spring declines yield level. Also, a rise in rain throughout the spring, winter, and summer seasons have a positive impact while its rise throughout the fall shows a negative marginal influence on the wheat yield. The outcomes are somewhat different for maize from the wheat results. Outcomes demonstrated that at available levels of rainfall, a temperature rise throughout summer and spring seasons would increase maize yield, while the same increase in winter and fall seasons would decrease the yield. Besides, analyzing season precipitations for maize showed that spring rain has a positive marginal effect while that of other seasons show a negative marginal effect. Marginal impacts of rice indicated that rising temperature in spring season has a significantly harmful effect on rice productivity. However, the increase in summer, winter and fall temperatures affect beneficially on rice yield. Also, increasing summer and fall precipitation increases rice yield. The annual marginal effects relating to rainfall and temperature for all the crops are positive.

Furthermore, the outcomes ascertained that the cereal production in Iran are less sensitive to rising precipitation levels than rising temperature levels. This difference could be because of application of irrigation to cultivate the crops. Therefore, the impact of rainfall changes on these products is not fully clear. This result has considerable effects for appropriate adaptation processes and strategies. For instance, these outcomes offer that research on breeding for drought tolerance rather than heat tolerance should shape future agricultural research in the country.

The key outcome of the present analysis is that climate variation is beneficial for main cereal crops in Iran. Considering the results of current study, the crops yields will enhance based on the estimation model. Though the current study demonstrates that climate variation does not threaten the agriculture economy of Iran, this event can be hazardous if unsuitable adaptation policies are implemented. Thus, the agricultural strategies must be taking into account for encouraging farmers to use suitable practices and techniques against climate variation. These strategies should help farmers for developing irrigation approaches, select suitable crops, and face with water shortage. Adaptation can be carried out through different methods. First and main one is the extreme challenge, i.e., teaching farmers about the events of climate variation and its effects. Hence, more effective extension programs are required to promote farmers' awareness of climate variation. Certainly, inhibition of damages can occur through more effective farm planning. Crop insurance, different economic bases of areas dependent on agriculture and developed monitoring/predictions of climate will also enhance adaption of crops cope to future variations. These strategies, however, must considered the large seasonal changeability on the response of crops.

Conclusion

The current paper attempts to estimate the impact of climate alteration on cereal production in Iran. Our results suggests that warmer summers are beneficial to all crops studied in the current work. The effect of warmer springs is harmful to wheat and rice but beneficial to maize. Warmer falls are beneficial for wheat and rice but harmful to maize. Wetter spring have a tendency to enhance yields for wheat and maize and wetter summers increase yields for wheat and rice. The key outcome of the present analysis is that climate variation is beneficial for main cereal crops in Iran. Moreover, the research shows that there are limited data on the economic influence of climate variation on agriculture in Iran and further studies and deeper analyses are needed in this field.

(Received 3rd Jul 2018; accepted 31st Aug 2018)

Abstract. Water pollution due to heavy metals has become a critical problem worldwide. In this study, the removal of chromium(III), cadmium and lead by graphene oxide adsorbent was examined. Graphene oxide nanosheets were synthesized through Hummer's method, and their characteristics were examined using FTIR, XRD, and SEM. The effect of independent variables, pH, contact time and initial concentration of solution on the removal efficiency of Cr(III), $Cd^{2+}$and Pb^{2+} was evaluated according to the experimental Box-Behnken Design using response surface methodology (RSM). Applying quadratic model, the adsorption rate of Cd^{2+} and Pb^{2+} was obtained as 99% and the adsorption rate of Cr(III) was obtained as 98%. ANOVA was applied as statistical analysis of responses. According to FESEM images, the average size of graphene oxide sheets was 1 to 3 μm. After optimization by RSM, adsorption capacities of Cr(III), Pb^{2+} and Cd^{2+} were found to be 38 mg/g, 136 mg/g and 68 mg/g, respectively. Examination of isotherms suggested that Cd^{2+} and Cr(III) adsorptions follow Langmuir, and Pb^{2+} adsorption follows Freundlich isotherm. The results showed that graphene oxide has a good effect on removing Cr(III), Cd^{2+} and Pb^{2+} ions from aqueous solutions. pH of the solution and initial concentration of the contaminant had the highest effect on adsorption of the mentioned heavy metals. The results of RSM analysis showed that the obtained data were in agreement with the predicted model.

Introduction

Growth of urbanization, rapid industrialization of cities and emission of heavy metals in the ecosystem - even at extremely low concentrations - have brought up concerns worldwide. Removal of heavy metals from water and wastewater has been at the center of attention owing to strict regulations on water pollution control in many countries (Amarasinghe and Williams, 2007). Lead, chromium, cadmium, zinc, and nickel are among the most water polluting heavy metals (Yang et al., 2014). Conventional methods for the removal of heavy metals from water include chemical oxidation, chemical precipitation, ion exchange, adsorption, filtration, reverse osmosis, solvent extraction and coagulation-flocculation (Rajasulochana

© 2018, ALÖKI Kft., Budapest, Hungary

and Preethy, 2016). Adsorption method is known to be better than other techniques due to high efficiency, flexibility, simple design, low cost, easy operation and minimum sludge production (Fu and Wang, 2011). The most important characteristics for an adsorbent are high adsorption capacity and rapid adsorption. These can be achieved when the adsorbent possesses a large specific surface area and abundant adsorption sites (Wang et al., 2012). Majority of adsorbents rarely have both of the mentioned characteristics. Therefore, an investigation on new adsorbents which can properly adsorb heavy metals is required (Pan et al., 2009). Among the studied adsorbents, graphene oxide nanoparticles, owing to adsorption capacity and large specific surface area, are applied either independently or along with other adsorbents in order to remove heavy metals from aqueous solutions (Liu et al., 2011; McGrail et al., 2016). Considerable physical properties of graphene include heat superconductivity, extremely high electron mobility (Jiang et al., 2010), high mechanical strength (Yu et al., 2008) and adsorption of some metal ions (Hao et al., 2012). Sitko et al. (2013) examined the adsorption of heavy metal ions from aqueous solutions using graphene oxide, and observed that maximum adsorption occurred at pH ranges of 4-8 for cadmium and 3-7 for lead and chromium. Fan et al. (2013) examined a mixture of graphene oxide and magnetic chitosan (MCGO) as an adsorbent and reached a maximum adsorption capacity of 96% for lead ions. Kumar et al. (2014) studied the removal of lead and arsenic using graphene oxide nanosheets and concluded that graphene oxide is highly efficient in removing heavy metals from aqueous solutions. Among the contaminants, chromium(III), cadmium and lead are the most environment-polluting elements since they are widely used in industry. The efficiency of adsorption processes depends on various parameters such as pH, temperature, type of adsorbent, adsorbent dosage and organic or inorganic contaminants (Liu et al., 2011). The water containing high concentration of chromium may cause serious environmental problems and also skin sensitivity, cancer and DNA damage to humans (Tchounwou et al., 2012). Cadmium is categorized as a carcinogenic element, which leads to lung cancer, kidney diseases, digestive and immune system disorders in human bodies (Jaishankar et al., 2014). According to EPA, lead, after entering the body, does not leave the body and precipitates in blood, skin, organs and tissues including muscles, bones and joints (Huang et al., 2014; Li et al., 2007) and causes environmental pollution with severe toxic effects on human health and other creatures (Uluozlu et al., 2008).

The conducted studies show that graphene oxide nanosheets are the most effective adsorbents used for the removal of heavy metals from aqueous environments and soil. The key reason for using graphene oxide nanosheets in this study is their simultaneous possession of several properties.

In this study, the efficiency of graphene oxide nanosheets in removing chromium(III), cadmium and lead from aqueous solutions was examined. The aim of this study was to evaluate the effect of pH, initial concentration and contact time on graphene oxide adsorption capacity. The variables analyzed by response surface method (RSM) were applied according to Box-Behnken design in order to optimize heavy metals removal from aqueous solutions. Also, absorption isotherm was investigated using Langmuir and Freundlich adsorption isotherms.

Materials and methods

Materials and instruments

Chemicals applied in the experiments were lab grade. All the chemicals including nitric acid 65% (HNO_3), sulfuric acid 97% (H_2SO_4), hydrogen peroxide 30% (H_2O_2), hydrochloric acid (HCl), sodium hydroxide (NaOH), sodium nitrate ($NaNO_3$), sodium chloride (NaCl), chromium(III) chloride ($CrCl_3$), potassium dichromate ($K_2Cr_2O_7$), potassium permanganate ($KMnO_4$), lead nitrate ($PbNO_3$) and graphite powder were provided by Merck, Germany. Deionized water was used in all the experiments. Synthesis of graphene oxide nanosheets was done using Hettich centrifuge (Model Universal 320 R), an ultrasonic bath (Elmasonic, E 60H Model, Germany) and a heater (IKA 2000 Model, Germany). Moreover, pH was determined by a pH-meter (pH-Meter 765, Germany), and agitation of the samples was carried out using an IKA-werke-KS260C shaker, Germany. The samples containing Cr(III), Cd^{2+} and Pb^{2+} ions were analyzed through ICP (Inductively Coupled Plasma) Varian-OES-710.

Synthesis of graphene oxide

Using the modified Hummer's method (which is suitable to synthesize graphene oxide), the synthesis of graphene oxide was carried out as follows. Initially, 200 mL concentrated sulfuric acid was poured into a 500 mL glass container and its temperature decreased after stirring in an ice-water bath for 30 min. Then, 4 g of sodium nitrate was added to the solution and its temperature decreased after stirring in an ice-water bath for 1 h. Afterward, 4 g of graphite (500 mesh) was added and mixed for 2 h in this condition. 4 g of graphite (500 mesh) was added to the solution and then mixed for 2 h. During 2 h, 24 g of potassium permanganate was added and stirred. The glass container containing the sample was fixed in an oil bath at 38 to 40 °C for 24 h. After removing the oil bath, 640 mL double distilled water was added to reaction container and stirred for 30 min. The reaction stopped by adding 140 mL hydrogen peroxide 30%. The sample was totally settled after three days. After removing the supernatant, the produced graphene oxide was washed four times using HCl (5%) and then filtered through a buchner funnel. The obtained suspension was washed four times using double distilled water. Then the suspension was treated by ultrasound for 30 min. Finally, the obtained brown solid substance was dried in a vacuum oven at 40 °C (Chaiyakun et al., 2012).

Determination of PZC

In order to examine the heavy metals removal more closely, pH of the zero charge point, where the adsorbent surface is electrically neutral and unladen, and also the adsorbent PZC (pH_{PZC}) were measured (Zhao et al., 2011, 2012). In order to measure PZC, 10 flasks containing 0.1 mol/L NaCl solution were used. The initial pH of the solution was adjusted in the range of 1 to 10 using NaOH and HCl 0.1 mol/L. Then, 0.1 g adsorbent was added to each solution, and the electrolyte solution was stirred with the adsorbent for 24 h. After reaching equilibrium, pH of the solutions was measured, ΔpH graph was drawn according to the initial pH, and pH_{PZC} was estimated.

Characterization of graphene oxide nanosheets

Morphology, size and shape of the synthesized adsorbent were examined using a field emission scanning electron microscope (FESEM model MIRA3, TESCAN).

© 2018, ALÖKI Kft., Budapest, Hungary

Characteristics of graphene oxide nanoparticles were determined using an x-ray diffraction model: X'Pert PRO MPD PANalytical. Fourier transform infrared (FTIR) of graphene oxide in the range of 400-4000 cm^{-1} was analyzed using Bruker, Tensor 27, Germany.

Adsorption experiments

All the experiments were conducted in a batch mode. Initially, the solutions containing Cr(III), Cd^{2+} and Pb^{2+} were prepared by adding a certain amount of potassium dichromate, cadmium nitrate and lead nitrate to 1 L of DI water. In order to study the effect of environmental pH on adsorbing metals within the range of 2-6, 0.05 g/L and 0.02 g/L of the synthesized graphene oxide were added to the lead and cadmium-containing solutions and chromium-containing solution, respectively (the initial concentration was within the ranges of 10-100 mg/L for Cd^{2+} and Cr(III) and 50-150 mg/L for lead, and contact time of 5-60 min was allotted to each metal). The solutions were studied by the presented model and stirred on a magnetic stirrer with a constant speed of 200 rpm for a specified time. Finally, the solutions were stabilized as the mentioned time passed. At the next step, the suspension was filtered by centrifugal method and passed through 0.2 µm filters. The heavy metals concentration after adsorption was measured using ICP. Adsorption efficiencies of Cr(III), Pb^{2+} and Cd^{2+} were calculated by *Equation 1* (Belay et al., 2010).

$$R = \frac{(C_0 - C_e)}{C_0} * 100 \quad \text{(Eq.1)}$$

Moreover, adsorption capacity of the synthesized graphene oxide at various heavy metals concentrations was determined using *Equation 2* (Li et al., 2011).

$$Qe = \frac{(C_0 - C_e)V}{m} \quad \text{(Eq.2)}$$

where, R is adsorption removal efficiency, Qe is the amount of the heavy metal adsorbed onto the adsorbent in equilibrium conditions (mg/g), C_0 is the initial concentration of the heavy metal in solution (mg/L), C_e indicates equilibrium concentration of the heavy metal after equilibrium time elapsing (mg/L), V is volume of the solution in liter, and m is mass of the adsorbent in gram.

Experimental design and data analysis

RSM along with experimental techniques was used to assess the relationship among the effective variables in the experiment (Ghafari et al., 2009). ANOVA was applied as a statistical method for analysis of responses. Response surface method was applied according to Box-Behnken design in order to optimize heavy metals removal from aqueous solutions. This method has several advantages such as reducing the number of test steps, time and cost, and saving the consumption materials. This method is used in this study because it can 1) test several levels of testing with different factors, 2) identify how removal efficiencies are affected by changes in the level of pH, initial concentration and contact time (as factors), and 3) specify the optimized combination of adsorbent pH, initial concentration and contact time for the efficient removal of heavy metals.

In this study, pH of the solution, concentration of contaminants and contact time were chosen as the independent variables affecting the heavy metals removal efficiency and labeled as pH (pH), concentration (conc) and contact time (Time), respectively (*Tables 1A, 2B,* and *3A*). Version 10 of Design-Expert software was used to investigate the effect of independent variables on response surface methodology (adsorption capacity of adsorbent and adsorption efficiency of heavy metals). Designing was carried out using the Box-Behnken design. The number of steps in the experiment was determined using *Equation 3:*

$$N = 2K\left(K-1\right) + C_o \quad \text{(Eq.3)}$$

where, K represents the number of factors investigated and C_o indicates the number of replication for the experiment (Khajeh, 2011). 17 experiments with five replicates at center points were done for each metal. Thus, totally 51 experiments were designed and conducted (Yetilmezsoy et al., 2009). A second-order polynomial regression model equation, which relates the removal efficiency to the investigated factors, can be presented as *Equation 4:*

$$Y = C_{k0} + \sum_{i=1}^{4} C_{ki}x_i + \sum_{i=1}^{4} C_{kii}x_i^2 + \sum_{i<j=2}^{4} C_{kij}x_i x_j \quad \text{(Eq.4)}$$

where, Y is predicted response; C_{k0}, C_{ki}, C_{kii} and C_{kij} are regression coefficients for intercept, linear effects, quadratic effects and double interactions, respectively; and x_i and x_j are coded values of the independent variables (Wu et al., 2012).

In order to evaluate the accuracy of the models, statistical analysis was carried out using ANOVA with p-value ($Prob \leq F < 0.0001$). Adequacy and predictability of the model were examined using lack of fit criterion, R^2 linear regression coefficient of determination, adjusted R^2, adequate precision and residual detection (Wu et al., 2012).

Results and discussion

Characterization of graphene oxide nanosheets

The FESEM images illustrate the morphology of graphene oxide nanosheets (*Fig. 1*). Morphology of the sheet structure of graphene oxide is clear in the images. The size of graphene oxide sheets is approximately 1-3 μm.

As can be seen in *Figure 1,* graphene oxide is semitransparent with some particles and lateral dimensions of several micrometer size and small holes, indicating the production accuracy of the synthesized graphene oxide sheets. FTIR spectra can be categorized into three classes: 2000-4000, 1300-2000 and 800-1300 cm^{-1}. The first class is usually concerned with hydrogen bonded O-H; absorbed H_2O; mostly free O-H; symmetric, dehydration and aliphatic units; and asymmetric stretching vibrations in CH_3, CH_2 or C-H, bonds. The second class includes the most significant oxygen functionalities characterized by N-O and C-O-containing structures. The third class is normally related to various C-O bonds such as those in phenols, hydroxyl groups and ethers (Omar and Moloukhia, 2008). FTIR spectra of graphene oxide nanosheets are indicated in *Figure 2.* For graphene oxide, IR band in the range of 1032 cm^{-1} is assigned to alkoxy C-O groups situated at the edges of the GO nanosheets. In the ranges of 1384

© 2018, ALÖKI Kft., Budapest, Hungary

and 1623 cm^{-1}, it is concerned with carboxyl C-O groups and C=C in stretching vibrations of aromatic structures, respectively. In the ranges of 1694, 2921, and 3422 cm^{-1}, IR band is assigned to stretching CH^2, SP of GO aromatic sheets and OH groups of GO, respectively.

Statistical analysis

The model and the quadratic equation were obtained using the Box-Behnken design. The maximum adsorption capacity of each experiment was finally recorded after adding the specified amounts of graphene oxide; adjusting the pH, concentration and time; and conducting the experiments. In order to examine the heavy metals removal, it is necessary to analyze the input data, output parameters, and optimized values.

The statistical significance of the variables was evaluated by analysis of variance (ANOVA) (*Tables 1C, 2C* and *3C*). The F-value implies that the terms in the model have a significant effect on the response. The p-value (<0.0001) indicates that the terms are significant at the probability level of 95% (*Tables 1A, 2A* and *3A*). The p-value of lack of fit (LOF) was not significant compared to the pure error, suggesting that the model fitted well with the experimental data. Adequate precision gives the ratio of signal to noise. The ratios greater than 4 are desirable. The predicted R^2 was in reasonable agreement with the adjusted R^2, which confirm the accuracy of the model (Hu et al., 2013; Tripathi et al., 2009). Software package of Design-Expert 10 version (Minneapolis, USA) was employed to design the experiments and analyze the obtained data.

Cadmium (Cd^{2+})

The following quadratic model was obtained using BBD and indicates the mathematical relation among the variables involved in Cd^{2+} (*Eq. 5*):

$$Qe = -(16.83) + (2.28 \times \text{pH}) + (0.36 \times \text{Conc}) + (0.35 \times \text{Time}) - (0.022 \times \text{pH} \times \text{Conc}) + (7.153 \times \text{pH} \times \text{Time}) + (0.709 \times pH^2\text{Conc}^2) - (5.85 \times \text{Time}^2) \quad \text{(Eq.5)}$$

Plus signs preceding the parameters represent the synergistic effect of the variable, and minus signs indicate a reduction or reverse effect. When the value of one variable increases due to the rise in that of another variable, a positive correlation coefficient is formed, which represents the synergistic effect. On the contrary, when the value of a variable increases due to the reduction in that of another variable, the correlation coefficient is negative (Talib et al., 2017). Considering the parameters and statistical analysis of the model, the R^2 linear regression coefficient value is high (R^2 = 0.9999)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_67096729
© 2018, ALÖKI Kft., Budapest, Hungary

and it reasonably agrees with the adjusted R^2 value of 0.9999. Consequently, the quadratic model fits the experimental data within the range of operating factors. As the value of R^2 is closer to 1, power of the model will be greater in describing the response variations as a function of independent variables (Zarei et al., 2015). The significance of the predicted model is represented by the F value which equals 16712 for adsorption of Cd^{2+} by the synthesized graphene oxide. The F-value of the model was found to be significant. The value of adequate precision represents the difference between the value of the predicted response and the average value of the prediction error. If this proportion reaches > 4, it will be indicative of adequate signal in the model. According to the results, the mentioned value is 485 for Cd^{2+} adsorption.

Comparative effects of the studied variables on removal efficiency

Figure 4 shows the effect of all the three variables on the removal rate at a point and the response level is visible and comparable in the designing method. Removal efficiency increased with the increase of pH (a) and concentration (b). However, increase in the contact time (c) did not have a significant effect on the value obtained for the heavy metals removal, and a different result was obtained for each metal.

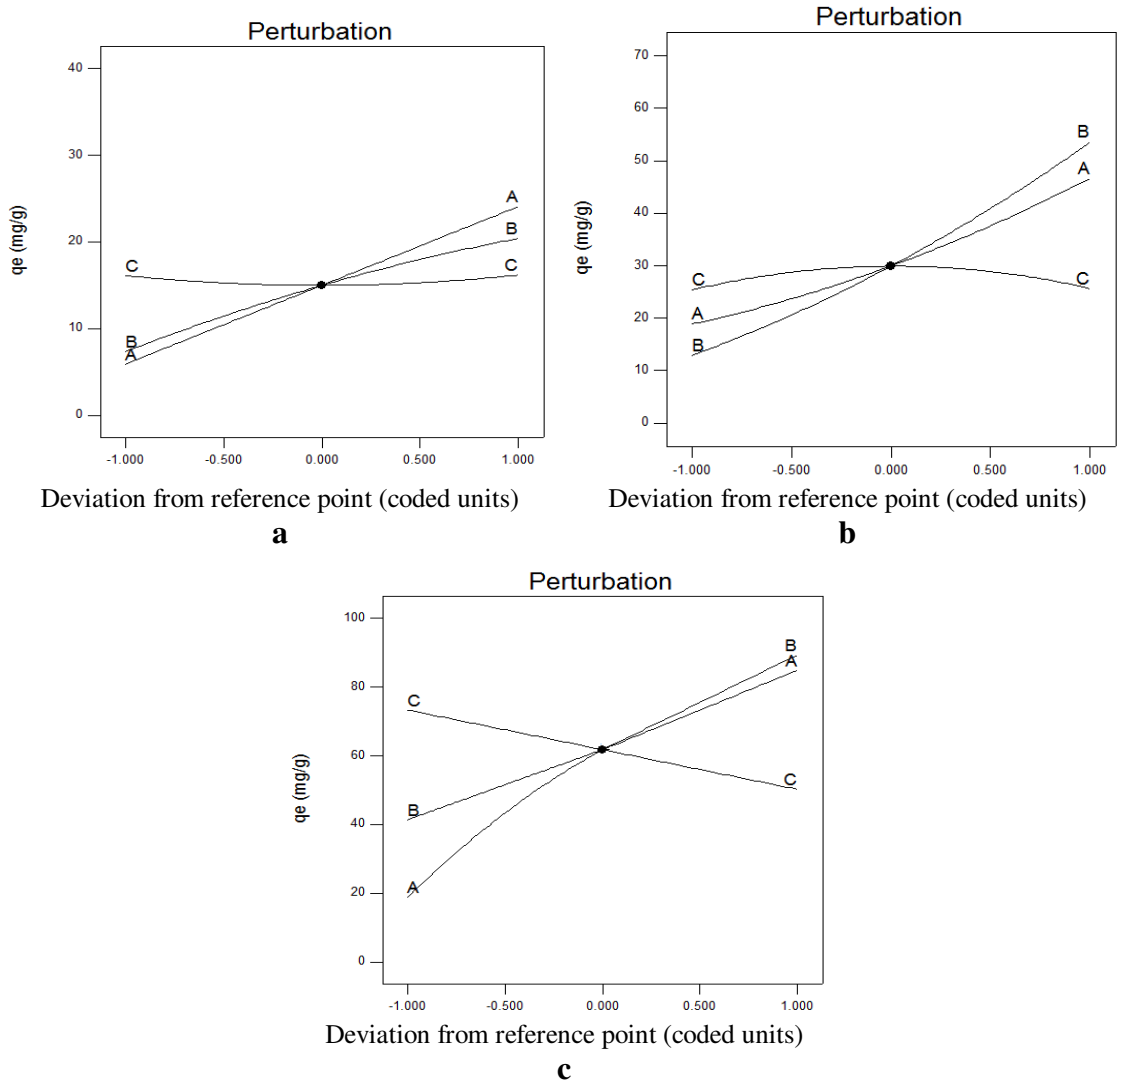

Figure 4. *Perturbation plots of removal by graphene oxide: a) chromium, b) cadmium, c) lead*

Effect of the variables on responses

Effect of pH

pH is a determinant factor in adsorption of Cr(III), Cd^{2+} and Pb^{2+} ions from aqueous solutions (Li and Wang, 2009; Ramkumar et al., 2008). To study the effect of pH on adsorption capacity of graphene oxide, pH of the solution was tested in the ranges of 2-6 for Cd^{2+} and Pb^{2+} and 2-4.5 for Cr(III). Adsorption capacity with contaminant concentration and also the contact time versus pH are illustrated in *Figure 5*. The value

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_67096729
© 2018, ALÖKI Kft., Budapest, Hungary

of pH_{PZC} for synthesized graphene oxide was obtained as 3. When pH of the solution is below 3, the adsorbent surface is positively charged. Any increase in pH leads to change of surface charge from positive to negative. This demonstrates that heavy metals adsorption onto graphene oxide and thereby heavy metals removal are higher in $pH \geq 3$ (Lingamdinne et al., 2008). Results showed that the removal of Cr(III), Cd^{2+} and Pb^{2} by graphene nanoparticles was affected by pH of the solution. In the adsorption process, two ions of OH^- and H^+ are responsible for decomposition (Zarei et al., 2015). For chromium, by raising the initial pH of the solution from 2 to 4.5, the adsorption capacity of graphene oxide increases from 4.5 to 36.5 on a constant trend. As can be seen in *Figure 5a* and *b*, the maximum Cr(III) adsorption occurred at pH = 4.5. Analysis of *Figure 5* indicates that the negatively charged groups on the adsorbent surface and ionization of binding sites in functional groups in the cell wall increase with the increase of pH. Consequently, the removal of Cr(III) ion from aqueous solution and adsorption capacity were increased. Zhang et al. (2018) concluded that pH is the most effective variable in adsorbing chromium, and changes in pH may have a marked effect on kinetic characteristics and adsorption equilibrium. They studied the pH range of 2-11 and demonstrated that the highest adsorption capacity of chromium occurred at the pH range of 3-5 and subsequently the adsorption capacity considerably increased with the increase of pH. Another study was conducted by Jiang et al. (2017) on the effective synthesis of graphite compounds for the effective removal of chromium from aqueous solutions. The mentioned study was carried out in the pH range of 1-9, the initial concentrations of 10-100 mg/L and time duration of 5 to 300 min. The best result was achieved at pH range of 4-6 and concentration of 100 mg/L. By increasing the time from 5 to 180 min, initially the adsorption efficiency increased rapidly and then reached the saturation point (Jiang et al., 2017). According to *Figure 5c* and *d*, the effects of variables on Cd^{2+} adsorption indicate that with the increase of initial pH from 2 to 6, the graphene oxide adsorption capacity increases from 0.2 to 32.2 mg/g. At the first stage, adsorption capacity rapidly increases with the increase of pH from 2 to 4.5. Afterwards, with the increase of pH from 4.5 to 6, the slope of curve constantly increases and the maximum adsorption capacity for Cd^{2+} occurs at pH = 6. According to the tested conditions, cadmium, lead and chromium began to precipitate at pH values greater than 6 and 4.5. Similar results have been reported in other studies, confirming that cadmium and lead begin to precipitate at pH values greater than 6 (Zhao et al., 2011). A study conducted by Sitko et al. (2013) on adsorption of metal ions using graphene oxide revealed that when pH increase from 3 to 4, Cd^{2+} adsorption capacity rapidly increases and becomes constant at pH range of 5-8 (Depci et al., 2012; Zhao et al., 2011). The effects of variables on Pb^{2+} ion are shown in *Figure 5c*. Adsorption increases from 23 to 89.9 mg/g with the increase of initial pH from 2 to 6. At the first step, the adsorption capacity increases quickly with the increase of pH from 2 to 4. Afterwards the adsorption capacity increases with a slight slope with the increase of pH from 4 to 6. According to the results obtained in other studies, Cr(III) and Pb^{2+} adsorptions rapidly increase at the pH range of 2-3, and then the increasing rate slows down (Lingamdinne et al., 2016; Hao et al., 2012). Other studies have shown that most of the Cd^{2+} and Pb^{2+} adsorption processes take place at the pH range of 5.3 to 6, and Cr(III), Cd^{2+} and Pb^{2+} ions start to precipitate at the pH values higher than 6 (Fan et al., 2012; Jafari et al., 2016). As a result, the maximum rate of Pb^{2+} and Cd^{2+} adsorption occurs at pH = 5.5 and the maximum rate of Cr(III) adsorption occurs at pH = 4.5. *Figure 5* indicates the

Effects of initial concentration and contact time on adsorption capacity

The effect of concentration on adsorption capacity in optimum conditions (25 °C) shows that the adsorption capacity of graphene oxide increases smoothly from 63 to 135 mg/g for Pb^{2+} with the increase of initial concentration from 50 to 150 mg/L. Also, with the increase of initial concentration of the solution from 10 to 100 mg/L, graphene oxide adsorption capacity increases from 5 to 38 mg/g for Cr(III) and from 1.2 to 68 mg/g for Cd^{2+}. As can be seen in *Figure 5,* the maximum adsorption rate took place at high concentrations. This can be due to the fact that increase of adsorbent concentration increases the area of adsorbent and facilitates the access to more adsorbed sites, thus increasing the rate of heavy metals absorption. Due to the large number of sites available for absorption and absorption equilibrium in the initial stage of absorption, the adsorption process progresses steadily (Vasudevan et al., 2011). At different initial concentrations of heavy metals, the adsorption intensity was initially constant; however, over time, minor changes happened, and finally, it reached a constant value. Reaching the equilibrium time, the amount of adsorbed ions did not noticeably change over time. According to surface plots, increase of contact time did not lead to a considerable change in adsorption efficiency. Many studies yet have been done about the effect of initial concentration and contact time of adsorbent on the removal of metal ions. In some studies it has been suggested that the optimum contact time to reach the equilibrium condition for the removal of metal ions is less than 60 min (Barassi et al., 2009; Ramana et al., 2012; Sari and Tuzen, 2009). After optimization, the best values for heavy metals were obtained at pH = 6 for Pb^{2+}, and the maximum adsorption capacity of adsorbent reached 136 mg/g in initial concentration of 128 mg/L and contact time of 30 min. However, for Cd^{2+} ion at pH = 6, the maximum adsorption capacity was 68 mg/g in initial concentration of 100 mg/L and contact time of 33 min. Also, for Cr(III) at pH = 4.5, the maximum adsorption capacity was 37.63 mg/g initial concentration of 100 mg/L and contact time of 6 min. In a similar study, the maximum graphene adsorption capacity for lead was found to be 120 mg/g at pH = 5 and contact time of 30 min (Vasudevan and Lakshmi, 2012). Also, in another study, the maximum adsorption capacity for lead was obtained as 101 mg/g at pH = 6 (Awad et al., 2017). In a study conducted by Sitko et al. (2013) on cadmium, the maximum adsorption capacity was 49 mg/g at pH = 5 and contact time of 120 min. In another study, the maximum graphene oxide adsorption capacity for cadmium (88 mg/g) was obtained in initial concentration of 30 mg/L and a contact time of 30 min (Sheet et al., 2014). In this study, the values obtained as the maximum graphene adsorption capacity for Cr(III), Cd^{2+} and Pb^{2+} were consistent with the findings reported in other studies.

