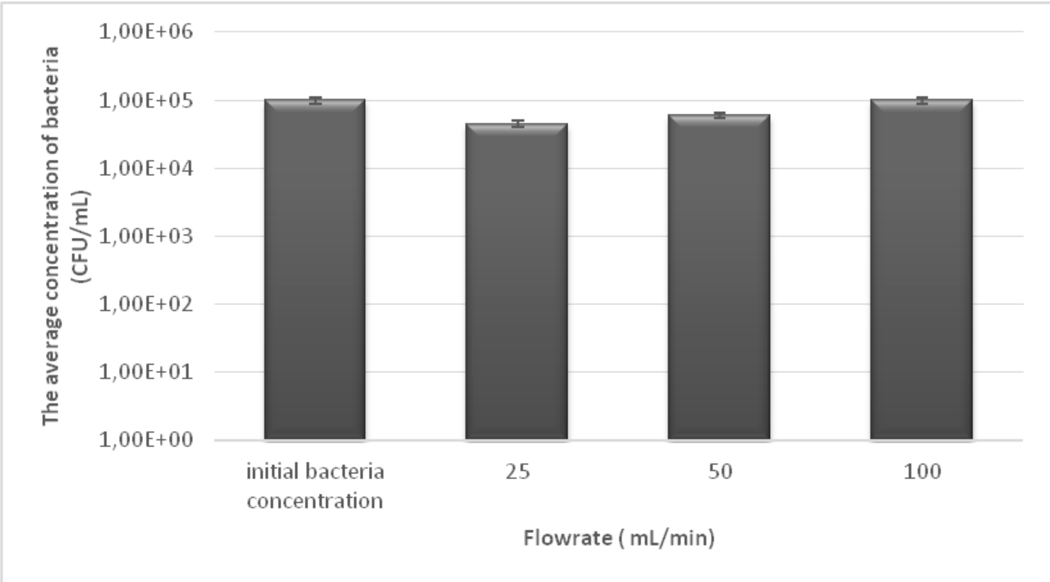

Figure 3. *The effect of bacteria removal at a 1×10^5 CFU/mL initial bacterial concentration in ultrasonic reactors at different flow rates (p value was calculated as 0.000020158 using one-way ANOVA test. This value showed that there is no significant difference of each measurements among each three independent disinfection experiment of three treatment conditions because $p < 0.01$)*

In the ultrasonic reactor, 0.5 log bacterial inactivation was achieved at the 25 mL/min flow rate. Bacterial inactivation increased with a decrease in flow rate. The result of the ultrasonic disinfection studies showed that ultrasound had no significant effect on inactivation of *Escherichia coli* in the case of single application. The mechanical effects of low-frequency ultrasound leading to cell membrane disruption of bacteria were probably insufficient for the inactivation of *Escherichia coli* (Joyce et al., 2003). It was stated that higher bacterial inactivation required higher power supply for ultrasound usage aiming disinfection in literature (Mason et al., 2003). In order to recover this disadvantages of ultrasound for water disinfection various ultrasonic reactor was produced with different frequency, power supply and different configuration. Cerecedo et al. (2018) conducted a disinfection study using rotor-stator device for water disinfection based on hydrodynamic cavitation and they reported that the water was infected with *E. coli* and *E. faecalis* with initial concentrations in the range 5×10^2–1.2×10^6 CFU/ml due to mechanical cavitation's cell membrane disruption.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_46674680

The disinfection efficiency of the UV reactor

Escherichia coli disinfection was conducted using an initial bacteria concentration of 3×10^8 CFU/mL with the aim of determining the efficiency of the UV reactor. The results obtained from the UV disinfection procedure conducted at different flow rates are given in *Figure 4*. A 5 log bacterial inactivation was achieved for both of the flow rates used in the studies. The UV reactor effectively disinfected very high initial bacteria concentrations. In single UV disinfection studies, bacterial inactivation efficiency was significantly higher than antibacterial column and ultrasonic reactor.

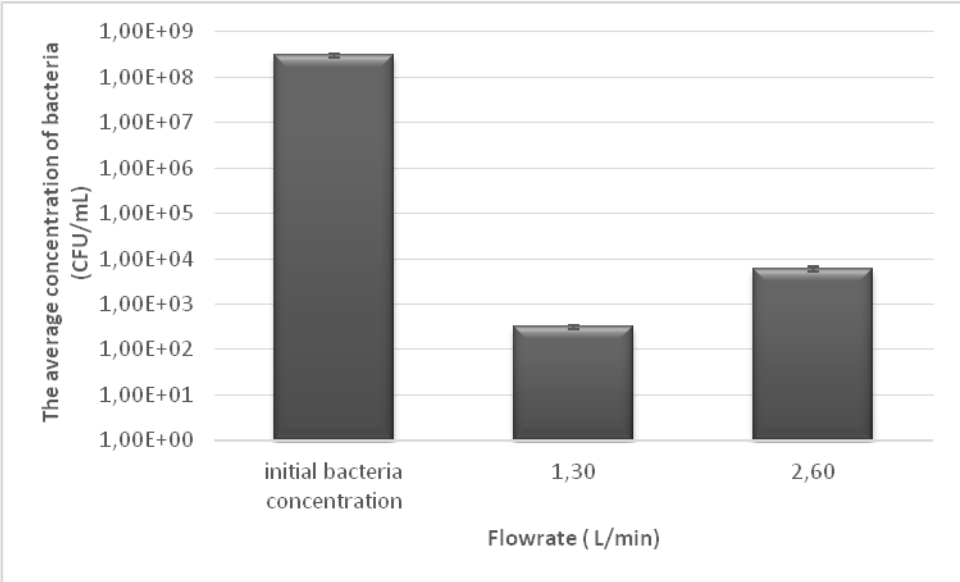

Figure 4. *The effect of bacteria removal at a 3×10^8 CFU/mL initial bacterial concentration in the UV reactor at different flow rates (p value was calculated as 0.000000070 using one-way ANOVA test. This value showed that there is no significant difference of each measurements among each three independent disinfection experiment of two treatment conditions because $p < 0.01$)*

The disinfection efficiency of successive systems

The results obtained from the studies conducted with the goal of determining the effectiveness of the dual antibacterial filled column and ultrasonic systems are given in *Figure 5*.

The silver ions were more evenly distributed inside the liquid media in the ultrasonic systems. Therefore, the efficiency of the disinfection was increased by providing continuous silver-bacteria contact inside the liquid media. Another factor increasing the efficiency of the disinfection was that the ultrasound damaged the cell membrane of the bacteria and the silver ions are much more effective when the cell membrane is damaged. In the studies conducted using the ultrasonic system after the antibacterial filled column all of the bacteria available in the media were inactivated and log 5 inactivation was achieved.

DOI: http://dx.doi.org/10.15666/aeer/1604_46674680

This study revealed that the dual ultrasonic and UV reactor system had a stronger disinfection effect than when each was used alone. When these systems were used together, a 6 log bacterial inactivation was achieved. The study using the antibacterial material-filled column and the UV reactor together aimed to examine the disinfection efficiency of the dual system. The results obtained from the studies are given in *Figure 7*. When the antibacterial filled column and the UV reactor were used together the disinfection efficiencies increased. 7 log bacterial inactivation was achieved using this system successively.

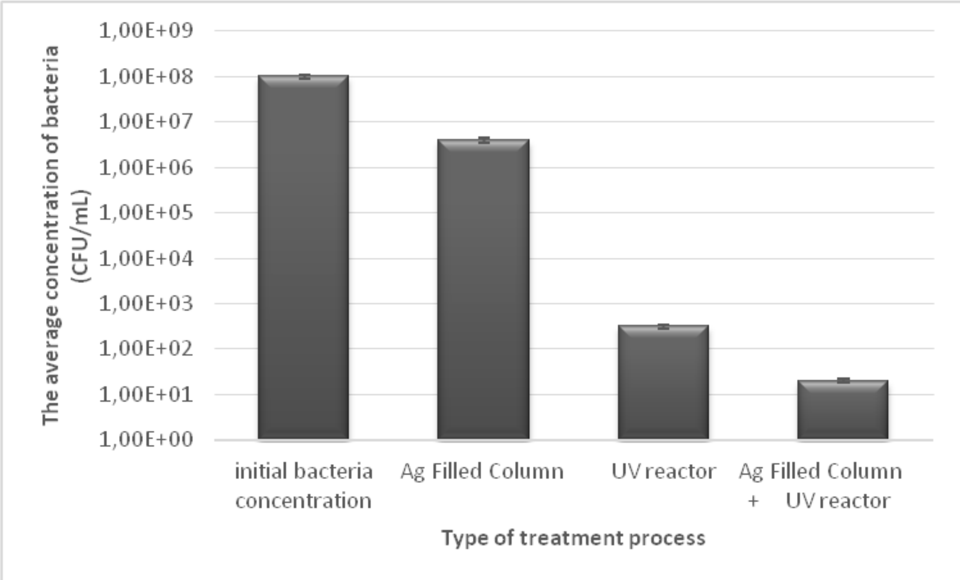

Figure 7. *The successive effect of antibacterial filled column and UV reactor at a 1×10^8 CFU/mL initial bacterial concentration (p value was calculated as 0.000000016 using one-way ANOVA test. This value showed that there is no significant difference of each measurements among each three independent disinfection experiment of three treatment conditions because $p < 0.01$)*

These result demonstrated that successive application of three systems could be successfully performed for *Escherichia coli* disinfection reducing total silver amount released to the water related and increasing mechanical effects of low frequency ultrasound. Also, the efficiency of UV treatment was improved with synergistic effects of ultrasound and silver ion. It was observed that the use of successive systems increases the efficiency of disinfection. The effectiveness of each disinfection system increases when the bacteria has sufficient contact with the disinfectants. The ultrasound reactor contributed to the effectiveness by decreasing the shielding effect in the bacteria. The Ag ion was better distributed inside the system when the ultrasound reactor was used and the disinfection effectiveness of the systems when used together was higher.

The disinfection efficiency of triple successive systems

Triple hybrid studies were conducted using the antibacterial filled column, the ultrasound reactor and the UV reactor together. The results obtained from the study are given in *Figure 8* and post hoc statistic test results of final disinfection study were summarized in *Table 1*.

The most effective disinfection was achieved in the successive system consisting of the antibacterial filled column, the ultrasonic reactor and the UV reactor used together. The triple hybrid system studies were conducted at 40 °C with the goal of determining the effect of the temperature. Better results were obtained in the studies conducted at 40 °C with a 2.6 L/min flow rate than at 25 °C. 2 log inactivation increases was observed with the increase in temperature. 8 log bacterial inactivation was achieved by the triple hybrid system. It was determined that the triple hybrid system showed a synergetic effect.

When triple hybrid studies were conducted using the antibacterial filled column, the ultrasound reactor and the UV reactor together, the disinfection efficiency of *Escherichia coli* was 8 log after disinfection period. This indicates that *Escherichia coli* disinfection with triple hybrid studies was performed reducing separate disadvantages of single application of three systems. Although mechanical effects of low-frequency ultrasound were insufficient for disinfection in single treatment, it improved other antibacterial column efficiency with cavitation mass transfer effects of silver ion from filling material surface to bacterial cell membrane. When ultrasound used with UV in successive or triple hybrid system, ultrasound prohibited regrowth of bacteria, which is most common problem in UV treatment, due to mechanical effect on cell membrane. In successive and triple application with antibacterial column, it improved the disinfection efficiency of UV treatment for water samples with high turbidity characteristic. These results indicated that using successive and triple hybrid system application of antibacterial column, UV and ultrasound vanish individual disadvantages of single application of three systems. Temperature effect accelerated the disinfection efficiency for strength microorganisms presented in water to obtain eligible inactivation ratio additionally.

This study was successfully indicated that innovative successive and hybrid disinfection process conducted with silver, ultrasound and UV can be used in order to escape serious problems when faced their single usage.

Conclusion

In this paper, the targeted *Escherichia coli* disinfection efficiency was obtained using successive and triple hybrid application of antibacterial column, ultrasound and UV aiming more sufficient inactivation ratio using lower individual disadvantages of these three treatment methods. The highest *Escherichia coli* inactivation ratio was determined in UV in single treatment application and ultrasound was insufficient for *Escherichia coli* disinfection due to week mechanical effect of cavitation. The result of successive studies demonstrated that UV, ultrasound and silver ion created synergy to achieve adequate water disinfection efficiency. Increasing disinfection efficiency with successive or triple hybrid systems was expected results but single treatment process of both antibacterial column, ultrasound and UV indicated that synergic effect was not only formed of ultrasound. The hybrid disinfection using antibacterial column, ultrasound and UV provided higher bacterial inactivation efficiency in shorter disinfection period than single processes of these treatment methods, especially when need to more powerful disinfection efficiency for strength microorganisms assisting temperature effect. This study demonstrated that hybrid application of antibacterial column, ultrasound and UV could be performed effectively for water disinfection with less environmental risks and reducing individual disadvantages of disinfection methods.

(Received 29th Mar 2018; accepted 12th Jun 2018)

Abstract. The paper presents water retention of alluvial soils in the Odra valley. Floodplain soils are one of the most fertile intrazonal soils in Europe. The relevant field studies and laboratory tests were carried out during the vegetation seasons (2012 and 2013) on arable lands located in Tworków (south of the Silesian Province, Poland). A three pedotransfer functions (PTFs) parameter van Genuchten type model was used to describe the water retention curves of alluvial soils. Fitted soil water retention curve (SWRC) parameters were regressed linearly with a different number of soil physical properties in the RETC and Rosetta. The first model (PTF-1) uses soil textural classes, consisting of a lookup table that provides parameter averages for each USDA textural class. The second model (PTF-2) uses sand, silt, and clay percentages as input, and the third model (PTF-3) includes bulk density as a predictor. The simulation results were considered for each layer separately and as a whole for all soil profiles. The predicted values of water content of the RETC and Rosetta for each soil layer are close to the measured values (R^2 = 0.825–0.995). Simulated values of water content (all soil profiles) by PTF-3 are very similar to the measured values. The predicted values of the residual soil water content (θr) and the saturated soil water content (θs) by PTF-3 provided good simulation results R^2 = 0.860 and R^2 = 0.667, respectively. The specific alluvial soil conditions affect the high water content in the soil, which is reflected in the content of water available for plants. This information should contribute to the rational management of water resources in the agricultural area, what can be used to mitigate the effects of drought.
Keywords: *water properties of soil, floodplain soil, RETC program, Poland*

Introduction

Soil is a non-renewable natural resource that is essential to life. Water movement, water quality, land use, and vegetation productivity all have relationships with soil (Schoonover and Crim, 2015). Diversity of alluvial soil types has been the subject of much less study than typical mineral soils. Thus, studies focused on physical and hydraulic parameters of alluvial soils are essential for a better understanding of how alluvial ecosystems function (Ľuptáčik et al., 2012).

Alluvial soils have the highest productivity with respect to other soils (Huong et al., 2013). They are present mostly along rivers and are carried by its streams during weathering of rocks. Most vegetable production is on alluvial soil generally succeed. The key role in creating alluvial soil is a high ground water level (Dobrovol'ski et al., 2011; Pirastru and Niedda, 2013; Liu et al., 2015; Dwevedi et al., 2017; Yassoglou et al., 2017).

River alluvial soils are formed from silts deposited chiefly by flood-waters, from here are often called floodplain soils. Soil formation is in this case very long, in consequence, alluvial soils have, as a rule, an undeveloped profile. The natural soils in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_46814699

river-valley bottoms are almost wholly used for meadows, pastures and tilled fields (Szafer, 1966). According to Bednarek and Prusinkiewicz (1999) alluvial soils constitute about 5% of Poland's area.

As a result of soil cultivation, farmers can change some of its physical and hydraulic parameters, such as: soil compaction, soil water permeability, relations between water and air (Cameira et al., 2003; Pagliai et al., 2004; Hakl et al., 2007; Nawaz et al., 2013; Bogdał et al., 2014; Kahlon and Khurana, 2017). Soil compaction is a significant problem of agriculture nowadays. It is directly connected with the mechanization of field treatments. Compaction is a physical form of soil degradation: it changes the soil structure, water and air permeability, porosity, and it inhibits penetration by plant roots (Hakl et al., 2007; Nawaz et al., 2013).

Knowledge of the soil hydraulic properties is indispensable to solve many soil and water management problems related to agriculture, ecology, and environmental issues. The most important hydraulic properties of soils are the soil water retention curve (SWRC) and soil water permeability (Shwetha and Varija, 2015; Qanza et al., 2015). Soil hydraulic properties depend mainly on soil texture, organic matter content and bulk density (Hillel, 1998). In scientific research, many methods and types of models are used to determine the hydraulic parameters of soils (Minasny et al., 2004; Šimůnek et al., 2005; Pandey et al., 2006; Nasta et al., 2013). The role of water retention in soil has been analyzed and reviewed in many scientific studies (Van Genuchten et al., 1991; Minasny et al., 2003; Merdun et al., 2006; Wassar et al., 2016; Nguyen et al., 2017).

Modeling water flow in soil requires knowledge of soil hydraulic properties, which are water retention curves. As an alternative to direct measurement, indirect determination of these functions from basic soil properties using pedotransfer functions (PTFs) has attracted the attention of researchers in a variety of fields such as soil scientists, hydrologists, and agricultural and environmental engineers (Merdun et al., 2006; Fashi et al., 2016).

Water retention characteristics are fundamental input parameters in any modeling study on water flow and solute transport. These properties are difficult to measure and for that reason, we usually need to use direct and indirect methods to determine them. An extensive comparison between measured and estimated results is needed to determine their applicability for a range of different soils (Wassar et al., 2016).

The RETC can be useful for estimating the hydraulic parameters from retention data only with laboratory, or simultaneously from observed retention and hydraulic conductivity data and other physical parameters (Van Genuchten et al., 1991).

The objective of this study is to evaluate the water retention of the alluvial soil and the estimation of van Genuchten parameters by the three intelligent pedotransfer models RETC.

Materials and methods

Study area

The study area lies on alluvial soils located in the catchment of the Odra River on arable land in Tworków, in the south of Poland (the Racibórz District, the Silesian Province) (*Fig. 1*).

The average altitude of the object is 190.00 m a.s.l. According to the geographical division by Kondracki (2011), the object is situated in the Central European Lowlands province (31), in the macroregion of the Silesian Lowlands (318.5) and in the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_46814699

mesoregion of the Raciborska Basin (318.59), in terms of climate is considered as one of the warmest areas in this region. In general, Poland has mostly temperate climate, in transition between oceanic climate dominating in the north and west of the country, and continental climate in the south and east (Kundzewicz et al., 2017). In the multiannual period 1971–2000, average annual air temperature was 8.5 °C and total precipitation was 616 mm (according to the IMGW – Institute of Meteorology and Water Management – station in Racibórz). Depending on changes in meteorological conditions, there are periodically too high moisture contents in soil. The characteristics of meteorological conditions are shown in *Table 1*.

Field analysis

The field soil tests were carried out in the two agricultural seasons: 2012 and 2013 on arable lands. The alluvial soils are the predominant soil type here on account of height

APPLIED ECOLOGY AND ENVIRONMENTAL RESEARCH 16(4):4681-4699.

of the region's surface water, which makes them good/very good in terms of soil fertility classes.

In field four soil pits were made up to a depth of 150 cm (*Fig. 2; Table 2*). Undisturbed soil samples were taken from each genetic horizons using Kopecky's cylinders (in 3 replications) to find the soil water content (SWC), bulk density (BD), total porosity and soil water potential. Also, approximately 1 kg, disturbed soil from each genetic horizons to find the soil texture and other laboratory analysis were taken.

Laboratory analysis

From the soil samples that were collected the following properties were determined:

- Soil texture by the Bouyoucose-Casagrande areometric method modified by Prószyński. The modification consisted in measurement of suspension of soil by Prószynski's hydrometer, which gives percentages sedimentation fraction content between the two readings in the time. Suspension density is read in the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_46814699

terms, which set out in the tables developed by Prószyński. The content of particle size classes (sand, 2.0–0.05 mm; silt, 0.05–0.002 mm; clay, <0.002 mm) is determined according to the Soil Taxonomy system that was made known by the United States Department of Agriculture (USDA) (Soil Survey Staff, 1999).

- Particle density (ρ_s) by the pycnometer method as average density of the mineral grains of the soil (*Eq. 1;* Mocek and Drzymała, 2010; Phogat et al., 2015):

$$\rho_s = \frac{M_s}{V_s}\left(g \cdot cm^{-3}\right) \tag{Eq.1}$$

where M_s is the mass of mineral grains of the soil sample (g) and V_s is the volume of the mineral grains of the soil (cm^3).

- Soil bulk density (ρ_b) by the gravimetric method in Kopecky's cylinders (100 cm^3) as the mass of dry soil per volume. The weight of this soil core is then determined after drying in an oven at 105 °C for about 18–24 h. The dry bulk density for each core sample was then calculated using equation (*Eq. 2;* Hao et al., 2008; Phogat et al., 2015):

$$\rho_b = \frac{M_s}{V_t}\left(g \cdot cm^{-3}\right) \tag{Eq.2}$$

where M_s is the mass of dry soil weight (g) and V_t is the soil volume (cm^3).

- Soil moisture (volume wetnees) by the gravimetric method in Kopecky's cylinders (100 cm^3) as the ratio of the amount of water in the soil sample to the dry weight of the soil, after drying in an oven at 105 °C for about 18–24 h, then calculated using *Equation 3* (Mocek and Drzymała, 2010; Phogat et al., 2015):

$$\theta_v = \left[\frac{V_w}{V_t}\right] \cdot 100\left(cm^3 \cdot cm^{-3}\right) \tag{Eq.3}$$

where V_w is the volume of water in the soil sample (cm^3) and V_t is the volume of soil sample (cm^3).

- Water storage in layer as (*Eq. 4;* Mocek and Drzymała, 2010):

$$S_w = \frac{\theta_V \cdot h}{10}\,(mm) \tag{Eq.4}$$

where θ_v is soil moisture (% cm^3·cm^{-3}), h is thickness of the soil layer (cm), *10* – water conversion from Mg·ha^{-1} to mm water.

- Soil water retention using set for pF determination with ceramic plates in the 5 and 15 Bar Pressure Plate Extractor. The pressure plate equipment used in this study is made by the American Soil Moisture Equipment Corporation. In engineering practice, soil suction has usually been calculated in *pF* units (*Eq. 5;* Schofield, 1935):

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_46814699

$$pF = log\ h\ (cm\ H_2O) \qquad \text{(Eq.5)}$$

where h is the suction of water (in cm).

In laboratory the soil water potentials were measured at pF: 0.0, 2.0, 2.2, 2.5, 2.7, 3.0, 3.4, 3.7 and 4.2 (*Table 3*). The total available water capacity (TAWC) was determined as a difference between the moisture retained at pF 2.5–4.2. Easily and hardly available water were determined as a difference between the moisture retained at pF 2.5–3.7 and at pF 3.7–4.2, respectively. The field capacity (FC) was considered at pF 2.5 and the permanent wilting point (PWP) at 4.2 (Mocek and Drzymała, 2010).

Table 3. *The pressure applied to determine the pF curves*

Number of measurements	pF	cm H_2O	kPa	bar	mm Hg
1	0.0	0	0.00	0.0000	0.0
2	2.0	100	9.81	0.0981	73.6
3	2.2	159	15.54	0.1554	116.6
4	2.5	316	30.99	0.3099	232.4

8	3.7	5000	490.33	4.9033	3677.8
9	4.2	15849	1554.26	15.5426	11657.9
10	7.0	10 000 000	1 000 000	10 000	735538.1

- Total organic carbon (TOC) content by the Tiurin's method, then converted to soil organic matter content (SOM) according to the formula (*Eq. 6;* Mebius, 1960; Mocek and Drzymała, 2010):

$$SOM = TOC \times 1.724\ (\%) \qquad \text{(Eq.6)}$$

- pH value by means of the potentiometric method in KCl of 1 mol·dm^{-3} concentration in one repetition (Mocek and Drzymała, 2010).
- On the basis of results obtained total porosity was calculated from bulk density and particle density, as (*Eq. 7;* Mocek and Drzymała, 2010; Phogat et al., 2015):

$$f = \left[1 - \frac{\rho_b}{\rho_s}\right] \cdot 100(\%) \qquad \text{(Eq.7)}$$

Soil classification was established according to the Polish Soil Classification (PTG, 2011), the World Reference Base for Soil Resources – IUSS Working Group WRB (2006) and USDA soil taxonomy (Soil Survey Staff, 1999).

Modeling the soil water retention in the RETC program

The RETC (*Retention Curve Program*) is a computer program which may be used to analyze the soil water retention and hydraulic conductivity functions of unsaturated soils, especially to predict the hydraulic conductivity from observed soil water retention data assuming that one observed conductivity value (not necessarily at saturation) is available (Van Genuchten et al., 1991; Hollenbeck et al., 2000).

The shape of water retention curves (pF) can be characterized by several models, one of them known as the van Genuchten model (1991) (*Eq. 8*):

$$\theta_{(h)} = \theta_r + \frac{\theta_s - \theta_r}{[1 + (\alpha |h|^n)]^m} \quad \text{(Eq. 8)}$$

where, $\theta_{(h)}$ is the soil water content ($cm^3 \cdot cm^{-3}$), θ_r is the soil residual water content at pF > 4.2 ($cm^3 \cdot cm^{-3}$), θ_s is the soil saturated water content at pF 0.0 ($cm^3 \cdot cm^{-3}$), h is soil water potential (kPa), α is a scale parameter inversely proportional to mean pore diameter (cm^{-1}), n and m are the shape parameters of soil water characteristic

$$m = \frac{1}{n};\ 0 < m < 1.$$

Retention curves (pF) were compared against those obtained from the RETC program estimations and laboratory measurements. The water retention parameters according to Van Genuchten (1980) with predicted hydraulic functions were estimated by a published neural networks program *Rosetta Lite v. 1.1.* The necessary input data for the RETC model (e.g. % soil texture and bulk density) were determined in laboratory analysis of soil samples from different soil horizons (*Tables 2, 3* and *4*). The unknown parameters (θ_s, θ_r, n, α) were determined in the RETC program (Van Genuchten et al., 1991) using measured soil water retention data. *Rosetta* offers five pedotransfer functions (PTFs). To estimate of the water retention parameters (θ_r, θ_s, α, n), were used only three of them with limited or more extended sets of predictor. The first model (PTF-1) uses soil textural classes, consisting of a lookup table that provides parameter averages for each USDA textural class. The second model (PTF-2) uses sand, silt, and clay percentages as input, and in contrast to PTF-1, provides hydraulic parameters that vary continuously with texture. The third model (PTF-3) includes bulk density as a predictor (Schaap et al., 1998, 2001).

Statistical analysis

The data set consisted of analytical results of soil samples collected at the four soil pits located in the Odra River valley during two vegetation seasons (2012 and 2013). For statistical analysis, the procedures provided by the program *Statistica PL version 12.5* were used. A 5% significance level was used. A statistical method was chosen after checking data normality (Shapiro-Wilk test). For each analysed physical and water parameters of soil its minimum and maximum values were determined its arithmetic mean, median, standard deviation (SD) and coefficient of variation (CV) were computed. The performances of the RETC model and laboratory measurements in predicting measured data were assessed using a coefficient of determination (R^2).

DOI: http://dx.doi.org/10.15666/aeer/1604_46814699

Moreover, the Spearman's correlation relationship (r) between the granulometric composition and the organic matter of soils and their physical and water values were calculated. The correlation strength and direction of a linear relationship between two variables were determined based on a scale (Rumsey, 2016): exactly ±1 – a perfect downhill/uphill (negative/positive) linear relationship; ±0.70 – a strong downhill/uphill (negative/positive) linear relationship; ±0.50 – a moderate downhill/uphill (negative/positive) relationship; ±0.30 – a weak downhill/uphill (negative/positive) linear relationship; 0 – no linear relationship.

Results

Physical properties of soils

As shown in *Table 4* and *Figure 2*, the alluvial soils are heterogeneous in terms of texture. In each soil profile, five genetic levels were specified. The granulometric composition of the profiles was classified into to seven soil texture groups (acc. to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_46814699

USDA) as: silty loam (SiL), silty clay loam (SiCL), loam (L), sandy clay loam (SCL), sandy loam (SL), clay (C) and clay loam (CL). The high coefficient of variation (CV) values was observed, which is the measure of empirical data deviations from average values. The highest CV was in silt (62.4%). Sand content in the profiles was between 16 and 76%, silt content between 16 and 62%, and clay content between 8 and 65%. Finally, according to the Polish Soil Classification (PTG, 2011), World Reference Base for Soil Resources – IUSS Working Group WRB (2006) and USDA soil taxonomy (Soil Survey Staff, 1999), examined soils were classified as:

- Order 7. Chernozemic soils (Polish: Gleby czarnoziemne; WRB: Chernozems, Phaeozems; ST: Mollisols – Aquolls, Udolls).
- Type 7.4 "Chernoziemic fluvisols" (Polish: Mady czarnoziemne; WRB: Mollic Fluvisol, Endofluvic Phaeozem; ST: Fluvaquentic Endoaquolls)

The soils formed mostly in recent alluvium on flood plains. Many of the soils have been artificially drained and are used as cropland, but some are used as pasture or forest (Soil Survey Staff, 1999).

The basic physical and chemical properties of soils with descriptive statistics for each sites is given in *Table 5*.

High soil moisture values were observed in soil profiles. The average soil moisture content was 0.3907 $cm^3 \cdot cm^{-3}$, which means it is very close to average value of water content at the field's water capacity (*Table 6*). Bulk density (BD) was in range 0.44–1.81 $g \cdot cm^{-3}$ and predominantly increasing with a depth and yielding a very high value for total porosity from 31.95% to 73.96%. Mean particle density value is very similar in whole profiles about 2.56 $g \cdot cm^{-3}$, only in profile no. 1 in fourth genetic horizon (rich in organic matter) it is much smaller (1.69 $g \cdot cm^{-3}$). According to coefficient of variation (CV), the behaviour in the soil profiles can be considered as a low variability (see *Table 5*). Mean organic matter content, about 2.03%, was highest in top layers and decreasing with depth. The pH values were in a wide range from 3.71 to 7.27, which corresponds to very acidic to alkaline soils. The high values of water storage ranged 477–715 mm in soil profiles was observed.

Hydraulic properties of soils

The data of soil water retention, incuded available water for plants, from laboratory analysis are presented in *Table 6*. The water retention curve for the studied soils showed a mean value of soil moisture of about 0.4754 $cm^3 \cdot cm^{-3}$ at saturation (pF 0.0), 0.4294 $cm^3 \cdot cm^{-3}$ at field water capacity (pF 2.5), and 0.2065 $cm^3 \cdot cm^{-3}$ at permanent wilting point (pF 4.2). Mean share of easily accessible water for plants contributed 77% of the total available water for plants (TAWC), whereas hardly accessible water accounted 23% TAWC.

The determination coefficient (R^2) of observed and fitted values in each layers of soil profiles ranges from 0.825 to 0.995. These results are very satisfactory and show that the estimation procedure works well (*Tables 7, 8* and *9*). *Tables 7, 8* and *9* present different values of the van Genuchten parameters (θ_r, θ_s, α, n) obtained.

Table 7. *Characteristic parameters of soil water content from model PTF-1 with soil USDA textural classes*

The graphs of the fitted the van Genuchten model with the RETC to the soil water retention data with laboratory measurements for soil pit no. 1 – from depth of 0–30 cm and for soil pit no. 2 – from depth of 34–52 cm are illustrated in *Figure 3*, as examples. It is observed that both the results of research fit well.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_46814699

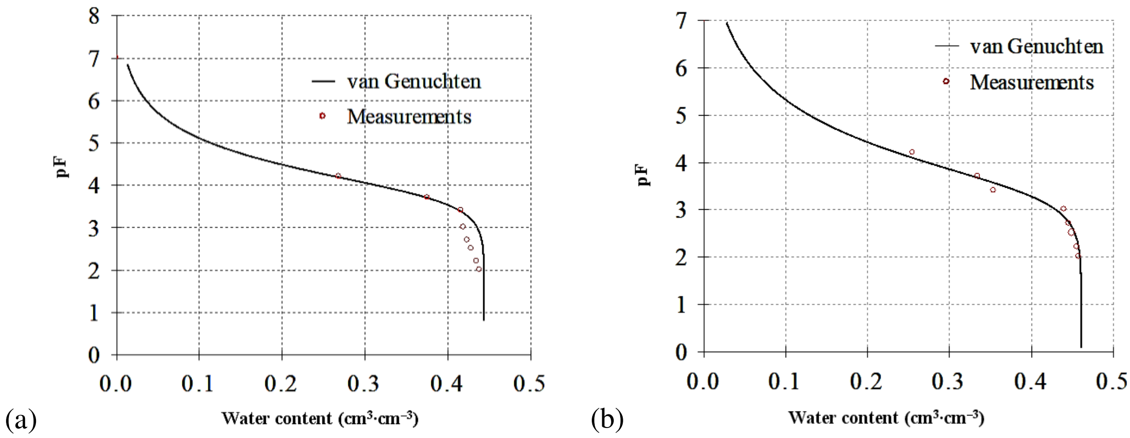

Figure 3. *Water retention curve (pF): a) – soil pit no. 1; b) – soil pit no. 2*

Figures 4 and *5* illustrate the comparison of the predicted water content of the RETC and Rosetta with that of measurement for three pedotransfer models (PTF-1, PTF-2 and PTF-3). The measured results from all soil profiles for θ_s and θ_r were compared with fitted results those of the RETC and Rosetta.

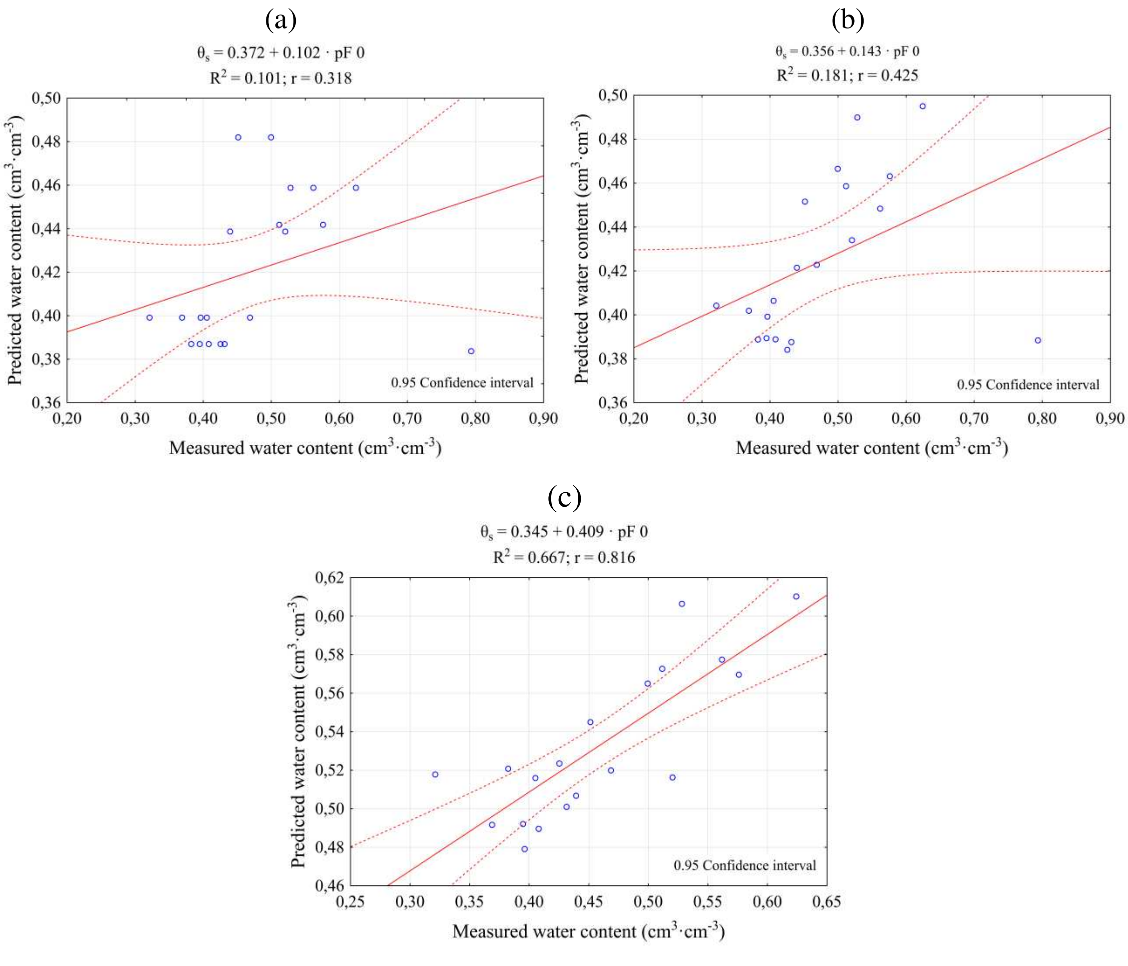

Figure 4. *Estimated vs. measured water contents (θ_s) of the RETC a) for first model (PTF-1), b) second model (PTF-2), c) for third model (PTF-3)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_46814699

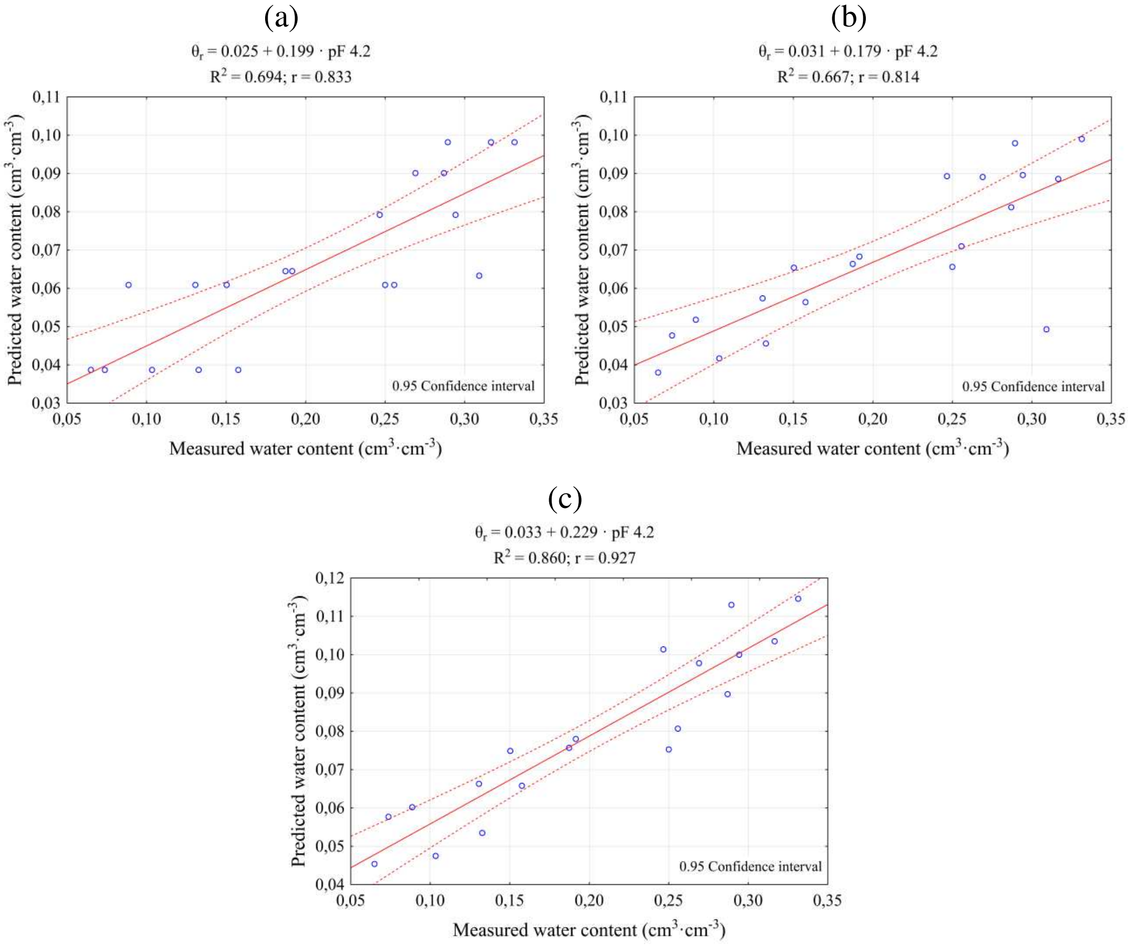

Figure 5. *Estimated vs. measured water contents (θr) of the RETC a) for first model (PTF-1), b) second model (PTF-2), c) for third model (PTF-3)*

The results of the three pedotransfer functions show statistically increase in the R^2 for θ_r (PTF-1 – $R^2 = 0.694$, $p < 0.05$; PTF-2 – $R^2 = 0.667$, $p < 0.05$ and for PTF-3 – $R^2 = 0.860$, $p < 0.05$). On the other hand two neural network models show statistically low R^2 and also no statistically significant for θ_s (PTF-1 – $R^2 = 0.101$, $p > 0.05$ and for PTF-2 – $R^2 = 0.181$, $p > 0.05$) only in case of PTF-3 results was high and statistically significant ($R^2 = 0.667$, $p < 0.05$).

In order to find interrelations of soil properties a correlation R Spearman analysis was conducted. The correlation (*Table 10*) displayed significant correlation between particle size distribution (i.e. sand, silt, clay content) and soil organic matter (SOM) content, and physical and water properties of soil.

Sand content was statistically significance ($p < 0.05$) negatively correlated with field capacity (FC), hardly accessible water and pH, whereas silt content was statistically significance positively correlated with pH. Also clay content was statistically significance positively correlated with FC and hardly accessible water. Soil organic matter was statistically significance positively correlated with water content, total porosity, FC and available water but statistically significance negatively correlated with BD and particle density. The correlation strength between SOM and soil moisture, BD,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_46814699

particle density, total porosity and FC was statistically very high ($r > 0.7$), while between SOM and available water was statistically high ($0.5 < r < 0.7$).

*Values in bold indicate that correlation relationships are statistically significant ($p < 0.05$)

Discussion

The examined alluvial soils are very specified and diversity in terms of texture (Iqbal et al., 2005; Bullinger-Weber et al., 2007; Ľuptáčik et al., 2012) and showed high water content values (at saturation 0.4754 $cm^3 \cdot cm^{-3}$ and wilting point 0.2065 $cm^3 \cdot cm^{-3}$). This feature may be related to the high silt (35.9%) and clay (26.1%) for all soil profiles and also mean organic matter content about 2.03% (Rawls et al., 2003; Rubio and Poyatos, 2012). Minasny et al. (2003) reported. that the hydraulic parameters are mostly sensitive to sand content and saturated water content. Gama-Castro et al. (2000) found, that the high productivity of alluvial soils is largely due to the plant available water. According to Hong et al. (2013) the most important values for agricultural use is a field water capacity (at pF 2.5), which in this case ranged between 0.2690 and 0.6784 $cm^3 \cdot cm^{-3}$.

The maximum retentive capacity (at pF 0.0) measured in laboratory was slightly different than total porosity calculated from bulk density and particle density. Paluszek (2011) stated that the difference between maximum retentive capacity and total porosity may be especially visible in the soils with high content of swelling clay minerals because maximum retentive capacity was directly determined after capillary rise to the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_46814699

state of full saturation, while total porosity was calculated on the basis of the particle density and bulk density.

Bulk density (BD) is one of important physical soil properties that characterizes soil compaction (Reynolds et al., 2002). The BD range of alluvial soils can be very wide – smaller values were observed in the Ap horizons and increased with depth (Gama-Castro et al., 2000). We observed that bulk density was related to organic matter contents, which is not in agreement with the findings of Gama-Castro et al. (2000), where they assumed that the presence of more noncrystalline material due to increased pumice weathering contributes to the low bulk density through the development of a porous soil structure.

Used the pedotransfer models of artificial neural network program Rosetta in this case, produces promising results only for sand, silt, and clay percentages and bulk density as data input. This might be due to the fact that the van Genuchten's parameters. which express the shape of the water retention curve, are sensitively affected by the wide ranges of soil properties as in this alluvial soil. Even though the data used in this study was obtained from a relatively small area, large spatial and temporal variability in physical and hydraulic properties of this alluvial soil may cause such a low performance in predictions. Similar results were observed by Minasny et al. (1999), Nemes et al. (2002) and Merdun et al. (2006).

Conclusions

In conclusion the course of the water retention curves obtained on the basis of non-linear regression analysis (R^2) for each layers of soil profiles indicates a good adjustment of the approximating functions used to the retention capacity obtained from the measurements. The pedotransfer models of artificial neural network program RETC and Rosetta in this case produces promising results and its advantages can be utilized by developing of water hydraulic characteristics of alluvial soils in future studies. The simulation of the RETC using the van Genuchten equation with a percentages of sand, silt and clay and also bulk density entry value was adequate to estimate soil water contents for four soil profiles located in the Odra River valley, in spite of the differences obtained between observed and predicted data.

On the basis of the conducted research it can be concluded that share of easily accessible water for plants was higher of the hardly accessible water for plants. It is very important from the viewpoint of the production and cultivation. Alluvial soil can hold moisture and is very fertile so in dry years plants do not suffer from a shortage of water.

Studies on water retention of alluvial soils should be extended in order to obtain more data that will be used for proper statistical inference. Other properties of alluvial soils, e.g. water permeability, should also be carried out.

Abstract. Forest fires have been regarded as a common phenomenon that has endangered forests throughout the history of the world. It changes the vegetation and forest floor suddenly and drastically. Kernel density estimation (KDE) is a frequently employed approach in order to transform historical wildfire data into a smooth and continuous 2-D surface during the spatiotemporal analysis of forest fires. The most crucial step in KDE is to choose the appropriate bandwidth parameter. In this study, a novel approach to obtain an appropriate smoothing parameter is introduced by adapting a powerful nonparametric spline fitting methodology, namely, multivariate adaptive regression splines (MARS) into the KDE analysis of wildfires for the first time. Spatial and temporal analysis of wildfires between 2000 and 2017 in Mumcular Forest Subdistrict in Turkey is investigated by using the MARS-based KDE analysis. The proposed methodology in this paper produces a single smoothing parameter, instead of a range of values laying within a certain fixed interval, and it appears more robust to the positional uncertainties in the historical fire data, and more reliable than nonobjective visual analysis of maps generated by using alternating smoothing parameter values.
Keywords: *forest fires, kernel density, kernel bandwidth, MARS, Mumcular*

Introduction

Wildfires may often lead to serious damage to the ecosystems of forested landscapes, as well as to the diversity of flora and fauna. Preparing wildfire risk maps by using temporal fire occurrence data is very important for reducing these negative effects of forest fires. However, a wildfire event is generally recorded with its x and y coordinates by assuming each fire event as a point process, which negatively alters its 2-D exterior characteristics and propagation style. Additionally, temporal wildfire data mostly suffer from inappropriate or inadequate information and precision due to the fact that it is operationally and logistically hard to obtain the real coordinates of locations where a wildfire event starts.

This problematic issue significantly degrades the geolocational accuracy of wildfire data. These errors can eventually propagate wildfire liability estimates and result in unforeseeable negative impacts on the related risk maps. In order to tackle with this problem, two main approaches exist: *i*) to overlay a 10 × 10 km Universal Transverse Mercator (UTM) grid on administrative borderlines and to force the wildfire starting locations (i.e., points) to be confined in a polygonal area demarcated by the 10 × 10 km net, administrative borders and prescribed wild-land sites, or *ii*) to increase the resolution of lattice superimposed over the recorded wildfire starting locations in order

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47014716

to decrease geolocational inaccuracies, which, in turn, may often cause complications regarding abstraction and reduction in geospatial variability (Koutsias et al., 2004).

Derivation of a density function by using the locations of recorded observations is often considered as an effective approach to create a continuous raster surface from point data. Kernel density estimation (KDE) is a commonly preferred approach to obtain such a 2-D raster surface. KDE is a nonparametric method and its output is a surface that models the hidden density function (Anderson, 2009). KDE is a widely-recognized methodology and used in wildlife ecology (Horne et al., 2007; Katajisto and Moilanen, 2006; Kie et al., 2010), in geology and geophysics (Kagan and Jackson, 2000; Lasocki and Orlecka-Sikora, 2008), in spatial epidemiology (Anderson and Titterington, 1997; Robertson et al., 2010), in transportation planning and management (Okabe et al., 2009; Xie and Yan, 2008), in crime analysis (Chainey et al., 2008; Nakaya and Yano, 2010), in civil and mechanical engineering (Chen et al., 2000; Worden et al., 2003; Yu and Su, 2012), and in medicine (Rossiter, 1991; Zou et al., 1997).

Preceding studies

Koutsias et al. (2014) conducted a study in order to obtain a map that reveals the fire occurrence zones of Greece at a national scale by using KDE. In the study, they employed 4 different kernel widths as 1000, 2000, 3000 and 4000 m, and statistically compared them by Monte Carlo randomization test. The results indicated that increasing the width of kernels above 1000 m did not have any influence on the density surfaces.

To investigate the relationship between the fuel phenology and the spatiotemporal patterns of wildfire events in Sardinia, Italy, Bajocco et al. (2017) used KDE to convert wildfire ignition points to a 2-D raster density surface. According to the results of the study, wildfire locations were significantly associated to both anthropogenic pressure and to the spatiotemporal variation of fuel conditions in the study area.

In the study of Camarero et al. (2018), the impact of anthropogenic factors and climate systems on historical fire incidence in Mediterranean black pine forests were investigated within a long time interval (i.e., 1800-2000). Three input parameters, i.e., charcoal accumulation rates, historical records of wild fire events and tree-ring data, were collected in Sierra de Gredos (central Spain), and employed in the analysis. The historic fire data in point format were transformed into a continuous 2-D density surface by using KDE approach. The results of the study pointed that extensive grazing and uncontrolled use of forests and grasslands, together with enormous warm spring temperatures could lead to increased wildfire occurrence in Mediterranean pine forests.

The studies of Koutsias et al. (2014), Bajocco et al. (2017) and Camarero et al. (2018) have revealed that KDE is an effective way to convert the temporal wildfire data with inherent point characteristic and a certain degree of uncertainty into a continuous raster surface for defining spatial arrangement of wildfire occurrences at regional dimensions and analyzing their spatial scope, and it has also been applied by many other researchers to investigate the spatiotemporal patterns of such events (Del Hoyo et al., 2011; Gonzalez-Olabarria et al., 2012; Gralewicz et al., 2012; Hély et al., 2010).

Basics of kernel density estimation

KDE is a fundamental data smoothing problem and a nonparametric statistical technique to estimate a real valued function. In order to calculate KDE for a finite data

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47014716

sample, *i*) a grid with predefined spatial resolution is overlaid on the study area, *ii*) and the intensity at each crossing of the grid is predicted by putting a symmetrical surface on each of the point event locations (cf. *Fig. 1*). KDE in bivariate form can be defined as (*Eq. 1;* Hastie et al., 2009; Worden et al., 2003):

$$\hat{f}(\mathbf{z}) = \frac{1}{nh^2} \sum_{i=1}^{n} K\left(\frac{\mathbf{z} - \mathbf{Z}_i}{h}\right), \quad \text{(Eq.1)}$$

where $\hat{f}(\mathbf{z})$ is the prediction for the real intensity function, n denotes the number of total event records which are in point data format, h is the width of the kernel window (also referred as Parzen window (Hastie et al., 2009)), which is commonly known as a smoothing parameter, $\mathbf{z}$ gives the vector of coordinates at which the density is calculated (i.e., intersection of overlaid grid), $\mathbf{Z}_i$ represents the geolocation of each event point (i.e., x and y coordinates of wildfire events), and K indicates the kernel function that meets the following requirement (*Eq. 2*):

$$\int K(z)\,dz = 1. \quad \text{(Eq.2)}$$

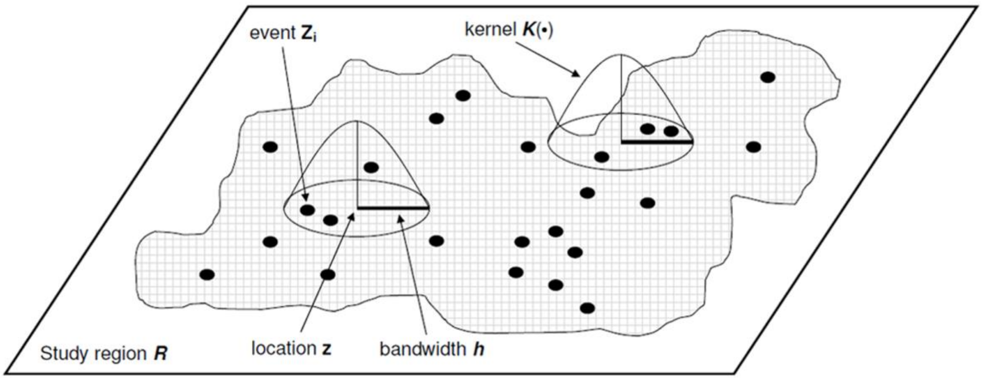

Figure 1. *KDE of a set of point observations in 2-D. (Adapted from Bailey and Gatrell, 1995)*

The choice for K can be made from a range of options such as triweight, uniform and normal. In this study, normal kernel (i.e., Gaussian), the widely recognized and employed kernel function, is preferred and its bivariate form is given as (*Eq. 3;* Wand and Jones, 1993)

$$K(\mathbf{x}) = \frac{1}{2\pi} \exp\left(-\frac{1}{2}\mathbf{x}^T\mathbf{x}\right). \quad \text{(Eq.3)}$$

At this point, it is of value to mention that the type of the kernel function does not have a significant impact; however, the selection of smoothing parameter directly and strongly affects the estimated density values. While small choice of h causes insufficient smoothing and gives spikier density values rather than the underlying density function, large values of h result in over-smoothed estimates that obscure important features of the underlying structure (Bowman and Azzalini, 1997; Wand and Jones, 1993; Worden et al., 2003).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47014716

For KDE analysis, there are several data-driven methods introduced by researchers in order to calculate the bandwidth parameter (Bailey and Gatrell, 1995; Williamson et al., 2008; Worton, 1989), yet enumerating them all with details is out of our scope. Selecting the bandwidth value by visual inspection is another frequently used method in such analysis and this approach can be found satisfactory for many applications (Kie et al., 2010; Wand and Jones, 1995). However, a profound and extensive information and a high level of expertise regarding the area of study are required in this approach, which may not always be satisfied by the analyst.

Main motivation

In our study, as a novel contribution to KDE analysis of wildfire events, a state-of-the-art multivariate adaptive regression splines (MARS) (Friedman, 1991) algorithm is applied to predict a suitable value for smoothing parameter. For this purpose, Mumcular Forest Subdistrict located in City of Muğla, Turkey is selected as study area, and wildfire data of the region between years 2000 and 2017 are used. KDE maps with different bandwidths are produced, and then compared by correlation analysis. Correlation values are plotted against bandwidths for building the MARS model function. By using the generated MARS model function, the appropriate value of smoothing parameter is decided. Then, KDE maps of wildfire events in the study area are produced to expose the behavior of wildfires in both spatial and temporal domains in the region. Then, final density map is obtained and converted into a mean density map representing the average intensity values for each of the administrative polygons in the entire region.

The paper is organized as follows. The next section represents the materials and methods including a brief mathematical background of the MARS approach, study area, the wildfire data and the estimation of suitable smoothing parameter. The results then are discussed in the third section. And finally, the last section concludes our study.

Materials and methods

Multivariate adaptive regression splines (MARS)

In this subsection, a brief introduction to MARS algorithm is given based on Friedman (1991), Hastie et al. (2009), Nalcaci et al. (2018) and Özmen et al. (2018).

MARS is a nonparametric spline regression method and it uses one-dimensional piecewise linear basis functions (BFs) in order to define a relationship between a response variable and its predictors. MARS has many successful implementations in almost every branch of science and engineering (Alp et al., 2011; Çevik et al., 2017; Durmaz et al., 2010; Özmen et al., 2014; Quirós et al., 2009).

The BFs of MARS are in the following form (*Eq. 4*):

$$[x-t]_+ = \begin{cases} x-t, & \text{if } x > t, \\ 0, & \text{otherwise,} \end{cases} \qquad [t-x]_+ = \begin{cases} t-x, & \text{if } x < t, \\ 0, & \text{otherwise,} \end{cases} \tag{Eq.4}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47014716

where t is a univariate knot determined using the dataset. The range of each predictor variable is cut into subsets of the full range by using knots which defines an inflection point along the range of a predictor. The MARS model in its general form can be expressed as (*Eq. 5*):

$$Y = \beta_0 + \sum_{m=1}^{M} \beta_m B_m \left(\boldsymbol{X}^m \right) + \varepsilon. \qquad \text{(Eq.5)}$$

In *Equation 5, Y* is the response, β_0 is the intercept, β_m denotes an unknown coefficient of the mth BF, or the constant 1 ($m = 0$), M is given as the number of BFs in the present model, B_m is a BF or product of two or more BFs, $\boldsymbol{X}^m$ is the vector of predictor variables contributing to the function B_m, and finally, ε is an additive stochastic component with zero mean and finite variance.

The basic form of the mth BF is given as (*Eq. 6*):

$$B_m \left(\boldsymbol{X}^m \right) := \prod_{j=1}^{K_m} \left[s_{\kappa_j^m} \cdot \left(x_{\kappa_j^m} - \tau_{\kappa_j^m} \right) \right]_+ . \qquad \text{(Eq.6)}$$

In *Equation 6, K_m* denotes the total number of truncated linear functions multiplied in the mth BF, $x_{\kappa_j^m}$ indicates the input variable corresponding to the kth truncated linear function in the mth BF, $\tau_{\kappa_j^m}$ is the knot location for $x_{\kappa_j^m}$ and, finally, $s_{\kappa_j^m} \in \{\pm 1\}$.

The final MARS model is determined with a two-step process including *forward pass* and *backward pass* stages. Forward pass generally creates an over-fit model. At the backward stage, the over-fitted model is simplified in terms of its complexity without degrading the overall fit to the data by imposing a *lack-of-fit* criterion defined by the following *generalized cross-validation* (GCV) formula (*Eq. 7*):

$$\mathrm{LOF}(\hat{f}_\alpha) = \mathrm{GCV}(\alpha) = \frac{\sum_{i=1}^{N} (y_i - \hat{f}_\alpha(\boldsymbol{X}_i))^2}{(1 - Q(\alpha)/N)^2}, \qquad \text{(Eq.7)}$$

where $Q(\alpha)$ denotes the effective number of parameters in the model, and N is the number of observations.

Study area

In the Mediterranean and Aegean regions of Turkey, forest fire is still one of the greatest natural hazard problems. Forest Subdistrict of Mumcular in Muğla province (cf. *Fig. 2*) located in the south-west Aegean region of Turkey is selected, since this region has experienced large number of wildfire events for the last two decades. The study site covers an area of nearly 322 km^2, and its altitude varies between 0 to 870 m above mean sea level. Forested lands constitute nearly 67% (214 km^2) of the study area, the canopy density of 43% of the forested lands ranges from 41 to 100%. Cultivated lands cover 29% of the area (i.e., 93 km^2). The land classification is derived by using the latest digital stand map of the subdistrict in ArcMap shape file format and can be seen in *Figure 3*. “*Pinus brutia*” is the prevailing tree species in the subdistrict region and it is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47014716

extremely flammable and fire-prone due to its resinous structure. The detailed info on study area is given in *Table 1*.

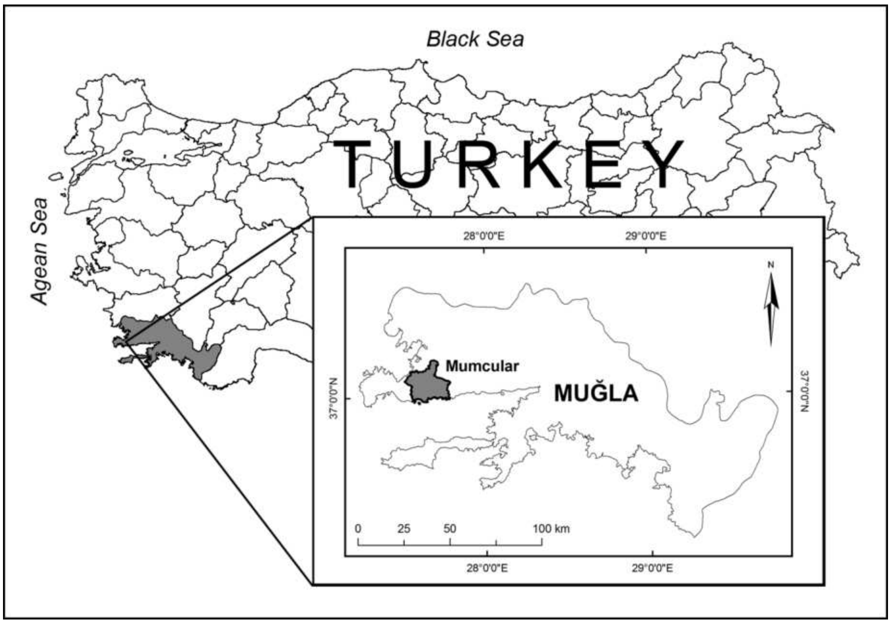

Figure 2. *Study area*

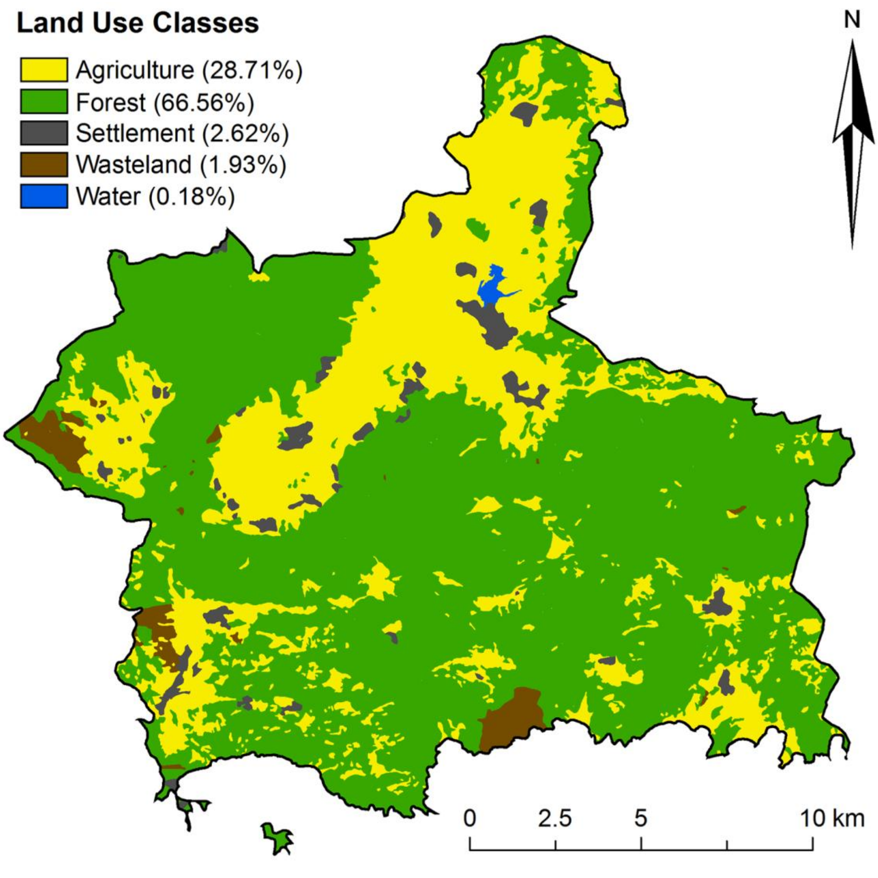

Figure 3. *Land-use map of the study area (Produced from the latest version of the digital stand map of the area supplied by Mumcular Forest Subdistrict)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47014716

Table 1. *Basic information on the forest subdistrict area*

Surface area	321.7 km^2
Number of compartments (polygons)	373
Average value of wildfire occurrence per compartment	0.582
Number of wildfire events (years 2000-2017)	217
Min. compartment area	0.0029 km^2
Max. compartment area	9.43 km^2
Average compartment area	0.83 km^2

Dataset

The temporal wildfire events data supplied by Mumcular Forest Subdistrict are in spread sheet format and belong to years between 2000 and 2017. There are 217 fire ignition locations in total. The coordinate system of the digital stand map of the subdistrict conforms with WGS84/UTM projection. The map comprises 373 compartments, which can be defined as administrative polygons (cf. *Fig. 4*). As a preliminary preparation prior to the analysis, the complete wildfire data are merged with the digital stand map in *ArcMap 10.3*.

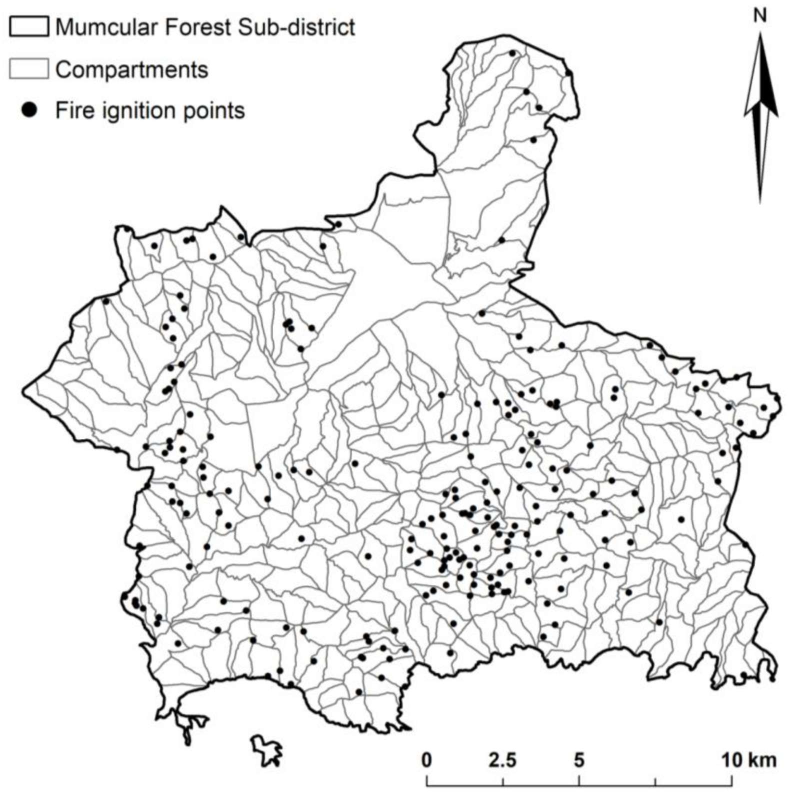

Figure 4. *Compartments of the digital stand map and ignition points*

Choice of KDE smoothing parameter

Although true geolocations of wildfires are not known, the true number of wildfire events is available for each compartment. Therefore, instead of utilizing above

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47014716

mentioned traditional methods, three completely unique and distinct random point distributions are created (i.e., R1, R2 and R3), and by this way, exact number of wildfire occurrences in each of the administrative polygons (i.e., compartments) is realized.

This approach lets us not only provide the ability of introducing randomness into the analysis, but also confine the wildfire starting points in relatively smaller administrative areas (i.e., compartments in the stand map) as compared to the traditional method (i.e., superimposing 10 × 10 km net over the area). As a result of this process, an improvement over positional inaccuracies is achieved.

To select an appropriate smoothing parameter (i.e., *h*), a different and a novel strategy is followed. First, KDE maps for various *h* taking values within the set {1,2,…5000} are obtained for each random point distribution, i.e., R1, R2 and R3, which means that 15000 KDE maps are generated on aggregate. Then, mutual comparison between each pair of KDE maps for each value of *h* is carried out via a simple analysis of correlation. Correlation values for each random point distribution for several *h* values (i.e., 100, 500, 2500 and 5000 m) are given in *Table 2*.

Table 2. *Correlation coefficients vs. smoothing parameter h*

Random distributions→ *h*↓	**R1-R2**	**R1-R3**	**R2-R3**
100 m	0.4015275	0.4427352	0.4259254
500 m	0.9225721	0.9245119	0.9205818
2500 m	0.9993016	0.9990487	0.9994646
5000 m	0.9990197	0.9990199	0.9990199

Next, in order to include more stochasticity in the process, random noise is added to the correlation values of each pair of random point distributions. This noise mimics the uncertainties inherited in the coordinates of the wildfire locations which may eventually propagate to the correlation analysis between each pair of point distributions. By this way, extra randomness in the positional inaccuracies of wildfire events is introduced. The standard deviation of the noise added is equal to the standard deviation of the correlation values of that specific pair. The plots of the correlation values with noise with respect to *h* for three random point distributions are depicted in *Figure 5*.

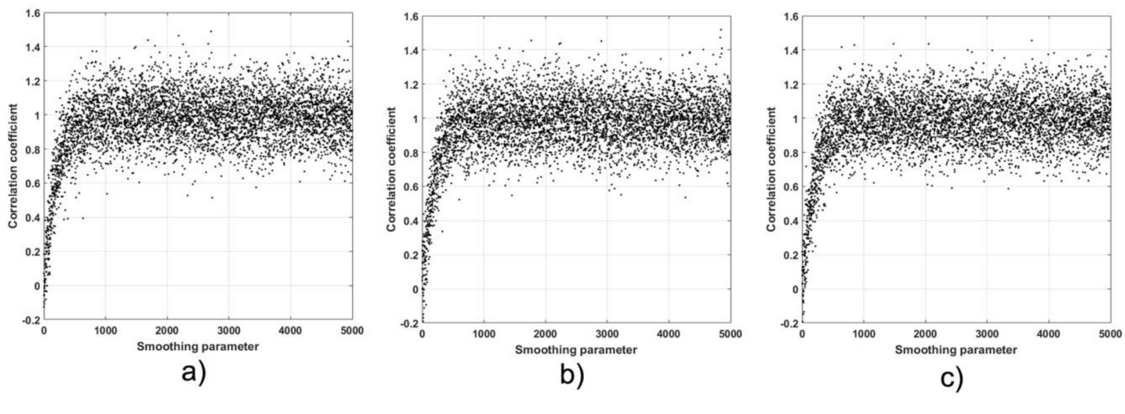

Figure 5. *Correlation coefficients with stochastic noise vs. smoothing parameter for a) R1-R2, b) R1-R3, and c) R2-R3. (Please note that the range of correlation values exceeds the usual range of [0, 1] due to the added stochastic noise)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47014716

Then, the corresponding MARS model that gives the best fit to the correlation coefficient data with noise for each pair of random point distributions according to GCV criterion given in *Equation 7* is obtained. The graphs of individual MARS models are available in *Figure 6*.

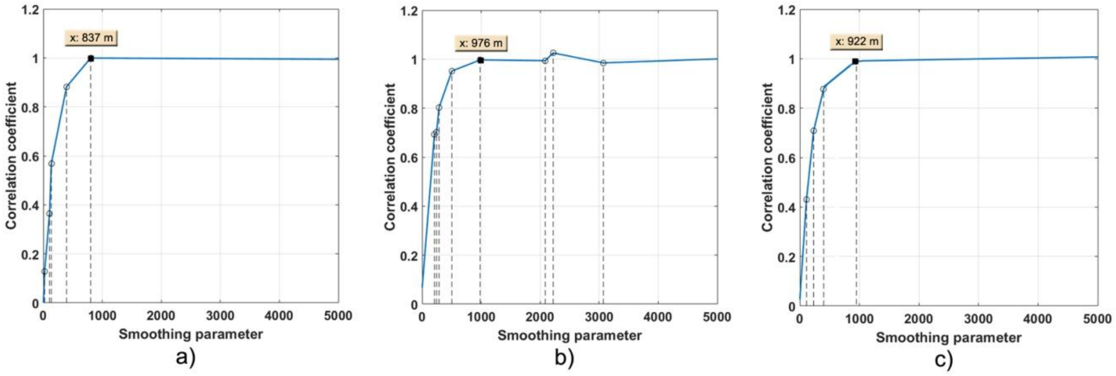

Figure 6. *Plots of MARS model functions for a) R1-R2, b) R1-R3, and c) R2-R3. In the figure, o indicates the location of knot points (i.e., t) between two consecutive BFs, and ■ denotes the position of the knot location where further increase in h results in over-smoothing in the corresponding KDEs*

The obtained MARS models for R1-R2, R1-R3 and R2-R3 are given as:

for R1-R2:
$BF_1 = \max[0, 395 - x_1]$,
$BF_2 = \max[0, 137 - x_1]$,
$BF_3 = \max[0, x_1 - 837]$,
$BF_4 = \max[0, x_1 - 23]$,
$BF_5 = \max[0, x_1 - 107]$ and,
$Y = 1.1146 - 0.00092793 \cdot BF_1 - 0.0056183 \cdot BF_2 - 0.00028838 \cdot BF_3 - 0.0037535 \cdot BF_4 + 0.0040407 \cdot BF_5$,

for R1-R3:
$BF_1 = \max[0, x_2 - 976]$,
$BF_2 = \max[0, 209 - x_2]$,
$BF_3 = \max[0, 503 - x_2]$,
$BF_4 = \max[0, 287 - x_2]$,
$BF_5 = \max[0, 2219 - x_2]$,
$BF_6 = \max[0, x_2 - 2087]$,
$BF_7 = \max[0, x_2 - 2531]$,
$BF_8 = \max[0, 2531 - x_2]$ and,
$Y = 0.97569 - 0.00009659 \cdot BF_1 - 0.00148852 \cdot BF_2 - 0.000631463 \cdot BF_3 + 0.00072293 \cdot BF_4 - 0.00052987 \cdot BF_5 + 0.0003719 \cdot BF6 - 0.00027321 \cdot BF7 + 0.00043687 \cdot BF8$,

and finally for R2-R3:
$BF_1 = \max[0, x_3 - 401]$,
$BF_2 = \max[0, x_3 - 113]$,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47014716

$BF_3 = \max[0, 113 - x_3]$,
$BF_4 = \max[0, x_3 - 233]$,
$BF_5 = \max[0, 922 - x_3]$ and,
$Y = 0.68602 - 0.00050397 \cdot BF_1 + 0.0018125 \cdot BF_2 - 0.0031154 \cdot BF_3 - 0.0013047 \cdot BF_4 - 0.00050019 \cdot BF_5$.

In the above equations, x_1, x_2 and x_3 denote the correlation values of R1-R2, R1-R3 and R2-R3, respectively.

As indicated by the correlation coefficient values in *Table 2*, resemblance between R1, R2 and R3 becomes more obvious when the value of smoothing parameter gets larger. Actually, this is an expected result since over-smoothed KDE estimates are generated with increasing values of *h*, which results in less variability, or i.e., higher similarity between the maps. On the other hand, for narrower choices of smoothing parameter, spikier estimates containing lots of spurious local structure are obtained. This behavior is illustrated in *Figure 7*.

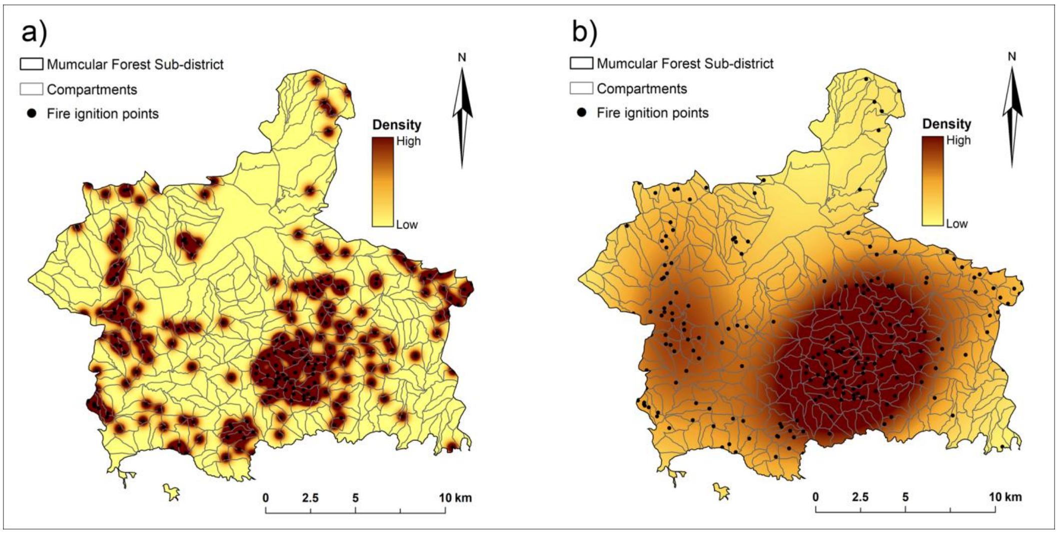

Figure 7. *KDE maps of the study area: a) h = 250 m, and b) h = 2500 m*

Results and discussion

Although the increments between successive correlation values with increasing *h* values are not so distinctive as depicted in *Table 2*, the amount of variation against increasing values of *h* can be observed very clearly in *Figure 6* for R1-R2, R1-R3 and R2-R3. A very sharp increase in the rate of change in correlation values are observed, and then the each curve exhibits a stabilized behavior above a certain *h* value (i.e., over-smoothing prevails).

The advantage of using MARS approach which employs piecewise linear splines in modelling is that the selection of knot locations is completely data-driven, i.e., specific to the dataset. Since the BFs that give smallest increase in the residual sum of squares are omitted from the model at each iterative step, an optimal model is generated at the end. The mean square error (MSE) versus GCV values for each MARS model shown in *Figure 6* is also illustrated in *Figure 8*. The change in MSE and GCV values during the iterations in the backward step can easily be observed in *Figure 8*. For a typical MARS

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47014716

model building process, lines of MSE and GCV seem close to each other at the early stages. However, as the number of BFs included in the model increases, GCV diverges from MSE and rises up. The corresponding MSE and GCV values of the final MARS models are given *Table 3*.

Table 3. *MSE and GCV values of the final MARS models*

MARS model	MSE	GCV
R1-R2	0.01804	0.01812
R1-R3	0.01829	0.01842
R2-R3	0.01771	0.01779

As it is obvious in *Figure 6,* the specific knot location between the two consecutive BFs where the MARS model curve forms a kink shape indicates the specific value of *h* for that random point distribution. Further increase in *h* brings no significant change in the correlation values which simply indicates that the over-smoothing effect dominates in that specific KDE.

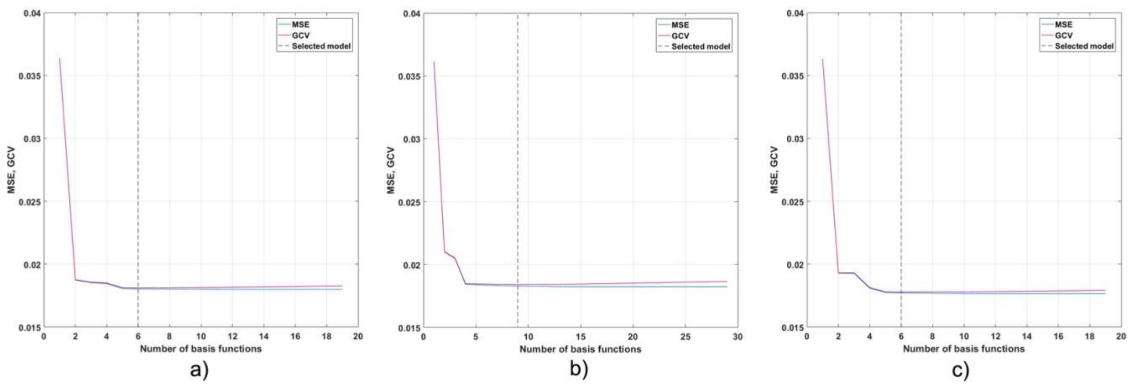

Figure 8. *MSE vs. GCV values for the MARS models of a) R1-R2, b) R1-R3, and c) R2-R3*

According to Silverman (1998), an appropriate choice of smoothing parameter is a crucial factor for the success of a KDE, and plotting several density estimates with various *h* values and choosing the one in accordance with the user's idea about the density often gives quite satisfactory results. This approach is also known as subjective choice of smoothing parameter (i.e., smoothing by eye). However, as again indicated in Silverman (1998), an inexperienced user may need somewhat an automated way to find a value of *h* which can be used as a reliable starting point for further subjective adjustment. In the studies of Koutsias et al. (2014) and Bajocco et al. (2017), smoothing parameter was chosen based on nearest neighbor distance method; however, this approach only generates rough estimates for the value of smoothing parameter when the inevitable positional uncertainties in the wildfire locations are considered.

On the other hand, the use of MARS has unique advantages in the modelling of complex environmental dynamics with uncertainties at some degree. Since the method is nonparametric, it does not make any specific assumption about the underlying functional relationship between the dependent and independent variables. Additionally, the selection of BFs is specific to the dataset in MARS which makes it and adaptive

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47014716

procedure to handle large and complex datasets. During MARS-model building, the BFs are directly obtained from the observations and their space partitioning property results in an adaptive model. By this way, the flexible piecewise spline BFs of MARS can smoothly approximate the discrete data with noise and model its inherent characteristics. As it is obvious in *Figure 6*, our KDE approach integrated with MARS gives unique smoothing parameter values which can definitely be employed as reference point for further adjustment by the user.

The specific h values for R1-R2, R1-R3 and R2-R3 are 837, 976 and 922 m, respectively. Very similar h values from the three different random point distributions reveal that even though these three random point distributions are spatially distinctive from each other and their pair wise correlation values include stochastic noise, MARS is able to capture the inherent characteristic of the dataset by using smoothing and data-driven space partitioning properties of the piecewise linear BFs.

Thus, the final smoothing parameter value of the Gaussian KDE for the study area is taken as the average of these three, which is equal to 912 m. The seasonal KDE maps and the final KDE map of the study area are prepared accordingly by using *CrimeStat 3.3* software (Levine, 2004).

When the seasonal KDE maps are analyzed (cf. *Fig. 9*), fire events in the study area temporally and spatially exhibit different cluster patterns.

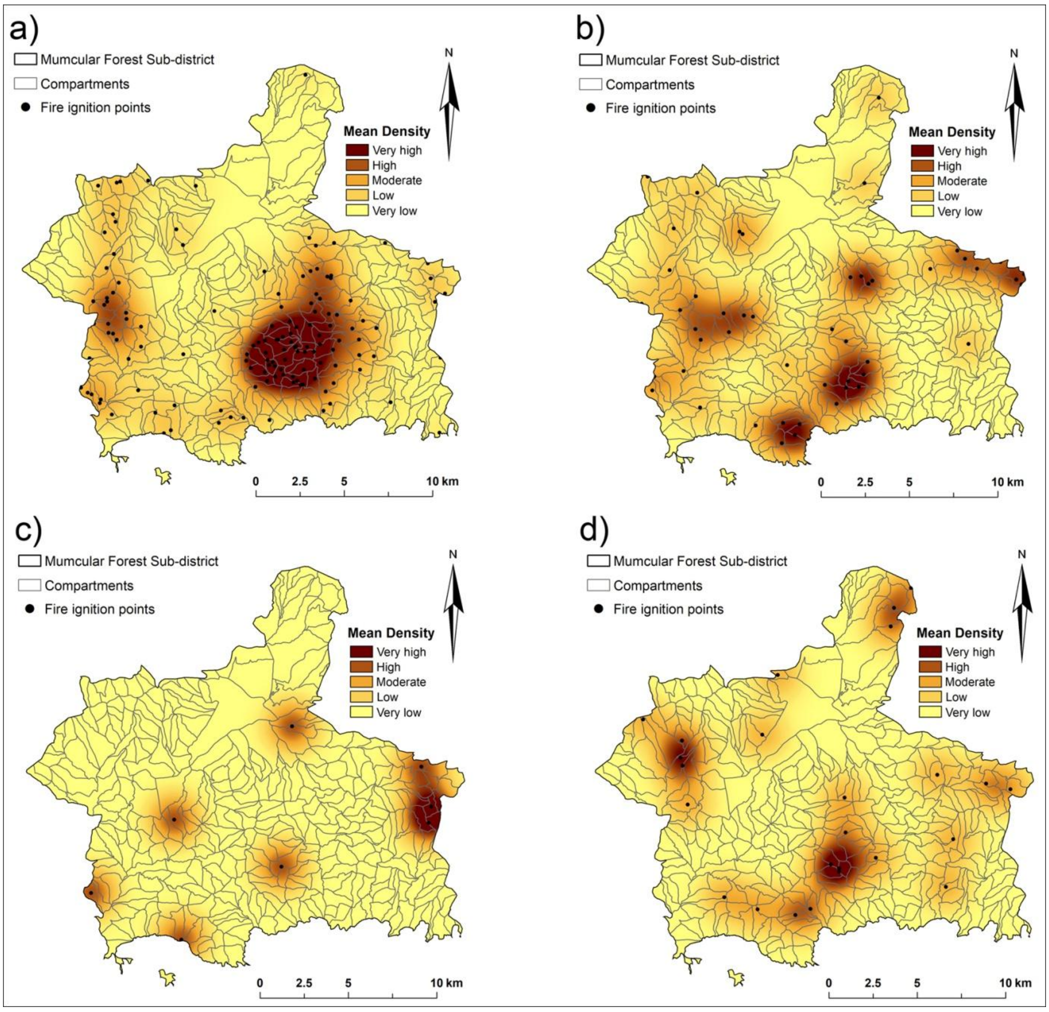

Figure 9. *Seasonal KDE maps: a) summer, b) fall, c) winter, and d) spring*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47014716

The majority of forest fires (i.e., 67.6%) occur in the summer seasons (cf. *Fig. 9a*), which is obviously expected, and they are manly concentrated in the south-east central part, and small clusters are observed along the western part. Fire incidents that take place in summer are mostly located either in dense forested areas with closed canopy structure or around agricultural lands that are also close to settlement areas. Thus, these fire events would be associated with two factors: *i*) higher rate of human activities for recreational purposes during summer season, and *ii*) fires ignited on purpose by farmers for the removal of husk, which is often encountered in agricultural regions of Turkey.

Fire events that happen in fall have a 19.5% share in total incidents and exhibit a bit more homogenous spatial characteristic than summer season events (cf. *Fig. 9b*). They are mainly observed along the west side, in both south central and south parts, and small clusters exist along eastern side. A few events are observed in the dense forested areas; however, most of the incidents are located around the agricultural areas in the west and the north. This kind of spatial structure may arise from the raise in straw fire events.

Fire events in winter have the smallest share in all the seasons (i.e., 2.8%) and only limited number of events is observed in the central region, as well as the middle and upper parts of the western border (cf. *Fig. 9c*). Following the winter, spring fire events have an increasing trend in number (10.1%) and they are clustered in the central-south and eastern areas of the region, a few events are observed at northern cape as well (cf. *Fig. 9d*). Since the harvest season is not started yet in spring, these events can hardly be related with straw fires, but can be attributed to increasing recreational activities.

As the final step, the mean density map that shows the average intensity for each administrative polygon (i.e., compartment) is generated by employing the final intensity map of the area (cf. *Fig. 10*).

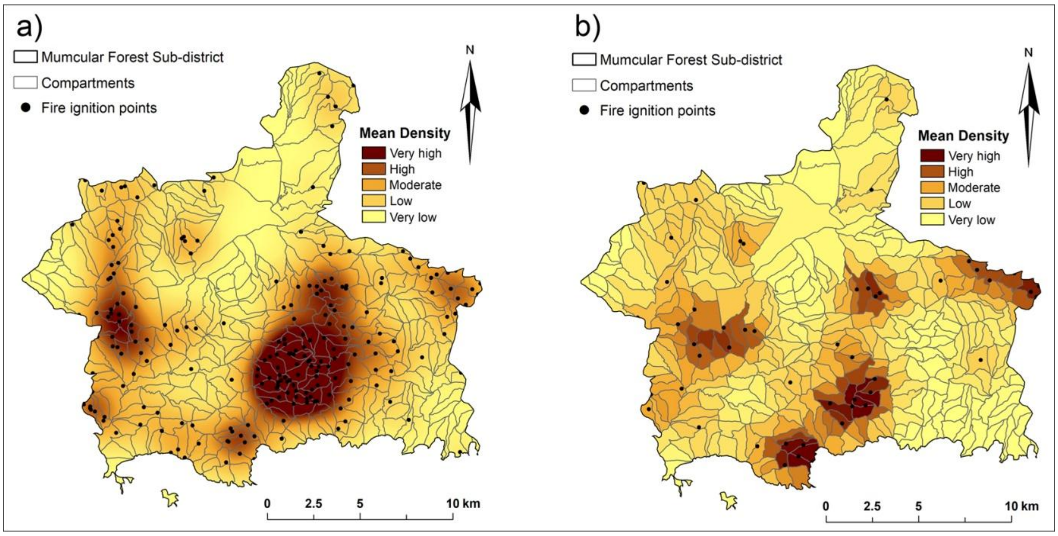

Figure 10. *a) Final density map, and b) mean density map of the study area*

Conclusion and outlook

Fire management planners always demand for elaborately prepared maps, which reveal the relation between wildfire events and several contributing characteristic attributes of the area of study, like topography, demographic structure, meteorological factors etc., for proper analysis of forest fire risk. However, historical fire data used in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47014716

this kind of analysis are mostly in point format and seriously suffer from positional inaccuracies. KDE method is often preferred for converting such data into continuous raster surface, and finding an appropriate smoothing parameter value that suits to the area under investigation would be of vital importance.

In this study, above mentioned points are addressed within the frame of Mumcular Forest Subdistrict case, and quite effective solutions are introduced in order to deal with them. These methods can easily be applied on different geographical areas.

The method employed to reduce the positional uncertainties is simply based on utilizing the temporal wildfire records at a finer spatial resolution, i.e., compartments in the stand map. Even though the geolocation of wildfire starting points at this spatial resolution may still include some level of uncertainty, an improvement is achieved by confining the wildfire starting locations into smaller administrative polygons.

In order to determine an appropriate smoothing parameter value h, a novel methodology is proposed by utilizing MARS for the first time in the KDE-based analysis of historical wildfire data. The results of our study indicate that MARS is an effective method for modelling dynamic and complex environmental processes, as in the case of wildfires, particularly, when expert judgment is not readily available. The results show that MARS is a proper choice to select suitable value of smoothing parameter for the KDE of wildfire events, and we definitely consider that the effectiveness of the MARS approach for dynamic modelling of wildfires should be further investigated by other case studies.

MARS provides important results on modelling the KDE of wildfires in Mumcular Forest Subdistrict in a 18-year period. It can enable us to obtain valuable and reliable information on spatiotemporal patterns of wildfires. This information is quite important for fire management planners' analytic studies on short- and long-term planning. As illustrated in this study, incorporating effective application of modern applied mathematics within geospatial analysis tools would have a significant contribution to fire departments and help them take more effective and timely measures for more risky areas.

In future researches, this study can be extended in order to produce a comprehensive wildfire assessment map of the study area by the inclusion of significant contributors to wildfires such as topographical, meteorological and anthropogenic factors together with KDE analysis. Within this phase of the study, topographic factors such as elevation, slope and aspect would be derived from the digital elevation model of the area. Meteorological data (i.e., temperature, rainfall and wind) would be acquired from the local ground stations in the area and interpolated by using kriging technique in order to produce the corresponding 2-D raster surfaces. For anthropogenic factors, distance from road networks and residential areas with certain population densities would be considered and realized by creating associated buffer zones.

Acknowledgements. We, as authors, would like to express our gratitude to the officials in Mumcular Forest Subdistrict for their kind helps and data sharing.

(Received 2nd Apr 2018; accepted 29th Jun 2018)

Abstract. With the acceleration of urbanization in China, the phenomenon of occupying ecological green space is becoming more serious in the process of urbanization, especially in Chinese Nationally Designated Garden Cities. The study simulates the dynamic change of Qujing in Yunnan Province of the 1993-2015 period. According to different ecological green space protection intensity, four kinds of scenarios were set up to predict the urban expansion in 2030. The spatial and temporal characteristics of urban expansion under different scenarios are quantitatively studied by using the Urban Expansion Intensity Index (*UEII*) and Urban Expansion Speed Index (*UESI*). The results show that the SLEUTH model has strong applicability and can better reflect the spatial and temporal characteristics of the urban expansion in Garden City. In four scenarios, the urban area shows an increasing trend, and the urban expansion speed and urban expansion intensity decrease with the increase of ecological protection intensity. Comparing four scenarios, we found that the urban development trend predicted by the ecological development scenario is more similar to the urban planning, and this conclusion has been confirmed by the distribution of urban areas of 2018. In ecological development scenario, the urban ecological land has been effectively protected and the development of the city has not been affected, which is beneficial to the sustainable development and the protection of the ecological environment. For urban planning, the suitable measures of ecological green space protection can restrain the urban expansion, and the ecological protection-oriented development mode accords with the development trend of Garden City.
Keywords: *ecological green space, urban expansion, SLEUTH model, dynamic change, sustainable development*

Introduction

Urban expansion is the inevitable result of social and economic development (Hansen et al., 2005). With the acceleration of urbanization in China, a large number of ecological green spaces were occupied in the process of urban construction. This phenomenon is more prominent in Chinese Nationally Designated Garden Cities, leading to a large number of urbanization problems, such as heat island effect, city haze, soil erosion and so on (Black, 1999; Peck, 2005). Most urban development researches attach importance to the solution of two problems: one is about ensuring the sustainable development of cities, another concerns minimizing the impact on ecological environment during urban expansion (López et al., 2001; Roberts and Diederichs, 2016; Boulos, 2016).

In recent years, many researchers have established a large number of models to simulate and predict the spatial expansion of cities. On the basis of two experiments conducted in San Francisco and the Washington area, Clarke (1997) and Silva (2002) pointed out that with its high accuracy, the SLEUTH model not only can be used to simulate urban evolution by making use of historical data, but also can be applied to predicting urban expansion from a macro perspective and a meso perspective (Silva and Clark, 2005). Pijanowski (2002) used the Land Transformation Model (LTM) to explore the consequences of future urban changes of 2020 and 2040 with the help of non-urban sprawl and urban-sprawl trends. Results of this work have significant implications for the Lake Michigan Lake Area Management Plan developed by the United States Environmental Protection Agency recently. But the model did not embody the influences of terrain and policy on the urban expansion. The Cellular Automata (CA) model can be used to simulate different urban forms and developments in the planning of sustainable cities (Yeh et al., 2001). However, due to the fact that the conversion rules of cell can not be quantified in practical application, the accuracy of model simulation is low. Yea explored the simulation of urban growth by applying SLEUTH model to Yilan, Luodong and Suao in the Yilan Delta area of northeast Taiwan, so that he can make use of some historical data and study the dynamics of the region. He found that the result of the model's application for predicting city development in the Yilan Delta area shows that the cities of Yilan and Luodong are developing and expanding more evenly from the city center (Yea and Yang, 2007). It is found that when CA model is applied to simulating the dynamic evolution of complex urban expansion, the transformation rules and parameters of the model are difficult to design quantitatively and it is difficult to explain the physical meaning of the model parameters.

SLEUTH model can simulate and forecast urban expansion based on cellular automata. It can predict the possibility of urban expansion according to traffic, topography and urban development constrains because pixels of the current city fucntion as seed points to present the future development of the city through their diffusion (Herold et al., 2003; Xian and Crane, 2005; Silva and Clark, 2005). Compared with the traditional CA model, the most important feature of SLEUTH model is the optimal parameter combination for urban expansion process calculated by Monte Carlo iterative simulation. Because of its high simulation precision, easy access and portability, the model has been widely used in the study of urban expansion simulation and prediction (Dietzel and Clarke, 2004). At present, the SLEUTH model is often used in dynamic simulation studies of large cities. However, there are few researches on Garden Cities with higher greening coverage (Laura et al., 2008; Dietzel and Clarke, 2007; Mc and Justin, 2013). Based on the existing theory of urban expansion and the application of SLEUTH model, this paper takes the Nationally Designated Garden Cities (Qujing) as the research area. According to the actual situation of the research area, four kinds of scenarios are set up based on the protection intensity of different ecological green space, and the spatial expansion of the city is simulated and forecasted. The spatial and temporal characteristics of urban sprawl in different scenarios are quantitatively studied by using the Urban Expansion Intensity Index (*UEII*) and Urban Expansion Speed Index (*UESI*). Comparing four scenarios with urban planning of 2030, the most similar scenario with urban development trends was identified, and the conclusion was confirmed by the distribution of urban areas of 2018. Basic laws and trends of urban spatial expansion in the research area are revealed, which provide

references for the sustainable development and urban planning of Nationally Designated Garden Cities in China.

Materials and methods

Study area

Qujing, located in the eastern part of Yunnan Province, China, is an important industrial and commercial city and transportation hub in Yunnan province. It is adjacent to Guizhou province and Guangxi Zhuang Autonomous Region. With the rapid urbanization construction, the whole city has been increased from 81.27 km^2 in 1997 to 253.8 km^2 in 2016, but its urban green space area has also reduced (Ding, 2010). Located in the low latitude area, Qujing has a subtropical plateau type monsoon climate. The annual average temperature is 14.5 °C, and the annual rainfall at the urban area is over 1,008 mm. The difference between summer temperature and winter temperature in most areas is small, which means the climate is very mild and suitable for human habitation. The average forest coverage is about 45%, and the urban green coverage is 36.16%, it is a typical Nationally Designated Garden City in the west of China. In this paper, the study area is the central area of Qujing, which covers the northern Qiling District and southern Zhanyi District. The research area lies between longitude 103°42’18” to 103°54’54” east and latitude 25°24’18” to 25°38’24”north, the total area is about 1061.9 km^2 (Yuan et al., 2017). The research area locates in the plain area; the terrain is low in the middle: the middle is flat dam area, the east-west side is mountainous. The spatial pattern shows the area’s transition from the city core to the suburb (*Fig. 1*).

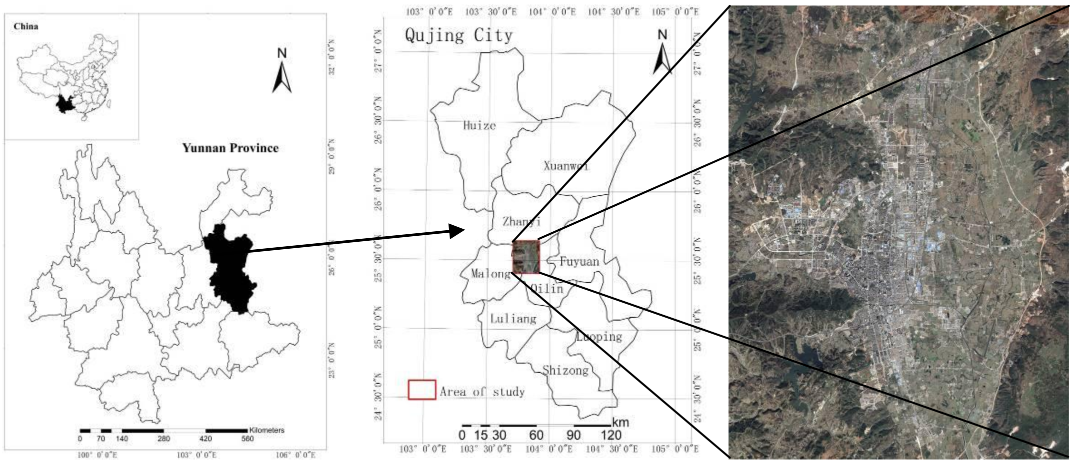

Figure 1. *Location map and high-resolution image of the research area. (Image photos from Google Earth in September 2017)*

Data acquisition and preprocessing

The basic data of the study area were gathered from 1993 Landsat TM images, 2000 Landsat ETM images, 2009 Landsat TM images and the Landsat OLI images in 2015 and 2018 (*Fig. 2*), which were collected in September to December. The cloud cover was less than 5% and they can be used for visual interpretation (Morf, 2011). In

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47174734

addition, the data of digital elevation model (DEM) for 2015 in the research area, the urban road traffic map of the corresponding year and the urban planning map of the research area were collected. The classification of remote sensing images was based on supervised classification method, through which researchers classified the images in accordance with six land use types including urban land, bare land, farmland, forestland, grassland and waters. Then we used the Government Gazette of Qujing and the data of field survey to test the precision of classification results. The total precision data of the classification resulting in four periods were 83.17%, 86.52%, 85.45% and 87.89% respectively. Additionally, the kappa coefficients of these periods were higher than 0.79, which can meet the needs of this paper. According to the operational requirements of the SLEUTH model, the traffic road layer, slope layer, shadow layer, city range layer and exclusion layer were made by ArcGIS (Rafiee et al., 2009; Feng et al., 2008).

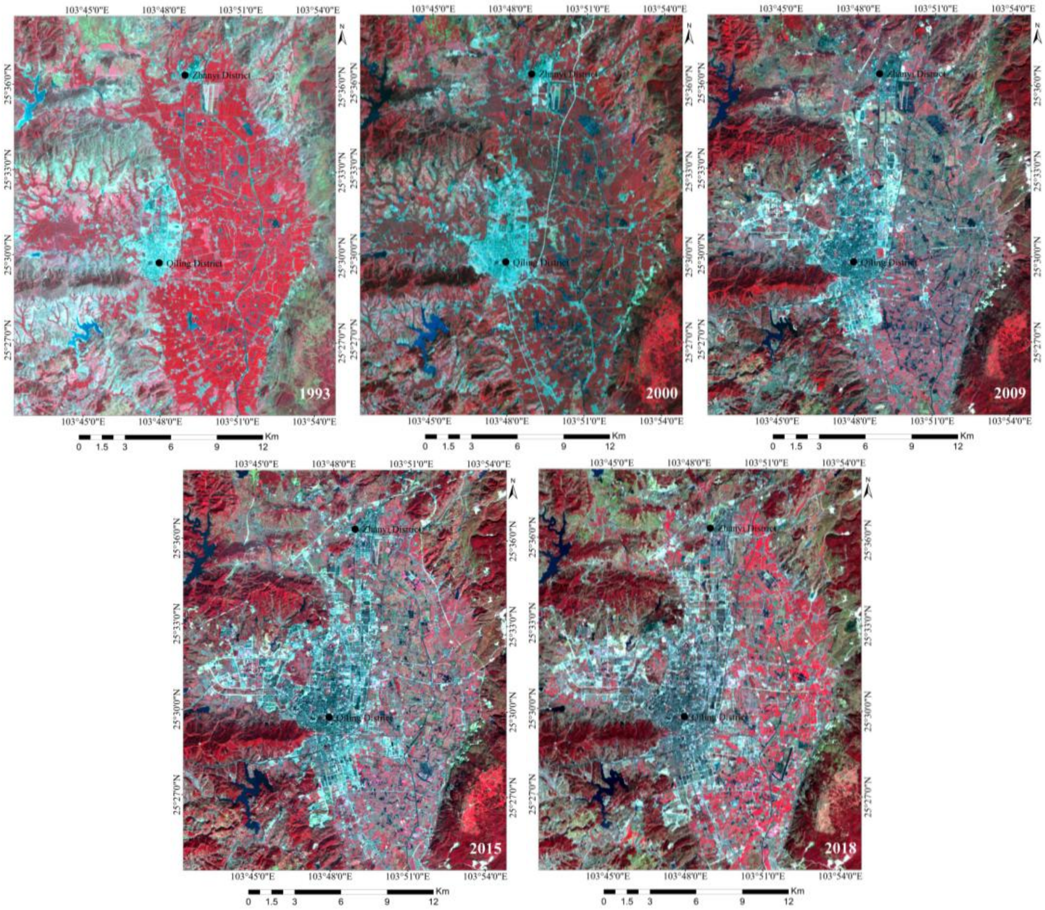

Figure 2. *Remote sensing images from 1993 (Landsat 5), 2000 (Landsat 7), 2009 (Landsat 5), 2015 (Landsat 8) and 2018 (Landsat 8) in the central areas of Qujing. (The false color composite of Landsat5 (RGB)432, Landsat7 (RGB)432 and Landsat8 (RGB)543)*

Based on the urban road traffic map of the year, the layer of the traffic road was created by digital processing. According to the classification of road grade, they were given different weights, among which the main urban road was given a weight value of 100, the urban secondary road was given a weight value of 50, and the non-road

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47174734

assignment is 0. Researchers collected the urban range vector data through the supervision of the classification of the years and then convert them to different spatial resolution grids with the use of the ArcGIS Toolbox and the classification of the generation of research areas of the city map. Upon finishing this work, the urban layer was created in the fourth period of remote sensing image prepossessing. The slope layer was generated by the re-projection and re-sampling of DEM data, which was expressed as a percentage slope value. The shadow layer was the background of the model image output which improves the spatial visual effect of the simulated urban spatial expansion process. The shadow layer was embedded as a background layer and was not involved in the operation of the model. The exclusion layer, whose range is 0-100, was a constrained layer that restricted the simulated expansion of the urban area. When this value tends to be 0, the probability of urbanization is higher, and when this value tends to be 100, the probability of urbanization is lower. All of the input layers were converted to 8-bit grayscale raster images projected by horizontal Mercator (UTM_WGSl984 48N), and the data format was required to be in GIF format.

SLEUTH model and the setting of multiple scenarios

The SLEUTH model was developed by Professor Clark of the University of California. The model is capable of predicting the dynamics of urban growth. The basic urban growth procedure of SLEUTH is a cellular automaton, in which urban expansion is modeled in a GIS environment (Chaudhuri and Clarke, 2014; AlShalabi, 2013). The major characteristic of the model is that the computer can automatically judge the coincidence degree between the simulation result and the actual situation. It can find the combination scheme with the least error, and works out the best parameter combination. The model assumes that the future phenomenon could be simulated by the past real evolution trend, while assuming that the historical growth trend is sustained. The model can simulate and predict urban dynamics through the application of four growth rules: spontaneous growth, new expansion centers, marginal growth, and Road-Influenced, which are controlled by five parameters: diffusion, breed, spread, slope and road gravity (Silva and Clarke, 2002). In order to enable the simulation result to be more accordant with the real situation, the model can adjust the growth coefficient through the self-adjusting function (Sangawongse et al., 2005). By altering the self-organization constraints or changing parameter values that affect the expansion of the urban area, scenarios for different planning goals can be transplanted into the SLEUTH model, and patterns of future urban area differing in quantity and location may be generated (Solecki et al., 2004; Feng et al., 2008; Liu and Ying, 2012). SLEUTH model has now been updated to the 3.0 beta version, and it is available on the United States Geological Survey website. The new version SLEUTH model can better simulate the historical trend of urban growth and improve the calibration efficiency of the model compared to the previous version in the calibration module (Watkiss, 2008). The city simulation module of the model was applied to this investigation and was debugged and compiled by using Cygwin software in the Windows system before running.

The SLEUTH model cannot reflect the influence of government decision and social economy on urban expansion, for this reason different scenarios are often introduced to simulate the future growth of the city (Xiang and Clarke, 2003; Feng et al., 2012; Dezhkamet al., 2014). When setting up the forecast scenarios, the future of urban planning and the actual situation were taken into consideration. According to “The Urban Master Planning of Qujing from the Year 2016 to 2030” (CAUPD and QCPB,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47174734

2016), the eastern region will be protected in the course of future urbanization, because of the plenty of protected ecological land in that region. According to the existing research results and the actual situation of the research area, four scenarios were determined and assigned to the local classes in this investigation, and the specific assignment is shown in *Table 1*. In general, the existing cities appeared in the exclusion layer were assigned 0, some of the lakes and waters were assigned 100, while woodland, arable land, bare land, and grassland were assigned a value of 0-100 according to the study. We mostly assigned greater value to the ground classes that need to be protected, so that these areas are less likely to be urbanized, and the protected areas designed in this investigation are based on urban planning (Jantz et al., 2004). In the scenarios of natural development, it was assumed that the future expansion of urban space would be based on the existing urban space, and urban spatial expansion is not affected by planning, policy, ecological environment and so on, only assigning 100 to waters. In the planning-oriented scenario, it was assumed that the future cities would took the construction of urbanization as the dominant factor, some farmland, grassland and the forest land may be urbanized. In the ecological development scenario, it was assumed that the future city would be in the protection of the existing urban ecological pattern on the basis of expansion, so as to avoid the land occupancy and protect the cultivated land during urbanization. In the scenario of ecological protection, by increasing the protection of ecological green space and reducing the speed of urbanization in the future, the waters, forestland and key protected areas in the research area were designed as being forbidden to be urbanized, and the protection level of bare land, farmland and grassland were designed to be higher correspondingly (*Fig. 3*).

Table 1. *Excluded assignments of scenarios 1-4*

Scenario settings	Urban land in 2015	Waters	Bare land	Farm land	Grassland	Forest land	Protected land
Scenario 1 (Natural development)	0	100	0	0	0	0	–
Scenario 2 (Planning-oriented)	0	100	0	25	25	50	–
Scenario 3 (Ecological development)	0	100	50	25	25	100	100
Scenario 4 (Ecological protection)	0	100	50	50	50	100	100

Spatial-temporal analysis indicators of urban expansion

Urban Expansion Speed Index (*UESI*) and Urban Expansion Intensity Index (*UEII*) are the common indices for the study of urban expansion quantitative characteristics. They are used to characterize the speed and degree of urban expansion (Al-Sharif et al., 2014; Wang et al., 2016). These two indexes simply describe and analyse the change of material space from the result of urban expansion by comparing the speed and strength of urban expansion in different periods, studying the characteristics of the change of urban expansion form, and revealing the spatial and morphological evolution law of urban expansion (Terry, 1995; Salvati et al., 2014). In order to explore the temporal and spatial patterns of urban land use growth in Qujing, the two analytical indices are introduced in this paper.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47174734

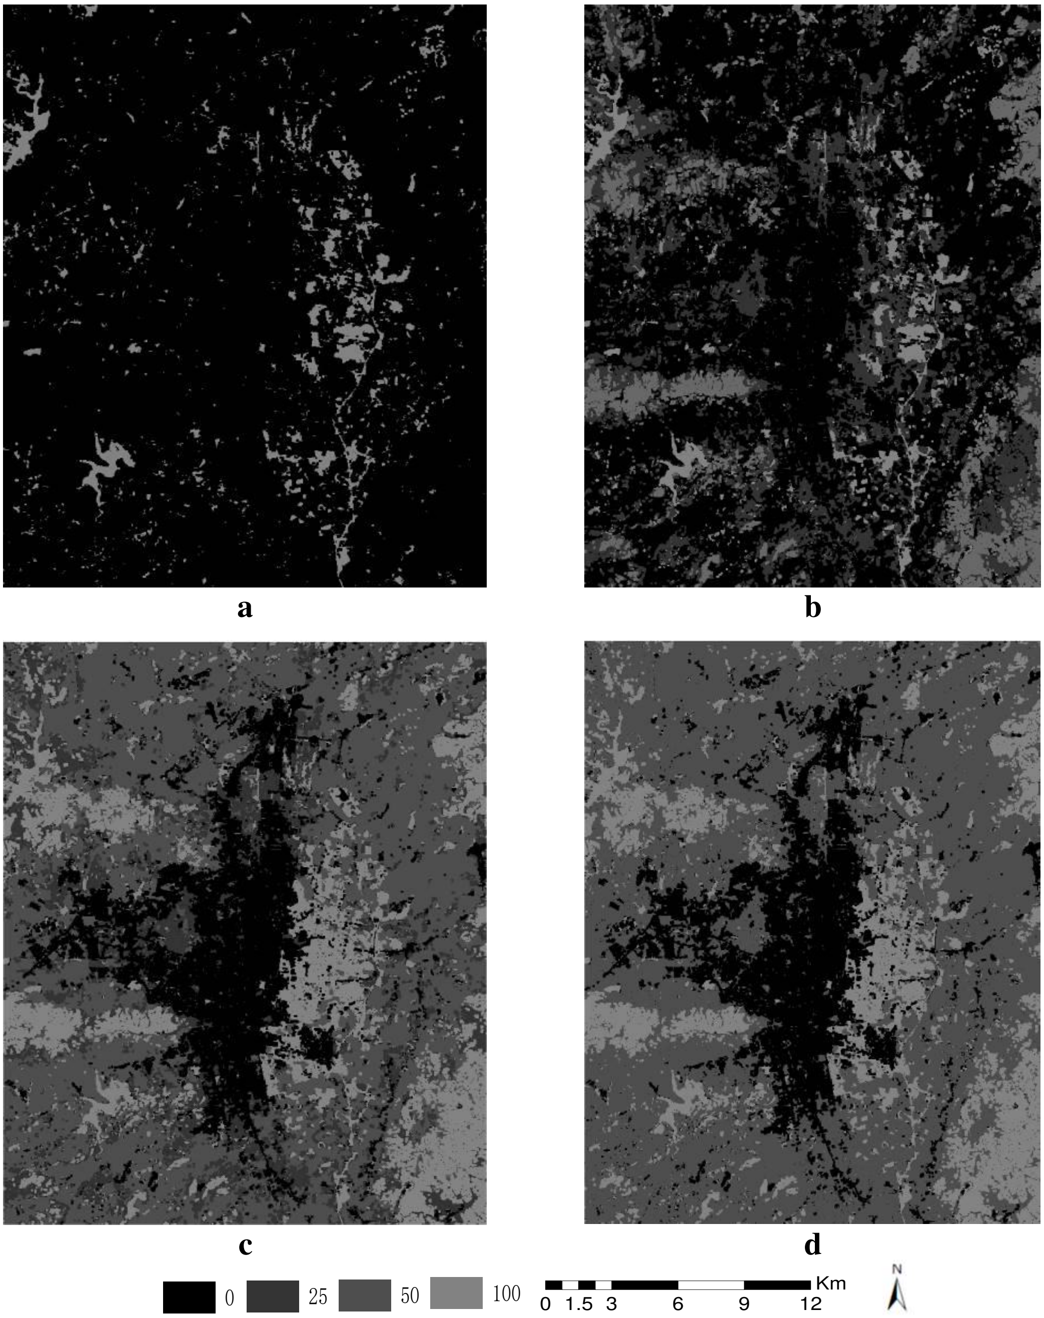

Figure 3. *The exclusion layer of scenario 1-4.* ***a*** *Scenario 1,* ***b*** *scenario 2,* ***c*** *scenario 3,* ***d*** *scenario 4*

(1) Urban expansion speed index

The *UESI* indicates the range of urban land area change at a certain time, which can reflect the overall scale and trend of urban expansion, and the formula is shown as follows (*Eq. 1*):

$$UESI = \frac{\left(UA_{n+i} - UA_{i}\right)}{n} \tag{Eq.1}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47174734

(2) Urban expansion intensity index

The *UEII* is used to reflect the percentage of the total urban land area in a certain period. If the index increases, it means that the urban area expands at a faster rate in this period. The formula is shown as follows (*Eq. 2*):

$$UEII = \frac{\left(UA_{n+i}\text{-}UA_i\right)}{UA_i} \quad \text{(Eq.2)}$$

In the above formula: *UESI* represents the expansion rate of urban land use, *UEII* represents the expansion intensity of urban land use. UA_{n+i}, UA_i is the $n+i$ year and i year urban area, n represents the time interval in years.

Results and discussion

The correction result of SLEUTH model and validation of the simulation results

In general, the Compare Index and Lee-Sallee Index were often used to evaluate the precision of the simulation results (Clarke et al., 1997; Silva and Clarke, 2002). In this experiment, the Compare Index is 0.83 and Lee-sallee Index is 0.67, which indicate that the total number of urbanized pixels and urban boundary in the simulated year coincide with the actual situation. In the previous study, the Compare Index can generally reach more than 85%, Lee-sallee Index is generally from 0.3 to 0.7. But to some cities in the western part of China, these two indices may be less affected by topography and ecological environment (Herold et al., 2003; Mc and Justin, 2013; Zhao et al., 2014). The calibration process and parameters are shown in *Table 2*. The optimal parameter combination was obtained by final correction, and the walking coefficient and propagation coefficient were 15 and 18, which indicated that the effect of the study area on the urban development was small. The diffusion coefficient was 86, which indicated that the urban expansion was autonomous by marginal growth. The slope coefficient was 20 while the road coefficient was 72. It is indicated that the slope has limited restriction in the process of urban expansion. On the contrary, the increasing effect of road gravity is obvious, which is consistent with the results of other applications in China (Yuan et al., 2011; Feng et al., 2012; Zhao et al., 2014).

Table 2. *The correction result of SLEUTH model*

Growth factors	**Rough correction**		**Accurate correction**		**Final correction**		**Final reference value**

In order to verify the simulation results of the SLEUTH model, we simulated the urban expansion process from 1993 to 2015 with the parameters obtained from the final correction. The data of simulation results and the real situation were gathered in 2000, 2009, and 2015 (the starting year is 1993, so the data of 1993 are not included in *Fig. 4* and *Table 3*).

Table 3. *Comparison between simulation results and actual situation*

Year	2000	2009	2015
Number of urban pixels in the actual situation /unit	13741	19802	24098
Number of urban pixels in the simulated result /unit	16021	23870	31976
Precision of simulation /%	85.77	82.96	75.36

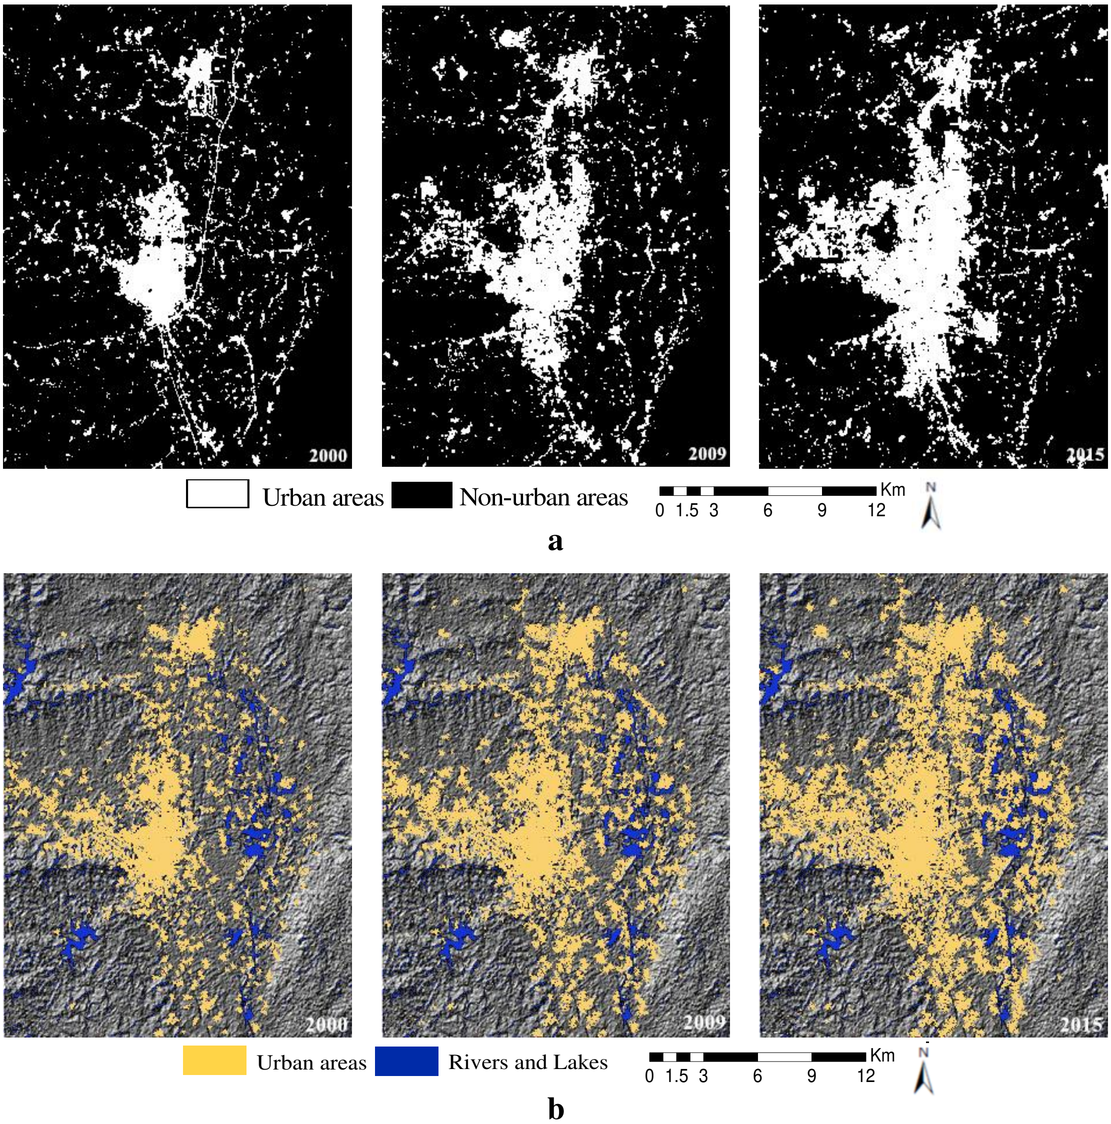

Figure 4. *Comparison of simulation results of SLEUTH model with actual situation in Qujing city.* ***a*** *The actual situation and* ***b*** *the simulated results of Qujing city in 2000, 2009 and 2015*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47174734

As can be seen from *Figure 4,* the simulation results are similar to the actual spatial distribution: the simulated urban areas mainly extend along the road, and the old town is centered around Qujing, which accords with the characteristics of the development along the road and the edge growth. However, the difference between the two is very prominent, because the government prohibits the occupation of the large amount of ecological land in the eastern region, and as a result the expansion of the city in the eastern region is limited. However, in the simulation of urban settlements, a large scale of expansion also appeared in the eastern part, which is mainly caused by the high spread coefficient (Mc et al., 2013; Rafiee et al., 2009). The result of the simulation can not fully reflect the transfer of urban development center caused by the change of government behavior, because the cell is very dependent on the neighboring state, which is easy to expand outwards on the basis of the existing city, and the new diffusion center is not easy to appear (Salvati et al., 2014; Liu et al., 2010; Chaudhuri and Clarke, 2014).

We not only used the Compare Index and Lee-scale Index to evaluate the accuracy of simulation results, but also compared the actual situation with simulation results. Additionally, data about the number of pixel points and the precision of simulation are collected (*Table 3*). It can be seen that the precision is higher than 75% in three periods, which indicates that the simulation results are in accordance with the actual situation. The precision of simulation is 85.77%, 82.96 and 75.36% in 2000, 2009 and 2015 respectively. With the increase of the simulated year, the precision decreases gradually, while similar situations have occurred in other studies (Clarke and Gaydos, 1998; Liu et al., 2010). This is mainly due to the shift of the city center during the expansion, which was not taken into account in the process of urban simulation (Aerts et al., 2009). Therefore, it is necessary to integrate urban planning factor into urban expansion data. The exclusion layer of sleuth model in urban expansion forecast can solve this problem effectively.

The prediction results of the urban expansion

The reference value of each coefficient is observed in the final correction. 100 times Monte Carlo iteration is used to predict the urban spatial expansion while the 2016 to 2030 forecast years were designed. The results are shown in *Figure 5 and Table 4*.

Table 4. *The prediction results of scenario 1-4*

Urban area	Scenario 1	Scenario 2	Scenario 3	Scenario 4
Current urban area (yellow)/km²	213.27	213.27	213.27	213.27
Urbanization rate 70-100% (red)/km²	105.98	74.86	51.48	20.21
Urbanization rate 40-70% (green)/km²	19.65	20.60	21.37	19.12
Urban area in 2030/km²	338.9	308.73	286.12	252.6

From *Figure 5a* it can be seen that in the natural development scenario, the development of the city is almost free from any restrictions. Cities occupy a large amount of ecological green space in the process of expansion, which is more prominent in the suburbs of the eastern part of the city. In this scenario, the urban land area would be a total of 125.63 km² in 2030 with an average annual growth rate of 3.93%. Besides,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47174734

a large number of urbanized pixels can be seen from the eastern part of the study area, which means the probability of urbanization ranging from 70% to 100% by 2030. Most of the newly added urban land was originally the outskirts of the city, which led to the fragmentation of the spatial pattern and aggravate the contradiction between urban development and ecological protection.

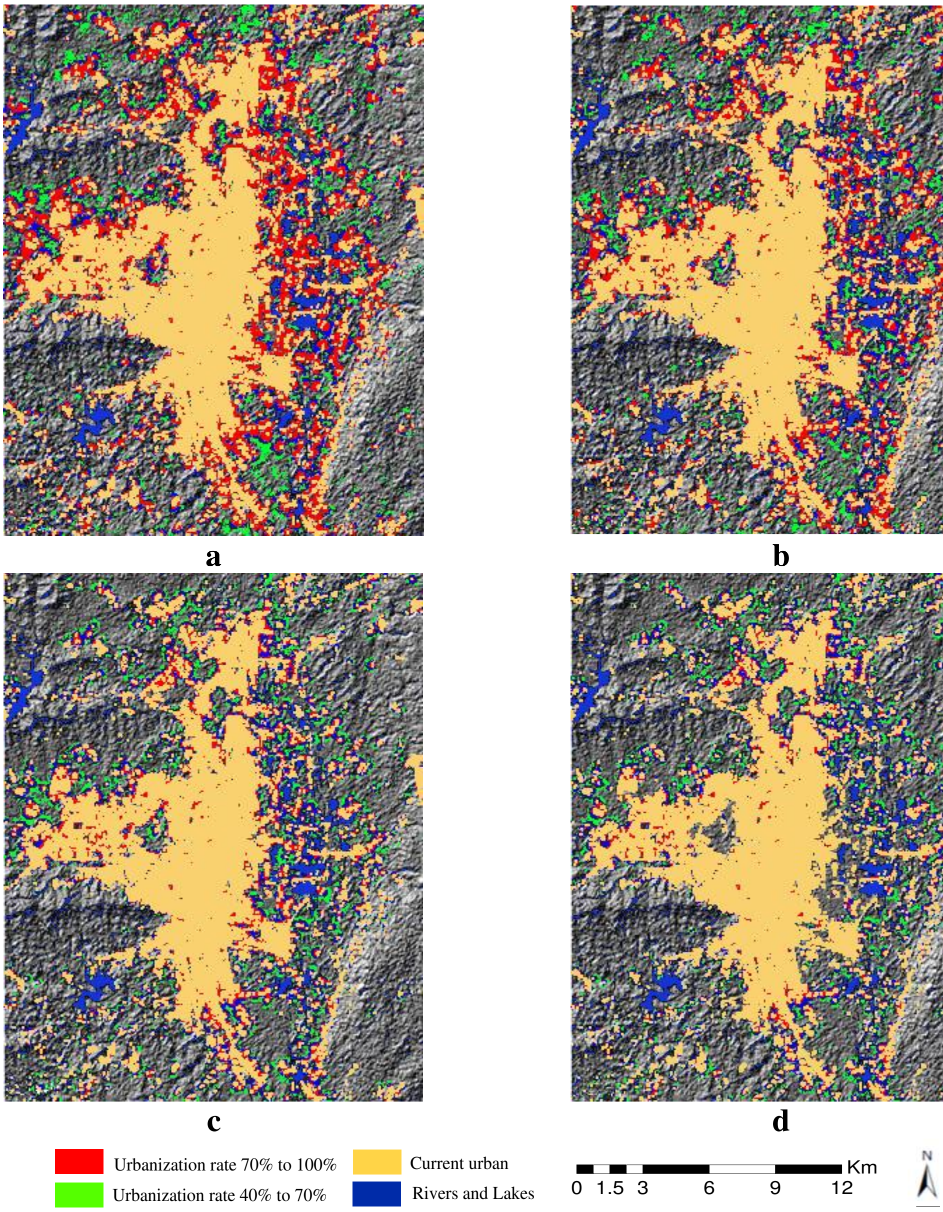

Figure 5. *Urban expansion prediction of scenario 1-4.* ***a*** *Scenario 1,* ***b*** *scenario 2,* ***c*** *scenario 3,* ***d*** *scenario 4*

Figure 5 (b and *c)* shows that the cities mainly extend to the north, the south and the west. The model which predicts the spatial pattern of urban development is basically consistent with the established urban planning, realizing the integrated urban structure system. The distribution of newly added city image element is obviously concentrated on the traffic road and the existing city periphery. It indicates that the road has played a

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47174734

major role in urban expansion (Rafiee et al., 2009; Dezhkam et al., 2014). However, in the planning-oriented scenario, there is still a large amount of ecological green spaces occupied in the process of urban expansion. This phenomenon is more prominent in the Qusheng Highway which lies in the east of the Daihe and Huangjiazhuang area. In the scenario of ecological development, the city carries out ecological construction at the same time and focuses on building the ecological cultural belt of the urban area with Mount Liaokuo and Nanpan River as the core. In this scenario, the city has realized the long-term ecological development plan of ecological landscape green corridor, which leads to the sustainable and harmonious development of the society, economy and culture. In this situation, through a series of the ecological landscape green corridor and other measures, the "one city, one river, one mountain" mode and the long-term blueprint of the scenic area have been achieved, which benefits the city's sustainable and coordinated development. *Figure 5d* shows that in the ecological protection scenario, due to improved protection of forests and farmlands, rapid urban expansion has been effectively controlled and urban land growth rate has dropped to 1.23%. But this restriction has obviously restricted the development of the city, which means by 2030 the area of the city would only increase by 39.33 km². From the forecast results of four scenarios, it can be seen that the future cities mainly expand by marginal growth and road traction growth while the new urban center would hardly come into formation, and the impact of the slope is insignificant. The results are similar in other experiments (Dietzel and Clarke, 2007; Al-Shalabi et al., 2013). The inclusion of the exclusion layer can better guide the city development according to the established urban planning, so as to avoid the disordered urban development and the destruction of ecological green space. The four kinds of forecast scenarios can well reflect the predefined planning policy (Aerts et al., 2003; Jantz et al., 2004).

The comparison of prediction results in four scenarios

From 1993 to 2030, the urban land of the study area has always been increasing. The urban land growth rate remains at above 3%. This phenomenon can be identified from *Figure 6 (a* and *b)* indicates that the study area has maintained a rapid development since 1993. The growth rate of the urban area increased first and then decreased in the period of 2000-2015, which indicates that the study area was at a time of rapid development before 2009, and the urban land increase rate was flat after 2009. However, according to forecast results, all the four kinds of scenarios present the growth tendency of the urban area.

According to the UESI (*Fig. 6c*), *UESI* has been more than 3.3 since 1993 and presented a growing trend. During the rapid expansion period of 1993-2009, the expansion rate slowed from 2009 to 2015 with the 2015 *UESI* being 6.34, and the city was in the middle-speed expansion stage (Wang et al., 2016). In the four scenarios, the *UESI* was gradually decreasing with the increase of urban ecological protection intensity. In the natural development scenario, *UESI* is as high as 8.37 in 2015-2030, much higher than *UESI* of the historical period; the city will be at a rapid growth rate of annual 8.37 km². In the planning-oriented scenario, the city basically maintains the existing urban expansion speed and it is in the middle-speed expansion stage. In this scenario, *UESI* and the previous stage are quite. In the ecological development scenario, the city is at a low-speed expansion period, and the expansion speed drops slightly (Al-Sharif, 2014). In the ecological protection scenario, the *UESI* is only 2.62, the urban expansion is at the low-speed expansion stage, the growth rate declines to 2.62 km²

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47174734

every year, and the urban expansion is obviously reduced compared with the historical periods.

According to *Figure 6d,* the *UEII* has been more than 3.4% since 1993; during 1993-2009, the *UEII* reached 4.9%. However, it dropped to 3.6% during 2009-2015. This is mainly because the government has made a local adjustment to the urban master plan, which restricts the construction and development of some ecological protection areas. In the four scenarios, the *UEII* gradually decreases with the increase of urban ecological protection intensity. In the natural development scenario, *UEII* is basically flat compared with the previous period from 2015 to 2030, the city will continue to maintain the strength of the strong expansion of urban development (Wang, 2016; Salvati et al., 2014). In planning-oriented scenarios and ecological development scenarios, the future expansion intensity of the city will be slightly lower than that of the previous period, but the *UEII* still maintain 2.3% to continue the development of the city. In the ecological protection scenario, the *UEII* descends to 1.23%, which is far below the level of the recorded extended intensity o and the future expansion of the city will be obviously restricted.

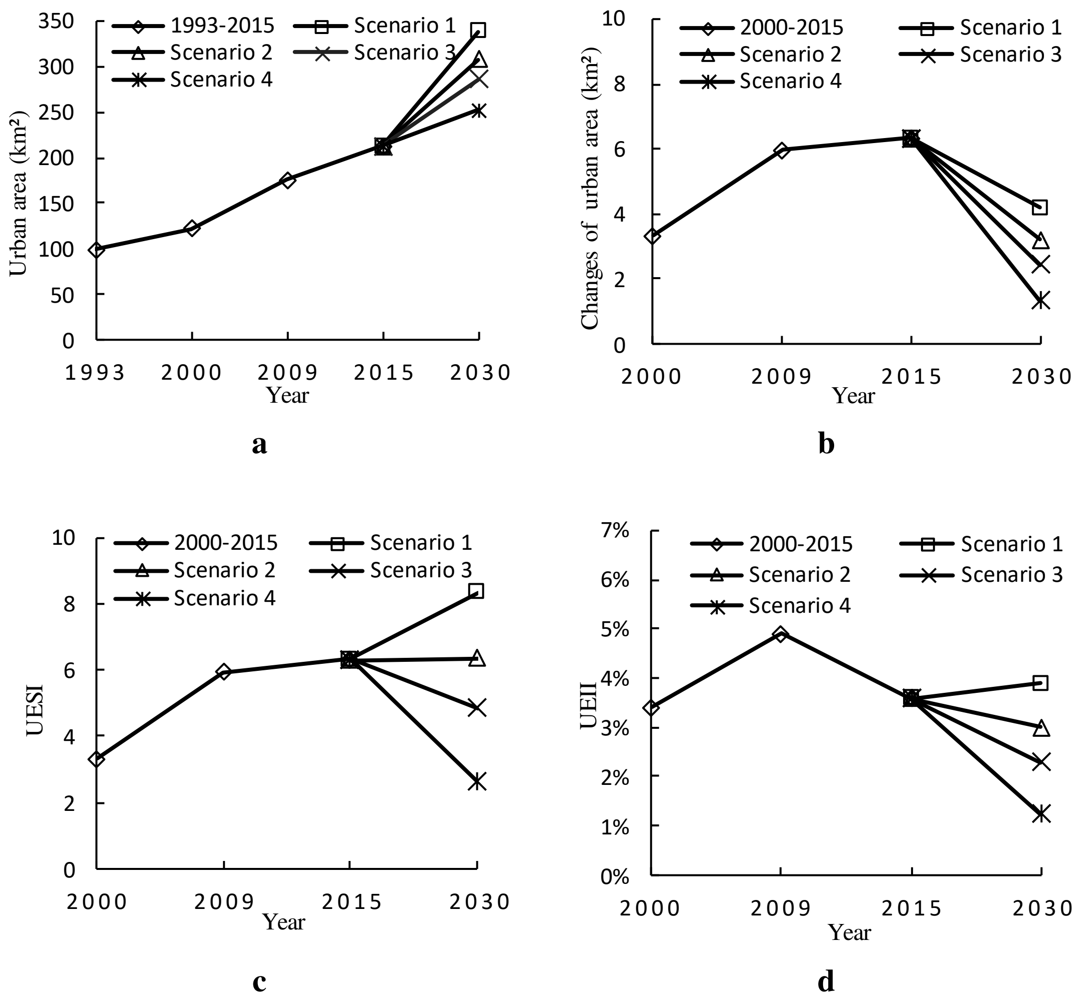

***Figure 6.** The statistics of urban area changes in different scenario. Changes in **a** total urban area, **b** urban area in each period, **c** urban expansion speed index and **d** urban expansion intensity index*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47174734

In order to choose the best forecast scenario, the predicted results of four scenarios were compared with the Urban Planning Project of 2030 (CAUPD and QCPB, 2016). We found that the predicted results of the ecological development scenarios were in accordance with the urban development requirements, especially in the urban spatial distribution. To prove this assumption, we extracted the urban land area data through the remote sensing image, with the image preprocessing and classification method being the same as other years'. The urban land of the research area is 225.5 km^2 in 2018. It can be seen from *Figure 7a* that the urban area is closest to the result of the ecological development scenario. During this period, the urban area increased 12.23 km^2, which exceeded the results of the four scenarios (*Fig. 7b).*

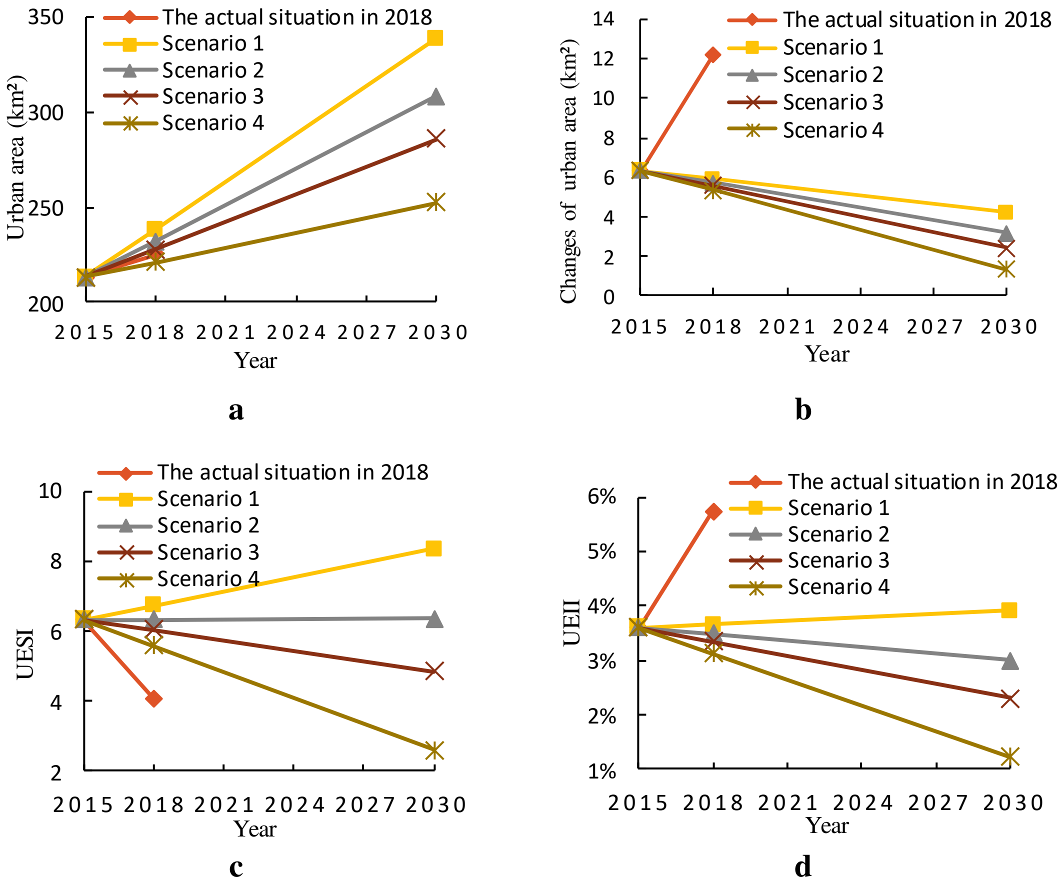

Figure 7. *The comparison between the actual situation of research area and four scenarios. Comparison of* ***a*** *total urban area,* ***b*** *urban area in each period,* ***c*** *USEI and* ***d*** *UEII*

The speed of urban expansion is limited to 4.07 (*Fig. 7c*), which is below the average velocity level of four scenarios (The average of four scenarios is 6.18). However, the urban expansion strength reached 5.3, which is much higher than the four scenarios predicted results (*Fig. 7d*). We speculate that because the government has strengthened the protection of ecological green space, the urban construction transfer from the blind expansion to high-quality development, and the rapid urbanization process was restricted. Therefore, from the perspective of the whole city, the speed of urban expansion has decreased. However, a large number of construction activities have

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47174734

occurred in some local areas of the city, which mainly occur in the fringe of urban settlements in the eastern part of the city; for example, people build large numbers of new houses and occupy farmland for commercial activities. These human activities explain why the growth of *UESI* slowed down but the *UEII* increased in the process of urban expansion.

Conclusion

This investigation integrates GIS, RS and SLEUTH model to simulate and predict the urban spatial expansion of the typical Chinese Nationally Designated Garden City (Qujing), and to explore the urban expansion trend under different ecological green space protection. Comparing the urban evolution laws in different scenarios, the results show that the SLEUTH model excels with a higher spatial matching degree with historical data, which enjoys better applicability and portability. The model can be used in Nationally Designated Garden Cities with dense vegetation and it can provide a reference for the sustainable development and urban planning of Nationally Designated Garden Cities in China. Under the protection intensity of different ecological green space, the urban area is obviously increased in four scenarios, and the other land types are occupied. This result indicates that the increase of urban land use is affecting the future space use pattern. By increasing the protection intensity of the ecological land around the city, the urban spatial expansion will be obviously restricted. It is mainly manifested by the decrease of *UESI* and *UEII*. Comparing the results of different scenarios, it is found that the future cities will spread around the present urban area in the natural development scenario. In the other three scenarios, the trend of urban expansion is expanding to the north, the south and the west, and would ultimately achieve the spatial integration of the Qiling and Zhanyi District, which is consistent with the requirements of urban master planning. Comparing with four scenarios, we found that the urban development trend predicted by the ecological development scenario is more similar to the urban planning, and this conclusion is confirmed by the 2018 distribution of urban areas. In the ecological development scenario, the urban ecological land has been effectively protected and the development of the city has not been affected, which is beneficial to the sustainable development of the city and the protection of the ecological environment. The ecological development scenario can minimize the impact on the urban ecological environment by increasing the protection of natural environment, controlling the development intensity and clarifying the direction of urban development. It is beneficial to the sustainable development of the city and the protection of the ecological environment.

We propose to use the SLEUTH model to reflect the spatial and temporal characteristics of urban expansion, and forecast urban expansion from both macroscopic and medium perspective (Silva and Clarke, 2005; Watkiss, 2008). In this case, the main factors affecting urban expansion, such as road, topography, lake and river are integrated into the urban expansion process. In this way, the results are more in accordance with the actual urban change. At the same time, the temporal resolution and spatial resolution of the image data will have certain influences on the prediction result of the model (Xiang and Clarke, 2003; Al-Shalabi et al., 2013; Chaudhuri and Clarke, 2014). This study selects four periods of city-wide data to test, and each designed period interval is between 6 to 9 years and the image space resolution is 30 m. The application of higher resolution remote sensing imagery and increased urban base period data

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47174734

would help to improve the accuracy of urban expansion simulations. In addition, the setting of the exclusion layer is the key link that directly affects the prediction results (Aerts et al., 2003; Clarke et al., 1997). How to embed the factors suitable for population, greening coverage, built-up area greening, per capita public green area based on SLEUTH model, and how to comprehensively consider the influence of various factors in the process of urban expansion will be the focus of the next research.

Abstract. Application of herbicides inhibit development of weeds, but at the same time they can negatively influence soil microbial activity. The microbiological indicators allow estimating changes in soil contaminated with herbicides. The aim of the study was to assess the influence of selected post-emergence herbicides: Stellar 210 SL + Olbras, Maister Power 42.5 OD, Laudis 44 OD, Collage 064 OD, Hector Max 66.5 WG + Trend 0.1 % and Arigo 51 WG + Trend 0.1% on the microbial activity of soil under maize plantation. The research included assessment of the count of selected groups of microorganisms, the activity of soil enzymes and soil fertility (BIF), as well as soil sensitivity (RS) to the preparations tested in the experiments. The results of study show that in some cases the count of the groups of microorganisms under study increased (the total bacterial count, the count of copiotrophs), especially immediately after the herbicide treatment, i.e. at the first term of analyses. The study showed that sixty days after the herbicide treatment all the xenobiotics exhibited strongly negative influence on the dehydrogenase activity (DHA). The activity of alkaline phosphatase and catalase became significantly reduced thirty days after the soil treatment with all of the herbicides used in the experiment. The highest values of biological index of fertility (BIF) were noted thirty days after the herbicide treatment and were strictly correlated with DHA and PAC.
Keywords: *post-emergence herbicides, total bacteria, fungi, dehydrogenase, phosphomonoesterases, BIF*

Introduction

For many years chemical crop protection products have been commonly used in farming practice to achieve the highest possible yield and desirable quality of crops. Intensive agricultural production as well as large numbers of pests and weeds cause increased use of pesticides (Baćmaga, 2007a). Herbicides are a group of crop protection products. They are considerably diversified and provide highly effective protection of particular crops. Long-term use of herbicides results in their accumulation in soil and it may cause a wide range of side effects (Walker et al., 2001). At present there are new EU regulations concerning integrated crop protection methods (introduced in Poland in 2014), which prefer non-chemical to chemical crop protection. The same active substances cannot be used consecutively in order to reduce the negative effect of agriculture on the environment.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47354752

Modern herbicides biodegrade rapidly and they are effective even at small doses or at divided doses. Nevertheless, whenever the active substance of the pesticide is applied, it may affect the population and species composition of soil microorganisms. It may also indirectly influence the biochemical processes in which these microorganisms take part (Baćmaga et al., 2013). When herbicides are applied, the microbial biomass of soil may increase, decrease or remain the same (Singh and Ghoshal, 2010). Both the active substance and its decomposition products may be more toxic than the input products. They also influence the population and bioactivity of microorganisms (Arias-Estévez et al., 2008).

The count of soil microorganisms and the soil enzymatic activity are the indicators which enable assessment of changes in soil pollution and fertility (Baćmaga et al., 2007b).

The aim of the study was to assess the influence of selected post-emergence herbicides: Stellar 210 SL + Olbras, Maister Power 42.5 OD, Laudis 44 OD, Collage 064 OD, Hector Max 66.5 WG + Trend 0.1 % and Arigo 51 WG + Trend 0.1% on the microbial activity of soil under maize plantation. The research included assessment of the count of selected groups of microorganisms (total bacteria, actinobacteria, moulds, oligotrophs and copiotrophs), the activity of soil enzymes (dehydrogenase, acid and alkaline phosphatase, catalases) and soil fertility (BIF), as well as soil sensitivity to the preparations tested in the experiments.

Material and methods

Between 2015 and 2016 experiments were conducted in the village of Swadzim (52°26 N, 16°45 E) in fields belonging to the Experimental and Educational Station Gorzyń, Poznań University of Life Sciences, Poland.

The experiments were conducted in plots on *Haplic Luvisols* (according to the FAO/WRB classification [IUSS Working Group WRB, 2007]), derived from loamy sands. (*Table 1*).

The soil texture was determined using sieving (sand fraction) for silt and clay fraction (Van Reeuwijk, 2002).

Table 1. *The texture of soil material sampled from 0-25 depth*

Percentage content of soil fractions %				Texture class
Fraction	sand 2 – 0.05 mm	silt 0.05-0.002 mm	clay < 0.002 mm	
	78	18	4	LS

LS – loamy sand

P9175 maize cultivar (FAO 280) was sown in plots of 28 m^2, in four replications for each treatment. The cultivar is highly resistant to water deficit and high temperatures.

Soil samples were collected at three terms, which differed in the number of days following the application of individual herbicides. The samples were collected at the following terms:

1st term –3 days after herbicide treatment,
2nd term – 30 days after herbicide treatment,
3rd term – 60 days after herbicide treatment.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47354752

Individual experimental samples were collected from seven variants, which differed in the type of herbicides applied. One variant did not receive any chemical protection and was used for reference (*Table 2*).

Table 2. *The field experiment scheme*

Treatment	Activity substances of herbicide	Doses of herbicide
1. Control	without herbicide	without herbicide
2. Stellar 210 SL + Olbras	Dicamba, topramezon + adjuvant	1.25 l/ha + 1 l/ha
3. Maister Power 42.5 OD	Iodosulfuron-methyl-sodium, foramsulfuron, methyl thiencarbazone	1.25-1.5 l/ha
4. Laudis 44 OD	Tembotrione	2-2.5 l/ha
5. Collage 064 OD	Nicosulfuron, thifensulfuron-methyl	1 l/ha
6. Hector Max 66.5 WG + Trend 0.1 %	Nicosulfuron, rimsulfuron, dicamba + adjuvant	330-440 g/ha
7. Arigo 51 WG + Trend 0.1 %	Mesotrione, nicosulfuron, rimsulfuron + adjuvant	330 g/ha

Weather conditions

It is generally accepted that climatic conditions found throughout Poland are suitable for maize cultivation. This species needs approx. 500 mm annual precipitation to grow. The weather conditions during the experiment were characterised with Sielianinov hydrothermal coefficient K (Skowera, 2004). Selyaninov hydrothermal coefficient K was calculated according to the formula $K = (P \cdot 10)/(T \cdot L)$, where K Sielianinov hydrothermal coefficient, P – total monthly precipitation, T – average monthly temperature, L – number of days in the month (*Fig. 1*). In all the years mean air temperature ranged from 8.6 to 10°C and it was comparable to the multiannual mean. A crucial element of optimal growth and biomass yielding conditions is also total precipitation, particularly its distribution. Variability of weather conditions in the years of the study was reflected in the values of the Sielianinov coefficient. More advantageous moisture conditions for maize were found in the year 2016 than in the drier 2015 ($K = 0.9$).

Interpretation of the Sielianinov hydrothermal coefficient:

$K > 1.5$ – excessive moisture for all plants

$K = 1.0$-1.5 – sufficient moisture

$K = 0.5$-1.0 – insufficient moisture

$K < 0.5$ – moisture level below the requirement for most plants – drought.

Soil enzymatic activity

The analyses of the enzymatic activity of soil in different variants (each in four replication) were based on the colorimetric method applied to measure the dehydrogenase activity (EC 1.1.1. DHA), where 1% TTC (triphenyl tetrazolium chloride) was used as a substrate. The measurement took place after a 24-hour

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47354752

incubation at a temperature of 30°C and a wavelength of 485 nm and it was expressed as µmol TPF (triphenyl formazane)·24 h^{-1} g^{-1} dm of soil (Thalmann, 1968).

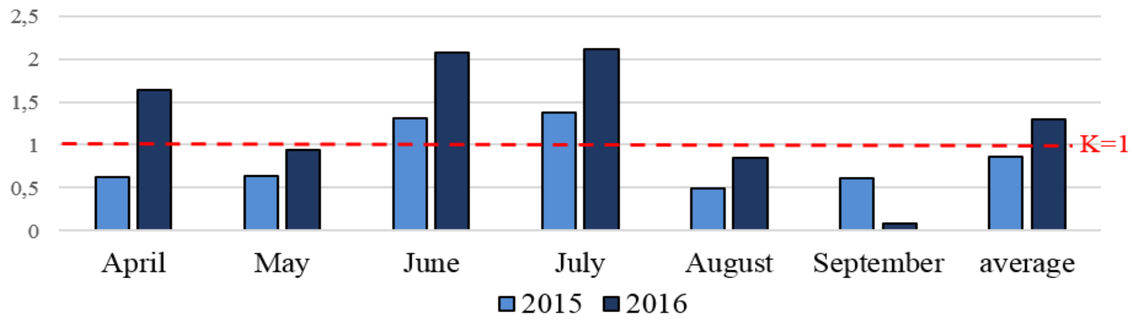

Figure 1. *Humidity characteristic of the months of the vegetation period of 2015–2016 according to the value of the Sielianinov hydrothermal coefficient (K)*

Apart from that, the acid and alkaline phosphomonoesterase (EC 3.1.3.2, PAC/PAL) activity were analysed with the method developed by Tabatabai and Bremner (1969). The activity was analysed using disodium p-nitrophenyl phosphate tetrahydrate as a substrate after 1 h incubation at a temperature of 37°C and wavelength of 400 nm. The results were converted into µmol (p-nitrophenol) PNP h^{-1} g^{-1} dm of soil.

The catalyse activity (EC 1.11.1.6) was analysed manometrically with the method developed by Johnsons and Temple (1964), where 0.3% H_2O_2 was used as a substrate. After a 20 minute incubation at room temperature (20°C) it was titrated with 0.02 M $KMnO_4$ until its colour was light pink. The value was expressed as mmol $H_2O_2g^{-1}$ d.m. min^{-1}.

Measurement of biological index of fertility (BIF)

The biological index of fertility (BIF) was measured using the dehydrogenase activity (DHA) and catalyse activity (CAT) in the formula: (DHA +kCAT)/2, where k is the proportionality factor amounting to 0.01 (Saviozzi et al., 2004).

Microbial analyses

Soil samples were collected at a depth of 0-20 cm from interrows in the maize plantation. Volume of the samples to microbiological and biochemical tests was 700 - 800 g, which was sampled by using Egner's sticks from 10 points of each variant plot.

The serial dilution method developed by Koch was applied to measure the count of microorganisms on appropriate agar mediums (in five replicates). The average count of colonies per dry mass of soil was calculated:

- the total bacterial count was measured on ready Merck-Standard count agar after 5 days of incubation at 25°C;
- moulds were measured on a Martin medium after 5 days of incubation at 24°C;
- actinobacteria were measured on a Pochon medium after 5 days of incubation at 25°C;
- copiotrophs were measured on an NB (Nutrient Broth) medium (Ohta and Hattori, 1980) after 5 days of incubation at 25°C;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47354752

- oligotrophs were measured on a DNB (Dilution Nutrient Broth) medium (Ohta and Hattori, 1980) after 5 days of incubation at 25°C.

The formula (*Eq. 1*) proposed by Orwin and Wardle (2004) was used to estimate soil resistance (RS) to contamination with the herbicides under analysis:

$$RS = 1 - \frac{2\left| D_0 \right|}{C_0 + \left| D_0 \right|} \quad \text{(Eq.1)}$$

where:
C_0 – soil resistance under natural conditions over time t_0,
P_0 – resistance of soil subjected to pressure over time, $D_0 = C_0 - P_0$.

Statistical analysis

Two-way analysis of variance (α = 0.05) was used to compare the mean values of biological parameters at individual terms of analyses and the influence of selected herbicide combinations. Next, post-hoc Tukey HSD test was applied. Principal Component Analysis (PCA) was used to analyse the bioactivity date at individual maize development phases in consequence of herbicide treatment.

Results

Microbial number

The results of microbial analyses are mean values of the two years of the research. Our results in general were consistent in the years of study so we decided to make a synthesis from years. The two-way analysis of variance showed that the factors under study significantly influenced the total bacterial count as well as the count of actinobacteria, copiotrophs and oligotrophs. There was no significant dependence between the factors and the count of moulds (*Table 3*).

Table 3. *F test statistics and significance levels of two-way analysis of variance for the number of selected groups of microorganisms associated with herbicides and terms research fixed factors (*** p = 0.001. ** p = 0.01. * p = 0.05. ns - not statistically significant)*

Parameter	Time	Treatment	Interaction
Total bacterial count	23.31^{***}	5.77^{***}	8.15^{***}
Moulds	0.15^{ns}	0.80^{ns}	1.21^{ns}
Actinobacteria	77.02^{***}	3.34^{**}	10.20^{***}
Copiotrophs	29.34^{***}	2.29^{*}	2.87^{**}
Oligotrophs	97.19^{***}	22.05^{***}	15.60^{***}

The research showed the influence of individual herbicides on the total bacterial count (*Table 4*). In comparison with the control variant, the xenobiotic treatment with Stellar 210 SL + Olbras (a.s. dicamba, topramezone + adjuvant), Laudis 44 OD (a.s. tembotrione) and Collage 064 OD (a.s. nicosulfuron, thifensulfuron-methyl) caused an

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47354752

increase in the total bacterial count at all the three terms. When Maister Power 42.5 OD (a.s. iodosulfuron-methyl-sodium, foramsulfuron, thiencarbazone-methyl) was applied, the total bacterial count was similar to the count in the control variant during the whole period of the research. When Hector Max 66.5 WG + Trend 0.1% (a.s. nicosulfuron, rimsulfuron, dicamba + adjuvant) and Arigo 51 WG + Trend 0.1% (a.s. mesotrione, nicosulfuron, rimsulfuron + adjuvant) were applied, the count of bacteria was greater than in the control variant at the first and third term. However, at the second term the bacterial count was respectively about 60% and 70% lower than in the soil which had not been treated with the herbicides.

The research revealed that the herbicides caused considerable fluctuations in the count of oligotrophs. Three days after the application (the first term) of Stellar 210 SL + Olbras (a.s. dicamba, topramezone + adjuvant), Collage 064 OD (a.s. nicosulfuron, thifensulfuron-methyl) and Hector Max 66.5 WG + Trend 0.1 % (a.s. nicosulfuron, rimsulfuron, dicamba + adjuvant) the crop protection products stimulated the growth of oligotrophs, as their count was greater than in the control variant *(Table 4)*. At the second term of analyses, i.e. thirty days after the herbicide treatment, the count of oligotrophs increased in the variants where Stellar 210 SL + Olbras (a.s. dicamba, topramezone + adjuvant), Maister Power 42.5 OD (a.s. iodosulfuron-methyl-sodium, foramsulfuron, thiencarbazone-methyl) and Collage 064 OD (a.s. nicosulfuron, thifensulfuron-methyl) had been applied. Sixty days after the herbicide treatment the count of these microorganisms dropped in all the variants, as compared with the control sample.

Like oligotrophs, the count of copiotrophs fluctuated during the whole period of the research. It depended on the chemical product and the time after the treatment.

Table 4. *The effect of herbicides on the number of microorganisms*

Hector Max 66.5 WG + Trend 0.1 %	23.92 de ± 3.46	20.54 b-e ± 5.32	7.31 a-c ± 2.47
Arigo 51 WG + Trend 0.1 %	23.74 c-e ± 3.84	25.34 de ± 5.83	2.79 a ± 1.43

Note: data are represented as means of five replications. Values after means are standard deviations ±; mean values ± standard errors; a, b, c, d, e – homogenous groups according to Tuckey's test; different letters denote statistical differences at level $\alpha = 0.05$; n = 5

In comparison with the control soil variant, immediately after treatment with the crop protection products and thirty days after the treatment the count of copiotrophic bacteria increased in the variants with Stellar 210 SL + Olbras (a.s. dicamba, topramezone + adjuvant), Hector Max 66.5 WG + Trend 0.1 % (a.s. nicosulfuron, rimsulfuron, dicamba + adjuvant) and Arigo 51 WG + Trend 0.1 % (a.s. mesotrione, nicosulfuron, rimsulfuron + adjuvant). However, sixty days after the treatment there was an inverse dependence – the count of copiotrophic bacteria decreased. When Maister Power 42.5 OD (a.s. iodosulfuron-methyl-sodium, foramsulfuron, thiencarbazone-methyl) was applied, it inhibited the count of copiotrophs at each of the three terms of analyses, as compared with the soil which was not treated with herbicides *(Table 4)*. The count of copiotrophs in the variants where Laudis 44 OD (a.s. tembotrione) and Collage 064 OD (a.s. nicosulfuron, thifensulfuron-methyl) were applied fluctuated continuously during the whole research period.