Examination of adsorption isotherms

Isotherm is the most important parameter in the design of adsorption systems. It represents the relation between the adsorption capacity of an adsorbent and the adsorbate concentration. The Langmuir and Freundlich adsorption isotherm models are used in this study. Langmuir isotherm is based on monolayer adsorption and homogeneity of the adsorbate with equal energy on the whole surface of the adsorbent. Contrary to Langmuir isotherm, Freundlich isotherm is on the basis of multilayer adsorption and heterogeneity of the adsorbate on the adsorbent (Jamali et al., 2015). The results of adsorption experiments with different pH values, contact times and initial concentrations of heavy metals have been analyzed using Langmuir and Freundlich

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_67096729
© 2018, ALÖKI Kft., Budapest, Hungary

models. The values of adsorption isotherms are obtained using the equations presented in *Table 4*.

Table 4. *Linear equations and isotherm parameters*

Model		Parameters
Isotherm	Langmuir	$\frac{C_e}{q_e} = \frac{1}{Q^\circ b} + \frac{C_e}{Q^\circ}$
	Frendlich	$\log(q_e) = \log(K_f) + \frac{1}{n}\log(C_e)$

In Langmuir and Freundlich equations, C_e represents equilibrium concentration of heavy metals in mg/L; q_e indicates the amount of heavy metals adsorbed in equilibrium time in mg/g; Q° and b are Langmuir parameters related to the maximum absorption capacity and the energy of absorption correlation, respectively; and K_f and n are Freundlich constants which represent adsorption capacity and desirability of adsorption process, respectively. Values of K_f and n parameters are, respectively, determined through intercept and linear regression slope of $\log(C_e)$ versus $\log(q_e)$. In this model, n-values less than 1 indicate weak adsorption. The values between 1-2 and 2-10 represent difficult and desired adsorption, respectively (Jamali et al., 2015).

Referring to *Table 5,* "n" constant values of 1.9 for Cd^{2+} and Cr(III) and 7.4 for Pb^{2+} show the higher fitness of Freundlich model for Pb^{2+}. R^2 values for Cd^{2+} and Cr(III) obtained from Langmuir isotherm are greater than those obtained from Freundlich model, indicating the higher fitness of Langmuir isotherm for Cd^{2+} and Cr(III). However, Freundlich model has a higher fitness for Pb^{2+} ion (*Fig. 6*). Surface adsorption of Pb^{2+} ions takes place onto the monolayer of the adsorbent surface. Adsorption sites are equally and similarly present on the surface area of the adsorbent (Iram et al., 2010).

Table 5. *Values of adsorption isotherm models*

Heavy metals	Langmuir model			Freundlich model		
	R^2	b (L/mg)	q_{max} (mg/g)	R^2	N	K (mg/g) $(L/mg)^{1/n}$
Cr(III)	0.985	21.32	41.32	0.928	1.94	22.84
Pb^{2+}	0.072	0.031	833.33	0.958	7.42	24.46
Cd^{2+}	0.997	0.264	87.71	0.958	1.94	18.23

Conclusion

In the present study, graphene oxide nanoparticles were used to examine the removal of Cr(III), Cd^{2+} and Pb^{2+} which were synthesized by Hummer's method. RSM was used according to the Box-Behnken design to evaluate the effect of independent variables on response function. Properties of the synthesized adsorbent were studied using FESEM, FTIR, and XRD. In FESEM images, the size of graphene oxide sheets was 1 to 3 μm with wrinkled morphology. FTIR spectra were classified into three groups, and it was observed that ranges of alkoxy groups, carboxyl groups, stretching vibration of aromatic, stretching CH_2, aromatic sheets and OH groups of graphene oxide sheets were in agreement with the results of previous studies. XRD spectra exhibited an intense peak at $2\Theta = 11.3^{o}$ for graphene oxide. Some of the effective parameters for the removal of Cr(III), Cd^{2+} and Pb^{2+} were optimized. After optimization, the maximum adsorption capacity of adsorbent reached 136 mg/g for Pb^{2+} at pH = 6, initial concentration of 128 mg/L and contact time of 30 min. However, the maximum adsorption capacity was 68 mg/g for Cd^{2+} ion at pH = 6, initial concentration of 100 mg/L and contact time of 33 min. Also, the maximum adsorption capacity was 37.63 mg/g for Cr(III) at pH = 4.5, initial concentration of 100 mg/L and contact time of 6 min. The high value of R^2 linear regression coefficient was desirable. Values of R^2, adjusted coefficient (Adj. R^2) and predicted coefficient (Pred. R^2) were acceptable. The high value of R^2 linear regression coefficient guarantees the desirability of the presented quadratic equation and is representative of good fitness of the data with the predicted model. According to the results, all linear, quadratic and interaction effects of the variables were significant with a safety factor of 95%, indicating the effect of the variables on Cr(III), Cd^{2+} and Pb^{2+} removal using graphene oxide adsorbents. Adequate precision indicated the noise ratio, and the values greater than 4 represented the desirability of the quadratic equation

model for prediction. Replicability of the model, with C.V value of less than 10%, indicated a good condition. Values obtained from Langmuir isotherm equation for Cr(III) and Cd^{2+} exhibit the maximum fitness of this model with Cr(III) and Cd^{2+}. However, the values obtained from Freundlich isotherm for Pb^{2+} ions showed the maximum fitness of this isotherm with Pb^{2+} ions. The results showed that graphene oxide was effective in removing heavy metals from aqueous solutions. It was concluded that the adsorption process is a function of pH value, initial concentration of the solution and contact time, and graphene oxide can be effectively used to remove heavy metals from polluted waters. Finfings in this study can be applied in the treatment of industrial wastewater. Further studies should be carried out to investigate the efficiency of the proposed method for the removal of heavy metals at lower concentrations.

Abstract. Sweet sorghum has drought resistance, waterlogging resistance, salt and alkali resistance, wide adaptability and excellent resistance to leaf diseases, and is one of China's important food crops, sugar crops and energy crops. In the face of the energy crisis, as an energy crop, sweet sorghum has a high conversion rate of ethanol, which shows an attractive prospect for development and utilization and has attracted the attention of many countries. One of the main indicators to measure the use value of sweet sorghum is its high sugar content, and it is of great significance to increase the sugar content. In this study, we examined the expression of sucrose phosphate synthase (SPS) in leaves of sweet sorghum and sorghum and found the rules of sugar accumulation in sweet sorghum. The effect of SPS gene expression on sucrose accumulation in sweet sorghum and the factors affecting the difference of sugar content between sweet sorghum and sorghum cultivars were studied. The sweet sorghum LTR102 (as the female in this experiment), and common grain sorghum 654 (as the male), and hybrid F5 high and low sugar individuals were used as experimental materials. The gene expression of sucrose phosphate synthase was detected by real-time PCR. According to the qualitative and quantitative analyses of SPS gene, the SPS gene is not only the key factor for the accumulation of sucrose, but also the factor that causes the difference in sugar content between sweet sorghum and common sorghum. At different growth stages, the high sugar individuals showed superiority in sucrose accumulation, SPS activity and SPS gene expression compared to the other three individuals.
Keywords: *quantitative expression, RT-PCR, sucrose content, developmental stage*

Introduction

With the increasing scarcity of fossil fuels and the increasing environmental pollution, biomass energy has become an increasingly attractive alternative to fossil fuels as a renewable clean energy source, reducing greenhouse gas emissions and supporting agricultural development (Guo et al., 2016). The name "sweet sorghum" is used to distinguish those varieties of sorghum (*Sorghum bicolor* (L.) Moench), which accumulate high concentrations of soluble sugars like sucrose, glucose and fructose in the stem juice, from the common grain sorghum (Rao et al., 2013). Sweet sorghum is a C4 plant with a high photosynthetic rate, and has excellent characteristics such as drought resistance, waterlogging resistance, salt and alkali resistance. It has a short growing period, the use of seeds to reproduce and the amount of seeds used is much lower than that of sugar cane (*Saccharum officinarum*), and is suitable for sowing, so the production cost of sweet sorghum is much lower than that of sugarcane (Luo et al.,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

2012; Zhang et al., 2018). Far lower than sugarcane, and suitable for sowing, so the production cost of sweet sorghum is much lower than sugarcane. And a lot of research has been carried out and will create economic benefits (Luo et al., 2012). At present, sweet sorghum is one of the most promising renewable energy sources. In recent years, sweet sorghum as a sugar crop, feed crop, energy crop and industrial crop has important significance for global economic development and environmental protection (Zhao et al., 2015; Jiang et al., 2012; Tang et al., 2012). Although sweet sorghum varieties have important agronomic traits and invaluable economic values, the high sugar metabolism-related genes have been little known so far (Li et al., 2014). Thus, it is great significance to understand the accumulation pattern of sugar in sweet sorghum and to investigate the effect of SPS gene expression on sucrose accumulation in sweet sorghum and the differences in sugar content between sweet sorghum and sorghum.

Sucrose-phosphate synthase (SPS, EC 2.4.1.14) is a key enzyme in sucrose biosynthesis in both photosynthetic and nonphotosynthetic tissues of plants. It is encoded by different gene families. SPS exists in multiple forms which show differential distributions and functional specializations in the plant tissues. The expression of SPS was higher in sugarcane as compared with maize (*Zea mays* L.), while in contrast no PCR amplification was obtained with the Arabidopsis plants (*Arabidopsis thaliana* (L.) Heynh.) (ElSayed, et al., 2013). At the transcript level, the rice (*Oryza sativa* L.) SPS genes, particularly SPS1, were preferentially expressed in source tissues. Diurnal changes in SPS gene expression, SPS activity, and soluble sugar content in leaf blades were investigated. The expression of all the SPS genes, particularly that of SPS1 and SPS11, tended to be higher at night when the activation state of the SPS proteins was low, and the mRNA levels of SPS1 and SPS6 were negatively correlated with sucrose content. The temporal patterns of SPS gene expression and sugar content under continuous light conditions suggested the involvement of endogenous rhythm and/or sucrose sensing in the transcriptional regulation of SPS genes (Okamura et al., 2011). The association among sucrose content, tree phenology and elevated SPS gene expression also implicates both enzyme and product in regulating poplar developmental processes (Park et al., 2009). SPS activity is highly regulated by hierarchy of mechanisms including transcriptional control (Taneja and Das, 2014). Therefore, to understand the accumulation and metabolism of sugar in plants, it is essential to study the regulation of SPS and gene expression.

Real-time PCR (real-time quantitative PCR technology) can quantify the initial template, it is simple and quick to operate, with strong specificity and high sensitivity. Because the entire process does not require post-processing of PCR products, it can effectively prevent contamination and false positives in the detection process, greatly improving the detection efficiency, and fluorescence quantification can also prevent non-specific amplification by melting curves, probes, etc. Thus, real-time PCR has the tendency to replace conventional PCR. It refers to the addition of fluorescent groups to the PCR reaction system, real-time monitoring of the entire PCR process using fluorescence signal accumulation, and finally the quantitative analyses of unknown templates using standard curves (Hou, 2009). Okamura et al. (2011) investigated the tissue- and developmental stage-specific expression patterns of the rice SPS gene family using real-time RT-PCR techniques. The diurnal changes in SPS gene expression and activity in leaves were also examined. Based on the results presented, predictions of the key transcriptional regulator of each SPS gene were discussed. Therefore, RT-PCR technology plays an important role in the determination of SPS enzyme activity.

For sweet sorghum, sugar content is an important trait indicator. The study of the correlation between the changes of SPS activity and gene expression and sucrose content is the theoretical basis to find out the factors influencing sugar sorghum accumulation in sweet sorghum. In this study, the relationship between SPS activity and gene expression patterns and sugar accumulation was studied, which provided the theoretical basis for the selection and breeding of sweet sorghum new varieties and the determination of the best harvest stage.

Research design and methods

Plant material

Sweet sorghum LTR102 (as the female parent in this experiment), common grain sorghum 654 (as the male parent) and F5 high and low sugar plants from the cross of the first two were supplied by Liaoning Academy of Agricultural Sciences. Through subculture techniques, the genotypes were continuously purified to screen for high sugar varieties. Three replicates of each treatment were sampled to extract the sugar and determine the sugar content at the seedling stage, jointing stage, heading stage and mature stage.

Determination of SPS activity

The sample (1 g) was homogenized to a fine powder in pre-chilled mortar and added to 2.5 mL phosphate buffer (twice). These supernatant liquor were collected after centrifugation at 10,000xg (4 °C) for 15 min, the reaction mixture contained in a final volume of 50 μL supernatant liquor, 50 μL phosphate buffer, 20 μL $MgCl_2$, 20 μL UDPG and 20 μL 6-phosphate fructose. Then, vibrated it and incubated the tubes for 30 min in a water bath at 30 °C. The reaction was stopped by the addition of 200 μL of NaOH and the tubes placed in a water bath at 100 °C for 10 min. After cooling the tubes to room temperature, the tissue sample was added to 1.5 mL HCl (30%) and 0.5 mL resorcinol and then, the tubes placed in a water bath at 80 °C for 10 min. After cooling the tubes to room temperature, absorbance was measured at 480 nm.

Total RNA extraction and cDNA synthesis

Total RNA was extracted by improved Trizol method. The leaf tissue was homogenized to a fine powder in liquid nitrogen. And then added 1 ml Trizol to each 50-100 mg of tissue, the sample volume should not be exceeded 100 μL at room temperature for 5 min. Then, the leaf tissue was added 0.2 mL chloroform to the tubes and vibrate it for 15 s, static cultivation at room temperature for 5 min. These supernatant liquor were collected after centrifugation at 12,000xg (4 °C) for 15 min and then, collected the supernate into tubes. The samples were added 0.5mL isopropanol at room temperature for 5 min. These samples were collected after centrifugation at 12,000 g (4 °C) for 10 min and then, the supernatant liquor was discarded. The precipitate was added 1 mL ethanol to the tubes to dissolve RNA precipitate. Similarly, the samples were collected after centrifugation at 12,000xg (4 °C) for 5 min. If it used for reverse-transcription PCR, repeat the above steps twice (discard supernatant liquor and dissolve RNA precipitate). Dried for 5-10 min at room temperature. Then dissolved the sample by TE (30-60 μL). Then take analyses of the extracted RNA purity and RNA

© 2018, ALÖKI Kft., Budapest, Hungary

integrity. RNA samples that were diluted 100-fold or 200-fold with RNase to solubilize RNA samples. Absorbance was measured at 260, 280, 230 nm.

Determine the RNA concentration of the original sample: RNA μg/μL = A(260, 280, 230) × 33 × T / 1000. A: Absorbance; T: Dilution times.

After electrophoresis on a 1.0% agarose gel at 90 V for 45 min, the clarity and integrity of the RNA bands were visualized on a gel imager.

Design of SPS primers

Based on the known cDNA sequence of a sweet sorghum SPS3-1 gene coding region (Liu, 2009), primers were designed using Oligo6 software and Primer primier software (Zhang et al., 2004). And it was named SPS-1, β-Actin is the housekeeping gene *(Table 1)*.

Table 1. *Primers for SPS gene amplification*

Primer	Length of primer (bp)	TM	Primer sequence	Amplified length
SPS-1 forward primer	20	58	GGCAAGAAATAGAAGAGCAG	121bp
SPS-1 reverse primer	20	58	ACCATACGAGGCATAAAACG	
Actin-F forward primer	20	58	AGATGGTGTCAGCCACACTG;	210bp
Actin-R reverse primer	20	58	CGAGCTTCTCCTTCATGTCC	

Quantitative PCR systems and conditions

RT-PCR was used to determine the expression of SPS in sweet sorghum. RT-PCR was performed with primers according to *Table 1*. The RNA from all sample was reverse transcribed using QuantiTect Reverse Transcription Kid, primed with 50 pmol of reverse primer (Oligo dT) by following the manufacturer's protocol and carried out in a PTC 100 Peltier Thermal Cycler (MJ Research, Ramsey, MN, USA).

The PCR reaction was performed in a volume of 25 μL containing 10×Buffer (2.5 μL), 25 mg/mL $MgCl_2$ (2.5 μL), 100 μmol/L dNTP (0.5 μL), 5 U/μL Taq enzyme (0.5 μL), 0.2 μmol/L Forward Primer (1.0 μL), 0.2 μmol/L Reverse Primer (1.0 μL), cDNA template (1.0 μL), and sterile ddH_2O added up to the final volume.

This PCR program was performed with initial denaturation at 94 °C for 2 min, (denaturation 94 °C 30 s → annealing 53 °C 20 s → extension 72 °C 80 s) 32 cycles → extension 72 °C 10 min and saved at 4 °C (Yao et al., 2009; Li et al., 2007).

Detection of the expression of SPS using real-time quantitative PCR

Correlation analyses of SPS gene and housekeeping gene expression

In this experiment, Comparative Delta-delta Ct method was used for relative quantitative analyses of the target gene. Dilution of cDNA into 5 gradients (2^2, 2^4, 2^5, 2^6, 2^7), using SYBR Green I real-time PCR of target gene SPS and housekeeping gene β-actin. Create the standard curves for two genes and detect amplification efficiency. By calculating the difference between the two standard curves M (slope) is less than 0.1, it is proved that the relative quantitative analyses can be used.

Real-time PCR reaction system and conditions

The PCR program was performed with initial denaturation at 95 °C for 15 min, ten cycles of 94 °C for 20 s, 53 °C for 20 s, 72 °C for 80 s with 35 cycles and final 53-95 °C extension for dissolution curve program. Three replicates of each treatment were sampled to set no template negative control. The PCR product was analyzed and subjected to 1% agarose gel electrophoresis to determine the product specificity. The experimental data was processed and analyzed by SPSS software.

Results

Correlation analyses of SPS activity and sucrose content

By measuring the activity of SPS in the leaves of the male and female parents, and the F5 high sugar population and the low sugar population they hybridize, we can understand the changes of SPS among different groups in different periods. The variation of SPS was increased. At the mature stage, the activity of three sweet sorghum varieties (the female parent, high sugar individuals and low sugar individuals) reached the maximum of 14.86, 17.63, 13.76 μmol/h.g.fw, respectively. The SPS activity of the male parent at the mature stage was more minor than the heading stage. In spite of the SPS activity of four species was similar at the seedling stage, the large differences in SPS activity from the jointing stage. The SPS activity of the cross of the high and low sugar individuals grew linearly, the rate of increase in activity was faster than that of the parents and high sugar varieties had the highest SPS activity at mature stage. Analyses of correlation for sucrose and SPS activities in leaves in sorghum and sweet sorghum showed that sucrose was significant positive correlation with SPS activity ($R = 0.763$, $P < 0.01$) (*Fig. 1*).

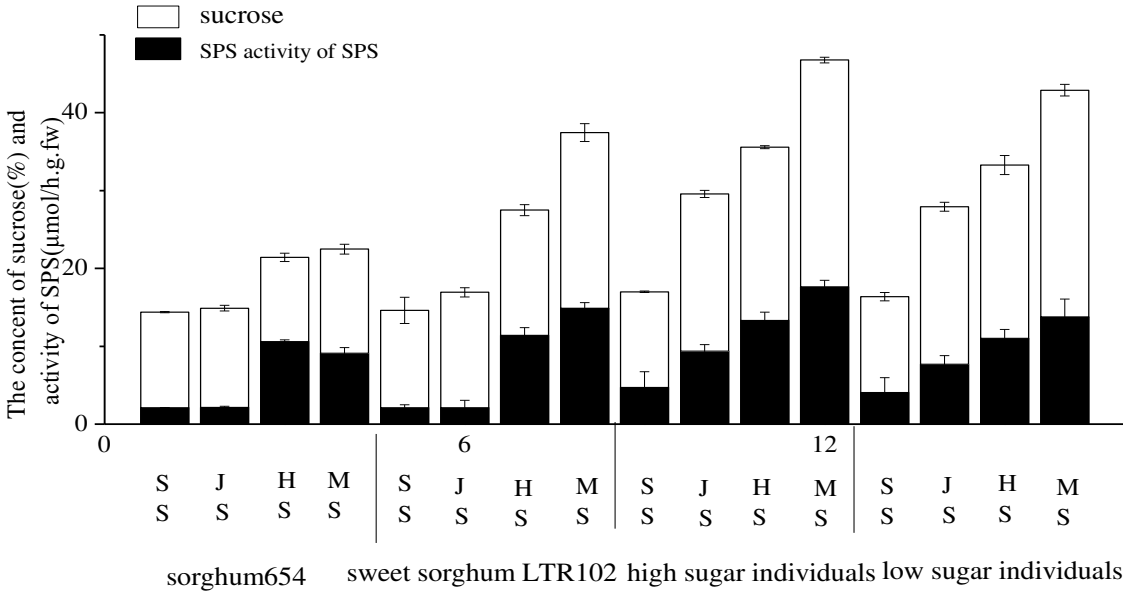

Figure 1. *The relationship between the activity of SPS and sucrose of different group at different growth stages (SS: seeding stages; JS: jointing stages; HS: heading stages; MS: mature stages)*

Analyses of extraction results of RNA

Agarose gel electrophoresis showed that the RNA extracted by the modified Trizol method had three bands, and the brightness of the 28S bands in the total RNA was about twice that of the 18S band, indicating that it was less degraded during the extraction process. The integrity of the extracted RNA was intact, indicating that the RNA was not contaminated and could be used as a template in the next experiment (*Fig. 2*).

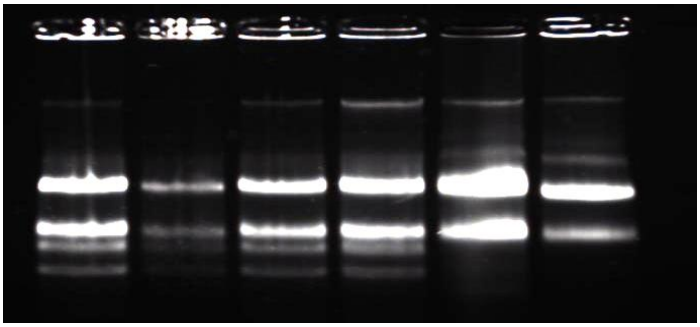

Figure 2. *1% agarose gel electrophoresis of total RNA extracted*

Qualitative analyses of SPS gene expression

At the seedling stage, parents, the SPS gene expression of F5 high and low sugar leaves (*Fig. 3*). In the figure, bands 1 to 4 were used as templates for the cDNAs of paternal, maternal, high-sugar and low-sugar individuals, and β-Actin was a PCR product amplified by primers. The fragment length was about 210 bp. The bands 5 and 6 were used as templates for the cDNAs of the paternal, maternal, high- and low-sugar individuals, and SPS-1 was a PCR product amplified by primers. The fragment length was 121 bp. At the seedling stage, the SPS gene has already begun to express.

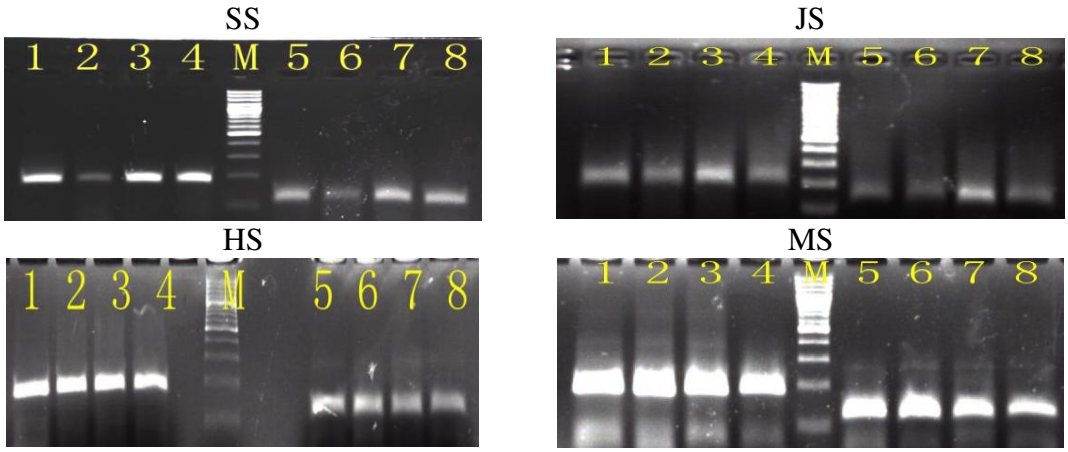

Figure 3. *The electrophoresis of SPS gene and housekeeping genes at developmental stages [top left: SS (seeding stages); top right: JS (jointing stages); bottom left: HS (heading stages); bottom right: MS (mature stages)]*

At the jointing stage, parents, the high sugar individuals showed strong expression, and the SPS gene expression of the paternal parent at the jointing stage was not as

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_67316740
© 2018, ALÖKI Kft., Budapest, Hungary

strong as high sugar individuals. At the heading stage, the brightness and thickness of the target fragment were stronger than those of the previous two stages, indicating that the expression level of the SPS gene was greater than that at the seedling stage and the jointing stage. At the mature stage, the degree of brightness and thickness of the target fragment reached the maximum, which fully demonstrated that the expression level of SPS gene reached a large value during the mature stage (*Fig. 3*).

Using β-Actin and SPS-1 as primers, the desired target fragment can be amplified with clear. From *Figure 3* we can see that the SPS gene can be detected at the seedling stage. With the extension of the growth period, the expression level of SPS gene gradually increases, and the expression level reaches the maximum at the mature stage. This is similar to the variation of sucrose content, and it can be initially demonstrated that the expression of SPS affects the accumulation of sucrose. On the basis of RT-PCR detection was performed to more accurately understand the change pattern of SPS gene.

Quantitative analyses of SPS gene expression

Comparative analyses of quantitative expression of SPS gene at seedling stage

Relative quantitative analyses of SPS gene expression in the parental, F5 high and low sugar individuals at different growth stages was performed using the Comparative Delta-delta Ct method. In comparison with the relative concentration of SPS gene in female leaves, the relative concentration of SPS gene in the high-growth individuals at the seedling stage was higher, which was 1.59 times that of the parental SPS gene. The relative concentration of the parental SPS gene was the minimum and was only half of the parental SPS gene expression *(Table 2)*.

Table 2. *The comparison of different breeds of the SPS gene expression at seedling stage*

Replicate name	GOI CT	Norm. CT	Delta CT	Delta-delta CT	Relative conc.	Calibrator
Male parent	25.44	20.30	5.14	0.88	0.54	
Female parent	27.09	21.97	5.12	0.00	1.00	Yes
High sugar	26.15	21.70	4.45	-0.12	1.59	
Low sugar	25.59	20.51	5.07	0.36	1.03	

Comparative analyses of quantitative expression of SPS gene at jointing stage

At the jointing stage, the relative concentration of SPS gene in the female parent leaves was also used as a control. The parents, F5 high sugar and low sugar plants had little difference in expression at this stage. The highest SPS gene expression level in the high-sugar individual was only 1.25 times that of the minimum low-sugar individual (*Table 3*).

Table 3. *The comparison of different breeds of the SPS gene expression at jointing stage*

Replicate name	GOI CT	Norm. CT	Delta CT	Delta-delta CT	Relative conc.	Calibrator
Male parent	25.44	20.3	5.14	0.24	0.84	
Female parent	27.09	22.19	4.9	0	1.00	Yes
High sugar	26.37	21.45	4.83	-0.07	1.05	
Low sugar	25.59	20.52	5.07	0.18	0.88	

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_67316740
© 2018, ALÖKI Kft., Budapest, Hungary

Comparative analyses of quantitative expression of SPS gene at heading stage

The relative concentration of SPS gene in the paternal leaves was the minimum, and the expression levels in the other three individuals were not significantly different. This indicated that the difference in expression levels of SPS genes between sweet sorghum and sorghum increased from the heading stage. The expression level of SPS gene in sweet sorghum was about 2 times higher than that of sorghum (*Table 4*).

Table 4. *The comparison of different breeds of the SPS gene expression at heading stage*

Replicate name	GOI CT	Norm. CT	Delta CT	Delta-delta CT	Relative conc.	Calibrator
Male parent	24.28	19.09	5.19	0.88	0.54	
Female parent	24.39	20.27	4.31	0.00	1.00	Yes
High sugar	24.46	20.62	4.19	-0.12	1.08	
Low sugar	24.62	19.96	4.66	0.36	0.78	

Comparative analyses of quantitative expression of SPS gene at mature stage

At the mature stage, the relative concentration of SPS gene in the female parent leaves was used as a control. Parents, F5 high-sugar and low-sugar populations had different expression levels at this stage. The expression level of the SPS gene in the maximum high-sugar individual was approximately 15 times that of the minimum low-sugar individual (*Table 5*).

Table 5. *The comparison of different breeds of the SPS gene expression at mature stage*

Replicate name	GOI CT	Norm. CT	Delta CT	Delta-delta CT	Relative conc.	Calibrator
Male parent	27.65	21.96	5.69	1.31	0.40	
Female parent	26.48	22.11	4.38	0.00	1.00	Yes
High sugar	26.07	24.28	1.80	-2.58	5.98	
Low sugar	28.52	23.80	4.73	0.35	0.78	

In summary, the relative concentration of maternal SPS gene was used as a control at each stage. The maximum expression level was high-sugar individuals, and the minimum expression level was the male parent. The order of SPS gene expression from high to low was high-sugar individuals, maternal, low-sugar group and paternal. At the mature stage, this change trend is similar to the accumulation pattern of sucrose and the change of SPS activity. It can be seen that the expression of SPS gene influences the accumulation of sucrose, and the higher the expression level of SPS gene, the higher the sucrose content.

In the test materials selected for this experiment, the male parent was the pure sorghum or hybrid sweet sorghum. At the maturing stage, the SPS gene expression was lowest in the male parent leaves, and it was up to 15 times higher than the high-sugar individual with the maximum expression. It is further explained that the difference in sucrose content is one of the causes of the difference in sugar content between ordinary sorghum and sweet sorghum.

Discussion and conclusion

Sweet sorghum is an important sugar crop. The accumulation of sweet sorghum sugar is mainly based on sucrose. Comparing the gene expression levels of SPS at different stages of different varieties of sweet sorghum has important significance for increasing the sugar content of sweet sorghum (Ye et al., 2012). In this experiment, the improved Trizol method can propose high-quality, non-polluting RNA easily and rapidly. The qualitative analyses of the sweet sorghum SPS gene revealed that the spectrum detected at the mature stage was the most distinct, and the SPS gene expression reached the maximum level during the mature period. The correlations between sucrose and SPS activity in leaves of sorghum and sweet sorghum were analyzed. The results showed that there was a significant positive correlation between sucrose and SPS activity, and it could be initially proved that SPS gene expression was a factor affecting sucrose content.

The experiment of RNA extraction must always be careful not to degrade RNA (Zong et al., 2011). Compared with conventional PCR technology, real-time fluorescence quantitative PCR technology has high sensitivity, specificity, reproducibility, fast and simple operation, and can directly perform qualitative analyses and quantitative analyses (Liu et al., 2011). Real-time PCR technology is a very effective experimental method and has been widely used in molecular biology, genetic engineering, medical diagnosis and other fields (Ren et al., 2007). In this experiment, by analyzing the correlation between SPS gene and housekeeping gene expression, the dissolution profiles of the two genes were single peaks, indicating that the specificity of the reaction and accurate in the PCR amplification process and there are no non-specific amplifications and primer dimers. It is an ideal dissolution curve, indicating that the selected primers can be applied to Comparative Delta-delta Ct method relative quantitative analyses of parental, F5 high glucose and low sugar populations at different growth stages of SPS gene expression.

By comparing the changes of the relative concentrations of SPS gene in female parent at different growth stages, it can be seen that the change pattern of SPS gene in sweet sorghum is consistent with the variation law of sucrose content and SPS activity, and both of them reach the maximum value at mature stage. Yekai et al. (2012) showed that the highest value of the sorghum SPS enzyme activity appeared in the maturity stage of No. 9, which was consistent with this experiment. The correlation analyses of sucrose and SPS gene relative concentrations in leaves of sorghum and sweet sorghum showed that the relative concentration of sucrose and SPS gene was positively correlated. By understanding the changing pattern of SPS genes and providing theoretical basis for determining the selection and breeding of new sweet sorghum varieties. It is great significance to understand the laws of sugar accumulation in sweet sorghum, the principle of SPS, metabolism and regulation. It is also possible to breed sweet sorghum varieties with high sugar content to guide production practices and have good reference for other crops.

Abstract. The current study was aimed at screening allelopathic potential of *Lantana camara* L. against some noxious weeds (i.e. *Phalaris minor, Avena fatua, Chenopodium album, Euphorbia helioscopia* and *Rumex dentatus*) of wheat crop. The screening test of these weeds was carried out in laboratory on filter paper, soil and agar by three solvent extracts (viz., aqueous, hexane and methanolic) and sandwich method. The methanolic *L. camara* extract significantly suppressed germination percentage of *E. helioscopia*, *P. minor R. dentatus* and *A. fatua* measuring at 65%, 63%, 61% and 60%, respectively. Likewise, *L. camara* significantly suppressed radical length of *A. fatua*, *P. minor and C. album* with 54%, 53% and 52%, respectively compared to the control. Besides, plumule length of *E. helioscopia*, *C. album, R. dentatus* and *A. fatua* was also inhibited at 56%, 55%, 53% and 53%, respectively by *L. camara* methanolic extract. It can be concluded that *L. camara* methanolic extract significantly reduced seed germination, radical and plumule length of selected weeds and have potential to be used in further detailed evaluation for searching bioherbicide from this plant.
Keywords: *allelopathic activity, bio-herbicide, filter paper, noxious weed, sandwich method, screening test, wheat*

Introduction

Wheat (*Triticum aestivum* L.) that belongs to family Poaceae, is one of the most important cereal crops of the world. It provides human nutrition to the most of human populations. Weeds are growing in cultivated crops and compete for light, moisture, other vital elements of nutrition and space and cause low quality and less productivity with raised costs of production (Arafat et al., 2015). Controlling weeds through traditional methods is time consuming with more labor cost. While weed control through synthetic chemicals, is expensive and hazardous that also cause environmental pollution (Dallali et al., 2017). This situation necessitates developing alternate weed management strategies (Thi et al., 2008). Certain plants produce many chemicals which are released by certain processes like, exudation, leaching and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

decomposition, etc. These chemicals can be obtained from different parts of certain plants like, flower, roots, stem and leaves. Such chemicals become a source of allelopathy, commonly called as allelochemicals. Allelopathy is a form of plant interference that can significantly influence ecosystem and agro ecosystem dynamics (Michelangelo et al., 2016). Allelochemicals come from the class of secondary metabolites. These are produced as byproducts in the primary metabolic ways of the plants (Anwar et al., 2013). Like many other natural compounds, these chemicals have the capacity of producing wide array of biological effects and can be quite useful for weed control processes as well as agriculture systems (Zhou et al., 2004).

Lantana camara L. belongs to Verbenaceae family. This plant possessed certain aromatic compounds which can inhibit early growth and seed germination of adjacent plant by outcompeting for soil nutrients and fluctuating micro environment by producing dense thickets (Dobhal et al., 2010). Keeping this in view, this study was undertaken for evaluating allelopathic activity of *L. camara* against some major weeds (viz., *Phalaris minor, Avena fatua, Chenopodium album, Euphorbia helioscopia* and *Rumex dentatus*) of wheat crop.

Materials and methods

Collection and mechanical processing of L. camara

This research was carried out at Plant Physiology Laboratory, Department of Botany, Pir Mehr Ali Shah Arid Agriculture University, Rawalpindi (PMAS-AAUR), Pakistan. The mature leaves of *L. camara* were collected from district Rawalpindi (73° 02' E longitude and 33° 36' N latitude, 508 m above sea level), Punjab, Pakistan and washed for several times under running tap water to remove dust. The same leaves were dried in blotting paper for 4 weeks in shade at room temperature (20-25 °C). The dried leaves were crushed using heavy duty blender (warring Lab.), to make fine powder, passed through mesh size 2 mm and kept in air tight plastic zip lock bags separately at 4 °C (Anwar et al., 2013).

Procurement and surface sterilization of test species seeds

Seeds of some noxious weeds sensitive to herbicide (Shahid et al., 2006) such as *Avena fatua*, *Chenopodium album, Euphorbia helioscopia*, *Phalaris minor* and *Rumex dentatus* and wheat (Wafaq-2001) were procured from the Barani Agricultural Research Institute (BARI), Chakwal (72.7211° E longitude and 32.9309° N latitude), District Rawalpindi, Punjab, Pakistan. These weeds are reported to be the most densely populated weeds of wheat crop (Qureshi and Bhatti, 2001; Qureshi et al., 2009). Seeds were surface sterilized with 2% (w/v) solution of Sodium hypochlorite (NaOCl) for 5-8 min. After disinfection, the seeds were washed several times with distilled water (Anwar et al., 2016).

Studied parameters

Subsequent three growth parameters were used for screening allelopathic potential as follows:

a. Germination percentage
b. Radical length (cm)
c. Plumule length (cm)

© 2018, ALÖKI Kft., Budapest, Hungary

Aqueous extract preparation

An aliquot (10 g) of dried leaf powder of *L. camara* was soaked in 100 ml distilled water in a flask and agitated at room temperature (20-25 °C) for 24 h on an orbital shaker (160 rpm). The extract was strained through muslin cloth and finally filtered through Whatman filter paper No. 1. Aqueous extract was obtained as filtrate of the mixture and final volume was attuned to 100 ml, this gives 10% water extract (Maharjan et al*.,* 2007). This stock solution was then diluted with distilled water to prepare the different concentration of the extract i.e. T_1 (100%), T_2 (75%), T_3 (50%) after Sahu and Devkota (2013). The control was distilled water (0%), indicated as T_4. The extract was stored at 4 °C in pre-disinfected flasks. To evade adulteration and forthcoming chemical modifications, the extracts were ensured to be used within 3-4 days (Anwar et al., 2017a).

Hexane extract preparation

An aliquot (10 g) of dried leaf powder of *L. camara* was mixed with hexane (0.5 L) repeated three times for 6 h on shaker. This extract was filtered, concentrated and dried over a rotary evaporator in pre-weighed flask. The obtained residue was 6.14 g. The stock solution was then diluted with hexane to prepare three concentrations i.e. T_1 (100%), T_2 (75%), T_3 (50%) and T_4 (0% control). These stored at 4 °C in pre-sterilized flasks (Sahu and Devkota, 2013).

Methanolic extract preparation

An aliquot (10 g) of dried leaf powder of *L. camara* placed on shaker with methanol (to extract polar compounds) (0.5 L) repeated three time for 6 h on shaker. This extract was filtered, concentrated, and dried over a rotary evaporator in pre-weighed flask. The obtained residue was 25.29 g. The stock solution was than diluted with methanol to prepare three concentrations i.e. T_1 (100%), T_2 (75%), T_3 (50%) and T_4 (0% control). These stored at 4 °C in pre-sterilized flasks (Sahu and Devkota, 2013).

Bioassay techniques

An aliquot (15 ml) of *L. camara* extract added on 25 g soil per Petri dish and 5 ml extract was added on filter paper per Petri dish while distilled water, hexane and methanol used as control in aqueous, hexane and methanolic extraction respectively. Ten seeds of selected test species were used per Petri dish. Each treatment was replicated for five times. The Petri dishes were wrapped with squash tape, enclosed with Aluminum foil and incubated in the growth chamber (NTS Model MI-25S) at room temperature (20-25 °C) for 15 days. The germination percentages, lengths of radical and plumule were calculated of each test species by comparing with control (Khan et al., 2008).

Sandwich method

The sandwich method was followed after Fujii et al. (2003, 2004). Five ml of 0.75% (w/v) agar (Nalge Nunc Intl., Roskilde, Denmark, gelling temperature 30-31 °C) was poured in each of the six-well (10 cm^2 area /well) into multi-dish plastic plate. The agar solution was left for solidification. *L. camara* leaf powder @ 10 and 50 mg were placed in wells of the plate and were roofed by a thin layer of 0.75% (w/v) agar. After solidification, 10 seeds of each test species were placed on agar gel in each well of the plate. The multi-well plastic plates were then wrapped with the plastic tape and incubated

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

in the growth chamber (NTS Model MI-25S) at room temperature (20-25 °C) for 15 days. In the control treatment, only agar gel without dried leaves powder was used as a seed bed for test species seeds. Each treatment was replicated five times. The germination percentages, lengths of radical and plumule for each test species were calculated by comparing with control. An aliquot (10 mg) of dried leaf powder of *L. camara* added on filter paper along with 5 ml distilled water per Petri dish while an aliquot (50 mg) of dried leaf powder of *L. camara* added on 25 g soil along with 15 ml distilled water per Petri dish (Raana et al., 2012). Ten surface sterilized seeds of test species were placed to each sterilized Petri plate. The Petri dishes were wrapped with squash tape, enclosed with Aluminium foil and incubated in the growth chamber (NTS Model MI-25S) at room temperature (20-25 °C) for 15 days. The germination percentages, lengths of radical and plumule were calculated of each test species by comparing with control (Anwar et al., 2017b).

Statistical analysis

A completely randomized design (CRD) with five replications was used for the experiments. The statistical analysis was completed by STATISTIX 9 and means were separated by using Fisher's protected LSD test (Nekonam et al., 2014).

Results

Allelopathic potential of L. camara aqueous extract

Germination percentage

The results revealed that *L. camara* aqueous extract significantly inhibited germination percentage of *R. dentatus* (58%), followed by *E. helioscopia* (56%), *A. fatua* (57%) and *P. minor* (55%) on filter paper, whereas, no significant effect on germination percentage of *T. aestivum* and *C. album* (*Table 1*). The aqueous extract on soil significantly inhibited seed germination of *E. helioscopia* (64%), followed by *P. minor* (63%), *R.* dentatus (61%) and *A. fatua* (60%) as compared to control (*Table 2*). The results further indicated that maximum (96% germination was observed for *T. aestivum* and *C. album* (*Table 1*). Besides, minimum germination was noted for *R. dentatus* (42%) and *E. helioscopia* (36%) on filter paper and soil, respectively (*Tables 1* and *2*). The statistics also recommended that germination percentage reduction of the *R. dentatus, E. helioscopia*, *A. fatua* and *P. minor* was concentration dependent (*Fig. 1a*).

Means followed by different letters within one column differ significantly at $P < 5\%$
*Significant at $P < 1\%$

Radical length

The data revealed that the highest radical length inhibition activity was exhibited by *A. fatua* (52%), *P. minor* (51%) and *C. album* (49%) in *L. camara* aqueous extract on filter paper. The results further indicated that extract on soil caused significant radical length reduction of *A. fatua* (54%), *P. minor* (53%) and *C. album* (52%) as compared to control. While the radical length of *T. aestivum, R. dentatus* and *E. helioscopia* remained unaffected. The results also illustrated that minimum radical length was noted for *A. fatua* i.e. 48% and 46% on filter paper and soil, respectively (*Tables 3* and *4*). The maximum radical length (97%) was noted for *T. aestivum, R. dentatus* and *E. helioscopia* (*Fig. 1b*).

Plumule length

The data obtained exhibited that the aqueous extract of *L. camara* significantly inhibited the plumule length of *E. helioscopia* (52%), *A. fatua* (50%), *R. dentatus* (50%) and *C. album* (50%) as compared to control on filter paper. There was no significant effect on plumule elongation of *T. aestivum and P. minor*. Likewise, *L. camara* aqueous extract significantly inhibited plumule length of *E. helioscopia* (56%), *C. album* (55%), *R. dentatus* (53%) and *A. fatua* (53%) in soil. The statistical data concluded that minimum plumule length was noted for *E. helioscopia* i.e. 48% and 44% on filter paper and soil, respectively (*Tables 5* and *6*). The statistical figures also proposed that maximum plumule length (96%) was noted for *T. aestivum and P. minor* (*Fig. 1c*).

Allelopathic potential of L. camara hexane extract

Germination percentage

There was significant reduction of germination of *E. helioscopia* (35%), followed by *P. minor* (33%) and *A. fatua* (32%) on filter paper (*Table 7*), whereas, no significant effect on the germination of *T. aestivum, R. dentatus* and *C. album,* showing resistance to the extract. The data illustrated that the highest seed germination inhibition was noted for *P. minor* (40%), followed by *A. fatua* (39%) and *E. helioscopia* (38%) by the incorporation of *L. camara* hexane extract into soil. The maximum (97%) germination noted for *T. aestivum, R. dentatus* and *C. album*. In the present study, minimum germination was noted for *E. helioscopia* (65%) and *P. minor* (60%) on filter paper and soil, respectively (*Tables 7* and *8*). The statistics also recommended that allelopathic inhibitory effect was concentration dependent for *E. helioscopia*, *P. minor* and *A. fatua* with concentration increase, suppression potential was gradually enhanced (*Fig. 2a*).

Radical length

The experimental results of the current study indicated that the highest radical length inhibition activity was exhibited by *A. fatua* (38%) and *R. dentatus* (34%) in *L. camara* hexane extract on filter paper. statistical data concluded that hexane extract on soil

Plumule length

Analysis of the data revealed that *L. camara* hexane extract significantly inhibited the plumule length of *R. dentatus* (46%) and *A. fatua* (42%) as compared to control on filter paper. Interestingly, there was no significant effect on plumule elongation of *T. aestivum, P. minor, E. helioscopia* and *C. album*. Likewise, *L. camara* hexane extract significantly inhibited plumule length of *R. dentatus* (49%) and *A. fatua* (45%) in soil. The statistical data concluded that minimum plumule length was noted for *R. dentatus* i.e., 54% and 51% on filter paper and soil, respectively (*Tables 11* and *12*). The statistical figures also proposed that maximum plumule length (95%) was noted for *T. aestivum, P. minor, E. helioscopia* and *C. album* (*Fig. 2c*).

Allelopathic potential of L. camara methanolic extract

Germination percentage

The statistical data exposed that *L. camara* methanolic extract significantly inhibited germination of *R. dentatus* (68%), *A. fatua* (66%), *E. helioscopia* (63%) and *P. minor* (62%) on filter paper, whereas, no significant effect on germination of *T. aestivum* and *C. album* showing resistance against extract. Similarly, *L. camara* methanolic extract on soil significantly suppressed seed germination of *A. fatua* (76%), *E. helioscopia* (73%),

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

R. dentatus (70%) and *P. minor* (69%). It was noted that maximum (95%) germination was observed for *T. aestivum* and *C. album*. In the present study, it was recognized that minimum germination was noted for *R. dentatus* (32%) followed by *A. fatua* (24%) on filter paper and soil, respectively (*Tables 13* and *14*). The results revealed that germination reduction of the *R. dentatus, A. fatua, E. helioscopia* and *P. minor* were concentration dependent (*Fig. 3a*).

Radical length

The results obtained in the study indicated that *L. camara* methanolic extract significantly inhibited radical length of *C. album* (60%)*, P. minor* (63%) and *A. fatua* (66%) on filter paper, whereas, no significant effect was noted for *T. aestivum*, *R. dentatus* and *E. helioscopia* showing resistance against extract. Similarly, the applications of extract into soil significantly suppressed radical length of *A. fatua* (68%)*, P. minor* (66%) *C. album* (63%) and *E. helioscopia* (55%) as compared to control (*Tables 15* and *16*). The maximum (96%) radical length was observed for *T. aestivum* and *R. dentatus.* The final data concluded that minimum radical length was noted for *C. album (*40%) and *A. fatua* (32%) on filter paper and soil, respectively (*Fig. 3b*).

Plumule length

The data obtained exhibited that *L. camara* methanolic extract significantly suppressed the plumule length of *R. dentatus* (63%)*, A. fatua* (63%), *C. album* (61%) and *E. helioscopia* (59%) as compared control on filter paper. Interestingly, there was no significant effect on plumule elongation of *T. aestivum and P. minor*. Likewise, *L. camara* methanolic extract significantly inhibited plumule length of *E. helioscopia* (67%), *R. dentatus* (66%), *A. fatua* (65%) and *C. album* (64%) in soil. The statistical data concluded that minimum plumule length was noted for *R. dentatus* (37%) and *E. helioscopia* (33%) on filter paper and soil, respectively (*Tables 17* and *18*). The statistical figures also proposed that maximum plumule length (96%) was noted for *T. aestivum and P. minor* (*Fig. 3c*).

Allelopathic potential of L. camara leaf powder

Germination percentage

The data revealed that *A. fatua* (60%)*, R. dentatus* (58%), *P. minor* (54%) and *E. helioscopia* (53%) possessed significant germination in *L. camara* leaf powder on filter paper, whereas, no significant effect on germination of *T. aestivum* and *C. album* showing resistance to dry powder. It is also clear from the result that *E. helioscopia* (65%)*, P. minor* (64%)*, A. fatua* (64%) and *R. dentatus* (61%) showed inhibition respectively as compared to control in powder applied into soil. The results also declared that maximum (95%) germination was noted for *T. aestivum* and *C. album.* In the present study, it was demonstrated that minimum germination was noted for *A. fatua* (42%) and *E. helioscopia* (45%) on filter paper and soil, respectively. The experimental results of the current study indicated on agar the highest germination reduction was noted for *E. helioscopia* (59%), followed by *P. minor* (58%), *R. dentatus* (56%) and *A. fatua* (56%) at 10 mg conc. Similarly, the highest germination reduction was noted for *E. helioscopia* (63%), followed by *P. minor* (62%), *A. fatua* (60%) and *R. dentatus* (59%) at 50 mg conc. The statistical data concluded that minimum germination was noted for *E. helioscopia* i.e. 41% and 37% at 10 mg and at 50 mg conc., respectively. The statistics also recommended that with the increase of concentration, the inhibitory effect was progressively increased for *E. helioscopia, P. minor, A. fatua* and *R. dentatus*

Radical length

The data revealed that *C. album*, *P. minor* and *A. fatua* showing 52%, 5% and 50% radical length inhibition respectively as compared to control in *L. camara* leaf powder on filter paper, whereas, no significant effect on radical length of *T. aestivum, R. dentatus* and *E. helioscopia* showing resistance to dry powder. It is also clear from the result that *C. album, P. minor* and *A. fatua* showed 55%, 53% and 52% radical length inhibition respectively as compared to control in powder applied into soil. The results also declared that maximum (98%) radical length was noted for *T. aestivum, R. dentatus* and *E. helioscopia* (*Table 20*). In the present study, it was demonstrated that minimum radical length was noted for *C. album* i.e. 48% and 45% on filter paper and soil, respectively. The results of the current study indicated on agar the highest radical length reduction was noted for *P. minor* (36%), followed by *A. fatua* (33%) and *C. album* (32%) at 10 mg conc. Similarly, the highest radical length reduction was noted for *C. album* (53%), followed by *P. minor* (51%) *A. fatua* (50%) at 50 mg conc. The statistical data concluded that minimum radical length was noted for *P. minor* (64%) and *C. album* (37%) at 10 mg and at 50 mg conc., respectively (*Fig. 4b*).

Discussion

Natural herbicides obtained from allelopathic plants can help in reducing usage of synthetic herbicides for weed controlling. Resultantly these may environment friendly better agricultural products as well as alleviate human health concerns (Khan et al., 2014). *Lantana camara* is reported to possess phenolic, alkaloids and aromatic compounds which inhibit the growth and seed germination of adjacent plant by competing soil nutrients and fluctuating micro environment by producing dense thickets (Dobhal et al., 2010). Keeping this in view, the present study was performed for evaluating *L. camara* as allelopathic potential against some major weeds (*Phalaris minor, Avena fatua, Chenopodium album, Euphorbia helioscopia* and *Rumex dentatus*) of wheat crop.

The aqueous extract of *L. camara* significantly inhibited seed germination of *A. fatua* (42%) and *E. helioscopia* (36%) on filter paper and soil, respectively. Besides, there was lowest radical length (cm) in *A. fatua* being the most susceptible weed, while lowermost plumule length was noted in *E. helioscopia*. These results are in-line with past studies. The aqueous extract of *L. camara* significantly suppressed the growth and seed germination of different plant species including agricultural crops (Sharma et al., 2005; Ahmed et al., 2007). Our results were also in accordance with those of Hussain et al. (2011) who reported that leaf extract *L. camara* to be the most toxic for test species. Iramus et al. (2011) had observed that the retardation in root length of *Vigna radiata* was due to inhibitory effect of *L. camara* leaf extract and suppressive effect was concentration dependent. Jabeen and Ahmed (2009) stated that germination and subsequent growth of *Cucurbita pepo* was significantly reduced by leaf aqueous extract of *L. camara*. The germination inhibition was due to allelopathic action of some inhibitory chemical substances excreted by plants. Tadele (2014) described that the potential of leaf aqueous extract of *L. camara* on root and shoot elongation was species specific and concentration dependent. Enyew and Raja (2015) observed that *L. camara* leaf aqueous extract caused significant retardation in root elongation of *Zea mays* that may be attributed to the secondary metabolites produced by the extract. The germination and subsequent growth of *Eichhornia crassipes* was significantly checked

© 2018, ALÖKI Kft., Budapest, Hungary

by aqueous extracts from mature and young leaves of *L. camara*, caused tissues decay and damages in *E. crassipes* (Saxena, 2000).

The analysis of the data of hexane extract indicated that there was significant reduction in germination of *E. helioscopia* (35%), followed by *P. minor* (33%) and *A. fatua* (32%) on filter paper, while lowest radical length was observed in *A. fatua* and the lowermost plumule length in *R. dentatus.* Tadele (2014) stated that leaf hexane extract of *L. camara* significantly decreased germination of *Eragrostis teff*. Padhy et al. (2000) described that growth suppression in seed germination and vigor may be due to the presence secondary metabolites in *L. camara* extract. The allelopathic potential of leaf extracts of *L. camara* different concentrations were retarder to all growth parameters of *Vigna radiata* seeds. The growth of *Setaria italica*, *Lactuca sativa* and *Pennisetum americanum* was significantly checked by all parts of *L. camara* extracts (Hussain et al., 2011).

The methanolic extract of *L. camara* significantly inhibited seed germination of *R. dentatus* (68%)*, A. fatua* (66%)*, E. helioscopia* (63%) and *P. minor* (62%). Besides, the same extract significantly reduced radical length of *A. fatua* and plumule length of *R. dentatus* and *E. helioscopia*. Mishra (2015) presented the similar results and stated that *L. camara* has allelopathic effect on *Lepidium sativum* germination and growth. Ahmed et al. (2007) described the inhibitory potential of *L. camara* in different crops. Mishra (2012) stated that *L. camara* extract checked seed germination of *Parthenium hysterophorus* demonstrating the presence of inhibitory phytochemicals. Oudhia (2000) noticed significant reduction in seed germination of *Melilotus alba* by extract *L. camara*.

The results of sandwich method indicated significant reduction in germination percentage of *A. fatua* and *E. helioscopia* on filter paper and soil by applying *L. camara* leaf powder. There was no inhibitory effect on *T. aestivum, R. dentatus* and *E. helioscopia*. There was minimal radical length in *C. album* and plumule length in *E. helioscopia* that showed the most sensitive weeds against the *L. camara* leaf powder. Some of the studies reported inhibitory effect of *L. camara* on the germination and growth of various crops. The leaf powder of *L. camara* inhibited germination, radical and plumule length of radish and lettuce (Qiaoying et al., 2009), *P. hysterophorus* (Mishra and Singh, 2012), *Albizia procera, Acacia auriculiformis, Paraserianthes falcataria, Amaranthus tricolor, Abelmoschus esculentus, Vigna sinensis, Oryza sativa* and *Cucurbita pepo* (Mishra, 2012). Das et al. (2012) also noticed inhibition linked with the production of allelochemicals from the *L. camara* leaves that inhibit growth of adjacent plants by outcompeting for soil nutrients and altering micro environment by forming dense thickets.

Conclusion

This study was aimed at evaluating allelopathic potential of *L. camara* against some major weeds of wheat crop. The selected solvent extracts (i.e. aqueous, methanolic and ethanolic) and dried leaf materials significantly inhibited seed germination, radical and plumule length of the selected weeds without harming the wheat plants. Among all the tested extract, methanolic ones showed its supremacy in terms of growth and germination inhibition of the studied weeds. It can be concluded that *L. camara* methanolic extract can be explored in future studies in purifying and identifying herbicidal compounds to be used in future herbicidal products development.

Abstract. This research was carried out in order to determine the effect of fertilization, or lack of it, on N_2O emission in different conditions of soil reaction and grown grass species. The pot experiment was conducted in a randomized block design with three replications in 2014–2016 (Poland). Four grass species were grown in mineral soil under mineral or organic fertilizing (Σ = 150 N kg), or lack of fertilization and different soil reaction. The effect of N-fertilization dose was determined, too. The difference of groundcover density of tested grass species was assessed. The results indicated that N_2O emission was reduced with subsequent doses by 13, 15 and 18% compared with the initial values. The application of mineral fertilization caused a higher increase of the grass biomass than the use of organic fertilizer – without any marked effect of soil reaction. The N_2O emission was influenced by the type and dose of nitrogen fertilization, the reaction of mineral soil and the biomass of the cultivated grasses. With an increase in biomass of grasses, N_2O emission was found to decrease, generally at neutral soil reaction. The highest groundcover density was found for *Festuca pratensis* and *Lolium perenne*, which translated into increased nitrogen uptake and, consequently, reduced N_2O emissions. It was determined as the optimum technique of grassland management for the reduction of N_2O emission.
Keywords: *greenhouse gas, grassland, mineral or organic fertilization, Lolium perenne, Festuca pratensis*

Introduction

Emission of N_2O is considered the most harmful emission depleting the ozone layer and, according to Ravishankara et al. (2009), it will remain such in the 21st century. The global warming potential related to the emission of this compound is 298 times greater than CO_2 emission (Myhre et al., 2013). The dangers of N_2O emission stem from the fact that its amount is not regulated under the Montreal Protocol (MP, 1987). The largest source of emissions of this anthropogenic greenhouse gas is agriculture (Bellido et al., 2015; Mori, 2016). Additionally, at the end of the 19th and the 20th century, the atmospheric accumulation rates of N_2O exceeded the projections regarding agricultural production as limited to N fertilizers and biologically fixed nitrogen fertilizers (Davidson, 2009). Out of agricultural activities, permanent grassland, i.e. meadows and pastures, contribute to a significant amount of nitrous oxide emission due to microbial nitrification and denitrification of nitrogen mineralisation in soil (Mu et al., 2009). From the perspective of environmental protection, management of grassland constitutes

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

a challenge as it occupies 40% of the earth's surface and efficient shaping of its effect on the atmosphere is difficult (Maillard et al., 2017).

According to research by Chang et al. (2017), Europe has experienced a greater warming than that presented for the globe since the pre-industrial era and the warming trend is expected to increase at an even faster rate in the 21st century. Climate models for various climate scenarios project an increase of 1–5.5 °C in the annual average temperature in Europe in the period 2071–2100 as compared to 1971–2000. Grassland ecosystems play an important role in the global nitrogen cycle and provide vital ecosystem services for many species. Consequently, numerous activities have been taken to assess the pan-European reaction of grassland to anticipated climate change. The emission of N_2O can be reduced by introducing to soil the appropriate amount of mineral fertilization applicable for a given crop (Shimizu et al., 2013) or by application of manure and its subsequent mineralization (Mori and Hojito, 2015). Bouwman (1996) and Sosulski et al. (2014) identified several factors affecting N_2O emission, including soil conditions, type of crop, nitrogen (N) fertilizer type and soil and crop management. The authors highlight the fact that the observed N_2O emission from mineral soil was higher than from mineral soil – a fact also observed by Aurangojeb (2017). Dobbie et al. (1999) also pointed to the effect of nitrogen fertilization dose, temperature and amount of precipitation on N_2O emission. Signor et al. (2013) stress the role of soil reaction in N_2O emission. In turn, Koncz et al. (2017) examined the influence of grassland management depending on grazing and mowing treatments.

The literature on the subject confirms the increase in N_2O emission with an increase in the applied mineral or organic fertilizer (Bouwman, 1996; Dobbie et al., 1999; Soussana et al., 2007, 2010; Chang et al., 2015; Ciais et al., 2010; Zhang et al., 2010; Koncz et al., 2017; Aurangojeb, 2017). There is no to big information in the recent publications on the effect of split application of N fertilizer on N_2O emission levels in cultivation of species: *Dactylis glomerata* L., *Festuca pratensis* Huds., *F. rubra* L. and *Lolium perenne* L. The search for optimal techniques of grassland management for the purpose of decreasing N_2O emission led the authors of the present paper to conduct the analysis of N_2O emission and biomass of grass in the conditions of split application of nitrogen fertilizer depending on the type of fertilization and soil reaction.

The aim of the study was to determine the effect of applied fertilization, or lack of it, on nitrous oxide emission in different conditions of soil reaction and grown grass.

Material and methods

Experimental design

In the period 2014–2016, a pot experiment was conducted in a greenhouse on Faculty of Environmental Management and Agriculture of West Pomeranian University of Technology in Szczecin, Poland.

The granulometric composition of the soil material in a pot (11 kg each) corresponded to sandy loam (sand: 2–0.05 mm – 60.9%, silt: 0.05–0.002 mm – 35.1%, colloidal clay: 0.002 mm – 4.0%). It was also characterized by slightly acid reaction (pH = 5.9), total organic carbon – 9.6 $g \cdot kg^{-1}$, humus – 16.6 $g \cdot kg^{-1}$, organic substance – 37.6 $g \cdot kg^{-1}$, total nitrogen – 0.75 $g \cdot kg^{-1}$, and low content of available phosphorus – 28 $mg \cdot kg^{-1}$, potassium – 83 $mg \cdot kg^{-1}$ and magnesium – 24 $mg \cdot kg^{-1}$. Each of the four species (*Dactylis glomerata* L., *Festuca pratensis* Huds., *F. rubra* L., *Lolium perenne*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_67616777
© 2018, ALÖKI Kft., Budapest, Hungary

L.) was sown in an amount of 270 seeds on ¼ of the study area of the pot under the variable fertilization and soil pH conditions.