Actinobacteria were another group of microorganisms under study *(Table 4)*. At the first term of soil sample collection the count of actinobacteria in most of the herbicide variants was similar to the count in the control variant. Only treatment with Collage 064 OD (a.s. nicosulfuron, thifensulfuron-methyl) caused the count of actinobacteria to increase by more than 100%. Thirty days after the herbicide treatment Maister Power

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47354752

42.5 OD (a.s. iodosulfuron-methyl-sodium, foramsulfuron, thiencarbazone-methyl) had the most stimulating effect on actinobacteria as their count was almost 5 times greater than in the control variant. At the last term of analyses, i.e. sixty days after the herbicide treatment, only Collage 064 OD (a.s. nicosulfuron, thifensulfuron-methyl) and Hector Max 66.5 WG + Trend 0.1% (a.s. nicosulfuron, rimsulfuron, dicamba + adjuvant) caused an increase in the count of actinobacteria, whereas the other herbicides resulted in a decrease. The greatest decrease in the count of actinobacteria at the last term of analyses was noted in the Maister Power 42.5 OD variant (a.s. iodosulfuron-methyl-sodium, foramsulfuron, thiencarbazone-methyl).

Like all groups of microorganisms, moulds also responded to the herbicide treatment with changes in their count in soil (*Table 4*). At the first term each of the crop protection products decreased the population of these microorganisms. Arigo 51 WG + Trend 0.1% (a.s. mesotrione, nicosulfuron, rimsulfuron + adjuvant) was the most toxic as it decreased the count of moulds by more than 56%, as compared with the control variant. Thirty days after the herbicide treatment Stellar 210 SL + Olbras (a.s. dicamba, topramezone + adjuvant), Maister Power 42.5 OD (a.s. iodosulfuron-methyl-sodium, foramsulfuron, thiencarbazone-methyl) and Arigo 51 WG + Trend 0.1% (a.s. mesotrione, nicosulfuron, rimsulfuron + adjuvant) caused an increase in the count of moulds. Sixty days after the herbicide treatment only the Arigo 51 WG + Trend 0.1% variant (a.s. mesotrione, nicosulfuron, rimsulfuron + adjuvant) had negative effect on the population of these microorganisms.

Soil biochemical activity

The herbicides had significant influence on the enzymatic activity of alkaline phosphatase, catalase and BIF. They did not have significant influence on the activity of dehydrogenase or acid phosphatase (*Table 5*).

Table 5. *F test statistics and significance levels of two-way analysis of variance for the enzymes activity associated with herbicides and terms research fixed factors (*** p = 0.001. ** p = 0.01. * p = 0.05. ns - not statistically significant)*

Parameter	Time	Treatment	Interaction
Dehydrogenase	0.03^{ns}	0.82^{ns}	1.89^{*}
Alkaline phosphatase	495.52^{***}	87.40^{***}	82.66^{***}
Acid phosphatase	32.59^{***}	0.65^{ns}	0.62^{ns}
Catalase	19051.80^{***}	4312.67^{***}	2691.16^{***}
BIF	39.00^{***}	8.77^{***}	9.05^{***}

As can be seen in *Figure 2* the greatest fluctuations in the dehydrogenase activity were observed thirty days after the herbicide treatment. Maister Power 42.5 OD (a.s. iodosulfuron-methyl-sodium, foramsulfuron, thiencarbazone-methyl), Laudis 44 OD (a.s. tembotrione) and Arigo 51 WG + Trend 0.1% (a.s. mesotrione, nicosulfuron, rimsulfuron + adjuvant) caused increased activity of these enzymes. The last variant increased the dehydrogenase activity nearly 5 times. Sixty days after the treatment the activity of these enzymes in all the variants with herbicides dropped below the value noted in the control variant.

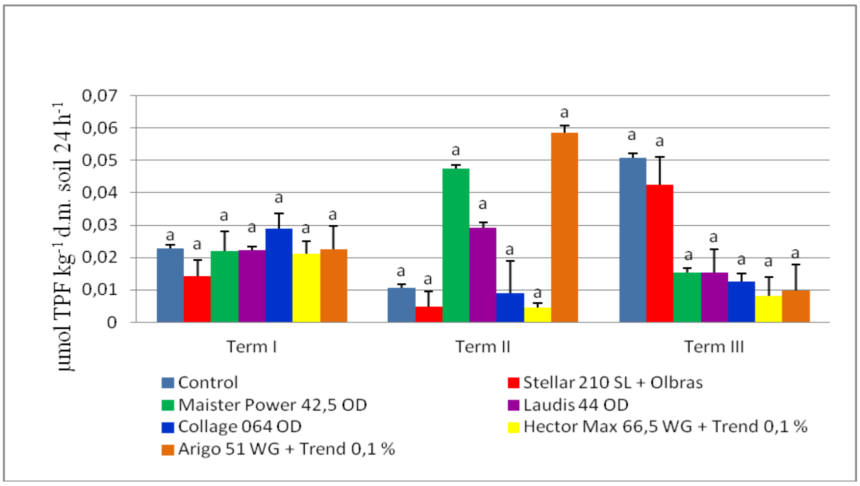

Figure 2. *The effect of herbicides on dehydrogenase activity. Note: data are represented as means of five replications. Vertical bars are standard deviation ±; mean values ± standard errors; a, b, c, d, e – homogenous groups according to Tuckey's test; different letters denote statistical differences at level α = 0.05; n = 5*

The alkaline phosphatase activity in the samples collected three days after the herbicide treatment was similar in all the variants of the experiment (*Fig. 3*). At the second term of analyses the activity of these enzymes was lower in the variants treated with herbicides than in the control soil sample. Sixty days after the treatment with xenobiotics the alkaline phosphatase activity increased only in the Stellar 210 SL + Olbras (a.s. dicamba, topramezone + adjuvant) and Maister Power 42.5 OD variants (a.s. iodosulfuron-methyl-sodium, foramsulfuron, thiencarbazone-methyl). Laudis 44 OD (a.s. tembotrione) was the most toxic herbicide to alkaline phosphatase at that term of analyses. In comparison with the control variant the activity of this enzyme was reduced by more than 80%.

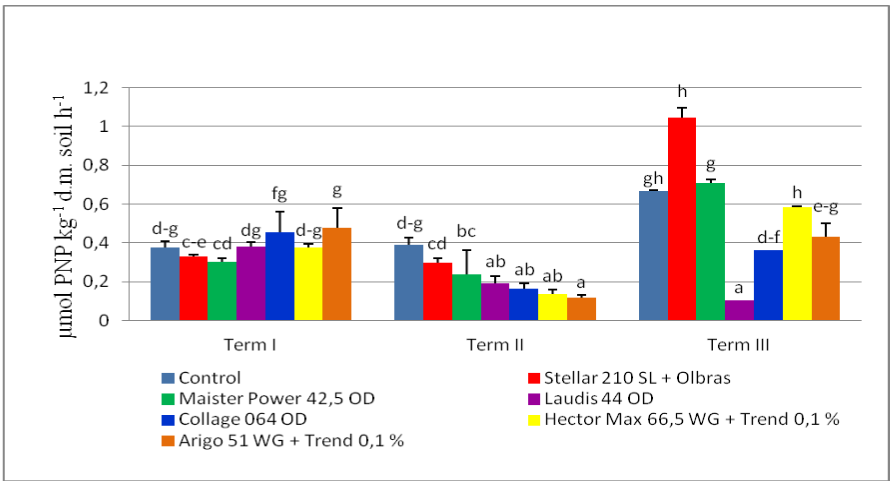

Figure 3. *The effect of herbicides on alkaline phosphatase activity. Note: data are represented as means of five replications. Vertical bars are standard deviation ±; mean values ± standard errors; a, b, c, d, e – homogenous groups according to Tuckey's test; different letters denote statistical differences at level α = 0.05; n = 5*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47354752

The results in *Figure 4* show that only at the second term of analyses all the herbicides caused an increase in the acid phosphatase activity, as compared with the control variant. The highest acid phosphatase activity was observed when Arigo 51 WG + Trend 0.1% (a.s. mesotrione, nicosulfuron, rimsulfuron + adjuvant) was applied. At the other terms there were slight fluctuations in the enzyme activity, as compared with the control variant.

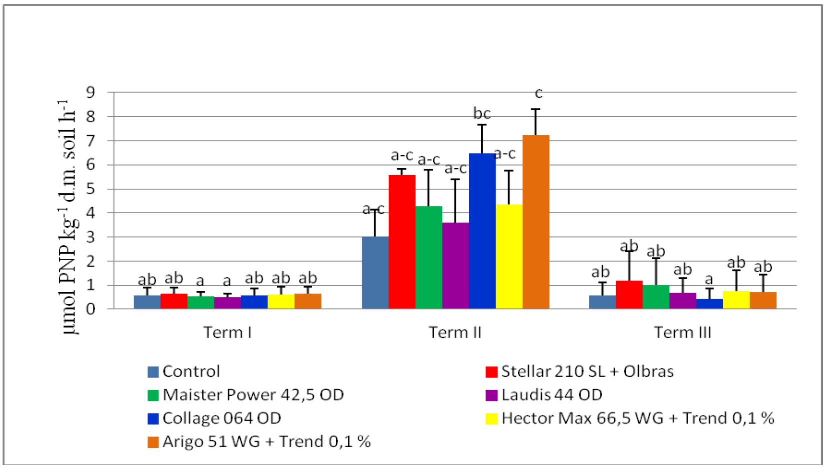

Figure 4. *The effect of herbicides on acid phosphatase activity. Note: data are represented as means of five replications. Vertical bars are standard deviation ±; mean values ± standard errors; a, b, c, d, e – homogenous groups according to Tuckey's test; different letters denote statistical differences at level α = 0.05; n = 5*

The catalase activity was also measured to assess the microbial state of soil. The data in *Figure 5* show that only at the first term of analyses the activity of this enzyme was stable and remained at a high level. There were no significant changes in comparison with the control sample. After thirty days of the experiment most of the herbicides reduced the catalase activity, as compared with the control sample. Nevertheless, the catalase activity in the variants with Arigo 51 WG + Trend 0.1% (a.s. mesotrione, nicosulfuron, rimsulfuron + adjuvant) and Collage 064 OD (a.s. nicosulfuron, thifensulfuron-methyl) increased 9 and 2 times, respectively. At the last term of analyses, i.e. sixty days after the treatment with xenobiotics, the catalase activity in the variants with Arigo 51 WG + Trend 0.1% (a.s. mesotrione, nicosulfuron, rimsulfuron + adjuvant) and Collage 064 OD (a.s. nicosulfuron, thifensulfuron-methyl) was higher than in the control variant.

The research also enabled measurement of the biological index of fertility (BIF) in all the variants (*Fig. 6*). The index value was based on the dehydrogenase and catalase activity. The highest values of the index were noted thirty days after the herbicide treatment (2nd term). The treatment with Arigo 51 WG + Trend 0.1% (a.s. mesotrione, nicosulfuron, rimsulfuron + adjuvant), Maister Power 42.5 OD (a.s. iodosulfuron-methyl-sodium, foramsulfuron, thiencarbazone-methyl) and Laudis 44 OD (a.s. tembotrione) resulted in higher values of the index. At the last term the results noted in the variants treated with the herbicides were lower than in the control variant.

The sensitivity value (RS) in *Table 6* shows that the soil enzymes differed in their response to pollution with the herbicides. This index of resistance is bounded by -1 and +1, where the value of +1 shows that disturbance had no effect (maximum resistance),

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47354752

whereas lower values indicate stronger effects (lower resistance). The lowest RS value for dehydrogenase in the soil was noted immediately after the treatment with Stellar 210 SL + Olbras (a.s. dicamba, topramezone + adjuvant) and Arigo 51 WG + Trend 0.1% (a.s. mesotrione, nicosulfuron, rimsulfuron + adjuvant). At the consecutive terms of analyses, i.e. thirty and sixty days after the herbicide treatment, the RS value for dehydrogenase was close to ‘1’ and it ranged from 0.785 to 0.983 and from 0.887 to 0.904, respectively. The sensitivity of alkaline phosphatase to the herbicides was different during the experiment. The lowest RS value was noted thirty days after the herbicide treatment. It amounted to -0.029 after the treatment with Hector Max 66.5 WG + Trend 0.1% (a.s. nicosulfuron, rimsulfuron, dicamba + adjuvant). Sixty days after the herbicide treatment the highest sensitivity of the enzyme was observed in the Laudis 44 OD (a.s. tembotrione) and Collage 064 OD (a.s. nicosulfuron, thifensulfuron-methyl) variants *(Table 6).*

The results concerning the influence of the herbicides on the soil bioactivity were illustrated by means of principal component analysis (PCA) (*Fig. 7*). The analysis showed highly significant dependences occurring in the soil environment under maize plantation after the herbicide treatment. There was a high positive correlation between the biological parameters such as the total bacterial count and the count of actinobacteria and the alkaline phosphatase activity sixty days after the herbicide treatment. On the other hand, the dehydrogenase activity, the biological index of fertility (BIF) and the count of moulds were negatively correlated with the effect of the crop protection products at all the terms of the analyses.

Discussion

The count of microorganisms and the enzymatic activity are important biological indicators of soil. The dynamics of changes in the count of microorganisms may be caused by cultivation, fertilisation and chemical crop protection. Herbicides may influence the count of soil bacteria, which participate in the processes responsible for soil fertility.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47354752

The results of our study show that the crop protection products used during maize growing had diversified influence on the groups of soil microorganisms under analysis, which depended on the products and the term of analyses. Apart from that, there was high diversification in the populations of different microorganisms colonising the soil environment after the application of the chemical crop protection products. The research results showed that the products significantly disturbed the microbial balance, causing changes in the count of oligotrophic and copiotrophic bacteria, actinobacteria, moulds and the total bacterial count.

Hector Max 66.5 WG + Trend and Arigo 51 WG + Trend significantly reduced the total bacterial count thirty days after the treatment. The same herbicides significantly reduced the population of oligotrophs thirty and sixty days after the treatment, whereas Maister Power 42.5 OD had significant negative influence on the development of actinobacteria also at the last term of analyses.

Sixty days after the herbicide treatment the count of actinobacteria and oligotrophs may have been reduced because of the high toxicity of metabolites formed in consequence of the decomposition of the active substances in the herbicides. When pesticides are applied, they undergo various processes in the environment, such as: transformation, degradation, sorption-desorption, volatilisation, uptake by plants, runoff to surface water and transport to groundwater (Chowdhury et al., 2008). Transformation and degradation are two of the major processes regulating the state of the soil environment. Pesticides are transformed into secondary metabolites or they are completely mineralised (Singh et al., 2006). Although abiotic degradation plays a significant role in many cases, the biodegradation of pesticides by microorganisms is usually the most important and predominant process (Karpouzas and Walker, 2000; Chen et al., 2012a, b; Cycoń et al., 2014; Silva et al., 2015). The negative influence of crop protection products on the proliferation of microorganisms was also observed by Sebiamo et al. (2011), who studied atrazine, primextra, paraquat and glyphosate. Niewiadomska et al. (2018) made similar observations.

The results of our study concerning the influence of the active substance in herbicides show that in some cases the count of the groups of microorganisms under study increased (the total bacterial count, the count of copiotrophs), especially immediately after the herbicide treatment, i.e. at the first term of analyses. There are publications (Fečko et al., 2010) which confirm this reaction of the soil microflora and stress the fact that some species of microorganisms use herbicides as a source of carbon and nutrients. Due to the fact that crop protection products have been used in agriculture for decades, microorganisms have adapted to the polluted environment. They have developed natural mechanisms of biodegradation of toxic substances. The capacity of some microorganisms to biodegrade pesticides partly reduces the toxic substances which might affect the yield. It also improves the biological properties of soil. Many studies proved that strains such as *Pseudomonas* (Fernandes et al., 2014), *Acinetobacter* (Singh et al., 2004*)*, *Rhodococcus* (Batra et al., 2009; Fazlurrahman et al., 2009), *Arthrobacter* (El Sebaï et al., 2011), *Bacillus* (Wang et al., 2014), *Variovorax itp.* (Zhang et al., 2012) were capable of total degradation of atrazine (Zhang et al., 2012) and glyphosate. However, in most cases the effectiveness of biodegradation of herbicides by bacteria is significantly correlated with the soil pH, temperature and availability of building elements such as carbon and nitrogen.

The soil enzymes which participate in the biodegradation of natural and anthropogenic compounds are often used as indicators of changes in the soil

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47354752

environment caused by the use of crop protection products, including herbicides (Wang et al., 2009; Baćmaga et al., 2012).

The study showed that the enzymes under analysis were sensitive to the herbicides applied in the experiment. Sixty days after the herbicide treatment all the xenobiotics exhibited strongly negative influence on the dehydrogenase activity. The negative influence was also observed thirty days after the treatment with Stellar 210SL + Olbras and Hector Max 66.5 WG + Trend 0.1%. There were similar observations made by Cycoń et al. (2010, 2013), who studied the influence of napropamide and linuron in herbicides, and by Baćmaga et al. (2014), who researched the influence of metazachlor on the dehydrogenase activity.

Our study also showed that alkaline phosphatase exhibited high sensitivity. The activity of this enzyme became significantly reduced thirty days after the soil treatment with all of the herbicides used in the experiment. This phenomenon may have been caused by the low content of organic matter in the soil and by the inhibitory effect of herbicides on local moulds, which are known to produce alkaline phosphatase in soil (Cycoń et al., 2013). On the other hand, at the same term of analyses the acid phosphatase activity in the soil variants treated with the herbicides was higher than in the control variant.

Pesticides and their metabolites may also influence physiological processes in microorganisms such as cell lysis and changes in the cell membrane, thus modifying the activity of soil enzymes (Hussain et al., 2009; Romero et al., 2010).

The soil ecosystem is regarded as stable if it can resist stress factors and regain balance shortly (Griffiths and Philippot, 2013; Orwin and Wardle, 2004). Soil stability is usually assessed on the basis of resistance (RS) and resilience (RL). In our study the RS value was calculated by estimating the resistance of soil to contamination with the herbicides and adjuvants (*Table 6*).

The RS values calculated in our study show that immediately after the herbicide treatment alkaline phosphatase was the least sensitive enzyme, whereas dehydrogenase was the most sensitive. However, alkaline phosphatase exhibited the highest sensitivity thirty days after the treatment. The herbicides caused greater disturbance to the phosphatase activity than to the dehydrogenase activity. Griffith and Philippot (2013) stress the fact that when the soil ecosystem is exposed to long-lasting stress factors, it becomes more stable due to the development of defence mechanisms responsible for its biostability.

Conclusion

Tested post-emergence herbicides applied to maize caused a statistically significant biological imbalance in the soil, reducing the actinobacteria as well as the number of moulds at the beginning of vegetation, three days after the treatment. The research revealed very high sensitivity of dehydrogenases and alkaline phosphatase to the soil contamination caused by the application of herbicides. The field doses of the xenobiotics used in the research significantly reduced the dehydrogenase activity in sixty days after the herbicide treatment. The dehydrogenase activity values were strictly correlated with BIF and PAC.

Abstract. Poor germination capacity of stevia is a major problem in its cultivation. Moreover, drought stress is one of the most major environmental constraints, which influences seed germination and early seedling growth of many crops. The aim of this research was to evaluate the impact of seed priming with salicylic acid (SA), zinc (Zn) and iron (Fe) on some germination parameters and physiological attributes of stevia seedlings under drought stress induced by polyethylene glycol (PEG) 6000 (0, – 3, – 6 and – 9 bars). The results revealed that germination traits (germination percentage, germination rate, mean germination time, germination value, seedling length, and seedling vigor index) and chlorophyll (Chl) content were negatively affected by drought stress. However, the reduction of germination parameters in seedlings exposed to drought stress in most cases was moderated by seed priming, which also increased the Chl content at all levels of drought stress as compared with the control. Drought stress also increased the proline accumulation and the enzymatic activity of catalase (CAT) and peroxidase (POD) in all priming treatments, but these enhancements were significantly higher in primed seedlings than those in unprimed ones. Among all priming treatments, priming with SA + Fe + Zn was found to be more effective than other treatments to improve growth and physiological characteristics under normal and drought stress conditions. Thus, we suggest that seed priming with SA, Fe, Zn and particularly the integrated application of these three agents at a suitable concentration can promote the poor germination performance of stevia and improve the seedling growth by increasing the antioxidant capacity under drought conditions.
Keywords: *antioxidant enzymes, chlorophyll, proline, salicylic acid, seed germination*

Introduction

Stevia (*Stevia rebaudiana* Bert.), a member of the Asteraceae (Compositae) family, is an herbaceous perennial and short-day species (Yadav et al., 2011; Ucar et al., 2016). Naturally, this plant grows between 22–24° south and 53–56° west in South America (Paraguay and Brazil), where it is called ka'ahe'ê (or sweet herb) (Lemus-Mondaca et al., 2012). Stevia is widely grown for its non-caloric sweet compounds. The sweetness of the stevia plant is related to the presence of *ent*-kaurene-type diterpene glycosides (stevioside and rebaudiosides), which can be 300 times sweeter than sucrose (Hajihashemi and Ehsanpour, 2014; Aghighi Shaverdi et al., 2018). Since the sweet herb has self-incompatible flowers, its pollination is probably carried out by insects and wind (Ucar et al., 2016; Shahverdi et al., 2017). As a result, stevia produces often few pollinated flowers which have low germination percentage and poor establishment (Yadav et al., 2011; Lemus-Mondaca et al., 2012). In general, the poor germination

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47534771

capacity of stevia continues to be a major impediment for the plantation of this plant on a large-scale (Abdullateef et al., 2015).

Plants are frequently subjected to a lot of abiotic environmental stresses such as drought, high salinity, heavy metals, high/low temperatures and, or heat (Brito et al., 2016). Drought stress is considered as the most major environmental problem that severely affects crop growth and development worldwide, especially in arid and semi-arid regions (Askari et al., 2018). Among various stages of the plant's life cycle, seed germination and seedling emergence are the most sensitive stages to environmental stresses (Patade et al., 2011). Because of the reduction in water potential and water absorption during drought stress, seed germination may be limited (Farooq et al., 2009) and with increasing intensity of water deficit, the complete inhibition of seedling growth can occur (Kaya et al., 2006). Moreover, some investigations have pointed out that drought stress can accelerate the generation of reactive oxygen species (ROS) in plants (Zhang et al., 2015), resulting in reduced growth, cellular damage and eventually plant death (Al Hassan et al., 2017). To improve drought tolerance in plants, one of the most effective methods is the adoption of physiological improvement approaches like seed priming (Zheng et al., 2016). It has been reported that different priming treatments have a good potential to enhance germination uniformity, germination rate, seed vigor, as well as stronger seedling growth under stressed conditions (Patade et al., 2011; Paparella et al., 2015). The higher tolerance of primed seeds against environmental stresses can be occurred due to the activation of free radical scavenging enzymes such as SOD, POD, CAT, and the accumulation of osmoprotectants (e.g. proline) (Rouhi et al., 2012).

Under environmental stresses, seed priming with various plant growth regulators (such as SA) is a common and effective technique for modulating the destructive effects of stress (Ashraf and Foolad, 2005; Hussain et al., 2016). SA (2-hydroxybenzoic acid), a phenolic compound, is known as an endogenous signal hormone that activates a wide range of diverse physiological and biochemical processes in plant cells in response to stressful conditions (Kabiri et al., 2014; Najafabadi and Ehsanzadeh, 2017). In this regard, SA has been successfully applied to alleviate the adverse effects of drought stress on wheat germination parameters (Movaghatian and Khorsandi, 2013).

Micronutrients are essential for normal growth and development of plants, and most of the arable soils in Iran have the severe deficiency of micronutrients, especially Zn and Fe (Mirshekari et al., 2012). Among various priming techniques, seed priming with micronutrients (nutri-priming) has been reported to be a physiological beneficial method for overcoming the micronutrient deficiency in seeds which improves seedling emergence (Farooq et al., 2012). Various studies have revealed that this technique significantly improves germination rate, seed quality, early seedling growth and stress tolerance in different plants (Mirshekari et al., 2012; Imran et al., 2017; Shahverdi et al., 2017; Reis et al., 2018).

According to the seed germination problem in stevia and on the other hand the lack of sufficient information about the role of SA and micronutrients on the improvement of germination behavior and early seedling growth of stevia, the present study was conducted to examine the effect of seed priming with SA and micronutrients (Fe and Zn) on germination indices and biochemical characteristics of stevia under control and drought stress conditions.

Materials and methods

The present experiment was carried out at the Seed Science and Technology Laboratory of Agricultural College, Shahed University of Tehran, Iran in 2017.

Seed material and storage

New mature seeds of stevia (Var. Bertoni) used in the experiment were purchased in late November 2017 from stevia production fields located in Fars province, Firoozabad city, Iran (34° 37' N, 54° 45' E and 1790 m ASL). The average of 100-seed weight was 27.7 ± 0.5 mg and seed moisture content was around 8.64% (on a dry weight basis). To keep the seed vigor during the course of experimentation, the seed samples were stored in paper bags at 4 ± 1°C and 20% relative humidity before being utilized for experiments. The 1.5-month seed samples were used in this research.

Priming and drought stress treatments

The study was a factorial experiment based on a completely randomized design (CRD) with three replications in which the experiment factors included four levels of drought stress induced by PEG 6000 (0, – 3, – 6 and – 9 bar) and seven combinations of priming (SA, Fe, Zn, SA + Fe, SA + Zn, Fe + Zn, SA + Fe + Zn), and unprimed dry seeds were considered as control. In this experiment, Fe and Zn were supplied from sources of iron (II) sulfate heptahydrate ($FeSO_4.7H_2O$, 26% Fe) and Zinc sulfate heptahydrate ($ZnSO_4.7H_2O$, 21% Zn) respectively, as well as SA (2-hydroxybenzoic acid, Sigma Aldridge Company Ltd.) in powder form, was used.

Germination process

Prior to conducting the experiment and based on three separate tests, the best duration and concentration of pretreatment for each of the priming agents (Fe, Zn and SA) were optimized. The factors evaluated in these experiments were five priming durations (0, 6, 12, 18 and 24 hours) and six concentrations of micronutrients (0, 0.25%, 0.5%, 1%, 1.5% and 2%) and SA (0, 0.25, 0.5, 1, 1.5 and 2 mM), which were tested separately. According to the results, the best duration and concentration of seed priming with micronutrients (Fe, Zn) and SA were 24 hours at the concentration of 0.5% and 24 hours at the concentration of 1 mM, respectively. These data were used in the experiment (data not shown).

To conduct the germination test, first, all used equipment and seeds were thoroughly disinfected. Stevia seeds were sterilized in 70% (v/v) ethanol for 1 min and 20% (v/v) sodium hypochlorite solution for 15 min and then were rinsed three times with sterile distilled water (Hajihashemi and Ehsanpour, 2013). The priming treatments were prepared in distilled water. Stevia seeds were entirely immersed in determined concentrations of priming media (1 mM SA, 0.5% Fe, 0.5% Zn, 1 mM SA + 0.5% Fe, 1 mM SA + 0.5% Zn, 0.5% Fe + 0.5% Zn and 1 mM SA + 0.5% Fe + 0.5% Zn) at 15 °C in darkness (Bradford, 1986). After the end of the priming process, the treated seeds were surface washed with distilled water and then dried at room temperature (about 21 °C) for 24 h back to the initial moisture content. After that, 100 primed and unprimed (control) seeds were counted and placed between double layers of sterilized Whatman paper (No. 2) in 12-cm-diameter Petri dishes and based on various levels of drought stress, 7 mL of PEG solution was added to each Petri dish. The osmotic

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47534771

potentials of – 3, – 6 and – 9 bars were obtained by adding 148.01, 219.54 and 274.65 g of PEG 6000 in 1000 mL of distilled water, respectively. The required amount of PEG 6000 was calculated by Michel and Kaufmann's (1973) formula (*Eq. 1*):

$$\Psi s = -\left(1.18\times10^{-2}\right)\times C - \left(1.18\times10^{-4}\right)\times C^2 + \left(2.67\times10^{-4}\right)\times CT + \left(8.39\times10^{-7}\right)\times C^2T \quad \text{(Eq.1)}$$

Ψs, C, and T are osmotic potential (bars), the concentration of PEG (g L^{-1} of distilled water) and temperature (°C), respectively. The distilled water potential is zero, so it was used as the control treatment (without drought stress). Petri dishes were wrapped with impermeable parafilm to avoid the loss of moisture and evaporation. Subsequently, all dishes were transferred in a programmed germination chamber at 23 ± 2 °C, 16/8 h light/darkness and 75% relative humidity (Liopa-Tsakalidi et al., 2012). The germinated seeds were daily counted, and the germination test was ended when the germination was not observed for three consecutive days. The seeds which had radicles with 2 mm long or more were considered as germinated seeds (ISTA, 2010). Eventually, at the end of the germination period (14 days), germination percentage, germination rate, mean germination time, seedling vigor index and germination value were calculated based on the relationships presented in *Table 1*.

Table 1. *The computing relations of the parameters studied in the experiment*

Parameters	Formula	Reference
Germination percentage	GP = (N × 100)/M	Liopa-Tsakalidi et al., 2012
Germination rate	$GR = \sum_{i=1}^{n} \frac{si}{Di}$	Maguire, 1962
Mean germination time	$MGT = \frac{\sum(Dn)}{\sum n}$	Salehzade et al., 2009
Germination value	GV = GP × MDG	Czabator, 1962
Seedling vigor index	SVI = GP × Mean (SL) /100	Abdul-Baki and Anderson, 1973

N: the sum of germinated seeds at the end of the experiment, M: the total number of planted seeds, S_i: the number of germinated seeds in each enumeration, D_i: the number of day from the start of the test to the enumeration of n^{th}, D: the time from the start of the experiment to the i^{th} observation, n: the number of germinated seeds at time D, MDG: mean daily germination, SL: mean of seedling (root + shoot) length (mm)

After two weeks of growth, the seedlings from each replicate were collected and immediately frozen in liquid nitrogen and stored in the ultra-low freezer at –80 °C for biochemical studies.

Antioxidant enzymes assay

To evaluate the activity of antioxidant enzymes, 0.5 g of frozen samples were homogenized in 5 mL of cool extraction buffer (50 mM potassium phosphate buffer (pH = 7.5)), containing 1 mM ethylenediaminete-traacetic acid (EDTA), 1 mM dithiothreitol (DTT) and 2% (w/v) polyvinylpyrrolidine (PVP)). The homogenate was centrifuged at 15,000 × *g* for 25 min and obtained supernatants were used as the enzyme source for CAT and POD assays. The whole extraction process was done at 4 °C.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47534771

Peroxidase assay

The POD activity (EC 1.11.1.7) was determined following the method of MacAdam et al. (1992) with some modification. In this method, The enzymatic activity was assayed by adding 50 µL of enzyme extract to the reaction mixture (3 mL), containing 0.1 M potassium phosphate buffer (pH 6.0), 50 µL guaiacol and 50 µL H_2O_2 (3%), and absorption alterations were immediately recorded at 436 nm for 3 min per 15 s by spectrophotometer. The control contained 3 mL of 0.1 M potassium phosphate buffer, 50 µL guaiacol and 50 µL H_2O_2.

Catalase assay

The CAT activity (EC.1.11.1.6) was assayed according to the method of Chance and Maehly (1955) which is briefly described here. The reaction mixture consisted of 50 mM sodium phosphate buffer (pH = 7.0), 15 mM H_2O_2, and 25 µL of the enzyme extract in a total volume of 3 mL. The absorbance at 240 nm for 1 min at 25 °C was recorded spectrophotometrically. One unit of CAT was defined as the amount of enzyme that decomposes 1 µmol of H_2O_2 per min.

Proline determination

The free proline content was measured using the method described by Bates et al. (1973). Frozen samples (0.5 g) were homogenized in 10 mL of 3% (w/v) sulpho salicylic acid and centrifuged at 4000 × g for 10 min. After centrifugation, this homogenized solution was filtered with Whatman's paper (No. 2) and then 2 mL of filtrated solution was mixed with acid-ninhydrin (2 mL) and glacial acetic acid (2 mL) in a test tube. The mixture was placed at 100 °C for 1 h in a water bath and immediately transferred to an ice bath for a few minutes. After cooling, the reaction mixture was thoroughly mixed with toluene (4 mL), and then the absorbance was measured at 520 nm.

Total chlorophyll content

The Chl content was measured using the methods of Lichtenthaler (1987). In this method, chlorophyll was extracted in chilled 80% acetone in dark. After centrifugation at 5000 × *g* for 10 min, the total chlorophyll content was determined at 663.2 and 646.8 nm with a spectrophotometer. The total chlorophyll content was calculated according to *Equation 2:*

$$\text{Total Chl} = 7.15\ (\text{A}663.2) + 18.71\ (\text{A}646.8) \qquad \text{(Eq.2)}$$

where A is absorbance at the specific wavelength.

Statistical analysis

After checking the data distribution normality (Kolmogorov-Smirnov and Shapiro-Wilk test) assumption, the studied traits were statistically analyzed by the Statistical Analysis System software (SAS Institute, Cary, NC, USA, Version 9.4). The differences among means were separated using least significant difference test (LSD) at 0.05 statistical probability level and the graphs were drawn by MS–Excel.

Results

Germination percentage (GP)

The effects of drought stress due to PEG, priming treatments and the interplay between them were significant ($P \leq 0.01$) on GP parameter (*Table 2*). The results of stevia seed germination under drought stress after various priming treatments are shown in *Table 3*. The highest GP was observed in seeds primed with SA + Fe + Zn and Fe + Zn under control conditions (without drought stress), as well as seeds primed with SA + Fe + Zn at – 3 bar (66.66%, 60.33% and 60.33%, respectively). GP was drastically affected by drought stress, so that the minimum GP was obtained from unprimed seeds at – 9 bar (72.4% reduction compared to unprimed seeds under the osmotic potential of 0 bar). The priming treatments improved seed germination of stevia under normal and drought stress conditions. At the highest level of drought stress (– 9 bar), the maximum GP (33.6 and 32.33%) was achieved from primed seeds by Fe + Zn and SA + Fe + Zn, respectively (*Table 3*). The listed treatments improved the GP parameter by 57.4% and 55.7% as compared to the control seeds (without priming) at this level.

Germination rate (GR)

Drought stress, priming and the interaction of these two factors had highly significant effects ($P \leq 0.01$) on GR trait (*Table 2*). The results showed that the GR of stevia seeds was significantly decreased with increasing drought stress levels (*Table 3*). Nevertheless, the amount of this trait was higher in the primed seeds than in unprimed ones under normal and drought stress conditions. The most value of GR (18.52 seed per day) belonged to seeds which were treated by SA + Fe + Zn under normal conditions. The lowest amounts of GR were found in unprimed seeds and primed seeds by SA, Fe, and Zn under the osmotic potential of – 9 bar (2.11, 2.52, 3.02 and 3.01 seed per day, respectively). The results clearly indicated that the integrated application of priming agents was more effective than their separate application to alleviate the drought-induced damaging effects on GR (*Table 3*).

Table 2. *Analysis of variance for the effect of priming treatments and drought stress on stevia seed germination indices*

Sources of variance	df	Mean squares and significance					
		GP	GR	MGT	GV	SVI	SL
Drought (D)	3	5489.5^{**}	576.08^{**}	29.1^{**}	18.04^{**}	808.3^{**}	1420.8^{**}
Priming (P)	7	561.6^{**}	25.1^{**}	0.24^{ns}	1.77^{**}	162.9^{**}	334.1^{**}
D × P	21	33.9^{**}	1.9^{**}	0.33^{**}	0.08^{ns}	10.11^{**}	13.31^{**}
Experimental error	64	15.1	0.81	0.11	0.057	2.91	4.67

ns, * and **: non-significant, significant at 5% and 1%, respectively. df: degrees of freedom, GP: germination percentage, GR: germination rate, MGT: mean germination time, GV: germination value, SL: seedling length, SVI: seedling vigor index

Mean germination time (MGT)

As shown in *Table 2*, drought stress and the interaction of drought stress and priming treatments had highly significant effects on MGT parameter ($p \leq 0.01$). In response to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47534771

drought stress, MGT was significantly increased so that the maximum values of MGT were observed at the highest level of drought stress (– 9 bar) while the lowest required times for germination (4.12, 4.15, 4.18, 4.56 and 4.65 days) were recorded in the absence of stress (0 bar) in seeds treated with Fe, SA, SA + Fe + Zn, SA + Fe and Fe + Zn, respectively. At – 9 bar, those seeds primed with SA + Fe + Zn had the shortest required time for germination (6.68 days), which was significantly lower than unprimed seeds at this level.

Table 3. *Mean comparison of the interaction between different priming treatments and drought stress for stevia seed germination indices*

Means in each column with the same alphabetical letter (s) are not significantly different at 0.05 probability level according to LSD test. GP: germination percentage, GR: germination rate, MGT: mean germination time, SL: seedling length, SVI: seedling vigor index

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47534771

Seedling length (SL)

Based on the analysis of variance, drought stress, priming treatments and the interaction among them had highly significant effects ($P \leq 0.01$) on SL trait (*Table 2*). Drought stress was found to severely limit the seedling growth of stevia. The longest SL pertained to the seeds primed by SA + Fe + Zn at – 3 and 0 bar (control) levels of drought stress (38.2 and 37.4 mm, respectively), and the shortest SL was observed at the highest level of drought stress (– 9 bar) in unprimed seeds (5.76 mm) (*Table 3*). Under severe drought stress, the SL in SA + Fe + Zn treatment was 60% higher compared to the control.

Seedling vigor index (SVI)

According to the results, the effect of drought stress, priming treatments and the interaction among them was highly significant ($p \leq 0.01$) on SVI (*Table 2*). Depending on the reduction in SL and GP under drought stress, SVI was gradually reduced with increasing drought stress levels, so that the lowest means were recorded at – 9 bar (*Table 3*). On the other hand, priming treatments, especially the integrated application of SA, Fe, and Zn increased SVI under drought and normal conditions compared to unprimed seeds. The highest amount of this trait was detected in primed seeds with SA + Fe + Zn under the osmotic potentials of 0 and – 3 bar (25.01 and 23.11, respectively) (*Table 3*).

Germination value (GV)

Variance analysis of data revealed that the GV parameter was significantly affected by drought stress and priming agents ($p \leq 0.01$), but the interplay of seed priming × drought stress on this trait was not significant (*Table 2*). Comparison of mean values at different levels of drought stress showed that the increase of PEG concentration from the control to the highest level (– 9 bar) resulted in an 81.85% reduction in GV of stevia seeds. Presented results in *Table 4* showed that all the seed priming treatments except SA treatment had a significant positive effect on GV compared with unprimed seeds. In comparison with the control (without priming), various priming treatments enhanced the GV of stevia seeds between 10.78 – 56.03%. The best result in this respect (with an average of 2.07) was achieved by applying the composition of SA, Fe and Zn (*Table 4*).

Free proline content

The proline content was significantly affected by drought stress and tested priming compounds ($p \leq 0.01$). Drought stress due to PEG at all the studied concentrations gradually increased the accumulation of free proline in stevia seedlings, so that the highest and the lowest content of proline were observed at the osmotic potentials of – 9 and 0 bar (control) (0.363 and 0.233 μmol g^{-1} FW respectively) (*Table 4*). Also, the proline content in primed seeds was significantly higher as compared to the control seeds (without priming). Among all studied priming treatments, the highest amount of the proline content belonged to seeds which were treated by SA + Fe + Zn, Fe + Zn and SA + Zn, respectively. The proline content in SA, Fe, Zn, SA + Fe, SA + Zn, Fe + Zn and SA + Fe + Zn treatments was increased by 48.56, 53.26, 53.72, 56.79, 59.02, 59.14 and 59.6% compared with the control (*Table 4*).

Total chlorophyll content

Data recorded in *Table 5* shows that the total Chl content was significantly affected by drought stress, priming agents ($p \leq 0.01$) and the interaction between them ($p \leq 0.05$). The Chl content was significantly decreased with increasing PEG concentration in all studied treatments when compared with the control conditions (without drought stress). However, priming treatments alleviated effectively the damaging effect of drought stress on Chl content. The lowest amount of Chl content was recorded at the highest level of drought stress (– 9 bar) in unprimed seeds. The highest values of total Chl content were recorded in the combination of three priming agents (SA + Fe + Zn) and the combination of Fe and Zn under normal conditions (2.22 and 2.04 mg/g FW, respectively). At all levels of drought stress, the most effective priming treatments with the highest total Chl content were SA + Fe + Zn and Fe + Zn (*Fig. 1*).

Table 5. *Analysis of variance for the effect of priming treatments and drought stress on physiological traits of stevia seedling*

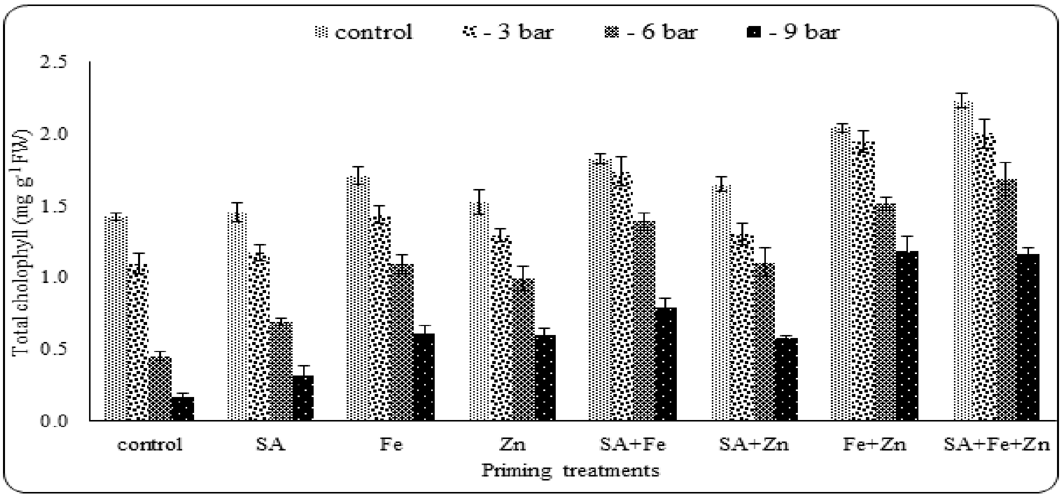

Figure 1. *Total Chlorophyll content in primed and unprimed seedlings of stevia under normal and drought stress conditions (LSD 5%= 0.185). Error bars indicate standard error (SE)*

CAT activity

Statistical analysis demonstrated that the enzymatic activity of CAT varied significantly in response to drought stress, priming treatments ($p \leq 0.01$) and the interaction between them ($p \leq 0.05$) (*Table 5*). Data regarding the CAT activity in primed and unprimed seedlings of stevia under drought stress are shown in *Figure 2*. The CAT activity was significantly increased in primed and unprimed seedlings with increasing drought stress. On the other hand, seed priming promoted the CAT activity in the stevia seedlings under drought stress, so that the maximum values of enzymatic activity were obtained from primed seeds with SA + Fe + Zn at the osmotic potential of – 9 bar (2.23 Unit/mg protein.min, respectively). In comparison to the control, under severe drought stress (– 9 bar), the enzymatic activity of CAT was significantly increased in the seedlings which were raised from primed seeds by SA + Fe + Zn, Fe + Zn, SA + Zn, SA + Fe and Fe (*Fig. 2*).

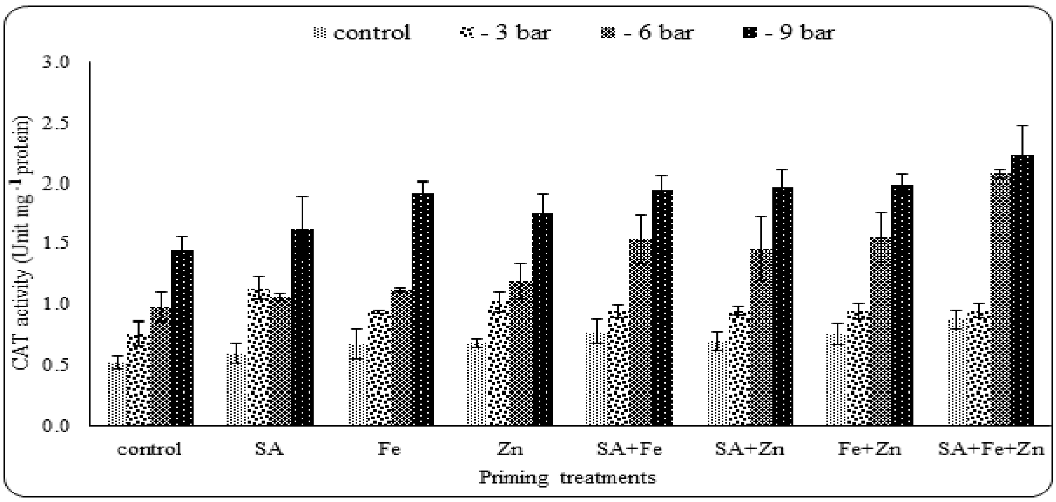

Figure 2. *The catalase (CAT) activity in primed and unprimed seedlings of stevia under normal and drought stress conditions (LSD 5%= 0.35). Error bars indicate standard error (SE)*

POD activity

According to the results, drought stress, priming treatments ($p \leq 0.01$) and the interaction between them ($p \leq 0.05$) had significant effects on the POD activity (*Table 5*). Results regarding the POD activity of stevia seedlings under the influence of drought stress and different priming treatments are presented in *Figure 3*. The enzymatic activity of POD was considerably enhanced with elevating of drought stress in all studied treatments, so that the lowest POD activity for all treatments was observed under the controlled conditions. The average values revealed that the priming treatments caused an increase in the POD activity of the stevia seedlings compared to the control seeds. The maximum activity of POD was recorded in seedlings primed with SA + Fe + Zn and Fe + Zn at the osmotic potential of – 9 bar (14.04 and 13.15 Unit/mg protein.min, respectively). Compared with the control seeds (without priming), the SA + Fe + Zn, Fe + Zn, SA+ Fe, Zn and Fe were the most effective treatments regarding the POD activity at the highest level of drought stress (*Fig. 3*).

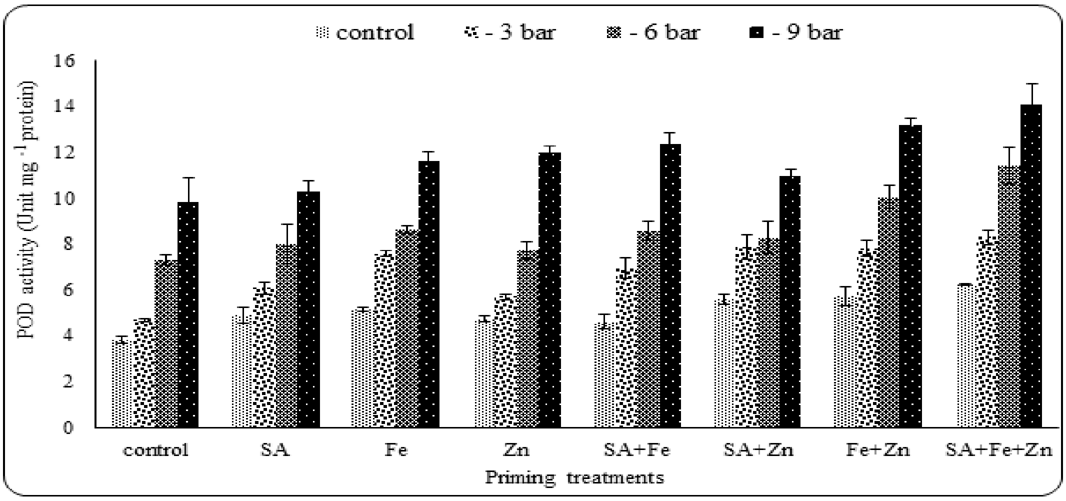

Figure 3. *The peroxidase (POD) activity in primed and unprimed seedlings of stevia under normal and drought stress conditions (LSD 5%= 1.29). Error bars indicate standard error (SE)*

Discussion

Evaluation of drought stress effect on some seed germination and physiological characteristics of stevia seedlings was one of the objectives in the present investigation. In recent years, drought stress is known as an important environmental factor which seriously impacts the productivity of many crops and can retard growth and development of them (Lipiec et al., 2013). The results of our study showed that the seed germination indices of stevia were affected by the deleterious effects of drought stress induced by PEG, so that GP, GR, and GV were significantly decreased along with the increase of PEG concentration (*Table 3*). In the present study, it was found that the average of GP was dropped to below 24% at the highest PEG concentration (– 9 bar). Poor and erratic germination might be attributed to the lower water uptake by seeds and the elevation of ROS levels under water deficit (Kaya et al., 2006). It has been reported that under stress conditions, the alteration of some enzymes and hormones found in the seed could lead to the reduction of final germination (Botía et al., 1998). Also in this study, SL and SVI (the product of SL and GP) which are the important traits in the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47534771

primary establishment of seedling were obviously reduced with increased drought stress (*Table 3*). This might be due to the reduction of water content in plant tissues under water stress which declines turgor pressure in cells, and consequently inhibits cell enlargement, cell division and plant growth (Farooq et al., 2009). These results are consistent with the findings presented in some previous research in other plants (Patane et al., 2013; Zaher-Ara et al., 2016). Additionally, the decrease of water potential was accompanied by a significant increase of MGT (*Table 3*), because seeds under water deficit require more time to reach an adequate level of hydration to initiate germination (Steiner et al., 2017). The increase of required time for germination under drought stress has been reported in the research done by Steiner et al. (2017) in wheat and black oat.

In our study, the comparative performance of different priming treatments for improving drought tolerance at germination and early growth stages of stevia was also evaluated. The results showed that seed priming with SA and micronutrients (Fe and Zn) not only improved the measured germination parameters and seedling growth of stevia in both normal and stress conditions but also alleviated drought stress damages. In this regard, it was observed that the integrated application of priming agents in most of the cases was more effective than their separate application. The beneficial effects of seed priming on germination might be related to the stimulation of pre-germination metabolic procedures, the increment in protein synthesis, the repair and the build-up of nucleic acids, the repair of membranes and osmotic adjustment (Ibrahim et al., 2016). As can be seen in *Table 3*, at all drought stress levels, the highest values of GP, GV as well as SL and SVI were noticed in seeds primed by SA + Fe + Zn. The reason of the increment in seedling weight and length as a result of nutri-priming might be due to the role of these elements in increased cell division, cell expansion and meristematic growth, which caused an increase of plant growth (Shahverdi et al., 2017). It has been reported that in the presence of zinc, hormones such as auxin are increased. Therefore, it seems that the increase of auxin in seed due to the presence of zinc increases the growth of seedling (Laware and Raskar, 2014). In this regard, Munawar et al. (2013) reported that treating seeds of *Daucus carota* L. with Zn (1.5%) and Mn (1.5 and 2%) resulted in the highest mean values of the shoot and root length. Begum et al. (2014) concluded that canola seed priming with $ZnSO_4$ and $CuSO_4$ leads to higher GP, GR and SL under NaCl stress. Previously, various studies on dill (Mirshekari et al., 2012), maize (Imarn et al., 2017) and wheat (Reis et al., 2018) have reported the enhanced germination and yield after priming with micronutrients. On the other hand, several studies have revealed that pre-soaking of seeds in the optimal concentrations of plant growth regulators such as SA could improve the germination of crops, particularly under stress conditions (Ansari and Sharifzadeh, 2012; Arbaoui et al., 2015; Kumari et al., 2017). Sakhabutdinova et al. (2003) reported that SA prevents the reduction of Indole acetic acid (IAA) and cytokinin levels in plant tissues, and alleviates the inhibitory effects of water stress on plant growth. The findings of Wang et al. (2016) also indicated that seed priming with SA improved the seedling emergence and growth of rice.

Chl is one of the main components of chloroplast in photosynthesis. Under water stress, the reduction of Chl content has been considered a usual symptom of oxidative stress (Fathi and Tari, 2016). In our study, the total Chl content was significantly diminished with an increase in the level of applied PEG as compared to the control seedlings. The priming treatments (especially Fe + Zn, SA + Fe + Zn and SA + Fe) did not only moderate the adverse effect of drought stress on the Chl content, but also had a significant stimulatory effect on the biosynthesis of Chl, so that under severe drought

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47534771

stress (– 9 bar), the maximum amount of Chl was recorded in the seedlings which were raised from primed seeds by Fe + Zn and SA + Fe + Zn (*Fig. 1*). The decrement of Chl content under drought stress is mainly due to damage to the chloroplast membrane and Chl degradation as result of the activity of ROS (Madany and Khalil, 2017). These findings are in agreement with previous results that drought stress reduced the total Chl content, whereas priming treatments minimized the deleterious effects of stress conditions (Hussain et al., 2017; Madany and Khalil, 2017). Zn is an essential element for Chl synthesis, pollen function, and germination (Cakmak, 2008). It has been reported that Zn element by the protection of the sulfhydryl group keeps the Chl content (Latef et al., 2017). Fe is an essential element required for the maintenance of chloroplast structure and is involved in Chl synthesis (Rout and Sahoo, 2015). The limitation of this element has a remarkable effect on the productivity of photosynthetic organisms (Tewari et al., 2013). Shahverdi et al. (2017) reported that stevia seed priming with Fe alone and the integrated application of selenium (Se) and boron (B) significantly increased the total Chl content under salinity stress. In another research, Li and Zhang (2012) concluded that rice seed priming with SA increases the photosynthetic activities in this plant.

In plant cells, ROS are generated in both normal and stress conditions, but in response to different environmental stresses such as drought stress, the production of ROS is significantly increased which could result in the progressive oxidative damages (Sharma et al., 2012). Plants usually have several defensive mechanisms to overcome the oxidative stress (Lipiec et al., 2013), which include enzymatic and non-enzymatic (such as proline) antioxidants and as well as reparation systems that orchestrate stress signaling and block the adverse effects of ROS (Demidchik, 2015). Proline is known to act as an osmolyte /osmoprotectant agent under drought stress (Lehmann et al., 2010) and has the important role in the osmotic pressure adjustment, scavenging free radicals, stabilizing sub-cellular structures (e.g. membranes and proteins) and storing carbon and nitrogen (Bartels and Sunkar, 2005). The results of our study demonstrated a significant increase in the amount of proline content under drought stress. According to the results, all priming treatments (especially SA + Fe + Zn, Fe + Zn and SA + Zn) significantly enhanced (48.5-59.6%) the accumulation of free proline in stevia seedlings (*Table 4*). The better ability of primed seeds is attributed to a wide range of metabolic and physiological improvements (Shehab et al., 2010). In agreement with our results, Kabiri et al. (2014) reported that the seedlings derived from primed seeds of fennel with SA had the higher values of the proline content than unprimed seeds under drought stress. Fallah et al. (2018) have documented that the various priming treatments such as $ZnSO_4$ (0.5%) increase the proline content in *Nigella sativa* L. under drought stress. Also, it has been reported that seed priming by micronutrients increases the proline content under salinity stress (Shahverdi et al., 2017). Hayat et al. (2010) reported that SA treatment enhances the proline accumulation with a concomitant induction of different stress enzymes.

CAT and POD are described to be two of the most important antioxidant enzymes that protect plants against cell oxidative damages caused by drought and other environmental stresses (Huang et al., 2016). These enzymes play an important role in scavenging of H_2O_2 (Hussain et al., 2016). In our study, drought stress activated the activity of CAT and POD in stevia seedlings, so that the lowest activities were observed under the controlled conditions. The increasing of the enzymatic activity, as seen in our study has been considered a part of seed strategy to overcome free radicals (Chiu et al.,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47534771

2005). Also, in primed seedlings, the activities of CAT and POD were higher than those in unprimed ones which eventually helped in alleviating the effect of oxidative stress on germination indices. The increased antioxidant activity in the primed seedlings, resulting in the better growth might be related to their higher ROS scavenging ability under stress conditions (Hussain et al., 2016). Generally, among studied priming treatments, SA + Fe + Zn had the most positive effect in increasing the activity of these enzymes (*Figs. 2* and *3*). Zn is used in numerous physiological and biochemical processes in plant cells, including protein synthesis, membrane function, and gene expression. It is a metal component of many important enzymes, acting as a regulatory cofactor for many enzymes, and has the major role in defense systems of plants against stress conditions (Cakmak, 2000; Reis et al., 2018). In this connection, Aboutalebian and Nazari (2017) mentioned that osmopriming with $ZnSO_4$ increased the activity of SOD, POD and CAT enzymes in canola under chilling stress. Fe element also is well known as an important co-factor for many antioxidant enzymes (such as CAT and POD) (Kusvuran et al., 2016). Ruiz et al. (2000) reported that the activities of the CAT and POD enzymes were correlated with the Fe content in leaves. SA has been found to act as the endogenous signal molecule which participates in the regulation of many physiological processes in plants in response to stressful conditions (Kabiri et al., 2014). Pouramir-Dashtmian et al. (2014) stated that seed priming with SA could ameliorate the destructive effects of oxidative stress caused by the generation of ROS by increasing the antioxidant defense system in rice. In this regard, Hara et al. (2012) mentioned that SA in low concentration could increase the oxidative capacity in plants. Similar findings were also reported by Sheykhbaglou et al (2014), who claimed that seed priming by SA increased the antioxidant activity and led to the improvement of germination parameters in sorghum, which coherent with the present study.

Conclusion

It is concluded from findings of our research that PEG-induced drought stress had inhibitory effects on all germination parameters studied in stevia, nevertheless, seed priming effectively promoted germination characteristics, seedling growth, the total Chl content and the antioxidant capacity under different levels of drought stress as compared to the unprimed ones. The better germination performance and vigorous seedling growth in stevia through seed priming treatments under drought stress could be related to the enhanced enzymatic activities of POD and CAT and the higher accumulation of free proline. Accordingly, our results suggest that seed priming with SA and micronutrients (Fe and Zn) particularly the concurrent application of them at the appropriate concentration can improve drought tolerance of stevia in germination stage. Nevertheless, confirmatory trials under natural field conditions over several years are needed to ensure whether studied priming treatments would result in the improvement of seedling emergence and vegetative growth of stevia as well as its resistance to drought stress on the farm. Also, it is recommended to develop more comprehensive results and evaluate the effect of seed priming with other micronutrients in combination with different plant hormones on germination behavior and the physiological and biochemical changes of stevia during unfavorable conditions. Besides, further researches at transcriptomic and proteomic levels are required to decipher the molecular mechanisms of seed priming-induced drought tolerance in stevia plants.

Abstract. This study was conducted to compare the effects of nano and chemical fertilizers on physiological efficiency and essential oil yield of *Borago officinalis* L. during 2013 and 2014 crop years. The different levels of fertilizers were used as main factors in 11 levels including iron-sulphate and nano-iron, zinc and nano-zinc, urea and nano-urea, potassium sulphate and nano-potassium, micro-complete and micro-complete nanosuper and control. The application methods of fertilizers were considered as secondary factor (soil application, foliar application and combined application). Physiological efficiency of nitrogen, phosphorous, potassium, zinc and iron, dry and fresh weight of aerial parts, number of secondary branches, chlorophyll content, 100 grains and essence yield were evaluated. Our findings showed that chemical fertilizers had no beneficial effects in comparison to nano fertilizers ($P > 0.05$). In addition, nano-urea and urea fertilizers increased essential oil yield because of increased wet and dry weight of aerial parts and number of secondary branches. In conclusion, nano-fertilizers can be used in order to improve the essence production and also as environmentally friendly fertilizers.
Keywords: *environmentally friendly fertilizers, foliar application, nano-fertilizers, essential oil production, Borago officinalis* L.

Introduction

Medicinal plants are used in order to treat some incurable chronic disorders and by about 80% of the people of the world are dependent on medicinal plants for health and treatment (Ibrahim et al., 2013). There are increasing interest to use the medicinal plants because of side effects of synthetic drugs. Borage (*Borago officinalis* L.*)* is belonging to *Boraginaceae* family and it is traditionally used for therapeutic uses. Borage oil seed is rich source of essential fatty acids such as linoleic acid and γ-linolenic acid which can have beneficial effects on human health (Mhamdi et al., 2007). Some medicinal plants are known to have antioxidant and anti-inflammatory properties (Balasubramanian and Palaniappan, 2001) which are attributed to their essential oils. However, yield and content of essential oils are dependent on climate and geographical conditions, harvest time and application of fertilizers (Baranauskiene et al., 2003). Considering increased needs medicinal plants and effect of fertilizers on quantity and quality of essential oils, it is essential to use the best fertilizers in order to increase the efficiency of medicinal plants. Studies have reported that fertilizers increase the production of medicinal plants (Das et al., 2007; Sharma and Kumar, 2011). There are increasing interest to use the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47734788

nanoparticles for industrial and pharmaceutical purposes (Siddiqui and Al-Whaib, 2014). Nanoparticles have high surface/volume ratio that increase biochemical activities and reactivity (Lee et al., 2008, 2010). It is still unknown interaction between biological systems and nanoparticles (Barrena et al., 2009). Nanotechnology is a strategy in order to increase the value of agriculture products and decreasing environmental problems (Elfeky et al., 2013). Kottegoda et al. (2011) have produced slow-released nanoparticles and nano powders. Studies have shown beneficial effects of nanoparticles on germination, growth and development in plants (Roghayyeh et al., 2010). Elfeky et al. (2013) reported positive effects of nano-iron on chlorophyll content, total carbohydrate, essential oil content and growth characteristics of *Ocimum basilicum*.

Nitrogen and potassium are nutrients influencing on production and quality in plants. Nitrogen modulates in chlorophyll synthesis and photosynthetic efficiency, but potassium regulates cell wall permeability and activity of different elements (Akamine et al., 2007). Potassium and nitrogen fertilizers increased turmeric production but had not significant effects on curcumin production (Akamine et al., 2007).

Regarding the use of chemical fertilizers in start of season, part of chemical form may be converted to other forms and/or deleted, resulting in increased economical harmful. In order to increase the efficiency of nutrients intake, fertilizers must provide essential nutrients during long times. Application methods can have significant effects on plants yield. Foliar application of some fertilizer may have more beneficial effects in comparison to soil application. It seems that the use of nano fertilizers may increase efficiency of essential oil production (Kennedy et al., 2004).

Physiological efficiency of elements can be defined as production of dry matter/unit absorbed nutrient element (Moll et al., 1982). The efficiency of element absorption is controlled by growth and morphology of root system in plants (Barbieri et al., 2008). Application of nitrogen fertilizers can have positive effects on grain yield and also develop procedures in order to improve the management of nitrogen (Flowers et al., 2004). Fertilizers efficiency can be applied in order to investigate the yield/per unit (Delbert and Ulter, 1989). Increased absorption efficiency and the use of nitrogen in grain yield are required in order to efficient processes for absorption, transformation, assimilation and nitrogen redistribution. The relative relation of processes and genotypic differences in nitrogen efficiency can be changed among genetic populations and different climates (Moll et al., 1982). Medicinal plants are required because of their high advantages. However, high production by nano fertilizer can be beneficial and environmentally friendly. To the best our knowledge, any study has not been conducted to compare of chemical and nano fertilizers on performance, essential oil yield and physiological efficiency of medicinal plants. Thus, the present study was conducted to evaluate the effects of chemical and nano fertilizers by methods of foliar and soil application on essential yield and physiological efficiency of elements in borage.

Materials and methods

This experiment was conducted during 2013 and 2014 crop years in Agriculture station of Islamic Azad University, Tabriz-Iran in the north-west of Iran (37° 24’ N, 46° 17’ E; 1360 m). Soil pH was ranged from weak alkaline up to medium alkaline and the threat of salinity was not considered (*Table 1*). Seeds were prepared from Pakan Institute, Isfahan-Iran. This experiment was conducted in spilt plot trial based on randomized block completely design with 3 replications. The different levels of

DOI: http://dx.doi.org/10.15666/aeer/1604_47734788

fertilizers were considered as follows; 1-iron-sulphate fertilizer, 2-nano-iron 10% (2-3 kg or 4 L/ha in irrigation form and/or foliar form in 2 ppm concentration), 3- zinc sulphate, 4-nano-zinc 20% (1-2 kg or 2-4 L/ha in irrigation form and/or foliar form in 2 ppm concentration, 5-urea, 6-nano-urea (2-3 kg or 4 L/ha in irrigation form and/or foliar form in 2 ppm concentration), 7- potassium sulphate, 8-nano-potassium 23% (1-2 kg or 2-4 L/ha in irrigation form and/or foliar form in 2 ppm concentration), 9- micro-complete, 10- nano super micro-complete (2-3 kg or 4 L/ha in irrigation form and/or foliar form in 2 ppm concentration) and 11-non-application of fertilizer (control). The method of fertilizer application was considered as secondary factor (soil application, foliar application and combination of soil and foliar application). Experimental treatments were as follows:

1) Soil+foliar application of zinc
2) Soil application of zinc
3) Foliar application of zinc
4) Soil+foliar application of nano-zinc
5) Soil application of nano-zinc
6) Foliar application of nano-zinc
7) Soil+foliar application of complete
8) Soil application of complete
9) Foliar application of complete
10) Soil+foliar application of complete nano
11) Soil application of complete nano
12) Foliar application of complete nano
13) Soil+foliar application of potassium

25) Soil+foliar application of urea
26) Soil application of urea
27) Foliar application of urea
28) Soil+foliar application of nano-urea
29) Soil application of nano-urea
30) Foliar application of nano-urea
31) Control

Number of experimental plots was 99 plots with length of 4 m, width 3 m with 4 rows planting and distance 75 cm. The seeds were planted in distances of 15 cm. Secondary plots were consecutively planted and a line was considered as non-planting. In order to prepare the land for planting, sowing and plotting were conducted. Fertilizer application was conducted on basis 150 kg/ha for urea fertilizer and 200 kg/ha for

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47734788

phosphorous and potassium fertilizers. The levels of iron, zinc, copper, boron and manganese were essential for growth requirements (*Table 1*).

Table 1. *Some of physicochemical characteristics of field soil*

	Depth (cm)	Iron	Copper	Zinc	Manganese	Total N%	Phosphorous	Potassium	Boron
		(ava) ppm					(ava) ppm		
2013	0-30	0.43	0.38	0.8	1.15	0.11	39.72	352	2.12
2014	0-30	2.04	0.42	1.02	1.82	0.086	47.5	381	2.36

The seeds were planted in 3 up to 5 cm depths of soil. Field irrigation was conducted by soil humidity condition and environmental conditions. After planting, foliar application was conducted. Foliar application of iron-sulphate, zinc sulphate (concentration of 5 ppm), potassium sulphate and urea fertilizer (5 ppm), complete fertilizer (2 ppm) and nano fertilizers (2 ppm) were conducted. Dry and fresh weight of aerial parts, 100 grain weight, chlorophyll index content, stem and leaf dry weight, leaf number, harvest index and plant height were measured. While growing plant, samples were collected from per plot (Mhamdi et al., 2007). While flowering plant, 5 plants were harvested for preparation of essential oil. Samples were then evaluated in order to determine the elements. Physiological efficiency of elements was calculated based on *Equation 1*.

$$\text{PE}\left(\text{kg.kg}^{-1}\right) = \left(\text{BYf - BYu}\right)/\left(\text{Pf - Pu}\right) \qquad \text{(Eq.1)}$$

where BYf is biological function (grain+straw) in fertilized plot (kg), BYu is biological function (grain + straw) in non-fertilized plot (kg), Pf is fertilizer absorption (grain+ straw) in fertilized plot (kg) and Pu is fertilizer absorption (grain+ straw) in non-fertilized plot (kg).

Crop efficiency can be resulted from economical production/absorption unit of nutrients based on *Equation 2*.

$$\text{APE}\left(\text{kg.kg}^{-1}\right) = \left(\text{Gf - Gu}\right)/\left(\text{Pf - Pu}\right) \qquad \text{(Eq.2)}$$

where Gf is grain yield/fertilized plot (kg), Gu is grain yield/non-fertilized plot, Pf is fertilizer absorption (grain+straw)/fertilized plot and Pu is fertilizer absorption (grain+straw)/non-fertilized plot.

The collected data was analyzed and the means were compared by using Duncan test at levels of 5%. The SAS software was used to analyze the data and figures were illustrated by Excel software.

Results and discussion

The data for analysis of variances of the evaluated traits are presented in *Table 2*.

ns: non- significant, ** and * significant at the 1% , 5% probability levels, respectively

Number of secondary branches

The variance analysis of data showed significant interaction between fertilizer type and application method (*Fig. 1*) (P < 0.01). The most number of secondary branches (13.29 & 13.14) were observed in soil application + foliar application of nano-urea and soil application of nano micro-complete. A combination of soil and foliar application of nano-urea fertilizer increased 1.14% number of secondary branches in comparison to nano micro-complete; indicating that similar efficiency the both fertilizers. The lowest number of secondary branches was firstly observed in foliar application of iron (8.85), followed foliar + soil application of urea (8.95), foliar application of potassium (9.00) and foliar application of nano-zinc (9.04). However, application of complete nano, nano-potassium and nano-urea increased secondary branches compared with control group (P < 0.05). The increased branch numbers in nano-urea treatment may be attributed to slow-degraded of urea and its role in growth and development. On the other words, increased branches in nano-urea treatment can be explained by increased penetration rate of required nutrients for growth reactions. Increased nitrogen rate could increase secondary branches in *Matricaria chamimilla* L. (Dastborhan et al., 2010). Increased nano treatment can be explained by increasing permeability nano fertilizers into leaf tissue and increasing nutrient penetration which increases growth parameters. Controlling elements is one of nanotechnology advantages (Hassani et al., 2015). The lowest number of branches was found in iron treatment. Iron is essential for plants growth but its application may have adverse effects on growth and development in plants, because it induces oxidative stress in plants (Briat et al., 2010). In addition, phyroferitine degrades and releases iron, produces hydroxyle iones (Zhang et al., 2013) and finally decreases growth.

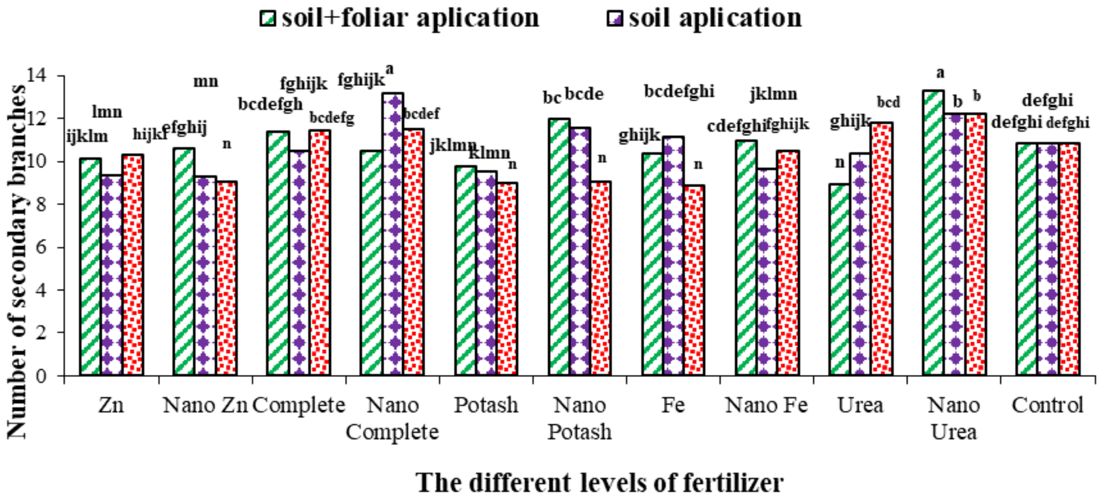

Figure 1. *Effects of fertilizer and application type on number (n) of secondary branches in borage*

Wet and dry weight of flowering aerial parts

The highest fresh weight of flowering aerial parts was observed in foliar and soil application treatment of urea. Our findings showed that foliar application of urea increased weight by 51.1% in comparison to control group (*Fig. 2*). Urea, nano-urea, nano-iron, iron and nano-potassium had higher weight in comparison to control group.

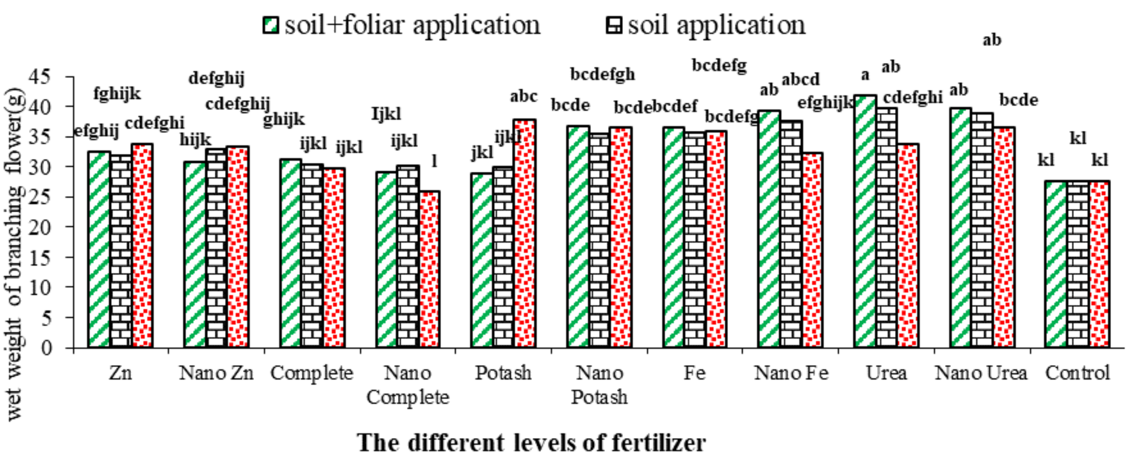

Figure 2. *Effects of fertilizers type and utilization methods on fresh weight (g) of the branching flower*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47734788

The mean comparison of fertilizer types showed that the highest dry weight of aerial parts was observed in urea treatment (4.20 g). Application of urea could cause significant differences in comparison to nano-zinc, micro-complete and complete nano. The lowest dry weight of aerial parts was observed in control group (2.87 g) and application of urea increased dry weight of aerial parts in comparison to control group by 46% (*Fig. 3*).

The comparison of chemical and nano fertilizers did not show significant differences between chemical and nano fertilizers for dry weight of aerial parts, but nano fertilizers showed more efficiency compared to chemical fertilizers (P > 0.05). Except zinc fertilizers, application of nano-zinc in combined method, complete, complete nano and potassium in combined application and soil application could show better efficiency in comparison to control group. Nitrogen is an essential nutrient in order to increase the growth parameters in medicinal plants (Akamine et al., 2007). Deficient nitrogenous fertilizers decreased chlorophyll contents in leaves and immature death in plants. Chlorophyll level was appropriate in urea and nano-urea groups and it was no observed difference between urea and nano-urea for chlorophyll in combined application method. Nanofertilizers may prevent to loss nitrogen and longtime use of microorganisms. Slow-released of nitrogen in nano-urea fertilizers may decrease toxic effects in high application (Gendy et al., 2013). Nitrogen not only participates in structure of purines, pyrimidines and enzymes but also participates in chlorophyll and cytochrome structure (Gendy et al., 2013). However, results showed that urea and nano-urea fertilizers had most efficiency. This result shows that nanoparticles are absorbed by root apex, cell wall and vascular system in plants (Lv et al., 2015).

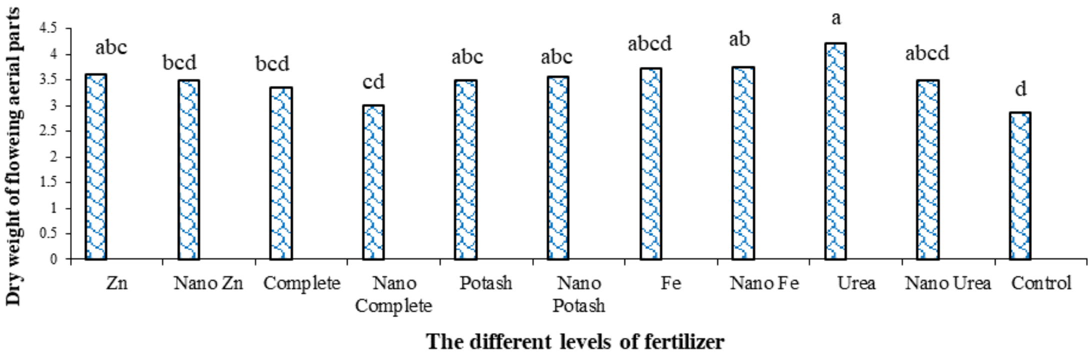

Figure 3. *Effects of fertilizers type and application methods on dry weight (g) of aerial parts in borage*

Leaf area

Interaction between different levels and application methods of fertilizers on leaf area was significant (*Table 2*). The highest leaf area (1706 cm^2) was observed in soil + foliar application of nano-urea and foliar application of urea (*Fig. 4*). Application of zinc fertilizers in soil application, foliar + soil application of zinc, combined application of complete, soil application of complete fertilizers respectively increased leaf area 64%, 3%, 37% and 50% in comparison to control group (*Fig. 4*). It seems that nano-urea fertilizer is slowly released in soil and increases leaf area and photosynthetic activity in plants (Kottegoda et al., 2011). Increased efficiency of nitrogen is one of critical factors in order to decrease environment pollutants. Increased leaf area not only

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47734788

depends on genetically factors but also leaf nitrogen. Nitrogen supplement can have significant effects on leaf activity. On the other hand, nitrogen modulates in growth and development in plants. Increased number and leaf area increased the chlorophyll structure, involved enzymes and increasing essential oil yield (Briat et al., 2015).

Chlrophyll contents index

Analysis of variance showed significant interaction between the different levels of fertilizer and application method on chlorophyll index (*Table 1*). The mean comparison showed that highest chlorophyll index was observed in soil application of complete (CCI = 50.91) and nanozinc (CCI = 48.35) (*Fig. 4*). The lowest chlorophyll index (CCI = 18.4) was observed in control treatment (*Fig. 6*). Zinc, nanozinc, complete, nano complete, potassium, nano potassium, urea and nano-urea fertilizers had chlorophyll indexes in comparison to control group. Application of urea and biological fertilizers increased chlorophyll contents in guar (Gendy et al., 2013). They have also reported increased chlorophyll contents can be attributed to levels of nitrogen and its role in chlorophyll synthesis. Nitrogen participates in chlorophyll synthesis and photosynthetic efficiency. Potassium regulates permeability of cell wall and activity of different cells (Akamine et al., 2007). Amujoyegbe et al. (2007) reported that nitrogen and magnesium can be released by chemical fertilizers and participate in porphyrine ring of chlorophyll molecule.

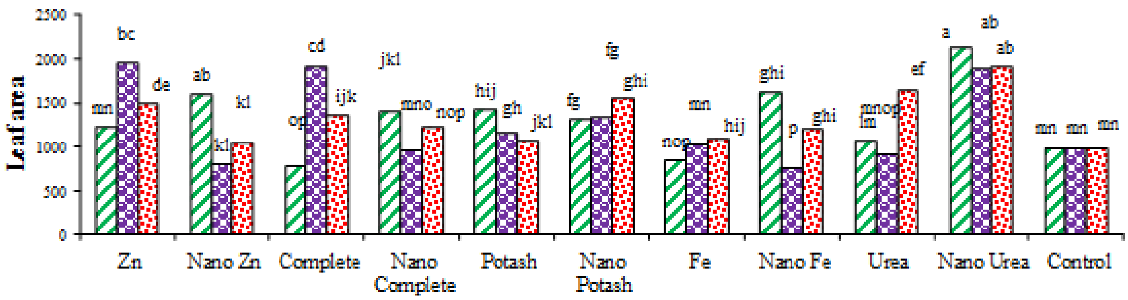

Figure 4. *Effects of fertilizers type and application methods on leaf area (mm^2) of borage*

Essence percentage

Mean comparison of essence showed that nano-urea fertilizer and control treatments had most and lowest essence contents, respectively. Nano-urea treatment could increase essence percentage in comparison to zinc and control treatments 200% and 191.4%, respectively. There are conflicts reports in relation with nitrogenous fertilizers. Biesiada and Kucharska (2008) reported increased use of nitrogenous fertilizers increased the essence and phenolic contents. Lucy et al. (2004) have reported a reverse relation between essence percentage and nitrogen content. Gendy et al. (2013) showed that use of nitrogenous fertilizers and biological fertilizers increased essence percentage in guar. Fhatuwani (2008) showed increased essence yield and phenol production by nitrogenous fertilizers.

DOI: http://dx.doi.org/10.15666/aeer/1604_47734788

Essence yield

The mean comparison showed significant effect of different fertilizers on essential oil yield during 2013 years (P < 0.05, *Fig. 5*). Nano-urea fertilizer (10.96 mg/ha) and control treatment showed highest and lowest essential oil yield, respectively (*Fig. 6*). Results showed that application of nano-urea fertilizers did not have significant difference with nano potassium and micro-complete (P > 0.05). The mean comparison of treatments showed that application of nano-zinc fertilizer increased essential oil yield in comparison to chemical fertilizers, but the difference was not significant. Application of nano-zinc fertilizer increased essential oil yield (105.4%) in comparison to control group (*Fig. 5*).

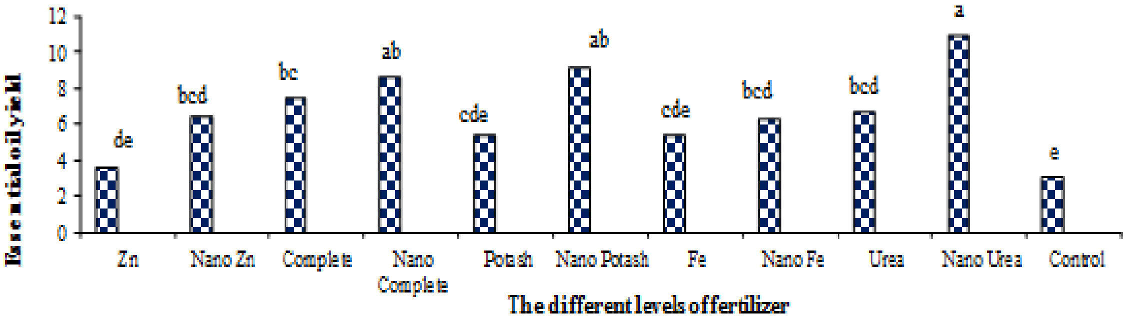

Figure 5. *Effects of different fertilizers on essential oil yield (%) during 2013 year*

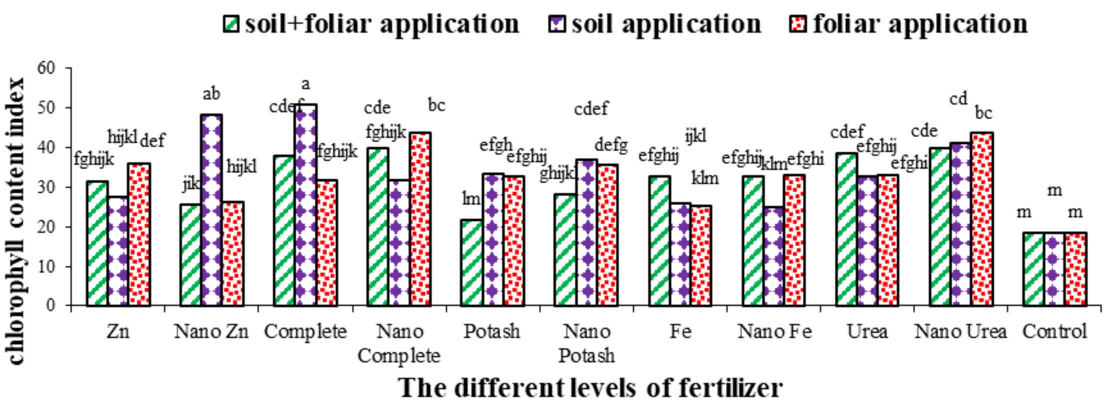

Figure 6. *Effects of fertilizers type and application methods on chlorophyll content index in borago*

Micro-complete and potassium fertilizers increased essential oil yield 15.4% and 71.5% in comparison to micro-complete and potassium fertilizers, respectively. It was no observed significant difference between nano potassium fertilizer in comparison to nano micro-complete (*Fig. 5*). Results showed that nano fertilizer had most essential oil yield but it was no observed significant difference with nano potassium and complete nano. With regards to the different levels of chemical fertilizers, micro-complete treatment (7.5 mg/ha) showed most essential yield in comparison to control group (*Fig. 5*). Results also showed that micro-complete treatment increased essential oil yield rather than potassium (39.6), iron (37.3) and urea (11.9) fertilizers (*Fig. 5*). Nanozinc,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47734788

complete, nano-complete, nano-potassium, nano-iron, urea and nano-urea increased essential oil yield in comparison to control group. Nano-potassium rather than potassium, nano-urea rather than urea showed significant increase in essential oil yield.

Our findings showed significant interaction between fertilizer type and application method on essential oil yield during 2014 years (*Table 3*). Results showed that the highest essential oil yield was observed in combined application of nano iron (12.17 mg/ha), followed foliar application of nano-urea (12.07 mg/ha), soil application of nano-urea (11.92 mg/ha), combined application of nano-urea (11.83 mg/ha) (*Fig. 7*). Results showed that foliar + soil application of nano iron, foliar application of nano-urea, soil application and combined application of nano-urea and soil application of nano iron had not significant effects on essential oil yield (*Fig. 7*). Results showed that soil application of nano-zinc increased essential oil yield by 25.5% and 25.1% in comparison to foliar+soil application of nano-zinc and soil application of nano-zinc (*Fig. 6*). Soil application of nano potassium increased essential oil yield in comparison to foliar application of nano potassium, combined application of potassium and foliar application of nano potassium. Mean comparison of iron fertilizer showed that most essential oil yield was observed in combined application and soil application of nano iron (*Fig. 6*). Nano-urea fertilizer showed significant difference with urea fertilizer (*Fig. 6*).

Control	2.87^{cd}	3.03^{j}	1.05^{gh}	1.17^{ijk}

Means by the uncommon letter are significantly different according to Duncan tests ($p<0.05$).

Biesiada and Kucharska (2008) have reported increased nitrogen could enhance essential oil yield and phenolic contents. Studies have reported reverse relation between essential oil yield and nitrogen content (Lucy et al., 2004). Najafi Vafa et al. (2015) stated that the use of nano-zinc increased essential oil yield in savory. El Gendy et al. (2013) showed that the use of nitrogenous fertilizers and biological fertilizers increased essential oil percentage in guar. Fhatuwani (2008) related essential oil yield with increased phenolic compounds by nitrogenous fertilizers. Regarding increased leaf area,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47734788

it can be stated that photosynthesis and photosynthetic productions have direct relation with essential oil production. With regards to correlation between photosynthesis and essential oil production, it can be stated that carbon dioxide and glucose are essential oil for essential oil production. Considering the states mentioned, it seems that increased of leaf area, number of pores and glucose are essential for energy supply. Potassium and phosphorous improve effect of nitrogen on photosynthesis by oligodynamical role or participation in energy transformation, activating kinases and participating in osmotic absorption. Comparing nano-urea, urea and control show that as chlorophyll index increases, photosynthesis increases which can have major effect on essential oil production. Nitrogen modulates in cell division and development of new cells and also participates in chlorophyll structure and involves in carbon metabolism and essential oil yield (Briat et al., 2015). It seems that fresh weight of branches can have major impacts on essential oil yield.

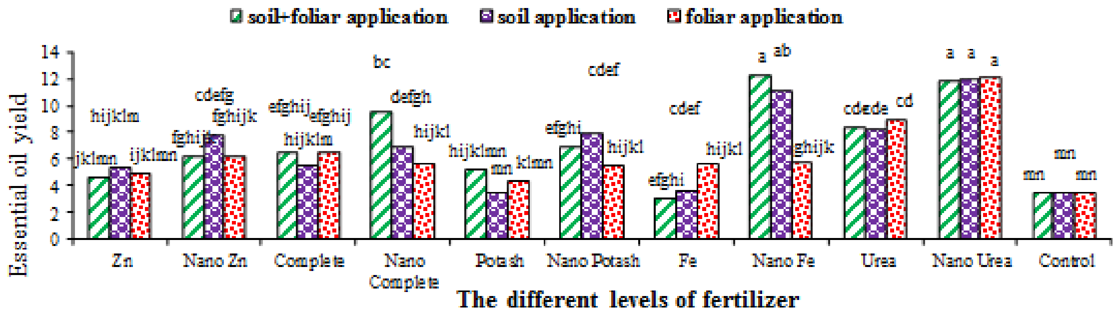

Figure 7. *Interaction between type and application procedure of fertilizers on essential oil yield (%) during 2014 year*

Nitrogen physiological efficiency

Analysis of variance of nitrogen physiological efficiency showed that year, fertilizer type and application method had no significant effect on the mentioned parameters (*Table 4*). Physiological efficiency can be influenced by geographical condition. On the other hand, the loss of nitrogen in environment is known as reason for decreased nitrogen efficiency (Fallah and Tadayyon, 2010). The lack of difference among groups may be attributed to similar loss in all the groups. Some studies have shown inappropriate release of nitrogen regarding plant needs as reason for difference among groups (Russo et al., 2009). Increased the traits depends on ability the use of absorbed nitrogen, so that as plant produces more grain yield, physiological efficiency increases. Thus, one of efficient factors in increasing nitrogen physiological efficiency is chlorophyll production and produced dry matter. It can be stated that similar production of chlorophyll and produced dry matter can be reason for similar nitrogen physiological efficiency.

Phosphorous physiological efficiency

Analysis of variance for phosphorous physiological efficiency during 2013 and 2014 years showed that fertilizer type and application method had no significant effect on phosphorous physiological efficiency. As phosphorous efficiency increases, phosphorous can be fixed in soil (Bahl and Toor, 2002). It seems that fixation have not occurred in the current study.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47734788

Potassium physiological efficiency

Analysis of variance for potassium physiological efficiency during 2013 year showed that fertilizer type, application method and its interaction on the mentioned parameters were not significant ($P > 0.05$). Results indicated a significant interaction between fertilizer type and application method on potassium physiological efficiency (*Table 4*). Analysis of variance for potassium physiological efficiency showed a significant interaction between fertilizer type and application type in 2014 year ($P < 0.05$). Results showed that the most potassium physiological efficiency was observed in combined application and/or foliar application of nano iron (0.70 kg/kg), potassium (0.63 kg/kg) and soil application of nano-urea (0.58 kg/kg) and nano-iron (0.56 kg/kg). Foliar and combined application of nano-iron increased potassium physiological efficiency in comparison to soil and combined application of iron fertilizer by 91%. It seems that application of potassium fertilizer increases efficiency which can be attributed to provide the nutrients for plant growth.

Table 4. *Analysis of variance of physiological efficiency (kh/kg) in borage*

Sources of variation	df	Nitrogen physiological efficiency	Phosphorous physiological efficiency	Potassium physiological efficiency	Zinc physiological efficiency	Iron physiological efficiency

ns: non- significant, ** and * significant at the 1% , 5% probability levels, respectively

Results also showed that foliar application of nano-zinc (0.48 kg/kg) had the most potassium physiological efficiency but it had not significant difference with foliar application of nano-zinc (0.27 kg/kg) and soil application of nano-zinc (0.33 kg/kg). Foliar and combined application of complete fertilizers increased potassium physiological efficiency. Results showed that soil application of complete fertilizer and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47734788

foliar application of nano-complete decreased potassium physiological efficiency but it was no observed significant difference between the mentioned treatments. It can be stated that potassium fertilizers had highest potassium physiological efficiency in comparison to other treatments. Results also showed that soil application of nano-iron (3.84 kg/kg) increased potassium physiological efficiency, but the difference was not significant with soil application of nano-iron (3.48 kg/kg). Results showed that application of nano-iron could show significant difference with iron chemical fertilizer. Results showed that the lowest potassium physiological efficiency was observed in foliar application of urea. The most potassium physiological efficiency was observed in application of urea (2.70 kg/kg).

Zinc physiological efficiency

Analysis of variance showed that fertilizer types and their application had no significant effects on zinc physiological efficiency during 2013 year. There was significant interaction between fertilizer types and fertilizer application during 2014 year. The data for analysis of variance showed that year, fertilizer type, application method and their interactions on zinc physiological efficiency were not significant (*Table 4*).

Iron physiological efficiency

Analysis of variance showed that different levels of fertilizer on iron physiological efficiency was significant ($P < 0.01$). Mean comparison of iron physiological efficiency showed that highest iron physiological efficiency was observed in zinc fertilizer (0.016 kg/kg). The lowest iron physiological efficiency (0.003 kg/kg) was observed in complete nano and iron which had no significant difference with other treatments. Results also indicated significant interaction between year and fertilizer type on iron physiological efficiency ($P < 0.01$). The data for mean comparison showed that highest iron physiological efficiency (0.016 kg/kg) was observed in zinc fertilizer in first year.

Conclusion

This study was conducted to investigate the effects of chemical and nano fertilizers on crop physiological efficiency and essential oil production under foliar and soil application during 2013 and 2014 years. Our findings showed that nano-urea fertilizer had the most essential oil yield in comparison control group. Results showed that highest potassium physiological efficiency was observed in soil application and combined application of nano-iron and the most zinc physiological efficiency was observed in zinc fertilizer. It can be stated that urea and nano-urea fertilizers increase essential yield by increasing chlorophyll index, leaf area and increased fresh weight. For increasing the essential oil yield, use of nano-urea can be suggested.

Conflict of Interest. The authors report that they have no financial or personal relationships that could inappropriately influence or bias the content of the paper.

Abstract. This phytosociological study conducted during 2013-2017 summed up 15 communities including 5 each for trees, shrubs and herbs. Quantitative attributes of vegetation were recorded by using quadrate method i.e. 10 m^2 trees, 5 m^2 for shrubs and 1 m^2 quadrate for herbs. Edaphic attributes were enumerated by employing standard methods. Among tree species highest Family Importance Value was recorded for Pinnaceae (190.85) and lowest for Anacardiaceae (2.39). For shrubs Rosaceae (101.44) had highest FIV and lowest for Rubiaceae (1.89). For herbaceous members highest FIV was recorded for Poaceae (182.15) and lowest for Paeoniaceae (0.42). Three communities viz. *Pinus- Diospyros- Quercus* community, *Indigofera- Cotoneaster- Jasminum* community and *Apluda-Cynodon-Heteropogon* community were established at Lower Chail site. While Upper Chail comprised *Pinus-Quercus-Juglans*, *Rubus-Isodon-Ricinus* and *Apluda-Heteropogon-Poa* communities. Community structure was quite different at Shanku site which established *Quercus-Abies-Pinus*, *Sarcococca-Daphne-Berberis* and *Cynodon-Apluda-Bergenia* communities respectively. Similarly, *Cedrus-Abies-Pinus*, *Parrotiopsis-Vibernum-Berberis* and *Chrysopogon-Themeda-Cynodon* communities were established at Dabargai. At Bishigram, *Picea-Pinus-Abies*, *Parrotiopsis-Cotoneaster-Indigofera* and *Cenchrus-Medicago-Rumex* communities were present. Soils were mildly acidic and had low organic matter content. Vegetation was found to be under severe biotic stress. Deforestation is threatening these ecosystems and conservation of montane temperate forests in this zone is need of the day.
Keywords: *phytosociology, edaphic parameters, maturity index, similarity index, moist temperate vegetation*

Introduction

Study of plant communities and their classification is termed as phytosociology (Mishra et al., 2012; Ahmad and Shaukat, 2012). Primarily phytosociology helps in understanding the multilateral relationships between plants and their environment. It deals with quantitative, qualitative and synthetic attributes of plant communities (Badshah et al., 2016; Ali et al., 2015). Urbanization and industrialization coupled with anthropogenic influences have resulted in forest degradation at an alarming rate across the globe (Sarmah et al., 2011; Nagendra and Utkarsch, 2003). In Pakistan, montane temperate forests have coniferous vegetation with sparsely distributed broad-leaved species (Hussain and Illahi, 1991). Altay et al. (2012) recorded the plant communities in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47894811

urban habitats of Istanbul, Turkey. They documented 13 plant communities and studied the impact of physico-chemical characteristics of soil on these vegetation types. Digiovinazzo et al. (2010) reported that phytosociological thresholds provide guidelines for conservation strategies. Wahab et al. (2008) assessed vegetation structure at 5 monitoring sites of Dangam District, Afghanistan. Vegetation structure of Amazonian Ecuador was studied by Maestre et al. (2006). In Mwanihana forests of Tanzania, Lovett et al. (2006) used phytosociological techniques to conclude that higher species diversity is found at high altitudes. Gould et al. (2006) assessed the structure and composition of vegetation along an elevation gradient in Puerto Rico. Angassa (2005) documented shrubby and grass vegetation in Borna Rangeland ecosystem. Dondeyne et al. (2004) studied the vegetation and soil attributes in woodlands of Southeastern Tanzania. They reported profound impact of edaphic variables on vegetation structure. Vegetation structure of Maasai Mara National Reserve was studied by Salvatori et al. (2003). They also explained the impact of fire and grazing on vegetation structure. Luis et al. (2002) recognized two major vegetation types in Cufada Lagoon in Guinea-Bissau. Grillini et al. (2001) carried out phytosociological studies in Chambura Gorge, Queen Elizabith National Park. Some phytosociological works from Pakistan are presented here. Urooj et al. (2016) conducted vegetation analysis on wetland area around Mangla Dam, Azad Kashmir. Noor and Khatoon (2013) studied vegetation patterns and soil attributes in Astor Valley, Gilgit Baltistan. Shaheen and Qureshi (2011) assessed vegetation of Lesser Himalayan Subtropical forests in Bagh, Azad Kashmir. They also recorded anthropogenic impacts on vegetation structure. Phytosociology and soil characteristics of Quercus forests of Chitral was studied by Khan et al. (2010). Siddiqui et al. (2010) documented the phytosociology of moist temperate Himalayan forests in Pakistan. They classified the vegetation into 3 major groups. Ahmad et al. (2010) presented a review on status of vegetation analysis in Pakistan. Hussain et al. (2009) recorded plant communities from Nurpur reserved forest, District Chakwal. Wazir et al. (2008) identified 5 vegetation types in Chapursan Valley, Gilgit. Ahmad et al. (2008) studied the spatio-temporal effects on plant associations in Soone Valley. From Khyber Pakhtunkhwa province studies of community ecology are summed up here. Ilyas et al. (2015) studied the vegetation structure of Kabal valley, Swat. Wahab et al. (2010) studied vegetation structure in 25 forest types in District Dir. Shah and Hussain (2009) documented the vegetation structure in Hayatabad, Peshawar, establishing 5 plant communities. Hussain et al. (2005) described 7 plant communities from Ghalegy hills, Swat. Hussain and Badshah (1998) documented the vegetation of Pirghar hills, South Waziristan. Review of literature clearly indicates that no comprehensive study is available on vegetation structure of Chail, Shinku, Bishigram and Shinku, hence present study will fill the research gap in these areas which have rich floral diversity. Present study was carried out to map vegetation and to assess the threats to montane temperate forests in Hindukush range, Swat, Pakistan.

Materials and methods

Study area

The research work was carried out in Hindukush range, District Swat. Swat is located from 34° 34’ to 35° 55’ North latitudes and 72° 08’ to 72° 50’ East longitudes. The study area spreads over an area of 24148 acres, including villages of Chail, Shinku,

DOI: http://dx.doi.org/10.15666/aeer/1604_47894811

Dabargai and Bishigram (*Fig. 1*). Most part of the area falls under moist temperate zone with typical flora and fauna.

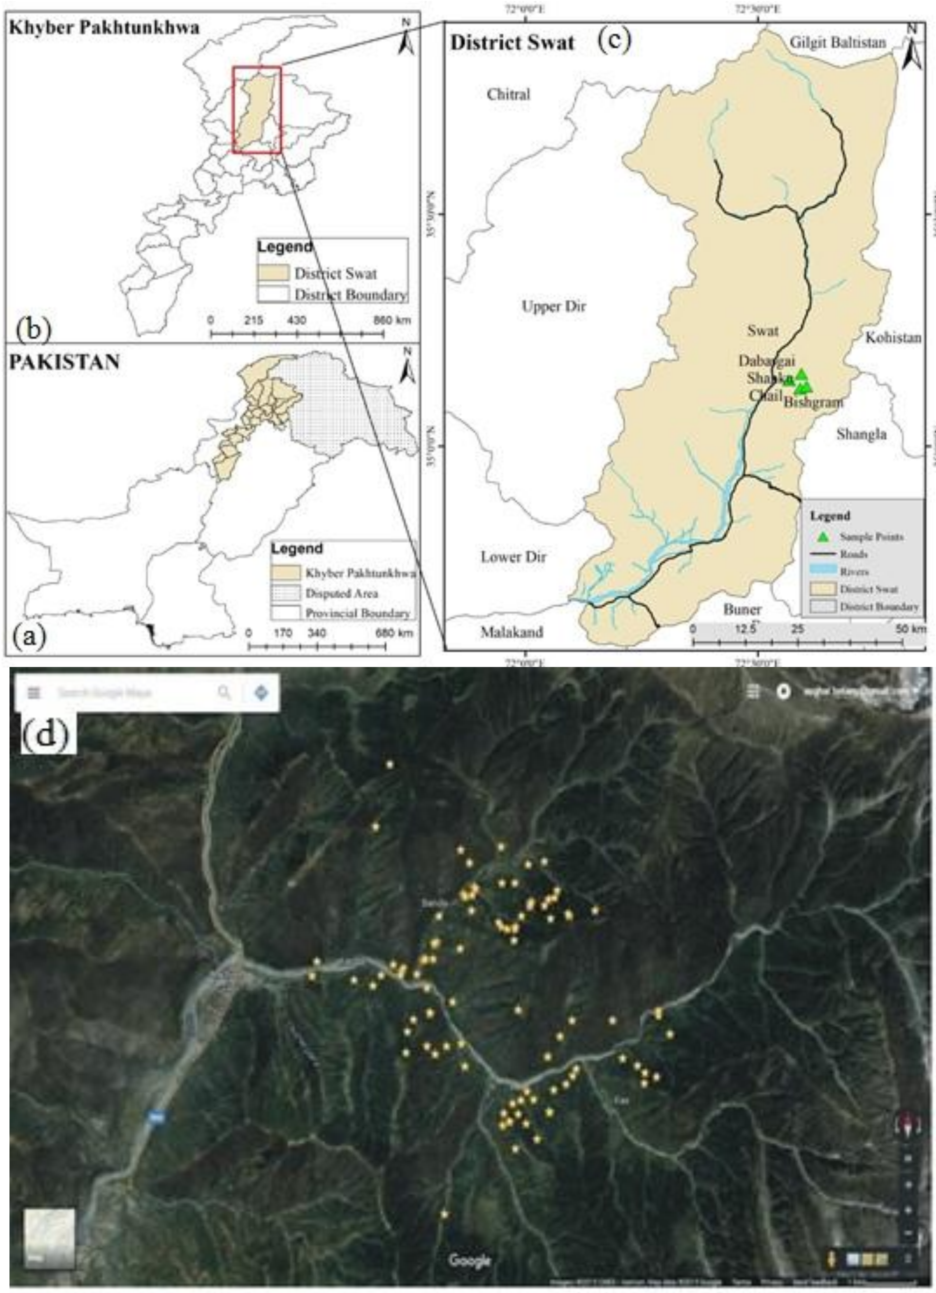

Figure 1. (a) Map of Pakistan. (b) Map of Khyber Pakhtunkhwa Province. (c) Enlarged map of District Swat and monitoring sites. (d) Map of the study area showing all the sampling sites

Phytosociology

Phytosociological studies were conducted in 5 monitoring sites. These sites were chosen based on species composition, habitats, and physiognomic contrast. Vegetation was analyzed by using 5 (10 x 10 m) quadrats for trees, 10 (5 × 5 m) quadrats for shrubs and 15 (1 × 1 m) quadrats for herbs at each monitoring site. Density, cover and

APPLIED ECOLOGY AND ENVIRONMENTAL RESEARCH 16(4):4789-4811.

DOI: http://dx.doi.org/10.15666/aeer/1604_47894811

frequency of each species were measured and values were changed to relative values to calculate IV (Importance value) and FIV (Family importance value). The plant communities were established based on highest importance values following Ahamd and Shaukat (2012), Hussain (1989).

Maturity index

Community maturity index was obtained by Pichi-Sermolli (1948) method.

Similarity index

Similarity index was calculated by using Sorensen's index (Sorensen, 1948) as modified by Motyka et al. (1950).

Soil analysis

Standard methods were applied to estimate Soil texture (Brady, 1990; Bouyoucos, 1936), pH (Jackson, 1962), Organic matter, $CaCO_3$ (Rayan et al., 1997), Electrical conductivity (Rhoades, 1996), Sodium absorption ratio and Sulphates (Richard, 1954). Nitrogen was determined by Kieldahl method of Bremner and Mulvaney (1982). Phosphorous, Potassium, Calcium and Magnesium were enumerated by Inductively Coupled Plasma Optical Emission Spectroscopy (ICP-OES).

Results

Present study was conducted in Hindukush range of District Swat, Pakistan during 2013-2017. Five monitoring sites viz. Lower Chail, Upper Chail, Shinku, Dabargai and Bishigram were established. The study area displays a unique floristic and vegetation structure. A total of 202 species were recorded in sampling units, of which trees were represented by 33 species, shrubs by 36 species and herbs by 133 species. Based on importance value (IV), three communities respectively of trees, shrubs and herb layer were established at each monitoring site. Tree communities comprised of 16 families, with Pinnaceae as the leading family with an FIV of 190.85 followed by Fagaceae (64.97), Juglandaceae (45.51), Ebenaceae (38.54), Moraceae (31.64). Rosaceae (30.41), Simoroubaceae (22.36) and Salicaceae with 19.86. Oleaceae, Taxaceae, Punicaceae, Meliaceae and Ulmaceae had importance values ranging from 16.8 to 5.13. Shrubby vegetation was represented by 21 families, dominated by Rosaceae, with highest FIV value of 101.44. It was followed by Papilionaceae (59.27), Hammelidaceae (41.62), Berberidaceae (33.47), Thymelaceae (33.44), Oleaceae (31.91), Buxaceae (30.21), Myrsinaceae (27.14), Lamiaceae (26.16) and Caprifoliaceae (23.43). Similarly, Buddlejaceae, Euphorbiaceae, Elaeagnaceae, Grossulariaceae, Rhamnaceae, Acanthaceae, Urticaceae, Rutaceae and Plumbaginaceae were the associated families having FVI ranging from 16.98 to 4.96. Herbaceous layers were represented by 47 families with Poaceae as the leading family with FIV value of 182.15. Asteraceae (43.06), Lamiaceae (27.55), Papilionaceae (24.06), Polygonaceae (23.15), Saxifragaceae (17.4), Brassicaceae (14.24), Euphorbiaceae (14.09), Rosaceae (13.82) and Apiaceae (12.35) were the sub dominant families. Other important families of herbaceous layer included Plantaginaceae, Ranunculaceae, Caryophyllaceae, Sapotaceae, Solanaceae, Amaryllidaceae, Scrophulariaceae, Urticaceae and Oxalidaceae (*Tables 1* and *2*).

Lower Chail (Site-I)

Plant communities at this site were established at Southern and South-Eastern aspects at an elevation of 1390 m up to 1480 m. Soil at this locality was loamy-sand, with 9.2% clay particles, 53.2% silt and 37.6% sand particles. Nitrogen content of the soil was estimated to be 0.1035%, phosphorous 470 µg/g, potassium 6398 µg/g, calcium 34448 µg/g and magnesium 22188 µg/g. sodium absorption ratio (SAR) of the soil was 0.52 millieq/L while sulphates were found to be 516 µg/g. Soil pH at this monitoring site was recorded as 5.2 which reflected the podzolic nature of the soil. Organic matter was found to be 2.07% which is typical to the podzolic soils. $CaCO_3$ content was low at this site i.e. 2.5% while electrical conductivity was 0.43 dsm^{-1} (*Table 3*).

1. Pinus-Diospyros-Quercus community (PDQ)

This plant community was recorded from South facing slope at an elevation of 1480 m. *Pinus wallichiana* was the dominant species with IV of 25.39. Second dominant was found to be *Diospyros lotus* with an IV of 23.38, forming a close

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47894811

association with *Pinus wallichiana* at lower parts of the slopes. As the plant yield edible fruits with medicinal value the population density of *Diospyros lotus* was high with a considerably uniform dispersion. *Quercus dilatata* with an IV of 15.62, was mostly dispersed among *Pinus wallichiana* members at higher altitudes. Other prominent members of this community included *Juglans rigia* (12.93 IV), *Ailanthus altissima* (9.21 IV), *Ficus carica* (8.94 IV) and *Crataegus songarica* (4.49 IV). Common herbs growing around this community included *Rumex hastatus, Solidago virga-aurea, Fragaria vesica, Plantago himalayica, Medicago polymorpha, Sonchus asper, Cuscuta europaea* and *Salvia moorcroftiana.*

2. Indigofera-Cotoneaster-Jasminum community (ICJ)

On South facing slope this shrubby community was recorded. Dominant species was *Indigofera heterantha* var. *gerardiana* with an IV of 13.36 followed by *Cotoneaster nummularia* with an IV of 13.25. These shrubs made thick randomly dispersed patches on mostly tree-less aspect of the cliffs. Co-dominant was found to be *Jasminum humile* with an IV of 10.23. The rest of the shrubs included *Spiraea canescens* (10.01 IV), *Buddleja crispa* (9.6 IV), *Myrsine africana* (7.34 IV), *Rubus fruiticosus* (7.23 IV) and *Daphne mucronata* (6.84 IV). Other members of the shrub layer in this locality were *Rubus ellipticus, Elaeagnus umbellate, Vibernum cotinifolium* and *Sageretia thea*.

3. Apluda-Cynodon-Heteropogon community (ACH)

This community was recorded from South-eastern aspect at an elevation of 1390 m. In Lower Chail area therophytes dominated the landscape. This community was dominated by *Apluda mutica* with an IV of 14.57, almost uniformly distributed in the locality making strong association with the second dominant *Cynodon dactylon* with an IV of 13.35. Just around the shrubby vegetation *Apluda mutica* formed mixed patches with third dominant *Heteropogon contortis* with an IV of 6.64. The other associated species were *Fragaria vesca* (5.82 IV), *Bergenia ciliata* (5.07 IV), *Artemisia vulgaris* (4.93 IV) and *Origanum vulgare* (4.3 IV). Remaining species such as *Arthraxon prionodes, Bistorta amplexicaulis, Buplerum falcatum, Cichorium intybus, Clematis grata, Clinopodium umbrosum, Cuscuta europaea, Euphorbia prostrata, Medicago polymorpha, Pennistum orientale, Plantago himalaica, Rumex hastatus* and *Salvia moorcroftiana* had IV values ranging between (1.32 to 3.92) (*Table* 2).

Upper Chail (Site-II)

Plant communities established at this monitoring site were found on an elevation of 1620 m. Soil analysis displayed a contrasting picture with reference to adjoining Lower Chail area. Soil was silt-loam at this site with 5.2% clay particles, 47.2% silt and 47.6% sand particles. Soil reaction was mildly acidic with a soil pH of 5.4. Organic matter content was estimated as 2.76%. Nitrogen content was 0.138% followed by phosphorous 430 µg/g, potassium 10634 µg/g, calcium 16722 µg/g and magnesium 15433 µg/g. Sodium absorption ratio of the soil was estimated as 0.2 millieq/L and sulphate content was recorded as 556 µg/g. Floods of recent past have eroded soil in the Upper Chail to a huge extent and main water tributary of the valley, Chail stream, is still a big threat to remaining vegetation cover in the valley floor. Highest value for $CaCO_3$ were recorded from upper Chail i.e. 7.5% while electrical conductivity was 0.08 dsm^{-1} (*Table 3*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47894811

1. Pinus-Quercus-Juglans community (PQJ)

This community was recorded at an elevation of 1620 m, *Pinus wallichiana* was found to be dominated with an IV of 18.06. This was associated with *Quercus baloot* having an IV of 15.52. *Juglans regia* with an IV of 13.36 was next in abundance. These were followed by *Olea ferruginea* (8.42 IV), *Salix denticulata* (6.66 IV), *Alianthus altissima* (6.42) and *Punica granatum* (5.91 IV). In addition to this *Ficus carica, Populus alba, Prunus persica, Morus nigra, Malus pumiula, Crataegus songarica* and *Diospyros lotus* had IV values ranging between 4.32 to 2.87. *Phalaris minor, Achillea millefolium, Cannabis sativa, Viola canescens, Fumaria indica, Urtica dioca, Capsella bursa-pastoris, Chenopodium album* and *Plantago major* were the common herbaceous flora intermingled with trees association.

2. Rubus-Isodon-Ricinus community (RIR)

Rubus ulmifolius with an IV of 15.92 dominated this community with uniform distribution. It had thick patches of *Isodon rugosus* as second dominant with an IV of 13.67. But on low elevation *Ricinus communis* formed randomly dispersed clumps with an IV of 11.67. These were followed by *Mrsine Africana* (8.9 IV), *Sarcococca saligna* (8 IV), *Indigofera heterantha* var. *gerardiana* (7.31 IV), *Jasminum officinale* (6.94 IV) and *Debergeasia salicifolia* (6.21 IV). Other shrubby members of the community such as *Daphne mucronata, Justicia adhatoda, Lespedeza juncea, Berberis lyceum* and *Lonicera asperifolia* had IV ranging between 5.49 and 3.62.

3. Apluda-Heteropogon-Poa community (AHP)

This community of Upper Chail was dominated by *Apluda mutica* with an IV of 9.81. Though herbs were not forming a uniform cover, due to severe soil erosion by Chail stream in past few years, but still thick patches of herbs were recorded on banks of Chail stream. Second dominant species was *Heteropogon contortis* with an IV of 8.34 which formed association with *Poa annua* having an IV of 7.92. These dominants were followed by *Phalaris minor* (6.54 IV), *Artemisia scoparia* (5.19 IV), *Urtica dioca* (3.81 IV), *Verbascum thapsus* (3.71 IV), *Plantago major* (2.89 IV) and *Chenopodium album* (2.83 IV) (*Table 2*).

Shinku (Site-III)

Plant communities at this site were established at elevation of 2150 m on Northern and North-Western slopes. Soil analyses indicated that soils at this site are silt-loam with 7.2% clay particles, 65.2% silt particles and 27.6% sand particles. Soil pH was recorded as 5.4 and organic matter was estimated as 1.38%. Nitrogen content was low i.e. 0.069%. Phosphorous was estimated as 494 µg/g while potassium was found to be 8925 µg/g. Calcium content was a bit higher i.e. 24148 µg/g and magnesium was 17056 µg/g in the soils. Sodium absorption ratio was also a little low in comparison with Lower and Upper Chail i.e. 0.3 millieq/L. Sulphates were estimated as 450 µg/g. Soil had only 3% lime and electrical conductivity remained at 0.026 dsm^{-1} (*Table 3*).

1. Quercus-Abies-Pinus community (QAP)

Quercus-Abies-Pinus community of trees was recorded at an elevation of 1495 m up to 1680 m on Northern and North-Western slopes in Shinku area. In this community the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47894811

dominant member was *Quercus incana* with an IV of 18.91. Second dominant was *Abies pindrow* with an IV of 18.6, making strong association with *Quercus incana* on North-Western aspect and *Pinus wallichiana* with IV of 12.56. The other important contributors to this community were *Juglans regia* (11.59 IV), *Taxus fauna* (8.88 IV), *Pyrus pashia* (4.16 IV) and *Cedrus deodara* (4.02 IV). *Taxus fauna* was more abundant on North-Western aspect than on Northern aspect. On lower elevations, mixed patches of *Diospyros kaki* (3.64 IV), *Crataegus songarica* (2.04 IV) and *Ailanthus altissima* (1.89 IV) were recorded. Some notable herbaceous members found within this community were *Oxalis corniculata, Euphorbia prostrata, Anagallis arvensis, Scandix pecten-veneris, Avena fatua, Taraxacum officinale, Stellaria media, Silene conoidea, Hypericum perforatum, Poa annua* and *Clematis grata*.

2. Sarcococca-Daphne-Berberis community (SDB)

Shrubby layer was much prominent making thick strips from Northern to North-Western aspect. This community was found at an elevation of 1491 m up to 1516 m. *Sarcococca saligna* with an IV of 19.01 was the dominant making thick uniformly dispersed clumps with next dominant *Daphne mucronata* with an IV of 17.29. *Berberis lyceum* with an IV of 13.6, was common to Northern slopes. Other important members of this community included *Indigifera heterantha* var. *heterantha* (10.24 IV), *Cotoneaster nummularia* (7.3 IV), *Myrsine africana* (6.62 IV) and *Buddleja crispa* (6.05 IV). *Rosa webbiana* was randomly distributed at higher elevations with an IV of 3.51.

3. Cynodon-Apluda-Bergenia community (CAB)

Herbaceous community was found at elevation of 1490 to 1610 m. *Cynodon dactylon* appeared to be dominant with an IV of 13.97, followed by *Apluda mutica* with an IV of 12.47 as co-dominant. *Bergenia ciliata* appeared as the next dominant with an IV of 6.88 near small water falls on both aspects. This community also included *Fragaria vesca* (6.74 IV), *Artemisia vulgaris* (6.46 IV), *Rumex hastatus* (4.63 IV), *Poa annua* (4.22 IV), *Sassurea albescense* (4.11 IV), *Avena fatua* (3.53 IV) and *Nacrissus tazetta* (3.16 IV) (*Table* 2).

Dabargai (Site-IV)

Plant communities at this site were established at an elevation of 2371 m on North-Eastern and Southern aspects. Soil was loam with 7.2% clay particles, 49.2% silt particles and 43.6% sand particles. Soil pH was recorded as 5.8 and it was evident from a higher degree of podzolization in the soils of the study area with considerably low organic content i.e. 2.08%. Nitrogen content was estimated as 0.1104%. Phosphorous and potassium were recorded as 385 µg/g and 4162 µg/g respectively. Calcium content was found to be 39159 µg/g while magnesium content was 25127 µg/g. Sodium absorption ratio was 0.13 millieq/L and sulphates were only 496 µg/g. $CaCO_3$ was estimated to be 2.5% and electrical conductivity was 0.03 dsm^{-1} (*Table 3*).

1. Cedrus-Abies-Pinus community (CAP)

This tree community was found between elevation ranges of 1935 to 12371 m. *Cedrus deodara* with an IV of 22.07 was the abundantly growing tree. *Abies pindrow*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47894811

and *Pinus wallichiana* with an IV of 16.01 and 13.38 respectively were the second and third dominants. In addition to these dominant forms other important members of this community included *Olea ferruginea* (5.53 IV), *Ficus carica* (4.41 IV), *Taxus fauna* (4.06 IV), *Quercus baloot* (3.88 IV), *Juglans regia* (3.27 IV), *Moras alba* (3.02 IV) and *Cedrela serrata* (2.91 IV). Notable herbaceous elements of this community were *Thymus linearis, Ammi visnaga, Apluda mutica, Dactylis glomerata, Centaurea iberica, Notholirion thomsonianum, Dioscorea deltoidea, Amaranthus viridis, Verbascum thapsus, Gagea elegans, Micromeria biflora* and *Sisymbrium irio*.

2. Parrotiopsis-Vibernum-Berberis community (PVB)

Shrubby layer was randomly dispersed on North-Eastern and Southern slopes. *Parrotiopsis jacquemontiana* was dominant with an IV of 25.51 making randomly dispersed thick patches mostly on North-Eastern aspect. *Vibernum grandiflorum* was second dominant with an IV of 13.08 making continuous strips with *Berberis lyceum* (IV 12.26). Some other important contributors to this community included *Indigifera heterantha* var. *gerardiana* (7.08 IV), *Maytenus royleanus* (4.63 IV), *Myrsine Africana* (4.28 IV), *Ribes himalense* (4.05 IV), *Isodon rugosus* (3.86 IV) and *Jasminum humile* (3.46 IV).

3. Chrysopogon-Themeda-Cynodon community (CTC)

This community is dominated by *Chrysopogon fulvus* with an IV of 10.89. *Themeda anathera* with an IV of 9.33 was more common to Southern aspect on lower elevations. *Cynodon dactylon* with an IV to 8.64 was the next dominant. Some other important members of this community included *Avenia fetua* (3.58 IV), *Bergenia ciliata* and *Verbascum thapsus* both with IV of 3.09, *Salvia moorcroftiana* (3.04 IV), *Sisymbrium irio* (2.46 IV), *Cannabis sativa* (2.39 IV) and *Artemisis absinthium* (2.36 IV) (*Table 2*).

Bishigram (Site-V)

Plant communities at this monitoring site were established at an elevation of 2698 m on Northern and Southern aspects. Soils in the area were loamy-sand in texture with 9.2% clay particles, 37.2% silt particles and 53.6% sand particles. Soil pH was 6 and organic matter content was estimated as 2.48%. Nitrogen content was 0.1242% which was better than Lower Chail, Upper Chail and Shinku areas displaying a healthy rate of saprophytic activity in the soils. Phosphorous content was 475 μg/g, potassium 13059 μg/g and calcium 14568 μg/g. Magnesium was recorded as 13738 μg/g. Sodium absorption ratio was low i.e. 0.21 millieq/L and sulphates were abundant i.e. 661 μg/g. $CaCO_3$ content was highest at this site i.e. 10% and electrical conductivity was recorded as 0.023 dsm^{-1} (*Table 3*).

1. Picea-Pinus-Abies community (PPA)

This tree community was found at an elevation range of 2475 to 2698 m on both aspects. *Picea smithiana* with an IV of 22.07 followed by *Pinus wallichiana* (14.54 IV) were the leading trees in this community. On higher elevations *Picea smithiana* formed an association with *Abies pindrow* with an IV of 12.36. Other notable contributors were *Juglans rigia* (4.36 IV), *Diospyros lotus* (4.12 IV) and *Ficus carica*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47894811

(3.6 IV). On Southern aspect there was a mixed patch of *Platanus orientalis* (3.6 IV), *Acer cappadocicum* and *Pinus roxbergii* (each with 3.07 IV). In addition to this *Cedrus deodara* made randomly dispersed clumps on Northern aspect with IV of 2.92. On higher elevations at Northern aspect *Quercus dilatata* and *Taxus fauna* were found with an IV of 2.79 each, delimiting a thin strip of *Quercus semicarpifolia* with an IV of 2.76. At this monitoring site the common herbs included *Arenaria serpyllifolia, Brachiaria reptans, Eryngium coeruleum, Pseudognaphalium affine, Eragrostis minor, Angelica glauca, Calanthe tricarinata, Portulaca oleracea, Apluda mutica* and *Podophyllum emodi*.

2. Parrotopsis-Cotoneaster-Indigofera community (PCI)

Parrotiopsis jacuemontiana with an IV of 16.11 making a very prominent stretched patch on Northern slopes and clumped pattern on Southern aspect. It was accompanied by *Cotoneaster nummularia* with an IV of 14.82. *Indigofera heterantha* var. *heterantha* was the companion shrub with an IV of 11.95. It was more common to Southern aspect than to Northern slopes. *Cotoneaster nummularia* displayed a uniformed dispersion on both slopes. Other important contributors to this community were *Limonium cabulicum* (4.96 IV), *Rubus fruiticosus* (4.84 IV), *Jasminum humile* (4.6 IV), *Ribes orientale* (4.54 IV), *Spiraea canescens* (4.47 IV) and *Berberis lyceum* (3.94 IV). Notable shrubs but with lesser IV included *Isodon rugosus, Lespedeza juncea, Phlomis spectabilis, Andrachne cordifolia, Sarcococca saligna, Skimmia laureola* and *Himalrandia tetrasperma.*

3. Cenchrus-Medicago-Rumex community (CMR)

Herbaceous community was found to have rich diversity with *Cenchrus pennisetiformis* as dominant, having an IV of 18.92 forming uniform strips on both slopes. It was found making good association with *Medicago lupulina* having an IV of 11.87. While on lower elevations *Rumex hastatus* with an IV of 8.97 was dominating both the aspects. This community also had *Poa annua* (3.8 IV), *Cyanodon dactylon* (3.4 IV), *Aristida cyanantha* (3.12 IV), and *Sisymbrium irio* (2.83 IV) (*Table 2*).

Maturity index

Maturity index was calculated according to Pichi-Sermolli (1948). At Lower Chail, tree community had 48.57 maturity index, shrubs had 31.66 and herbaceous community had a 28.61 maturity index. The mean value for the site was 36.28. At Upper Chail, tree community showed a maturity index of 34.28, followed by shrubby layer with a value of 23.07 and herb layer having 16.06. The mean value for these three communities was 24.47. In Shinku, tree community had a maturity index of 44. Shrub community with a maturity index value of 27.27 while herb community had only 19.62. Mean value for maturity index at this site was 30.29. Maturity index for tree community at Dabargai area was found to be 28.88 followed by 16.31 value of shrub community and 12.73 value for herbaceous community. Mean value for the maturity index at this site was 19.30. At Bishigram, tree community had a maturity index of 27. At this site shrub had a maturity index of 20 followed by herb layer having a maturity index of 10.86. Mean value of maturity index at this site was 19.28 (*Table 4*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47894811

***Table 4.** Maturity index*

	Lower Chail	Upper Chail	Shinku	Dabargai	Bishigram
Trees	48.57	34.28	44	28.88	27
Shrubs	31.66	23.07	27.27	16.31	20
Herbs	28.61	16.06	19.62	12.73	10.86
Mean	**36.28**	**24.47**	**30.29**	**19.30**	**19.28**

Index of similarity

1. Tree communities

According to Motyka's index of similarity (Motyka et al., 1950), PDQ tree community of Lower Chail was found to be 16.09% similar, to PQJ community of Upper Chail. The similarity between PDQ community and QAP community at Shinku was found to be 10.56%. The analysis showed that similarity between PDQ community and that of CAP community at Dabargai area was 10.62%. Lowest value of similarity was observed between PDQ community and PPA community of Bishigram, i.e. 10.54%. Similarity between PQJ tree community of Upper Chail and that of QAP community at Shinku was 11.96%. PQJ community was 12.61% like tree community CAP at Dabargai area. Only 11.09% similarity was observed between PQJ community and PPA community of Bishigram area. QAP tree community at Shinku area showed more similarity with CAP tree community of Dabargai area i.e. 16.42%. QAP community was 16.04% like PPA community at Bishigram. CAP tree community at Dabargai area showed maximum similarity with PPA tree community at Bishigram i.e. 18.11% (*Table 5*).

***Table 5.** Similarity indices of tree communities*

PDQ	PQJ	QAP	CAP	PPA
X	X	X	X	X
16.09	X	X	X	X
10.56	11.96	X	X	X
10.62	12.61	16.42	X	X
10.54	11.09	16.04	18.11	X

2. Shrub communities

Shrubby vegetation showed little similarities among communities based on Motyka's index. ICJ community at Lower Chail site was 6.71% like RIR community at Upper Chail. ICJ shrub community was found 10.45% similar to SDB shrub community at Shinku. Similarity between ICJ community and PVB community at Dabargai area was 7.07%. The ICJ community was least similar to PCI community at Bishigram i.e. 5.31%. Shrub community at Upper Chail i.e. RIR was 10.36% similar to SDB shrub community at Shinku. Same RIR community was 6.95% similar to PVB community of shrubs at Dabargai. A 5.17% similarity was observed between RIR community and PCI shrub community at Bishigram. Comparison of shrub community at Shinku area i.e. SDB community and PVB community at Dabargai showed 11.81% similarity while between SDB community and PCI community at Bishigram 9.73% similarity was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47894811

observed. Shrub communities at Dabargai i.e. PVB and that of Bishigram i.e. PCI community showed maximum similarity i.e. 14.6% (*Table 6*).

Table 6. *Similarity indices of shrubby communities*

ICJ	RIR	SDB	PVB	PC1
X	X	X	X	X
6.71	X	X	X	X
10.45	10.36	X	X	X
7.07	6.95	11.81	X	X
5.31	5.17	9.73	14.6	X

3. Herbaceous communities

Among herbaceous communities, ACH community at Lower Chail was 7.06% similar to AHP herb community at Upper Chail. The ACH community was found to be 19.64% similar to CAB community at Shinku while its similarity with CTC community at Dabargai site was 8.27%. The herb community ACH was least similar to Bishigram herb community with a similarity index of just 3.03%. The herb community of Upper Chail i.e. AHP was 4.57 same as CAB herb community at Shinku, 6.13% similar to CTC community at Dabargai and 5.87% similar to CMR community at Bishigram. The CAB herb community of Shinku was 10.68% like CTC community at Dabargai and 6.40% similar to CMR community at Bishigram. Similarty between CTC community at Dabargai and CMR community at Bishigram was found to be 6.88% (*Table 7*).

Table 7. *Similarity indices of herbaceous communities*

ACH	AHP	CAB	CTC	CMR
X	X	X	X	X
7.06	X	X	X	X
19.64	4.57	X	X	X
8.27	6.13	10.68	X	X
3.03	5.87	6.40	6.88	X

Discussion

Vegetation was classified into tree, shrub and herbaceous communities which is in line with the works of Ahmad et al. (2016), Dad (2016), Ali et al. (2015), Saurav and Das (2014), Sharma et al. (2014) Saglam (2013), Ahmad et al. (2010), Digiovinazzo et al. (2010), Hussain et al. (2010), Mohler et al. (2006) Munhoz et al. (2006) and Padalia et al. (2004). At Site-I, PDQ-ICJ-ACH communities were established for trees, shrubs and herbs respectively. Distribution of trees showed clumping rather than a uniform pattern of distribution due to lavish wood cutting in the area. Scanty trees and comparatively thick shrub cover near the foothills indicated the disturbed nature of habitat which is under tremendous biotic stress. Increasing population and construction of residential units is the main reason behind the species loss in this locality. Similar communities are reported from their respective study areas by Ahmad et al. (2016), Urooj et al. (2016), Haq et al. (2015), Ilyas et al. (2015), Dad (2016), Shaheen and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_47894811

Qureshi (2011), Ahmad et al. (2010), Ahmad (2009), Hussain et al. (2010) and Jabeen and Ahmad (2009). Site-II had PQJ-RIR-AHP communities. Tree and shrub members showed a clumped dispersion pattern at this monitoring site. Impacts of soil erosion were more visible at Site-I and Site-II where eroded soils had herbaceous members like *Rumex hastatus, Plantago himalayica, P. major, Salvia moorcroftian and Verbascum thapsus* which are indicator species of eroded soils. Similar communities but with different IV are reported by Ahmad et al. (2016), Dad (2016), Khan et al. (2016), Akhtar and Bergmeier (2015), Shaheen et al. (2015), Ilyas et al. (2015), Sharma et al. (2014), Hussain et al. (2010) and Khan et al. (2010). Site-III exhibited QAP-SDB-CAB communities. This site had a uniformly spread thick Oak forest mixed with conifers. Deforestation was also not that alarming as compared to that of Lower and Upper Chail monitoring sites. At higher elevations the forest was almost undisturbed however the habitat will face biotic stress, especially the anthropogenic pressure from increasing population in the low laying villages in next few years. *Apluda mutica* was observed to form randomly dispersed thick patches all along the Northern slopes at this monitoring site. These findings are backed by works of Bokhari et al. (2016), Dad (2016), Ali et al. (2015), Ilyas et al. (2015), Shaheen et al. (2015), Siddiqui et al. (2015), Ahmad et al. (2010) and Ahmad (2009). CAP-PVB-CTC communities were found at site-IV. *Cedrus-Abies* forest was much thicker on North-Eastern aspect and showed degradation on Southern slope. *Chrysopogon fulvus* had a uniform dispersion on North-Eastern aspect than on Southern slopes. This is line with findings of Ahmad et al. (2016), Dad (2016) Bokhari et al. (2016), Khan et al. (2016), Ali et al. (2015), Akhtar and Bergmeier (2015), Ilyas et al. (2015), Shaheen et al. (2015), Sharma et al. (2014) and Ahmad et al. (2010), Hussain et al. (2010), Ahmad (2009) Jabeen and Ahmad (2009). At site-V, PPA-PCI-CMR communities were recorded. Forest at this site was found in good health with the exception on Northern slopes where deforestation was quite evident due to fuel wood extraction by locals. These results are in line with the works of Ahmad et al. (2016), Bokhari et al. (2016), Khan et al. (2016), Akhtar and Bergmeier (2015), Haq et al. (2015), Sharma et al. (2014), Khan et al. (2012), Ahmad et al. (2010) and Hussain et al. (2010) and Ahmad et al. (2006).

Conclusion

This study reveals results of vegetation mapping based on 150 sampling units at 5 monitoring sites. Results of soil analysis cover 12 parameters. Spatial variation among plant communities at different monitoring sites is attributed to variations in edaphic variables, temperature, moisture and slope. Vegetation in the study area is threatened and needs conservation before it is too late. Anthropogenic influences, over grazing, natural calamities and erosion are reducing the vegetation cover. Expansion in agricultural fields is also causing a damage to forest cover in addition to overgrazing. Extraction of wood from forest, especially during harsh winters by the local communities, is not only reducing the tree density but is also increasing the rate of soil erosion. Climate change has not spared Hindukush Range vegetation and floral biodiversity is reducing with every passing year. Coniferous forests in this part of the world are threatened habitats because of accelerated deforestation. Impacts of anthropogenic pressure are evident from low scores for maturity index. Highest maturity index value was recorded for tree community at Site-I i.e. 48.57 followed by tree community at Site-III i.e. 44. Highest maturity index for shrub layer was recorded

DOI: http://dx.doi.org/10.15666/aeer/1604_47894811

at Site-I i.e. 31.66 followed by Site-III with a value of 27.27. Similar trend was recorded for herbaceous communities. Low values for maturity index indicate inability of the plant communities to cope with anthropogenic, edaphic and climatic stresses. Similarly, low values for similarity index shows the heterogeneity among plant communities. Reforestation programs need to be initiated in the area to protect and conserve the indigenous floristic wealth. But extreme care in this regard is suggested so that no alien plant species is introduced as it will further increase stress on plants in the locality. Well trained *Ecologists* should be invited to chart out a plan for conservation of biodiversity in the study area. Vegetation structure is suggestive that local flora is fighting a war of its survival. Once covered beneath a thick vegetation blanket now bare patches are visible on mountain slopes. Open canopy has enabled some shrub species to make well developed layers. Provision of alternative sources of energy to the locals will reduce pressure on populations of *Pinus roxburghii, P. wallichiana, Cedrus deodara, Picea smithiana, Abies pindrow* and other tree species. This will in turn reduce the extant of deforestation in the locality. This study strongly recommends detailed studies on fuelwood consumption in these monitoring sites to quantify the extent of fuelwood consumption per-annum. Proper grazing management should be ensured for regeneration of understory plants. Influential elders of the area can play a vital part in protection of climax communities as well as in enforcing moderate and rotational grazing routines. Soil in the study area had low organic matter content. Acidic soils show a slow rate of humification which is the reason behind low organic matter in the soil.

Abstract. In order to evaluate the effect of application of biological fertilizers and different amounts of urea fertilizer under low water stress conditions on physiological traits of *Calendula officinalis* L. an experiment was conducted during two years of cultivation of 2015-2016 and 2016-2017 at the research farm of Islamic Azad University (IAU), Varamin-Pishva Branch, Iran. The experiment was split-split plot based on randomized complete block design with three replications. The experimental treatments included different levels of dehydration as the main factor in two levels (lack of water stress (control), irrigation interruption during boiling stage), levels of biological fertilizers in four levels as a sub-agent (no use of biological fertilizer, application of *Azotobacter chroococcum*, application of *Azospirillum brasilense*, combination of Azotobacter and Azospirillum), and urea fertilizer sources at four levels as a sub-subtype (non-consumption (control), recommended amount of urea fertilizer with sulphur coating, 75% of the recommended amount of urea fertilizer with sulphur coating was recommended as the most common form of urea fertilizer (157 kg/ha based on soil test). The results showed that irrigation in boiling stage increased activity of the enzyme di-hydroxy Guanuzyn, glutathione peroxidase, superoxide dismutase also, production of the total phenol, total flavonoid and biomarker of di-tyrosine. In this study, drought stress and application of Nitroxin fertilizer resulted in increased malondialdehyde in the first year. In both years, the application of Nitroxin with the recommended amount of urea fertilizer with sulphur coating resulted in an increase in total flavonoid and Glutathione Peroxidase enzymes. The purpose of this study was to investigate the effect of bacteria in the plant, along with the amount and sources of nitrogen fertilizer to reduce nitrogen fertilizer application on plant yield, as well as sustainable agriculture management through integrated nutrition in different plant conditions.
Keywords: *azospirillum, azotobacter, biomarker, total phenol*

Introduction

Calendula officinalis is a plant native to southern Europe and can be found in countryside fields. Calendula is an annual or sometimes biennial plant with erect stems up to 40-70 cm tall and deep taproot. It belongs to the Asteraceae family, its English name is Marygold. It is one of the well-known medicinal plants today, flowers and essential oils are used in pharmaceutical and cosmetic industries. Pharmacological studies have confirmed that flowers have a large amount of biological effects and pharmacological activity of the liver and antispasmodic protection (Arora et al., 2013).

Medicinal plants have high economical value due to the presence of effective compounds in them. An agricultural crop is economically valuable medicinal plant when secondary metabolites have reached the optimum level and the purpose of this plant is to exploit the effective ingredients in flowers, especially petals. Nitrogen is one of the elements that is lacking in most arid and semi-arid regions, because the amount of organic matter in these areas is very low as the main source of nitrogen storage or it decomposes rapidly due to high heat (Saneoka, 2004). If available nitrogen is toxic or deficient for the plant, the vital processes of the plant cause a disorder that may occur in various forms such as high growth, reduced transpiration, or even cessation of reproductive growth (Saneoka, 2004). Since most nitrogen fertilizers are wasted shortly after consumption, nitrogen management as well as crop should be done accurately during the growing season. In the meantime, Sulphur Coated Urea fertilizer (S.C.U.) on the one hand is a supplier of nitrogen and on the other hand, it is very important to pay attention to the valuable role of sulphur in plant nutrition and the improvement of agricultural soils, especially in our country, which accounts for over 70% of calcareous agricultural land and high pH (Moallem and Eshghizadeh, 2007). One of the basic pillars of sustainable agriculture is the use of bio-fertilizers in crop ecosystems with a view to eliminating or reducing the use of chemical organs (Shubbra et al., 2004). These bacteria, in addition to the role of elemental absorption, reduce disease, improve soil structure, stimulate more plant growth, increase product quality and quantity, and increase resistance to environmental stress (Nagananda et al., 2010). Drought is the most important limiting factor for plant growth and crop production around the world (Abedi and Pakniyat, 2010).

Dehydration also reduces water absorption by plant root system, reducing transpiration, reducing Stomatal conductance and photosynthesis, as well as breaking the hormonal balance of the plant (Auge et al., 2015). Superoxide dismutase is very important for plant tolerance to oxidative stress, which has been reported by many researchers (McKersie et al., 2000). Therefore, superoxide dismutase seems to be at the forefront of oxidative stress protection and the increase of superoxide dismutase is correlated with increasing the protection of damages from environmental stresses (Pang et al., 2005; Sigaud-Kutner et al., 2002). In a study, drought stress resulted in an increase in antioxidants in an *Calendula officinalis* plant (Sedghi et al., 2012). Oxidative stress during drought stress and increased free radicals by reducing the antioxidant defense results in damage to tissues, lipids, proteins and nucleic acids, and the concentration of biomarkers such as malondialdehyde, di-tyrosine and di-hydroxy Guanuzyn increased (Jose et al., 1999). Data were analyzed using (SAS) statistical software (v.9.12) and the meanings were compared by Duncan's multiple range tests at the 5% level. Draw charts with Excel (2010) software. Considering the above, the purpose of this study was to investigate the effect of application of Bio-fertilizers along with fertilizers of the hunchback on physiological characteristics of an ever-spring medicinal plant under stressed water conditions.

Materials and methods

In order to evaluate the effect of application of biological fertilizers and different amounts of urea fertilizer under low water stress conditions on physiological

N1: non-consumption (control), N2: 75% of the recommended amount of urea fertilizer with sulphur coating, N3: recommended amount of urea fertilizer with sulphur coating, N4: (common form) recommended amount of urea fertilizer, S1: (control) lack of water stress, S2: irrigation interruption during boiling stage, B1: (control) no use of biological fertilizer, B2: Azotobacter, B3: Azospirillum, B4: Azot and Azos

Test site located at latitude 35.19 degrees east longitude 51.39 and the altitude is 1050 m above sea level, with dry and desert weather conditions, and steppes with an average annual precipitation of about 175 mm. The experiment was split-split plot based on randomized complete block design with three replications. The experimental treatments included different levels of dehydration as the main factor in two levels (lack of water stress (control), irrigation interruption during boiling stage) levels of biological fertilizers at four levels as a sub-agent (no use of biological fertilizer, application of *Azotobacter chroococcum*, application of *Azospirillum brasilense*, combination of Azotobacter and Azospirillum (Nitroxin) and urea fertilizer sources in four levels as a subtype (non-consumption (control), recommended amount of urea fertilizer with sulphur coating, 75% of recommended amount of urea fertilizer with sulphur coating, was recommended as the most common form (mentioned area) of urea fertilizer (The amount of fertilizer usage based on fertilizer suggestion, 157 kg/ha^{-1}).

Inoculation of seeds took place with bio-fertilizer by (CFU) method (Bapat et al., 2006). Before planting, to determine the physical and chemical characteristics of the soil, from 0-30 cm depth and 30 to 60 cm soil, two locations for sampling were carried out, the full specifications of which are given in *Table 2*. After the leveling of the land, a 6×2 m plot was made, each plot having six rows and a row spacing of 30 cm and a spacing of 10 cm. The cultivation took place in the first week of June. The first drip irrigation was carried out after planting and until the emergence stage, irrigation was carried out with 3-day courses. After emergence of the seeds, the irrigation interval increased to 5 days and continued to 7-8 leaf stage. After the shrubs were fully deployed, at the beginning of budding, the irrigation was stopped for 10 days (Varamin district, Tehran province). The amount of fertilizer application was based on soil test.

After harvest, the specimens were transferred to the laboratory to measure the traits and there are traits such as total phenol, total flavonoid, di-hydroxy Guanuzyn enzyme, glutathione peroxidase, superoxide dismutase, malondialdehyde biomarker and di-tyrosine were measured. To determine the amount of superoxide dismutase, Sairam et al. (2001) method was used. To prepare the reaction mixture of 13 ml of methionine, 25 µM of Nitroblutterazolium, 6 µM of 0.5 (MEDTA) solution, 1.5 ml of a solution of 1 M buffer phosphate (pH = 7.8), 60 mM Molybucent riboflavin and 50 mM sodium bicarbonate. Then, 2.9 ml of the resulting mixture was poured into a sterilized tube, immediately after adding 2 µM of riboflavin and 0.1 ml of the enzyme extract, for 15 min, a fluorescence lamp of 15 × 2 watts was placed.

Table 2. *Soil field characteristics*

B (ppm)	Mn (ppm)	Cu (ppm)	Zn (ppm)	Fe (ppm)	K (ppm)	P (ppm)	N (%)	OM (%)	OC (%)	TNV (%)	pH	EC ($dS.M^{-1}$)	Silt (%)	Sand (%)	Clay (%)	Type of experiment

C: Clay, S: Sand, S: Silt, EC: Electrical Conductivity, TNV: Total Neutralising Value, OC: Organic Carbon, OM: Organic Matter, N: Nitrogen, P: Phosphorus, K: Potassium, Fe: Iron, Zn: Zink, Cu: Copper, Mn: Manganese, B: Boron

To determine the amount of activity of the superoxide dismutase enzyme in the mixture, Spectrophotometer was measured at 560 nm at 23 ± 2 °C spectrophotometry (to measure, 5 leaves from each line was cultivar, in the morning they were harvested from the field). The amount of enzyme changes was determined by Paglia (1997) to calculate the Glutathione Peroxidase enzyme (2 leaves of plant from each line). Di-hydroxy Guanzine assay was performed according to the method (fresh plant tissue (leaf) was homogenized by homogenization and then centrifuged at 5000 rpm for 60 minutes with a centrifugal machine) (Bogdanov and Bical, 1999). Measurement of malondialdehyde and di-tyrosine was determined by the method (The extract used to measure 8-oH-dG is based on the thiobarbetabic acid method with MDA) (Steven and Joseph, 1978). The absorption rate of Flavonoids was measured by Krizek et al. (1993) at three wavelengths of 300, 330 and 270 using the (RAY LEIGH UV 1601) spectrophotometer (24 g samples of dried petals were needed). Also, total phenol measurements were dried by extraction of flower samples and at a rate of 2 g of dried matter *Calendula officinalis* (Extraction of polyphenols from flowers collected using the company protocol Naturalin (Professional of Natural Ingredients)). Data were analyzed using (SAS) statistical software (v.9.12) and the meanings were compared by Duncan's multiple range tests at the 5% level. Draw charts with Excel (2010) software.

Results and discussion

Total phenol

In both years of experiment, the effect of drought stress (S), biological fertilizer (B) and urea fertilizer (N) on this trait was significant at 1% level (*Table 3*). Drought stress in both years of experiment led to a significant increase in this trait. So that the Total Phenol in stress conditions increased 8.3% and 8% in the first and second years respectively (*Table 4*). The application of Nitroxin biological fertilizer in both years led to a significant increase in Total Phenol the Total Phenol in terms of Nitroxin

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_48134827

application increased 19.2% and 14.8% in the first and second year respectively (*Table 5*). Also, application of recommended amount of urea fertilizer with sulphur coating and recommended amount of urea fertilizer in both years of experiment resulted in significant increase of Total Phenol (*Table 6*). High antioxidant Phenolic compounds such as anthocyanin and Flavonoids play a major role in plant resistance to stress and reduce the damage caused by it (Nasibi, 2005; Prasad, 2002).

Total flavonoid

In both years of experiment, the effect of drought stress (S), biological fertilizer (B) and urea fertilizer (N) sources on 1% was significant on Total Flavonoid. Also, in the first year of effect (B×N) at 1% level and in the second year at 5% level, this significant trait was significant (*Table 3*). Drought stress in both years of the experiment led to a significant increase in this trait. The total flavonoid in stress conditions increased 11.4% and 9.6%, respectively, in non-stress during the first and second years (*Table 4*).

Comparing the average interactions of biological fertilizers and urea, the results showed that in the first year, the highest total flavonoid in the treatment of Azotobacter and Azospirillum (Nitroxin) and the recommended amount of urea fertilizer (21.91 mg/g dry extract) and combined treatment Azotobacter and Azospirillum (Nitroxin) and application of recommended amount of urea fertilizer with sulphur coating (22.57 mg/g dry extract). In the second year under Nitroxin application, the use of all three sources of urea fertilizer resulted in an increase in total flavonoid (*Table 7*). Flavonoid antioxidants have a protective effect during dry stress. Many Flavonoids are active ingredients in medicinal plants and have medicinal properties. As active physiological compounds, stress-protecting agents and as absorbents play an important role in plant resistance (Tattini et al., 2004).

Di-hydroxy guanuzyn enzyme

In both years of experiment, the effect of drought stress (S) on the level of 1% was significant on the amount of Di-hydroxy Guanuzyn enzyme (*Table 3*). Drought stress in both years of the experiment led to a significant increase in this trait. The di-hydroxy Guanzine enzyme in stress conditions increased 10.6% and 10.2% in non-stress during the first and second years respectively (*Table 4*). Increasing the amount of di-hydroxy Guanuzyn increased production of superoxide radicals as a result of the occurrence of oxidative stress in the plant. Increasing of di-hydroxy Guanosine under drought stress indicates damage to plant synthetic structures and destruction of nucleic acids (Wenho and Russel, 2000). The results of Davoudi Fard et al. (2012) indicate a significant increase in di-hydroxy Guanuzyn due to drought stress.

Glutathione peroxidase enzyme

In both years of experiment, the effect of drought stress (S), biological fertilizer (B) and urea fertilizer (N) sources on Glutathione Peroxidase enzyme activity was significant at 1% level. Also in the first year of effect (B×N) at 5% level and in the second year at 1% level this trait was significant (*Table 8*). Drought stress in both years of the experiment led to a significant increase in this trait so that the activity of Glutathione Peroxidase enzyme in stress conditions increased 56.6% and 56.2%, respectively, compared to non-stress conditions in the first and second year (*Table 9*). Results showed that in both years, the effect of Glutathione Peroxidase in the treatment of Azotobacter and Azospirillum (Nitroxin) and application of recommended amount of urea fertilizer with sulphur content was highest (*Table 7*).

One of the mechanisms can increase the tolerance of the plant to stress, by activation of antioxidant systems. A large number of physiological disorders in plants are due to the increased production of active oxygen species due to environmental stresses such as drought (Sgherri and Navari-Lzzo, 1995; Zhang and Kirkham, 1994; Miller et al., 2010). Since one of the common effects of drought stress, like other environmental stresses, is primarily oxidative damage (Chen, 2000), plants to cope with oxidative stress and overcome these active species, antioxidant defense system with enzymatic and non-enzymatic mechanisms such as superoxide dismutase, catalaze..., along with a number of non-enzyme antioxidants such as Ascorbic acid, Glutathione, Alpha-tocopherol, and Cartenoids constitute the bulk of this defense system (Nasibi, 2005; Prasad, 2002). The results of Sedghi et al. (2012) indicate that antioxidant enzymes increase the activity of drought stress in an evergreen plant.

Enzyme activity of superoxide dismutase

The results of analysis of variance showed that in both years the effect of drought stress (S) on 1% level was significant on the activity of the enzyme superoxide dismutase (*Table 8*). Drought stress in both years of the experiment led to a significant increase in this trait. The level of enzyme activity of superoxide dismutase in stress conditions increased to 85.7% and 100.6% in the first and second year respectively (*Table 9*). Kawakami et al. (2010) reported that superoxide dismutase enzyme activity increased significantly under drought stress. In this regard, drought stress has been reported to increase the activity of superoxide dismutase in wheat (Tian and Lei, 2007) and rice (Sharma and Dubey, 2005). The results of Sedghi et al. (2012) indicate increased activity of the enzyme superoxide dismutase due to drought stress.

In each column, the same letters indicate that there is no significant difference between the mean of the treatments

Biomarker malondialdehyde

In both years of experiment, the effect of drought stress (S), biological fertilizer (B) and urea (N) fertilizer sources on 1% level was significant on malondialdehyde

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_48134827

biomarker. Also in the first year of interaction (B×N) at 5% level and in the second year of effect (B×N) and (S×N) at 1% level, this significant trait was significant (*Table 8*). Application of recommended amount of urea fertilizer with sulphur coating in both years of experiment resulted in significant increase of this trait. So, the amount of biomarker of carotene Dialledium in application of recommended amount of urea fertilizer with sulphur coating increased 61.2% and 60%, respectively, compared to control treatment in the first and second year. In the first year, there was no significant difference between the application of the recommended amount of urea fertilizer with sulphur coating and the application of the recommended amount of urea fertilizer in this regard (*Table 6*).

Comparison of the mean interactions of drought stress and biological fertilizer showed that in the first year of experiment, the highest trait in terms of stress and the combination of Azotobacter and Azospirillium (11.99 Nmol/mg protein) and stress and application of Azospirillum (59.11 nmol/mg^{-1} protein) was obtained (*Fig. 1*). Comparing the mean interactions between drought stress and urea fertilizer sources, the highest biomarker of calcium diphtheria was obtained in the second year under stress conditions and application of recommended amount of urea fertilizer with sulphur coating (5.43 nmol/mg protein) and the lowest in terms non-stress and non-use of urea fertilizers were obtained (*Fig. 2*). Results showed that in the second year, the combination of Azotobacter and Azospirillum (Nitroxin) with three sources of urea fertilizer resulted in a significant increase in this trait (*Fig. 3*). Many plants, when placed in a dry environment, are injured seriously and increase their malondialdehyde content (Grmaetxe, 1998; Saneoka, 2004).

There are reports of reduced malondialdehyde due to the maintenance of membrane lipids from damage induced by free oxygen radicals (Ozdamir et al., 2004). The results of Davoudi Fard et al. (2012), (Pan et al., 2006), (Zhang et al., 2006), (Habibi et al., 2009) and (Li Wen et al., 2006) indicate a significant increase in malondialdehyde due to drought stress.

Biomarker di-tyrosine

In both years of experiment, the effect of drought stress (S) and biological fertilizer (B) on the amount of di-tyrosine biomarker was significant at 1% level (*Table 8*). Drought stress in both years of the experiment led to a significant increase in this trait. So, the amount of biomarker di-tyrosine in stress conditions increased 10.9 and 15.7% in non-stress during the first and second years respectively (*Table 9*).

The application of Nitroxin biological fertilizer in both years led to a significant reduction in the amount of di-tyrosine biomarker. The highest amount of this trait was obtained every two years in non-use of biological fertilizers. In the second year, there was no significant difference between the absence of Bio-fertilizer application and Azotobacter application (*Table 5*). The results of Davoudi Fard et al. (2012) indicate a significant increase in di-prozine due to drought stress. In this study, the use of Bio-fertilizer resulted in the reduction of this trait.

This is consistent with the findings of Davoudi Fard et al. (2012). This conclusion is likely to indicate that bacteria reduce the effects of drought stress through another defense mechanism, which has been prevented from rising levels of Di-tyrosine and antioxidant enzymes. Because antioxidant enzymes activity is reported to be the only defense mechanism against free radical oxidants produced under stress conditions increasing proline can also reduce the free radicals produced under drought stress

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_48134827

conditions (Aktas et al., 2007). As a result, due to the reduction of the production of free radicals, the amount of protein degradation and, consequently, the production of biomarker of di-tyrosine is reduced (Jose et al., 1999).

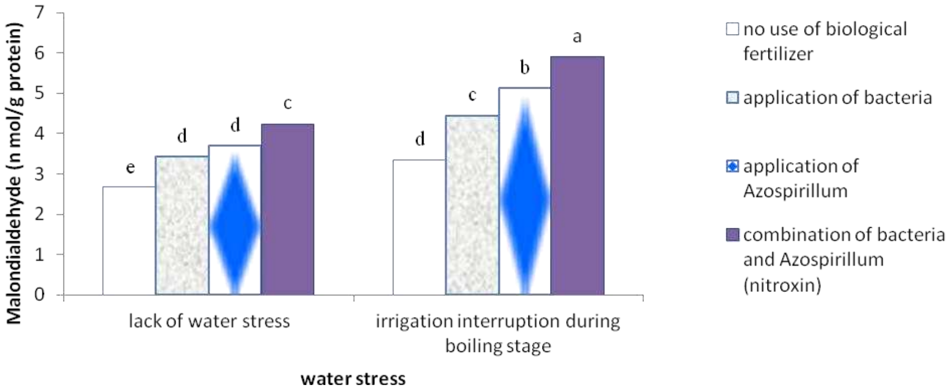

***Figure 1.** Effect of drought stress and biological fertilizer on malondialdehyde biomarker in the first year*

DOI: http://dx.doi.org/10.15666/aeer/1604_48134827

Overall conclusion

The results showed that irrigation cut in the boiling stage led to increases in the enzyme di-hydroxy Guanuzyn, glutathione peroxidase, superoxide dismutase, total phenol, total flavonoid and biomarker di-tyrosine. In general, the use of Nitroxin led to an increase in all of these traits except di-tyrosine.

The application of the recommended amount of urea fertilizer with sulphur coating resulted in an increase in total phenol and biomarker malonaldehyde. There was no significant difference between in malonaldehyde, application of recommended amount of urea fertilizer with sulphur coating and the usual form of recommended urea fertilizer. Whilst, results showed that in both years, the effect of Glutathione Peroxidase in the treatment of Azotobacter and Azospirillum (Nitroxin) and application of recommended amount of urea fertilizer with sulphur content was highest. Also, application of recommended amount of urea fertilizer with sulphur coating and recommended amount of urea fertilizer in both years of experiment resulted in significant increase of Total Phenol. In this study, drought stress and application of Nitroxin fertilizer resulted in increased malondialdehyde in the first year. In the second year, malondialdehyde was affected by the interaction of drought stress and urea fertilizer resources. Drought stress and application of recommended amount of urea fertilizer with sulphur coating resulted in increased malondialdehyde. In both years, the application of Nitroxin with the recommended amount of urea fertilizer with sulphur coating resulted in an increase in total flavonoid and glutathione peroxidase enzymes. Comparing the average interactions of biological fertilizers and urea, the results showed that in the first year, the highest total flavonoid in the treatment of Azotobacter and Azospirillum (Nitroxin) and the recommended amount of urea fertilizer and combined treatment Azotobacter and Azospirillum (Nitroxin) and application of recommended amount of urea fertilizer with sulphur coating. In the second year under Nitroxin application, the use of all three sources of urea fertilizer resulted in an increase in Total Flavonoid. There was no significant difference between the recommended amount of urea fertilizer with sulphur coating and urea fertilizer with sulphur coating for Total Flavonoids. Future debate should promote the promotion of information and culture in the field of medicinal plants, as well as the expansion of international cooperation in medicinal plant science and technology, the protection of monolithic plant species, planning for the development of cultivation and domestication of species Important medicinal plants with economical value, the transfer and absorption of the advanced sciences and technologies of other countries in the field of medicinal plants.

(Received 17th May 2018; accepted 11th Jul 2018)

Abstract. The dynamics of the physical and chemical factors that regulate oceanographic processes on the continental shelf off the state of Maranhão (northeastern Brazil) was evaluated using a transect along São Marcos Bay (01°41'S-02°28'S and 43°47'W-44°13'W) in January, March, May, July and September 2014, with a total of seven sampling stations. Water samples were collected from the surface using a Van Dorn water sampler. The following hydrochemical variables were analyzed: water transparency (m), temperature (°C), salinity, conductivity (mS cm^{-1}), total dissolved solids (TDS, g L^{-1}), pH, dissolved oxygen (mg L^{-1}), turbidity (NTU), total suspended solids (TSS) and dissolved nutrients (phosphate, nitrite and silicate). The relationship between these variables and seasonality in the region [rainy season (January to June) and dry season (July to December)] were also evaluated. For data with normality and equal variances, a one-way analysis of variance (ANOVA) was used for the spatial and temporal comparisons of the physicochemical variables. Results showed that the spatial and temporal variability of the physicochemical variables analyzed in this study is associated with local dynamics governed by river discharge, tidal movements, currents and meteorological events. The fluvial transport from the rivers of the state of Maranhão and other freshwater sources in the Amazon region are apparently the major contributors responsible for the maintenance of nutrient availability on the Maranhão continental shelf.

The present paper aims to broaden the knowledge of the spatial and temporal variability in the physicochemical variables in continental shelves and adjacent waters the coast of Maranhão (North Brazil).
Keywords: *surface water masses, hydrochemical variables, spatial distribution, dissolved nutrients, biogeochemical activity, influence of the discharge freshwater*

Introduction

The continental shelf is an environment with strong biogeochemical activity due to matter transported from land combined with water-sediment interactions and processes of biological absorption, respiration and re-mineralization. Coastal waters receive sediments and discharge from freshwater and underground sources and are therefore more affected by human activities than the open ocean (Lefèvre et al., 2017).

Physicochemical variables are often used to characterize masses of water along continental shelves and adjacent coastal waters and are also important to the determination of biogeochemical processes in response to land and oceanic inputs (Braga et al., 2008). The dynamics of the physical and chemical factors that regulate oceanographic processes on the continental shelf off the state of Maranhão (northeastern Brazil) are not yet fully understood, especially those related to small-scale and medium-scale events governed by freshwater discharge, wave energy, trade winds, macro-tide patterns and the Intertropical Convergence Zone (ITCZ).

The seasonal cycle of the migration of the ITCZ in the tropical Atlantic reflects the behavior and position of surface currents (Stramma and Scott, 1999). The mesoscale circulation in the region of the continental shelf off the state of Maranhão is strongly influenced by the North Brazil Current, directly affecting the spread of the plume of the Amazon River (Nikiema et al., 2007). This cyclic phenomenon alters physicochemical properties and the concentration of nutrients in coastal waters of the São Marcos Estuarine Complex and controls the distribution and abundance of migrant fishing resources in the Gulf of Maranhão.

It is presumed that freshwater discharge from the São Marcos Estuarine Complex serves as an obstacle to the advance of lower temperature marine waters, while also exerting a strong influence on the input and redistribution of nutrients on the inner continental shelf. Thus, the determination of these variables would enable an understanding of the variability in the structure of surface water masses and contribute knowledge on the complex hydrodynamics of the Gulf of Maranhão.

The present paper aim to broaden the knowledge of the spatial and temporal variability in the physicochemical variables in continental shelf and adjacent waters the coast of Maranhão (North Brazil), associated with local dynamics governed by river discharge, tidal movements, currents and weather events.

Material and methods

Study area

The coastal region of the state of Maranhão is classified as being on the northern coast of Brazil, based mainly on the morphology of the coast, climate, oceanographic variables, sediment coverage and width of the continental shelf. This stretch of the coast has been subdivided into three sectors form corresponding to the coast of Maranhão on the eastern Amazonian coast, with a large number of small estuaries bordered by hills

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_48294847

formed by tertiary sediments of the Barreiras Formation, currently in complete regression (El Robrini et al., 2006). Mangroves occur in protected areas, accentuating the irregularities of the coastline and generating broad tidal plains (Mochel and Ponzoni, 2007).

The coast of Maranhão extends 640 km, with a wide continental shelf and relatively shallow waters under the influence of the discharge of a large number of rivers. The physical characteristics of the coastline enable a division into two distinct parts. The first extends from the border of the state of Pará to Tubarão Bay and is characterized by a low coast of mangroves and deep indentations forming a series of bays and estuaries (denominated the *Reentrâncias Maranhenses*). The second area extends from Tubarão Bay eastward to the mouth of the Parnaíba River. In this area, the coastline is regular and part is covered by a vast area of sand dunes, denominated the *Lençóis Maranhenses*.

The Gulf of Maranhão is located in the center of the coast and is where São Luís Island is located, which separates the gulf into two large bays. São Marcos Bay lies to the west, which is an active estuary where the Mearim and Pindaré Rivers converge. The most intense tides are recorded in the mouth of this bay. São José Bay to the east of the island is a region with shallow depths that receives waters from the Itapecuru and Munim rivers (Silva et al., 2018). Off the Gulf of Maranhão, the continental shelf has a mean width of 150 km and depths less than 45 m, reaching a depth of 75 m near the break of the shelf and dropping abruptly to 2.000 m at the base of the continental slope (Silva and Alvarenga, 1994).

The Maranhão continental shelf can be classified as a high-energy region due to the combined effects of the coastal currents generated by different hydrodynamic forces, such as tides, waves, trade winds and the discharge of the Itapecuru/Munim rivers and Pindaré/Mearim rivers that respectively form the São José Estuarine Complex and São Marcos Estuarine Complex. The volume transported from the Pindaré/Mearim Rivers to the São Marcos Estuarine Complex corresponds to 10 km^3 per year (Jennerjahn et al., 2010), with maximum discharge occurring in March/April, which is the peak of the rainy season.

Data collection

Data were obtained from a transect determined in São Marcos Bay (01°41’S-02°28’S and 43°47’W-44°13’W) in January, March, May, July and September 2014, involving seven sampling stations (*Fig. 1*). Station 1 was located near the city of São Luís and Station 7 was located on the continental shelf before the 50-meter isobath at approximately 100 km from Station 1.

Water samples were collected from the surface using a van Dorn hydrographic bottle. The following hydrochemical variables were determined in the field: water transparency, measured by the depth of the disappearance of the Secchi disk (m); temperature (°C), salinity (g kg^{-1}), conductivity (mS cm^{-1}), total dissolved solids (TDS, g L^{-1}) and pH, using a HANNA HI-9828 multiparameter probe; dissolved oxygen (mg L^{-1}), using a HANNA HI-9146 oximeter together with the Winkler analytical method, as cited in Strickland and Parsons (1972); and turbidity (NTU), using a Tecnopon TB1000® turbidity meter. For the determination of total suspended solids (TSS), water samples were kept refrigerated at -4 °C until filtered and analyzed in the laboratory. TSS (mg L^{-1}) was measured using the gravimetric method, as described in APHA

DOI: http://dx.doi.org/10.15666/aeer/1604_48294847

(2001). Dissolved nutrients (phosphate, nitrite and silicate) were determined using the method described by Grasshoff et al. (1999).

Climatologic data were acquired from the databank available by INMET (Brazilian Meteorological Institute) recorded by the São Luis meteorological station.

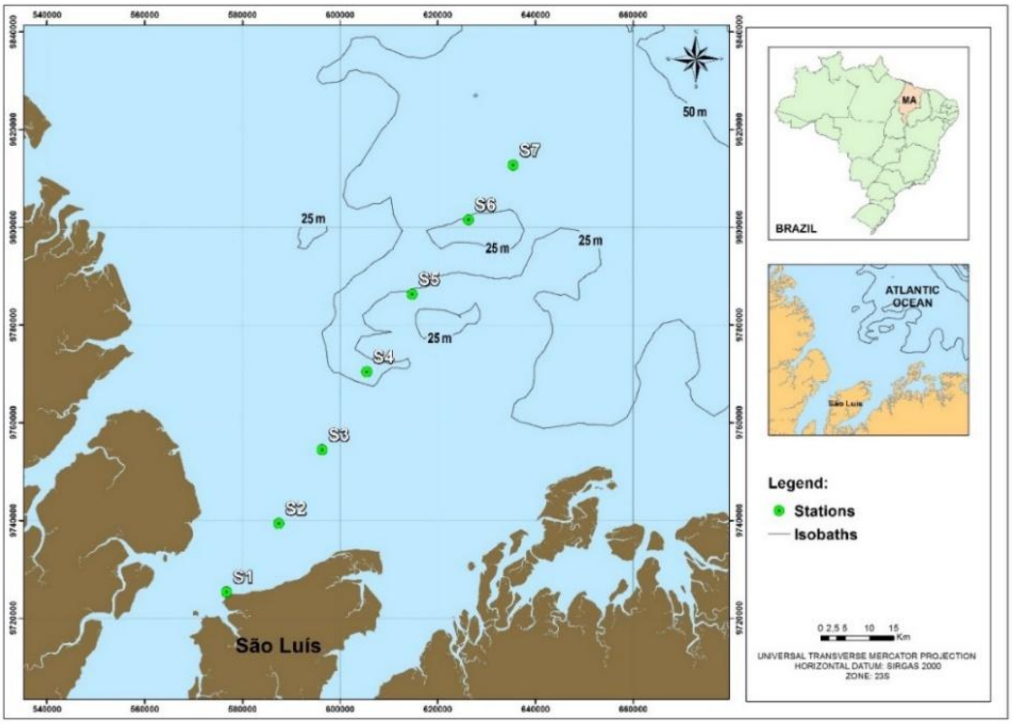

Figure 1. *Location of sampling stations along transect on continental shelf off state of Maranhão*

Data analysis

The physical and chemical variables were expressed as mean, standard deviation, minimum and maximum values determined for each sampling period. The relationship between these variables and seasonality in the region [rainy season (January to June) and dry season (July to December)] were also evaluated. The Shapiro-Wilk test and Levene's test were used to determine the normality of the data distribution and equal variance, respectively. For data with equal variances, one-way analysis of variance (ANOVA) was used for the spatial and temporal comparisons of the physicochemical variables. In cases for which the null hypothesis of variance was rejected, a multi-comparison test (Tukey's test) was used to identify which pairs of means differed significantly. For data with unequal variances, the spatiotemporal comparisons were made using the Kruskal-Wallis (H) test, followed by the Mann-Whitney U test when the null hypothesis was rejected. Principal component analysis was used to identify the main components responsible for the variations in the data on the Maranhão continental shelf, using the correlation matrix as the basis. The significance of Pearson's correlation table was calculated using a two-tailed *t*-test with two degrees of freedom. Excel 2010 and PAST 3.14 were used for the data analysis as well as the creation of the graphs and tables (Hammer et al., 2001). The statistical analyses were evaluated for a critical significance level of $\alpha = 0.05$ (Zar, 2010).

Results

Hydrological conditions

The accumulated monthly rainfall for 2014 at Station 1 showed values always higher than 100 mm in the months of January to June (*Fig. 2*). In the oceanic region, the precipitation followed the same seasonal cycle compared to the coastal region, with usually slightly lower accumulated rainfall values. The INMET data gave higher rainfall during the wet season. The wet season was associated with the presence of the ITCZ located at its southernmost position in March-April.

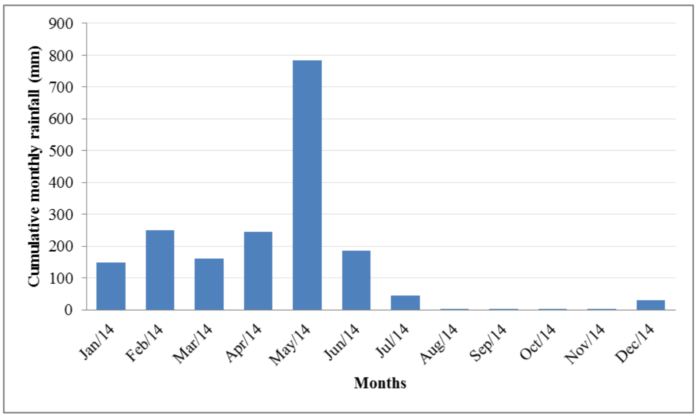

Figure 2. *Accumulated monthly rainfall for 2014 at Station 1 (São Luís, Maranhão). (Source: BDMEP, INMET)*

Abiotic variables

Table 1 displays the mean, standard deviation, maximum and minimum values for the physical and chemical variables of the surface waters measured on the Maranhão continental shelf. Water surface temperature ranged from 27.37 °C to 30.33 °C, corresponding to the wet and dry seasons, respectively (*Fig. 3a*). The mean for all months analyzed was 28.7 °C, which reflects the characteristic of the equatorial region, with small horizontal variations, mean amplitude of approximately 1 °C in the rainy season and 2 °C in the dry season. In statistical terms, temperatures were significantly lower in September 2014 ($H = 14.59$; $p < 0.0001$), but with no significant differences among the different sampling stations ($F = 1.61$; $p > 0.05$).

The spatial distribution of salinity (*Fig. 3b*) ranged from 25.95 g kg^{-1} to 38.08 g kg^{-1} throughout the study. The means per station were 30.98, 32.11, 34.64, 35.39, 35.91, 36.28 and 36.14 g kg^{-1} for S1, S2, S3, S4, S5, S6 and S7, respectively.

A progressive increase in salinity was found with the increase in distance from the coast, with significantly higher values at Stations 5, 6 and 7 in comparison to Station 1 ($F = 4.22$; $p < 0.05$. Mean salinity was 35.04 g kg^{-1} in the rainy season and 33.68 g kg^{-1} in the dry season, with significantly higher values in January 2014 ($Hc = 16.33$; $p < 0.0001$). In May 2014, the lowest salinity was found at Station 1 (25.95 g kg^{-1}), which contributed to the mean value in the rainy season (32.2 g kg^{-1}) and coincides with the period of greater rainfall intensity in the region, with an accumulated rainfall of 784.3 mm in May 2014. The highest mean salinity was found in January 2014 (36.72 g kg^{-1}), which was likely due to the low rainfall in the final trimester of the previous year.

On the Maranhão continental shelf, total dissolved solids (TDS) ranged from 20.51 g L^{-1} to 29.90 g L^{-1}, with means of 25.62 g L^{-1} and 26.83 g L^{-1} in the dry and rainy seasons, respectively (*Fig. 3c*). In statistical terms, TDS demonstrated similar patterns to salinity, with higher concentrations in January 2014 ($F = 6.05$; $p < 0.00$). The value at Station 2 was significantly lower in comparison to the values found at Stations 4, 5, 6 and 7 ($F = 2.54$; $p < 0.05$).

The pH values remained basic, ranging from 7.65 to 8.47 throughout the study, with a mean of 8.01 in the rainy season and 7.88 in the dry season (*Fig. 3d*). Values were higher in January 2104 compared to March and September 2014 ($F = 5.97$; $p < 0.0001$).

Dissolved oxygen (DO) concentrations ranged from 3.67 mg L^{-1} to 5.01 mg L^{-1}, with a mean of 4.26 mg L^{-1} in the rainy season and 4.39 mg L^{-1} in the dry season (*Fig. 3e*). The seasonal and spatial distribution of DO demonstrated similar concentrations, indicating a homogeneous pattern for this variable throughout the Maranhão continental shelf.

Spatial distribution of total suspended solids (TSS) concentrations ranged from 0.40 mg L^{-1} to 163.00 mg L^{-1}, with mean concentrations from 23.37 mg L^{-1} in the rainy season to 48.70 mg L^{-1} in the dry seasons, with no statistically significant difference (*Fig. 3f*). Higher concentrations of TSS were found near the coast, with a progressive reduction toward oceanic regions, especially during the campaigns performed in the dry season. The highest concentration was 163.00 mg L^{-1} at Station 1, which differed significantly from all other stations ($H = 21.02$; $p < 0.0001$), except Station 2. The finding suggests the influence of inputs from the mainland combined with tide dynamics.

Turbidity ranged from 0.13 NTU to 80.00 NTU, with a mean of 15.51 NTU in the rainy season and 14.40 NTU in the dry season, demonstrating no significant seasonal

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_48294847

difference (*Fig. 3g*). A spatial gradient was found during all sampling campaigns, with greater turbidity near the coast (Stations 1 and 2) and a progressive reduction toward the oceanic region to values close to 0 ($H = 20.4$; $p < 0.0001$). Such a pattern was expected due to the influence of total suspended solids and organic matter due to river discharge and the influence of the estuarine plume.

The spatial distribution of nitrite in the surface waters of the Maranhão continental shelf showed a maximum of 0.50 μmol L^{-1}. The highest values were found in July 2014 ($H = 17.6$; $p < 0.0001$), probably due to the advance of the estuarine plume toward the continental shelf. This is corroborated by the increase in organic and inorganic mater demonstrated by the variations in TSS and turbidity, which were higher at the end of the rainy season. Nitrite concentrations were lower than 1 μmol L^{-1} at all sampling stations (*Fig. 3h*).

Phosphorus concentrations ranged from 0.03 μmol L^{-1} to 0.96 μmol L^{-1}, with a mean of 0.23 μmol L^{-1} in the rainy season and 0.35 μmol L^{-1} in the dry season (*Fig. 3i*). Small variations in phosphate concentration were found during the sampling campaigns, with significantly higher concentrations in May 2014 (0.52 ± 0.28 μmol L^{-1}) and September 2014 (0.55 ± 0.23 μmol L^{-1}) ($H = 22.5$; $p < 0.0001$), likely due to the contributions of river runoff and rainfall. In spatial terms, no significant differences were found throughout the sampling stations along the Maranhão continental shelf.

Silicate concentrations ranged from 0.08 μmol L^{-1} to 12.99 μmol L^{-1}, with a mean of 4.75 μmol L^{-1} in the rainy season and 3.82 μmol L^{-1} in the dry season (*Fig. 3j*). Although this transport is evidenced on the Maranhão continental shelf by the increase in rainfall, however no statistically significant difference was found ($F = 0.52$; $p = 0.72$), demonstrating a lack of seasonal heterogeneity with regard to the concentration of silicate. On the spatial scale, however, sampling stations closer to the coast (Stations 1 and 2) had higher silicate concentrations throughout all campaigns ($F = 14.83$; $p < 0.0001$), which was likely due to the strong influence of rainfall and river discharge. Data from the Analysis of Variance (*Table 2*) show the significance of the physicochemical variables in relation to the months and sampling sites.

In the principal component analysis of the environmental variables, the first two axes explained 58.3% of the variability in the data (*Fig. 4*). The significance of the axes was tested using the "broken stick" random model with 9999 bootstrap replicates (Jackson, 1993), which indicated that Components 1 and 2 were sufficient to represent the factorial variance.

Component 1 (41.1%) was positively related to turbidity, total suspended solids, silicate, dissolved oxygen and phosphate, with a tendency toward higher values in the rainy months (January, March and May) as well as at sampling sites closer to the coast, especially Stations 1 and 2. Although July and September are considered to be part of the dry season, both months apparently demonstrated the influence of adjacent drainage stemming from rainfall in the previous months, leading to the maintenance of high turbidity, suspended solids, DO, silicate and nitrite.

Component 1 was negatively correlated with TDS, conductivity, salinity and transparency, with an absence of a pattern in seasonal terms and an expected increase in values at sampling sites more distant from the coast (Stations 3, 4, 5, 6 and 7), which are characterized by greater transparency and dissolved minerals.

Component 2 (17.2%) was negatively correlated with phosphate (PO_4^{3-}) and pH. Phosphate was associated more with May and September. Moreover, the similar distribution throughout the sampling stations suggests the absorption of this nutrient,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_48294847

making its concentration quite homogeneous throughout the Maranhão continental shelf. pH was associated more with May, when the highest values were found, as well as sampling sites more distant from the coast (Stations 5, 6 and 7), which is an expected pattern due to the alkaline tendency of oceanic water.

Table 2. *Results of ANOVA the physicochemical variables in the spatial temporal scale. The equal letters represent statistical similarity at the level of 5% of significance, considering each one of the parameters in function of the months and the sampling stations*

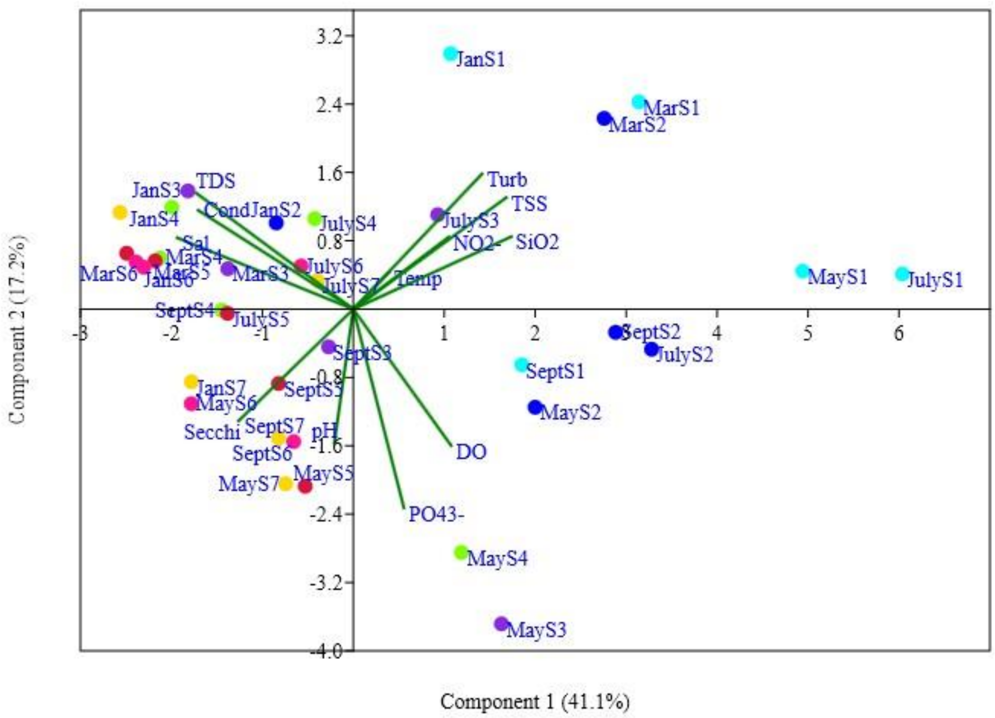

Figure 4. *Principal component analysis of environmental variables sampled on Maranhão continental shelf. Turb = turbidity, TSS = total suspended solids, Temp = temperature, DO = dissolved oxygen, Secchi = transparency, Sal = salinity, Cond = conductivity, TDS = total dissolved solids*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_48294847

In the correlation analysis of the environmental variables (*Table 3*), salinity, TDS and conductivity had the largest number of significant correlations with other variables and were positively correlated with transparency and negatively correlated with DO, TSS, silicate, phosphate and nitrate. Silicate was negatively correlated with transparency (r = -0.53) and positively correlated with both turbidity (r = 0.79) and TSS (r = 0.74), confirming the influence of river discharge and rainfall, with higher concentrations of silicate at sites closer to the coast. Nitrite was positively correlated with DO (r = 0.38) and TSS (r = 0.57), which demonstrates its contribution to the increase in biological activity associated with primary productivity and a greater concentration of particulate matter.

Discussion

The distribution of surface temperature in the ocean is approximately zonal and temperature isolines approximately follow latitude parallels, reaching around 28 °C just north of the equator and diminishing to -2 °C at polar latitudes (Pickard and Emery, 1990). Evidence indicates that inter-annual variability in surface water temperature in the tropical Atlantic occurs more due to local dynamics and interactions with the ocean-atmosphere interface than external perturbations, such as those caused by the El Niño-Southern Oscillation (Hameed et al., 1993; Hastenrath and Greischar, 1993).

Eschrique (2011) found that temperatures demonstrated typical characteristics of the northeastern region of Brazil, with high values throughout the year and stability regarding the period and degree of solar radiation in tropical regions. In studies conducted on the continental shelf off the state of Pará on the border with the state of Maranhão, Nogueira Neto (2013) found surface temperatures around 29.50 °C. Silva et al. (2007b) found a temperature of 28.50 °C in the dry season in an oceanic area adjacent to the Maranhão continental shelf. In studies conducted in the coastal zone of the state of Pará, Martorano et al. (1993) report that high temperatures are typical of equatorial environments, describing a range between 22 °C and 30 °C and monthly means ranging from 24 to 28 °C.

The salinity range is greater in regions that receive with large volumes of river discharge. The influence of the rivers, together with rainfall, are the main factors responsible for the dynamics of the salinity gradient in the region, which is also strongly affected by the discharge from the Amazon river (Silva et al., 2007a; Araujo et al., 2011). Santos et al. (2008) found a range of 2.49 g kg^{-1} to 36.17 g kg^{-1} along the plume of the Amazon River, with lower values in coastal regions closer to the mouth of the river and higher concentrations in areas more distant from the coast, confirming the enormous influence of the Amazon River on equatorial marine waters. Different behavior is found on the Maranhão continental shelf during the dry season, when rivers contribute very little to the fluvial volume. This explains the increase in salinity at sampling stations closer to the coast due to the oceanic characteristics of tropical water. The increase in the evaporation rate, low river input and high surface water temperatures are directly associated with the intrusion of more saline oceanic water on the Maranhão continental shelf (Pontes and El-Robrini, 2008).

The spatial and seasonal distribution of electrical conductivity demonstrated a similar pattern to that found for salinity, which confirms the correlation between these two variables described by Millero (2006), who states that condumetric ratios have the same proportion as salinity, even if the composition of the salts in surface waters differs. Conductivity depends on concentrations of ions and indicates the amount of salts in water, increasing with the increase in the amount of dissolved solids and demonstrating a close relationship with salinity.

With regard to total dissolved solids (TDS), an understanding of the diverse processes involved enables the identification of interferences in hydrodynamics, affecting tide propagation and the dispersion of suspended nutrients and matter from the mainland basin to the ocean (Vilela, 2011). According to Tundisi and Matsumura Tundisi (2008), all minerals in the water are part of the TDS, including non-ionic components and dissolved organic compounds. Therefore, this variable has a direct and proportional correlation with electrical conductivity due to the concentration of ions, as demonstrated in the present study, in which TDS demonstrated quite similar spatial distribution to that found for salinity and conductivity.

The variable pH is governed by tidal cycles and photosynthesis and/or respiration rates. In aquatic ecosystems, a process of neutralization occurs due to the buffer effect, which maintains pH in a stable balance, with maximum values obtained in environments with greater salinity (Macêdo et al., 2000). Although no significant spatial differences were found, the pH was slightly lower at sampling stations closer to the coast, likely due to the input of freshwater, which has more acidic characteristics stemming, above all, from the large quantity of dissolved organic acids, such as sulfuric, nitric, oxalic, acetic and carbonic acids made available by the metabolic interactions of microorganisms in aquatic environments (Esteves, 2011). The gradual increase in pH toward the open ocean corresponds to carbonate and bicarbonate reactions, which dissociate and increase the alkalinity of surface waters. Santos et al. (2008) found pH values ranging from 7.46 to 8.56 in a transect influenced by the plume of the Amazon River and lower variability in oceanic regions (8.13 to 8.44), which is in agreement with the present study, as pH demonstrated smaller variations at sampling stations located more distant from the coast.

Carvalho et al. (2016) evaluating the phytoplanktonic composition in the continental shelf of Maranhão, also analyzed several physical and chemical variables, however, with a unique seasonal approach (rainy season and dry season). For the present study,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_48294847

the approach was taken on a spatial-temporal scale, however, without necessarily grouping the exclusively rainy and dry months, in order to try to show other influencing factors, for the physical and chemical dynamics on the continental shelf of Maranhão.

According to Millero (2006), this relative stability is characteristic of the Atlantic Ocean, unlike records for the Pacific Ocean, for which a range of 7.2 to 8.2 is described.

In tropical coastal regions, the concentration of dissolved oxygen (DO) in the surface layer is subject to rapid fluctuations influenced by external agents, such as river inputs, rainfall, evaporation, winds and tidal patterns, whereas photosynthetic production can contribute to an increase in DO concentrations in the open ocean (Demaster et al., 1996; Santos et al., 2008; Macêdo et al., 2009). In studies conducted in the region of the Saint Peter and Saint Paul Archipelago within the scope of the REVIZEE [Live Resources of the Exclusive Economic Zone] Program, Becker (2001) found minimum and maximum DO values of 2.56 and 4.41 mg L^{-1}, respectively. DO levels ≤ 4 mg L^{-1} in natural waters favors anaerobic processes, which produce a large amount of reducing substances that consume a large quantity of the available oxygen for their oxidation (Esteves, 2011).

With regard to suspended particulate matter, the influence of the tide, geomorphology of the coast and outflow bathymetry in shallow coastal environments are determinants of the re-suspension process. In the present study, Stations 1 and 2 were subject to a greater influence of tidal flow, producing higher TSS values, with lower values at sampling stations more distant from the coast. According to Millero (2006), the decrease in the frequency and intensity of the agitation of bottom layers and the emergence of inorganic and biological reactions in oceanic regions lead to a reduction in suspended particulate matter and more stable TSS values. The values found in the present study were higher than those reported by Souza et al. (2003) in the coastal zone of the continental shelf off eastern Brazil. The authors recorded the distribution of suspended solids in two sampling campaigns conducted off the states of Sergipe, Bahia, Espírito Santo and Rio de Janeiro, with TSS values of 13 mg L^{-1} in the dry season and 90 mg L^{-1} in the rainy season.

On the Maranhão continental shelf, contrary to the expected behavior, the concentration of TSS was greater in the transition between the rainy and dry seasons, with a maximum value in July 2014. This increase may be explained by the periodic dragging of the canals that offer access to the Itaqui port complex, which invariably redistributes the sediment stored on the bottom to the surface layer, thereby contributing to an increase in the concentration of TSS in regions closer to the coast, which are subsequently transported by tidal currents and/or winds to other compartments of the Maranhão continental shelf.

Suspended solids are directly related to turbidity, water transparency and primary productivity, as a greater amount of TSS results in greater turbidity and lower transparency (Macedo, 2003). An increase in the concentration of TSS exerts a direct influence on the reduction in the rate of photosynthesis due to the extinction of light in the photic zone and exerts an negative impact on the availability of food for some species, leading to an imbalance in the marine food chain. Moreover, suspended sediment can be contaminated with pesticides, heavy metals and other toxic substances, which can have a negative impact on the reproduction of fish and other species (Silva, 2006). Da Silva et al. (2009) found higher turbidity in the coastal zone of Maranhão, evidencing the influence of the estuarine sediment plume and the hydrodynamic energy of tidal forces, with the re-suspension of sediments in the water column leading to a

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_48294847

turbidity range of 14.80 to 39.29 NTU in the dry season and 55 to 200 NTU in the rainy season.

Dissolved inorganic nutrients (nitrite, phosphate and silicate) were recorded in the present study, as the occurrence of these nutrients indicates mainland inputs that affect primary production in marine environments. The allochthonous origin stems from processes such as atmospheric deposition, the infiltration of ground water by lixiviation, the entrance of marine water in estuaries and the flow of rivers, whereas the internal contribution is based mainly on the benthic and pelagic re-mineralization of organic matter. Understanding nutrient distribution patterns and marine biogeochemical cycles remains a considerable challenge (Conkright et al., 2000). Continental shelves are transition zones between the mainland and ocean with a large supply of particulate and dissolved matter stemming from river discharge (Nittrouer et al., 1995), where complex oceanographic processes co-occur on distinct spatial and temporal scales (Arndt et al., 2011).

The increase in biological activity associated with nutrient availability may be attributed to both biogeochemical processes and other oceanographic processes that cause the re-suspension of organic matter (upwelling, small vortices or internal waves), leading to an increase in biological production (Admiraal et al., 1990; Turner and Rabalais, 1994). Along the continental shelf, the spatial distribution of dissolved nutrients is controlled by vertical and horizontal mixtures caused by tides, waves and wind on the water surface (Sánchez-Arcilla and Simpson, 2002). The synergic action of these variables can cause an increase in dissolved nutrients and total suspended solids, thereby increasing primary production (Mann and Lazier, 1996). In coastal zones of tropical regions, estuarine systems serve as a storage site for suspended nutrients, which then become available to the adjacent continental shelf (Ovalle et al., 1999). For instance, Amazon coastal zone is potentiated by the abundance of mangroves and high hydrodynamic energy, creating a rich supply of dissolved nutrients directed to the continental shelf region (Demaster et al., 1996; Kineke et al., 1996; Nittrouer and Demaster, 1996; Pereira et al., 2010).

On the Maranhão continental shelf, nitrite values were low and very similar among all sampling stations ($F = 0.67$; $p > 0.05$), which is in agreement with data described by Demaster and Pope (1996) for various transects determined on the continual shelf of the Amazon. Low nitrite values are typical of tropical waters, except when resulting from re-mineralization, re-suspension of the bottom or input from rivers. Santos (2012) confirms this nitrite instability on the continental shelf off the northeastern region of Brazil, with mean values ranging from 0.02 to 0.05 µmol L^{-1}, which is characteristic of oligotrophic environments. In the period between the rainy and dry seasons (July 2014), an increase was found in the variation of nitrite concentrations, with a mean of 0.32 µMol L^{-1}. This increase can lead to an increase in biological production rates, a greater availability of suspended matter as well as increases in OD, TSS and turbidity, suggesting an increase in the photosynthetic rate and primary production at stations in oceanic regions. All these aspects contribute to an increase in the production of aquatic organisms in this period in regions more distant from the coast. In contrast, lower values were found in the dry season, as occurred in September 2014, when no nitrate was detected. Therefore, nitrate became more unstable in this period, favoring the development of bacterial oxidation, which increases the availability of ammonia. Pereira et al. (2012) report different behavior in a study conducted in the Amazon

coastal zone; the authors found mean nitrite values of 0.11 µmol L^{-1} at the end of the rainy season and 0.49 µmol L^{-1} in the dry season.

Phosphate concentrations fluctuate little in tropical estuaries. The mainland is the main source of these nutrients in the marine environment, with concentrations tending to diminish with the distance from the source (Eschrique et al., 2010). Monteiro et al. (2015) report values of 0.11 µmol L^{-1} to 1.08 µmol L^{-1} in an Amazonian estuary near the island of Marajó in the state of Pará. However, Lara and Dittmar (1999) found phosphate concentrations between 1.5 and 5.0 µM L^{-1} in a tidal channel in the municipality of Bragança in the same state. Pereira et al. (2012) found low concentrations (mean: 0.11 µmol L^{-1} in the rainy season and 0.92 µmol L^{-1} in the dry season) in a coastal environment in northeastern Brazil, demonstrating the low influence of seasonality on the final concentration of phosphate in this environment.

The rapid absorption of phosphate in oceanic areas by primary producers and bacteria explain its low concentration and availability. In the present study, concentrations were low at the majority of sampling stations. Ramin et al. (2012) and Eschrique et al. (2006) report that phosphate regeneration processes through re-mineralization, excretion by zooplankton and absorption by phytoplankton occur at an accelerated rate, making its residence time in oligotrophic waters extremely short (a matter of minutes) and making its particulate form the main compound found in oceanic waters. The coastal region of the Maranhão continental shelf, which is influenced by a large number of mangroves, is an important vehicle for the transport of nutrients to the oceanic region.

Scientific records describe a reduction in the concentration of dissolved nutrients from the estuary to the coastal region, favoring the development of mixture diagrams as a powerful tool for the characterization of nutrient removal processes from masses of water. According to Noernberg (2001), the transport of sediment through the coastal zone reaches an average of 15 nautical miles in the direction of the open sea, with the coastal environment the main redistribution route of nutrients to oceanic regions. Santos et al. (2008) found high nutrient concentrations in the rainy season at a distance of 120 km from the coast on the continental shelf off the state of Pará, with silicate as the most representative nutrient (range; 14.48 µmol L^{-1} to 108.59 µmol L^{-1}), confirming the considerable capacity and influence of Amazonian rivers in the distribution of this nutrient to the open ocean. In the present study, silicate demonstrated dispersion capacity through the plume of rivers, thereby reflecting the influence of transport from rivers to oceanic regions of the Maranhão continental shelf and giving this nutrient the greatest capacity for concentration and distribution in the area investigated.

The ordination analysis revealed the influence of river discharge and rainfall on the concentration patterns of different physicochemical variables, which is in agreement with data described by Pereira Filho et al. (2009). Pereira Filho et al. (2003) also report the influence of river discharge on the greater presence of nitrogenated nutrients, which are involved in the nutritional process of phytoplankton. Braga et al. (2008) report that the availability of phosphate is closely linked to the mainland input, with the influence of the Prata River and upwelling in the region of Cape Santa Marta in the state of Santa Catarina (southern Brazil). In the present study, the considerable outflow from the mainland, especially from the Mearim and Pindaré Rivers, and the macrotide conditions, with the capacity to transport nutrients from the mangroves, contributed greatly to the availability of phosphate on the Maranhão continental shelf, with means ranging from 0.05 µmol L^{-1} in January 2014 to 0.55 µmol L^{-1} in September 2014. Braga

et al. (2008) report similar figures for the Santa Catarina continental shelf, whereas Santos et al. (2008) report lower figures for the Amazon continental shelf.

Silicate is a potential tracer of sediment transported from rivers to oceanic regions, enabling the identification of the distribution caused by this flow (Braga et al., 2008). The analyses also indicate an association between silicate and sampling points closer to the coast, demonstrating negative correlations with salinity, TDS and conductivity, for which higher values were found at more external sampling stations along the Maranhão continental shelf. Ciotti et al. (1995) and Weber et al. (1994) also found a greater concentration of silicate in waters closer to the coast. Braga et al. (2008) describe freshwater and terrestrial inputs along the coast as being major contributors to the high concentrations of silicate on the southern/southeastern continental shelf in summer, which is in agreement with the present findings and demonstrates the importance of climate as a regulating agent for the availability of this nutrient. It is therefore important to maintain the levels of river outflow due to the transport of nutrients to the Maranhão continental shelf, which contribute to biological development as well as the maintenance of trophic, reproductive and developmental aspects of species and, consequently, fishing resources, which have dietary, economic and cultural importance to tropical cities in coastal areas.

Conclusion

The spatial and temporal variability in the physicochemical variables analyzed (transparency, temperature, salinity, conductivity, dissolved oxygen and suspended solids) is associated with local dynamics governed by river discharge, tidal movements, currents and climatologic events;

Very low salinity was associated with higher concentrations of nutrients, indicating the influence of terrestrial inputs to the Maranhão continental shelf, especially in areas closer to the coast.

Phosphate concentrations were similar throughout the sampling stations and lower than silicate concentrations. In turn, silicate concentrations were significantly higher in areas closer to the Gulf of Maranhão;

The highest nitrite concentrations were found in July 2014, soon after the period of greater rainfall in the region, demonstrating a direct association with mainland inputs and a greater biological production rate, as nitrite values were positively correlated with dissolved oxygen and total suspended solids;

The fluvial transport from the rivers of the state of Maranhão and other freshwater sources in the Amazon region are apparently the major contributors responsible for the maintenance of nutrient availability on the Maranhão continental shelf, where seasonal influences affect phosphate and nitrite availability, with higher concentrations during and soon after the rainy season. In contrast, silicate values are similar throughout the year.

It is recommended in future studies the increase of transects that would be simultaneously sampled to produce maps of the spatial distribution of physicochemical variables from two-dimensional interpolations (2D).

Acknowledgements. We acknowledge support from FAPEMA (Fundação de Amparo à Pesquisa e ao Desenvolvimento Científico e Tecnológico do Maranhão) and AIRD (Agence Inter-établissements de Recherche pour le Développement) BIOAMAZON project (grants 01739/2013 - AIRD_GUYMAZ). We also acknowledge the support of the Departamento de Oceanografia e Limnologia (DEOLI, UFMA) for kindly providing reagents and spectrophotometer time for nutrient analysis. In addition, we wish to thank two anonymous reviewers for constructive comments on the MS.

(Received 22nd May 2018; accepted 11th Jul 2018)

Abstract. In this study, the goal was the germination and propagation of *Orchis sancta* L. which is endangered due to uncontrolled collection and used in obtaining salep, *in vitro* conditions. By the addition of 0 (control group), 20, 40, 60, 80, and 100 g/l concentrations of sucrose, glucose, maltose, galactose, and fructose of carbohydrate forms into Van WaesDebergh culture medium, sugars of effects were determined on germination and development of *Orchis sancta* L. seeds. In the study, germination, formation of protocorm and shoot periods and ratios were examined. The highest average germination ratio was obtained as 77.85% in Maltose40, the lowest average as 44.36% in Galaktose100 mediums. In protocorm formation, when the highest average ratio was detected as 68.53% in Sucrose100, the lowest average as 25.33% in Fruktose100 mediums. Germination period as 12.50-21.33 days, protocorm formation period as 22.50-50.83 days and shoot formation period as 50.66-105.33 days' intervals were determined.
Keywords: *culture medium, germination, orchid, protocorm, shoot*

Introduction

Orchidaceae is one of the largest families of flowering plants in terms of the number of species. While the total of 150 orchid species, of which 13% being endemic, have been specified in Turkey (Erdem, 2004) that there are 117 orchid species among these are used to produce salep (Sezik, 2002). Turkey is one of the richest countries in Europe and Middle East in terms of middle zone orchids, but growing industrialization, rapid urbanization and population growth bring about social, economic and cultural imbalances. The biggest problem faced by the salep orchids, which are among the endangered and damaged plant species in the world, is the excessive uprooting of the plant because of the pharmaceutical importance of the plant drug and its commercial value particularly in the ice-cream and hot drink sector. Hatipoğlu (1981) has listed salep under bulbous-tuberous and rhizomatous ornamental plants, uprooted from natural vegetation without being propagated. According to Sezik (1984), tubers weigh 2 to 7 g when they are fresh. If an average of 4 g is considered, 250 orchids should be removed for 1 kg of fresh tubers. A salep collector normally can collect up to 1 kg of fresh tubers per day. Approximately 1000 to 4000 tubers are required for 1 kg of salep. İşler (2005) stated that the price of 1 kg of mountain salep collected and dried in Van province is 100 Turkish Liras (TL), while meadow salep is sold for 25 TL. It is known that wild collection of orchid tubers for salep production threatens orchids collected in the mountainous areas more compared to the ones collected from the meadows. With each tuber collected, next generation plant and plenty of seeds to be produced by this plant

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_48494864

are prevented. According to Tekinşen (2006), 15 to 20 tonnes out of 35 to 65 tonnes of salep produced in Turkey is exported in powder from.

Due to its increasing price, powdered tubers of *Muscari* plant, which contains muscarinic substance which can cause harm to human health, and tubers of other plants are used as additives in salep (Hatipoğlu, 1981). The researcher emphasized in those years that heavy wild collection problem due to increasing prices is not at international level like citrus and viticulture, but is greatly a concern of Turkey. It is further mentioned that salep is not consumed in high amounts in the developed countries as in Turkey; even the foreign countries are responsive to destruction of our flora and genetic resources; and they are concerned with this issue. Glicomannan, the active substance of salep, swells with milk or water and generates a fluid solution. Thus, salep has become an essential drink in cold winter days. Additionally, salep is put into the famous Maraş ice-cream to provide late melting and hardness. Among these usages, salep has also a medical importance. It is pointed out that Avicenna (Book of Ibn Sina in C.E. 980-1037) recommends the use of salep as expectorant, appetizer, anti-stroke substance and aphrodisiac (Sezik, 1984). Nonetheless, instead of being used primarily for these purposes, salep is consumed as beverage and gains economic value in ice-cream production. To attain salep, being so useful and having commercial importance, there is an irrepressible and enormous collection from the nature. Among tuberous orchids, salep is rather extracted from orchids with ovoid tuber such as *Anacamptis, Orchis, Ophrys, Serapias, Himantoglossum, Barlia,* and from some species with amorphous tuber such as *Dactylorhiza*. The harvest of every tuber prevents the plant of next year with its many seeds to grow up. Because of this uncontrolled collection, alternative production and propagation methods are aimed and constantly new techniques are developed with seeds in laboratories.

Orchis sancta L. is also an orchid species that has been collected for these purposes and is being studied to be propagated with different methods. This study aims at providing asymbiotic propagation and species continuity of *Orchis sancta* L., a salep orchid, in vitro conditions.

Literature review

According to Stewart and Kane (2010), the role of carbohydrates *in vitro* orchid seed germination and protocorm formation has received some attention, although little in recent years. In the earlier study about asymbiotic orchid seed germination, researchers realized that some carbohydrate sources were better suited to support seed germination than others, and that this response was genus- or species-specific (La Garde, 1929; Smith, 1932; Wynd, 1933). Little attention has been paid by modern researchers to the effects of carbohydrate source on asymbiotic orchid seed germination and protocorm/seedling development, and little information exists on the role of different carbohydrates in the asymbiotic germination of terrestrial orchids (Stewart and Kane, 2010).

Smreciu and Currah (1989) reported that very small orchid seeds have small testas, formed with loose and transparent cell layer and have very small embryos. Germination of orchid seeds which have limited proliferation capacities and do not contain endosperm, an appropriate mycorrhizal relation with a mycorrhizal fungus is required in the environment in addition to appropriate temperature, light, humidity and oxygen conditions (Sezik, 1984). As orchid seeds do not contain nutrient reserves, successful germination do not occur unless a carbohydrate source such as glucose is provided from

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_48494864

outside (Ingold and Hudson, 1993). Adding carbohydrate to the culture medium as a germination method in addition to symbiotic germination with mycorrhiza might be successful. This way, orchid seeds' utilization of the substances in the culture medium might be changed. These alterative techniques can be tried at different stages such as germination, protocorm and shoot formation, even root and tuber formation. As a result, every study on germination and propagation and every method resulting in yield, first in the laboratory environment and then in the adaptation phase on the land, is treasured for the species continuity. Thanks to this awareness and determination, orchids will be able to seen on the ground, in their living environment.

Material and methods

Seeds

In the study, mature seeds of *Orchis sancta* L. species naturally grown around Aydın province in Turkey but collected and thus destroyed to obtain salep were used and 50 seeds, randomly selected before sowing, were put to Tetrazolium Chloride (TTC) viability test. The seeds soaked with distilled water in Petri dishes were kept for 12 h and the embryo sections were left in 1% tetrazolium chloride solution. While the pink-red coloured ones of the seeds kept at room temperature for 12 h are considered alive, the white-coloured ones are considered inanimate (Grabe and Peters, 1998; AOSA, 2002). According to the test results, 85% of the seeds were alive. The photos of the seeds were captured with OLYMPUS SZ61 binocular microscope dp20 camera and 10X x 1.2 software (*Fig. 1*).

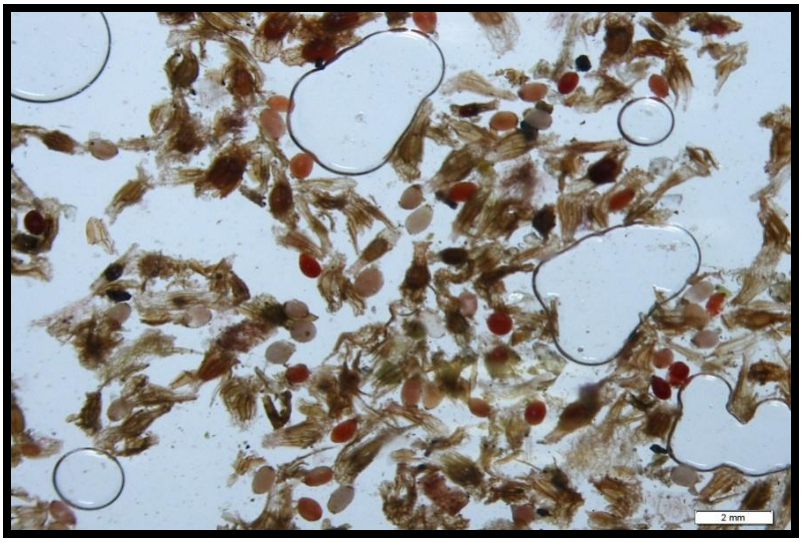

Figure 1. *Aspect of Orchis sancta L. seeds under binocular microscpoe*

The seeds are counted so as to sow 100 units to each Petri dish. The orchid seeds packed in coarse filter paper envelopes were sterilized for 12 min with 1-2 drops of Tween-20 and 10% NaOCl and rinsed 3 times with sterile distilled water after 5 min of shaking with 2% H_2SO_4 (Çığ and Yılmaz, 2016). Sterilized seeds are sown in a total of 15 glass Petri dishes including culture media, in 3 replicates with 5 times for each replicates.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_48494864

Preparation of culture medium and seed sowing

Culture mediums were formed by adding 0, 20, 40, 60, 80 and 100 g/l concentrations of the sugar forms of sucrose, glucose, fructose, galactose and maltose into the VWD medium (Van Waes and Debergh, 1986). 0.85 g/l agar was used for all mediums; and were autoclaved at 121 °C and 1.2 atmosphere pressure for 20 min after the pH was adjusted to 5.8 with 1 N HCl and 1 N NaOH. The sterilized Petri dishes with sown seeds were stored in 23 ± 1°C and in dark place and were taken to a light/dark room for 16/8 h with the formation of protocorm. The subculturing process was repeated once a month in aseptic conditions.

Statistical evaluations

In terms of the emphasized specifications, mean and standard error are indicated with descriptive statistics. To determine any possible difference of these specifications between the concentration and culture medium, completely randomized factorial design analysis is implemented (Montgomery, 2001).

The effects model is

$$y_{ijk} = \mu + \tau_i + \beta_j + (\tau\beta)_{ij} + e_{ijk}$$

where, $i = 1,\dots,6;\ j = 1,\dots,5;\ k = 1,\dots,90$; μ is the overall mean effect, τ_i is the effect of the i^{th} level of concentration, β_j is the effect of the j^{th} level of medium, $(\tau\beta)_{ij}$is the effect of the interaction between τ_i and β_j, and e_{ijk} is a random error component.

An angular transformation is applied to the measured percent variance analysis.

$$Y = arcsine\sqrt{p} = sine^{-1}\sqrt{p}$$

Where p is the proportion and Y is the result of the transformation. The result may be expressed either in degrees or radians. The usual rule of thumb is that they should be used when there are a number of proportions close to 0 and/or close to 1. The transformations will “stretch out” proportions that are close to 0 and 1 and “compress” proportions close to 0.5. The amount of germination, protocorm and shoots was subjected to angular transformation and expressed in terms of their original values in *(Tables 1* and *2).*

Tukey Multiple Comparison test was used in determining significant difference between concentrations and carbohydrates following the variance analysis. The statistical significance level was taken as $p < 0.01$ and the calculations were done with ANOVA procedure by the statistical package JMP 5.0.1a software.

Results and discussions

In the study investigating in vitro germination, protocorm and shoot formation potentials of *Orchis sancta* L., five different carbohydrate (sugar) forms of galactose, glucose, maltose, fructose and sucrose were added into the culture medium with 20, 40, 60, 80 and 100 g/l concentrations (doses) were applied and differences were observed statistically with a significance level of ($p < 0.01$) in the characteristics examined (*Tables 1* and *2*).

**In the same column, the difference between the averages indicated by the same letter is insignificant at level $p < 0.01$

Germination rate of the seeds (%)

While germination occurred in all mediums and doses, it was observed that the highest germination average is obtained from Maltoz40 with 77.85% (*Table 1*). The lowest average value of germination is obtained from the Galactose100 medium with 44.36%. Taking into consideration all sugar forms in general, it appears that germination rates decrease as the used doses increasing. This suggests that the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_48494864

increasing of sugar concentration has a reducing effect on the germination of *O. sancta* seeds (*Figs. 2* and *3*).

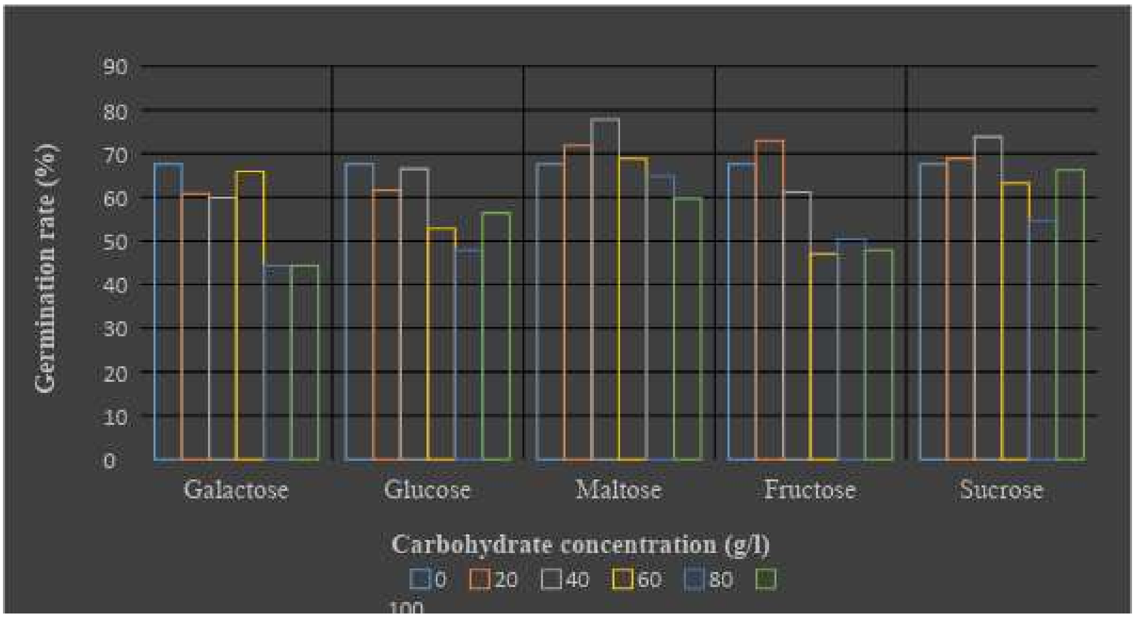

Figure 2. *Effects of carbohydrate forms and concentrations on germination rates (%)*

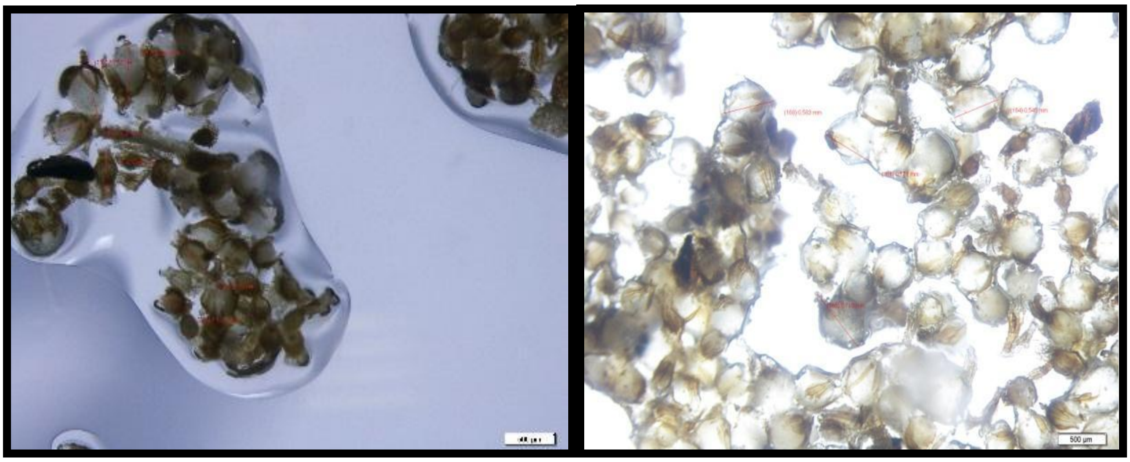

Figure 3. *Germinated O. sancta seeds in culture medium*

In vitro asymbiotic germination of orchid seeds, some inorganic substances and sucrose, glucose and other sugars are useful for the culture medium; dextrose and sucrose can also be used as sugar sources (Harvais, 1973). In our study, sucrose and glucose were sugars that had an effect on germination after maltose. Van Waes and Debergh (1986) reported that sucrose is more effective on germination compared to other sugars, and mentioned a negative effect of galactose. Galactose has the lowest germination rate in our study. Mead and Bulard (1975), succeeded in adding sucrose in their study with species of *Orchis* and *Ophrys* genus. In another study on *Dactylorhiza* species, it is reported that germination was stimulated through glucose and sucrose (Wotavová-Novotná et al., 2007). Considering previous studies, it can be concluded that

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_48494864

glucose and sucrose induce germination at the most. In our study, these two types of sugar have the highest second and third mean values following maltose (*Fig. 2*). It is presumed that the culture medium and orchid species used by the researchers may be different. Culture mediums used in germination studies on rather different species vary as well. This study of *O. sancta* species has the highest percentage of germination under maltose impact in the VWD medium.

In a study with nine orchid species, in which three of them generated positive results, the germination rate of *O. sancta* was found 100% (Önal, 1999). Yet in another study, 20% sugar was added to 1/10 MS (Murashige & Skoog) medium and ultrasonication was applied to germinate the seeds; and the *Orchis italica* seeds were germination with the rate of 81% (Yararbaş, 2008). 30 g/l of sucrose was added during the study with 6 orchid species executed in full strength MS, VWD and KC (Knudson-C) mediums and ½ MS medium. A germination rate of 7.34%, which is the highest, occurred in VWD medium (Gümüş et al., 2008). In the study with *O. sancta* seeds, KC and VWD mediums with added GA_3, BAP, coconut milk, banana and potato extract was used and the germination rate was found as 20-40% in VWD medium and 20-100% in KC medium Sarı et al. (2011). Bulunuz Palaz et al. (2012) has found the highest germination rate among five orchid species as 30% for the *O. sancta* species. In another study of the researchers, *O. sancta* seeds showed a germination rate of 79.08% in EBP + AC (activated charcoal) medium (Bulunuz Palaz et al., 2014).

Protocorm formation rate (%)

The protocorm phase is described as the formation of a nail-like structure after germination (Sezik, 2002), and the protocorm amount is obtained by calculating percentage ratios to germinated seeds. Again in 60 g/l and above applications of sugar concentrations used in parallel with germination, decreasing mean values were obtained. Protocorm formed in all applied mediums and doses (*Fig. 4*) and the highest protocorm formation rate was obtained from Sucrose100 with 68.53% (*Table 1*). The lowest protocorm mean value was obtained from Fructose100 medium with the rate of 25.33%. Taking into account all sugar forms in general, protocorm ratios decreases with increasing doses. However, the 60 g/l dose seems to be a breaking point and then the protocorm formation increases again in general (*Fig. 5*).

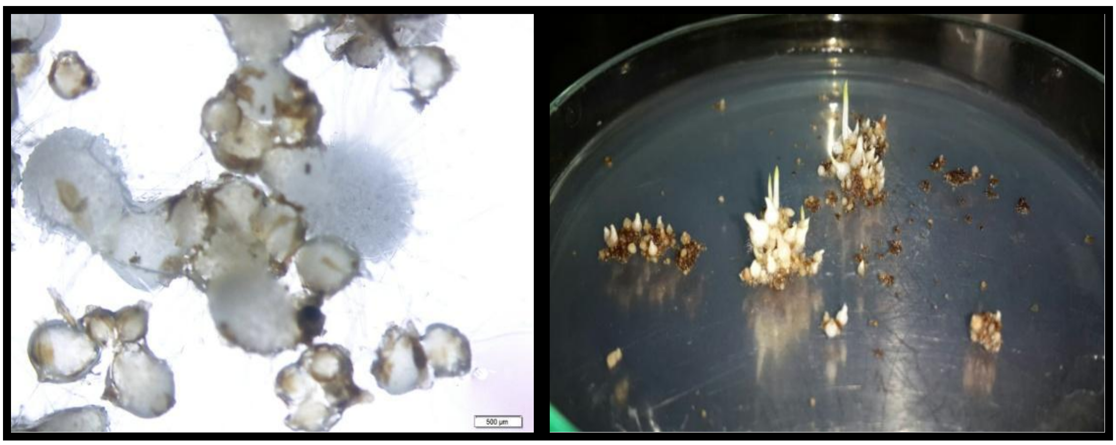

Figure 4. *Protocorm formation in germinated O. sancta seeds in culture medium*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_48494864

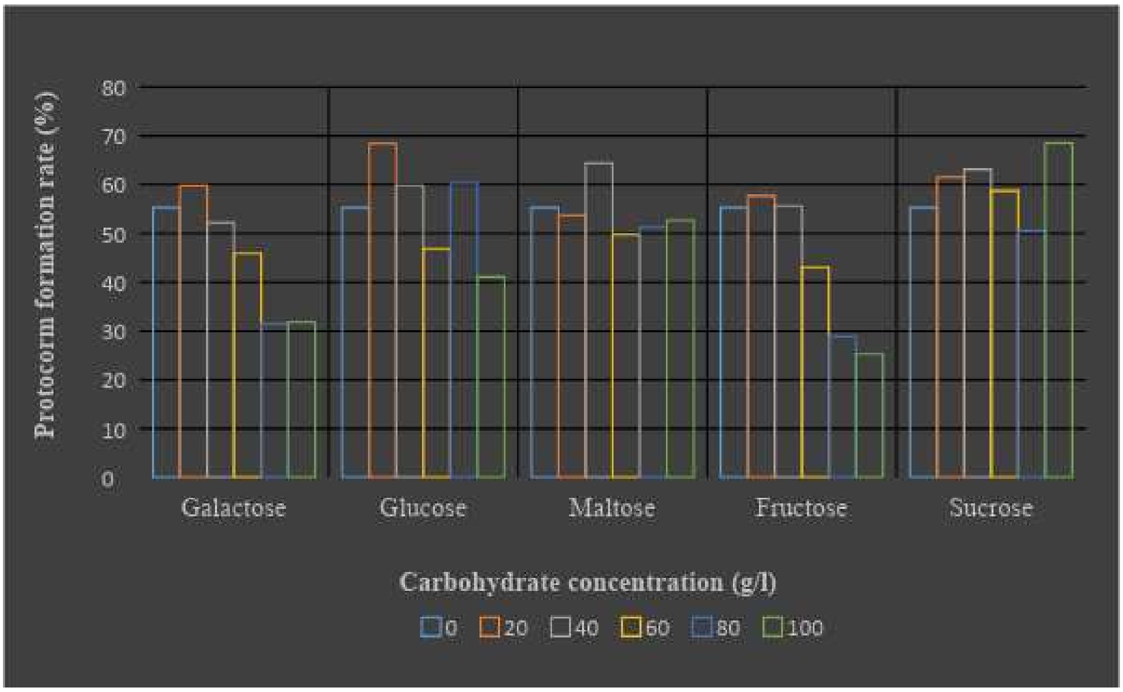

Figure 5. *Effects of carbohydrate forms and concentrations on protocorm formation rates (%)*

The highest rate of protocorm formation for six orchid species was 13.11% (Gümüş et al., 2008). The highest protocorm formation in six orchid species, germinated in five different culture mediums, has been obtained in KC and VWD mediums with a rate of 62.92% (Çığ and Yılmaz, 2016). In the study using KC and KC + 1 mg/l GA_3 mediums for cultivation, protocorm formation occurred in 5.34% of *O. sancta* species which is the highest among the five orchid species (Bulunuz Palaz et al., 2012). In an in vitro study on eight orchid species, *O. sancta* seeds have formed 78.12% protocorm in EBP+AC medium (Bulunuz Palaz et al., 2014). In an in vitro study on five orchid species, the highest rate of protocorm formation occurred in a medium including tripton; recorded 28% for *Serapias vomeracea* species, 48% for *O. sancta* species and 48% for *Orchis coriophora* species (Karakuş, 2015).

As we can conclude from similar studies, protocorm generally showed successful development in VWD mediums. It is thought that especially the rate of 78.12% mean value obtained from *O. sancta* is a result of the EBP+AC medium. A protocorm formation rate of 5.34% was obtained from KC +1 mg/l GA_3 medium, but despite it contained hormones, this was considerably below the mean value occurred in our study. The effect of culture medium on the protocorm formation of *O. sancta* species is obvious.

Shoot development rate (%)

Shoot development did not occur in all mediums and concentrations (*Fig. 6*). In some doses of glucose and fructose; and in all doses of sucrose, shoot development was observed. Shoots were developed with the rate of 0-9.02% in the glucose group; 0-13.16% in the fructose application and 3.50-13.30% in the sucrose application.

The sucrose application was an effective sugar in protocorm formation, while it had the same effect also in shoot development. Likewise, glucose was also a sugar type that

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_48494864

followed sucrose; nonetheless, while fructose had a lower performance in protocorm formation compared to other sugar types, it showed a more positive effect on shoot development (*Fig. 7*).

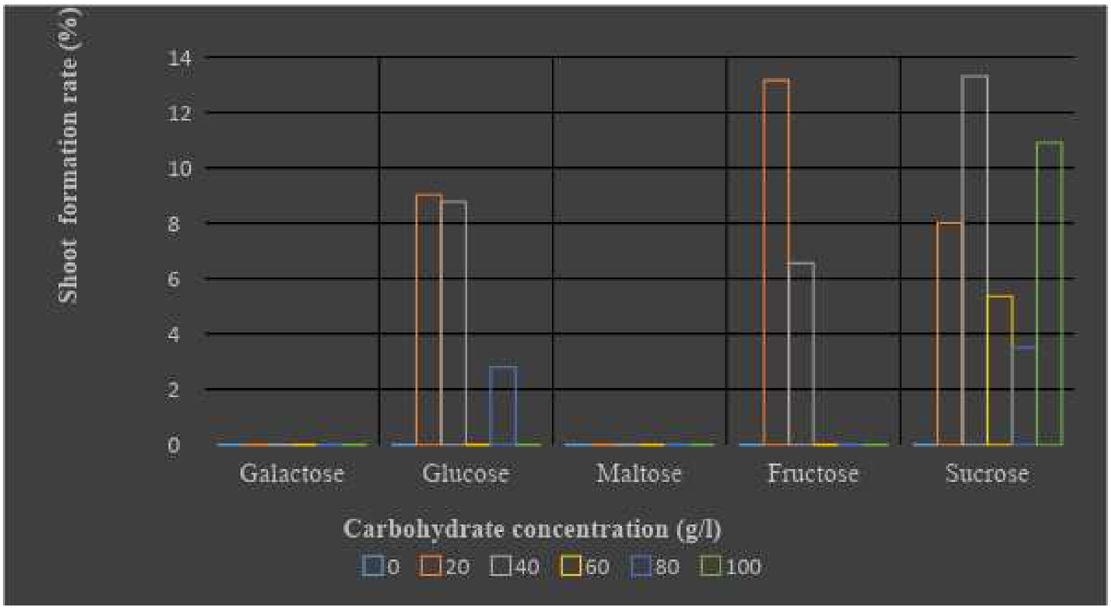

Figure 6. *Effects of carbohydrate forms and concentrations on shoot formation rates (%)*

Figure 7. *Developed O. sancta shoots in culture medium*

On the other hand, maltose and galactose exhibited a negative effect on shoot development, while having positive effects on protocorm formation. It is reported that sucrose has the most positive effect among sugars used for germination and development (Van Waes and Debergh, 1986); and that glucose, glucose, mannose, maltotriose and maltopentaose can be used for seedlings cultivated from in vitro applications (Ernst and Arditti, 1990). In all phases of *O. sancta* seeds, from germination to shoot development, the negative effect of galactose is observed. On the contrary, glucose and sucrose had a stimulating role in all the levels of the study.

In previous research, the amounts of plantlets stemming from protocorm were obtained with rates of 1.86% (Çağlayan et al., 1998) and 80% (Önal, 1999). The highest

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_48494864

shoot development rates obtained from protocorm was observed in KC medium, MS and 1/10 MS mediums (Çığ and Yılmaz, 2016). In the study with five orchid species applied in two culture mediums, the highest plant development rate determined as 3.5% in *O. sancta* (Bulunuz Palaz et al., 2012). In the study with 8 orchid species, *O. sancta* seeds had a shoot development at the rate of 72.50% in EBP+AC medium (Bulunuz Palaz et al., 2014).

Germination period (day)

The highest germination period was obtained in Galactose80 as 21.33 days; while the lowest period was 12.50 days in Glucose40, Maltose40 and Sucrose20 (*Table 2*). Considering the mediums separately in terms of germination period, the average values were 14.66-21.33 days in the galactose application; 12.50-15.83 days in the glucose application; 12.50-15.33 days in the maltose application; 13.16-20.83 days in the fructose application and 12.50-15.33 days in the sucrose application (*Fig. 8*).

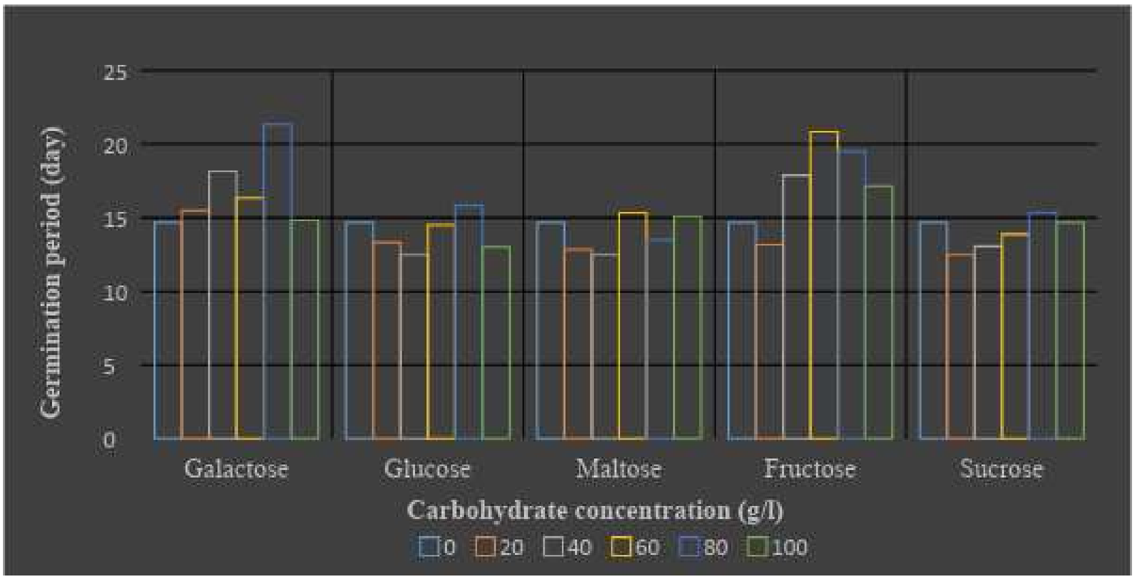

Figure 8. *Effects of carbohydrate forms and concentrations on germination periods (days)*

Germination of seeds cultivated in vitro conditions was observed in 58 days in orchid seeds (Çağlayan et al., 1998), and in15 days in *Orchis italica* seeds (Yurarbaş, 2008). In a study with *O. sancta* and other seed species, the earliest germination was observed in *O. sancta* seeds after a month (Önal, 1999); and after two weeks in another study (Bulunuz Palaz et al., 2012). In a study with Modified Lucke (LM), MS, Lindemann, Vacin & Went, Malmgren Modified (MM) and KC mediums; BAI, Zea, Kin, 2-iP cytokinins and 0/24, 16/8, 24/0 light/dark photoperiods, the *Habenaria macroceratitis* terrestrial orchid seeds showed the highest germination rate of approximately 89% in LM and KC mediums at the 7th week of the study (Stewart and Kane, 2006). In another study, cracking and decolourization were observed in cultivated seeds in 15-20 days (Sarı et al., 2011). The germination period of 4 orchid species cultivated in KC, VWD and Pfeffer nutrient mediums was observed as 3 months (Kısakürek, 2011). In a study to identify the effects of VWD, KC, MS, ½ MS and 1/10 MS culture mediums on the germination period of orchid seeds; the effect of VWD medium on germination

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_48494864

appeared in the range of 27.67-130.53 days (Çığ and Yılmaz, 2016). Considering the other mediums, this range was 22.00-191 days.

Table 2. *Effects of carbohydrate forms and concentrations on germination, protocorm and shoot development periods (day)*

**In the same column, the difference between the averages indicated by the same is insignificant at $p < 0.01$

According to the studies, the germination period varied in terms of species with diverse mediums and applications (15-191 days). However, in this study, getting close results to those obtained in the previous in vitro study, specifying the germination periods of 1 month and 2 weeks especially with *O. sancta* species, reveals the early

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_48494864

germination period of the seeds of *O. sancta* species. It is believed that the added carbohydrate and its concentrations of the culture medium were effective.

Protocorm formation period (day)

While glucose, maltose and sucrose applications showed the earliest effect on germination, the mediums with the earliest results in protocorm formation were identified as maltose, sucrose and galactose (*Table 2*). Despite the highest protocorm formation period was obtained from Galactose80 with 51.33 days, the difference with the value of 50.83 days obtained from Fructose60 was considered statistically insignificant. The lowest protocorm formation period averages were obtained from Galactose20 as 22.50 days and Glucose20 as 22.83 days (*Fig. 9*).

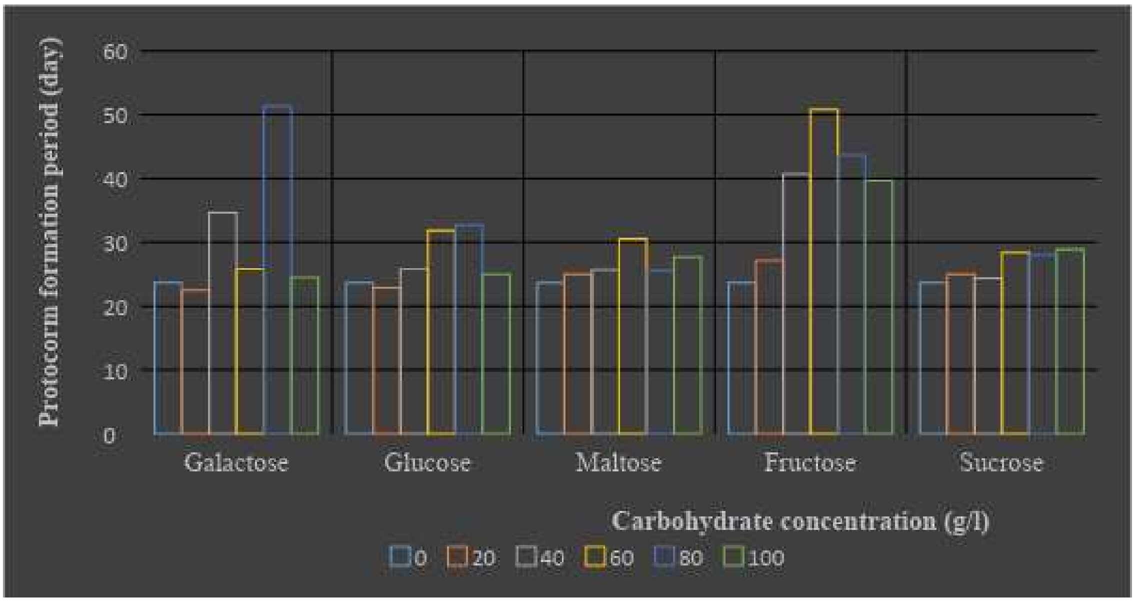

Figure 9. *Effects of carbohydrate forms and concentrations on protocorm formation periods (days)*

Protocorm was obtained in two months in the seeds of *Orchis lutea* and *Orchis fusca*, cultivated in modified Curtis medium (Barroso et al., 1990). Examining the effects of different nutrient mediums, plant growth regulators and light/dark applications on the protocorm formation of *Habenaria macroceratitis* terrestrial orchid, protocorm development was observed in MM medium between 7 and 16 weeks (Stewart and Kane, 2006). In studies utilizing bioreactors, protocorm formation was obtained in 8 weeks (Paek et al., 2001; Young et al., 2000); and in 40 days (Yang et al., 2010) after sowing. In a study, no further development occurred during 8 months after sowing seeds, but protocorm formation was observed after this period by adding 2 mg/l IAA to the nutrient medium (Sarı et al., 2011). As protocorm formation periods ranged between 53.50-309.94 days when all mediums are considered, the periods in VWD medium were 58.50-309.94 days (Çığ and Yılmaz, 2016). In a study to follow the germination and protocorm formation of *Orchis sancta*, which is shown among endangered species, full strength and ½ strength Lindemann (LDM) medium containing 20 g/l sucrose and 7 g/l agar was used and protocorm formation was observed in the 12th week (Acemi et al., 2013).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_48494864

Comparing the protocorm formation period of *O. sancta* in this study and the period of the previous one, it is clear that success was achieved in a considerably short time. The protocorm formation range in other studies appears as 40-309.94 days. It is inferred that this period varies in association with the cultivated plant species and medium contents

Shoot development period (day)

The highest shoot development period was obtained from Fructose40 with 105.33 days and Sucrose100 with 104.50 days (*Table 2*). The lowest average shoot development period was obtained from Sucrose40 with 50.66 days (*Fig. 10*). Besides, shoot development was not observed in all the galactose and maltose applications; in 0, 60, 100 g/l doses of glucose; 0, 60, 80 and 100 g/l doses of fructose and 0 g/l dose of sucrose, and therefore, shoot development periods could not be recorded.

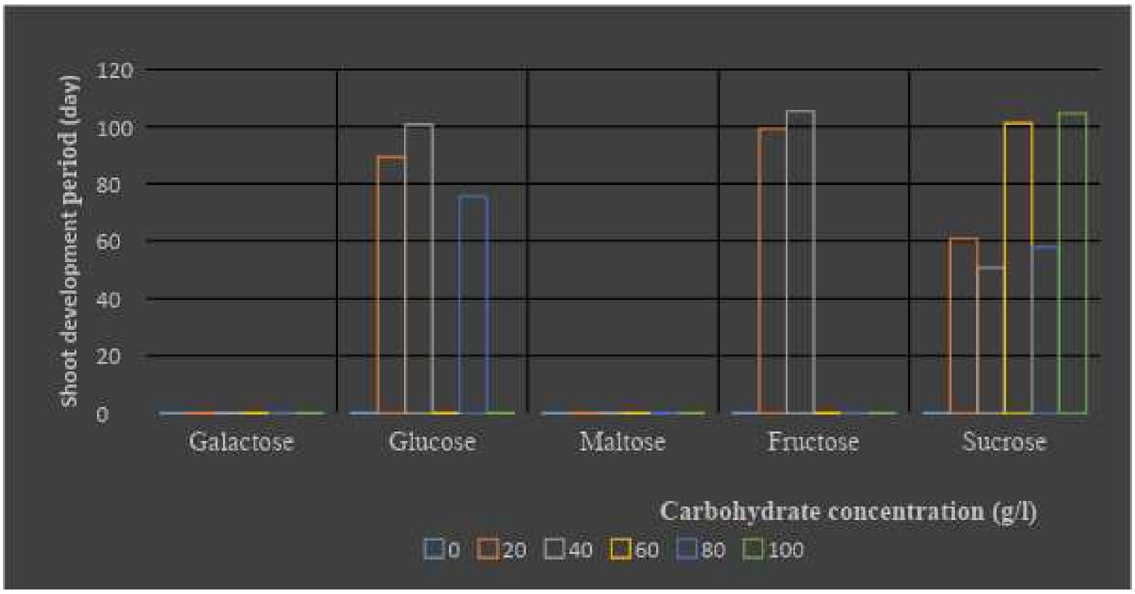

Figure 10. Effects *of carbohydrate forms and concentrations on shoot development periods (day)*

Shoot tips of *Orchis mascula* seeds cultivated in six different nutrient mediums has occurred in 4-5 months (Valetta et al., 2008). The first leaves developed from *Orchis italica* seeds after 2 months (Yararbaş, 2008).

Taking into account the effect of five different culture mediums on shoot development periods, the range of 79.00-406.83 days is noticeable; while the earliest shoot development in VWD medium was 95.33 days, and the latest shoot development emerged in 267.78 days (Çığ and Yılmaz, 2016). In a study testing three orchid species, it was found that sucrose, glucose and fructose were the best energy sources for the *Oeceocladesde caryana* species. It is reported that shoots of *Dactylorhiza majalis* developed slightly weak in fructose, and very weak in glucose (Ponert et al., 2011). These studies indicate that hexoses are not a good carbohydrates source for these species. *Ophrys lojaconoi* exhibited better development in sucrose, weak in glucose, and very week in fructose. Many protocorms have developed better in fructose containing mediums but could not grow further. This proved that fructose has an

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_48494864

inhibitive effect in the protocorm development. It is reported that sucrose is used more for in vitro orchids but that fructose and glucose are also used (Michl, 1988; Rasmussen, 1995).

Since orchid seeds do not have endosperms, carbohydrate supplement is required to initiate germination. As with the type of carbohydrate, its concentration added in the culture medium is also important. That is because the stimulating role of sugar can be inhibitive in some doses. This study reveals that the sugar types and their concentrations have different effects in germination, protocorm and shoot development phases of *O. sancta* seeds.

Conclusions

As a result, in vitro germination of the *O. sancta* species, the best performances were achieved from maltose, and then sucrose among five sugar types used in the study. Sucrose was the most effective sugar type for protocorm formation. In shoot development, the first sugar with performance was fructose, then sucrose and glucose at last. It is thought that maltose can be used in the germination of *O. sancta* or other orchid species; and sucrose in the protocorm and shoot development. Applications specific for each species as well as general adaptations might be possible. For *O. sancta*, maltose in germination, sucrose in protocorm formation; fructose in shoot development; and as sugar concentrations, doses such as 0, 20 and 40 g/l in germination; 20 and 40 g/l in protocorm; 100 g/l in shoot development can be used. Hence, it is understood that low concentrations for germination and protocorm formation can be used, while high doses should be avoided. The applications in this study to be suggested for the use of sugar and doses together might be: Maltoz40 for germination; Glucose20 and Sucrose20 for protocorm; Furctose20 and Sucrose40 for shoot development.

(Received 22nd May 2018; accepted 17th Jul 2018)

Abstract. This study examined the effects of nitrogen doses rate on grain yield (GY) and yield components of spring triticale (×*Tritico secale)* cultivars in dry area, based on cultivars plus cultivar × nitrogen doses interaction GGE biplot and AMMI analysis. The research was designed to evaluate the effects of different nitrogen fertilization levels (0, 40, 80, 120 and 160 kg ha^{-1} of N) on the grain yield and agronomic performance of two cultivars in two growing seasons (2015-16/2016-17). Split plot layout with in randomized complete block design with 3 replications was used in both years. The response to fertilization levels were evaluated through GGE (Genotype main effects and Genotype x Environment interaction) biplot graphic methodologies and regression. Combined analysis of variance of nitrogen applications of two cultivars showed highly significant ($p < 0.01$) difference between the cultivars, nitrogen applications and interaction. The grain yield of triticale was most of all affected by cultivars (70.8%) and then by nitrogen doses (23.5%) and interaction (5.7%). On the other hand, the study showed that plant height, number of spikes per m², number of grain of ears and grain yield increased depending on the increasing nitrogen doses of the cultivars. The highest performance of grain yield of both cultivars were associated with nitrogen N_3 (120 kg/ha) fertilization in regression and AMMI analysis. The results showed that 80 kg/ha N application can be recommended in triticale traits and grain yield with Esin (new) cultivar. Further more, we found that the GGE biplot method generated highly useful results with high visual quality in the study.
Keywords: *triticale, nitrogen doses, yield, yield components*

Introduction

Triticale is a new species in field crops and it is expected to be regarded as a seed in the future as well as being evaluated as forage. It is already produced for seed purposes in many African countries. Especially in dry farming areas, where barley and wheat are not well cultivated, in areas where extreme temperatures are experienced and rainfall is insufficient, triticale can be more economically grown than other cereal crops. In these places, triticale is contribute the several advantages in cropping system because cereal grains can use N, captured in soil profile after lentil or chickpea crops. After lentil and chickpea farming it can use N to accumulate in the soil. In addition, because of the fact that the triticale is abstinent plant, so it is able to get better nitrogen from soil in dry areas compared to wheat and barley. The Syrian border, where the research was carried out, is quite dry and it has become almost impossible to grow wheat without watering. Under these conditions, farmers tend to other cereal crops that may be an alternative to wheat in arid conditions. For this reason, growing triticale is becoming increasingly important (Kendal, 2015; Kendal et al., 2016).

Triticale was designed in order to both biotic and abiotic stressors and thus more suitable for cultivation in marginal areas than wheat (Kendal et al., 2012; Villegas et al., 2010). Triticale is often reported as an interesting product for adverse environmental conditions where environmental factors limit product cultivation (Ugarte et al., 2007;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_48654878

Estrada-Campuzano et al., 2008). In such places, each plant does not use the same nitrogen in the same way and the plant cannot make maximum use application amount of nitrogen. Proper N management, are important for obtaining optimum crop yields and positive economic returns while limiting negative environmental impacts of crop production (Gibson et al., 2007). Many authors have reported positive effect of N fertilization on grain yield and the studies showed that N fertilization is one of the most important crop management techniques for spring triticale production (Gülmezoglu, Kinaci, 2004; Lestingi et al., 2010). The weather conditions is affect spring triticale grain yield performance and nitrogen (N) fertilization effect total 35.7% grain yield increase, compared with unfertilized spring triticale (Janušauskaitė, 2013).

Nitrogen is needed for early tiller development of plant to set up the crop for a high yield potential. On the other hand; nitrogen fertilization has an important effect on the final harvest, thus if this element is not take from plant, yield is decreases (Moreno et al., 2003). The amount of nitrogen, barley crop needs to reach maximize yield and quality, will depend on the seasonal conditions, soil type, and rotational history of the soil as well as the potential yield of the cultivars. Nitrogen is the key nutrient input for achieving higher yield of triticale (Alazmani, 2015). The farmers have not enough information about use nitrogen fertilizers and adequate information concerning actual soil requirements. Therefore, the study of use N dozes in triticale cultivars is necessary to recommend optimum nitrogen doses for high yield and yield components in different environment conditions.

The yield of each variety in any environment is a sum of environment (E) main effect, genotype (G) main effect and genotype by environment interaction (GE or GEI) (Farshadfar et al., 2013; Kilic, 2014; Sayar et al., 2013). On the other hand; farmers need varieties that show high performance in terms of yield and other essential agronomic traits by use nitrogen fertilizer. Different statistical analysis, such as correlation, path coefficient and principal component analysis (PCA) can be used to reveal associations between yield and other agronomic traits. The impact of GGE Biplot methods and regression analysis has been clearly showed by different researchers using relationship among factors. This methods; provide the correlative size and interaction (Asfaw et al., 2009; Sayar and Han, 2015; Kendal and Sayar, 2016). So it is very important to identify the use of nitrogen fertilization doses to cultivars for high yield and best quality. The objective of study is to determine the effect of different N rates on yield, yield components, and to identify optimal N deses rate using GGE Biplot analysis to recommend doses for application in Southeast Anatolia Region of Turkey.

Material and methods

The experiment was conducted in the research field of the Kiziltepe Vocational and Training High School, Mardin, Turkey. The experiment was conducted on the basis of split plot layout with completely randomized block design with 3 replications. Main plot was different level of nitrogen fertilizer (0, 40, 80, 120 and 160 kg ha^{-1} of N and sub plot was different two spring triticale cultivars (*Table 1*).

This research was conducted in 2015-2016 and 2016-2017 growing seasons. The seeding rates were 500 seeds m^{-2}. Plot size was 7.2 m² (1.2 × 6 m) consisting of 6 rows spaced 20 cm apart. Sowings were made by using an experimental drill. The fertilization rates for all plots were different N ha^{-1} doses and 60 kg P ha^{-1} with sowing time and different N ha^{-1} doses was applied to plots in double ridge stage. Harvests were

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_48654878

made using Hege 140 harvester in 6 m². Other normal agronomic practices for barley production were followed. During both of growing seasons, heading time (date), spike per square (m^2), maturity time (date) plant height (cm), length of spike (cm), number of grains per spike, thousand grain weight (g), grain yield (kg/ha^{-1}), hectoliter weight (kg hl), Protein Content (%) were examined (Kendal and Sayar, 2016). The soil analysis results are shown in *Table 2* and the climate data of growing seasons are shown in *Table 3* (Mardin Regional Directorate of Meteorology). Different nitrogen use efficiency (NUE, kg kg^{-1} N) was calculated for each treatment: NUEX Trait = (X trait N – X trait N0) / Nx, where X trait N is X trait from nitrogen (N) fertilized treatments, Xtrait N0 – X trait in unfertilized treatment, and Nx– nitrogen input (N40, N80, N120, N160, kg ha^{-1} N).

The data obtained from the study related to the investigated grain yield and yield components were analyzed respectively for each year and combined with nitrogen doses by using the JMP 5.0.1 statistical software package (SAS Institute, 2002), and the differences between means were compared using a least significant difference (LSD) test at the 0.05 probability level (Steel and Torrie, 1980). Also regression analysis was done by this program. On the other hand; GGE biplot analyses were carried out using GGE biplot software to show the differences among the applied nitrogen doses and crop characteristics and cultivar crop characteristics in two growing seasons (Dogan et al., 2016; Kilic, 2016). GGE biplot analysis also allows comparison amongst nitrogen doses in terms of their discriminating ability and representativeness. These values can be assessed using the discriminating power of the doses' biplot screen of the GGE biplot (Yan and Thinker, 2006). With the AMMI biplot analysis graph in the study: It was aimed at illustrating grain yield performance of N doses and status of triticale cultivars (*Fig. 1b*), grain yield performance of cultivar (*Fig. 1c*), the effect of N doses on grain yield on years (*Fig. 1d*). Also, with the GGE biplot analysis graphs in the study: It was aimed at revealing relation among examined doses and traits (*Fig. 1e*), sector analysis of doses and grouping traits (*Fig. 1f*), ranking of doses on traits (*Fig. 1g*), comparison of doses on traits (*Fig. 1h*)

Results

The combined ANOVA revealed highly significant differences among the years, cultivars and interaction of them for all components ($P < 0.01, 0.05$), the differences among nitrogen doses were highly significant ($P < 0.01, 0.05$) for all components as shown in *Tables 4* and *5*. Generally, breeders interested in the genotypes with high genotypic main effect (average over years and nitrogen doses) and with low fluctuation in yield or yield components (stable). On the other hand, the study showed that plant height, number of spikes per m², number of grain of ears and grain yield increased depending on the increasing nitrogen doses of the cultivars.

The mean grain yield (GY) of 2015/16 growing season (3878 kg ha^{-1}) was higher than that of 2016/17 (3819 kg ha^{-1}), the mean yield of growing seasons was changed from 3334 kg ha^{-1} (Esin) to 4362 kg ha^{-1} (Tacettinbey) in *Table 6*.

The results of grain yield showed that first growing season had high yield than the second year and Esin variety was yielding than Tacettinbey during two grooving seasons. The results of grain yield showed that first growing season had higher yield than the second year and Esin variety changed from 4760 kg/hl to 4933 kg/hl (N_3-2015/16-2016/17) had a higher yield Tacettinbey (2810-3087 kg/hl, N_0) during two growing seasons in *Table 7*. Nitrogen use efficiency (NUE) was considerably influenced by cultivars, using N doses and growing seasons. The main factor determining the differences in NUE yield of cultivars was changed from13.1% (Tacettinbey) to 19.6% (Esin) (*Table 7*). The influence of growing season on NUE_{yield} was changed from 21.6(2015-16) to 23.3% (2016-17). The highest NUE_{yield} of interaction was obtained from N_3 fertilization rate (35.9%) in 2016-17 growing season. As expected, depend on increasing basic N fertilization rate increased NUE_{yield}. Each N rate increasing by 40 kg increased NUE_{yield} by 2.5 kg kg^{-1}.

The mean thousand grain weight (TGW) of 2016/17 growing season (37.4 g) was high than 2015/16 (37.2 g), the mean thousand grain weight of cultivars of both years was changed from 34.8 g (Tacettinbey) to 40.0 g (Esin) in *Table 6*. The number of thousand grain weight of nitrogen doses and cultivar interaction of both year means were changed from 36.4 g (N_0) to 38.2 g (N_{4-} 2016/17). The application nitrogen doses of thousand grain weight were ranged from 36.4 g (N_0) to 38.0 g (N_3) in *Table 7*. The thousand grain weight was increased depend on nitrogen rate till N_3 application doses for both varieties.

The mean hectoliter weight (HW) of 2016/17 growing season (78.5 kg/hl) was high than 2015/16 (75.6 kg/hl), the mean hectoliter weight of cultivars of both years was changed from 76.8 kg/hl (Tacettinbey) to 80.2 kg/hl (Esin) in *Table 6*. The number of hectoliter weight of nitrogen doses and cultivar interaction of both year means were changed from 74.9 kg/hl (N_0-2015/16) to 79.9 g (N_3-2016/17). The application nitrogen doses of hectoliter weight were ranged from 75.6 kg/hl (N_0) to 77.6 kg/hl (N_3 and N_4) in *Table 7*. The hectoliter weight was increased depend on nitrogen rate till N_4 doses for both varieties. N3 and N4 doses had the same values, so the N_3 dose application is better for hectoliter weight in tiriticale.

The mean protein content (PC) of 2016/17 growing season (10.9%) was higher than 2015/16 (10.8%), the mean hectoliter weight of cultivars of both years was changed from 11.2% (Tacettinbey) to 10.6% (Esin) in *Table 6*. The number of protein content of nitrogen doses and cultivar interaction of both year means were changed from 10.3% (N_0-2016/17) to 11.4% (N_3-2016/17). The application nitrogen doses of protein content were ranged from 10.3% (N_0) to 11.3% (N_3) in *Table 7*. The protein content was increased depend on nitrogen rate till N_3 doses for both varieties. Nitrogen use efficiency (NUE) of protein content influenced by cultivars, using N doses and growing seasons. The main factor determining the differences in $NUE_{protein}$ of cultivars was changed from 5.3% (Tacettinbey) to 4.2% (Esin) (*Table 7*). The influence of growing season on $NUE_{protein}$ was changed from 4% (2015-16) to 7% (2016-17). The highest $NUE_{protein}$ of interaction was obtained from N3 fertilization rate (10.7%) in 2016-17 growing season. As expected, depend on increasing basic N fertilization rate increased $NUE_{protein}$. Each N rate increasing by 40 kg increased $NUE_{protein}$ by 1.5-2.5 kg kg^{-1} till N3 fertilization rate

The heading time (HT) was calculated from 01 January to heading time as day for both varieties separately in *Table 7*. The maturity time (MT) was calculated from heading time to maturity time as day for both varieties separately. On the other hand,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_48654878

ear per square (SS), plant height (PH), long of spike (LE), number of grain per spike (NGS) were recorded and results were showed in *Table 7*. The results showed that there is positive correlation between heading time and maturity time, and depend on N application doses heading time and maturity time are delayed. The cultivars are affected the same on application doses. On the other hand the study indicated the ear per square (SS) and grain per spike (NGS) are contributing the grain yield. Moreover, all traits results (HT, MT, LS, NGS and SS) were increased depend on nitrogen rate till N3 doses for varieties, years and interaction.

AMMI and GGE biplot analysis

Analysis of variance for nitrogen doses (ND) component (C), and the cultivar (C) × component (C) interaction showed significant ($P < 0.01$, $P < 0.01$) effect, and the total sum of squares explained for 96.15%, with PC1 and PC2 accounting 85.03% and 11.12% for nitrogen doses (ND) component (C) (*Fig. 1e-h*), Moreover, the AMMI analysis showed that the grain yield of triticale was most of all affected by cultivars (70.8%) and then by nitrogen doses (23.5%) and interaction (5.7%).

AMMI Analysis was done on grain yield for interaction nitrogen doses, cultivars and years (*Fig. 1b-e*). The results of interaction nitrogen doses and cultivars of grain yield (*Fig. 1b*) showed that grain yield is increased depend on nitrogen doses (*Fig. 1a*) till N_3 application doses, the contribute of N_1 and N_4 to grain yield of triticale is the same, but N_3 application dose is contribute to grain yield in highest level. The interaction of N doses and years showed that the highest grain yield was obtained from the first year (*Fig. 1c*), and the effect of N_3 doses on grain yield was highest than other N doses. The interaction of cultivars and years on grain yield indicated that first year (2015/16) is yielding than the second year (2016/17) and Esin variety is yielding than Tacettinbey variety for both years (*Fig. 1d*).

GGE biplot analysis shows the means over years for nitrogen doses relationships among yield components (*Fig. 1e-h*), the results of relationship between N doses and yield components showed that there is high correlation among components and N application doses (*Fig. 1e*). The figures show that there is high correlation between N_2 application dose and all yield components, while there is high correlation between N_3 doses and GY, LS, NGS, HW TGW and high correlation between N_4 and MT, PC, HT, PH and there is not any correlation among N_0, N_1 and yield components. The sector analysis of N doses and grouping of traits showed in *Fig. 1f,* the results indicated that four sectors occurred on the figure and MT, PC, HT, PH took places in first group in first sector with N_4, and GY, LS, NGS, HW TGW took places in second group in second sector with N_3, while N_2 took places in center of first and second sector, so this dose took places on center of all components. On the other hand N_0 and N_1 located in different sector and opposite of component group, so did not related with any component. The ranking biplot of N doses on components showed in *Fig. 1g,* and the figure indicated that N_2 dose is stable for all components, because N_2 dose located center of stable line with locate above mean of components line, while N_2 doses located side of GY, LS, NGS, HW TGW and desirable for these components, and N_2 desirable for MT, PC, HT, PH. On the other hand, N_0 and N_1 located in under mean of component line, so these doses are undesirable for all components. The comparison biplot of N doses on components showed in *Fig. 1h,* and the figure indicated that N_2 dose is stable for all components, because N2 dose located on ideal enter line, while N_3 doses located side of GY, LS, NGS, HW TGW and desirable for these components, and N_4 desirable

Discussion

Analysis of variance for grain yield and yield components showed that nitrogen dose, year and cultivar was the main independent factor determining the differences in values of parameters between N doses and results. The significant differences ($P < 0.001$, $P < 0.005$) found of the yield and yield components and the grain yield of triticale was most of all affected by cultivars (70.8%) and then by nitrogen doses (23.5%) and interaction (5.7%) in *Table 5,* therefore the effect of nitrogen doses gives a lead to high variable outputs yield and all its components every year. These results are accepted by Moreno et al. (2003), which proceeds that the N fertilizer highly depends on growing season's variations conditioned by environmental factors. Climatic data of both growing season were indicated that the season of 2015/16 had favorable climate conditions for grain yield, without more cold in winter and good rainfall in planting time (October, November) for early germination and for grain filling time occurs (April, May). On the other hand, the climate conditions for all components without grain yield were good in 2016/17 growing season.

According to results of the study, the application of nitrogen doses had positive effect on yield and yield components. The results increased in parallel with dose increase for both cultivars for all characters. Nitrogen application had positive influence on all the yield components (Fallahi et al., 2008). The best grain yield and majority components results were obtained with N_3 nitrogen dosing. Moreover, N_4 and N_2 nitrogen dosing can be advice for some special components depend on climatic data of seasons. The results of nitrogen use efficiency of the present study agree with the findings of Janušauskaitė (2013) who reported that nitrogen use efficiency for grain yield and protein content as affected by nitrogen rate and its splitting in spring triticale and Yildirim et al. (2007) the findings suggest that advanced breeding lines should be selected at different N levels for better N use efficiency and genetic investigations

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_48654878

should be conducted in multiple environments and Alaru et al. (2009) who reported that yield values are under the influence of application of N fertilization. There are more N rate application studies on components in different crop as well as triticale which agree in present study; Hadi et al. (2012), increase in number of time to spike by increasing N rate and it might be attributed to the increase in long time filling grain (Gursoy, 2011; Shafi et al., 2011). Hadi et al. (2012), increase SS m-2 by increasing N rate and it might be attributed to increase the time of number spike, Hadi et al. (2012), increase in PH by increasing N rate might be attributed to the increase in vegetative of plant. The increase SL depend on increasing N rate and available environmental in barley and wheat by researchers (Gursoy, 2011; Shafi et al., 2011). Subhan et al. (2004) and Shafi et al. (2011), increase NGS by increasing N rate and it might be attributed to increase the time grain occurs. Fallahi et al. (2008) Alazmani (2015), Yildirim et al. (2016), increasing N rate and it might be attributed to increase the grains per spike, and this is increasing GY.

GGE biplot analysis

The GGE biplot mainly allows the visualization of any crossover GE interaction, which is very important for the breeding program (Sayar, 2017; Kendal, 2015). The GGE biplot method has been widely used to analyze the stability and performance of the genotypes for yield and other components (Goyal et al., 2011; Tekdal and Kendal, 2017). Moreover, GEI and yield stability analyses are important for their consideration of both varietal stability and suitability for cultivation across seasons and ecological circumstances. The GT (genotype-trait) biplot provides an excellent tool for visualizing genotype × trait data (Kendal, 2015).

The AMMI analysis shows good visualization of interaction among nitrogen application doses and cultivars (*Fig. 1b*), among doses and years (*Fig. 1c*), among years and cultivars (*Fig. 1d*). The AMMI method provides considerable flexibility, allowing plant breeders to simultaneously select for yield and stability (Kendal and Sener, 2015).

The GGE biplot could be used to interpret the relationships among nitrogen doses, components, and groups of component (*Fig. 1e*). An understanding of the relationship between doses and components can aid in better understanding doses objectives and in identifying components that are positively or negatively correlated with nitrogen doses. This understanding can also aid in identifying components that can be indirectly selected by selecting for correlated components. It also helps to visualize the strengths and weaknesses of nitrogen doses, which is important for application in barley. If the angle of the vector was less than 90°, there was a positive correlation two observation factors. If the angle was equal to 90°, they were not correlated. There was a negative correlation if the angle was less than 90° (Yan and Thinker, 2006; Dogan et al., 2107). On the other hand, all components took place in two different groups, with N_2, N_3 and N4 doses (*Fig. 1f*). There is high correlation which is took places in same group (Kendal et al., 2016). Moreover, the GGE biplot was accurate in interpreting the ranking and comparing N doses and components (*Fig. 1g*). The doses with both high mean performance and high stability for all of the components were called as table dose (N_2). The dose located side of some components, it means that this dose can be advise for these components (N_3 an N_4). The center of the concentric circles (i.e., ideal dose) was the AEA in the positive direction. In the comparison biplot doses located closer to the ideal dose were more desirable than others (Yan and Tinker, 2006; Benin et al., 2012; Dogan et al., 2016). The result demonstrated that N_2 was ideal application dose in the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_48654878

both season for all components, as it was in the center circle for the ideal doses and on the AEA (*Fig. 1h*).

Conclusions

1. In the present study nitrogen application doses had positive effect on grain yield and yield components, and the values of component and grain yield increased in parallel with application nitrogen doses.

2. The nitrogen dose of N3 (120 kg ha^{-1}) are responsible for the maximum productivity of triticale crop in Mardin province environmental conditions. Esin variety showed that it is best cultivar for all components and grain yield except PC.

3. On the other hand; AMMI and GGE biplot analysis revealed that this analysis provided useful results and high image quality to show the correlation among doses, cultivars and components.

4. The results of study showed that the N_3 application of doses in triticale should be recommend for next studies both farm and research area.

(Received 31st May 2018; accepted 17th Jul 2018)

Abstract. *Fusarium dry* rot is one of the most important diseases of potato (*Solanum tuberosum* L.), affecting the tubers in storage and the seed pieces after planting. *Fusarium sambucinum* and *F. solani* are common pathogens causing dry rot of stored tubers in temperate areas. In this study, infection of *F. sambucinum* and *F. solani* on tissue discs prepared from tubers of potato varieties that are susceptible or moderately resistant to this disease was studied. Tubers were wounded, inoculated, incubated at 15-20 °C for 5 weeks and the size of the rot was assessed. All isolates were found pathogenic to potato tubers and differed in pathogenicity. Obtained results revealed that *Fusarium* isolates showed variable aggressivity upon the 17 tested potato cultivars. Furthermore, no cultivars were found to be completely resistant to the whole *Fusarium* isolates, and only one cultivar showed a lesser susceptibility to pathogen. This cultivar was Broke®. Moreover, *F. sambucinum* isolates were detected as more aggressive pathogens than *F. solani* in all cultivars. Additionally, one out of three isolates of *F. sambucinum* was more aggressive than the others. All isolates used in this study were identified both based on colony and conodial morphology and also confirmed by molecular methods.
Keywords: *Solanum tuberosum, Fusarium spp., dry rot, assesment, aggressivity, molecular detection*

Introduction

Potato (*Solanum tuberosum* L.) is among the top five crops growing world wide following cereals wheat, rice, corn and barley due to its high carbohydrate content and adaptability. It is an important source of calorie, protein and fat for humans, industrial raw material for starch and alcohol production and also feed for animals. Global annual production of potato in 2016 was about 376.827.000 tonnes (FAOSTAT, 2017). The annual yield loss of potato crop caused by insects, weed and diseases in the developing countries such as Turkey is determined to be 32.4%. Diseases alone are responsible for 21.8% of yield reduction (Eken et al., 2000). Losses associated with dry rot have been estimated to range from 6% to 25%, and occasionally losses as great as 60% have been reported during long-term storage (Estrada et al., 2010; Secor and Salas, 2001). Dry rot is caused by a number of *Fusarium* species affecting sprouting and emergence at the beginning of the season, which results in yield loss and damage to the quality of daughter tubers, especially during storage (Corsini and Pavek., 1986; Hooker, 1981; Al-Mughrabi, 2010; Borca and Carmen., 2013). Furthermore, there may be potential reductions due to other reasons, such as bacterial soft rot. *Fusarium* species are known to cause dry rot, particularly *F. sambucinum* and *F. solani* are the most common pathogens. To establish strategies for the control of this disease, the primary steps would be to make a correct diagnosis and identify the pathogen on potato. In recent

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_48794892

years, the increasing use of molecular methods in fungal diagnostics enabled a reliable and rapid identification. The most important method of control against this disease is to grow resistant varieties. But potato cultivars vary in their degree of resistance to *F. sambucinum* and other *Fusarium* species

The objectives of this study were: (1) to identify the *F. solani* and *F. sambucinum* isolates obtained from potato dry rot, (2) to identify the virulence of these isolates by comparison with each other, and finally (3) to test some commercial potato varieties for their tolerance to *F. sambicunum* and *F. solani* isolates causing potato dry rot in Turkey.

Review of literature

F. sambucinum Fuckel *(F. sulphureum* Schlecht)- teleomorph *Giberella pulicaris* (Fr.) Sacc.- is the most common pathogen worldwide causing dry rot of stored tubers, but other *Fusarium* species are also known to cause dry rot, particularly *F. solani* (Mart.) Sacc*., F. avenaceum* (Fr.) Sacc. *F. oxysporum* Schltdl., *F. culmorum* (W.G. Sm.) Sacc*.,* and *F. graminearum* Schwabe *(*Boyd, 1972*;* Nelson et al., 1981; Hanson et al., 1996; Eken et al., 2000; Borca and Carmen, 2013; Stefańczyk et al., 2016). Among these fungi, *F. sambucinum* is the most aggressive species both in the world and in Turkey (Boyd, 1972; Hide et al.1992; Hanson et al., 1996; Secor and Salas, 2001; Eken et al., 2000; Du et al., 2012; Aydın et al., 2016). However, some researchers have suggested that other important *Fusarium* species may cause the dry rot. For example, *F. oxysporum* was reported to be the primary agent responsible for potato dry rot among 11 species in Michigan, USA (Gachango et al., 2012). According to Choiseul et al. (2007), *F. avenaceum* was found to dominate pathogens in *Fusarium* population that was examined on potato between 1997 and 2000 in Scotland. Three significant *Fusarium* species, namely *F. coeruleum*, *F. sambucinum* and *F. solani,* have been reported to principally cause the potato dry rot under temperate conditions (Corsini and Pavek, 1986; Daami-Remadi et al., 2006; Daami-Remadi et al., 2012). Isolated outbreaks of disease have been caused by highly pathogenic species and *F. sambucinum* in Scotland was associated with post-storage rotting (Cullen et al., 2005). In addition to destroying tuber tissues, *F. sambucinum* can produce toxins that have been implicated in mycotoxicoses of the human beings and animals (Richardson and Hamilton, 1987; Senter et al., 1991; Schisler et al., 1997; Sveeney and Dobson, 1999).

Potato cultivars vary in their degree of resistance to *F. sambucinum* and other *Fusarium* species (Jellis, 1975; Hooker, 1981; Jellis and Starling, 1983; Wastie et al., 1989). All of the commonly grown potato cultivars in North America are susceptible to the pathogen, but some are less susceptible than the others (Tivoli et al., 1986).

Sources of resistance to pathogens in potato tubers are given in some literature. In resistant tissues lesion enlargement is confined to the infection spot, which might be due to the suberin deposition in the host cells. It involves formation of lignin, suberin, waxes or wound gums in the immediate cells next to the wounded surface. However, further studies imply that formation of lignin and suberin components of periderm may actively be involved in the defense of pathogens. Independent genetic factors are involved in controlling resistance against major *Fusarium* species on potato (Vance et al., 1980; Wastie et al., 1989; Huaman et al., 1989; Valluru et al., 2016). According to Daami-Daami-Remadi et al. (2006) some *Fusarium* species indicated unstable aggressivity upon some of the tested potato cultivars. *F. graminearum* was the most aggressive pathogen on majority of the cultivars, whereas *F. sambucinum*, *F. solani* and *F.*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_48794892

oxysporum showed a comparable aggressivity on some cultivars used. All inoculated tubers showed dry rot symptoms with different degrees, which revealed that cultivars' resistance differed against *Fusarium* species (Daami-Remadi et al., 2006). *F. sambucinum* was found to be the most aggressive species in a study conducted by Du et al., 2012 in Chine and according to that study, 56% of the isolates belonged to these species and Sixty-seven clones were identified as susceptible to *F. sambucinum*. Another survey was carried out in Central Europe by Latus-Ziętkiewicz et al. (1987). According to this study, *F. sambucinum* was the main pathogen causing dry rot in Poland between 1985 and 1986.

To establish strategies for the control of this disease, the primary steps would be to make a correct diagnosis and identify the pathogen on potato. *(*Borca and Carmen, 2013; Aydın et al., 2016). It is primarily based on cultural and morphological characters such as the microscopic morphology including shape and size of the macroconidia, the presence or the absence of the microconidia and of the chlamydospores (Gerlach and Nirenberg, 1982; Burgess et al., 1994; Nelson et al., 1983). But in recent years, the increasing use of molecular methods in fungal diagnostics enabled a reliable and rapid identification. These methods are based on the PCR amplification of species-specific DNA fragments using fluorescent oligonucleotide primers, which were designed based on sequence divergence within the internal transcribed spacer region of nuclear ribosomal DNA sequences. This method provided an accurate, reliable and quick diagnosis of *Fusarium* species including *F. sambucinum* (Mishra et al., 2003; Visentin et al., 2009; Powel et al., 1996; Abd-Elsalam et al., 2003; Oechsler et al., 2009; Wang et al., 2011).

Material and methods

Potato cultivars

Potato cultivars tested in this study are listed in *Table 1*. They are provided by the various agricultural companies and they are stored in darkness at 4 °C until the experiments were carried out.

Microorganisms and identification

The strains of *F. sambucinum* (Fs2, Fs3 and Fs4) and *F. solani* (Fs1) are used in this study were taken infected potatoes from Afyon potato production area in the autumn season. They were isolated from the infected potato tubers of cv. Lady Rosetta with typical symptoms of dry rot and it was previously reported to be virulent on potato tubers (Aydın et al., 2016). The strains were maintained on potato dextrose agar (PDA, 38 g and sterile water, made up to 1 litre). Before starting work, pure tubers were infected with isolates and re-isolated. Thus, the isolates were maintained in virulence. The single spore technique was used to obtain a pure culture of *Fusarium* isolates. The color of colonies of strains obtained ranged from white to moderate pink. Isolates were stored in the tube at +4 °C until it starts to work. Synthetic Nutrient Agar (SNA, Difco), Potato Dextrose Agar (PDA, Merck) and 1/10 diluted PDA media were used for morphological and microscopic identification. All *Fusarium* isolates were initially identified according to their morphological and microscopic characters as described by Booth (1977), Gerlach and Nirenberg (1982), Nelson et al. (1983), Hasenekoğlu (1991), Burgess et al. (1994), Leslie and Summmerell (2006), Borca and Carmen (2013). And

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_48794892

then, identification of the isolates was further confirmed by molecular approach. Processes related to pathogen isolation and identification are given in *Figure 1.*

Molecular identification of Fusarium isolates

DNA isolation, PCR condition and phylogenetic analysis

Fungal Genomic DNA was extracted from mycelium by using the methodology as proposed by Doyle (1987). DNA quality was checked on 1% agarose gel, and then quantification was measured by using the Nanodrop (Thermo Scientific). To achieve the amplification of ITS4-ITS5 region of nuclear genome, PCR was performed in 25 µl volume. This volume occurred from 80 ng of total genomic DNA, 10 pmol both primers, 200 µM dNTP, 2 mM $MgCI_2$, 1X Taq buffer, 1U of Taq Polymerase (5 U/µL, catalog number: EP0402) and ddH_2O for complete the last volume. PCR products were separated by gel electrophoresis on 1.5% agarose gels, containing ethidium bromide, and photographed under UV light in a gel doc system. PCR products of ITS4-ITS5 region were sequenced by Iontek Company, Istanbul, Turkey.

Alignment and phylogenetic analysis

The obtained sequences were Blasted (basic local alignment search tool) by using the NCBI (National Center for Biotechnology Information) database and percent homology scores were assessed to identify *Fusarium* spp. Phylogenetic trees were made with MEGA version 7 (Tamura et al., 2007). Using a neighbor-joining algorithm, bootstrap analyses for 1000 replicates were performed.

Table 1. *Characteristics of potato cultivars tested for their tolerance to F. sambucinum and F. solani isolates causing potato dry rot in Turkey*

Cultivars*	**Tuber shape**	**Skin color**	**Flesh color**	**Dry matter (%)**	**Usage**
Marabel	Oblong	Yellow	White	19.2	Cooking
Madeleine	Round-oval	Yellow	Yellow	18.2	Cooking
Hermes	Round-oval	Yellow	Ochre	28.4	Crisps
Opal	Round oval	Yellow	Light yellow	Medium	Crisps
Brooke	Round oval	Yellow	Medium yellow	----	Crisps

Evaluation of dry rot susceptibility to F. sambucinum and F. solani

A total of 17 potato cultivars (*Table 1*) were selected to test their resistance to *F. sambucinum* (Fs1, Fs2, Fs3) and *F. solani* (Fs1). Symptom-free tubers of dry rot and other diseases were selected for the experiments and weighed from 80 to 100 g. They were washed in running tap water, dipped in sodium hypochlorite (5%) for 5 min, rinsed twice with double distilled sterile water and air-dried for 24 h. Potato tubers were wounded through inward with a drill 8 mm in diameter and 8 mm in depth. An 8 mm agar plug derived from the edge of a 7-day-old fungi colony on PDA was inserted into the drilled tuber hole. A control treatment consisting of a non-inoculated agar plug was inserted into the wounded tuber. The experiment was set up at room temperature of 15-20 °C in separate plastic boxes with sufficient relative humidity for five weeks. Every treatment was repeated for four times (one tuber x one wound). Treatments applied to seed pieces were: (1) not inoculated, (2) inoculated with *F. sambucinum* (Fs2); (3) inoculated with *F. sambucinum* (Fs3), (4) inoculated with *F. sambucinum* (Fs4) and (5) inoculated with *F. solani* (Fs1). After incubation period, tubers were cut through the inoculation site and the depth and width of the rot area were measured. Parameters of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_48794892

dry rot caused maximal width (w), depths (d) were noted, and tubers were calculated by applying the following formula devised by Lapwood et al. (1984):

$$\text{Penetration (mm): } [w/2 + (d\text{-}6)]/2$$

Cultivar's susceptibility to *F. sambucinum* (Fs2, Fs3, Fs4) and *F. solani* (Fs1) was estimated according to this scale: Less or moderately susceptible: mean penetration ≤ 12 mm; Susceptible: 12 mm <mean penetration < 15 mm; Highly susceptible: mean penetration ≥ 15 mm. The data were analysed with SPSS (version 20, SPSS Inc. Chicago, Illinois) and means were separated with Duncan's multiple range test.

Results and discussions

Molecular identification of F. sambucinum (Fs2, Fs3, Fs4) and F. solani (Fs1).

Both *F. sambucinum* (Fs2, Fs3, Fs4) and *F. solani* (Fs1) were identified based on morphological structures as described by Booth (1977), Gerlach and Nirenberg (1982), Nelson et al. (1983), Hasenekoğlu (1991), Leslie and Summerrell (2006) and Borca and Carmen (2013) respectively. In addition for molecular analysis, sequences of ITS4 and ITS5 regions were compared by using the BLAST (basic local alignment search tool) in NCBI (National Center for Biotechnology Information) database in GenBank. Phylogenetic tree generated from the ITS sequence data was found to have a quite consistent resolution with our estimations. The resulting dendrogram (*Fig. 2*) showed that the analyzed ITS gene region represented the variability to differentiate from the isolate of *Fusarium* spp obtained from NCBI.

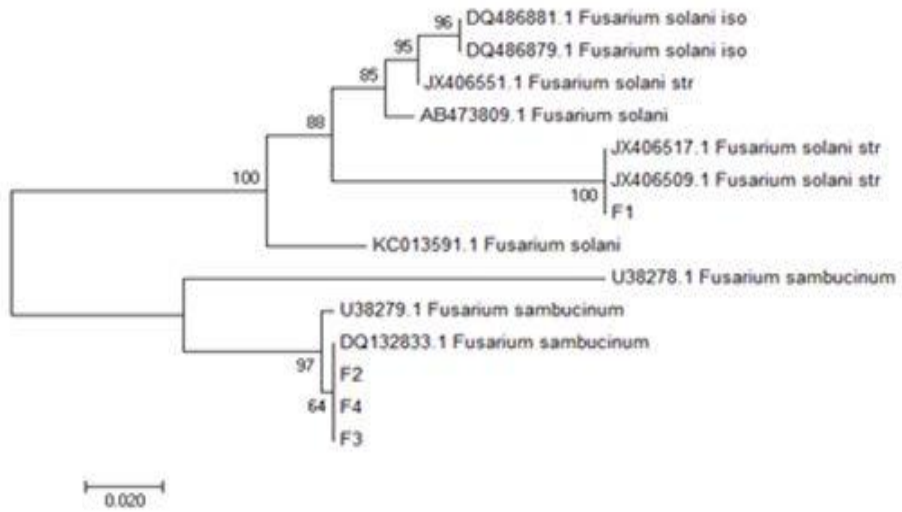

Figure 2. *Phylogenetic tree based on neighbor-joining analysis of ITS sequences from NCBI and 4 isolated Fusarium spp. Bootstrap values are given when above 64% (1,000 replicates)*

Analyzed isolates formed two main branches. First main branch was consisted of investigated F1 and *F. solani* isolates obtained from NCBI. So it can be argued that F1 isolates showed a kinship with *F. solani*. The second main branch was built up by the investigated F2, F3 and F4 and *F. sambucinum* isolates obtained from NCBI. So it can

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_48794892

be estimated that F2, F3 and F4 isolates showed a genetic kinship with *F. sambucinum.* We reach the conclusion that ITS region was found to be as a diagnostic tool to discriminate the investigated isolates in this study. Informative sequences of ITS region also help the close related *Fusarium* species such as *F. verticillioides* and *F. proliferatum* (Visentin et al., 2009). The least informative or low nucleotide sequence variation of the ITS region to clearly identify many complex species was also previously achieved (Oechsler et al., 2009; Wang et al., 2011). Determination of *Fusarium* spp. using thermal cycler amplification of ITS region of the rDNA using the right primer pairs are reliable, accurate and quick. Duggal et al. (1997) reported that the ITS region shows polymorphisms with in *Fusarium* spp. This is consistent with the previous study (White et al., 1990) and (O'Donnell, 1992) which under line the applicability of using the ITS region as a molecular marker to identify the *Fusarium* spp. It was also defined in these works that the rDNA region of *F. sambucinum* showed a highly conserved. Furthermore, small sequence divergence was found by using the ITS region that can determinate species from the same clan (Turner et al., 1998).

Evaluation of dry rot susceptibility to F. sambucinum (Fs2, Fs3, Fs4) and F. solani (Fs1)

Commercial variety susceptibility to *Fusarium* dry rot decay can affect the market value. Therefore, it is important to grow potatoes that are not susceptible to this disease. The mean dry rot scores are shown in *Table 2,* and analysis of variance is indicated in *Table 3*.

Table 2. *Dry rot severity caused by F. solani (Fs1) and F. sambucinum (Fs2, Fs3, Fs4) in potato tubers in vivo test*

Varieties	The average severity diseases of isolates				
	Severity of Fs1	Severity of Fs2	Severity of Fs3	Severity of Fs4	Mean
Marabel	7.63	13.06	13.88	14.26	12.20 h*
Madeleine	7.25	13.44	18.00	11.94	12.65 gh

Table 3. *Mean squares from the analysis of variance for dry rot inoculation tests*

Variation source (VS)	Degree of freedom (DF)	Sum of squares (SS)	Mean of square (MS)	F
Replication	3	17.088	5.696	2.09
Variety	16	1864.549	116.534	48.82**
Isolate	3	3103.692	1034.564	380.21**
Variety*Isolate	48	2213.389	46.112	16.94**
Error	201	546.939	2.721	
Total	271	7828.586		

Coefficient of variation (CV) = 9.05%

According to the variance analysis results, the disease reactions of the varieties against *Fusarium* isolates appear to be statistically significant at the level of 1%. Susceptibility of Potato varieties to *F. sambucinum* (Fs2, Fs3, and Fs4) and *F. solani* (Fs1) isolates had different grades with average lesion sizes ranging from 10.73 to 21.06 mm (*Table 2*). Cultivars were evaluated in laboratory for 5 weeks at 15-20 °C. Obtained results revealed that Broke had a less or moderately susceptible dry rot potential classification, whereas Musica, Melody, Vr.808, Surya, Alonso, Alegra, Borvira, Soraya had a high dry rot potential. The cultivars of Marabel, Madeleine, Hermes, Opal, Claire, Orchestra, Rossetta and Desire were also susceptible in terms of dry rot (*Table 4, Fig. 3*). Disease development of *Fusarium* dry rot can be increased depending on variety, harvest and handling conditions, tuber characteristics and storage temperatures. Previous studies have shown that the majority of varieties on the market were susceptible to this disease (Tivoli et al., 1986; Wastie et al., 1989; Kumar and Knowles, 2003; Burkhart et al., 2007; Lynch et al., 2003; Daami-Remadi et al., 2006; Du et al., 2012; Baturo-Cieśniewska et al., 2014; Stefańczyk et al., 2016). So, it is essential to incorporate good management practices in order to reduce *Fusarium* dry rot (Leach and Nielsen, 1975; Al-Mughrabi, 2010).

Table 4. *Potato variety susceptibility to Fusarium dry rot*

Less or moderately susceptible	Susceptible	Highly susceptible
Broke	Hermes	Musica
	Opal	Melody
	Claire	Vr.808
	Orchestra	Surya
	Rosset	Alonso
	Desire	Alegra
	Marabel	Borvira
	Madeleine	Soraya

Different rates in terms of disease severity have occurred among the varieties against the same isolate. For example, *F. solani* (Fs1) caused disease severity on Soraya, Alonso, Vr.808, Rossetta, 13.50, 12.38, 12.68 and 12.81 respectively. On the other hand, some isolate again caused on Marabel, Madeleine, Hermes, Opal and Broke 7.63, 7.25, 7.94, 7. 19, 7.75 mm, respectively (*Table 2, Fig. 3*). Similar results were obtained

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_48794892

in some studies conducted in different countries (Hooker, 1981; Jellis and Starling, 1983; Tivoli et al., 1986; Wastie et al., 1989). According to Daami-Remadi et al. (2006), all inoculated tubers showed dry rot symptoms with different degrees, which reveal that cultivars' resistance differed against *Fusarium* species.

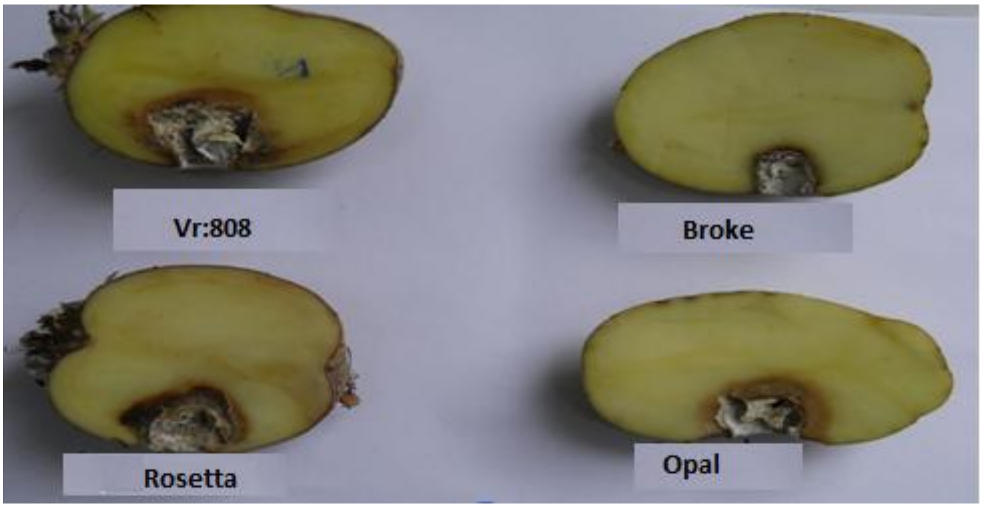

Figure 3. *Dry rot symptom caused by F. solani (Fs1) isolates on tubers of the cultivar Vr.808, Rosetta (left) and Broke, Opal (right) after 5 weeks of incubation at 15-20 °C*

The isolates of whole *F. sambucinum* were more aggressive pathogens than those of the *F. solani* in all cultivars (*Table 2*). As given in *Table 2,* the mean diseases Severity of *F. solani* (Fs1) is 9.43, but the isolates of *F. sambucinum* (Fs2, Fs3, Fs4) were between 16.40-18.15 mm. For example, all isolates (Fs4, Fs3, Fs2, Fs1) caused disease severity on Surya cultivar at different rates, 26.25, 28.06, 21.13, 8.81 respectively (*Table 2, Fig. 4*).

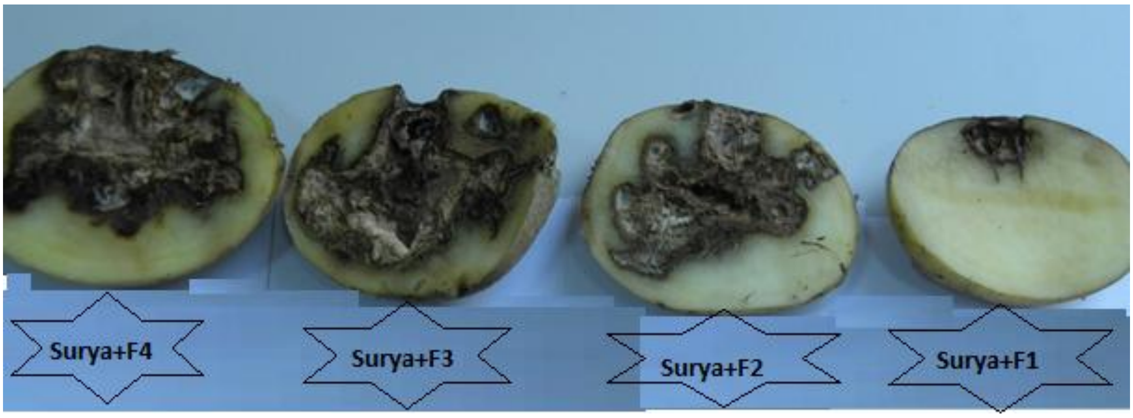

Figure 4. *Dry rot symptoms caused by F. sambucinum (Fs4, Fs3, Fs2) and F. solani (Fs1) isolates on tubers of the cultivar Surya after 5 weeks of incubation at 15-20 °C*

According to this study, *F. solani* (Fs1) was a weaker pathogen. This result is not supported by some researchers. For example, Lenc et al. (2008) and Peters et al. (2008) have reported *F. sambucinum* and *F. solani* are more frequently associated with dry rot

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_48794892

of tubers but *F. solani is* considered to be a more aggressive pathogen in most parts of Europe. However, this finding was supported by some other researchers who stated that *F. sambucinum* was more aggressive pathogen than the other *Fusarium* species which caused dry rot on potato (Corsini and Pavek, 1986; Wastie et al., 1988; Du et al., 2012; Aydın et al., 2016). In conclusion, this study also supports that several *Fusarium* spp. have been associated with potato dry rot. But depending on the geographic location and the season, the most frequent and devastating of these species is *F. sambucinum.* The isolates are used in this study obtained in Afyon potato production area in the autumn season. The severity of dry rot in this area was usually found to be high (Aydın et al., 2016).

As a result, susceptibility of varieties was found to be distinct to *F. sambucinum* isolates and *F. solani.* While Broke was less or moderately susceptible, other varieties such as Marabel and Madeleine were detected to be susceptible or highly susceptible to *Fusarium* dry rot according to the total disease severity of the four isolates on the varieties (*Table 4.*)

After *Fusarium* isolates grew on the PDA for seven days, they were classified into four different color groups based on mycelium shapes; white (Fs1), Light pink (Fs2), moderately pink (Fs3) and (Fs4). According to phylogenetic analysis also, Fs1 isolate was detected to be close to *F. solani* and the other three isolates are found to be close to *F. sambucinum* (*Fig. 2*). Regarding the color of colonies of isolates on PDA, Fs2 and Fs4 developed close to pink but Fs3 as moderately pink (*Fig. 5*).

Figure 5. *Regarding the color of colonies of isolates on PDA, F. solani Fs1 and F. sambucinum Fs3 (left); F. sambucinum Fs2 and F. sambucinum Fs4 (right)*

All inoculated tubers indicated dry rot symptoms with different degrees against *F. sambucinum* (Fs2, Fs3 and Fs4). Fs2 and Fs4 isolates shared similar levels of pathogenicity, whereas Fs3 caused more severe diseases (*Fig. 6*). Maybe we can make hypothesis that the dark pink of *F. sambucinum* isolates that developed on the medium had more virulence on the potato. Aydın et al. (2016) studied with a dark pink of *F.*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_48794892

sambucinum isolate on potato and assumed that the sprouts of tubers were infected with systemic symptoms and severely rot. Thus, it has been suggested that this isolate may be different from other in terms of both the symptom and the severity of the disease.

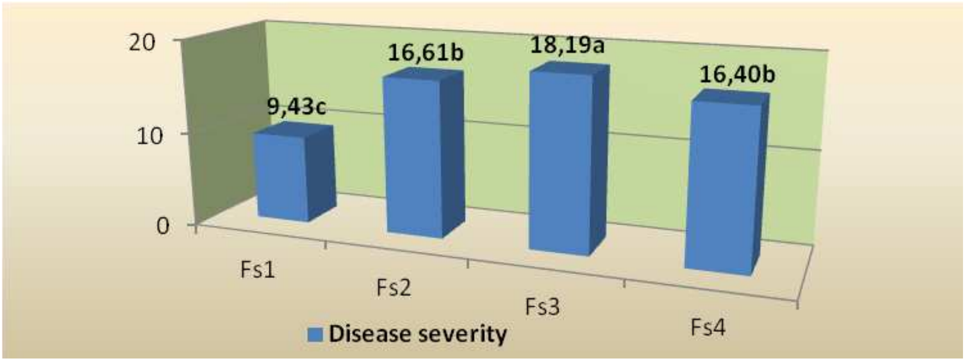

Figure 6. *The mean severity of dry rot caused by F. solani (Fs1) and F. sambucinum (Fs2, Fs3 and Fs4) isolates on potato*

This result shows that the isolates of *F. sambucinum* may be different from each other in terms of virulence. As already noted other researchers have also reported that the majority of the *F. sambucinum* isolates were pathogenic to the potato and caused an average lesion of 21.6 mm. But only one *F. sambucinum* isolate caused an average lesion size that was considerably lower, at 12.1 mm (Stefańczyk et al., 2016).

Conclusion

Briefly, dry rot disease caused by *F. sambucinum* is an economically important field and a postharvest disease throughout the world. This study also reached the conclusion that some strain of *F. sambucinum* investigated were aggressive than the others and caused more severe tuber rots compared to *F. solani.* Many potato cultivars used in this study were susceptible hosts to the pathogen *F. sambucinum.* Only one cultivar showed less or moderate susceptible to pathogen. Phylogenetic tree generated from the ITS sequence data is found to have a quite consistent resolution with our estimations.

Abstract. The aim of this study was to determine the possible effects on soil health and crop yield of the application of anaerobically digested sewage sludge (SS) at doses of 10 (SS_1), 20 (SS_2) and 30 (SS_3) t ha^{-1} yr^{-1} to degraded soils under maize (*Zea mays* L.) and cotton (*Gossypium hirsutum* L.) in the semi-arid Mediterranean ecosystem in Turkey. Application of SS at different doses did not show any disruptive effect on microbial biomass and activity in the soil. In the microbiochemical parameters analyzed in the soils under the two plant covers treated with SS, increases were seen of 29-30% compared with control, and of 28-30% in comparison with chemical fertilizer application. Yield increases secured by chemical fertilizers were statistically significantly higher than those from the SS_1. In maize grain yield, statistically significant increases were shown in comparison with the control of 90% with SS_3 and of 86% with SS_2. Similarly, seed cotton showed a statistically significant increase in yield of 72% with SS_3. Results obtained from the study show that for degraded soils in Mediterranean biodegradability conditions, application of SS at a rate of 30 t ha^{-1} yr^{-1} can be used both as a soil improver to maintain the soil and as an organic fertilizer to increase crop yield.
Keywords: *anaerobically digested sludge, soil enzymes, Mediterranean biodegradation condition, maize, cotton*

List of abbreviations: ALKPA – alkaline phosphatase enzyme activity; ArSA – aryl sulphatase enzyme activity; BSR – basal soil respiration; CF – chemical fertilizer treatment; DHG – dehydrogenase enzyme activity; GLU – ß-glucosidase enzyme activity; ha – hectare; MBC – soil microbial biomass carbon; N_{min} – N-mineralization; PRO – protease enzyme activity; SP_1 – first soil sampling period; SP_2 – second soil sampling period; SS – anaerobically digested sewage sludge; SS_0 – 0 t SS ha^{-1} yr^{-1} (control treatment); SS_1 – 10 t SS ha^{-1} yr^{-1} treatment; SS_2 – 20 t SS ha^{-1} yr^{-1} treatment; SS_3 – 30 t SS ha^{-1} yr^{-1} treatment; t – tonnes; UA – urease enzyme activity; yr – year

Introduction

The most important element necessary in ensuring sustainable soil fertility and productivity is soil organic matter. In conditions where soil organic carbon pool has not been well managed, long-term intensive agricultural activity inevitably results in a degradation of soil health. Examining soils affected by the Mediterranean climate, it is seen that the characteristics hindering fertility and crop development are high lime content and pH, and low organic material content. The soils of this region are also characterized by a progressive loss of fertility as a result of high degradation (Pascual et al., 1998). In order to increase soil fertility in a short time, it is necessary not only to add the plant nutrients which may be deficient in the soil by means of chemical fertilizers but also to rectify its characteristics in order to bring it into a sustainable condition. For this reason, in agricultural soils under the effects of the Mediterranean climate whose

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_48934917

organic material content is low, it is of vital importance to apply organic wastes which have high potential for use.

The sludge varies in the amount and quality of the organic materials remaining according to the stabilization method used, and this determines the direction and strength of its effect on the soil-plant ecosystem. This is because sewage sludge of better quality and with a greater quantity of organic matter will have a greater positive effect on microbial activity and thus on crop yield than the same amount of sludge containing heavy metals. Thus it has been shown not only by researchers working with sewage sludges stabilized by different methods such as thermal drying, aerobic composting, anaerobic decomposition or calcification (Selivanovskaya et al., 2001; Fernández et al., 2009; Jamal et al., 2011), but also by researcher studying with sewage sludge from different wastewater treatment plants of the same municipality (Wong et al., 2001) that the effect of all of them on the soil and crop ecosystem will vary.

The nutrients and organic materials remaining in the sewage sludge at the end of the treatment processes provide for one of the most important methods of disposal of the sludge, that is its use on the soil as a fertilizer or soil improver. The application of sewage sludge to agricultural land is an economical and sustainable method both of recovering nutrients and of disposing of sewage sludge (Lundina et al., 2004; Laturnus et al., 2007; Ghazy et al., 2011). Enriching the soil in organic materials and providing nutrient or fertilizing materials such as nitrogen and phosphorus are the major advantages of this treatment, which can result in an increase in the productivity of the soil (Walia and Goyal, 2010; Saviozzi and Cardelli, 2014). Detailed studies have been conducted on this topic by many researchers in various countries (Gascó and Lobo, 2007; Laturnus et al., 2007).

It has been established in previous studies that the application of sewage sludge improved the physical (Griffiths et al., 2005) and chemical (Speir et al., 2004) characteristics of the soil, and generally supported microbial growth and activity (Debosz et al., 2002; García-Gil et al., 2004). In various other studies, it has been shown that the application of urban sewage sludge has developed the physical characteristics of the soil, such as bulk density, aggregate stability, water retention capacity, total porosity and saturated hydraulic permeability (Kahapanagiotis et al., 1991; Silveira et al., 2003; Rezig et al., 2013), increased the content of organic material, and also prevented erosion (Singh and Agrawal, 2008; Alcantara et al., 2009; Franco et al., 2010; Annabi et al., 2011). However, it has also been shown that the addition of sludge can cause unwanted changes such as a fall in pH values or a rise in salinity, or the concentration of heavy metals (Navas et al., 1998; Veeresh et al., 2003; Singh and Agrawal, 2008). Besides, the long-term repeated addition of sludge can potentially have harmful effects such as the accumulation of toxic metals or damage to microbial communities and their functions, thereby threatening the long-term vitality of the soil. However, observations by different researchers have shown variations in the long-term effects of sludge on the microbial biomass of the soil (Flieβbach et al., 1994; Defra, 2005). The ability to establish the biological characteristics of the soil which give the fastest and most accurate response to all soil management practices in the short term will form an important basis for creating a long-term perspective. Also, there has as yet been little research into the short term effects of the use of dried organic wastes left over after the extraction of energy by anaerobic decomposition on the chemical and biochemical characteristics of the soil and on the yield of annual plants.

The aim of this study, designed from this starting point, was to research and compare the effect on cotton and maize yield of various doses of sewage sludge (SS) from the Çiğli Wastewater Treatment Plant of İzmir Metropolitan Municipality, stabilized in anaerobic conditions and converted to granules of 90% dryness, with the biochemical characteristics of a degraded soil in a semi-arid Mediterranean agro-ecosystem. In addition, variations in the heavy metal content of the soil were examined. Enzymes considered in the study were those involved in cycling in the soil: protease and urease of N, β-glucosidase of C, alkaline phosphatase of P, and aryl sulfatase of S. Different from the others, the enzyme dehydrogenase is an enzyme which functions in the mechanisms of intracellular respiration and shows the total oxidative capacity of the microbial biomass.

Materials and methods

Anaerobically digested sewage sludge (SS)

The sewage sludge used in the experiment was from the Çiğli Wastewater Treatment Plant of İzmir Metropolitan Municipality of Turkey, stabilized in anaerobic conditions and converted to granules of 90% dryness. Various characteristics of the SS are given in *Table 1*.

Table 1. *Mean values of the some physicochemical properties of anaerobically digested sewage sludge (SS) from Çiğli Wastewater Treatment Plant used in the experiment*

Parameter	Mean[a]	Turkish directive	European directive	USA (Part 503)

The sewage treatment process was designed according to an advanced biological purification method, biologically removing phosphorus and nitrogen and able to produce water of a better quality, with a capacity of approximately 605 t day^{-1}. The facility has four digestion tanks, two biogas collection tanks and four dryers, each with the capacity to process 200 t day^{-1} of sludge cake. In 2015, the sludge digestion and drying unit produced a total of 11550 t of dried sewage sludge and 11755000 m^3 of biogas (İZSU, 2018). The heavy metal content of the SS used in the study was below the values allowed by Europe Directive 86/278/CEE (CEC, 1986), US (EPA, 1993) and Turkish regulations (RG, 2010) (*Table 1*).

Field experiments

Field experiments were conducted in 2015 at the Research, Application and Production Farm of Ege University Agriculture Faculty (longitude: 27°01'20"-27°01'22" E; latitude: 38°34'47"-38°34'45" N; average altitude 5 m), on sandy loamy soil (sand, silt and clay 558.4, 314.4 and 127.2 g kg^{-1} respectively). *Figure 1* shows the experimental area location and some photos of the experimental period. The soil is classified as Typic xerofluvent (Soil Survey Staff, 2010). The physicochemical properties of the experimental field at the beginning of the experiment are given in *Table 2*. The Menemen Plain, where the research area is located, has a Mediterranean climate, with hot dry summers and cool rainy winters. According to long-term (55 year) climate data, mean total annual precipitation is 525.3 mm. Approximately 50% of this precipitation occurs in winter, 25% in spring, 23% in autumn and 2% in summer. The mean temperature is 16.9 °C, mean relative humidity is 57.5%, and mean annual evaporation is 1532.1 mm (Anonymous, 2009).

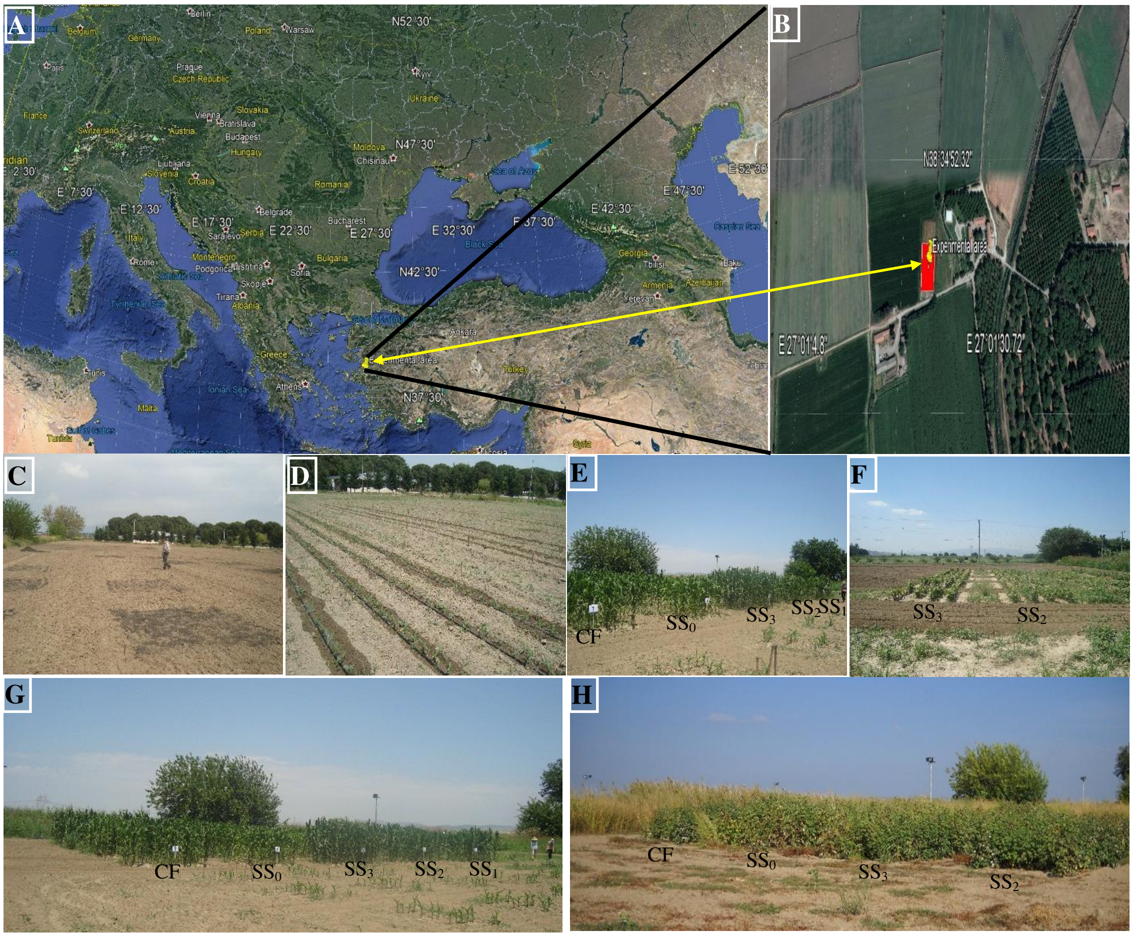

Figure 1. *Map showing (A) the location of the Research, Application and Production Farm of Ege University Agriculture Faculty experimental area in the İzmir Province, Turkey and (B) close-up view of the experimental field, (C) photo of sewage sludge applications, (D) photo of drip irrigation activity, (E) and (G) photos of the maize experiment, (F) and (H) photos of the cotton experiment*

The experiment was performed in four randomized blocks of soil plots (3 m × 3 m) with four replications cropped with maize (*Zea mays* L. var. ZP 737) and cotton (*Gossypium hirsutum* L. var. GSN 12), at the same time. Soil plots were either unamended (SS_0) or amended with SS at rates of 10, 20 and 30 t ha^{-1} on a dry weight basis (SS_1, SS_2 and SS_3, respectively). After application of the SS to the surface of the soil in the experiments, the soil was mixed to a depth of 15 cm using a rotary tiller (21 April 2015). 1 t ha^{-1} 15-15-15 composite fertilizer was used for the mineral fertilizer application in the maize experiment (CF). Maize sowing took place on the same day, 21.4.2015, on all experimental plots after the application of sewage sludge. Seeds were sown in rows 70 cm apart, at 18.3 cm intervals, using a seed drill. As mineral fertilizer, 150 kg ha^{-1} urea fertilizer (46% N) was applied as a top dressing on 4 June 2015. Cotton sowing took place on 29 April 2015. In the cotton experiment, 500 kg ha^{-1} of 15-15-15 composite fertilizer was applied as basic fertilizer to the mineral fertilizer plots (CF) on 21 April 2015. As a mineral fertilizer application in the cotton experiment, 150 kg ha^{-1} of urea fertilizer was applied to the plots as a top dressing on 4 June 2015. The second top dressing in the cotton experiment was applied during the flowering period (8 July

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_48934917

2015), with only mineral fertilizer at a dose of 270 kg ha^{-1} of CAN (calcium ammonium nitrate). In both the maize and the cotton experiments, drip systems were set up for irrigation purposes. In order to meet the water requirement of the test plants, irrigation activities were carried out every 15 days from the sowing of seeds, taking into consideration the regional climatic conditions and producer practices. Irrigation water was given for maize plant in 6 times (total 600 mm) and for cotton plant in 8 times (800 mm in total) with 100 mm in each irrigation period.

The first soil samling period (SP_1) was taken fifteen days after the application of the SS. The second soil sampling period (SP_2) was taken 120 days later (19 August 2015) for maize and 189 days later (27 October 2015) for cotton. Soon after the plants were harvested individually, surface soil samples were collected randomly from the arable layer (Ap horizon, 0–15 cm depth) of each plot. Each soil sample consisted of a mixture of 10 soil cores, each 3 cm in diameter. Soil samples for biological and biochemical analyses were stored at 4 °C at field moisture. *Table 3* shows the results of the analysis of the soil samples (First period n = 40, second period n = 40) of the microbiological parameters microbial biomass carbon (MBC), basal soil respiration (BSR), N-mineralization (N_{min}), alkaline phosphatase enzyme activity (ALKPA), dehydrogenase enzyme activity (DHG), protease enzyme activity (PRO), urease enzyme activity (UA), ß-glucosidase enzyme activity (GLU) and aryl sulphatase enzyme activity (ArSA), while *Tables 4* and *5* show the Pearson correlation matrix for the chemical parameters analyzed with these parameters for maize and cotton vegetation respectively. When the maize plants came to harvesting maturity, the middle two rows of the four rows on each plot were used (19 August 2015). The cotton bolls were also harvested by hand (27 October 2015). At the end of harvest, plot yields were calculated and converted to t ha^{-1}.

Chemical analysis of soil and sewage sludge

Prior to analysis, soil samples were air-dried and passed through a 2 mm sieve. The principal chemical properties of soil and SS samples were determined by standard methods (Sparks et al., 1996). In particular, the pH was measured on satured soil and on mixtures of sludge:water = 1:2.5; the EC was measured on a 1:5 sample:water extract; and the TOC content was determined by dichromate oxidation of the sample and subsequent titration with ferrous sulfate heptahydrate. The total N content was obtained by the Kjeldahl method (Keeney and Nelson, 1982). Available P content was determined according to the Olsen method (Olsen and Sommers, 1982); and available K content was measured by Flame Photometer in 0.5 M ammonium acetate soil extracts using a ratio of soil to extractant of 1:10 (Sparks et al., 1996). For determination of heavy metals, the soils were extracted with 3 parts HCl + 1 part HNO_3. The concentrations of Pb, Ni, Cr, Co, Hg, As and Cd in the extracts were determined by atomic absorption spectrometry (AAS) (ISO, 1995, 1998). For determination of boron, soils were extracted with hot water for 5 min, centrifuged and filtered. Boron was determined using azomethine-H. Reagents formed using ammonium acetate and disodium ethylenediamine-tetra-acetate for this study are those used by Gupta (1979). The SS samples were dried at 70 °C for 72 h, and their dry weights were recorded. The samples were then ground to pass through a 2 mm sieve for subsequent analysis. After nitric and perchloric acid digestion (4:1), total Mg, Fe, Cu, Mn, Zn, Cd, Pb, Ni, Hg and Cr concentrations in the SS were determined using AAS, and Ca, K and Na concentrations were determined by flame photometry (Kacar and İnal, 2008). Total P content in the acid digest was determined using a spectrophotometer after developing

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_48934917

the vanadomolybdophosphoric yellow color complex in a nitric acid medium (Kacar and İnal, 2008).

Soil biological and biochemical analyses

Basal soil respiration (BSR) was found using a 0.1 N NaOH solution after a 24 h incubation period at 25 °C (Isermeyer, 1952; Jäggy, 1976). In order to determine microbial biomass carbon (MBC), the moisture content of soil samples was determined, and after fumigation according to Jenkinson (1976), they were agitated with 0.5 M K_2SO_4 (Vance et al., 1987). After that, the amount of C in the filtrate was determined by wet digestion in the presence of strong acid (a mixture of H_2SO_4 and H_3PO_4) and 0.4 N $K_2Cr_2O_7$, after which the excess dichromate was titrated with a 25 mM 1.10-fenantrolin iron sulfate complex indicator solution (Kalembasa and Jenkinson, 1973; Vance et al., 1987). A kEC factor of 0.45 was used in the calculations (Jenkinson and Ladd, 1981). N-mineralization (N_{min}) was assayed according to the method of Keeney (1982). This method involves the incubation of a soil sample under waterlogged conditions at 50 °C. After seven days, NH_4-N released from the soil water mixture was determined with a modified Bertholet reaction. Dehydrogenase enzyme activity (DHG: EC 1.1) was determined after adding TTC (triphenyl tetrazolium chloride) solution at different concentrations according to the soil texture and the amount of organic matter to the soil samples and incubating for 16 h at 25 °C, by photometric measurement at a wavelength of 546 nm of the resulting TPF (triphenyl formazan) (Thalmann, 1968). The activity of urease, an enzyme of the hydrolase group (UA: EC 3.5.1.5), was determined by incubating the soil where urea was used as a substrate at 37 °C for 90 min, and determining the resulting ammonia with a modified Bertholet reaction after extracting it with 2 M KCl (Kandeler and Gerber, 1988). To determine alkaline phosphatase enzyme activity in the soil samples (ALKPA: EC 3.1.3.1), buffered p-nitrophenyl phosphate solution was added and p-nitrophenol, incubated for 1 h at 37 °C, and resulting by phosphomonoesterase activity, was colored with sodium hydroxide and measured photometrically at 400 nm (Eivazi and Tabatabai, 1977; Tabatabai and Bremner, 1970). For protease enzyme activity (PRO: EC 3.4), soils where casein was used as a substrate were incubated at 50 °C for two hours, and the resulting aromatic amino-acids were colored in an alkaline environment with folin-ciocalteu, and detected colorimetrically at 700 nm (Ladd and Butler, 1972). The soil samples were incubated for three hours at 37 °C with salicin, after which the resulting saligen was determined spectrophotometrically at 578 nm in order to determine β-glucosidase activity (GLU: EC 3.2.1.21) (Hoffman and Dedeken, 1965). In order to determine the activity of aryl sulfatase, which has a role in the sulfur cycle (ArSA: EC 3.1.6.1), a solution of p-nitrophenylsulfate was added to the soil samples as a substrate, and the resulting nitrophenol was measured photometrically at a wavelength of 430 nm (Tabatabai and Bremner, 1970).

Statistical analysis

All data were tested for normality and homogeneity of distribution, and were log-transformed if required prior to analyses. Multivariate analysis of variance (MANOVA) test was used to study the effects of treatment on soil chemical, biochemical and microbiological properties. Comparison of average values was performed with the Duncan multiple comparison test and with a significance level of $\alpha = 0.05$. Pearson

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_48934917

correlation analyses were performed on all the chemical, microbiological and biochemical data. All statistical analyses were performed using the IBM SPSS 20.0. Standard deviation values showing distribution according to the average of data obtained in each period were also calculated by means of the same program.

Results and discussion

Maize and cotton yield

Figure 2 shows the effects on the yield of maize and cotton of SS applied at different doses. It was observed that SS applied in the experiment had no toxic effect on either of the crops. In fact, statistically significant increases in yield parameters of the crops were seen with increasing doses of SS in comparison with the SS_0. A yield increase of 90% was determined in maize grain yield with SS_3 compared to the control. Similarly, seed cotton yield increased by 72% with the same treatment. In a study conducted with maize in a hot, moist and semi-arid eco-subregion soils of India which climate is dominated by monsoons and strongly influenced by the Himalayas and the Thar Desert, a determination was made of the effect of the application of compost, stabilized sewage sludge and nitrogen fertilizer to the crop. According to the results of the field experiments, the two highest doses of stabilized sludge (80 and 160 t ha^{-1}) gave significant increases in yield, but at the same time increases were determined in the heavy metal contents of the crop. The researchers found that treatment at the level of 40-60 t ha^{-1} yr^{-1} of sewage sludge was the most suitable to achieve acceptable crop growth and a minimum of adverse effects on crop and soil quality (Begum, 2011). In a study, laboratory incubation and pot experiment were carried out to determine the effect of heavy metal concentration, adverse effects were shown in the growth of Indian mustard of applications of 40 and 80 t ha^{-1} of sewage sludge which had a heavy metal concentration of twice the limit set by the European Union (Walia and Goyal, 2010).

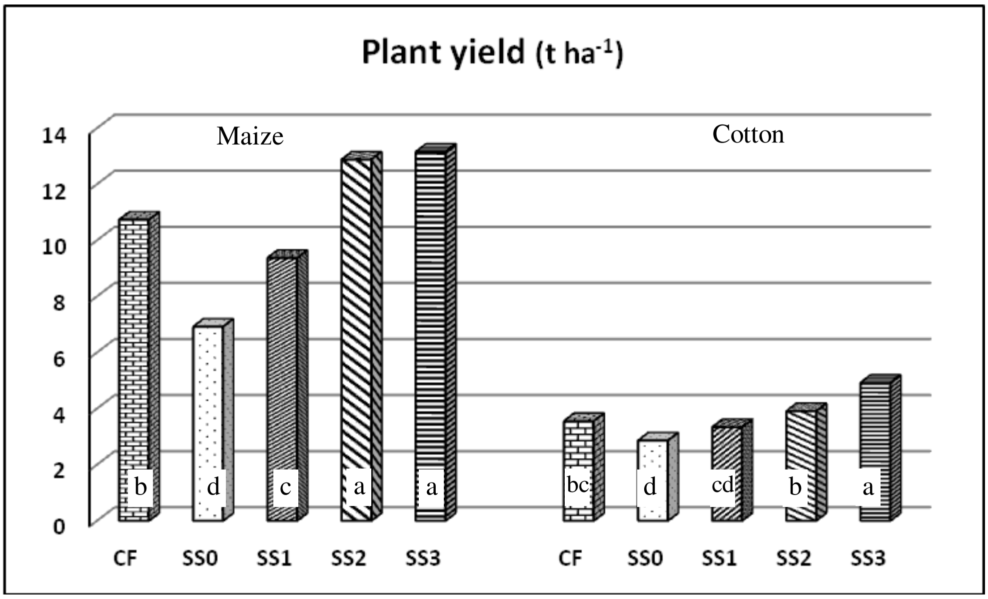

***Figure 2.** The effect of sewage sludge on grain yield of maize and seed cotton yield. Each value is the mean of four replicates. Results within treatmentsof each plant capped with different letters are significantly different (Duncan's test: P < 0.05)*

The response of the yield parameters of maize to the application of sewage sludge was clearer than that of cotton. In a study by Al Zoubi et al. (2008) on Syrian soils under the effect of a Mediterranean climate, an increase was shown in maize yield with increasing doses of sewage sludge compared with the application of chemical fertilizer. On the other hand, the same researchers found no difference between wheat yields with the application of sludge or inorganic fertilizer. Thus, the effects of the application of sewage sludge vary according to the type of crop. Examining the results obtained in the present study, because not only the increase of 86% in maize grain yield was obtained with the SS_2 but also there was statistically no difference between the SS_2 and SS_3 doses, application at 20 t SS ha^{-1} (SS_2) to Mediterranean soils where maize is grown may be recommended. Additionally, less heavy metal will be added to the soil with the SS_2 than with the SS_3 dose. However, a similar effect was not seen as per seed cotton yield. The statistically greatest yield was obtained with the highest sewage sludge application (SS_3), and so a dose of 30 t SS ha^{-1} may be recommended for soils where cotton is grown in Mediterranean climatic conditions. Of course, even when concentrations of nutrient elements in the sewage sludge are the same for the two crops, the differences in the morphological characteristics of the plants can cause differences to emerge in results in the same field. Similar results in terms of varieties of plant species have been obtained in studies of the effects of the application of sewage sludge on crop yield in field conditions. In a study by Tamrabet et al. (2009) examining the effect of the application of sewage sludge to the soil on the yield of durum wheat (*Triticum durum* Desf.), doses of 33 kg ha^{-1} of mineral fertilizer (urea) and doses of 20, 30 and 40 t SS ha^{-1} were applied to the soil under semi arid cropping conditions of Algeria. It was determined that the most effective application of sludge for wheat yield was 30 t ha^{-1}, and that in semi-moist conditions sewage sludge had a positive effect on the yield of that wheat variety, and could be used safely.