In order to obtain variability of soil pH, calcium oxide was introduced to half of the pots producing pH = 7.0. In a growing season, the fertiliser was applied to pots three times (every six weeks, starting from the half of May, 10 days after the 1st and 2nd mowing) in two fertilization variants (mineral fertilizer – ammonium nitrate, organic fertilizer – fresh slurry) in the amount of 0.355 g of N per pot, corresponding to 50 kg $N \cdot ha^{-1}$. The control sample were pots with the analysed grass species without fertilization. The experiment was conducted in three repetitions in each subsequent year of the study. At the beginning of the experiment, phosphorus fertilization in the form of superphosphate was applied to all pots in the amount of 40 kg $P_2O_5 \cdot ha^{-1}$. In case of mineral fertilization, potassium level in the soil material was supplemented with a dose of this element in the form of K_2SO_4 to the value determined for fresh slurry, i.e. 4 $kg \cdot m^{-3}$. Pot experiment was arranged in a randomized block design.

Climatic conditions of plant growth

The climate in Szczecin is moderately warm. The average annual temperature is 8.6 °C. During the experiment period of 2014–2016 the temperature varied from 9 to 24 °C, from 9 to 27 °C and from 8 to 26 °C for the respective years. The annual time of sun exposition in this period amounted to 1015 h, 955 h and 1001 h respectively. The grass was grown outdoors under controlled and optimum humidity conditions, i.e. 60% of field water capacity (the TRIME FM P3 Eikelkamp meter). Water deficits were compensated by watering and the pots were protected from atmospheric precipitation.

Measurement of N_2O fluxes

Measurements of nitrogen dioxide emission were conducted with the use of a closed static chamber after a few hours from the application of each different nitrogen fertilizer and before each mowing. Measurements of N_2O were carried out using photoacoustic field gas monitor INNOVA 1412, LumaSense Technologies, Inc.® (Burczyk et al., 2008). N_2O concentration in the chamber was recorded every minute and emission levels were noted every 15 min.

Measurement and analysis of biomass tested grass species

Each year of the experiment, during each of the three mowing treatments, a percentage density of ¼ of the study area covered by each of the tested grass species was determined on the basis of plant density. The assessment of plant density was based on the percentage share of covered area as determined according to step values (26%, 38%, 50%, 63%, 75%, 88%, 100%), partly modelled on Braun-Blanquet method (Dzwonko, 2007). Cut fresh weight (at the height of 1–2 cm) of all the tested grass species grown in each of the 18 pots in the three years of the experiment was weighed on an analytical weight. Additionally, yield of sward was determined for each mowing.

Calculations of N_2O fluxes in optimisation grassland management

The values of N_2O emission in reference to 1 kg yield of the three mowing treatments were calculated according to particular stages of the experiment as presented in *Figure 1*. Total time period covered by the calculations amounted to 4.1 months,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_67616777
© 2018, ALÖKI Kft., Budapest, Hungary

starting from the application of the 1st dose to 10 days after the last mowing. Determination of the optimum management conditions was based on the calculated smallest N_2O emission in reference to 1 kg of grass biomass for all three mowing treatments.

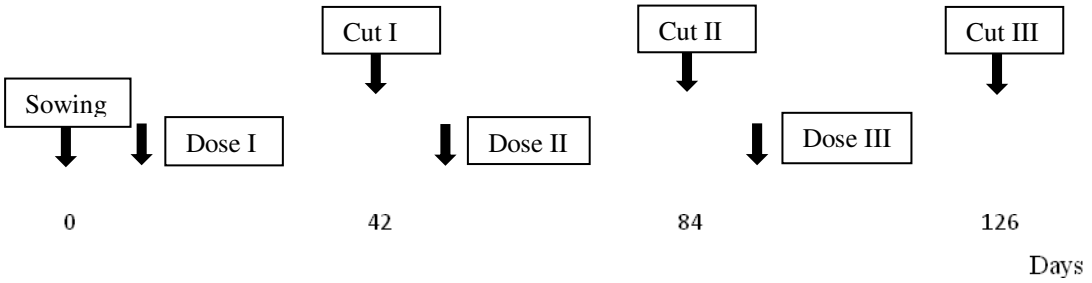

Figure 1. *Scheme of experimental design of the study: a time of sowing and a time application N-fertilizer and measurements of N_2O emission after cutting and application N-fertilizers*

Statistical analysis

Results obtained of N_2O and grass biomass were elaborated statistically with the method of two-factor analysis of variance (ANOVA: 1st factor – type of fertilization, 2nd factor – type of soil reaction) and one-way analysis of variance (dose N-fertilizer) *Statistica 12* software (StatSoft Poland). The linear correlation between analysed gas grass biomass was performer. The significance of differences between mean values and the value of Pearson correlation coefficient were evaluated with the HSD Tukey's test at $P < 0.05$. To assess the area covered by the tested grass species, a radar chart showing mean values of the nine measurement of the area covered by grass was used. Mean value of the area coverage was used for the one-way analysis of variance (grass species).

Results and discussion

Emission of N_2O fluxes from soil and after cutting of grasses

The main threats due to greenhouse gases relate to organic soil, however more and more studies address the issue in relation to mineral soil (Dobbie et al., 1999; Mu et al., 2009; Skiba et al., 2012; Aurangojeb, 2017). The experiment conducted as a part of the present study contributes to the discussion on the role of environmental factors of N_2O emission from mineral soil.

Numerous management techniques are introduced for the purpose of limiting N_2O emission, among others: split application of fertilizer (Weerasekara et al., 2018), introducing legumes to sward (Fuchs et al., 2018), injecting fresh slurry to a specific depth (Webb et al., 2010), control of soil density (Langevin et al., 2015), and the use of nitrification inhibitors (Dai et al., 2013; Duan et al., 2017).

Imer et al. (2013) report that N_2O emission is shaped by the type of climatic zone, type of soil and its pH as well as the source of nitrogen supply to soil. Moreover, emission of nitrogen greenhouse gas is additionally determined by the plant cover of soil. Consequently, lack of the plant cover results in increased emission levels. Linn and

Doran (1984) reported, that emission of N_2O from N-fertilized, no-tillage soils was 9.4 times greater than with conventional tillage. Nitrous oxide production from nonfertilized soil was slightly greater for no tillage.

Organic nitrogen fertilizers foster the release of significant amount of ammonia and nitrous oxide (Ball et al., 2007). In our conducted experiment, following the first application of fertilizer (50 kg·N·ha^{-1}) to soil without plant cover, the highest N_2O emission levels were recorded in the conditions of acidic soil reaction and application of fresh slurry (*Fig. 2*). Under the same conditions in this experiment, mineral nitrogen fertilization applied in the same dose as organic nitrogen fertilization was found to produce a statistically lower emission of this gas. Emission levels following application of mineral and organic fertilizers to soil material of neutral pH were comparable. In the controlled conditions (without nitrogen fertilization), the value of nitrous oxide emission was approximately 50% lower than the values recorded for each type of fertilization. Merbold et al. (2014) report that following tillage and harrowing there was a pronounced increase in N_2O emission. Žurovec et al. (2017) demonstrated that with fertilization in the amount of 67.5 kg·N·ha^{-1}, reduced soil cultivation, similarly to lack of cultivation treatments, can bring favourable environmental effect due to a decrease in N_2O emission levels as compared with the conventional soil cultivation.

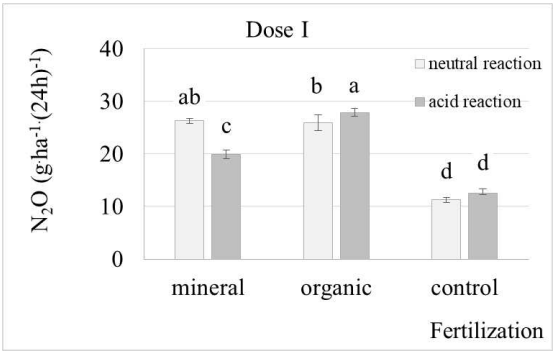

Figure 2. *N_2O emissions from soil without a plant soil cover; different letters (a, b, c, d) indicate significant difference at $P < 0.05$ among different N-fertilizer in the same variety*

Data presented in the literature on the subject show that the highest levels of N_2O emission were recorded on different dates from fertilizer application, for example following a week (Flechard et al., 2007), two weeks (Merbold et al., 2014) or on the day of organic fertilizer application (Imer et al., 2013). In our experiment, the N_2O emission in consecutive doses associated with increasing fertilizer dose (I cut – 50 kg N·ha^{-1} – 24.98 g N_2O ha^{-1} 24 h^{-1}; II cut – 100 kg N·ha^{-1} – 15.22 g N_2O ha^{-1} 24 h^{-1}; III cut – 150 kg N·ha^{-1} – 12.61 g N_2O ha^{-1} 24 h^{-1}) differed significantly ($F = 162$; $P < 0.000$). The measurements of nitrous oxide emission was conducted a few hours after application of nitrogen fertilizer, therefore it is difficult to conclude whether the recorded emission levels were indeed the highest. Following the application of the second dose of nitrogen (*Fig. 3*), it was found that in the controlled conditions the N_2O emission with respect to both types of fertilization was 75% lower. It is important to note that N_2O emission for both fertilizer forms was 50% lower than that recorded in the first measurement. In turn, after the second mowing and application of the third and the last fertilizer dose, N_2O emission was found to decrease, on average, by 20% in both types of fertilization. In the

© 2018, ALÖKI Kft., Budapest, Hungary

control conditions, the values remained at the same level with respect to the effect observed following the application of the second dose. Differences in terms of N_2O emission depending on soil pH to which a given nitrogen fertilizer was applied were not remarkable, yet statistically significant following the 1st and the 2nd mowing and application of the second dose.

In our experiment, the results indicated that N_2O emission was reduced with subsequent doses by 13%, 15% and 18% as compared with the initial values.

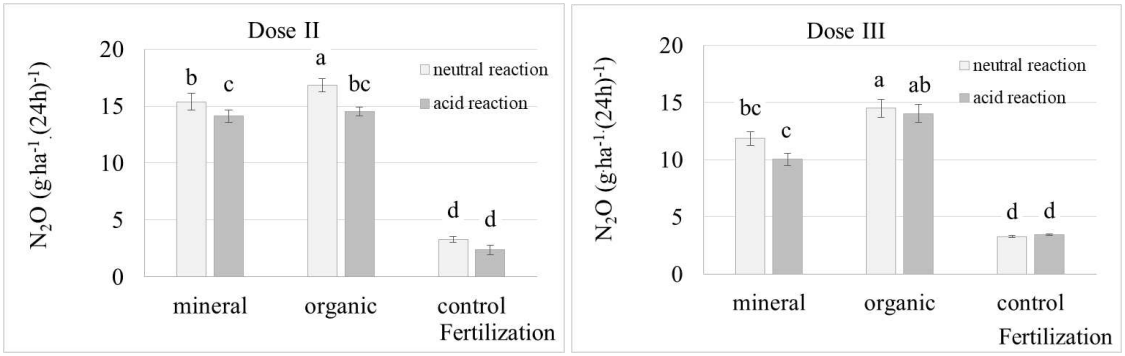

Figure 3. *N_2O emissions under conditions of 10 days after 1st and 2nd cut; different letters (a, b, c, d) indicate significant difference at $P < 0.05$ among different N-fertilizer in the same variety*

Emission of N_2O fluxes from soil after cutting grasses and grasses biomass

Grass seeds need mineral nutrients, including nitrogen, to germinate and grow (Springer, 2017). In our experiment, a 50% reduction in N_2O emission levels was observed on the day of the 1st mowing in comparison with the measurements taken following the application of the first dose of fertilizer (*Figures 2* and *4*). This resulted from nitrogen uptake by developing grass species as well as natural processes in the soil connected with nitrogen cycle and release of its gaseous form to the atmosphere (Kering et al., 2012). In our experiment, the results of N_2O emission on the day of the 1st mowing showed that this parameter was approximately 10 times greater with mineral nitrogen fertilization than organic fertilization or lack of fertilization – in this particular case, regardless of soil material pH (*Fig. 4*). Merbold et al. (2014) observe that following mineral fertilization the emission, as compared with background, increased 4–10 times. The smaller N_2O emission for slurry is due mainly to less inorganic N in slurry as compared with synthetic fertilizer as the same as reported Mori and Hojito (2011) for emission factor of manure. Similarly, the results obtained by Dobbie et al. (1999) show that nitrous oxide fluxes varies widely. In our experiment, fluxes generally increased sharply after N-fertilizer additions before tailing off to very low values, which continued until the next fertilizer addition (*Figs. 2, 3* and *4*).

In our experiment, the N_2O emission in consecutive cuts associated with increasing fertilizer dose (I cut – 50 kg $N \cdot ha^{-1}$ – 3.181 g N_2O ha^{-1} 24 h^{-1}; II cut – 100 kg $N \cdot ha^{-1}$ – 3.687 g N_2O ha^{-1} 24 h^{-1}; III cut – 150 kg $N \cdot ha^{-1}$ – 1.316 g N_2O ha^{-1} 24 h^{-1}) differed significantly ($F = 16.7$; $P < 0.000$). In the conditions of the second mowing in comparison with the first mowing, N_2O emission decreased by 30% with the application of mineral fertilizer, however, there was a ten-fold increase when organic fertilizer was used. The controlled conditions showed a two-fold increase in emission levels (*Fig. 4*). The results of the second moving (12–15 kg N_20-N per 100 kg N) showed higher values

DOI: http://dx.doi.org/10.15666/aeer/1605_67616777
© 2018, ALÖKI Kft., Budapest, Hungary

than that obtained by Dobbie et al. (1999) for cut grassland (0.3–5.8 kg N_20-N per 100 kg N) grown on mineral soils. In the last mowing, in our experiment, N_2O flux following mineral fertilization was almost 33% lower than in the previous cutting, and with organic fertilization the values were 25% lower. The emission from soil without fertilization showed a decrease, however only by 50% (*Fig. 4*).

Another feature of soil which could have an effect on N_2O emission is soil pH which can affect nitrification, denitrification and N_2/N_2O ratio. It is generally believed that N_2O reduction is inhibited at low pH (Bouwman et al., 1993). However, other authors stress that the same soil modified for different pH values showed no measurable differences in terms of N_2O emission. These results are contrary to data obtained by Sajeev et al. (2018) who observed a 21– 55% reduction in N_2O emission due to change in soil pH.

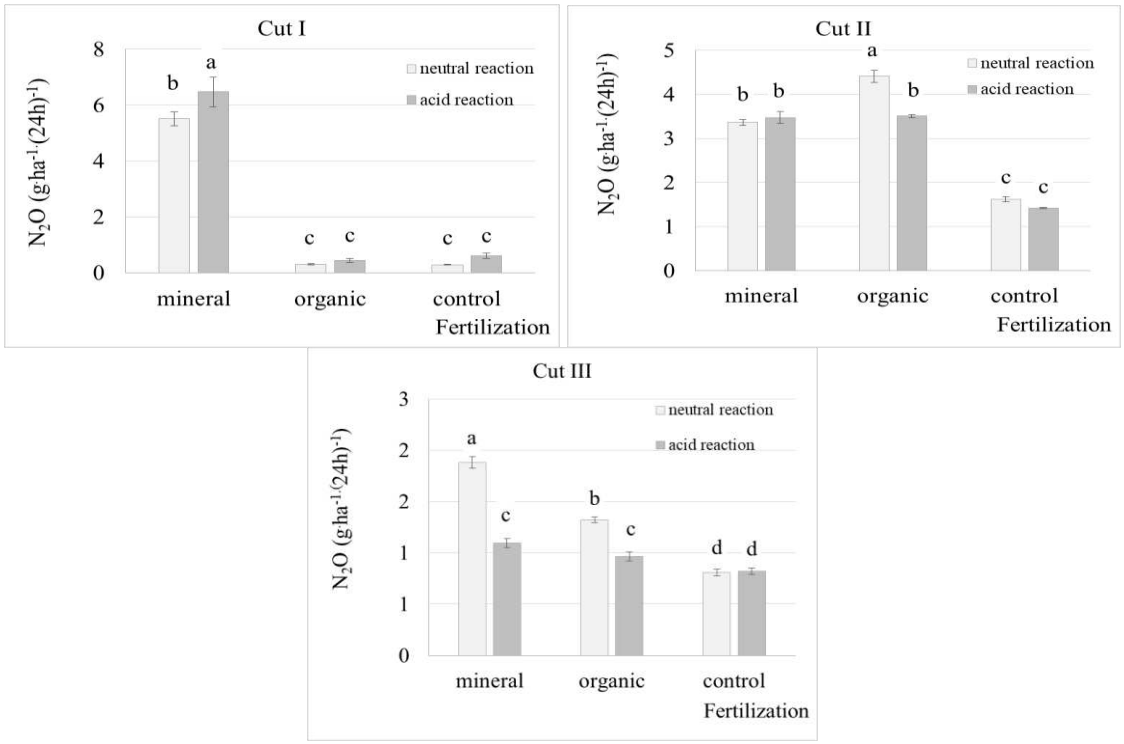

Figure 4. *N_2O emission from soil under I, II and III cut conditions; different letters (a, b, c, d) indicate significant difference at $P < 0.05$ among different N-fertilizer in the same variety*

Signor et al. (2013) demonstrated that N-fertilization implies a higher plant biomass production. In our experiment, on the basis of statistical analysis, it was found that grass biomass was dependent on the type of fertilization and soil material pH. From analysed grasses, *Lolium perenne* L. was provided with very favourable conditions for development with respect to mineral soil, as indicated by other authors (Bernal et al., 1998; Baggs and Blum, 2004; Harkot et al., 2015) and appropriate soil reaction, both slightly acidic as well as neutral, and nitrogen availability (*Fig. 5*). Hebeisen et al. (1997) pointed that high viability of the plant, even in the conditions of low nitrogen availability, is connected with the possibility of developing the root system to a depth of as much as 1.5 m and, therefore, obtaining the element from deeper layers of soil.

Similarly to ryegrass, the conditions of *Festuca pratensis* Huds. development in our experiment also were favourable as the plant favours compact and medium compact mineral soils with sufficient moisture. Moreover, Borawska-Jarmułowicz et al. (2016) indicated that the plant's root system is well developed and reaches 1.2 m deep into the soil profile. Sosnowski (2012) demonstrated that in the conditions of nitrogen fertilization *Festuca pratensis* Huds., *Lolium perenne* L. and *Dactylis glomerata* L. showed an increase in yield – as is confirmed by the our results obtained in the 1st, 2nd and 3rd mowing treatment with the use of both types of nitrogen fertilization in comparison with the control (*Fig. 5*).

Dactylis glomerata L. shows tolerance to acidic as well as alkaline pH of mineral soil. Due to developing greater number of generative shoots (Borawska-Jarmułowicz et al., 2016), this plant is capable of a specific physiological adaptation to variable levels of mineral nutrients in soil (Crossley and Bradshaw, 1968; Zarzycki and Bedla, 2017) and shows a higher mean average increase in sward height as compared with *Festuca* variation. However, in the conditions of the experiment conducted as a part of this study, the biomass and groundcover density were found to be significantly lower as compared with *Lolium perenne* L. and *Festuca pratensis* Huds (*Fig. 5*).

In comparison to other tested grass species, *Festuca rubra L.* is characterised by a considerably lower growth rate (Zarzycki and Bedla, 2017), which translated into insignificant groundcover density observed in our experiment (*Fig. 5*).

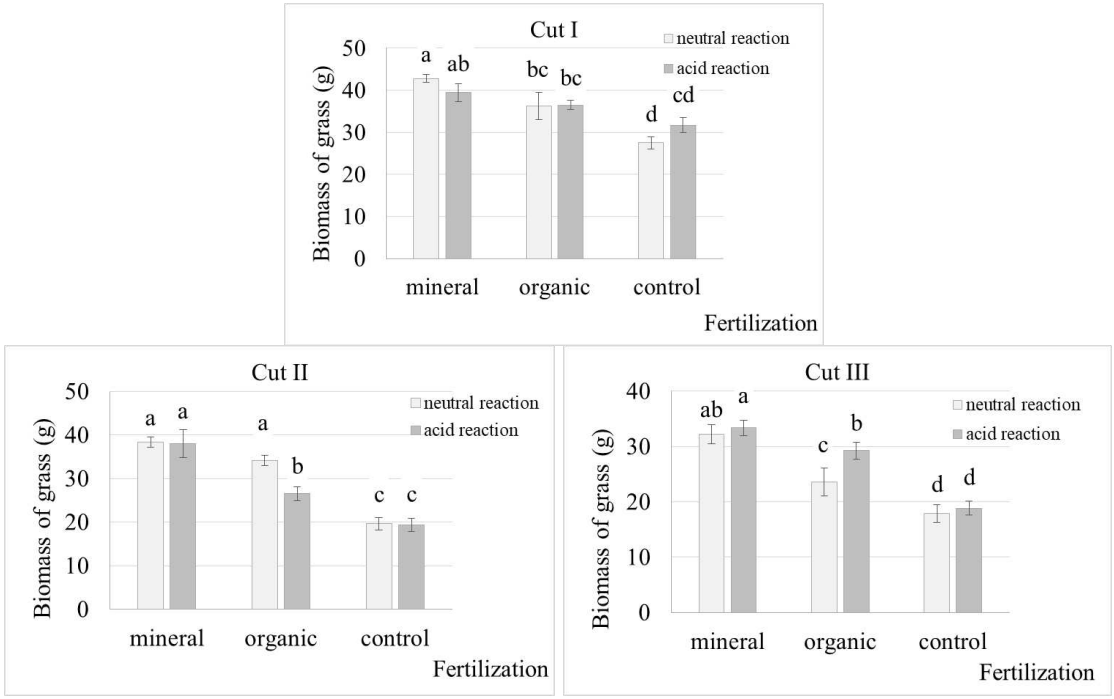

Figure 5. *Grass biomass depending on fertilization and soil reaction in the first, second and third cut; different letters (a, b, c, d) indicate significant difference at $P < 0.05$ among different N-fertilizer in the same variety*

Temperature and duration of sun exposition are important factors for plant yielding. Zhang et al. (2017) pointed that the amount of hours of daily sun exposition has an effect on the yield of grass only in periods of drought. In our experiment, constant soil

© 2018, ALÖKI Kft., Budapest, Hungary

moisture was maintained. The mean air temperature recorded in the subsequent years for the period between seeds sowing and the first cut was 15, 14 and 16 °C, for the period between the first and second cut, respectively 18, 18 and 19 °C, and for the period between second and third cut 18, 19 and 18 °C (*Fig. 6*). Biomass of the analysed grass for given moving treatments was connected with life process of the grown species and air temperature.

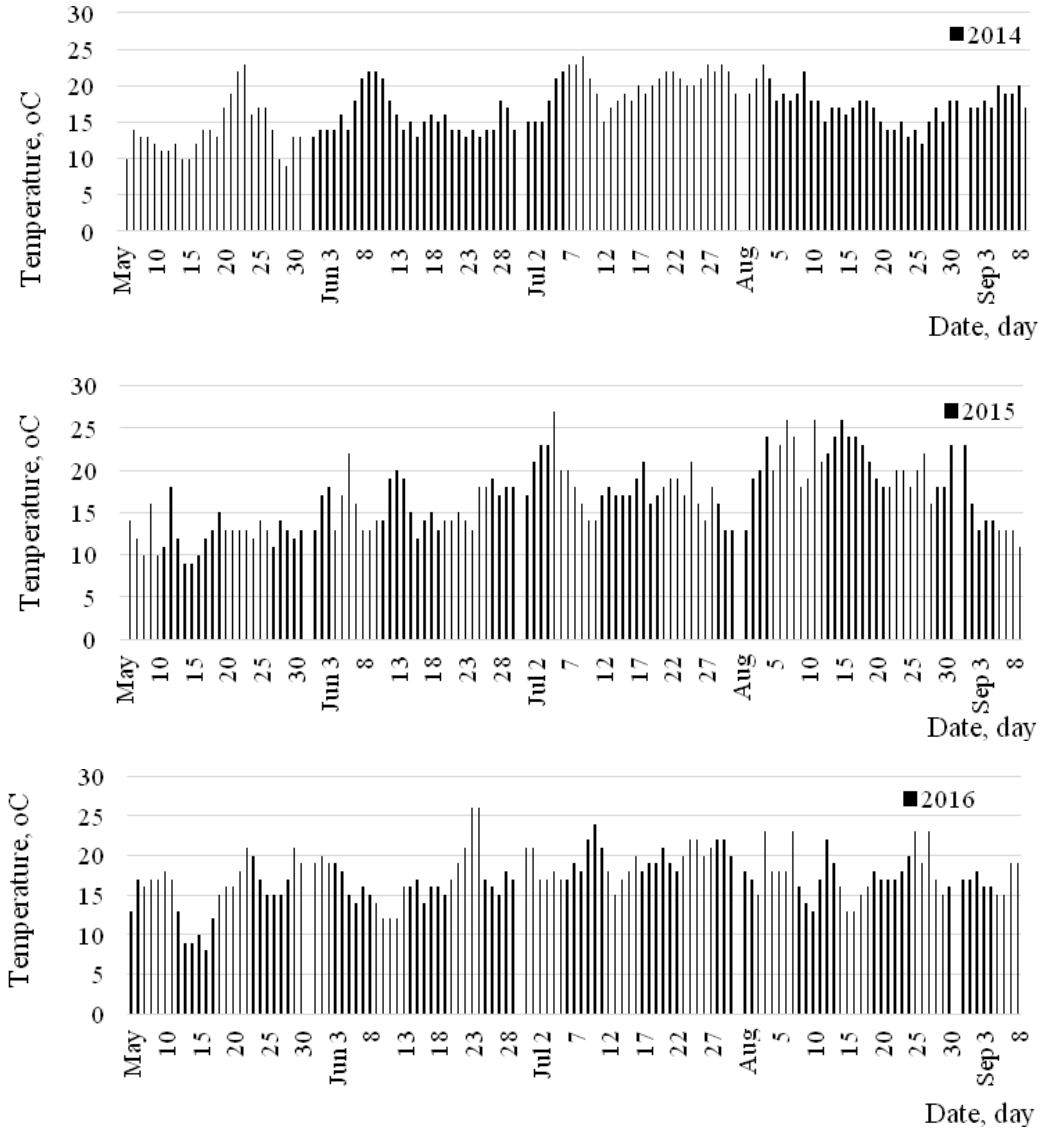

Figure 6. *Average daily air temperature from 16 May to 30 September in 2014–2016*

The lowest biomass yield for each of the mowing treatments was obtained in the conditions without nitrogen fertilization (*Fig. 5*). Markedly increased biomass in acidic soil pH was found only for the first mowing. On average, as compared with the first mowing, biomass showed a 33% and 38% decrease with subsequent mowing treatments. Biomass of the tested grass at application of mineral fertilization was higher than with the use of organic fertilizer – without any marked effect of soil material reaction. In subsequent mowing treatments, under the aforementioned fertilizing

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_67616777
© 2018, ALÖKI Kft., Budapest, Hungary

conditions, biomass showed a decline of 8% and 34%. In the case of organic fertilization, the effect of soil pH on biomass amount was found to be more pronounced. This was observed for the 2nd and 3rd moving with a reverse trend in terms of biomass amount. For subsequent mowing treatments, biomass showed a decrease of 18% and 26%.

Share of grass species in the cover of the study area

From sowing to the last cut the temperature and the number of sunshine hours had a positive effect on the development of grasses. Despite the diversity of the grass species and their sensitivity to temperature variability, optimal habitat conditions, in particular air temperature, were maintained during the experiment. Nevertheless, the rate of growth and sensitivity differed strongly between red fescue and ryegrass as indicated by Jankowska-Huflejt (2013) and Jankowski et al. (2018).

Out of the tested grass species, in the conducted experiment the best yield was obtained for *Festuca pratensis* Huds. and *Lolium perenne* L. *Dactylis glomerata* L. showed substantially worse results and *Festuca rubra* L. the worst. The share of the latter two species amounted to, on average, 1/3 of the biomass obtained from individual mowing treatments.

Generally, for all cuts it was found that *Lolium perenne* L. (average in the range of 75% to 88%) and *Festuca pratensis* Huds. (average in the range of 75% to 88%) significantly ($F = 19904$; $P < 0{,}000$) occupied a larger area than *Dactylis glomerata* L. (average in the range of 50% to 63%) and *Festuca rubra* L. (average in the range of 38% to 50%). The density of the tested grass species showed an increasing tendency in the second mowing, and decreasing in the third as compared to the first mowing treatment (*Fig. 7*). The lowest density in subsequent mowing treatments was recorded for *Festuca rubra* L. (50%/50%/38%), followed by *Dactylis glomerata* L. (63%/63%/50%), and *Lolium perenne* L. with *Festuca pratensis* Huds. (75%/88%/63%). There was no effect of the type of fertilization and soil pH on density of the tested grass species ($P > 0.05$). However, biomass analysis shows that for particular mowing treatments there was a statistically significant effect of fertilization and soil reaction on the development of the tested grass species (*Fig. 5*).

In individual mowing treatments, mean area covered by the tested grass species amounted to 27, 21 and 39% which could affect N_2O emission levels (*Fig. 4*), as is also shown in studies by Linn and Doran (1984). They suggested that this gas emission from non-fertilized soil was slightly greater for no tillage.

Assessment of the relationship between N_2O emission and biomass

It was found that out of 18 variants tested in the course of the experiment, 14 showed a statistically significant linear correlation – 13 out of which were negative (*Table 1*). With an increase in biomass of the tested grass species, N_2O emission was found to decrease, always at neutral soil reaction. In the control conditions and with organic fertilization only in the first mowing treatment there were no significant correlations at acidic pH of soil material. In the case of mineral fertilization, such correlation was recorded in all mowing treatments. Negative correlations confirm the relationship between high nitrogen dependence of species such as *Dactylis glomerata* L. and the resultant decreased N_2O emission alongside an increase in plant biomass – an observation which has also been made by other authors (Abalos et al., 2018).

Annual of N_2O fluxes

Due to specific management strategies, organic farming may have an effect on reduction of greenhouse gases emission – including nitrous oxide (Lorenz and Lal, 2016). Grassland cultivation can mobilize large pools of N in the soil, with the potential for N leaching and N_2O emissions. Numerous studies report various N_2O emission levels from grassland in particular regions of the European Union depending on, among others, manner of use (Ciais et al., 2010; Koncz et al., 2017). For example Soussana et al. (2007) and Flechard et al. (2007) reported that 9 sites reached 1.0 ± 0.5 kg N-N_2O ha^{-1} yr^{-1}. Similar results were obtained by Chang et al. (2015) who demonstrated that indirect N_2O emissions from fertilized grassland soils were 1.2 ± 0.4 kg N-N_2O ha^{-1} yr^{-1}. In turn, Zhang et al. (2010) observed a several times lower N_2O flux from meadows located in mountain regions in the western part of China: 0.26, 0.14 and 0.38 kg N-N_2O ha^{-1} yr^{-1}. Calculated annual emission of our analysed experiment showed very different values (mineral fertilization: acid reaction 0.4–7.3 and neutral reaction 0.7–9.6; organic fertilization: 0.2–10.2 and 0.1–10.5, without fertilization: 0.2–4.6 and 0.1–4.1 N-N_2O ha^{-1} yr^{-1}, respectively).