Another result emerging from our study was that the yield increase obtained with the application of chemical fertilizer was higher than that obtained with the 10 t SS ha^{-1} given with the SS_1, but lower than the yield increase provided by SS_2 and SS_3. It was seen that much more effective plant nutrition was achieved by the application of plant nutrient elements provided to the soil by sewage sludge together with the addition of organic materials, especially those which are not present in chemical fertilizers. Therefore, increasing the low level of organic carbon of approximately 7.73 g kg^{-1} in the soil may allow plants to benefit more effectively from plant nutrient elements either in the soil or mineralized in connection with SS applications. In addition to this, it must not be forgotten that organic soil improvers applied to sandy loamy soils can also support an increase in yield by improving the physico-chemical characteristics of the soil. Similar to our findings, a statistically significant values similar to that of a mineral fertilizer treatment were obtained in grain yield of maize at the end of 10 years due to increasing sewage sludge doses which accumulated in each treatment 50, 100 and 147.5 t ha^{-1} in total at the end of the experimental period in agricultural Oxisol under a tropical climate of Brazil (Melo et al., 2018). Researchers have suggested that purification sludge applications can meet all of the benefits of chemical phosphorus and microelement fertilization, while chemical nitrogen fertilization can be partially replaced without loss of yield in the maize plant.

Soil microbiological and biochemical activities

A brief overview on soil health

All of the doses of SS applied to the soils affected the microbiological parameters analyzed significantly at a rate of 1%. The level of effect varied in connection with the type of crop, and it is thought that the greatest effect was the difference in the crop vegetation periods. Additionally, it can be said that when the root morphology and root secretion of the two test crops are considered, the differences in the rhizosphere zone also have an effect on managing microbial activity. It was observed that biological activity in maize plants with regard to the parameters examined was approximately 6.5% higher than that of cotton (*Table 3*). In maize soils, SS_3 more stimulated microbiological and biochemical parameters at a statistically significant level. The situation was somewhat different with soils under cotton, and it can be said that the effect of sewage sludge was almost the same on a dose basis. Thus, it can be seen from *Table 3* that an effect was shown at the same level of statistical significance on seven of the nine microbiological and biochemical parameters analyzed by both SS_3 and SS_2, and on three by SS_1. This is one of the important conclusions emerging from the results of the experiment: that is, that in soils under cotton, which has a longer growing period than maize, the differences between the microbiological and biochemical parameter values analyzed resulting from the treatments are reduced. The reason for this may be said to be that after the easily available carbon in SS is applied to the soil, it is used in a short time by heterotrophic microorganisms as a source of energy and carbon, leaving in the soil a valuable and stable humus which is resistant to breakdown. Looking at the overall picture, what emerges is that with crops with a short growing period, sewage sludge can be used as an organic fertilizer because of its capacity for mineralization.

[a]SP, sampling period; [b]SS_0, Unamended soil; [c]CF, Chemical fertilizer; [d]SS_1, 10 ton ha^{-1} SS; [e]SS_2, 20 ton ha^{-1} SS; [f]SS_3, 30 ton ha^{-1} SS; [g]same small letters in the same column (different treatments) do not differ by adjusted Duncan test ($P < 0.05$); [h]Basal soil respiration (mg CO_2-C g^{-1} 24 h^{-1}); [i]Microbial biomass carbon (µg C_{mic} g^{-1}); [j]Dehydrogenase enzyme activity (µg TPF g^{-1}); [k]Alkaline phosphatase enzyme activity (µg p-NP g^{-1} h^{-1}); [l]Protease enzyme activity (µg Tyrosin g^{-1} 2 h^{-1}); [m]Urease enzyme activity (µg N g^{-1} 2 h^{-1}); [n]Aryl sulphatase enzyme activity (µg p-NP g^{-1} h^{-1}); [o]β-glucosidase enzyme activity (µg Saligenin g^{-1} 3 h^{-1}); [p]Nitrogen mineralization (µg NH_4-N g^{-1} 24 h^{-1}). *Each value was given on a dry matter basis as the average of four replicates

Even the heavy metal content of the 10, 20 and 30 t ha^{-1} doses of sewage sludge applied to the experimental soils in treatments SS_1, SS_2 and SS_3 respectively was not shown to have any statistically significant adverse biological activity on the soil. As can be seen from *Tables 4* and *5*, there was not even a negative correlation between the values of heavy metal in the sludge and microbiological activity in the soil. Many of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_48934917

enzymes which are catalyzers of the microorganisms playing an active role in changes and cycles occurring in the soil contain various heavy metals. Examining the correlations of the analysis results, it was seen that DHG activity showed a greater number of positive correlations with the chemical parameter total Cu than with other parameters (*Tables 4* and *5*). A positive correlation of between 1% and 5% was found between all microbiological parameters and Hg and B content in cotton soils, while As content showed a significantly negative correlation with most parameters. In contrast to maize soils, these correlations found between B and As concentrations and microbiological parameters are thought to arise from the larger amounts of irrigation water supplied to the area where cotton is grown: the irrigation periods and thus the amount of irrigation water are greater than for maize.

Also, increases were seen of on average 29-30% compared with the SS_0 and 28-30% against the CF in the microbiological and biochemical parameters of the soils under each plant. Considering the average values obtained from soils under maize and cotton, all increases occurring with SS applications compared to SS_0 and CF treatments were found to be statistically significant ($\alpha = 0.05$). The greatest increase in the experimental area under each crop was related to PRO activity. According to the variance analysis of the maize experiment, sampling periods were statistically significant apart from ALKPA, PRO and Nmin, while treatments had a significant effect on all parameters except BSR. Period x treatment interaction was only significant on DHG and BSR. However, according to the variance analysis of the cotton experiment, periods were statistically significant apart from parameters other than ALKPA, GLU and UA, while treatments had a significant effect on all parameters other than MBC. Period x treatment interaction was found to be significant only on ALKPA. Examining the results obtained regarding the times of sampling of the soils in the experimental area, in relation to the soil samples taken 15 days after the application of sewage sludge (SP_1), the sampling in the harvest period (SP_2) was 120 days after the application of sewage sludge (19 August 2015) for maize, and 189 days after it (29 October 2015) for cotton growth, and it was seen that the values of the parameters analyzed in the soil samples were determined to be on average 13.5% lower. However, this reduction did not obstruct the difference in the effect on microbial activity which could occur in connection with the applications. It is thought that the slight reduction which occurred between sampling periods arose from the harvest times not providing suitable conditions for microbial activity in terms of the soil moisture in the soils under maize and the climatic conditions in the soils under cotton. In fact, this decline was expected to be more pronounced for the reasons given, but unexpectedly, only a slight decrease was determined in our study. The high enzyme activity determined in the soil samples taken in the first period after the application of SS shows the existence of large amounts of substrates which can be broken down biologically in these soils, which is consistent with high unstable-C content, stimulating microbial activity. However, the process of root development in the cotton rhizosphere especially can support biological activity in the soil up to the period of harvest sampling. Root secretion, which mostly stimulates microbial growth, is a side product which represents a part of growth and development, and apart from allowing the development of symbiotic relationships, in a simple way becomes the substrate of microorganisms (Uren, 2007). In addition, plant roots are accepted to be a source of extracellular enzymes in the soil (Egamberdieva et al., 2011). The low levels of difference in activity between the sampling times may also be an indicator of the continuation, even though slight, of the mineralization process of the SS, and this is of

great importance from the point of view of sustainable management of organic matter in soils under the effect of a Mediterranean climate, especially those degraded by intensive agriculture.

Evaluating the experimental results, it is seen that one remarkable finding was the positive correlation between total Hg concentration in the soils and the analyzed microbiological and biochemical parameters. This correlation, found to be significant at a level of 1% to 5%, was determined in all parameters except BSR in the maize experiment (*Table 4*) and in all parameters in the cotton experiment (*Table 5*). Similar to this finding, it was shown in a study by Campos et al. (2018) in Spain that microbial biomass parameters and DHG activity were not adversely affected in the expected way by pollution levels caused by the toxic metal Hg.

Soil microbiological activities

Basal soil respiration (BSR)

Organic materials found in or applied to the soil are used as a carbon and energy sources by heterotrophic microorganisms. As a result of the growth and activities of them heat, CO_2, water vapor and humus are formed (Epstein, 1997) while the amount of CO_2 generated is defined as BSR. Taking into account the mean values of BSR obtained in the results of the experiment, there was a statistically significant increase in maize

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_48934917

soils with SS_3, and in cotton soils with SS_1, SS_2 and SS_3 in comparison with SS_0 and CF. It is thought in studies conducted with sewage sludge that climatic conditions where the soils to which SS was applied are located were significant in the variation in the effect of the sludge. In a similar study in Russia, where climatic conditions are different, it was found that applications of sewage sludge stabilized by anaerobic decomposition did not have a statistically significant effect on MBC and BSR (Selivanovskaya et al., 2001). In our study, a significant high positive correlation was also found between BSR and the other biological parameters examined independent of crop type. The highest positive correlation with BSR in the experimental soils was with DHG (r = 0.668**) and the highest negative correlation was with total As (r = 0.372*) (*Table 5*).

Microbial biomass carbon (MBC)

Regarding the mean MBC values, the application of 20 t ha^{-1} of sewage sludge (SS_2) was found to provide an increase in both maize and cotton soils which was statistically significant (α = 0.05) in comparison with SS_0 and CF (*Table 3*). It was observed that the MBC values of soils under both crops were affected by the SS_3 dose, and showed the greatest activity with SS_2. A decrease was determined in the amount of MBC in connection with sewage sludge applied at 30 t ha^{-1} compared to the dose in SS_2 because of the concentration of heavy metals, of 26% in maize soils and of 19% in cotton soils. In spite of this decrease, the MBC values of soils under both crops were still analyzed to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_48934917

be at high levels compared to plots with SS_0 and CF treatments. Furthermore, according to some studies (Flieβbach et al., 1994; Filip and Bieleck, 2002), a decrease in MBC can be the result of metal pollution.

Microbial biomass is an available storage of nutrients in the soil, such as C, N, S and P, and an indicator of the cycle of organic materials in the soil (Jenkinson and Ladd, 1981). Although it represents a small amount of the total soil N, C and P, N and other plant nutrients make an important contribution to plant nutrition because of their rapid mineralization. The higher MBC value is thought to be caused by the organic C content of SS. In plots to which the SS_2 dose was applied it was found to be 47% higher than the control and 33% higher than the plot treated with chemical fertilizer. Alongside the heavy metal load of the sewage sludge, the stabilization method may have an effect on its mineralization levels. In a study conducted in field conditions over three years with two different sewage sludges stabilized by composting and thermal drying, microbial biomass increases at the end of three consecutive years of 20 t ha^{-1} yr^{-1} of SS were 3.5 times greater than the control in the case of the SS stabilized by composting and 1.8 times greater in the case of the SS stabilized by thermal drying (Fernández et al., 2009). As was shown in previous studies, when substrate C is added to soils, it stimulates growth in the autochthonous soil microbiota in relation to an increase in energy sources in the soil (Antolín et al., 2005; Pascual et al., 2007). However, in the same study, even though an increase was observed in MBC value with an application of the highest dose of sewage sludge (80 t ha^{-1} yr^{-1}) similar to that of our study, this increase was lower than that provided by 20 t ha^{-1} yr^{-1}. Therefore, microorganisms can to a certain extent tolerate potential toxic effects with both the C content and mineralization potential of SS, which are effective parameters on MBC. When the dose of SS increased beyond a certain point, toleration levels decrease, but MBC activity was still higher than that of the control or that of the chemical fertilizer treatment. In addition, the effects of two different crops on the MBC were not clearly revealed.

Although a significant correlation was found between MBC content and DHG and ArSA activity at the 1% level and GLU and UA enzyme activity at a level of 5%, no correlation was determined between ALKPA and PRO enzyme activities (*Table 4*). In cotton soils, DHG activity showed the highest correlation, while ArSA and PRO enzyme activities showed a slight correlation with MBC content. These results show that ArSA, GLU, UA and PRO activities, and especially DHG enzyme activity, were a good indicator of general microbiological activity in the soils examined in this study, and in addition to this, they can provide valuable information on plant nutrient cycle processes. In both maize and cotton soils, MBC gave the highest positive correlation with DHG activity, and the only negative correlation with total As.

Nitrogen mineralization (N_{min})

N-mineralization, the conversion of nitrogen in organic form to its inorganic form, is performed by microorganisms in the soil with various physiological characteristics. The realization of this process depends on the suitability of environmental conditions, the presence of the relevant microorganisms in the environment, and a supply of suitable organic material. An increase was observed statistically in N_{min} values in relation to SS_0 and CF soils with all three doses of sewage sludge applied to the experimental soils. Also, from among the three doses, SS_3 had the greatest effect on N_{min}. It is thought that the observed increase in nitrogen mineralization during the growing period of each of the crops is an indicator that this waste has a high potential to increase crop

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_48934917

productivity. Similarly, in a study in which SS was applied to sandy soil at a rate of 20-320 g kg^{-1} for 100 days, it was shown that N mineralization took place although at a low rate, and for this reason N was added to the soil by mineralization throughout the production season for plants growing in a single year (Alva et al., 2006). Also, the fact that no decline was determined in the levels of N-mineralization with increasing SS doses. This showed that the SS applications up to 30 t ha^{-1} did not have a restrictive effect on ammonification and nitrification bacteria in the same year. The N_{min} value shows a high correlation with the other microbiological and biochemical parameters analyzed in the soils under both crops (*Tables 4* and *5*). N_{min} showed the highest positive correlation in maize soils with ALKPA (r = 0.830**) and on cotton soils with DHG (r = 0.806**).

Soil biological activities

Dehydrogenase enzyme activity (DHG)

Dehydrogenase is an intracellular enzyme which functions inside living cells. Different from the other enzymes examined, which function both inside and outside cells, DHG gives more reliable information on the size and activity of the living microbial population (Bergstrom et al., 1998). Applications of sewage sludge, and especially treatments SS_2 and SS_3, increased DHG by between 42 and 53% in relation to treatments SS_0 and CF, with a 5% level of significance. Similar studies are also to be found in which SS applied to soils increased DHG activity (Fernández et al., 2009; Mondal et al., 2015). On the other hand, some researchers have reported that DHG activity was inhibited by the toxic effects of heavy metals with the addition of organic wastes rich in Pb (Marzadori et al., 1996) and Cu (Chander and Brookes, 1991). Thus, the lack of a statistically significant difference between DHG activity analyzed in relation to SS_2 and SS_3 treatments in maize soils and all three applications in cotton soils is an indicator of the lack of a clear increase in the number of living microbial cells. The observed trend in MBC values supported this situation. However, even though an increase in the amount of organic C added to the soil provided by the increased doses did not seem to support a numerical increase in living cells, positive changes observed in other microbiological and biochemical parameters may be an indication that various species of microorganisms with different functions in the ecosystem are supported. High positive correlations were found between DHG and all the microbiological parameters analyzed (*Tables 4* and *5*). With the result that there is a positive correlation between the heavy metal content of the soil and DHG, it may be concluded that soils to which sewage sludge is applied for a single year are not negatively affected in terms of microbial activity.

Alkaline phosphatase enzyme activity (ALKPA)

Phosphatase enzymes hydrolyze organic phosphorus compounds to ortho-phosphate, a form which plants can uptake (Amador et al., 1997). Because they are only produced by microorganisms, alkaline phosphatases are directly related to microorganism activity in the soil (Cayuela et al., 2008). A statistically significant increase was seen in ALKPA activity at an average of 37-41% compared to SS_0 and CF treatments with SS_3, and this was found to be 911.04 µg p-NP g^{-1} h^{-1} for maize soils and 894.97 µg p-NP g^{-1} h^{-1} for cotton soils. In another study, conducted with soils in a Mediterranean climate, aerobically stabilized sewage sludge was applied to soils in proportions varying

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_48934917

between 6.2 and 10 g SS kg^{-1} soil (equivalent to 0.5 g P_2O_5 kg^{-1} soil). After incubation periods of 25 and 87 days following the incorporating of sewage sludge to the soil, an increase was found in phosphatase enzyme activities which decreased with a lengthening of the incubation period (Criquet et al., 2007). Other studies have shown similar patterns in soil enzyme activities following the application of SS (Pascual et al., 1998; Antolín et al., 2005; Criquet et al., 2007). Considering all these similar results, it is seen that sewage sludge has a short-term increasing effect on soil phosphatase activities, followed by a rapid decrease. Although we determined a decrease in ALKPA activity, it cannot be said that this decrease was on a large scale. Presumably, just as the quantity of living microorganisms in the sewage sludge and later their activity in the soil to which it was applied may result in an increase in enzyme activity (Dick and Tabatabai, 1984), at the same time the content of the existing substrates in the soil is increased due to SS has various organic substrates, and in this way the activity of microorganisms is supported (Kizilkaya and Bayrakli, 2005). These existing substrates include acid and alkaline phosphomonoesterase substrates (García et al., 1993) and phosphodiesterases (Turner and Haygarth, 2005) in generally large amounts in the organic matter in sewage sludge. Thus, when the amount of available P in the soil is a limiting factor for microbial growth, microorganisms can increase phosphatase production in order to be able to mineralize available P from organic P substrates added to the soil with SS (Criquet et al., 2007). Another result emerging from our study concerned correlations. The highest positive correlation with ALKPA was with PRO for maize and cotton vegetations ($r = 0.866^{**}$and 0.849^{**}, respectively).

Protease enzyme activity (PRO)

Protease hydrolyzes proteins into polypeptides, oligopeptides and amino acids. Because most N compounds are in an organic-related form in mineral soils, organic nitrogen must be converted to an inorganic form in order for N to be taken up by plants. Organic wastes applied to the soil stimulate protease (Rezende et al., 2004), but the breakdown products of these wastes can hinder this enzyme (Dilly and Nannipieri, 2001). In the present study, higher protease activity was determined in the soils to which the three doses of sewage sludge were applied than in SS_0 and CF soils; breakdown products of the sewage sludge did not hinder this enzyme, but on the contrary increased the amount of substrate necessary for the enzymatic reaction. Among the treatment doses, SS_3 resulted in PRO activity at the highest and most significant levels for maize soils, while with cotton soils, SS_2 and SS_3 showed PRO activity at a significant level. The highest correlations with the PRO value were shown by ALKPA both in maize soils ($r = 0.866^{**}$) and in cotton soils ($r = 0.849^{**}$).

Urease enzyme activity (UA)

Urease is an enzyme catalyzing the hydrolysis of urea to ammonia or ammonium, depending on soil pH (Tripathi et al., 2007). According to García et al. (2000), the presence of substrates or the demand of plants and microorganisms for nutrients increases the activity of this enzyme involved in the N cycle. Indeed, as Fernández et al. (2009) determined previously, the highest UA levels in connection with SS applications coincide with the highest crop yield parameters determined (*Fig. 2*). Statistically significant increases of 12-20% were determined with SS_2 and SS_3 compared to treatments SS_0 and CF. Nickel is necessary as a co-factor for the urease enzyme. In

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_48934917

other words, in order for the urease enzyme to become active, it must join with two nickel ions for each sub-unit. The positive correlation (r = 0.467**) between UA and total Ni determined in maize soils may be an indication of this.

Aryl sulfatase enzyme activity (ArSA)

Aryl sulfatase enzyme which is responsible for the hydrolysis of aryl sulfate esters by the fusion of oxygen-sulfur bonds (Tabatabai, 1994). Ester sulfate, the substrate of aryl sulfate, is only found in fungi, and therefore it can also be a direct indicator of the presence of fungi in the soil (Bandick and Dick, 1999). ArSA was determined at approximately the same levels with all SS treatments, showing that there was a suitable substrate of the enzyme at approximately the same amounts in all sewage sludges. Renella et al. (2005) indicated that the coarse sandy soils from long-term field experiments under maize contaminated with high Cd–Ni-containing sludge reduced arylsulfatase and β-glucosidase activities and were significantly inhibited them by Cd and Ni at concentrations of 13.1 and 52.3 mg kg^{-1}, respectively. On the other hand in our study, the highest ArSA activity analyzed in maize soils was 248.25 μg p-NP g^{-1} h^{-1} with SS_3, and this value was achieved in cotton soils at a level of 246.47 μg p-NP g^{-1} h^{-1} with SS_2. ArSA activity showed an increase of 13-30% with SS applications relative to SS_0 and CF. Positive correlations were determined between ArSA and all microbiological and biochemical parameters. The highest correlation for maize soils was with GLU activity (r = 0.850**), and for cotton soils with DHG activity (r = 0.705**).

β-glucosidase enzyme activity (GLU)

Sugars with low molecular weight, which are hydrolysis products of glucosidases, are an important source of energy for soil microorganisms. One of the most important glucosidases in the soil is β-glucosidase which catalyzes the hydrolysis of cellobiose and contributes to the mineralization of the main organic carbon compound in nature, cellulose (Landgraf et al., 2003). The highest GLU activity in soils was shown with SS_3 in maize soils (86.61 μg Saligenin g^{-1} 3 h^{-1}), and in cotton soils with SS_2 (85.08 μg Saligenin g^{-1} 3 h^{-1}). An average increase of 22-32% was achieved in relation to SS_0 and CF. Hattori (1988) and Dick et al. (1988) determined higher GLU in applications of stable organic material containing cellulose. The highest positive correlation with GLU activity for maize soils was with ArSA (r = 0.850**), and for cotton soils with ALKPA (r = 0.678**).

Conclusions

Increases were seen in all microbiological parameters analyzed in relation to sewage sludge treatments and were found to be 22% for SS_1, 35.5% for SS_2, and 33% for SS_3 in relation to SS_0 and CF. In particular, it was observed that the SS applications of 20 and 30 t ha^{-1} increased microbiological parameters more. Correlation matrices showed that the SS doses of 10, 20 and 30 t ha^{-1} yr^{-1} applied did not result in a negative correlation between heavy metals and microbiological parameters, but rather showed positive correlations. This is because the result of the application to the soil of sewage sludge containing organic matter of a quality and amount to encourage microbial activity in the soil is to mask the negative effect created by the heavy metals it contains either on

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_48934917

microorganisms or on the plant. Even though there was a decrease of 13.5% in the biological parameters analyzed in the second period compared with the first period, this decrease was not at a level to eliminate the differences between SS applications. Moreover, this is important for the management of sustainable organic matter in agricultural soils, and it brings the sewage sludge stabilization method to the fore. Biological activity in soils under different vegetation was also different. Microbial activity in the rhizosphere area of maize plants was found to be 6.5% greater than that of cotton. The highest dose of SS gave an increase in maize grain yield of 90% and in seed cotton yield of 72% over CF soils, and these increases were both much greater than the increases secured by chemical fertilizer applications and also different at a statistically significant level. The potential of organic matter to improve the physicochemical characteristics of a sandy loamy soil may have made a positive contribution to this. Even with the highest dose of sewage sludge applied in the experiment (SS_3), no toxic effect was observed in either maize or cotton plants. Therefore, in soils with a poor light-textured and low organic matter content in a Mediterranean climate and with one-year applications of sewage sludge, applications of stabilized sewage sludge at a level of 30 t ha^{-1} whether for the purpose of sustainable management of the soil's organic matter or to increase the crop yield can be used without ecotoxicological effects. This study, however, was conducted in a representative area of the Mediterranean Basin where arid and semi-arid climate conditions are dominant, so the results obtained can also be applied to other Mediterranean countries where SS incorporating to agricultural soil at a rate up to 30 t ha-1 yr-1 can be a cheap valuable solution to manage and utilize this waste as both fertilizer and soil conditioner. Our results suggest that attention should be paid to reducing the environmental risks of heavy metals in sludge utilization as soil improvement, not only to control the sewage sludge application dosage, but also to cultivate appropriate plant species. In the future, more field experiment is needed to evaluate the long-term residual effects of sewage sludge in the soil in terms of microbiological and biochemical properties of soils under different climate conditions and crop patterns

Acknowledgements. This study was prepared partly with the help of data from the project A Study of the Possibilities for the Use of Sewage Sludge in Agriculture and Purified Waste Water in Irrigation, supported financially by İzmir Water and Sewerage Administration General Directorate (İZSU) of İzmir Metropolitan Municipality. The authors would like to thank Agricultural Engineers Recep Serdar KARA, Onur BAYIZ and Sevde AYYILDIZ for their unstinting support in field work and laboratory analyses.

Abstract. Different methods have been used to predict soil properties and obtain continuous spatial distributions. However, studies that compare the accuracy of these methods are scarce. In addition, few studies considered human activity variables as well as landscape ecology variables to predict soil properties. The objective of this research was to determine the optimal method for predicting soil properties using human activity and landscape ecology variables in regions with complex topographies. The study results are as follows. (1) Introducing land-use type as human activity variable to the soil-landscape model can improve the accuracy. (2) In the study region, the mean absolute error (MAE) and mean relative error (MRE) of the soil organic matter, pH, and soil particle size predicted by the soil-landscape model were lower than those predicted by ordinary Kriging method. (3) Specifically, the regions in which the soil-landscape prediction model was more accurate were all concentrated in the central and west hilly regions in the study region, whereas the regions in which the geostatistical interpolation was more accurate were mainly in the east plain region. The differences in the results are based on the topography of the study area.
Keywords: *soil-landscape, geostatistical interpolation, Donghai County, hilly region, precision comparison*

Introduction and review of literature

The purpose of soil sampling is to acquire the spatial distribution characteristics of target variables and study the soil characteristics across an entire study region. Soil surveys can achieve optimal land management by exploiting the available information in the study region (Dent and Young, 1981; Carter, 1993; Minasny and McBratney, 2006). Because current land management is becoming more refined and soil sampling is limited by human, material, and financial resources, methods that reduce sampling costs through rational sampling yet can still satisfy soil survey accuracy requirements have received increasing attention. Current scholars have conducted plenty of in-depth research on sampling design optimization methods. Some scholars (Hengl and Rossiter, 2003) have constructed a prediction model of soil properties using auxiliary variables and simultaneously optimized the distribution of sampling points. In addition, some researchers (van Groenigen et al., 2000; Ferreyra et al., 2002; Simbahan and Dobermann, 2006; Brus and Heuvelink, 2007) optimized the number and spatial

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_49194934

distribution of sampling points using a simulated annealing algorithm and obtained the optimal distribution of soil sampling points. However, optimizing the methods of collecting soil samples may promote a heterogeneous spatial distribution of soil sampling points and soil properties, which can affect the accuracy of soil quality assessments. Under the assumption that additional soil sampling points cannot be added, methods that infer soil property information in unknown regions must be used to obtain a continuous spatial distribution of soil properties. Current soil studies primarily apply soil-landscape models and geostatistical methods for predicting different soil properties.

Soil-landscape models are derived from Jenny's equation (Jenny, 1941). This equation describes soil as a function of climate, potential biota, relief, parent material, and time (Jenny, 1941; Zhou and Wang, 2004). Numerous studies have used this model to predict soil properties. Jones (1973) studied the West African Savannah and found that the soil carbon, nitrogen and soil particle size were related to annual precipitation. Some research (Jones, 1973) found a piecewise linear relationship between the soil organic carbon, nitrogen, pH value and the gradient angle. Using soil-landscape models, Grunwald (2016) predicted the soil organic carbon content under different land-use types using a neural network with climate and topography factors as the input variables. A geostatistical approach was first applied by the South African mining engineer Krige (1951) for mineral exploration calculations used in the mining industry in the early 1950s. In soil property studies, the spatial variability of soil physical properties became a focus starting in the 1970s in North America and certain Western European countries (Krige, 1951; Minasny and McBratney, 2006).

In summary, numerous studies have investigated issues related to soil property predictions performed using soil-landscape models as well as geostatistical methods. However, the study regions in which these two methods were applied to predict soil properties were mostly concentrated in plains regions where the soil properties were relatively homogenous. Studies on regions with large topographic variations (such as mountains and hilly regions) are scarce, and comparative studies on the prediction results and accuracy of the two methods are limited. Therefore, in the present study, (1) the Huanghuaihai hilly region of Donghai County in Jiangsu Province was selected as the study region, and based on the large amount of data available for this study region, a soil-landscape model and a geostatistical model was used to predict the soil properties and then the prediction results and accuracy of the two methods were compared to provide information for selecting methods of predicting soil properties in regions with large topography variations; and (2) based on the frequent human activities in the study region, land-use types were added to represent of the effects of human activities as landscape factors to improve the prediction accuracy of the soil-landscape model and then analysed and verified the prediction results.

Materials and methods

Study area

Donghai County (*Fig. 1*) is located in the northeast of Jiangsu Province, China at 34°11′~34°44′N, 118°23′~119°10′E. Donghai County encompasses a plains hilly region at the southeast margin of the Huanghuaihai region. Its area is 2073 km^2. The elevation is high in the west and low in the east. The east plains region is flat and presents numerous lakes and reservoirs, the west region is a hilly region with an undulating relief, and the centre region presents gentle slopes as the plains transition to hills. The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_49194934

Maling Mountains, on the western boundary, extend from north to east. The substrate consists of purple sandshale, and purple soil is distributed as well. The parent material of the purple soil is the weathered remnants of the purple sandshale. In the centre and west, numerous hills and gullies are distributed and cross each other, and the terrain is primarily hilly. The parent material of the brown soil distributed throughout these regions is the weathered remnant of acidic metamorphic granitic gneisses, representing an ancient alluvial deposit covered by slope wash. The elevation of the lacustrine plain in the east is only 2-5 m, and the parent material of the soil is secondary ancient fluvial-lacustrine loessial deposits formed in the Quaternary.

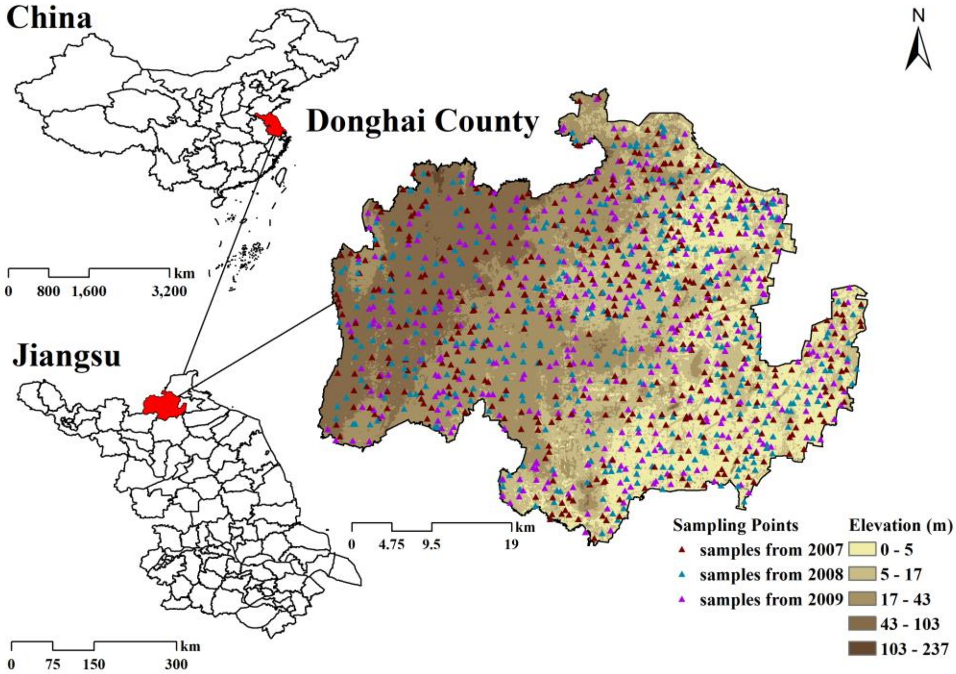

***Figure 1.** Location map of the study region and design of the sampling points*

Soil sampling

The 1268 sample points used in this study were collected in November 2007, November 2008, and November 2009. Each soil sample has been collected only one time in three-year period (detailed design shown in *Fig. 1*). The sampling locations were all on farmlands, and the collection times were all after the rice harvesting period and before the winter wheat sowing period. The sampling locations were determined using geographic coordinates obtained with Garmin-76 GPS receivers to reduce the accuracy errors associated with global positioning systems. The soil samples were all collected using stainless steel soil samplers, which collected soil from the 0-20 cm topsoil layer. At each sampling location, 5 samples were collected along 10-m diagonals and then mixed homogenously. After that, 1 kg of soil was retrieved by quartering, and the samples were sealed in plastic bags and brought back to the laboratory. Plant roots and rocks in the collected soil samples were removed, the soil samples were spread out on plastic disks, and naturally dried in ventilated locations. The dried samples were crushed and ground using wood rods or mortars, passed through 20-mesh, 60-mesh, and 100-mesh nylon sieves, and separately sealed in plastic bags until the physiochemical

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_49194934

analyses. The physiochemical analyses of the samples were conducted at the Institute of Soil Science, Chinese Academy of Sciences, in Nanjing. Each sampling point included measurements of the pH value, organic matter content, and soil particle size. During the laboratory evaluation, each sample was divided into four parts and tested paralelly to prevent any errors that may occur during test to ensure the accuracy of soil properties. The three soil indices used in this study and their measurement methods were as follows: (1) soil pH was determined using the potential method; (2) soil organic matter was determined using the potassium dichromate volumetric method; and (3) soil particle size was determined using a laser particle size analyser and the Malvern method following the US grade system. 70% of the sample points were randomly selected (918) as the training set to build the soil-landscape prediction model and geostatistical model (ordinary Kriging interpolation). The remaining 30% of the sample points (350) were used as the test dataset for the models.

The statistical features of the three soil properties measured in areas with different land-use types are shown in *Table 1*. The organic matter in the soil from dry lands was significantly less than that from paddy fields. The soil moisture in the paddy fields was high, and organic matter decomposed slowly and accumulated more easily. The soil from the dry land was more acidic than that from the paddy fields. The particles of the soil from the paddy field were significantly larger than those of the soil from dry land, and the paddy field soil was mainly loamy and clayey, whereas the dry land soil was mainly sandy. The three soil properties of the paddy field showed a more significant normal distribution pattern, whereas the soil properties of the dry land showed a skewed distribution, with high kurtosis and concentrated data.

Table 1. *Statistical features of the soil properties of the different land-use types in intensively sampled regions*

		Minimum	Maximum	Mean	Variation coefficient	Skewness	Kurtosis
Paddy field	Organic matter (g/kg)	3.5	41.0	20.7	30.68%	0.42	-0.24
	pH value	5.0	8.2	6.8	8.85%	0.17	-0.31
	Soil particle size (%)	4.0	89.7	41.1	58.35%	0.15	-1.30
Dry land	Organic matter (g/kg)	1.2	28.7	12.5	29.63%	0.70	2.11
	pH value	5.1	9.9	6.4	8.45%	1.29	8.77
	Soil particle size (%)	3.5	78.3	17.8	65.73%	1.68	4.15

The above analysis indicates that the differences in the three soil properties from the paddy field and dry land were significant. The data statistics showed that the land-use types significantly affected the soil properties and that land-use types should be used as a factor in soil-landscape models.

Soil-landscape multivariate stepwise regression method

Soil-landscape models establish quantitative relationships between soil properties and different environmental factors (topography, landscape, hydrology, and human activities) by studying the correlation features between soil and environmental factors, and variation patterns of the spatial and temporal distribution of the soil properties are

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_49194934

predicted based on quantitative relationships (Gessler et al., 2000; Kerry and Oliver, 2004; Grunwald, 2016).

This study determined the environmental factors that affect the soil in the study region based on the soil-forming factor theory and soil-landscape multivariate stepwise regression method. The soil-forming factor theory determined five categories of soil formation factors: climate, parent material, relief, potential biota, and time. The soil-landscape model theory proposes that different soil environmental conditions can form different soil types. When specific combinations of soil-landscape factors are determined, the soil type that is formed is also uniquely determined (Grunwald, 2016). Therefore, this study selected landscape factors that are relevant to soil forming and predictive for topography, morphology, climate, hydrology, vegetation, and human factors. For the soil factors, the soil organic matter and pH in the study region are important soil properties. Furthermore, because the study region is hilly, the soil particle size varies significantly. Additionally, the organic matter, pH, and soil particle size represent the comprehensive index, chemical index, and physical index of the farmland soil quality, respectively, and can be used to represent farmland soil quality to a great extent (Xia et al., 2000; Yuan et al., 2008; Zhu, 2008). Therefore, this study selected soil organic matter, pH, and soil particle size as the soil property indices. The definitions, equations, and meanings of the landscape factors in this study are provided in *Table 2*. To acquire specific data acquisition, a 30 m × 30 m digital elevation model (DEM) of the study region was used to select the relevant topographic factors in ArcGIS 9.3, including the elevation, gradient angle, plane curvature, profile curvature, topographic wetness index, and stream power index. The 5-year mean normalized difference vegetation index (NDVI) value was calculated in the region based on 30 m Landsat Thematic Mapper (TM) remote sensing data for the five year period 2005-2010. The land-use types were identified based on the current land-use map of Donghai County for 2010 (1:5000 scale). This study used the soil properties of the 918 sample points in the training set and a multivariate stepwise regression method to build the soil-landscape prediction model.

Geostatistical interpolation method

To predict the target variables (soil properties) of many independent and common variables in space, the commonly used geostatistical interpolation method, the ordinary Kriging (OK) method, was used. Based on the 918 sample points, the ordinary Kriging interpolation was used to predict the soil organic matter, pH value, and soil particle size in the study region. The Kriging interpolation is also called the spatial local interpolation method, and it is based on variogram theory and structural analyses and yields the best unbiased estimations of regionalized variables in limited regions. The Kriging method is one of the most important methods in geostatistics and provides the best linear unbiased estimations of elevation based on the spatial location of the points to be interpolated and the measured elevation of neighbouring points. The original topography in the study region is represented by a Kriging interpolation map of the elevation. The overall equation is as follows (*Eq. 1*):

$$\mathrm{Z}(x_0) = \sum_{i=1}^{n} \lambda_i Z(x_i) \quad \text{(Eq.1)}$$

where $\mathrm{Z}(x_0)$ represents the value of the unknown sample points; $Z(x_i)$ represents the value of the known sample points surrounding the unknown sample points; N is the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_49194934

number of known sample points; and λ_i is the weight of the i[th] sample point. This equation is determined by a semivariogram analysis, and based on the statistical requirements of unbiased and optimal, the equation between the weights and semivariance can be derived using Lagrange's minimization principle. For a more detailed and comprehensive description of the method, please refer to Cressie (1988), Odeh et al. (1995), and Mishra et al. (2009).

Table 2. *Definitions, equations, and meanings of the landscape factors*

Environmental factor	Definition and equation	Representation
Elevation (m)	Vertical distance from a point to the absolute reference surface	Changes in vegetation and hydrothermal conditions, affects soil development
Gradient angle	Angle between the normal and vertical directions at a ground point $\alpha = \arctan\sqrt{f_x^2 + f_y^2}$ (Gunstensen et al., 1991)	Reflects the degree of tilt of the local surface, which affects the topsoil stability and surface runoff discharge and convergence
Plane curvature (m-1)	At any given surface point, the curvature of the curve defined by the intersection between the horizontal plane passing through this point and the ground surface $H_c = -\frac{f_y^2 f_{xx} - 2f_x f_y f_{xy} + f_x^2 f_{yy}}{(f_x^2 + f_y^2)(1 + f_x^2 + f_y^2)^{3/2}}$ (Roddier, 1988)	Affects the convergence and divergence of the movement of surface material
Profile curvature (m-1)	At any given surface point, the curvature of the curve defined by the intersection of the plane passing through the normal direction and the direction with the maximum elevation gradient at this point and the ground surface $P_c = -\frac{f_y^2 f_{xx} + 2f_x f_y f_{xy} + f_x^2 f_{yy}}{(f_x^2 + f_y^2)(1 + f_x^2 + f_y^2)^{3/2}}$ (Zevenbergen and Thorne, 1987)	Affects the acceleration and deceleration of the movement of surface material
Topographic wetness index	$\mathrm{TWI} = \ln\left(\frac{A}{L \times \tan\alpha}\right)$ (Barling et al., 1994)	Quantitatively reflects the comprehensive condition of soil water storage and discharge
Stream power index	$\mathrm{SPI} = \frac{A \times \alpha}{L}$ (Hack, 1973)	Quantitatively reflects the potential erosion capability of runoff
Normalized difference vegetation index	$\mathrm{NDVI}_i = \frac{band4 - band3}{band4 + band3}$ $\overline{NDVI} = \sum_i^n \mathrm{NDVI}_i$ (Townshend and Justice, 1986)	Quantitatively reflects the vegetation distribution and coverage in the region
Land use type	Paddy field, dry land	Different land use types reflect the degree of human disturbance and change to soil

Note: f_x and f_y are the first derivatives of the elevation surface in the x and y directions, respectively; f_{xx} and f_{yy} are the second partial derivatives of the elevation surface in the x and y directions, respectively; f_{xy} is the second mixed partial derivative of the elevation surface in the x and y directions; A is the confluence area; and L is the length of the contour lines

Method of analysing accuracy errors

The method of determining the accuracy errors in this study includes the mean absolute error (MAE) and mean relative error (MRE) indices to describe the differences between the model predictions and the measured values. Smaller values indicate a higher accuracy of the model predictions. $\widetilde{Z}_i$ is the predicted value, and Z_i is the measured value (*Eqs. 2* and *3*).

$$\mathrm{MAE} = \frac{1}{n}\sum_{i=1}^{n}\left|\widetilde{Z}_i - Z_i\right| \tag{Eq.2}$$

$$\mathrm{MRE} = \frac{1}{n}\sum_{i=1}^{n}\left|\widetilde{Z}_i - Z_i\right|/Z_i \tag{Eq.3}$$

Results

Prediction results of the two prediction methods

Soil-landscape models

The study object in this study is farmland; thus, all of the sample points were on farmland. Prediction models were built separately for paddy fields and dry land, which are shown in *Table 3*. All of the prediction models passed the F test at the 95% confidence level. The test analysis results showed that the model prediction results were good. The R^2 values of the soil property prediction models showed that the goodness of fit of the prediction model for the three soil properties in the paddy fields was higher than that in the dry land. The landscape factors in the paddy fields could explain 65.9%, 51.7%, and 63.5% of the spatial variance of the soil organic matter, pH value, and soil particle size, respectively. The soil-landscape factors in the dry land could explain 56.1%, 46.4%, and 48.3% of the spatial variance of soil organic matter, pH value, and soil particle size, respectively.

Table 3. *Soil-landscape prediction models for the different soil properties*

Land use	Soil property	Regression equation	R^2	F
Paddy field	Organic matter	$y_1 = 27.647 - 4.489\ln x_1 + 0.245x_2 + 4.832\,x_3 + 2.713x_7$	0.659	183.49
	pH	$y_2 = 6.753 - 0.119\ln x_1 + 0.009x_5 + 0.244\,x_7$	0.517	108.05
	Soil particle size	$y_3 = 0.443 - 0.122\ln x_1 + 0.016\,x_2 + 0.005x_5 + 0.194x_7$	0.635	128.88
Dry land	Organic matter	$\ln y_1 = 3.382 - 0.234\ln x_1 - 0.04331\ \ln x_4$	0.561	77.02
	pH	$y_2 = 6.572 + 0.153\ln x_1 - 0.062x_4 - 0.06221\ \ln x_5$	0.464	44.62
	Soil particle size	$y_3 = 0.371 - 0.043\ln x_1 - 0.00771\ \ln x_6$	0.483	46.84

Note: x_1: elevation; x_2: gradient angle; x_3: plane curvature; x_4: profile curvature; x_5: topographic wetness index; x_6: stream power index; and x_7: NDVI

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aer/1604_49194934

For the three soil properties, the goodness of fit of the prediction models was highest for organic matter. The soil-landscape model provided accurate predictions of the condition of the soil organic matter. Among the eight soil-landscape factors in the paddy fields and dry land, elevation was always a factor for the prediction models, indicating that elevation is one of the most important factors that affects soil properties.

Using the above soil property prediction models, The organic matter content, pH value, and soil particle size was separately predicted in the paddy fields and dry land. The prediction results are shown in *Figure 2*.

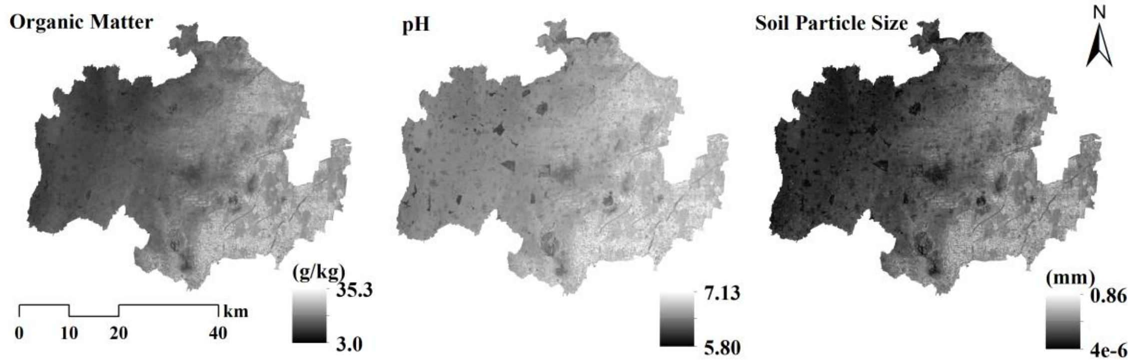

Figure 2. *Soil property prediction results of the soil-landscape model*

The results indicate that the soil organic matter content gradually decreased spatially from east to west. The pH values were high in the east and west of the study region but low in the centre. The soil particle size showed a similar spatial variation as the organic matter. The soil in the east region was made up of large/small particles, whereas the soil in the west region showed more sandy content.

Geostatistical interpolation

Ordinary Kriging interpolation was used to predict the soil organic matter content, pH, and soil particle size for the 918 sampling locations in the study region, and the results are shown in *Figure 3*.

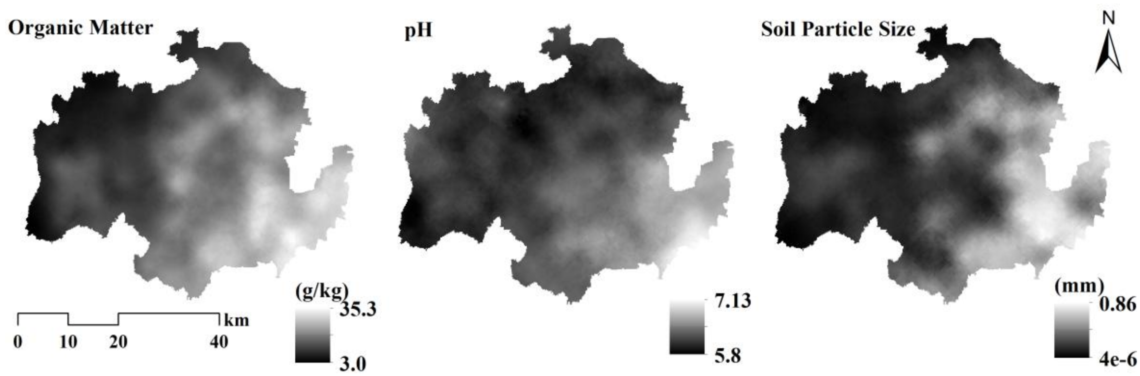

Figure 3. *Soil property prediction results of the Kriging interpolation*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_49194934

Based on the spatial distribution of the interpolation results, the overall spatial distribution pattern of the three soil properties were similar between the Kriging interpolation results and soil-landscape model prediction results. However, certain local regions showed significant differences. The Kriging interpolation prediction was based on the characteristics of the data statistics and spatial distribution of the interpolation points. The spatial variation of the soil properties in the interpolation results was smooth, although several regions showed a significant ‘bull’s eye’ effect. Several extremely high or low property data values strongly affected the interpolation results, which is expected when using this geostatistical interpolation method.

Accuracy errors of the two prediction methods

Soil-landscape model

350 sampling points were used to construct a test set and then quantitatively analysed the accuracy of the soil property prediction results in relation to the measured values.

The error analysis of the soil property prediction results is shown in *Table 4*. The analysis results show that the difference between the predicted results and measured values of the three soil properties in the paddy fields and dry land was extremely small; therefore, the three soil properties predicted by the model and interpolation method were accurate based on the prediction results. The mean absolute errors of the soil organic matter content, pH, and particle size in the dry land were smaller than those in the paddy fields by 41.18%, 20.00%, and 121.28%, respectively, although the relative error of the prediction results for the organic matter content in the paddy fields was smaller than that in the dry land by 13.33%, indicating that the model prediction results for the organic matter in the paddy field were more accurate than those in the dry land. The relative errors of the pH, soil particle size, and topsoil thickness in the paddy fields were extremely close to those of the dry land. All of the differences presented a significance of 0.01, which indicated that the prediction accuracy of the three soil properties by the prediction models was similar between the paddy fields and dry land.

Table 4. *Error analysis of the prediction results by the soil-landscape models*

Soil property	Paddy field (n = 220)				Dry land (n = 130)			
	Measured value	Predicted value	MAE	MRE	Measured value	Predicted value	MAE	MRE
Organic matter (g/kg)	20.6	21.2	0.24	0.13	12.1	12.6	0.17	0.15
pH	6.7	6.7	0.24	0.04	6.4	6.4	0.2	0.03
Soil particle size (%)	38.9	41.8	10.71	0.48	16.8	18.9	4.84	0.47

The relative errors of the 350 test points were interpolated to further study the spatial distribution of the prediction errors for the three soil properties predicted by the soil-landscape models in the whole study region. The results are shown in *Figure 4*.

The spatial distribution of the relative errors of the prediction results indicated that the relative error of the predicted soil organic matter content was high in the dry land in the west; therefore, the model showed low accuracy in this region. The relative error of the prediction results for soil pH value was high in the paddy fields in the centre and east of the study region but low in dry land, and the relative error of the prediction

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_49194934

results for the soil particle size was high in the central study region. Overall, the accuracy of the soil-landscape model predictions for the three soil properties was spatially heterogeneous and showed high values in most regions and low values in certain regions.

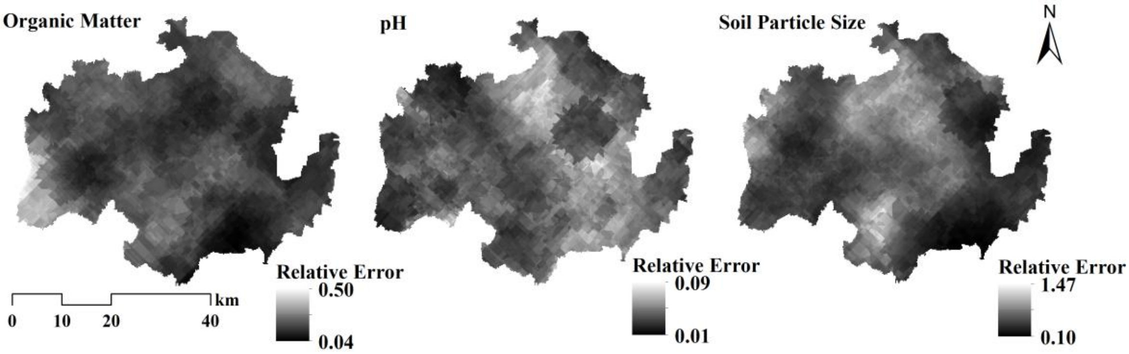

Figure 4. *Spatial distribution map of the relative error of the soil property predictions by the soil-landscape models*

Geostatistical interpolation

The accuracy of the soil properties predicted by the statistical interpolation was calculated, and the error analysis of the interpolation results is shown in *Table 5*. Among the three soil properties, the MAE and MRE of the interpolation results for the organic matter content and pH value in the paddy fields were slightly smaller than those in the dry land, with the MAE’s smaller by 3.57% and 6.90%, respectively, and the MRE’s smaller by 40.00% and 20.00%, respectively. These results indicate that the Kriging interpolation results for the organic matter content and pH value in the paddy fields were more accurate than those in the dry land. The MAE and MRE of the interpolation results for the soil particle size in the paddy fields were larger than those in the dry land by 29.17% and 8.47%, respectively, which indicated that the accuracy of the Kriging interpolation results for this soil property was higher in the dry land area.

Table 5. *Error analysis of the prediction results by the Kriging interpolation*

Soil property	Paddy field (n = 220)				Dry land (n = 130)			
	Measured value	Predicted value	MAE	MRE	Measured value	Predicted value	MAE	MRE
Organic matter (g/kg)	20.6	21.1	0.27	0.15	12.1	13.1	0.28	0.25
pH	6.7	6.7	0.27	0.04	6.4	6.5	0.29	0.05
Soil particle size (%)	38.9	42.2	10.76	0.64	16.8	21.0	8.33	0.59

A kriging interpolation was conducted on the relative errors of the 350 test points to further study the spatial distribution of the prediction errors of the three soil properties predicted by the Kriging interpolation for the entire study region. The results are shown in *Figure 5*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_49194934

Based on the spatial distribution of the relative error of the prediction results, the relative error of the predicted soil organic matter content and pH value was high in the west dry land region. The accuracy of the results predicted by the Kriging interpolation for the organic matter content and pH value in this region was low. The relative error of the interpolation results for the soil particle size was low in the central study region, whereas the accuracy of the predicted soil particle size was high in this region.

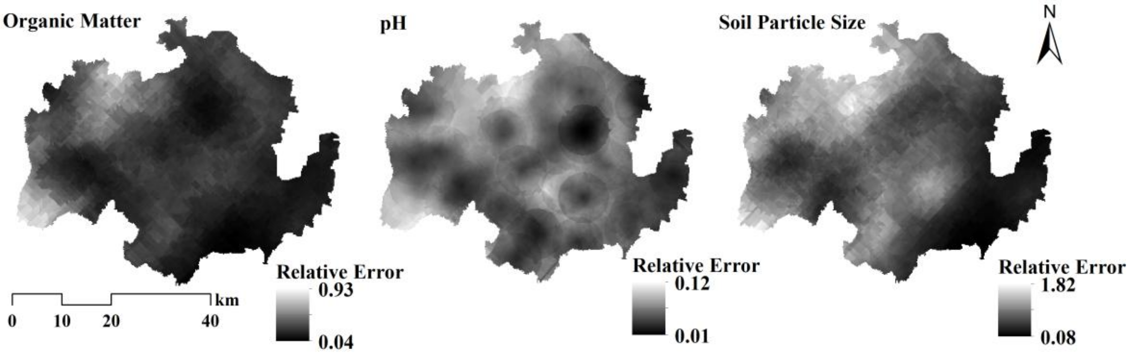

Figure 5. *Spatial distribution map of the relative errors of the soil properties predicted by the Kriging interpolation*

Comparison between the accuracy of the two prediction results

The comparison between the errors of the predicted soil properties by the two prediction methods is shown in *Table 6*. The results indicate that the MAE and MRE of the soil-landscape model predictions for the soil organic matter, pH value, and soil particle size were all smaller than those of the Kriging interpolation, indicating that the overall accuracy of the three soil properties predicted by the soil-landscape model was higher than that of the Kriging interpolation.

Table 6. *Error comparison of the results predicted by the soil-landscape model and Kriging interpolation*

Soil property	Soil-landscape model				Kriging interpolation			
	Measured value	Predicted value	MAE	MRE	Measured value	Predicted value	MAE	MRE
Organic matter (g/kg)	17.0	18.0	0.21	0.14	17.5	18.1	0.27	0.19
pH	6.6	6.6	0.23	0.03	6.6	6.6	0.28	0.04
Soil particle size (%)	30.7	33.3	8.53	0.48	30.7	34.3	9.86	0.63

The spatial distribution of the errors of the two prediction results (the MRE of the soil-landscape model - the MRE of the Kriging interpolation) were subtracted and further compared the spatial distribution of the accuracy of the two prediction results. The regions in which the MRE difference was less than 0 represent regions where the soil-landscape model was more accurate, and regions in which the MRE difference was higher than 0 represent regions where the Kriging interpolation was more accurate. The prediction accuracy of the three soil properties were partitioned based on these results,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_49194934

which is shown in *Figure 6*. In the figure, GIP represents geostatistical interpolation optimum and SLP represents soil-landscape optimum.

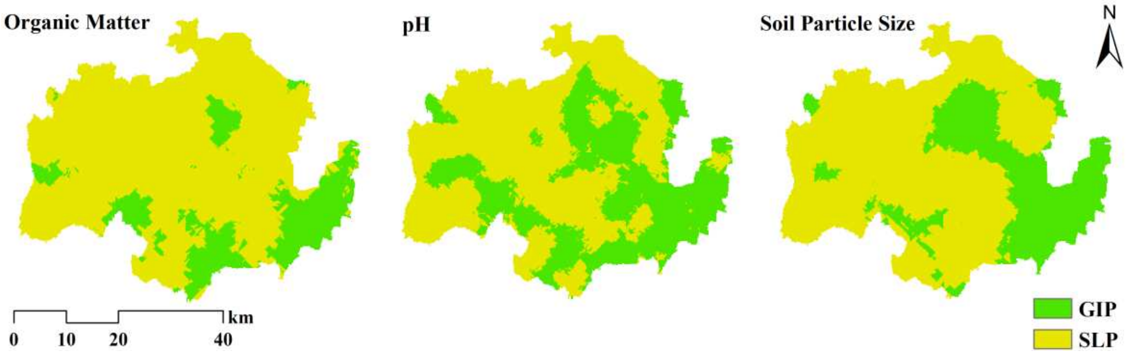

Figure 6. *Partitioned prediction accuracy of the soil-landscape model and geostatistical interpolation (the yellow colour represents areas where the prediction accuracy of the soil-landscape model is better, and the green colour represents areas where the prediction accuracy of the geostatistical interpolation is better)*

Based on the partitioned accuracy map, the prediction accuracy for organic matter, pH value, and soil particle size by the soil-landscape model was higher than that of the geostatistical interpolation method in most regions. For organic matter, the regions in which the soil-landscape prediction model was more accurate were mainly in the centre and west of the study region and constituted 80.59% of the total area. The regions in which the geostatistical interpolation was more accurate were mainly in the southeast region. For the pH value, the regions in which the soil-landscape prediction model was more accurate were mainly in the centre and west of the study region and constituted 60.82% of the total area. The regions in which the geostatistical interpolation was more accurate were distributed in the east and southwest regions. For the soil particle size, the regions in which the soil-landscape prediction model was more accurate were also mainly in the centre and west regions and constituted 70.58% of the total area. The regions in which the geostatistical interpolation was more accurate were mainly in the east region. Therefore, the soil-landscape model was more accurate for the three studied properties in the centre and west of the study region, and the relative error of the prediction results was smaller than that of the geostatistical interpolation by more than 20%. In the east study region, however, the prediction accuracy of the geostatistical interpolation was slightly higher than that of the soil-landscape model, and the relative error of the prediction results was smaller than that of the soil-landscape model by approximately 10%.

Discussion

Comparison with previous study on soil properties prediction

As mentioned before, Donghai County belongs to hilly region in Jiangsu Province, which usually makes it difficult to predict soil properties. To solve this problem, Former researchers took data from terrain attributes to raise the accuracy of predictions. Compared with their work such as results form Florinsky et al. (2002), higher R^2 can be achieved (0.561 vs 0.37) is this research. It is mainly because our soil-landscape model

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_49194934

use terrain data in addition with landscape data such as TWI and NDVI. In addition. Human activity data is taken consideration in this research. This finding shows that landscape data and human activity data can improve the performance of soil prediction model in hilly regions.

Accuracy comparision between soil properties

In this research, it can be found that no matter what method is used, the prediction error of soil particle size is greater than that of organic matter and pH. It can be seen from *Table 1* that the variation coefficient of soil particle size is large yet variabilitys of soil organic matter and ph are small. At the same time, soil particle size is affected by precipitation, agricultural activities as well as organisms (Tyler and Wheatcraft, 1992), far r exceeding the coverage of the factors constructed in this study. While the physical and chemical processes of soil organic matter and ph are clearer and the changes are more stable. The above reasons explain why the MAE and MRE of soil particle size is always slightly worse than soil organic matter and pH.

Error analysis of two prediction methods

When it comes to the results from soil-landscape model, results indicated that the MAE and MRE of the three soil properties were relatively small. The prediction accuracy of the soil properties by the prediction model was good, which verified and further extended the stepwise linear relationship between the soil organic carbon content and pH value and the gradient angle observed by previous studies (Mishra et al., 2009). The mean absolute errors of the soil pH and particle size in the dry land region were all less than those in the paddy fields, which is mainly because paddy fields and dry land present different types of human activities. The differences among the three soil properties were significant. The dry land region is in the west hilly regions of the study region, and values for the three soil properties were significantly lower in this region compared with that in the paddy fields. Therefore, under the same error conditions, the absolute errors in the paddy fields will be naturally higher than those in the dry land. The relative error of the organic matter content in the paddy field was smaller than that in the dry land, which indicated that the prediction results for the organic matter in the paddy field by the prediction models were more accurate than those in the dry land. External factors (e.g., land management measures, such as fertilizing) reduce the effect of internal factors (e.g., soil-forming factors, such as soil-forming parent material) (Yasrebi et al., 2009). Therefore, the present study introduced land-use types to represent the effect of external factors to improve the model prediction accuracy.

When it comes to the results from kriging, the MAE and MRE of the interpolation results for the organic matter content and pH value in the paddy field were slightly smaller than those in the dry land, which indicated that the Kriging interpolation results for the organic matter and pH value in the paddy field were more accurate than those in the dry land. The MAE and MRE of the interpolation results for the soil particle size in dry land were smaller than those in the paddy field, indicating that the Kriging interpolation results for this soil property were more accurate for the dry land region. The main reason for this result is that the organic matter and pH value in the paddy fields were high and the spatial variance was weak; therefore, the prediction results by the Kriging interpolation were better. The dry land region presented the opposite results, with the organic matter and pH values showing significant spatial variations; thus, the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_49194934

accuracy of the interpolation prediction was low. The overall soil particle size in the dry land was low and presented small variations and weak spatial variance; thus, the accuracy of the interpolation prediction was good. These results are consistent with the findings of Yasrebi et al. (2009), who indicated that the prediction accuracy of Kriging interpolations was generally affected by the variation coefficient.

Comparison between two prediction methods

As proposed by previous studies, soil property prediction methods that consider topographic properties predict more smooth values and show a reduced effect of outliers on the prediction performance (Junxiao et al., 2016). The soil-landscape model in this study considered topographic factors. Thus, when comparing the accuracy of the soil property predictions based on the soil-landscape model and geostatistical interpolation, the accuracy of the prediction results by the soil-landscape model was overall higher than that of the geostatistical interpolation results.

Specifically, for the organic matter, pH, and soil particle size, the regions in which the soil-landscape prediction model was more accurate were all concentrated in the centre and west of the study region, whereas the regions in which the geostatistical interpolation was more accurate were mainly in the east region, which is because the centre and west of the study region are hilly regions with large topographic variations. The landscape factors in the soil-landscape model reflected this topographic difference, whereas the geostatistical method only predicted the soil properties based on data similarity. Therefore, the prediction results by the soil-landscape model in the hilly region were more accurate compared with the prediction results by geostatistical interpolation. Inversely, the east study region is a flat plain, and the soil properties were relatively homogenous. Therefore, the prediction accuracy of the geostatistical interpolation was better than that of the soil-landscape model.

Conclusions

The following specific conclusions can be reached.

- The study object was farmland soil in which human activities have strongly affected soil properties. Therefore, when the soil-landscape model was constructed, land-use types were added to represent the effect of human activities on the soil properties. The study results indicated that in the hilly region with large topographic variations, introducing the human activity variable improved the soil property predictions.
- The study region belongs to the Huanghuaihai hilly region. A comparison of the accuracy of the soil property predictions based on the soil-landscape model and geostatistical interpolation in the study region showed that the soil-landscape model was more accurate than the geostatistical interpolation. Specifically, for the organic matter content, pH, and soil particle size, the regions in which the soil-landscape prediction model was more accurate were all concentrated in the central and west hilly regions in the study region, whereas the regions in which the geostatistical interpolation was more accurate were mainly in the east plain region. Therefore, the prediction results by the soil-landscape model in the hilly region were more accurate compared to the prediction results by geostatistical interpolation.

DOI: http://dx.doi.org/10.15666/aeer/1604_49194934

However, this study attempted to introduce a human activity variable into soil-landscape models to improve prediction accuracy; therefore, the variables in this model must be selected more rigorously, comprehensively, and appropriately. For example, taking into account the geo-environmental factors of the soil itself, the influence of human activities and the similar area with the same topography in the study area, we need to select variables that are suitable to local conditions. These issues require further study.

Abstract. Changes in land use affect the structure, processes, and functions of ecosystems, and thus influence the ability of ecosystems to serve human beings. The prediction of land use and ecosystem services value can provide reference for the rational planning of land resources and relevant policy-making. Based on the CA-Markov model and the service value per unit area of terrestrial ecosystems in China, the area of land use types and ecosystem services value were predicted for 2030 and the corresponding countermeasures and suggestions were put forward. The study found that from 2015-2030, the area of forest land had the largest increase, while the area of land for construction had the largest decrease. The spatial distribution of land use in 2030 was predicted to be almost the same as that in 2015. The slight increase in the value of ecosystem services in 2030 was mainly due to improvement in the service capacity of waste treatment and gas regulation. The contribution rate of the service value of forest land to the total ecosystem services value was predicted to gradually decrease from 2015-2030.

Introduction

Land use involves the long-term and cyclical management activities undertaken on land through use of biological resources and technology in accordance with the natural characteristics of the land and the purposes of economy and society (Fu et al., 2013, 2015; Lawler et al., 2014; Song et al., 2015). Ecosystem services refer to the environmental conditions and utilities formed by ecosystems necessary for the survival and development of human beings (Tolessa et al., 2016; Gaglio et al., 2017; Inkoom et al., 2017). Land use change affects the composition, function, and processes of ecosystems by altering the type of land cover, thereby affecting the availability of ecosystem services and human well-being (DeFries et al., 2004; Koellner et al., 2013). Prediction of land use change is a topic of interest in current research on land use change (Liu et al., 2009). However, there is less research in this area at present. Research on the prediction of land use change and ecosystem services value is helpful for governments to realize the ecological planning of land with comprehensive consideration of the national economy and social development (Inkoom and Frank and Fürst, 2017), to understand the supply capacity and demand of land in order to develop programs for land use planning according to the optimization of the ecological environment and sustainable development (Simmons et al., 2008; Cetin, 2016), and to carry out eco-friendly land use in order to fully utilize the ecological functions of land to ensure ecological security and to promote sustainable land use (Cetin, 2015; Cetin et al., 2018).

Land use change assessment examines the land's utility and its limitations. According to the intended use of land, the assessment can be divided into the suitability of land for agriculture and cities. The assessment allows us to clarify whether the regional land is suitable for production in various industries, such as agriculture, fruit, forestry, aquaculture, and urban construction, and can also examine the quantity, quality, and distribution of land resources with unreasonable use. It provides scientific basis for the adjustment of regional land use structure and planning. Therefore, land use change assessment is an important method for studying land use change and developing land use policy (Veldkamp and Verburg, 2004).

The land use change model is a powerful tool for land use assessment, and it can help decision-making authorities to formulate land use policies (Veldkamp and Verburg, 2004; Verburg et al., 2004). Land use models can be divided into three categories according to different combinations. The first is a quantitative prediction model, such as the Markov model (Yang et al., 2007; Subedi et al., 2013). This model is based on probability theory and stochastic processes, which can be used to predict land use changes in future years or decades using the initial state of various types of land use and mathematical algorithms, such as the transfer matrix. It is more commonly used in the prediction of land use change because the conditions for using the model are simple; only the area and transfer matrix of land use categories are needed to predict land use changes in future decades. However, the model is not perfect because it cannot reflect the spatial location information, but instead simulates the changes in area of various types of land (Kim and Lee, 2007).

The second type of model is a spatial prediction model, such as a cellular automaton model. This type of model adds spatial information. The cellular automaton model, or CA model, was invented by von Neumann in 1950 (Zhao et al., 2011). This model is based on cells with discrete properties that are scattered in a grid with a set of rules and are changed according to changing rules. Cells with various properties form a complex system through simple interactions. However, there are deficiencies in these cells. The state of a cell in the next moment depends on the state of itself and its neighboring cells. However, the state of the cell should also be related to socio-economic factors, such as population, policies, and transportation (Li et al., 2010). In addition, the simulation accuracy of the CA model is affected by the subjectivity of land use conversion rules.

In addition to the above-mentioned models, there is a third type of model called the CA-Markov model, which is the coupling of the first two models. This coupled model has the advantages of the first two models in that it has both spatial information and improved accuracy of land use simulation (Ramezani and Jafari, 2014). Therefore, we used the CA-Markov model to predict land use changes and ecosystem services value in this study.

The Western Taiwan Straits Economic Zone was established in 2010. Fujian Province is at the core of the zone, and it also includes areas in Zhejiang Province and Jiangxi Province. It aims to cooperate with Taiwan to establish a new pole of economic growth in the southeast of China, thus driving economic growth in China. Nanping City, the study area, is located in the central position of the Economic Zone because it is situated at the border of Fujian Province, Jiangxi Province, and Zhejiang Province. Therefore, it has an important significance in predicting the change in land use and ecosystem services value in Nanping. In addition, Nanping City is at the headstream of the Minjiang River, which is the drinking water source for Fujian Province. Therefore, research on the prediction of land use change and ecosystem services value in Nanping

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_49354954

can provide useful information for ecological security, using land resources rationally, alleviating the contradiction between humans and land, and promoting social harmony and sustainable development.

In this study, we aimed to determine the future change in land use and ecosystem services value in Nanping City from 2015 to 2030 based on the CA-Markov model and the equivalent value per unit area of ecosystem services created by Costanza (1997) and Xie et al. (2006, 2010). This research not only can reveal the future change in land use and ecosystem services value in Nanping, but also can provide a reference for scientific and effective land use planning and for research on ecosystem services value in other provinces and regions.

Materials and methods

Study area

Nanping City was chosen as the study area in this research. It is located in the southeast part of China across the sea from Taiwan (*Fig. 1*).

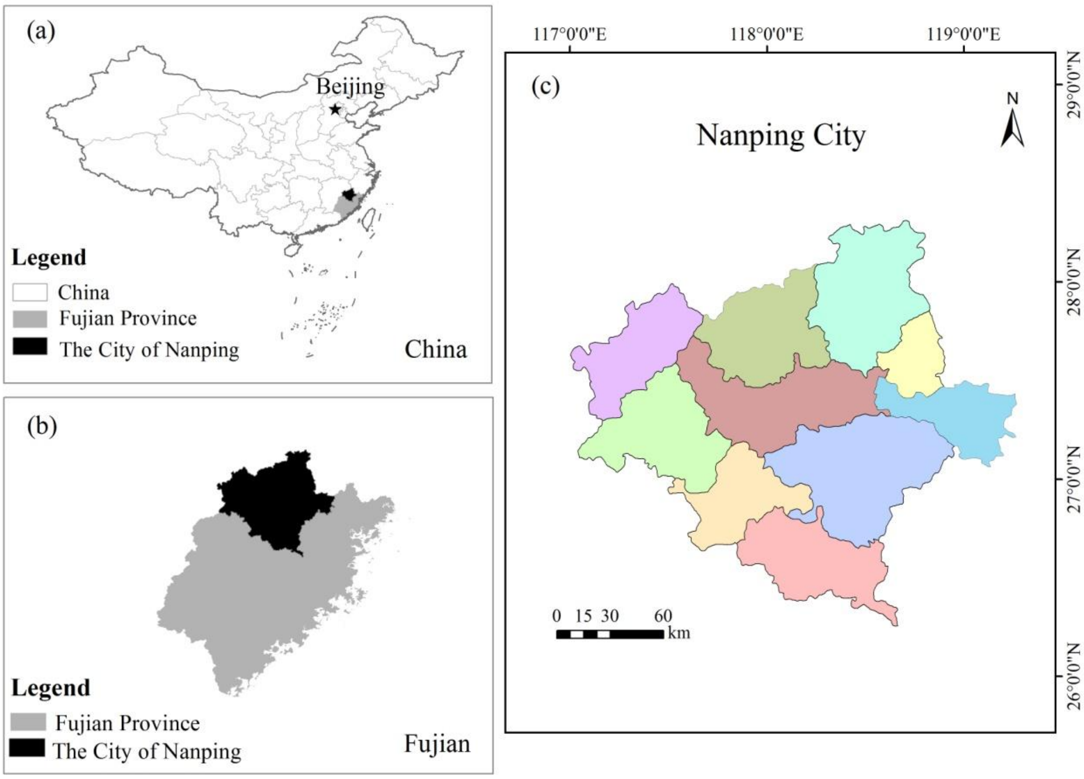

Figure 1. *Map of study area*

The area has a subtropical humid monsoon climate with an annual average temperature of 17-19 °C, an average winter temperature of 6-9 °C, an average summer temperature of 28-29 °C, and an average annual rainfall of 1684-1780 mm. Nanping City has a history of over 4,000 years and is one of the cradles of culture in Fujian Province. Nanping City is the largest city in the province with an area of 26,300 km^2, accounting for about one-fifth of the total area of the province. The area of cultivated land and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_49354954

forest land in Nanping accounts for approximately one-quarter of that in the province. The area of bamboo forest land accounts for approximately one-tenth of that in China. By the end of 2015, the forest coverage rate was 74.75%, the total household registration population was 3.2 million, and GDP was 20.933 billion USD. Nanping is also the food production base of Fujian Province; its grain output ranks first among that of other cities in the province. Nanping has one of the best ecological environments compared to other areas at the same latitude. Wuyishan, which is under the jurisdiction of Nanping, is one of the four World Natural and Cultural Heritage Sites in China.

Data source

Acquisition and processing of remote sensing data

We downloaded remote sensing images, including Landsat 5 (2005 and 2010) and Landsat 7 (2015) images, from the Chinese Geospatial Data Cloud (Xu et al., 2016). The images from Landsat 7 were processed using strip processing. The images with cloud coverage of less than 10% were selected. Seven scenes fully covered the total study area, so twenty-one scenes were downloaded for the research. Then, color synthesis, mosaic, clipping, and object-oriented classification were conducted using ENVI 5.2 to process these images.

In this study, bands 5, 4, and 3 (RGB) were used for color synthesis. According to the needs of the study and the geographical features of Nanping City, we divided the land use types into 6 categories, including forest land, grassland, cultivated land, construction land, water area, and unused land. After the object-oriented classification was conducted, post-classification maps for three periods were created (*Fig. 2*). Finally, the areas of all land use types for three periods were extracted using ENVI (*Table 1*).

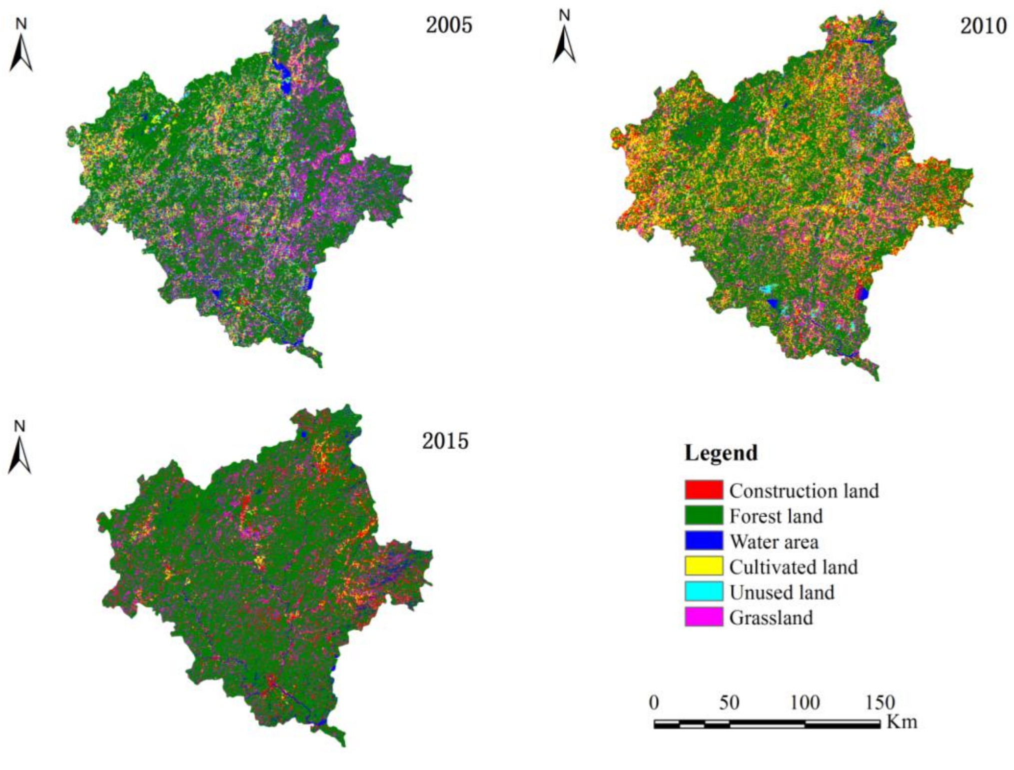

Figure 2. *The distribution of land use types in three periods in Nanping*

DOI: http://dx.doi.org/10.15666/aeer/1604_49354954

Table 1. *Area of different land use types in three periods (km²)*

Land use types	2005	2010	2015
Construction land	498.94	1350.44	1101.63
Forest land	19495.21	19258.94	21380.69
Water area	712.06	645.76	624.84
Cultivated land	2124.34	2452.60	1106.44
Unused land	1076.98	770.43	410.36
Grassland	2362.45	1796.45	1644.75

Preparation for creation of a suitability atlas

In this study, the CA-Markov module in IDRISI 17.0 was used to predict land use change in Nanping City. A gradient vector map and vector maps of the water system buffer and administrative center buffer were needed before using the CA-Markov model.

Acquisition of the gradient map

Chinese land use planning is a project of the development, utilization, governance and protection of land in a specific area, time and space according to the requirements of Chinese sustainable development as well as local natural and economic conditions (Zhang and Feng, 2017). According to the grading standards adopted in Chinese Land Use Planning, the slope of land use in Nanping City was divided into five grades (*Table 2*). The gradient map was then obtained using digital elevation model (DEM) and ArcGIS 10.1 software (*Fig. 3*). It can be seen from *Table 2* that the area with a gradient >6° accounted for 84.73% of the total study area, while the area with a gradient of 0-6° only accounted for 15.27% of the total area. This also confirms that mountains are the major landform in Nanping.

Table 2. *Gradient classification and area in Nanping City*

Grades	Gradient (°)	Area (km²)	Proportion (%)
1	0-2	1009.52	3.85
2	2-6	2995.24	11.42
3	6-15	9978.90	38.05
4	15-25	8290.77	31.60
5	>25	3954.76	15.08

Acquisition of the buffer maps of the water system and administrative centers

The buffer maps of the water system and administrative centers (*Fig. 4b* and *d*) were obtained by setting up four buffer zones at intervals of 1 km, which was the influence area of the water system and administrative centers, by means of distribution maps of the water system, the county government, and ArcGIS 10.1 (*Fig. 4a* and *c*).

Study methods

CA-Markov model

The CA model was proposed by Stanislaw Ulam in the 1940s. It has been widely used in geography, ecology, information science, military science, social science, and other fields since being improved by a number of scholars.

The CA model formula is as follows (*Eq. 1*):

$$A = (G, U, E, f_x) \tag{Eq.1}$$

where, G represents the cell grid; U refers to the cell neighborhood; E is the initial state of the cell; f_x represents the transformation rules of cell x; and A is the cellular automaton model.

Each cell is in different states at different times, and the states change according to the rules. Cellular automaton can be seen as a model of cellular assembly with rules. It can be used to study land use change because it can change over time and space, which is similar to the process of land use change, and the structure and composition of the cells in cellular automata are similar to those of raster data.

The Markov model can also be used to predict land use change using a transition probability matrix. *Equation 2* describes the transition process from land use type E_t to another land use type E_j. P_0 is the probability of land use type E_t being transformed to another land use type E_j.

$$P(E_t \to E_j) = P(\frac{E_t}{E_j}) = P_0 \tag{Eq.2}$$

Equation 3 is the state transition probability matrix. P_{ij} represents the state transition probability from land use type E_i to another land use type E_j.

$$P_{ij} = \begin{bmatrix} P_{11} & P_{12} & \cdots & P_{1n} \\ P_{21} & P_{22} & \cdots & P_{2n} \\ \vdots & \vdots & \vdots & \vdots \\ P_{n1} & P_{n2} & \cdots & P_{nn} \end{bmatrix} \tag{Eq.3}$$

Before using the Markov model, we must assume that the change in each land use type is only related to the state in the present moment, and not related to the state in any previous moment. At the same time, the probability of transition from one type of land use to any other type of land use is needed (*Eqs. 4* and *5*).

$$\begin{cases} 0 \le P_{ij} \le 1 (i, j = 1, 2, \cdots, n) \\ \sum_{j=1}^{n} P_{ij} = 1 (i = 1, 2, \cdots, n) \end{cases} \tag{Eq.4}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_49354954

$$\pi_j(k) = \sum_{i=1}^{n} \pi_i(k-1) P_{ij} (j = 1,2,\Lambda\ ,n) \tag{Eq.5}$$

where $\pi_j(k)$ represents the probability that the land use type transitions into the final land use type after the passing of k time from the initial state. P_{ij} is the transition probability from one state of land use to another.

We can achieve the value of P_{ij} from *Equation 6:*

$$P_{ij} = \frac{f_{ij}}{\sum_{j=1}^{n} f_{ij}} \tag{Eq.6}$$

where f_{ij} represents the time of transition from state i to state j in one step.

$$S^{(k)} = S^{(0)} \cdot \pi_j^{(k)} \tag{Eq.7}$$

where $S^{(k)}$ is the state of land use at k moment. $S^{(0)}$ is the initial state of land use and $\pi_j^{(k)}$ represents the transition probability matrix after K steps. From *Equation 7* we can obtain the state of land use at any time by means of the initial state of land use and the transition probability matrix after K steps.

Both the CA model and Markov model are discrete mathematical models in terms of time and state. They are widely used in the fields of geography and ecology. However, they both have drawbacks. The Markov model relies mainly on the transfer matrix of each type of land use to make a prediction. It does not take into account the fact that the driving force of land use change is constantly changing. In addition, the Markov model can provide data on how land use will change, but cannot predict the spatial distribution of land use change. Therefore, the accuracy of predicting land use change using the Markov model is lacking. The CA model can simulate the dynamic spatiotemporal changes of land use in the future. However, the prediction accuracy of the CA model depends on the conversion rules of land use, which are subjective. Additionally, the state of the cells in the CA model are not only affected by spatial location, but are also affected by many other aspects, such as nature, economy, and society. To summarize, the CA-Markov model combines the Markov model and the CA model, and takes into account the impact of the drivers of land use change, thereby more accurately predicting land use change in the study area.

Operation of IDRISI

In this study, the CA-Markov module in IDRISI 17.0 was used to predict the land use change in Nanping City. The grid maps of land use post-classification, Markov transfer probability matrix, and multi-criteria evaluation module (MCE) suitability atlas were prepared before using the model to predict trends in land use change.

Grid maps of land use post-classification

The vector maps of land use post-classification described in 2.2.1 were transformed into grid maps using the conversion tool of ArcGIS 10.1.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_49354954

Markov transfer probability matrix

The matrices of the Markov transfer probability from 2005-2010 and from 2010-2015 were obtained using IDRISI: GIS Analysis-Change/Time Series-Markov (*Tables 3* and *4*).

Table 3. *The transfer probability matrix of land use from 2005-2010 (%)*

2005 / 2010	Construction land	Forest land	Water area	Cultivated land	Unused land	Grassland
Construction land	27.04	8.86	14.73	14.51	16.07	9.48

Creation of a suitability atlas

A suitability atlas is a set of images containing rules. Using the atlas can better simulate the influence of factors on land use change. The creation of the atlas is a key and difficult component in predicting land use change. We used the MCE module in IDRISI to create the suitability atlas. In the MCE module, we set up the images according to Boolean rules, which were that 1 indicated suitability and 0 indicated unsuitability, and conversion rules. These conversion rules were as follows:

(1)The conversion rules of cultivated land

a) The area with a slope >25° was chosen as an unsuitable area for cultivated land.
b) The zones within 2 km of administrative centers were set as inappropriate areas for cultivated land.

(2)The conversion rules of construction land

a) The conversion of construction land to any other type of land use was forbidden.
b) The conversion of an area with a slope >15° to construction land was forbidden.

(3)The conversion rules of forest land, grassland, and water area

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_49354954

The restrictions of forest land, grassland, and water area were simpler compared to other types of land because of their functions of environmental protection. Hence, their rules were as follows:

a) The conversion of forest land and grassland to cultivated land was prohibited.
b) The conversion of water area within 1 km of a water system to construction land was forbidden.

(4)The conversion rules of unused land

The conversion of unused land to other types of land use was prohibited, and unused land could only be allocated to areas with a larger gradient.

Suitability images for each land use type were created by combining each image, obtained using the rules above, using Boolean intersection in the MCE module. We then created the suitability atlas using the Collection Editor tool. Finally, the future change in land use in Nanping was predicted using the CA-Markov module in IDRISI.

Accuracy of the prediction of land use change

In order to ensure the feasibility of the CA-Markov model in predicting land use change, we tested the accuracy of the model. There were two ways to test the accuracy: the quantitative accuracy test, which tested the accuracy of the structure and quantity of land use types; and the spatial accuracy test.

The quantitative accuracy test

The equation of this method is as follows (*Eq. 8*):

$$a = \frac{x_{ib} - x_{ia}}{x_{ib}} \times 100 \quad \text{(Eq.8)}$$

where a is the error precision and i indicates a specific land use type. x_{ib} and x_{ia} represent the values of the predicted and actual areas, respectively. When $a > 0$, it indicates that the predicted value is greater than the actual value.

The spatial accuracy test

$$y = \frac{|(x_{ib} - x_{ic}) + (x_{ia} - x_{ic})|}{x_{ia}} \times 100 \quad \text{(Eq.9)}$$

where y represents the spatial error of the land use prediction and i indicates a specific land use type; x_{ia} and x_{ib} represent the number of cells in the reference image and the predicted image, respectively; and x_{ic} represents the cell number of the overlapping parts of x_{ia} and x_{ib}.

Value per unit area of ecosystem services

According to the research results of Costanza et al. (Costanza, 1997) and Xie et al. (Xie et al., 2006, 2010) combined with the actual situation in China, a table of equivalent value per unit area of terrestrial ecosystem services in China was created,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_49354954

which provides a reference for the calculation of ecosystem services value in China (*Table 5*). The table is widely used by Chinese scholars (Liu et al., 2009; Xu et al., 2016; Li et al., 2010; Peng et al., 2016; Wang and Sun, 2016; Xu et al., 2016). According to the study by Xie (Xie and Xiao and Lu, 2006), we chose 9 types of ecosystem services, including gas regulation, climate regulation, water conservation, soil formation and protection, waste treatment, biodiversity conservation, food production, supply of raw materials, and entertainment and culture.

Table 5. *Equivalent value per unit area of terrestrial ecosystem services in China*

Ecosystem services	Forest land	Grassland	Cultivated land	Wetland	Water area	Unused land
Gas regulation	3.50	0.80	0.50	1.80	0.00	0.00
Climate regulation	2.70	0.90	0.89	17.10	0.46	0.00
Water conservation	3.20	0.80	0.60	15.50	20.38	0.03
Soil formation and protection	3.90	1.95	1.46	1.71	0.01	0.02
Waste treatment	1.31	1.31	1.64	18.18	18.18	0.01
Biodiversity conservation	3.26	1.09	0.71	2.50	2.49	0.34
Food production	0.10	0.30	1.00	0.30	0.10	0.01
Supply of raw materials	2.60	0.05	0.10	0.07	0.01	0.00
Entertainment and culture	1.28	0.04	0.01	5.55	4.34	0.01

In this study, the land use types were divided into 6 categories, including forest land, cultivated land, water area, unused land, grassland, and construction land. Therefore, *Table 5* was slightly modified to form a table of equivalent value per unit area of terrestrial ecosystem services in Nanping City (*Table 6*). Construction land was not included in *Table 6* because ecosystem services provide a positive utility that meets the needs of human beings. However, construction land, such as rural residential land and industrial and mining land, constantly releases sewage, waste gas, and solid waste to the environment, which have a devastating effect on the natural ecological environment. Consequently, we did not account for the value of ecosystem services of construction land.

Table 6. *Equivalent value per unit area of terrestrial ecosystem services in Nanping City*

Ecosystem services	Forest land	Cultivated land	Water area	Unused land	Grassland
Gas regulation	3.50	0.50	0.00	0.00	0.80
Climate regulation	2.70	0.89	0.46	0.00	0.90
Water conservation	3.20	0.60	20.38	0.03	0.80
Soil formation and protection	3.90	1.46	0.01	0.02	1.31
Waste treatment	1.31	1.64	18.18	0.01	1.95
Biodiversity conservation	3.26	0.71	2.49	0.34	1.09
Food production	0.10	1.00	0.10	0.01	0.30
Supply of raw materials	2.60	0.10	0.01	0.00	0.05
Entertainment and culture	1.28	0.01	4.34	0.01	0.04

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_49354954

We can see from *Table 6* that the equivalent value per unit area of ecosystem services of these land use types is based on the value per unit area of food production of cultivated land in Nanping, which can be calculated by *Equation 10*:

$$E_a = \frac{1}{7} \cdot T_a \cdot T_b \qquad \text{(Eq.10)}$$

where E_a represents the value per unit area of food production of cultivated land (CNY/hm^2); T_a refers to the average grain yield per unit area (kg/hm^2) in the study area; and T_b is the average grain price in China (CNY/kg). By consulting the Nanping Statistical Yearbook, we found that the average grain yield per capita in Nanping City in 2015 was 5,700 kg/hm^2, and that China's average grain price in 2015 was 5.24 CNY/kg. Hence, we obtained the value per unit area of food production of cultivated land in Nanping, which was 4266.85 CNY/hm^2, by means of *Equation 10*.

The values per unit area of ecosystem services for land use types, except for cultivated land, were obtained using *Equation 11* and *Table 6*.

$$CV_{ij} = E_a \cdot f_{ij} \qquad \text{(Eq.11)}$$

where i is a specific land use type. j represents a specific ecosystem service. CV_{ij} represents the value per unit area of specific ecosystem services of a specific land use type (CNY/(hm^2·year)). E_a represents the value per unit area of food production of cultivated land (CNY/hm^2). f_{ij} refers to the equivalent value per unit area of specific ecosystem services of specific land use types.

Table 7. *The value per unit area of ecosystem services of land use types in Nanping City (ten thousand CNY/hm^2)*

Ecosystem services	**Forest land**	**Cultivated land**	**Water area**	**Unused land**	**Grassland**
Gas regulation	1.4933	0.2133	0.0000	0.0000	0.3413
Climate regulation	1.1520	0.3797	0.1962	0.0000	0.3840
Water conservation	1.3670	0.2560	8.6953	0.0128	0.3413
Soil formation and protection	1.6640	0.6229	0.0042	0.0085	0.5589
Waste treatment	0.5589	0.7012	7.7567	0.0042	0.8320
Biodiversity conservation	1.3909	0.3029	1.0624	0.1450	0.4651

Supply of raw materials	1.1093	0.0427	0.0042	0.0000	0.0213
Entertainment and culture	0.5461	0.0042	1.8517	0.0042	0.0171
Total	9.3243	2.9497	19.6136	0.1791	3.0891

Prediction of ecosystem services value

The predicted value of ecosystem services of all land use types can be calculated by *Equation 12:*

$$ESV = \sum_{i=1}^{n} \sum_{j}^{m} A_i \times CV_{ij} \qquad \text{(Eq.12)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_49354954

where ESV is the predicted value of ecosystem services, A_i is the predicted area of a specific land use, and CV_{ij} represents the value per unit area of ecosystem services of specific land use types. n and m refer to the number of land use types and ecosystem services, respectively.

Results

Prediction accuracy of land use change

The area of land use types in Nanping City in 2015 was predicted using the CA-Markov model and the area of land use types in Nanping City in 2005 and 2010. According to *Equations 8* and *9,* quantitative and spatial errors were present (*Table 8*). We found from *Table 8* and *Figure 5* that the quantitative and spatial prediction accuracy were greater than 90% and 89.85%, respectively. Therefore, it is feasible to predict future changes in land use with the CA-Markov model.

Table 8. *Accuracy of prediction of land use in 2015*

2015	Construction land	Forest land	Water area	Cultivated land	Unused land	Grassland
Actual value (km^2)	1101.63	21380.69	624.84	1106.44	410.36	1644.75
Validated value (km^2)	1154.26	21057.99	645.50	1212.29	429.36	1775.21
Quantitative error (%)	4.78	-1.51	3.30	9.56	4.63	7.93
Spatial error (%)	13.09	4.28	12.32	12.76	7.41	11.05

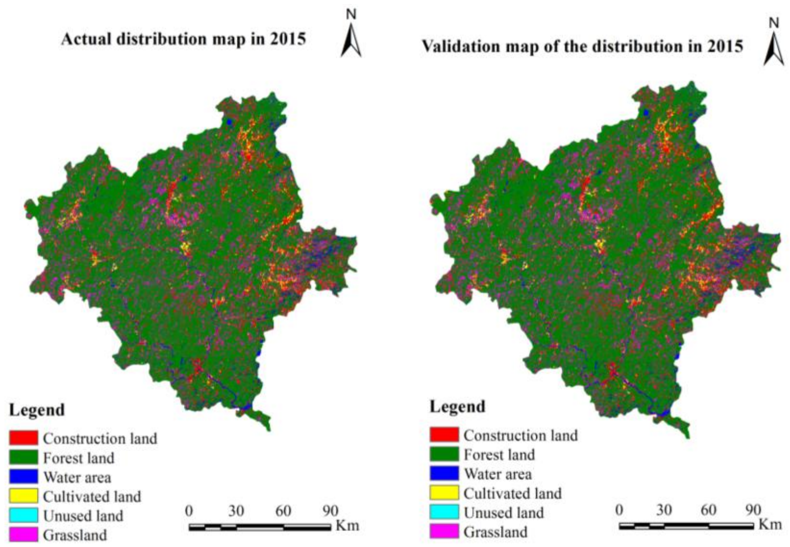

Figure 5. *Comparison of the actual distribution and validated distribution of land use in 2015*

Prediction of land use change

After completing the accuracy test, we predicted the change in land use types in 2020, 2025, and 2030 in Nanping by changing the number of simulated cycles in IDRISI to 5, 10, and 15, respectively. However, the change in land use was insignificant from 2015-2025, so we only demonstrated the results of land use change in 2030. As

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_49354954

shown in *Table 9* and *Figure 6,* there were observable characteristics in the future changes in land use in Nanping.

Table 9. *Comparison of the change in area of land use in 2015 and 2030*

Land use types	2015		2030		2015-2030
	Area (km^2)	Proportion (%)	Area (km^2)	Proportion (%)	Area change (km^2)
Forest land	21380.69	81.39	21780.14	82.89	399.45
Grassland	1644.75	6.26	1430.55	5.44	-214.20
Cultivated land	1106.44	4.21	1189.61	4.53	83.17
Construction land	1101.63	4.19	846.36	3.22	-255.27
Water area	624.84	2.38	592.86	2.26	-31.98
Unused land	410.36	1.56	435.10	1.66	24.74
Total	26268.71	100.00	26274.62	100.00	5.91

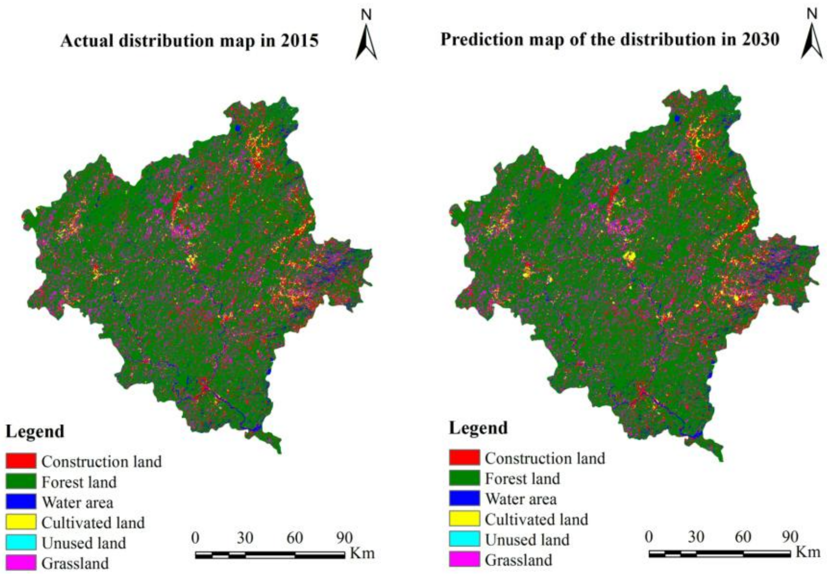

Figure 6. *Comparison of the distribution of land use in 2015 and 2030*

In the 2030 prediction, the total area of forest land reached 21780.14 km^2 and the proportion of forest land to the study area increased from 81.39% in 2015 to 82.89% in 2030, which is an increase of 1.50%. This shows that over the 15 years, the ecological environment continues to be strengthened and the forest cover rate is sustained.

Compared to the area of grassland in 2015, the area in 2030 showed a significant reduction with a decrease of 214.20 km^2. The decrease was closely linked with the development of the regional economy and the constant adjustment of the industrial structure. Consequently, more attention should be given to pasture degradation caused by overgrazing and natural disasters (Wang, 2013).

The area of cultivated land was predicted to increase by 83.17 km^2 during the 15 years, indicating that the government's policy of protecting basic farmland and stabilizing the food supply will continue to play a role in this stage.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_49354954

Water area would decrease slightly in 2030 compared to 2015. Due to the continuous increase in population, the change in life style, and the increase in water utilization for agriculture and industry, the water area could continue to decrease, which should be given adequate attention.

By 2030, the area of construction land would be reduced from 1101.63 km^2 in 2015 to 846.36 km^2 in 2030, which is a decrease of 255.27 km^2. This means that the intensive development of land would increase in the process of urban construction and economic development in Nanping during those 15 years.

The change in area of unused land during the 15 years would not be significant. This is due to the fact that most of the unused land is situated in regions with harsh natural conditions and steep slopes, which is not easily accessible to humans.

Prediction of ecosystem services value

The services value and rate of contribution of ecosystems in 2015 and 2030 were calculated using *Tables 7* and *9* and *Equation 12*.

It can be seen from *Table 10* that the service value of the ecosystems from 2015-2030 would continue to increase slightly. By 2030, the total value of the services in Nanping would reach 227.72 billion CNY, which is an increase of 2.69 billion CNY. From the services value of different ecosystems, the value of forest land showed a slow growth but it remained at a relatively high value during the 15 years. The contribution rate of forest land in 2030 was 0.58% higher than that in 2015. The services value and contribution rate of cultivated land and unused land also increased slightly. However, during the 15 years, the services value of water area and grassland continued to decrease, with a total decrease of 0.63 billion CNY and 0.66 billion CNY, respectively. The contribution rate of ecosystem value of water area and grassland was predicted to decrease by 0.35% and 0.33%, respectively. Consequently, more attention should be given to the reduction in the services value of water area and grassland during these 15 years.

Table 10. *The services value and contribution rate of different ecosystems in 2015 and 2030*

Ecosystem types	Ecosystem services value (billion CNY) and contribution rate (%)				Changing services value (billion CNY)	Changing contribution rate (%)
	2015		2030		2015-2030	2015-2030
Forest land	199.36	90.61	203.08	91.18	3.72	0.58
Cultivated land	3.26	1.48	3.51	1.58	0.25	0.09
Water area	12.26	5.57	11.63	5.22	-0.63	-0.35
Unused land	0.07	0.03	0.08	0.04	0.01	0.01
Grassland	5.08	2.31	4.42	1.98	-0.66	-0.33
Total	220.03	100.00	222.72	100.00	2.69	0.00

As shown in *Table 11*, excluding the service of waste treatment, the value of the remaining service types showed a slight increase over the 15 years. Most notably, the service values of soil formation and protection, gas regulation, and supply of raw materials in 2030 were over 0.40 billon CNY higher than those in 2015. The order of various service values in 2030 were as follows: soil formation and protection > water conservation > gas regulation > biodiversity conservation > climate regulation > raw

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_49354954

materials > waste treatment > entertainment and culture > food production. In short, the total value of ecosystem services in Nanping was predicted to steadily increase over the 15 years.

Table 11. *The value of ecosystem services in Nanping City in 2015 and 2030 (billion CNY)*

Ecosystem services	2015	2030	Changing value over 15 years
Gas regulation	32.72	33.26	0.54
Climate regulation	25.80	26.20	0.40
Water conservation	35.51	35.72	0.21
Soil formation and protection	37.19	37.78	0.59
Waste treatment	18.94	18.79	-0.15
Biodiversity conservation	31.56	32.01	0.45
Food production	1.41	1.64	0.23
Supply of raw materials	23.80	24.24	0.44
Entertainment and culture	12.86	13.02	0.16
Total	219.82	222.71	2.89

Discussion and suggestions

Land is a precious natural resource that is necessary for the survival of human beings and for urban development. Sustainable land use and rational planning of land are basic requirements for the development of the city, and are also the issues of most concern for land use decision-making departments (Bateman et al., 2013). Therefore, we provide the following countermeasures and suggestions according to the study results, which are aimed at providing useful information for land administration departments.

(1) Cultivated land

From the above prediction results, it was found that the area of cultivated land would decrease slightly from 2015 to 2030. However, the population in Nanping City will continue to increase during these 15 years. It would be particularly important to guarantee the basic supply of grain. Therefore, the protection of basic farmland as a basic land use strategy is of great significance for maintaining regional grain production and regional ecological security. The specific countermeasures and suggestions are as follows:

a) High-quality areas of cultivated land are defined as a basic farmland protection area, ensuring that the area and the quality of basic farmland do not decrease.

b) It is forbidden for other land uses to occupy basic farmland areas.

c) For ordinary cultivated land, construction projects should use as little cultivated land area as possible. If it is necessary to occupy cultivated land, only farmland with poor quality should be occupied.

d) Due to the abandonment of rural areas in Nanping City, it is forbidden to abandon cultivated land. Check the farmland that has been abandoned, and take corresponding measures to resume farming.

e) Developing unused land with a moderate slope as a reserve resource for cultivated land. It is forbidden to develop areas with slopes greater than 25°.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_49354954

f) Developing a responsibility system for farmland protection; designating the relevant leaders of the government as the first responsible person, and ensuring that the tasks of farmland protection are completed.

(2) Grassland

This study found that the grassland area would be significantly reduced by 2030. Therefore, appropriate measures should be taken to protect the grassland area.

a) Implementation grassland development plans to increase grassland utilization so as to ensure adequate forage supply for livestock raised by farmers.

b) Planting grass according to scientific methods and actively introduce suitable pasture varieties.

c) Protecting the grassland and forbidding the burning of grassland. When weeds are eliminated and pests and diseases are removed, scientific measures must be taken to prevent damage to the grasslands.

d) It is forbidden to overgraze so as to prevent degradation of grassland. For degraded grasslands, measures should be taken to increase grass production and livestock husbandry.

e) Destruction of grassland should be investigated.

For forest land, construction land, and unused land, the prediction results performed well, but it is still necessary to make recommendations to ensure that this favorable situation is maintained. The specific recommendations are as follows:

(3) Forest land

It is forbidden to develop and use natural forests. Practice the closing of mountains and forests, and encourage tree planting on barren slopes.

(4) Construction land

a) Construction land should be used intensively. Develop and utilize ground and underground space to support the construction of multi-level industrial plants in order to improve the utility rate of space.

b) Encouraging farmers to build houses in a centralized manner and prohibiting scattered distribution of rural buildings.

(5) Unused land

On the premise of protecting the ecological environment, developing the gentle slope zone will provide backup support for other land resources.

Conclusions

Based on CA-Markov model and equivalent value per unit area of terrestrial ecosystem services in China, we predicted the area of the land use types and ecosystem services value in 2030. The following main conclusions are as follows.

From 2015 to 2030, the area of the forest land and cultivated land increase obviously. The area of the grassland and construction land show a significant decrease, while the water area and unused land area do not change significantly. Compared with 2015, the change of the spatial distribution pattern of land use types in 2030 is not significant.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_49354954

It has been found that the total value of ecosystem services will continue to rise from 2015 to 2030. It has been estimated that the ecosystem services value in Nanping City will reach 222.72 billion CNY in 2030. The increasing speed of the service value of forest land will slow down, but the contribution rate of forest land in 2030 is still 0.58% higher than 2015. The improvement of the ecosystem services value in the study area is mainly due to the increasing value of service types such as gas regulation, soil formation and protection, biodiversity conservation and supply of raw materials. More significantly, the services value of the gas regulation and soil formation and protection increase by over 0.50 billion CNY during the 15 years.

Abstract. In this study, changes in the morphological traits of the leaves of elm tree (Ulmus minor 'Umbraculifera') were investigated against the air pollution in Tehran City, capital of Iran. For this purpose, the healthy and fully developed leaves were sampled from even-aged trees of the same diameter class from 3 districts of Tehran City with different traffic volume and air pollution load. Then, the micro-morphological traits of the stoma including length, width, density, size, stomatal shape, trichome density, and theoretical stomatal resistance were measured using Scanning electron microscopy (SEM) images. The macro-morphological traits, including length, width, shape, and area of the leaf, as well as the number of teeth on the blade, length of petiole, and asymmetry of the blade were measured. Determining the wet and dry weights and leaf turgor, the specific leaf area and relative water content were estimated. The results showed that the macro-morphological traits of the leaves were resistant and did not change significantly in the presence of air pollutants. In the contaminated areas, unlike the stomatal density that showed an increase, the stomatal size decreased. With increasing leaf thickness in the polluted areas, the stomatal density also showed an increase. Due to the inherent resistance of the leaves of elm tree to the reduction of leaf water potential, the failure of the photosynthesis rate, caused by the presence of pollutants, is compensated. In the species of elm, the traits of stomatal density and size are better descriptors for reflecting leaf changes in different environmental conditions.
Keywords: *air pollutants, urban areas, stomatal density, stomatal size, green space development, resistance plant*

Introduction

Air pollution in urban and industrial areas affects the survival of plant species. Although plants in industrial environments can be effective in controlling and reducing air pollution, they are affected by air pollutants and damaged (Dineva, 2004). Different plants show different sensitivity and performance in the face of air pollution (Dineva, 2004; Verma and Singh, 2006; Stevovi et al., 2010). The response of plants to environmental conditions and changes is strongly associated with their structural and functional characteristics (Gostin, 2009; Wang et al., 2011). Environmental changes lead to anatomical and morphological changes in the organs of plants (Verma and Singh, 2006; Wuytack et al., 2010; Stevovi et al., 2010).

Several studies have been done on the structure and anatomy of vegetative organs under conditions of environmental pollution (Arriaga et al., 2014; Chaturvedi et al., 2013; Lima et al., 2000; Kardel et al., 2010; Balasooriya et al., 2009). Plant species that are resistant to air pollution can show adaptations and continue to grow. The resistance of different tree species to air pollution is different, and some species are able to withstand pollutants and can remain normal and healthy (Magtoto et al., 2013). Among plant organs, leaves are more sensitive to environmental tension because most of the physiological processes, such as photosynthesis, are carried out through leaves. However, leaves have greater flexibility to adapt to the environmental conditions (Dineva, 2004; Rani et al., 2006). Hence, studying the reactions and adaptations of leaves in the face of air pollutants can be a good indicator of the performance of plant species in polluted environments. In cities and industrial areas, wooden species and trees, with their high leaf area, are effective in controlling and reducing air pollutants (Saebo et al., 2012; Petrova et al., 2013).

Having informed on the capability and performance of species and determining the ability of different species to deal with air pollution can be the first step to maximize the benefits of trees in urban and industrial areas (Escobedo et al., 2011; Saebo et al., 2012). It also provides a suitable basis for the selection of plant species and improving air quality (Wang et al., 2011).

Tehran, as the largest city in Iran, is considered as one of the world's populous cities (Naddafi et al., 2012). The city faces problems such as high population density and heavy traffic jam. It is the most industrialized city of Iran. Many industries such as power plants, refineries, furnaces, and metal processing and smelting plants are located on the outskirts of the city (Kermani et al., 2016). In Tehran, air pollution is a serious problem, and pollutants from vehicle traffic are a major contributor to this pollution (Kermani et al., 2016, 2003; Naddafi et al., 2012; Salmanzadeh et al., 2015; Kord et al., 2010; Leili et al., 2008; Sowlat et al., 2011). The present study was carried out to study the capabilities and resistance of elm (Ulmus minor 'Umbraculifera') tree against air pollution. The study seeks to answer the question that is it advisable to plant elm tree with the purpose of development of green spaces in urban and industrial areas with high rate of air pollution. Accordingly, changes in the morphological traits of the leaf of street-side trees of Tehran City were investigated.

Materials and methods

Study area

Tehran is the capital city of Iran, located in 35° 36' northern latitude and 50° 53' eastern longitude. The average altitude of the city is 1191 m above sea level. The maximum and minimum levels of temperature are, respectively, 22.5 °C and 11.2 °C. Majority of industries are located on the western part of the city and its suburbs where the prevailing wind blows towards the east-west direction (Alijani and Safavi, 2005). Tehran's topographic conditions are such that the mountains surround the city from the north and east and these elevated barriers prevent the evacuation of pollutants from the city. Moreover, on the west side, due to being openness, suburban pollutants also enter the city with the help of winds (Alijani and Safavi, 2005; Golbaz et al., 2010).

Research procedure

Three districts of Tehran City were selected to take samples from the leaves of street-side elm trees. These three districts in terms of the traffic volume and air pollution load were divided in two categories of low emission (Site 1: Chitgar Station) and high emission (Site 2: Azadi Street and Site 3: Gisha Bridge) (*Fig. 1*).

The first site, Chitgar Station, was located in a forest park on the western outskirt of the city with a dense green space, where the traffic volume was very low. The distance of Site 1 from the nearest highway (Tehran-Karaj Highway, as most crowded highway of Iran) was more than 1000 m. Despite the low traffic of this station, under the influence of the prevailing wind direction, numerous small and large industrial sites in the region, and the discussed topographic conditions, this site deals with the consequences of air pollution.

Since majority of the particles released from the vehicles are sedimentated at the shortest distance from the emission source, attempts were made to collect the samples from the leaves of road-side trees.

Samples in Site 2 were collected from street-side trees in Azadi Square, the west and southwest of Tehran. Traffic volume in Azadi Square is very heavy. However, due to wide streets and pedestrian walkways, as well as lower density of residential and commercial buildings, air conditioning is better in this site, compared to the Site 3.

Site 3 is located in the central part of Tehran. A vehicle overpass, the intersection of two highways, proximity to residential and commercial structures, such as higher education institutions and offices have caused massive traffic jams and reduced air conditioning in this part of the city.

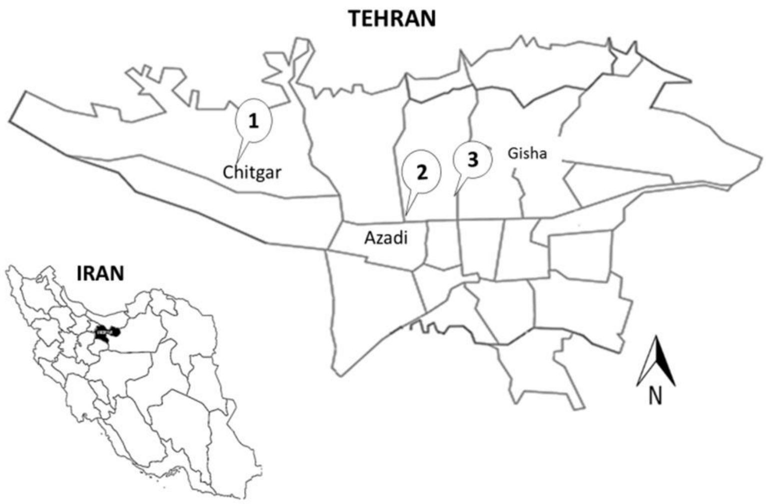

Figure 1. *Situation of the sampling sites in Tehran City and in Iran*

Figure 2 shows air quality indicators of Tehran in 2014. The data were obtained from the annual report on air quality of Tehran in 2014 published by Tehran Air Quality Control Company. The Site 1 was located in a forest park in the outskirt of the city, where there was no active air monitoring station nearby. The nearest air monitoring stations to the Sites 2 and 3 were placed at a distance of about 500 m away from the sampling area (*Fig. 2*).

Sampling and analysis

Traits of elm tree

Elm (Ulmus SPP.) includes 20 to 45 species, scattered in the northern hemisphere and mountainous parts of tropical regions (Wheeler and Manchester, 2007). Iran is one of the countries wherein some elm species have been expanded (Oladi et al., 2013). Because some species of elm, due to their vault-like crown, are widely used in development of green spaces in urban areas.

Leaf sampling

In each sampling site, 5 healthy and disease-free trees with the least distance from the street were selected randomly. The orientation of the trees towards the street and the direction of sunlight and wind were considered to be the same. The trees were even aged and selected from similar diameter classes. The sampling was done at the end of the growing season in the second half of September, 2014.

The perfectly healthy leaves were collected from the street side outermost part of the canopy. To ensure the opening of stomata, the leaves were collected at 10 to 11 am. They were placed in a wrapped nylon in an ice tank with minimal hand contact and transferred to the laboratory in the shortest time. To take images with Scanning Electron Microscopy (SEM), the leaves were dried in a dry place away from sunlight at normal room temperature.

Using the images taken from the lower leaf surface, micro-morphology traits of the leaves, including Stomatal pore length (µm) (SL), Stomatal pore width (µm) (SW), Stomatal density (SD), Stomatal pore shape (SPS) (length to width ratio of stomatal), Stomatal Pore Surface (SPS), and Theoretical minimal stomatal resistance (Rs) were measured. Assuming the oval shape of the pores, the SPS was measured for other pores using *Equation 1* (Balasooriya et al., 2009). The Rs was also calculated using *Equation 2* (Balasooriya et al., 2009).

$$SPS = \frac{(SL \times Sw \times \pi)}{4} \quad \text{(Eq.1)}$$

$$Rs = \left(4\frac{l}{n} \times \pi \times Sl \times Sw \times D\right) + \left(Sl + \frac{Sw}{4n \times Sl \times Sw \times D}\right) \quad \text{(Eq.2)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_49554968

where Rs is the stomatal resistance (sm^{-1}), l is the stomatal pore depth (m), D is the water vapor diffusion coefficient in air (24.2×10^{-6} m^2s^{-1} at 20 °C), and n is the stomatal density (number of stomata m^{-2}). Stomatal depth was considered to be 10 µm (Samson et al., 2000; Olyslaegers et al., 2002). To study the macro-morphological parameters of the leaves, from each tree base, the images of 50 leaves were prepared in a JPEG format with the help of a scanner. According to which, the parameters of Leaf length (LL), Leaf Width (LW), LS (length to width ration), Leaf area, teeth density, petiole length, and fluctuating asymmetry blade (FA) (*Eq. 3*) were calculated using Image J software (Kovacic and Nikolic, 2005).

$$Fa = \frac{|Wl - Wr|}{(Wl + Wr)} \quad \text{(Eq.3)}$$

in which Wl is the left half area of leaf blade and Wr refers to the right half area.

To measure SLA, 30 leaves were collected from each tree. From each leaf, 4 cm^2 pieces were punched and dried for 24 h at 60 °C. The weight of the dried parts was measured by a digital scale with a precision of 0.001 g. Then, the SLA was calculated using *Equation 4*. SLA = area of the punched parts/weight of the punched parts (cm^2 g^{-1}).

To measure Relative Water Content (RWC), 20 leaves were sampled from each tree and punched into the 4 cm^2 pieces. The wet weight of the punched pieces was measured. These pieces were placed in distilled water in low light intensity for 4 h. After measuring their turgor weight, they were dried at 60 °C for 24 h and weighed (Ritchie and Nguyen, 1990) (*Eq. 4*).

$$RWC = \lfloor (\text{wet weight} - \text{wet weight}) | (\text{turgor weight} - \text{dry weight}) \rfloor \times 100 \quad \text{(Eq. 4)}$$

Statistical analysis

The normality of the data was tested by Kolmogorov–Smirnov test in SPSS 16.0 software. Homogeneity of variance was tested using Levene's test. To compare the data, ANOVA was used. For multiple comparisons of the average values, Duncan, Kruskal-Wallis, and Mann-Whitney U tests were used.

Results and discussion

As *Figure 2* suggests, the level of most of the pollutants in Gisha Bridge is higher than Azadi Square. This is mainly due to the lower wind speed, high density of buildings, heavy traffic, and transport of worn out vehicles at the central parts of Tehran City (Shamsipour et al., 2013; Naddafi et al., 2012; Leili et al., 2008). *Figure 3* shows a SEM image taken from LSS of elm leaf.

Micro-morphological traits of elm leaves

The results of statistical testes showed a significant difference between the average values of the leaf micro-morphological traits in tree sampling stations, including SL (Sig = 0/000), SSH (Sig = 0/000), stomatal density (Sig = 0/000), stomatal pore surface (Sig = 0/001), and RS (Sig = 0/000) (*Fig. 4*). No significant difference was found between the measured values of SW in the three sampling sites (Sig = 0/289) (*Table 1*).

DOI: http://dx.doi.org/10.15666/aeer/1604_49554968

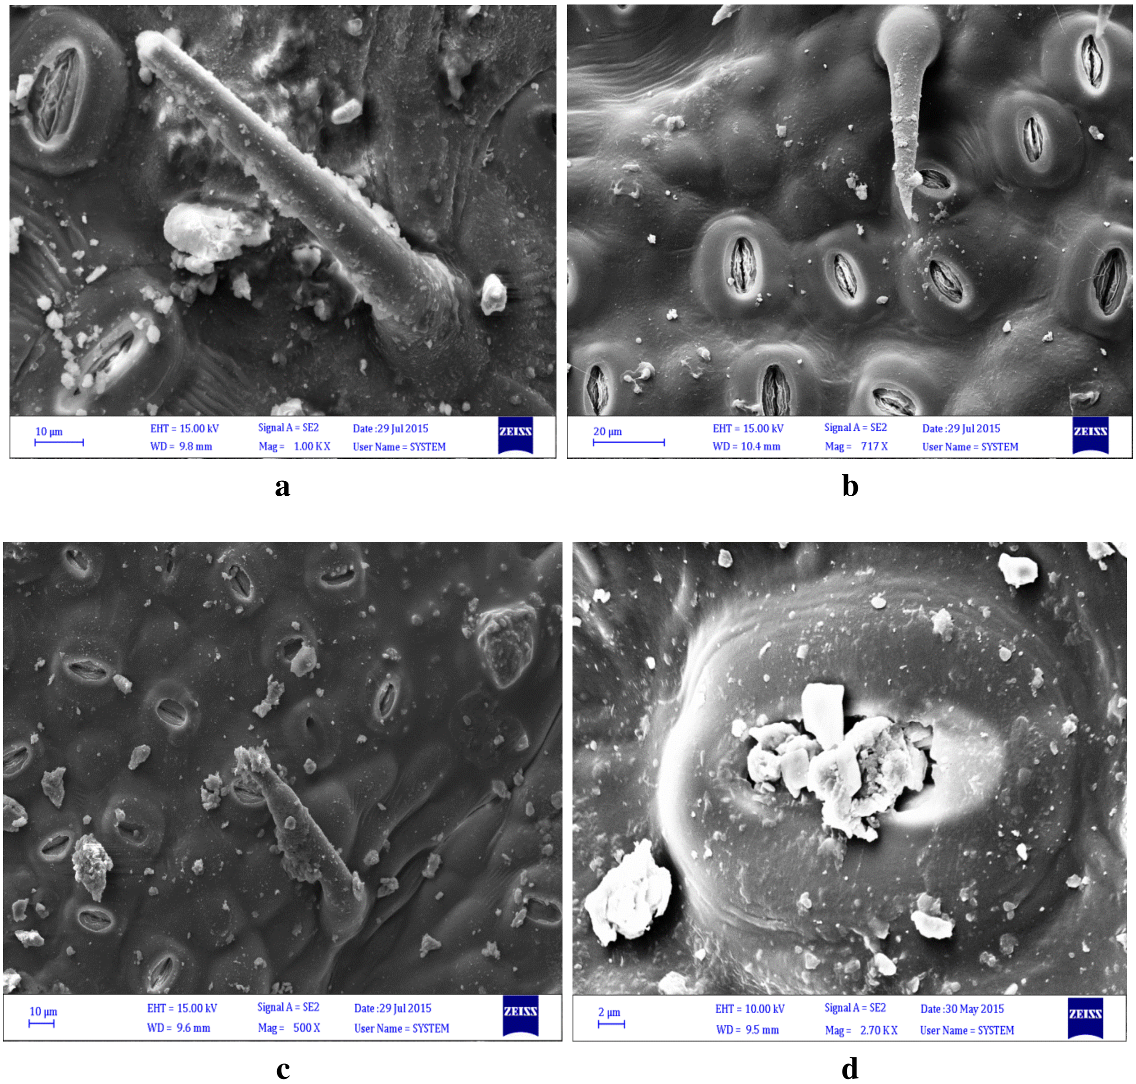

Figure 3. *SEM images taken the lower surface pores of elm leaf.* ***a*** *Chitgar Station,* ***b*** *Gisha Bridge,* ***c*** *Azadi Square,* ***d*** *complete blockage of stomata by airborne particulates*

According to the table, the SL value, compared to Chitgar Station, showed a decline of 27% in Azadi Square and 19% in Gisha Bridge (*Fig. 4a*). In addition, the values of stomatal length-to-width ratio in Azadi Square and Gisha Bridge were respectively 27% and 17% lower than that in Chitgar Station. (*Fig. 4b*). Comparison of the average stomatal density in the studied areas showed that in Azadi and Gisha, 31% and 144% increase in density was observed in comparison with Chitger (*Fig. 4c*). Stomatal pore surface was reduced in the polluted sites so that its value at Azadi and Gisha was 31% and 26% lower than Chitgar, respectively (*Fig. 4d*). The Rs increased in Gisha Bridge compared to Chitgar and was 30% less than Azadi (*Fig. 4e*).

The response of stomata to tension and mechanisms for reducing and controlling the input of pollutants into leaves are one of the most important traits of plants under stress conditions (Andersen, 2003). Balasooriya et al., 2009). Stomatal density is an important eco-physiologic parameter, which affects gas exchange between the atmosphere and plant (Lake et al., 2001; Uprety et al., 2002; Pompelli et al., 2010).

Researchers have found that traits such as stomatal density, epidermal cell density, and stomatal pore length are not hereditary and influenced by environmental conditions. Stomatal pore shape, increased stomatal density, and reduced stomatal pore surface in polluted areas are mechanisms for adapting species to contaminated environments (Wagoner, 1975; Kardel et al., 2010; Wuytack et al., 2010; Rani et al., 2006).

Increasing the stomatal density and reducing the size of the stomach can control and reduce gas exchanges and the entry of pollutants through the stomata (Wuytack et al., 2010; Alves et al., 2008). The entry of pollutants into plants through stomata has an inhibitory effect on plant physiological activities, such as photosynthesis (Younis et al., 2013). Therefore, plants reduce the size of stomata to minimize the entry of pollutants (Verma and Singh, 2006). Plants, which have good resistance to air pollution, can offset photosynthetic deficiency, caused by reduced gas exchange, by increasing pore density.

In the present study, decreasing changes in stomatal pore length, stomatal pore surface, and stomatal pore shape as well as increasing stomatal density from clean areas towards contaminated areas indicates the strong and effective correlation of these parameters with each other in order to adapt the species to air pollution. Many studies highlighted the importance of measurement of stomatal resistance under air pollution conditions (Alessio et al., 2002; Wuytack et al., 2010). Alessio et al. (2002) believed that stomatal resistance increases in areas with heavy traffic to reduce gas exchanges with the surrounding environment under tension conditions (Verma and Singh, 2006; Wuytack et al., 2010).

DOI: http://dx.doi.org/10.15666/aeer/1604_49554968

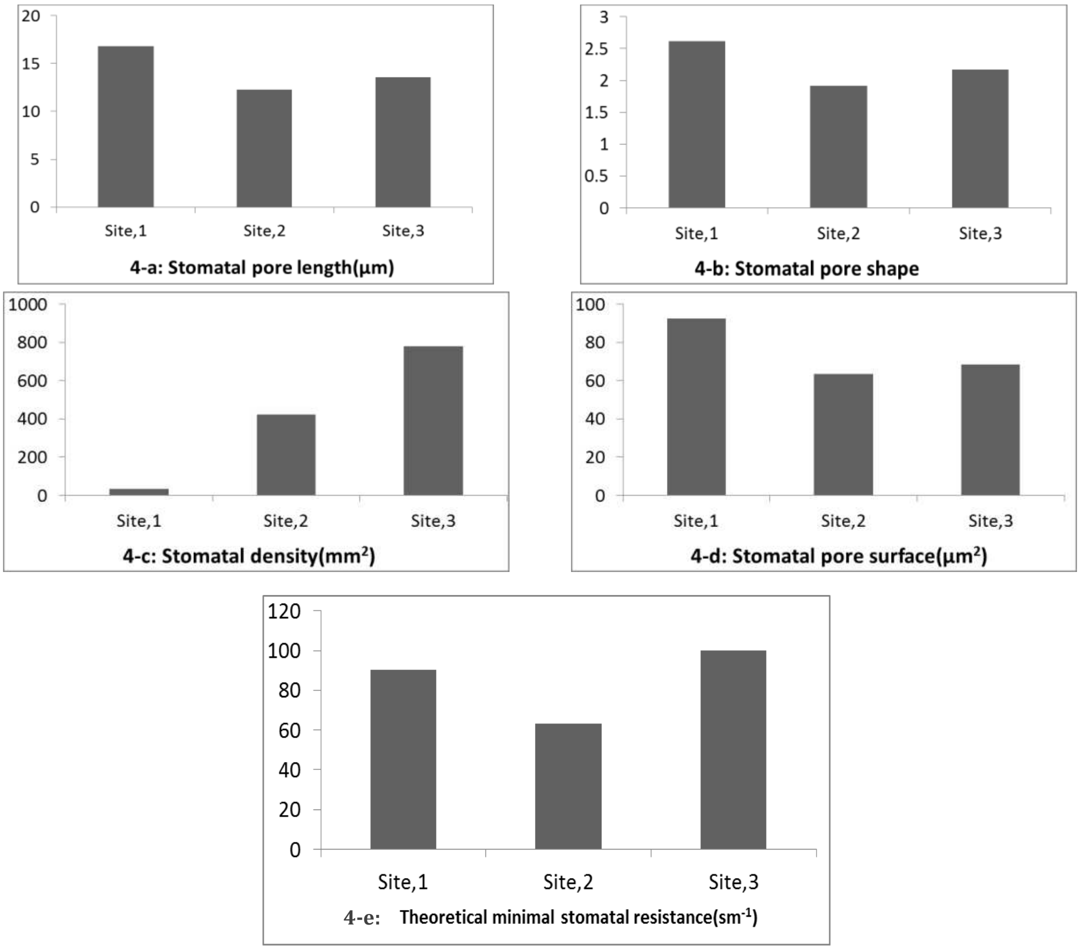

Figure 4. *Micro-morphological traits of the lower surface stomata of elm leaf in the sampling sites*

In the present study, in the site of Gisha Bridge, in addition to increasing the stomatal density and decreasing the SPS, the Rs showed an increase. This finding is in line with that reported by Wuytack et al. (2010). Mahecha et al. (2013) found that stomatal resistance increases with increasing age. As time passes, stomatal resistance decreases with the activation of tension adaptation mechanisms such as changes in stomatal and enzyme activities. In the present study, Rs reduced as a response to air pollution. The reduction of stomatal resistance in leaves may be due to premature aging caused by environmental tension. In Azadi Site, as the tension increased in leaves, the mechanisms of adaptation were quickly applied; these adaptations caused premature aging, replacement of new leaves, changes in stomatal density and stomatal pore surface, reduced Rs, and increased mesophyll conductance of the leaves. It is also necessary to note that in the present study, stomatal resistance was not measured in the environment; hence the trend of observed stomatal resistance could be due to the effect of local climates and local temperature changes in the sampling areas.

Macro-morphological traits of the leaves of elm tree

As *Table 1* shows, there was found no significant difference between the average values of leaf length (Sig. = 0.73), leaf width (Sig. = 0.64), leaf area (Sig. = 0.64), leaf

DOI: http://dx.doi.org/10.15666/aeer/1604_49554968

shape (length-to-width ratio of leaf blade) (Sig. = 0.40), and teeth density (Sig. = 0.11) in the sampling stations. No significant difference was observed between the average values of fluctuating asymmetry blade (Sig. = 0.00) and petiole length (Sig. = 0.02) in the three sampling sites (*Table 2*).

Despite the insignificant difference found in the average values of leaf area in three sites, this parameter in the sites of Azadi Square and Gisha Bridge increased respectively by 15% and 25% compared to the clean environment in Chitgar Site.

Although the difference between the average values of fluctuating asymmetry blade of the three sites was not confirmed statistically, however the parameter in the sites of Azadi and Gisha Bridge increased respectively by 21% and 136% compared to Chitgar. Petiole length in Azadi and Gisha Bridge increased respectively by 61% and 77% compared to Chitgar. Although there was found no significant difference in the average

DOI: http://dx.doi.org/10.15666/aeer/1604_49554968

values of number of teeth per unit area, it reduced respectively by 43% and 31% in Azadi and Gisha Bridge, compared to Chitgar. The comparison of the average values of specific leaf area in the sampling sites showed no significant difference among them (Sig. = 0.47) comparing the average values of relative water content in the sampling sites showed a significant difference (Sig = 0/00) and demonstrated a reduction of 44% in Azadi Site compared to Chitgar, and it was relatively equal in Gisha Bridge and Chitgar.

Under tension conditions, plants make adaptations that decline gas exchange to the environment in order to reduce contact surface with the polluted environment (Kardel et al., 2010; Arriaga et al., 2014; Verma and Singh, 2006; Balasooriya et al., 2009). The alteration of plant traits in air pollution conditions has been emphasized by many researchers, such as Vujic' et al. (2015) and Glukhov et al. (2015).

Various studies have referred to the reduction of leaf length, leaf width, and leaf area in different plant species under polluted conditions (Kardel et al., 2010; Arriaga et al., 2014; Verma and Singh, 2006; Lima et al., 2000; Balasooriya et al., 2009). Balasooriya et al. (2009) and Verma and Singh (2006) reported that the leaf area in contaminated sites is one of the most important biological markers for contamination monitoring In the present study, the lack of significant difference in mean leaf length, leaf width, leaf area, teeth density, and leaf shape indicated that the macro-morphological variations of elm leaf in polluted sites are not noticeable. The elongation of the leaf and the petiole represents its tolerance to stress (Xu et al., 2009). The findings of the present study confirm those reported by Xu et al. (2009). Incremental changes in petiole length, leaf area, and dry weight from the clean site to the polluted areas showed a positive relationship between these parameters and adaptation of the species to environmental pollutants (Meziane and Shipley, 2001; Chaturvedi et al., 2013).

By reducing the specific leaf area, the amount of chloroplast per unit area of plants increases. Thick leaf has a higher photosynthetic potential. In better words, the concentration of chlorophyll of chloroplast increases in thick leaves and the loss of light or the light passing through the leaves decreases. Consequently, leaf photosynthetic capacity increases.

Those species maintain their photosynthesis rate under tension conditions will be more responsive to stress Insignificant statistical differences in the present study indicated that elm, with the preservation of the photosynthesis potential in the leaves, can resist contamination and continue its growth.

In the polluted sites of Azadi and Gisha Bridge, a reduction in specific leaf area was observed. This is a strategy to improve stress tolerance (Xu et al., 2009). The leaf area variation reflects the growth rate of plants (Meziane and Shipley, 1999). Its reduction reduces water loss and transpiration. It also slows leaf growth and increases resistance of species to tension. Plants that are resistant to tension have higher relative water content (Mahecha et al., 2013). By increasing the thickness of leaves, the water loss is reduced and the relative water content is maintained at an optimum level.

In the present study, there was found no statistical difference between the relative humidity content of clean and contaminated sites, indicating the resistance of the species against the reduction of water content and the increase of transpiration in the presence of air pollutants. Changes in relative water content and specific leaf area revealed a negative relationship between these variables in order to adapt to environmental tension conditions.

Based on the macro-morphological traits of the elm leaf in this study, it can be argued that the elm leaf is resistant to air pollutants. The elm, in conditions of increased stress, can increase its resistance to airborne contaminants, with adaptations.

Conclusion

The results of the study suggested that the macro-morphological traits of elm leaf, such as its shape, area, width, and length in the presence of air pollutants do not change significantly and are relatively resistant. The stomatal traits at the lower leaf surface of elm showed that the tree controls the entry of air pollutants by reducing the size of stomata, and stomatal density increases to compensate for the shortage of gas exchanges.

The elm tree can maintain the water contents of leaf tissue to the optimum level, and by increasing the leaf thickness, preserve the photosynthetic potential of its leaves.

In the polluted sites, with increasing leaf thickness, stomatal density also increased. Regarding the inherent resistance of this species to the reduction of leaf water potential, the loss of photosynthetic rate caused by the presence of pollutants was compensated. Reducing the relative water content at Azadi Site can lead to the closure of stomata and eventually reduced photosynthesis. In this site, the species also reduced the size of stomatal pore to cope with this tension. According to the findings of this study, elm can resist against air pollution by applying cost-saving mechanisms. The findings showed that the traits of the elm leaf on polluted sites vary hardly. Hence, based on morphological studies of elm leaf, it can be admitted that the elm species is resistant to air pollution stress in industrialized cities and industrial areas, as well as the sites with high traffic volume. Anatomical studies of leaf can supplement this idea.

In many studies, stomatal density and stomatal pore surface are introduced as a good indicator for well differentiation of the sites with different air quality. Similarly, in elm species these two parameters were obviously better descriptors of leaf changes in different environmental conditions. The findings of the present study indicated that in urban and industrial areas that need green spaces resistant to air pollution, the planting of elm tree can play an effective role in achieving this goal.

Abstract. Floods, which are frequently occurring natural disasters, may interrupt the social and economic activities, and cause serious environmental and health problems in the region under effect. Floods may cause environmental problems such as soil loss, pollution of fresh water resources and epidemic diseases transported by floodwater. In order to prevent these adverse effects, flood risk maps, flood prevention and sustainable flood management plans must be established at the settlements which are vulnerable to floods. In this study the flood frequency analysis of Porsuk River basin located between the Porsuk Dam (which is the only source of domestic water of the city) and Eskisehir city center was conducted. The return period and probability distribution of flood magnitude were identified by flood frequency analysis. The effects of floods on the region located between the Porsuk Dam and Eskisehir city center were examined, the probable maximum flood for 25, 50, 100, and 500 years of flood return periods were determined by Log Pearson III method using the maximum flow data of years 1963-2009. MIKE 11 was presented in this study as one-dimensional flood model, which was conducted to determine the flood risk with efficient, easy and quick decision making approaches in Turkey.
Keywords: *flood risk, flood frequency analysis, flood modelling, one-dimensional modelling, MIKE 11, flood mapping*

Introduction

Floods are listed between natural disasters with huge detriment forces because of their adverse effects on environment, health and economy in vulnerable areas (Düzgün, n.d.; Uşkay and Aksu, 2002). In environmental aspect, floods affect biodiversity of flora and fauna (Tingsanchali and Karim, 2005), cause soil depletion (Uşkay and Aksu, 2002), pollute surface water sources (Haltaş, 2013), create epidemic disasters by infectious microorganisms and death (Çetin, 2013). Also, floods have social impact, such as, physiologic health problems caused by natural disaster, and the damaging of historical buildings and economic effects (Morss et al., 2005).

Recently, focus has shifted towards developing most appropriate strategies, including the promotion of vulnerability assessment and development of skills, methods and technologies to cope with flood, the assessment of costs and benefits and flood management methods (Calder and Aylward, 2006; Zhang et al., 2008; Marchi et al., 2010; Merz et al., 2010). Floods Action Program and Directive on The Assessment and Management of Flood Risk (2007/60/EC) was published by European Parliament in October 2007 to create general frame politics of water bodies', develop flood management plans for every basin areas, and aim reducing the devastating effect of floods (Griffiths, 2002). The major goals of the directive are both decreasing food risks

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_49694983

and determining possible effects caused by climate changes (Brown and Damery, 2002). In line with the Flood Action Programme, Ministry of Forestry and Water Affairs in Turkey organized National Basin Management Framework (NBMF) with aim to protect water basin, sustainable and profitable usage of water resources, and providing guidance to investment programs engendered as a result of long-term discussions with different institutes with different views (Çetin, 2013; Hopur, 2013; Ün, 2013). Under the scope of NBMF, the Ministry planned to create twenty five basin management committees including local authorities, universities, civil organizations, and other foundations and these committees provide the implementation of the principles of NBMF in order to prevent the adverse effects caused by the floods on the environment, generate flood risk maps, and establish flood prevention and sustainable flood management plans (Düzgün, n.d.; Akpınar, 2013; Aras, 2013).

The evaluation of increased flood risk has been investigated among engineers and economists. The areas under the flood risk are determined with the return period, the water depth and the flowrate of flood (Düzgün, n.d.; Uşkay and Aksu, 2002: Tiryaki, 2013). Different hydraulic models such as one-dimensional hydraulic models (1-D), two-dimensional hydraulic models (2-D), and integrated hydraulic models (1D-2D) can used to investigate flood risk. HEC-RAS (Özdemir, 2013), HEC-GEORAS (Özdemir, 2013) and MIKE 11 (Thompsona, 2004; Patro et al., 2009) 1-D hydraulic models are performed to determination the water depth of flood with the flowrate and the return period along the rivers and canals. 2-D hydraulic models can be listed MIKE 21, FLO2D, and CCHE2D providing flood depth with cross-section area along the rivers and canals. The integrated models like MIKE FLOOD (Liu et al., 2007; Patro et al., 2009) combine both 1-D hydraulic models (MIKE 11) and 1-D hydraulic models (MİKE 21) to determine flooded area settled around the rivers and canals.

MIKE 11 is a 1-D modelling system for rivers, channels, reservoirs and structures. The model is a world standard in 1-D river modelling for simulating flow and water level, water quality and sediment transport in rivers, floodplains, irrigation canals and other inland water bodies. The model application range is large enough to include simple design investigation and huge forecasting projects requiring complex hydraulic structure operation policies as well (Thompsona, 2004; Patro et al., 2009). This model is a versatile modelling platform enabling hydrodynamic modelling of rivers, irrigation systems, flood control, advection dispersion modelling, water quality modelling and sediment transport modelling (Tingsanchali and Karim, 2005; Marchi et al., 2010; Wen, 2013; Wolfs, 2013).

The structure of the model includes data and modules of the basin such as, rainfall-runoff data, river hydrodynamics, advection-dispersion data, water quality, topographical data and time series data of the river. The topographical data are the channel cross-section, the floodplain topography, the roughness and the structure geometry, Time series data are the boundary conditions of the river, the water levels, the discharges and the Q-h boundary data of the river. Modelling of unsteady flow via MIKE 11 is based on three fundamental elements, which are a differential relationship expressing the physical laws, a finite difference scheme producing a system of algebraic equation, and a mathematical algorithm to solve these equations. MIKE 11 general assumptions are listed below:

- Incompressible and homogeneous fluid,
- The flow is one-dimensional (uniform velocity and water level in cross-section),

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_49694983

- The bottom slope is small,
- Small longitudinal variation in geometry, and
- Hydrostatic pressure distribution.

This paper presents an approach that can be used to identify flood risk and creating flood risk map in Porsuk River basin. According to flood risk assessment framework introduced to our country by EU Flood Risk Directive, this study can demonstrate an integrated approach used to determine flood impact assessment, flood modelling, economic tool, and risk assessment. The method, MIKE 11 was presented in this study, can be considered as an important, easy and quick decision support tool that can develop existing decision making approaches like HEC-RAS, which are generally used for flood risk in Turkey. Also, this study will be useful in design of dams, culverts and flood control structures in the mentioned area in relation to urban drainage, river basin and canals.

Materials and methods

In this study the flood frequency analysis, the return period and probability distribution of flood magnitude were identified by flood frequency analysis for Porsuk River basin. The one-dimension flood modelling was performed on the region located between the Porsuk Dam and Eskisehir city center. The probable maximum flood of flood return periods were determined using the maximum flow data.

Working area

The project area selected in this study is located in Porsuk River basin. The Porsuk River is the sub basin of Sakarya River basin, and covers an area of 11325 km² in the northwest Anatolia Basin. The basin is located between 29°38'-31°59' east longitude and 38°44'-39°99' north latitude and has 202 km in length to the East-West direction and 135 km in length to the North-South direction. The Basin contains Eskisehir and Kutahya centers, and the 7 district of these two cities and some parts of it can be bordered by Ankara, Usak and Afyon borders. More than 60% of the basin is mountainous. The project area has been identified between area of Eskisehir and Porsuk Dam and it covers an area of 4253 km². The project area is shown in *Figure 1* and its properties between the town and dam are listed in *Table 1*.

Table 1. *The project area properties in the Porsuk River basin*

Property	Value
X (top left)	107951.11978

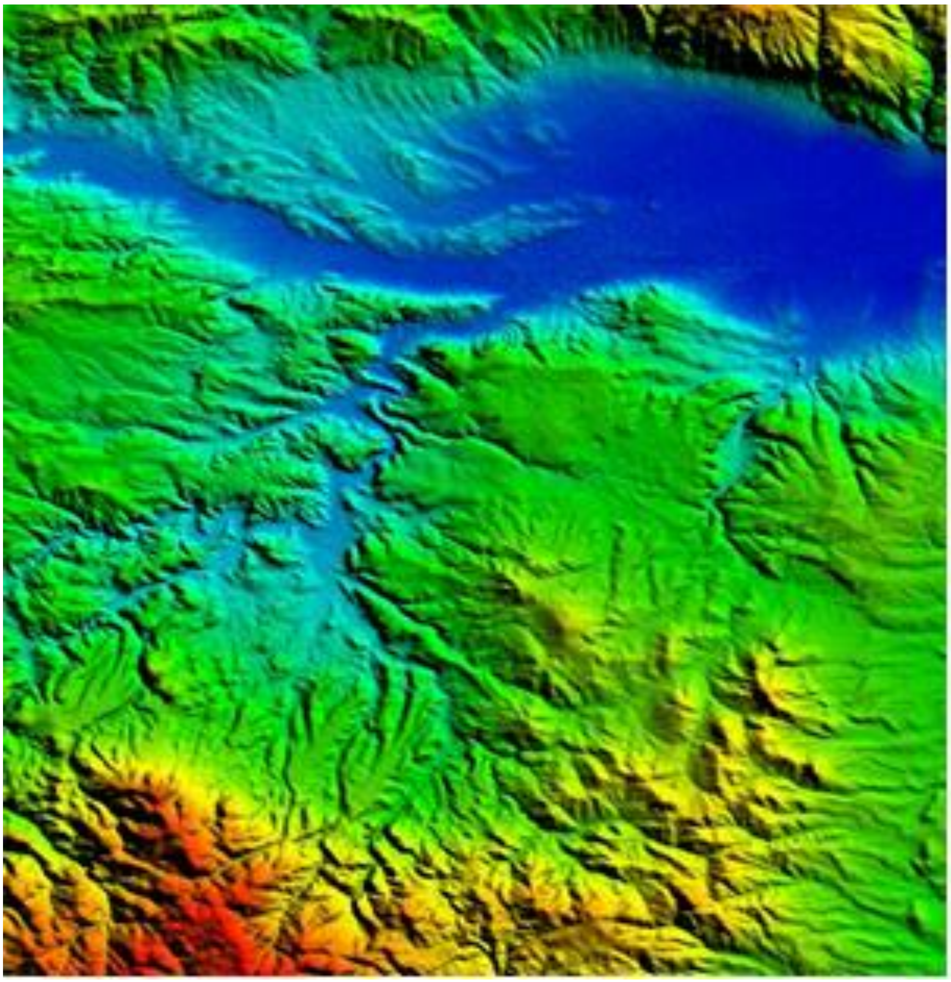

Figure 1. *The project area in the Porsuk River basin*

Determination of flood return period in Porsuk River basin

The return period and probability distribution of flood magnitude were identified by flood frequency analysis. The effects of floods on the region located between the Porsuk Dam and Eskisehir city center were examined, the probable maximum flood for 25, 50, 100, and 500 years of flood return periods were determined by Log Pearson III method using the maximum flow data of years 1963-2009 (47 years period) provided by The State Hydraulic Works in Turkey.

MIKE 11-one dimension flood modelling

MIKE 11 (MIKE, DHA 2012 SOFTWARE) 1-dimensional simulation software is composed of four subfiles associated with the data files. These files are the network data for the river line, the river cross-section file, and the boundary data file of the study area boundary conditions, and the files of river hydrodynamic parameters. The file of river hydrodynamic parameters has been identified as high-order full dynamic. After entering the files associated with the sub-model to simulation model, 1D simulation models was performed with prepared data by the return period of flood. MIKE 11 model setup is shown in *Figure 2*.

DOI: http://dx.doi.org/10.15666/aeer/1604_49694983

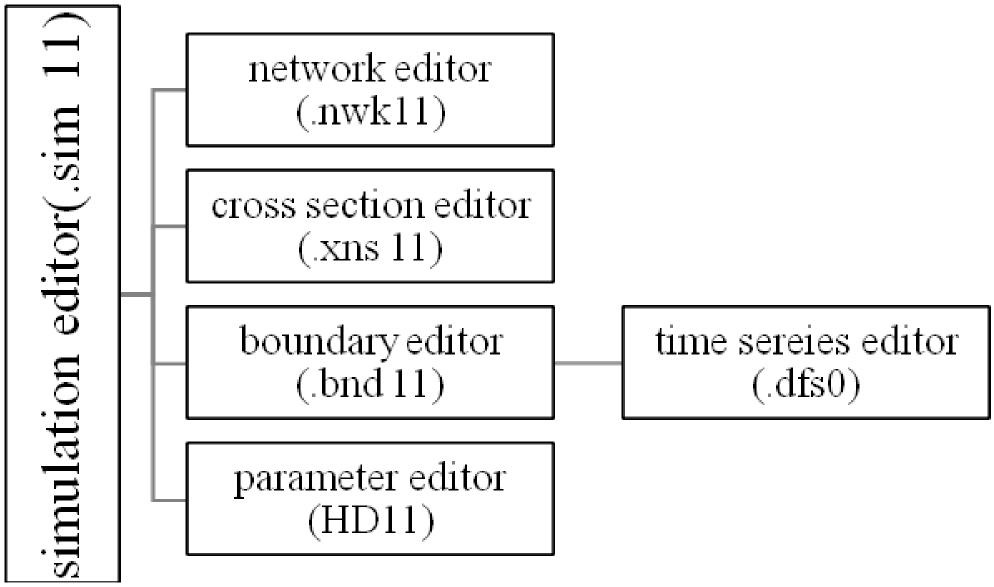

Figure 2. *MIKE 11 model setup*

To perform, MIKE 11 with data of Log Pearson III methods, a background map of the study area, the shape files map contains the river line, the field measurement data including the river cross-section, the data with the topographic heights of the study area, the boundary conditions for the workspace to create a terrain mesh and the flood periods files of the water level and the height of the flood flow were prepared. A background map (bacground.gif) for the work area to create the model grid, the shape file map (network.shp) containing the Porsuk River line, the site measurement data (surveyed_cross-section.txt) containing river sections, the topographic heights of the study area (dem.xyz), the boundary conditions for the study area and the water level heights of the floods and the floods were prepared as sub-file entrance data to run simulation model for MIKE 11.
Firstly, a background map of the working area was digitized by the manual marking method in the file containing the river line data in network editor (. nwk 11), the representation on the associated background file was shown in *Figure 3* after digitizing. The section data obtained by field measurements previously was transferred to the file containing the data for the river section line (. xns 11), the graphs of the processed and unprocessed section data are shown in *Figure 4*. Manning's n value for the river line was chosen as 0.025.

The existing water level was used as the downstream limit condition in the file containing the boundary conditions of the river lines (. bnd 11), triangular hydrographs of 65, 124, 166, 220, 261, 309, 408, 450 m^3/s and the peak condition with one-hour interval calculated by respectively 2, 5, 10, 25, 50, 100, 200, 500 and 1000 years flood frequency period, was used as the upstream limit condition. The sample hydrograph constructed for a 2-year periodic renewal was shown in *Figure 5*. In the file containing the hydrodynamic parameters, the wave approximation is defined as "high order full dynamics". After the sub files created by using the prepared model bases were associated with the simulation file, 1-dimensional models were created by entering the simulation period of the flood flowrates.

Results

Results of flood return period analysis

The return period and probability distribution of flood magnitude were identified by flood frequency analysis in the region located between the Porsuk Dam and Eskisehir city. The probable maximum flood return periods were determined by Log Pearson III method using the maximum flow data of years 1963-2009 (47 years period) provided by State Hydraulic Works in Turkey. The results of the flood return period analysis are given in *Table 2*.

Table 2. *Results of flood return period analysis*

i	Return period (years)	Possibility *P* (%)	Frequency coefficient (*K*)	$Y = \log(Q)$	Flood flow rate Q (m^3/s)
1	2	50	0.296	2.232	480
2	5	20	0.786	2.921	834
3	10	10	0.916	2.985	966
4	25	4	0.991	3.022	1051
5	50	2	1.018	3.035	1083
6	100	1	1.031	3.041	1100
7	200	0.5	1.038	3.045	1108
8	500	0.2	1.044	3.047	1115
9	1000	0.1	1.045	3.048	1117

As a result of flood return period analysis, the lowest flood flowrate is 480 m^3/s and the return period is 2 years with 50% possibility. The biggest flood flowrate is 1117 m^3/s and the return period is 1000 years with 0.1% possibility. 52-h flow rate based on the flood return period and their flowrates was used for MIKE 11 simulation. The 52-h calculated flowrates used in simulations were given in *Table 3*.

Results of MIKE 11-one dimension flood modelling

Determining the areas risked by flood hazard in the area, the modelling methods were chosen by using the flood return period and the flood water level. With the aim of using 1D hydraulic modelling, MIKE 11 software powered by DHI was used in this study. In this model, the flood water level is obtained with the flood flow rates depending the flood return periods. The return period for simulation was specified with 52 h, depending on the calculated flood flowrate data.

The flood level of area between Porsuk River and Eskisehir city was simulated with MIKE 11 according to 25, 50, 100, and 500 years-return period and possible flood flowrates. The simulation results obtained for specified periods are given in the *Figure 6* by the result of MIKE View Program. The relation between return period-flood flow and the relation between the return period- flood water level are illustrated in the *Figure 7*.

When the flood return period is 25 years with 4% possibility, the flood flow rates are 1051 m^3/s and the flood water will be observed in the river is 4.1 m. In case of the return period is 50 years with 2% probability, flood flow rates equal to 1083 m^3/s and the flood water levels are 4.3 m. In case of the return period is 100 years with 1% probability, flood flow rates equal to 1100 m^3/s and the flood water levels are 5.2 m. If the flood return period is 500 years with 0.1% possibility flood flow rate danger from 1115 m^3/s and the flood level will be observed in the river is 5.15 m. As a result of one-dimensional flood model of project area, it was stated that there is no linearity both between the return period and flood flow (R^2:0.5826) and also between return period and flood water level (R^2:0.4256).

Discussion

Within the scope of the study, the necessary return period and flood size probability distribution were determined using flood frequency analysis for project area located in Porsuk Dam - Eskisehir City. Result of the flood frequency analysis, maximum possible flood flow rates were determined and these flow rates were used for one-dimensional model to determine flood water level. Validation and calibration studies were not performed in project area due to lack of real data of flood flow rate and flood water level. However, previous researchers performed validation and calibration studies of MIKE 11. Panda et al. (2010) calibrated MIKE 11 model for the monsoon periods of the years 2006 and 2001 and they stated that simulated flood levels by MIKE 11 one dimensional model fit real data in validation studies (R^2: 0.921) and calibration studies (R^2:0.912). Also they determined that observed peak water levels in MIKE 11 fit better than other artificial neural network models because of their hidden neurons in the hidden layer (Panda et al., 2010). Haldar and Khosa (2015) stated that MIKE 11 hydrodynamic model was useful to diminish the flood risk level for river zone and they validated the model for the year 2000 with short available data.

Our results can be evaluated within the scope of the objectives of the National Flood Management Strategy for other settlement which have flood risk. There are similar researches in literature especially in Europe. Booij (2003) argued that decision support systems could be used to select the plan to be used for flood control and ecosystem rehabilitation. In his study, he created the model environment for the Red River basin aiming decision support system usage. Meteorological, hydrological, hydraulic, social and economic data of Red River were used to the PCRaster system. Also Birkland et al. (2003) emphasized that the environmental damage caused by floods in river ecology has increased due to the inadequate flood hazard control policies, and the environmental, social and environmental impacts of flood risk areas have been increasing in order to improve ecosystem functions, protect sensitive environmental resources, they argued that local governments should take an active role in creating an optimized flood management policy from economic approaches.

Akadiri et al. (2008) aimed to improve the resilience of the buildings located on the coast of England against flood in his study. He listed the factors affecting flood risk as soil type, basic geological structure and humidity conditions of existing soil, density of precipitation, average annual precipitation, rainfall transport capacity of the channel and precipitation regime. He stressed that the most serious effects created by climate change are accelerated sea level rise and greater coastal overflow due to rising winds. DEFRA cited increased flood numbers with climate change by referring to 2004 data. Again based on this data; the preliminary views on the total number of domestic, industrial and commercial buildings under flood risk, the human population to be affected by flood risk, the total value of vulnerable agriculture areas against floods, annual average flood protection and costs to avoid losses. The homeowners ranked flood-resistant buildings with proposals increase the defense strength of their buildings against floods. The one dimensional model created in the study can be used as a base and 2D and integrated models can be created for Porsuk Dam - Eskisehir City. Flood frequency analysis performed in this study; Porsuk Dam - Eskişehir City can be used for engineering purposes in the design of bridges, dams, culverts and flood control structures. It also provides the necessary data to determine the economic value of flood control projects, clarify the flood deposits and determine the area on the flood bed.

In this study, the area between Porsuk Dam, which is source drinking water source of project area, and Eskisehir was simulated to investigate flood risk and flood frequency analysis and flood water level was determined by MIKE 11 model. Flood frequency analysis performed in this study for area between Porsuk Dam- Eskisehir. The results of one-dimension flood model can be used for engineering purposes to design urban basins, dams, culverts and flood control of these structures. In addition to determining the economic value of flood control projects, the results of MIKE 11 model provide efficient, easy and quick response in the case of emergency action against flood risk to reduce flood detrimental effects.

Formation of flood risk maps and flood protection schemes of our country, which is taking important steps in the process of accession to the European Union, is ultimately required in accordance with the Council of Europe and the European Parliament Directive 2007/60/EC of October 23, 2007 on Flood Risk Assessment and Management. For all these reasons; In areas under flood risk; appropriate flood prevention structures should be determined by investigating the environmental, social and economic effects that floods can create, creating flood risk maps, flood intervention and prevention plans of risky areas in water and river basins.

Abstract. The forcing type ventilation at the current fully mechanized heading face is inadequate to meet the requirement of underground coal mine, which could lead to serious disaster of dust and gas explosion and environmental pollution in the roadway. In this paper, the airflow field, dust field and gas field at different distances from the duct outlet to the heading face were numerically simulated, the formation mechanism of each field and the reasons of unreasonable distribution were analyzed, an airflow adaptation adjustment method was proposed for realizing the optimal distribution of airflow, dust and gas by comprehensively changing the position, caliber and direction angle of the duct outlet. The method was applied to Ningtiaota coal mine in Northern Shaanxi of China. The adjustment schemes obtained with airflow adaptability adjustment method provided better results when prepared to before optimization. The dust concentration at the driver position decreased by 35% and the gas concentration reduced by 54%, which provides a theoretical basis for the scientific management of ventilation in the fully mechanized heading face.
Keywords: *duct outlet, airflow field, dust field, gas field, optimal adjustment of airflow*

Introduction

The fully mechanized heading face is vulnerable to the severe disaster of dust and gas explosion. Currently, the expansion of cross-section size and overlong distance excavation contribute to the dust and gas accumulation and severely pollute the underground working environment (Zhou et al., 2017; Wang and Ren, 2013). The caliber and the distance between the outlet and heading face of traditional forcing type ventilation cannot be changed. Under the premise of the specific total capacity of ventilation air, with the continuous extension section of drivage roadway, the airflow cannot efficiently dilute gas and dust within effective range due to the wind energy losses caused by the increasing air resistance along the roadway (Whang, 1999). If the air volume increases in the process of ventilation, the energy wasting, secondary dust (Geng et al., 2018) and discomfort feelings of workers will occur. Besides, the direction angle of the outlet cannot be changed, causing the limitation of airflow path. Thus, even increasing in air volume, the gas and dust still cannot be efficiently diluted because they are accumulated in the blind ventilation zone at the heading face. Therefore, the current forcing type ventilation cannot meet the requirements for underground coal mine. In order to satisfy the actual needs under various conditions, the dynamic adaptability adjustment of airflow in the fully mechanized heading face is essential. Domestic and foreign scholars have carried out a lot of researches on distribution laws and optimization analysis in the single field, including airflow field, dust field and gas field (Li, 2016; Wang et al., 2015; Zhou et al., 2014; Luo et al., 2015; Zhang et al., 2016). However, the study on the comprehensive consideration of airflow, dust and gas field

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_49855003

under the different parameters of duct outlet, including caliber, direction angle and back-forth distance, has not been proposed yet. In light of the current situation of underground coal heading face and based on analysis of the migration mechanism and distribution law of airflow, dust and gas field, the optimum migration of airflow, dust and gas field is realized by changing the parameters of outlet, which provides a theoretical basis for the safety, energy-saving and green ventilation environment in fully mechanized heading face.

Materials and methods

Material

We propose a method of the optimal adjustment for distribution of dust and gas in fully mechanized heading face. This method is applied in the Ningtiaota coal mine, which is located in Ningtiaota industrial park in Northern Shaanxi province of China in *Figure 1*. It is one of the four mining fields in the state's planning for the southern district of Shenfu mining, and the total output is 12.00 mt/a. The forcing type ventilation is uesd in Ningtiaota mine. The air duct outlet cannot be adjusted, the path of airflow is limited, the problems of gas accumulation, dust accumulation and ventilation of dead corner in heading face should be solved.

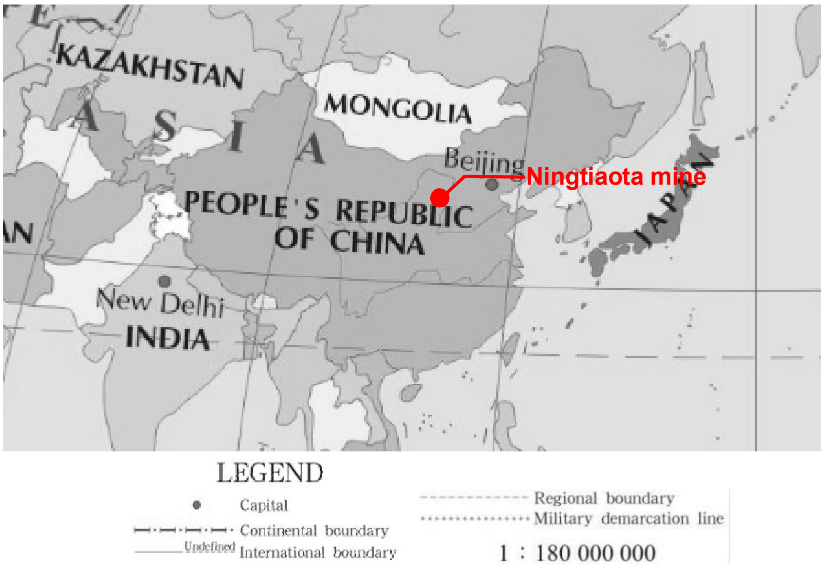

Figure 1. *Location of study area in China*

Theoretical analysis

(1) Airflow

Assuming no heat source in the roadway and neglecting the thermal radiation from the wall, the air flowing meets the continuity equation and the momentum conservation equation. For the flowing mode is a restricted-wall-attached jet, the airflow is turbulent, incompressible fluid, whose diffusion is a random orbit model, thus the SIMPLEC (Tang et al., 2015) algorithm and Realizable k-ε turbulence model are used to control and calculate the flow field.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_49855003

k equation (*Eq. 1*):

$$\frac{\partial}{\partial t}(\rho\varepsilon)+\frac{\partial}{\partial x_i}(\rho\varepsilon u_i)=\frac{\partial}{\partial x_i}\left((u+\frac{u_i}{\sigma_k})\frac{\partial k}{\partial x_j}\right)+G_k+G_b-\rho\varepsilon-Y_M+S_k \qquad \text{(Eq.1)}$$

ε equation (*Eq. 2*):

$$\frac{\partial}{\partial t}(\rho\varepsilon)+\frac{\partial}{\partial x_i}(\rho\varepsilon u_i)=\frac{\partial}{\partial x_j}\left[\left(\mu+\frac{\mu_t}{\sigma_\varepsilon}\right)\frac{\partial\varepsilon}{\partial x_j}\right]+\rho C_1 S_\varepsilon-\rho C_2\frac{\varepsilon^2}{k+\sqrt{v\varepsilon}}+C_{1\varepsilon}\frac{\varepsilon}{k}C_{3\varepsilon}G_b+S_\varepsilon \qquad \text{(Eq.2)}$$

where ρ (kg/m^3) is the density of airflow, x_i, x_j coordinate element, k (J) is the turbulence kinetic energy, σ_k, σ_ε are the prandtl number, it indicates the relationship between temperature boundary layer and flow boundary layer, ε is the dissipation rating of k, S_ε (kg/m^3 s) is the coupling for additional equations, G_k (J) is turbulent kinetic energy formed by average air speed, the G_b (J) is the turbulent kinetic energy formed by buoyancy, Y_M is the affect from the expansion of turbulent motion on ε, μ is the viscosity coefficient of molecular, μ_t is the viscosity coefficient of turbulent, $C_2 = 1.9$, $C_{1\varepsilon} = 1.44$, S_k, S_ε (kg/m^3 s) are the source item defined by customer.

(2) Gas field

The assumptions of gas field are as follows: the same wall roughness along the roadway and the gas migration in roadway meets the species mass conservation equation, which is shown as (*Eq. 3*):

$$\frac{\partial(\rho c_s)}{\partial t}+\frac{\partial(\rho c_s u)}{\partial x}+\frac{\partial(\rho c_s v)}{\partial y}+\frac{\partial(\rho c_s w)}{\partial z}=\frac{\partial}{\partial x}\left(D_s\frac{\partial(\rho c_s)}{\partial x}\right)+\frac{\partial}{\partial y}\left(D_s\frac{\partial(\rho c_s)}{\partial y}\right)+\frac{\partial}{\partial z}\left(D_s\frac{\partial(\rho c_s)}{\partial z}\right)+S_s \qquad \text{(Eq.3)}$$

where ρc_s (kg/m^3) are the species mass conservation equation, D_s is diffusion coefficient of components, u, v w (m/s) is the component of velocity vector in the three directions of x, y, z, S_s (kg/m^3 s) is the quality source item of gas component.

(3) Dust field

The dust in the heading face is a sparse phase, dust particles are a discrete phase, and air flows continuously. And the discrete phase model (DPM) of Euler-Lagrange method is used to simulate the motion of dust. The force between dust particles is neglected because the quality of particles is light, dust particle should be loaded with gravity, buoyancy pressure gradient force, etc. (Liu, 2010). Two-phase gas-solid flow mathematical model is used to analyze the migration law of dust. The mechanical model is as follows (*Eqs. 4* and *5*):

$$\frac{du_p}{dt}=F_D(u-u_p)+\frac{g_x(\rho_p-\rho)}{\rho_p} \qquad \text{(Eq.4)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_49855003

$$F_D = 0.75 \frac{C_D \rho \left| \mu_p - \mu \right|}{\rho_p d_p} \tag{Eq.5}$$

where $F_D(u\text{-}u_p)$ (N/kg) is the mass per unit mass drag force, C_D is the drag coefficient, u (m/s) is the air velocity of fluid phase, u_p (m/s) is the particle velocity, μ (m^2/s) is the fluid viscosity, ρ (kg/m^3) is the fluid density, ρ_p (kg/m^3) is the particle density, d_p (m) is the particle diameter.

Finite element analysis method and verification

The air duct is installed at the upper of the side of roadway wall. For ensuring the precision of model calculation, the roadheader is simplified into two parts, one is a machine part, and another is a cutting part. The end of the outlet is set as an inlet, the tail section of the roadway is set as an outlet, the outlet pressure is 0, and there is no slip on the wall surface. In the gas field, the exposed coal wall at heading face is set as the gas emission source. In dust field, the dust source is set at the heading face. Tetrahedron method is used to mesh the geometric model, and the surface mesh unit is set as a triangle. The adjustment schematic diagram of duct outlet on the fully mechanized heading face is shown in *Figure 2*, and the formulas are as follows.

Hydraulic caliber (*Eq. 6*):

$$d_H = \frac{4A}{S} \tag{Eq.6}$$

where d_H (m) is the hydraulic caliber, A (m^2) is the fluid cross-sectional area, S (m) is the wetted perimeter.

Reynolds number (*Eq. 7*):

$$\mathrm{Re}_H = \frac{\rho v d_H}{\mu} \tag{Eq.7}$$

where ρ (kg/m^3) is the air density, v (m/s) is the speed of airflow, μ (Pa·S) is the coefficient of viscosity.

Formula turbulence intensity can be derived from *Equations 8* and *9*:

$$I = 0.16(\mathrm{Re}_H)^{-\frac{1}{8}} \tag{Eq.8}$$

where I is turbulence intensity, R_{eH} is Reynolds number.

Gas emission source term:

$$s_i = \frac{CQ\rho\varphi}{60V} \tag{Eq.9}$$

where s_i ($kg{\cdot}m^{-1}{\cdot}s^{-1}$) is the gas emission source term, C (g/m^3) is the concentration of emission gas, Q (m^3/min) is the air volume in roadway, ρ (kg/m^3) is the gas density, V (m^3) is the volume of emission gas, φ is the proportion of each gas component.

Figure 2. *Schematic diagram of air outlet adjustment in the fully mechanized mining face*

Taking Ningtiaota coal mine as the research object, the numerical simulation scheme is established, and the feasibility of the numerical simulation scheme is verified. The cross-section of roadway is rectangular (6.25 m × 3.75 m), the airspeed at the duct outlet is 8.089 m/s, and the parameters of other boundary conditions of airflow field and gas field are set as shown in *Tables 1*, *2* and *3*. The geometric model and finite element model of the fully mechanized heading face are shown in *Figure 3*.

The air velocity at the height of pedestrian breathing in the air return side at the distance of 6 m from outlet to heading face and the dust concentration at the distance of 8 m from the duct outlet to heading face are selected as measured objects, the measured points 1 as shown in *Figure 4*. The results of comparing the measured data and simulation data are shown in *Figure 5* that indicates the distribution of airflow and dust is consistent with the actual situation, which proves the numerical simulation scheme of dust field is feasible.

According to the contour of the gas concentration of different cross-section at the distance of 6 m from the duct outlet to heading face (see *Figure 6*), Z = 1.0 represents

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_49855003

X-Y plans, which is 1.0 m away from heading face, and the direction of Z axis is the reverse direction of roadheader working. It is known that the gas concentration at the side of duct outlet is apparently lower than that at the air return side. According to the average values of simulation, the gas concentration at the cross section of Z = 0.2 m and Z = 1 m are 0.186% and 0.147%, which is consistent with the measured values of 0.187% and 0.146%, respectively, verifying the numerical simulation scheme of gas field is feasible.

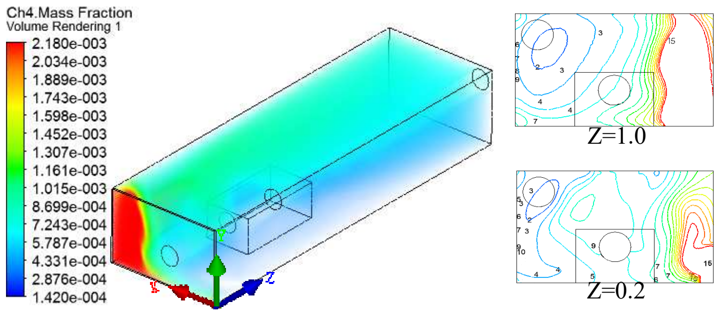

Figure 6. *Contour map of gas concentration at roadway cross section*

Migration mechanism and existing problems in airflow dust and gas field

Migration mechanism and existing problems in airflow field

According to the definition of hydrodynamic, it is known that the airflow at the duct outlet is restricted attachment jet-flow under the forcing type ventilation (Wang et al., 2004), and the jet-flow zone is in front of duct outlet (see *Figure 7*).

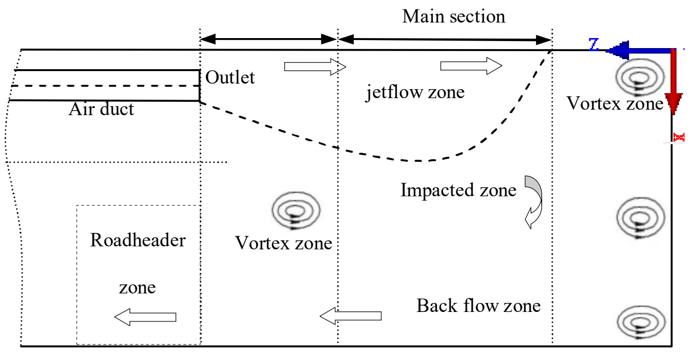

Figure 7. *Schematic diagram of air flow structure in the fully mechanized heading face*

In the process, the airflow will continuously absorb air surrounding, resulting in energy loss. Then with the jet expanding continually, the airspeed at the axis of outlet is equal to the initial velocity at the outlet and keeps constant, which is the start section of jet-flow. Then the speed begins to decrease to 0, which stage is the main section, the effective range of the jet-flow includes the start section and the main section. With the increasing distance from the outlet to the heading face, the effective range is reduced by the resistant force along the roadway. The air-flowing is attached to the wall and limited by roadway boundary, leading to the backflow formed at the bottom of roadway. The dust and gas will be brought out utilizing the backflow. However, the airspeed at return

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_49855003

side is low, which has a slight influence on the air disturbance at the upper and lower corners of the air-return side where the original air keeps relatively stable state. When the boundary layer of original air is loaded by tangential friction force or disturbed by air, the vortex is formed. Similarly, the jet-flow boundary layer disturbs air at the rear of roadheader where the vortex is formed, and the airflow of normal migration is affected and the vortex formed in front of the heading machine for the large volume of roadheader.

According to the literature (Zan et al., 2010), the motion parameters of restricted attachment jet-flow are related to restriction degree *n*, the calculation formula of jet restriction degree is as follows (*Eq. 10*):

$$n = \frac{A_0}{A} \tag{Eq.10}$$

where A_0 (m^2) is the section area of the outlet, A (m^2) is the section area of roadway.

From the formula above, the smaller restriction degree n is, the stronger the characteristics of the free-wall-attached jet will be, whereas the restricted-wall-attached jet characteristics become weaker.

The distribution regularity of airflow field, gas field and dust field are simulated at distances of 5, 6, 7, 8, 9 and 10 m, respectively, from the duct outlet to the heading face, then the existing problems of original field are obtained.

Turbulence is the main factor for gas dust diffusion, and vortex should be emphasized (Gong et al., 2017a). To analyze clearly the airflow distribution law at workers' activity district and ensure the position of turbulence, the airflow distribution under different distances from the outlet to heading face is shown in *Figure 8*, the specific results of air distribution shown in *Table 4*.

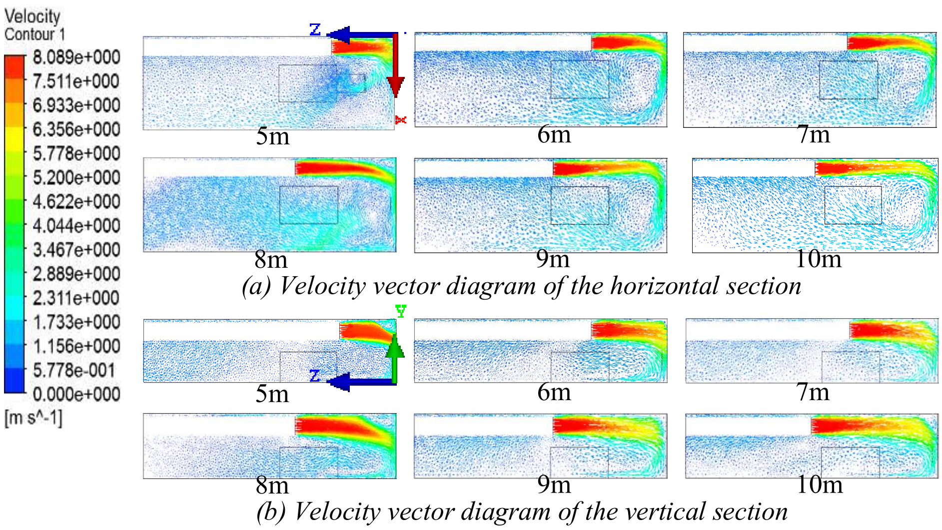

Figure 8. *Airflow distribution under different distance from outlet to heading face*

The simulation results show that when the duct outlet is close to the heading face (5 m), the driver will feel extremely uncomfortable because of overhigh velocity of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_49855003

airflow. The vortex formed above the roadheader, when the airflow impacts the heading face and destroys air return zone, which causes dust accumulation and environment pollution. Expanding outlet can decrease airspeed and shorten the effective range of jet-flow to make sure the back-flow district formed at the heading face, which is conducive to bringing gas and dust out effectively. Whereas, when the duct outlet is far away from the heading face (9-10 m), the irregularly circulated motion of gas and dust occurs for the vortex formed in the front of roadheader. At the same time, the jet zone becomes longer, but the effective range will be reduced by resistance along the roadway, leading to the low air velocity when it arrives in the heading face, and resulting in the dust and gas at the producing source are difficultly diluted. Consequently, the caliber and the distance from outlet to heading face should be in a reasonable range.

Table 4. *Airflow field distribution*

Distance from heading face (m)	Air velocity at diver place (m/s)	Air velocity at walking place (m/s)	Turbulence formed position
5	0.3~1.4	0.2~4.7	The end of the jet-flow
6	0.28~3.0	0.27~2.9	In front of roadheader
7	0.3~2.8	0.25~3.0	The right side of roadheader
8	0.25~0.8	0.22~0.75	Above the jet flow zone and the right side of roadheader
9	0.1~0.8	0.23~0.8	The right side and in front of roadheader
10	0.1~0.9	0.2~1.7	In front of roadheader

Migration mechanism and existing problems in gas field

The wall is a porous medium in roadway, and gas flows out from heading face, gas molecules are irregularly moved from high to low concentration. The gas is mainly produced from heading face, its density is lighter than that of air and easily accumulated on the roof. The gas at the upper corner will be disturbed by airflow, then vortex formed. However, the wind intensity at the lower corner is weak, so that its disturbance to the gas is light, resulting in the gas concentration at lower corner is higher than that at upper corner. The gas in the air-return area is brought out, because vortex formed near the roadheader.

The method of gas diluting is to blow fresh air to the heading face. We proposes the gas in the ventilation dead corner of roadway should be diluted by changing the caliber, direction angle and distances from the heading face, then the air volume be controlled at heading face.

The explosion would most likely occur due to the high gas concentration. The gas concentration distribution at different distances from the duct outlet to the heading face are numerically simulated, and the reasons of gas accumulation are investigated. Aimed at revealing the gas field distribution, we obtained the gas concentration distribution at the closest distance (5 m), middle distance (7 m) and the farthest distance (10 m) as shown in *Figure 9*.

The simulation results show that: with the increase of distance from the heading face, the gas concentration increases, but the average gas concentration gets lower. It is mainly accumulated in the upper and lower corner of the air return side, and the gas is difficult to be brought out because the airflow is weak in the lower position. The gas

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_49855003

concentration tends to be stable as the distance further away from the heading face. When the duct outlet is 5 m away from the heading face, the airflow impacts the heading face, and the ventilation return path cannot be formed, resulting in the gas diffussion thus it is difficult for gas to be efficiently moved out. When duct outlet is 6 m from the heading face, compared with the gas concentration at the backflow side, it is lower in the jet flow zone. When the distance from duct outlet to heading face is 7-8 m, the jet flow disturbs the air, and gas is well diluted. When the duct outlet is 9-10 m from the heading face, the jet flow will be affected by resistance in the roadway, causing the effective range becomes shorter and severe gas accumulation takes place at the heading face. Based on the analysis above, we should focus on optimizing the gas field at specific distances of 5-10 m between duct outlet and heading face.

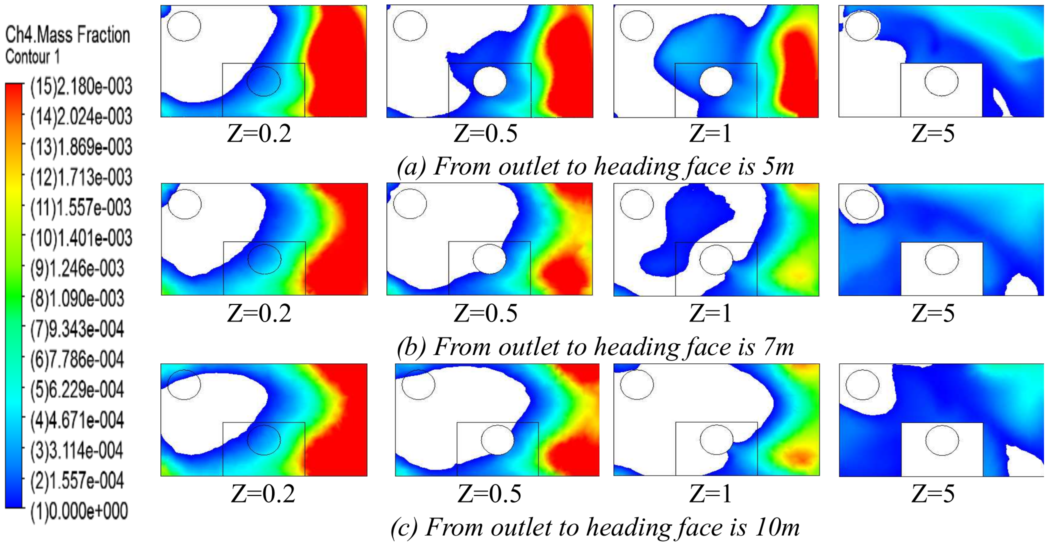

Figure 9. *Contour of gas concentration in different cross-section of roadway*

Migration mechanism and existing problems in dust field

The jet flow zone is generated by the directly impact of airflow from the outlet, which can effectively disperse dust. The dust concentration is lower than that in the vortex zone. At the same time, the jet absorbs the dust in the surrounding air, the absorbed dust will be taken to the heading face, resulting in high dust concentration. The vortex formed at the front of roadheader, causing the dust diffusion in the roadway and difficultly settle down. Under the forced type ventilation, the air velocity is low at the back of roadheader. The respirable dust tends to move toward the backflow side, where the small particle dust accumulates mainly at the upper corner (Alam, 2006; Candra et al., 2014), thus the dust concentration in the backflow zone is higher than that in the jet zone (Gong et al., 2017b).

To better describe the distribution of dust concentration in each zone, calculation models in each zone were established (Liu et al., 2002), and the equations are as follows (*Eq. 11, 12* and *13*):

$$\overline{C}_a = C_0 + \frac{GQ'}{Q_0(Q_0 + Q')} \qquad \text{(Eq.11)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_49855003

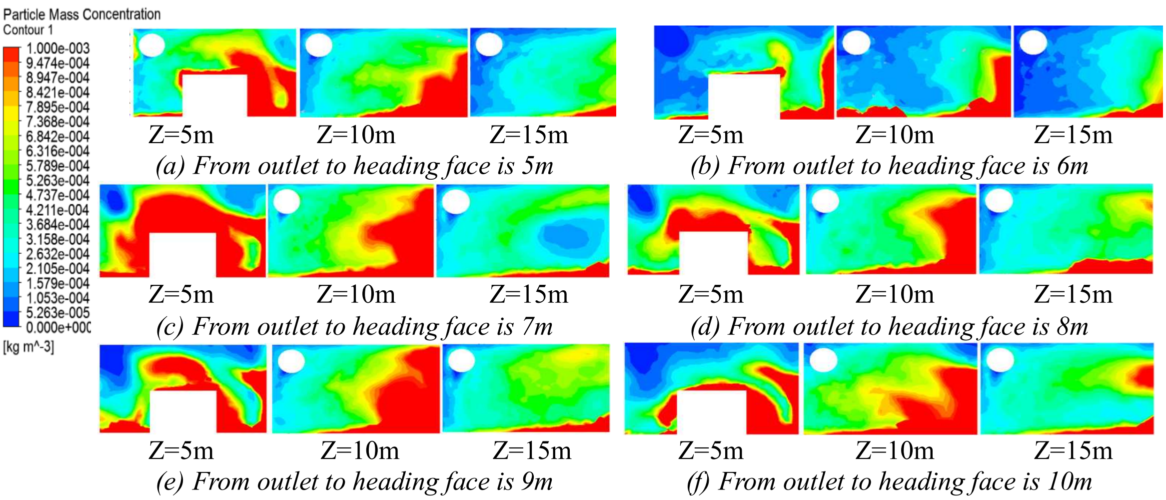
$$\overline{C}_b = C_0 + \frac{G}{Q_0} \qquad \text{(Eq.12)}$$

$$\overline{C}_c = C_0 + \frac{G}{Q_0} \qquad \text{(Eq.13)}$$

Where ,$\overline{C}_a$ (mg/m^3) is dust concentration in jet-flow zone, ,$\overline{C}_b$ (mg/m^3) is dust concentration in vortex zone, ,$\overline{C}_c$ (mg/m^3) is dust concentration in backflow zone, C_0 (mg/m^3) is dust concentration in air-flow, Q_0 (mg/m^3) is forced air volume, Q_1 (mg/m^3) is air volume discharged from heading face, Q' (mg/m^3) is suction volume in jet-flow, G (mg/m^3) is dust intensity.

According to the formula analysis, it is concluded that the dust concentration in the jet area, vortex area and backflow area are positively correlated with the dust intensity, and negatively correlated with forced air volume. And under the premise of the reasonable distribution of the airflow field, the larger the air volume is, the better effect of the dust dilution will be.

Considering that dust concentration is the main cause of pneumoconiosis and environmental pollution, the numerical simulations of dust field at different distances from the outlet to heading face are carried out, and the dust concentration at the different cross-sections of roadway are shown in *Figure 10.*



(a) From outlet to heading face is 5m
(b) From outlet to heading face is 6m
(c) From outlet to heading face is 7m
(d) From outlet to heading face is 8m
(e) From outlet to heading face is 9m
(f) From outlet to heading face is 10m

Figure 10. *Dust concentration distribution at different distances from air outlet to heading face*

As can be seen from *Figure 10*, the dust concentration on the return side wall and the air duct side gradually decreases as the distance from the outlet to the heading face increasing. According to the actual working environment, the range of 5-10 m is working positions for drivers, and within this range, affected by the roadheader, vortex is formed and dust accumulated, which obstruct the driver's vision. When the distance from the outlet to heading face is 5-6 m, the dust concentration is low in driver's position and heading face. When the distance is 7-10 m, the dust concentration increases in backflow, which is not conducive to safe production. The specific location of dust accumulation is shown in *Table 5*.

Results

Influence of air outlet caliber change on airflow dust and gas distribution

To improve the utilization rate of underground energy, under the premise of constant air volume, we propose that the outlet caliber should be adjustable for changing the airflow speed. According to the migration mechanism of the airflow dust and gas, reasonable airflow distributions will have a direct influence on the gas and dust distribution in heading face. The distribution of airflow field at calibers of 0.7, 0.8, 0.9, 1.0, 1.1 and 1.2 m are numerically simulated, respectively. The velocity distribution of airflow field at the horizontal plane is shown in *Figure 11*.

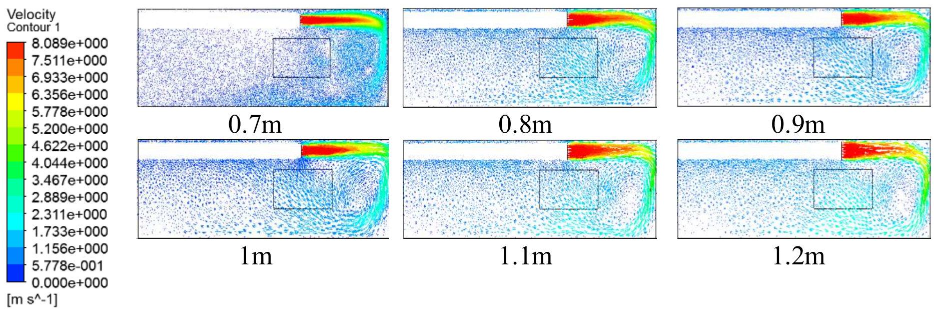

***Figure 11.** Airflow velocity distribution under different caliber*

As the caliber increases, the effective range of jet becomes short, and the airspeed at the heading face decreases. The vortex is formed at front of roadheader and is beneficial to diluting the dust and gas at the heading face; and the larger the caliber of the air outlet, the larger radius of curvature of backflow is. Under the premise of the certain total air volume, when the outlet is far away from the heading face, the axial velocity of jet can be increased by caliber necking; and when the outlet is close to the heading face, the air velocity is decreased by reducing the impact force on the heading face. In summary, the adjustment methods of outlet caliber are put forward to meet the Coal Mine Safety Regulations on the air velocity ranging of 0.25-4 m/s. When the distance from the outlet to the heading face is 5 m, the caliber should be extended to 1.1 and 1.2 m; when the distance is 6-8 m, the caliber’s unchanged (at 1 m), and it is necked to 0.8 and 0.9 m when the distance is 9-10 m. At distances of 5 m and 10 m, the distribution of the airflow dust and gas field under different caliber are shown in *Figures 12* and *13*.

The different value of Y in *Figures 12a* and *13a* mean different X-Z plans, for example, Y = 1.0 m indicates the X-Z plan, which is 1.0 m away from ground.

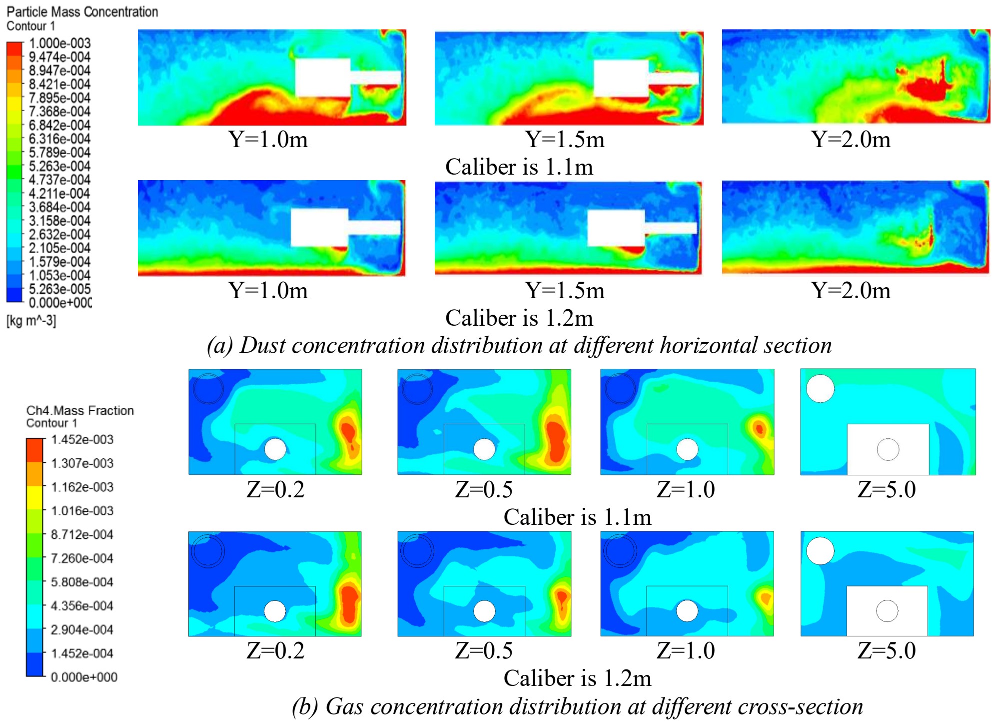

Figure 12. *Dust and gas concentration distribution under different caliber of outlet at the distance of 5 m from heading face*

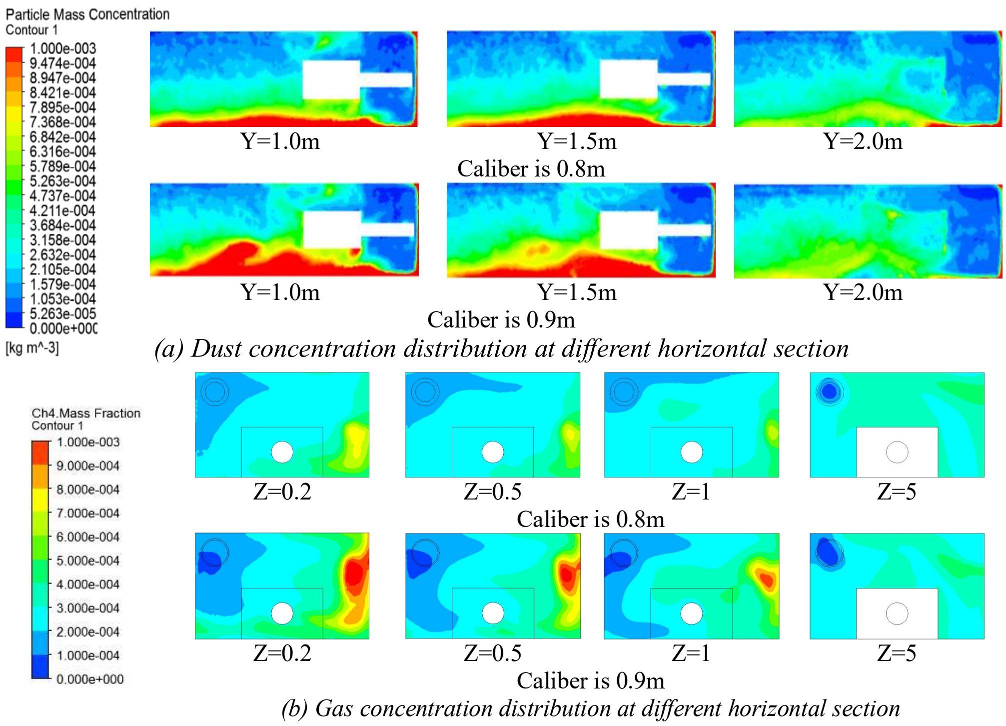

Figure 13. *Dust and gas concentration distribution under different caliber of outlet at the distance of 10 m from heading face*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_49855003

At the distance of 5 m, extending caliber can effectively decrease the dust and gas concentration (see *Figure 12*). When the caliber is 1.1 m, dust is accumulated above the heading face, which will seriously pollute the working environment of driver, and the gas concentration at the air return side is a tendency of decreasing-increasing-decreasing. When the caliber is 1.2 m, the dust concentration is low with uniform distributions, the orange area gradually gets shrunk, indicating that gas concentration decreases. At the distance of 10 m, the necked caliber can effectively improve the distribution of the dust and gas field (see *Figure 13*). When the caliber is 0.8 m, the orange area representing the dust and gas accumulation at air return side is smaller than that of 0.9 m of caliber. According to the above analysis, the reasonable range of caliber is: at the distance of 5 m, select 1.2 m of caliber; at distances of 6-8 m, select 1 m of caliber, when it is 9-10 m, select 0.8 m of caliber.

Influence of air outlet angle direction change on air-flow dust and gas distribution

Due to the limitation of the geometric size of the roadway section and the premise of normal operation of roadheader, according to the existing problems in the airflow field, dust field and gas field, the velocity in backflow should be improved to break the vortex around the roadheader and dilute the dust and gas at the heading face and dead corner area. The angle of outlet should be adjusted at the horizontal right deviation of 5°-25° and vertical upward deflection of 2°-8°. Selecting the angle of horizontal right deviation at 5°, 10°, 15°, 20° and 25° and vertical upward deflection of 2°, 4°, 6° and 8°; respectively, the numerical simulation experiments were carried out on the distribution of the air, dust and gas in fully mechanized heading face. *Figure 14* only shows the numerical simulation results of airflow velocity distribution, gas concentration distribution and dust concentration distribution under different outlet angles when the outlet is 5 m away from the heading face owing to the space constraints.

The numerical simulation results show that the problems of low velocity, dead corner of ventilation and vortex area in the local area of original field can be improved by changing the angle of outlet. Under the premise of constant caliber, the angle adjustment can improve the airflow distribution near the roadheader, but it still impacts the heading face, indicating that the velocity of outlet is too high. Therefore, the velocity of outlet should be decreased by changing the caliber. Considering the reasonable distribution of the airflow gas and dust, the reasonable range of outlet angle should be in the horizontal right-skew of 5°-15° and vertical up-skew of 2°-6°. To realize comprehensive optimization for the airflow field, dust field and gas field at the fully mechanize heading face, it is necessary to determine the specific angle parameter value of outlet.

Airflow adaptability adjustment for dust and gas

Design of comprehensive optimization scheme

In light of the existing problems of the airflow field, dust field and gas field, combined with the reasonable value range of outlet parameters, we put forward a comprehensive optimization adjustment scheme for the airflow field, dust field and gas field under different distances (5, 6, 7, 8, 9, and 10 m) from outlet to heading face (see *Table 6*).

Table 6. *Design of optimization adjustment scheme*

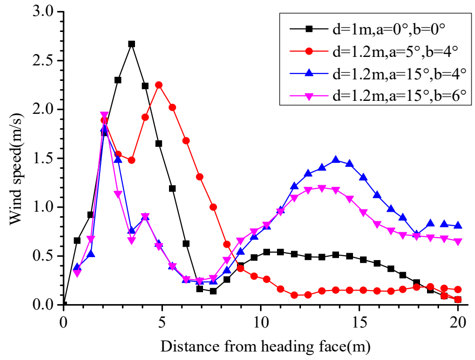
Scheme	5m	6m	7m	8m	9m	10m
Scheme 1	Caliber 1.2m, right 5, up 4	Caliber 1m, right 5°, up 2°	Caliber 1m, right 5°, up 2°	Caliber 1m, right 5°, up 2°	Caliber 0.8m, right 5°, up 4°	Caliber 0.8m, right 5°, up 4°
Scheme 2	Caliber 1.2m, right 15, up 4°	Caliber 1m, right 10°, up 2°	Caliber 1m, right 10°, up 2°	Caliber 1m, right 10°, up 2°	Caliber 0.8m, right 10°, up 6°	Caliber 0.8m, right 10°, up 4°
Scheme 3	Caliber 1.2m, right 15°, up 6°	Caliber 1m, right 15°, up 2°	Caliber 1m, right 15°, up 2°	Caliber 1m, right 15°, up 2°	Caliber 0.8m, right 15°, up 2°	Caliber 0.8m, right 15°, up 2°

Discussion

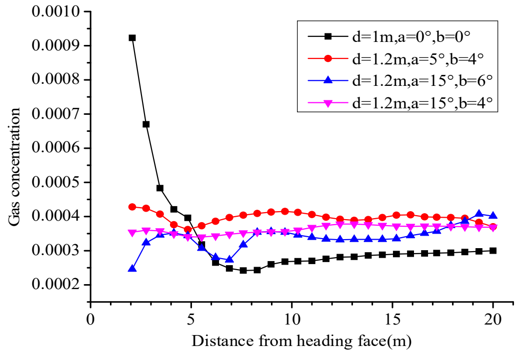
The comprehensive optimization results of the airflow, dust and gas under different adjustment schemes are compared and analyzed. The air velocity and the concentration distribution of dust and gas in backflow side at the distance of 5 m are shown in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_49855003

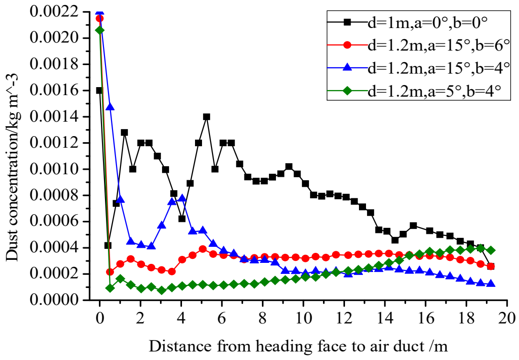
Figure 15. The optimization result of dust particle size distribution was shown in *Figure 16*.



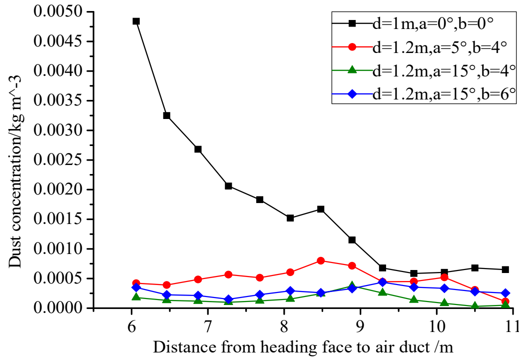
(a) Air velocity distribution at backflow side



(b) Gas concentration at backflow side



(c) Dust concentration at backflow side



(d) Dust concentration at driver position

Figure 15. *Air-flow, dust and gas distribution under different adjustment scheme (d-caliber, a-right-skewed angle value, b-up-skewed angle value)*

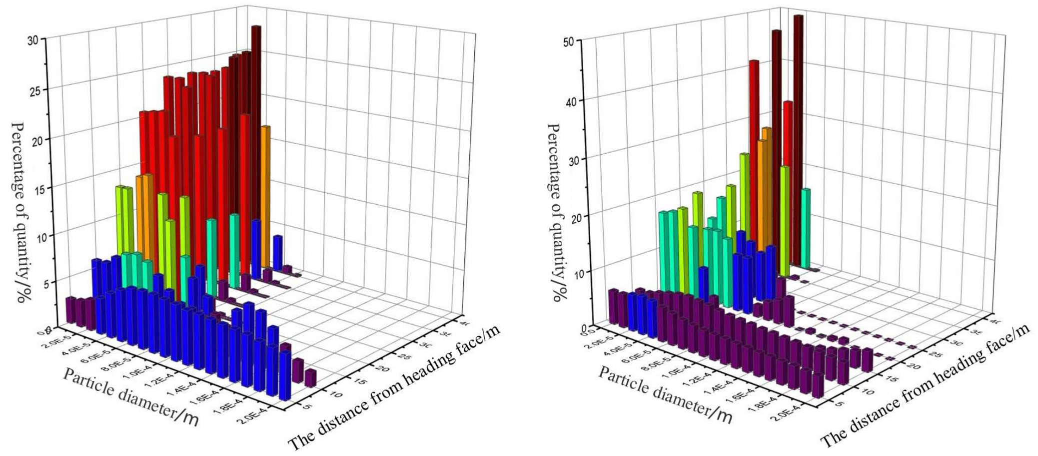
As shown in *Figure 15*, when the caliber of outlet is 1.2 m and the angle is at right-skewed 15° and up-skewed 6°, the impact force of air-flow on heading face is reduced, and the problem of ventilation at dead corner is solved thanks to the larger caliber of outlet. Compared with other scheme, the gas concentration can be decreased from 0.1% to 0.023% and the air velocity is at 0.3-2 m/s in the return side. The dust concentration at the air return side is substantially reduced (the lowest concentration is 0.01%), indicating that environment for drivers has signifcantly been improved.

The scheme of caliber 1.2 m at the right-skew of 15° and up-skew of 6° can effectively improve the airflow field. Compared with the original air duct, when the caliber is extended, the impact force of airflow on heading face is reduced, especially adjusting the angle of outlet at the right-skew of 15° and up-skew of 6° is conducive to breaking vortex and solving the ventilation problem in the dead area. And at velocities ranging of 0.3-2 m/s, the gas concentration is declined from 0.1% to 0.023% and the dust concentration is greatly reduced.

As shown in *Figure 16*, the dust particle size distribution is uniform at distances of 0-10 m from the heading face. At distances of 15-20 m, the large-sized particles begin to settle down, and the quantity of small-sized particles accounts for majority, especially presenting the larger percentage of respirable dust (particle size < 7μm). From

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_49855003

Figure 16, we can see that dust concentration is much lower, which reduces the harm for workers.



Before After

Figure 16. *Comparison of particle size distribution in roadway*

Using the same method above, the distribution of dust and gas at different distances (6, 7, 8, 9 and 10 m) between the outlet and heading face is comprehensively optimized, and the corresponding adaptability optimization adjustment method for air-flow is obtained, as shown in *Table 7*.

Table 7. *Optimization adjustment scheme*

Distance from heading face	Adjustment scheme	Velocity of air duct side	Dust concentration at driver position	Gas concentration at upper corner
5m	d=1.2m, a=15°, b=6°	Reduced by 60% at end of the jet-flow	Reduced by 35%	Reduced by 26%
6m	d=1m, a=15°, b=2°	Increased by 30% at front of roadheader	Reduced by 30%	Reduced by 28%
7m	d=1m, a=10°, b=2°	Increased by 27% at right of air duct	Reduced by 29%	Reduced by 30%
8m	d=1m, a=5°, b=2°	Increased by 31% in front of air duct	Reduced by 31%	Reduced by 32%
9m	d=0.8m, a=10°, b=6°	Increased by 56% at front of roadheader	Reduced by 29%	Reduced by 54%
10m	d=0.8m, a=5°, b=4°	Increased by 65% at front of roadheader	Reduced by 28%	Reduced by 48%

Conclusion

The caliber, angle and the distance from the outlet to heading face of the duct outlet have a certain influence on the air, dust and gas field distribution in the fully mechanized heading face. The caliber adjusting of outlet can change the effective range of airflow as well as wind the velocity of duct outlet; the angle adjusting can change the direction of wind flow, which effectively solves the problems of dust and gas accumulation and ventilation in dead corner area; different distances from outlet to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_49855003

heading face have different requirements for parameters adjustment of outlet. According to the dust and gas migration law under different distances from duct outlet to heading face, the outlet parameters are adjusted using the method of airflow adaptability. The results show that the airflow adaptability adjustment not only improves the ventilation efficiency but also reduces the dust and gas accumulation to improve the environmental conditions for miners.

Through the numerical simulation analysis of the existing problems in the air, dust and gas field, the airspeed, gas concentration and dust concentration at the side of air duct are higher than that at the backflow side. The gas is easily accumulated at the upper and lower corners of the backflow side of heading face and near the heading machine, which causes dust accumulation and more attention should be paid.

Taking Ningtiaota coal mine in Northern Shaanxi of China as an object for practical application, the airflow, dust and gas field in the fully mechanized heading face was optimized comprehensively. The optimized simulation results were compared with those of the original field. Then the various optimization adjustment schemes were obtained at the different distances from the duct outlet to heading face. The dust concentration at the at driver position was decreased by 35% and the gas concentration reduced by 54% after the optimization. When the duct outlet is at the distance of 5 m from the heading face, the caliber of outlet should be expanded to 1.2 m, which can rationally decrease airspeed at duct outlet. When the air outlet is at the distance of 9-10 m from the heading face, the outlet should be necked to 0.8 m to increase the effective range of airflow.

Abstract. Enhancement in yield and quality of sunflower by foliar spray of abscisic acid (ABA) under water deficit condition was studied during 2016 and 2017. Three irrigation treatments were applied. Four irrigations (at 4-6 leaf, at vegetative, at flowering and at grain formation stage), three irrigations (at 4-6 leaf, at pre flowering and at grain formation stage), three irrigations (at 4-6 leaf, at vegetative and at grain formation stage). Sunflower hybrid (S-278) was sprayed with different ABA concentrations (0, 10 µm and 20 µm) at 4-6 leaf, vegetative, flowering and grain formation stage. Foliar application of 10 µM ABA under water stress at vegetative stage significantly enhanced plant height, head diameter, achene yield and biological yield. It also enhanced sunflower water relations by increasing water potential. ABA application and water deficit showed opposite results for yield and oil quality. Water deficit at vegetative or at flowering stage maximized stearic and oleic acid contents and minimized palmitic and linoleic acid contents, whereas foliar spray of ABA under water stress at both stages reduced stearic and oleic acid but maximized palmitic and linoleic acid.
Keywords: *abscisic acid, relative water contents, turgor pressure, oleic acid, palmitic acid, linoleic acid, sunflower*

Introduction

Drought is the foremost yield-limiting feature for sunflower (*Helianthus annuus* L.) productivity in semi-arid areas (Rauf et al., 2015; Daryanto et al., 2016). In different parts of the world oil and achene yield losses due to drought stress were described (Woli et al., 2014; Yin et al., 2014). Water scarcity encourages significant alterations in physiological and biochemical processes implicated in biomass production, and alters dry matter partitioning (Fernández et al., 2012; Wu et al., 2017). Breeding for drought tolerance is thus indispensable to diminish yield losses in sunflower in drought-prone

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50055023

regions (Rauf et al., 2015). In order to recognize probable sources of drought tolerance, cultivated sunflower breeding lines from different sources were assessed on the basis of comparative performance under drought stress (Hussain et al., 2017). Nevertheless, the narrow genetic base of breeding lines was one of the major restrictions for the possibility of such studies.

Several studies showed, abiotic stresses activate several biochemical, physiological and molecular responses that effect several plant processes at cellular level (Wang et al., 2003; Hasanuzzaman et al., 2013; Tsironi and Taoukis, 2017). To fight several environmental pressures, dynamic methods and techniques should be developed (Yin et al., 2017). Among various control measures and monitoring tools (remote sensing) to assess the impacts of drought stress on crop plants (Villegas et al., 2017; Natsagdorj et al., 2017; Song et al., 2017), agronomic measures for water conservation and chemical plant growth regulators are of great interest (Ahmad et al., 2016). Phytohormone engineering could be considered as a preferable technique to increase the production. Phytohormones are the substantial regulators in plant growth and development and also intermediaries of environmental stress responses (Sreenivasulu et al., 2012). Among several phytohormones, abscisic acid is the vital regulator of abiotic stress resistance in plants and synchronizes an arrangement of roles (Finkelstein, 2013; Wani and Kumar, 2015), allowing plants to survive with diverse stresses. In the plant, the level of abscisic acid increases through abscisic acid biosynthesis when environmental conditions are harsh. The augmented abscisic acid binds to its receptor to start signal transduction causing cellular responses to different stresses (Ng et al., 2014); thus, ABA is also termed a stress hormone (Mehrotra et al., 2014). ABA was firstly suggested to be implicated in abscission and has later been revealed to play a role in plant growth and development, comprising cell division followed by elongation, embryo maturation, seed dormancy, germination, root growth, floral initiation, and responses to both biotic and abiotic stresses, such as osmotic stress, chilling, high salinity, drought, pathogen attack and UV radiation (Finkelstein, 2013; Yoshida et al., 2014; Sah et al., 2016). ABA is significantly increased under drought or salinity stress conditions, stimulating stomatal closure, change in gene expression, and adaptive physiological responses (Kim et al., 2010; Sah et al., 2016). Abscisic acid also plays a vital role in many processes at cell level including dormancy, seed development, vegetative growth, germination etc. (Finkelstein et al., 2013; Saradadevi et al., 2017) and variation in root morphology (Harris, 2015). Meanwhile the discovery of abscisic acid, numerous struggles have been dedicated to understanding how abscisic acid is produced under stress conditions. In stressful conditions like extreme temperature, drought, and high salinity, content in plants enhances significantly, stimulating stress-tolerance effects that support plants, acclimatize, and endure under these stressful conditions (Ng et al., 2014). Under non-stress situations, abscisic acid is also mandatory for plant overall growth and development.

Around the globe enormous research has been done on various crop plants to enhance water use efficiency (WUE) by sowing better varieties and improvement of drought tolerance by foliar application of abscisic acid (ABA). But little or no data is existing on the interaction of abscisic acid and use of diverse cultivars of *Helianthus annuus* to alleviate the impacts of water stress in different agro-ecological conditions of Pakistan. Therefore the current study has been planned to adjust ABA application stage for attaining greater yields of sunflower under water stress and to associate the performance of different *Helianthus annuus* hybrids under water stress environments.

Materials and methods

Study area, soil and weather condition

Field experiments were conducted to study the response of spring planted sunflower hybrids to different irrigation schedules and foliar spray of abscisic acid. Trials were conducted in 2016 and 2017 at the Agronomic Research Farm, University of Agriculture, Peshawar, Pakistan. The climate of Peshawar region is semi-arid (34.01°N, 71.35°E) at an altitude of 350 meters above sea level. Peshawar is situated about 1600 km north of the Indian Ocean. All the analytical work associated to research was conducted in the Stress Physiology Laboratory, Nuclear Institute for Food and Agriculture, NIFA, Peshawar. Soil analysis of the experimental soil was given in *Table 1*. The climate of the area is semiarid where the mean annual rainfall is very low (300 to 500 mm), 60–70% rainfall occurs in summer, whereas the remaining 30–40% rainfall occurs in winter (*Fig. 1*).

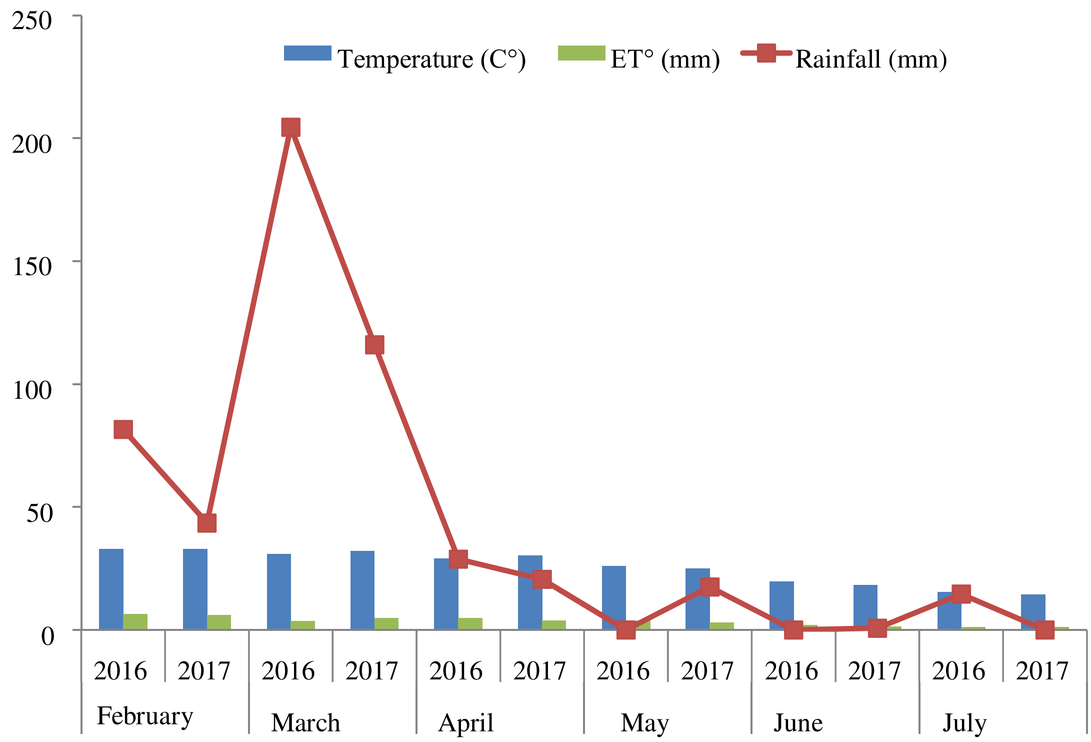

***Figure 1.** Monthly meteorological data for experimental years 2016 and 2017 of Agronomic Research Farm, University of Agriculture, Peshawar, Pakistan*

Experimental design and treatments

The layout of experiment was randomized complete block design (RCBD) with factorial arrangement with three replications. Net plot size was 3.0 m × 6.0 m. Three irrigation schedules (I) were imposed which were (I_1) four irrigations (at 4-6 leaf, at vegetative, at flowering and at grain formation stage), (I_2) three irrigations (at 4-6 leaf, at pre flowering and at grain formation stage), (I_3) three irrigations (at 4-6 leaf, at vegetative and at grain formation stage) and five ABA concentration (C_1: control, C_2: 10 µM ABA at vegetative stage; C_3: 10 µM ABA at flowering stage, C_4: 20 µM ABA at

DOI: http://dx.doi.org/10.15666/aeer/1604_50055023

vegetative stage and C_5: 20 µM ABA at flowering stage. The first irrigation was applied when the plant had 4-6 leaves (25 DAS), the 2nd irrigation was applied at vegetative stage (45 DAS) excluding the plots, which were exposed to water deficit at this stage, the 3rd irrigation was applied at flowering stage (67 DAS) excluding the plots, which were exposed to water deficit at this stage. The 4th irrigation was given to all plots at grain formation stage (90 DAS). ABA was weighed according to per treatment and was added in a graduated cylinder and volume was made 1 L in volumetric flask with distilled water. Afterward Knapsack sprayer was calibrated (250 L ha^{-1}) and used to spray solution. While distilled water was sprayed on the control plots.

***Table 1.** Physicochemical analysis of soil during 2016-17*

Characteristic	Unit	Value

Available K	ppm	135	131

Crop husbandry

The seedbed was prepared by pre-soaking up to 10 cm irrigation then cultivating the field for 2-3 times with tractor-mounted cultivator. *Helianthus annuus* hybrids were sown on 19th and 13th of February 2016 and 2017, on ridges using dibbler with seed rate of 8 kg ha^{-1}. Ridges were made 75 cm distant and plant to plant distance of 25 cm was kept. Seed of sunflower hybrid S-278 were obtained from Syngenta Company. were obtained from Fertilizers were applied at the rate of 100 kg P_2O_5 ha^{-1} in the form of triple super phosphate (TSP) and 150 kg N in the form of urea. Half nitrogen and full phosphorus were applied at sowing, whereas remaining nitrogen was applied with 1st irrigation. Irrigation was done as per treatment by flooding. To keep field free from weeds field hoeing was done. Plant protection measures were conducted to keep crop free of insect pests, diseases and parrots. For control of whitefly and head rot Polo and Radomil Gold were applied, respectively. The crop was harvested on May 30, 2016 and June 6, 2017.

Measurements

Agronomic traits

From each plot, ten plants were selected randomly. The plant height was determined with measuring tape and then averaged. In order to find head diameter, 10 heads were

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50055023

randomly selected from each plot and their diameter was measured with the help of a measuring tape and then averaged. For calculation of achene yield plants were harvested at maturity, sunflower' heads were detached after drying then threshed manually to find the achene yield plot^{-1}. The moisture contents were calculated from random achene samples. The achene yield was attuned to 10% moisture content and expressed in kg ha^{-1}. Weight of air-dried plants (excluding achenes) was noted on plot basis and then converted into kg ha^{-1}. To compute total biological yield, noted weight was added to the already calculated achene yield (kg ha^{-1}).

Plant water relations

Water potential, relative leaf water content, turgor pressure and osmotic potential were recorded 10 days after the ABA foliar application. To find the relative leaf water content (RLWC), third leaf from the top (fully expanded) of two different plants from different treatment was taken. Leaves were cut at base of lamina and wrapped in plastic bags then transported to laboratory immediately. Fresh weight (FW) was calculated after two hours. After that turgid weight (TW) was found by saturating leaves in distilled water for time period of 16-18 h at room temperature. After saturation, leaves were prudently and rapidly blotted dry to find turgid weight. Dry weight (DW) was calculated after drying of leaf samples in oven for time period 72 h at 70 °C. Relative leaf water content (RLWC) was calculated through the procedure of Schonfeld et al., 1988 and then averaged (*Eq. 1*).

$$RLWC\ (\%) = (FW - DW)/(TW - DW) \times 100 \qquad \text{(Eq.1)}$$

where, FW= fresh weight of leaf; DW= dry weight of leaf; and TW = turgid weight of leaf.

Leaf water potential was ranged from 8.00 to 10.00 A.M. It was computed through Scholander pressure chamber by following the method of Scholander et al. (1965). In order to compute, water potential, leaf was kept in a freezer at -20 °C for 7 days. After that frozen leaf was defrosted in order to extract cell sap through a disposable syringe. Then osmotic potential was computed from extracted sap via an osmometer (Wescor 5500). Turgor pressure was calculated from the difference of water potential (Ψw) and osmotic potential (Ψs) (*Eq. 2*).

$$(\Psi p) = (\Psi w) - (\Psi s) \qquad \text{(Eq.2)}$$

Quality parameters

Oil content

Oil content in seeds was calculated using Soxhlet Fat Extraction method (AOAC, 1990). For about 10 h, seeds were dried in an oven at 105 °C. Seeds were weighed before and after drying for determination of moisture content. For oil content determination, two grams of achenes per thimble were crushed in a coffee mill. Thimbles were weighed individually, crushed seeds were added and the final weight was estimated. Later, the thimbles were placed in extractors. Six dry and clean round bottom 250 ml flasks were weighed and their weight noted. Solvent (petroleum ether) was added to flasks, attached to the extractors and placed on heating mantles attached to with condensers. Flasks were heated and extraction was continued for at least 6 h,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50055023

stopped extraction, removed thimbles and then reheated the flasks, so that all of the solvent might be collected in the Soxhlet extractors. The apparatus permitted to cool and flasks dried at 105 °C for 1 h. After cooling, the flasks and oil were weighed together. Percent oil content was calculated via the following equation (*Eq. 3*).

$$Oil\ contents\ (\%) = \frac{(flask\ weight + oil\ weight) - flask\ weight}{(flask\ weight + seed\ weight) - flask\ weight} \times 100 \quad \text{(Eq.3)}$$

Fatty acid profile

Gas liquid chromatography was used to determine fatty acid composition in sunflower oil by following Martin (1979). Oil was extracted from seed of *Helianthus annuus* hybrids by using Rancy oil seed crusher. In a loop of oil, 0.5 ml petroleum and 1 ml methylating solution ether was added in test tube. Solution was swirled to disperse loop and petroleum ether was also added to rinse loop during sampling. After addition of 1 ml distilled water; it was kept for 10 min. One µl solution was taken from upper layer and injected into the gas chromatograph. The total peak area and area of each fatty acid peak was computed by an electronic integrator and expressed as percentage of the total area of the peak.

Statistical analysis

Collected data was analyzed by using Fisher's analysis of variance technique in MSTAT-C. The differences among treatments, means etc. was compared through least significant difference (LSD) test at 5% probability (Steel et al., 1997). Factorial experiment under Randomized Complete Block Design was used for analysis over years. Microsoft Excel Program was used for contrast study (Microsoft, version 2013).

Results

Response of agronomic traits of sunflower to irrigation schedules and ABA application

Effect of year on plant height was statistically found non-significant during 2016 and 2017 but taller plants were observed in 2017 over 2016 (*Table 2*). Irrigation levels and ABA application exhibited significant impact on plant height during 2016-17 while their interactions were found non-significant. Under no water stress, plant height was significantly enhanced. Water deficit significantly reduced plant height with a larger reduction in plant height when stress was enforced at vegetative over at flowering stage. Negative impact of water deficit at both stages might be mitigated by spraying of ABA. In different ABA concentrations and its application stages, 10 µM ABA spray under water deficit at vegetative or at flowering stage considerably maximized plant height (*Table 2*). Orthogonal contrasts showed that 4 irrigations produced taller plants over three irrigations; ABA applied at vegetative stage produced taller plants over when applied at flowering stage. The contrast between 10 µM and 20 µM ABA was non-significant (*Table 2*).

Effect of year on head diameter was statistically not-significant during 2016 and 2017 but larger head diameter was observed in 2017 over 2016. Head diameter was significantly influenced by irrigation schedules and foliar spray of ABA at diverse growth stages while interactive effect had non-significant impact during both years of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50055023

study (*Table 2*). Water deficit reduced head diameter over no stress. Water stress imposed at flowering stage caused significant reduction in head diameter and this reduction was more prominent in those treatments where stress was imposed at vegetative stage. Negative impact of water stress at both stages might be declined by foliar spray of ABA (*Table 2*). Orthogonal contrasts showed that 4 irrigations vs. 3 irrigations, ABA application at vegetative stage vs. ABA application at flowering and 3 irrigations (miss at vegetative) vs. 3 irrigations (miss at flowering) were significant but orthogonal contrast 10 µM ABA vs. 20 µM ABA was statistically non-significant during 2016-17.

3 irrigations (missed at vegetative stage) vs. 3 irrigations (missed at flowering stage)	*	*	*	*	*	*	*	*

*: Significant, ns: non-significant

Effect of year was statistically significant for achene yield during both years and significantly maximum achene yield was observed in 2017 over 2016 (*Table 2*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50055023

Analysis of the data exhibited that achene yield was significantly influenced by irrigation levels and spray of ABA at diverse growth stages while interactive impact had not-significant impact during both years (*Table 2*). Water stress reduced achene yield over no stress. When drought was enforced at flowering stage achene yield was significantly reduced and this reduction was more over stress imposed at vegetative stage. Damaging impacts of water stress at both stages might be decreased by foliar ABA spray (*Table 2*). Orthogonal contrasts for 4 irrigations vs. 3 irrigations, ABA application at vegetative stage vs. ABA application at flowering stage and 3 irrigations (miss at vegetative) vs. 3 irrigations (miss at flowering) were significant but orthogonal contrast 10 µM ABA vs. 20 µM ABA was statistically non-significant during 2016-17.

Year impact on biological yield was statistically significant during 2016-17 and significantly maximum biological yield was observed in 2017 over 2016. Irrigation levels and ABA spray significantly affected biological yield while their interaction was found insignificant. Biological yield was significantly increased in control treatments (no water stress) over stress imposed at vegetative or flowering stage (*Table 2*). Under various irrigation schedules influence of ABA application was deviating (*Table 2*). When the crop encountered no water stress, foliar spray of 10 or 20 µM ABA at vegetative or flowering stage considerably reduced biological yield with respect to that of the control during 2016-17. Orthogonal contrasts between 4 irrigations vs. 3 irrigations, ABA application at vegetative vs. ABA application at flowering 3 irrigations (miss at vegetative) vs. 3 irrigations (miss at flowering) were significant for biological yield whereas orthogonal contrast 10 µM ABA vs. 20 µM ABA was statistically non-significant during both years.

Response of plant water relations to irrigation schedules and ABA application

Effect of year on leaf water potential was non-significant during 2016 and 2017 and leaf water potential was maximum in 2017 over 2016. Levels of irrigation and foliar ABA spray effect was prominent on leaf water potential during both years. Water deficit significantly reduced leaf water potential over control. Leaf water potential was significantly reduced when water stress imposed at flowering over vegetative stage. Mean values clearly showed that foliar ABA application significantly influenced the leaf water potential (*Table 3*). When crop encountered water deficit at vegetative stage, the application of 10 µM ABA significantly improved leaf water potential with respect to control but it was statistically comparable with 20 µM ABA spray at vegetative stage (*Table 3*). Orthogonal contrasts for 4 irrigations vs. 3 irrigations, ABA application at vegetative vs. ABA application at flowering and 3 irrigations (miss at vegetative stage) vs. 3 irrigations (miss at flowering) were significant but the contrast 10 µM ABA vs. 20 µM ABA was statistically non-significant during 2016-17.

Year impact on leaf osmotic potential was statistically significant during 2016-17 and significantly maximum leaf osmotic potential was observed in 2016 over 2017. Irrigation schedules and ABA application significantly influenced leaf osmotic potential while their interactions during both years were found insignificant. Water stress at both vegetative and flowering stage significantly reduced leaf osmotic potential over control. Leaf osmotic potential was reduced when water stress executed at flowering over vegetative stage. Mean values showed that foliar application of ABA significantly influenced the leaf osmotic potential. Under diverse irrigation schedules, performance of foliar application of ABA was divergent. When crop encountered no water stress at vegetative or flowering stage, foliar ABA spray reduced leaf osmotic potential during

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50055023

2016-17. Orthogonal contrast between 4 irrigations vs. 3 irrigations and 3 irrigations (miss at vegetative stage) vs. 3 irrigations (miss at flowering stage) for leaf osmotic potential were significant during 2016 and 2017 but orthogonal contrast for ABA application at vegetative stage vs. ABA application at flowering stage was non-significant in 2016 and statistically significant in 2017. Likewise contrast 10 µM ABA vs. 20 µM ABA was statistically non-significant during 2016-17.

Effect of year on leaf turgor pressure was statistically significant during 2016 and 2017 and statistically higher leaf turgor pressure was observed in 2017 over 2016. Leaf turgor pressure was significantly influenced by irrigation schedules and foliar application of ABA at various growth stages while their interaction had non-significant impact during 2016-17. Water deficit reduced leaf turgor pressure over no stress (*Table 3*). Turgor pressure was significantly reduced when water stress was enforced at flowering stage and this reduction was higher over when stress was enforced at vegetative stage (*Table 2*).

Application of 10 µM ABA under water deficit at vegetative stage improved leaf turgor pressure with respect to control. Water deficit at vegetative stage and application of 20 µM ABA enhanced turgor pressure than control and this enhancement was statistically comparable with 10 µM ABA application at vegetative stage. When crop confronted water deficit at vegetative stage but ABA (10 or 20 µM) was sprayed at flowering stage, it considerably reduced turgor pressure over control. Comparable observation was noted during 2016-17. Orthogonal contrasts between 4 irrigations vs. 3 irrigations, ABA application at vegetative stage vs. ABA application at flowering stage and 3 irrigations (miss at vegetative) vs. 3 irrigations (miss at flowering stage) were significant for turgor pressure but contrast 10 µM ABA vs. 20 µM ABA was statistically non-significant during both 2016-17 (*Table 3*).

*: Significant, ns: non-significant

Effect of year on relative leaf water content was statistically not-significant during 2016-17 but relative leaf water content was slightly higher during 2017 over 2016. Analysis of the data revealed that relative leaf water content was significantly influenced by irrigation schedules and foliar application of ABA at diverse growth stages while their interaction had non-significant impact during both years (*Table 3*). Water deficit reduced relative leaf water content over no stress. When water deficit was imposed at flowering stage relative leaf water content was significantly reduced and this reduction was higher over where stress was enforced at vegetative stage. Negative impact of water deficit at both stages might be decreased by foliar spray of ABA (*Table 3*). Influence of foliarly applied ABA was different under diverse irrigation levels (*Table 3*). No water deficit at both growth stages, foliar application of ABA reduced relative leaf water content during 2016-17. Orthogonal contrasts between 4 irrigations vs. 3 irrigations, ABA application at vegetative stage vs. ABA application at flowering stage and 3 irrigations (miss at vegetative stage) vs. 3 irrigations (miss at flowering stage) were significant for relative leaf water content but orthogonal contrast for 10 µM ABA vs. 20 µM ABA was statistically no-significant during 2016-17.

Response of quality parameters of sunflower to irrigation schedules and ABA application

Effect of year on achene oil content was statistically non-significant but oil content was higher in 2017 with respect to 2016 (*Table 4*). Mean values exhibited that oil content was significant during irrigation treatments and foliar application of ABA at various growth stages while their interactions was found non-significant during both years (*Table 4*). Water stress reduced oil content compared to no stress. Oil content significantly reduced when water deficit was executed at flowering stage and this reduction was higher over when deficit was enforced at vegetative stage (*Table 4*). Under water deficit condition foliar spray of 10 µM ABA at vegetative stage improved oil content over control. Water deficit at vegetative stage and 20 µM ABA application also enhanced oil content than control but this enhancement was statistically comparable with 10 µM ABA application at vegetative stage. When crop confronted water deficit at vegetative stage but ABA (10 or 20 µM) was sprayed at flowering stage, it significantly reduced oil content than control. Comparable observation was observed during 2016-17.

DOI: http://dx.doi.org/10.15666/aeer/1604_50055023

Impact of year on stearic acid content was statistically significant during 2016-17 and maximum stearic acid content was observed during 2016 over 2017. Analysis of the data revealed that irrigation levels and ABA application exhibited significant impact on stearic acid content during 2016-17. Water deficit significantly improved stearic acid content and maximum increment in stearic acid content was noted when water deficit was executed at flowering stage over at vegetative stage (*Table 4*). Foliar spray of 20 µM ABA at flowering stage by enforcing stress at vegetative stage significantly enhanced stearic acid content over all treatments. Whereas spraying 10 or 20 µM ABA at vegetative stage under water stress at vegetative stage reduced stearic acid content than control. Similar trend was noticed during 2016-17. Orthogonal contrasts between 4 irrigations vs. 3 irrigations and 3 irrigations (miss at vegetative stage) vs. 3 irrigations (miss at flowering stage) were significant for stearic acid content but orthogonal contrasts 10 µM ABA vs. 20 µM ABA, and ABA application at vegetative stage vs. ABA application at flowering stage were statistically non-significant during 2016-17.

Orthogonal contrasts for 4 irrigations vs. 3 irrigations, ABA application at vegetative stage vs. ABA application at flowering stage and 3 irrigations (miss at vegetative stage) vs. 3 irrigations (miss at flowering stage) were significant for oil content but orthogonal contrast 10 µM ABA vs. 20 µM ABA was statistically non-significant during 2016-17.

Effect of year on oleic acid content was statistically significant during 2016 and 2017 and statistically higher oleic acid was observed in 2016 over 2017. Oleic acid content was statistically influenced by irrigation levels and ABA spray while their interaction was found insignificant. Water stress significantly improved oleic acid content and maximum increment in oleic acid content was noted when water deficit was executed at vegetative stage over at flowering stage (*Table 4*). Water stress at vegetative stage and spraying of 20 µM ABA at flowering stage had significantly improved oleic acid content over all treatments. Enforcing water deficit at vegetative stage and spraying 10 µM ABA at flowering stage also significantly improved oleic acid content with respect to control but this increment was lower with respect to spraying of 20 µM ABA at the similar stage. Whereas spraying 10 or 20 µM ABA at vegetative stage under water deficit at vegetative stage reduced oleic acid content than control. Same trend was observed during 2016-17. Orthogonal contrasts for 4 irrigations vs. 3 irrigations was significant but orthogonal contrasts 10 µM ABA vs. 20 µM ABA and ABA application at vegetative stage vs. ABA application at flowering stage and 3 irrigations (miss at vegetative stage) vs. 3 irrigations (miss at flowering stage) were statistically non-significant during both years.

Palmitic acid content was significantly affected during 2016 and 2017 and statistically higher palmitic acid content was observed in 2017 over 2016. Different irrigation levels and foliar spray of ABA at diverse growth stages significantly affected palmitic acid content while their interaction was found insignificant. Water stress reduced palmitic acid content over no stress. Palmitic acid content was considerably minimized when water stress was enforced at flowering stage and this reduction was maximum than where water deficit was enforced at vegetative stage (*Table 4*). Spray of 10 µM ABA under water stress at vegetative stage statistically increased palmitic acid content over all treatments. Water stress at vegetative stage and application of 20 µM ABA also enhanced palmitic acid content than control but this enhancement was lower than spraying of 10 µM ABA at vegetative stage. When crop confronted water stress at vegetative stage but ABA (10 or 20 µM) was sprayed at flowering stage, it significantly reduced palmitic acid content over control. Same results was noted during both years.

reduced linoleic acid content over no stress. Considerably lesser linoleic acid was noted when water stress was enforced at flowering stage than where water deficit was enforced at vegetative stage (*Table 4*). Spray of 10 µM ABA under water stress at vegetative stage statistically augmented linoleic acid content over control. Water stress at vegetative stage and application of 20 µM ABA also enhanced linoleic acid content than control but this enhancement was lower than spraying of 10 µM ABA at vegetative stage. When crop confronted water deficit at vegetative stage but ABA (10 or 20 µM) was sprayed at flowering stage, it considerably reduced linoleic acid content over control. Same observation was recorded during 2016-17. Orthogonal contrasts for 4 irrigations vs. 3 irrigations was significant for linoleic acid content but orthogonal contrasts 10 µM ABA vs. 20 µM ABA and ABA application at vegetative stage vs. ABA application at flowering stage and 3 irrigations (miss at vegetative) vs. 3 irrigations (miss at flowering stage) were statistically non-significant during both years.

Discussion

Agronomic and yield related traits

Water stress is one of the severe threats to crop production in semi-arid and arid areas of Pakistan. In present trial, foliar spraying of abscisic acid d to sunflower under water deficit either at vegetative or flowering stage has been noticed to considerably enhanced crop growth, yield, osmotic adjustment, development, water relations, achene quality and fatty acid profile over no spray of ABA under water stress.

Water deficit both at vegetative or flowering stage declined sunflower plant height and maximum decrease in plant height was recorded when water deficit happened at bud initiation (Unger, 1983). Exogenous ABA application under no water stress condition reduced plant height. Under no water stress condition, shoot growth reduced by ABA application in maize seedling (Zhang et al., 2012) which finally reduced plant height. ABA foliar application under water stress enhanced plant height since it perform as shoot growth regulator under water scarce environments (Zhang et al., 2012). In the current trial less concentration (10 µM ABA) supported vegetative growth under water stress whereas the greater concentration (20 µM ABA) could have facilitated in survival of plant by regulating processes like plant size growth and stomatal opening (Sah et al., 2016). Controversially foliar spray of ABA under water stress and no stress condition decreased height of shoot in *Populus davidiana* which was owed to lesser accumulation of dry matter and its maximum distribution to *Populus davidiana* roots (Chunyang et al., 2004).

Water stress significantly reduced head diameter of sunflower and maximum reduction in head diameter happened when crop encountered water deficit at flowering over vegetative stage (Hussain et al., 2015, 2017). This decrease was due to reduction in photosynthates production (Dong et al., 2017; Mila et al., 2017) and their minimum distribution to the floral parts (Dong et al., 2017). Spraying of 10 µM ABA under water deficit at flowering stage considerably enhanced head diameter because abscisic acid useful in water maintenance response of plants and may have enhanced plant growth through improvement in water use efficiency (WUE) (Wei et al., 2015; Dong et al., 2017).

For better production of crops, normal irrigations are essential but under water scarcity situation, it is significant to recognize important growth stage where irrigation can be missed without significantly reducing crop production (Wang et al. 2017). Water

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50055023

deficit both at vegetative or flower initiation stage reduced achene yield along with its attributes in Helianthus (Hussain et al., 2014, 2015). Harsh water scarcity effects were more apparent at flower initiation stage over at vegetative stage (Hussain et al., 2015). ABA foliar application during normal irrigation also considerably declined the yield, as it only enhanced yield during water deficit both at vegetative or flower initiation stage. From tolerance to dehydration, the plant hormone ABA played imperative (Wani et al., 2016) by helping dispersion of roots of maize in soil (Zhang et al., 2012) which finally augmented production of assimilates and yield through enhancing osmotic adjustment and water relation in plants like sunflower (Hussain et al., 2014, 2015; Wani et al., 2016; Dong et al., 2017). Abscisic acid sprayed under water deficit altered the sorghum physiology and growth and its application on seed enhanced grain yield (Traore and Sullivan, 1990). Contrary Ayub et al. (2000) described that foliar spray of abscisic acid during water stress to mung bean exhibited non-significant response to grain yield.

In current study biological yield of Helianthus was maximally reduced when water stress was enforced at vegetative over at flowering stage. Foliar application of 10 or 20 µM ABA under water stress at vegetative stage enhanced biomass but maximum increment in biomass was observed when 10 µM abscisic acid sprayed during this stage. This enhancement in biomass was due to decrease in shoot' water loss, roots deeper dispersion and increment in WUE which eventually augmented production of crop. Same findings were reported in Helianthus (Zhang et al., 2012; Hussain et al., 2015; Dong et al., 2017) and maize (Hartung et al., 1994). Contradictory ABA foliar application under water deficit and well-watered condition decreased biomass production in *Populus* which is owed to lesser dry matter accumulation and maximum distribution to roots of plant (Chunyang et al., 2004) ultimately may reduce above ground vegetation.

Plant water relations

Results of current trial showed that water potential became more adverse under water scarcity both at vegetative or at flowering stage and the exogenous application of abscisic acid considerably averted the negative impact of water stress by making the water potential in sunflower plants less negative. When ABA sprayed at vegetative stage over at flowering stage water potential became less negative. This enhancement in water potential indicate improvement of water shortage tolerance in helianthus by foliar application of abscisic acid, which eventually retained plant moisture through restricted and steady stomatal closure and by increasing root penetration and lastly help in plant survival through dehydrin protein production under cellular desiccation. Alfredo and Setter (2000) described that Cassava has capacity of partial stomatal closure under water stress due to abscisic acid accumulation in vegetative parts specifically in leaves which decreased leaf development and lastly continuation of growth happened after watering the crop again. Foliar application of abscisic acid responds to water stress condition by storing dehydrin protein in sunflower vegetative tissues (Aguado et al., 2014), poplar and wheat (Pelah et al., 1997). Dehydrin protein saves plants from cellular desiccation (Baker et al., 1988; Dure et al., 1989; Close, 1996). Jones and Corlett (1992) noticed contrary plant response as plant metabolic processes were more prone to cell size and turgor pressure compared to absolute water potential.

Water deficit both at vegetative or flowering stage depressed the water potential which also triggered a comparable reduction in osmotic potential. Ultimate decrease in osmotic potential was result of solutes accumulation in various plant parts through

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50055023

osmotic adjustments (Serraj and Sinclair, 2002; Hussain et al., 2015). ABA foliar application to helianthus caused osmotic potential less adverse. When ABA was sprayed at vegetative stage over at flowering stage, osmotic potential became less negative. This enhancement in osmotic potential was the result of compatible solutes accumulation like glycinebetaine (Serraj and Sinclair, 2002), proline (Hussain et al., 2015) and total soluble sugars. Such compounds are supportive in delay of desiccation through ROS detoxification, maintenance of membranes in addition to enzymes arrangement (Ludlow and Muchow, 1990; Subbarao et al., 2000). Hussain et al. (2015) exhibited that under water stress condition, key physiological mechanism was decrease in osmotic potential to keep leaf turgor pressure. Contrarily ABA foliar application may increment the action of definite enzymes such as ribonuclease and α-amylase. These enzymes may be involved in breakdown of starches plus other related materials thus making osmotic potential more adverse (Dong et al., 2017; Mila et al., 2017).

Water stress at vegetative or flower initiation stage considerably decreased turgor pressure of leaf. Decrease in turgor pressure of leaf was owed to reduction in water potential and already reported in wheat (Blum, 1997) and Helianthus (Hussain et al., 2015). ABA foliar application during water stress considerably enhanced leaf turgor pressure which was maximum at vegetative over at flower initiation stage. This enhancement in leaf turgor potential was result of plant efforts to maintain moisture. These types of findings were also reported in maize (Zhang et al., 2012) and in poplar (Pelah et al., 1997).

Results of the current study exposed that water stress at vegetative or flowering stage severely decreased sunflower relative water content of leaf. Decline in relative leaf water content in Helianthus was also noticed by Hussain et al. (2015). Further reduction in relative water content of leaf was noticed when water deficit imposed at vegetative over flower initiation stage. ABA foliar application considerably improved relative leaf water content under water deficit situations. These enhancements in relative water content of leaf was owed to plant moisture preservation through limited and steady stomata closure, root proliferation for water abstraction and dehydrin protein buildup which ultimately rescued plant from cellular desiccation. The same result was noticed in poplar, wheat and cassava (Pelah et al., 1997; Alfredo and Setter, 2000; Aguado et al., 2014). Contrary to this, ABA foliar application to maize during water stress did not increment relative water content of leaf (Unyayar et al., 2004).

Oil contents and fatty acid profile

Water stress both at vegetative and flower initiation stage decreased achene oil content. Oil content was observed to increase when water deficit was applied at flower initiation stage over vegetative stage. Water deficit applied prior to reproductive stage (Saleem et al., 2013), at flower initiation stage (Hammadeh et al., 2005) and for the duration of seed filling stage (Mekki et al., 1999; Hussain et al., 2015) of Helianthus declined oil content. In contrast the seed oil content exhibited constancy during incrementing water scarcity (Khan et al., 2000). Hussain et al. (2015) also reported no significant reduction in oil content under water deficit. ABA spraying under water deficit at vegetative or at flower initiation stage statistically enhanced oil content. Seed oil content may be improved by abscisic acid foliar spray because its spray result in limited stomata closure, reduced transpiration rate, repressed shoot development and improved root proliferations (Alfredo and Setter, 2000; Saleem et al., 2013) which eventually improved water accessibility for oil production in achene yield.

Water deficit and ABA foliar application under water deficit or well-watered conditions influenced fatty acid profile. Results of present trial emphasized that oleic acid and stearic acid reduced whereas linoleic acid and palmitic acid improved during well-watered and ABA foliar application improved oleic acid and stearic acid whereas reduced linoleic acid and palmitic acid. Water deficit at vegetative and at flower initiation stage slightly improved oleic acid and stearic acid whereas linoleic acid and palmitic acid reduced. Further increment was noticed in stearic acid when water deficit imposed at flower initiation stage whereas same response was noticed in oleic acid when sunflower encountered water deficit at vegetative stage. Linoleic acid and Palmitic acid were reduced under water shortage situation imposed at vegetative or at flower initiation stage but further decrease in both fatty acids was noted in crop that confronted water deficit at flower initiation stage. Flagella et al. (2002) also described reduction in oleic acid and stearic acid and increment in linoleic acid and palmitic acid in Helianthus under irrigation. Contrary, in Helianthus, oleic acid decreased and palmitic acid improved under water shortages (Saleem et al., 2013; Hussain et al., 2015). ABA foliar application both at vegetative and at flower initiation stage under water shortage somewhat reduced oleic acid and stearic acid, whereas its application to some extent enhanced palmitic acid and linoleic acid. This decrease in stearic and oleic acid and enhancement in linoleic and palmitic acid revealed that abscisic acid was useful in extenuating the negative impacts of water stress through enhancing water availability to plants. Water availability may be enhanced through maintaining moisture content in plant by restricted stomatal closure, decrease in transpiration rate, increment in root proliferation and inhibiting shoot growth (Alfredo and Setter, 2000; Hoad et al., 2001; Saleem et al., 2013; Hussain et al., 2015, 2017; Dong et al., 2017;).

Conclusion

It is concluded from this experiment that foliar spray of 10 µM ABA under water sacristy at vegetative stage significantly enhanced plant height, head diameter, achene yield and biological yield with respect to no abscisic acid. It also enhanced water relations by enhancing turgor pressure and water potential which specifies that ABA foliar application was useful in improving sunflower drought tolerance.

Foliar application of 10 µM abscisic acid at flowering stage by enforcing water stress at this stage also enhanced plant height, head diameter, achene yield and biological yield as compared to no ABA but this increment was lower than with the 10 µM ABA foliar application at vegetative stage after enforcement of water deficit at this stage.

Abstract. Mires in the Danubian Lowland (Northern part of the Pannonian Basin) are typically overgrown with common alder (*Alnus glutinosa*). Similar stands at this location are unfortunately very rare, what is caused by continuous human intervention in landscape and its natural pattern from Early Holocene. Peatland degradation near Pusté Úľany village started in the mid - eighteenth century, what is supported by historical maps. In the previous century a huge peat extraction took place at this specific mire. Despite these anthropogenic changes, there are still some remnants of natural habitats present, mostly dependant on ground water level. Methodology includes historical map's analysis, digital terrain model and vegetation cover mapping. Actual map of biotopes was completed for the current state of the vegetation cover acquaintance. Historical map's analysis revealed changes and development in the vegetation cover as well as the further relevant landscape changes in the mire during drainage system building. The first artificial drainage channel was built in the second half of the eighteenth century. Subsequently, dense system of the drainage channels was built near Továrniky settlement, continuing the drainage of this area for meadows, pastures and arable land acquisition. This wetland habitat was probably one of the largest mires in Slovakia during Holocene. Its area used to be markedly larger and its sedimentary basin presented much more important influence on landscape development. However, the historical sources revealed higher occurrence of common alder in the past, as well as typical xerothermic oak forest in this area. 27 biotopes were identified, from which 13 biotopes was purely human induced. Most of the area is currently abandoned for its own vegetation succession.
Keywords: *biotope mapping, landuse, DTM, Pusté Úľany, Danubian lowland*

Introduction

Historical settlements on the Danubian Lowland, dated to Neolithic, means rather early human interference into natural vegetation cover in this area (Jamrichová et al., 2017; Opršal et al., 2016). Peatland and lowland mire prospection is a very important topic in the context of vegetation development research and climatic changes during Holocene (Petr et al., 2013; Szabó et al., 2016). Lowland mires present an important image about vegetation development in regional context as well (Petr et al., 2013). The important element in interpretation of vegetation development is sedimentary basin area of the mire (Sugita, 2007). Relevant factor in interpretation of vegetation development

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50255045

and landscape change is also human interventions and its influence on natural habitats. Archaeological records about Danubian lowland extends back to 7 500–7 600 cal years BP. (Jamrichová et al., 2017). Historical maps offer the cover of recent history, mostly to seventeenth or eighteenth century, however more precise and quantifiable (Pišút et al., 2007; Hrnčiarová et al., 2016). Changes of water-bounded communities reach and natural succesion process is visible precisely on the historical maps. Peatlands and mires were subject to severe mining for various purposes. Some of these areas were subject to permanent protection as protection areas. Unfortunately, as mire near village Pusté Úľany was too large in its area, there were many efforts to drain this area and use it for agriculture. Similar large areas of peat accumulation in Danubian lowland are for example Šúr in the north of the Danubian lowland near Little Carpathians Mts. (Petr et al., 2013) or Parížske močiare wetland mires in the southeast of Danubian lowland (Jamrichová et al., 2014, 2017), or Cerová-Lieskové on the Záhorská nížina lowland (East Wienna basin) (Kvaček et al., 2014).

In 1950s an intensive peat extraction took place in mire near Pusté Úľany. Drainage canal systems are visible in landscape in the surrounding area as a part of protected bird area (Protected bird Area of Úľany wetland, which is one of the 38 bird areas in Slovakia in the Natura 2000 network. The problem about this area is “no monitoring” (Kopecká, 2011, 2013). After peat extraction, degraded landscape with large ponds remained left for new vegetation succession (Kopecká, 2011, 2013; Hreško and Guldanová, 2012; Bubíková et al., 2016). So the aim of this article is to answer several inquiries about this area:

- What was the original area of the water-bounded communities of the mire near Pusté Úľany?
- How was this area changing on the historical maps?
- In what manner human intervention was part of this changes and what is the actual condition of these biotopes now?

Materials and methods

Research area

Pusté Úľany village is located in the west part of Slovakia between towns of Senec and Galanta. Mire is located between the villages Pusté Úľany and Veľký Grob (*Fig. 1*). Currently the remains of the mire are visible mostly from orthophotomaps as peat extraction depressions. This mire is however tectonic interface between slightly curved Upland of Trnava loessic plain and Danubian plain (Mazúr and Lukniš, 1978). Geomorphologically it is a subassembly of Trnavsko-dubnická panva plain and Blatnianska priehlbina depression (INGEP, 2007; Maglay, 2005). In the residues of this Trnava looesic plain there are several depressions and depression valleys present including mire depression near Pusté Úľany (INGEP, 2007; Maglay, 2005).

Geologically is the origin of the depressions scheme fixed to the complex of Trnava Upland, which is leaning towards south-east, where underground water is reaching the topsoil and produced organic sediments (peat). They are bounded to the local depressions with mires such as mire near Pusté Úľany or Šúr near Little Carpathians Mts. (Maglay, 2005). Research area is restricted to the boundary connecting loose sediments and dominating alluvium. Mentioned alluvium is formed by grey and bright clays, silt, sand and gravels. Gravel sediments of the lower fluvial terraces of Váh River

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50255045

are located as well near Pusté Úľany (Maglay, 2005). Research area is a depression part with gently sloping tectonic subsidence. Tectonic faults are usually directed NE–SW. Hydrogeologically it is district QN 050, named Quaternary of the Trnava Upland as a part of looesic sediments on fluvial terraces (Hrašna, 2002).

Nowadays, the hydrological surrounding is formed by Stoličný stream basin flowing into the Čierna voda river. Stoličný stream is 38.9 km long and it is flowing from the Little Carpathians Mts. Near wetland area in the Uľanská mokraď it is crossed by Čatajský stream near Veľký Grob village.

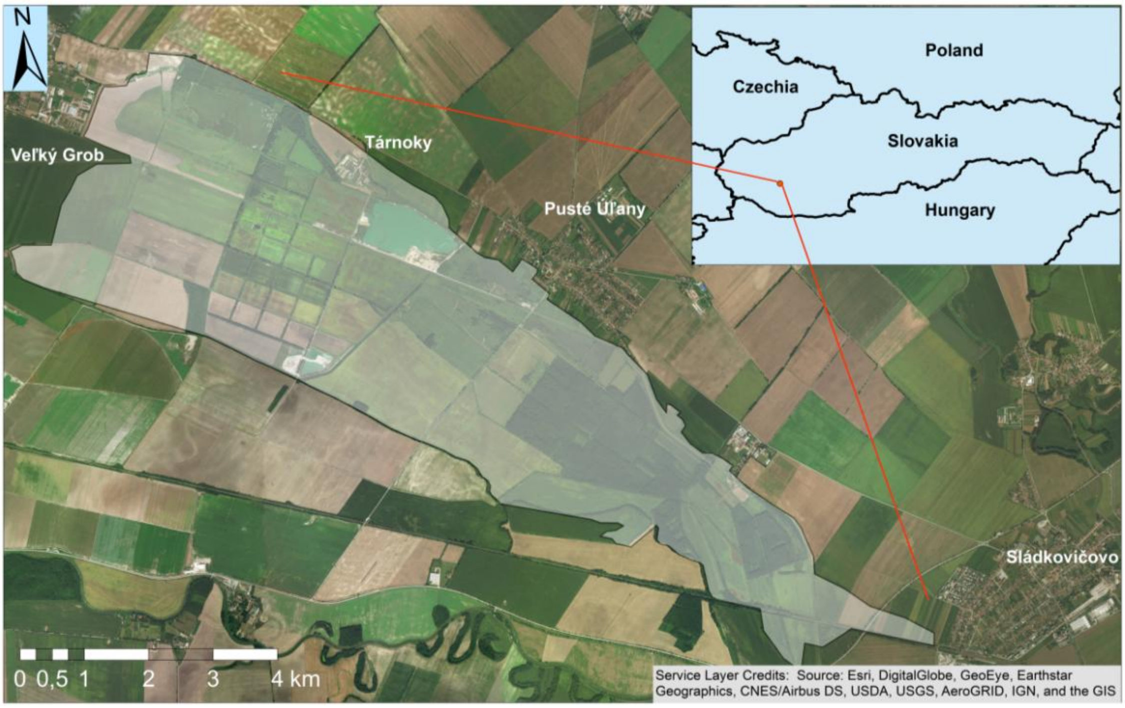

Figure 1. *Current area of water-bounded communities reach in the mire near Pusté Úľany*

Secondary landcover structure reflects the changes of the last century, mostly intensification in landuse with typical deforestation for crops, which after 1. and 2. world wars started to be cultivated with automated machines and it formed the highest area of use in 1950s (Kopecká, 2011). Soil substrate is characteristic by the very fertile soil types like chernozem or fluvic mollisols, so the cultivated land is in the direct proximity of the mire. Area of mire that is too waterlogging is not suitable for cultivation and that is why even more intensive draining of this area took place in the past (Hreško and Guldanová, 2012). In 1950s the intensification was finalised by peat extraction (Krippel, 1956), which degraded the landscape of this mire and large water areas – peat extraction lakes were formed with accumulated water.

Methodology

DEM

Digital elevation model was obtained from National Institute of Forestry (Zvolen). Measuring took place with terrestrial laser scanner (TLS) with 50 cm cell size of raster resolution. Outputs were processed in AcrGIS environment, version 10.3.1.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50255045

Historical maps

Series of historical maps were analysed and vectorised in ArcGIS environment (version 10.3.1.) and on its basis the spatial differentiation of landuse was reconstructed in several time horizons. Also original area of the mire was determined. Maps of greater and middle scales from the eighteenth and nineteenth century were used, including military surveys (1.m.m. in 1782-1785 and 2.m.m. in 1839) and map based on cadastral maps in the end of nineteenth century. Separated cartographic sources are cited in the list in the end of this article. In text interpretation we used map portal (Topographical Institute in Zvolen) – aerial scanning orthophotomaps in 1949 (http://mapy.tuzvo.sk/HOFM/). Actual state of the landcover was evaluated with orthophotomap in basemap 2018 (©ArcGIS).

After transformation of the historical maps to currently used S-JTSK coordination system, selection of the maps was used. Work with map of „*Vestigium operationis*...(number 1 in the list of cartographic sources cited in the end of this article in bibliography) was possible to rectify only with points of village establishments (churches) as main orientation points or for example Esterházy palace near town Senec. Anyway the mean error is too excessive. Map *Comitatus Posoniensis*…., published in 1757, is of better precision. However, the error of rectification was still notable (*Table 1*). Hence these too maps were visualized in text only as cut out section figures from the original maps.

The first and the second military surveys was available in better form already rectified on mapportal mapire (http://mapire.eu/en/), so it was easier to rectify map sheets already obtained from Hungarian Library (Hungaricana – Hungarian Cultural Heritage Portal) in digital form.

Table 1. *Residual mistake of rectification (first polynomial transformation) in georeferenced historical maps (years 1757 and 1760)*

Year	Name	Number of maps	Mean error of transformation	Number of control points for transformation	Type of transformation
1757	Map of Bratislava coun ty *(Comitatus Posoniensis...) [S 68 / X. / No. 94.]*	1 cut out section	1345.54	11	First order polynomial
1760	*Csádé* wetland mapping in Bratislava district	Whole map	133.242	5	First order polynomial
1782-1785	1. Military Survey	2 sheets	182.642	11	First order polynomial
1839	2. Military Survey	3 map sheets	50.750	9	First order polynomial
1890-1897	Cadastral maps of Bratislava district *(Pozsony megyei)* [001-091]	4 map sheets [56, 57, 64, 65]	67.088	17	First order polynomial
1949	Orthophotomap of Slovakia in 1949	1 cut out section	23.569	6	First order polynomial

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50255045

Biotope mapping

Actual state of biotopes was reviewed directly in ArcGIS environment (version 3.5.1.) using basemap. Standard methodology for biotopes mapping in Slovakia was used by Ružičková et al. (1996) by or photomaps interpretation and terrain confirmation. At first a preparation phase took place, obtaining necessary sources about research area forming the initial list of legend items. Boundaries of individual polygons were mapped from orthophotomaps and corrected during field work.

Boundary of the mire was depicted with consideration to the current area of depending biotopes with a ground water as the main factor of its origin. Since the biotopes mapping methodology in Slovakia came through some development in recent years and it has several specifics adapted to our landscape (different type of biotopes with range from lowlands to highlands), we decided to use the older methodology of biotopes mapping (Ružičková et al., 1996), as it differentiates the anthropogenic biotopes on the very detailed level that were necessarily needed. Appertaining English name was referred to the original Slovak names and codes of the biotopes. Finally, corresponding codes of biotopes for new methodology of mapping was attached to the table as well as NATURA 2000 code equivalent if available.

Results

Notes to the georelief topography

Mire near Pusté Úľany is a part of the Úľany depression. Digital elevation model (DEM) displays the Úľany depression and shows the higher position of adjacent Trnava Upland (about 15 m higher) in the NE position of the allocated research area (*Fig. 2*).

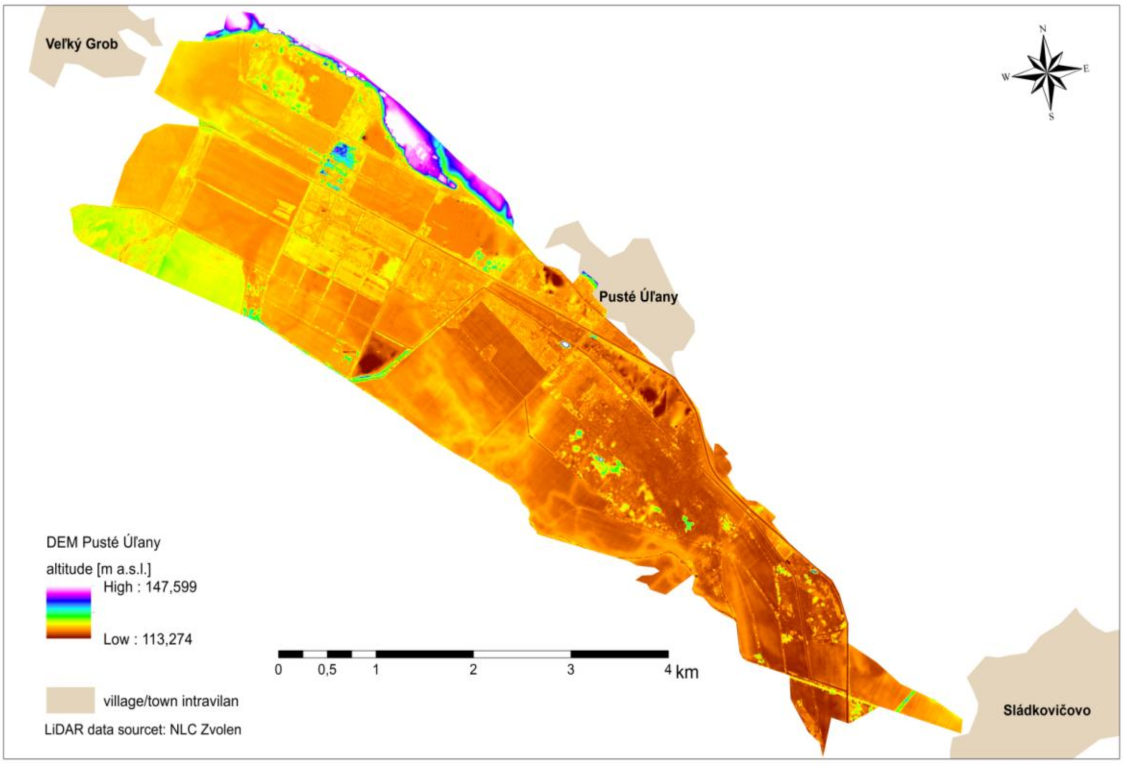

***Figure 2.** Digital elevation model of the wetland area near Pusté Úľany*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50255045

Depression is descending in SE direction along the Pusté Úľany village continuing down to the south. The vertical segmentation of the terrain is 34.3 m. Sedimentary basin was probably much larger than today, however the remains of the depression influenced by ground water is concentrated in the part close to the boundary of the tectonic slit between the Upland and the lowland. Generally, the highest parts of the area over 135 m a.s.l. are located in the northern part and the lowest parts below 120 m a.s.l. are concentrated in the south of the research area. NE part of the area on *Figure 2* is showing the edge of Trnava Upland part. The actual mire is located in the elevation between 128 m a.s.l. and 114 m a.s.l. The bottom parts of the extraction lakes (116–113 m a.s.l.) are ascending on the colour spectrum as a result of peat extraction and consequential terrain subsidence. Gravel extraction is still in progress in the area. Some of the appeared upper parts of the DEM are caused by anthropogenic structures and others by vegetation cover, therefore these were further investigated directly during field research. This area represents the humid alluvial depression between merging two river flows: Stoličný stream around, which this wetland area is formed now, discharges into the Čierna voda River. This area between two water flows is contributing to the humidity storage.

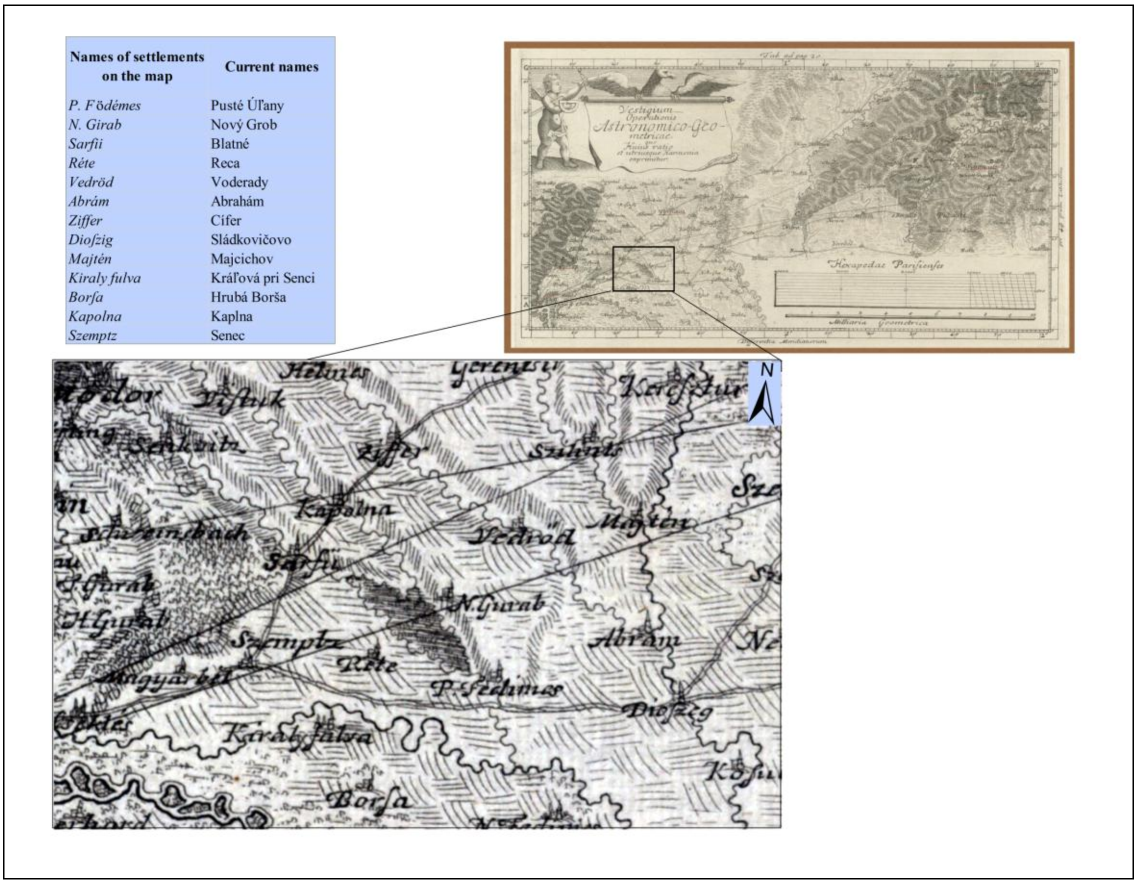
Historical maps and literature sources

First detailed information about the mire near Pusté Úľany came from Matthias Bel and his work *Notitia…* (Bel, 1736, Volume 2, Section VI.) which contains a detailed descriptions of villages located in administrative region of the Outer Bratislava District (*Processus Superior Externus*). Significant is a passage about Pusté Úľany village where it stands that to the south of the village there is an area suffering from frequent floods. "*There is a low-lying ground so boggy, that it is not able to hold even people, nor cattle on the ground, that are diving into it like into the swirls. This wetland is locally named Csádék. But after all, it brings some benefits to the local people as well, as it grows alders, suitable for extraction*" (page 189). Important information about the mire are as well in description of Blatné village: „*From this point* (= i. e. Červený vrch Hill) *a large wetland plain starts to extend with numerous lakes between the villages Čataj, Nemecki Grob, Senec, Kráľová, Réca, Boldogfalva and Pusté Úľany, or even further. In the favourable years it is typical with rich grasslands, but if the weather is too rainy it is easily covering in mud. From* (this swamp) *some people also derive the name of the village Blatné* (*Sárfö* in Hungarian; *sár* means mud, therefore *Sárfö means "head of a swamp*"*).* Matthias Bel also mentions the possible benefits of regulation of the stream Sisak (*Sziszak*) and its conversion from wetland to meadows (Bel, l.c., page 195 and 196).

The first volume of the work of Mathias Bel (1735) also contains the first and in this time very geometrically precise map, covering the area of the mire. It is the **map of Bratislava County** authored by Samuel Mikovíni in 1735 (number 2 in the maps citation list). For the aim of our work, its easily available Homann´s edition from 1757 (number 3 in the maps citation list) was used. Map of Mikovíni as a cartographic source significantly integrates the text information from M. Bel. It also directly relates to another, somewhat older Mikovíni map ***Vestigium Operationis Astronomico-Geometricae*** (number 1 in the maps citation list), which is probably the oldest and relatively accurate projection of the mire (*Fig. 3*). This map was originally part of a letter, where Mikovíni drafted the principles of his method of the maps compliance (Purgina, 1958). According to these maps the waterlogged area and/or wet meadows

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50255045

stretched from the Veľké Úľany village neighbouring the Pusté Úľany village continuing to the Čataj and Blatné, while from the western part it was protruding to the Boldogfalva. In general, it covered much larger area as it is nowadays. It is interesting that this wetland area was the very factor of connection for currently two separate settlements – villages Veľké Úľany and Pusté Úľany. Originally both were a part of one larger settlement during the Middle Ages, its inhabitants first mentioned as "*apiary*" (meaning beekeepers), later in 1221 as "*Fudemus*" in Hungarian language. The whole area reaching also the disappeared village of Dudvágszeg was later divided between several owners (Sedlák, 1994). Even map of Mikovíni (1735) has an interesting detail marked near Pusté Úľany village – map sign for the lonely standing church and farmstead (*Tárnok*). It was a remnant of the additional disappeared medieval village of *Tovarníky, that existed in thirteenth century (mentioned in 1301 as a nobleman´s settlement). The assumption that the villagers were dealing with trade is also supported by the patronicium of the local church: St. Jacob was the patron of traders (Sedlák, 1994).



Names of settlements on the map	Current names
P. Födémes	Pusté Úľany
N. Girab	Nový Grob
Sarfii	Blatné
Réte	Reca
Vedröd	Voderady
Abrám	Abrahám
Ziffer	Cífer
Diofzig	Sládkovičovo
Majtén	Majcichov
Kiraly fulva	Kráľová pri Senci
Borfa	Hrubá Borša
Kapolna	Kaplna
Szemptz	Senec

Figure 3. *Mire near Pusté Úľany plotted on the cut out section from the map "Vestigium Operationis...". (Cited as number 1 in cited maps section) authored by Mikovíni, 1732)*

For the history of draining the studied territory a **map from the second half of the eighteenth century** (approximately dated to 1760, *map number 4 in the maps citation list*) is of key importance. This map represents the oldest detailed cartographic depiction of mire, or in other words the area from the mouth of the **Čády stream into the Little**

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50255045

Danube (i. e. in to the Čierna voda river: "*Influxus aquae Csády ad minorem Danubium"*) up to the Blatné village (*Sarfö*) in the North. The most humid terrain was in the middle and lower parts of the bounds of Veľký Grob, Továrniky and Pusté Úľany. From the North the wetland was supplied by the waters from the Little Carpathians Mts. including the Vištuk brook, that was dividing into two separate branches near Čataj village and these two streams were surrounding the wetland area by each side. The key element of the map is a depiction of new drainage canal – *Novus Canalis exsiccatorius*, that begins on the boundary of the bounds of Borša, near Pusté Úľany copying the edge of Trnava loessic pseudoterrace and flowing into the side river channel near the town Sládkovičovo - *Dioszég* (*Naturalis Alveus Dioszegiensis*). The main straight channel also had a three shorter side branches. Four bridges were built through the channel to facilitate passing communications. Even the map has no legend at all, it is possible to conclude it actually represents the first project of draining this mire or it was made shortly after excavation of the canal as the previous maps did not contain this structures.

The identical condition of man-made canal is shown on the map of the **First Military Survey** two decades later (*maps number 5 and 6 in the maps citation list*). It is obvious from these maps that also a stream called Sisak from Šenkvice village was flowing into the wetland from the North as well and this very stream gave a name to the artificial drainage canal - *Sissak Graben* (ditch "Shishak"– Šišak in Slovak language). The hydronyme comes from the Croatian colonists from Šenkvice village and its variable name is still being used as Šifák, Sifák, Sisak or Sisek (Beláková, 2014). New element on this map are two additional narrow drainage canals marking the boundaries of *Továrniky settlement, flowing into the main drainage canal. The area of the mire in this stretch was thus changed to meadows and pastures. In the southern parts there are visible at least two open water areas, marked on this map. One of this water areas is named *See Tsadek* – lake Čádek (*Figs. 4* to *8; Table 2*).

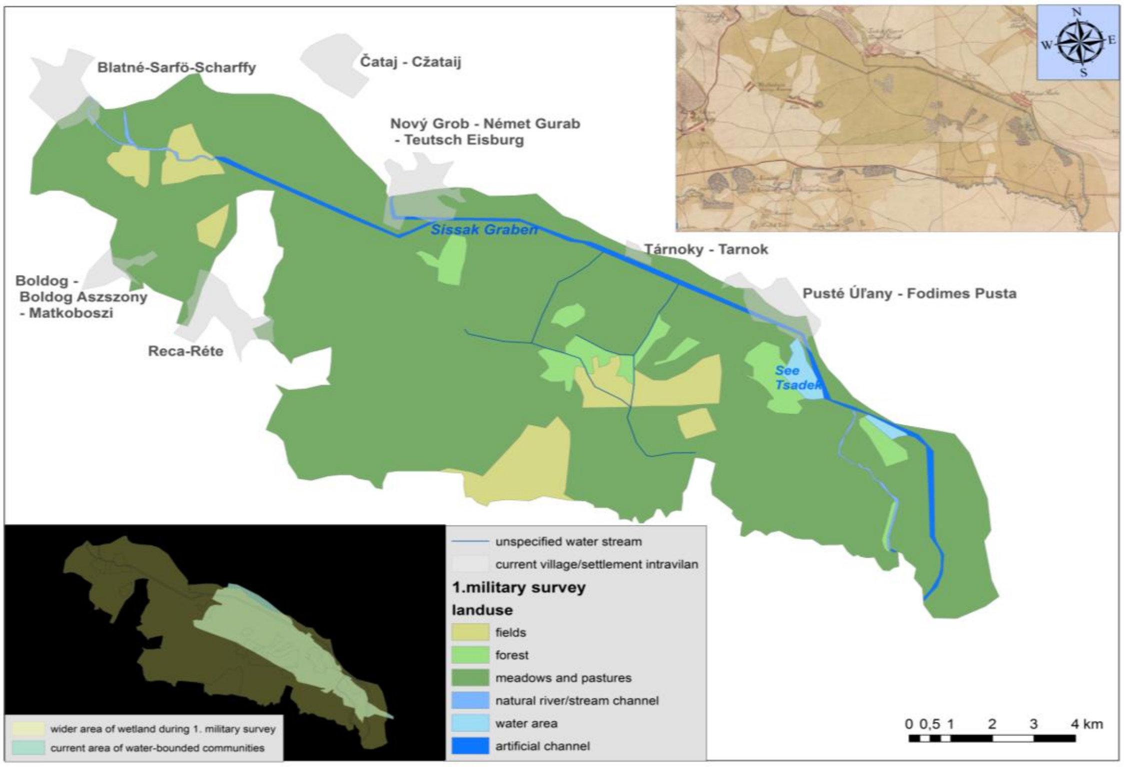

Figure 8. *Area and landuse of the mire near Pusté Úľany during 1. Military Survey (1782-1785)*

The descriptive part of the 1st military survey also contains some notes available to the specific map sheet. At the description of Pusté Úľany village (*Pusta Födimes*) and the *Tovarníky farmstead (*Tarnok*) is mentioned, that "the local meadows are mostly dry, gaining moisture only after rainy periods" (In German: "*Die Wiesen sind nur bey Regen Wetter sumpfigt, ausser den aber trocken.*"). In contrast, the meadows of Veľký Grob village are usually dry (*meist Trocken*). In the "roads" column which mainly characterised the passability of the country for wagon convoys there is a statement that roads near Továrniky are "dry on the upland parts (Trnava Upland) but good and/or bad on the meadows in the lower grounds (= Úľany depression), depending on the weather" ("*...so wie das Wetter, gut und auch schlecht.*"). Also a mentions abouth local forests merits attention. For example, woods of the Veľký Grob village, located outside the artificial canal consists of young oak stands ("*Das jenseits das Wasser befindliche kleine Wäld bestehet aus jungen Eichen.*"). Forests of Úľany and Tovarníky situated between the meadows partly consist of thin scrubland (= cippiced alderwood?), and partly of the oak thickets (*Die Waldung auf der Wiesen ... und ist theils schütteres Buschwerk, theils junge Eichenwaldung;* Arcanum, 2004).

Interestingly enough, also a sketch of the mire on the respective map sheet from the Atlas of Korabinsky from 1804 (*map number 7 in the maps citation list*) is provided. In the area of Úľany map suggests a wetland area along the stream flowing into the Čierna voda (*Schwartz Wasser*). Mire, respectively the stream is named *Tsadek* (Čadek). Map has a sketch of drainage canal as well – *Sissak Graben*, which is marked incorrectly as it is heading from the Čadek influx into Čierna voda river to the Sládkovičovo town (*Dioszeg*), respectively Košúty village (*Kossut*) in *Figure 9*.

Figure 9. *Stream Čádek (Tsadek) and the draining channel on the section selected from the Atlas of Karabinsky*

On the **map sheet of the 2. Military Survey** (*Fig. 10*) from 1839 (*map number 8-10 in maps citation list*) there is the main drainage canal named *Comitats Kanal*, i. e. County Canal. This proves that the draining of the mire in the eighteenth century was organised and financed by the official bodies of Bratislava County. The main identifiable change on the map is a systematic draining of mire in the bounds of Továrniky by combined system of rectangular canals. These structures divided the area into square and rectangle shapes. It helped to convert the mire in this part from mire to meadows and pastures without no alder forest stands (*Fig. 11*).

On the **map from the last 1890s** (Map number 11 in the maps citation list), that originated by compilation of cadastral map sheets, the main drainage canal has a Hungarian name Megyei csatorna. The new element of the drainage system is except for more drainage canals, added to the existing system, is a new channel (Uj patak) localised from the Pusté Úľany village in the southern part of the mire area and other parallel channel in the bounds of Sládkovičovo (Magyar ée Német Diószeg in Hungarian language, *Figs. 11* and *12*).

Therefore, the mire used to reach more to the North in the past, but after draining of the territory most of the water was concentrated in the lowest parts of the mire and the upper parts were drained as the water flow distribution and outflow was accelerated.

During aerial scanning in 1949, the area consisted mostly of the arable land. After collectivisation the drainage of the area was more intensified and every possible part od the landscape was used as arable land. Mire was not really visible on these orthophotomap (*number 12 in the maps citation list, Fig. 13*). Krippel in his work from 1957 near Tovarníky settlement describes, that the top soil layer is drained and changed into typical fluvic mollisols, however there are rich peat sedimentary accumulation underneath this layer just about 90 cm to 270 cm deep (Krippel, 1957).

Biotope mapping

By our research of current vegetation cover, the research area was set as the reach of ground-water influenced stands. The southern boundary was more difficult to isolate

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50255045

from the alluvium of Čierna voda stream, where originally the wetland area was probably stretched. The most of the area was covered with crops in 1949, however the ground water was still high in some years so it was difficult for tillage. The research area was mapped in terrain in the distance of the water areas until the signs of any humidification by ground water was present in the vegetation cover. This area is very reduced in present day as a result of long term human interference.

During the terrain research, several polygons of different water biotopes were identified. In our notes the bottom-rooted macrophytes and the bottom-rooted surface-flowing macrophytes were determined. In the Tovarníky pond the species of *Salvinia natans* was identified. Large area of these extraction ponds is covered with hedges and reeds stands, especially on the edge of the open water areas of these ponds. Though, these areas are disturbed and degraded by local fishermen club as they are cutting reed stands in order to get the access to the open water area for fishing. Generally, these ponds are following the water succession and they are continuously overgrowing the open water area depending on the date of the extraction works shutdown. Originally, the mire was typical by alder and oak forest stands. Characteristic biotope with common alder (*Alnus glutinosa*, code 2111500) is present only marginally in the Tovarníky part of the mire. Close to this polygon the representative alluvial forest with *Fraxinus excelsior* and *Ulmus carpinifolia* at least fifty years old (present in the area on the orthophotomap in 1949 as well). Nevertheless, the typical alluvial stand of this type is missing the oak species (*Quercus sp.*).

The ground water level during field research in November (2016) was stable around 20 cm to 2 meters or more. The mean level was around 90 cm (found out during soil probes measuring near Tovarníky pond). Several drainage canals are overgrown by vegetation and they are ideal environment for bird nesting such as *Asio flammeus* (Vďačný, 2001) and other types of protected fauna. In the vicinity area of the extraction ponds the underground water level is higher and surrounding crops are currently not cultivated as they are subject to succession of different types of shrubs. In the southern parts of the wetland area, near Pusté Úľany village the forested area is managed by forest management as poplar monocultures. This management supports the prevalence of invasive species in the herb vegetation layer, what is degrading the natural communities. Number of identified biotopes is 27 (*Fig. 14; Table 3*), from which the 13 types is purely of anthropogenic origin. It is remarkable there are several marginal areas of natural vegetation after major degradation in this area (2111500). Most of the area is used as arable land and major abandonment of the agricultural landscape is situated near the open water areas.

Discussion

Human intervention can change the wetland landscape very dramatically (Guette et al., 2018). The similar changes in landuse of wetlands were mentioned as a result of collectivisation also in other countries of the Eastern bloc (Deak, 2007; Skalos et al., 2017; Jepsen et al., 2015).

Based on historical maps analysis it was found out that the area of mire had its active part in the north as well covered the area up to Blatné village, it would be better to have larger DEM in our possession. The mire was presented more as the wetland than the open water body mire area, and that is also the reason for difficulty of evaluating the mire activity in different time scales. As this area started anthropically induced drainage in eighteenth century it is really possible that a further research such as palynology or macrofossil analysis is needed to understand the genesis and the origin of the mire. However, it is depending on the further suitability of the sediment.

According to historical sources it was concluded that the mire was supplied by not only the Little Carpathians Mts's streams, but also by the high flows of the Little Danube. Historical name of the mire "Csádé" or Csádek respectively is probably an older Hungarian hydronyme (*csádé, csáté*) with meaning of "wetland" or "shrubs dominated land" (Czuczor and Fogarasi, 1862-1874). In southern part, the alder stands were historically prevailing for the longest time (*Felsö Puszta Födémesi Erdö, Erlenwald*, 1839; *Egresi Erdö*, 1897). Area of the mire and especially its extent to the south-west direction was dynamically changing. In dry years the meadows were productive, but in the wet years, meadows were more characterised as wetlands and deposition of the mineral sediments took place and the major part was impassable. In the deepest parts the open water areas were formed (lake Tsadek). At first the western part of the mire has undergone degradation (Veľký Grob – Blatné) after drainage canal construction in the second half of the eighteenth century. Hence the research was focused on the southern part as our major part for research of current biotopes (Veľký Grob – Pusté Úľany). Yet historical maps need to be considered, as they were the part of the larger image, for example the historical map of whole Bratislava County (1957), where the mire drawing could be only estimation.

The drainage in the eighteenth century was very standard solution in the Austro-Hungarian empire. For the comparison the similar degradation was proceeded in Parížske močiare wetlands were the first drainage took place in 1819 (Procházka et al., 2015), but in the lake Šúr near Svätý Jur the drainage took place only in 40. of the twentieth century (Pišút et al., 2010).

Currently the major problem of the prospected area is as well the abandonment of agricultural landscape, what is quite characteristic for the Eastern bloc countries (Lieskovský et al., 2015; Jepsen et al., 2015; Burgi et al., 2017). Landcover analysis in this area was described by Kopecká (2011) with emphasis to the protected bird's occurrence. The secondary landscape structure during the twentieth through to the twenty-first century was prospected in the Úľanská wetland bird's area (Hreško and Guldanová, 2012) and it is providing the similar results with stable major areas of arable land with considerable changes during intensification and collectivisation. Different ongoing studies in Slovakia (Špulerová et al., 2011; Skokanová et al., 2017) and in Czechia (Kilianová et al., 2017) are copying similar landcover changes and development, especially covering the arable land areas. Currently, this trend in the research area and Slovakia as a country, is turning to land fragmentation and numerous ownerships of the arable and as well non-arable land (Muchová and Lusková, 2017;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50255045

Muchová, 2017). Future management is therefore necessary only with consideration to specifics of landcover changes in this region (Bezák et al., 2017; Klusáček et al., 2018; Jepsen et al., 2015).

Conclusion

Mire near Pusté Úľany was originally much larger and probably the biggest mire area in the Danubian lowland during Holocene. The theories of its origin are uncertain. Process of degradation of the mire started by drainage canal building around mid-eighteenth century, when from the Bratislava County financed a sophisticated drainage system construction to obtain land for pasture and cultivation. Since then, the human interference was huge into this ecosystem. Following peat extraction degraded the local landscape and destroyed the natural biotopes. Besides further research, appropriate protection and monitoring is needed to establish in this area as well as its further management. Some of the anthropogenic biotopes could reverse to a more natural state by this support and the favourable service of this area could be even recreation in the future and not only intensive forest management promoting the invasive species dominance. Currently the grasslands areas are forming in the direct proximity of this water areas as a result of fields desolation, which were cultivated in 1949. Water areas after peat and gravel extraction enables the repeated hydroserie succession forming rich sedge and reed stands that are seasonable biotope for water fowl and other endangered animal species.

MN^{2+} AND CU^{2+} ADSORPTION WITH A NATURAL ADSORBENT: EXPANDED PERLITE

TURP, S. M.

Department of Environmental Engineering, Bitlis Eren University, Bitlis, Turkey
(e-mail: smturp@gmail.com)

(Received 10th May 2018; accepted 5th Jul 2018)

Abstract. Water containing heavy metals causes many diseases including, in particular, cancer. For this reason, it must be completely purified before being discharged. In this study, the surface area of expanded perlite (EP) was determined to be 406.259 m^2/g by the method proposed by Brunauer, Emmet and Teller (BET). The removal efficiencies in terms of the heavy metals Mn^{2+} and Cu^{2+} were investigated according to this value. The optimum point of adsorption of manganese and copper with expanded perlite is 30 min and 5 min, respectively. The optimum absorbent dosage is 0.5 g for manganese and 0.4 g for copper. In the case of Mn^{2+} and Cu^{2+} adsorption, Log_q/Log_C values were plotted to determine the Freundlich isotherm on the expanded perlite. In addition, Langmuir isotherm constants were determined by plotting 1/q and 1/C values. It has been found that with 5 mg/L Mn^{2+} and Cu^{2+}, the Mn^{2+} heavy metals are compatible with the Langmuir isotherm model with $R^2 = 0.93$, and the Cu^{2+} heavy metals are compatible with the Langmuir isotherm model with $R^2 = 0.99$.
Keywords: *adsorption isotherms, heavy metal treatment, expanded perlite, Mn and Cu treatment*

Introduction

Industrial wastewaters contain various heavy metals, pesticides, salts and detergents, which cause chemical and physical changes in the water. Industrial waste pollutes not only the receiving environment, but also agricultural land and forests, and the surface and groundwater resources around it. The heavy metals in the wastewater resulting from industrial activities are often found in waste water from minefields, leakage waters of solid waste sources. These wastewaters accumulate in sediments mixed with rivers, lakes and underground waters. Even in a region remote from the discharge point, the level of heavy metal pollution is preserved. At the same time, metal compounds can be transformed into other compounds during transport. Many economical and effective methods for heavy metal removal have been used and new treatment methods have been developed. From these methods; ion exchange, chemical precipitation, reverse osmosis, evaporation, membrane filtration and biosorption are widely used, but the most effective method is seen as adsorption. The advantages and disadvantages of these methods used in heavy metal removal in *Table 1* are explained in detail (Hamutoglu et al., 2012).

It can cause pollution in agricultural land within the area affected by industrial establishments, the accumulation of heavy metal in soil, a decrease in productivity with regard to growing crops, and accordingly, the devaluation of agricultural land (Gonullu, 2004).

Copper and manganese, which are found in trace amounts in nature and in living things, are stored as heavy metals, especially in human and animal livers. Exposure to high doses of copper and manganese for long periods are harmful to health (Mudhoo et al., 2012). Regulations in Turkey with regard to water intended for human consumption in order to ensure the quality of the water, is regulated by technical and hygiene conditions (TS-266). The maximum values for copper Cu (II) and manganese Mn (II) were determined to be 2 mg/L and 0.05 mg/L, respectively (Published Official Gazette,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50475057

2012). In studies carried out for the removal of heavy metals which cause water pollution as a result of industrial activities, Xie et al. (2017) used sulfur micro-particles to remove copper from the aqueous solution. The adsorption process reached an equilibrium in 30 min and the optimum removal occurred at pH 4.5, ensuring compliance with the Freundlich isotherm model (Xie et al., 2017). Dai et al. compared two different carbon materials in their work. In addition, they investigated adsorption isotherms, contact time, pH and ionic strength. The Langmuir isotherm model is suitable for copper and zinc (Yingjie, et al., 2017). Mishra et al. (2017) in experiments involving Cu (II) and Ni (II) in red and black soil, kinetic and isothermal studies of metal ions were carried out to determine contact time, adsorbent dosage and metal concentration. Cu (II) and Ni (II) reached equilibrium after 480 min and 300 min of shaking, respectively. The maximum removal efficiency for Cu (II) by red soil was 97.3%, for Ni (II) by black soil was 99.9%. An examination of kinetic and adsorption isotherms has shown that adsorption experiments involving the pseudo-second-order equation and the Freundlich isotherm model, respectively (Mishra et al., 2017). Zahar et al. (2015) studied various variables in experiments to evaluate the ability of steel slag to remove manganese from an aqueous solution. The variables included contact time, adsorbent dosage, pH and initial manganese concentration. The equilibrium contact time was 10 h. An absorbent dosage of 1 g was found to be sufficient for removing heavy metals from the aqueous solution. A pH of 6 for manganese adsorption on steel slag was found to be the optimum. The Langmuir isotherm model adapted to Mn (II) adsorption by steel slag. In the Mn (II) adsorption of steel slag, the Langmuir isotherm was conformed (Zahar et al., 2015). Ateş and Akgül (2016) used natural zeolite obtained from the Manisa-Demirci region, modified with NaOH aqueous solution (0.5-2.0 mol/dm^3), and worked on manganese adsorption. The maximum manganese adsorption was obtained using NaOH-modified zeolite. Manganese adsorption with natural zeolite was consistent with the Langmuir isotherm model, whereas the use of manganese adsorption on modified zeolite was consistent with the Freundlich isotherm model (Ateş and Akgül, 2016). In 2010, Mesci and Turan investigated the removal of Cu (II) and Zn (II) by adsorption in the leachate of industrial using illite. They investigated the effect of illite, a natural clay species, as an adsorbent on the adsorption process in terms of pH, dosage and contact time. Experimental studies have shown that illite is effective in adsorbing Cu (II) and removing Zn (II), and can be used as an alternative to other adsorbents in the treatment of leachate water due to its low cost. Although active carbon is widely applied in adsorption processes, it is very costly. They found that illite, an inexpensive material that could be an alternative to activated carbon, had sufficient binding capacity for the removal of Cu (II) and Zn (II) from the leachate (Mesci and Turan, 2010). Xu et al. investigated the effect of operating parameters and electrolytes on the removal of toxic metals (cadmium, zinc and manganese) from synthetic mine molten effluent by bulk electrocoagulation. The results have shown that the removal of heavy metals increases the efficiency of the solution by increasing the pH and the current density of the solution. Fe-Fe electrode combination is more effective than other combinations (Al-AI, Al-Fe and Fe-Al). The interaction of heavy metal ions negatively affected the removal of Zn^{2+} by increasing the concentration of Zn^{2+} at the beginning. The single chlorine system confirms the optimized removal over Mn^{2+}. Xu et al. (2017) suggested that adding a small amount of sodium chloride to a high sulphate and hardness solution could accelerate the removal of heavy metals. In 2014, Ardali et al. used expanded perlite as an adsorbent in the removal of Cu (II) in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50475057

industrial waste leachate. In the study, the Cu (II) removal from industrial waste leachate was investigated by the discontinuous adsorption technique. The expanded perlite industrial leachate can be successfully used as an adsorbent for Cu (II) removal. Particle-to-particle diffusion and Elovich kinetic models are used. The removal rate of Cu (II) increases with an increase in the concentration of expanded perlite. The results have shown that expanded perlite leachate is a potential adsorbent for Cu (II) removal (Ardalı et al., 2014).

Table 1. *Advantages and disadvantages of methods used in heavy metal removal (Hamutoglu et al., 2012)*

Methods	Advantages	Disadvantages
Chemical precipitation and filtration	Simple and cheap	Difficult separation at high concentrations, ineffective, waste sludge formation
Electrochemical methods	Recovery of metal	Expensive, only active at high concentrations
Chemical oxidation and reduction	Inactivation	Ambient sensitivity
Ion exchange	Effective treatment and recovery of pure waste metal	Sensitive to particles and expensive resins
Evaporation	Pure waste disposal	Additional energy requirement, expensive, waste sludge formation
Reverse osmosis	Pure waste for recycling	High pressure, membrane size, expensive
Adsorption	Activated carbon use of sorbents	Application for all metals

In this study, the expanded perlite adsorption potential of manganese and copper heavy metals were evaluated. The adsorption experiments were carried out according to various parameters such as contact time, initial heavy metal concentration and adsorbent dosage. Isotherm models were applied to the data obtained from the experiments to compare the adsorption capacity of expanded heavy metal with expanded perlite.

Material and method

Adsorbent

The perlite used as an adsorbent material is an amorphous glassy volcanic rock with a pearl luster. When the perlite is heated to a softening temperature range of 760-1090 °C, it expands to about 20 times its constant volume. This expansion is due to the presence of 2-5% trapped water in the structure of the raw pearlite rock. As a result of this expansion, small amounts of granules form as hot and soft glassy particles. Turkey contains approximately 40% of the world reserves of perlite (Şahinoğlu, 2013). In Turkey, expanded perlite has a great variety of applications, while crude perlite is more limited in terms of fields of application. This property is mainly related to the chemical and physical properties of perlite (*Table 2*).

Adsorption study

The adsorption isotherms of the expanded perlite manganese and copper were made according to the Batch method (Atasoy and Yesılnacar, 2017). 1000 mg/L Mn^{2+} and Cu^{2+} stock solutions were prepared from $MnSO_4.7H_2O$ (Merck) and $CuSO_4.5H_2O$ (Merck) heavy metal salts, and aqueous solutions were prepared at 8 different concentrations between 1 and 250 mg/L. Removal of heavy metals was carried out in a laboratory environment. All aqueous solutions were prepared using deionized water (ELGA Purelab Option-Q). The prepared samples were supplemented with 0.1, 0.2, 0.3, 0.4, 0.5 g of expanded perlite in 500 mL beakers, respectively. The samples were mixed at 500 rpm using a magnetic stirrer (2 mag Mix 15 Eco) for different amounts of time (5, 10, 20, 30 min). Examples were measured on the Perkin Elmer Optima 5300 DV Optical Emission brand ICP-OES instrument. The recovery efficiencies were also calculated using the following formula (*Eq. 1*).

$$\text{Efficiency } (\%) = \frac{E_i - E_e}{E_i} \times 10 \qquad \text{(Eq.1)}$$

where:
E_i = Initial concentration (mg/L)
E_e = Exit concentration (mg/L)

Data analysis

Adsorption data were calculated using the Langmuir and Freundlich isotherm models. The analysis of the adsorption data is made according to the Langmuir equation (*Eq. 2*) and the Freundlich isotherm equation (*Eq. 3*).

$$\frac{1}{q_e} = \frac{1}{q_m \times K} + \frac{1}{C_e} \qquad \text{(Eq.2)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50475057

$$\log C_s = \log K_f + \frac{1}{nf} \times \log C_e \qquad \text{(Eq.3)}$$

The equation indicates a line between the values of C_e/C_s, and the angle of the slope gives $1/q_e$, whereas the angle of the slope gives 1/Ce in the slope on the *y* axis. K_f and $1/n_f$, Freundlich constants, C_s (mg/g) give the amount of expanded perlite adsorber, while C_e (mg/mL) gives the amount of Mn^{2+} and Cu^{2+} in solution. Since the equation specifies a straight line between logC_e and logC_s, the slope of the rectangle will give the value $1/n_f$, and the point on the y-axis the slope point, logK_f (Cooney, 1998).

Results and discussion

Effect of pH

To investigate the effect of pH on the adsorption of Mn (II) and Cu (II) with expanded perlite, the initial heavy metal concentration was 5 mg/L and the temperature was 25 ° C. The changes in pH value are shown in *Figure 1*. In *Figure 1,* the adsorption efficiency is increased at pH = 5, where adsorption is less at pH = 2. When the values in the graph are taken into account, the best pH-dependent removal efficiencies for Mn (II) and Cu (II) ions are; For Mn (II), pH = 5 – 81%, pH = 7 – 86%, pH = 9 – 87%, pH = 11 – 85%, and also for Cu (II), pH = 5 – 85%, pH = 7 – 84%, pH = 9 – 80% and 81% at pH = 11. Since the removal efficiency is lower than the higher pH values at low pH values, the excess H^+ ion positively expands the expanded perlite surface of the released H^+ ion, which affects the pushing force between the molecules, thereby causing a decrease in the amount of heavy metal adsorbed. Xie et al. Sulfur microparticles were used as adsorbents in copper removal experiments from aqueous solutions. In the adsorption experiments, the pH effect was investigated, and the optimum removal was carried out at pH 4.5 (Xie et al., 2017).

As shown in *Figure 1,* the pH adsorption study of Mn^{2+} and Cu^{2+} heavy metals was carried out at pH 2-11. The best adsorption for Mn^{2+} heavy metal was achieved at pH 5.5-6. As well as the best adsorption at pH 5 in Cu^{2+} heavy metal.

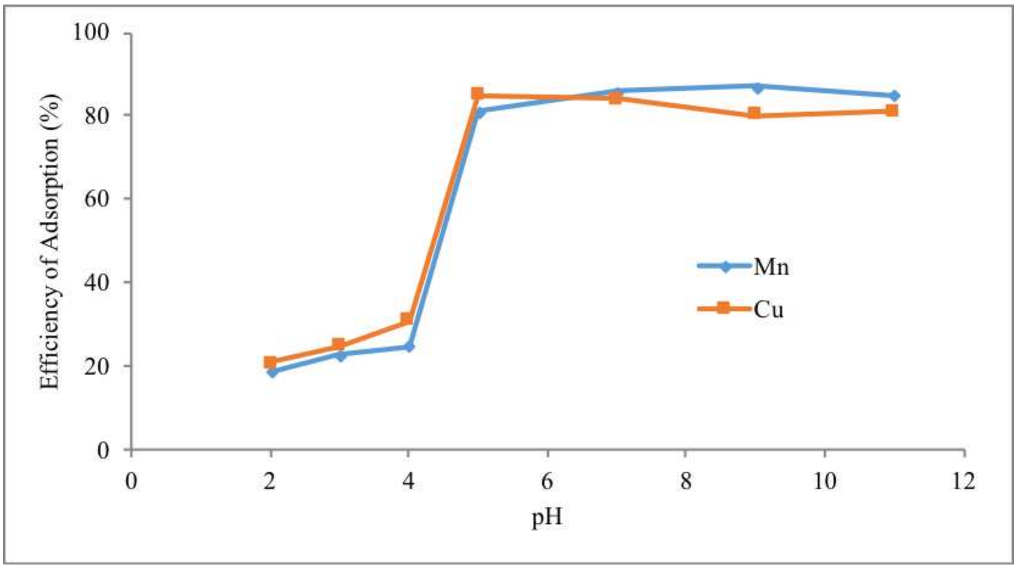

Figure 1. *Adsorption ratio depending on pH of Mn^{2+} and Cu^{2+} heavy metals*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50475057

Effect of contact time

According to the data obtained during the contact period, Mn^{2+} and Cu^{2+} ions showed a tendency to adsorb rapidly in the first 5 min on the expanded perlite. The initial concentration was chosen to be 5 mg/L, which is the best yield in terms of the two heavy metals. The optimum time point in terms of the best adsorption values for Mn^{2+} and Cu^{2+} was assumed to be 30 min and 5 min respectively. The contact times needed to achieve the optimum point were also identified in the isotherm study. As the adsorbent and adsorbed molecules increase the collision time, the efficiency of adsorption increases with the increase of contact time, and after a while, it reaches equilibrium. Compared to the amount of ions adsorbed at the time of initial adsorption by rapid adsorption, it is easy to see that the adsorption level drops. The contact time at which the turning point was reached (30 min for Mn (II), 5 min for Cu(II)) was then used to determine the adsorbent dosing and isotherm studies. Mishra et al. (2017) reported that copper reached equilibrium after 300 min of contact with copper. *Figure 2* shows the percentages of Mn^{2+} and Cu^{2+} adsorbed by the expanded perlite.

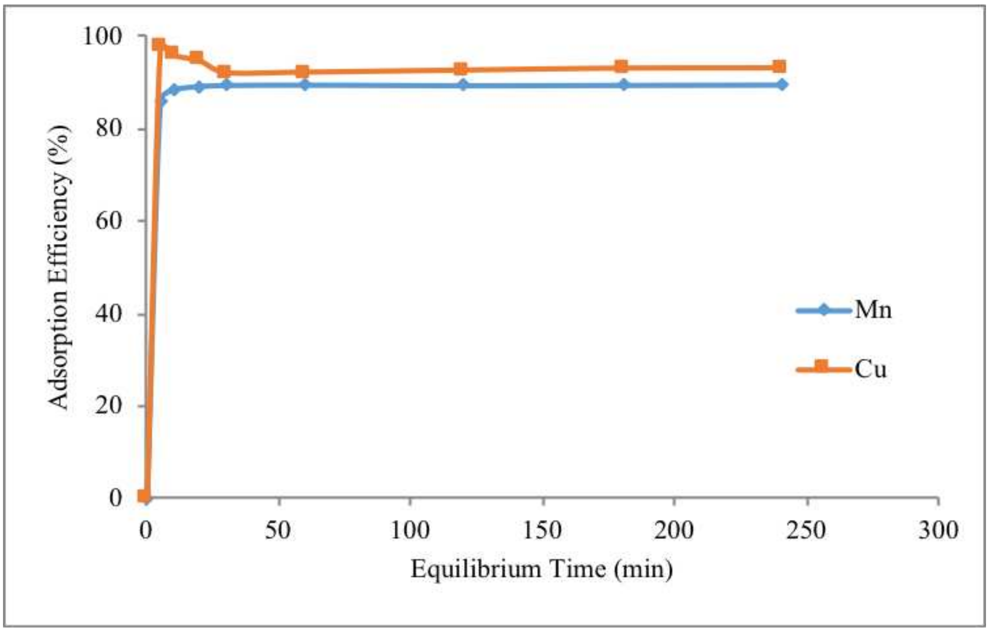

Figure 2. *Adsorption ratio depending on contact time of Mn^{2+} and Cu^{2+} heavy metals: adsorbent dosage - 0.5 g for manganese, 0.4 g for copper, 5 mg/L for initial concentration, pH - 5, T - 25 °C and shaking speed - 500 rpm*

Optimum adsorbent dosage

The adsorbate dose was studied by taking 0.1, 0.2, 0.3, 0.4, 0.5 g respectively. The adsorbent dosage experiment was carried out depending on the results obtained as a result of the experiments performed to determine the contact period. The amount of heavy metals adsorbed per gram of adsorbent was higher in the lower adsorption dose, higher in the higher adsorption dose. Although the removal efficiencies for Cu (II) were nearly similar, the best efficiency was 0.4 g of expanded perlite and the best efficiency of Mn was 0.5 g of expanded perlite. Zahar et al. found that 1 g of adsorbent dosing was sufficient for heavy metal removal from aqueous solutions (Zahar et al., 2015). The

DOI: http://dx.doi.org/10.15666/aeer/1604_50475057

effect of the adsorbent dose in terms of heavy metal removal at an initial concentration of 5 mg/L manganese and copper is shown in *Figure 3*.

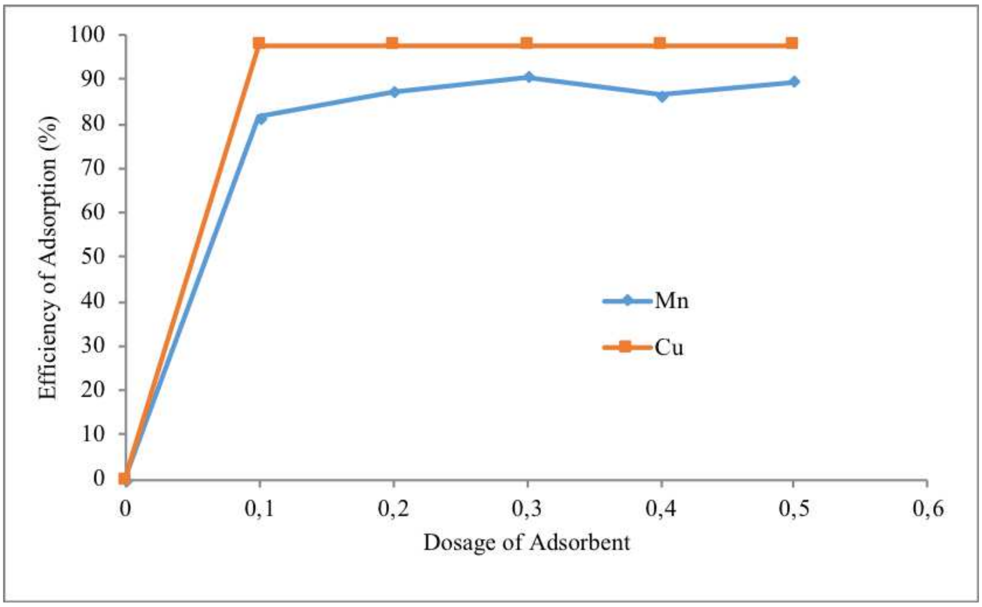

Figure 3. *The effect of the adsorbent dosage on the adsorption of Mn^{2+} and Cu^{2+} heavy metals: initial concentration - 5 mg/L, pH - 5, T – 25 °C and agitation speed - 500 rpm*

Effect of initial concentration

At different initial concentrations for each metal, 0.5 g adsorbent for manganese and 0.4 g adsorbent for copper, 25 °C of temperature, pH 5 for each heavy metal, shaking speed of 500 rpm, contact time of 30 min for manganese, 5 min for copper. The effect of the initial concentration on the adsorption yield according to the determined properties is shown in *Figure 4*.

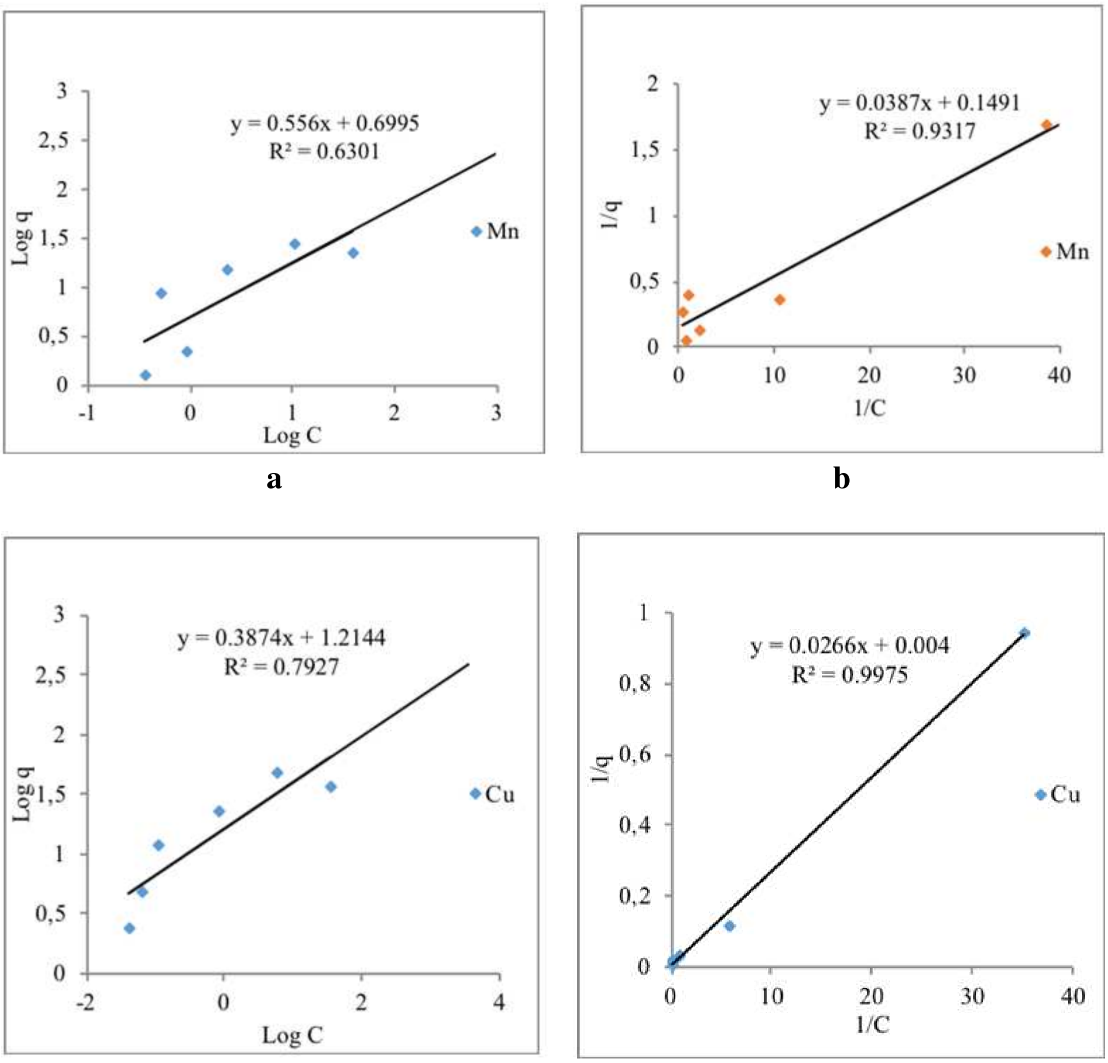
Adsorption isotherms

Manganese adsorption isotherm

Freundlich and Langmuir isotherm curves and equations for manganese adsorption applied with regard to the expanded perlite are shown in *Figure 5a* and *b*. In *Table 3,* isotherm constants and correlation coefficients are given. At the initial concentration of 5 mg/L of Mn^{2+} heavy metal, the turning point was assumed to be 30 min since 0.5 g of expanded perlite achieved the highest adsorption value. In the study, Mn^{2+} heavy metals were found to conform to the Langmuir isotherm model with R^2 = 0.93.



a **b** **c** **d**

Figure 5. ***a*** *Mn^{2+} Freundlich isotherm.* ***b*** *Mn^{2+} Langmuir isotherm.* ***c*** *Cu^{2+} Freundlich isotherm.* ***d*** *Cu^{2+} Langmuir isotherm*

A correlation value of 0.93 for Langmuir isotherm was obtained. It can be said that Langmuir isotherm is compatible with this high correlation value. Langmuir isotherms indicate that the adsorbent surface is homogeneous, and the surface is covered with a single layer.

BET surface area of expanded perlite

BET surface area analysis was performed with the Quantachrome Nova Touch LX4 instrument. The BET device can detect surface area measurements, micro, meso and macro pore size and pore size distribution at low pressures and high resolution by physical adsorption method in solid or powder samples. Prior to the test, the samples are placed in the degas unit (up to 300 °C) which is vacuum-heated for purification and sludge treatment, after which the samples are analyzed with nitrogen gas, which is used as adsorbate in the liquid nitrogen temperature. As a result of these experiments, an "adsorption isotherm" is obtained which indicates how much nitrogen the substance holds at which pressure. Once the adsorption isotherm has appeared, parameters such as BET Surface Area (Single or Multipoint), Micropore Size Distribution (0.5 nm - 2 nm), Mesopore Size Distribution (2 nm - 50 nm), Total Pore Volume, Average Pore Size can be calculated. The surface area of the expanded perlite, adsorption, desorption and average pore width were measured. According to the results in *Table 5,* single point surface area of expanded perlite is 406.259 m^2/g, multipoint surface area of expanded perlite is 1171.73 m^2/g and the average pore size is 0.823 nm. The high surface area of the expanded perlite allows for the absorption of the absorbent feature. At the same time, the pore size is directly related to the diameter of the desired heavy metal molecule.

Conclusion

In this study, the expanded perlite was used as an adsorbent for the adsorption of heavy metals such as Mn (II) and Cu (II). The effects of contact time, pH, adsorbent dosage and inlet concentration parameters were investigated in adsorption experiments. According to the batch method, Mn^{2+} and Cu^{2+} ions showed fast adsorption tendency in 30 min for Mn^{2+} and 5 min for Cu^{2+} on the expanded perlite used as the adsorbent material as a result of the experiments to determine the turning point depending on the contact time. For both heavy metals these values were accepted as turning point. In the study where the amount of adsorbent is determined, the adsorbent amount in which a large part of the Mn^{2+} and Cu^{2+} concentrations are adsorbed is determined as 0.5 g/L for Mn and 0.4 g/L for Cu. It has been observed that the increase in the removal of the expanded perlite Mn^{2+} and Cu^{2+} is at pH 5. In the adsorption of Mn^{2+} and Cu^{2+}, $\log_q/\log_C$ values were plotted to determine the Freundlich isotherm, while Langmuir isotherm constants were determined by plotting $1/q$ and $1/C$ values. At an initial concentration of 0.5 mg/L Mn^{2+} heavy metal, the optimum point was assumed to be 30 min since 0.5 g of expanded perlite achieved the highest adsorption value at this time. In the study, Mn^{2+} heavy metals R^2 = 0.93 were obtained. It can be said that Langmuir isotherm is compatible with this high correlation value. Langmuir isotherm compliance indicates that the adsorbent surface is homogeneous and that the surface is covered by a single layer. At a concentration of 5 mg/L Cu^{2+}, the optimum point was assumed to be 5 min since 0.4 g of expanded perlite achieved the highest adsorption value at this time. In the study, Cu^{2+} heavy metals were found to conform to the Langmuir isotherm model with R^2 = 0.99. In this study, it has been found that economically expanded perlite can be used as an effective adsorbent material in the removal of heavy metals. Different processes can be developed by undertaking additional laboratory studies.

Abstract. Catalytic oxidation of formaldehyde (HCHO) at ambient temperature is regarded as a promising technology for removal and destruction of HCHO contaminated air. In this study, three types of catalyst which are commercial HCHO catalyst, the catalyst of granular activated carbon supported Pt (Pt/GAC catalyst) and the catalyst of granular activated carbon supported MnOx (MnO_x/GAC catalyst) were chosen for oxidizing HCHO. The impact of superficial velocity, reaction bed height and the type of catalyst to the removal efficiency of HCHO was investigated. The fact that removal efficiency of HCHO increased firstly and then decreased with the decrease of superficial velocity illustrates its effect on the catalytic oxidation existed at an optimum value, depending on the nature of different catalysts, design of the reaction bed and the operation conditions. The steady state removal efficiencies of HCHO were all above 99% when the superficial velocity was 0.5, 1.0 and 1.5 m/s respectively, yet the needed height shortened with decreasing the superficial velocity. Among the three types of catalysts, Pt/GAC catalyst shows the effective and stable catalytic activity, whose removal efficiencies reached over 90% and the conversion did not change too much with the time increasing.
Keywords: *Pt/GAC catalyst, MnO_x/GAC catalyst, commercial HCHO catalyst, HCHO removal, reaction bed height, room temperature*

Introduction

Formaldehyde (HCHO) is regarded as one of the most common indoor air pollutants, which is emitted from building and furnishing materials (Perry, 1995). Owing to the teratogenicity and carcinogenicity, its pollution problem gets more and more attention (Salthammer et al., 2010; Lu et al., 2017). A series of efforts have been made for abating its emission at room temperature to meet the environmental regulations. Although the physical adsorption or chemical reaction has been proven to remove HCHO, the effectiveness is limited by the material's capacities (Nakayama et al., 2002). On the contrary, due to its low energy consumption and environment-friendly reaction conditions, room-temperature catalytic oxidation, which can completely oxidize HCHO into harmless CO_2 and H_2O, has become a promising technology for removal and destruction of HCHO contaminated air and has attracted extensive attention (Spivey, 1989; Qi et al., 2015; Yan et al., 2016; Ye et al., 2016; Yang et al., 2017).

Recently, dozens of studies have shown that the supported noble metal catalysts (such as Pt, Ru, Pd, Au and so on) exhibit high catalytic activity at room temperature (Yang et al., 2017; Zhang et al., 2006; Huang et al., 2011; An et al., 2013; Quiroz et al., 2013). Among them, the high efficiency of catalytic oxidation by supported Pt catalysts has been proven (Peng and Wang, 2007). It was reported by Zhang et al. (Zhang et al.,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50595069

2006) that 100% HCHO decomposition into CO_2 and H_2O was achieved over 1 wt% Pt/TiO_2 catalyst at ambient temperature. However, because of high cost, this catalyst cannot be widely applied in the engineering field (Yusuf et al., 2017).

Another approach for removing HCHO is to combine activated carbon adsorption with catalytic oxidation (Granqvist et al., 2007). Many catalysts have been shown to have high removal efficiency when applied with activated carbon, such as photo-catalysts (Bashkova et al., 2011), silver catalysts (Li et al., 2016), metal oxides catalysts (Fang et al., 2017) and so on. Li et al. (Li et al., 2016) reported that the catalyst of granular activated carbon supported MnO_x had a high activity to remove HCHO at ambient temperature, but its removal efficiency dropped from 75% to 10% after running continuously for 30 h. Fang et al. (Fang et al., 2017) investigated the effectiveness of coconut shell activated carbon supported MnO_x for catalytic oxidation of HCHO at room temperature. The HCHO removal efficiency was kept almost at 100% during a 1000 min period.

For HCHO, the efficiency of the catalytic reaction is strongly affected by factors, such as temperature, humidity, gas hourly space velocity (GHSV), inlet HCHO concentration and the properties of the catalyst (preparation method, morphology and structure, specific surface active area, active sites, low-temperature reducibility and surface active oxygen species) and so on. It was reported that the removal efficiency of HCHO decreased with the increase of the inlet HCHO concentration and GHSV (Xia et al., 2010; Han et al., 2016). Chen et al. (Chen et al., 2013) examined the effect of GHSV on HCHO conversion over 1 wt% Au/CeO_2 (DPU) at room temperature in the range of 34000-143000 h^{-1}. The steady conversion of HCHO reached 100% at all GHSV (34000, 95500, 143000 h^{-1}), but the reaching time was reduced with the increase of GHSV. Besides, Han et al. (Han et al., 2016) investigated that HCHO catalytic efficiencies for all the prepared catalysts increased with the rising reaction temperature. Though various factors influencing the HCHO decomposition have been reported in many kinds of literature, there are few studies related to the effect of superficial velocity. Besides, finding high activity of catalyst to oxidize low-concentration HCHO at room temperature also needs to be investigated further (Zhang et al., 2005; Tang et al., 2008).

On the bases of the reports above, studies on the catalytic oxidation of low-concentration HCHO at room temperature still need to be further developed and completed. Therefore, in this study, we investigated the properties and efficiencies of two different typical catalysts (Pt/GAC catalyst and MnO_x/GAC catalyst) for removing HCHO, compared with the commercial HCHO catalyst. Moreover, the effects on catalytic oxidation were studied concerning the factors of superficial velocity, reaction bed height and the types of catalysts.

Materials and methods

Catalyst preparation

The catalysts used in this study were commercial HCHO catalyst ($10 \times 10 \times 10$ cm^3, five blocks), Pt/GAC catalyst ($10 \times 10 \times 10$ cm^3, one block), and the MnO_x/GAC catalyst. The activated carbon used in this study was coal-based columnar carbon with an averaged diameter of 4 mm. The carbon tetrachloride adsorption activity of GAC was 82.95%. The details of Pt/GAC catalyst preparation were as follows: Chloroplatinic acid solution with Pt was prepared and used as the impregnation liquid, then GAC ($10 \times 10 \times 10$ cm^3 per block) was immersed in the solution at room temperature till they

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50595069

are mixed completely. A series of steps including dehumidification, purification and reduction reaction were completed in the preparation (Zhang et al., 2015; Zhu et al., 2016). The MnO_x/GAC catalyst was obtained via in-situ reduction of potassium permanganate with GAC. The MnO_x/GAC catalyst was prepared by the reaction of in-situ synthesis. The details of MnO_x/GAC catalyst preparation were as follows: the GAC was immersed in the $KMnO_4$ solution (concentration of 1%) for 1 h. The obtained MnO_x/GAC catalyst was then filtered and dried at 120 °C for 1 h (Fang et al., 2017).