On the basis of the equation by Bouwman (1996): E = 1 + 1.25 * F, with fertilization dose in the amount of 50 $kg \cdot N \cdot ha^{-1}$, annual N_2O emission level was identified at 63.5 $kg \cdot N \cdot ha^{-1}$. The results of our studies showed that for the first mowing, there was a variability in N_2O emission which was dependent on the type of nitrogen fertilization (Nmin-69.6 $kg \cdot N \cdot ha^{-1}$ and Norg-4.3 $kg \cdot N \cdot ha^{-1}$). The greater was the dose of nitrogen fertilization, the more the results differ from the values calculated with the equation by Bouwman (1996) for mineral soil. A decrease in N_2O flux in subsequent mowing treatments was most likely connected with phenological development of given grass species and with temperature decrease, particularly in the third mowing. The effect of temperature on N_2O emission levels was indicated by, among others, Dobbie et al. (1999), Soussana et al. (2010), Aurangojeb (2017).

Soil pH is another important factor influencing N_2O emissions, because nitrous oxide reductase is inhibited by low pH and in the presence of O_2. Generally, if denitrification is the main source of N_2O, higher pH values decrease the soil N_2O emissions, but if nitrification is the main process of N_2O production, then an increase in the soil pH stimulates the N_2O production (Signor et al., 2013). In our experiment, this effect was observed from the moment of the application of the second fertilizer dose, through the second mowing, third fertilizer dose and third mowing treatment. As emissions increased with temperature and rainfall, Ball et al. (2007) recommended to restrict tillage operations to cool, dry conditions, and being aware of possible soil compaction which may also promote denitrification. Soussana et al. (2010) pointed to the fact that emission factor of N_2O from mowed synthetically fertilised permanent grassland increased in the range from 0.1% to 5.7% alongside an increase in mean average air temperature from 5.2 to 15.8 °C, and atmospheric precipitation in the range 1160–2595 mm yr^{-1}.

Assessment of the possibilities of management optimization on crop of grasses

The search for optimum techniques of grassland management in order to reduce nitrous oxide emission led the authors to conduct the analysis of N_2O flux and biomass of grass due to split application of nitrogen fertilizer. On the basis of estimates and the adopted method of N_2O flux assessment with respect to 1 kg of grass biomass for each

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_67616777
© 2018, ALÖKI Kft., Budapest, Hungary

of the three mowing treatments in a 4.1 month long period, optimum management conditions were determined (*Table 2*). It was found that with the application of 50 $kg \cdot N \cdot ha^{-1}$ dose at the beginning of the experiment, the expected effect can be achieved with the use of mineral fertilizer in a slightly acidic soil material (0.083 g $N_2O \cdot kg^{-1}$ yield grass; 10.9 $Mg \cdot ha^{-1}$ grass yield). An increase in gas emission was recorded using 100 $kg \cdot N \cdot ha^{-1}$ in aggregate, in a system: 1st and 2nd dose – mineral fertilization in a slightly acidic environment (0.096 g $N_2O \cdot kg^{-1}$ grass yield; 13.6 $Mg \cdot ha^{-1}$ grass yield). An even greater increase of the analysed emission was recorded using 150 $kg \cdot N \cdot ha^{-1}$ in a system: 1st, 2nd and 3rd dose – mineral fertilization, always in a slightly acidic environment (0.097 g $N_2O \cdot kg^{-1}$ grass yield; 15.6 $Mg \cdot ha^{-1}$ grass yield).

Table 2. *Emission of N_2O on grass yield and grass yield*

Conclusions

In conclusion, the N_2O emission was influenced by the type and dose of nitrogen fertilization, the reaction of mineral soil and the biomass of cultivated grasses. With an increase in biomass of the tested grass species, a decrease in N_2O emission was observed, especially in neutral soil reaction. Among the tested grass species, in the experimental conditions, the highest density of ground coverage was found for *Festuca pratensis* and *Lolium perenne*, which contributed to an increased nitrogen uptake and, consequently, reduced N_2O emissions. It was established as the optimum technique of grassland management in order to reduce N_2O emission. The use of 50 $kg \cdot N \cdot ha^{-1}$ mineral fertilizers resulted in the smallest emission of nitrous oxide per 1 kg of yield in a slightly acidic soil. Second application of the same fertilizer dose induced a 16% increase in emission per 1 kg of yield when the second dose was the mineral fertilizer. When the dose was applied three times (1st, 2nd and 3rd – mineral fertilizer in a slightly acidic environment), the emission increased only by 1% per 1 kg of yield. In the next study we would like to test and describe the influence of soil moisture on N_2O emission.

(Received 8th Jul 2018; accepted 6th Sep 2018)

Abstract. The aim of this study is to determine new distribution records of Asiatic wildcat in Northeastern Turkey. Latest distribution and status of this elusive cat was uncertain due to limited wildlife research in Turkey. This study was conducted in 2015 and 2016. Field studies were carried out based on direct and indirect observations. Besides obtaining camera trap photos, direct observations were conducted by one or two teams, each of which consisting of two wildlife experts. In indirect observations, all tracks, feces, spaw, scrape, urine and food remains were benefited from. As a result of the study, 6 camera trap video records belonging to Asiatic wildcat were obtained. Asiatic wildcat, once regarded as least concern species, is declining rapidly in its natural habitat because of habitat fragmentation followed by the pressure of large predators and excessive use of agricultural pesticides. This present study is an update on current distribution of Asiatic wildcat in Northeastern Anatolia of Turkey.
Keywords: *distribution, camera trap, wildcat, Bingöl, Turkey*

Introduction

There are twenty three recognized species of small wildcats worldwide (Yiqing and Yong, 1990; Nowell and Jackson, 1996; Jutzeler et al., 2010), being relatively primitive types and wild ancestors of domestic cats (Gao, 1987). Very simply, the European wildcat (Felis silvestris Schreber 1777) is distributed throughout Europe except for the northern regions; the African wildcat (*F. s. libyca* Forster 1780) is distributed in all African countries and south-western Asia; the Asiatic wildcat (*F. s. ornata* Gray 1830) is distributed in central and western Asia (Allen, 1938; Ellerman et al., 1951; Gao, 1987; Nowell and Jackson, 1996; Ablimit et al., 2010). The existence of distinguishable phenotypes across this wide distribution, along with apparently considerable local variation (Pocock, 1951; Yamaguchi et al., 2015), has left wildcat taxonomy in a state of confusion for many years (Guggisberg, 1975). The wildcat is a polytypic species with three wild subspecies, the European, African and Asiatic wildcats (Ragni and Randi, 1986, 1991; Wozencraft, 1993; Johnson and O'Brien, 1997). African and European wildcats are closely related and split recently, probably towards the end of the Last Glacial Maximum, as suggested by paleontological, biochemical and molecular data (Davis, 1987; Randi and Ragni, 1991; Masuda et al., 1996). Nowell and Jackson (1994) divided wildcats into three different forms; these three wildcat species seem to be more of a division of subspecies.

Domestic and wildcats can hybridize and generate fertile offspring both in captivity and in nature (Robinson, 1977; Ragni, 1993; Pierpaoli et al., 2003). The wildcats are now distributed worldwide due to deforestation, the spread of agriculture and the eradication of large predators, which have probably favoured the expansion of free-

© 2018, ALÖKI Kft., Budapest, Hungary

ranging, often in sympatry with wildcat populations in Europe and Africa (Nowell and Jackson, 1996).

There are five members of the Felidae family cat species in Turkey. Those are Leopard (*Panthera pardus*), European wildcat (*Felis silvestris*), Jungle cat (*Felis chaus*), Lynx (*Lynx lynx*) and Caracal (*Caracal caracal*) (Sarı, 2018). However, ecology, taxonomy, latest status and correct distribution and population sizes of those species are uncertain due to limited wildlife researches. The present research provided a new distribution record of the Asiatic wildcat in a narrow area of Turkey.

Materials and methods

Study area

Study area is located in Yedisu county of Bingöl province (39°23'52"N; 40°36'39"E) in Northeastern Anatolia, Turkey (*Fig. 1*). Our main goals were to obtain distribution records of Asiatic wildcat from both Turkish and foreign literature and observed by local hunters, wildlife officers and unconfirmed information provided by local people. Therefore, this area was chosen as the study area.

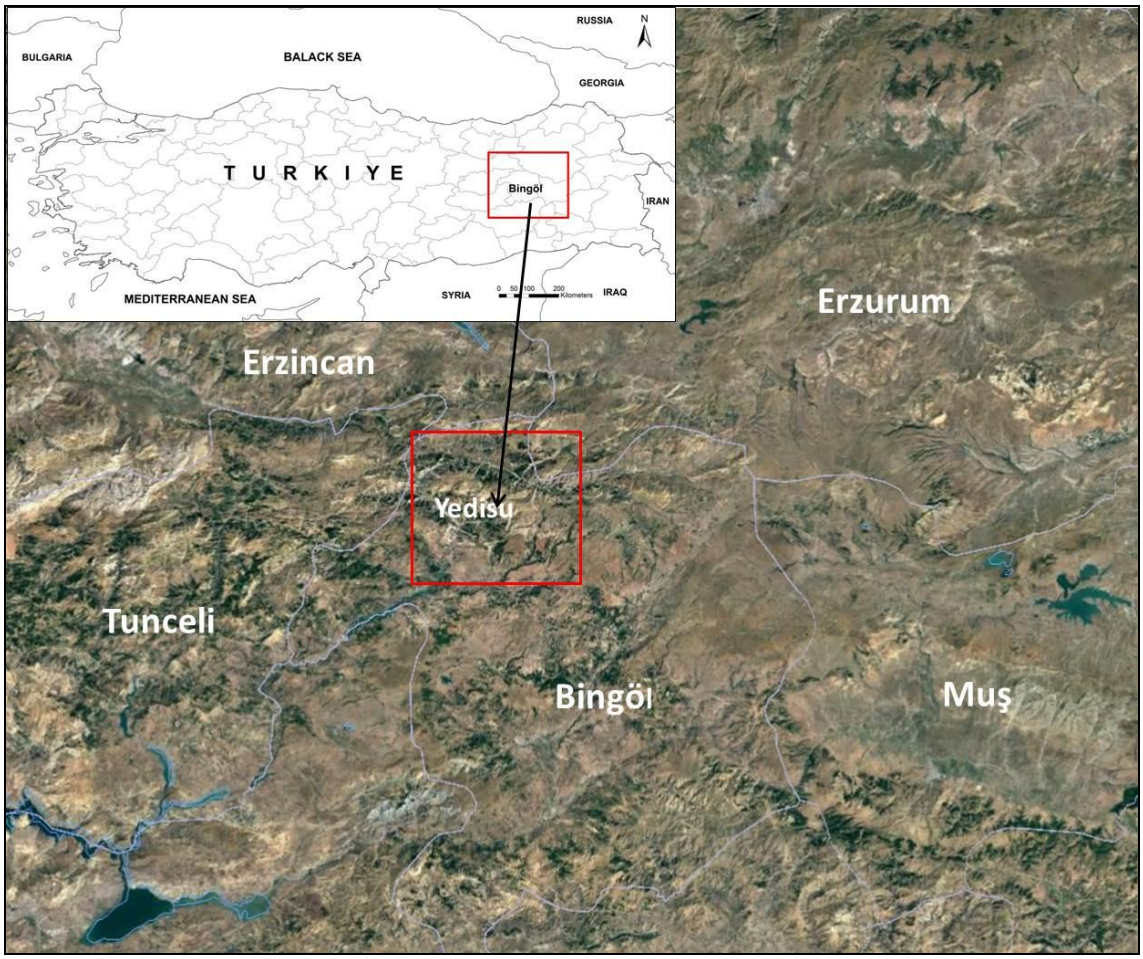

Figure 1. *Location of study area (Google Earth, 2018)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_67796785
© 2018, ALÖKI Kft., Budapest, Hungary

The land in the study area is quite rugged and high, with an average elevation of 1500 m. Mountains and hilly areas occupy a very large space. The study area is surrounded by Çavuşlu Mountain (2660 m.) in the east, Devil Mountain (2950 m.) in the south, Bağır Mountain (3173 m.) in the west and Koşan Mountains (3078 m.) in the north. The heights of the high plateaus and plains on the mountains are not below 2000 m. Even most plains are located on over 1000 m from sea level. The upper parts of the mountains cover the glacial lakes and the skirts cover moraine remains. On majority lands of Bingöl province, the dominant climate is continental. Winters are long and harsh, and summers short and hot. Annual mean temperature is 5.1 °C. Considering the course of temperature in the year, the coolest month is January (-9 °C), while the hottest month is August (39 °C). Annual mean precipitation in Bingöl is 32.9 mm. The study area is predominantly the Iranian-Turanian floristic region in terms of vegetation. For this reason, in the regions where the study areas are located, plant societies generally consist of forest and steppe formation. The mountains are covered with sparsely forested, with parts of the southern parts of the mountains are often empty. Scots pine (*Pinus sylvestris*) forests are pure and mixed with a sparse and fragmented spread in the average 1300-2000 m. Oak forests (*Quercus sp.*) are located in the lower part of 1200 m, and Common aspen (Populus tremula) and Silver birch (*Betula pendula*) trees are covered also scattered fragments.

Materials

A total of 21 camera traps which have infrared features were used and placed along the line during the study (*Fig. 2*). Swarovski 10x42 LC binocular and ATS/STS 80 (HD) (20-60x) telescope were used for direct observation. Various digital cameras (3x optical zoom-5.0 Mega Pixels and 12x optical zoom-6.0 Mega Pixels) and video recorder (24x optical zoom) were used to take photographs of species, their habitats and to record observations. Global Positioning System (Magellan Explorist 500L) was employed to record the altitude and coordinates in the field. We also conducted interviews with national park officers, Turkish military services, villagers, and shepherds: field situation in the past, poaching, and whether the species of special interest to the local people was discussed.

Methods

Field studies were conducted in 2015 and 2016 within a 150 km^2 area. We focused on making correct identifications of specimens and assessing the accuracy of observations by local hunters, wildlife officers and information provided by local people.

In external appearance Asiatic wildcat can only be confused with European wildcat, which has been characterized by its bushy tail, which ends as a broadly rounded black tip, and long soft fur with relatively conspicuous stripes (Yamaguchi et al., 2004). Asiatic wildcat has a slimmer build than European wildcat, a light brown or grey coloration with dark spots and a slim tail (Yamaguchi et al., 2004; Firouz, 2005; Yamaguchi et al., 2015). It was tried to obtain photographs and video images with camera traps in general. The camera traps were scattered randomly in the study area and were checked at certain times. The locations of camera traps were constantly changed according to tracks and indications obtained in the study area. Besides obtaining camera trap photos, direct observations were conducted by one or two teams, each of which consisting of two experts. In indirect observations, it was benefited from all tracks, feces, spaw, scrape, urine and food remains.

Results and discussion

Although specimens and living individuals of European wildcat have been reported in different parts of Turkey, The Asiatic wildcat records were obtained first in Yedisu, Bingöl in 2016 June. The Asiatic wildcat was only probably distributed in Northeastern of Turkey according to Demirsoy (1996). There is not any data about distribution of the Asiatic wild cat from Demirsoy (1996) in Turkey.

A total of 35625 photos and 161 hours of videos were recorded over 314 nights, making a total of 6594 trap nights for all the camera traps. As a result of the study 6 different camera trap video images belonging to one Asiatic wildcat were obtained. We checked all these data and found them to be *F. s. ornata*. Asiatic wildcat has distinct dark spots on its flanks as seen in the photos (*Fig. 3*). Our findings are in agreement with Ablimit and Khan (2013), that individuals identified in this study have a similar morphological structure with their findings. The coat pattern (color and points) of identified specimen are quite similar with them. Morphological criteria especially helped to resolve these identification problems in our study.

While European wildcats may be confused with domestic or feral cats, distinguishing them from Asiatic wildcat is easy. The wildcat's fur varies from tawny grey to light grey or sand colored, showing pronounced stripes and spots on the flanks, head and limbs, and also distinct rings on the black-tipped tail (Yamaguchi et al., 2004; Firouz, 2005). The European wildcat has been characterized by its bushy tail, which ends as a broadly rounded black tip, and long soft fur with relatively conspicuous stripes (Yamaguchi et al., 2015). The Asiatic wildcat is the least known and inhabits Eurasia from the Middle East to western India, through Central Asia to Mongolia and northwestern China. It is similar to the African wildcat, but is distinguishable by its coat pattern, which consists mainly of distinct dark spots instead of stripes. In most of the Middle East, including Iran, the Asiatic wildcat has spots on its flanks and head, while the coat of the European wild cat is uniformly greyish, without spots (Yamaguchi et al., 2004).

Domestic and wildcats can interbreed and produce fertile offspring both in captivity and in nature (Robinson, 1977; Ragni, 1993; Pierpaoli et al., 2003). However, Randi and Ragni (1991) determined that the rate of hybridization of domestic cat and wild cats was very low and they used their own large gene pools in breeding. In this study, it is thought that Asiatic cat individuals not hybrid individuals from European wild cat and domestic cat. But this problem is planned to be revealed in the future with another genetic study.

Figure 3. *Camera-trapped video images Asiatic wildcat in the study area*

Considering the habitat type characteristics of the areas belonging to the Asiatic wildcat, it has been determined that the important habitats are degraded Oak forest areas, rocky areas and pasture-grazing areas. These areas consist of grift shrub and trees and steep rocks. This habitat structure provides a number of concealed and escaped areas that can protect the Asiatic wildcat from larger compete predators such as leopard, lynx, wolf and bear.

There is limited information on the seasonal habitat use of Asiatic wildcat. However, it seems that the habitat use of the animal is strongly associated with the movements of its prey and human disturbance. Deforestation, the spread of agriculture and the eradication of large predators have probably favoured the expansion of free-ranging and feral cats, which are now distributed worldwide, often in sympatry with wildcat populations in Europe and Africa (Nowell and Jackson, 1996). The most important threats observed in the study for Asiatic wildcat are the habitat deterioration caused by overgrazing activities and the predatory pressure created by stray dogs and larger carnivore species.

Conclusions

In Turkey, wildlife studies on mammalian species are still not enough. This is the first documented report of the Asiatic wildcat's distribution from Turkey. As a conclusion, Northeastern Turkey should be thoroughly and regularly studied in order to better understand the Asiatic wildcat status and develop urgent conservation measures in these areas. It is important that further work be carried out to ascertain the size of the remaining Asiatic wildcat population in the other parts of Turkey. Despite the small size of the forest, the area is still rich in both fauna especially rodents and flora. It was observed that the populations of species that may be a food source for the Asiatic wildcat such as European hedgehog (*Erinaceus concolor* Martin 1837), European hare (*Lepus europaeus* Pallas 1778), Common Tortoise (*Testudo graeca* Linnaeus 1758) and Williams's jerboa (*Allactaga williamsi* Thomas 1897) were in very good condition. The Asiatic wildcat being the predator, has an important role in maintaining the health of the ecosystem. Therefore, the population size of the Asiatic wildcat could be used as indicator of sustainable conservation and management of the species in the area. Unknown and population size is critically small, any fatality of Asiatic wildcat individuals may lead to population extinction in the study area. Therefore, more studies should be carried out to investigate the reproduction status and sex composition of the Asiatic wildcat population in the study area. This would help the managers to control the population size over successive years using suitable management techniques.

Abstract. The past ten years have been a period of rapid urbanization in China, and are meaningful to evaluate urban landscape ecological pattern of this period. The urban landscape can be divided into the architectural space and 6 types of open space with different functions. Based on this kind of classification, this study used an urban area with 101 km^2 to evaluate landscape ecological pattern. This study chose 4 indices, namely, Patch density, Landscape shape index, Contagion index and Shannon's diversity index. Using ArcGIS and Fragstats, this study evaluated the landscape ecological patterns of various scales and multiple time points in the case area. The study found that at the macro level, except for the Patch density, which has the relatively obvious growth trend, the landscape ecological pattern indices of other overall levels are not significantly different in time series. However, at the micro level, the spatial differentiation characteristics of each index between 1 km^2 spatial units are very obvious and they have great changes according to the different time periods. Therefore, the evaluation of the landscape ecological pattern of the rapidly growing urbanization areas should pay more attention to the spatial unit comparison of the micro level, so as to discover the special areas in the urban space where the landscape ecology is unbalanced and unstable.
Keywords: *open space system, urban geography, landscape ecology, evaluation*

Introduction

Recently, China has witnessed rapid development of urbanization, and various elements in urban space have undergone drastic changes with rapid urbanization process. In this process , Chinese researchers have carried out many studies in combination with the practical situation of China (Chen et al., 2014; Wu et al., 2014). There are a series of problems to urban landscape ecology that need to be solved. Researchers and institutions have paid more attention to the related urban landscape ecological pattern research. It has been pointed out that the landscape ecological pattern of the city is suitable for observation and evaluation through multi-scale and flexible spatial classification (Li et al., 2010; Jun-Hyun et al., 2016; Grafius et al., 2018).

The ecological pattern of urban landscape should be viewed from the macro and micro level. At the macro level, observe the whole change of indicators, and at the micro level, observe the differences of indicators of different spatial units. The city is a spatially heterogeneous, and complex adaptive system. Landscape pattern and its changes are the results of the interaction of natural, social and biological elements

(Turner, 2003; Forman, 2016). The intensified human activities lead to fragmentation of landscapes, which have a series of impacts on ecosystems, and damage to the health and integrity of ecosystems, bringing about changes in ecosystem service functions. At the macro level, the city is human habitation, and is often used as a continuous construction site in ecological research. Its internal ecological features are different to express in large-scale space. Meanwhile, at the micro level, because the inner city is divided into different lots by artificial roads, its ecological features and ecological functions are very different from the macro scale.

The main reasons for the study of urban landscape ecology at the micro level are the accuracy of data and the classification of spatial elements (Wang, 2010). In the traditional study, many large scale studies regard 30-m square as a basic grid element. These studies juxtapose urban construction land and forest land, fields, water bodies, etc. which are outside the main urban area as large-scale elements, but ignore the complexity and diversity of urban landscape ecology. The essence of ecological function in urban open space system is that the basic space unit is an organic whole which are associated with each other. The urban green space system was once the main research object of urban landscape ecology. But the analysis and optimization of urban green land mostly stay on the classification of lots on drawings. The green space on drawings has a large subjective qualitative component which cannot reflect the ecological effects such as real green coverage in a region at the middle and micro level and cannot quantify the urban landscape ecological pattern.

Landscape ecological classification is the basis and prerequisite for landscape pattern analysis and landscape function evaluation (Xiao et al., 1998). In recent years, the theory of urban open space systems studied by Chinese domestic scholars has made new developments in spatial classification (Wang, 2005; Wang et al., 2012; Wang, 2010; Shao, 2011; Mao et al., 2016a, b). Open space is a general term of surface space outside the building in the city. Therefore, urban landscape can be divided by the most basic architectural space and the open space. At first, the open space is divided into green open space which represents green coverage and gray open space which represents road, square, waste land, etc. (Wang, 2005). With the continuous study of researchers, the open space can be divided into 6 types: green open space, blue open space (Wang, 2010), light gray open space, dark gray open space, yellow green space ("Production land" in the original paper, Shao, 2011) and brown open space. Together with the architectural space, these six types form the basic landscape classification for our study. The meaning of various types of space can be seen in *Table 1*.

Table 1. *Table of landscape ecological elements based on open space classification*

Space classification	Meaning
Green open space	Trees, shrubs, lawns and other cities have plants covered space
Blue open space	Rivers, ditches, lakes and other water bodies in cities
Light grey open space	Piazza, open-air stadium, open car park and outdoor temporary stacking sites
Deep grey open space	Urban traffic space, such as road, track, viaduct, etc.
Brown open space	Bare land, abandoned land, urban space under demolition and construction
Yellowish open space	Agricultural planting areas in urban space
Architectural space	The space occupied by buildings in the city or the space beyond the open space

This classification method combines the author's thinking on the classification of open space. It has strong identifiability in remote sensing, aerial photography and other resources, and reflects the ecological value of different levels. There were similar practice studies before (Wang, 2010). So study group consider that this open space classification can well reflect the urban landscape pattern. Using this classification method to interpret and classify high-precision satellite imagery cannot only satisfy the macro-scale landscape ecological pattern evaluation, but also meet the micro-scale landscape ecological pattern evaluation.

Case area and data

Case area

The study area is located in Xinxiang City, China. Xinxiang City is located in 35°18' north latitude and 113°54' east longitude, which is one of the core cities of China's Central Plains urban agglomeration (*Fig. 1*). Xinxiang City covers an area of 422 km^2 and a total area of about 140 km^2, with the population of 1.4 million. The research object of this time is the main city of Xinxiang City (*Fig. 2*). It is surrounded by the loop line which is comprised by four roads. It is 101 km^2. The main city area of Xinxiang City is flat and the boundary is composed of four outer loop expressways. It is clear and complete. The traffic in the urban area is basically a square road network. It is an ideal plain landscape ecological city model.

Case data

The study chose time-series high-definition satellite imagery (mostly with 0.85-m resolution, a small amount with 1.85-m resolution), and comprehensively carried out a variety of methods including visual interpretation, and combined with the basic grid unit for refined opening spatial elements extract in categories, so as to achieve full coverage of urban spatial classifications. Finally, in the case area, the classified data resources of 5 time nodes (2008, 2010, 2012, 2014, and 2016) were obtained. These data can reflect the spatial and temporal evolution of landscape ecology in the last 10 years of Xinxiang City's main urban area in a more detailed and comprehensive way.

Method

Many researchers used remote sensing images and related geospatial data as information sources, and used GIS technology and landscape pattern software to classify and analysis. Wang Shengnan divided open space into green, blue, gray and other types in her doctoral dissertation (Wang, 2010), through landscape ecological pattern analysis and other methods were used to analyze the evolution mechanism of the main city area of Luoyang in the process of rapid urbanization. In Shao Dawei's doctoral dissertation, he used remote sensing data and landscape pattern indicators to analyze the spatial evolution of Nanjing (Shao, 2011). At the same time, it is more common to study urban microcosmic spatial analysis with unit grids (Guo, 2016; Gao, 2014). The unit scale of these studies is basically 1 km^2. These studies provide an important reference to software selection and index selection of this paper.

Study software

The software used in the research mainly includes ArcGIS and Fragstats. ArcGIS is a most used geographic information software in the world nowadays. By using ArcGIS, various kinds of geographic data can be connected and matched. Transformation between vector data and grid data can also be finished. Fragstats are mainly used to deal with landscape ecological pattern index. There are many softwares for analyzing or simulating landscape ecological pattern, such as Fragstats, Patch Analyst, APACK, SIMMAP, etc. Fragstats is a software for calculating landscape index which was developed by the Department of Forest Science at Oregon State University in America. Because it is free and easy to use, it can support a series of landscape pattern index at three levels: Patch Metrics, Class Metrics and Landscape Metrics. At present, Fragstats is a computer program for quantitative analysis of landscape structure and spatial pattern, which can calculate including landscape area, density, size and difference, edge, shape, core lot, nearest neighbor structure, diversity structure, aggregation and dispersion structure and hundreds of indices which are combined with statistics. There are many cases of landscape ecology research using these two software (Hua et al., 2008; Midha and Mathur, 2010; Kupfer, 2012; Ojoyi et al., 2017; Yan et al., 2018). So choosing these two software is very suitable.

Index selection

Based on the previous research results (Wu, 2007; Hong et al., 2011; Liu et al., 2013), patch density, landscape shape index, contagion index and Shannon's diversity index were selected as analysis indicators in this study.

Patch density

Patch density (PD) is an index of the number of patches divided by the total area (Wu, 2007), and it is generally used to observe landscape fragmentation (see *Eq. 1* for calculation). In the equation, N represents the number of patches and A represents the area. The larger the patch density is, the greater the fragmentation is, so it is regarded as a reverse index in this study.

$$PD = N/A \quad \text{(Eq.1)}$$

Landscape shape index

The landscape shape index (LSI) is the total length of all plaque boundaries in the landscape (m) divided by the square root of the total area of the landscape (m), multiplied by the square correction constant (Wu, 2007; see *Eq. 2* for calculation). In the equation, E is the total length of all patch boundaries in the landscape, and A is the total area of the landscape. In urban space, the high value area of LSI value is usually the area where human activities are dense and the degree of fragmentation is higher.

$$LSI = \frac{0.25E}{\sqrt{A}} \quad \text{(Eq.2)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_67876799
© 2018, ALÖKI Kft., Budapest, Hungary

Contagion index

Contagion index (CONT) is considered to describe the degree of agglomeration or extension trend of different piecemeal types in the landscape (Wu, 2007; see *Eq. 3* for calculation). In the equation, m is the total number of plaque types, and P_{ij} is the probability that two adjacent grid cells randomly selected belong to type i and j. Like other indicators of ecological pattern, its significance of the Numbers will vary according to the interpretation of different majors and directions. Generally speaking, the high contagion index indicates that a certain dominant block type in the landscape has formed a good connectivity, while the low value indicates that the landscape fragmentation degree is high.

$$CONT = \left[1 + \sum_{i=1}^{m}\sum_{j=1}^{n}\frac{P_{ij}\ln(P_{ij})}{2\ln(m)}\right](100) \quad \text{(Eq.3)}$$

Shannon diversity index

Shannon diversity index (SHDI) is obtained by multiplying the area ratio of various patches by the negative value of the sum of the natural logarithm of that value (Wu, 2007; see *Eq. 4* for calculation). In the equation, m represents the number of species and P_i represents the proportion of individuals belonging to the first species in the sample. In ecology, Shannon's diversity index is a sensitive index, which is generally used to reflect landscape heterogeneity. When the index is 0, it shows that the patch is a single patch, and the greater the value of the patch is, the more balanced each patch is, and the higher the land use degree is.

$$SHDI = -\sum_{i=1}^{m}\left[P_i\ln(P_i)\right] \quad \text{(Eq.4)}$$

Research steps

First item

This research first carries on the analysis from the macroscopic scale. Taking ArcGIS 10.2 as the basic software platform, the vector data of the case area that has been interpreted and classified are projected and converted into grid data of 1 m × 1 m. Loading raster data into fragstats can quickly get macro-scale indicators.

Second item

For the microscopic scale, this study chose to generate 1 km × 1 km grids in the UTM projection coordinate system (*Fig. 3*), and took each grid as the microscopic observation unit of the case area. In *Fig. 3,* for ease of study, the researchers digitally represent the abscissa and alphabetically represent the ordinates of the table. Such grid units can be named, for example, A01, A02, etc. At the same time, In ArcGIS, the generated grid is used to cut the transformed grid data, which will allow you to generate hundreds of separate grid files. Then, the batch processing function in fragstats can be used to quickly analyze and get the index value of each unit.

© 2018, ALÖKI Kft., Budapest, Hungary

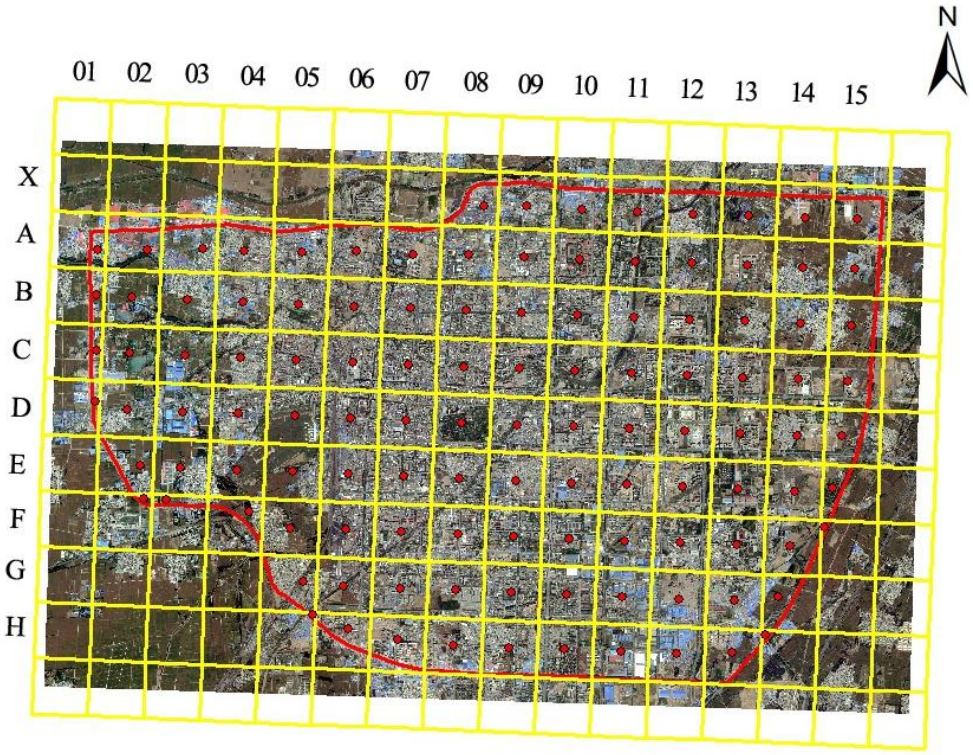

Figure 3. *case area satellite picture divided by 1 km× 1km grid*

Third item

The spatial unit can be connected with the index in ArcGIS by format conversion of the obtained spatial unit index values. By classifying the connection results, the micro-scale landscape ecological pattern of the case area can be visualized in ArcGIS.

Results and analysis

Macro-scale

This study first used software to calculate the indicators for landscape ecological pattern in case area from 2008 to 2012 (*Table 2*). *Table 2* shows that the number of patches in (NP) declined gradually, while it rose overall from 2012 to 2016, which shows that a certain degree of fragmentation of urban space is not a linear change but dynamic development.

Table 2. *Table of indicators for landscape ecological pattern in case area (2008-2016 years)*

YEAR	PD (patch density)	LSI (landscape shape index)	CONT (contagion index)	SHDI (Shannon diversity index)
2008	482.290	167.860	47.355	1.649
2010	468.196	169.820	46.154	1.687
2012	466.767	168.244	47.562	1.637
2014	509.865	177.523	46.086	1.675
2016	493.580	173.527	47.250	1.641

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_67876799

According to the number of different types of patches, the number of blue patches and yellow-green patches decreased linearly, while the number of other types of patches fluctuated. The change of landscape shape index (LSI) is small, showing a fluctuating and rising state, which indicates that the intervention of artificial behavior on the environment has increased to a certain extent. In 2008-2016, due to the solidification of the boundary of the main urban area, the indexes of the overall level, such as contagion index, Shannon's diversity index and aggregation index, all changed little, and the indicators need to be compared with each other in a downsized scale.

Micro scale

According to *Figure 4,* there are obvious spatial differences. The scale of the value is obtained by determining the global median and then the arithmetical difference. The minimum value of unit's PD increased from 45 in 2008 to more than 100 in 2016, and the maximum value increased from about 1400 in 2008 to more than 1600, indicating that the rapid urbanization has brought about increased spatial fragmentation. There are continuous units with high patch density in the northwest and central part of the main urban area for a long time. These units belong to the living area of the old city and the small industrial factory area, the buildings are mostly low stories, the building density is generally high, and the open space is broken up seriously. Besides, the patch density of the southeast part of the main urban area is relatively low, the building is generally multi-storey, the high level is high, and the open space is relatively complete.

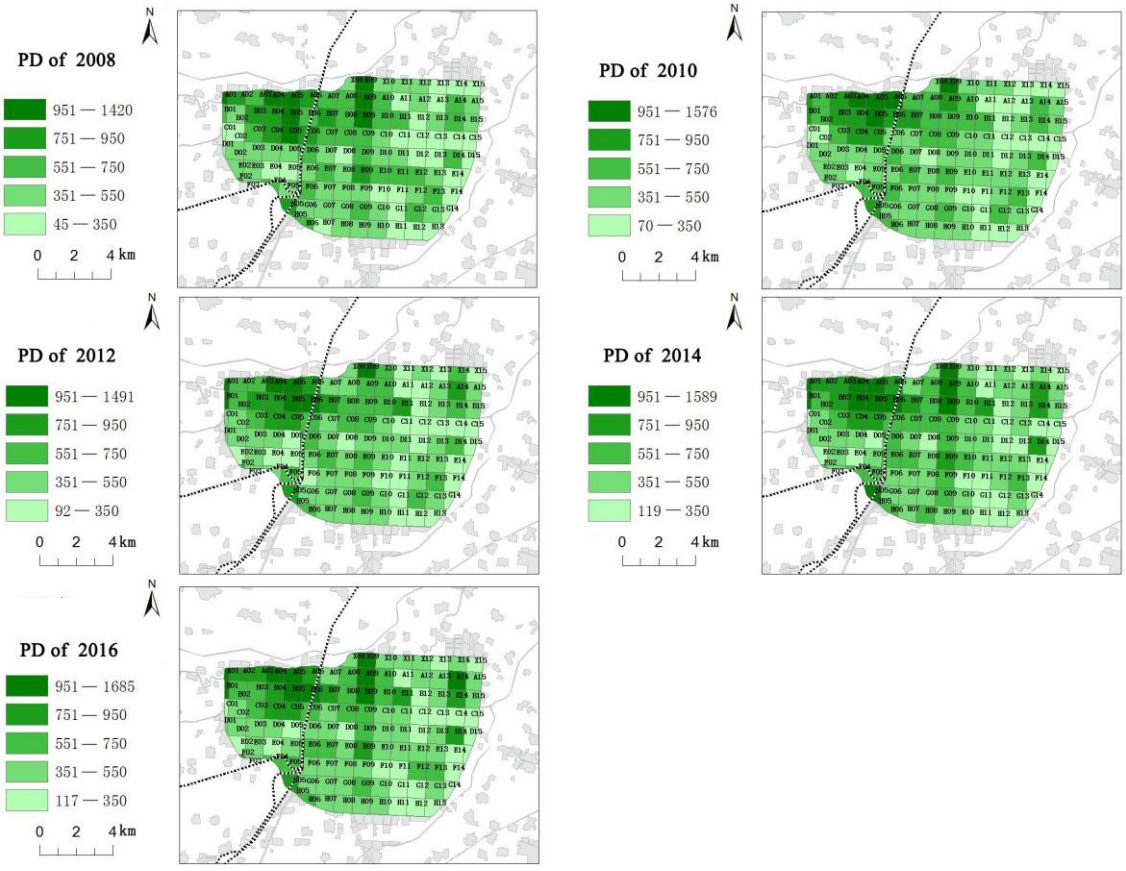

Figure 4. *Pattern maps of patch density based on Xinxiang grid units in 2008-2016*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_67876799
© 2018, ALÖKI Kft., Budapest, Hungary

From *Figure 5* it can be seen that the difference between the unit and the surrounding area of the people's park is very obvious, and the contrast between the old urban area in the west and the new urban area in the east is also obvious. Green open space, large proportion of yellow and green space landscape shape index are relatively low. Because of the village in the city, the landscape shape index of the east and south of the main urban area is decreasing, while the central and northern land block is in high value for a long time.

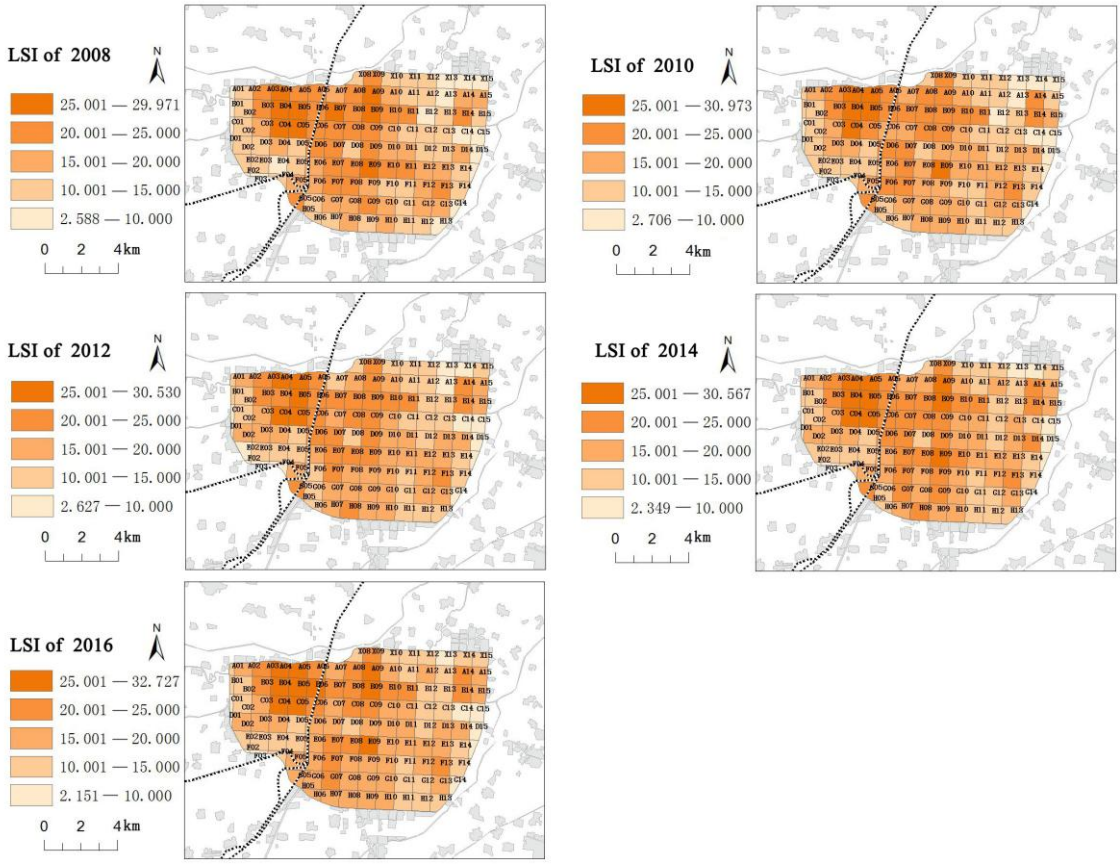

Figure 5. *Pattern maps of Landscape shape index based on Xinxiang grid units in 2008-2016*

From 2008 to 2016, *Figure 6* shows that the high value units of the spreading degree gradually change from the edge of the main urban area to the central zone of the main urban area, which reflects the recent decade of urban construction on the yellow and green space (suburban farmland) erosion. While the contrast between the high value units and the adjacent low value units in the central part of the city is becoming more and more obvious, which reflects that there is still a large imbalance in the urban center area.

According to *Figure 7,* the main urban area of Xinxiang city as a whole presents the distribution pattern of low central area and high surrounding area. And there are obvious low value continuous units around the railway line and in the northeast of the main urban area. The number of very low value units and very high value units has declined in the last decade, which reflects that the urban construction of the main urban area has entered a more stable period.

Comparative analysis

It is found that the landscape ecological pattern in the main urban area of Xinxiang is not consistent in macro scale and micro scale, especially in micro scale. On the one hand, the distribution of green open space and blue open space is not balanced. The green coverage rate of old urban area, shantytown and village in city is very low, and it is the key area of ecological development. On the other hand, brown open space is an important factor affecting urban ecological environment, and its volume is very large. The spatial distribution of the blue open space is quite different, so it is recommended to actively repair the city river and build the ecological corridor. The generation of brown open space occurs more frequently in the process of urban renewal and transformation, and the new construction land is more likely to produce brown open space. Moreover, brown open space is also characterized by a rapid transformation into a green open space. The conversion of green open space and brown open space is also worthy of attention.

Conclusions

The dynamic trajectory of cities can never be fully predicted or controlled, but can and should be influenced or guided in more desirable directions through planning and design activities that are based on urban ecological knowledge and sustainability principles (Ramalho and Hobbs, 2012; Ahern, 2013; Kattel et al., 2013; Wu, 2014; Tanner et al., 2016). For landscape ecological pattern, different scale and precision of observation can obtain different study results. Compared with previous studies, this study is more innovative based on the latest classification of open space and the combination of micro grid units. Based on high resolution image and open space classification, this study classified and extracted the urban space system of the case area. This study analyzed Patch density, Landscape shape index, Contagion index and Shannon's diversity index from the macro level and the micro level. Comparative analysis at the micro level can discover some problem areas that are not found at the macro level. At the micro level, the spatial differentiation characteristics of each index between spatial units are very obvious and they have great changes according to different time period. Therefore, the evaluation of the landscape ecological pattern in the rapidly growing urbanization areas should pay more attention to the spatial unit comparison at the micro level, so as to discover the special areas in the urban space where the landscape ecology is unbalanced and unstable. Urban construction and planning should be able to timely monitor and pay attention to the spatial units with low landscape ecological patterns. These can serve the current "Urban Repair" and "Ecological Restoration" services and improve the overall ecological quality of cities and regions.

Abstract. Drought stress may affect the yield and sucrose accumulation of sugar beet by restricting leaf and root growth**.** The effect of inoculation of nine IAA-producing, N_2-fixing, P-solubilizing and ACC deaminase-containing bacteria on the yield and morpho-physiological parameters of sugar beet under five different water regimes was investigated. The diminishing water supply caused a gradual decrease in the plant growth, chlorophyll contents, root and leaf weight and sugar content, accompanied by increasing activities of drought stress markers (GR, GST, G6PD, 6PGD, MDA and H_2O_2). Although it varied depending on the water regimes and bacterial strains, the results of two pot experiments show that inoculation with multi-traits plant growth promoting bacteria stimulated overall plant growth, including enzyme activity, sugar content, fibrous and storage roots development and leaf yield and the contents of leaf chlorophyll, N, P, K, Ca, Mg, Na, Mn and Zn, but decreased MDA and H_2O_2 contents, which might partly contribute to the activation of the processes involved in the alleviation of the effect of water stress.
Keywords: *water stress, enzyme activity, nutrients uptake, plant growth-promoting bacteria, malondialdehyde content (MDA), hydrogen peroxide (H_2O_2)*

Introduction

Beta vulgaris L. (sugar beet) is a very significant industrial sugar product, and the most significant input for sugar beet production is mineral fertilizer. Sugar beet production demands more water, but recently, stress of water has turn into an important limitation to sugar beet production, causing serious reductions in productivity. Drought is described by the decrease of water content. One of the most widespread environmental factors affecting plant fertility is drought. During the drought, level of water in leaf decrease and turgor is diminished. As result, reduces cell growth and yield with stoma closes. Drought inhibits the photosynthesis of plants, and thus reduces growth and development. Water stress reduces the production rate of dry matter and is considered as one of the major limiting factors for sugar beet root and leaf yield (Pidgeon et al., 2006; Romano et al., 2013). As evidenced, sucrose concentration and photosynthesis extremely responsive to drought because of its activity reduces with the growing water shortage (Bloch et al., 2006).

Plant-growth-promoting rhizobacteria (PGPR) improve many physiological, nutritional, morphological and biochemical plant responses, and thus, it enhances the plant resistance to abiotic and biotic stresses. The inoculation of selected drought-tolerant strains can reduce the yield limitation caused by water deficit and improve the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_68016813
© 2018, ALÖKI Kft., Budapest, Hungary

ability of plant tolerance to drought stress (Marulanda et al., 2009; Castillo et al., 2013). In this regard, the use of PGPR is seen as a different tactic to induce stress endurance in cultivation. PGPR has skill to fix nitrogen, solubilize inorganic phosphate, generate 1-aminocyclopropane-1-carboxylate (ACC) deaminase and indole acetic acid (IAA), and support plant development. The bacteria which having ACC deaminase can decrease the negative effects of ethylene causing stress of water (Safronova et al., 2006). Under stress conditions in plants, while "stress ethylene" production increases if the bacteria prevent the ethylene synthesis and containing ACC deaminase, plants can reduce the level of ethylene, expected to provide protection against the inhibitory effects of stress in plants (Çakmakçı et al., 2009).

For increase the crop production, we need to selected effective bacteria which plant growth-promoting rhizobacteria. In addition to there are a few number of studies which against water stress using PGPR. Different approaches are required for better water wasting due to the lack of water resources for this reason, this study was governed for research the effect of varied ACC deaminase-containing, IAA-producing, N2-fixing and/or P-solubilizing bacterial species on the growth, antioxidant and pentose phosphate oxidative cycle enzymes, root yield and quality, in the sugar beet, under different water regimes (150%, 100%, 75%, 50%, and 25% of water-holding capacity). In this study, under limited water conditions, we aimed to reduce the loss of quality and efficiency depending on the stress and to increase the water stress resistance of sugar beet by using bacteria inducing the plant growth.

Materials and methods

Bacterial species

The bacterial species *Bacillus subtilis* RC11, *Bacillus subtilis* RC63, *Pseudomonas fluorescens* T26, *Rhodococcus erythropolis* RC9, and *Variovorax paradoxus* RC21 were isolated from the rhizosphere of wild red raspberries, and *Paenibacillus polymyxa* RC05 was isolated from wheat (Çakmakçı et al., 2007, 2009). The other four strains (*Pseudomonas putida* RC310, *Pseudomonas fluorescens* PF8/6, and *Bacillus megaterium* A21/3) were isolated from the rhizosphere of tea (Çakmakçı et al., 2010). Some features of bacteria used in the experiment are given in *Table 1*.

Table 1. *Some features of bacteria used in the experiment*

Used bacterial isolates	IAA-production (μg mL^{-1} OD_{600} $unit^{-1}$)	Nitrogenase activity (nmol C_2H_4, 10^7 cfu h^{-1})	P- solubilization (μg P mL^{-1} d^{-1})	ACC deaminase activity (nmol α-ketobutyrate mg^{-1} protein h^{-1})
Rhodococcus erythropolis RC9	22.6 ± 1.5	0.55 ± 0.11	27.8 ± 1.5	577.8 ± 26.7
Pseudomonas fluorescens T26	23.9 ± 2.1	0.61 ± 0.13	27.7 ± 1.2	796.1 ± 35.2
Paenibacillus polymyxa RC05	32.8 ± 2.6	0.68 ± 0.14	10.1 ± 0.9	682.1 ± 33.7
Bacillus subtilis RC11	29.4 ± 1.8	0.32 ± 0.12	16.6 ± 0.4	539.2 ± 21.2

Experiments and growth conditions

This study was established under natural light in green house Department of Field Crops, Faculty of Agriculture, Atatürk University of Erzurum during 2010-2011 production season. Sugar beet seedlings were grown in a greenhouse during the initial period in a night- day cycle of 10-14 h light, 15 to 24 °C, and 60% humidity and during the development period in 15-9 h day-night, 16-28 °C and 55-60% relative humidity. Two different trial sets were established as a factorial arrangement (treatments x water regimes) in randomized complete block design with five replications. Totally 11 applications existed in both test sets; (1) control (no bacteria and no mineral fertilizers), (2) NP-fertilizers (55 mg of N + 40 mg P/kg soil), (3) *R. erythropolis* RC9, (4) *P. fluorescens* T26, (5) *P. polymyxa* RC05, (6) *B. subtilis* RC11, (7) *V. paradoxus* RC21, (8) *P. putida* RC310, (9) *P. fluorescens* PF8/6, (10) *B. subtilis* RC63 and (11) *B. megaterium* A21/3, and five water regimes, randomly distributed into pots filled with equal amounts of soil. The soil was a sandy clay loam with an organic substance content of 3.2%, pH 7.6, present Olsen-phosphorus content of 16.2 mg kg^{-1} and total N content of 15.7 mg kg^{-1}. Replaceable K, Ca, Mg and Na were 448, 3420, 472 and 78 mg kg^{-1}; present Fe, Mn, Zn and Cu contents were 5.9, 9.6, 1.2 and 1.7 ppm. Bacterial inoculation of the seeds was carried out according to Sahin et al. (2004).

Two pots essay were made on sugar beet fully watered (100% of water-holding capacity (WHC)), under waterlogging (150% of the maximum WHC), and continuous moderate (75% and 50% of WHC) and severe water stress (25% of WHC). At the beginning of the experiment, pots were saturated with water to determine the water-holding capacity (WHC) per pot; pots were covered to prevent evaporation and they were left for free drainage. After the drainage was stopped, pots were weighed and WHC was found. After sugar beet was planted, all the pots were irrigated at the rate of 65 ± 5% of WHC to provide the seedling emergence and seedling hold for 3 weeks after planting. After three weeks from planting, different irrigation levels were started to be applied in both sets of experiment. Irrigation applications were determined by the amount of available moisture in the soil. By this method, to determine the available moisture in the soil, the amount of moisture, which can bring WHC to the same soil, was determined and different ratios were discussed for the consummation of the lost moisture. Amount of irrigation water that would be given for each pot determined that difference as coefficient (150% 100, 75%, 50%, 25%) multiplying. The pots were measured every three days), the amount of irrigation water diminishing from each group was completed by adding according to pot's own capacity.

After two weeks from planting, seedlings were thinned in the pots, in each pot, 5 plants were remained in five leaf period for the first and 1 plant was allowed in seven leaf period for the second experiment. Using a chlorophyll meter SPAD-502 (Minolta, Japan), Chlorophyll contents of leaves which the top fourth and fifth was evaluated. The first experiment set was harvested 65 days after sowing and the second set was harvested 130 days after sowing. A t 80 °C, dry weightiness was detected by drying for 48 h. Sugar beets' sugar contents in storage-root were detected during harvesting and it was expressed as a weight per plant.

Definition of enzyme activities and protein concentrations

Leaves which washed three times in total was adjusted as ph 8.0 and Using liquid nitrogen, plant examples were homogenized The activities of glutathione reductase

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_68016813
© 2018, ALÖKI Kft., Budapest, Hungary

(GR; EC 1.8.1.7), glutathione S-transferase (GST; EC 2.5.1.18), glucose-6-phosphate dehydrogenase (G6PD; EC 1.1.1.49) and 6-phosphogluconate dehydrogenase (6PGD; EC 1.1.1.44) were determined with the according to Carlberg and Mannervik (1985), Habig and Jacoby (1981) and Beutler (1984). Each enzyme activity was detected spectrophotometrically (Shimadzu Spectrophotometer UV-1208, Kyoto, Japan) at 25 °C. Protein concentration was calculated according to the method of Bradford (1976) with help to 595 nm absorbance measurement by using as the standard of bovine serum albumin.

Measurement of H_2O_2 and MDA

The content of H_2O_2 was assessed according to the method described by Sairam and Srivastava (2002). The density of H_20_2 was determined spectrophotometrically by reading the absorbance of the titanium-hydro peroxide complex and calculated using a standard curve drawn with a known H_2O_2 concentration. Lipid peroxidation was determined by estimating the malondialdehyde (MDA) content in fresh leaf weight according to the method of Heath and Packer (1968), prepared in 10% trichloroacetic acid containing 0.65% 2-thiobarbituric acid (TBA) and it was heated at 95 °C for 25 min, and then quickly cooled. The concentration of MDA was calculated from the absorbance at 532 nm and expressed as nmol g^{-1} FW.

Macro and micro element content of sugar beet leaf

The leaf samples were dried in the oven at 68 °C for 48 h and milled to 1 mm. Total N was measured by The Kjeldahl method and a Vapodest 10 Rapid Kjeldahl Distillation Unit (Gerhardt, Konigswinter, Germany). Following the extraction process, Macro- (P, K, Ca and Mg) and micro-elements (Fe, Mn, Zn and Cu) were detected by the inductively Coupled Plasma spectrophotometer (Optima 2100 DV, ICP/OES, Perkin-Elmer, Waltham MA, USA).

Statistical analysis

Analysis of variance from SPSS 13.0 (SPSS Inc.) programme was performed on the data obtained from both trials and then in conformity with Duncan's Multiple Range Test, the means were separated. The level of enzyme activities was evaluated in three samples from each replicate.

Results

In terms of sugar beet root dry weight for both harvests (65-day and 130-day harvest), all treatments, except for *P. fluorescens* PF8/6, gave better results compared to control (*Table 2*). According to the average irrigation level, the highest dry root weight was achieved with *P. putida* RC310 and *B. subtilis* RC63 inoculations in both trials. If sugar beet was harvested at early period, it was found that water restriction importantly reduced the root weight. Inoculation with RC310 and RC63 increased fresh and dry leaf weight compared to control and fertilizers, but other inoculations gave the same result with mineral fertilizer. Strains RC310, RC63, RC11, T26, and RC21 were most effective in promoting fresh and dry leaf weight of sugar beet in both trials set. Moreover, these strains were found to be effective in terms of fresh and dry leaf and root weight at water constraint applications at levels of 75%, 50% and 25% of WHC. In

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

the excessive water application of both trial sets, primarily IAA-producing and N_2-fixing *P. polymyxa* RC05 and *R. erythropolis* RC9, all bacteria inoculations importantly increased dry root and leaf weight, and the amount of sugar per plant compared to control. Water-stressed plants inoculated with the effective PGPR recorded improved the plant growth in terms of dry root weight, and sugar per plant compared to the un-inoculated, water-stressed plants (*Table 2; Fig. 1*). As an average of the five water regimes, PGPR inoculation increased dry storage root weight by 0.3-41.5% and 2.1-45.6% at the first and second trials, whereas, NP fertilizer increased root weight by 20.2 and 31.8%, respectively, compared with control (*Table 2*). In the application of water at the rate of 25% of WHC, inoculation with RC310 and RC11 achieved an increase respectively of 37.6 and 35.5%, and 43.0 and 39.5% in the trial first and second compared with control. These were, however, higher than 6.1% and 9.2% increases by NP fertilization over control.

Table 2. *The effect of PGPR and fertilizer application on the dry storage root leaf weight of sugar beet in different harvest and under different water regimes*

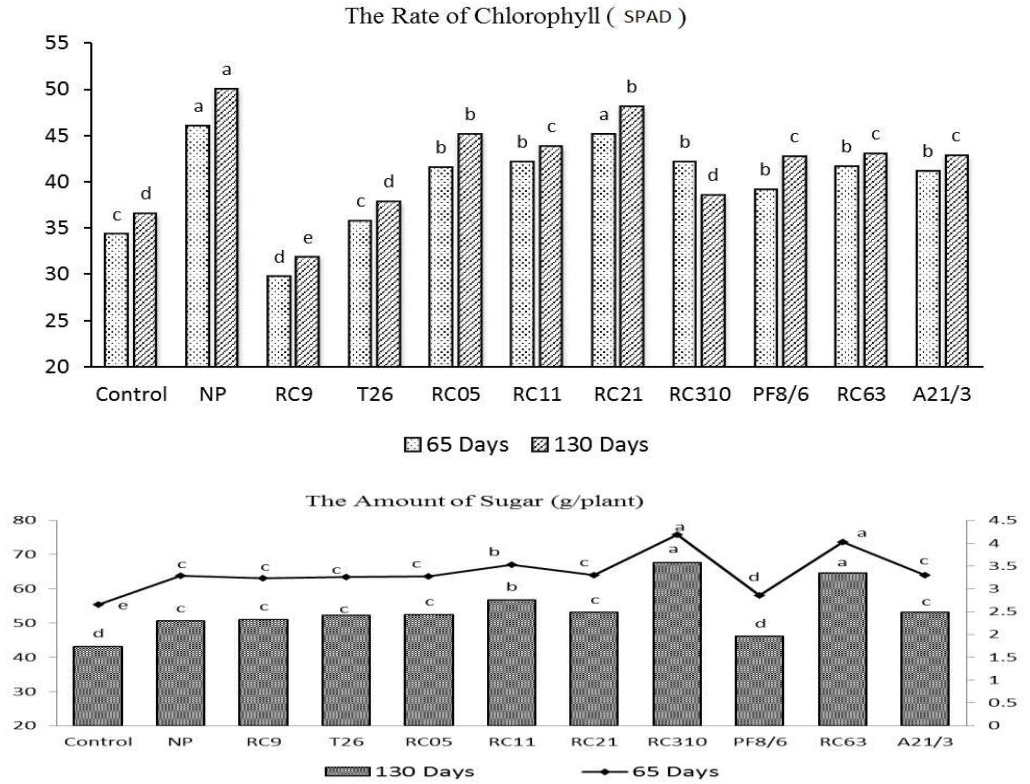

Figure 1. *Effect of PGPR and mineral fertilizer on the chlorophyll content and sugar per plant at the first (65 days) and second trial (130 days) average of five water regimes*

Under waterlogging stress (150% of WHC), sugar beet chlorophyll contents importantly raised NP fertilizer, RC21, A21/3 and RC05 inoculation. The maximum chlorophyll contents in the sugar beet leaves was found after RC21, followed by RC11, RC310 and RC05 inoculations under water stress applied at 75%, 50% and 25% WHC in both experiments (*Fig. 1*). In both trial sets, water stress decreased the chlorophyll contents of sugar beet, and generally, inoculation of the multi traits bacteria under water stress improved the chlorophyll contents, but responses were strain-specific. Chlorophyll content was positively and importantly correlated ($p \leq 0.01$) with dry root weight ($r = 0.35^{**}$), dry leaf weight ($r = 0.36^{**}$) and sugar per plant ($r = 0.34^{**}$) contents.

Of the bacterial inoculations, RC310 and RC63 produced the highest sugar per plant compared to control and mineral fertilizer while other inoculations gave the same result with mineral fertilizer. The highest ACC deaminase-containing RC63, RC310, RC11, and T26 inoculation were found to be effective according to the amount of sugar per plant at water constraint applications with 75%, 50% and 25% WHC (*Fig. 1*).

On average of five water regimes, inoculation of PGPR significantly raised the N and P content leaves of the sugar beet except RC9 and RC05, respectively, compared to control. On the other hand, all bacterial strains tested importantly raised the K, Ca and Zn content of the sugar beet leaf. N and K content were the greatest with RC310 and RC63, whereas maximal P, Ca and Mg was with strain RC21 and A21/3 inoculations (*Table 3*). In addition, six of the strains (RC05, PF8/6, RC6/3, RC310, RC9, and RC21) importantly raised the Mn content of sugar beet plants, but not Fe and Cu concentrations (*Table 3*).