Experimental setup

The general configuration of the apparatus used to test the catalytic performance with the commercial HCHO catalyst or the Pt/GAC catalyst is depicted in *Figure 1.* The apparatus consisted of three parts: gas distribution system, catalytic system and detection system. Liquid HCHO (ACS reagent grade) was delivered by a syringe pump (LongerPump, LSP01-2A, United Kingdom), evaporated and mixed with contaminant-free compressed air. The air mixture flowing through a rotameter and a buffer to measure and regulate the gas flow contained 9 ppm HCHO and clean air, which was introduced as the reactants. The catalytic system included a wind turbine and catalytic reactor. Owing to the large catalyst resistance, the catalytic system had a wind turbine. The catalytic oxidation of HCHO was performed in a quartz tubular fixed-bed reactor (five levels) under atmospheric pressure at room temperature (25 ± 1 °C). The catalyst was respectively loaded in the five-story reactor, installing a perforated stainless-steel plate at the bottom of each section. Valves were installed in the front of and behind every catalytic unit to measure contaminant concentrations.

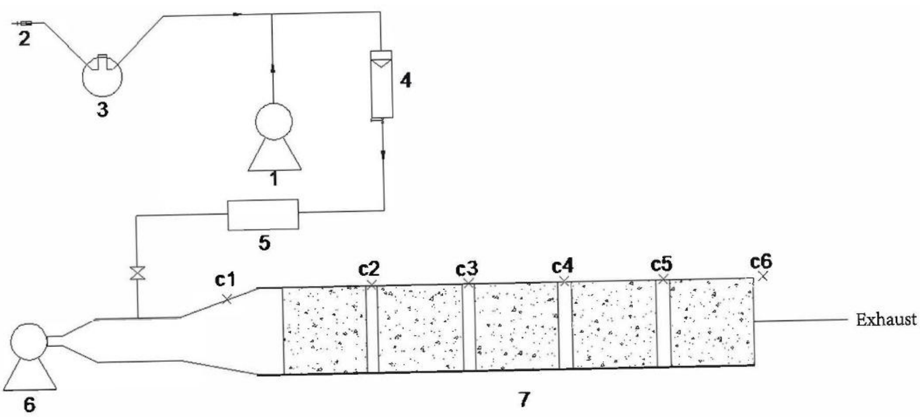

Figure 1. *Schematic diagram of apparatus used for catalytic performance with the commercial HCHO catalyst or the Pt/GAC catalyst. (1, 6: blower; 2: syringe pump; 3: temperature-controlled magnetic stirrer; 4: rotameter; 5: surge flask; 7: catalytic unit; c1-c6: sampling port)*

The Catalytic performance with the MnO_x/GAC catalyst in the experiment was set up as shown in *Figure 2.* As in the above process, the air mixed with HCHO, then adjusted to the desired concentration. The catalyst (the depth of 10 cm) was installed in the packed-columns which were made of glass (i.d. 40 mm) and operated in the downflow mode. Valves were installed before the catalytic unit inlet and after the catalytic column to measure contaminant concentrations.

Experimental testing and analytical techniques

During the catalytic oxidation of HCHO, ~9 ppm HCHO was injected mixed with clear air as a contaminated gas. The superficial velocity was set by 0.5, 1.0, 1.5 m/s for the commercial HCHO catalyst and Pt/GAC catalyst and 0.2, 0.5, 1.0 m/s for the MnO_x/GAC catalyst. The HCHO in the airstream was analyzed by an HCHO monitor (Formaldemeter 400, PPM Technology, United Kingdom).

The results of removal efficiency of HCHO under different parameters were compared and analyzed statistically. The multivariate analysis was applied to identify the significance of selected differencing factors.

Equation 1 below shows the complete reaction process of HCHO decomposition in the catalytic oxidation:

$$HCHO + O_2 \rightarrow CO_2 + H_2O \tag{Eq.1}$$

The results of each selected influencing factors of removal efficiency were analyzed statistically. The HCHO removal efficiency was calculated by *Equation 2* as follows:

$$\text{The Removal efficiency of HCHO} = \frac{[HCHO]_{in} - [HCHO]_{out}}{[HCHO]_{in}} \times 100\% \tag{Eq.2}$$

where $[HCHO]_{in}$ and $[HCHO]_{out}$ are the inlet and outlet HCHO concentration respectively (both expressed in ppm).

Results and discussion

The influence factors of the catalytic reaction, including superficial velocity, reaction bed height, the types of catalysts, were studied to evaluate the catalytic activity and stability of the catalysts.

Effect of superficial velocity on removal efficiency of HCHO

Superficial velocity has a vital effect on the adsorption time and catalytic oxidation time, but only limited studies focused on it. Keeping the inlet HCHO concentration of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50595069

9 ppm, the impact of superficial velocity on the catalytic performance was investigated by setting the velocity from 0.5 to 1.5 m/s for the commercial HCHO catalyst and Pt/GAC catalyst and from 0.2 to 1.0 m/s for the MnO_x/GAC catalyst. The results are shown in *Figure 3*. For the Pt/GAC catalyst (*Fig. 3b*) and the MnO_x/GAC catalyst (*Fig. 3c*), when the superficial velocity was increased, the removal efficiency for HCHO would be decreased. However, for the commercial HCHO catalyst (*Fig. 3a*), the removal efficiencies from the highest to the lowest were SV = 1.0 m/s > SV = 1.5 m/s > SV=0.5 m/s.

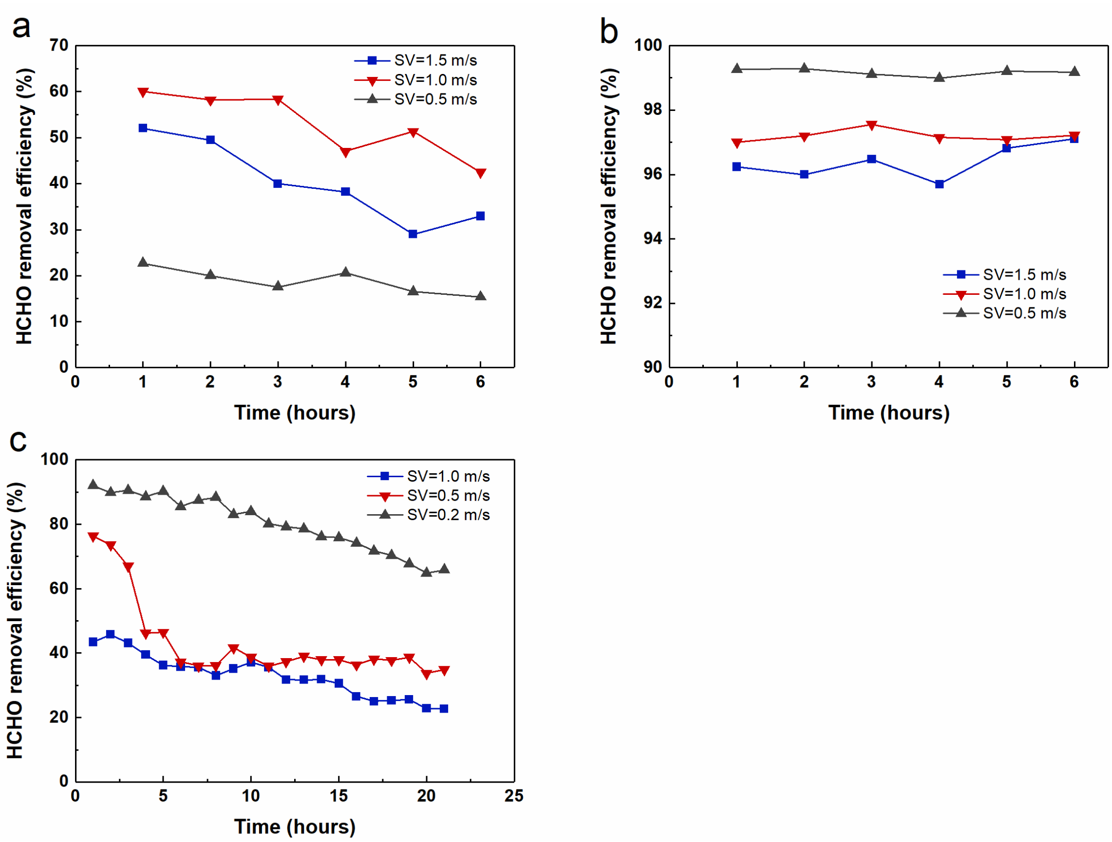

Figure 3. *Removal efficiencies of HCHO over three types of catalysts under different superficial velocities. (a: the commercial HCHO catalyst; b: the Pt/GAC catalyst; c: the MnOx/GAC catalyst; SV refers to superficial velocity)*

According to the *Figure 3,* the nature of different catalysts showing different catalytic activities was related to the influence of superficial velocity on removal efficiency of HCHO. For the commercial HCHO catalyst, in a certain scale, the removal efficiency increased with the reduction of superficial velocity. Further decrease of the superficial velocity to 0.5 m/s appeared no positive effect on HCHO conversion, even a sharp decrease. These results can be understood by considering the fact that HCHO molecules fully exposed to the catalyst and participated in the removal reaction per unit would increase with the decrease of superficial velocity, which resulted in improving the removal efficiency correspondingly. Zhang et al. (Zhang et al., 2005) investigated the impact of air-flow rate on catalytic performance, which illustrates that the removal efficiency of HCHO in the catalytic oxidation was inversely proportional to the air-flow

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50595069

rate and the correlation coefficient (R^2) reached 0.99. However, below a certain range of superficial velocity, because of the increase of residence time and HCHO molecules, the competition for the active catalytic sties on the catalyst surface would strengthen, leading to a decline of the removal efficiency. The Pt/hydrophobic catalyst was tested under different gas flow rates by Chuang et al. (1994), where HCHO conversion percentage showed a small increase when the gas flow rate increased from 6 to 18 L/h. The fact shows that the catalytic oxidation was dominated by the diffusion rate of HCHO molecules onto the surface of catalyst. For the Pt/GAC catalyst and the MnO_x/GAC catalyst, the fact that removal efficiency of HCHO rose with a decrease in the superficial velocity indicated that the catalytic oxidation was dominated by HCHO molecules onto the catalyst surface, and the competitive reactions between molecules were not obvious. Therefore, the optimal superficial velocity of the Pt/GAC catalyst and the MnO_x/GAC catalyst needed to be investigated further. Huang et al. (Huang et al., 2011) confirmed the conversion of HCHO decreased with the increase of GHSV through examining the effect of GHSV on the catalytic oxidation of HCHO in the range of 40000-240000 h^{-1}. The steady conversion of HCHO was 100% at 40000 h^{-1} which dropped to 90.5% at 240000 h^{-1}.

Overall, these results show that superficial velocity is an important factor which influences the removal efficiency of HCHO, which has the two-side influence on the catalytic oxidation. For one thing, due to the external mass transfer, higher superficial velocity can increase the removal efficiency of HCHO. For another thing, the residence time reduces with the increase of the velocity, resulting in the decrease of removal efficiency. Therefore, the effect of the superficial velocity on the catalytic oxidation existed an optimum value, depending on the nature of different catalysts, design of the reaction bed and the operation conditions (Pei and Zhang, 2011).

Effect of reaction bed height on removal efficiency of HCHO

The effect of reaction bed height on the removal efficiency over the commercial HCHO catalyst at ambient temperature was further investigated by keeping the inlet HCHO concentration at 9 ppm. A plot of removal efficiencies versus reaction bed height determined in the present study operated under different operation times and superficial velocities were conducted as shown in *Figure 4*. The reaction bed heights of 0-50 cm correspond to the height of measured sampling point 1-6, respectively.

For each superficial velocity, the similar trend of removal efficiency appears at different operation time – that the removal efficiency of HCHO at different operation time increased with the rise of reaction bed heights and kept almost unchanged over a certain height. This result suggests that higher reaction bed height provides more reaction time as a result of the fact that the removal efficiency of HCHO increases more.

From *Figure 4a,* keeping the superficial velocity of 1.5 m/s, removal efficiency of HCHO in the height of 10 cm follows the order: T = 1 h > 2 h > 3 h > 4 h > 6 h > 5 h at different operation time, and the efficiency was 52.06% at 1h, dropping to 29.01% at 5 h. With the increase of reaction bed height, the difference of removal efficiency at different operation time decreased gradually, and the efficiencies all reached to above 98% in the height of 40 cm.

As shown in *Figure 4b,* keeping the superficial velocity of 1.0 m/s and removal efficiency of HCHO in the height of 10 cm follows the order: T = 1h ≈ 2h ≈ 3h > 5h > 4 h > 6 h at different operation time, and the efficiency was 60.06% at 1 h, dropping to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50595069

42.52 % at 6 h. Compared with the efficiency under the superficial velocity of 1.5 m/s, the difference among different operation time narrowed, and the efficiency had improved some. When the height was above 20 cm, the efficiency has little difference at different operation time, reaching to about 95%.

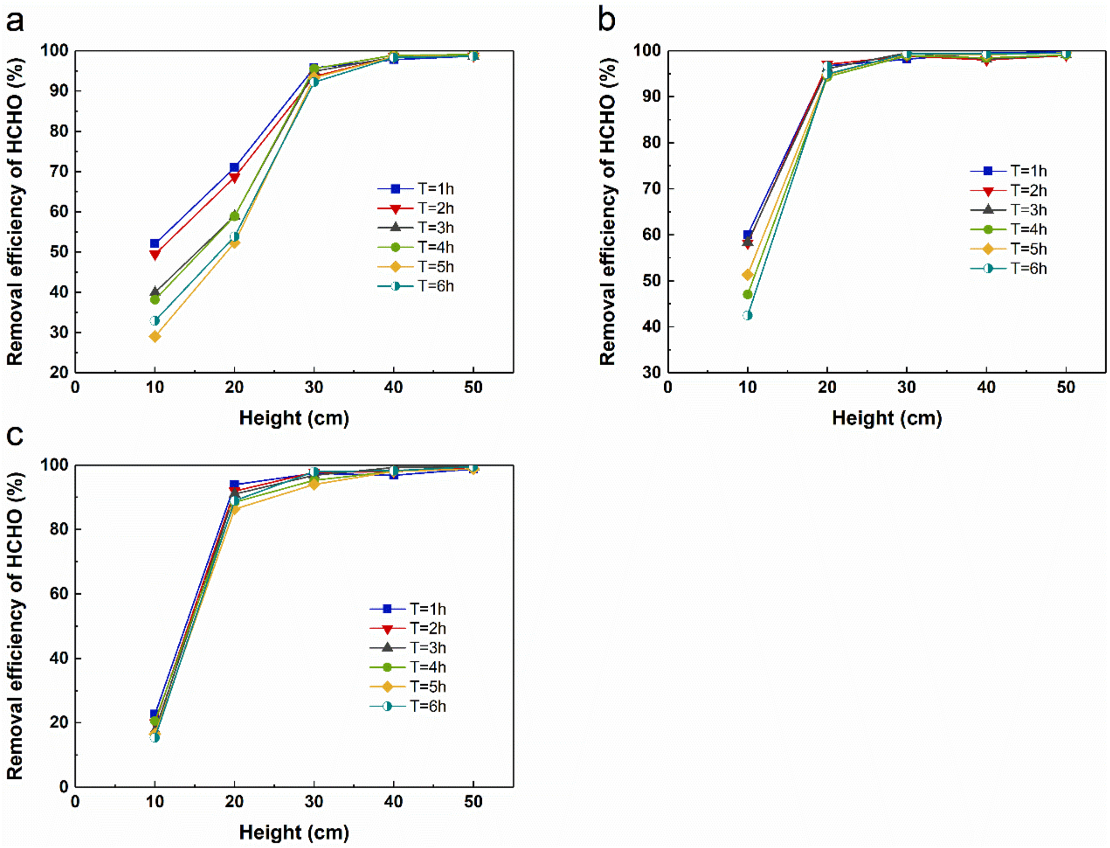

Figure 4. *Removal efficiencies of HCHO over the commercial HCHO catalysts under different reaction bed heights. (a: superficial velocity = 1.5 m/s; b: superficial velocity = 1.0 m/s; c: superficial velocity = 0.5 m/s)*

The change of removal efficiency with reaction bed height under the superficial velocity of 0.5 m/s was seen in *Figure 4c*. There was little difference at the different operation time in the same height. However, the removal efficiency of HCHO decreased when superficial velocity dropped to 0.5 m/s, only 20% or so at the height of 10 cm.

Overall, the steady state removal efficiencies of HCHO were all above 99% when the superficial velocity was 0.5, 1.0 and 1.5 m/s respectively, yet the needed height shortened with decreasing the superficial velocity, which means that superficial velocity and reaction bed height both play important roles in the catalytic oxidation for HCHO.

To further discuss the effect of reaction bed height to the HCHO destruction, experimentally measured HCHO concentration changing curves, conducted under different superficial velocities and reaction bed heights are shown in *Figure 5*. Each data point in the graph illustrates the average of outlet concentration measured when it ran for one hour.

From *Figure 5,* it is evident that HCHO concentration collected when superficial velocity was 0.5 and 1.0 m/s reduced to 0.2 ppm under the height of 20 cm. However,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50595069

HCHO concentration measured when the superficial velocity was 1.5 m/s dropped to 0.2 ppm under the height of 30 cm. With the increase of superficial velocity, the residence time and contact time reduced, which led to the fact that it decreased the removal efficiency of HCHO and needed higher reaction bed to meet the emission standard. After the contaminated air was treated under a certain value, no influence of reaction height was observed on the HCHO concentration.

From the micro-perspective, the slope of that curve represents removal rate of HCHO. According to the results, in the certain height range, the removal rate of HCHO increased with the rise of reaction bed height. When the concentration dropped to certain levels, the removal rate began to decrease rapidly and down to zero finally. This result was consistent with the variation of removal efficiency with reaction bed height.

Multivariate analysis was applied to determine the significance of height and superficial velocity which indicates that reaction bed height has important influence in the removal efficiency of HCHO ($F = 46.362 > F$ crit $= 3.326$) and superficial velocity has no reliable effect ($F = 0.969 < F$ crit $= 4.103$).

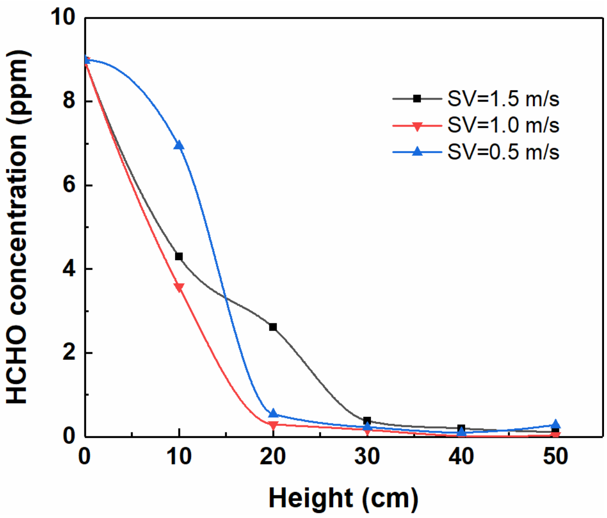

Figure 5. *HCHO concentration over the commercial HCHO catalysts under different reaction bed heights. (SV refers to superficial velocity)*

Effect of catalyst types on removal efficiency of HCHO

The effect of catalyst types on the removal of HCHO was studied to enhance the removal efficiency and improve the catalytic oxidation method. The catalytic activities of three types of catalysts were evaluated for HCHO conversion under the same superficial velocity (0.5 and 1.0 m/s respectively) as shown in *Figure 6*.

In the case of Pt/GAC catalyst, HCHO could be almost degraded into CO_2 and H_2O under both superficial velocities, whose removal efficiencies reached over 90% and the conversion did not change too much with the time increasing. However, the other catalysts showed lower effects in the same conditions. While the superficial velocity was 1.0 m/s, the commercial HCHO catalyst had a better removal effect than the MnO_x/GAC catalyst, but the conclusion was opposite when superficial velocity dropped to 0.5 m/s. As shown in *Figure 6a,* the removal efficiency of commercial HCHO catalyst dropped slowly from 60.06% to 42.52% after continuously running 6 h, while the efficiency over MnO_x/GAC catalyst fluctuated around 40%. From the *Figure 6b,* the

removal efficiency of HCHO over MnO_x/GAC catalyst at the superficial velocity of 0.5 m/s dropped dramatically from 76.42 to 37.27% within 6 h, while the efficiency over commercial HCHO catalyst changed little, always taking up 20% or so. Therefore, it can be concluded that the influence of catalyst on HCHO removal rate was related to superficial velocity. Besides, these findings illustrated that different activities of different types of catalysts depend on the different capacities for oxidizing HCHO (Zhang and He, 2007). In addition, the support makes a difference in the catalytic oxidation of HCHO at ambient temperature (Colussi et al., 2015).

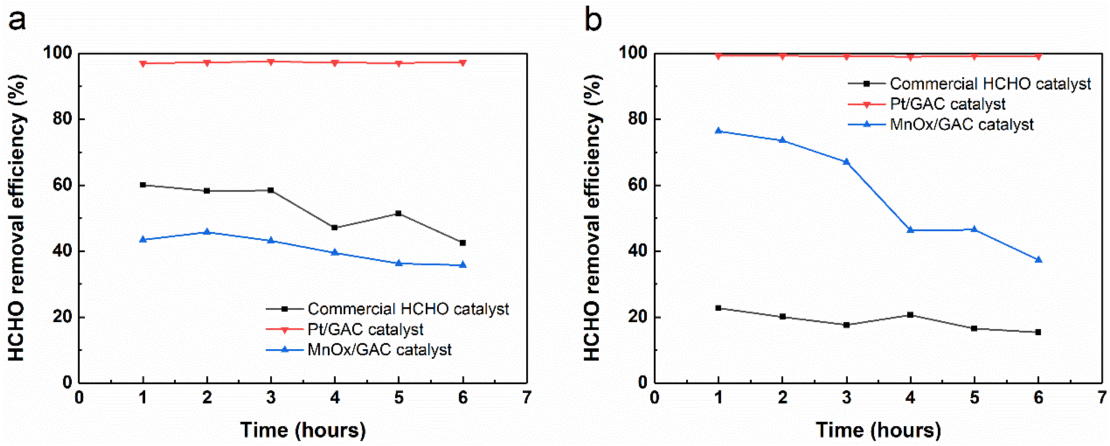

Figure 6. *Removal efficiencies of HCHO over three types of catalysts under different superficial velocities. (a: superficial velocity = 1.0 m/s; b: superficial velocity = 0.5 m/s)*

Among the three catalysts, the fact that Pt/GAC catalyst shows the effective and stable catalytic property suggests that it is a promising catalyst for HCHO oxidation, but the expensive cost blocked its application from commercialization. The commercial HCHO catalyst possessed the best economical interest and certain catalytic ability but had poor stability. There was no advantage in both the price and catalytic performance of commercial HCHO catalyst. Hence, the selection of catalyst needs to consider the effects of multiple factors such as removal performance, residence time and economy comprehensively.

Conclusions

In this study, compared with the commercial HCHO catalyst, two typical catalysts (Pt/GAC catalyst and MnOx/GAC catalyst) were studied for catalytic oxidation of HCHO at ambient temperature. Different influencing factors of catalytic oxidation on the removal efficiency such as superficial velocity, reaction bed height and the type of catalyst were investigated.

According to the results, the superficial velocity influenced the removal efficiency of HCHO, and there was an optimum value for catalytic oxidation which depends on the type of catalyst. The removal efficiency of HCHO increased firstly and then decreased with the decrease of superficial velocity. For the commercial HCHO catalyst, the removal efficiencies of HCHO from the highest to the lowest were SV = 1.0 m/s > SV = 1.5 m/s > SV = 0.5 m/s. The removal efficiency over the commercial HCHO catalyst could be enhanced by increasing the reaction bed heights.

DOI: http://dx.doi.org/10.15666/aeer/1604_50595069

HCHO concentration measured when superficial velocity was 0.5 and 1.0 m/s reduced to 0.2 ppm under the height of 20 cm, but when the superficial velocity was 1.5 m/s, the height has to be 30 cm to meet the emission standard. Among the three types of catalysts, Pt/GAC catalyst shows the effective and stable catalytic property, whose removal efficiencies reached over 90% and the conversion did not change too much with the time increasing.

Abstract. The work presents results of studies conducted from 2008 to 2011 to determine the effect of undersown catch crops, which were either autumn-incorporated or left on the soil surface as mulch for spring incorporation, on the content microelements in potato tubers cultivated in various production systems. The following two factors were examined: I. − manuring with an undersown catch crop: control, farmyard manure, white melilot, white melilot + westerwolds ryegrass, westerwolds ryegrass, white melilot applied as mulch, white melilot + westerwolds ryegrass applied as mulch, westerwolds ryegrass applied as mulch; II. − production system: integrated and organic. Potato tuber samples were taken to determine microelements. The results demonstrated that manuring of potato with undersown catch crops, in particular autumn-incorporated white melilot, increased iron, zinc and boron contents, and reduced copper and manganese contents in potato tubers. Potatoes cultivated in the integrated production system had a higher concentration of copper, manganese and zinc whereas organic tubers had more iron and boron.
Keywords: *root crop, green manure, mulch, integrated cultivation, organic cultivation, minerals*

Introduction

Potato is undoubtedly one of our most valuable crop plants and farmyard manure is the basic natural manure applied in potato cultivation. As farmyard manure production has been declining due to a decreasing number of livestock and the development of integrated and organic potato growing, alternative solutions are being sought. In these circumstances, green manures are increasing in popularity (Redulla et al., 2005; Rożyło and Pałys, 2009; Płaza et al., 2015), and undersown catch crops seem to be the cheapest source of organic matter (Płaza et al., 2017). It has been observed that they beneficially affect yields and chemical composition of potato tubers (Różyło and Pałys, 2009; Wierzbicka and Trawczyński, 2011; Płaza et al., 2017). The nutritional value of potato tubers is also determined by minerals, including micronutrients, which after digestion and absorption into the blood are used by the body as a building material or a factor regulating life processes (Wszelaki et al., 2005). In order for the human body to function properly, it must receive from the outside all the necessary micronutrients, especially iron, zinc, boron, copper and manganese. However, there is a paucity of Polish studies on the influence of undersown white melilot on the potato tuber content of microelements. Consumers expect potato producers, in particular organic potato growers, to provide more nutritious tubers, but there is still little research comparing the chemical composition of potato tubers produced in various production systems. Hence,

the need arises to conduct this type of research. The purpose of the study reported here was to determine the effect of undersown catch crops, which were either autumn-incorporated or left as mulch on the soil surface for spring incorporation, on the content of microelements in the tubers of potato grown in various production systems.

Materials and methods

A field experiment was carried out at the Zawady Experimental Farm (50°20’ N, 22°30’ E) which belongs to Siedlce University of Natural Sciences and Humanities, Poland in 2008-2011. The experimental soil was Albic Luvisol (Arenic), soil valuation class IVa. The soil contents of available minerals were as follows: P 5.29 $mgkg^{-1}$, K 11.59 $mgkg^{-1}$, Mg 5.60 $mgkg^{-1}$, Mn 114 $mgkg^{-1}$, Cu 1.8 $mgkg^{-1}$, B 0.54 $mgkg^{-1}$, Zn 7.5 $mgkg^{-1}$, Fe 654 $mgkg^{-1}$. Soil reaction was neutral and humus content amounted to 1.37%. The experiment was a split-block arrangement with three replicates. The following two factors were examined: I. − manuring with an undersown catch crop: control (no undersown catch crop manure), farmyard manure (30 tha^{-1}), *Melilotus albus* (seed sowing rate 26 $kgha^{-1}$), *Melilotus albus* + *Lolium westerwoldicum* (seed sowing rate 13 + 10 $kgha^{-1}$), *Lolium westerwoldicum* (seed sowing rate 20 $kgha^{-1}$), *Melilotus albus* applied as mulch (seed sowing rate 26 $kgha^{-1}$), *Melilotus albus* + *Lolium westerwoldicum* applied as mulch (seed sowing rate 13 + 10 $kgha^{-1}$), *Lolium westerwoldicum* applied as mulch (seed sowing rate 20 $kgha^{-1}$); II. − production system: integrated and organic.

In autumn, fresh matter yield of undersown catch crops, including their root mass to the depth of 30 cm, was determined in a 1 m^2 area in each plot. The average yields calculated across three years in the integrated and organic production systems were, respectively, 27.5 and 22.9 tha^{-1} for *Melilotus albus*, 31.7 and 25.8 tha^{-1} for *Melilotus albus* + *Lolium westerwoldicum*, and 35.4 and 27.6 tha^{-1} for *Lolium westerwoldicum*.

Table potato was preceded by spring triticale grown for grain which was undersown with catch crops. In the integrated production system, mineral fertilisers were applied to the whole experimental area in early spring. Their rates per 1 ha were as follows: 90 kg N, 36.9 kg P and 99.6 kg K. The rates were adjusted to soil availability and projected yield levels. In autumn-ploughed plots, mineral fertilisers were spread in the spring and mixed with the soil by means of a cultivator with a harrow attached to it. In mulched plots, a disc harrow was followed by a cultivator. In the organic system, instead of mineral fertilisers farmyard manure was applied at the rate of 30 tha^{-1} to the whole experimental area, and followed by spring triticale which was undersown with catch crops. Potatoes were planted in late April and harvested in mid-September. In the integrated production system, weeds, pests and diseases were controlled using mechanical practices and chemicals. Prior to emergence, potatoes were hilled and harrowed every 7 days, and just before emergence, they were sprayed with a mixture of the herbicides Afalon 50 WP + Reglone Turbo 200 SL (1 kg + 1 dm^3ha^{-1}). Colorado potato beetle and late blight were controlled by means of two applications of, respectively, the pesticide Fastac (0.1 dm^3ha^{-1}) and the fungicide Ridomil MZ WP (2 dm^3ha^{-1}). Organic potatoes were mechanically protected against weeds. Colorado potato beetle was controlled using two applications of Novodor SC (2.5 dm^3ha^{-1}), and Miedzian 50 WP (4 $kgha^{-1}$) was applied three times to keep late blight in check. During potato harvest, after 10 tuber samples were collected in each plot to analyse for microelements. Cu, Fe, Mn, Zn and B contents were determined in the dry matter of potato tubers by means of the Inductively Coupled Plasma Optical Emission

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50715080

Spectrometry (ICP-OES) at wavelength: Cu 327.393 nm, Fe 238.204 nm, Mn 257.601 nm, Zn 206.200 nm, B 249.677 nm.

Data obtained for each of the characteristics studied was analysed by means of ANOVA suitable for the split-block mathematical model, according to the model: yijl = n + ai + gj + eij (1) + bl + ejl (2) + abil + eijl (3), where a = 1.2; b = 1, 2..8; n = 1, 2, 3 (number of repetitions); yijl – value of the examined feature; ai - the effect of the i-th factor A; gj - the effect of repetitions (blocks); eij (1) - error 1 resulting from factor A interaction and repetition; bl - the effect of the 1st level factor B; ejl (2) - error 2 resulting from interaction factor B and repetitions; abil - effect of factor interaction A and B; eijl (3) - random error. When significant sources of variation were detected, Tukey test was applied to separate the means.

Results

The copper content of potato tuber

Copper content in potato tubers was significantly affected by the experimental factors and their interaction (*Table 1*). The highest copper content was recorded in the tubers of control potato. An application of farmyard manure and undersown catch crops contributed to a significant decline in the potato tuber content of copper. The highest content was recorded in the tubers of potato following autumn-incorporated white melilot. Also production system had a significant effect on the concentration of copper in potato tubers, it being higher in the tubers of potato grown using integrated farming practices than in organic tubers. An interaction between the experimental factors was confirmed. It indicated that the highest copper content was found in the tubers of control potato following mineral fertiliser only, in the integrated production system, and the lowest concentration was determined in the tubers of organic potato following farmyard manure and undersown catch crops.

Table 1. *Copper content in potato tubers depending on the manuring with undersown catch crop and production system (means over 2009-2011), mgkg^{-1} d.m.*

Manuring with undersown catch crop	Production system		Means
	Integrated	**Organic**	
Control	5.085	4.763	4.924

The iron content of potato tuber

Statistical analysis revealed a significant influence of the experimental factors and their interaction on iron content in potato tubers (*Table 2*). The lowest iron content was recorded in the tubers of potato harvested in the control unit. A application of farmyard manure and undersown catch crops resulted in a significant increase in the potato tuber content of iron. The highest concentration of this element was recorded in the tubers of potato following spring-incorporated white melilot. Iron content in the tubers of potato manured with an autumn-incorporated mixture of white melilot and westerwolds ryegrass, and white melilot left as mulch on the soil surface for spring incorporation differ insignificantly from the concentration of iron in the tubers of potato following farmyard manure. In the remaining plots, iron content was lower compared with farmyard manure. Production system significantly affected iron content in potato tubers, it being higher in the tubers of organic potato. An interaction between the experimental factors was confirmed, which demonstrated that the highest iron content was recorded in the tubers of potato manured with autumn-incorporated white melilot in the integrated and organic potato system, it being the lowest in the tubers of control potato, following mineral fertilisers only, in the integrated production system.

Table 2. *Iron content in potato tubers depending on the manuring with undersown catch crop and production system (means over 2009-2011), mgkg^{-1} d.m.*

Interaction	0.001		1.43

The manganese content of potato tuber

Manganese content in potato tubers was significantly affected by the experimental factors and their interaction (*Table 3*). The lowest concentration of manganese was determined in the tubers of control potato. An application of farmyard manure and undersown catch crops contributed to a significant decline in the potato tuber content of manganese. The lowest concentration of this element was recorded in the tubers of potato following undersown catch crops, whether they had been ploughed down in autumn or left as mulch on the soil surface for spring incorporation. Production system

had a significant influence on the potato tuber content of manganese, it being higher in the tubers of potato grown in the integrated versus organic production system. An interaction between the experimental factors was confirmed. It explains why the highest manganese content was found in the tubers of control potato, which followed mineral fertiliser only, in the integrated production system, and the lowest concentration was determined in the tubers of organic potato manured with *Melilotus albus*, regardless of when the undersown catch crop had been incorporated.

The zinc content of potato tuber

Statistical analysis demonstrated a significant effect of the factors examined in the experiment and their interaction on zinc content in potato tubers (*Table 4*).

Table 4. *Zinc content in potato tuber depending on the manuring with undersown catch crop and production system (means over 2009-2011), mgkg^{-1} d.m.*

DOI: http://dx.doi.org/10.15666/aeer/1604_50715080

The highest zinc content was recorded in the tubers of potato harvested in the control unit. An application of farmyard manure and undersown catch crops resulted in an increase in the concentration of zinc in potato tubers. The highest zinc content was determined in the tubers following autumn-incorporated white melilot. There were no significant differences between the zinc contents in the tubers of potato following farmyard manure and the remaining undersown catch crops. Production system significantly affected the potato tuber content of zinc, too. The concentration of this element was higher in the tubers of potato cultivated using integrated farming practices rather than organic management. An interaction between the experimental factors was confirmed. It explained why the highest zinc content was recorded in the tubers of potato manured with autumn-incorporated *Melilotus albus* and a mixture of *Melilotus albus* and *Lolium westerwoldicum* in the integrated production system, and the lowest concentration of zinc was in control tubers grown in both the production system.

The boron content of potato tuber

Boron content in potato tubers was significantly affected by the experimental factors and their interaction (*Table 5*).

Table 5. *Boron content in potato tuber depending on the manuring with undersown catch crop and production system (means over 2009-2011), mgkg^{-1} d.m.*

Interaction	0.001		0.087

The lowest boron content was found in the tubers of control potato. An application of farmyard manure and undersown catch crops contributed to an increase in the potato tuber content of boron. The highest concentration of this element was recorded in the tubers of potato grown in plots amended with *Melilotus albus*, whether it was autumn-incorporated or left as mulch on the soil surface for spring incorporation. Boron content in the tubers of potato following a mixture of *Melilotus albus* and *Lolium westerwoldicum* differ insignificantly from the value recorded determined in the tubers harvested in farmyard manure-amended plots. In the remaining units manured with undersown catch crops, boron content in potato tubers was significantly lower compared with the tubers of potato following farmyard manure. Production system had

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50715080

a significant impact on the potato tuber content of boron. The concentration of this element was higher in the tubers of organic potato compared with the integrated production system. There was a confirmed interaction between the experimental factors which provided an explanation why the highest boron content was recorded in the tubers of organic potato following autumn-incorporated *Melilotus albus*, and the lowest concentration was determined in control tubers, following mineral fertiliser only, in the integrated production system.

Discussion

Microelements are as important as macroelements. However, their content in potato tubers is much lower. They are components of enzymes which activate a range of biochemical processes (Różyło and Pałys, 2009; Wierzbicka and Trawczyński, 2011; Wierzbicka, 2012).

In this study, the highest copper content was determined in control tubers which were harvested in plots where only mineral fertilisers had been applied. Also Klikocka (2009) as well as Braun et al. (2011) obtained a higher copper content in the tubers of potato following mineral fertiliser. In the experiment reported here, an application of farmyard manure and undersown catch crops prior to potato cultivation contributed to a significant decline in the tuber content of copper. Trawczyński and Bogdanowicz (2007), Wierzbicka and Trawczyński (2011), Wierzbicka (2012) and Osvalde et al. (2016) found that vermicompost and green manures reduced copper content in potato tubers. Wierzbicka and Trawczyński (2011) in organic potato cultivation with the use of stubble catch crops with white mustard, field pea and serradella in irrigation conditions showed a decrease in copper content in tubers. This is in line with the results of the Wierzbicka study (2012), which investigated the copper content in potato tubers of cultivated also in the organic production system of manured with stubble catch crops without irrigation. However, in the discussed experiment a different form of green manure was used, undersown catch crop, both plowed in autumn and left to spring in the form of mulch, which in Polish conditions has not been studied so far. It was shown that manuring the potato with *Melilotus albus* also caused a decrease in copper content in tubers. The experiment was carried out in two production systems, not only in organic one, as in the studies of Wierzbicka and Trawczyński (2011) or Wierzbicka (2012).

Similarly to Hajšlovă et al. (2005) Wang et al. (2008), Hunter et al. (2011) and Sawicka et al. (2016), in the present study, copper content was lower in organic potato tubers.

In the experiment reported here, the lowest iron content was determined in control tubers, which supports findings reported by Braun et al. (2011), Hadi et al. (2014) and Ashafzadeh et al. (2017) who demonstrated that iron content was the lowest in the tubers of potatoes following mineral fertiliser only. In the current study, farmyard manure and undersown catch crops contributed to an increase in the potato tuber content of iron. It follows from the fact that farmyard manure and green manures introduce additional amounts of macroelements and microelements into the soil (Wierzbicka and Trawczyński, 2011; Płaza et al., 2017). In the experiment discussed here, tubers of organic potato following green manures and farmyard manure contained significantly more iron compared with the integrated system. Such a relationship was also observed

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50715080

in the studies by Wiśniowska-Kieljan and Klima (2007), Wierzbicka (2012) and Sawicka et al. (2016).

In the present study, the highest manganese content was determined in the tubers of control potato following mineral fertiliser only. Similar findings were reported by White et al. (2009), Braun et al. (2011), Hadi et al. (2014) and Baranowska et al. (2017). Undersown catch crops and farmyard manure applied in the experiment reported here contributed to a significant decline in the potato tuber content of manganese, which corresponds with results obtained by Redulla et al. (2005) as well as Różyła and Pałys (2009). Also Baranowska et al. (2017) demonstrated that soil conditioner application was associated with a decline in manganese content in potato tubers. In the present work, a higher manganese content was determined in the tubers of potato cultivated in the integrated versus organic production system, the finding being similar to results reported by Wszelaki et al. (2005) and Sawicka et al. (2016).

In the trial discussed here, the lowest zinc content was determined in the tubers of control potato. Also Braun et al. (2011), Hadi et al. (2014) and Ashrafzadeh et al. (2017) found the lowest concentration of zinc in the tubers of potato following mineral fertiliser. In the present study, farmyard manure and undersown catch crops, which provide potato plants with macroelements and microelements, contributed to an increase in the potato content of zinc. Trawczyński and Bogdanowicz (2007), Różyło and Pałys (2009), White et al. (2009) as well as Wierzbicka and Trawczyński (2011) have demonstrated that green manures increase zinc content in potato tubers. In this study, zinc content was higher in the tubers of potato grown in the integrated versus organic production system. A similar relationship was found by Hajšlovǎ et al. (2005), Wang et al. (2008) and Sawicka et al. (2016).

In the present work, control potatoes contained the lowest amounts of boron, which agrees with reports by Sayed et al. (2015) and Osvalde et al. (2016). Farmyard manure and undersown catch crops contributed to an increase in the potato tuber content of boron. Also Wierzbicka and Trawczyński (2011) as well as Osvalde et al. (2016) observed that green manures and vermicompost increased the concentration of boron in potato tubers. In the present study as well as in the works by Hajšlovǎ et al. (2005), Wierzbicka and Trawczyński (2011) and Wierzbicka (2012), a higher boron content was recorded in the tubers of organic potato.

In the conducted study, it was discovered that potato manuring with the form *Melilotus albus*, both plowed in autumn and left to the spring in the form of mulch, most preferably affects the content of micronutrients in tubers. Increases the content of iron, zinc and boron in potato tubers, and decreases the content of copper and manganese. Potato from the organic production system contained more iron and boron, and from the integrated production system more copper, manganese and zinc, which indicates a more favorable content of micronutrients in tubers from the organic production system.

Conclusions

1. Potato manuring with undersown catch crops, and especially with the little clover plowed in autumn, increases the content of zinc and boron iron in potato tubers, and reduces the content of copper and manganese (micronutrients of lesser nutritional importance).

DOI: http://dx.doi.org/10.15666/aeer/1604_50715080

2. Potatoes cultivated in the integrated production system were characterized by a higher concentration of copper, manganese and zinc, and cultivated in the organic production system a higher content of iron and boron.

3. In the conducted research, it was discovered that potato manuring with one year's form of *Melilotus albus*, both plowed in autumn and left to spring in the form of mulch in an ecological production system, provides the most beneficial micronutrient content in tubers.

Abstract. Industrial waste landfills might cause contamination of agricultural land, forests, surface water and groundwater through migration of toxic substances, including heavy metals, posing a threat to all living organisms, including humans. The aim of the study was to assess the variation in Cd, Pb, Zn and Cu content in plants growing on a zinc and lead post-flotation tailings dump. The concentrations of the elements in the shoots and leaves of silver birch, black locust, common rowan, herbaceous plants and soil were determined by the flame atomic adsorption spectrophotometry (FAAS) method. The statistical nalysis indicates a significant relationship between the Pb and Zn concentrations and the plant species, plant part, and location on the dump. Differences in cadmium concentrations depending on the plant species were also statistically significant. None of these relationships was significant in the case of copper content. The mean biological concentration factors (BCF) were higher in plants growing on the southern slope of the dump. Of the elements analysed, zinc and cadmium were accumulated in larger quantities than lead and copper.
Keywords: *post-flotation tailings, heavy metals, bioindicators different plant species, ore mining residues*

Introduction

Human activity is associated with the generation of waste. Its quantity increases every year as a result of continuous technological progress and the development of civilization. It should be noted that new technologies used for extraction and processing of raw materials increase the diversity of generated waste (Salihoglu, 2010; Janas and Zawadzka, 2017; Koolivand et al., 2017). By-products of human activity generated during extraction and industrial processing of raw materials are known as industrial waste. The composition and quantity of industrial waste are linked to the type of production and the specific industry. An important consideration is the environmental harm and nuisance caused by this waste. According to Eurostat data, the total amount of waste from mining and extraction activity in the EU in 2014 was 700.8 billion kg. At the end of that year, 2,123.9 billion kg of mineral waste remained deposited in landfills (Eurostat, 2017). In Poland, 31.2 billion kg of waste was generated in flotation enrichment of non-ferrous ores in 2016. At the end of that year, 635.4 billion kg of this type of waste remained deposited on landfills, of which 38.4 million Mg was in sites located in Małopolska (PCSO, 2017). Industrial and post-industrial sites are found all over the world, and more attention and research should be devoted to them due to the threat they pose to the environment (Grattan et al., 2003; Pyatt et al., 2000, 2005; Stefanowicz et al., 2014; Teršič et al., 2009; Alloway, 2013). Industrial waste landfills could cause contamination of agricultural land, forests, surface water and groundwater through the migration of toxic substances, including heavy metals, thereby posing a threat to all living organisms, including humans

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50815094

(Tordoff et al., 2000; Wong, 2003; Klojzy-Kaczmarczyk et al., 2005). Heavy metals can persist in high concentrations for decades or even millennia. Their transport to agricultural soils, sediments and watercourses occurs gradually and is associated with high levels of pollution of the natural environment. None of the technologies currently in use completely protects the environment from the negative impact of landfills. Both external factors (topography, microclimate conditions, vegetation or type of protective barrier) and internal ones (deposition technology, physical and chemical properties of the waste, or means of protecting the substrate) affect the type and degree of the nuisance, as well as the amount of pollutants coming from a given site (Michałkiewicz, 2009; Adeolu et al., 2011). The aim of the study was to evaluate the variation in cadmium, lead, zinc and copper concentrations in plants growing on the reclaimed Trzebionka zinc and lead post-flotation tailings dump and to analyse factors generating this variation.

Material and methods

Study location

The research area was the reclaimed zinc and lead post-flotation tailings dump of the former “ZG Trzebionka S.A” (*Fig. 1*). Mining Plants, located on the administrative border of the Chrzanów and Trzebinia communes, in the western part of the Małopolska Voivodeship, south of Poland (Klojzy-Kaczmarczyk et al., 2012).

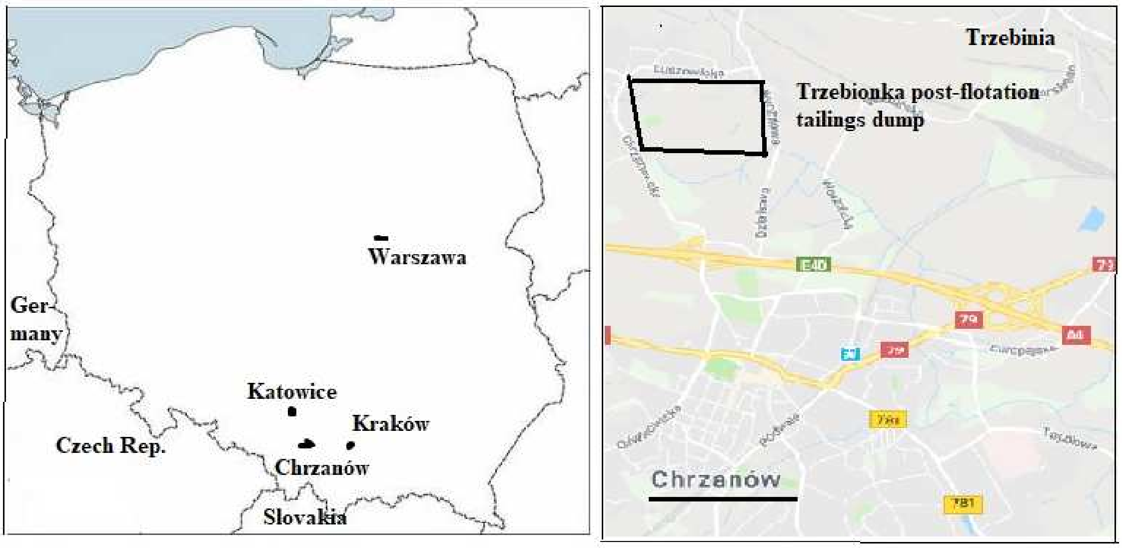

Figure 1. *Localisation of research area within the border of Poland (European Union)*

The dump, which was established in 1966, is one of the largest ponds collecting tailings from the production of zinc and lead ore concentrates in Poland. It covers an area of about 64 ha and rises about 60 m above the ground, and the surface of its crown is 20 ha. Waste was transported in the form of an aqueous suspension of finely ground dolomite with zinc and lead carbonates and sulphides with a particle size of less than 0.2 mm. The content of Zn and Pb was low – 0.92% and 0.41%, respectively. The bottom of the pond consists of concentrated and compact sediments whose

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50815094

average particle size decreases towards the centre (Klojzy-Kaczmarczyk et al., 2005; Nowak, 2008). During deposition, the coarsest fraction of the tailings was used to build the embankments by means of clay grouting, the finest fraction was used to seal the bottom of the pond, and the rest was placed inside the pond, where the solids underwent sedimentation. The finest waste covered the outermost layer on the crown, and when operation of the landfill was discontinued, the tailings dump underwent reclamation (Neya, 1997; Klojzy-Kaczmarczyk et al., 2009, 2012). The reclamation work consisted in covering the active surface of the dump with latex and creating a sprinkler system (measures to reduce airborne dust), covering the slopes with humus, planting trees and shrubs, sowing grass and legumes, application of stabilized sewage sludge, and pumping water to the irrigation system (the pond was drained prior to reclamation of the top). Vegetation for reclamation was chosen taking into account the difficult conditions (Klojzy-Kaczmarczyk et al., 2009, 2014).

Sampling and analyses

The research material was obtained by moving about the dump study area from the base of the embankment to the crown and collecting samples in three characteristic research areas (the base of the embankment, the middle of the embankment and the crown of the dump), on the south-west and north-east slopes. Three sampling plots were selected for each research areas. Each sampling plot was an area of about 100 m^2, from which we collected five primary samples of the shoots of herbaceous plants and the shoots and leaves of trees – silver birch (*Betula pendula* Roth), black locust (*Robinia pseudoacacia* L.), and common rowan (*Sorbus aucuparia* L.), as well as soil samples. Following homogenization, these samples constituted an average sample of about 1000 g fresh matter in the case of the plants, and about 500 g in the case of soil. The aerial parts of the plants were collected using stainless steel secateurs, and the soil samples were collected using a soil sampler from a depth of 0–0.1 m. After air-drying, the plants were ground in a high-speed rotor mill.

The collected soil samples were dried and then sifted through a sieve with a 1 mm mesh. In soil prepared this way, basic soil properties were determined: pH in 1 mol KCl by the potentiometric method, content of organic carbon using annealing method (Ostrowska et al., 1991). Besides that, total concentrations of cadmium, lead, zinc and copper along with forms of these elements extracted with 1 mol dm^{-3} HCl. Dry mineralization was performed using a mixture of concentrated HNO_3 and $HClO_4$ for plant material (Ostrowska et al., 1991; Haluschak, 2006). Concentrations of cadmium, lead, zinc and copper were determined by atomic flame absorption spectrometry, using a Unicam Solaar M6 spectrometer. Samples were collected at late summer 2017 year.

The migration conditions of trace elements in the soil–plant system were analysed based on the bioaccumulation factor (BCF) (Nannoni et al., 2016; Li et al., 2007; Marchiol et al., 2013), which illustrates the average ability of plants to accumulate metals from the soil and is calculated as the ratio of the metal concentration in the plant to the metal content of the soil. BCF values greater than 1 indicate high accumulation of metals in the plant, values from 0.1 to 1 indicate moderate accumulation, 0.01 to 0.1 – low accumulation, and below 0.01 – no accumulation (Laskowska and Wiechuła, 2015; Marchiol et al., 2013; Łaszewska et al., 2007). In addition, the coefficient of specific relative accumulation (CSRA *Eq. 1*) was calculated as the quotient of the concentration of a given element in a given plant and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50815094

the content of this element in other plant species present in the area (Stawinoga et al., 2007).

$$CSRA = \frac{c_r}{c} \quad [-] \qquad \text{(Eq.1)}$$

where:
c_r – mean quantity of element in the plant
c – mean quantity of element in all plant species present in the area

The Shapiro–Wilk test showed that the variables did not have normal distribution, so a generalized linear model was used for Poisson distributions to test the relationship between the plant species (black locust, silver birch, rowan and herbaceous plants) and plant part (leaves or shoots) and the location on the landfill (side) and height (base of the embankment, middle or crown). Statistical analyses were performed in Statistica 12.0 software.

Results

In the present study, cadmium content ranged from 0.14 mg·kg^{-1} to 4.49 mg·kg^{-1}, with the lowest content in the rowan and successively higher content in the black locust, silver birch and herbaceous plants growing on the crown of dump on the north-east side. In most of the samples, this metal was accumulated mainly in the leaves of the plants *(Figure 2a)*. An exception was the black locust growing on the middle of the embankment on the south-west side, which had higher cadmium content in its shoots, amounting to 1.05 mg·kg^{-1} (*Table 1*). The cadmium concentrations were also higher in the shoots of the rowan trees growing on the base and crown of the embankment on the north-east side: 0.63 mg·kg^{-1} and 0.21 mg·kg^{-1}, respectively (*Table 2*). Among all the trees, the rowan had the lowest mean cadmium content, similar on all sampling plots, in both the leaves (0.16 mg·kg^{-1}–0.54 mg·kg^{-1}) and the shoots (0.18 mg·kg^{-1}–0.63 mg·kg^{-1}). In silver birch, irrespective of the sampling location, the cadmium content was similar and higher than in the other trees (0.91 mg·kg^{-1}–1.93 mg·kg^{-1}) (*Figure 2a*). The highest variation in this metal was recorded in the herbaceous plants – 89%, followed by the black locust shoots – 55%, and the lowest in the black locust leaves and silver birch leaves – 3%. The analysis confirms statistically significant variation in the content of this element in the plant species tested *(Figures 2a* and *3a (p < 0.001); Table 3)*.

* $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$, ns = not significant

The variation in cadmium concentrations in the plants was associated to a lesser degree with the height gradient (*Figure 3a; p < 0.01*). No statistically significant

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50815094

differences were found in the content of this element in the plant parts or its content in the substrate depending on the research (slope) area where the samples were taken.

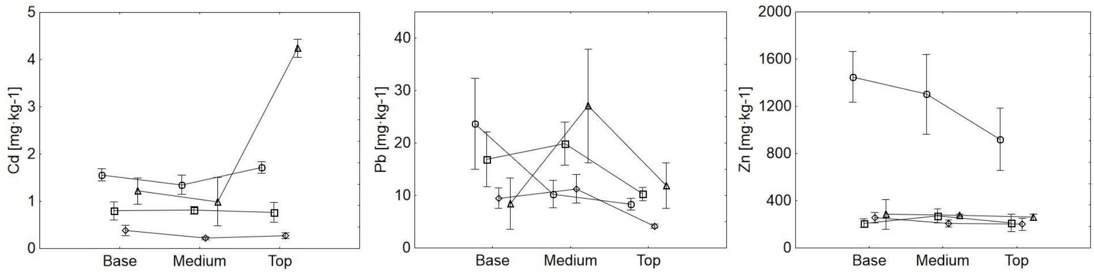

Figure 3. *Distribution of mean heavy metal concentrations in the plants: silver birch (circles), black locust (squares), common rowan (diamonds) and herbaceous plants (triangles)*

The lead content in the vegetation growing in the study area ranged from 3.0 mg·kg^{-1} (north-eastern part, base of embankment, herbaceous plants) to 39.5 mg·kg^{-1} (south-western part, middle of the embankment, herbaceous plants). The highest coefficient of variation on the south-west slope was found for the herbaceous plants (49%) and black locust shoots (47%), and on the north-east side also for the herbaceous plant samples (60%), as well as for the shoots of silver birch (79%). In most of the samples, on both the south-west and north-east embankments, the shoots accumulated higher lead content. In the case of herbaceous plants, rowan, and black locust, higher lead content was found in the middle of the embankment on the south-west slope than in the other sampling plots. Moreover, as the height increased, the metal content decreased in silver birch (base > middle > crown). On the north-eastern embankment, the concentration of lead in silver birch and black locust decreased in this order: base > middle > crown of embankment. The rowan and herbaceous plants collected from the middle of the embankment had higher content of this metal in comparison with the other sampling plots (the base and crown of the embankment). The analysis confirms a statistically significant relationship between the Pb concentration and the plant species, plant part, and location on the landfill (both the side of the slope and the height) *(Figures 2b* and *3b (p < 0.001); Table 3)*. The zinc content on the Trzebionka post-flotation tailings dump ranged from 96.5 mg·kg^{-1} (south-west side, crown, black locust shoots) to 2226.6 mg·kg^{-1} (south-west, middle, silver birch leaves). On the southern slope, the highest variability in the content of zinc was observed in the shoots of black locust (73%). On the northern embankment, the highest variability was recorded for common rowan (42%). In the silver birch and black locust trees growing on the north-east embankment, higher concentrations of this element were found in the leaves. The reverse was true in the case of rowan, in which the shoots contained higher amounts of zinc. A similar tendency was noted in most of the samples collected on the south-west slope. The analysis confirmed the statistically significant impact of the sampling location, plant species and plant part on the content of this metal *(Figures 2c* and *3c (p < 0.001); Table 3)*. Copper content in all plants was similar on individual sampling plots and ranged from 2.91 mg·kg^{-1} (south-west, middle of embankment, black locust shoots) to 6.58 mg·kg^{-1} (south-west, crown, rowan shoots). In most of the samples in the study area, this element was stored mainly in the shoots. There was also an increase in the content of this metal in the herbaceous plants along the height transect, from 3.08 mg·kg^{-1} to 4.48 mg·kg^{-1} on the south-west embankment and 5.38 mg·kg^{-1} to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50815094

6.30 mg·kg^{-1} on the north-east side. The highest coefficient of variation for the south-west side of the landfill was 27% for rowan shoots and 25% for black locust shoots, while for the north-east side of the site it was 13% for silver birch shoots. This element showed the least variation of all metals analysed. The statistical analysis did not indicate a significant relationship between the plant species, plant part or location on the landfill and the content of this metal *(Table 3)*.

Discussion

Areas where waste is deposited are usually unfavourable substrates for plant growth, due to the lack of organic matter, unsuitable pH, high concentrations of toxic metals, high salinity, low water retention capacity, low nutrient content, lack of micro-organisms, poor physical structure and susceptibility to erosion (Krzaklewski and Pietrzykowski, 2002; Szarek-Łukaszewska and Niklińska, 2002; Wong, 2003; Ye et al., 2002). These properties exert strong selective pressure on colonization by plants, and consequently the waste is often completely devoid of vegetation or exhibits a specific and unique composition of plant species spontaneously appearing there (Woch et al., 2016).

Nadgórska-Socha et al. (2016) tested the efficiency of accumulation of trace elements in black locust leaves. The research was carried out in areas contaminated with heavy metals and the results were compared to uncontaminated areas. The results indicated that this species can grow in metal-contaminated areas and that the contamination affects the physiological parameters of the plant. The average content of elements in the black locust leaves from the Trzebionka dump was 0.89 mg·kg^{-1} for Cd, 11.92 mg·kg^{-1} for Pb, 271.0 mg·kg^{-1} for Zn and 3.65 mg·kg^{-1} for Cu. In the immediate vicinity of the Miasteczko Śląskie Zinc Smelter, Nadgórska-Socha et al. (2016) reported concentrations of 3.01 mg·kg^{-1} for Cd, 17.69 mg·kg^{-1} for Pb, 109.64 mg·kg^{-1} for Zn, and 13.11 mg·kg^{-1} for Cu. As in our research, the levels of Cd accumulated in the trees were the lowest; Cu, Pb and Zn were accumulated in higher concentrations. Hu et al. (2014) also assessed the content of heavy metals in various plant species, including black locust, in an industrial region, in a residential area, and by a motorway. The concentrations of elements differed depending on the plant species and on the sampling site. The highest concentrations were recorded near the motorway and in the industrial area. The authors presented the mean content of Cd (1.10 mg·kg^{-1}), Pb (4.55 mg·kg^{-1}), Cu (3.88 mg·kg^{-1}) and Zn (5.18 mg·kg^{-1}) for black locust. The concentrations for Pb and Zn were very different from the results obtained in our study, but are arranged in the same, the most common hierarchy of accumulation: Cd < Cu < Pb < Zn. The results obtained by Hu et al. (2014) and from the Trzebionka dump indicate that the black locust accumulates lower content of harmful substances than other analysed plant species. Tzvetkova and Petkova (2015) examined black locust leaves in industrial regions of Bulgaria in order to determine the accumulation characteristics of this tree and to evaluate it as a biomonitor of heavy metal pollution. The study was carried out on plantations near the industrial area of Devnya in eastern Bulgaria, which is heavily contaminated by cement plants, nitrogen fertilizers and polyvinyl chloride factories. The leaves of damaged and control plants were tested. The concentrations of heavy metals were higher than those obtained in the Trzebionka tailings dump for lead (30.7 mg·kg^{-1}) and copper (17.2 mg·kg^{-1}); the exception was zinc, with a concentration of 19.0 mg·kg^{-1}. The authors showed that the black locust leaves accumulated Pb, Zn and Cu as the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50815094

concentration of these metals increased in the soil. The average content of heavy metals in the rowan tree leaves (*Sorbus aucuparia*) was 0.31 $mg \cdot kg^{-1}$ for Cd, 6.23 $mg \cdot kg^{-1}$ for Pb, 4.20 $mg \cdot kg^{-1}$ for Cu, and 215.00 $mg \cdot kg^{-1}$ for Zn, while the concentrations in the shoots were 0.27 $mg \cdot kg^{-1}$ for Cd, 10.38 $mg \cdot kg^{-1}$ for Pb, 4.73 $mg \cdot kg^{-1}$ for Cu, and 229.7 $mg \cdot kg^{-1}$ for Zn. In comparison with other trees, this species did not accumulate the highest heavy metal concentrations. Woch et al. (2017), who carried out research on waste heaps left by historical Zn-Pb mines, reported that rowan was one of the most common trees in the contaminated area. The authors also state that such areas have diverse species of woody vegetation. Compared with other tree species, silver birch (*Betula pendula*) shows much greater affinity for zinc, accumulates high concentrations of heavy metals – above the average values given for plants in the literature, and grows rapidly, even in areas with difficult conditions. This is an example of the features necessary in a species suitable for phytoremediation. Research on this species has been carried out by Wisłocka et al. (2006), Margui et al. (2007) and Dmuchowski et al. (2012, 2014). Dmuchowski et al. (2014) conducted work to assess the suitability of silver birch for phytoremediation of zinc contaminated soils. The trees grew on contaminated metallurgical waste heaps and under control conditions. The study showed the potential of this species to accumulate large amounts of zinc in the leaves in both controlled and polluted environments. The authors conclude that silver birch is a species that meets the requirements for plants used for phytoremediation and can be used to clean a zinc contaminated substrate. The analysis showed that in the environment contaminated with zinc, the soil near the trunks of *Betula pendula* contained much less of the heavy metal than the soil at a distance of 7 m. Dmuchowski et al. (2014) suggested that *Betula pendula* can be included among zinc hyperaccumulators. Analysis of the results of our research indicates that silver birch has the capacity to store large amounts of zinc (2226.5 $mg \cdot kg^{-1}$ in leaves collected from the middle of the embankment on the south-west slope). It should be noted here that among all substrate samples, the lowest Zn content was found in a sample from the middle of the slope on the south-west side of the landfill. Dmuchowski and Sołtykiewicz (2007) reported that the leaves of silver birch contained on average from 300 $mg \cdot kg^{-1}$ (Białowieża Forest) to 1344 $mg \cdot kg^{-1}$ of zinc (waste heap of a non-ferrous metal smelter near Olkusz), and in their final conclusion classified the tree as a zinc hyperaccumulator. On the Trzebionka dump, the silver birch leaves accumulated much higher concentrations of this metal (from 1172.3 $mg \cdot kg^{-1}$ to 2226.5 $mg \cdot kg^{-1}$), thus allowing the species to be counted among hyperaccumulators that can be used in soil phytoremedation processes in areas enriched with trace elements (Krzciuk, 2015). The mean content of zinc in silver birch on the Trzebionka dump was 1670.48 $mg \cdot kg^{-1}$ in the leaves and 666.63 $mg \cdot kg^{-1}$ in the shoots, which were the highest values among the plants analysed. Marguí et al. (2007) determined the content of zinc in silver birch in an abandoned lead-zinc mining area in northern Spain. To ensure maximum metal accumulation, the samples were collected in autumn, as in the present study. The concentration of zinc was also high, ranging from 1660 to 3100 $mg \cdot kg^{-1}$, while the sample from the control area contained 225 $mg \cdot kg^{-1}$ Zn. Chaabani et al. (2017) conducted research on the content of Pb, Zn and Cd in various species of herbaceous plants found on the site of former zinc and lead ore mines in northern Tunisia. The concentrations of these elements reported in the aerial parts of the plants were in the following ranges: Cd 0.3–886 $mg \cdot kg^{-1}$, Pb 2.2–341 $mg \cdot kg^{-1}$, and Zn 30.1–1048.5 $mg \cdot kg^{-1}$. The maximum concentrations of cadmium and lead are many times

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50815094

higher than those found in our study. However, it should be noted that the soils in those locations also have extremely high concentrations of these elements. Wójcik et al. (2014) analysed the content of heavy metals in the shoots of 38 species of herbaceous plants found on mining and metallurgical waste landfills. Zinc in the shoots of the plants ranged from 59.24 to 901.5 mg·kg^{-1}, lead from 3.23 mg·kg^{-1} to 116.92 mg·kg^{-1}, and cadmium from 0.54 mg·kg^{-1} to 26.86 mg·kg^{-1}. In this case as well, the maximum concentrations of these elements were significantly higher than in our research. Bech et al. (2012) report the following average concentrations for the stems of herbaceous plants growing on the site of an antimony mine in the eastern Pyrenees: for Pb 3.3–289 mg·kg^{-1}, Zn 17–81 mg·kg^{-1}, Cu 12–36 mg·kg^{-1}, and Cd < 0.1–0.2 mg·kg^{-1}. One of the factors influencing the accumulation of heavy metals in plants is their species. Calculations of coefficients such as the enrichment factor and translocation factor are used to obtain information on the suitability of plants for removing metals from contaminated soil. Plant testing can be used in remediation of contaminated soils, e.g. by lead and zinc. In addition, among a set of analysed species we can choose the ones that are suitable for reclamation and those that are candidates for stabilization of metals in the soil and for soil protection (Kirat and Aydin, 2015; Zhao and Duo, 2015). Zhao and Duo (2015) draw attention to the risk of heavy metals returning to the environment in the phytoextraction process. According to the authors, shoots of plants with accumulated harmful substances should undergo appropriate recovery and treatment. Neither the herbaceous plants nor the trees included in the study accumulated Cd, Pb, Zn and Cu intensively (BCF < 1). The silver birch and herbaceous plants had a moderate biological concentration factor (0.1 ≤ BCF ≤ 1.0) for Cd and Zn. Black locust and rowan growing on the middle of embankment and on crown of the on the south-west side had moderate zinc biological concentration factor. Regarding lead content, it should be noted that the herbaceous plants on the south-west embankment of the landfill had a low level of bioaccumulation of this metal (0.01 ≤ BCF ≤ 0.06). Bioaccumulation of this element was also low in the silver birch (0.01 ≤ BCF ≤ 0.03) and black locust (0.01 < BCF < 0.02) growing at the base and middle of the embankment on the same side. On the north-east side, weak accumulation of lead (BCF = 0.02) was found in a couple of samples of silver birch and black locust growing at the base of the embankment, but no accumulation of this metal (BCF ≤ 0.01) was noted in the remaining plants. Regarding copper content, accumulation of this element was weak in all tested plants growing on the southern side of the embankment: herbaceous plants (0.03 ≤ BCF ≤ 0.06), silver birch (0.05 ≤ BCF ≤ 0.08), black locust (0.04 ≤ BCF ≤ 0.07) and common rowan (0.03 ≤ BCF ≤ 0.08). On the north side, copper accumulation was weak in herbaceous plants growing in the middle of the embankment and on the crown (BCF = 0.02).

Higher mean values for the biological concentration factor were found in plants growing on the south-west slope of the dump. Of the elements analysed, zinc and cadmium were accumulated in greater quantities than lead and copper. Comparison of BCF valuesbetween plants reveals that the silver birch trees and herbaceous plants had higher average values for this factor than the black locust and rowan *(Table 4)*. To determine the selective metal accumulation capacity, the coefficient of specific relative accumulation (CSRA) was calculated. This coefficient can be used to categorize plant species according to their ability to accumulate individual elements (Łaszewska et al., 2007; Parzych et al., 2016). Furthermore, calculation of this coefficient enables a more complete illustration of the problem of metal accumulation, as it provides information

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50815094

relating to other plants growing in a given area (Stawinoga et al., 2007). Comparison of the CSRA coefficients for the plant species included in the study shows that silver birch had the highest zinc accumulation capacity (CSRA = 2.39 and 2.33), while the herbaceous plants had the highest capacity to accumulate cadmium (CSRA = 2.02 and 2.04). In the case of lead, the greatest storage capacity was found for the herbaceous plants on the southern slope (CSRA = 1.87) and for black locust (CSRA = 1.80) and silver birch (CSRA = 1.63) on the north-east slope. In the case of copper, the CSRA values were similar (0.80-1.33). It can also be seen that the rowan trees had the lowest capacity to accumulate Cd, Pb, Zn and Cu.

Table 4. *Comparison of mean BCF values on the northern and southern embankments of the dump*

Conclusions

The variation in accumulation of the investigated metals between the analysed plant species, plant parts, and locations on the landfill is particularly evident in the case of lead and zinc. These features are less significant in the case of the distribution of cadmium and copper concentrations. Neither the herbaceous plants nor the trees included in the study showed intensive accumulation of the metals tested (BCF < 1). Higher mean values for the bioaccumulation factor were found for plants growing on the south-west slope of the post-flotation tailings dump. Among the species analysed, rowan (*Sorbus aucuparia*) accumulated smaller amounts of metals than the other plants, while silver birch (*Betula pendula*) showed the capacity for hyperaccumulation of zinc, which confirms that it is a suitable species for reclamation processes.

Abstract. Water resources are facing nowadays with two main problems: climate change and land cover variation. Their influences on environment and water resources have been evidenced worldwide. In this work, we have applied a complex methodology based on Geographical Information System (GIS) to combine the spatial information of several parameters that allow to obtain the groundwater vulnerability under climate and land cover modifications. The spatial analysis performed in this paper includes the aquifers, water availability, load pollution index, and infiltration map raster grids data of Carpathian Mountains area, from Central Europe. The analysis presented in this study follow three periods, which include 30 years climate data models of 1961-1990 (1990s), 2011-2040 (2020s), and 2041-2070 (2050s). Land cover projections forecast future changes in artificial areas, agriculture areas, and forest areas for 2020s and 2050s. For both periods (2020s and 2050s), the very low vulnerability class area is reduced while the high class appears on a large area. The worst scenario is forecasted for 2050s (high vulnerability class increase up to 2.41% of the whole study area) and is mainly due to agriculture. These findings evidence the negative impact of land cover and climate changes on the groundwater resources in the Carpathians Mountains area. The original maps carried out in this work together with the concise methodology integrated in GIS may be a useful tool for the water resources management and future strategies plans of this region.

Introduction

Groundwater represents the most important freshwater resources for human purposes. Several authors highlighted the influence of climate and land cover changes occurred in the last decades on groundwater, both in term of quality and quantity. In particular, severe impact took place in Mediterranean countries and South-central Europe. Galleani et al. (2011), Čenčur Curk et al. (2014), Nistor et al. (2015) signalled the negative effect of climate change on groundwater. Kløve et al. (2014) illustrated the negative impact of climate changes on the related ecosystems. The recent climate warming (Haeberli et al., 1999) indicates negative effects on the natural and semi-natural places (Nistor and Mîndrescu, 2017). Due to climate change, in the next decades the mean annual temperatures are expected to increase (IPCC, 2001) and several models indicate rise of temperature during the 21st century (IPCC Assessment Report 5, 2013; Stocks et al., 1998; Shaver et al., 2000; Stavig et al., 2005; The Canadian Centre for Climate Modelling, 2014). Aguilera and Murillo (2009), Jiménez Cisneros et al. (2014), Kløve et al. (2014) signalled several problems that appeared in the biodiversity and surface waters depletion related to climate change. In the temperate zone of South Europe and Turkey, the precipitation amount will reduce (Čenčur Curk et al., 2014; Cheval et al., 2017; Nistor and Mîndrescu, 2017). The dynamics of the land cover and the human activities at continental scale are going to affect the water resources, which are sensitive to urbanization, agricultural lands' exploitations, and improper forest management, e.g. deforestation, chaotic building in the forest proximity. With respect to the decrease of precipitation, the groundwater recharge is influenced from quantity point of view (Nistor et al., 2015). On other hand, the possibility of rainfall intensity increase will affect directly the infiltration rate on short-term period.

The temperature pattern together with the land cover contribute at the evapotranspiration processes taking place on the recharge areas. In the central and eastern Europe, the Carpathian Mountains area represents a precious reservoir of water resources, especially for many establishments of the region, but also for the large cities located out of the Carpathians, such as Bucharest and Cluj-Napoca. Moreover, the studies show that the crop evapotranspiration (ETc) increase from the past period to 2050s (Nistor et al., 2016) and the deforestation of the several sectors in the Carpathian Mountain area could damage the regime of watershed basins.

The goal of this work is to define the most sensitive layers for groundwater at climate change and cover modifications on long-term and to generate the spatial analysis for groundwater vulnerability in the Carpathian Mountains area. We used high-resolution climate models of mean annual air temperature, mean annual precipitation, and annual ET0 for 1990s, 2020s, and 2050s periods and the CORINE land cover dated from 2010 (World Land Cover 30m) and three projections for 2050s. In addition, the aquifers layer of the study area and the digital elevation model (DEM) were integrated in the methodology of the paper. Thus, the determination of groundwater vulnerability in the study area is based on a spatial analysis by weights using ArcGIS environment.

Following the method of Nistor et al. (2015), tested in a small area of the Beliş district from Apuseni Mountains, our approach and obtained results are reliable at large scale, being important instruments for the panning of this large mountain area.

Materials and methods

Study area

The Carpathian Mountains area extends from 44°28’ to 49°51’ N and from 18°00’ to 26°46’ E (*Fig. 1*). The geographical position in the central part of Europe and the large natural sectors of these mountains makes the Carpathians to be the most important ecosystem from this side of the continent (Nistor et al., 2016). Here, we simply defined the Western Carpathians in the northwestern side of the study area, the eastern Carpathians mainly in Romania and Ukraine, and Southern Carparthians. In addition, we highlighted the Curvatures Carpathians and Apuseni Mountains as two units used in the paper for descriptions and toponymy points of view. Moreover, the analysed area represents a significant source of drinking water with valuable aquifers (e.g. highly productivity fissured aquifers, highly productive porous aquifers). In base of the geomorphology present in the region, the orography of the Carpathians is much diversified and could be reflected in the runoff pattern and infiltration processes. The elevations ranges mainly from 300 m in depression and valleys to 2642 m in Gerlachovský Peak from Slovakia. The geology of the territory is complex and could be easier reflected into the aquifers composition. The main geological formations are represented by gneisses, mica schists and amphibolites in the Southern Carpathians and by marlstones, limestones, clays, marls, sandstones and sands in the Curvatures Carpathians and Eastern Carpathians. Pyroclastic rocks, volcanic rocks, marlstones, dolomitic limestones, gravels and clays are presented in the Western Carpathians and Apuseni Mountains. *Figure A1* in the *Appendix* (BGR and UNESCO, 2013) shows the geological formations of the Carpathian Mountains area. In base of the BGR and UNESCO (2013) map, the aquifers types are divided in six categories of productivity: highly productive fissured aquifers, highly productive porous aquifers, low and moderately productive fissured aquifers, low and moderately productive porous aquifers, locally aquiferous rocks - porous or fissured, practically non-aquiferous - porous or fissured. *Table 1* indicates the aquifers types in the Carpathian region area.

The climate of the study area has oceanic influences in the West and North-West, Baltic influence in the North and Mediterranean influence in the South-West. According to the Köppen–Geiger climate classification, the Carpathian Mountains area has Dfb climate in the main part pf territory, with fully humid climate and warm summers (Kottek et al., 2006). In the eastern sectors of the Romanian and Ukrainian Carpathians, in the central parts of the Slovakian Carpathians and in South Poland, the study area have a Dfc climate type, characterized by fully humid precipitation conditions and cool summers (Kottek et al., 2006). During the 1990s, the mean annual temperature in the study area ranged from –3.1 to 11.4 °C (*Fig. 2*). The precipitation pattern shows values between 546 mm to 1695 mm year^{-1} during 1990s (*Fig. 2b*). The annual ET0 in the Carpathian Mountains area ranged from 279 mm up to 548 mm during 1990s (*Fig. 2c*).

The land cover of the Carpathian Mountains area is composed at high elevations (over 1000 m asl) by forest and pasture (coniferous, mixed and broad-leaved forests), the valleys and depressions are covered by agricultural cultivated lands, villages and also cities. The cities and rural localities compose the artificial areas in the Carpathian mountain region. For groundwater vulnerability determination, the land cover has a quantitative role with respect to the evapotranspiration and water availability and a qualitatively role due to the phosphorous and load pollution present in each type of land cover.

Climate data

High spatial-resolution data (1 km^2) in three periods (past – 1961-1990, present – 2011-2040, and future – 2041-2070) of monthly mean precipitation, monthly ET0, and annual ET0 were used in this study to carry out the water availability. The climate models of temperature and precipitation were developed and validated for whole Europe (Hamann et al., 2013).

Regarding the source of base dataset and type of meteorological stations, as well as the number of stations included in the normal period (1961-1990), we would like to mention that the data used in this paper is online available (http://www.cru.uea.ac.uk/) and it belong to the CRU TS 2.1 project (Mitchell and Jones, 2005). The dataset contains mean monthly precipitation and mean, minimum, and maximum monthly temperature and it were quality controlled and checked for inhomogeneities (New et al., 1998). For Europe, gridded climatological data, at finer spatial resolution of 0.5° lat X 0.5° long, were constructed using surface observations from about 1644 stations for temperature (344 for mean monthly temperature, 647 for minimum monthly temperature, and 653 for maximum monthly temperature). For the precipitation gridded data were used about 1333 meteorological stations.

The models performed by Hamann et al. (2013) were done in base of Parameter Regression of Independent Slopes Model (PRISM) for precipitation and ANUSplin for temperature, considering the Representative Concentration Pathway (RCP) of 4.5 for emission, which means a moderate climate changes projection, based on a globally predicts of +1.4 °C (±0.5). The ANUSplin interpolation procedure is in line with Mitchell and Jones (2005). In the climate models creation ClimateEU v4.63 software was used, available on the website (http://tinyurl.com/ClimateEU). The base-dataset is in principle described by Wang et al. (2016) in their study about historical and future climate in North America (https://sites.ualberta.ca/~ahamann/publications/pdfs/Wang_et_al_2016.pdf).

The climate models represent an ensemble average of 15 AOGCMs, consider the CMIP5 multi-model dataset accordingly IPCC Assessment Report 5 (2013). To represent the main clusters of similar AOGCMs, the individual models were selected (Knutti et al., 2013). The chosen of these models was based on the high validation statistics in the CMIP3 equivalents (Scherrer, 2011). The models which compose the ensemble average of AOGCMs are reported in the *Table 1*.

The bilinear interpolation was used to correct the artefacts in the AOGCM grid cells, for the adjacent areas. A Change Factor (CF) method for the GCM results have been

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50955116

applied instead the bias correction. The methodology of the climate models is in line with Daly (2006). Moreover, the models were validated and described by Hamann and Wang (2005), Mbogga et al. (2009), Wang et al. (2016), Dezsi et al. (2018). At the continental and regional scales, the evapotranspiration studies were completed by Nistor (2018a, b) and Nistor et al. (2018).

Aquifers data

The Carpathian Mountains area has a diversified geology, composed by clays, conglomerates, metamorphic, limestones, carbonated, and plutonic rocks (*Fig. A1*). Accordingly to the geological compositions, the International Hydrogeological Map of Europe (IHME), dating from 2013 at 1:1,500,000 scale (BGR and UNESCO, 2013) reported six types of aquifer's productivity (*Fig. 1*). In base of the productivity of aquifers, the vulnerability factor for each aquifer was assigned into the GIS database (*Table 2*) and further at spatial scale of Carpathian Mountains region (*Fig. 3*). For each media that compose the aquifer, the potential infiltration coefficient (PIC) was assigned accordingly to the hydrogeological specific literature (Civita, 2005). The importance of infiltration coefficients for groundwater highlights the aquifers sensitivity in term of quality (Čenčur Curk et al., 2014). *Figure A2* in the *Appendix* shows the PIC spatial distribution in the Carpathian Mountains area.

Table 2. *Aquifers productivity in Carpathian Mountains region. (Source: IHME, 2013; Čenčur Curk et al, 2014)*

Aquifers type	Vulnerability factor
Highly productive fissured aquifers (including karstified rocks)	0.8
Low and moderately productive fissured aquifers (including karstified rocks)	0.4
Highly productive porous aquifers	0.7
Low and moderately productive porous aquifers	0.3
Locally aquiferous rocks, porous or fissured	0.1
Practically non-aquiferous rocks, porous or fissured	0.05
Snow field/ice field	0

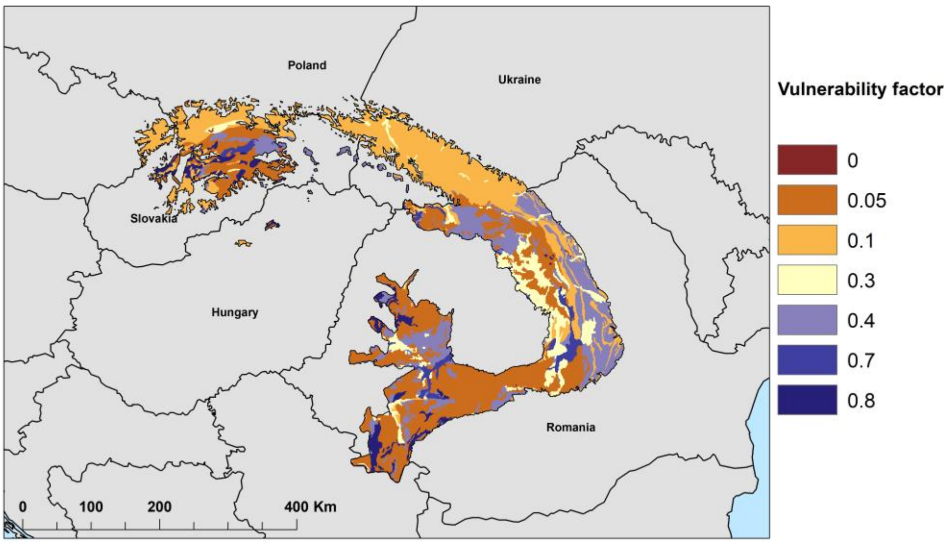

Figure 3. *Vulnerability factor distribution at spatial scale of the Carpathian Mountains region*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50955116

Terrain data and infiltration map

The infiltration process is mainly controlled by the terrain configuration and lithology. In base of the Nistor et al. (2015) approach, the infiltration map is calculated as the ratio between PIC and slope angle. Thus, the digital elevation model (DEM) of the Carpathians region have been used to generate the slope angle and from the geological map it was processed the PIC. This reasoning considers that where the PIC is higher and the slope angle is lower, the infiltration values will be higher. The calculations were performed in ArcGIS software using normalized values (0 to 1) of the PIC and slope angle raster grid data. *Figure 4* depicts the infiltration map of the Carpathian Mountains area used in the groundwater vulnerability mapping.

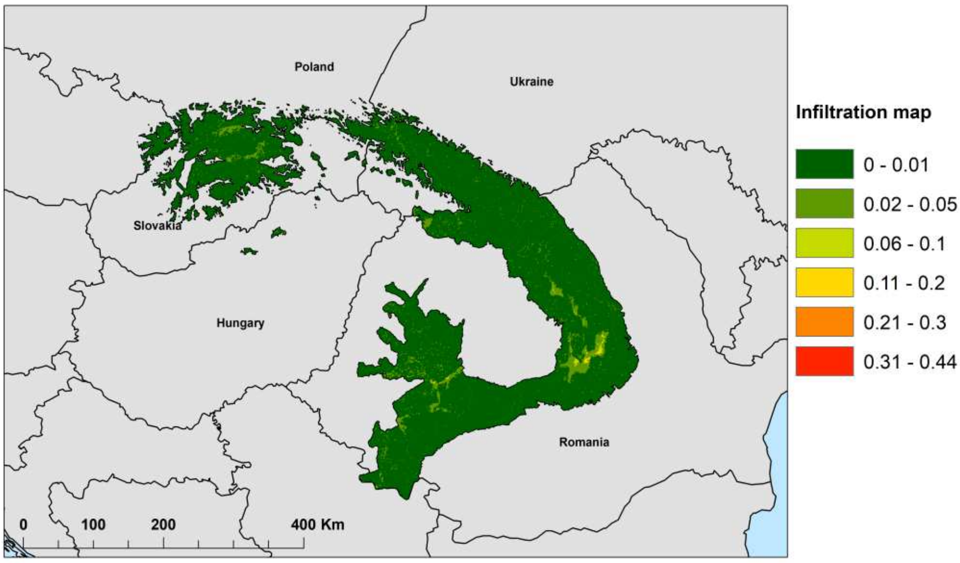

Figure 4. *Infiltration map of the Carpathian Mountains region*

Land cover data

The vegetation layer, bare soil, water bodies, and artificial areas over Carpathian Mountains area were collected from the World Land Cover database elaborated by China in collaboration with the United Nations. This land cover is 30 × 30 m in spatial resolution and cover entire study area indicating 10 classes of cover type. The future projections of the land cover were done accordingly to Nistor et al. (2015) only for the artificial, agricultural, and forest areas. All transformations have been processed on the vector layer of and cover, applying a linear buffer to the vector feature of artificial areas by 23 m, to agriculture by 41 m, and to forest by 80 m. Thus, the resulted surfaces were clipped and integrated in the original land cover vector layer for present and future (*Fig. A3*). *Table 3* reports the values of pollution load index (PLI) used in the present study. The resolution of the PLI at spatial scale (*Fig. 5*) were set at 1 km^2, to be in line with the climatological data.

Potential evapotranspiration (ET0)

Thornthwaite (1948) method (*Eq. 1*) was adopted for the long-term calculations of monthly ET0 during the three set time periods: 1961-1990 (1990s), 2011-2040 (2020s),

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50955116

and 2041-2070 (2050s). Even if old, this approach is still used in the regional studies of climate, hydrology, and agriculture (Zhao et al., 2013). The monthly and annual ET0 and water availability have been computed for whole Europe by Dezsi et al. (2018) and the gridded data are available through open access web site (https://doi.org/10.5281/zenodo.1044306). In base of monthly ET0 we have computed the annual ET0 and further annual ETc and AETc raster maps.

$$ET_0 = 16\left(\frac{10T_i}{I}\right)^{\alpha} \quad \text{(Eq.1)}$$

where:

ET_0 – monthly potential evapotranspiration [mm]
T_i – average monthly temperature [°C], $ET_0 = 0$ if mean temperature < 0
I – heat index (*Eq. 2*)
α – complex function of heat index (*Eq. 3*)

$$I = \sum_{i=1}^{12} \left(\frac{T_i}{5}\right)^{1.514} \quad \text{(Eq.2)}$$

where:

T_i – monthly air temperature

$$\alpha = 6.75 \times 10^{-7} I^3 - 7.71 \times 10^{-5} I^2 + 1.7912 \times 10^{-2} I + 0.49239 \quad \text{(Eq.3)}$$

where:

I – annual heat index

Table 3. *Corine Land Cover classes and relative pollution load index applied the Carpathian region. (Source: Wochna, 2011; Čenčur Curk et al., 2014; Nistor et al., 2015)*

CLC code 2012	CLC description	Pollution load index	Normalized values

ETc, AETc, and water availability

In base of crop coefficients (Kc) assigned to each land cover type we have carried out the ETc. Allen et al. (1998) present the standard Kc for various types of crops. Moreover, Grimmond and Oke (1999) calculated the Kc in the urban areas indicating the specific Kc for several cities in the United States. In South Europe, Nistor and Porumb-Ghiurco (2015) set a methodology for the ETc mapping at spatial scale.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50955116

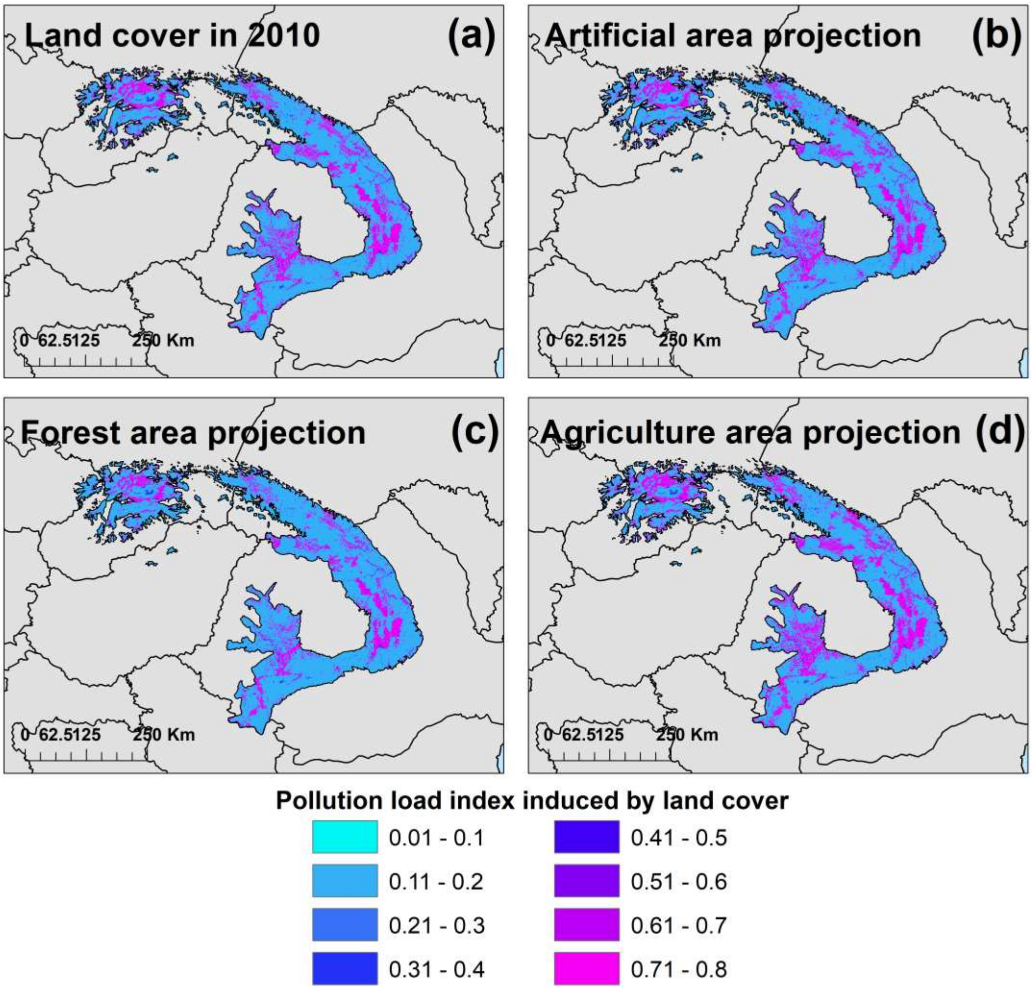

Figure 5. *Pollution load index calculated in base of land cover in the Carpathian Mountains region. (a) Pollution load index pattern related to land cover 2010. (b) Pollution load index pattern related to artificial area projection. (c) Pollution load index pattern related to forest area projection. (d) Pollution load index pattern related to agricultural area projection*

The calculation of ETc is the product of the ET0 and Kc (*Eq. 4*). We prefer to incorporate the land cover in the evapotranspiration calculation because the aquifers recharge is in base of effective precipitations, which are not included in the water demand for crops. In this work, we have used the standard annual Kc values (Nistor and Mîndrescu, 2017) together with the annual ET0 to determinate the annual ETc for the past, present, and future. The annual Kc values, for the land cover classes related to Carpathian Mountains are presented in the *Table 4*.

Budyko approach (1974) was adopted to carry out the AETc calculation. This method is often used in the hydrology and related studies which required the water balance determination (Gerrits et al., 2009).

$$\text{Annual ETc [mm]} = \text{annual ET0 [mm]} \times \text{annual Kc [mm]} \qquad \text{(Eq.4)}$$

From the difference between precipitation and AETc, we have found the water availability. Budyko (1974) formula is expressed in *Equation 5*. The water availability

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50955116

(*Eq. 7*) for 1990s, 2020s, and 2050s was subtracted from the annual AETc and annual precipitation. All raster grids operations were performed in ArcGIS environment.

$$\frac{AETc}{PP} = \left[\left(\varphi \tan\frac{1}{\varphi}\right)\left(1 - \exp^{-\varphi}\right)\right]^{0.5} \quad \text{(Eq.5)}$$

where:

AETc – actual land cover evapotranspiration [mm]
PP – total annual precipitation [mm]
Φ – aridity index (*Eq. 6*)

$$\varphi = \frac{ETc}{PP} \quad \text{(Eq.6)}$$

$$\text{Effective precipitation [mm]} = \text{annual precipitation[mm]} - \text{annual AETc[mm]} \quad \text{(Eq.7)}$$

Groundwater vulnerability assessment using Spatial Analyst Tools

The groundwater vulnerability mapping was determinate by multi-layers analysis using Spatial Analyst Tools from ArcGIS. The method adopted here is based on the methodology applied by Nistor et al. (2015). In European regions, Čenčur Curk et al. (2014) performed the groundwater vulnerability in the South East Europe using weights. In the works of Stempvoort et al. (1993), Daly et al. (2002) and Dixon (2005), the appropriate weights for each layer were found.

We consider that the water availability represents one of the most important layers related to the water recharge quantity, which is driven by climate. Secondly, the land cover variability and implication for PLI and ecosystems play also an important role of the groundwater quality. Due to these reasons, we agree that water availability and ecosystems may have the same weights of 30%. For the aquifers vulnerability factor

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50955116

and infiltration map were set the equal weights of 20%. All layers were pondered using weights like in *Equation 8*. These weights represent the relative importance of the parameter in the group. The water availability and ecosystems have a balancing factor that shows the relative importance to the maximal deviations of the respective layer and its limitation to substitute another layer.

All layers were normalized under the standard method between 0 and 1. Final vulnerability map was divided in classes as follow: 0–0.2 for very low, 0.21–0.4 for low, 0.41–0.6 for medium, 0.61–0.8 for high, and 0.81–1 for very high. The groundwater vulnerability map was divided in four classes of vulnerability: very low, low, medium, and high.

$$GW\ V = (1\text{-}WA)^{1.5}\ X\ 0.3 + AV\ X\ 0.2 + IM\ X\ 0.2 + ES^{1.5}\ X\ 0.3 \qquad \text{(Eq.8)}$$

where:

GW V = Groundwater Vulnerability
WA = Water Availability
AV = Aquifer Vulnerability
IM = Infiltration Map
ES = Ecosystem Services

Results and discussion

The climate change in Europe and in the Carpathian Mountains area indicates significant variation in the mean air temperature and evapotranspiration values for 2020s and 2050s, but also slightly modifications in the precipitation extremes. In base of the climate models observations, the mean annual temperature is expected to increase from –0.8 to 13.5 °C during the 2020s (*Fig. 6a*) in the Carpathian Mountains area. The future projections indicate values of the mean air temperature from 0.2 to 14.4 °C during the 2050s period (*Fig. 6b*) in the study area. The precipitation pattern shows values between 460 mm and 1667 mm year-1 for the 2020s (*Fig. 6c*) and between 478 mm to 1730 mm year^{-1} for 2050s (*Fig. 6d*). The annual ET0 in the Carpathian Mountains area is expected to range from 312 mm to 674 mm during 2020s and from 327 mm to 713 mm during 2050s (*Fig. 6e* and *f*).

Climate change effects on the Carpathian Mountains are reflected into the annual ETc. During 1990s, the annual ETc ranges 56 mm to 740 mm while in the future periods the ETc is expected to increase up to 910 mm (2020s), respective 963 mm (2050s). *Figure A4* depicts the spatial variation of annual ETc in the study area, highlighting the high values (over 700 mm) in the Apuseni ad Eastern Carpathians, especially during the 2020s and 2050s periods. The large area with high values is represented by the forest projection scenario (*Fig. A3d*) while in the artificial and agricultural scenarios for 2050s the ETc pattern do not differ too much (*Fig. A3c* and *d*).

The implication of the annual ETc (*Fig. A4*) in the groundwater vulnerability is reflected through AETc and water availability. Thus, the annual AETc varies in the past period from 55 mm to 525 mm showing the maximum values in the Western Carpathians. During 2020s period, the annual AETc ranges from 63 mm to 575 mm indicating high values (over 500 mm) in the Western and Southern Carpathians. For the 2050s period, the annual AETc ranges from 66 mm to 596 mm, depicting the high values (over 500 mm) in western, southern, and eastern sides of the study area. In the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50955116

future years of 2050s, a larger area with high values of the annual AETc occupies the territory in comparison with the 1990s and 2020s. *Figure A5* illustrates the spatial distribution of annual AETc in Carpathian Mountains area.

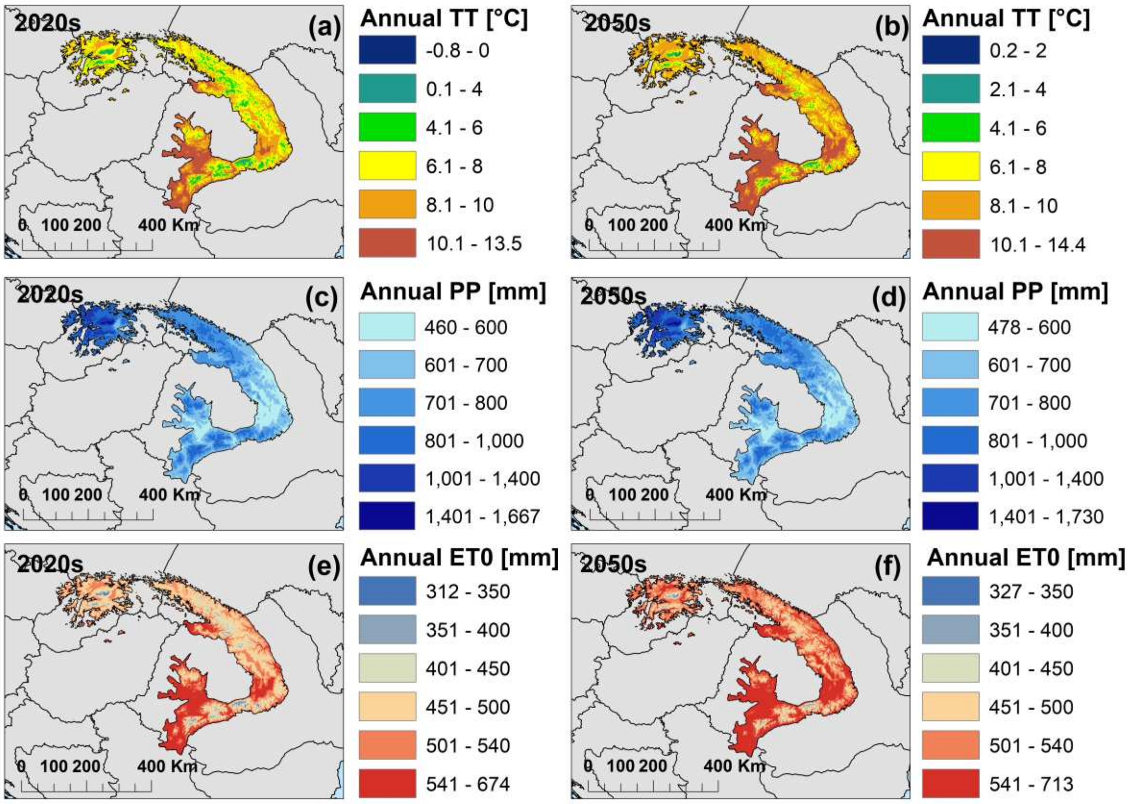

Figure 6. *Models projections of temperature, precipitation, and ET0 in the Carpathian Mountains region. (a) The average of mean annual air temperature between 2011 and 2040 (2020s). (b) The average of mean annual air temperature between 2041 and 2070 (2050s). (c) The average of mean annual precipitation between 2011 and 2040 (2020s). (d) The average of mean annual precipitation between 2041 and 2070 (2050s). (e) The average of annual ET0 between 2011 and 2040 (2020s). (f) The average of annual ET0 between 2041 and 2070 (2050s)*

Considering the annual AETc and precipitation patterns, the annual water availability was carried out for the 1990s, 2020s, and 2050s periods. In the Carpathian Mountains area, the water availability ranges during 1990s from 129 mm to 1635 mm (*Fig. 6a*), indicating the lower values (below 200 mm) in the South of Apuseni Mountains, in the western sides of the Curvatures Carpathians, eastern side of the Eastern Carpathains. The high values (over 800 mm) of the water availability spread in the Southern Carpathians and Western Carpathians, but also in the North of Eastern Carpathians. During the 2020s period, the water availability ranges from 66 mm to 1603 mm illustrating a large area with low water availability (below 200 mm) in the Southern and Eastern Carpathians. The annual water availability ranges in the 2050s from 69 mm to 1663 mm depicting low values of water availability in the Apuseni Mountains, Southern and Eastern Carpathians. *Figure 7* shows the water availability variation in the Carpathian Mountains area at spatial scale.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50955116

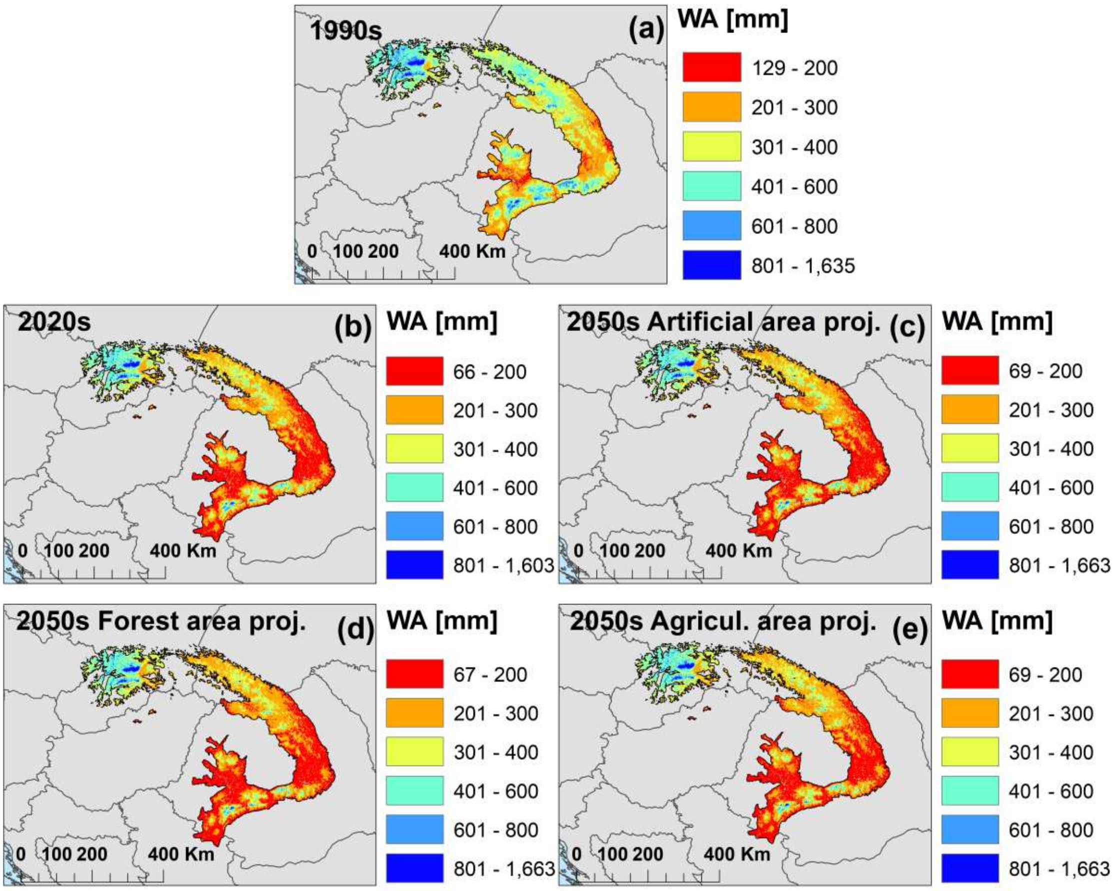

Figure 7. *Spatial distribution of water availability (WA) in the Carpathian Mountains region. (a) WA related to the past period (1990s). (b) WA related to the present period (2020s). (c) WA related to the future period (2050s) artificial area projection. (d) WA related to the future period (2050s) forest area projection. (e) WA related to the future period (2050s) agricultural area projection*

Groundwater vulnerability at spatial scale in the Carpathian Mountains area was calculated using spatial analysis by weights in the ArcGIS environment. A complex methodology was applied using climate models, geological data, DEM, and land cover of the study area. *Figure 7a* depicts the groundwater vulnerability map of Carpathian Mountains area during 1990s. The groundwater vulnerability in the 1990s shows major part of the territory as low vulnerable at climate change and land cover. The very low class was depicted in the Western and Southern Carpathians only in the elevated areas (above 2000 m). The high vulnerability areas were found in the Curvatures Carpathians and South of Apuseni Mountains. During the 2020s years the groundwater vulnerability map (*Fig. 8b*) indicates a large area of high vulnerability class, especially in the Curvatures Carpathians, while the very low vulnerability reduced at spatial scale. The future scenarios (Fig. *8c–e*) show decreasing in area of very low vulnerability class and increase of the high vulnerability class. The forest projection indicate the maps of worst scenario with 2.41% from the total area with high vulnerability, followed by the artificial area projection (*Table 5*).

(d) Groundwater vulnerability map related to the future period (2050s) forest area projection. (e) Groundwater vulnerability map related to the future period (2050s) agricultural area projection*

The main aim of this work was to calculate the groundwater vulnerability at spatial scale of Carpathian region area. The analysis of multi-layers data in ArcGIS was focused on the climate models and land cover projections. Under the climate change, the southern areas of Carpathians are negatively affected in terms of groundwater vulnerability increases. These modifications are related to the increase of territory with low water availability (below 200 mm) for the 2020s and 2050s, in all scenarios. In this sense, the groundwater vulnerability increase from the quantitative point of view

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50955116

because the recharge of aquifers might a reduction. The quality of the groundwater was mainly controlled in our analysis by aquifers potential infiltration coefficient (PIC) (*Fig. A2*) and the pollution load index (PLI) (*Fig. 5*). As a first driver of groundwater quality, the higher PIC varies in the Carpathian Mountains region overlapping with the existing aquifers in limestones, sandstones, sandy, and gravels. These aquifers are defined as highly productive porous aquifers located mainly in the intermountain depressions. In these types of aquifers the hydraulic conductivity in relatively higher than in the aquifers formed by schists and gneisses or plutonic rocks. Secondly, the PLI factor follow the land cover distribution (*Fig. A3*). Thus, the artificial areas and agricultural lands influence the increases of groundwater vulnerability, while the forest and grass form the ecosystems, which provide an advantageous media for groundwater quality. For this reason, the low vulnerability extends on larger area (around 77.73%) in the forest projection model.

Table 5. *Percentage area of groundwater vulnerability calculated in Carpathian Mountains area*

Vulnerability classes	GW vulnerability 1990s (area %)	GW vulnerability 2020s (area %)	GW vulnerability 2050s, artificial projection (area %)	GW vulnerability 2050s, forest projection (area %)	GW vulnerability 2050s, agriculture projection (area %)
Very low	6.19	3.50	2.75	2.49	2.67
Low	70.45	71.73	72.29	77.73	68.66
Medium	22.16	22.64	22.83	17.87	26.25
High	1.19	2.13	2.13	1.91	2.41

The methodology of groundwater calculation and land cover projection applied in this survey is close to the procedure followed by Nistor et al. (2015). They used the appropriate data to determine the groundwater vulnerability on a district from Apuseni Mountains, in Romanian Carpathians. Here, we extrapolated the methodology to entire area of Carpathians Mountains using spatial analysis in ArcGIS. With few changes regarding the utilization of high-resolution climate models and geology implication, our results indicate appropriate pattern of groundwater vulnerability with the studies carried out by Čenčur Curk et al. (2014), Nistor et al. (2015). The limitations of this study may be improved using in-situ monitoring of spring's groundwater to observe the climate change effects on seasonal periods. In this study, we have focused on long-term period analysis, so the runoff and water availability variables on short-term period were neglected. Using additional methods, such as VESPA index (Galleani et al., 2011),) or spring variability in base of hydrographs, the groundwater vulnerability could be performed in specific locations and further to create various models at spatial scale. At this level, GIS techniques were the best solutions in sense of long-term period, land cover projections, and layer analysis.

Conclusions

Spatial analysis by weights in ArcGIS environment contributed to determine the groundwater vulnerability in the Carpathian Mountains area. A complex methodology including the climate models in three periods, aquifers and geology, morphometric

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_50955116

terrain data, and the dynamic land use layers indicates a quarter part of the Carpathian Mountains area territory suffers high and very high groundwater vulnerability under climate change. Moreover, the future scenarios highlight almost a third part of the region in the high and very high vulnerability class. These results evidence that the territory of the Carpathian Mountains area is faced with the actual global threats that may occur also at regional scale. These problems are mainly related to both a reduction of precipitation amount and an increase in the mean air temperature. These findings can help the policymakers and the administrative staff of the region to take the counterbalance measures against the natural changes that are expected during the 21st century. The maps carried out in this study may represent strategic tools for the landscaping and delineating the areas with more restrictive actions.

We presented a long-term analysis which is based on spatial data and empirical formulas. Considering the complexity of the data used here, the errors may be neglected for the long period. However, the methodology was applied for other study cases from Europe and we assume that our results are valid. To be more accurate, the future work could be conducted at site scale to assess the groundwater vulnerability in situ (i.e. springs, check quality of groundwater in wells). The groundwater quality in the agricultural areas and different flow models of groundwater may improve the results at local scale.

Acknowledgements. The authors would like to thank Andreas Hamann from Alberta University for the climate models data and support during the revision process.

Abstract. Dodder *(Cuscuta campestris)* control is a challenge and dodder is one of the factors limiting the cultivation of sugar beet in many regions of Iran. New herbicides can be useful in chemical control of dodder. This study was conducted to evaluate the effect of new mixture of herbicides on dodder control in sugar beet field. Results showed that the Propyzamide (3 L ha^{-1}) had the highest effect on dodder weed weight loss% and this treatment led to 99.59% reduction in its fresh and dry weight. In addition, herbicide treatments were significant at 0.01 significance level within 15 and 30 days; after this time application of Propyzamide 3 L ha^{-1} led to 90.63 and 100% reduction in dodder weed, respectively. The Propyzamide 3 L ha^{-1} led to 80.63% increase in sugar beet foliage dry weight within 30 Days After Herbicide Application (DAHA). In addition, between treatments the highest increase percentage of sugar beet yield was obtained by Ethofumesate (2 L ha^{-1}) along with Gallant Supper (1 L ha^{-1}) and the removal of broad leaf about 86.55% compared to control. Totally, Propyzamide (1.9 L ha^{-1}) along with Gallant Supper (0.75 L ha^{-1}) showed the best results with the lowest dosages.
Keywords: *chemical control, Ethofumesate, mixture herbicides, parasitic weed, Propyzamide*

Introduction

It is believed that parasitic weeds have emerged as a serious challenge in agricultural production globally. Research show that roughly 20 families (3,000–5,000 species) of higher plants are parasitic in the plant kingdom. They are likely to inflict production losses of 30–80% in main food and industrial crops around the world. Contrary to other weeds, conventional methods cannot control the parasitic weeds because of their life style. They mixed thoroughly with the host and their metabolic feature is strikingly similar to the host, which cannot be distinguished by treatments. Some of the parasites locate closely to the host root, which is hidden and cannot be detected until final are observed. Various approaches have been introduced including cultural, mechanical, chemical, use of resistant varieties, and biological to curb the negative effects of parasitic weeds; but most of them failed to achieve this aim.

One of the parasitic plant is field dodder, which is found on the stems and leaves of broadleaf plants, including weeds, field crops, vegetables, and ornamentals around the world. It is not easy to control field dodder because of close intimacy and interaction between the host and the parasite; thus, there must be herbicide that attacks the parasite without inflicting damage on the host (Sarić-Krsmanović and Vrbničanin, 2017).

Cuscuta campestris, also known as field dodder, has emerged as a widespread weed in several continents including Africa, Asia, Europe, Australia, and South America (Parker and Riches, 1993). All species of the genus *Cuscuta* receive their required mineral, water, and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_51175125

carbohydrates from their host plants because of the lake roots and leaves; besides some of the species of this genus are not able in terms of photosynthesis, including forage crops (especially alfalfa) and vegetables, some tree crops (grapevine, coffee), and ornamentals plants (Albert et al., 2008).

Dodder affects the growth and yield of the infected plants and it causes losses, which range from slight to complete destruction of the crop (Agrios, 1978 and Saric-Krsmanovic et al., 2017). Estimated yields sugar beet losses ranges are reduced by 3.5–4 t ha^{-1} (Aly et al., 2003). Sarić-Krsmanović et al. (2015) conducted a study to investigate to see how glyphosate, propyzamide, imazethapyr, and diquat herbicides are able to curb field dodder in alfalfa of Pot and field trials in Novi Sad (location Rimski Šančevi) and in the field at Popovići (in the vicinity of Mladenovac). The highest effectiveness of 95% and 97.5%, was reported by two glyphosate application rates (288 and 360 g a.i. ha) respectively.

If weed control is neglected, because of widely spaced rows and slow crop development in the early growing stages of sugar beet, up to 95% yield disappears (Petersen, 2004). The reduced use of herbicides has become a necessity to limit environmental pollution and safeguard human health. Consequently, in the last years, the general trend was to achieve a gradual reduction in doses applied in pre and post-emergence using several blends of products to assess their synergic effects. The reduced use of herbicides can be obtained by replacing herbicide treatments with revaluation of agronomic techniques and minimizing the dose rate of herbicides (Cioni and Maines, 2010). Chemical control plays an important role in weed control in sugar beet production, until sugar beets become established; they are very susceptible to competition from weeds. That is one reason why many growers like to use pre-plant or pre-emergence herbicides. Early poste-mergence herbicide applications also help reduce competition from weeds while the sugar beets are small (Morishita, 2003). The most important herbicide mixtures contain the following active ingredients: metamitron, phenmedipham, desmedipham and ethofumesate (Vasel et al., 2012). Several studies have been conducted to evaluate the effects of herbicides on weeds. Longden (1989) reported that Weed beet did not affect the concentration of sugar (sucrose), potassium, sodium, α amino nitrogen, or invert sugar in the crop beets. Root and sugar yields were progressively reduced by increasing densities of weed beet.

The results of the study by Khaksar et al. (2017) showed that weed management had significant effect on root yield and sugar yield. Mean compared results illustrated that plots treated with chemical control and hand weeding were superior to control in terms of root yield and sugar yield with less impurity. Mekki (2016) evaluated treatments such as unweeding, one-hand hoeing, two-hand hoeing and chemical herbicide application (Acetochlor) at a rate of 0.750 L/feddan as pre-emergence, (one feddan = 0.42 ha) on weed control of sugar beet. Twice hand-hoeing resulted in a sharp decrease in total fresh and dry weights of weeds at 75, 90 and 105 days after planting (DAP) and recording the highest root yield and its components in comparison with the other treatments. However, quality parameters were less affected using one or two-hand hoeing. Sharifi Ziveh et al. (2013) mentioned that consideration of the environmental negative effects of propyzamide and low environmental impact of ethofumesate herbicide is recommended for control dodder in the beet fields. The results of the study by Weinberg et al. (2003) showed that bleaching symptoms were observed in field dodder stems following the Flurochloridone, sulcotrione, and mesotrione treatments. Flurochloridone exerted its effects quickly; bleaching was observed in the stem 2 days after treatment (DAT) containing only 2% β-carotene and having a considerable accumulation of phytoene in comparison with the control. Nevertheless, stem elongation was not prevented by Flurochloridone treatment. Full recovery of pigment composition at newly elongated stems

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_51175125

was recorded 6 DAT; sulcotrione and mesotrione exerted similar effects Flurochloridone made the recovery take more time with less speed.

Many factors are responsible for reduced yield in sugar beet in Iran from which the most important factor is weed (Mansourian et al., 2016). Parasite weeds are competitive with the sugar beet crop for light, nutrients and water resources (Zimdahl, 1980). In addition, sugar beet seedlings are not able to compete well enough with weeds (Draycott, 2008). The aim of this research was to evaluate the effect of tank mixture of herbicides on Cuscuta spp in sugar beet field.

Materials and methods

Study site and experimental design

This research was conducted at the Research Farm of Iranian Research Institute of Plant Protection, in Meshkin-Dasht-e-Karaj, Alborz province, Iran. Geographical parameters of the site are the followings: latitude of 35 ° and 41 min, longitude of 51 ° and 50 min east, height of 1200 m above sea level and its climate belongs to the semi-arid region in 2015.

This experiment was conducted in a randomized completed block design with 16 treatments and four replications (*Table 1*).

Table 1. *Experimental treatments and rates*

	The trial treatments
1	Propyzamide (2 L ha^{-1})
2	Propyzamide (2.5 L ha^{-1})
3	Propyzamide (3 L ha^{-1})
4	Ethofumesate (1.5 L ha^{-1})
5	Ethofumesate (2 L ha^{-1})
6	Ethofumesate (2.5 L ha^{-1})
7	Propyzamide (2.5 L ha^{-1}) + Betanal progress OF (3 L ha^{-1}) + the removal of grass leaf
8	Propyzamide (2.5 L ha^{-1}) + Gallant Supper (1 L ha^{-1}) + the removal of broad leaf
9	Ethofumesate (2 L ha^{-1}) + Betanal progress OF (3 L ha^{-1}) + the removal of grass leaf
10	Ethofumesate (2 L ha^{-1}) + Gallant Supper (1 L ha^{-1}) + the removal of broad leaf
11	Propyzamide (1.9 L ha^{-1}) + Betanal progress OF (2.25 L ha^{-1}) + the removal of grass leaf
12	Propyzamide (1.9 L ha^{-1}) + Gallant Supper (0.75 L ha^{-1}) + the removal of broad leaf
13	Ethofumesate (1.5 L ha^{-1}) + Betanal progress OF (2.25 L ha^{-1}) + the removal of grass leaf
14	Ethofumesate (1.5 L ha^{-1}) + Gallant Supper (0.75 L ha^{-1}) + the removal of broad leaf
15	Betanal progress OF (3 L ha^{-1}) + the removal of grass leaf
16	Gallant Supper (1 L ha^{-1}) + the removal of broad leaf

The experimental plots were set to consist of 12 m^2 (2 m in width and 6 m in length) including four planting lines (50 cm width). Seed was cultivated with an appropriate depth of 2 cm.

Each experimental plot was divided to two parts, in which 4 m^2 from top side of each plot was considered as witness (without herbicides application). It should be mentioned that herbicides application were applied only in 8 m^2 bottom down each experimental plot. Herbicides were applied when sugar beet was in two to four leaves stage (at the time of the complete attachment of the dodder to the host in each plot). Finally, the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_51175125

treatment assessments were in 15 and 30 day intervals after the application of herbicides.

For determination of dodder dry weight 30 days after treatment application, also to determine the total dry weight of weeds at the end of the growth season, they were collected by a 1 × 1 m^2 quadrature and placed in an oven for a period of one week at 75 °C after transferring to the laboratory until their drying. After drying, they were weighed by digital scales. In addition, eye scoring according to the EWRC (European Weed Research Council), scale was performed to determine the effect of herbicide treatments. At the end of the growth period, the roots of sugar beet were harvested in each experimental plot; after washing and cutting off the limbs, weighed to determine the yield.

Statistical analysis

Analysis of variance and comparisons were conducted using SAS (Version 9.1) software. The mean comparison was carried out by using Duncan's multiple range tests. Differences were accepted as significant at (P = 0. 05). Reporting of data as tables was conducted using Microsoft Excel 2016.

Result and discussion

Dodder weight loss%

The results showed that the effect of treatments on weight of dodder weed was significant at 1% significance level (*Table 2*). According to the results obtained after 30 days of herbicides application, Propyzamide (3 L ha^{-1}) had the highest effect on dodder weed fresh weight and this treatment led to 99.59% reduction in comparison with control (*Table 3*). Also, Propyzamide (2.5 L ha^{-1}), Propyzamide (2 L ha^{-1}), Propyzamide (2.5 L ha^{-1}) along with Betanal progress OF (3 L ha^{-1}) led to 99.57 98.47 and 97.08.14% reduction in dodder weed fresh weight. Different herbicides in dodder control have been studied. Sohrabi et al. (2001) reported three herbicides of Trifluoralin, Ethofumesate and Propyzamide with 0.8, 1.5 and 1.6 kg ha^{-1} respectively, Propizamide herbicide (1.6 kg ha^{-1}) reduced dodder density by 53% compared with control. Meighani et al. (2017) reported that Propizamide 2.5 kg ha^{-1} with 57% reduction in dry weight of dodder was the best treatment compared to the control and there was no significant difference between Ethofumesate 2, and 2.5 L ha^{-1} and Propyzamide 2 and 2.5 L ha^{-1}.

Results of Dodder dry weight loss% (30DAHA) showed that the highest losses (99.59%) obtained by Propyzamide 3 L ha^{-1} and this treatment showed no significant differences with Propyzamide 2.5 L ha^{-1}, Propyzamide 2 L ha^{-1}, Propyzamide (2.5 L ha^{-1}) along with Betanal progress OF (3 L ha^{-1}), Propyzamide (2.5 L ha^{-1}) along with Gallant Supper (1 L ha^{-1}), Ethoefumesate 2.5 L ha^{-1}, Ethofumesate 2 L ha^{-1}, Ethofumesate 1.5 L ha^{-1}, Ethofumesate (2 L ha^{-1}) along with Betanal progress OF (3 L ha^{-1}), Propyzamide (1.9 L ha^{-1}) along with Betanal progress OF (2.25 L ha^{-1}), Propyzamide (1.9 L ha^{-1}) along with Gallant Supper (0.75 L ha^{-1}) (*Table 5*).

Dodder visual weed control rating according to the EWRC

The results indicated that there is a significant difference between herbicide treatments in comparison with the control within 15 and 30 days after spraying ($P < 0.01$). After 15 days from spraying, the application of Propyzamide 3 L ha^{-1}, Propyzamide 2.5 L ha^{-1}, Propyzamide 2 L ha^{-1}, Propyzamide (2.5 L ha^{-1}) along with Gallant Supper 1 L ha^{-1} and the removal of broad leaf, Propyzamide 2.5 L ha^{-1} along with Betanal progress OF L ha^{-1} and the removal of grass leaf, Propyzamide 1.9 L ha^{-1} along with Gallant Supper 0.75 L ha^{-1} and the removal of broad leaf led to 90.63, 87.5, 87.5, 87.5 and 84.38% reduction in dodder weed in comparison with the control (*Tables 3* and *4*). In the follow-up, after 30 days application of Propyzamide 3 L ha^{-1}, led to 100% reduction in dodder weed in comparison with control (*Table 5*); also, other treatments decreased the dodder weed and it was founded that Propyzamide 2.5 L ha^{-1} caused 98.82% reduction.

According to results Ethofumesate (2 L ha^{-1}) along with Betanal progress OF (3 L ha^{-1}) and Ethofumesate (2 L ha^{-1}) along with Gallant Supper (1 L ha^{-1}) led to 76.25 and 76.33% reduction in herbs dry weight, respectively. In addition, it was found that Propyzamide 2 L ha^{-1} treatment had the lowest effect on herbs dry weight control. Sarić-Krsmanović et al. (2015) reported that using propyzamide (1500 and 2000 g a.i. ha) was not effective enough (85% and 87%, respectively).

The increase of sugar beet root yield and sugar beet foliage weight according to the results of this study, herbicide treatments had significant effect on root yield at 1% probability level (*Table 2*), between treatments the highest yield mean was obtained by Ethofumesate (2 L ha^{-1}) along with Gallant Supper (1 L ha^{-1}) and the removal of broad leaf, which means about 88.55% increase compared to control. Also other treatments increased root yield through weed control, Ethofumesate (2.5 L ha^{-1}) along with Gallant Supper (1 L ha^{-1}) and the removal of broad leaf, Propyzamide (2.5 L ha^{-1}) along with Gallant Supper (1 L ha^{-1}), Gallant Supper (1 L ha^{-1}), Betanal progress OF (3 L ha^{-1}), Propyzamide (1.9 L ha^{-1}) along with Gallant Supper (0.75 L ha^{-1}), Ethofumesate (1.5 L ha^{-1}) along with Gallant Supper (0.75 L ha^{-1}) and Ethofumesate (2 L ha^{-1}) along with Betanal progress OF (3 L ha^{-1}) resulted in 85.66%, 84.95%, 84.79%, 84.67%, 78.59% and 78.03%, respectively in comparison with the control. The lowest increase in yield was obtained by Propyzamide 2 L ha^{-1} by 18.2% in comparison with control (*Table 5*). Also, it was founded that Propyzamide (2.5 L ha^{-1}) along with Gallant Supper (1 L ha^{-1}) and Propyzamide (2.5 L ha^{-1}) along with Betanal progress OF (3 L ha^{-1}) treatments led to 93.96 and 93.97% increase of sugar beet leaf weight as the highest effects, respectively. In this regard, the effect of some herbicide treatments were studied on dodder fresh and dry weight and sugar beet yield by Meighani et al. (2017); their results indicated Propyzamide Burst 2.5 L ha^{-1} as the best herbicide treatment and causing the highest decrease in dodder fresh and dry weight (93 to 99%, compared to dodder infested control). Based on field studies of these researchers, Propyzamide Burst 2 to 2.5 L ha^{-1} and ethofumesate 2.5 L ha^{-1} were the best treatments. Since SC formulation is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_51175125

safer and easier to apply than WP formulation, Propyzamide Burst 2 to 2.5 L ha^{-1} and ethofumesate 2.5 L ha^{-1} are recommended for dodder control in sugar beet.

Conclusion

According to the results of the present study, Propyzamide (3 L ha^{-1}) had the highest effect on dodder weed weight. After 15 and 30 days from spraying, the application of Propyzamide 3 L ha^{-1} led to 90.63 and 100% reduction in dodder weed, respectively in comparison with control. Accordingly, Propyzamide (2.5 L ha^{-1}) along with Gallant Supper (1 L ha^{-1}) and Propyzamide (2.5 L ha^{-1}) along with Betanal progress OF (3 L ha^{-1}) treatments demonstrated the best visual weed control ratings after both periods. In addition, between treatments the highest yield mean was obtained by Ethofumesate (2 L ha^{-1}) along with Gallant Supper (1 L ha^{-1}) and the removal of broad leaf. Gallant Supper treatment illustrated the highest effect on sugar beet yield (84.95%) compared to Betanal progress. Although different dosages of Propyzamide (2, 2.5, and 3 L ha^{-1}) showed better control on dodder fresh and dry weight loss, but sugar beet yield is not affected by specific weed and vast range of weeds are effective on sugar beet yield. Therefore, it sounds that tank mixture of herbicides such as Propyzamide along with Gallant Supper led to suitable control of most weeds and increase of sugar beet yield. Totally, according to the aims of this research, which was reduced use of herbicides by tank mixture of herbicides together, Propyzamide (1.9 L ha^{-1}) along with Gallant Supper (0.75 L ha^{-1}) showed the best results with the lowest dosages.

(Received 23rd May 2018; accepted 17th Jul 2018)

Abstract. Glyphosate is the most used herbicide in the world. In 2015, it was declared as probably carcinogenic to humans by the International Agency for Research on Cancer. In Valle del Mayo, Sonora, México, more than 20000 L of this herbicide are sprayed per year. Therefore, the objective of this work was to assess human health risk associated with exposure of water contaminated with glyphosate and aminomethylphosphonic acid (AMPA) on a population in agricultural fields of Valle del Mayo communities. A cohort study was performed among the exposed populations; glyphosate and AMPA concentrations were measured in water drains, private wells, and groundwater by high-performance liquid chromatography (HPLC). Health risk was subsequently assessed obtaining a hazard ratio. Concentrations for glyphosate were lower than 5 µg L^{-1} while those for AMPA were 15-342.5 µg L^{-1} or µg g^{-1}. The results showed a statistical correlation among people consuming water from private wells with diabetes ($p \leq 0.03$) and hypertension ($p \leq 0.004$). The resulting risk assessment hazard ratio was 0.22 for agricultural laborers and 0.39 for brick makers when an acceptable daily dose of 0.03 mg kg^{-1} d^{-1} was taken into account, indicating a potential health risk.
Keywords: *herbicide exposure, occupational exposure, HPLC, AMPA*

Introduction

The yield has been reduced in agricultural practices all over the world due to weeds, thus the reason for using herbicides. Glyphosate (N-Phosphonomethylglycine) is a systemic non-selective post-emergent herbicide, whose average soil life, fluctuates from 2 to 197 days, resisting the environment for up to three years (Chufan et al., 2014; Quarles, 2012). Its use has been recorded in at least 130 countries, commercially known as Faena®, Roundup®, Dicamba, among others (Dill et al., 2010; Cattani et al., 2014) even more 750 products contain glyphosate as active ingredient (NPIC, 2015). Glyphosate is an herbicide for residential, urban and agricultural everyday use around the world, its formulations are the most sold at world level, of which 6.1 thousand millions of kg of glyphosate have been applied only in the last decade (Benbrook, 2016). The mechanism of glyphosate on plants is by the shikimate metabolic pathway. It is a chemical highly water-soluble; in the soil it degrades rapidly to sarcosine acid and aminomethylphosphonic acid (AMPA), the last one is the main metabolic intermediary (Amrhein et al., 1980).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_51275140

International disagreements exist with respect to the classification of glyphosate as carcinogenic. According to the International Agency for Cancer Research (IARC), glyphosate is “probably carcinogenic for human beings” while for the United States Environmental Protection Agency (USEPA) “it is probably not carcinogenic”. However, exists scientific research with evidence that glyphosate produces: infertility, kidney problems (USEPA, 2015), endocrine disruption (Gasnier et al., 2009), apoptosis, cytotoxicity, and neurotoxic oxidative effects (Chaufan et al., 2014; Cattani et al., 2014; Ma and Li, 2015). It has also been related to minor illnesses, such as autism, Alzheimer, Parkinson, anxiety disorders, osteoporosis, inflammatory intestinal disease, osteomalacia, cholestasis and thyroid dysfunction (Samsel and Seneff, 2015). Also, has been proved that AMPA causes genotoxicity (Mañas et al., 2009; IARC, 2016).

Exposure to glyphosate and its degrading products in air, soil, and water is unavoidable, mainly in populations close to agricultural fields. In these places, aerial and mechanical pesticide applications are constant (up to 45 times per year). Despite people are not exposed directly to these chemical agents, they could be in contact with glyphosate or AMPA either by occupation or diet, which could be regarded as a human health risk. Occupational exposure is considered of a greater risk (Nawaz et al., 2014; Parrón et al., 2014; Angeli et al., 2015).

Valle del Mayo is one of the largest agricultural producers in northwestern Mexico where an extensive irrigation system provides water to more than 93000 ha of cultivation (INEGI, 2017). The most widely used herbicide is glyphosate at 1% in canals while a mixture of glyphosate with Tordon is used at 1.5% in drains. In total, more than 20000 L of glyphosate is sprayed in this region per year just to eliminate grass in irrigation canals and drains. In Mexico, no regulations exist for glyphosate while a regulation project proposed a permissible concentration of 100 $\mu g\ L^{-1}$ (PROY NOM-250-SSA1-2014); although, it is not officially approved yet.

Most of the agricultural laborers of Valle del Mayo live next to the irrigation drains for generations. They do not have a public water supply in their homes and municipality authorities sends trucks to deliver water to these places; however, delivery delays. Some houses have private wells built a few meters from the irrigation drains, which might imply infiltration of contaminants. Additionally, in most of the housing units, kitchens are found outdoors, which could cause food contamination and skin exposure to the applied herbicides. Due to this problem, the objective of this work was to assess health risk associated to exposure of contaminated water with glyphosate and AMPA in populations of agricultural fields in the communities of Valle del Mayo, Sonora, Mexico.

Materials and methods

Geographical location of the study

It is located in Valle del Mayo (26° 31’ 54” N 109° 38’ 02” W) in the municipalities of Navojoa, Etchojoa, and Huatabampo in the southern part of the State of Sonora in northwestern Mexico. The communities close to irrigation canals were selected by cartographic research related to the Irrigation District of Rio Mayo. The following criterions were considered for the selection: (1) Housing of participants less than 50 m from an irrigation canal or drain; (2) Drains or canals with weed problems; (3) Herbicide applied at least twice a year; (4) Difficult access to drinking water; (5) Communities with private wells; (6) People working close to drains and canals.

Assessment of health risk by glyphosate and aminomethylphosphonic acid

Hazard identification

Environmental samples collection. The points were selected in areas were herbicide formulated with 1% of N-Phosphonomethylglycine at 99% and 0.001% of adherent in canals and a mix of 1.5% of N-Phosphonomethylglycine at 99% and tordon, and 0.001% of adherent in drains. The sample collection was carried out in irrigation drains or canals close to communities with private wells were the application of glyphosate is constant. GPS coordinates are the follow: Tres Carlos 26.919385, -109.512457, Saucobe 26.958041, -109.498360, Colonia Soto 26.907112, -109.602550, Sebampo 26.878628, -109.571211, La Esquina 26.804662, -109.716644, Ramal 26.792826, -109.767667, Moroncarit 26.734392, -109.614932, Entronque 26.860334, -109.636900 and Huatabampo 26.826744, -109.650587 (*Fig. 1*).

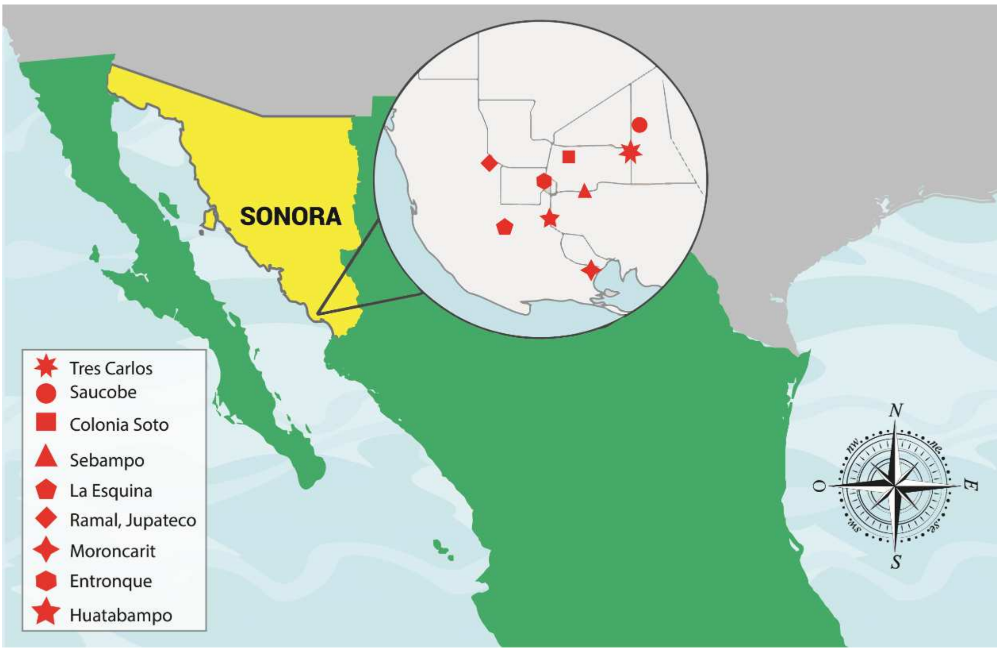

Figure 1. *Location of the selected communities for the risk assessment study of glyphosate and AMPA in Valle del Mayo, Sonora, Mexico*

The samples were collected in sterile 100 mL polypropylene wide-mouth flasks. Drain and/or canal water was taken during glyphosate application (when the brushwood was grown and the application was necessary); is for this reason the samples per place are different. In the case of soil, sediment or drain/bottom canal was also sampled where water was previously collected with a difference of one month, collecting approximately 200 g following standard methods. Well water samples were taken approximately every two months and always after herbicide application. Both were collected in the selected points from February 2016 to May 2017. All samples were transported in a cooler to the laboratory and preserved at -80 °C until analyses were performed.

HPLC analytic method. The method was adapted and modified for water and soil (Olivo et al., 2015; Peruzzo et al., 2008). Water and soil samples were purified by filtration through a cellulose acetate membrane of 0.45 µm (MF-Millipore^{TM}). Soil samples purification was performed by duplicate extraction shaking 15 g of the sample

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_51275140

with 25 mL of KH_2PO_4 0.1 M for 15 min and subsequently filtered through Whatman^{TM} paper (Sigma-Aldrich, MO. U.S.A.) and centrifuged at 3500 rpm for 10 min. The obtained extract was filtered following the protocol for water samples (Peruzzo et al., 2008).

Derivatization was performed mixing 3-mL purified sample and 2-mL FMOC-Cl (0.005 M) (23186 Sigma-Aldrich, MO, U.S.A.) prepared with chloroform (650498 Sigma-Aldrich, MO, U.S.A.). It was maintained for 45 min avoiding radiation. After the reaction, 3-mL methyl chloride (270997 Sigma-Aldrich, MO, U.S.A.) were added to remove excess of FMOC-CL; subsequently, the supernatant was filtered using SPE polymeric columns (Strata-X^{TM}, Torrance, CA, U.S.A.) (Olivo et al., 2015). The collected filtered solution was taken for high-performance liquid chromatography (HPLC) (Agilent 1200 series, Santa Clara, CA, U.S.A.).

Modifications to chromatographic conditions were established as follows: Column Agilent C18 250 x 4.6 mm, the injection volume of 20 µL, water flux mobile phase 1 Ml min^{-1}, UV 240 nm and FL excitation 266 emission 315. Total analysis time per each sample was 30 minutes.

Method validation. The calibration curves were performed using one blank run and different aqueous concentration patterns of glyphosate and AMPA. The concentrations tested were from 5-25 and 15-90 µg L^{-1} for glyphosate and AMPA respectively.

Glyphosate and aminomethylphosphonic acid concentrations in vegetables washed with contaminated water with herbicides. It is possible to estimate the risk in vegetables based on the risk developed for water (Haas et al., 1999; Shuval et al., 2007; Mota et al., 2009). Taking into account that the population in the Mayo Valley uses irrigation water from drains for domestic activities, in this case, wash vegetables before eating them; the volume of water retained by the most consumed vegetables was calculated applying *Equation 1:*

$$CV = CxVr \tag{Eq.1}$$

where *CV* is the concentration in vegetables (mg g^{-1}); *C,* is the concentration of herbicide in water, and *Vr,* is the volume of water retained in the vegetable. Considered rough-texture vegetables, which have been reported to retain approximately 0.108 mL g^{-1} and 0.0036 mL g^{-1} the smooth ones (Mota et al., 2009).

Exposure evaluation

Cohort/population study. An agricultural health study was developed, which included individuals located in areas close to drains and who made use of water for domestic activities and consumption.

Population size. A total of 586 persons lived at ≤ 50 m from irrigation drains in Valle del Mayo, which was estimated visiting populations. Population size was estimated with a margin of error of 10% and confidence level of 90% using the statistical software Epi Info 7.2 (CDC, 2017).

Exposure estimation. Socioeconomic, consumption, health and symptomatology surveys were applied to the sampling populations, estimating water and food consumption patterns (portion size and frequency). The population was characterized in age, sex, occupation, schooling, socioeconomic condition, feeding, and water consumption groups.

Three exposure scenarios were established for the analysis: (a) Participants drink water from private wells close to irrigation drains (always/never); (b) Days accumulated to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_51275140

which they are exposed to (if well water is used some days or always); (c) If participants are present during herbicide application (aerial exposure).

The levels of intensity were estimated using data from the questionnaires. Aliments with higher frequency were assessed and associated with glyphosate exposure.

Toxicity assessment

The dose of a potential toxin for the human body by contact with contaminants (water, soil) should indicate the amount of the chemical substance ingested per kilogram of corporal weight per day (mg kg^{-1} day^{-1}). To calculate the dose for each source, *Equation 2* (USEPA, 1989; CIDA, 2009) was used:

$$\text{Dose (soil, water, food ingestion)} = C \times I \times AF \times Dh \times Dd \times Dw / BW \times 16 \quad \text{(Eq.2)}$$

Where C (mg kg^{-1} or L^{-1}), is the concentration of soil or water contaminants; I (kg day^{-1}), is water or soil intake in children or adults; AF, is the absorption factor in the gastrointestinal tract wherein agreement with oral exposures the value of 1 is used (HC, 2014); Dh, hours of exposure per day (0-16); Dd, days of exposure in a week (0-7); Dw, weeks of exposure in a year (0-52); BW (kg) corporal individual weight.

Risk characterization

The risks by exposure to soil and water were estimated by integrating the results of the toxicity assessment in each source and comparing them with tolerable daily intake (TDI) (HC, 1995) or also named reference dose (RfD) (USEPA, 2017) to obtain the hazard quotient, which is defined with *Equation 3:*

$$HQ = \frac{\sum Doses}{RfD} \quad \text{(Eq.3)}$$

The following RfD doses were compared in this research: 0.03 mg kg^{-1} day^{-1} (HC, 1995), 0.1 mg kg^{-1} day^{-1} (USEPA, 2017), 0.5 mg kg^{-1} day^{-1} (EFSA, 2015).

It is considered to be a potential human health risk when HQ is greater than 0.2.

Statistical methods

Concentrations and calibration curves were processed using calculus sheets of Microsoft Excel, 2016. The dose and hazard quotient was performed with the software Risk Calculation Tools (CIDA, 2009). In addition for exposure assessment were calculated significant differences to associate the consumption of contaminated water with herbicides and the suffering from diseases were analyzed using StatCalc tables 2 x 2 x N from statistical software Epi Info 7.2, 2017.

Results and discussion

The selected communities are shown in *Figure 1.* In method validation by calibration curves, a correlation coefficient (R^2) of 0.994 was obtained for glyphosate whereas that for AMPA was 0.9917. Retention times were 8.3 min and 26.5 min for glyphosate and AMPA, respectively.

Hazard identification

During the sampling period, herbicide was applied 3 times in Saucobe and in La Esquina, and 2 times in Colonia Soto and in Sebampo; in the other sampling points no weed problems were presented and only one application was recorded. A total of 90 results of glyphosate and AMPA from 45 samples (15 for irrigation water, 15 for well water and 15 from soil); where, 70% of the samples were positive for AMPA; these results are in agreement with IARC monograph (2016) which mention that are mayor percentage of positive samples of AMPA in superficial waters. For glyphosate, the samples showed concentrations lower than 5 µg L^{-1} whereas those for AMPA were from 15-342.5 µg L^{-1} or µg g^{-1} (*Table 1*).

Table 1. *Glyphosate and AMPA concentrations in water and soil samples in different communities of Valle del Mayo, Sonora, Mexico*

DOI: http://dx.doi.org/10.15666/aeer/1604_51275140

The positive samples (60%) for AMPA in the private wells maintained the following characteristics: built scarcely a few meters (6-8 m) from drains or irrigation canals covered by stone, brick or cement and excavated from 3-6 m in depth, which infers infiltration (*Fig. 2*). The results proved that glyphosate degrades rapidly although its presence in soil could reach groundwater by lixiviation (IARC, 2016).

Figure 2. *Photographs of private wells in the selected sites of Valle del Mayo, Sonora, Mexico (right: La Esquina private well, left: Saucobe private well)*

Exposure to glyphosate at a dose of 300 mg kg^{-1} causes severe toxicity signs; a dose from 1000 to 5000 mg kg^{-1} causes death. The maximum permissible glyphosate concentration is different in drinking water depending on the country (700 µg L^{-1} in the U.S.A; 280 µg L^{-1} in Canada; 10 µg L^{-1} in Australia) (Laubli et al., 2016). With respect to the glyphosate concentration found (≤ 5 µg L^{-1}), the detection limit of the method used in this study could be improved.

Exposure evaluation

Among the participants of the cohort study (n = 64) (*Fig. 3*), 40% of those surveyed came from the Mayo indigenous ethnic group. Age range oscillated from 15 to 81 years old; the maximum level of studies registered were secondary school and 43% of the participants were low-average socioeconomic status. As to occupation, 18.75% of the workers surveyed were brick makers, 15.63% agricultural laborers and the rest were housewives and students. As for water use, 23.81% used drain water for domestic activities; 10.94% drain water for drinking; 53.7% private well water for domestic activities; and 37.5% private well water for drinking. Brick makers used irrigation drain water for making the bricks. Housewives (22%) mentioned their children used drain and canal water for recreational activities.

The surveyed population declared (we verify with the prescriptions of the participants) having diabetes, obesity, hypertension; and dermatological, gastrointestinal and respiratory problems, among others (*Fig. 4*). Individuals, who expressed water consumption from private wells, recorded greater frequency in getting sick ($p \leq 0.01$). With respect to the correlation between water consumption from private wells and frequent diseases, statistical significance was found with diabetes ($p \leq 0.03$) and hypertension ($p \leq 0.004$). Concerning these results is necessary to take into account that the place where these people live is agricultural and they may be exposed to a large number of agrochemicals, which are used in this area. Arrebola et al. (2015) have demonstrated that individuals with obesity, exposure to high levels of certain persistent organic contaminants, were associated with the risk of developing hypertension,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_51275140

independently of other factors, such as age, tobacco or alcohol consumption. Moreover, the high risks of these contaminants doubled this risk. The glyphosate applied in the drains of the Valley is a mix with tordon at 1.5% of the total formulated; mixtures can be more harmful to human health (Hernández et al., 2013).

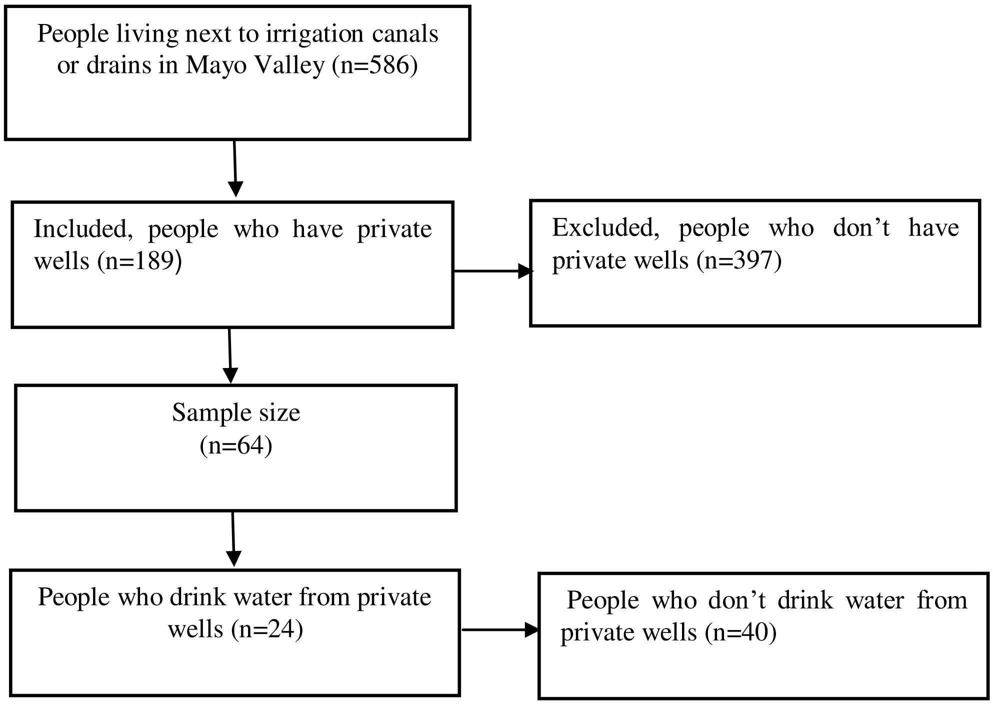

Figure 3. *Systematic selection of the inclusion and exclusion criteria*

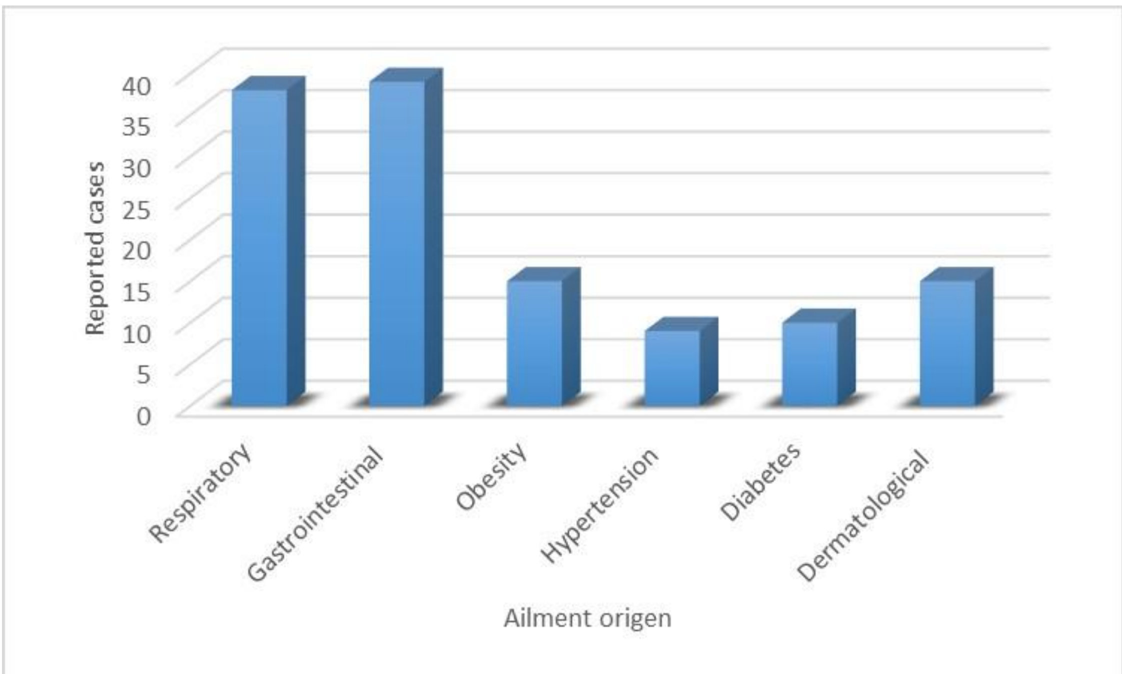

Figure 4. *Most common diseases between the population of Valle del Mayo, Sonora, Mexico*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_51275140

Swanson et al. (2014) made a correlation between glyphosate application and chronic diseases. The diseases with statistical significance were autism, thyroid cancer, senile dementia; significance was also observed with incidence and prevalence of diabetes, obesity, pancreas and kidney cancer and hypertension with a correlation lower than 90%, different from the present research where hypertension recorded a high correlation.

Among the fresh vegetables most consumed by the individuals in the communities, were lettuce, squash, carrot, cucumber, chard or purslane.

Toxicity assessment

The gastrointestinal absorption is the quotient of the fraction of chemical absorbed orally between the fraction absorbed in principal study. Different parameters, obtained from the survey, were considered to assess health risk by glyphosate and AMPA exposure, in agricultural laborers, brick makers, housewives, and children from 2 to 16 years old and toddlers. For each one of the different receptors, the following was taken into account: housewives washed clothes with well water, which they also used it to wash food before ingesting, implying oral and dermal contact. Children in the communities usually took baths and swim into drain water, and finally, agricultural laborers and brick makers drank water from the well and consumed food washed with well water. With respect to soil, intake was considered accidental, as well as dermal contact with soil and drain water (*Table 2*).

Risk characterization

This study obtained a hazard quotient of 0.39 and 0.22 for brick makers and agricultural laborers respectively using, according to the formula, an RfD of 0.03 mg kg^{-1} day^{-1}, which determined the potential health risk for AMPA in Valle del Mayo populations.

In the past, different countries used to have standardized ADIs of 0.03 mg kg^{-1} day^{-1} (HC, 1995), 1.75 mg kg^{-1} day^{-1} (USEPA, 2009), 0.1 mg kg^{-1} day^{-1} for glyphosate and AMPA (FAO and WHO, 2011). Currently, laws regulate different ADIs: 0.3 mg kg^{-1} day^{-1} (APVM, 2017), 0.5 mg kg^{-1} day^{-1} (EFSA, 2015). The hazard quotients obtained using EFSA regulation are shown in *Table 3.* These results indicate that no health risk hazard exists on the population of Valle del Mayo.

One of the concerns is that no sufficient regulations exist for AMPA. It the past was reported that there are not enough concentrations in the environment to consider it a health problem (HC, 1995). However, other studies in the literature, as well as the present, found AMPA concentrations in well water greater than those of glyphosate (Kolpin et al., 2006; Battaglin et al., 2014).

The regulations of different countries agreed to a wide range of acceptable daily intake (ADI) for glyphosate and AMPA of 0-1 mg kg^{-1} day^{-1} (FAO and WHO, 2016). Controversially, several regulations and organizations have emphasized that the glyphosate studies, which IARC have based on, were badly designed, so they cannot be used as evidence to prove its carcinogenic effects. Other agencies (USEPA and EFSA) clarified there was not enough proof to support glyphosate as probably carcinogenic, so they establish the herbicide as “probably does not cause cancer”. Despite before the IARC publication, all these regulatory agencies had graded glyphosate as currently the most harmful considering a lower ADI (EFSA, 2016; USEPA, 2017; APVM, 2017).

With the assurance of the majority of the regulatory agencies worldwide that glyphosate is not hazardous to health, the Food and Agriculture Association (FAO) and the World Health Organization (WHO) agreed that due to its low toxicity, it is not necessary to establish a reference dose for glyphosate in food residues (FAO and WHO, 2016). This new regulation allows glyphosate-resistant genetically modified cultivations, which represent approximately 56% of glyphosate use worldwide (Benbrook, 2016). It is important to mention FAO reported that 795 millions of individuals in the world are undernourished, of which 780 million live in underdeveloped regions (FAO, 2015), which is why both the use of herbicides and the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_51275140

convenience of eradicating famine should weigh up improvement in agriculture production and possible health problems.

The position of glyphosate as probable carcinogenic was assessed by IARC with enough background evidence in animal experiments to grade it as such for humans. The monograph published by the IARC is a thorough global compilation of the main scientific research on glyphosate, which clearly showed that glyphosate was harmful to flora and fauna and could cause cancer to humans (IARC, 2015).

*[1]Glyphosate, is the dose (mg kg^{-1}) per day that ingests the exposure population
*[2]TDI, is the sum of all doses by exposure matrix type
*[3]Acceptable Daily Intake, is the amount of glyphosate or AMPA that can be ingested without health risk
*[4]Hazard Quotient, is according to USEPA (2017), the ratio of the potential exposure to the substance and the level at which no adverse effects are expected

Conclusions

Currently, ADIs regulation for glyphosate and AMPA to compare the present quotients, unlikely health risk exists on the population of Valle del Mayo, Mexico. Therefore, these results using an ADI of 0.03 mg kg^{-1} day^{-1} suggest a potential health risk due to glyphosate and AMPA in the agricultural laborers and brick makers of this region. The permissible reference dose of glyphosate and AMPA has a very large margin (0-1 mg kg^{-1} day^{-1}) even traces in food are permissible according to current regulations. In addition, we determinate that water consumption from the private well near to irrigation canals correlated statistically with diabetes ($p \leq 0.03$) and hypertension ($p \leq 0.004$). It is necessary to develop more toxicity studies that indicate an accurate value to establish that the herbicide and its metabolite do not cause harm to the human beings in a short and long-term.

(Received 23rd May 2018; accepted 31st Jul 2018)

Abstract. Germination and propagation of terrestrial orchids is highly challenging due to their small size seeds and absence of endosperms. Some orchid species are extremely dependent on fungi for germination of their seeds. Although germination occurs symbiotically between the seed and the fungus, it is not coincidental that fungus species are specific to orchid species. Aim of this study is to show the impact of the fungi, isolated from the tubers of ten naturally grown species of orchids, collected from mountainous area of Van province, Turkey, on in vitro symbiotic germination of the seeds. The collected orchids species were *Dactylorhiza romana* (Seb.) Soo subsp. *georgica* (Klınge) Soo ex Renz & Taub., *Orchis pinetorum* Boissier & Kotschy, *Orchis spitzelii* Saut. ex W.D.J. Koch, *Orchis coriophora* L., *Orchis collina* Banks & Solander, *Orchis anatolica* Boiss., *Orchis simia* Lamarck, *Ophrys straussii* H. Fleischmann & Bornmüller, *Dactylorhiza umbrosa* (Kar. & Kir.) Nevski, *Anacamptis pyramidalis* (L.) L. C. Rich. In the study from orchid tubers, *Rhizoctonia* sp., *Aspergillus* sp., *Alternaria* sp., *Penicillium* sp., *Trichoderma* sp. and *Fusarium* sp. fungi species are isolated. Firstly, orchid seeds and fungal isolates placed in oat culture medium were transferred to Van Waes & Debergh culture medium in subculture. The highest germination rates obtained in the seeds are 71.19% in *Dactylorhiza romana* subsp. *georgica* species with *Rhizoctonia* sp.; 78.26% in *Orchis pinetorum* species with *Penicillium* sp.; 27.77% in *Orchis spitzelii* species with *Fusarium* sp.; 83.07% in *Orchis coriophora* species with *Rhizoctonia* sp.; 75.00% in *Orchis collina* species with *Fusarium* sp.; 38.88% in *Orchis anatolica* species with *Alternaria* sp.; 73.91% in *Orchis simia* species with *Fusarium* sp.; 91.60% in *Ophrys straussii* species with *Fusarium* sp.; 93.75% in *Dactylorhiza umbrosa* species with *Fusarium* sp. and 56.00% in *Anacamptis pyramidalis* species with *Rhizoctonia* sp. At the end of the study, it was understood that the fungi isolated from their own or other tubers had different effects on the germination of each orchid species.
Keywords: *fungal isolates, in vitro, mycorrhiza effect, symbiotic germination, terrestrial orchid*

Introduction

The most distinctive features of the orchid seeds are their very small size, absence of endosperm and undeveloped embryo. These seeds have a length of 0.25-1.2 mm, width of 0.09-0.27 mm and weight of 0.3-1.4 mg (Arditti, 1967). The orchids grown at high altitudes occasionally fail to grow and set seed due to low temperatures or the ones grown under dense forests grow slowly and cannot reach to a desired level of development due to lack of light (Sezik, 1984). Thus, in addition to appropriate temperature, light, oxygen, moisture and soil conditions required in the microclimate of the environment in which the seed fall to germinate, an appropriate symbiotic relationship should be established with a mycorrhizal fungus for germination of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_51415155

seeds (Sezik, 1984). As the orchid seeds do not contain nutrient reserves, successful germination cannot be achieved unless a carbohydrate source, such as glucose, is provided (Ingold and Hudson, 1993).

The symbiotic capacity of a fungal isolate depends primarily on the nature of the isolate and then the orchid species with which it coexists. The results obtained on the existence of a specificity between orchid species and mycorrhizal fungi indicate that there is no strict specificity at the species-species level, and that, on the other hand, orchid-fungus relationships are not entirely random. According to Batty et al. (2001), terrestrial orchids may have narrow or broad potential specificity (Warcup, 1981; Alexander and Hadley, 1983; Muir, 1989), but the specificity of their associations with endophytes in natural habitats is still poorly understood. The specificity of the orchid–mycorrhiza association is variable between species (Steinfort et al., 2010). An orchid may form mycorrhizal associations with more than one fungal species, and a fungal species might associate with more than one orchid under in situ conditions (Bonnardeaux et al., 2007; Otero et al., 2004).

When these relations existing in the nature are moved to the laboratory conditions; the fungal isolates are isolated from the orchid tubers and roots and inoculated into the medium. In this study, the impacts of the fungal isolates isolated from orchid tubers, collected from the nature and inoculated into nutrient medium, on germination of the seeds are determined.

Material and methods

The material of the research consists of orchid seeds and fungi obtained from the tubers of the plants. The plants used in the research are naturally grown in Van province, Turkey, collected from Gevaş District Altınsaç neighbourhood in July-2014 when the plants formed capsules, and identified according to Davis (1984).

Orchid species

The orchid species examined in the study are *Dactylorhiza romana* (Seb.) Soo subsp. *georgica (*Klınge) Soo ex Renz & Taub., *Orchis pinetorum* Boissier & Kotschy, *Orchis spitzelii* Saut. ex W.D.J. Koch, *Orchis coriophora* L., *Orchis collina* Banks & Solander, *Orchis anatolica* Boiss., *Orchis simia* Lamarck, *Ophrys straussii* H. Fleischmann & Bornmüller, *Dactylorhiza umbrosa* (Kar. & Kir.) Nevski, *Anacamptis pyramidalis* (L.) L. C. Rich.

Dactylorhiza romana subsp. *georgica, Orchis pinetorum* ve *Orchis spitzelii* species were determined in the same location (N 38°23'30.2" and E 42°53'43.8") while *Orchis coriophora* and *Dactylorhiza umbrosa* species were obtained in the same location (N 38°24'16.2" and E 42°53'76.6"). *Anacamptis pyramidalis, Orchis collina, Orchis simia,* and *Ophrys straussii* species were collected from N 38°23'61.7" and E 42°55'03.2" coordinates while *Orchis anatolica* species was collected from N 38°23'59.3" and E 42°54'98.1" coordinate *(Table 1* and *Fig. 1).*

Fungi

Fungi obtained from isolations in tuber samples, collected during seed collection, are used.

Figure 1. *Locations where orchid species are collected (Google Earth, 2018)*

Surface sterilization of the seeds

Orchid seeds are sterilized in small envelopes made from coarse filter papers as they are very small and have a dusty structure. Seeds of each species weighting 100 mg are enveloped and used for experiments. For each experiment, 100 mg of the seeds were planted in total of 9 petri dishes containing Potato Dextrose Agar (PDA) media in 3 replicates, 3 pots in each replicate.

The seeds were shaken for 5 min with 2% sulfuric acid, sterilized with 1-2 drops of Tween-20 and 10% commercial bleach for 12 min and then rinsed 3 times with sterile distilled water before sowing to Çığ and Yılmaz (2017).

DOI: http://dx.doi.org/10.15666/aeer/1604_51415155

Fungus isolation from tubers

The orchid tubers, washed from the soil in the tap water, were shaken in the sterilized cabinet for 3 min in 3% bleach solution and then rinsed 3 times with sterile distilled water and wiped with sterilized drying papers. 2-3 pieces of tuber, cut into sections with 0.5-1 cm length with scalpel, were planted in PDA petri dishes and incubated for 3-4 days at 24 °C. The PDA medium was prepared with 39 g/l potato dextrose agar dose (Zettler et al., 2001; Sharma et al., 2003) and sterilized for 20 min in an autoclave operating at 121 °C and 1.2 atmosphere pressure.

Developed fungal hyphae were identified on light microscope after being transferred to water agar (WA, 15 g/l) petri dishes and stored in refrigerator in glass tubes. Fungus isolation procedures and identification were done in Mycology Laboratory of the Department of Plant Protection, Faculty of Agriculture at Yüzüncü Yıl University.

Identification of isolates

Morphological and microscopic features of the fungi incubated in PDA and WA for 7 days at 25 °C were used in identification of the isolates obtained in the study (Barnett, 1965; Booth, 1971; Burgess et al., 1994; Domsch et al., 1980; Gilman, 1959; Singh et al., 1991; Ogoshi, 1975). Identification of *Trichoderma* species was done by using the interactive key http://nt.arsgrin.gov/taxadescriptions/keys/TrichodermaIndex.cfm (Samuel et al., 2006).

Composition of the oat medium (OM)

In order to create the oat medium described by Clements and Ellyard (1979), 2.5 g milled and powdered oat was boiled in 1000 ml of distilled water for one hour and drained from the gauze. The pH of the cooled medium was adjusted to 5.5 and it was autoclaved by adding 7 g/l agar as in the PDA medium.

Seed sowing in symbiotic culture medium

The fungi used in the study were planted in petri dishes containing PDA in advance and 0.5 cm discs were taken with cork borer when they were 10 days old. Each disk was placed on one side of the petri dish containing OM, which is a symbiotic medium. Petri dishes were incubated in the dark at 24 °C for a couple of days. Seed sowing was done on the other side of the petri dishes where there is no fungus. The petri dishes were kept at 23 ± 1 °C in the dark during germination. The seeds were taken to Van Waes & Debergh (VWD) (1986) culture medium while sub-culturing.

Statistically analysis

The data were analyzed using the statistical software package SPSS. The means were grouped using the Duncan multiple comparison test (Düzgüneş et al., 1987).

Results and discussions

Fungus isolation and identification

Six orchid tuber samples/orchid species were used for fungal isolation. The identification of the fungi was done by the references after isolations from tuber

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_51415155

samples. *Rhizoctonia* sp., *Aspergillus* sp., *Fusarium* sp., *Penicillium* sp., *Trichoderma* sp., and *Alternaria* sp. were isolated from orchid tubers. The identification was based on morphological and microscopic features (*Table 2*).

Table 2. *Morphological and microscopic features of the fungi isolated from tuber samples*

Fungi	Morphological and microscopic features		References
	Colony color in PDA	**Shape of conidia**	
Rhizoctonia sp.	White/brown	No conidia	Ogoshi, 1975

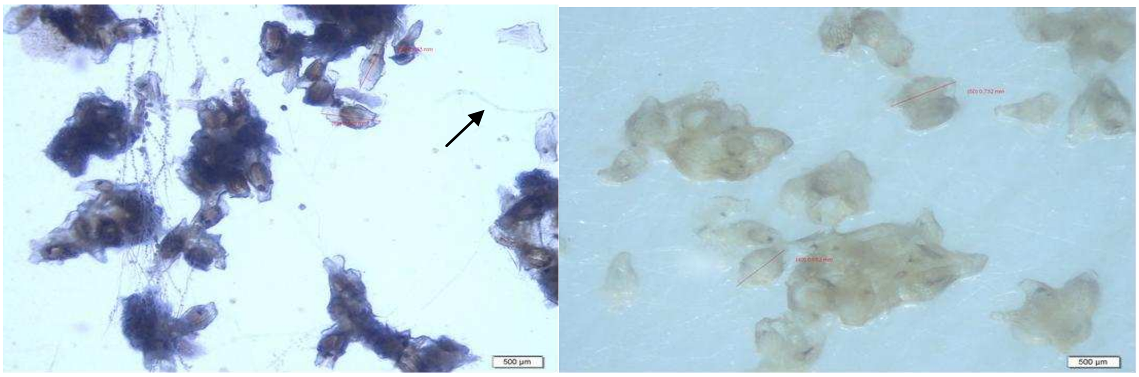

***Figure 2.** Symbiotic germination*

The effects of the isolated fungi on the germination of orchid seeds were found statistically significant ($p < 0.05$) (*Table 4*). 71.19% germination rate is observed in *Rhizoctonia* (R) fungus obtained from the tuber of *D. romana* subsp. *georgica* (species number 1) (*Fig. 3*). No germination is observed with the fungi obtained from tubers of species number 2 *O. pinetorum* (*Fig. 4*), while the impact of R and Fo isolated from the tubers of species number 3 *O. spitzelii* on germination is found as 16% and 27.77%, respectively (*Fig. 5*). T isolate, isolated from the tubers of species number 4 *O. coriophora,* provided 65.86% germination rate (*Fig. 6*). From the species number 5 *O. collina,* only sub-culturing is done and the impact of its own seeds on germination was determined as 48.59% (*Fig. 7*). As no fungus was isolated from the tubers of species number 6 *O. anatolica*, germination is obtained using fungi isolated from tubers of other orchid species (*Fig. 8*). In the symbiotic germination between the seeds of species number 7 *O. simia* and F fungus isolated from its tubers, a success rate of 25.98% is achieved (*Fig. 9*). Fs and P fungi isolated from the tubers of species number 8 *O. straussii* had impacts of 15.38% and 20.83% respectively on germination of its own seeds (*Fig. 10*). R, R1, R2, Alt and F fungi isolated from the tubers of species number 9 *D. umbrosa* had impacts of 61.29%, 17.64%, 76.77%, 68.75% and 17.14% on germination of its own seeds, respectively (*Fig. 11*). F, Alt, As and P fungi isolated from the tubers of species number 10 *A. pyramidalis* had impacts of 34.04%, 7.93%, 23.07% and 12.5% respectively on germination of its own seeds (*Fig. 12*).

Bernard (1909) stated that the symbiotic relationship between the orchid and the fungus is specific to species, while other researchers reported no such specific relation between a mycorrhizal fungus and an orchid species exists (Burgeff, 1936; Curtis, 1939). In another study, it was determined that fungi isolated from orchid tubers were *Rhizoctonia, Corticium, Armillaria, Fomes, Hymenochaeta* species, while *Aspergillus, Penicillium, Phytophtora* and *Trichoderma* were reported to be initiating and promoting germination (Arditti, 1967).

Clements and Ellyard (1979) reported that the effect of the nutrient medium content on symbiotic culture experiments was important for in vitro germination of orchid seeds and suggested primarily to obtain the most effective *Rhizoctonia* isolate and to prepare the optimal medium for the isolate. In line with this, it has been reported that some fungi have no or little effect on orchid seed germination and the most suitable nutrient medium for controlling parasitic condition is oat medium with additives (Hadley, 1983; Tsutsui and Tomita, 1986). Clements et al. (1986) reported in their study on symbiotic germination of the temperate zone orchids in Europe that *Ceratobasidium*-like fungi are affective on *Dactylorhiza* species and *Tulasnella*-like fungi are affective on *Orchis, Ophrys* and *Serapias* orchid species. Researches show that although ground oat added to the symbiotic culture medium used in the studies on *Rhizoctonia* sp. fungus and orchid seed combination has a stimuli effect on germination, amounts above a certain concentration reduces the degree of stimulation. Smreciu and Currah (1989) have shown that the fungal isolates obtained from an orchid species are symbiotic in germination of another orchid species, and even can act in different development stages of the orchid plant. From 19 fungal isolates isolated from different orchid species collected between March and May in the Eastern Mediterranean Region, 8 pieces of *Fusarium* sp., 2 pieces of *R. solani*, 2 pieces of *Macrophomina* sp., 2 pieces of *Trichoderma* sp., 2 pieces of *Pythiaceous* sp. and 2 pieces of *Absidia* sp. fungi are identified (Vakkasoğlu, 1995). 44 out of 47 fungal isolates in a study, in which mycorrhiza forming fungi were isolated from the roots and tubers of various orchid species collected in the Aegean and the Mediterranean Region in April, were identified as *Fusarium*, while 2 were identifies as *Rhizoctonia* and 1 was identified as *Papulaspora* species (Gezgin, 2004). Another study, in which *Fusarium* sp. was isolated in greater proportions than others, was conducted using *Serapias vomeracea* subsp. *laxiflora* and it was determined that they are contaminant (Özkoç, 1991). *Alternaria, Aspergillus, Fusarium, Macrophomina, Rhizoctonia, Trichoderma* and *Verticillium* fungi species were isolated from eleven orchid species belonging to *Anacamptis, Cephalanthera, Dactylorhiza* and *Orchis* genus collected in Van province (Çığ and Yılmaz, 2014). According to the literature, the fungi isolated from orchid tubers in our study stimulate seed germination and plant growth. This is also evident from the results we have obtained. The germination rate varied with species. Not all the orchid species germinated with all fungi. On the contrary, it is observed that one fungal isolate yielding germination success in one species did not achieve the same effect in another one. In some cases, the fungus has not succeeded in germinating the seeds or did not have a high germination rate with the plant it was isolated from. This can be explained by not achieving 100% of the ecological conditions in the aseptic environment and by the special relationship between the orchid species and the fungus. Özkoç and Dalcı (1993) reported that not all the isolates had the same effect on *Orchis laxiflora* seeds cultivated in oat medium (OM) and modified oat medium (MOM) in the presence of 11 fungal isolates brought from different countries and found that two Turkish isolates were

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_51415155

ineffective in germination. In the germination experiment with 11 fungal isolates in *Serapias vomeracea* subsp. *laxiflora* and *Orchis laxiflora* species, it was observed that not all the isolates did have the same effect (Özkoç, 1991). According to the results obtained from our study, the lowest germination rate in species number 1 was 17.64% with T isolate; and the highest germination rate was obtained with R isolate with 71.19%. In species number 2, the lowest and highest germination rates were found as 31.57% and 78.26% respectively with P isolate. In other species, the lowest and highest germination percentages and fungi isolates in which they are symbiotic were obtained as follows: for species number 3 as 16% (R) - 27.77% (Fo); for species number 4 as 27.58% (F) - 83.07% (R); for species number 5 as 10.63% (As) - 75% (F); for species number 6 as 6.66% (R) - 38.88% (Alt); for species number 7 as 18.18% (As) - 73.91% (F); for species number 8 as 9.19% (As) - 91.60% (F); for species number 9 as 16.66% (As) - 93.75% (F) and for species number 10 as 7.93% (Alt) - 56% (R).

Successful germination of *Dactylorhiza iberica* (Bieb. ex Willd.) Soó, *Dactylorhiza umbrosa* (Kar. et. Kir.) Soó and *Orchis palustris* Jacquin species with binucleus *Rhizoctonia* and *Rhizoctonia solani* isolates in the oat medium and the modified oat medium is achieved (Çığ and Yılmaz, 2017). The overall expected effect of *Rhizoctonia* isolate in orchid germination studies is success, however, as can be seen in our study, *Rhizoctonia* sp. fungus, which plays a role in seed germination of many species, did not have proportionally the highest average germination figure. When we look at the success rates of fungal isolates along with the ones that cannot stimulate germination, the highest average is provided by *Fusarium* isolate by 93.75%. In this case, it is clear that fungal isolates and species give different germination success rates together. According to Salifah et al. (2011), a total of 31 different species of fungus was isolated and inoculated onto *Grammatophyllum speciosum* seed on oat meal agar. The result obtained from the test demonstrated that seed germination rates were best when co-cultured with *Fusarium* sp. number 3. Initial seed germination rates were best when co-cultured with *Fusarium* sp. 3 and *Trichoderma* sp. 2, yielding an increment in 63.3% and 55.7%, respectively when compared to the seeds' original size.

The relationship between orchid species and fungal isolates may vary from symbiosis to parasitism, as some researchers have found that parasitic properties of the fungus can increase and unbalance the relationship between the orchid and fungus by depletion of nutrients in the culture medium and fungus might have a parasitic effect in symbiotic environments with high nutrient content (Tomita and Tsutsui, 1988; Özkoç, 1991). Seeds germinated in oat medium were sub-cultured in VWD culture medium. During this process, fungal isolates have developed to such an extent that encapsulates the whole petri dish due to high nutrient concentration and had parasitic effect on germinating seeds. On the other hand, germinated seeds did not have enough required nutrients to develop in oat medium.

Environmental factors such as relative humidity and temperature were reported to have a profound influence on the infectiveness of a variety of fungi (Ibrahim et al., 2011). According to the researches, growth rate of fungi varies depending on temperature and relative humidity. The optimum growth temperatures for the majority of fungi studied was found to fall from 25 to 30 °C (Sharma and Razak, 2003). For example, the growth of *Fusarium oxysporium* was found to reach its maximum at 30 °C after 7 days of incubation which was drastically reduced below 15 °C and above 35 °C (Farooq et al., 2005). As can be seen, for a successful orchid germination protocol, both fungi and seeds enter into symbiotic life together with the common satisfaction of them.

Conclusions

As a result of the study, different germination success rates were achieved in each orchid species in the presence of fungal isolates. The idea of using a more diluted media during sub-culturing or even using temperature applications to control fungal growth will be given in the methodology section of subsequent new studies to be undertaken with consideration of culture media in which germination took place. But the most important step that must be taken before anything else is to make a molecular identity in order to reveal the true identity of the isolated fungi.

(Received 28th May 2018; accepted 31st Jul 2018)

Abstract. A study on water quality status of Tekala River, Selangor, Malaysia was conducted at two sampling times. A total of six sampling stations were selected along the river representing the upstream (S1 and S2), the middle stream (S3 and S4) and the downstream (S5 and S6) of the Tekala River. In this study, in-situ and ex-situ analyses were conducted to determine the quality of Tekala River. Physical, chemical and biological parameters included biochemical oxygen demand (BOD), chemical oxygen demand (SOD), ammoniacal nitrogen, total suspended solids (TSS), dissolved oxygen (DO), pH, temperature, total dissolved solid (TDS), salinity, conductivity, *Escherichia coli*, coliform and macroinvertebrate. According to the result obtained from this study, Tekala River is classified under Class I and Class II based on water quality index and National water quality standard. Two-way ANOVA showed a significant difference between parameters (ammoniacal nitrogen, BOD, pH, temperature, conductivity, DO and TDS) of sampling station. Significant difference was found between ammoniacal nitrogen, pH and temperature with sampling time. The correlation test revealed that there is relationship between *Escherichia coli* with ammoniacal nitrogen, temperature and DO. There is also relationship found between coliform with pH and BOD.
Keywords: *water quality, biomonitoring, water pollution, water management, biological parameters*

Introduction

Over the centuries, river has been very important to the human society. River has also provided water for irrigation, industrial and domestic uses. Additionally, river plays an important role in assimilating municipal and industrial effluents as well as runoffs from agricultural land and the surrounding area in a watershed (Al-Badaii et al., 2013). The importance of water quality has become a serious matter especially when it involves the assessment of producing the biologically-accepted water system as a whole (Ashraf and Hanafiah, 2017; Muhammad Mansoor et al., 2018). The demand for safe and clean drinking water has increased by leaps and bounds in developing countries that have deteriorated environment (Gelover et al., 2006). The target of the Millennium Development Goal (MDG) which is the 'access to safe drinking water' has set its track globally with about 6.1 billion people in 2010 using improved drinking water sources, an increase of over 2 billion since 1990 (MDG, 2012).

Selangor state can be divided into several districts which are Klang, Kuala Langat, Gombak, Kuala Selangor, Hulu Langat, Hulu Selangor, Petaling, Sabak Bernam and Sepang. Selangor is one of the most populated and industrialized state in Peninsular Malaysia. As the most populated state, rivers in Selangor are facing serious

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_51575174

contamination due to anthropogenic activities. On the other hand, study by Al-Badaii et al. (2013) found that Semenyih River, Selangor was contaminated with NH_3-N, TSS, COD and NO_3 and highly polluted with PO_4 and faecal coliform. The sources of contamination were originated from industrial, agricultural, livestock farming and erosion. Mohamad Ali (2010) stated that the main pollution in Selangor River is from poultry farms, wet market activities and industrial wastewater.

Tekala River is a recreational river that has potential to be contaminated with faecal pathogens (such as bacteria and viruses) from human sewage and animal manure. Contaminated recreational water can cause diseases. Therefore, this study aims to measure the water quality status of Tekala River based on the physico-chemical and biological parameters. In view of the above facts, Tekala River has been chosen due to its importance as recreational area. If this river is classified as not safe then further action should be taken to maintain and improve its quality.

Materials and methods

Study area

This study was conducted at Tekala River, Selangor, Malaysia (*Fig. 1a*) within Tekala River Recreational Park (TRRP) that was established since 1982. The highest level of the river leads up to a sparkling waterfall which cascades into a natural rock pool. TRRP is located 13 km from Semenyih via Jalan Semenyih – Hulu Langat and 50 km from Kuala Lumpur.

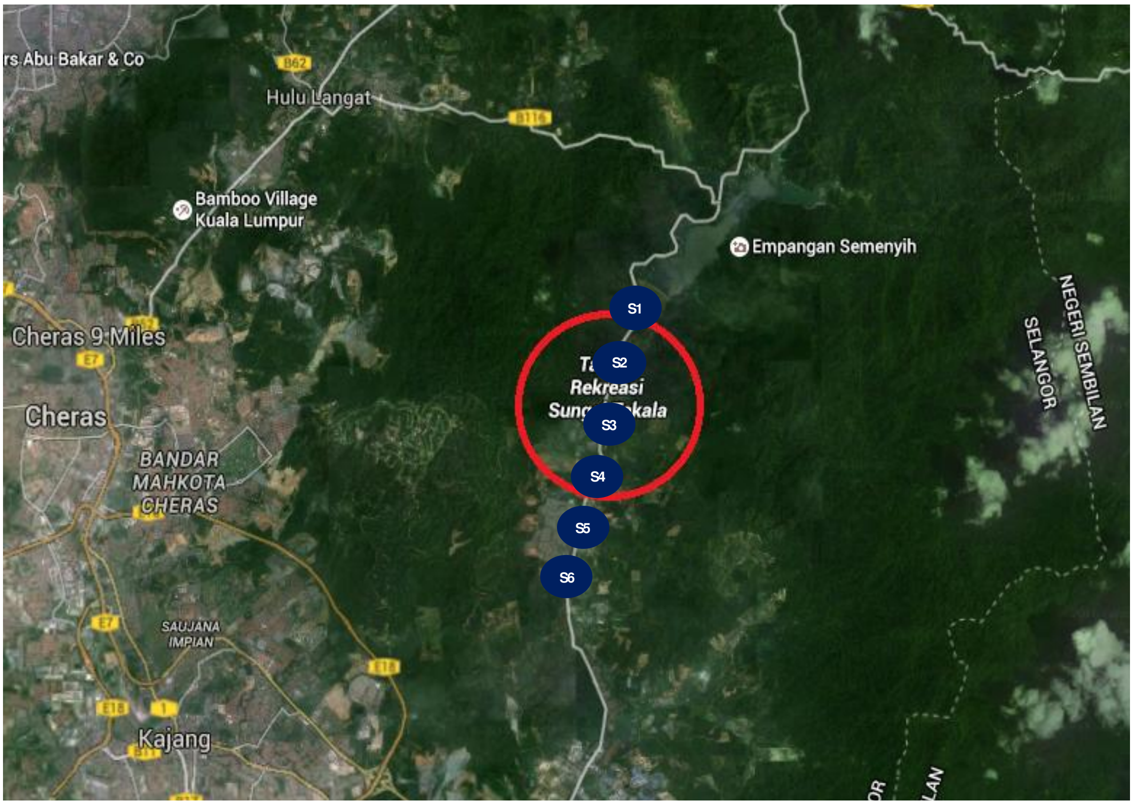

Figure 1. *Map of Tekala River and locations of six sampling points*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_51575174

Measurement of ex-situ parameters

The water quality index was determined based on the physico-chemical and biological parameters. The parameters include biochemical oxygen demand (BOD), chemical oxygen demand (COD), ammoniacal-nitrogen (NH_3^-N), total suspended solids (TSS), dissolved oxygen (DO), pH, water temperature, total dissolved solid (TDS), salinity, conductivity, *Escherichia coli (E. coli)*, coliform and macroinvertebrate.

Samples collection and preservation

Water samples were collected from the selected river and have been collected for two visits in May 2017 and October 2017. A total of 18 water samples were collected from 6 sampling stations and the samples were kept in polyethylene bottles. For BOD sample, another 18 water samples were collected in glass bottle wrapped with aluminium foil. This is to avoid sunlight from penetrating the bottles and react with sample and cause changes in the BOD. During sampling for BOD, no air bubble was observed as it can influence the oxygen content of the sample. All bottles were preserved at 4–10 °C in an ice box before transported to the laboratory. Preservation of samples need to be done to maintain the actual composition of water samples and can minimize changes in chemical composition during transportation to the laboratory.

DO, water temperature, TDS, salinity, conductivity and pH values were measured in-situ. The COD, TSS, BOD, ammoniacal-nitrogen, *E. coli* and coliform in the water were analysed in the laboratory using standard procedure of HACH. For macroinvertebrate, samples were collected by using Surber net at 6 stations based on different habitats. All collected samples were transferred into plastic. Then, samples were preserved by using 70% ethanol in the laboratory for further identification.

Water was kept in dark condition and in temperature around 4–5 °C to reduce biological activity, to avoid changes and to preserve the actual condition of sample as it is before conducting any analysis. BOD samples were kept in glass bottle preserved at 30 °C for about 5 days prior to measurement. The use of glass bottle can avoid any changes in activity and microorganism metabolism. Samples for *E. coli* and coliform test were kept at 4–5 °C and analysis was conducted at least 4–8 h after sampling activity.

Biological Oxygen Demand (BOD) was determined by using conventional method by incubating the water samples for a standard time period in incubator at 20 °C and the oxygen consumption was determined at the end of the incubation period. The first measurement of DO values (DO_1) was carried out within 24 h after sampling by using YSI model 5000. The reading was recorded on a data sheet. The second reading of DO values was determined after 5 days of incubation (DO_5). BOD values were obtained from the difference in DO values of the first reading (DO_1) and the second reading (DO_5). The BOD value is expressed in milligrams per liter using *Equation 1:*

$$\text{BOD (mg/l)} = DO_{initial} - DO_{final} \qquad \text{(Eq.1)}$$

Chemical oxygen demand

COD was measured by using Reactor Digestion Method approved by USEPA for reporting wastewater analysis. Samples were first homogenized to dissolve containing solids for better representative samples. The homogenized water samples were then added into glass vials containing strong oxidizing agent, potassium dichromate. This mixture was heated for 2 h at 150 °C to allow them to react. Colorimetric determination of COD

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_51575174

with high range using HACH DR/2010 was used to measure COD value in the water samples.

Total suspended solid

Whatmann filter paper with pore size of 0.45 µm was put in petri dish each and dried in the drying oven at the temperature of 105 °C for 1 h. After an hour, the petri dish was taken out and cooled for 30 min in the desiccator. Before performing filtration of the samples, the weighed filter paper was obtained. This was the initial weight of the filter paper (A). This filter paper then was used in filtration process. For the filtration process, the filter paper was inserted between the Buchner funnel and the suction flask. The water sample in the bottle was shaken and about 200 ml of sample was used in the filtration. After that, the filter paper was put back into petri dish and was dried in the drying oven at 105 °C and the final weight of the filter paper was recorded (B).

For the calculation (*Eq. 2*),

$$x\,mg/L = \frac{(B-A)\ X\ 1000}{\text{Volume of sample used (ml)}} \qquad \text{(Eq.2)}$$

where,

A = initial weight of the filter paper (mg)
B = final weight of the filter paper + soluble solid (mg)

Ammoniacal-nitrogen

Ammoniacal-nitrogen was measured by using HACH DR 2700 based on Nessler Method. 25 ml of sample and 25 ml of deionized water (blank) were transferred into glass cell each and then three drops of mineral stabilizer, three drops of polyvinyl alcohol and 1.0 ml of Nessler reagent were added to each transferred sample. The mixture was measured by using spectrometer at 425 nm. Deionized water was used as blank and the reading was recorded for each sample.

Measurement for biological parameter

Escherichia coli and coliform

100 ml of water sample was used for determination of *E. coli* and coliform. Water samples were filtered in cellulose membrane filter. After filtration, Eosin Methylene Blue (EMB) agar was added with no air bubbles observed on the agar. The agar was preserved for 22 ± 2 h at 35 °C. Organisms that produce a colony with golden-green metallic within 24 h of incubation on the agar were considered members of *E. coli* group. While organisms that produce colony with light purple were classified as coliform group.

Quantitative data was obtained by counting the number of each colony formed by assumption that each colony represents one bacterium. Colony of coliform and *E. coli* that grow was counted and expressed in unit of cfu (colony forming unit) (APHA, 1980) and calculated as below (*Eq. 3*):

$$E.coli/100\,ml = \frac{100\ X\ Number\ of\ colony}{\text{Volume of sample filtered (ml)}} \qquad \text{(Eq.3)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

Macroinvertebrate

All the samples from the river were taken to the laboratory for identification process. Sample from different stations were put in different bottles. Each sample was analyzed by identifying specific characteristics for each species such as head shape, body segment and type of wings. Samples that had already been identified were preserved in 70% ethanol.

Water quality classification

Classification in water quality index (WQI) was determined based on the water quality index as below (*Eq. 4*):

$$\begin{aligned} \text{WQI} = &\left(0.22 \text{ x SIDO}\right) + \left(0.19 \text{ x SIBOD}\right) + \left(0.16 \text{ x SICOD}\right) \\ &+ \left(0.15 \text{ x SIAN}\right) + \left(0.16 \text{ x SITSS}\right) + \left(0.12 \text{ x SIpH}\right) \end{aligned} \quad \text{(Eq.4)}$$

where:
SIDO = Sublndex DO (% saturation)
SIBOD = Sublndex BOD
SICOD = Sublndex COD
SIAN = Sublndex NH_3-N
SISS = Sublndex SS
SipH = Sublndex pH
Statistical analysis was conducted by using IBM SPSS Statistics 20. Two-way ANOVA was conducted for comparing water quality parameter at different stations and sampling times. Correlation analysis was also conducted to determine the relationship between physico-chemical and biological parameters.

Results

Physico-chemical parameters

Mean value for total suspended solid (TSS) for two sampling times is shown in the *Figure 2a*. TSS ranged from 1.67 mg/L to 8.17 mg/L. The average value of TSS is 4.15 ± 0.48 mg/L and this value is categorized under Class I of NWQS. Based on the Two-way analysis of variance (ANOVA) result, there is no significantly different between TSS versus station and sampling time ($P > 0.05$, $P = 0.746$).

Figure 2b presents the mean value for ammoniacal nitrogen (NH_3^-N) for both sampling times. It was found that NH_3^-N were ranged from 0.03 mg/L to 0.31 mg/L with an average value of 0.18 ± 0.04 mg/L and falls under Class I of NWQS. Two-way analysis of variance (ANOVA) shows that there is significantly different between NH_3^-N and station ($P < 0.05$, $P = 0.000$). There is also significant difference between NH_3^-N and sampling times ($P < 0.05$, $P = 0.038$). Significantly different was also found between the effect of different stations and different sampling times on NH_3N ($P < 0.05$, $P = 0.037$).

Mean value for biological oxygen demand (BOD) for two sampling times is shown in *Figure 3a* is ranged from 0.04 mg/L to 1.42 mg/L. The average value of BOD is 0.78 ± 0.14 mg/L, categorized under Class I of NWQS. There is no significantly

DOI: http://dx.doi.org/10.15666/aeer/1604_51575174

different between BOD and sampling times (P > 0.05, P = 0.189). However, there is significant difference between BOD and station (P < 0.05, P = 0.000).

Figure 3b shows the mean value for chemical oxygen demand (COD) that were ranged from 0.33 mg/L to 1.67 mg/L, with an average value of .64 ± 0.22 mg/L (Class I). Two-way analysis of variance (ANOVA) shows that there is no significant difference between COD with station and sampling time (P > 0.05, P = 0.656).

pH was ranged between 5.00 to 6.8 with an average of 5.60 ± 0.67, classified under Class III and IV for the first and second samplings, respectively (*Fig. 4a*). A significantly different was observed between pH and sampling times and station (P < 0.05, P = 0.025) and (P < 0.05, P = 0.000), respectively. Mean value for temperature for two sampling times is shown in *Figure 4b* ranged from 20.76 to 21.49 °C. There is significant difference between temperature and sampling times (P < 0.05, P = 0.000) as well as between temperature and station (P < 0.05, P = 0.000).

It was found that the conductivity for both sampling times were ranged from 0.013 mS/cm to 0.017 mS/cm (*Fig. 5a*). The average conductivity is 0.0014 ± 0.0003 mS/cm and classified in Class I and IIA. Based on the result, there is no significant difference

DOI: http://dx.doi.org/10.15666/aeer/1604_51575174

between conductivity and sampling times (P > 0.05, P = 0.292), whereas there is significant difference between conductivity and station (P < 0.05, P = 0.006). For dissolve oxygen, the mean value for both sampling times were ranged from 5.32 mg/L to 7.86 mg/L as shown in *Figure 5b*. The average DO is 6.60 ± 0.29 mg/L (Class IIA and IIB). There is no significantly different between DO and sampling times (P > 0.05, P = 0.078). However, there is significant difference between DO and station (P < 0.05, P = 0.000).

Figure 6(a) shows the mean value for salinity for two times sampling ranged from 0.003 to 0.01 with an average of 0.007 ± 0.001 (Class I). No significantly different between salinity with station and sampling time was observed (P > 0.05, P = 0.813). The mean value for total dissolved solid ranged from 0.009 g/l to 0.011 g/l (*Fig. 6b*). The average of TDS is 0.009 ± 0.0001 and classified under Class I. There is no significant difference between TDS and sampling times (P > 0.05, P = 0.423), while significantly different was found between TDS and station (P < 0.05, P = 0.032).

Water Quality Index (WQI) for all stations times is shown in *Figure 7*. WQI has been considered as one criterion for surface water classifications, based on the use of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_51575174

standard parameters for water characterization. This index is a numeric expression used to transform large quantities of water characterization data into a single number, which represents the water quality level (Mohamad Ali, 2010). The WQI values recorded were ranged from 85.45 to 94.86 with the highest WQI recorded at station 2, while the lowest WQI was measured at station 4. The results show that WQI obtained from this study fall under Class I (clean category). Overall, the WQI value of Tekala River was classified under Class II which indicated as clean.

DOI: http://dx.doi.org/10.15666/aeer/1604_51575174

correlation was conducted to examine relationship between *E. coli* and coliform with the physico-chemical parameters (*Table 1*). Based on the test, there is relationship between *E. coli* with NH_3^-N, temperature and DO. For coliform, there is relationship between coliform with pH and BOD.

Macroinvertebrate

Total value for macroinvertebrate for two sampling times is shown in *Figure 9*. The abundance of macroinvertebrate was ranged from 10 to 68 (*Fig. 9*). Pearson's correlation was conducted to examine the relationship between abundance of macroinvertebrate with the physico-chemical parameters (*Table 2*). Based on the test, there is relationship between abundance of macroinvertebrate with temperature of the river.

Discussion

Physico-chemical parameters

Total Suspended Solids (TSS) are solids in water include a wide variety of material, such as silt, decaying plant and animal matter, industrial wastes, and sewage. High concentrations of suspended solids can cause many problems for stream health and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_51575174

aquatic life (Bilotta and Brazier, 2008). According to Wood and Armitage (1997), suspended solid in the river may be due to bank erosion, sediment load and anthropogenic activities or due to runoff from surrounding areas. In second sampling, station 2 surrounded by dense vegetation, thus recorded the highest TSS. Vegetation can reduce the erosion and increase sediment entrapment. However, there is no significant different between TSS with station and sampling time. The maximum threshold limit of TSS for Malaysian rivers which support aquatic life is 150 mg/l (Al-Badaii et al., 2013). TSS value recorded in this study are within the range of the limit.

Ammoniacal nitrogen (NH_3^-N) is a common pollutant in freshwater ecosystem and it is frequently found associated with organic compound or sometimes from industrial effluents (Alabaster and Lloyd, 1982; Magdalena et al., 2015). Abdel-Raouf (2012) stated that the presence of NH_3^-N in the water is mainly originated from the domestic sewage and waste water from certain types of industries. Ammoniacal nitrogen indicates nutrient status, organic enrichment and health of water body (Radojevic et al., 2007). Higher NH_3^-N values can be toxic to fish, but in small concentrations, it could serve as nutrients for excessive growth of algae (Al-Badaii et al., 2013). There is significant different between NH_3N with station and sampling times implying NH_3N is influenced by sampling location and time of sampling. The maximum threshold level of NH_3N for Malaysian rivers which support aquatic life is 0.9 mg/l. The value of NH_3N obtained from this study is still within the range.

Biochemical Oxygen Demand (BOD) is a measurement of the amount of dissolved oxygen used by aerobic microorganisms when decomposing organic matter in water. It is a measure of the quantity of oxygen used by microorganisms in the oxidation of organic matter. Microorganisms such as bacteria are responsible for decomposing organic waste. When organic matter such as dead plants, leaves, grass clippings, manure, sewage or even food waste is present in a water supply, the bacteria will begin the process of breaking down this waste. When this happens, much of the available dissolved oxygen is consumed by aerobic bacteria, affecting oxygen level needed for other aquatic organisms (USGS, 2016).

If there is a large quantity of organic waste in the water supply, there will also be a lot of bacteria present working to decompose this waste. In this case, the demand for oxygen will be high so the BOD level will be higher. When BOD levels are high, dissolved oxygen levels decrease because the oxygen that is available in the water is being consumed by the bacteria (Al- Badaii et al., 2013). Since less dissolved oxygen is available in the water, fish and other aquatic organisms may not survive. If there is no organic waste present in the water, there will be fewer bacteria present to decompose it and thus the BOD will tend to be lower and the DO level will be higher.

Chemical Oxygen Demand (COD) is a measurement of the oxygen required to oxidize soluble and particulate organic matter in water (Boyd, 1973; Kunlasak et al., 2013). It is used to measure the total quantity of oxygen-consuming substances in the complete chemical breakdown of organic substances in water. It does not differentiate between biologically available and inert organic matter. COD measurements can be made in a few hours while BOD measurements take five days (Othman et al., 2012). Generally, the lower COD level indicates a low level of pollution, while the high level of COD points out the high level of pollution of water in the study area (Al-Badaii et al., 2013). The COD value obtained in this study is low indicating this river has low level of pollution.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_51575174

pH of a water sample is a measure of the concentration of hydrogen ions (Tank and Chippa, 2013). If the pH of water is too high or too low, most of the aquatic organisms will not be able to adapt to the extreme condition. pH can also affect the solubility and toxicity of chemicals and heavy metals in the water. Various concentration of solution, solid or gaseous that enters into river can influence pH of the river due to reaction of dissociation which may produce H+ or OH- ions (Chang et al., 1983; Lelis et al., 2016). Based on the result, pH ranged from 5.00 to 6.88. There is significance different between pH with station and sampling times indicating pH is influenced by sampling location and time of sampling. pH slightly decreased from station 1 to station 6. pH of water body can be affected by several factors. One of the factors is the amount of plant growth and organic material within a body of water. Carbon dioxide is released when this material is decomposed. The carbon dioxide combines with water to form carbonic acid. Although this is a weak acid, large amounts of it will lower the pH. Decaying vegetation produces organic acids, thus change the pH of the river (Gasim et al., 2007). Station 1 to station 6 were surrounded by vegetation. Different station may have different rate of decaying vegetation. This might explain the decreased of pH from station 1 to station 6. Rainfall could also affect pH of water body due to the interaction with carbon dioxide molecules in the atmosphere. This creates H_2CO_3 in the raindrops, lowering the pH value of rainwater. A pH level of 5.65, though acidic, is not considered acid rain. Acid rain requires a pH below 5.0. If rain falls on a poorly buffered water source, it can decrease the pH of nearby water through runoff.

Water temperature is one of the most important characteristics of an aquatic system. It affects dissolved oxygen levels, species composition, chemical and biological processes (Tank and Chippa, 2013). A change in water temperature can affect the general health of the aquatic organisms, thus changing the quality of the stream. There is significant difference between temperature with sampling times and station. The temperature of surface water is usually between 0 ºC and 30 ºC. The lowest temperature was recorded at station 1 and the highest at station 6 for both samplings. There is slightly increased of temperatures from station 1 to station 6. Usually there is an increase in temperature from the first station to the last station (Bordalo et al., 2001). Water temperature varies along the length of a river with latitude and elevation. The geographical location of sampling stations are differ on elevation and environment. Station 1 and station 2 were located in upstream, station 3 and station 4 in the middle meanwhile stations 5 and 6 in the downstream. Vegetation cover may influence water surface temperature. Area from station 1 to station 6 were covered by vegetation. However, the vegetation in the upstream was denser than middle and downstream. The vegetation acts as protection to surface water from directly being heated by solar radiation. The forest canopies will shield the water surface from the emission of long wave radiation from the sun. Denser vegetation gives more protection to the surface water thus this might explain the reason why station 1 had low temperature compared to other stations. Human activities in the surrounding area might also influence the water temperature. The middle and downstream had a lot of human contact as the river is a recreational area. Downstream area vegetation had some disruption as a lot of facilities being built in this area. Water temperature can also be influenced by variation of precipitation. According to Shuhaimi-Othman et al. (2008) large volume of water inputs and higher flow rate were responsible for cooling down the river temperature. There is only little difference of temperature between first and second samplings.

DOI: http://dx.doi.org/10.15666/aeer/1604_51575174

Conductivity can be defined as an ability of the aquatic system to transmit electric current based on the level of dissolved ions in a water body. Conductivity in water is affected by the presence of inorganic dissolved solids such as chloride, nitrate, sulfate and phosphate anions or sodium, magnesium, calcium, iron, and aluminum cations. Conductivity normally coinciding with the level of dissolved salt in water and has a strong correlation with salinity. An increasing in level of dissolved salt would result an increased in conductivity. There is slightly difference of salinity based on times and location of the sampling in this study. Based on the result, there is no significance different between conductivity and sampling times but there is significant different between conductivity and different station which means conductivity is influenced by sampling location. Conductivity in streams and rivers is affected primarily by the geology of the area through which the water flows. Streams that run through areas with granite bedrock tend to have lower conductivity because granite is composed of more inert materials that do not ionize when washed into the water. On the other hand, streams that run through areas with clay soils tend to have higher conductivity because of the presence of materials that ionize when washed into the water. Soil and rocks release dissolved solids into the waters that flow through or over them. Therefore, the geology of a certain area will determine the conductivity. Most streams have a fairly constant range of conductivity under normal circumstances. Therefore, significant changes in conductivity can be an indicator that a discharge or some other source of pollution has entered the water. This might explain the reason why conductivity for different sampling times is constant and the difference can be seen mostly based on the sampling location. The conductivity was ranged from 0.013 mS/cm to 0.017 mS/cm. This is considered low and does not affect the water quality (Suki et al., 1988; Rashid et al., 2013).

Dissolved oxygen (DO) measures the amount of gaseous oxygen dissolved in an aqueous solution. Oxygen gets into water by diffusion from the surrounding air, by aeration and as a waste product of photosynthesis from phytoplankton, algae, seaweed and other aquatic plants (Othman et al., 2012). The amount of dissolved oxygen varies depending on temperature, pressure and salinity. Solubility of oxygen decreases as temperature increases. This is due to the fact that warmer surface water requires less dissolved oxygen to reach 100% air saturation compared to cooler water. There is negative correlation of DO and temperature which means higher temperature will reduce DO level. Temperature slightly increased from station 1 to station 6 and the DO level recorded is slightly reduced from station 1 to station 6. Dissolved oxygen decreases exponentially as salt levels increase. There is significance difference between DO and station. In freshwater systems such as lakes, rivers and streams, dissolved oxygen concentrations will vary by season, location and water depth and it will decrease with higher temperature, salinity and elevation (Beale et al., 2000). Oxygen concentrations vary with the volume and velocity of water flowing in a stream. Faster flowing water areas, such as in a mountain stream or large river tend to be more oxygen rich because more oxygen enters the water from the atmosphere in those areas than in slower and stagnant areas. Oxygen is more easily dissolved into water at low altitudes that at high altitudes. Oxygen is also more easily dissolved into water with low levels of dissolved or suspended solids. Removal of riparian vegetation may lower oxygen concentrations due to increased water temperature resulting from a lack of canopy shade and increased suspended solids resulting from erosion of bare soil. Upstream area has

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_51575174

faster flowing water compared to lower area thus this might explain why level of DO is higher in upstream area.

Salinity is the total concentration of all dissolved salts in water. Freshwater contains few salts and thus has low salinity. Most of natural freshwater do not show much different on level of salinity unless there are additional discharged from surrounding environment into the river. The salinity value recorded from this study is low thus it would not have huge impact in the environment.

Total dissolved solid (TDS) is a measure of the amount of material dissolved in a water sample. This material includes dissolved minerals and organic matter but can also include contaminants. There is significant difference found between TDS with station. TDS is influenced by sampling location. TDS can vary spatially and temporally due to natural and anthropogenic factors such as climate, soil type, relief, land use and human activities (Augustijn et al., 2011). TDS in water supplies originated from natural sources, sewage, urban and agricultural run-off and industrial wastewater. Water containing TDS concentrations below 1,000 mg/l is usually acceptable but water with extremely low concentrations of TDS may also be unacceptable to consumers because of its flat, insipid taste to consumers. No recent data on health effects associated with the ingestion of TDS in drinking-water appear to exist (WHO, 2004).

Water quality index (WQI) provides relative indication of the quality of water. A river with WQI value in the ranges 0-59 is considered polluted, 60-80 is considered slightly polluted and 81-100 is considered the water body is clean. A higher value indicates a better quality of water (Suki et al., 1988; Rashid et al., 2013). From this study, the average WQI calculated at each sampling station for both sampling times are described as follows: Station S1 (94.29: Class I), S2 (94.86: Class I), S3 (90.23: Class II), S4 (85.45: Class II), S5 (87.32: Class II) and S6 (87.17: Class II) (*Fig. 4*). The results show that WQI obtained from this study fall under Class I (clean category). Overall, the WQI value of Tekala River was classified under Class II which indicated as clean. Generally, WQI tends to decrease from upstream to downstream of river due to increasing of pollutant. WQI recorded slightly reduced from station 1 to station 6.

Biological parameter

E. coli is mainly originated from the feces of warm blooded organism. This type of bacteria usually entered into water surface by run-off from agricultural and residential areas (Pearson et al., 1987; Inatsuka et al., 2010). From the first sampling, there is a decrease of *E. coli* from station 1 to station 6. Second sampling recorded less number of *E. coli*. There is correlation relationship found between *E. coli* and NH_3^-N, temperature and DO. It is reported that fecal coliform levels were lower at higher temperature, high dissolved oxygen and high pH implying that one of the fecal coliform sources could be related to human recreational activities (Al-Badaii et al., 2013). This might explain the downtrend of bacteria from first station to the last station. Since this river is a recreational area, it probably potentially exposed to fecal contamination sources from human activities (swimming, camping) that cannot be detected by measuring physico-chemical parameters alone.

From the first and second samplings, there is a decrease of coliform from station 1 to station 6. Second sampling recorded less number of coliform. There is correlation relationship found between coliform with pH and BOD. Water with lower pH value helps in maintaining the survival of indicator bacteria (Parhad et al., 1974; Mara, 2013). A study done by Šolić and Krstulović (1992) also suggested that the optimal pH value

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_51575174

for coliform survival is between pH 6 and pH 7 and other pH value above or below these range can cause rapid decline in fecal coliform population. The bacteria population is influenced by favourable condition and food sources provided by the sediments for the bacteria (Davies et al., 1995). Lower temperature of surface water can cause rapid decline in coliform and *E. coli* population in the water (McDaniels et al., 1985; Pope et al., 2003).

Macroinvertebrate

Macroinvertebrates and water quality are interrelated to each other, as macroinvertebrates are a potential biological indicator of water quality. They are most frequently used in biomonitoring studies (Harikumar et al., 2014). Often many species within a community with varying sensitivities to stresses and relatively quick reaction times, resulting in a spectrum of graded, recognisable responses to environmental perturbation. The responses to different types of pollution have been established for many common species (Ollis et al., 2006). Stream communities are shaped by environmental influences at multiple spatial scales. Their distribution, interaction and adaptation can be influenced by abiotic factors which vary in space and time. Climate is one of the factors that influence population dynamics of aquatic insects (Nor Zaiha et al., 2015). In this study, the number of macroinvertebrate found is low. Most of the macroinvertebrate found belong to the same family. A study on surber net was conducted at the forested stream site by Wan Mohd Hafezul et al. (2016). They found very low species abundance was recorded by the surber net. Its small size makes it difficult to set on rough substrates in deep water and often results in the loss of large organisms that are fast enough to crawl out of the front of the sampler. Usually area disturbed within the surber net is exposed, providing an opportunity for aquatic fauna to escape (Wan Mohd Hafezul et al., 2016).

The most dominant insect found in all stations is water strider from family Gerridae. Based on the correlation test, there is relationship between abundance of macroinvertebrate and temperature. Water striders most prefer waters around 25 °C. Large numbers can indicate moderate, or slightly polluted water quality. In the upstream area, a few mayfly from order Ephemeroptera was caught in station 4. Ephemeroptera is a group of aquatic insects which is sensitive to environmental interference and can only survive in clean and oxygen-rich waters. Therefore, they are often considered as good biological indicators of water quality (Nor Zaiha et al., 2015). The most significant environmental factor affecting life-history patterns, especially growth rates and the seasonal timing of aquatic insects, is water temperature. Mayfly is widely distributed in peninsular Malaysia. It inhabits upstream rivers of peninsular Malaysia. Low water temperature seemed to favor mayfly abundance. Predators, particularly fish, play a role in the mayfly community (Suhaila et al., 2016). In station 4, there is no fish found in fast flowing water thus mayfly might prefer the area. From station 3 to 6, there is no more mayfly found. Station 3 has fish community, thus this area might not be preferred by mayfly. There is less human contact from station 1 to station 3, where visitor usually stay in area station 4 to station 6.

There are several other organisms that were found in the river such as freshwater shrimp, freshwater crabs and water penny. Freshwater crabs are one of the most ecologically important macro-invertebrate groups in tropical inland waters worldwide. These strictly freshwater decapods are found in almost all clean freshwater bodies in the tropics from moist lowland forests to rugged mountains. Crabs live in rivers, streams,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_51575174

waterfalls, wetlands, karsts, caves and many are semi-terrestrial. Almost all require pristine water conditions to survive and are excellent indicators of good water quality (Cumberlidge et al., 2009). Generally, it can be concluded that more abundant macroinvertebrate communities exist in the littoral zone than in the deeper river bed. The individual numbers are usually very low in the deep water zone which is dominated by continually shifting sand (Csányi et al., 2012). Type of food sources and physical properties of river determine the distribution of aquatic organisms (Cummins and Merritt, 1996).

Conclusions

From this study, physico-chemical parameters and biomonitoring analysis have been conducted to determine the status of water quality at Tekala River, Selangor. Water quality index for Tekala River were ranged from 85.45 to 94.86, thus indicated that the water quality status for both sampling times and six sampling stations are classified under Class I and Class II. It was found that there is significance different between ammoniacal nitrogen, pH and temperature. Correlation was also found between several physico-chemical parameters with biological parameter. From the Pearson's correlation test, there is relationship between *E. coli* with ammoniacal nitrogen, temperature and DO. For coliform, there is relationship between coliform with pH and BOD. The data from this study was also compared with the National water quality standard (NWQS) and most parameters were classified under Class I to Class IIB, implying that this river is safe to be used for recreational purposes. It is recommended that further research on other parameters on this river to be conducted in order to get better assessment on the water quality.

(Received 29th May 2018; accepted 17th Jul 2018)

Abstract. The aim of the study was to determine the influence of applied herbicides and their mixtures on the polyphenol content in tubers of three edible potato varieties. The field experiment was conducted in the years of 2008-2010 in the Agricultural Experimental Station Zawady (52°03'N and 22°33'E) belonging to the University of Natural Sciences and Humanities in Siedlce, Poland. The experiment was established as two-factor in the split-plot system in three repetitions. The studied factors included: I – three varieties: Cekin, Satina and Tajfun. II – five ways of care: 1. mechanical care – control object, 2. mechanical-chemical care - mechanical care + Command 480 EC (chlomazon 480 g·l), 3. mechanical-chemical care - mechanical care + Command 480 EC (chlomazon 480 g·l) + Dispersion Afalon 450 SC (linuron 450 g·l), 4. mechanical-chemical care - mechanical care + Stomp 400 SC (pendimethalin 400 g·l), 5. mechanical-chemical care - mechanical care + Stomp 400 SC (pendimethalin 400 g·l) + Dispersion Afalon 450 SC (linuron 450 g·l). Polyphenols were determined in a fresh mass of potato tubers using the Swain and Hillis method using the Folin-Ciocalteu reagent. The results of the research were statistically analysed using the analysis of variance. The conducted own studies showed that the polyphenol content in potato tubers was on the level from 155.8 to 162.5 $mg \cdot kg^{-1}$ of fresh weight and depended significantly on the variety cultivated. Also the herbicides and their mixtures used in the experiment had a significant influence on the concentration of polyphenols in tubers, causing them to increase (from 2.2 to 6.0 $mg \cdot kg^{-1}$ of fresh weight) in relation to the control object that was cultivated only mechanically. In addition, meteorological conditions significantly modified the accumulation of polyphenols. Their smallest (on average-50.5 $mg \cdot kg^{-1}$) content in potato tubers was obtained in 2009 with the smallest sum of precipitation in the examined three-year period and the average air temperature of 15.1 °C.
Keywords: *potato, phenols, methods of care, variety, antioxidants*

Introduction

For many years, it was believed that polyphenols are anti-nutritious substances, however, currently the importance of this group of compounds as active food components is significantly increasing, due to the recent studies on their pro-health effects on the human body (Gumul et al., 2005).

Polyphenols occur in various plant species, have a diversified structure, molecular weight, physical, biological and chemical properties and have a multidirectional effect on food, on the one hand, they shape the taste and colour, and on the other, they show

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_51755180

antioxidant activity, stabilizing fats and other labile food components (Jaszka et al., 2010; Perla et al., 2012; Rytel et al., 2014).

Polyphenols are one of the largest groups of antioxidants. They include over 8000 identified substances and are considered the most numerous antioxidants in our diet (Ross and Kasum, 2002; Manach et al., 2004).

The studies of many authors (Chun et al., 2005; Mattila and Hellström, 2007; Navarre et al., 2009; Ezekiel et al., 2013) show that potatoes are the most important source of polyphenols, after apples and oranges, which contain on average - 160 $mg \cdot kg^{-1}$ of fresh weight.

Many studies show that the chemical composition of potato tubers is modified by genotype, agrotechnical measures and atmospheric conditions during the growing season. Therefore, the purpose of these studies was to determine the effect of the herbicides used and their mixtures on the polyphenol content in tubers of three edible potato varieties.

Material and methods

The field experiment was conducted in the years of 2008-2010 in the Agricultural Experimental Station Zawady (52°03'N and 22°33'E) belonging to the University of Natural Sciences and Humanities in Siedlce, Poland. The experiment was established as two-factor in the split-plot system in three repetitions.

The studied factors included:

I – three varieties: Cekin, Satina and Tajfun.

II – five ways of care:

1. mechanical care – control object,
2. mechanical-chemical care, i.e., until the emergence hilling combined with harrowing, and about 7 days before the emergence the herbicide Command 480 EC (chlomazon 480 $g \cdot l$) in a dose 0.2 $l \cdot ha^{-1}$,
3. mechanical-chemical care, i.e. until the emergence hilling combined with harrowing, and about 7 days before the emergence spraying with a mixture of herbicides Command 480 EC (chlomazon 480 $g \cdot l$) in a dose 0.2 $l \cdot ha^{-1}$ + Dispersion Afalon 450 SC (linuron 450 $g \cdot l$) in a dose 1.0 $l \cdot ha^{-1}$,
4. mechanical-chemical care, i.e., until the emergence hilling combined with hailing, and about 7 days before the emergence herbicide Stomp 400 SC (pendimethalin 400 $g \cdot l$) in a dose 3.5 $l \cdot ha^{-1}$,
5. mechanical-chemical care, i.e., until the emergence hilling combined with hailing, and about 7 days before the emergence spraying with a mixture of herbicides Stomp 400 SC (pendimethalin 400 $g \cdot l$) in a dose 3.5 $l \cdot ha^{-1}$ + Dispersion Afalon 450 SC (linuron 450 $g \cdot l$) in a dose 1.0 $l \cdot ha^{-1}$.

The field experiment was established on soil classified to the department – autogenous soils, order – brown-ground soils, type – Luvisols made of light clay sands and strong loamy sands, the gradin class of IVa and IVb in terms of agricultural suitability classified as a very good rye complex. This soil was characterised by a slightly acid reaction, very high abundance of phosphorus, high abundance of potassium and the average wealth of magnesium. A potato was grown in the position after winter cereals. The experiment used the permanent organic fertilisation with manure 25 $t \cdot ha^{-1}$ and the mineral one in quantities: 100 $kg \cdot ha^{-1}$ N, 100 $kg \cdot ha^{-1}$ $P_2 0_5$ and 150 $kg \cdot ha^{-1}$ $K_2 0$.

DOI: http://dx.doi.org/10.15666/aeer/1604_51755180

Samples of potato tubers (50 tubers) were taken from plots during harvest and stored at 10-12 °C. Polyphenols were determined in a fresh mass of potato tubers using the Swain and Hillis methods with the Folin-Ciocalteu reagent (Swain and Hillis, 1959). The results of the research were statistically analysed during the analysis of variance. The significance of the sources of variation was tested by the "F" Fischer-Snedecor test, and the significance assessment of differences at the level of significance of p = 0.05 between the compared averages, using the multiple Tukey intervals.

Particular growing seasons during the studies were characterised by variable weather conditions (*Table 1*). The highest amount of rainfall was noted in the growing season in 2010 – 459.7 mm and the average air temperature was higher by 0.9 °C compared to the long-term average. The smallest amount of rainfall – 354.4 mm was noted in 2009, the average temperature was higher by 0.4 °C. The growing season 2008 was characterised by the rainfall at the level of 371.4 mm and the air temperature did not differ significantly from the long-term average 14.9 °C. According to the calculated hydrothermal coefficient of Sielianinow, the growing seasons of 2008, 2009 and 2010 were characterised by the lack of drought, however, the alternating months occurred with extreme conditions, from severe drought to the lack of drought.

Table 1. *Characteristic of weather conditions in the years 2008-2010 (Zawady Meteorological Station)*

Years	Months						
	IV	**V**	**VI**	**VII**	**VIII**	**IX**	**IV-IX**

*Value of coefficients Sielianinovs (Bac et al., 1998): <0.5 strong drought; 0.51-0.69 mild; 0.70-0.99 weak pure drought; ≥1 fault drought

Results and discussion

A study by many authors (Al-Saikhan et al., 1995; Reddivari et al., 2007a; Hamouz et al., 2013; Murniece et al., 2013) shows that the polyphenol content in potato tubers varies in a wide range from 53.0 to 1098.0 mg$\cdot$kg^{-1} of fresh weight and depends on both the genotype, agrotechnical factors and climatic conditions.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_51755180

The conducted own studies showed that the polyphenol content in potato tubers was on the level from 155.8 to 162.5 mg·kg^{-1} of fresh weight and depended significantly on the cultivar (*Table 2*). The highest amount of the discussed component was accumulated by the Satina variety – an average of 162.5 mg·kg^{-1}, significantly less in Tajfun – an average of 158.1 mg·kg^{-1}, which was confirmed in the studies of Reddivari et al. (2007b), Hamouza et al. (2010); Wierzbicka et al. (2015) and in the earlier studies by Gugała et al. (2017). In their opinion, the content of phenolic compounds in tubers depends mainly on the variety.

Table 2. *Content of polyphenols in potato tubers depending on the cultivar (mg·kg^{-1} fresh matter)*

Experimental factors	Cultivars			Mean
	Cekin	Satina	Tajfun	
1. Mechanical care – control object	152.5	160.3	153.2	155.3
2. Mechanical care + Command 480 EC (chlomazon 480 g·l)	154.7	161.2	156.4	157.5
3. Mechanical care + Command 480 EC (chlomazon 480 g·l) + Dispersion Afalon 450 SC (linuron 450 g·l)	156.8	164.2	160.2	160.3
4. Mechanical care + Stomp 400 SC (pendimethalin 400 g·l)	156.8	162.9	158.8	159.5
5. Mechanical care + Stomp 400 SC (pendimethalin 400 g·l) + Dispersion Afalon 450 SC (linuron 450 g·l)	158.3	163.8	161.9	161.3
Mean	155.9	162.5	158.1	-

$LSD_{0,05}$ - for: cultivars – 1.5; weed control methods – 2.1; interaction: cultivars x weed control methods - non-significant

The herbicides and their mixtures used in the experiment significantly influenced the concentration of polyphenols in tubers, causing them to increase (from 2.2 to 6.0 mg·kg^{-1} of fresh weight) in relation to the control object that was cultivated only mechanically (*Tables 2* and *3*). The highest concentration of the discussed component on average – 161.3 mg·kg^{-1} of fresh weight was noted on object 5, where the mixture of Stomp 400 SC (pendimethalin 400 g·l) + Dispersion Afalon 450 SC (linuron 450 g·l) herbicides was used and 3. (on average – 160.3 mg·kg^{-1} d.w.), sprayed with the mixture of Command 480 EC (chlomazon 480 g·l) + Dispersion Afalon 450 SC (linuron 450 g·l) herbicides. Also, in their earlier studies, Zarzecka and Gugała (2011) showed that under the influence of herbicides and their mixtures (Plateen 41.5, WG Plateen 41.5 WG + Fusilade Forte, Barox 400 SL, Barox 400 SL + Fusilade Forte), the discussed component increased. Similar changes were noted by Mickovski et al. (1984) using the Patoran herbicide with other preparations in tobacco cultivation. Hamouz et al. (2013) cultivating potatoes according to ecological and conventional methods obtained ambiguous results regarding the content of polyphenols. While Chauhan et al. (2013) after the application of the imidacloprid insecticide in potatoes noted a reduction in polyphenol content.

Meteorological conditions in the years of conducting the research significantly modified the accumulation of polyphenols (*Table 3*). It was found that their smallest (on average 150.5 mg·kg^{-1}) content in potato tubers was obtained in 2009 with the smallest sum of precipitation in the examined three year period and the average air temperature of 15.1 °C. While the highest content, on average – 163.5 mg·kg^{-1} of fresh weight was obtained in the growing season of 2010, which was characterized by the highest rainfall

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_51755180

and the highest air temperature. The influence of climatic conditions on this feature was also observed in own studied by Reddivari et al. (2007a, b), Zarzecka and Gugała (2011) and Hamouz et al. (2013).

Table 3. *Content of polyphenols in potato tubers depending on years of research [mg·kg^{-1} fresh matter]*

Experimental factors	**Years**			**Mean**
	2008	**2009**	**2010**	
1. Mechanical care – control object	159.0	147.6	159.4	155.3
2. Mechanical care + Command 480 EC (chlomazon 480 g·l)	161.2	148.6	162.6	157.5
3. Mechanical care + Command 480 EC (chlomazon 480 g·l) + Dispersion Afalon 450 SC (linuron 450 g·l)	164.3	150.4	166.6	160.3
4. Mechanical care + Stomp 400 SC (pendimethalin 400 g·l)	162.9	152.1	163.4	159.5
5. Mechanical care + Stomp 400 SC (pendimethalin 400 g·l) + Dispersion Afalon 450 SC (linuron 450 g·l)	164.4	153.7	165.9	161.3
Mean	162.4	150.5	163.5	-

$LSD_{0,05}$ - for: years – 1.5; weed control methods – 2.1; interaction: years x weed control methods - non-significant

No interaction was found between the years and methods of using herbicides and the varieties and ways of applying herbicides on the polyphenol content in potato tubers.

Conclusions

1. The cultivars accumulated a different amount of phenolic compounds in tubers. The Satina variety has accumulated the most of this component, while Tajfun the least.
2. The herbicides and their mixtures used in the study significantly increased the content of polyphenols in potato tubers.
3. The content of polyphenols in potato tubers depended on the weather conditions during the potato growing season.

(Received 1st Jun 2018; accepted 31st Jul 2018)

Abstract. The present study determined the reactions of common bean landraces grown in Lake Van Basin of Turkey against common bacterial blight disease (CBB) caused by *Xanthomonas axonopodis* pv. *phaseoli* (*Xap*). For this purpose 83 bean landraces collected from the basin and two resistant (HR-45, HR-67) and one susceptible (Dresden) lines were evaluated for their reaction to *Xap*. The experiments were conducted in randomized experimental design with three replications in a growth chamber having 23 ± 2 °C temperature and 16 h light-8 h dark period. Bean seeds were sown in the pots having 2:1 mixture of peat:perlite and *Xap* inoculated by spraying when the seedlings reached two trifoliate leaves stage. Disease severity was assessed three weeks after Xph inoculation using 1-5 scale. In light of the findings, it was detected that there was a variation with regard to tolerance to the disease among common bean landraces. While fourteen landraces were assigned as resistant against CBB, 49 landraces were found to be moderately susceptible to CBB. The present study demonstrated the existence of resistance sources against CBB within Lake Van Basin bean landraces that could potentially be used for breeding resistant cultivars.
Keywords: *disease, Phaseolus vulgaris L., landraces, Xap, artificial inoculation*

Introduction

Common bean is among the most widely grown species in the world and have been grown widespread in Turkey due to economical and nutritional aspects. It is originated in South and Central America (including Mexica, Guatemala, Colombia, and Peru) and has been cultivated since 5000 BC. Common bean has a wide distribution area from sea level to 3000 m altitude (Şalk et al., 2008; Koutsika-Sotiriou and Traka-Mavrona, 2008). While China is the first fresh bean producer in world, Turkey ranks fourth with 651.094 tons meeting about 2.75% of the world production (FAO, 2016). There has been a large variability in common bean having a widespread distribution in Turkey (Erdinc et al., 2013, 2017a, b). Common bean ranks third in the world in terms of importance in *Fabaceae* (Blair et al., 2009). It reported that besides common bean supplies 30% need of protein, it helps to fight many diseases because of the antioxidant

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_51815191

compounds it contains. Additionally common bean has been used cosmetic and paint industry (Singh et al., 2007).

Many abiotic and biotic stress factors have caused problems in common bean. Common bacterial blight (CBB) is one of the major seed-borne diseases which give rise to yield and quality losses and is caused by *Xanthomonas axonopodis* pv. *phaseoli* (*Xap*). Pathogen shows its detrimental effects in tropical, subtropical and temperate regions (Vandemark et al., 2008). Seed is a very significant factor in the spread of Xph because the viability of the pathogen can be maintained 30 years on the seed (Dursun et al., 2002; Shi et al., 2011a), sometimes leads to yield losses exceeding 40% (Vandemark et al., 2008). There is no satisfactory chemical control for CBB and usage of the resistant cultivars is one of the most effective and environmentalist approaches (Opio et al., 1996; Park et al., 1999).

It is indicated that CBB is a common threat today on all continents where grown common bean. In Turkey, it was determined first time by Sönmezalp in 1966. *Xap* was also identified in Nigde, Kayseri and Yozgat provinces and in some areas of East Anatolia (Bozkurt, 2009).

The climate of the Lake Van Basin differs from the cold Eastern Turkey where it is located. The basin has a microclimate which allows for production vegetable including common bean etc. (Erdinc et al., 2008). The province of Van is located between 37°55′ and 39°24′ north longitude and 42°05′ and 44°22′ east latitude and at an altitude of 1720 m above sea level. It has a continental climate. Comparatively rich genetic diversity was found among the Lake Van Basin common bean population by phenotypic and molecular markers (Ekincialp, 2012).

Many researchers reported that the resistance to *Xap* was managed by a dominant gene (Drijfhout and Blok, 1987; Silva et al., 1989; Urrea et al., 1999; Zapata et al., 2011). Resistance to CBB in common bean has been reported as a quantitative trait with low to medium heritability (Silva et al., 1989), conditioned by 1-5 genes with additive gene action (Tar'an et al., 2001). Therefore, screening of genetic resources of the region and providing the resistant or tolerant landraces in breeding programs by determining reactions against the disease of genetic material is important in development of resistant cultivars.

Material and methods

Plant materials and pathogen

Eighty two landraces of common bean and one runner bean genotype (G30) collected from Lake Van Basin of Turkey (Ekincialp, 2012), two resistant (HR-45 and HR-67) (Yu et al., 2004; Gillard et al., 2009; Shi et al., 2011a, b, 2012) and one susceptible lines (Dresden) (Shi et al., 2011a, 2012) from Dr. Ali Reza NAVABİ was used in the present study (*Table 1*). *Xap* isolate was obtained from Prof. Dr. Hüseyin BASIM (Akdeniz University, Agriculture Faculty, Department of Plant Protection).

Pathogenicity assays

In the first artificial inoculation trial, the eighty-three bean landraces and control lines (HR-45, HR-67 and Dresden) were tested against *Xap*, then based on the results, twelve landraces with control lines were selected for the second trial. Common bean seeds was sown to the pots including 2:1 mixture of peat:perlit in a randomized

Xap isolate was inoculated to the bean seedlings with two trifoliate leaves. In this stage, Xph grown on KB medium King B (pepton 20 g/L, gliserol 10 ml/L, K_2HPO_4 1.5 g/L, $MgSO_4$./H_2O 1.5 g/L, agar 18 g/L) at 28 °C for 48 h. (King and Raney, 1954) and then the grown Xph colonies were suspended in distilled water and adjusted to 10^8 cfu ml^{-1} (OD = 0.13) (Osdaghi et al., 2009). The bacterial mixture was spread onto 15 days old common bean seedlings with fully expanded trifoliate leaves. The benches with pots were covered with polyethylene sheet for providing moisture to favor development of *CBB*. After 48 h, the covers were opened. Plants were irrigated weekly including Hoagland nutrient solution. In twenty-first days after inoculation, CBB symptoms in the plants were assessed using 1-5 scale (*Table 2*) which was modified for this study and the disease severity was determined with Townsend–Heuberger equation (Townsend and Heuberger, 1943).

The disease severity was calculated using the following formula:

$$Disease\ severity = \frac{\Sigma\ (Rating\ number\ x\ Number\ of\ leaves\ in\ the\ rating)}{Total\ number\ of\ leaves\ x\ Highest\ rating}\ x100$$

Table 2. *The values of 1-5 scale that was used to determine the disease severity of Xap in the bean landraces*

Scale value	Statement
1	No visible symptom
2	Necrosis in 1-5% of leaf or single spots
3	Necrosis in 6-25% of leaf
4	Necrosis in 26-50% of leaf
5	Necrosis in leaf more than 50% or plant death

As a result of calculating of the scale values, the landraces were assigned as <2: resistant, <3: moderately susceptible, <4: susceptible, <5: extreme susceptible (Dursun et al., 2002; Osdaghi et al., 2009). In the both artificial inoculation trials, the data were analyzed using the statistical software package SPSS. The means were grouped using the Duncan multiple comparison test (Düzgüneş et al., 1987)

Results and discussion

First artificial inoculation trial

The results of the first artificial inoculation are given in *Table 3*. In the result of the analysis of variance, it was found that the differences between the landraces were significant ($p<0.05$). According to the results obtained, 14 of the landraces were scaled to 1-2 and rated as resistant to CBB and the genotype G99 was the most resistant genotype with a scale value of 1.42. The great majority of landraces (49 landraces) was ranged from 2 to 3 and was found to be moderately susceptible to CBB. It was also determined that 19 landraces were susceptible and their disease severity scales were varied from 3 to 4. The genotype G37 was the most susceptible one with a scale value of 4.32. Two resistant (HR-45 and HR-67) control lines were found to have lower scale values than the studied bean landraces and the susceptible line, Dresden, was found to

DOI: http://dx.doi.org/10.15666/aeer/1604_51815191

be in the group of sensitive landraces with a score of 3.29 (*Table 3*). When frequency distribution according to disease scale values were examined, 18.60% of the landraces including control lines were found to be resistant, 63.96% of them were moderately susceptible, 16.28% of them were susceptible and 1.17% of them were very susceptible (*Fig. 1*).

*There were significant differences among the different letter(s) at $P < 0.05$ level (according to Duncan's multiple comparison test). R: Resistant, MS: Moderately susceptible, S: Susceptible, HS: High susceptible

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_51815191

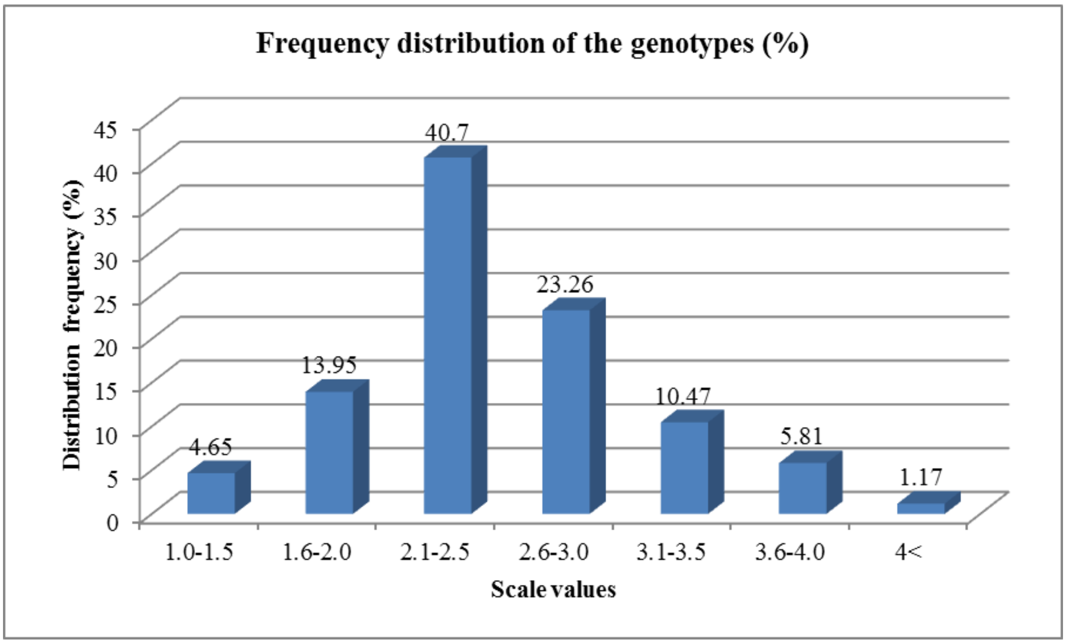

Figure 1. *Distribution frequency (%) of reaction to CBB of the bean landraces according to scale values*

Second artificial inoculation trial

Based on the first artificial inoculation trial, twelve landraces resistant to CBB with sufficient number of seeds (the landraces G12 and G32 were excluded) were artificially re-inoculated. Resistant (HR-45 and HR-67) and sensitive (Dresden) lines were also used for control in the second trial. When the disease severity values obtained at the end of the trial were examined, it was determined that the landraces had a scale value of 1-2 and showed resistance. It was determined that the lowest value of the landraces was 1.27 (in the genotype G27), while the highest value was found in the landraces G35 and G63 with 1.83. It was also found that the HR-45 and HR-67 lines reached lower scale values than the other landraces (scale values of 1.11 and 1.00, respectively). As a result of the analysis of variance, it was found that the differences between the landraces were statistically significant ($p<0.05$). Disease severity reactions of the resistant landraces have generally been observed to be similar to each other in both studies (*Fig. 2*).

Xap, among the most important seed-borne bacterial pathogens in bean (Bastas and Sahin, 2017), is also among the serious bacterial diseases causing yield and quality loses in Turkey (Demir and Gündogdu, 1994; Donmez, 2004). In surveys conducted in the Central Anatolia Region, Xap was reported to be among the most common bacterial pathogens with 11.11% of presence (Bastas and Sahin, 2017).

In current study, the severity of disease in artificial inoculation was evaluated after 21 days in both studies. As a matter of fact, Marquez et al. (2007) reported that even if an aggressive isolate is used, classifications that would have been made by previous evaluations on 14 days might be erroneous.

It has been determined that there is a variation in the reactions of the bean landraces to BCC. As a matter of fact, according to Ekincialp (2012), there is a high genetic variation in the morphological and molecular characterization studies carried out among these landraces. The landraces G30, G37, and G53 which are morphologically and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_51815191

genetically most distant from each other, have also been found to differ in their CBB disease reactions, while G30 is resistant and G53 is susceptible and G37 is highly susceptible. It has also been reported that the G30 genotype (*P. coccineus*) is differentiated from other landraces in terms of general habitus and morphological characteristics (number of flower buds in the cluster, seed width, seed length, seed height and seed weight) (Ekincialp, 2012).

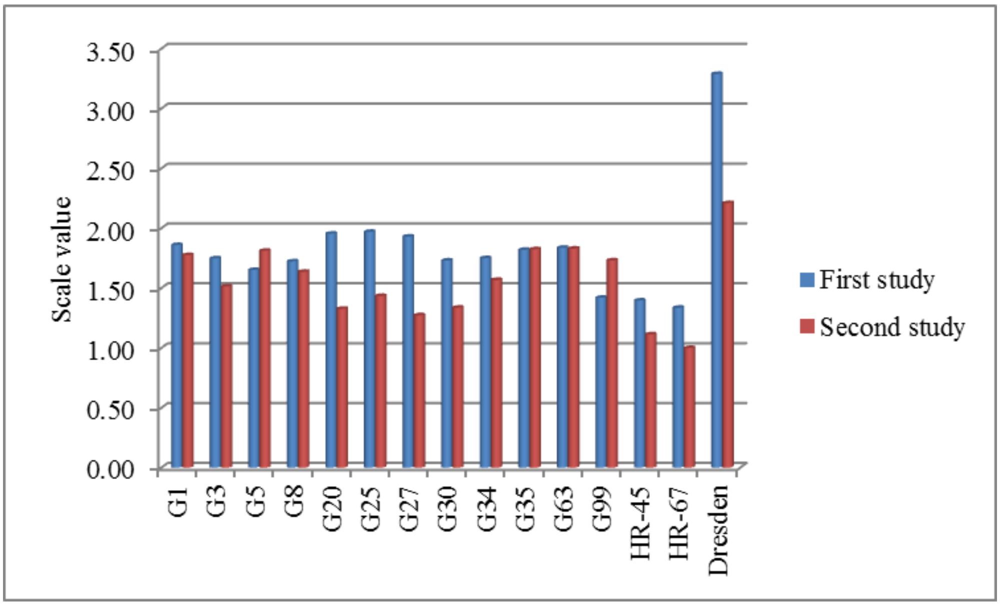

***Figure 2.** Reactions of the bean landraces were classified as resistant based on 1-5 scale in artificial inoculation method for CBB in first and second trials*

It was noticed that the landraces G12 and G30 that were resistant to bean anthracnose (Ekincialp and Sensoy, 2018) were also resistant to CBB in the present study. Moreover, all landraces susceptible to CBB have been found to be susceptible to anthracnose disease. It was observed that the G30 genotype belonging to *P. coccineus* was present in a group of resistant landraces in both studies. It is generally stated that *P. coccineus* (runner bean) has similar or higher resistance level as *P. vulgaris*, P. *acutifolius* (tepary bean) shows the highest level of resistance (Drijfhout and Blok, 1987; Singh and Munoz, 1999).

The results of the landraces used for control purposes during pathogenicity tests are shown in *Table 3* and *4*. As seen in the tables, the reactions of these landraces to the disease were determined as resistant (R) in HR-45 and HR-67 sensitive (S) in Dresden. It was also reported in the literature that HR-45 and HR-67 were resistant to *Xap* (Yu et al., 2004; Gillard et al., 2009; Shi et al., 2011 a, b, 2012) and Dresden was susceptible to XAP Shi et al., 2011a, 2012).

In the present study, a large number of bean landraces were screened and approximately 17% of them was found to be resistant to *Xap* (*Table 3*; *Fig. 3*). Halo blight and common blight screening studies were conducted in beans in different regions of Turkey; it was demonstrated that some landraces were resistance to halo blight (Benlioglu et al., 1994; Dursun et al., 2002) and only one variety was resistant to common blight (Dursun et al., 2002). It was determined that 50% of the landraces used in the mentioned studies were highly susceptible. Osdaghi et al. (2009) determined that

DOI: http://dx.doi.org/10.15666/aeer/1604_51815191

two of the 30 cultivars/lines were resistant to CBB. On the contrary, Fininsa and Tefera (2006) reported that 117 out of 201 landraces (approximately 58%) in Ethiopia were resistant to CBB.

Conclusions

Turkey is an important country in the production of green beans and meets 3% of the world production. Maintaining or advancing the current position will be through the development of highly productive, tolerant varieties that can meet consumer and producer demands. In the present study, the resistance status of bean landraces collected from Lake Van Basin, which is an important potential for vegetable production in the region, is revealed. From this point of view, it is noticed that there is a source of resistance. Resistant landraces are expected to be used as parents in bean improvement programs in the future. Considering the efforts of countries in recent years to protect their local gene resources, this situation is better understood. This is the first study and report of resistance against CBB in Lake Van Basin bean landraces. The present study demonstrated the existence of resistance sources against CBB within them that could potentially be used for breeding resistant cultivars.

(Received 2nd Jun 2018; accepted 17th Jul 2018)

Abstract. The phytosociological survey of western Himalayan subtropical and moist temperate forests of Tehsil Harighel, District Bagh Azad Jammu and Kashmir, Pakistan was carried out during 2015-2017. Sampling was done by using random stratified sampling technique at 12 different sites. Based on importance value twelve plant communities were recognized. They were merged into three plant associations using cluster analysis and Detrended correspondence analysis viz. *Olea -Dodonea – Micromeria* association, *Pinus- Oxalis-Dactylis* association and *Pinus-Diospyros -Myrsine* association. The average number of species per site varied between 17-48, Species richness 3.00 to7.01; Shannon Diversity 2.49 to 3.82; Evenness 0.46 to 0.72 and Equitability 0.73 to 0.91. Canonical Correspondence Analysis (CCA) revealed that altitude and edaphic characteristics like potassium, organic matter, saturation, electrical conductivity and pH play a significant role in controlling the distribution pattern of plant species. Low value of species diversity and associated components clearly reflect that forest structure is deteriorated in the investigated area with poor regeneration potential. Therefore, immediate conservation measures by integrating local populations' perceptions are urgently recommended.
Keywords: *environmental gradient, cluster analysis, richness, DCA, CCA*

Introduction

Vegetation structure, species composition, diversity and richness pattern, maturity value are the important ecological characteristics that are highly correlated with anthropogenic and environmental variables (Gairola et al., 2008; Shaheen et al., 2011a; Ahmad et al., 2013; Amjad et al., 2014a, b; Ilyas et al., 2015). Vegetation is the distinct physiognomic unit whose structure can be clearly differentiated from other such unit (Hussain and Illahi, 1991). Vegetation, soil and climate are interrelated with each other. The variation in any one of these components may bring change in the associated component (Kent, 2012; Amjad et al., 2014b; Ilyas et al., 2015). Geographical or topographical factors like altitude and aspect play critical role in structuring vegetation (Ellenberg, 1996; Gallardo-Cruz et al., 2009; Scherrer and Korner, 2010; Shaheen et al., 2011b). Vegetation is the chief component of environment in majority of habitat which

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_51935211

facilitates the ecosystem services and biodiversity (Gardner et al., 2009). Therefore assessment of vegetation structure is the main indicator in conservation and ecosystem management.

Species diversity is a function of the number of species present in a given area and reflects the productivity and health of ecosystem (Ruiz et al., 2008). The most easily interpretable indicator of diversity is species richness which is controlled by a complex of environmental variables (Whittaker, 1977; Shrestha and Jha, 2009) mainly altitude, aspect and moisture (Vetaas, 2000; Schuster and Diekmann, 2005) The precise diversity measurement is helpful in understanding the various phenomena involved in organization and development of plant communities (Shoukat et al., 1978; Malik and Malik, 2012). The anthropogenic pressure in the form of deforestation, overgrazing and fuel wood extraction can be clearly reflected from low species diversity and richness in the area. Thus vegetation structure information along with species biodiversity assessment is a prerequisite for biodiversity conservation and ecosystem management (Willoughby and Alexander, 2000, 2005).

The computer-based multivariate statistical techniques helps ecologists in structuring large data sets and analyzing impact of environmental factors on distribution pattern of plant species (Bergmeier, 2002; Anderson et al., 2006). Such techniques reduce the complexity of data by classifying vegetation and relating the results to abiotc (environmental) components (Dufrene and Legendre, 1997; McCune and Mefford, 1999; Ter Braak and Prentice, 1988). Various multivariate techniques such as Two way Indicator species analysis, Cluster analysis, Canonical correspondence analysis and Detrended correspondence analysis have been extensively employed by ecologists recognize the environmental gradient among vegetation structure and species diversity in mountainous ecosystems (Daubenmire, 1968; Vetaas and Grytnes, 2002; Tavili and Jafari, 2009).

Azad Jammu & Kashmir, Pakistan harboured diverse climate, soil type and rich diversity. Various studies have been conducted previously to analyze vegetation in different part of Azad Jammu & Kashmir (Siddiqui et al., 2010; Shaheen et al., 2011a; Malik and Malik, 2012; Amjad et al., 2014a,b; Bokhari et al., 2016; Amjad et al., 2017). However many potentially diverse remote areas like Harigal were not still explored by the ecologist particularly using advanced phytosociological techniques. Moreover previous studies are restricted to floristic inventory and quantitative attributes and lack novelty in term of multivariate analysis. Therefore present study was designed to analyze the variation among species diversity and vegetation structure along the environmental gradient using multivariate approach. The findings of current research work will be helpful for designing effective conservation strategies for sustainable management of plant resources of area particular for minimizing anthropogenic pressure.

Materials and methods

Study area

Tehsil Harighel of District Bagh, Azad Jammu & Kashmir, Pakistan is located in western Himalayan foot hills of Pir-Panjal range between latitude 33°54'-34°08' N and longitude 73°01'-73°38' E longitude. The altitude of area varies between 980 m to 2052 m. Total area of District Bagh is 1368 km^2 with 54.78% under forest cover. Population is 0.434 million (Anonymous 2007). The climate of area varies from

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_51935211

subtropical humid to temperate type at various elevations with mean annual precipitation of 1500 mm. The average annual temperature is 21 °C with maximum up to 40 °C during July and minimum up to 2 °C during January (Anonymous, 2009; Shaheen et al., 2011a).

Collection and identification of plant specimen

Three plant specimens of each species were collected. The specimens were carefully dried and mounted on herbarium sheet. Different floras and monograph of various areas of Pakistan were used for Identification of specimens. The identified specimens were confirmed at AJ&K Medicinal and Aromatic Plant Herbarium PARC, Pakistan. International Plant Name Index (IPNI) was used to obtain correct botanical name. The identified specimens were deposited in Herbarium of Women University of Azad Jammu & Kashmir Bagh.

Field sampling

Field surveys were carried out during 2014-2016 following specific locality procedure. Twelve sites were selected based on altitude, aspect and physiognomy (*Fig. 1*). The altitude and geographical coordinates of each site was determined by using GPS and aspect by using Suunto Tandem survey master compass. Detailed stratified sampling was done using quadrat method. The quadrat size was 1 ×1 m^2, 5 ×5 $m^2$and 10 × 10 $m^2$for herbs, shrubs and trees respectively. Composition and abundance data of plant species were recorded from each quadrat on prepared Excel data sheets.

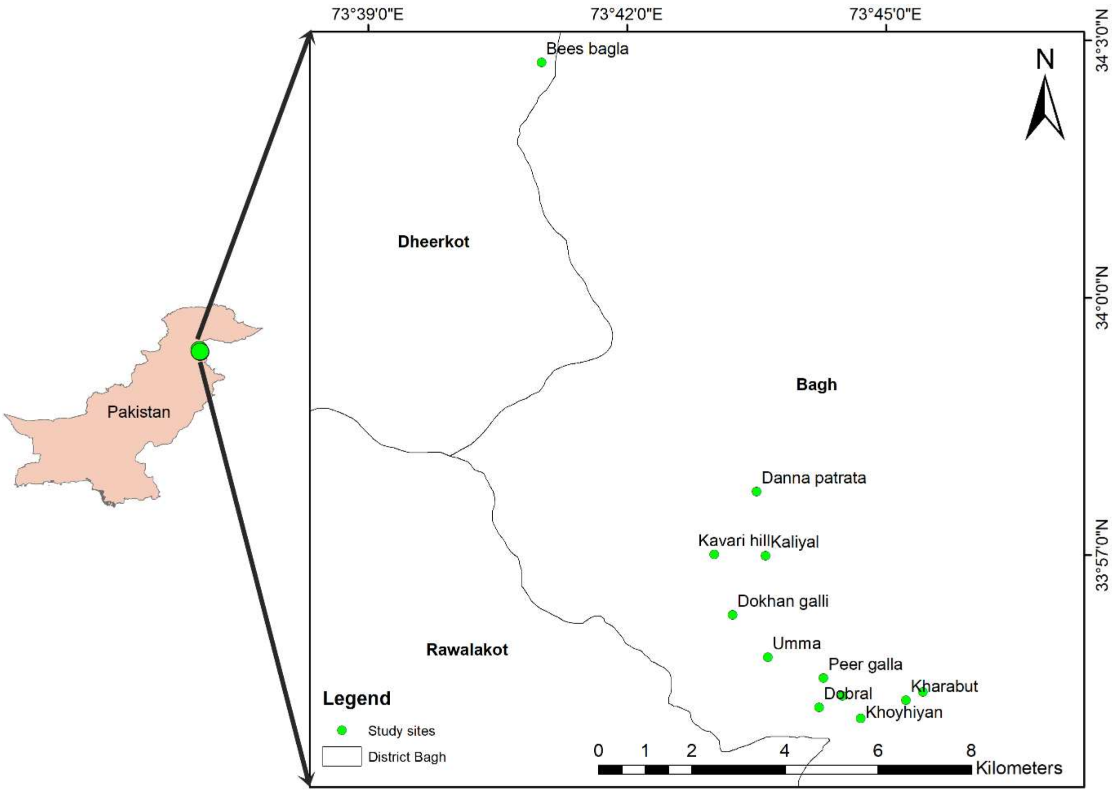

Figure 1. *Map showing location of different study sites*

DOI: http://dx.doi.org/10.15666/aeer/1604_51935211

Three soil samples were collected from each site at depth of 15 cm and mixed to make composite. Different physico-chemical properties of soil like texture, pH, organic matter, electrical conductivity, saturation, % of phosphorous, potassium and calcium carbonate were determined in Pakistan Soil and Water Testing Laboratory Rawalpindi using standard methods (Jackson, 1962; Hussain, 1989).

Data storage and analysis

The importance value of each plant species was recorded following Curtis and McIntosh (1950) by using *Equation 1:*

$$IVI = R.D + R.F + R.C. \tag{Eq.1}$$

where IVI = importance value index, R.D = relative density, R.F = relative frequency, and R.C. = relative cover.

Species diversity was calculated by following Shannon (1949) by using *Equation 2:*

$$H = \sum\left(\frac{n}{N} \times \frac{\ln (n)}{\ln (N)}\right) \tag{Eq.2}$$

where H = species diversity, n = number of individual of its species, N = total number of individual of all species.

Species richness was calculated by following Margalef (1958) using *Equation 3:*

$$R = \frac{S-1}{\ln (N)} \tag{Eq.3}$$

where R = species richness, N = total number of individual of all species.

Equitability was calculated by following Sheldon (1969) using *Equation 4:*

$$E = \frac{H}{\ln (S)} \tag{Eq.4}$$

where H = Diversity, S = total number of species.

Evenness was calculated by following Gibson’s evenness index using *Equation 5:*

$$G = \frac{eH}{S} \tag{Eq.5}$$

where, H = Diversity, S = total number of species.

Species maturity was calculated by following Pichi-Sermollis (1948) using *Equation 6:*

$$M = \frac{F}{S} \tag{Eq.6}$$

where, M= Species maturity, F = total frequency, S = total species number.

Species composition and abundance data of 158 species and 7 environmental variables from 390 quadrats at twelve different sampling sites (390 quadrats) were processed in MS Excel in accordance with the PCORD V.5 and CANACOO V.5 requirements. The grouping of plant species was carried out by using cluster analysis in PC ORD software (McCune and Grace, 2002; McCune and Mefford, 2005). Wards

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_51935211

method was used as linkage method to group the same stands. These associations were documented at three level of division on the bases of dendrogram. The vegetation and environmental data was further subjected to ordination analysis using CANACOO version 5.00 (TerBraak and Smilauer, 2002). DCA and CCA analysis was carried out to verify the faithfulness of grouping/association, check the ecological gradient of plant association and to find the vegetation environmental relation. The explanatory power (strength) of different environmental factors was checked by Monte Carlo Permutation test (reduced model, 4999 permutations).

Results

Based on cluster analysis and DCA, 158 plant species and 12 sites were grouped into three associations (*Fig. 2*) which are as follows:

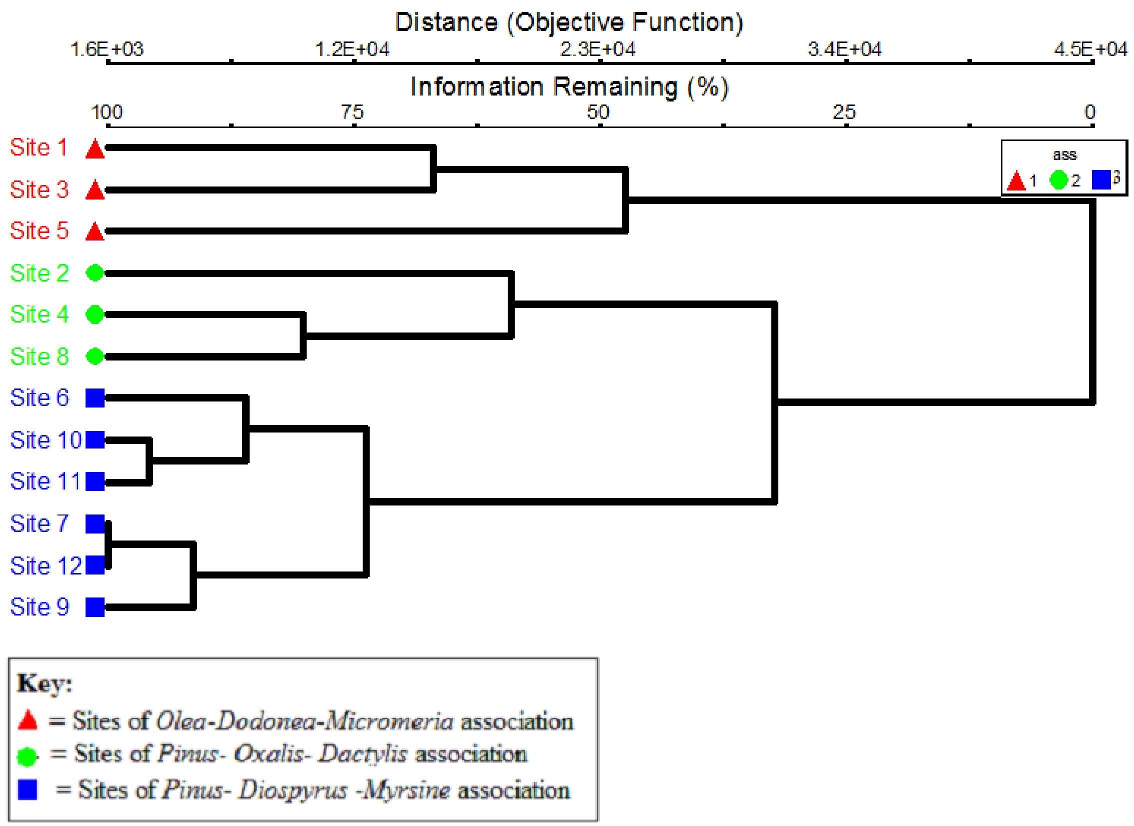

Figure 2. *Cluster analysis dendrogram representing three plant associations*

Olea-Dodonea-Micromeria (A) association

This association harboured at an altitudinal range of 980-1165 m. The association comprised of three communities having 51 species which include 3 trees, 15 shrubs and 33 herbs. The dominant species were *Olea ferruginea* (I.V = 60.02), *Dodoneae viscosa* (IV = 27.21) and *Micromeria biflora* (I9.92). Whereas *Berberis lycium*, *Maytenus nemorosa* and *Ficus palmata* were associated plant species (*Table 1*). Soil was loamy with average pH of 7.36. Soil saturation was 40%; electrical conductivity 0.83 µs/cm; organic matter 0.73%; phosphorus 3.66 mgKg^{-1} and potassium 106.66 mgKg^{-1}.

DOI: http://dx.doi.org/10.15666/aeer/1604_51935211

Pinus-Oxalis-Dactylis (B) association

This association lies in between 1079 and 1658 m and consisted of 3 plant communities having 79 Plant species which include 8 trees, 15 shrubs and 56 herbs. *Pinus roxburghii* (I. V = 33.65), *Oxalis spiralis* (I. V = 12.64) and *Dactylis glomerata* (I. V = 11.81) were dominant. Whereas *Myrsine Africana* and *Indigofera linifolia* were associated plant species (*Table 1*). Soil texture was loamy with average pH 7.17. Soil saturation 39.66%; electrical conductivity 0.70 µs/cm; organic matter 0.76%; phosphorus 4.4 mg kg^{-1} and potassium 120 mg kg^{-1}.

Pinus-Diospyrus-Myrsine (C) association

This association was recorded at an altitude of 1450-20520 m having 6 Plant communities having 110 species. *Pinus wallichiana* (I. V = 40.13), *Diospyrus lotus* (I. V = 11.84) and *Myrsine Africana* (I. V = 9.78) were dominant. *Quercus dilitata*, *Berberis lycium*, *Sarcococca saligna* and *Vibernum grandiflorum* were the associated plant species (*Table 1*). Soil was loamy with average pH of 7.23. Soil saturation was 40.05%; electrical conductivity 0.64 µs/cm; organic matter 0.81; phosphorus 5.33 $mgKg^{-1}$ and potassium 116.66 mg kg^{-1}.

A = Olea-Dodonea-Micromeria association; B = Pinus-Oxalis-Dactylis association; C = Pinus-Diospyrus-Myrsine association

Detrended correspondence analysis

Detrended Correspondence analysis is the indirect gradient analysis which applied here to highlight the ecological gradients controlling the spatial variations among the plant species. Sum of all variance or eigen values was 3.93. The first Eigen value was proven to be quite high (0.57) which reflect strong gradient strength in species distribution patterning along this DCA axis. The DCA diagram explains altitudinal, aspect and environmental gradient. The sites and species of lower altitude, northern aspect and mesic habitat (*Pinus-Diospyros-Myrsine* association) were positioned on right side of diagram whereas site and species of higher altitude southern aspect and xeric habitat (*Olea -Dodonea –Micromeria* association) were positioned on left side of diagram (*Figs. 3* and *4*).

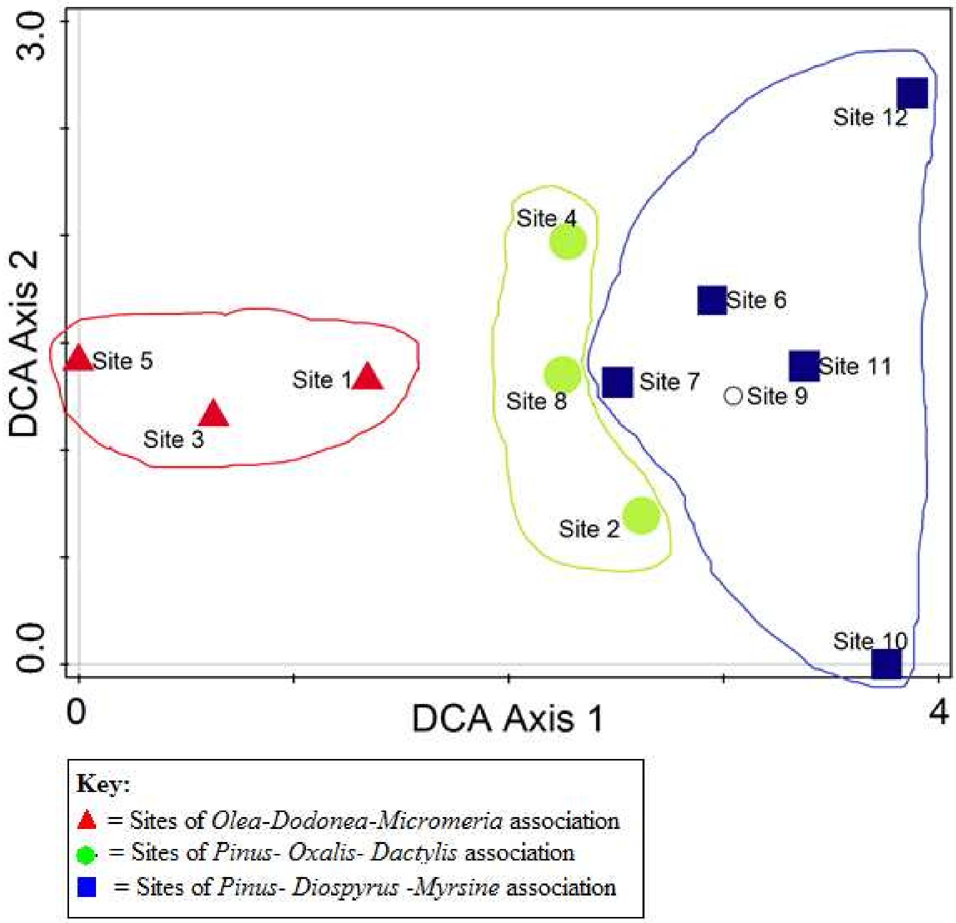

***Figure 3.** DCA analysis diagram representing distribution pattern of plant association*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_51935211

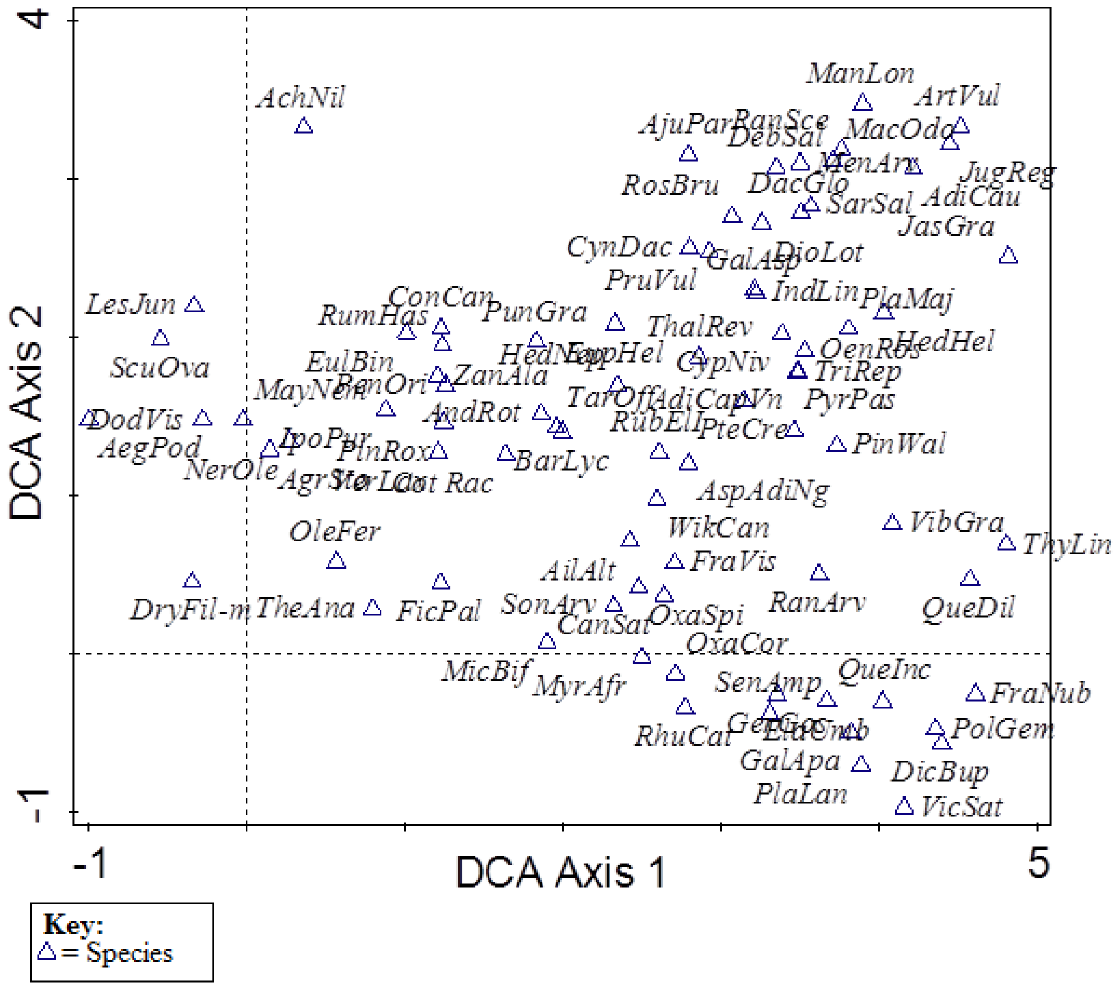

Figure 4. *DCA diagram showing distribution of plant species*

Canonical correspondence analysis

Canonical correspondence analysis (CCA) was carried out here to find the relationship between environmental factors and species distribution pattern in different zones of Tehsil Harighel. The high Eigen value of first axis explains high gradient strength along this axis. Nearly half of variation is explained by first two axes therefore remaining two axis were excluded. CCA revealed Altitude and soil physic-chemical properties particularly potassium content, organic matter, electric conductivity and pH play a significant role in the distribution of plant species while phosphorous and saturation play minor role. The communities harboured at site 1, site 6 and site 7 were under cumulative influence of pH and electric conductivity. The plant community of sites 2 and site 3 has significant correlation with electric conductivity. The plant communities of site 4 were under cumulative influence of electric conductivity and potassium. Whereas plant communities of site 9, site 11 and site 12 were under cumulative influence of altitude, potassium and saturation. Site 4 was outlier and not affected by any environmental variable (*Fig. 5*). Maximum number of species were not affected by any environmental variable as they are located in the center of diagram. E.C play a significant role in grouping of *Pinus roxburghii, Punica granatum, Indigofera*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_51935211

linifolia, Rubus ellipticus, *Rumex hastatus*. The pH showed strong correlation with *Olea ferruginea*, *Dodonea viscosa*, *Dryopteris filix-mas*, *Silybum marianum* and *Scutellariaovata*. Organic matter plays a significant role in distribution of *Jasminum grandiflorum*, *Dicliptera bupleuroides*, *Fragaria nubicola* and *Thymus linearis*. Saturation, phosphorus and potassium are important in distribution of *Machilus odoratissimus*, *Rosa brunonii*, *Cyprus niveus*, *Urticadioca*, *Scutellaria chamaedrifolia*, *Mentha arvensi* and *Mantha longifolia* (*Fig. 6*).

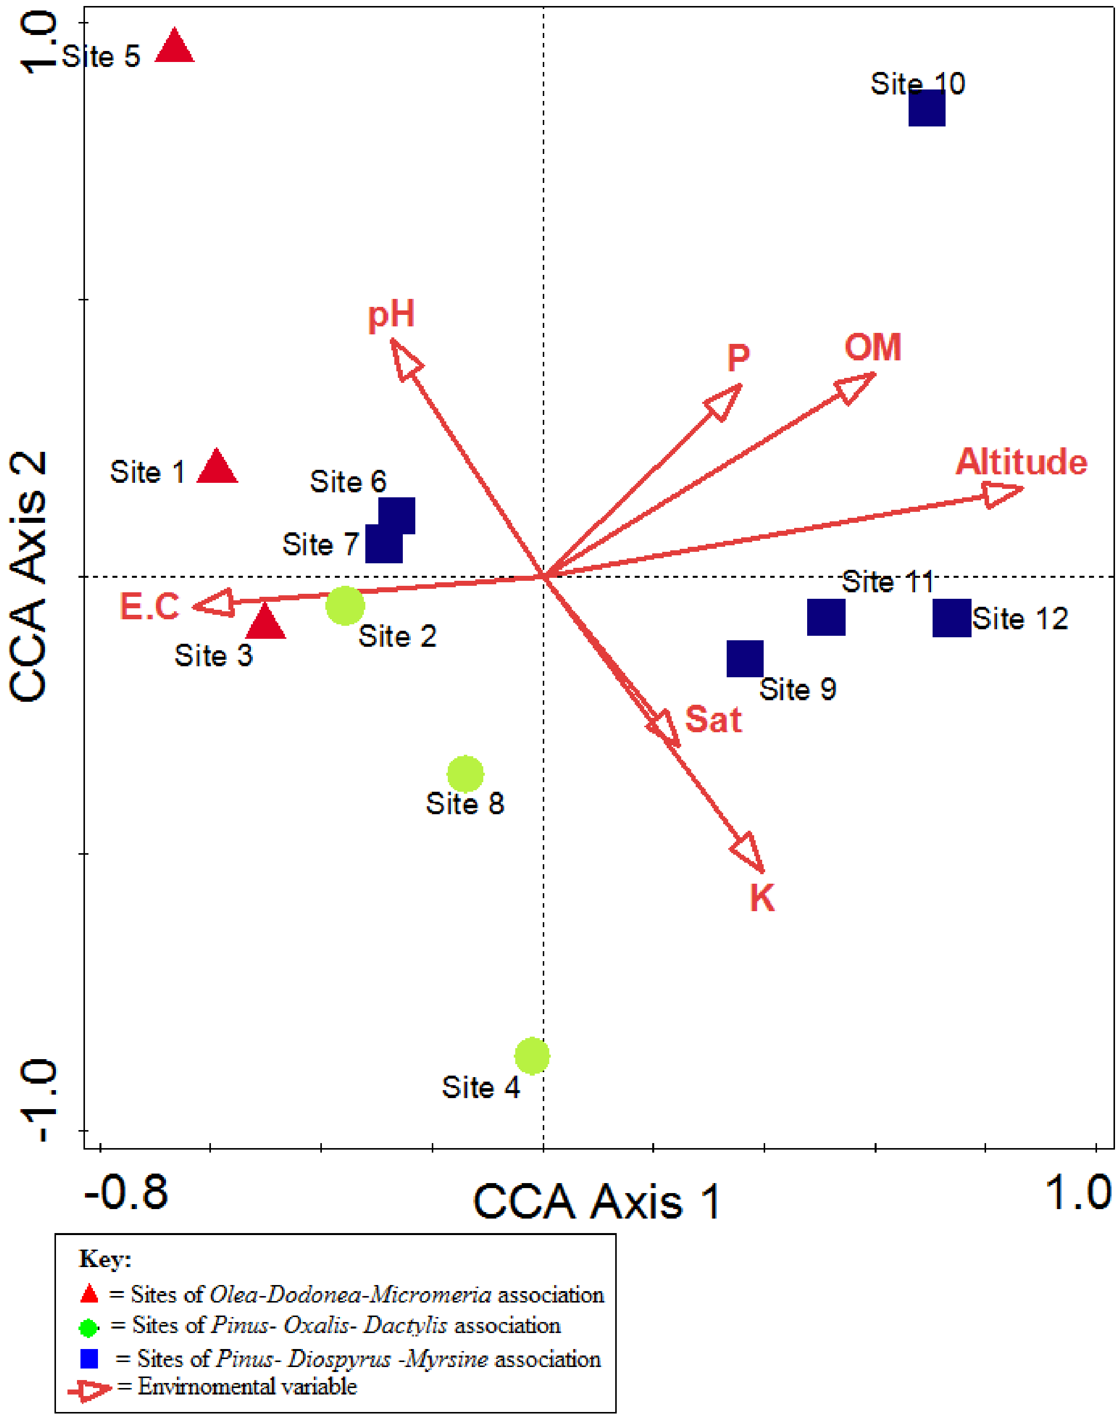

Figure 5. *CCA biplot diagram showing distribution of sites along the environmental variable*

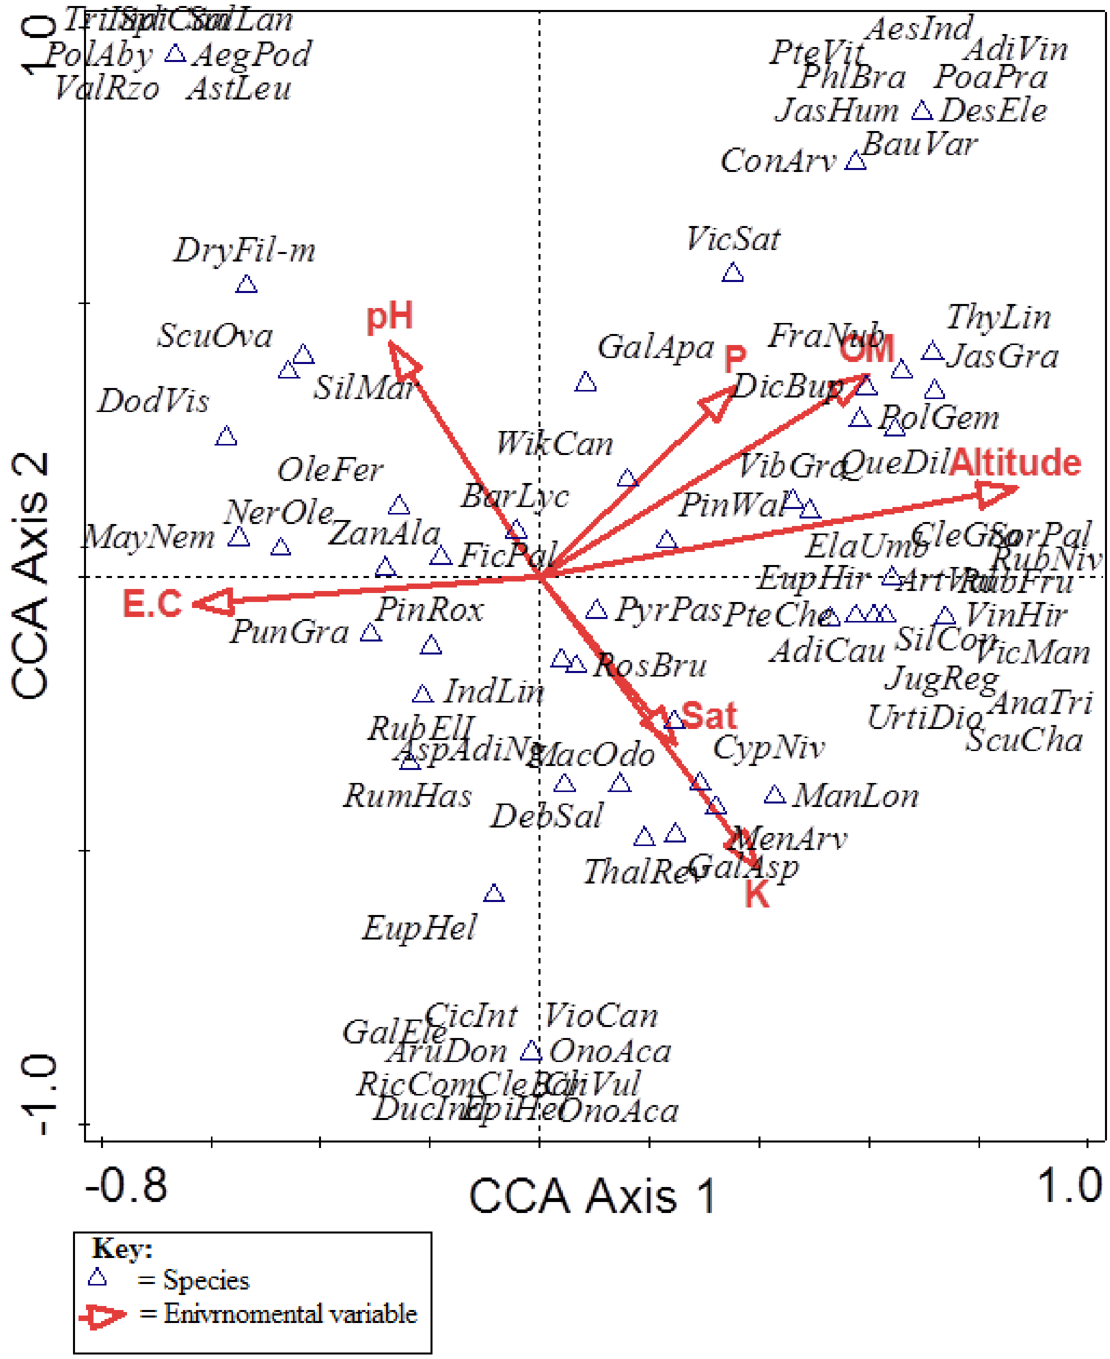

Figure 6. *CCA biplot diagram showing distribution of plant species along the environmental variable*

Species diversity and its associated components

The average Shannon diversity was 3.01 and ranged between 2.49 and 3.82. The average diversity was low (H = 2.55) in *Olea -Dodonea –Micromeria* association and high (H = 3.29) in *Pinus-Diospyrus–Myrsine*. The average species richness was 4.90 ranged between 3 and 7.01. The richness was low (R = 3.24) in *Olea-Dodonea-Micromeria* association and high (R = 5.50) in *Pinus-Oxalis-Dactylis* association. The altitude was significantly positively correlated with diversity and richness and explains

DOI: http://dx.doi.org/10.15666/aeer/1604_51935211

21% variation in diversity and 19% in richness. Average Evenness was 0.63 ranges between 0.46-0.72. Average equitability was 0.86 and ranged between 0.93-0.91. All the forest stands was immature as the maturity value is less than 60% (*Table 2*).

Discussion

Plant associations reflect the environmental condition under which they develop (Malik, 1986; Ilyas et al., 2015). The climate of Tehsil Harigal is of subtropical and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_51935211

temperate type (Shaheen et al., 2011a,b; Malik and Malik, 2012) but marked difference in microclimatic, topographic and edaphic factors lead to the establishment of three different plant association with respect to the floristic element and micro environmental conditions. The spatial distribution of plant species in these associations were controlled by different environmental factor like altitude, topography and physcio-chemical properties of soil. The micro gradient established due to variation and interaction among these factors result in different type of vegetation (Hanson and Churchill, 1965) DCA and CCA analysis clearly reflect that altitude and phsico-chemical properties of soil are the main governing factor in the distribution pattern of plant species. This was strongly supported by Ahmad et al. (2009); Shaheen et al. (2012), Amjad et al. (2014 b), Ilyas et al., (2015), Rahman et al. (2016) and Sadia et al. (2017). The large scale pattern in species distribution and physiognomy is mainly governed by climate but physico-chemical properties of soil also govern the distribution pattern on local or micro level (Bakkenes et al., 2002). Climate can be characterized by different variable mainly available moisture which mainly determines the distribution pattern (Leeman and Cramer, 1991). The moderate rainfall and high temperature of Tehsil Harigal result in the stratified forests. Soil is key factor that play important role in selection of plant by bringing evolutionary changes (Barbour et al., 1980). The vegetation of particular area has strong relationship with the soil (Ali et al., 2004). The physico- chemical properties are directly related to soil depth which play key role in establishment of plant association or communities (Khan et al., 2013) The Electrical conductivity of soil of *Olea-Dodonea-Micromeria* association was high whereas organic matter, pH, available moisture nutrient content as compared to *Pinus-Oxalis-Dactylis* association and *Pinus-Diospyros-Myrsine* association which result in establishment of different vegetation type. Slight differences in the available nutrients are positively correlated with variations in community structure (Noor and Khatoon, 2013).

Species diversity is reflection of the health and productivity of ecosystem. Diversity was low in the investigated area due to heavy grazing, deforestation, road construction and fuel wood extraction etc. (Ram et al., 2004; Kumar and Bhatt, 2006). The species diversity and richness was high in *Pinus-Diospyrus–Myrsine* association which might be due to number of coexisting and interacting plant species having overlapping niche (Saxena and Singh, 1982). Moreover the site of higher altitude (*Pinus-Diospyrus–Myrsine* association) are difficult to access by local inhabitant which also resulting high species diversity and richness. The species richness and diversity is positively correlated with altitude. Our findings are in accordance with Malik and Malik (2012) who reported positive correlation between diversity and altitude which might be due to increase in humidity. Differences in altitudes, aspects and slopes result in variation in species diversity and association types. The plant communities harboured at North facing slopes have high diversity with thick vegetation because of high moisture content on southern slope as compared to north facing slope. The same results were obtained by Khan et al. (2011); Amjad et al. (2014a) and and Haq et al. (2015). Plant growth and survival can be affected by amount of water runoff and infiltration which is dependent upon position and smoothness of slope. Aspect and steepness of slope affect the amount of solar radiation which in turn affect temperature on the ground surface (Sukopp and Werner, 1983) and the amount and type of soil accumulated (Monsen et al., 2004). The evenness and equitability is intermediate due to the long term stable climatic condition and uniform pattern of species distribution in majority of plant communities in Harigal. The maturity index reflects immature forest structure throughout investigated area because

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_51935211

plant species were less adapted to microclimate. The natural balance of plant communities was disturbed due to high anthropogenic pressures which further enhance this pattern (Saxena and Singh, 1982; Shaheen et al., 2011a).

Conclusion

The current study suggests that environmental gradient has profound influence on the distribution of plant species in Tehsil Harighel and association of plant change due to change in environmental variable. Further low value of species diversity and associated indices reflects deteriorating forest structure due to immense anthropogenic pressure in the form of intense grazing, severe deforestation for fuel, fodder and construction purpose, trampling and road construction etc. Therefore immediate conservations measures are needed to preserve the rich plant species diversity of these degraded forests. Land use mapping and vegetation assessment using modern software like ERDAS, arc GIS and NDVI, and are also recommended.

(Received 5th Jun 2018; accepted 1st Aug 2018)

Abstract. The aim of the work was to improve fertilisation recommendations for winter barley by investigating the effect of basic nitrogen (N) fertilisation (0, 40, 80, 120 kg ha^{-1} year^{-1}) on the nutritional status of this crop in a long-term mineral fertilisation experiment involving clearly distinct nutrient supply levels and by determining limiting values indicative of a satisfactory level of nutrition for nitrogen (N), phosphorus (P), potassium (K), sodium (Na), calcium (Ca) and magnesium (Mg) concentrations. Rising N supply levels gradually increased the N content of the aboveground organs of barley, reaching a maximum (4.11–5.61 N%) at the 120 kg N ha^{-1} dose. On this soil, which was well supplied with phosphorus, higher N levels only resulted in a significant increase in the P content of barley in two years. The soil was also well supplied with potassium, N fertilisation enhanced the K concentrations of winter barley at tillering in most years, but generally had no influence on the Na, Ca and Mg content of barley. In the tillering phase the nutritional status of barley was satisfactory at the following concentrations: 3.70–5.80 N%, 0.45–0.75 P%, 3.50–5.02 K%, 0.20–0.60 Na%, 0.40–0.60 Ca% and 0.18–0.30 Mg%.
Keywords: *tillering, macroelements, microelements, nutrient concentration*

Introduction

Investigations on the nutritional status of winter barley and the determination of limiting values for nutrient supply levels for use in diagnostic plant analysis have been an important area of fertilisation research for many decades, but few papers have been published in this field in recent years.

Although applying more nitrogen (N) helps achieve the desired yield (West et al., 2016; Mazur and Mazur, 2015), but results in greater levels of environmental pollution (Wang et al., 2016). According to various authors (Dobermann, 2005; Sebilo et al., 2013) 30-65% of the applied N fertilizer is taken up by crops. In the opinion of Roberts (2008) nutrient loss to the environment is only a concern when fertilizers or manures are applied at rates above agronomic need. The rate of uptake and partition of N is largely determined by supply and demand during various stages of plant growth. The N is needed for early tiller development of barley to set up the crop for high yield potential (Shafi et al., 2011). The N fertilisation of winter barley should be based on soil and plant analysis. Soil analysis is generally carried out prior to sowing, but a combination of monitoring the mineral N content (N_{min}) during the vegetation period and plant

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_52135226

analysis is rarely applied in Hungary. Plant analysis is of outstanding importance in checking the nutritional status of the crop, and its efficiency improves with the number of nutrients analysed (Németh et al., 2010). Plant analysis can play a major role when diagnosing mineral nutrition problems (Munson, 1998). Comparing soil and plant analysis results can greatly assist in the interpretation (Jones, 1998), but may have an adverse impact on the interpretation of plant analysis results (Munson, 1998). The dilution effect makes the interpretation of plant analysis results difficult, but it can be taken into account by relating plant data to a certain stage of growth (Roy et al., 2006). Mengel (1972) emphasised that if plant analysis is to be suitable for use in fertilisation recommendations, it is essential to determine the limiting concentrations representative of nutritional status, which is primarily the task of scientists (Németh et al., 2010; Izsáki, 2014). The optimum values for individual plant species are given, as the physiological requirements of the plant are similar in all regions and soils, only fluctuating over a narrow range (Kádár, 1992). It was suggested by Tarnawa et al. (2017) that reference values should be determined not only for each species but also for each cultivar, but this is complicated by the large choice of cultivars, the frequent changes in the cultivar grown and the time required to elaborate limiting values for nutrient supply levels (Izsáki, 2015). Various authors (Reuter and Robinson, 1997; Elek and Kádár, 1980) give a fairly wide range of limiting values (2.50–5.25%) for satisfactory N supplies to winter barley during the tillering phenophase. When judging the nutritional status of winter barley it is not sufficient to determine the N concentration; interactions between N and other nutrients should also be investigated, together with the various nutrient ratios. These were considered by Kádár and Lásztity (1981) to be the key components of plant analysis. In classical papers on plant analysis, nutrient content was regarded as the quantitative and nutrient ratios as the qualitative indicator of nutritional status (Németh et al., 2010; Kádár and Lásztity, 1981). Various interactions can be detected in the course of N nutrition, of which the N/phosphorus (P), N/potassium (K), N/magnesium (Mg), N/calcium (Ca) and N/copper (Cu) ratios are the most important (Németh et al., 2010; Armstrong, 1998; Debreczeniné and Sárdi, 1999; Usherwood and Segars, 2001). The interaction between N and other nutrients is still controversy among the reports available (Shah et al., 2017). Relatively few papers have been published on the N nutritional status and nutrient interactions of winter barley at tillering, and these cannot be regarded as up-to-date results due to the rapid genetic gain achieved by developments in breeding.

The aim of this paper was to describe the effect of N supply levels on the nutrient content of winter barley at tillering and on interactions between the nutrients, based on long-term mineral fertilisation experiments, and to determine limiting values for nutrient supply levels, which can be used to judge the nutritional status of winter barley in the tillering phase.

Materials and methods

Long-term mineral fertilisation experiment

The long-term mineral fertilisation experiment was set up at the Experimental Station of the Faculty of Economic, Agricultural and Health Sciences of Szent István University in Hungarian Great Plain, Szarvas, Hungary in 1989 (*Fig. 1*). The soil of the experimental station, a chernozem meadow soil calcareous in the deeper layers, had the following parameters: depth of the humus-containing layer 85–100 cm, pH potassium

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_52135226

chloride (KCl) of the ploughed layer 5.0–5.2, humus content 2.8–3.2%, no calcium carbonate ($CaCO_3$) content, upper level of plasticity according to Arany (K_A) 50, dry matter content 32%. The groundwater level was at an average depth of 300–350 cm. Before the experiment was set up in autumn 1989 the ammonium (NH_4)-lactate AL-phosphorus pentoxide (P_2O_5) content averaged 156 mg kg^{-1} and the AL- potassium oxide (K_2O) content 322 mg kg^{-1}, and the nutrient supply level of the soil, based on the methods and limiting values officially recognised in Hungary (Buzás et al., 1979), was medium–good for nitrogen (N), good for phosphorus (P), potassium (K), copper (Cu) and zink (Zn), and very good for magnesium (Mg) and manganese (Mn). The experiment included every possible combination (4^3) of four levels each of three factors (N, P and K fertilisation), giving a total of 64 treatments arranged in a split-split plot design with three replications. *Within the three true replications, the N fertiliser treatments were present in 48 internal replications and the P treatments in 16.*

Figure 1. *Experimental site*

Experimental factors and treatments

Factor A (K fertilisation) involved the following treatments:
K_0 = without K fertilisation,
K_1 = 300 kg ha^{-1} $year^{-1}$ K_2O from 1989–1992, 100 kg ha^{-1} $year^{-1}$ from 1993 onwards,
K_2 = 600 kg ha^{-1} K_2O in 1989, 1000 kg ha^{-1} in 1993 and 600 kg ha^{-1} in 2001,
K_3 = 1200 kg ha^{-1} K_2O in 1989, 1500 kg ha^{-1} in 1993 and 1200 kg ha^{-1} in 2001.
Factor B (P fertilisation) involved the following treatments:
P_0 = without P fertilisation,
P_1 = 100 kg ha^{-1} $year^{-1}$ P_2O_5,
P_2 = 500 kg ha^{-1} P_2O_5 in 1989, 1993 and 2001,
P_3 = 1000 kg ha^{-1} P_2O_5 in 1989, 1993 and 2001.
Factor C (N fertilisation) involved the following treatments:
N_0 = without N fertilisation,
N_1 = 80 kg N ha^{-1} $year^{-1}$ (40 kg ha^{-1} basic fertiliser + 40 kg ha^{-1} top-dressing),

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_52135226

N_2 = 160 kg N ha^{-1} $year^{-1}$ (80 kg ha^{-1} basic fertiliser + 80 kg ha^{-1} top-dressing),
N_3 = 240 kg N ha^{-1} $year^{-1}$ (120 kg ha^{-1} basic fertiliser + 120 kg ha^{-1} top-dressing).
N_{1B} = 40 kg N ha^{-1} $year^{-1}$ basic fertiliser
N_{2B} = 80 kg N ha^{-1} $year^{-1}$ basic fertiliser
N_{3B} = 120 N ha^{-1} $year^{-1}$ basic fertiliser
The results of the basic fertilizer treatments are included in the paper.

The aim of the periodic application of high rates of P and K fertiliser was to create clearly distinguishable supply levels in the soil in order to investigate different nutritional situations and to determine limiting values for soil nutrient supply levels. The N basic fertiliser and top-dressing was applied in the form of ammonium nitrate (34%), the P as superphosphate (18%) and the K as potassium chloride (40 or 60%).

Crop management

Each year four crops were sown in a full crop rotation on 4 × 192 plots, where the area of the main plots was 320 m², the subplots 80 m² and the sub-subplots 4 × 5 = 20 m². The forecrop of winter barley was fibre hemp (*Cannabis sativa*) in 2006 and 2007 and canary grass (*Phalaris canariensis* L.) in 2010 and 2011. The two-row winter barley cultivar GK Stramm was used in the experiment. The results recorded in the long-term experiment in the 17th–19th years (2005/2006, 2006/2007, 2007/2008) and in the 22nd (2010/2011) and 23rd (2011/2012) years are discussed in the present paper. In these years sowing took place between October 8th and November 3rd with a row distance of 12 cm and *5 million seed/ha*. No chemical weed control was required in the experiment. Other plant protection measures were carried out when necessary. Top-dressing was applied on a single occasion at the end of tillering after plant sampling. The winter barley was harvested at full maturity using a plot combine at the end of June.

Weather conditions

The weather conditions during the growing season are presented in *Table 1.*

Table 1. *Weather data of experiment during the period tested, (Szarvas, 2006-2008, 2011-2012)*

Year	Rainfall, mm			Average temperature, °C		
	Winter half year (X-III.)	Vegetation period (X-VI.)	Year total	Winter half year (X-III.)	Vegetation period (X-VI.)	Year total
Average 1901-1975	225	362	538	3.4	7.5	10.6
2005	-	-	721	-	-	10.2
2005/2006	204	379	537	2.2	6.9	10.7
2006/2007	159	293	548	6.5	10.2	12.2
2007/2008	200	370	464	4.2	8.4	11.7
2010/2011	282	435	373	3.6	8.2	11.5
2011/2012	121	230	363	3.1	7.9	11.5

In the 17th year of the long-term experiment (2005/2006) the rainfall quantity (379 mm) was slightly higher than the long-term mean (362 mm), while the mean temperature (6.9 °C) was lower than the long-term mean (7.5 °C). In the year with the least favourable weather (2006/2007) the total rainfall was 69 mm less than the long-term mean while the mean temperature was 2.7 °C higher. In 2007/2008 both the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_52135226

rainfall quantity and the mean temperature were close to the long-term mean (370 mm and 8.4 °C). The wettest growing season was the 22nd year of the experiment, with 73 mm more rain than the long-term mean and a mean temperature 0.7 °C higher than the mean. In the 2011/2012 growing season the temperature was similar to the long-term mean, while the rainfall quantity (230 mm) was well below the mean.

Soil contents

The K_2O and P_2O_5 contents of the soil were determined using the AL method (Hungarian standard MSZ 20135:1999). When evaluating the results, the K and P values recorded in the ploughed (30 cm) layer were used to represent the K and P supply levels in the soil. The K and P supply levels given for the various years are those recorded in the autumn of the previous year (*Table 2*).

Table 2. *P and K supplies of the soil, (Szarvas, 2006-2008, 2010-2011)*

Treatment	Years of experiment				
	2006	**2007**	**2008**	**2010**	**2011**
AL- K_2O in plought layer (mg kg^{-1})

P_2	186	193	158	194	186
P_3	282	273	269	251	233

Plant samples

Plant samples were taken from 2 × 1 m on each plot at tillering (growth stage 4–5 on the Feekes scale), prior to N top-dressing, to determine the nutrient content of winter barley. The nutrients N, P, K, sodium (Na), calcium (Ca) and magnesium (Mg) were analysed in five years (2006–2008 and 2011–2012) from dried, ground samples of the complete aboveground plant organs. The nutrient contents were determined using the inductively coupled plasma optical emission spectrometry method (ICP-OES) after digestion with first nitric acid and then hydrogen peroxide (*MSZ-08-1783-6:1983 3.1., MSZ-08-1783-26-34:1985, MSZ-08-1783-36:1985*). The data are given in terms of dry matter. In the present paper is discussed the effect of basic N fertilisation.

Statistical analysis

Statistical analysis was performed by means of analysis of variance followed by Student's t-test and least significant differences (LSD) at the 0.05 probability level, using the SPSS program, version 15.

Envelope curves

Correlation analysis on the extensive database was performed by plotting data pairs for N concentration and grain yield in a coordinate system and envelope curves were drawn for each set of points (Izsáki, 2014; Helget, 2016; Izsáki, 2017). Values located along the envelope curve represent cases when factors influencing the yield have optimum values and the yield is only influenced by the N concentration. Those located below the envelope curve indicate that one or more yield-influencing factors are not optimum, so the yield level does not depend only on the N nutritional status. The higher the yield level for which the optimum nutrient supply level is determined, the narrower the optimum range, while the range is wider for lower yield levels.

Results

Effect of N supply levels on the macroelement content of winter barley

The effect of N basic fertiliser (N_0 = 0, N_{1B} = 40, N_{2B} = 80, N_{3B} = 120 kg ha^{-1}) on the N, P and K contents of winter barley in the tillering phase, averaged over the P and K treatments, can be evaluated from the data presented in *Table 3*.

Table 3. *Effect of N supplies on the N-, P- and K-concentrations of winter barley at the tillering, (Szarvas, 2006-2008, 2011-2012)*

NS: non-significant. Values in each row followed by the same letters are not significantly different at $p < 0.05$ according to Student's t-test

Without N fertilisation the N content of the total aboveground organs of barley ranged over a relatively narrow interval (2.94–3.42%) in four of the five years. In the year that had average but favourably distributed rainfall supplies the N concentration reached a level of around 4%. Regardless of the year, increasing rates of N fertiliser led to significant increases in the N concentration of barley compared with the control given no N fertiliser (N_0). The N content of the aboveground shoot reached a maximum concentration of 4.11–5.61% in the N_{3B} treatment (120 kg N ha^{-1} year^{-1}) except in 2011. The winter half of the 2010/2011 growing season was extremely wet, and the 188 mm precipitation recorded in November and December leached a considerable quantity of NO_3-N out of the soil of N-fertilised treatments, with the result that the N concentration

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_52135226

of barley was the lowest in this year. The P concentration of barley at tillering was greatly influenced by the year and ranged from 0.32–0.65% in the N_3 treatment.

Even though the experiment was set up in 1989 the AL-K_2O content of the ploughed layer was 322 mg kg^{-1}, which dropped to 199 mg kg^{-1} by autumn 2006, in the 16th year of the experiment, without K fertilisation. The soil was also well supplied with K, and improvements in the N supply level increased the K content of barley at tillering in three of the five years. There was also a tendency for N fertilisation to increase the K concentration in the other two years. Except in the 2010/2011 growing season, the K concentrations exhibited little difference within each N supply level, with a value of 4.03–4.69% in the N_3 treatment.

The effect of basic N fertilisation on the Na, Ca and Mg contents of winter barley in the tillering phase, averaged over the P and K treatments, can be seen from the data in *Table 4*.

For most field crops, Na is not one of the essential macroelements, but winter barley takes up almost as much Na as Mg, especially on solonetz soils well supplied with Na. In two of the five years N fertilisation was found to induce a significantly greater rate of Na incorporation compared with the N_0 treatment. The Na concentration in the tillering phase differed considerably in the different years, with values ranging from 0.19–0.41% in the N_{3B} (120 kg ha^{-1} N) treatment. The Ca content of barley exhibited a significant increase with better N supplies in three of the years. The Ca content was not greatly influenced by the year. On this soil, which is extremely well supplied with Mg, a slight but significant increase in Mg concentration as the result of N fertilisation could only be detected in one year. Depending on the year and the N supply level, the Mg content of barley at tillering ranged from 0.17–0.26%.

Correlations between nutrient concentrations and the yield

The experimental data revealed clear differences in the N concentration of barley leaves at tillering in the various N treatments. Diagnostic plant analysis is only of practical interest if a correlation exists between the leaf N concentration and the yield, allowing limiting values to be determined for the N nutritional status of winter barley. Based on the correlation between the leaf N concentration of winter barley in the tillering phase and the grain yield (*Fig. 2*), the limiting value of satisfactory N supplies at a yield level of over 5.5 t ha^{-1} is 3.70–5.80 N%.

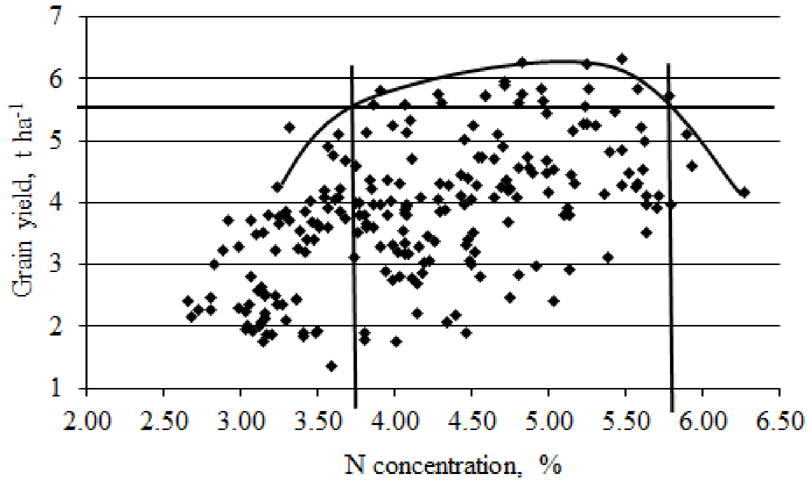

***Figure 2.** Relationship between the N-concentration of leaf at the tillering and the grain yield (Szarvas, 2006-2008, 2011-2012)*

The limiting values for satisfactory supplies of the other macroelements were determined by plotting the P, K, Na, Ca and Mg concentrations associated with grain yield in a coordinate system and then reading off the macroelement concentrations corresponded to a yield level that was at least 90% of the maximum value (*Figs. 3–7*).

Discussion

In a pot experiment on winter barley in the tillering phenophase, Kostadinova (2014) found that the application of mineral fertiliser at rates of 200 mg kg^{-1} P_2O_5 and 200 mg kg^{-1} K_2O without N fertiliser resulted in leaf N concentrations of 2.15%, which rose by more than 50% as the N supplies increased. Kádár and Csathó (2015) examined the effect of N fertilisation on the nutrient content of winter barley at tillering in a soil containing 128 mg kg^{-1} AL-P_2O_5 and 243 mg kg^{-1} AL-K_2O and reported that without N fertilisation the leaf N content was 1.86%, which rose significantly to 3.03% at a dose of 200 kg ha^{-1} N, tending to decline again at the maximum dose of 300 kg ha^{-1} N. In the opinion of Mills and Jones (1996) ranges of sufficiency are most commonly used in assessment of plant nutrition. In the present work the satisfactory N concentration for winter barley at tillering was found to be 3.70–5.80%, which deviated somewhat from the optimum N concentrations given by other authors. Fageria (2014) determined a very narrow range of satisfactory N concentrations (4.7–5.1%), while Reuter and Robinson (1997) reported a fairly wide range (2.5–5.0%). Under Hungarian conditions Elek and Kádár (1980) established a value of 4.70–5.25 N%. On this soil, which is well supplied with P, rising N supplies only led to a significant increase in the P content of barley in two years. According to Kádár and Csathó (2015) better N supplies reduced the P concentration of winter barley in the tillering phase, while in the present work the maximum P concentration was recorded in the N_2 treatment. Sanchez (2007) considers the value above 0.4 P concentration satisfactory. Both Elek and Kádár (1980) and Kádár (2012) stated that a P concentration of 0.4–0.5% represented satisfactory P supplies in winter barley, while a value of 0.45–0.75% was found in the present work and Reuter and Robinson (1997) reported an optimum range of 0.3–0.6%. In agreement with the present results, Kádár (2012) and Kádár and Csathó (2015) reported that better N supplies stimulated the cation uptake of winter barley. A K concentration of 4.2–5.0% was found by Elek and Kádár (1980) to represent satisfactory K nutritional status in winter barley at tillering, while this was later modified by Kádár (2012) to 3–4%. Reuter and Robinson (1997) considered a wider range of values to be acceptable (3.5–5.0 K%), the same range as found in the present work. If the Na concentration of barley in the tillering phenophase was higher than 0.8%, this was judged by Reuter and Robinson (1997) to be toxic, while values below 0.50% were found to be satisfactory.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_52135226

The present results showed that the satisfactory Na content for winter barley at tillering was 0.20–0.60%. In the case of Ca and Mg the present results were in good agreement with the limiting values given in the literature. Barczak (2008) has demonstrated that higher N supplies generally increased the content of macroelements in winter barley biomass in all the plant growth stages assayed. Kádár and Lásztity (1981) emphasised that nutrient ratios only provide information on the relative quantities of two nutrients, not on the actual quantity of the individual nutrients, so the knowledge of ratios alone is insufficient to determine whether the nutrients are present in optimum, excessive or deficient quantities. The quantity of a given nutrient in the plant depends on the available supplies of other nutrients and on the interactions between them (Füleky et al., 1999). Elek and Kádár (1980) pointed out that nutrient ratios are more constant and less dependent on plant age than the concentrations. Between N and P nutrients are positive interaction, but their physiological effects are antagonists of each other. The present results suggest that a satisfactory N/P ratio is in the range of 7.7–8.2, which is similar to the value of 8.3 recommended by Reuter and Robinson (1997), but lower than the 11.9–12.0 reported by Elek and Kádár (1980). In the case of the N/K ratio, which is negative interaction, similar values were determined in the present work (1.1–1.2) to those given in the literature. According to Brar et al. (2011) the N/K interaction **is** dependent on the form of N supplied. The satisfactory N/Na ratio calculated from the present data (9.6–18.5) was higher than the 5–10 optimum reported by Reuter and Robinson (1997). Higher ratios were also found for the N/Ca and N/Mg ratios (9.2–9.6 and 19.3–20.5, respectively) than those given by the same authors (5.0–8.3 and 16.6–17.5, respectively), while the K/Mg and Ca/Mg ratios found in the present work were similar to those given by Reuter and Robinson (1997).

The limiting values for satisfactory macroelement concentrations and the associated nutrient ratios are presented for winter barley in the tillering phenophase in *Table 5*.

Conclusions

1. Rising N supply levels gradually increased the N content of winter barley at the tillering phenophase, reaching a maximum (4.11–5.61 N%) at the 120 kg N ha^{-1} $year^{-1}$ dose.
2. The soil of the long-term fertilisation experiment is well supplied with phosphorus, the P concentration of barley at tillering was greatly influenced by the year, than N supply and ranged from 0.32–0.65% in the N_{3B} treatment.
3. On this soil, which was also well supplied with K, N fertilisation enhanced the K concentration of winter barley in most years.
4. N fertilisation generally had no influence on the Na, Ca and Mg concentrations of barley.
5. In the tillering phenophase the nutritional status of winter barley was satisfactory at the following concentrations: 3.70–5.80 N%, 0.45–0.75 P%, 3.50–5.02 K%, 0.20–0.60 Na%, 0.40–0.60 Ca% and 0.18–0.30 Mg%.
6. *The aim of experimental work was to develop fertilization consultancy with plant analysis, practical guidance for leaf fertilization.*

RELATIVE HUMIDITY MODELING WITH ARTIFICIAL NEURAL NETWORKS

KUZUGUDENLI, E.

Department of Forestry, Applied Sciences University of Isparta, Isparta, Turkey
e-mail: emrekuzugudenli@sdu.edu.tr

(Received 5th Jun 2018; accepted 2nd Aug 2018)

Abstract. Air humidity has great importance for living beings, especially plants. Air humidity controls vaporisation on earth's surface and transpiration of plant leaves. Additionally, it prevents most of the radiation from the sun and reflected sun rays from reaching the ground and prevents excessive heating or cooling. The purpose of this study is to predict relative humidity as an important climate parameter, based on annual total precipitation, average ambient temperature, and altitude. Regression and artificial intelligence network models were developed by using monthly average temperature, total precipitation, and altitude parameters obtained from 177 meteorological stations in Turkey to predict relative humidity. When analysed, the model developed with the artificial neural network method had greater predictive power ($R^2 = 0.84$) than the model developed with multiple linear regression ($R^2 = 0.76$). In this study may be applicable in climate conditions that are similar to those in Turkey.
Keywords: *Turkey, multiple linear regression, ANNs, humidity, climate*

Introduction

The amount of water in the air is referred to as air humidity. Air humidity is important for the development of plants and prevents most of the radiation from the sun and reflected sun rays from reaching the ground, thus preventing excessive heating or cooling. When the relative humidity of air decreases, the transpiration rate of plants increases. This causes decreased turgor pressure in plant cells. The relative humidity ratio in ambient air should be greater than 65% for turgor pressure to be balanced. If the relative humidity of air constantly decreases, transpiration increases; if water absorbed by the roots fails to correspond to water lost via transpiration, plant stomas will close and decrease transpiration. In this case, the gas exchange necessary for photosynthesis and respiration will fail, and as a result plant growth will either slow or completely stop (Cox et al., 2016).

The transpiration rate of plants is affected by sunlight, wind, air humidity, air pressure, and the amount of water in soil. During winter months, temperature and light intensity are relatively low. Therefore, the transpiration rate decreases and plants need less water. Generally, in places where temperatures are at low levels during summer or winter, plants need less water, whereas in places where temperatures are higher, plants need more water (Rohli and Vega, 2013).

Additionally, air relative humidity has an important role in storage of products. If relative air humidity in a barn is high, the amount of water in stored products will increase. Increased water retention will lead to product losses due to excessive heating, decay, and rotting (Pixton, 1982).

Because air humidity has an effect on water loss in an ecosystem, it is important in terms of ecology. Therefore, ground humidity is considered as a criterion in determining climate type. For example, places with more than 80% relative humidity are characterised as rain forests, whereas places with less than 20% humidity are characterised as extremely dry climates (Clarke, 1954).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_52275235

Air humidity controls vaporisation on the earth's surface and transpiration of plant leaves. As vaporisation and transpiration increase, the amount of water decreases inside root sections and on the ground surface. Fog as air humidity is important for dry regions. Although there may be no precipitation events in deserts for years, fog in the air supports plant survival. However, higher relative humidity or foggy and cloudy weather can cause various types of fungus that cause different diseases in plants to grow and spread, thus decreasing agricultural yield in humid regions (Yurtseven, 1999; Kanber et al., 1992).

Air humidity thus has great importance for living beings, especially plants. Yet, in analysing previous studies regarding prediction of climate parameters, there were few studies on relative humidity prediction. The purpose of this study is to predict relative humidity as an important climate parameter for ecologic studies, based on certain measurements that are believed to be related to relative humidity: annual total precipitation, average ambient temperature, and altitude.

Prediction models developed in this purpose are based on classical regression analysis (Tokar and Johnson, 1999) and artificial neural networks (ANNs) (Al-Alawi et al., 1998; Luk et al., 2000; Kumar et al., 2002; Çelik et al., 2016) that are increasingly important in recent years. Multiple linear regression techniques are the most widely used statistical tools for discovering the relationships among variables. ANNs are considered nonlinear statistical data modeling tools where the complex relationships between inputs and outputs are modeled or patterns are found. ANNs have been very useful in many aspects of climatical research and modeling in recent years (Terzi and Keskin, 2010; Keskin et al., 2011).

Comparison of regression and ANN models have shown that the performance values of the ANN models are better than the regression models in general (Yadav and Chandel, 2014; Kumar et al., 2015).

Materials and methods

Turkey is located in the northern hemisphere, between 36°-42° N and 26°-45° E. More than half of the country has an altitude of more than 1,000 m. Approximately one third of the country is covered with medium-height plainlands, highlands, and mountains, and 10% is at low altitude. The highest and most mountainous areas are located on the eastern side of the country. The most rugged area in the north is the North Anatolian Mountains, and the roughness of south, east, and southeast regions is caused by the Toros Mountains. The highest mountain in the country is Mount Ağrı, at 5,166 m. The largest plains are Çukurova, Konya Plains, and Harran Plains. The longest river with a spring source and flowing into the sea is Kızılırmak with a length of 1,355 m. The largest natural lake is Van Lake with an area of 3,713 km². Atatürk Dam Lake is the largest artificial lake with a 817 km² area. The largest island is Gökçeada with a 279 km² surface area. Total land area is 770,760 km², and total water area is 9,820 km² (Şahin, 2006).

Turkey is located between a temperate zone and sub-tropical zone. Although Turkey is surrounded by seas on three sides, differences in mountain elongation and land forms cause different climate types with different properties. The coastal section of Turkey has a temperate climate because of the tempering effect of the sea. The North Anatolian Mountains and Toros Mountain range prevent the mild sea climate from penetrating to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_52275235

the inner regions. Therefore, the inner regions of the country have a continental climate (Atalay, 1997).

Due to climate differences by location and geographical properties, natural vegetation consists of various plant formations, including forests, shrubs or bushes, or weeds. These plant groups that show humid, semi-humid, or dry characteristics based on the effects of climate differ in geographical spread, morphology, ecology, and floristic properties. In Turkey, there are approximately 12,000 plant taxa (Günal, 2013).

This study attempts to predict relative humidity by using certain parameters (average annual total precipitation, average ambient temperature, and altitude) collected between 1987-2017 from 177 large climate stations in Turkey. The location of these stations is given in *Figure 1*.

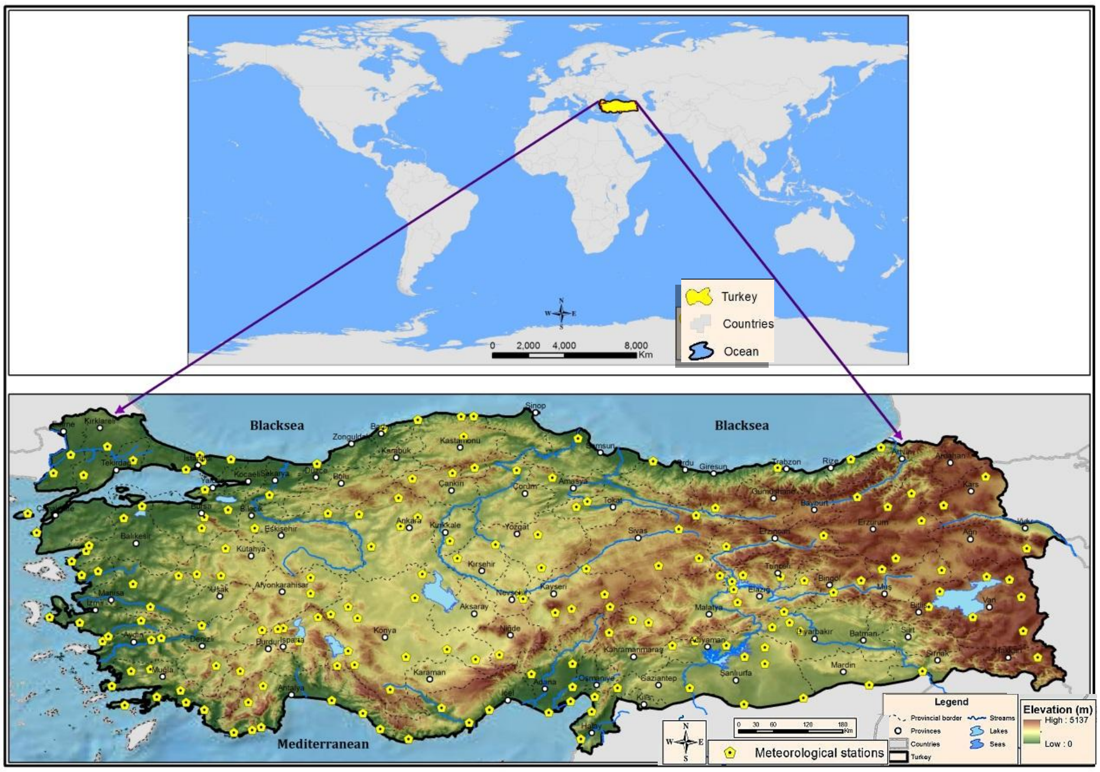

Figure 1. *Study area*

Regression analysis, which forms the basis of the multiple linear regression model adopted in the study, enables the development of a model of the relationship between dependent and independent variables; this model enables predictions (Kalıpsız, 1994).

The multiple linear regression model used in the analysis is presented in *Equation 1*.

$$Y = b_0 + b_1X_1 + b_2X_2 + b_3X_3 + \varepsilon i \qquad \text{(Eq.1)}$$

In this model, Y is the dependent variable, X_1 is temperature, X_2 is precipitation, and X_3 is altitude, b_0 is where the regression curve intersects the y axis, b_1 is the regression coefficient for the first independent variable, b_2 is the regression coefficient for the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_52275235

second independent variable, b_3 is the regression coefficient for the third independent variable; εi is a random error variable for zero average, and σ2 is variance.

Today, artificial intelligence applications are used for predicting meteorological events. Successful results were found especially in applications with artificial neural networks (Keskin and Terzi, 2006; Kumar et al., 2002; Saplıoğlu and Çimen, 2010; Zealand et al., 1999).

The artificial neural network (ANN) adopted in this study was developed based on learning with trial and generalisation concepts of the human brain. The biologic neural system can be explained as a three-layered system that constantly receives information, interprets this information, and produces decisions for this interpretation. Receiver neurons turn a stimulus within the organism or from the outside world into electrical signals that transfer information. Reaction neurons turn electrical impulses created by the brain into appropriate reactions as organism output. *Figure 2* shows a block diagram of a neural cell (neuron) (Öztemel, 2003).

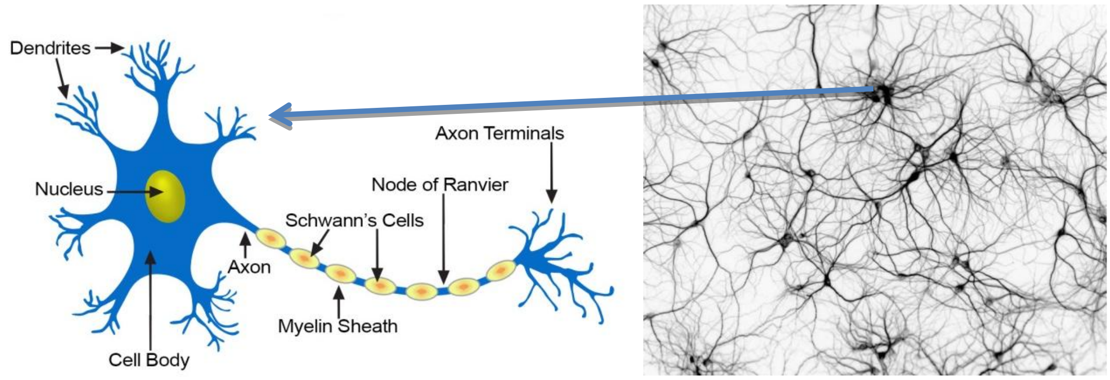

Figure 2. *Structure of neuron. (Anonymous, 2018a, b)*

An artificial neuron cell consists of five main components: inputs, weights, summation (uniting) function, activation (transfer) function, and output. Inputs are outside-world information to an artificial neuron cell. Information received from the outside world or a previous layer are sent to the artificial neuron cell as input. Weights indicate the importance of the information sent to an artificial cell and the effect on the neuron. These are coefficients determining the effect of inputs received by the artificial neuron. The summation function calculates net input to a cell. The value obtained from the summation function is processed by a linear or non-linear derivable activation function, and the output of operation elements is calculated. Activation functions enable curvilinear matching between input and output units. Out value is the value obtained after application of the activation function (Elmas, 2003; Öztemel, 2003).

Input and corresponding output information are fed into ANNs, and the neural network is trained to learn the relationship between input and output. ANNs can be grouped as feedforward and feedback or recurrent based on information flow type. In a feedforward network structure, information flows forward. Generally, in a feedforward network, there is one input layer, one or two hidden layers, and outputs layers. These networks are called multi-layered feedforward networks (Schalkoff, 1997).

Additionally, ANNs learn with supervised, unsupervised, and reinforcement learning. Back propagation algorithms in supervised learning have two types of connections. In the first form, corresponding outputs for certain inputs are computed in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_52275235

a forward connection and by using weights. In the second form, the connection is backwards; to minimise errors on output layers, weights are organised backwards. A feedforward operation transfers data on the input layer to the first hidden layer. In all these stages, the number of computing elements in each layer is important (Elmas, 2003).