Means followed with the same letter within each column are not significant different ($p < 0.05$)

On average of five water regimes, the highest GR activity was found effective at RC05, RC11, RC63 and mineral fertilizer, whereas the highest GST activity was found effective at PF8/6 and T26. Under waterlogging stress, sugar beet GR activity importantly raised after RC21, RC9 and RC11, while G6PD and 6PGD activity importantly raised after RC21, RC9 and RC63 inoculations. Under continuous moderate and severe water stress, the maximum GR activity in sugar beet leaf were found after RC63 inoculation, followed by A21/3, RC11, RC05 and 28/3, whereas the highest levels of GST activity were determined in treatments with PF8/6, followed by T26 and RC9. Moreover, under these stress, G6PD activity was found effective after RC310, RC05, RC21, and RC63; whereas 6PGD in sugar beet leaf was found effective after PF8/6, RC310, RC63, and RC05. In general, under water stress, there was an importantly raise in the enzyme activity in both inoculated and uninoculated treatments. In addition, enzyme activity in the uninoculated plants was lower than that of inoculated plants (*Fig. 2*).

While MDA and H_2O_2 decreased, sugar beet growth, root and leaf weight, sugar per plant and chlorophyll contents also increased. Water deficit treatment importantly raised the drought stress markers (MDA and H_2O_2), which showed the degree of oxidative damage posed with during stress. In all applications, levels of MDA and H_2O_2 were raised because of water stress. Also, when drought treatment, in all treatments show that H_2O_2 and MDA increased, whereas effective bacterial strains (RC310, RC63, RC26, RC11 and RC05) decreased the MDA and H_2O_2 content in the leaf (*Fig. 3*).

Discussion

One of the most negative factors of plant growth is certainly scarcity of water. Drought stress can also occur under irrigated conditions when use or availability of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

irrigation water is restricted (Tarkalson and King, 2017). Sugar beet is considered a drought-tolerant species based on the ability of established plants to survive transient periods of drought and recover when water subsequently becomes available (Wedeking et al., 2017). However, the stage of plant growth that emerged from stress is important to come from above the stress (Tatar et al., 2016). Water-restriction caused important yield losses and this effect was excessive in young plants affected by drought. When a temporary water stress appears at early period, it can be said that it reduces sugar beet root yield importantly. Indeed, when young beet plants were exposed to stress of water, it was found that sugar yield, the rate of photosynthesis and assimilation severely decreased Monti et al. (2006) and storage roots showed significant changes (Hoffmann, 2010). Bacterial activity was found higher than the beet harvested in the early period. Sahin et al. (2004) determined that the bacterial activity was higher at the early development stages. The water stress in growth stage may cause decrease of yield. Sugar beet root weight reduction decreased importantly under drought conditions, but this situation changed according to inoculated bacteria and irrigation level.

Bacterial inoculations and fertilizer application importantly raised fresh and dry leaf weight, and sugar per plant compared to control in the first and second trials. Generally, different PGPR applications give dissimilar response with different application of irrigation. The fact that inoculation of bacteria encouraged the growth of sugar beet leaves was in line with the results of previous researches (Çakmakçı et al., 1999; Schmidt et al., 2004; Shi et al., 2009). Similar to previous research findings (Romano et al., 2013), sugar beet root, leaf development and yield decreased under the water restrictions and drought stress.

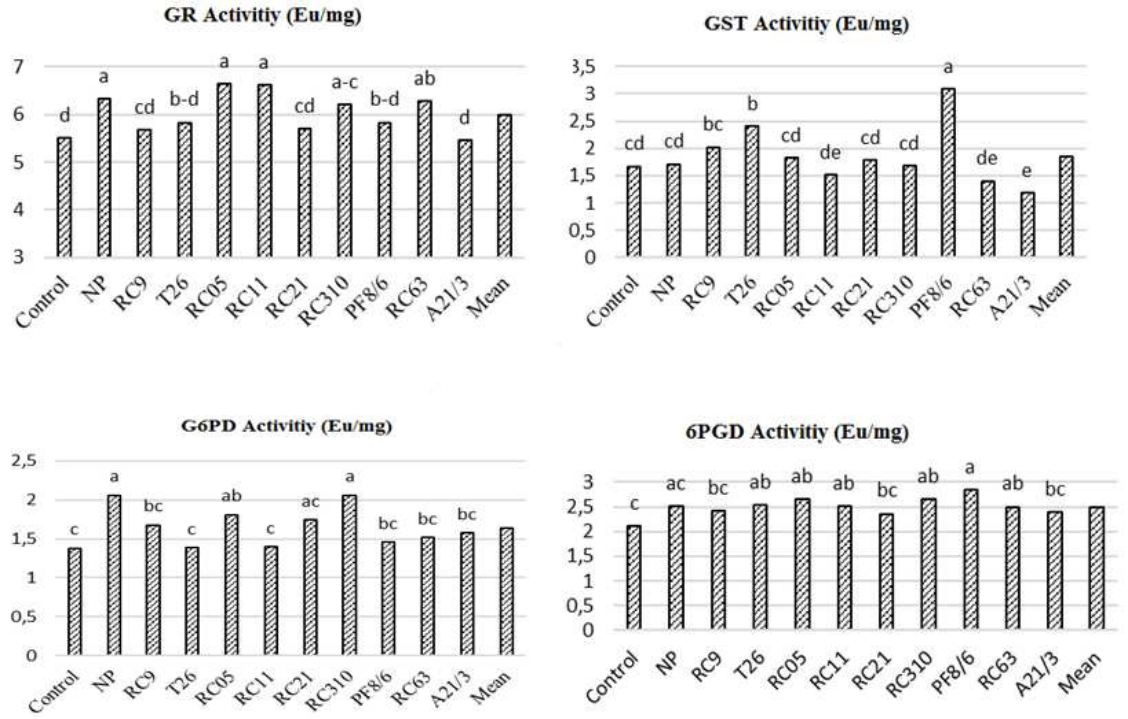

Figure 2. *Effect of PGPR and mineral fertilizer on the activities of anti-oxidant (GR and GST) and pentose phosphate oxidative cycle enzymes (G6PD and 6PGD) in sugar beet leaves in the second trial*

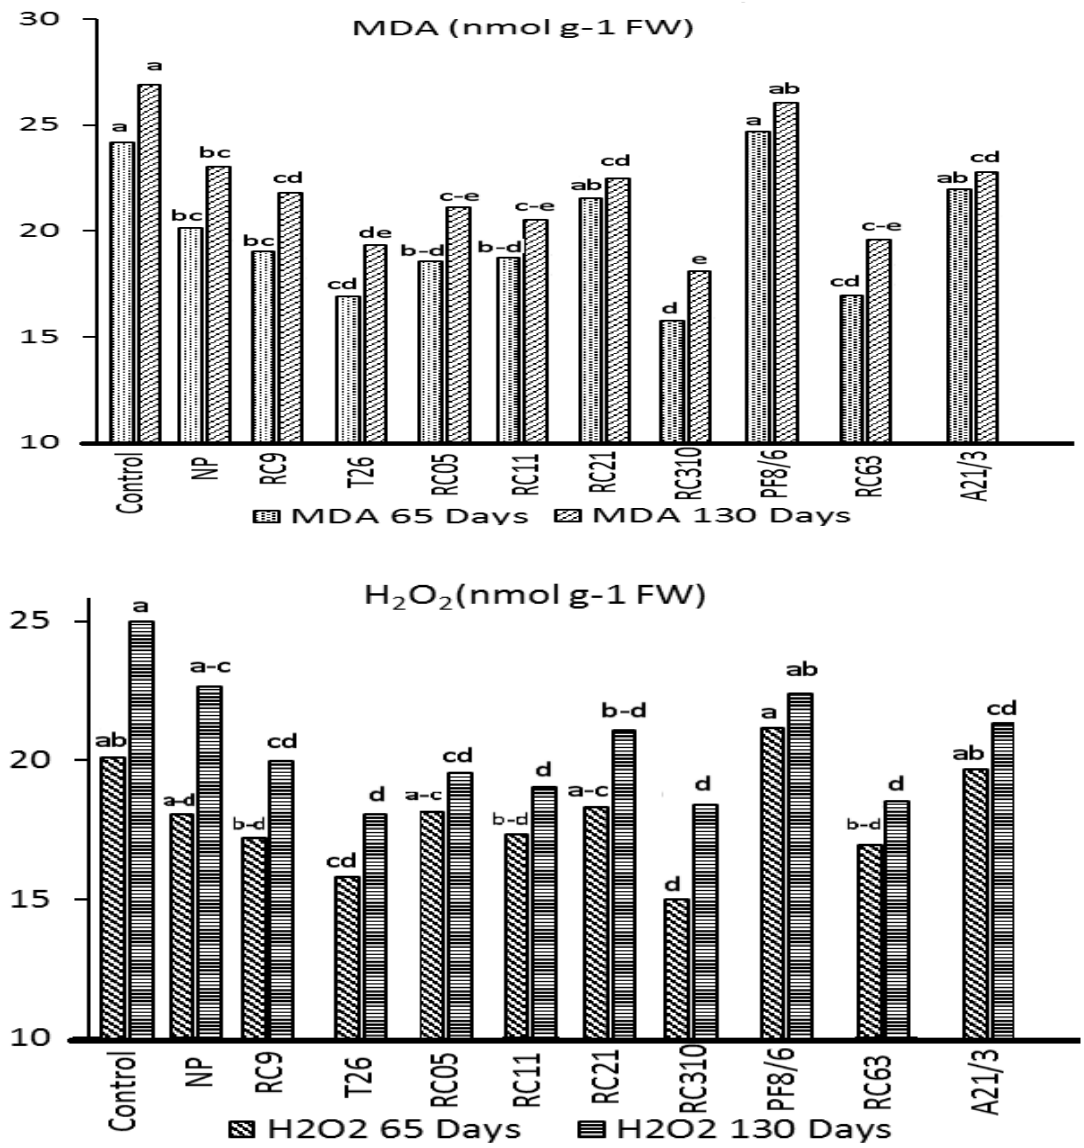

Figure 3. *Effect of PGPR and mineral fertilizer on the malondialdehyde (MDA) and hydrogen peroxide (H_2O_2) content of sugar beet leaves in the first (65 days) and second trial (130 days) average of five water regimes*

Under insufficient water supply, the sucrose concentration was higher than under well-watered conditions. In spite of the fact that sugar content ratio is high proportionally, the amount of sugar per plant is reduced at beet under water stress compared to optimum irrigation applications. Moreover, if water stress limits the use of sucrose in the growth at a higher rate than the decrease in photosynthesis, sugar rate increase can be the main reason of the more sugar in the roots. Drought could increase the sugar content in sugar beet, but reduce the root, leaf and sugar yield and the drought is clearly the main reason for the sugar beet yield losses (Jaggard et al., 1998; Pidgeon et al., 2001). Similarly, sucrose concentration increased with reduced water availability (Bloch et al., 2006). Our results showed that water stress reduced the vegetative growth and fresh weight, it increased sugar percentage and the percentage of fresh weight in root. Although there are a few studies in the literature on the main factor limiting the

© 2018, ALÖKI Kft., Budapest, Hungary

drought sugar yield (Pidgeon et al., 2006; Gobin, 2010), sugar beet's sensitivity to water restrictions and the response have not been studied enough (Habibi et al., 2011). Bacterial inoculation minimized the water stress-imposed effects importantly increasing the sugar per plant in sugar beet, but this changed depending on the inoculation bacteria and level of irrigations.

Reduction in water content due to drought can reduce food intake from soil. whereas application of PGPR increased the uptake of N, P, K, Ca, Mg, Mn and Zn in sugar beet. This parameter showed that using PGPR reduces the negative effects of water constraints in leaf macro- and micro-nutrient contents. Among the bacterial strains, the strains RC310 exhibiting better performance under severe water stress (25% of WHC) conditions was observed to have the highest K content in sugar beet leaf, which correlated well with their increased the amount of sugar per plant and weight of root and leaf (*Tables 2* and *3; Fig. 1*). As reported by Grzebisz et al. (2013), normalization of K intake in case of water stress can provide important advantage against too negative effects of water stress in plant growth and yield. Under drought conditions, increased nutrient uptake could improve water-use efficiency and alleviate drought stress effects on plant growth. Indeed, if nutrient uptake can be increased by using active bacteria, plant growth can be stimulated.

An alternative approach for increasing plant resistance against stress is to raise the plant antioxidant enzymes by using bacteria (Çakmakçı et al., 2007). Our studies show that PGPR can rise GR, GST, 6PGD and G6PD activities, together with the growth sugar beet lıke wheat and spinach plants (Çakmakçı et al., 2007, 2009). Therefore, investigating the ability to enhance enzymes activity in plants by using bacteria, similar to the first and pioneering work is required. Study has clearly demonstrated that some effective bacterial strains can promote plant growth together with antioxidant and oxidative pentose phosphate pathway enzymes in sugar beet under drought conditions. If plant antioxidant enzyme activity can be raised by using bacteria, it is being possible to increase the resistance of plants to stress conditions with plant growth. PGPR inoculation was shown to reduce the negative effects of water stress. Moreover, sugar beet can partly tolerate water stress protecting itself from oxidative damage by the increasing enzymes activities in leaves with the help of bacteria.

Of the bacterial inoculations, high ACC deaminase-containing RC310 and RC63 exhibiting better performance under moderate and severe water stress conditions were observed to have the highest level N and K content in sugar beet leaf, which was correlated well with their increased both fresh and dry weight of leaf and root (*Table 2*), 6PGD and G6PD enzyme activities and decreased both H_2O_2 and MDA content (*Fig. 3*), thus protecting the plants from water stress compared to the other bacteria and control. Increasing potassium and nitrogen by high N_2-fixing, P-solubilizing and for sustain the process of photosynthesis in leaves during drought, bacteria which ACC deaminase-including can decrease lipid peroxidation by rising the activity of antioxidant enzymes and decreasing MDA content. Therefore, Bacteria have nutrient uptake from soil and protect against to pests and diseases, also the bacteria provide protection to plants during water stress and drought.

In our study, drought caused a significant decrease in leaf weight as well as in root weight. Inoculation with PGPR could tolerate a certain degree of slow leaf development caused water constraint and they slowed leaf weight reduction occurred in the mineral fertilization. Positive effects of these selected strains on fresh and dry root and leaf weight, chlorophyll contents, enzyme activities and nutrient uptake of sugar beet plants

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_68016813
© 2018, ALÖKI Kft., Budapest, Hungary

showed the beneficial role of these PGPR, which might be attributed to IAA production, N_2-fixation, P-solubilisation, ACC deaminase activity, or even other non-evaluated PGPR traits that stimulated the plant growth. There are a great number studies that bacteria can provide protection plants against different stresses duo to they have produce IAA and ACC deaminase Glick (2012). Inoculation with IAA-producing Shi et al. (2009) and N_2-fixing and/or P-solubilizing Sahin et al. (2004) bacteria stimulate growth and increased root and sugar yields of sugar beet. Screening of rhizobacteria that show multiple PGP traits suggests that they have better potential in alleviating plant water stress and in improving the growth of sugar beet.

Conclusions

As a result of excess water applications, soil salinization, desertification, the loss of soil due to erosion occur with increasing costs. In addition, programs that provide the maximum production per unit of irrigation water in case of limited water and water constraint conditions in order to reduce the possible decline in production are important. This research has shown that sugar beet cultivation in PGPR can be used to minimize the harmful effects of water stress. Inoculation with ACC deaminase-containing bacteria partially eliminated the effects of water stress on growth, yield and quality of sugar beet. PGPR increases the uptake of plant nutrients (macro and micro). The effective bacterial strain tested in this study improved for enhanced plant growth promotion will be able to reduce the inputs of chemical fertilizers and the negative effect of water stress, and will have a potential to be used as a bio-fertilizer in sustainable and organic sugar beet production. Due to insufficient irrigation water and the high cost of water, in arid and semi-arid regions, inoculation with ACC deaminase containing PGPR can be used to prevent the reduction in yield. The PGPR can encourage plant growth and development, decrease stress sensitivity, and may conduce to the concept of biotechnology application in agriculture. As a result, RC310 and PF8 / 6 bacterial strains used in this study and other useful bacteria can use in organic sugar beet growing and in water-restricted areas. This study will also shed light on researchers working with sugar beets and PGPR. Inspired by this work, researchers can determine how affected of sugar beet by other stress conditions. Also researchers can search to ways to reduce the negative effect of other stress conditions with using PGPR.

Abstract. The objective of this study is to develop segmented polynomial taper equations using the nonlinear mixed-effects modeling approach for Caucasian fir (*Abies nordmanniana* (Steven) Spach. subsp. *nordmanniana*) - Oriental spruce (*Picea orientalis* (L.) Link.) mixed stands in Artvin-Ardanuç region of Turkey. For this purpose, the data obtained from 213 felled sample trees in total, which are 107 fir and 106 spruce, were used. Jiang et al.'s (2005) stem profile model produced the best prediction results for both tree species. The R^2_{adj}, RMSE, $\bar{E}$, MAE, AIC and BIC values of the model were found as 98.7% and 98.3%, 1.700 and 1.814 cm, 0.143 and 0.167 cm, 1.179 and 1.269 cm, 4142.2 and 3951.7, 4148.5 and 3957.8 for fir and spruce, respectively. Based on AIC, BIC and -2LnL criteria, the model including random-effects in two parameters (b_3 and b_4) were the best for both tree species. This mixed-effects model with two random parameters showed homogeneous residual variance and autocorrelation was almost removed. Mixed-effects models provided much better fits than their fixed model counterparts for both species. In addition, among 12 different calibration choices, the best results were obtained with the choice involving the measurement of five diameters that divide the sample tree measurements into two equal parts for fir and of four diameters that bottom of the sample tree for spruce.

Introduction

The correct calculation of the volume of trees and stands, and of the distribution of this volume among different commercial classes, is of great importance when formulating forest management plans and making projections concerning the future of the forestry products sector. Among the methods for the accurate estimation of tree volumes, the most effective and versatile approach is the stem taper model (Jiang et al., 2005; Özçelik and Brooks, 2012). Using this method, detailed estimations can be made of the types of wood that can be obtained from trees in demand under the ever-changing market conditions (Ercanlı and Kahriman, 2013; Kumaş and Kahriman, 2015).

There are two important reasons for the continuous increase in the number of studies on stem taper: The first reason is that the stem forms of all trees are not alike and that a theory has yet to be developed that reflects these differences in form; and the second is that a single method is yet to be developed that considers the changing standards in wood types under the ever-changing market conditions (Newnham, 1992; Diéguez-Aranda et al., 2006; Özçelik and Yaşar, 2015). Thus, it is quite easy to determine both the total stem volume and the merchantable volume using a simple stem taper model.

Stem profile equations not only identify the stem form but also estimate (i) the total stem volume, (ii) the merchantable stem volume, (iii) the volume of the stem section between any two heights, (iv) the volume of the stem section between any two diameters, (v) the stem diameter at any height, and (vi) the height at any stem diameter (Kozak, 2004; Özçelik et al., 2011).

Many different stem taper models have been developed over the last century, and they can be divided into three categories (Diéguez-Aranda et al., 2006) as follows: simple polynomial taper equations (Demaerschalk, 1972, 1973), variable-form taper equations (Newnham, 1992; Kozak, 2004) and segmented polynomial taper equations (Max and Burkhart, 1976; Parresol et al., 1987; Fang et al., 2000; Jiang et al., 2005). The performances of these stem profile functions vary depending on the tree species studied, the quality of the dataset, and the form and type of the selected model (Sakıcı et al., 2008; Özçelik et al., 2011; Şenyurt et al., 2017). Since the stem taper models that are compatible with the models used in this study divide the tree stem into parts and define each part individually, they can be used to estimate the entire stem profile in the most realistic way possible (Green and Reed, 1985). Another advantage of these stem taper models over other such models is that they can be easily converted into volume equations for the calculation of volumes (Fang et al., 2000).

The diameter data obtained from the various heights of a single tree can be used to develop a stem taper model, which indicates that successive measurement values are interrelated (Özçelik and Yaşar, 2015). In such hierarchical data structures, where each tree has a unique stem development, the problem of "autocorrelation", also known as "serial correlation", may be observed, which means that different items of data are dependent on each other (Leites and Robinson, 2004). Such serial correlations among the sample data may result in the confidence intervals in the parameter estimations concerning stem taper and stem volume equations being estimated with a systematic error, thus affecting the reliability of the model results in an adversely way (Searle et al., 1992; Kurt, 2014). In this regard, for hierarchical data structures in which the assumption of data independence cannot be met, and the problem of serial correlation exists in the data, the use of Nonlinear Mixed-Effects Models is recommended, as this enables the modeling of the variance-covariance matrix structure (Littell et al., 2005).

Regarding their ranges, incremental growth characteristics and economic value, the Caucasian Fir (*Abies nordmanniana* (Steven) Spach. subsp. *nordmanniana*) and the Oriental Spruce (*Picea orientalis* (L.) Link.) are among the leading forest tree species in Turkey. According to the 2015 forest inventory of the General Directorate of Forestry, the total areas covered by fir and spruce are 884,781 ha and 322,857 ha, respectively (General Directorate of Forestry, 2015).

According to the 2015 forest inventory of the General Directorate of Forestry, approximately 38% of forestry areas in Turkey (8,394,788 ha) are mixed forests, while forest inventory data from 2006 states that around 707 m^3 (55%) of the total tree wealth of Turkey is composed of mixed forests (General Directorate of Forestry, 2015), which suggests that mixed forests and mixed stands constitute a significant portion of Turkey's forestry lands.

The objectives of this research were to develop a stem taper and stem volume model that facilitates detailed volume estimations of the mixed stands of Caucasian fir and Oriental spruce that are abundant in the area covered by the Artvin Regional Directorate - Ardanuç Forest District Directorate. We fitted and evaluated taper functions using mixed-effect modelling techniques.

Material and methods

Study site

In the Artvin-Ardanuç region, where mixed stands of Caucasian fir (*Abies nordmanniana* (Steven) Spach. subsp. *nordmanniana*) and Oriental spruce (*Picea orientalis* (L.) Link.) can be found (40°54'54" - 41°15'31" N, 41°53'47"' - 42°22'52" E), the monthly average temperature varies between 2.8–21.0°C (annual average: 12.3°C), with the lowest temperature varies between +9.5 and -16.1 °C, and the highest temperature reaches 43°C. While annual average precipitation is 700 mm, annual average relative humidity varies between 60 and 70% (Turkish State Meteorological Service, 2016). The climate in Ardanuç is a mixture of continental and Mediterranean climates, where summers are hot and dry, and winters are partially warmer and less rainy than the normal continental climate.

There is around 75,535.4 ha of Caucasian fir, and 44,001.3 ha of Oriental spruce stands in the Artvin Regional Directorate, while 38,810.3 ha of this area is composed of mixed stands of Caucasian fir and Oriental spruce. The area of the mixed stands of Caucasian fir and Oriental spruce in the Ardanuç Forest District Directorate, as the study site, is 6,487.6 ha (General Directorate of Forestry, 2015). The ranges of the Caucasian fir and Oriental spruce mixed stands in Turkey, and the distribution of these two species in the study site are given in *Figure 1*.

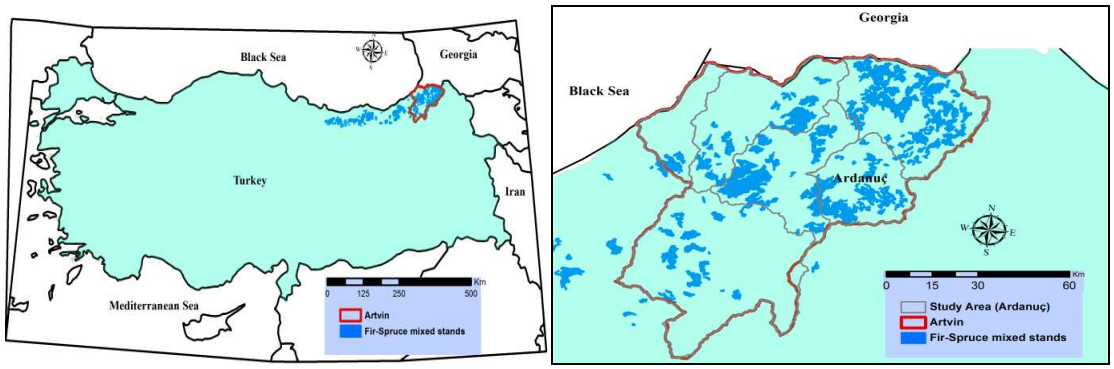

Figure 1. *Location of the study area*

Data

The data were obtained from 213 sample trees felled from the mixed stands of Caucasian fir and Oriental spruce within the boundaries of the Artvin Regional Directorate - Ardanuç Forest District Directorate, with 107 of them being fir and 106 being spruce. In selecting the sample trees, care was taken to ensure that the samples had a balanced distribution of various diameters and heights, and reflected the variation in volume development.

The sample trees used in this study were felled at the stump height level (0.3 m). Their stump diameter (0.30 m) and diameter at breast height (1.30 m) were measured, and after which, their diameter values were measured at 1 m intervals (2.3, 3.3, 4.3 m...). The total height values of the trees were measured with a steel measuring tape. If the tree stems were found to be oddly-shaped rather than cylindrical during measurement, two diameters perpendicular to the stem's cross section were measured, and their average was taken as the diameter measurement.

The data used in this study were divided randomly into two groups, with one being used in the estimation of the parameters of stem taper models and the other being used in the determination of the calibration responses of such models. Approximately 80% of the data (85 fir and 84 spruce trees) were included in group I as model data, and the remaining 20% (22 fir and 22 spruce trees) were included in group II as control data. *Figures 2* and *3* show a scatter plot of relative diameter of these trees against their corresponding relative height of the data used, for both fitting and validation data sets.

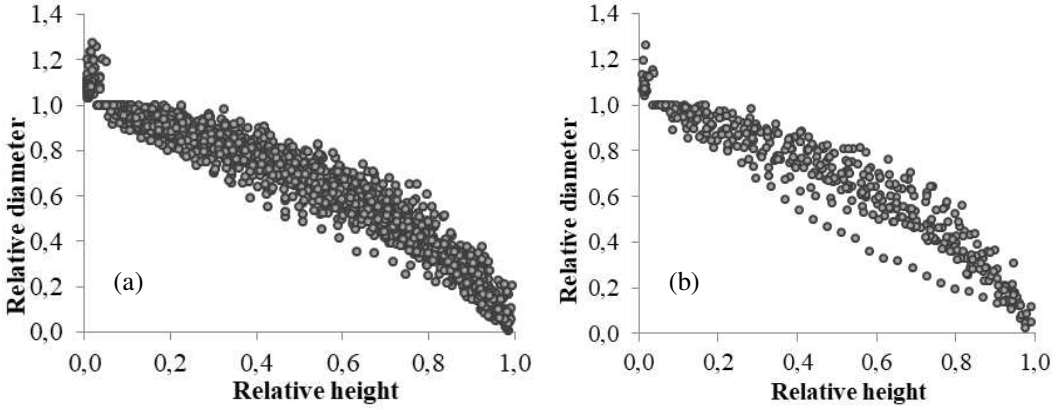

Figure 2. *Plot of the relative height versus relative diameter outside bark for (a) the fitting data points, and (b) the validation data points of Caucasian fir*

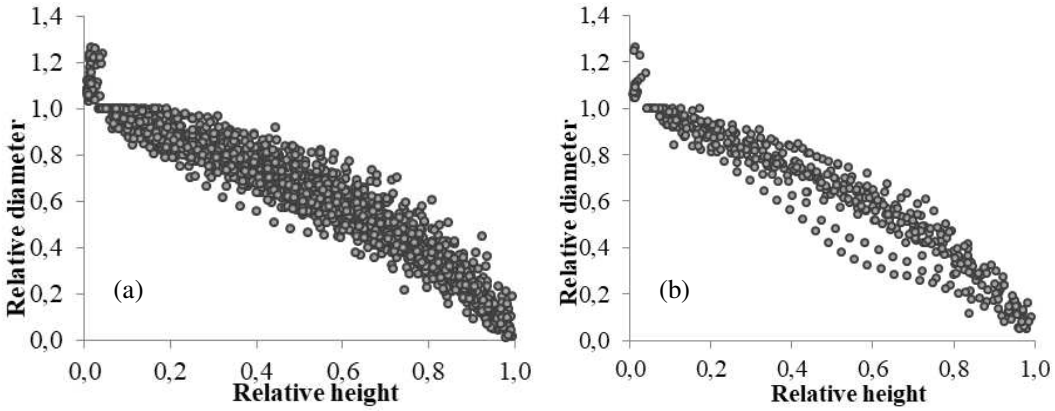

Figure 3. *Plot of the relative height versus relative diameter outside bark for (a) the fitting data points, and (b) the validation data points of Oriental spruce*

Table 1 provides the summary statistics of diameter at breast height, total height, tree volume, diameter outside bark at a height h and height above ground to the measurement point for model fitting and validation data set.

Selection of the best statistical regression models

The estimation of the parameters of these stem taper models was done with the NLIN procedure available in SAS/STAT® 9.3 software (SAS Institute, 2013). In this study, the adjusted coefficient of determination (R^2_{adj}), Root-Mean-Square Error (RMSE), Bias ($\bar{E}$), Mean Absolute Error (MAE), Akaike's Information Criterion (AIC) and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_68156833
© 2018, ALÖKI Kft., Budapest, Hungary

Schwarz's Bayesian Information Criterion (BIC) were used to evaluate the performance of the stem taper models for both species. It is desired that R^2_{adj} be close to 1 and that the RMSE, $\bar{E}$, MAE, AIC, and BIC values be low (Castedo-Dorado et al., 2006). The model evaluation criteria were as follows (*Eqs. 1–6*):

$$R^2_{adj} = 1 - \frac{(n-1)\sum_{i=1}^{n}(y_i - \hat{y}_i)^2}{(n-p)\sum_{i=1}^{n}(y_i - \bar{y}_i)^2} \quad \text{(Eq.1)}$$

$$RMSE = \sqrt{\frac{\sum_{i=1}^{n}(y_i - \hat{y}_i)^2}{n-p}} \quad \text{(Eq.2)}$$

$$\bar{E} = \frac{\sum_{i=1}^{n}(y_i - \hat{y}_i)}{n} \quad \text{(Eq.3)}$$

$$MAE = \frac{\sum_{i=1}^{n}|y_i - \hat{y}_i|}{n} \quad \text{(Eq.4)}$$

$$AIC = -2\ln(L) + 2k \quad \text{(Eq.5)}$$

$$BIC = -2\ln(L) + k.\ln(n) \quad \text{(Eq.6)}$$

where n is the number of observations; p is the number of coefficient in the model; y_i, $\hat{y}_i$ and $\bar{y}$ are observed, predicted and average observed the diameters outside bark, respectively, k is the number of parameters in the model; L maximum likelihood (ML) value.