Because there is no operation on the input layer of ANNs, the number of computing elements on input and output layers depends completely on the applied problem. The number of hidden layers and number of computing elements on hidden layers can be determined through trial and error, but the number of neurons on input and output layers is considered (Şen, 2004).

In ANNs, network input and output can be pre-processed to increase the efficiency of network training. This operation is called normalisation. In the literature, there are various data normalisation practices. This model adopted one of the most common methods, Min-Max, and data were reduced to between 0 and 1 (Jayalakshmi and Santhakumaran, 2011).

Results

In this study, regression and ANN models were developed to predict relative humidity in 177 regions in Turkey that have different geographical and climate conditions. Meteorological data of the past 30 years (1987-2017) in the 177 regions were obtained from Turkish State Meteorological Service (TSMS) and used for modelling (*Table 1*).

Table 1. *Descriptive statistics of sample plots*

	N	Minimum	Maximum	Mean	Std. Error	Std. Deviation	Variance
Altitude (m)	177	2	2400	722.93	45.062	599.516	359419.779
Precipitation (mm)	177	196.3	2279.5	627.146	20.6666	274.9511	75598.131
Temperature (°C)	177	3.7	20.2	13.169	0.2809	3.7367	13.963
Relative humidity (%)	177	46.7	82.0	63.338	0.4920	6.5455	42.843

Multiple regression analysis was used to determine the collective effect of dependent variables (temperature, precipitation, and altitude) on the independent variable (relative humidity). Based on multiple regression analysis, a mathematical equation with statistical significance of $p < 0.001$ and an R^2 value of 0.76 was computed (*Eq. 2*; *Fig. 3*).

$$RH(\%) = 105 - (2.477x\text{Temp.}) + (0.005xPrecip.) - (0.017xAltit.) \quad \text{(Eq.2)}$$

The Neural Network Toolbox plug-in for MATLAB was adopted to create the ANN model. In this ANN model, three input parameters (temperature, precipitation, altitude) and one output parameter (relative humidity) were predicted. When the model was structured, a 3-input, 1-output Levenberg-Marquardt (LM) algorithm was used for predicting relative humidity. First, on average 70% of data were used as “input” to train the network, 20% were used for testing the developed model, and 10% were used for validation purposes.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_52275235

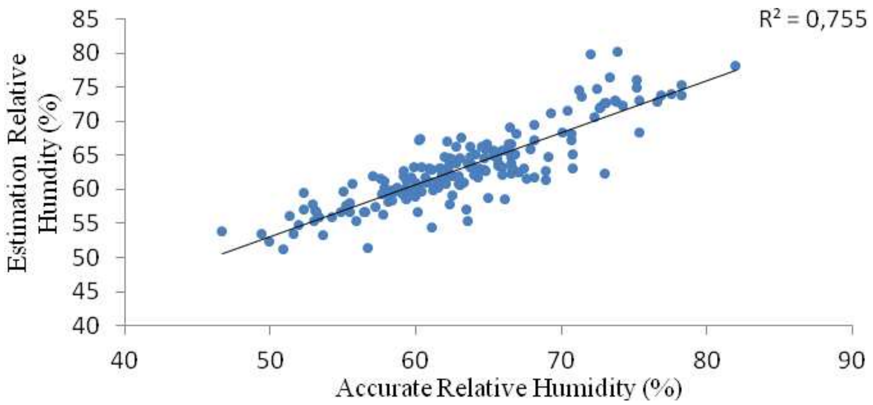

***Figure 3.** The relationship between accurate and estimation relative humidity (%)*

To determine the number of hidden layers and hidden neurons, various trials were conducted. The model with 1 hidden layer and 10 neurons provided the best results. Sigmoid activation function was used between layers. A maximum iteration number of 12 was obtained. In each execution, the algorithm was stopped after 6 epochs (*Fig. 4*). To determine the relationship between training data and output results obtained after training, regression analysis was applied. Analysis indicated an R^2 value of 0.84. Similarly, analysis was conducted on test data, validation data, and all data, with R^2 values of 0.83, 0.79, and 0.84, respectively (*Fig. 4*).

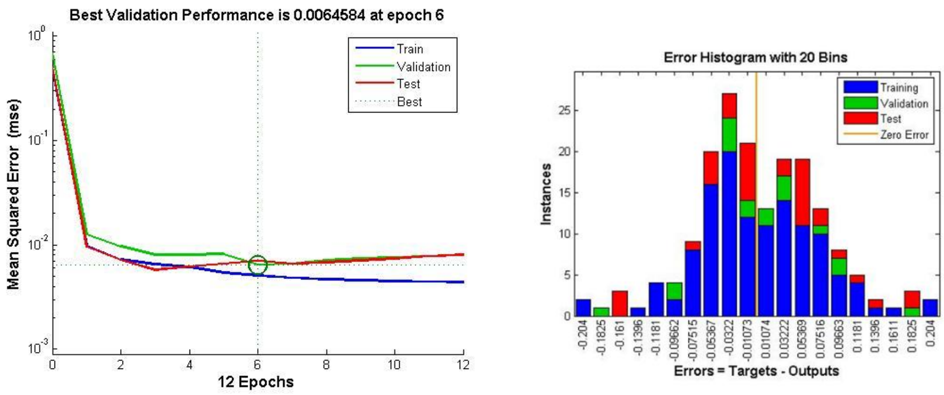

***Figure 4.** Best validation performance and error histogram of model*

To determine the relationship between training data and output results obtained after training, regression analysis was applied. Analysis result indicated R^2 value of 0.84. Similarly, analysis were conducted on test, validation, and on all data and R^2 values were found 0.83, 0.79, and 0.84 respectively (*Fig. 5*).

Discussion and conclusions

The purpose of this study was to predict certain parameters thought to related to relative humidity. To predict relative humidity, various models were developed by using temperature, precipitation, and altitude parameters. Calculated values for the model and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_52275235

real values were compared with statistical methods. Comparison results indicated that predicted and measured relative humidity values had good fit.

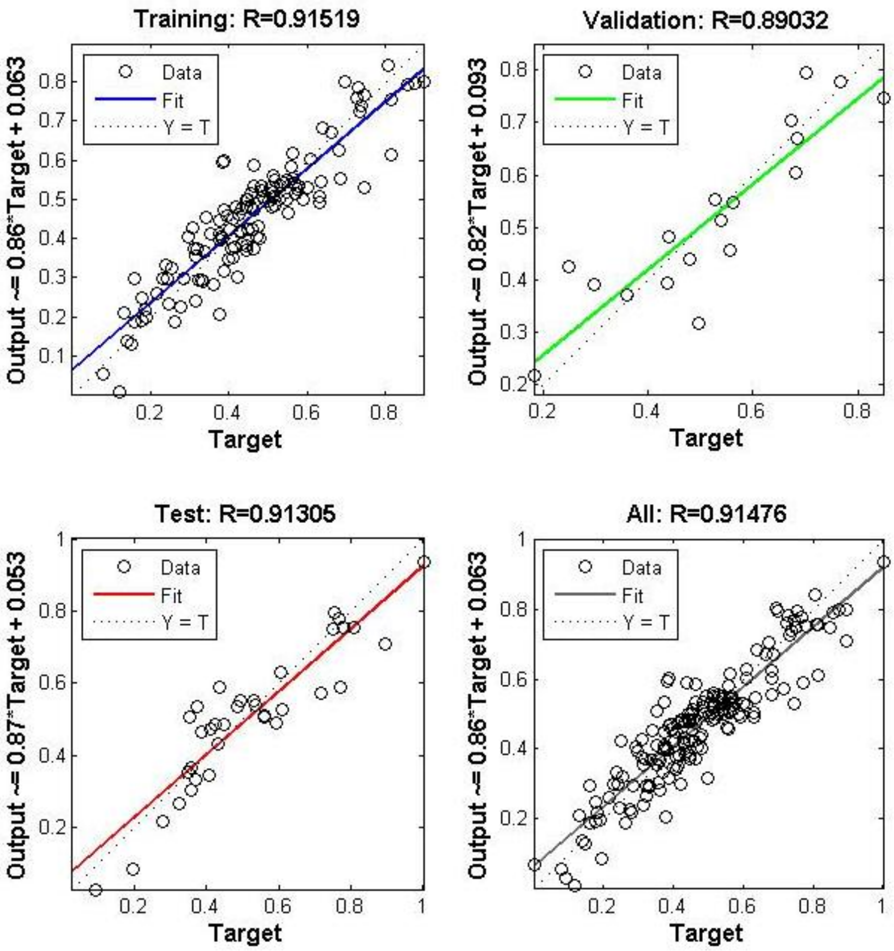

Figure 5. *Target and output relations of ANN model*

When analysed, the model developed with the ANN method had higher predictive power than the model developed with multiple linear regression. Similarly, Tokar and Johnson (1999) conducted a study to predict daily flow rate and used an ANN method with precipitation, temperature, and snow melting data. They compared results obtained from statistical regression and the ANN model and determined that the ANN model provided an extremely systematic approach. Kumar et al. (2015) predicted monthly average global solar radiations by using some parameters in ANNs and regression models. Comparison of ANNs and regression models have shown that the performance values of the artificial neural network models are better than the regression models as in this study. Yadav and Chandel (2014) predicted average global solar radiations by using some parameters in ANNs and regression models. ANNs had better performance than regression model too.

Similar studies were conducted by different researchers to predict other climate parameters. Erkaymaz and Yaşar (2011) predicted temperature by using water vapour pressure, relative humidity, wind, and air pressure parameters in an ANN method. In another study, Terzi (2006) predicted daily water temperatures of Eğirdir Lake by using

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_52275235

daily air temperature, solar radiation, and relative humidity parameters in ANNs, Saplıoğlu and Çimen (2010) predicted missing daily precipitation of Portland by using measured daily precipitation parameters in ANNs.

Nastos (2014) predicted maximum daily precipitation for the next coming year of Athens (Greece) by using some parameters in ANNs. Correlation coefficient between the measured and predicted maximum daily precipitation were found to be 0.48. Deo and Şahin (2015) determined of feasibility of the ANNs for predicting the monthly Standardized Precipitation and Evapotranspiration Index (SPEI). In this purpose, a total of 30 ANN models were developed with 3-layer ANNs by them.

They ever that the ANNs was a useful data-driven tool for forecasting monthly SPEI based on performance evaluation measures. Ramasamy et al. (2015) predicted wind speeds with ANNs. Temperature, air pressure, solar radiation and altitude are taken as inputs for the ANNs to predict daily mean wind speeds. Correlation coefficient between the measured and predicted wind speeds was found to be 0.98.

Applying this study in Turkey under different geographic and climate conditions is important as these models can also be applied in climate conditions that are similar to those in Turkey. Additionally, when of the models was investigated, the strength of the model with ANN model was much higher than regression analysis; therefore, it is believed that the ANN model can be used for relative humidity prediction.

Abstract. In Thailand, lotus flowers are one of exportable products for flower trade industry. Common blossom thrip (*Frankliniella schultzei*) contamination on cut lotus flowers after harvest has been a major problem for export. *F. schultzei* is a quarantine insect pest. Modified atmospheres (MA) without oxygen content are considered an alternative to methyl bromide fumigation to control thrips. MA treatment has been used to control insect pests in agricultural product commodities. Different combinations of carbon dioxide, nitrogen, ozone levels, and treatment times were used to effect mortality of the common blossom thrips and postharvest quality of cut lotus flowers. Exposure to different concentrations of O_3 fumigation for 2 days could kill almost all *F. schultzei* (100% of larvae and ≥ 96% of adults). However, a concentration of 50-250 ppm of O_3 could not control *F. schultzei* on lotus flowers completely. O_3 fumigation caused color change in lotus flowers. High concentrations of O_3 (≥ 150 ppm) had a negative effect on the visual quality of lotus flowers. The results revealed that thrips mortality increased with increased CO_2 level and storage time. 100% CO_2 caused 100% mortality of both adults and larvae of *F. schultzei* when there was a 6-h exposure. MA were more effective in disinfecting of thrips on cut lotus flowers after 9 h fumigation to ≥ 50% CO_2 caused complete mortality to *F. schultzei*. There was not much difference in lotus color in response to atmosphere modified by a combination of CO_2 and N_2. Therefore, CO_2 disinfestation treatment has the potential to be developed commercially as an alternative postharvest control for common blossom thrips on lotus flowers.
Keywords: *CO_2 fumigation, color change of lotus flowers, Frankliniella schultzei, post-harvest treatment, visual quality*

Introduction

Sacred lotus (*Nulumbo nucifera* Gaerth) is an interesting plant. All parts of the lotus can be utilized and processed into a variety of products. Thailand has a suitable climate for this plant. Currently, Thailand has plenty of wetlands and often there are flooding problems; therefore it is suitable for lotus planting. Growers can generate an income throughout the year. *N. nucifera* has the potential to develop into a Thai economic crop for export. Major lotus flower markets in the country include Pak Klong Market, Four Corner Thai Market, and flower markets in each province. The major foreign markets include Hong Kong, Singapore, the Netherlands, Japan, and the USA.

Thrips are a major problem for lotus flowers before and after harvest. *Frankliniella schultzei* (Trybom) are found throughout the year and predominantly attack lotus flowers (Bumroongsook, 2018). Therefore, postharvest control is an important process to export cut lotus flower. Lotus flowers for export require consistent quality and phytosanitary certification to meet international standards. However, it is difficult to find effective and sustainable pest management both in pre-harvest and post-harvest. The lotus shape contributes to the habitat for thrips. In order to control the thrip population among lotus flowers, growers regularly spraying insecticides, which is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_52375247

ineffective because not all of the thrips are killed. Therefore, it is necessary to remove post-harvest thrips in accordance with the standard of agricultural material export to foreign countries. The Thai Department of Agriculture has set the criteria for the removal of insect pests for orchids and ornamentals, with the methyl bromide rate of 20-24 g/m^3 for 90 min or insecticide dips (Thai Department of Agriculture, 2003). However, some shipments of lotus flowers have been rejected over the past few years because of the presence of thrips on lotus flowers.

Fumigation has been the primary method of postharvest disinfection for insect pests of cut flowers and agricultural products to meet export requirements (Pupin et al., 2013; Williams and Muhunthan, 1998). At present, methyl bromide is the main method which exporters use for insect disinfestation of cut flowers prior to export. It is smokeless, colorless, odorless, and non-flammable. It is an ozone-depleting substance; therefore, safe alternatives must be used to protect life and the environment. Innovative insect disinfestation techniques should be assessed. Modified atmosphere (MA) is defined as altering the composition of atmosphere in the storage packaging in order to extend the shelf life of agricultural products (Jayas and Jeyamkondan, 2002; Liguori et al., 2015). MA treatments have been used to control insects in agricultural product commodities (Beaudry, 1999, 2000; Liu, 2008, 2013). MA includes ultra low oxygen, ozone, carbon dioxide, and a dynamic concentration of carbon dioxide and oxygen (Kerr et al., 2013; Pinhero et al., 2009; Raffo et al., 2009; Tiwari et al., 2010). Ozone causes mortality throughout all life stages of the bean thrips (Leesch et al., 2007).

Carbon dioxide (CO_2) has direct and indirect effects on the physiological response and mortality of insects (Grodzinski et al., 1999). It affects the knockdown and recovery of insects (Nilson et al., 2006). In addition, it induces toxicity at the cellular level of living organisms; it can cause damage to the respiratory system of insects and deplete air reserves and prevents the exchange of oxygen through the insect egg chorion (Lagunas-Solar et al., 2006). The rate of insect egg development depends on the CO_2 concentration (Kerr et al., 2013). High levels of CO_2 concentration are applied as an anesthetic for insect knockdown. Badre et al. (2005) showed that CO_2 blocked glutamate receptors. High CO_2 concentrations caused hearts of *D. melanogaster* larvae to stop working and interfered with synaptic transmission at the neuromuscular junction. Carbon dioxide exposure might affect insect longevity, mating success and growth, feeding, development, reproduction, and behavior (Bartholomew et al., 2015). With a 24-h exposure time at 25 °C, a lethal concentration of CO_2 for all bed bugs stages was approximately 30% (Wang et al., 2014). The use of high CO_2 concentrations in gastight large bags is a possible method for preventing the occurrence of post-harvest pests on agricultural commodities, including rice, cocoa, beans, and various dried herbs during storage (Pons et al., 2010).

Ozone (O_3) is the most common air pollutant. It is a product of nitrogen oxides and volatile organic compounds under sunlight. It has harmful effects on humans, plants, and insects (Kampa and Castanas, 2008; Díaz-de-Quijano et al., 2012; Farré-Armengol, 2016). Surface ozone decreases crop production, disables forest growth, and effects plant species composition. (Ashmore, 2015). At relatively low concentrations, tropospheric ozone is toxic to susceptible plant species and causes chlorotic mottle, pigmented stipple, and necrosis. Foliar injury of cutleaf coneflower growing near the edge of the Clingmans Dome trail was significantly greater than that in the Purchase Knob (70% vs. 40% ozone-injured plants, respectively), due to different ozone exposures (Szantoi et al., 2009). Injury were consistent within species, genetic variation

DOI: http://dx.doi.org/10.15666/aeer/1604_52375247

among plants and diversification of physiological vigor (Brace et al., 1999). Ozone gas fumigation is a quarantine treatment to control stored pests and insect pests on fresh agricultural products (Hollingsworth and Armstrong, 2005). O_3 treatment can be used to control thrips and mealybugs on some selected agricultural products (Liu, 2013).

This research is undertaken to assess MA using dynamic concentrations of CO_2 balanced with N_2 and O_3 for thrip disinfestation and their impacts on the color of lotus flowers and quality.

Material and methods

Sample collection

Pesticide-free lotus farms that are situated at Ladkrabang District in Bangkok, Thailand were selected for sample collection. Standard buds of Roseum Plenum lotus flowers aged 9 to 10 days were collected from these lotus farms. Both adults and larvae of *F. schultzei* were obtained from blossom lotus flowers.

Experimental design

The experimental design was 6 × 7 factorial in completely randomized design to assess the effects of the combination of CO_2 and N_2 against *F. schultzei* on lotus flowers (30 replicates/group). Factor A is different composition of CO_2 balanced N_2 and factor B is exposure time.

Effects of O_3 against *F. schultzei* on lotus flowers was performed by using 7 × 7 factorial experiments in completely randomized design (30 flowers/group). Factor A is different composition of O_3 and factor B is exposure time.

The experiments were carried out at the entomological laboratory, King Mong's Institute of Technology Ladkrabang.

Effects of the combination of CO_2 and N_2 on F. schultzei

The experiment involved exposing MA to both adults and larvae of *F. schultzei*. *F. schultzei* were transferred to a young lotus petal and placed in a vial. Then, they were placed in a plastic chamber. The air was expelled and a gas mixture of CO_2 and N_2 was introduced into the air-tight plastic chamber. The experiments were conducted for various modified atmosphere packaging: 0, 25, 50, 75, 100% (v/v) CO_2 with remaining N_2, and stored for 1 to 3 days at 15 °C. After the treatments, insects were considered dead if they did not move. They were scored as alive if they moved. The dead insects were observed at 1, 2, and 3 days of exposure to the MA and storage temperature of 15 °C.

Effects of the combination of CO_2 and N_2 on F. schultzei on lotus flowers

A cut lotus flower aged 9 to 10 days was exposed to different combinations of CO_2 and N_2 and stored for 3-72 h. The ambient air was removed and the CO_2 and N_2 mixture was introduced into the polypropylene plastic package (10 × 15 inches) before being sealed by a gas filling vacuum packing machine (Hualiangthai model DZQ400/500). After the specified treatments, the package was opened to investigate dead or alive thrips after 1, 2, and 3 days of exposure to MA and a storage temperature of 15 °C.

Effects of O_3 on F. schultzei

F. schultzei was placed on a young lotus petal, transferred to a vial, and kept in a gas-tight plastic chamber. The experimental procedure exposed different concentrations of O_3 (0, 50, 75, 100, 125, 150, 250, 500, 750, and 1,500 ppm) using an ozone generator (Enaly model OZX-300 AT). The observation times were 3, 6, 9, 12, 24, 48, and 72 h. The mortality of adult and larva of *F. schultzei* was assessed.

Effects of O_3 on F. schultzei on lotus flowers

A cut lotus flower aged 9 to 10 days was placed in a plastic chamber and exposed to different concentrations of O_3 (0, 50, 75, 100, 125, 150, 250 ppm) and stored for 3 to 72 h at 15 °C. The observation times were 3, 6, 9, 12, 24, 48, and 72 h. The mortality of *F. schultzei* was assessed. The color of petals at the outer curvature was measured with a miniscan (EZ4500, Hunter) and displayed color as three numerical values: L *, a *, and b *.

Data analysis

Analysis of variance was used to evaluate these treatment differences by comparing the mean of the control with the mean of each treatment followed by the Duncan multiple range test for mean separation ($p \leq 0.05$).

Results

Effects of the combination of CO_2 and N_2 on F. schultzei

The experiments evaluated the effects of a CO_2 and N_2 mixture on *F. schultzei*. Total mortality was achieved at ≥ 6 h using 100% CO_2 atmospheres (*Table 1*). At 25% CO_2, the mortality of thrip larvae during all exposure time was significantly lower ($p < 0.05$) when compared with any other CO_2 concentration. At 100% N_2, the percentages of dead insects were 63% at an exposure time of 24 h. Complete mortality occurred in 72 h. Within 48 h of exposure time, 100%N_2 was more effective in controlling thrip larvae than 25% CO_2 ($p < 0.05$). At 72 h exposure time, all treatments killed 100% of thrip larvae.

[1]Means followed by different letters indicate significant difference between concentrations

The mortality of *F. schultzei* adults under different MA conditions and storage times are illustrated in *Table 2*. *F. schultzei* adults showed almost the same response to different levels of CO_2 and N_2 mixtures as did larvae (*Tables 1* and *2*). Total mortality

DOI: http://dx.doi.org/10.15666/aeer/1604_52375247

of adults occurred at ≥ 6 h using 100% CO_2 (*Table 2*). With the initial time of 48-h exposure, 100% N_2 was more effective in controlling *F. schultzei* adults than 25% CO_2 ($p < 0.05$). The results showed that complete mortality in all concentrations occurred 72 h after treatment.

[1]Means followed by different letters indicate significant difference between concentrations

Effects of the combination of CO_2 and N_2 on F. schultzei on lotus flowers

There was a significant effect of CO_2 balanced N_2 and exposure time on thrips mortality ($F_{5,1218} = 9457.12$, $p < 0.00001$; $F_{6,1218} = 27578.07$, $p < 0.00001$, respectively). Moreover, the significant interaction between treatments and exposure time on thrip mortality was observed ($F_{30,1218} = 1864.27$, $p < 0.00001$).

High mortality of thrips on lotus flowers packaged in plastic bags was observed under different MA and storage times (*Table 3*). The exposure time of 3 h and 100% CO_2 had the highest thrip mortality, followed by 100% N_2, 50% and 75% CO_2 having 46.29, 49.30, and 50.09% mortality, respectively whereby 25% CO_2 having the lowest mortality (39.21%). At 12 h of exposure time, the results showed no significant differences among treatments and no live thrips were observed with 100% N_2 and all concentrations of CO_2. Higher CO_2 concentrations and longer exposure time could increase mortality of mortality of *F. schultzei* (*Fig. 1*). All treatments killed 100% of *F. schultzei* kill after 48 h of exposure.

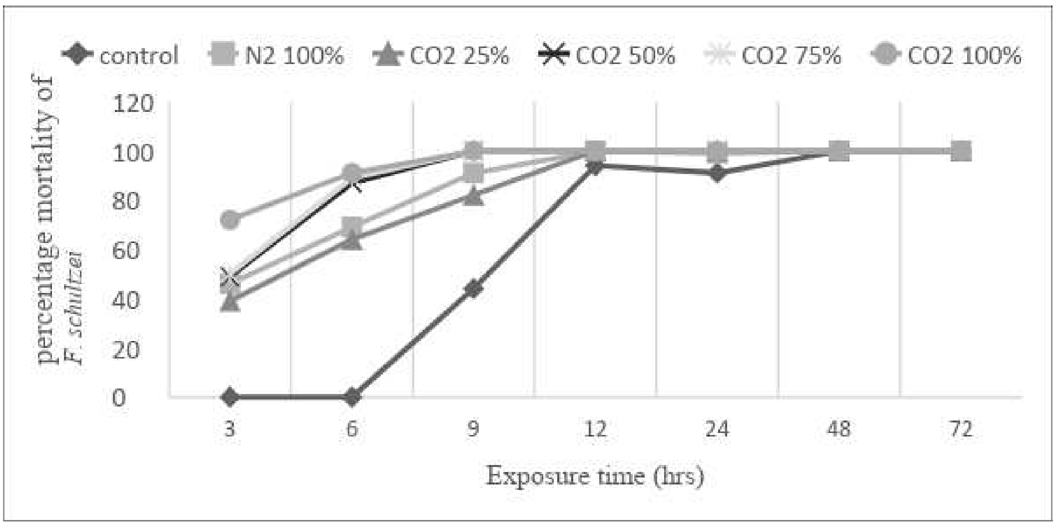

Figure 1. *Mortality of F. schultzei on lotus cut flowers under different concentration of CO_2 fumigation and exposure time*

Effects of the combination of CO_2 and N_2 on lotus flower color

The color of lotus flower was measured using miniscan (EZ4500, Hunter). The color parameters L* (lightness), a* (red–green), and b* (yellow–blue) of lotus flowers under MA treatments were compared. No differences ($p > 0.05$) in the value of L* and a* were observed at 1, 2, and 3 days of exposure (*Table 4*). The a* value in the control was less than that of all levels of CO_2 and 100% N_2 on day 1 and 2 after exposure. On day 3, all treatments showed no significant difference in L*, a*, and b* values ($p > 0.05$).

Table 4. *Color of Lotus flowers after fumigation treatment (N = 30)*

[1]Mean followed by different letters indicate significant difference between concentrations

Effect of O_3 on F. schultzei

The lethal concentration of ≥ 50 ppm O_3 to *F. schultzei* larvae in a plastic chamber was 100% thrip mortality at 48 and 72 h of exposure time (*Table 5*). After 12 h of exposure to ozone fumigation, ≥ 500 ppm O_3 caused 100% thrip mortality. The results observed indicated that 1,500 ppm O_3 was the highest effective concentration as compared with the other treatments, and it caused 100% thrip mortality at 3 h of exposure.

Effects of O_3 on *F. schultzei* adults had similar patterns of response to O_3 fumigation as in the larvae (*Table 6*). At 12 h of O_3 fumigation exposure, ≥ 500 ppm O3 caused 100% mortality of *F. schultzei* adults. The results revealed that 1,500 ppm O_3 at 3 h of exposure caused 100% mortality of adults.

Effects of O_3 on F. schultzei on lotus flowers

The experiment was conducted to evaluate the different levels of O_3 fumigation (50-250 ppm) for disinfestation of *F. schultzei* on lotus flowers. Significant effect of O_3

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_52375247

concentration and exposure time on thrips mortality was detected ($F_{6,1421}$ = 2762.65, p < 0.00001; $F_{6,1421}$ = 9,318.07, p < 0.00001, respectively). Moreover, there was a significant interaction between different O_3 concentration and exposure time ($F_{36,1421}$ = 34.88, p < 0.00001). Whereas, the results were displayed in *Table 7,* indicated that all these concentrations of O_3 could not eliminate the entire thrip infestation on lotus flowers. *F. schultzei* mortality increased, with increased O_3 levels and exposure time.

Effects of O_3 on lotus flower color

The L*a*b* value of lotus petals exposed to different levels of O_3 fumigation (50-250 ppm) were different from those of the control (*Table 8*). The b* value of lotus petals in 48 and 72 exposure hours were not significantly different among treatments ($p > 0.05$). The color of lotus petals exposed to O_3 fumigation were slightly yellow (negative a*values), and the petals from control treatments were red (positive a* values). The color change of lotus flower petals was a response to ozone fumigation. It might not be enough to show much variation in flower color. Ozone fumigation made lotus flower color paler and yellowish. Slight malformation of lotus flowers was detected.

Discussion

Arthropods reduce their metabolic rate and increase memebrane permeability under high levels of carbondioxide atmosphere (Mitcham et al., 2006; Zhou et al., 2001). Spiracular opening due to low level of CO_2 can cause insect death, whereas at higher CO2 concentrations, metabolic reduction is an important factor for mortality (Janmaat et al., 2001). Held et al. (2001) observed that exposure over 12 h to >99% N_2 or CO_2 accounted for 100% mortality of aphids, mites, thrips, and whiteflies. CO_2 levels > 20% are toxic to insects and higher concentration cause insect mortality (Carpenter and Potter, 1994; Mitcham et al., 2006; Zhou et al., 2001). Consistent with the previous studies, using different combination of CO_2 and N_2 for the disinsection of *F. schultzei* on lotus flowers in polypropylene plastic packaging could eliminate all thrips on lotus flowers at 12 h of exposure time.

The results obtained in this study agree with Niakousri et al. (2010) whereby lower ozone concentration required longer exposure time to have effective fumigation. Ozone is unstable and has a short half-life and converts to oxygen during ozonation. Our results indicated that under ≥ 150 ppm O_3 fumigation caused color change and slight malformation of lotus flowers. This caused the flowers to be unacceptable for the markets. All of the ornamental plants tested were blemished due to O_3 treatments (Hollingsworth and Armstrong, 2005). The studies indicated that ≥ 500 ppm of O_3 is needed to have complete control of *F. schultzei,* but the lotus flowers are damaged from this fumigation. The previous studies showed that agricultural products with waxy surfaces could tolerate the high concentrations of ozone fumigation such as waxy leaves, waxed oranges (Hollingsworth and Armstrong, 2005; Leesch et al., 2003). There was more moisture among lotus petals in the bag, which increased the control of thrips. Cut flowers lose water through transpiration (Sankat and Mujaffar, 1994). This might be one factor responsible for thrip mortality.

Gas concentration, fumigation time and temperature are three important key variables for the success of MA (Armstrong and Whitehead, 2005). An increase in concentration of CO_2 or O_3 in fumigation and exposure time would increase *F. schultzei* mortality. Dhouibi et al. (2015) use CO and CO_2 fumigation for *Ephestia kuehniella* and *Ectomyelois ceratoniae* in dates and indicated that insect mortality depended on gas levels and exposure time. Controlled atmosphere and temperature treatment system can control C. sasakii found in apples (Son et al., 2012). However, insect pest could become more resistance to MA treatment via a physiological adaptation (Chervin et al., 1996).

Conclusions

MA treatments are environmentally friendly methods and have no harmful effects to human health. Gas combination treatments and longer storage time along with low temperature during storage are variable factors for effective disinfestation control. MAP of any concentration of CO_2 balance N_2 at 9 h of exposure time had complete mortality of *F. schultzei*. Increased concentrations of CO_2 and longer exposure times increase thrip mortality. Ozone fumigation has the effect as CO_2, whereas the mortality of thrips increased as the concentration of O_3 increased. $O_3 \geq 500$ ppm caused 100% mortality in adult and larvae. However, at this concentration, petals had spot discoloration and slight deformation. Fumigation of lotus flowers with CO_2 balance N_2 could be used to replace methyl bromide for disinsection. Further research would be necessary to determine how the concentration of CO_2 changes during storage time and the moisture contents from plant transpiration in packaging and interaction among them effect thrip disinfestation.

Abstract. In today's world where humans have exceeded limits of the planet, natural resources are becoming increasingly important. Together with the concept of sustainable living, making the agenda to conduct ecological measurements in the early 1990s, the concept of ecological footprint offers great contributions to creating ecological risk profiles. Today, it can be seen that many countries' Ecological Footprint exceeds their biocapacity. One of the most important components of the concept, carbon footprint is strongly associated with society's consumption forms, perceptions and attitudes. In this study carried out in Izmir province, in Turkey, trends and perceptions towards reducing ecological footprints left by society were analysed within the scope of ecosystem services using survey method. As a result of the study, it has been observed that ecological deficit emerging as a result of humans' perspectives on the natural environment and their consumption habits is increasing with each passing day.
Keywords: *natural resources, ecosystem services, ecological footprints, society trends, sustainability*

Introduction

Environmental and social effects caused by modern societies measuring prosperity level with consumption are one of the most important current problems of humanity. In terms of seriousness of its magnitude, a need has emerged to develop new policies at global level. Within the framework of sustainable growth and due to economic and environmental problems including recent economic crisis, climate change etc., and new concepts have emerged such as environmental sustainability, green economy, green growth, low-carbon economy, sustainable production and consumption (Öztürk, 2012; Velioğlu and Aydın, 2017). In terms of Resource Efficiency Policies, it is necessary to keep damages given to natural life at minimum, ensure economic growth in a way to sustain world resources, thus, there is a need to determine level of efficient consumption of resources in terms of exhaustible resources (Reyhan, 2014).

Within the scope of United Nations Development Programme (UNDP) and United Nations Environment Programme (UNEP), an organization was established in which economic development and environment were discussed as two inseparable aspects together with "Climate Partnership" and "Poverty and Environment Fund" initiatives launched in Nairobi-Kenya as of February 2007. While Poverty and Environment Fund aims at improving environmental management and increasing environmental investments, Climate Partnership Initiative emphasizes capacity increase in terms of technology transfer and more in developing countries' fight against climate change. Thus, boundaries of ecology which was initially considered only as a natural sciences discipline rapidly

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_52495267

expand towards both economic and social fields, it is becoming increasingly possible for economy and ecology to meet on a common ground with social content.

Exceeding biophysical boundaries leads to damaging of systems that form basis of natural balance and economy. This situation, however, makes it more difficult to reach a certain quality of life in the future and maintain such a life. However, complex structure of natural systems makes it difficult to identify at which point lifestyle associated with consumption level strays from sustainability. Ecological Footprint is an indicator that measures ecological footprint in certain categories within the framework of narrow definition of natural services benefited from. Developed by Mathis Wackernagel and William Rees in early 1990s, this concept is defined in the form of production of natural resources containing agriculture, livestock, fishery and forest products and CO_2 emission, and in the form of biological productive field required to meet these demands (Ewing et al., 2010). Calculation of ecological footprint is extremely important in terms of seeing how much humans behave over the biocapacity while meeting their needs and in terms of determining how much humans use their natural resources by comparing countries' ecological footprints with biocapacity (Coşkun, 2013).

Ecological Footprint of Turkey in 2007 was 2.7 global hectare (gha), and this rate is equal to world average, and lower than the average of Mediterranean countries. Ecological Footprint of consumption in Turkey is 50% over global biocapacity per capita. This case is the sign of a non-sustainable lifestyle in Turkey as in the rest of the world. Since national biocapacity of 1.3 gha per capita is below world average (1.8 gha/person) in Turkey, its national ecological debt is much higher than its global deficit. This deficit called as "ecological limit excess" results in supplying biocapacity need partially from abroad.

Countries that calculate ecological footprint and analyse its outcomes will be able to determine ways to eliminate risks associated with ecological deficit. For our country and more importantly for the future of our world, we need to reduce our ecological footprint. Beyond our individual responsibilities with a view to reduce ecological footprint and promote more sustainable lifestyles, there are also some other designs that we should adopt globally (Keleş, 2007). One of the most important components of ecological footprint concept is carbon footprint. Carbon footprint is strongly associated with society's consumption forms (Ebadı, et al., 2016), perceptions and attitudes.

The aim of this study is to examine ecological footprint data of Turkey within the scope of ecosystem services, and to find out society's economic and social attitude on the subject. To do this, participants' carbon footprints were calculated based on their consumption data. Thus, it is considered that this study will contribute to definition of development goals that also consider environmental sustainability by means of preparing ecological footprint statement, and will contribute to determination of individual and social responsibilities to reduce adverse ecological affects emerging depending on the use of natural resources. In this sense, children and the young who will be individuals of the future and who should receive environmental education at an early age will see the concept of ecological footprint and limits of our consumerism as a society (Öztürk, 2010).

Theoretical foundations

Ecosystem services

Scientific history of the concept of ecosystem services dated back to the 1970s, use of this concept in the literature gained speed in the 1990s (De Groot et al., 2010). The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_52495267

concept of "Ecosystem Services" was defined firstly by Daily (1997) as "ecosystems required for maintaining human life, and situations and processes carried out by species". Costanza et al. (1997) describe ecosystem services as benefit from ecological functions; De Groot et al. (2002) describe them as benefits from both processes and functions; Boyd and Banzhaf (2007) describe them as only directly benefited products (Çoban and Yücel, 2018).

This concept has become more widespread with the United Nations Millennium Ecosystem Assessment (MEA) report published in 2015. In this report, while ecosystem services were described as natural capital, it was emphasized that natural capital's capacity of supporting future generations with human activities decreased. The second major international study following the MEA report is the research titled "The Economics of Ecosystem and Biodiversity (TEEB)" which emerged with the initiative of UN Environment Program. One of the most important objectives of TEEB report in which biodiversity, economics and interdisciplinary work was "to emphasize increasing costs of biodiversity loss together with degradation in ecosystem" (Demiroğlu and Karadağ, 2015). The concept of ecosystem services was discussed, interpreted and defined in different ways by associating more with ecosystem process and biodiversity subjects. Basically, ecosystem services are also defined as "situations, processes, functions, benefits and all products provided by ecosystems to maintain human life and ensure welfare among humans" (Albayrak, 2012).

Ecosystem services, in addition to the manufacture of products, also includes many life support functions such as regulation of climate, maintaining soil and flood control, clean-up, recycling and renovation of natural resources. In MEA report, ecosystem services were discussed by welding classifying them in 4 major ecological function groups including resource providing services, regulating services, cultural services and supporting services, and under 30 categories. In the TEEB report, ecosystem services were discussed by classifying in 4 major ecological function groups including resource providing services, regulatory services, culture and comfort services and habitat services, and under 22 categories (*Table 1*).

Today, the subject of ecosystem services is addressed as an important issue by government agencies, academicians, non-governmental organizations and the private sector. For example, one of the most important international conventions in which Turkey is also a party, United Nations Biodiversity Convention defines actions towards the protection of ecosystems and services they provide within the scope of Aichi Biodiversity Objectives.

The importance of ecosystem services is accepted not only with regard to processes of biodiversity but also in the field of sustainable development. In "Sustainable Development Summit" held in 2015, 17 Sustainable Development Objectives were determined by United Nations member countries to end poverty, to eliminate inequality and injustice and to fight against climate change until 2030. In this respect, protection, restoration and maintenance of ecosystems and their services were defined under various objectives. Addressing ecosystem services in such distinct conventions and legal processes is an indication of further increase in importance of this issue at global scale (URL-1, 2018).

However, social and economic development of community and thus providing a quality life have brought along many problems. Today, more than 50% of the world's population live in cities, and it is estimated that this figure will reach 70% in the year 2050 (Anna et al., 2016). Since urbanization changes forms of personal land use, transportation, industrial and agricultural production, consumption and social activities, it adversely affects natural resources. Scattered development of modern cities and expansion to large areas have adversely affected natural habitats. For example, Thailand has lost 96% of its wetlands, Australia has lost 95% of its wetlands, and USA has lost 53% of its wetlands (Çoban and Yücel, 2018). This situation has resulted in increasing importance of natural resources and growth of human-induced ecological footprints threating natural resources. In this context, the concept of Ecological Footprint has become one of most popular and widespread indicators for sustainability assessment and resource management.

Table 1. *Classification of ecosystem services: MEA (2015) and TEEB (2015) classifications*

Resource providing services (MEA)		Resource providing services (TEEB)	
1	Food	1	Food
2	Biological raw material	2	Raw materials
3	Decorative resources	3	Ornamental resources
4	Genetic resources	4	Genetic resources
5	Fresh water	5	Water
6	Biochemicals and medicinal products	6	Medical resources
Regulating services		**Regulatory services**	
7	Air quality arrangement	7	Cleaning the air
8	Climate regulation	8	Climate regulation (including C-sequestration)
9	Water flow control	9	Regulation of water flow
10	Erosion control	10	Erosion prevention
11	Water treatment and waste control	11	Waste treatment (especially water treatment)
12	Epidemic control	12	Biological control
13	Pest control	13	Corruption prevention or mitigation
14	Pollination	14	Fertilization
15	Natural risk mitigation	15	Continuity of soil productivity
Cultural services		**Culture and comfort services**	
16	Recreation and ecotourism	16	Recreation and tourism
17	Moral and ethical values	17	Spiritual experience
18	Social relationships	18	Social relationships
19	Information system	19	Information for cognitive process
20	Educational value	20	Educational value
21	Sense of place and space		
22	Aesthetic values		
23	Inspiration		
24	Cultural heritage value		
25	Cultural diversity		
Supporting services		**Habitat services**	
26	Nutrient recycling	21	Continuity of the life cycle
27	Hydrological cycle	22	Protection of gene pool
28	Photosynthesis		
29	Soil formation		
30	Primary production		

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_52495267

Concept of ecological footprint was firstly developed by Mathis Wackernagel and William E. Rees in early 1990s and used to conduct ecological measurements. This criterion denominates biologically productive soil and water field in global hectares that are required for production of resources consumed and disposal of waste created in the meantime by means of existing technology and resource management (Wackernagel and Rees, 1996; Tosunoğlu, 2014). Biocapacity, on the other hand, is indicator of production capacity of renewable natural resources in a geographical region. In other words, ecological footprint refers to used resource, and biocapacity refers to available resources. Identification of global hectare is used for measurements. A global hectare represents the production capacity of 1-hectare field over world's average efficiency. Thus, total amount of resources obtained from different types of field within a certain period of time and demand for these resources are degraded to a common unit and expressed in numeric values (WWF, 2012). This allows consistent measurement of global ecological footprint and biocapacity and comparison with each other (Wilson and Anielski, 2005; Wackernagel et al., 2014).

Ecological footprint is an important criterion that reveals how much land and water are needed to reproduction of natural resources consumed and recovery of wastes emerging in the meantime. This, in a way, describes the load that mandatory consumption of natural resources by humans to survive in this world establishes over sustainability of ecosystem (Keleş, 2007). As a part of nature, humans meet their biological and cultural needs from nature. Everyone has a powerful effect on the world. As a result of production and consumption, the sum of these effects creates ecological footprints. Many behaviors we do with habits brought along by our lifestyles actually result in growth of our carbon footprints (Kaypak, 2013). Ecological footprint, in general, is obtained by calculating components such as carbon footprint, cropland footprint, forest land footprint, grazing land footprint, built-up land footprint and fishing grounds footprint (WWF, 2012; Mancini et al., 2016).

Ecological footprint components and status in the world and Turkey

Natural balance of world's ecosystem is broken every day, and natural resources are insufficient to meet humans' needs. According to data from WWF (2012) Turkey's Ecological Footprint Report, Turkey's ecological footprint has tripled since 1961. In world ranking, Turkey is in the 63rd place among 154 countries (WWF, 2012). Analysing global ecological footprint and biocapacity rates per capita in *Figure 1,* it is remarkable that global ecological footprint started to exceed world's biocapacity in the 1970s and ecological deficit began to occur. Today, this deficit still continues to increase. Continuation of such increase in global footprint will bring along many problems.

In *Figure 2,* Turkey's ecological footprint and biocapacity rate are given. Analysing *Figure 2,* it can be seen that total ecological footprint in Turkey began to exceed national biocapacity for the first time in 1977, and this deficit continued increasing in following years. While Turkey's ecological footprint per capita was equal to global footprint average in 2005 with 2.7 gha, biocapacity per capita in the country was 1.3 gha. This situation shows that national level ecological debt among people living in Turkey is higher than world average. According to data from WWF (2012) Turkey's Ecological Footprint Report, percentage distributions of Turkey's global ecological footprint as per components are given in *Table 2*. Accordingly, carbon footprint created 55% of total footprint. Following the carbon footprint, cropland footprint is the second

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_52495267

biggest component threating the global ecological system with a rate of 21%. These are followed by forest land, grazing land, built-up land and fishing grounds footprints respectively. The fact that the carbon footprint ratio has such a large share requires focusing primarily on the carbon footprint. For example, the use of renewable resources instead of fossil resources will contribute significantly to reducing carbon footprint and thus reducing ecological footprint (Özsoy, 2015).

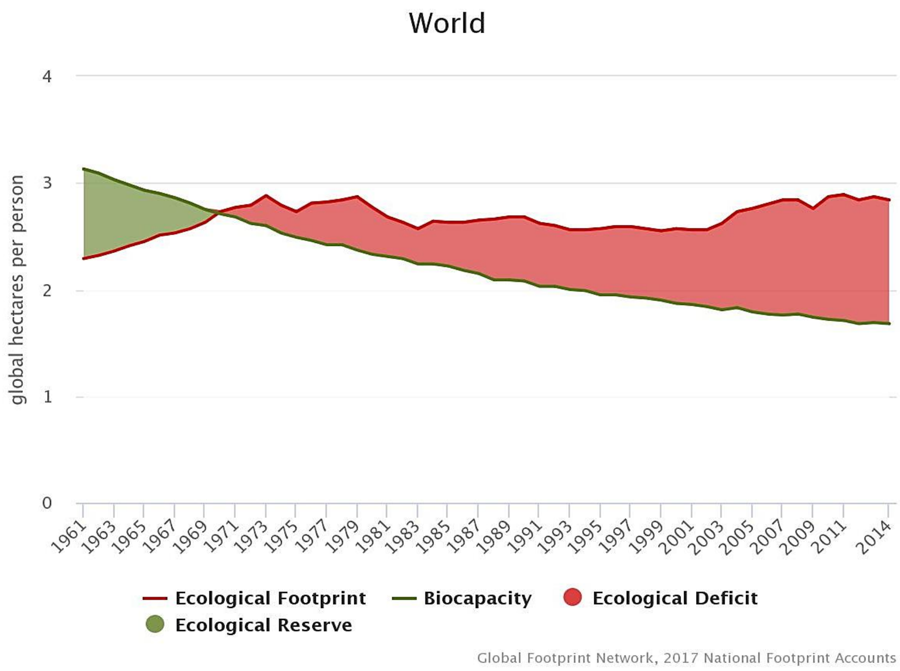

Figure 1. *The world's ecological footprint and biocapacity status (URL-2, 2018)*

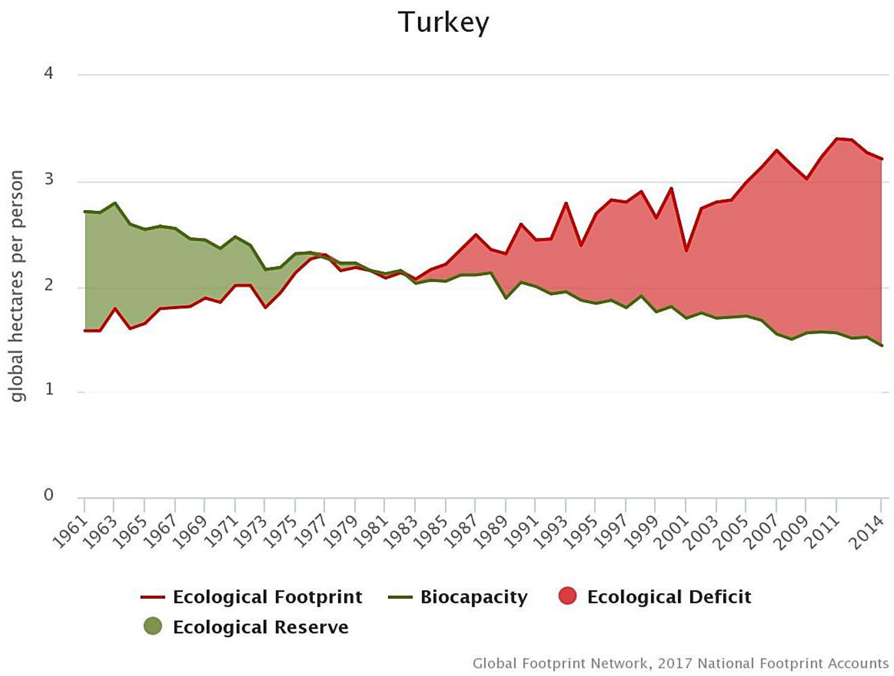

Figure 2. *Turkey's ecological footprint and biocapacity status (URL-2, 2018)*

DOI: http://dx.doi.org/10.15666/aeer/1604_52495267

Table 2. *Turkey's ecological footprint components (WWF, 2012)*

Ecological footprint components	Portion
Carbon footprint	0.55
Cropland	0.21
Forest land	0.10
Grazing land	0.08
Built-up land	0.03
Fishing grounds	0.03
Total	1.00

Seeing from which consumption category our personal footprint is originated is important in terms of understanding the relationship between our daily activities and usage of natural resources. Price of footprints is paid by the whole world in different forms. Humanity must find way to live in limits of capacity of natural resources as soon as possible and implement this way rapidly for a sustainable life, change their understanding of development and differ their consumption/management of natural resources. That is because there are no other planets to live. For this reason, it is necessary to maintain global biocapacity to ensure that current resources we use for meeting our needs will also be beneficial to future generations (Dinç, 2015). These socially, economically and ecologically left traces are not only personal but also social traces. To reach sustainability, both individualistic lifestyles should be analysed and resource productivity in social expenses should be questioned (Akman et al., 2000).

Materials and methods

Damages towards nature due to insensible usage of resources are increasing day by day, consequent adverse effects are felt more seriously especially in metropolises. In addition, consumptions among people living in metropolises and congruently their calculated global footprints tend to be higher. Therefore, the 3rd largest country of Turkey, İzmir, was selected in the study. İzmir province is located in the West of Turkey, in the coast of Aegean Sea. In İzmir, Mediterranean climate is dominant with hot and dry conditions in summer and warm and rainy condition in winter, annual precipitation is between 700-1200 mm. In terms of flora, its flora is under the influence of Mediterranean climate, and all kinds of Mediterranean plants grow in the province. In terms of field distribution, forest fields take 41% share, agricultural lands take 28% share, grass-pasture lands take 4.5% share, and other type of lands take 26.5% share (URL-3, 2017).

Research data was collected with a survey study carried out with observation and interview operations. Survey study was carried out with survey forms created for this purpose in February-April 2017. In this sense, the path followed in the study was in the form of (1) collecting necessary files-documents required for the research by means of literature analysis, (2) survey-interview studies towards participants, and (3) statistical analysis and evaluation of obtained data. In survey forms, questions towards determining socio-demographic characteristics and multiple-choice questions towards

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_52495267

participants' attitudes and perceptions were used. To determine participation in propositions, five-point Likert-type scale was used. In preparation of survey form, studies conducted by William (1992), Wackernagel and Rees (1996), Wilson and Anielski (2005), Keleş et al. (2008), Deniz and Ok (2016) Pamukoğlu et al. (2017) and Özmış and Tolunay (2017) were also used as reference. In accordance with objective of the study, questions prepared for calculating carbon footprint data among components of ecological footprint were based on questions used worldwide to calculate carbon footprint with a view to meet the standard and conduct comparisons. Carbon footprint was preferred in calculations since it is a component that can be increased or decreased depending on people's, thus society's, perception, attitudes and consumptions, and since it can be reduced with education, personal awareness and sense of responsibility. For this purpose, data was collected related to participants' food choices, organic food consumption amounts, dressing preferences, imported food and product consumption preferences, furniture and electronic appliances consumption preferences, recycling preferences, amusement activities, annual energy consumption amounts and annual travel conditions. CO_2 emissions occurring as a result of these activities were calculated with "Carbon Footprint Calculator" (URL-4, 2017).

Survey was carried out with the participation of 221 people. Survey forms were analysed using SPSS 20.0. In analyses, primarily all questions and answers were digitized as per order statistics, and frequencies and percentages were utilized according to characteristics of question. Kolmogorov-Smirnov and Shapiro-Wilk-W tests were used to determine whether data was parametric or not, it was determined that, at 95% confidence level, data did not have normal distribution ($P < 0.05$), in other words, not parametric (Mendes and Pala, 2003). Chi-square ($\chi 2$) independence test was used to check whether there were relationships among some variables (Eymen, 2007; Kalaycı, 2010). As a result of reliability analysis conducted for expressions provided in five item Study five-point Likert-type, Cronbach's Alpha value was calculated as 0.702. Alpha is an important concept in assessment of surveys and measurement of internal consistency, it tests how much closer a group of items is associated as a group and how much reliability a study offers (Tavakol and Dennick, 2011).

Results

Profile characteristics

Within the scope of the research, participants were asked some socio-demographical questions on their age, gender, education, work/professional status and monthly income. Analysing *Table 3,* it can be seen that a total of 221 people has participated in the study, 127 of them are female (57.5%), 94 of them are male (42.5%). In the study, five different education groups were formed. Educational status is one of most important factors for affecting, changing and guiding studies for participants' perceptions and attitudes. Obtained data shows that rate of participants with university graduate and postgraduate education is high. The participants were categorized into seven different professional groups. Especially unemployed and housewives were defined as separate groups. That is because housewives' attitudes towards food shopping, dress shopping and energy consumption have a decisive role on the footprint left by household. The participants were categorized into five income groups based on income level. The minimum wage is approximately 2000 TRY in Turkey (CSGB, 2018). This situation shows that 53.4% of participants have an income at minimum wage level.

Participants' preferences related to reduction of carbon footprints

Generally accepted questions were used in survey form with a view to calculate participants' carbon footprints, ensure consistency and make comparisons. Calculations were carried out with "Carbon Footprint Calculator" tool (URL-4, 2017). Analysing participants' answers given to these questions, participants' total carbon footprint, carbon footprint per participant and average carbon footprint amount per participant were calculated approximately. Besides, number of trees to be planted for reducing and compensating carbon footprint was determined approximately (*Table 4*).

Table 4. *Information regarding participants' ecological footprints*

Number of participants	Average CO_2 emission (ton/person)	Total CO_2 emission (ton)	Number of trees to be planted for reduction	
			Per person	Total
127 (Female)	5.22	662.94	8	976
94 (Male)	8.62	810.28	12	1162
221	6.67	1473.22	10	2210

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_52495267

Analysing *Table 4,* while the amount of CO_2 emissions per capita among women is 5.22 tons, the amount of CO_2 emissions per capita among men is 8.62 tons. Assessing the situation in terms of total amount of CO_2, women's total amount of CO_2 emission was calculated as 662.94 tons approximately, and men's total amount of CO_2 emissions was calculated as 810.28 tons approximately. As long as a tree lives, it converts approximately 0.73 tons of CO_2 (URL-4, 2017). Accordingly, to compensate 810.28 tons of CO_2 produced by male participants, approximately 12 trees per capita and a total of 1162 trees should be planted. To compensate 662.94 tons of CO_2 produced by women, approximately 8 trees per capita and a total of 976 trees should be planted. Total amount of CO_2 emission produced by 221 participants in the study is approximately 1473.22 tons. The amount of average CO_2 emission per capita is 6.67 tons, number of trees to be planted per capita for compensation of 6.67 tons of CO_2 produced is approximately 10 pieces. Number of trees to be planted for compensation of 1473.22 tons of CO_2 produced is approximately 2210 pieces.

One of the most important services that forest ecosystems are received within the scope of ecosystem services is carbon storage and thus reduction of carbon footprint (Coşkun and Gençay, 2011). In this context, participants' opinions on whether they will provide financial support to afforestation studies for reducing their carbon footprints they have left are presented in *Table 5.* According to findings obtained, 71.5% of participants reported that they may support afforestation in different amounts, and 28.5% of them reported that they would not support such studies. Analysing *Table 5,* 54 of participants indicated that they would contribute an amount of TRY 10, 25 of them would contribute TRY 20, 21 of them would contribute TRY 30, 14 of them would contribute TRY 40, 8 of them would contribute TRY 50 and 36 of them would contribute TRY 100.

Table 5. *Participants' amounts of contribution to afforestation works*

Amount of support (TRY)	**10**	**20**	**30**	**40**	**50**	**100**	**Not giving support**	**Total**
Participants	54	25	21	14	8	36	63	221
Percent (%)	24.4	11.4	9.5	6.3	3.6	16.3	28.5	100
Total amount of support (TRY)	540	420	630	560	400	3600	0	6150

With reference to these data, calculations towards afforestation works to be conducted for compensation of carbon footprint left by participants and relevant costs were made in accordance with the communiqué no. 298 issued in 2014 by General Directorate of Forestry (GDF) (OGM, 2014). Red pine species (*Pinus brutia* Ten.) was selected for calculations, since this species was suitable for ecological conditions of study area and it has been used in afforestation works by GDF. Accordingly, according to bill of costs for afforestation in 2016 issued by GDF, afforestation cost for 1 hectare of pine trees (*Pinus brutia* Ten.) is around TRY 12480 for İzmir province. Number of pine trees that should be included in 1 ha varies between 150-250 units depending on yield strength. Since number of trees to be planted for 1473.22 tons of CO_2 produced by 221 participants is a total of 2210 and considering the fact that number of pine trees to be planted in a hectare is accepted as 200 pieces, there is a need for approximately 2210/200 = 11 ha of afforestation. Since afforestation of 1 ha field is TRY 12248, there

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_52495267

is a need for a total of 11*12480 = TRY 137280 investment for 11 ha field. Participants indicated that they would contribute an amount of approximately TRY 6150. Deducting the obtained contribution amounts from the total amount of investment needed, an investment amount of 137280-6150 = TRY 131130 should be met by the government.

These calculations are quite overall calculations, these obtained figures are open to debate. Therefore, what is important here is services that forest ecosystems receive within the scope of ecosystem services and the fact that these services are offered to public for free. Forest ecosystems reduce carbon footprint left by the humanity thanks to their carbon storage services. However, how and until when this process will continue shape humans' perspectives on natural environment and their consumption formats. In this context, chi square test was used to analyse participants' socio-demographic characteristics and whether they would support afforestation studies to reduce carbon footprint. According to the findings of analysis, statistically significant relationship was found between participants' age, education, profession and monthly income and the subject of "*whether they would provide financial support in afforestation works towards reducing carbon emission*". Statistically significant relationships were not determined between gender and participants' responses (*Table 6*).

Table 6. *Participants' state of contribution to afforestation works*

Expression	Characteristics	$\chi 2$	sd	p
"Whether they would provide financial support in afforestation works towards reducing carbon emission"	Gender	4.536	6	0.605
	Age	38.773	24	**0.029***
	Education	59.498	24	**0.000***
	Occupation	65.801	36	**0.002***
	Income level	68.628	24	**0.000***

*<0.05

Analysing the situation in terms of participants' ages according to assessments made, while individuals between 18-30 age group preferred contributing to afforestation works, other age groups did not prefer supporting these works. Analysing the situation in terms of participants' educational levels, it was determined that, as participants' educational level increased, their rate of financial contribution also increased. Analysing the situation in terms of participants' professions, it can be seen that housewives group preferred not to support and academician/educators group preferred supporting more. Analysing the situation in terms of monthly incomes, while low income groups preferred not to support, higher income groups preferred supporting.

Participants' perceptions and attitudes towards ecosystem services and carbon footprints

According to the results of reliability analysis conducted with regard to reliability of expressions towards measuring participants' perceptions and attitudes for their ecological footprints and their answers, Cronbach's Alpha was calculated as 0.702. This situation shows that expressions towards measuring participants' perceptions and attitudes and their answers were reliable. Analyses conducted towards these statements were listed based on averages of answers given, and they are presented in *Table 7*. Accordingly, the statement "*I contribute to sustainable management of forests using*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_52495267

certificated forest products" is the highest-level expression with a rate of 4.01. The expression "*I leave places clean in recreation and picnic fields*" was the lowest rated expression with 1.48 rate. Analysing statements included in *Table 7,* it is remarkable that participants have quite complex attitudes towards reducing their ecological footprints.

Discussion and conclusion

The concept of ecological footprint was developed in the early 1990s and it is used for conducting ecological measurements. This criterion denominates biologically productive soil and water field in global hectares that are required for reproduction of resources consumed and disposal of waste created in the meantime by means of existing technology and resource management. In ecological footprint calculations, distinct components are used such as carbon footprint, cropland, forest land, grazing land, built-up land and fishing grounds. Among these footprints, carbon footprint was chosen in the study since it is dependent upon humans' consumption forms and it can be reduced by improving personal perceptions, attitudes and responsibilities.

Table 7. *Participants' expressions on their perceptions and attitudes towards footprints*

Expressions	Mean	Std. deviation	Variance
I contribute to sustainable management of forests using certificated forest products	4.01	1.254	1.573
I prefer driving LPG vehicles rather than petrol-driven vehicles	3.44	1.579	2.493
I collect domestic wastes such as cardboard, paper, metal, plastic etc. in different bags	3.38	1.424	2.029
I plant saplings to reduce carbon emissions	3.29	1.410	1.988
I do not prefer air transport which results in high CO_2 emissions	3.19	1.459	2.127
I prefer consuming white meat rather than red meat	3.01	1.468	2.154
I prefer organic foods rather than hormone-injected foods	2.74	1.088	1.183
I carry out my responsibilities to maintain ecological functions of forest ecosystems	2.69	1.216	1.478
I prefer public transportation if travel distance is distant	2.58	1.401	1.962
I travel to place in walking distance on foot or by bike	2.41	1.364	1.861
I plug out electronic appliances even when they are off since they continue to spend electricity	2.29	1.249	1.559
I use energy saving bulbs at home, workplace or in office rather than classical incandescent lamps	2.23	1.347	1.815
Forest ecosystems provide many benefits to society other than their wood products	2.16	1.163	1.352
Services offered to society by forest ecosystems are important in terms of their vital functions	1.68	0.884	0.781
Forest ecosystems are the most important component in prevention of global warming	1.65	0.885	0.783
I care not to waste water	1.64	0.855	0.731
I leave recreation and picnic fields clean	1.48	0.795	0.633

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_52495267

Accordingly, the participants indicated that they can support afforestation works by a total amount of TRY 6150 to reduce their carbon footprint. Deducting this support amount from required investment amount, remaining investment of TRY 131130 should be met by the government. In other words, these services observed by forest ecosystems are provided to society for free by the Government. However, global footprint left by the humanity as of the 1970s has exceeded World's biocapacity, and emerging ecological deficit is increasing with each passing day. However, how and until when this process will continue will determine humans' perspectives on natural environment and their consumption habits. Besides, in the study, it is also seen that participants have quite complex attitudes towards reducing their ecological footprints. Participants' complex responses to the statements that were specified in terms of reduction of their ecological footprints also show that they should develop new behavior forms related to their perceptions, attitudes and responsibilities. In this case, it will be suitable that decision makers and authorities will take measures that will allow development of behavior patterns towards changing society's consumption habits and reducing their ecological footprints.

According to the results of study, humans leave their ecological footprints on the Earth event in their most basic choices (for instance, housing, nutrition, travel etc.). It is possible to reduce these footprints with some measures implemented (especially reduction of consumption, prevention of wasting resources etc.). However, forest ecosystems have a crucial role in reducing footprints. This service provided by forest ecosystems is of vital importance. Afforestation investments bear an important task in completing this service. Usually, governments do not demand a direct charge from citizens for such investments. However, this situation does not mean that society does not require environmental responsibility, on the contrary, it makes it necessary for society to become more sensitive. Besides, afforestation works contribute to not only carbon storage services but also provision of many services including regulation of water regime and precipitation, prevention of erosion, visual and aesthetic values etc. On the other hand, the carbon footprint is the total amount of carbon dioxide emissions that occur at each stage of the product life cycle (Wiedmann ve Minx, 2008). For this reason, forest ecosystems are used to store every ton of carbon released into the atmosphere. If the size and productivity of this forest ecosystem is not sufficient to store the amount of carbon released to the atmosphere, then the ecological deficit arises (Özsoy, 2015). Since 1961, Mediterranean countries have been in a situation of biocapcity deficit, with its demand for ecological services increasingly exceeding supply. In order to maintain this situation, the import of ecological assets from regions outside the Mediterranean is necessary. When Turkey is compared with Mediterranean countries in this aspect, only two countries provide approximately 50 percent of the natural endowment (biocapacity) of the Mediterranean basin: France (31%) and Turkey (16%). The ecological footprints of the Mediterranean countries show great differences among themselves. For example, three countries among Mediterranean countries alone contribute to more than 50 percent of the Mediterranean region's ecological footprint: France (20%), Italy (19%) and Spain (15%) (Moore et al., 2018). Differences among countries' ecological footprint values are most likely driven by socio-economic factors, such as disposable income, infrastructure, and cultural habits (Baabou et al., 2017). Also, differences in consumption habits and quantities of these countries cause their footprints to be different. Especially food accounts for a large part of the Mediterranean countries' overall ecological footprint. According to result of other study, in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_52495267

Mediterranean countries food and beverages represents 28% of the regional ecological footprint (Galli, 2017). In also Turkey, ecological footprint of personal consumption is predominantly made up of food (52%) (WWF, 2012). Mediterranean countries also vary considerably in terms of their food supply. Most countries in the region have a daily food supply that is 20% to 40% higher than the average FAO determined minimum daily dietary energy requirement benchmark of 2500 kcal cap^{-1} day^{-1}. Moreover, comparison of countries' food footprint intensities reveals a considerable spread, with the lowest value found in Egypt and the highest in Portugal (FAO et al., 1985; Pimentel and Pimentel, 2003). These comparisons and assessments show that our personal and social consumption behaviors need to be revised.

According to research findings, participants have quite complex attitudes towards reducing their ecological footprints. For example (*Table 7*), the statement "*i contribute to sustainable management of forests using certificated forest products*" achieved the highest average, on the other hand, the expression "*forest ecosystems are the most important component in prevention of global warming*" achieved one of the lowest score averages with a rate of 1.65. Again similarly, while the idea of recycling wastes has a higher average score as a positive expression, reducing water waste has relatively lower average. These findings show that participants have some basic information and environmental responsibilities, also show that participants do not consider some components. A similar situation occurs between expressions "*i plant saplings to reduce carbon emissions*" (mean: 3.29) and "*forest ecosystems are the most important component in prevention of global warming*" (mean: 1.65). Accordingly, participants know that tree planting is effective in reducing carbon emissions, but they do not exhibit more sensitive approach. However, it shows that participants have low levels of awareness and sensitivity in terms of functions of forest ecosystems in prevention of global warming caused by carbon accumulation in the atmosphere (CO_2). These findings are important for future studies that will be conducted in the form of training, raising awareness and providing responsibility (Aoki and Akai, 2013; Sarıkaya et al., 2016). In addition, these data provide convenience for individuals following their resource use and sustainability (Mattila et al., 2011). On the other hand, these findings contribute to determination of social perceptions for planning and managing natural resources in a sustainable way. Thus, measures can be taken that will allow participants to reduce their ecological footprints. That is because people consume their natural resources rapidly and increase their ecological footprint amounts with each passing day.

Consequently, forest ecosystems carry out many vital services apart from being sources of wood origin products, and they bear vital importance for a sustainable life. Increasing society's level of knowledge and awareness related to forest ecosystems is significant in terms of ensuring continuity of ecosystem services and reducing ecological footprints left. However, it was found out that participants shaped components constituting their ecological footprints as per their consumption forms and they did not consider the effect of these behavior patterns in reducing their footprints. Therefore, public awareness should be raised in terms of vital importance of reducing ecological footprints, factors establishing ecological footprint and their relationships with each other. By acting as a whole for a sustainable life, ecological footprints should be reduced. This disrupted balance of the world is actually humanity's own balance.

APPENDIX

Survey Form

"Determination of Environmental Perceptions and Awareness Towards Reducing Carbon Footprint."

1. Gender: ( ) Female ( ) Male

2. Age group: ( ) 18-30 ( ) 31-40 ( ) 41-50 ( ) 51-60 ( ) 60<

3. Education level: ( ) Primary school graduate ( ) Secondary school graduate
( ) High school graduate ( ) University graduate ( ) Postgraduate

4. Work/Professional: ( ) Officer ( ) Self-employed ( ) Engineer ( ) Housewife
( ) Unemployed ( ) Retired ( ) Educator

5. Income level: ( ) 0 - 1000 TRY ( ) 1001 - 2000 TRY ( ) 2001 - 3000 TRY
( ) 3001 - 4000 TRY ( ) 4000< TRY

6. Your meal preference: ( )I'm a vegetarian. ( )I usually consume fish. ( )I usually consume white meat.
( ) I consume red and white meat. ( ) I consume red meat every day.

7. Your organic food consumption preference:
( ) I only buy organic products. ( ) Some of the products I buy are organic.
( ) I do not buy any organic products. ( ) I don't know if you buy organic products.

8. Your clothing preference: ( ) I use second-hand clothes. ( ) I buy new clothes if I need them.
( ) I follow the latest fashion.

9. Imported food and product consumption preference:
( ) I just consume domestic products.
( ) I usually consume domestic products.
( ) I rarely prefer to consume domestic products.
( ) Domestic or imported products, it does not matter to me.

10. Your furniture and electronics goods preference:
( ) I usually buy new products, but I use them for at least 5 years.
( ) I buy the latest technology or fashionable products.

11. Your recycling preference:
( ) All my garbage is recycled. ( ) Most of my garbage is recycled.
( ) Some of the my garbage is recycled. ( ) My garbage is not recycled.

12. Your entertainment activities:
( ) I do activities that do not produce carbon (e.g. walking, cycling).
( ) I usually go to movies, bars and restaurants.
( ) I make intensive carbon-producing activities (e.g. flight, motorcycle).

13. How many cars do you have?: ( ) 1 ( ) 2 ( ) Three and over ( ) I do not have a car

14. Your annual energy consumption:
( ) Electricity use (kWh)............ ( ) Natural gas (m3)………..
( ) Coal (Ton)……… ( ) LPG (Liter)……….. ( ) Other………

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_52495267

15. Number of round-trip flights per year:
( ) Short-haul flights (Turkey-Europe) ....
( ) Medium-haul flights (Turkey-China) ....
( ) Long-haul flights (Turkey-America) ....

16. Traveling by car: ( ) Car model…………… ( ) The annual amount of distance (km)………

17. The annual distance from your travel by bus and train (km)?
( ) Bus……..… ( ) Train………… ( ) Light rail……...… ( ) Subway…..…..…..

18. Trees are one of the most important elements that reduce carbon dioxide emissions and store carbon. Therefore do you want to provide financial support for afforestation efforts to reduce carbon emissions?

( ) 10 TRY ( )20 TRY ( ) 30 TRY ( ) 40 TRY ( ) 50 TRY ( ) 100 TRY ( ) No

Mark the following expressions as appropriate.

Expressions	Always	Often	Sometimes	Rarely	Never
I travel to place in walking distance on foot or by bike.					
I prefer public transportation if travel distance is distant.					
I prefer driving LPG vehicles rather than petrol-driven vehicles.					
I do not prefer air transport which results in high CO2 emissions.					
I plug out electronic appliances even when they are off since they continue to spend electricity.					
I use energy saving bulbs at home, workplace or in office rather than classical incandescent lamps.					
I collect domestic wastes such as cardboard, paper, metal, plastic etc. in different bags.					
I care not to waste water.					
I leave recreation and picnic fields clean.					
I plant saplings to reduce carbon emissions.					
I prefer organic foods rather than hormone-injected foods.					
I prefer consuming white meat rather than red meat.					
I contribute to sustainable management of forests using certificated forest products.					
I carry out my responsibilities to maintain ecological functions of forest ecosystems.					
Forest ecosystems provide many benefits to society other than their wood products.					
Services offered to society by forest ecosystems are important in terms of their vital functions.					
Forest ecosystems are the most important component in prevention of global warming.

(Received 13th Jun 2018; accepted 1st Aug 2018)

Abstract. Forest resources inventory is one of the essential parts of the sustainable forest management. Remote sensing applications have broad usage areas for this aim, since field measurements are costly, time consuming and laborious. Monitoring forest resources with various satellite images has found wide usage areas in forestry. In this study, the relationships between some stand attributes (mean diameter, basal area, stand volume and number of trees) and texture values obtained from Landsat 8 OLI satellite image were investigated for Crimean pine (*Pinus nigra* J.F. Arnold subsp. *pallasiana* (Lamb.) Holmboe) stands in Kastamonu region of Turkey. The multiple linear regression analysis and artificial neural networks (ANN) were utilized to fit stand parameters using texture values. To form the ANN architectures, various transfer functions in hidden and output layers and number of nodes ranged from 1 to 20 in hidden layer were used, and a total of 180 architectures were designed for each stand attribute. The results indicated that the regression models had low R^2 values (0.399 for mean diameter, 0.337 for basal area, 0.332 for stand volume, and 0.183 for number of trees), and the most of the ANN models were better than the regression models for predicting stand attributes. The model containing hyperbolic tangent transfer functions in both hidden and output layers for mean diameter (R^2 = 0.593), logistic transfer function in hidden layer and hyperbolic tangent function in output layer for basal area and stand volume (R^2 = 0.632 and 0.650, respectively), and hyperbolic tangent function in hidden layer and linear function in output layer for number of trees (R^2 = 0.610) were the best ANN models. This study concluded that the ANN models developed with Landsat 8 OLI were useful to predict stand parameters better than the regression models in Crimean pine stands located in Kastamonu, Turkey.
Keywords: *forest inventory, satellite image, artificial neural networks, multiple linear regression*

Introduction

Forest ecosystems provide so many different economic, ecological and social products and services such as wood and non-wood products, carbon sequestration, biodiversity conservation, wildlife contribution, water and soil protection, and recreation. However, these ecosystems face deforestation and desertification problems because of human activities, unusual climatic conditions due to global warming, insect attacks, erosion, wildfires, etc. In this negative situation, sustainable management of forests becomes more important. The inventory and monitoring of forest resources are the main parts of the sustainable forest management.

Traditional forest inventory based on ground measurements is very hard, time-consuming and costly in a great forest area (Lu et al., 2004). In addition to ground measurements, remote sensing data are also widely used for forest management planning (Holmgren and Thuresson, 1998). Particularly for predicting stand-level circumstances across great forest areas, remote sensing data have been utilized efficiently to offer valuable information regarding forest constructions for forest

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_52695285

managers (Cohen et al., 1995). Since the early 21st century, Landsat satellite data have had broad usage in many forestry studies such as land cover or land use change (Günlü et al., 2008; Huang et al., 2009; Hu et al., 2016), stand parameters predictions (Kahriman et al., 2014; Günlü and Başkent, 2015; Günlü and Kadıoğulları, 2018) and aboveground biomass estimations (Zheng et al., 2004; Lu et al., 2012; Günlü et al., 2014a).

Forest attributes such as mean diameter, stand basal area, stand volume and numbers of trees are important for forest management planning activities. In studies on predicting stand parameters using Landsat satellite images, the models were developed by using reflectance and vegetation indices values obtained from Landsat satellite data (Hall et al., 2006; Mohammadi et al., 2010; Günlü and Kadıoğulları, 2018). Besides, there are several studies to predict the stand parameters (especially for predicting aboveground biomass) by using texture values generated from Landsat satellite data (Kelsey and Neff, 2014; Safari and Sohrabi, 2016). In general, regression analysis was used to predict stand parameters with remote sensing data (Hyde et al., 2006; Gama et al., 2010). Recently, some studies have been performed to estimate the stand parameters using artificial neural networks (ANN) techniques (Ercanli et al., 2016; Reis et al., 2018).

The aims of this research are (*i*) to generate the ANN models estimating relationships between the stand parameters (mean diameter, stand basal area, stand volume and numbers of trees) obtained from ground measurements and texture values generated from Landsat 8 OLI satellite image, (*ii*) to assess the utilization of the ANN models for attaining the estimation of stand parameters by matching the regression analysis outcomes in pure Crimean pine stands of Kastamonu Regional Directorate of Forestry.

Materials and methods

Study area

This study was carried out on pure Crimean pine stands within the boundaries of Kastamonu Regional Directorate of Forestry located in the Black Sea Region of Turkey (*Fig. 1*). This directorate is the first among 28 regional directorates of Turkey in terms of growing stock (201.4 million m^3) and annual volume increment (4.3 million m^3), and these amounts equal to about 13% of the whole country. Forests cover a total of 1.26 million ha, which is about 66% of the total area of the region (General Directorate of Forestry, 2015). Crimean pine is also the most common tree species with 0.38 million ha distribution area in the region (General Directorate of Forestry, 2006).

Mean annual temperature and precipitation of the study area are 9.8 °C and 480 mm, respectively. The slope varies from 0% to 80%, and the elevation ranges between 604-1579 m above sea level, with an average of 1149 m. All sampled areas consist of naturally regenerated pure Crimean pine stands.

Field measurements

Field measurements for this study were conducted in 184 circular sample plots during summer seasons of 2015 and 2016. Sample plot sizes were determined considering stand crown closures, which is a key parameter to decide the sample plot sizes for forest inventory activities in Turkey. According to the crown closure classes of the stands (i.e., 11-40%, 41-70% and >71%), the sizes of circular sample plots were set

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_52695285

as 800, 600 or 400 m^2 with the radii of 15.96, 13.82 or 11.28 m, respectively. For some sample plots including excessive number of trees, the radii of the plots were reduced to 7.98 m (i.e., 200 m^2 in size). Sample plots were randomly selected to represent different stand characteristics, which directly affect the growth rate, such as stand densities, diameter classes and site qualities.

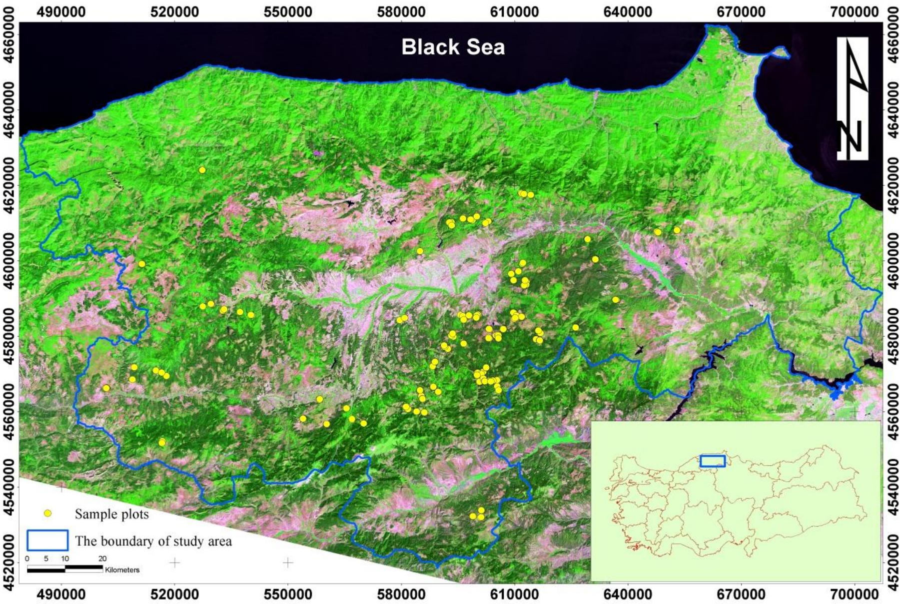

Figure 1. *Landsat 8 OLI satellite image of study area*

Measurements in the sample plots were initiated by recording UTM coordinates using a Global Positioning Systems (GPS) receiver placed at the center of every sample plot. In each sample plot, the diameter at breast height (*dbh*) over-bark was measured to the nearest 0.1 cm using calipers for each trees greater than 7.9 cm *dbh*, and the number of trees measured were counted. In total, 5757 trees were measured for *dbh*, and the number of trees measured in sample plots were ranged from 7 to 92 trees. Basal areas of each tree in sample plots were calculated. Volumes of the trees were predicted using the single-entry volume equation developed by Sakici et al. (2018) for Crimean pine stands located in the study area. After measuring and calculating the sample trees’ dendrometric values, total basal area and total volume of each sampling plot were calculated by summing basal areas and volumes of sample trees in sample plot, respectively. The total basal area and total volume of sample plots were ranged between 0.341-4.371 m^2 and 0.848-45.203 m^3, respectively. Then, stand parameters such as mean diameter (d_q), stand basal area (G), stand volume (V) and number of trees per hectare (N) were calculated using *Equations 1*, *2*, *3* and *4* for each sample plots.

$$d_q = \sqrt{\frac{\sum dbh^2}{n}} \quad \text{(Eq.1)}$$

$$G = \frac{10000}{A} g \quad \text{(Eq.2)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_52695285

$$V = \frac{10000}{A} v \qquad \text{(Eq.3)}$$

$$N = \frac{10000}{A} n \qquad \text{(Eq.4)}$$

where, d_q is the quadratic mean diameter (cm), *dbh* is the tree diameter measured at 1.30 m from the ground, G is the stand basal area (m^2 ha^{-1}), g is the total basal area of sample plot (m^2), V is the stand volume (m^3 ha^{-1}), v is the total volume of sample plot (m^3), N is the number of trees per hectare, n is the number of trees in the sample plot, and A is the sample plot area (m^2).

The 184 sample plots were randomly divided into two groups to generate the model development and validation data sets. The data from 138 sample plots (75% of total data) were used to develop the models. As independent data set, the data from remaining 46 sample plots (25% of total data) were reserved for validation process of the developed models. The summary statistics for the sample plots were given in *Table 1* for modeling and validation data groups, separately.

Table 1. *Summary statistics of sample plots*

	Mean diameter (cm)	Basal area (m^2 ha^{-1})	Stand volume (m^3 ha^{-1})	Number of trees (ha^{-1})
Modeling data (n = 138)				
Minimum	10.4	5.685	14.128	88
Maximum	51.7	75.873	882.648	1800
Mean	28.3	31.160	273.305	570
Standard deviation	10.3	16.172	177.385	345.6
Validation data (n = 46)				
Minimum	12.9	7.224	19.976	88
Maximum	53.7	66.113	639.660	1850
Mean	29.7	36.288	323.589	634
Standard deviation	10.8	14.202	150.482	380.6

Remote sensing data and processing

The Landsat 8 Operational Land Imager (OLI) satellite image used in this research was free downloaded from United States Geological Survey Global Visualization Viewer (URL-1, 2014). The Landsat 8 OLI satellite image has already included atmospheric and geometric corrections, and radiometric calibration. In this study, five bands (Band 2, 3, 4, 5 and 7) of Landsat 8 OLI satellite image with a spatial resolution of 30 meters were used. Eight different texture metrics (contrast, correlation, dissimilarity, entropy, homogeneity, mean, second moment and variance) for each band were produced using four different window sizes (3 x 3, 5 x 5, 7 x 7 and 9 x 9). To produce texture values, ENVI software was used. After that, depending on the size of the sample areas, buffer zones (with radius of 7.98, 11.28, 13.82 or 15.96 m) were composed around the sample plots' centers in accordance with UTM coordinates recorded by GPS receiver. The texture images produced for each band were overlaid using GIS with the sample plots. The texture values of each sample plot were calculated

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_52695285

by two different methods. If the sample plot centers were at or near the center of a pixel, the texture values of the sample plots were calculated as the value of a single pixel for 200, 400 and 600 m^2 sample plots, while calculated by taking the average of some pixel values in the buffer zone for 800 m^2 sample plots (*Fig. 2a*). However, in the second method, if the sample plot centers were far from the pixel centers, the texture values of each sample plot were computed by taking the average of pixel values in the buffer zone for all sample plot sizes (*Fig. 2b*). In this way, the texture values for five bands, four window sizes and eight different texture metrics were calculated. Thus, a total of 160 texture values were obtained for each sample plot.

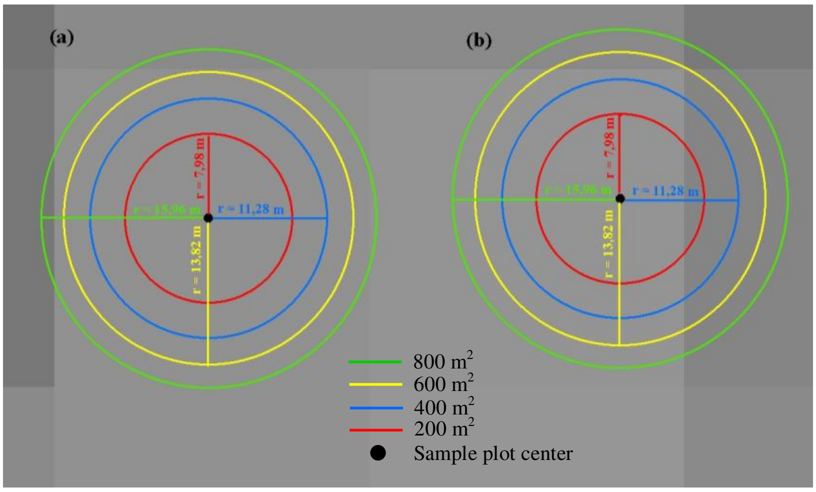

Figure 2. *Texture value calculation of sample plots according to buffer zones on satellite image*

Regression models

The multiple linear regression analysis was used to develop the equations modeling the interactions between stand parameters (mean diameter, stand basal area, stand volume and number of trees) and texture values obtained from Landsat 8 OLI satellite image. To obtain multiple linear regression models based on stepwise variable selection method, the ordinary least squares technique was used. The dependent variables in these models were quadratic mean diameter, stand basal area, stand volume and number of trees per hectare, and independent variables were 160 texture values of modeling data group containing 138 sample plots. The dependent variables were observed values from field works, while the independent ones were produced values from satellite image. The stepwise regression procedure in IBM SPSS 23 software was used to select the statistically significant ($p < 0.05$) texture values as predictor variables to estimate stand parameters. The relationships between stand parameters and texture values were assumed linear as given formula below (*Eq. 5*):

$$Stand\ Parameter = b_0 + b_1X_1 + b_2X_2 + \ldots + b_nX_n + e \quad \text{(Eq.5)}$$

where *Stand Parameter* is quadratic mean diameter, stand basal area, stand volume or number of trees per hectare, X_i (i = 1 to n) are texture values, b_i represent the model coefficients, and e is the error term.

Artificial neural networks

Artificial intelligence techniques were also employed to model stand parameters beside multiple linear regression analysis to determine prediction success of these techniques and to compare with regression modeling. For this purpose, artificial neural network (ANN) models were developed for each stand parameter examined in this study. For defining the architecture of neural networks, there are several criteria such as number of layers, learning algorithms, transfer function forms, number of nodes in hidden layer and determination of data sizes for training, verification and test processes. The ANN models developed in this study consist of three layers: input, hidden and output layers. The feed-forward back-propagation network structure was selected because of its success popularity in forestry literature (e.g., Özçelik et al., 2014; Diamantopoulou et al., 2015). The learning algorithm used in ANN models was the Levenberg-Marquardt algorithm. Three transfer function forms (linear, logistic and hyperbolic tangent) were examined in hidden and output layers, separately (*Eqs. 6*, *7* and *8*).

$$f(s) = purelin(s) = s \qquad \text{(Linear function)} \qquad \text{(Eq.6)}$$

$$f(s) = logsig(s) = \frac{1}{1 + e^{(-s)}} \qquad \text{(Logistic function)} \qquad \text{(Eq.7)}$$

$$f(s) = tanh(s) = \frac{1 - e^{(-2s)}}{1 + e^{(-2s)}} \qquad \text{(Hyperbolic tangent function)} \qquad \text{(Eq.8)}$$

where $s = \sum w_i x_i$, w_i are weights and x_i are the input variables.

To determine the most predictive alternatives, the number of nodes in hidden layers ranged from 1 to 20 adding one by one in training process of ANN models. Thus, a total of 180 ANN model architectures were created for each stand parameter (*Fig. 3*). The ANN models were built using the neural network toolbox in R2015a version of MATLAB software. The modeling data obtained from 138 sample plots were used for ANNs' fitting. Input variables of ANN models were texture values of satellite image determined as the best predictor for each stand parameter in multiple linear regression analyses, and output (target) variable was observed mean diameter, stand basal area, stand volume or number of trees according to the stand attributes fitted.

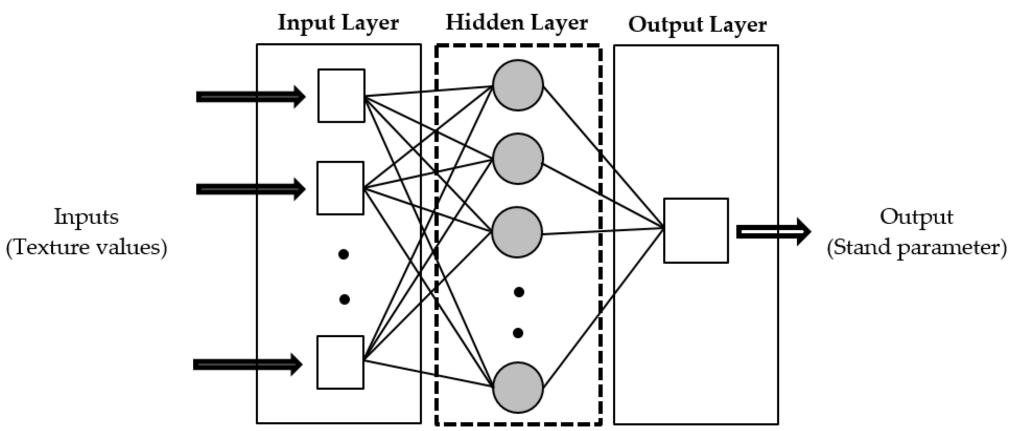

Figure 3. *ANN models architecture for stand parameters*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_52695285

Model comparisons and validation tests

The regression and ANN models were evaluated based on four goodness-of-fit statistics; the coefficient of determination (R^2), root mean square error (*RMSE*), bias and mean absolute error (*MAE*). Corresponding mathematical forms of statistical criteria utilized were defined as *Equations 9*, *10*, *11* and *12*.

$$R^2 = 1 - \frac{\sum(y_i - \hat{y}_i)^2}{\sum(y_i - \bar{y})^2} \quad \text{(Eq.9)}$$

$$RMSE = \sqrt{\frac{\sum(y_i - \hat{y}_i)^2}{n-1}} \quad \text{(Eq.10)}$$

$$Bias = \frac{\sum(y_i - \hat{y}_i)}{n} \quad \text{(Eq.11)}$$

$$MAE = \frac{\sum|y_i - \hat{y}_i|}{n} \quad \text{(Eq.12)}$$

In these equations; y_i and $\hat{y}_i$ are observed and estimated values of corresponding stand attribute, and n is sample size.

When comparing alternative models, it is desirable that the R^2 values are high while the others (*RMSE*, *Bias* and *MAE*) are low. For ranking of models, taking into account of all goodness-of-fit statistics together is better than the ranking of each criteria separately. The relative ranking method proposed by Poudel and Cao (2013) was used for model comparisons. In this method, the relative rank of model *i* for a statistical criterion is defined using *Equation 13*.

$$R_i = 1 + \frac{(m-1)(S_i - S_{min})}{(S_{max} - S_{min})} \quad \text{(Eq.13)}$$

where R_i is the relative rank of model i (i = 1, 2, …, m), S_i is the goodness-of-fit statistic of model i, S_{min} and S_{max} are the minimum and maximum values of S_i, respectively.

For each stand parameter, relative rankings of ANN models were first implemented according to number of nodes in hidden layer for transfer function pairs of hidden and output layers, separately, for each statistical criterion. So, four rankings with 20 ANN models were formed for nine transfer function pairs (i.e., linear, logistic and hyperbolic tangent functions were used in both hidden and output layers) for every stand parameter fitting. The model with the highest R^2 was ranked as 1 and the lowest R^2 was ranked as 20 for coefficient of determination, while the model with the lowest value was ranked as 1 and the highest value was ranked as 20 for *RMSE*, *Bias* and *MAE*. Then, four relative ranks of each model according to statistical criteria were summed. The second relative ranking was generated using total relative ranks of ANN models based on number of nodes ranged from 1 to 20 for each transfer function pairs. Thus, the most successful ANN models were specified for every transfer function pairs of each stand parameter fitting.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_52695285

To compare estimation success of regression and ANN models, the relative ranks of 10 models (a regression model and the best ANN models for nine transfer function pairs) were rebuilt for each stand parameter. So, the most successful models were identified for predicting stand parameters evaluated in this study. The validities of successful models were tested by comparing the validation data observed from 46 sample plots and models' results by Student's t-test (also called paired samples t-test) procedure in IBM SPSS Statistics 23 software. To exhibit the prediction abilities of the models, residual graphs based on observed vs. predicted stand parameters were also prepared.

Results

In this study, multiple regression and artificial intelligence techniques were conducted for predicting some stand parameters such as mean diameter, basal area, stand volume and number of trees using texture values obtained from Landsat 8 OLI satellite image, and regression and ANN models were developed with these techniques. To determine the best predictor texture values for predicting stand attributes and to develop linear regression models for each stand parameter, multiple linear regression technique was used. In this analyses, all stand parameters were tried to fit using 160 texture values as candidate independent variables. These variables were produced by combining five bands of Landsat 8 OLI satellite image, four window sizes and eight texture metrics. The results of regression analyses are given in *Table 2*. As seen in this table, six, seven, six and three variables included in regression models of mean diameter, basal area, stand volume and number of trees, respectively. All coefficients of these variables were statistically significant as well as constants of models except for number of trees ($p < 0.05$). It might be said that all stand parameters were fitted poorly with regression models due to the low R^2 values. The maximum coefficient of determination value was obtained for mean diameter ($R^2 = 0.399$), while the minimum was for number of trees ($R^2 = 0.183$). The R^2 values of basal area and stand volume models were similar, which were 0.337 and 0.332, respectively.

In regression models developed for stand parameters, texture value combinations containing Band 2 were not statistically significant for number of trees as well as Band 4 for mean diameter and number of trees and Band 7 for all stand parameters except mean diameter, while some combinations with Band 3 and Band 5 were significant for all. The combinations including 7 x 7 window sizes were found insignificant for number of trees, and 9 x 9 ones were for the parameters except basal area. Some combinations with 3 x 3 and 5 x 5 window sizes were significant for all stand parameters. Texture values comprising *contrast* for mean diameter, *dissimilarity* for all, *entropy* and *homogeneity* for the parameters except mean diameter, *mean* for number of trees, *second moment* for all except number of trees, and *variance* for basal area and number of trees were not statistically significant. Some combinations with *correlation* were significant for all stand parameters.

ANN models were also fitted for stand parameters using input variables found statistically significant in regression models. Totally 180 ANN architectures including various transfer functions in hidden and output layers and number of nodes from 1 to 20 in hidden layer were designed for every stand parameter. Thus, a total of 720 ANN procedures were implemented in this study. For all stand parameters evaluated, all ANN models were successfully completed the training process except architectures

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_52695285

comprising logistic transfer function in output layer. The ANN models with logistic transfer function in output layer could not give any result. It means that 120 ANN models could be ranked instead of 180 models for each stand parameter.

Table 2. *Multiple linear regression results for stand parameters*

Stand parameter	Independent variable	Variable combination (Texture value)			Coefficients (b_i)	R^2	SEE[a]

[a]Standard error of estimate
*p < 0.05, **p < 0.01, ***p < 0.001, ^{ns}non-significant (p > 0.05)

Four statistical criteria (R^2, *RMSE*, *Bias* and *MAE*) were used to rank the ANN models. These rankings were applied within six transfer function pairs, i.e. linear, logistic and hyperbolic tangent functions in hidden layer combined with linear and hyperbolic tangent functions in output layer, separately. Hence, a total of 24 ranking lists were produced due to the presence of four stand attributes and six transfer function pairs. Finally, the best ANN architectures within each ranking list were determined to compare with each other and regression models.

The regression models and all of the best ANN models for each stand parameter were re-ranked to decide the most successful models for predicting stand parameters.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_52695285

The final ranking lists are given in *Table 3*. In this table, it is seen that the regression models and the ANN models including linear transfer function in hidden layer were unsuccessful than the other ANN models. The ANN_4 models (i.e. the logistic function in hidden layer and hyperbolic tangent function in output layer) were the most successful for predicting basal area (with 12 nodes in hidden layer) and stand volume (with 9 nodes in hidden layer) having high R^2 values as 0.632 and 0.650, respectively. The ANN_6 model (i.e. the hyperbolic tangent functions in both hidden and output layers, and 10 nodes in hidden layer) was the best for mean diameter prediction ($R^2 = 0.593$), while ANN_5 (i.e. the hyperbolic tangent function in hidden layer, the linear function in output layer, and 9 nodes in hidden layer) was the best to predict number of trees ($R^2 = 0.610$). The other goodness-of-fit statistics had similar trends to the coefficient of determinations among the models compared. In the other words, the ANN models having higher R^2 values had lower *RMSE*, *Bias* and *MAE* values. As it can be understood from these conclusions, the powers of stand parameter predictions were considerably increased with artificial intelligence applications. These increases of prediction powers are approximately 50% for mean diameter, nearly 100% for basal area and stand volume, and more than 200% for number of trees.

If the ranking lists in *Table 3* are examined in detail, the regression models were weaker than the ANN models except the architectures containing linear transfer functions in both hidden and output layers (ANN_1). For number of trees prediction, the regression model was also stronger than the ANN model comprising the linear transfer function in hidden layer and the hyperbolic tangent transfer function in output layer (ANN_2). According to the transfer function in hidden layer, the ANN models with hyperbolic tangent function were more successful for mean diameter and number of trees predictions, while the models with logistic function for basal area and stand volume. Besides, according to the transfer function in output layer, the ANN model with linear function were more successful for number of trees prediction, while the models with hyperbolic tangent function for the other stand parameters. There was not any general trend for the ANN models with respect to the number of nodes in hidden layer. However, the node numbers were around 10 in the best models for all parameters.

The validities of the developed regression models and the best ANN models were tested with Student's t-test using independent data set obtained from 46 sample plots. For all the models tested, there were no significant differences between observed and predicted values ($p > 0.05$) and consequently it was decided that the models were statistically usable for predicting the aforementioned stand parameters (*Table 4*). Thus, because of their statistical successes, the ANN_6 model for mean diameter, the ANN_4 models for basal area and stand volume, and the ANN_5 model for number of trees estimations can be used.

The residual distributions of predicted stand parameters obtained by the best ANN models and regression models using all data from 184 sample plots are shown in *Figure 4*. When the residual distributions are examined, it is seen that the residuals were distributed randomly in all regression and ANN models. The regression and ANN models had similar residuals and the mean residuals were close to zero for each stand parameter. Mean residual values for mean diameter, basal area, stand volume and number of trees estimates were -0.4 cm, -0.37 m^2 ha^{-1}, -3.96 m^3 ha^{-1} and 18.6 ha^{-1} for regression models (*Fig. 4a-d*), and -0.1 cm, 0.64 m^2 ha^{-1}, -10.04 m^3 ha^{-1} and 5.5 ha^{-1} for the best ANN models (*Fig. 4e-h*), respectively.

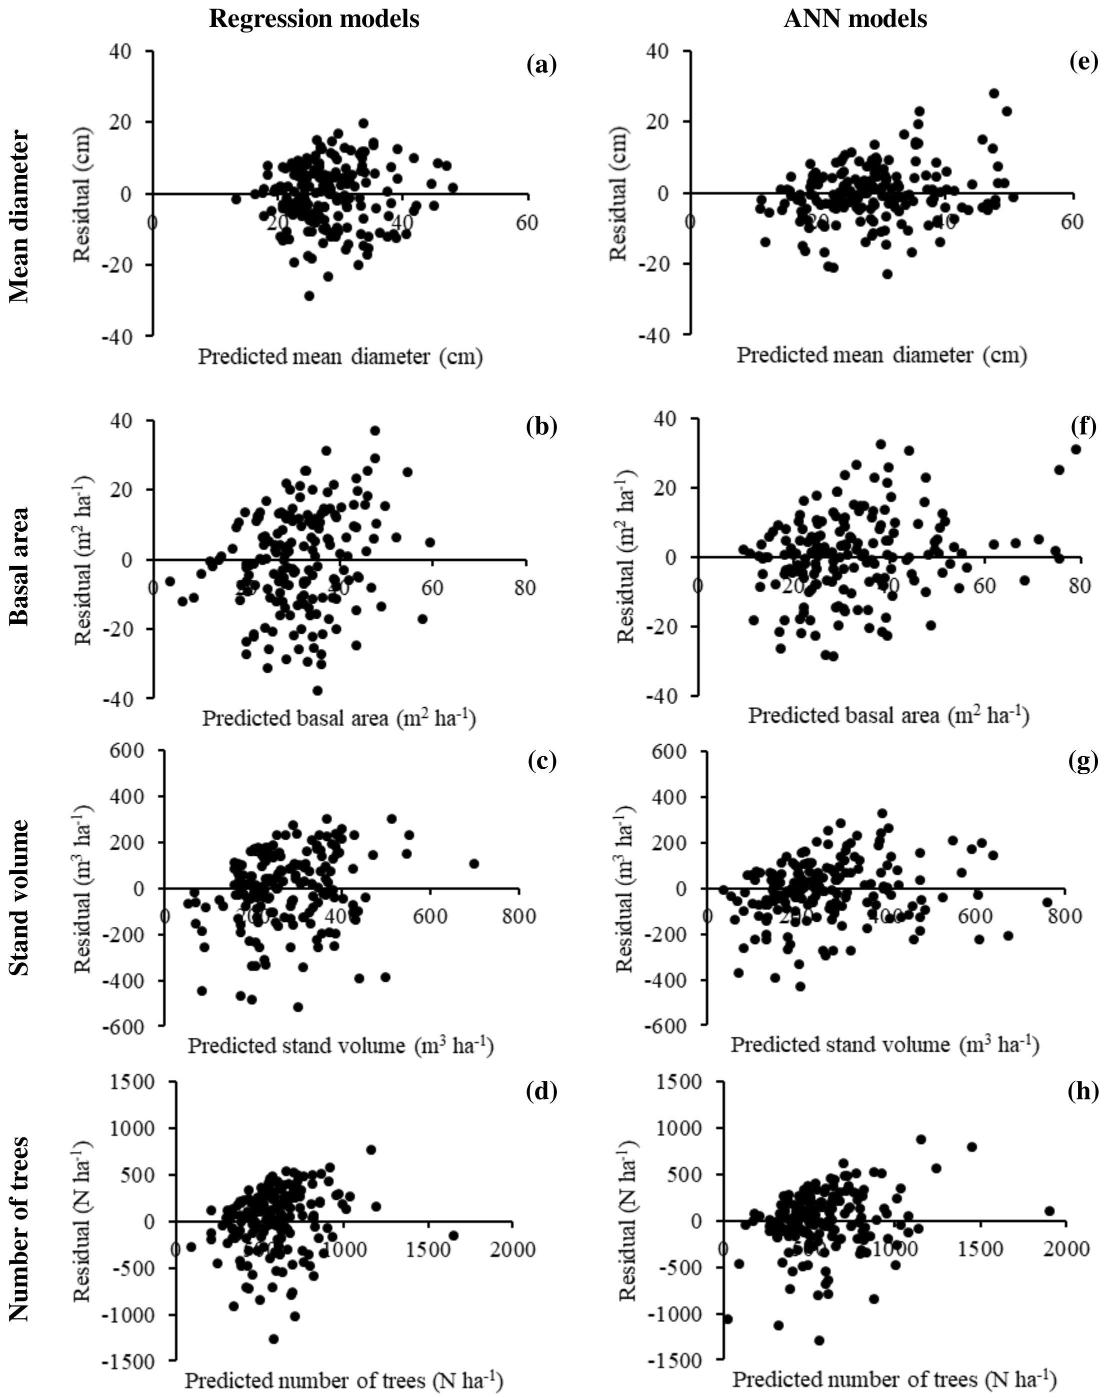

Figure 4. *Residual distributions of the regression models (a-d) and selected ANN models (e-h)*

When the observed stand parameters and predicted values of these parameters with two modeling approaches were compared considering *Table 4*, the mean diameter predictions of the regression and ANN_6 models were similar to observed values with mean differences of 1.4 and 1.5 cm, respectively. The basal area predictions of the ANN_4 model were very close to the observed values with mean difference of 0.860 m^2, while the regression model's predictions were quite different with of 5.221 m^2 per hectare. Since mean differences of the regression and ANN_4 models were 65.586 and

DOI: http://dx.doi.org/10.15666/aeer/1604_52695285

44.559 m^3 per hectare, the ANN_4 model was more prosperous for the stand volume estimations. The comparison for the number of trees was resulted different from the other stand parameters, since the mean difference of the regression model was positively 45.4 trees while of the ANN_5 model was negatively 63.5 trees per hectare. However, the ANN_5 model was superior than the regression model for the number of trees prediction when the mean residuals of the models took into consideration.

Discussion and conclusions

In this study, the relationships between some stand attributes (mean diameter, basal area, stand volume and number of trees) and texture values obtained from Landsat 8 OLI satellite image were predicted for Crimean pine stands in Kastamonu region of Turkey. The multiple linear regression analysis and ANN technique were performed to fit stand attributes using texture values. The stand attributes estimation models developed by ANN models performed better than multiple linear regression models except ANN_1 for basal area, stand volume and number of trees and except ANN_1 and ANN_2 for mean diameter.

The band reflectance and vegetation indices were used as independent variables in some published studies performed to estimate the stand parameters using the Landsat satellite images (Mohammadi et al., 2010; Kahriman et al., 2014; Günlü and Kadıoğulları, 2018). However, in the literature no studies have been found to predict mean diameter, basal area, stand volume and number of trees using texture values obtained from Landsat satellite images. On the other hand, there are some studies on estimating stand parameters such as aboveground biomass and carbon stock using textures values obtained from Landsat satellite data images (Kelsey and Neff, 2014; Zhao et al., 2016; Safari and Sohrabi, 2016 In addition, there are many studies on estimating stand parameters such as stand volume, basal area, number of trees, aboveground biomass and carbon stock using texture values obtained from the other satellite data images (Castillo-Santiago et al., 2010; Özdemir and Karnieli, 2011;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_52695285

Eckert, 2012; Pu and Cheng, 2015; Wallner et al., 2015; Xie et al., 2017). In general, regression analysis is used in the studies to estimate stand parameters using remote sensing data images (Castillo-Santiago et al., 2010; Mohammadi et al., 2011; Günlü et al., 2014b; Kahriman et al., 2014).

The reflectance values, vegetation indices and texture values were utilized as independent variables of a multiple linear regression model in some studies on the subject. For instance, the models using vegetation indices obtained from Landsat ETM+ data had the R^2 values as 0.43 for stand volume and 0.73 for tree density (Mohammadi et al., 2010), while the texture variables of IKONOS-2 explained 35% of the variation in basal area of even-aged stands in temperate forests (Kayitakire et al., 2006). In other studies, the reflectance and vegetation indices values obtained from Landsat TM satellite data explained 61% and 70% of tree density, respectively, in mixed forest areas, and generated from pan-sharpened IKONOS satellite data explained 41% and 43% of stand volume, and 55% and 59% of basal area, respectively (Kahriman et al., 2014; Günlü et al., 2014b). In the multiple linear regression models with digital number values of Landsat TM, the R^2 values for mean diameter, basal area, stand volume and number of trees were founded as 0.25, 0.32, 0.37 and 0.44, respectively (Günlü and Kadıoğulları, 2018). In the same study, the R^2 values of the multiple linear regression analyses obtained from vegetation indices values for mean diameter, basal area, stand volume and number of trees were founded as 0.17, 0.34, 0.36 and 0.28, respectively.

The results of our study indicated that the R^2 values of the multiple linear regression analyses generated with texture values from Landsat 8 OLI satellite image for mean diameter, basal area, stand volume and number of trees were founded as 0.40, 0.34, 0.33 and 0.18, respectively. When the results obtained from our study are compared with some other studies mentioned above (Mohammadi et al., 2010: Kahriman et al., 2014; Günlü and Kadıoğulları, 2018), the regression model generated from texture values is not suitable for estimating mean diameter, basal area, stand volume and number of trees due to the low R^2 values.

In recent years, the ANN method used in some published studies on predicting leaf area index (Shoemaker and Cropper, 2010), stand volume and basal area (Shataee, 2013; Santi et al., 2015), stand carbon stock (Ercanli et al., 2016), and aboveground biomass (Ni et al., 2017; Yan et al., 2018). We also used the ANN method to predict the stand parameters in this study. The comparisons between multiple linear regression and ANN models for estimating stand parameters show that the abilities of the ANN models are higher. In other words, the R^2 values of the best ANN models increased between 48% and 239% for the stand parameters compared to the regression models. Similar results were published in some rare studies. For instance, Ercanli et al. (2016) modelled aboveground stand carbon stock using multiple linear regression analysis and ANN with vegetation indices obtained from Landsat TM satellite data and founded that the R^2 values of 0.43 and 0.65, respectively. In another study, a comparative analysis was conducted for different satellite data and modeling techniques (e.g. ANN, random forest, linear regression, *k*-nearest neighbor, support vector regression) for aboveground biomass prediction in different forest types (Gao et al., 2018). The results obtained from this study showed that the ANN models were more accurate for mixed, broadleaf and conifer forest types (*RMSE* values ranged 30.0-36.0 Mg/ha, 24.0-26.4 Mg/ha and 28.2-30.9, respectively) than linear regression model (*RMSE* values ranged 32.6-37.0 Mg/ha, 24.4-31.0 Mg/ha and 28.2-32.4, respectively). It is seen that there are few studies to predict the stand parameters using both regression analysis and ANN method. Thus, our

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_52695285

study is one of the rare studies that use both the multiple linear regression and ANN models in estimating of stand parameters using remote sensing data, especially texture values. Therefore, investigating the estimation success of the ANN models using satellite data for stand attributes is essential for further studies.

The ANN models can be suggested as more suitable than regression models for predicting stand attributes such as mean diameter, basal area, stand volume and number of trees using remote sensing data, since the estimation power of the ANN models are higher than the regression models. The texture values might be used successfully as predictor variables in these models. The utilization of different model techniques such as random forest, *k*-nearest neighbor, support vector regression and mixed effect modeling and various satellite data such as optical, active and combined can improve the model achievement criteria in various forest ecosystems.

Abstract. The Buyuk Menderes basin is very wide and the people living here deal with farming, which increases the importance of the river to the region. The pollution of the river increases because the industry, urbanization and agricultural activities are very intense in the river basin. For this reason, the aim of this study is to map the extent of pollution of Buyuk Menderes River, to detect sources causing pollution in the river and also to suggest solutions for taking necessary precautions. Anionic detergent, phosphate, boron and heavy metal concentrations were determined in water samples taken from Buyuk Menderes River in this study. Mean concentrations of anionic detergent, phosphate, boron, copper, chrome, nickel and lead were found 0.2345 mg l^{-1}, 0.0181 mg l^{-1}, 0.8352 mg l^{-1}, 0.0035 mg l^{-1}, 0.0045 mg l^{-1}, 0.0247 mg l^{-1}, 0.0002 mg l^{-1}, respectively.
Keywords: *surfactant, freshwater, nickel, pollution, water quality classes*

Introduction

Rapid population growth, the spreading of industrialization and mechanization of agriculture, cause pollution of the environment and the waters. Pollution is caused by the inability of people to perceive the importance of environmental conditions for life. Due to uncontrolled domestic and industrial wastes and agricultural activities, it is known that pollution reaches important dimensions in many water resources today (Akın and Akın, 2007). Büyük Menderes River is one of Turkey’s important and large river. The River has been polluted by factors such as domestic wastewater, industrial wastewater, excessive, untimely and incorrect use of fertilizer and pesticide. These incidents require investigating pollution levels of the river. For this reason, the aim of this study is to map the extent of pollution of Buyuk Menderes River, to detect sources causing pollution in the river and also to suggest solutions for taking necessary precautions.

There are also detergents among pollutants coming from domestic and industrial wastes to aquatic environments. Detergents are used in general cleaning work. The detergents contain anionic surfactants such as alkyl sulphate or alkyl aryl sulphonate as the main cleaner and other materials that help the cleaning process. Detergents are mixtures of powder, granule, soft consistency or liquid. The detergents cause problems

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_52875298

like disturbing the taste of drinking water, making foam, preventing the water cleaning process, damaging the aquatic organisms by reducing the amount of dissolved oxygen, shortening the aging process of lakes by eutrophication due to phosphate content and damaging the aquatic life (Egemen, 2011).

Approximately half of phosphorus comes from the phosphate in the composition of detergents used in domestic wastewater. 91% of the phosphorus comes from domestic and industrial wastes and 9% from agricultural areas to water resources (Egemen, 2011).

Boron compounds are commonly found in surface and ground waters. The toxic limit value of the boron element is 1.0 mg l^{-1}. This value is determined for plants, animals and humans. Also this value is an acceptable for drinking and irrigation waters and wastewater (Kabay et al., 2006).

Elements like selenium, iron, manganese and cobalt are mixed from the soil to the water. Magnesium, potassium and cobalt are passed from the sea to the air. Toxic elements such as zinc, copper, cadmium, mercury, antimony, arsenic, argon, lead, chromium, selenium mix to the air, water and soil by anthropogenic activities (Samsunlu, 1999).

Materials and methods

The cities of Aydın and Denizli are located in the Aegean region. These cities are important industrial and agricultural centers of Turkey.

The Buyuk Menderes River comes from Afyon, passes through Usak, Denizli and Aydın, reaches to the Aegean Sea. The total length of the Buyuk Menderes is about 584 km and its basin covers 25 000 km^2 (Boyacioglu et al., 2004).

In this research, six stations were determined in the discharge regions in Buyuk Menderes River (*Fig. 1*). The coordinates of the stations were showed in the *Table 1*.

6	Soke	37°42'26.93" N, 27°28'36.62" E

As a research material, water samples taken from six stations were selected. The water samples were taken on a monthly basis. They were collected between July 2012–June 2013. pH, temperature, dissolved oxygen, total dissolved substance and conductivity parameters were measured by TOA WQC (Water Quality Checker) – 20A.

The method in the determination of anionic detergent is based on the spectrophotometric measurement of methylene blue by being dissolved in the chloroform of the blue colored salt resulting from the anionic surfactant reaction (Anonymous, 1995). Orthophosphate phosphorus is determined by measuring the blue-colored phosphomolybdic acid in the spectrophotometer resulting from the reaction with ascorbic acid, ammonium molybdate and potassium antimony tartrate in acidic environment (Parsons et al., 1984). Determination of the amount of boron is based on the spectrophotometer measurement of the color compound formed with the carmin, a specific reagent of the tube (Hatcher and Wilcox, 1950; Anonymous, 2005). Heavy metal analysis of prepared water samples were made in ICP-MS (Inductively Coupled Plasma – Mass Spectrophotometer).

Statistical analyzes were performed using Windows, Graphpad Prism software package. "One-way Anova" variance analysis was applied to detect whether the amounts of anionic detergent, phosphorus, boron and heavy metals showed significant difference among months and stations. "Tukey test" was applied to detect in which stations and months the significant differences.

Result and discussion

In this study, anionic detergent, phosphate, boron and heavy metal concentrations were detected in the water samples from Buyuk Menderes River that flows from Denizli and Aydın cities centers. pH, temperature, dissolved oxygen, total soluble substance and conductivity parameters were measured. On average, pH 8.24, temperature 15.6 °C, dissolved oxygen 6.04 mg l^{-1}, total soluble substance 426 mg l^{-1} and conductivity 470 µS/cm were found. The river water in terms of pH and dissolved oxygen parameters 2nd quality and in terms of all other parameters 1st quality in water class were found, according to the Water Pollution Control Regulation (Official Gazette, 2004) (*Table 2*).

These mean values were compared with the Aboveground Water Quality Regulation "Quality Criteria According to Classes in Terms of General Chemical and Physicochemical Parameters of Coastal Waters" (Official Gazette, 2012). The river water was determined as the 2nd quality in terms of pH and conductivity parameters and the 3rd quality in terms of dissolved oxygen parameter (*Table 3*).

Nickel (µg l^{-1})	20	50	200	>200	**24.7**
Lead (µg l^{-1})	10	20	50	>50	0.2

Table 3. *Quality criteria (Official Gazette, 2012)*

Water quality parameters	**Water quality classes**				**This study**
	1st	**2nd**	**3rd**	**4th**	
pH	6–9	6–9	6–9	6–9	**8.24**
Conductivity (µs)	< 400	1000	3000	> 3000	**470**
Dissolved oxygen (mg l^{-1})	> 8	6	3	< 3	**4.94**

Mean concentrations of anionic detergent, phosphate, boron, copper, chrome, nickel and lead were found 0.2345 mg l^{-1}, 0.0181 mg l^{-1}, 0.8352 mg l^{-1}, 0.0035 mg l^{-1}, 0.0045 mg l^{-1}, 0.0247 mg l^{-1}, 0.0002 mg l^{-1}, respectively. Anionic detergent, phosphate, boron and heavy metal concentrations mean values were presented in *Table 4*. These concentrations were compared with the Water Pollution Control Regulation (Official Gazette, 2004). Buyuk Menderes River is in the class of less polluted water (2nd class) in terms of anionic surfactant and nickel (*Table 2*). Because the Buyuk Menderes River is close to the settlements, it is thought that the discharges are reaching to the river. Due to domestic waste load, the anionic detergent load increases. The average anionic detergent concentration (0.2345 mg l^{-1}) is below the surfactant concentration, which is considered to be ≤ 0.3 mg l^{-1} in European Union quality criteria. The average heavy metal values were compared with the heavy metal concentrations allowed in the irrigation waters specified in the Water Pollution Control Regulation Technical Procedures Bulletin (Official Gazette, 1991) and the metal concentrations were found to be low.

According to the One Way ANOVA test, statistically significant differences were not found for heavy metals, pH, dissolved oxygen, total soluble substance and conductivity ($p > 0.05$) and differences were found for phosphate ($p < 0.05$). Also the difference among the stations was statistically insignificant ($p > 0.05$) and the difference among the months was statistically significant ($p < 0.05$) for anionic detergent and boron amounts (*Table 5*).

The differences among the months and stations were determined by the Tukey test. Tukey test results are shown in *Tables 6, 7* and *8*. Especially in summer, the decline in detergent quantities can be attributed to the decline in population at residential areas as well as the decline in domestic waste loads in these months (*Table 6*). 50% of the amount of phosphorus in domestic wastewater is caused by the detergent-based phosphates used in houses. As a result, the amount of phosphate has decreased in parallel with the decrease in the amount of detergent (*Table 7*). Increase in detergent values in winter months, can be considered as an increase of domestic waste load transport to river with the increase of rainfall. Significant boron differences were showed in May and June (*Table 8*). Boron concentrations were high in May and June. Especially in May and June, together with agricultural irrigation using groundwater resources, abundant amounts of boron in underground waters are mixed in to Buyuk Menderes River.

When we compared the values with the results of other studies which investigated anionic detergent, phosphate, boron and heavy metal levels of Buyuk Menderes, we measured similar values in present study. In the study in Buyuk Menderes River, average copper 0.011 ppm, chromium 0.012 ppm, nickel 0.01 ppm, lead 0.011 ppm, iron 0.006 ppm, mangan 0.09 ppm, zinc 0.051 ppm, cobalt 0.08 ppm were found (Akcay et al., 2003). The average boron value of the Buyuk Menderes River was determined as 0.6 mg l^{-1} in another study. According to all parameters, it was stated that the water was mostly polluted in Saraykoy and Nazilli regions (Kucuk, 2007). Boron content was found to be between 0.33 and 6.41 mg l^{-1}. The boron concentration is high especially in the regions of under ground thermal water resources (Aydın and Seferoglu, 2000). And the boron concentration was found to be 1.1 mg l^{-1} due to geothermal wastewater discharges to the river and river water used for agricultural irrigation affected the production of agricultural products (Akar, 2007). Buyuk Menderes River is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_52875298

in the third class pollution level due to domestic and industrial wastes and agricultural activities (Akın and Akın, 2007).

"Pollution of the Buyuk Menderes is to pollute the future" in the project final report, the mean values were compared with the Water Pollution Control Regulation. Buyuk Menderes River is 2nd class, namely in the class of less polluted water in terms of lead and 1st class, namely it is high quality water in terms of copper, chrome and zinc. It is below the permissible limits when compared with the maximum allowable concentrations of heavy metals and toxic elements in irrigation waters (Durdu et al., 2012).

It is stated that the most serious problems in terms of water quality in rivers in Buyuk Menderes basin are excessive organic matter, nitrogen, pH, boron and heavy metal pollution (Tubitak Mam, 2013).

Isıklı Lake is on resources that feed the Buyuk Menderes River. Isıklı Stream is a branch of the Buyuk Menderes River. Isıklı Lake and Isıklı Stream were determined to be as 2nd class (less contaminated water) in terms of anionic detergent parameter (Cakir and Minareci, 2015). Also in Isıklı Lake, it was found that organic pollution significantly increased and the amount of dissolved oxygen decreased in summer in some stations of the lake. It is stated that the important source that pollutes the lake is Buyuk Menderes River (Bulut et al., 2012). Adıguzel Dam Lake is on the Buyuk Menderes River. Adıguzel Dam Lake was categorized as less contaminated water in terms of anionic detergent parameter (Minareci and Cakir, 2018).

The measured values in the different rivers in the same region are higher than the measured values in our study. The Gediz River is highly polluted surface water in the Gediz Basin. Due to domestic and industrial wastes and agricultural activities, the river is determined as IV. class water quality in terms of nitrogen, organic matter and heavy metals (Akın and Akın, 2007). In the study carried out in Gediz River, copper 0.034 ppm, chromium 0.099 ppm, nickel 0.062 ppm, lead 0.218 ppm, iron 0.121 ppm, manganese 0.053 ppm, zinc 1.181 ppm, cobalt 0.006 ppm, cadmium 0.0036 ppm were found. The river was found dirty in terms of chrome and lead (Minareci et al., 2009a). In another study in Gediz River, boron concentrations are found between 0.19–2.25 mg l^{-1} (Demirbas and Orhun, 2008). The average boron value was 2.428 mg l^{-1} in Gediz River and Gediz River was determined as very polluted water for boron parameter (Minareci, 2014).

In Kucuk Menderes River, copper concentrations 0.01–0.02 ppm, chrome concentrations 0.01–0.02 ppm, nickel concentrations 0.03–0.08 ppm and lead concentrations 0.08–0.12 ppm were found between these amounts (Egemen et al., 2005). In the study conducted by Gundogdu and Ozkan (2006) in Kucuk Menderes River in 2006, it was determined that the iron value is 3rd class water quality. In another study, it has been reported that the Kucuk Menderes River is in the 4th class pollution level in terms of nitrogen, organic matter and heavy metals from domestic and industrial wastes and agricultural activities (Akın and Akın, 2007). It was determined that other heavy metal concentrations except Ni, Cu and Zn were low in surface water of Kucuk Menderes River (Turgut, 2003).

Anionic detergent and heavy metal levels of Berdan Stream have been found higher than the standard levels (Kumbur and Vural, 1989).

The anionic detergent values are shown comparatively in *Table 9*. The obtained phosphate values from Buyuk Menderes River were lower than the obtained values from many other rivers (*Table 10*).

Conclusions and recommendations

The Buyuk Menderes River water is 2nd quality in terms of pH, conductivity, anionic surfactant and nickel parameters. Also the river water is 3rd quality in terms of dissolved oxygen parameter. Because the Buyuk Menderes River is close to the settlements, the discharges reach to the river. Due to domestic and industrial waste load, pollution load increases.

For the sustainable productivity of the Buyuk Menderes Basin lands and the protection of all aboveground and underground waters from pollution,

- The protection of the Buyuk Menderes River from all kinds of pollution (especially domestic and industrial wastes),
- Analysis of surface and groundwater should be done periodically,
- The water not suitable for irrigation should not be used,
- Fertilizer should be used as much as necessary,
- The farmers are directed to organic farming,
- Use of pesticides should be minimized,
- Industrial facilities and local governments should establish and use wastewater treatment facilities,
- The chemical fertilizers and agrochemicals must be controlled by authorized institutions.

As a result, the investigation of the underground and surface water quality of Buyuk Menderes Basin should be continued periodically, the factors that decrease the quality should be revealed and necessary precautions should be taken.

(Received 22nd Jun 2018; accepted 7th Aug 2018)

Abstract. This study aimed to determine the efficacy of two standards strawberry (*Fragaria* x *ananassa* Duch.) cultivars 'Rubygem' and 'Sabrina' grown under protected cultivation system in Mersin province in Turkey. The fruit quality preservation during storage in Modified atmosphere packaging (MAP) at different storage temperatures as well as preservative compatibility under Ultraviolet-C (UV-C), hot water and combined applications were studied. Strawberry fruits kept in cold temperatures (0 °C and 5 °C) for 20 days and biochemical changes (total phenolic content, total antioxidant capacity, vitamin C content and sugar content) were measured after harvest and storage The 'cv. Rubygem' kept its quality for 16 days in all treatments and for 20 days in UV-C and UV-C + hot water applications when kept at 0 °C. Also, the fruits stored at 5 °C kept their quality for 12 days and it was observed that hot water and UV-C + hot water treatments got better results in the same period and at the same storage temperature. In the 'cv. Sabrina' results showed that fruit samples at 0 °C were successfully maintained in control as well as the other 3 treatments until the 12th day. The preservation was continued in UV-C, hot water and combined treatments on the 16th day of the storage and the best ones were the hot water and UV-C + hot water at the end of the 20th day. As a result, it was observed that total phenolic contents, total antioxidant activity and sugar were found decrease at the end of storage for both cultivars while fluctuations in vitamin C.
Keywords: *biochemical changes, hot water, UV-C, sugar, vitamin C, total phenolic, antioxidant*

Introduction

Strawberry (*Fragaria* x *ananassa* Duch.) fruit is consumed abundantly by consumers and has many positive effects (Çağlarırmak, 2006) such as strengthening defense mechanisms and protecting against cancer and infections, protection against DNA damage in the organism (Vinson et al., 2001), protection against cardiovascular disease and lipid peroxidation, because it is rich in antioxidants (Wang et al., 1996; Araque et al., 2018) including anthocyanins, flavanoids and phenolic materials, as well as its unique color, flavor (Gao et al., 2016), aroma, texture, high-order elagic acid (Aybak, 2005).

It is very important to protect the post-harvest quality of strawberries, because they are located in a group of fruit berries that break down quickly and easily after harvest.

The main soluble sugars found in the structure of strawberry berry are glucose, fructose and sucrose, and glucose and fructose are known to dominate sucrose in total sugar content (Cordenunsi et al., 2003).

Strawberry fruit contains as high as 92% water. For this reason, water loss is one of the important issues after harvest. In addition to water loss, a number of insecticides and fungicides are used both on the field and before harvesting to prevent the losses caused by diseases and pests. Applications that are environmentally friendly to prevent postharvest decay include applications such as hypobaric applications (Romanzzi et al., 2001), modified atmosphere packaging (Silva et al., 1999), Ultraviolet-C (UV-C) and hot water applications (Keskin et al., 2014, 2015).

For the last ten years UV-C (180-280 nm λ = 254 nm) in horticulture products has been considered as an alternative to fungicides to control post-harvest diseases. Moreover, many investigators have reported that UV-C protects fruits and vegetables against decay after harvesting (Marquenie et al., 2003; Allende and Artes, 2003; Allende et al., 2006; Keskin et al., 2014, 2015). It has also been used to delay the ripening of fruits and vegetables by extending their shelf life (Darvishi et al., 2012). When UV-C is applied in appropriate dose and duration, it increases the accumulation of phytoalexins (Keskin and Kunter, 2017), which is effective on the mechanism against disease and damage plants (Keskin et al., 2014, 2015). However, there is still a lot of work to be done to optimize UV-C applications.

In recent years, hot water applications have been implemented to increase the shelf life of fruits and vegetables and to reduce the use of chemical substances in the fight against diseases and pests (Lurie, 1998). Hot water applications are made by immersion (Barkai-Golan and Phillips, 1991) or by special hot water spraying (Fallik et al., 1996).

Due to short life time of post harvested strawberry fruit, the effect of modified atmosphere packaging (MAP) with different treatments have been widely considered.

In this study, effects of different postharvest treatments including UV-C and hot water were studied on biochemical changes of two commercially strawberry varieties stored at different temperatures in in MAP (modified atmosphere packaging) condition.

Materials and methods

Cultivars used in research

In the study, ‘Sabrina’ and ‘Rubygem’ strawberry cultivars, which are grown under greenhouse by a private company named Roseland and harvested in similar maturity in Tarsus district in Mersin province in Turkey, were used as research materials.

Strawberry fruit was first pre-cooled at 0 °C for 1 day. Later, the fruits of the same maturity were divided into 4 different groups. The first group of fruits was separated as controls. The second group of fruits was irradiated with 254 nm UV-C (0.25 kJ m^{-2}) with Vilber Lourmat UV-C lamp on both surfaces as 5 min at 20 cm distance. The third group of fruits was kept at 60 °C for 10 seconds in a hot water bath. In the fourth group, both UV-C and hot water applications were applied. Then fruit samples were placed in 250 gr plastic bags.

Fruits were maintained at 0 °C and 5 °C in Van Yüzüncü Yıl University Faculty of Agriculture Department of Horticulture’s cold-air storages with a relative humidity of 90-95% for 20 days.

Total phenolic substance amount and total antioxidant activity

Total phenolic contents in ‘Rubygem’ and ‘Sabrina’ strawberry cultivars were determined by spectrophotometer (Varian Bio 100, Australia) by Folin-Ciocaltaeu calorimetric method (Swain and Hillis, 1959). Absorbance values of the solutions

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_52995310

were read in spectrophotometer (Thermo Fisher Scientific, G10S UV-Vis) at 725 nm wavelength and the total amount of phenolic substance expressed as gallic acid equivalent (GAE) mg kg^{-1} fresh weight (FW).

Ferric Reducing Antioxidant Power (FRAP) (Iron (III) Reduction Antioxidant Power) method was used to determine antioxidant activity (Benzie and Strain, 1996). 300 µ L freshly prepared FRAP reagent [25 mL acetate buffer (300 mmol/L, pH 3.6), 2.5 mL TPTZ (10 mmol/L) in 40 mmol/L HCl, and 2.5 mL $FeCl_3 \cdot 6H_2O$ solution (20 mmol/L) were mixed as required to prepare working FRAP reagent] was warmed to 37 °C, and a reagent blank reading was taken at 593 nm; 10 µ L of each fraction extract solution of an appropriate concentration was then added along with 30 µ L H_2O. The 0–4 min absorbance change ($\Delta A_{593\ nm}$) was calculated for each sample and related to $\Delta A_{593\ nm}$ of a Fe^{2+} standard solution tested in parallel to obtain the FRAP value of each sample. Antioxidant activity values were reported as µmol trolox equivalent (TE) mg^{-1}.

Vitamin C (ascorbic acid)

The method specified by Cemeroğlu (2007) was applied to determine the content of vitamin C. 3 g of the strawberry fruit were weighed and homogenized in 6 ml of 6% metaphosphoric acid, then centrifuged at 12000 rpm for 15 min at 4 °C. In the HPLC (Agilent 1100 series) analyzes, C vitamins C18 (Phenomenex Luna C18, 250 x 4.60 mm, 5 µ) were performed. Readings was carried out in the DAD (DE33225146) detector at a wavelength of 254 nm. L-ascorbic acid (Sigma A5960), prepared at different concentrations, was used to identify vitamin C pick and to determine the amount of vitamin C (Karadogan and Keskin, 2017).

Sugar content

After the fruit samples of ‘cv. Rubygem’ and cv. ‘Sabrina’ were homogenized, a 5 g sample from each replicate was added in 10 ml of 6% metaphosphoric acid and then centrifuged at 15.000 rpm for 15 min at 4 °C. Sugar determinations were made on HPLC (Agilent 1100 series) after filtration through filters with a hole diameter of 0.45 mm in the supernatant sample. For this purpose, Phenomenex Rezex RCM monosaccharide column, 80% acetonitrile and refractive index detector were used as carrier phase. The definitions for sucrose, glucose, fructose and maltose were made using external standards, taking into consideration the structural changes of ‘Rubygem’ and ‘Sabrina’ (Özgökçe, 2016).

Statistical analysis

Experiments were conducted with three replication. The descriptive statistics for the traits studied are expressed as mean and standard error. In terms of these characteristics, factorial (Four Factors) Variance Analysis was performed to determine whether there was a difference between storage period, applications, temperature and cultivars. Following the variance analysis, Duncan test was used to identify the different groups. The statistical significance level was taken as $p < 0.05$ in the calculations and the SPSS statistical package program was used for the calculations.

Results

Total phenolic content

During storage, it was observed that total phenolic contents of the ‘cv. Rubygem’ and ‘cv. Sabrina’ strawberry cultivars decreased at both storage temperatures. In the ‘cv. Rubygem’ strawberry cultivar; the highest total phenolic content at 0 °C was found to be 498.486 mg kg^{-1} with UV-C on day 16 and the lowest value was found in the control group as 247.946 mg kg^{-1} on day 20. At 5 °C, the highest total phenolic content was determined in hot water application on day 8 as 496.054 mg kg^{-1}, while the lowest value was found in the control group with 206.189 mg kg^{-1} on the 12th day.

The highest total phenolic content in ‘cv. Sabrina’ was found to be in hot water application with 515.919 mg kg^{-1} on 8th day and the lowest value was found in UV-C application on the 20th day with 117.405 mg kg^{-1}. At 5 °C, it has been identified that the highest value application was 484.297 mg kg^{-1} with UV-C + hot water application on day 0 and the lowest total phenolic compound value was with UV-C application on day 8 with 385.784 mg kg^{-1} (*Fig. 1*).

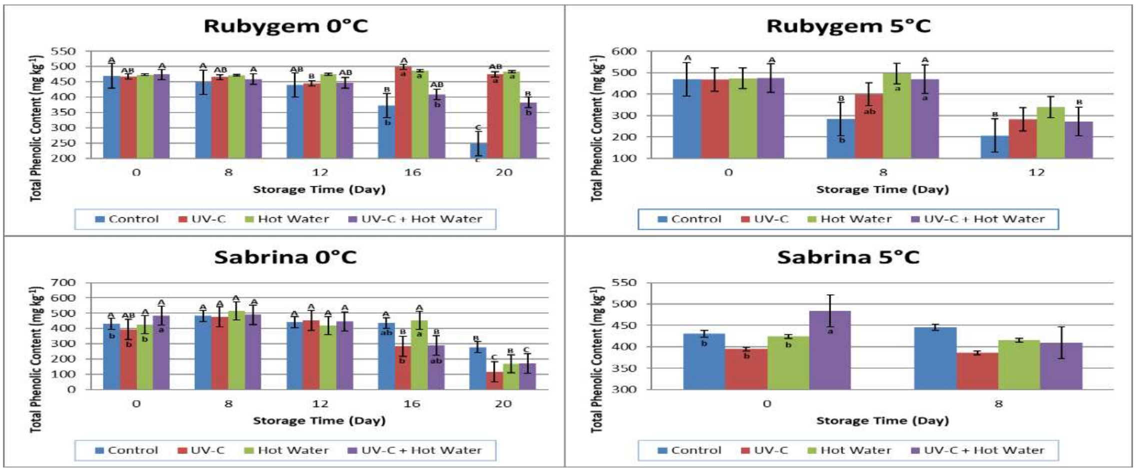

Figure 1. *Changes in total phenolic content as a result of storage of ‘cv. Rubygem’ and ‘cv. Sabrina’ strawberry cultivars at 0 and 5 °C. (a, b, c, d: The difference between the applications of the same kind, same storage period and different lower case letters at the same storage temperature is significant (p < 0.05) [Comparison of applications]. A, B, C, D: The difference between storage times of the same kind, same application and different capital letters at the same storage temperature is significant (p < 0.05) [Comparison of storage periods])*

Total antioxidant activity

Total antioxidant activity was found to decrease at the end of storage at both types and at the storage temperature. Therefore, in the ‘cv. Rubygem’, the highest value in total antioxidant activity at 0 °C was found to be 73.650 mg 100 g^{-1} in the hot water application and the lowest value in the control group with 9.600 mg 100 g^{-1} in the 20th day. The highest total antioxidant capacity at 5 °C was found to be 66.300 mg 100 g^{-1} in hot water at 0th day, and the lowest total antioxidant value in 12th day at 3.250 mg 100 g^{-1} in UV-C + hot water application. The ‘cv. Sabrina’ has the highest antioxidant value at 0 °C, Hot water application with 47.250 mg 100 g^{-1} on the 8th day and hot water application on the 20th day with the lowest value of 6.600 mg 100 g^{-1}. At 5 °C, the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_52995310

highest antioxidant amount was 40.100 mg 100 g^{-1} UV-C + hot water application on day 0, while the lowest was 23.050 mg 100 g^{-1} UV-C on day 8 (*Fig. 2*).

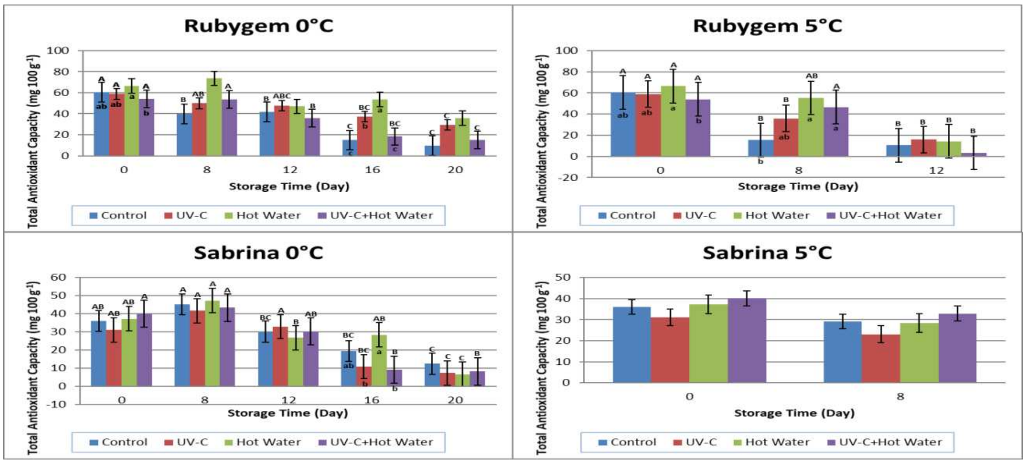

Figure 2. *Changes total antioxidant capacity resulting from storage of 'Rubygem' and 'Sabrina' strawberry cultivars at 0 and 5 °C*

Vitamin C (ascorbic acid)

During storage, fluctuations in vitamin C value are observed. In the 'cv. Rubygem', the highest vitamin C concentration at 0 °C was on 0th day with 343.723 mg 100 g^{-1} and the lowest vitamin C concentration was 16th day with 78.041 mg 100 g^{-1} in UV-C + hot water application. According to analysis results, at 5 °C, the highest value of vitamin C was detected in the application of UV-C + hot water with 343.723 mg 100 g^{-1} on day 0, while the lowest value of vitamin C was in the control group with 32.492 mg 100 g^{-1} on day 8. When the 'cv. Sabrina' was examined, it was determined that the highest value at 0 °C was in hot water application with 382.854 mg 100 g^{-1} on day 0 (*Fig. 3*).

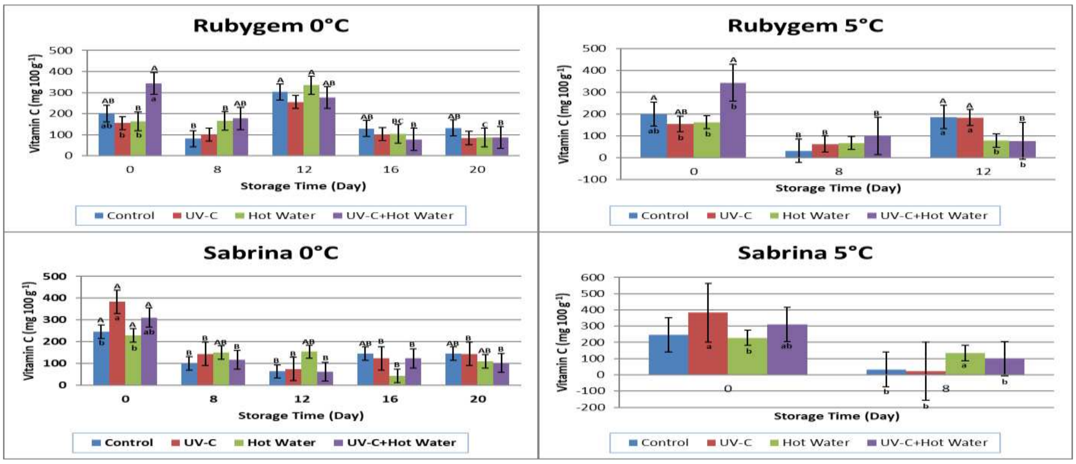

Figure 3. *Changes in the value of vitamin C as a result of storage of 'Rubygem' and 'Sabrina' strawberry cultivars at 0 and 5 °C*

The lowest values were found to be 43.273 mg 100 g^{-1} and 16 days in hot water application. The highest value of C vitamins at 5 °C was found in UV-C application at

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_52995310

382.854 mg 100 g^{-1} on day 0. The lowest value was determined in UV-C application on day 8 with 22.906 mg 100 g^{-1}.

Sugar content

At the end of storage of the 'cv. Rubygem' at 0 °C, the application with the highest fructose value was found in the control group on day 0 with 30.404 mg g^{-1}, while the lowest value was found in the control group on day 20 with 4.180 mg g^{-1}. At 5 °C, the application with the highest fructose content was 30.404 mg g^{-1}, while the lowest value application was with hot water at 3.876 mg g^{-1} on the 12th day. When the variations in the 'cv. Sabrina' at 0 °C were examined, it was found that the highest fructose value was 22.793 mg g^{-1} on 8th day in UV-C application and the lowest value was 1.539 mg g^{-1} on 20th day in UV-C application were determined according to the analysis results. At 5 °C, the highest fructose value was found to be 22.556 mg g^{-1} with UV-C application on day 0 and the lowest value was found with UV-C application on day 8 with 11.372 mg g^{-1} (*Fig. 4*).

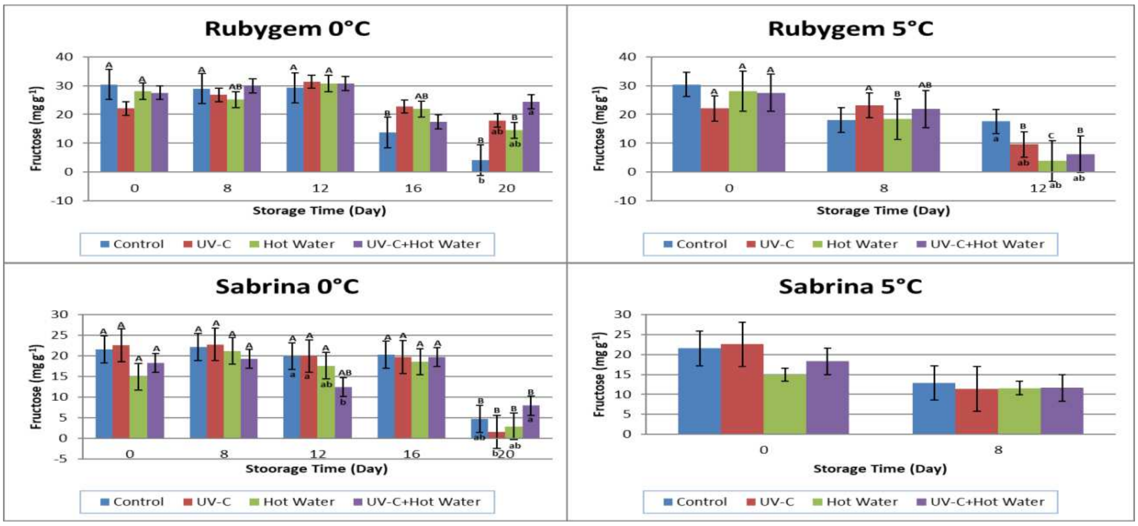

Figure 4. *Changes in fructose values resulting from storage of 'Rubygem' and 'Sabrina' strawberry cultivars at 0 and 5 °C*

Glucose has decreased regularly at both cultivars and storage temperatures. In this context, it has been determined that the lowest values in both cultivars and storage temperatures are in hot water application. As a result of storage of the 'cv. Rubygem' at 0 °C, the highest glucose value was found to be in the control group with 26.539 mg g^{-1} on day 0, while the lowest value was found to be in hot water application with 0.577 mg g^{-1} on the 20th day. The highest glucose value for 5 °C was the control group with 26.539 mg g^{-1} on day 0, while the lowest glucose value was found to be 1.086 mg g^{-1} on the 12th day with hot water application. In the 'cv. Sabrina', it was determined that the maximum value at 0 °C was 16.945 mg g^{-1} in UV-C application on 8th day, while the lowest value was 0.762 mg g^{-1} in hot water on 20th day. The highest glucose value at 5 °C was found to be 16.284 mg g^{-1} in UV-C application on day 0, while the lowest value was found in hot water application on day 8 with 5.676 mg g^{-1} (*Fig. 5*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_52995310

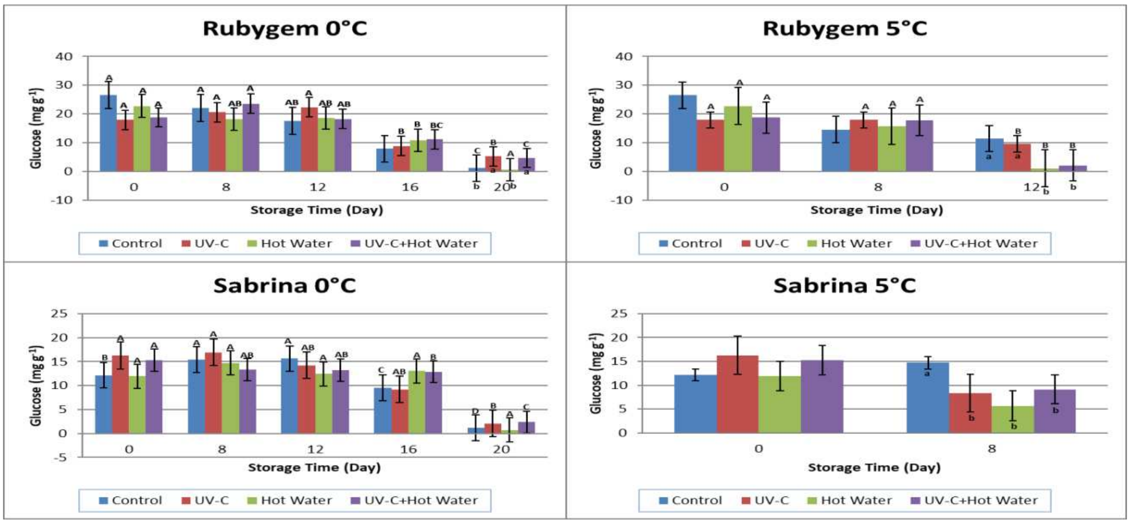

Figure 5. *Changes in glucose values resulting from storage of 'Rubygem' and 'Sabrina' strawberry cultivars at 0 and 5 °C*

When the changes in the sucrose value were examined, it was determined that there were fluctuations in both strawberry cultivars and storage temperatures. In the 'cv. Rubygem', it was determined that the highest value at 0 °C was 0.304 mg g^{-1}, the UV-C + hot water application on 16th day, and the lowest value was UV-C application on day 0 with 0.027 mg g^{-1}. At 5 °C, the highest sucrose level was detected in fruit samples treated with 0.300 mg g^{-1} of UV-C + hot water on day 8, while the lowest value was found to be in UV-C application on day 0 with 0.027 mg g^{-1}. According to the results of the analysis, in the 'cv. Sabrina', the highest sucrose value at 0 °C was found in the control group at 0.466 mg g^{-1} in the hot water application on 0th day and the lowest value application was in the control group on the 16th day with 0.033 mg g^{-1}. The highest sucrose value at 5 °C was determined to be 0.466 mg g^{-1} in hot water application on day 0, while the lowest value was found to be in the control group with 0.094 mg g^{-1} on the 8th day (*Fig. 6*).

Looking at the changes in maltose value, it was determined that the variations for the ‘cv. Rubygem’ were parallel to each other, while the ‘cv. Sabrina’ was found to be fluctuated. In this case, it was determined that the lowest value of the ‘cv. Rubygem’ was at 0 °C, the highest maltose value was in the control group with 29.497 mg g^{-1} on day 0. The lowest value was found in the control group with 4.20 mg g^{-1} on the 16th day. The highest maltose concentration at 5 °C was determined in the control group with 29.497 mg g^{-1} on 0th day, whereas the lowest value application was found to be the control group with 1.178 mg g^{-1} on 12th day. In the ‘cv. Sabrina’, the highest maltose value at 0 °C was found to be 20.094 mg g^{-1} in UV-C application on day 0, while the lowest value was found to be 2.592 mg g^{-1} in UV-C + hot water application on day 8. At 5 °C, the application of the highest maltose value was found to be 20.095 mg g^{-1} on day 0 with UV-C application, while the lowest value was found to be in the control group with 3.285 mg g^{-1} on day 8 (*Fig. 7*).

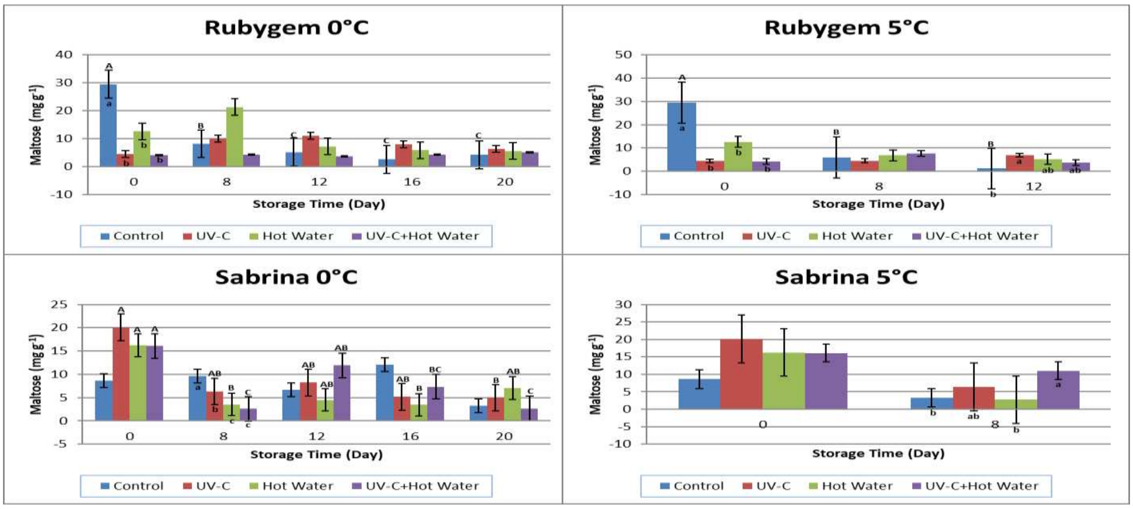

Figure 7. *Changes in the maltose value resulting from storage of ‘Rubygem’ and ‘Sabrina’ strawberry cultivars at 0 and 5 °C*

Discussion

Statistical analysis among different treatments on total phenolic contents in ‘cv. Rubygem’ and ‘cv. Sabrina’ cultivars showed that there was no significant difference in ‘cv. Rubygem’ stored at 0 °C in 0, 8 and 12 days. On the other hand, the difference between UV-C and hot water applications on the 16th day and also difference between control and UV-C + hot water applications on the 20th day was found statistically significant. The difference between the applications of hot water, UV-C + hot water, and control application on the 8th day was found to be significant, whereas the applications on the 0th and 12th day were not statistically significant when considering the differences between applications at the other storage temperature of 5 °C (*Fig. 1*). In the ‘cv. Sabrina’; the differences between the applications on days 8, 12 and 20 were not significant. The difference between UV-C + hot water application on day 0 and UV-C application and hot water application on day 16 were significant. Differences between applications at the ‘cv. Sabrina’ at 5 °C, another storage temperature; UV-C + hot water application was statistically significant at day 0, whereas it was not significant at day 8 applications (*Fig. 1*). In both types and temperatures there was a decrease in the total

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_52995310

amount of phenol in almost all applications. These findings are similar to those of Pan et al. (2004). Results of this study showed that the highest amounts of phenolic substances in 'cv. Rubygem' could be observed at 0 °C storage temperature by using hot water and at 5 °C by using UV-C and hot water treatments. In this study that we have conducted, it has been determined that the application that protects the phenolic materials, which are so important in terms of human health, is hot water application at 0 °C, and UV-C and hot water applications at 5 °C in the 'cv. Rubygem'. In the 'cv. Sabrina', the result is that the hot water application is the best at both storage temperatures. Previous studies have shown that the total amount of phenolics in strawberries depends on the storage temperature and the composition of the atmosphere (Wang and Zheng, 2001; Ayala-Zavala et al., 2004; Cordenunsi et al., 2005). This high phenolic material in strawberries has increased the shelf life of fruit.

Differences in application with respect to total antioxidant capacity; the difference between the 'cv. Rubygem' and the 'cv. Sabrina' stored at 0 °C was statistically significant. The difference between the applications in the 'cv. Rubygem' type stored at 5 °C is significant, while the 'cv. Sabrina' is not significant (*Fig. 2*). Antioxidant substances naturally occur in plants. These plant antioxidants include anthocyanins and phenolic compounds. It was determined that the amount of antioxidant decreased regularly in both cultivars and 4 different applications. When the applications are evaluated on the basis of the amount of antioxidant in the 'cv. Rubygem', UV-C and hot water application is the application that best protects the amount of antioxidant compound at both storage temperatures. In the 'cv. Sabrina', it is determined that UV-C and hot water applications are the best application for strawberry fruit stored at 0 °C and control and UV-C + hot water applications for the fruits stored at 5 °C. The successful results have been obtained in terms of protection of antioxidants, especially in applications that we have made in the 'cv. Rubygem'. The study we conducted is similar to that of Vicente et al. (2004) with a study of grape fruits, indicating that the amount of antioxidants decreased both at the end of storage and that hot water and UV-C treatments were effective.

The comparison of different treatments on amounts of vitamin C showed that in 'cv. Rubygem' at 0 °C, the difference between UV-C + hot water application with UV-C and hot water applications on day 0 was statistically significant. Also, there wer no significant differences among storage days (8, 12, 16 and 20 days). At 5 °C, the difference between applications on day 0 and 12th day of storage were statistically significant, whereas on 8th day was not meaningful (*Fig. 3*). Difference between applications in the 'cv. Sabrina': at 0 °C, the difference between control and hot water applications of UV-C application was statistically significant at day 0, whereas the difference between applications at 8, 12, 16 and 20 days was not significant. At 5 °C, the difference between UV-C and hot water was significant at day 0 and hot water at day 8 and other applications (*Fig. 3*). Vitamin C values during storage: In the 'cv. Sabrina', except for UV-C applications, there was a decrease in vitamin C value at both temperatures and applications. Both types and at both storage temperatures (except for the 'cv. Sabrina' stored at 5 °C) have been the control group that best protects Vitamin C. With this study, both UV-C applications and hot water applications are thought to reduce the amount of vitamin C.

When the changes in sugar content were examined, the difference between the applications of fructose in both types of storage (except the 'cv. Sabrina' at 5 °C) was found to be significant (*Fig. 4*). The difference between the applications at the end of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_52995310

the storage of the ‘cv. Rubygem’ strawberry in terms of glucose was found statistically significant. In the ‘cv. Sabrina’, the difference between applications was not statistically significant at 0 °C. At 5 °C, the difference between treatments was found to be insignificant on day 0, whereas on day 8, control was statistically significant (*Fig. 5*). When the difference between the applications for sucrose value was examined, the difference between UV-C + hot water application and control and UV-C applications on day 0 in the strawberry cultivars stored at 0 °C was statistically significant, while the difference between the practices on the day was not statistically significant on days 8, 12, 16 and 20. When the difference between the applications is examined in the ‘cv. Rubygem’, the difference between UV-C + hot water application and control and UV-C applications was statistically significant on day 0 at 5 °C, whereas the difference between the applications on days 8 and 12 found to be insignificant (*Fig. 6*). The difference between the application of UV-C and UV-C + hot water at 0 °C on the 0^{th} day was found to be statistically significant when looking at the difference between applications for the changes in the value of sucrose in the ‘cv. Sabrina’. On the 8^{th} day, the difference between control and UV-C applications was not statistically significant, while UV-C + hot water application was statistically significant with hot water, control and UV-C applications. The difference between the applications of storage on the 12^{th}, 16^{th} and 20^{th} day was not statistically significant. When the difference between the applications was observed at 5 °C storage temperature of the ‘cv. Sabrina’ fruits, the difference between the applications of hot water and UV-C + hot water on the 0^{th} day was significant, but the difference between the applications on the 12^{th} day was not statistically significant (*Fig. 6*). At 0 °C, maltose content of the ‘cv. Rubygem’ was statistically significant at day 0, whereas applications on 8, 12, 16 and 20 days were not statistically significant. At 5 °C, the control application on 0^{th} day and the difference between control and UV-C applications on 12^{th} day was found to be statistically significant in the ‘cv. Rubygem’ (*Fig. 7*). The difference between the applications in the ‘cv. Sabrina’: While the difference between hot water and UV-C + hot water applications at 0 °C on the 8^{th} day was not statistically significant, the difference between control and UV-C applications of these applications was found statistically significant. The difference between the applications on 0, 12, 16 and 20 days was not statistically significant. At 5 °C, the difference between control and hot water applications with UV-C + hot water application on the 8^{th} day of the ‘cv. Sabrina’ was found to be statistically significant (*Fig. 7*). When fructose, glucose, sucrose and maltose sugar compositions were examined in strawberry fruit, these values decreased in almost all applications at the end of storage. This is why the fruits need energy to perform various reactions inside the cell so that they can survive even when they are picked up. This energy is obtained by using sugars, organic acids and oils present in the fruit. In other words, sugar is used during respiration.

Conclusion

In this study, the ‘cv. Rubygem’ and the ‘cv. Sabrina’ strawberry cultivars were placed in the plastic bags with control, UV-C, hot water and UV-C + hot water applications and stored at 0 and 5 °C, the fruits of the ‘cv. Rubygem’ were successfully preserved in 4 groups of applications until the 16^{th} day and at the end of 20^{th} day UV-C, hot water and UV-C + hot water applied fruit samples were successfully preserved. Changes in the same fruit samples at 5 °C were observed for 12 days and during this

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1604_52995310

period it was determined that hot water and UV-C + hot water treatments could last 12 days at this storage temperature. When the changes occurred at the end of preservation of the 'cv. Sabrina' are examined, it is thought that fruit samples at 0 °C can be successfully preserved in all applications up to 12th day. It has been determined that UV-C application in this cultivar is preserved for 16 days, hot water and UV-C + hot water applications are preserved up to 20 days. It was determined that the 'cv. Sabrina' fruit samples kept at 5 °C lasted for only 8 days. As a result, it was observed that total phenolic contents, total antioxidant activity and sugar were found decrease at the end of storage for both cultivars while fluctuations in vitamin C.