Table 1. *Descriptive statistics for Caucasian fir and Oriental spruce sample trees*

Species	Variable	Initial model development (80%)				Model validation (20%)			
		n	Mean	S.D.	Range	n	Mean	S.D.	Range
Caucasian fir	D (cm)	85	33.6	15.5	9.4-66.0	22	35.1	15.8	7.9-65.5
	H (m)	85	21.2	7.5	5.7-39.8	22	21.5	8.0	7.7-40.0
	v (m^3)	85	1.36	1.36	0.03-5.68	22	1.48	1.58	0.03-6.66
	d (cm)	1830	25.5	14.7	0.2-75.0	451	24.0	13.2	1.2-66.3
	h (m)	1830	12.0	8.2	0.3-39.3	451	11.2	7.5	0.3-34.3
Oriental spruce	D (cm)	84	32.6	14.9	8.0-80.0	22	36.6	16.4	8.7-72.1
	H (m)	84	20.2	6.7	6.8-38.5	22	21.3	6.5	7.5-31.1

© 2018, ALÖKI Kft., Budapest, Hungary

used for the calibration of such models. Group I contains approximately 80% of all data (1830 stem diameter measurements of 85 sample fir and 1703 stem diameter measurements of 84 sample spruces), whereas group II contains approximately 20% of all data (451 stem diameter measurements of 22 sample fir and 466 stem diameter measurements of 22 sample spruce).

After identifying the best among the six stem taper models used in this study, the next step was the application of the Mixed-Effects Modeling process on the best stem taper model.

Statistical nonlinear mixed-effect modeling approach

In developing the stem taper models, the diameter values measured along the stem of each tree are used. When these diameter values, which are interdependent (serial correlation "autocorrelation") are used in model development, the principle of data independence, as one of the fundamental assumptions of a regression analysis, is violated (Valentine and Gregorie, 2001), which may result in the confidence intervals of the parameters being estimated with a systematic error, the reliability of model results being adversely affected and erroneous estimations (Ye, 2005). To account for such serial correlations, the mixed-effects approach has been widely recommended in modelling, as this enables the modeling of the variance-covariance matrix structure (Littell et al., 2005).

Unlike in linear and nonlinear regression analyses, the model structure in a mixed-effects modeling approach is based on a structure in which the parameters are divided into two groups, namely parameters for fixed effects and those for random effects. While fixed-effect parameters refer to the general relationships that apply to the entire population, random-effect parameters refer to the variability among the different sampling units (sample trees). The equation structures of the mixed models are given below (*Eq. 7*):

$$Y_{ij} = f(\Phi_i, X_{ij}) + \varepsilon_{ij} \quad \text{(Eq.7)}$$

Here, Y_{ij} denotes the value of the dependent variable measured in the jth measurement on the ith sample tree, X_{ij} the value of the independent variable measured in the jth measurement on the ith sample tree, Φi the parameter values of the model, and $\mathcal{E}_{ij}$ the model errors (Castedo-Dorado et al., 2006; Crecente-Campo et al., 2010). The division of model parameters by mixed models into two groups, namely, fixed-effect and random-effect parameters can be demonstrated with the following formula (*Eq. 8;* Castedo-Dorado et al., 2006).

$$\Phi_i = A_{ij}\beta + B_{ij}b_i \quad \text{(Eq.8)}$$

Here, β is the fixed effect parameter and is calculated for the entire population, while b_i is the random-effect parameter, and indicates the variation among the sample trees. In mixed models, the fundamental assumption for the random-effect parameter and model errors is as follows (*Eqs. 9* and *10*):

$$b_i \sim N(0, D) \quad \text{(Eq.9)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_68156833
© 2018, ALÖKI Kft., Budapest, Hungary

$$\varepsilon_{ij} \sim N(0, R) \quad \text{(Eq.10)}$$

Here, b_i (random-effect parameter) is normally distributed with an arithmetic mean of 0 and a variance of D, and $\mathcal{E}_{ij}$ (model error) is also normally distributed with an arithmetic mean of 0 and a variance of R. The estimation of the components in these assumptions constitutes a significant aspect of mixed models (Lappi, 1997). While component D is the positive-definite variance-covariance matrix that represents the variation among the sample trees (variation among trees), component R is the variance-covariance matrix that defines the variation among the data obtained from the sample trees (variation within a tree). The formulas of such variance-covariance matrices that define and model the variation both among sample trees and among the data measured on sample trees are shown below (*Eqs. 11* and *12*):

$$D = \begin{bmatrix} \sigma_u^2 & \sigma_{uv}^2 \\ \sigma_{uv}^2 & \sigma_v^2 \end{bmatrix} \quad \text{(Eq.11)}$$

$$R = \sigma^2 I_i \quad \text{(Eq.12)}$$

Here, σ_u^2 denotes the variance of random-effect parameter u, σ_v^2 the variance of random-effect parameter v, σ_{uv}^2 the covariance between the random-effect parameters, σ^2 the value of the model error, and I_i the value of the diagonal matrix defining the non-constant variance, in which the number of rows and columns is equal to the number of items of data to be used for the sample tree on which the mixed-effects model will be applied (Castedo-Dorado et al., 2006; Trincado et al., 2007).

The variance components and fixed parameters of the best compatible nonlinear stem taper model were estimated with PROC NLMIXED procedures of the SAS/ETS 9.3 package (SAS Institute, 2013). Using this method, different random parameter combinations for the best stem taper model were tested. As the criteria for determining the best random-effect parameter combination, Akaike's Information Criterion (AIC), Schwarz's Bayesian Information Criterion (BIC) and twice the negative log-likelihood (-2Ln(L)) were used.

Calibration response

Another important issue that needs to be considered and resolved in mixed-effects modeling is the calibration responses of the model. Calibrated models allow more accurate, consistent and reliable estimations to be made (Castedo-Dorado et al., 2006; Trincado and Burkhart, 2006; Yang et al., 2009; Crecente-Campo et al., 2010; Cao and Wang, 2011). In mixed-effects models, the observed values obtained newly from the sample areas are used to calculate random parameters, and by adding these random parameter values (or subtracting, if negative) to the fixed effect parameter values that apply to the entire population, the parameter values that apply to the sample area in question are calculated. In calibrating mixed models in forestry applications, the Best Linear Unbiased Predictor (BLUPs) method employed first by Lappi (1997) in a forestry study, and also known as Henderson's equations, is used.

The Best Linear Unbiased Predictor (BLUPs) method requires the measurement of a certain amount of new data in the sample area of the growth environment to be calibrated, particularly for the estimation of the random-effect parameter (Crecente-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_68156833
© 2018, ALÖKI Kft., Budapest, Hungary

Campo et al., 2010). In particular, the determination of which trees (the thickest, thinnest or medium-diameter trees) will be measured in the sample area is referred to as the calibration response of mixed-effects models. For this purpose, random parameters are calculated using a varying number of trees with different qualities, and subsequently, the error values of the estimations made are analyzed. Using this method, the random-effect parameter is estimated by using *Equation 13*.

$$\widehat{b}_i \approx DZ'_i\left(R + Z_i DZ'_i\right)^{-1}\left(Y_i - A_{ij}\beta\right) \quad \text{(Eq.13)}$$

Here, components D and R denote the pre-defined variance-covariance matrices, component Z_i the design matrix for random-effect parameters, and z'_i the inverse of the matrix Z_i. Furthermore, component (Y_i-$A_{ij}\beta$) in the equation above is calculated by subtracting the estimation made using only the fixed effect parameters in the mixed model from the observed value.

To determine the calibration response of the mixed-effects models, the Root-Mean-Squared Error (RMSE), Sum of Squared Error (SSE) and Mean Squared Error (MSE) values were used to identify the option that gives the best result among the compared options (Castedo-Dorado et al., 2006).

Results and discussion

Stem taper model selection

The values for the various model success criteria concerning the stem taper models for both species in this study are given in *Table 3*. As can be seen in *Table 2,* the evaluation of the values concerning the model success criteria identified Model 5, developed by Jiang et al. (2005), as the most successful model for both tree species, explaining 98.7% of the variance in the stem taper estimation for fir trees and 98.3% for spruce trees. The RMSE, $\bar{E}$, MAE, AIC and BIC values of the most successful stem taper equation for firs and spruces were also found to be 1.700 and 1.814 cm, 0.143 and 0.167 cm, and 1.179 and 1.269 cm, 4142.2 and 3951.7, 4148.5 and 3957.8 respectively (*Table 3*).

The equation of Jiang et al. (2005) has produced relatively successful results in the modeling of stem tapers in numerous studies. Using this four-segmented polynomial equation structure (Jiang et al., 2015) to model the stem taper, the adjusted coefficient of determination (R^2_{adj}) and Root-Mean-Square Error (RMSE) values were found to be 98.37% and 1.2798 cm in Jiang et al.'s (2005) study, and 98.4% and 0.7505 for Balsam fir, 98.2% and 0.8517 for Red spruce, and 97.2% and 1.4205 cm for White pine in the study conducted by Li and Weiskittel (2010), 98.13% and 1.3848 cm in the study by Özçelik and Bal (2013), 94.44% and 2.2029 cm in the study by Atalay (2014), 98.43% and 0.9843 cm in the study by Kurt (2014), 97.7% and 1.6302 cm in the study by Kumaş and Kahriman (2015), 92.6% and 2.4190 cm in the study by Doyog et al. (2017), and 97.6% and 1.4755 cm in the study by Şenyurt et al. (2017), respectively.

The parameter estimates, standard error values, t-test values and significance levels within the most successful stem taper model (M5: Jiang et al., 2005) for both species are given in *Table 4*.

d is diameter outside bark at a height h (cm), D is diameter outside bark at breast height (cm), h is height above ground to the measurement point (m), H is total tree height (m), a_1 and a_2 are the join points to be estimated from the sample data for Max and Burkhart (1976) model, a is the join point to be estimated from the sample data for Parresol et al. (1987) model, F diameter outside bark at 5.3 m above ground (cm), h_1 and h_2 are the heights from ground level where the two inflection points assumed in the Fang et al. (2000) model occur, k is equal to π/40 000, a metric constant for converting from diameter squared in square centimeters to cross-sectional area in square meters, h_{st} is stump height (m), a_1-a_3, b_1-b_4, p_1-p_2 are coefficients to be estimated

In the equation of Jiang et al. (2005), it is hard to measure the diameter at a height of 5.30, although this variable can be estimated using the tree's height and diameter at breast height. For both tree species, the equation for estimating the diameter value at a height of 5.30 m using the height and diameter at breast height values is given below (*Eqs. 14* and *15*).

for Caucasian fir $$F_{d5.3} = D\left(0.923 + \left(-0.832\frac{5.27}{H}\right)^2\right) \quad \text{(Eq.14)}$$

for Oriental spruce $$F_{d5.3} = D\left(0.893 + \left(-0.668\frac{5.27}{H}\right)^2\right) \quad \text{(Eq.15)}$$

where $F_{d5.3}$ is diameter at a height of 5.30 m, D is diameter at breast height (cm), and H is total tree height (m).

All parameters in the equations concerning Caucasian fir and Oriental spruce were found to be statistically significant at a significance level of $p < 0.001$. The adjusted coefficients of determination (R^2_{adj}), Root-Mean-Square Error (RMSE), mean errors ($\bar{E}$) and mean absolute errors (MAE)) for both species were found to be 0.986 and 0.987, 1.725 and 1.520 cm, 0.044 and 0.015 cm, and 1.279 and 1.145 cm, respectively.

Nonlinear mixed-effect modeling

In this study, the parameters of the Jiang et al. (2005) equation, as the most successful equation in modeling the diameter of trees along their stem, were also

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_68156833
© 2018, ALÖKI Kft., Budapest, Hungary

estimated through mixed-effects modeling. A test was made of the one, two, three and four-way random-effect parameter combinations of parameters b_1, b_2, b_3 and b_4 of the stem taper model, thus testing a total of 15 different combinations. The Akaike's Information Criterion (AIC), Schwarz's Bayesian Information Criterion (BIC) and twice the negative log-likelihood (-2LnL (L)) were used to determine the best random-effect parameter combination, and the garnered data is presented in *Table 5*.

Table 5. *The goodness-of-fit statistics for different random parameters for the Jiang et al. (2005) taper model*

AIC, BIC and -2LnL values are preferred over coefficients of determination when comparing mixed-effects nonlinear regression models, with regression models that produce smaller information criteria values being considered successful (Castedo-Dorado et al., 2006). As can be seen in *Table 5*, the values of AIC, BIC and -2LnL indicate that the model with random-effect parameters b_3 and b_4 is the most successful for both fir and spruce. Including more than two random parameters either produced failed model convergence or non-significant parameters at a significance level of 0.05 for some variance and covariance parameters and fixed parameters for both species. The parameter estimations of the mixed-effects model are given in *Table 6*.

Also compared nonlinear and mixed effects models to Jiang et al. (2005) stem taper model. These results indicated that all mixed effects models except for the model with random-effect parameters (b_2), (b_1,b_2), (b_1,b_3,b_4), (b_2,b_3,b_4), (b_1,b_2,b_3,b_4) for fir and (b_2), (b_1,b_3,b_4), (b_2,b_3,b_4), (b_1,b_2,b_3,b_4) for spruce provided much better fits than their fixed model counterparts (*Tables 3* and *5*). The reduction rates in AIC and BIC for fir and spruce were 12.8% (1.0-16.5), 13.6% (1.0-18.1) and 12.7% (1.0-16.4%), 13.4% (1.0-18.0) respectively. Mixed effects models were more accurate and precise than those fitted without random effects as root-mean-square error (RMSE) was reduced by 28.2% (2.5-35.5) for fir and 29.5% (2.4-38.4%) for spruce growth prediction. The reduction rates in RMSE, AIC and BIC for fir and spruce were 35.3, 16.2, 16.1% for fir and 37.8, 17.8, 17.7% for spruce with random-effect parameters b_3 and b_4.

The relative height-error distribution in the nonlinear and mixed-effects models for Caucasian fir and Oriental spruce is given in *Figures 4* and *5,* respectively. For both species, the model with random-effect parameters has a more homogenous error variance structure than that of the nonlinear model at all relative height values (*Figs. 4* and *5*). In other words, as is seen in *Figures 4* and *5,* the error variance values rise in parallel to the relative height values in the nonlinear model but remain constant in the mixed-effects model (Trincado and Burkhart, 2006; Yang et al., 2009; Sharma and Parton, 2009; Özçelik et al., 2011; Özçelik and Yaşar, 2015; Şenyurt et al., 2017).

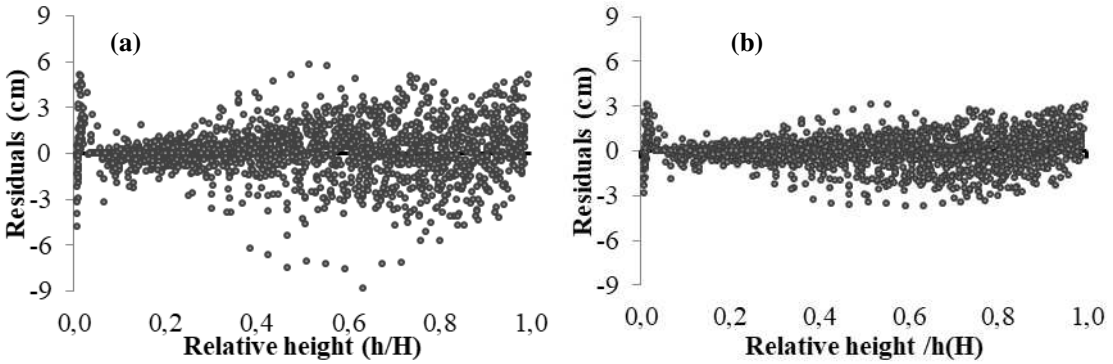

Figure 4. *Residual plots for the (a) nonlinear and (b) mixed effects model for Caucasian fir*

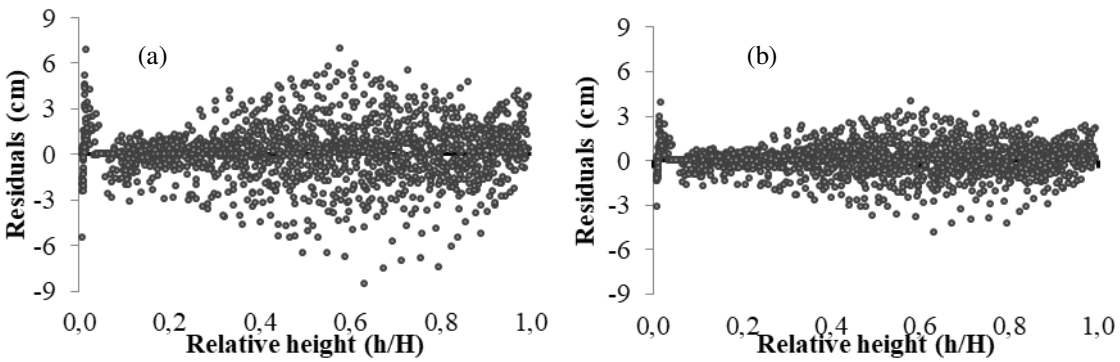

Figure 5. *Residual plots for the (a) nonlinear and (b) mixed effects model for Oriental spruce*

The error autocorrelations for Lag 1 for Caucasian fir and Oriental spruce are given in *Figures 6* and *7*, respectively. Here, a positive correlation is observed in the nonlinear regression model, and the error-related autocorrelation problem is remedied once the random-effect parameters are added to the model for both species. (*Figs. 6b* and *7b*).

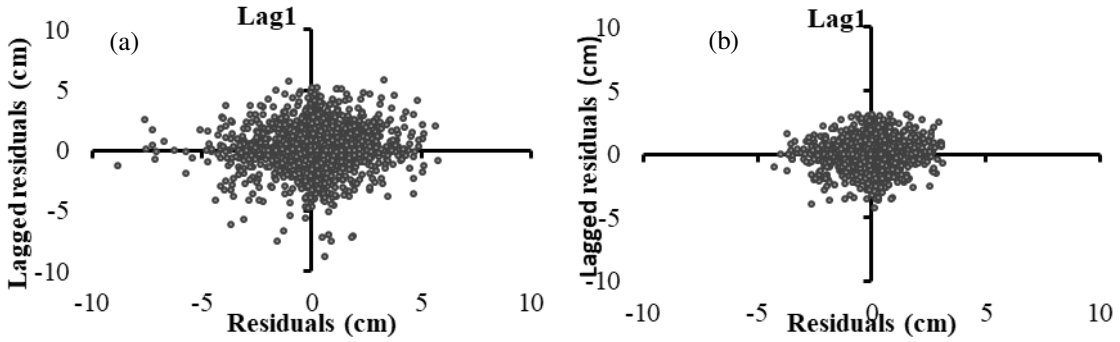

Figure 6. *Residuals plotted against lagged residuals for (a) nonlinear regression Jiang et al. (2005) model and (b) nonlinear mixed effect regression model of Caucasian fir*

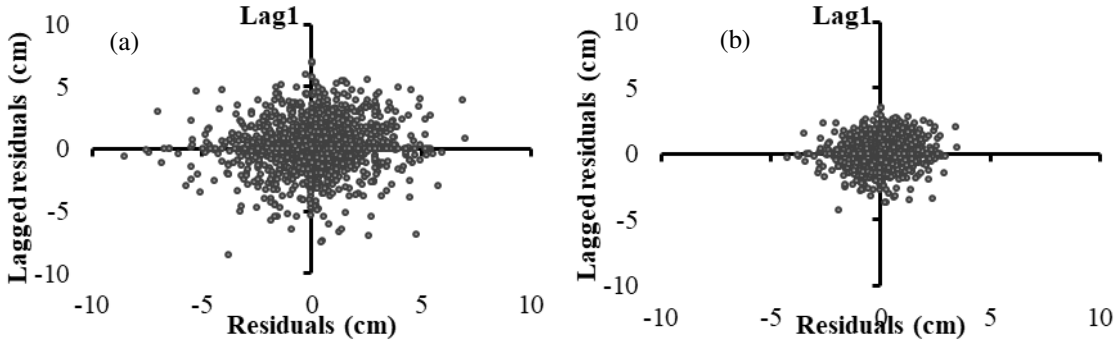

Figure 7. *Residuals plotted against lagged residuals for (a) nonlinear regression Jiang et al. (2005) model and (b) nonlinear mixed effect regression model of Oriental spruce*

As obtained in some studies (Trincado and Burkhart, 2006; Sharma and Parton, 2009; Gomez-Garcia et al., 2013; Özçelik and Yaşar, 2015; Ercanlı, 2015; Şenyurt et al., 2017; Zheng et al., 2017), the error (RMSE) of the models decreased from 1.700 to 1.100 cm for Caucasian fir and from 1.814 to 1.129 cm for Oriental spruce in the transformation of the nonlinear model to the mixed-effects model (*Tables 3* and *5*).

For the compatible stem taper model of Jiang et al. (2005) to set an example for taper estimations through the use of nonlinear mixed-effects regression parameters, the graphical results of the taper estimations for three trees in the small-, medium- and large-diameter classes are given in *Figure 8*. The trees were randomly selected from approximately thin, medium and thick diameters at breast height. The diameters of these trees being 22.4, 38.4 and 60.1 cm for firs and 18.2, 36.1 and 56.1 cm for spruces and the heights are 16.2, 26.8 and 36.1 m for firs and 13.9, 23.0 and 31.2 m for spruces. As seen in *Figure 8*, the mixed-effects model is successful to define the stem form of both Caucasian fir and Oriental spruce trees, and similar results have been obtained in previous studies in which the stem taper model was obtained through mixed-effects modeling (Trincado and Burkhart, 2006; Yang et al., 2009; Sharma and Parton, 2009; Li

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

and Weiskittel, 2010; Subedi and Sharma, 2011; Gomez-Garcia et al., 2013; Chiu et al., 2015; Özçelik and Yaşar, 2015; Şenyurt et al., 2017).

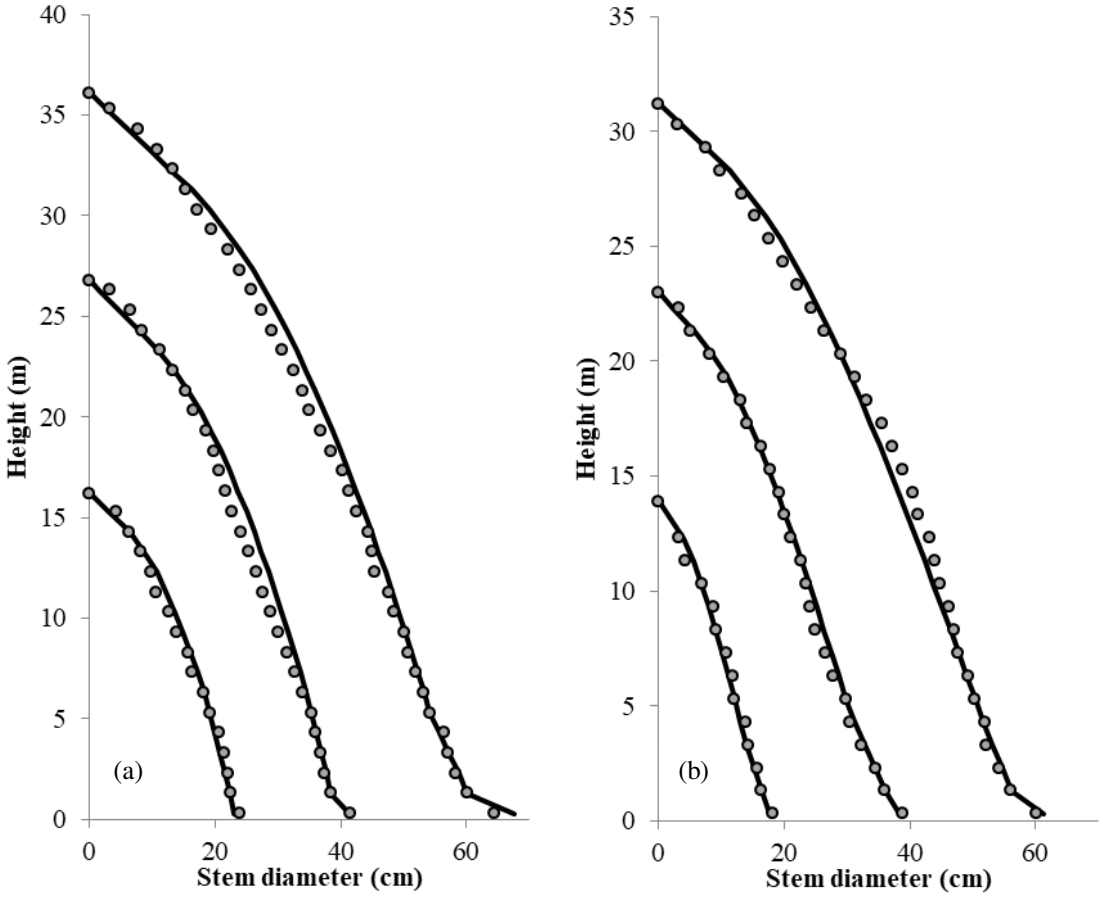

Figure 8. *Stem profile curves of taper equations to three sampled trees using mixed-effect model with b3 and b4 having random effects for (a) Caucasian fir and (b) Oriental spruce*

One of the major steps in the mixed-effects modeling process is the presentation of the calibration responses of the model that is found to be the most successful in modeling the stem taper. For this purpose, the model of Jiang et al. (2005) was calibrated using data related to 22 samples trees from each species that had not been used in the formation of the models or the estimation of parameters. In determining the calibration responses of mixed-effects models, the different scenarios suggested by Garber and Maguire (2003), Trincado and Burkhart (2006), Yang et al. (2009), Sharma and Parton (2009), Özçelik et al. (2011), Cao and Wang (2011), Subedi and Sharma (2011), Gómez-García et al. (2013, 2016), and Şenyurt et al. (2017) were also considered. These calibration response options are as follows: (i, ii, iii) 3, 4 or 5 diameter values at the lowest base section of trees; (iv, v, vi) 3, 4 or 5 diameter values obtained by dividing the measured diameters into two equal parts of sample trees; (vii, viii, ix) 3, 4, or 5 diameter values from the top sections of the trees; (x) a total of 3 diameter values from heights of 0.30 m, 1.30 m and 5.30 m; (xi) a total of 4 diameter values at heights of 0.30 m, 1.30 m, 5.30 m and in the top section of trees; (xii) a total of 5 diameter values from heights of 0.30 m, 1.30 m and 5.30 m, the diameter that divides

© 2018, ALÖKI Kft., Budapest, Hungary

the measured diameter values into two equal parts of tree ($d_{h/2}$) and the diameter of the top section.

With *Equation 13* regarding the Best Linear Unbiased Predictor (BLUP) method, the random-effect parameters for the sample trees were calculated using the SAS program code of Trincado et al. (2007). The random-effect parameter values (parameters u and v) that were calculated in 12 different ways for each sample tree from both species (22 sample trees) were added to parameters b_3 and b_4. As a result, when the values of parameters b_3 and b_4 were changed for each sample tree, different stem taper equations were obtained for these trees. Subsequently, in the calibration of mixed-effects models, the estimations for the diameter values measured along the stems of 22 sample trees were obtained using different stem taper equations, obtained through random parameters, and calculated based on 12 different calibration options. The Sum of the Squared Error (SSE), Mean Squared Error (MSE) and Root-Mean-Squared Error (RMSE) values for the estimations related to the sample trees from each species are given in *Table 7*. The best estimation results from among these calibration options were obtained from the calibration option based on the measurement of five diameters from the middle section of firs (SSE: 451.0, MSE: 0.9999 and RMSE: 1.0090) and four diameters from the stump section of spruces (SSE: 548.0, MSE: 1.1760 and RMSE: 1.0939).

Table 7. *Comparison of the predictive performance for some sampling scenarios*

Conclusions

In this study, a compatible stem taper model is developed that uses the mixed-effects modeling technique for the mixed stands of Caucasian fir and Oriental spruce in the Artvin-Ardanuç region. To model the stem taper of the trees, six compatible stem taper models developed by Demaerschalk (1972, 1973), Max and Burkhart (1976), Parresol et al. (1987), Fang et al. (2000) and Jiang et al. (2005) were used.

An evaluation of the success criteria values revealed that the model developed by Jiang et al. (2005) was the most accurate in modeling the stem diameter for both species (*Table 3*). The model developed by Jiang et al. (2005) used in this study explains 98.7% of the variance in the stem taper estimation for fir and 98.3% of the variance in the stem

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

taper estimation for spruce (*Table 3*). The RMSE values in the most successful stem taper equation for firs and spruces were found to be 1.700 and 1.814 cm, respectively.

The most significant advantage of the mixed-effects modeling technique over conventional regression models is that mixed-effects modeling technique allows the elimination of the problem of autocorrelation among the data and the homogenization of the distribution of error variance. In this study, the autocorrelation problem was all but eliminated using the mixed-effects modeling technique, and the distribution of error variance was transformed into a homogenous structure for all relative height classes. After the addition of the random-effect parameters to the model for both species, the error-related autocorrelation problem was eliminated (*Figs. 6b* and *7b*), and the model with random-effect parameters had a more homogenous error variance structure at all relative height values (*Figs. 4b* and *5b*). Moreover, the decrease in the RMSE values in the mixed-effects modeling approach from 1.700 cm to 1.100 cm for Caucasian fir and 1.814 cm and 1.129 cm for Oriental spruce in the transformation from the nonlinear regression model is another successful aspect. Mixed effects models provided much better fits than their fixed model counterparts for both species.

Calibrated models allow more accurate, consistent and reliable estimations to be made (Trincado and Burkhart, 2006; Yang et al., 2009; Cao and Wang, 2011). The best estimation results from the 12 different calibration options in this study were obtained through the calibration option, which involved the measurement of five diameters from the middle section of firs and four diameters from the stump section of spruces. In studies by different researchers, calibration responses are analyzed using the values of one, two, three, four, or five diameters at various stem heights (Trincado and Burkhart, 2006; Yang et al., 2009; Lejeune et al., 2009; Sharma and Parton, 2009; Özçelik et al., 2011; Gómez-García et al., 2013; Şenyurt et al., 2017).

All of these assessments have shown that successful diameter estimations could be made using the nonlinear mixed-effects modeling technique for the stem diameter estimations of both species in mixed stands of Caucasian fir and Oriental spruce in the Artvin-Ardanuç region. Thus, the success of the diameter estimations has a direct effect on volume estimations. In practical forestry applications, it is more important to accurately estimate the volume of trees than their diameter at breast height diameter. The mixed-effects model approach is substantial, and will allow forest managers to better predict tree volumes to any utilization standard. It is worth noting that when one of the models with a similar level of success in estimation needs to be selected for a specific species in any region, the practical implementation of the method and the preferences of the forest managers is also important.

Acknowledgements. This study was supported by the Scientific Research Projects Unit of Artvin Çoruh University under Project 2016.F10.01.02. This study was produced from a master's thesis prepared by Celal Yavuz ÇAKIR and supervised by Dr. Aydın KAHRİMAN for the Institute of Natural and Applied Science, Artvin Çoruh University, Turkey. The authors wish to thank the other researchers in this project and employees of Ardanuç Forest Enterprise who contributed to this project. We also thank Dr. İlker Ercanlı and Professor Dr. Ramazan Özçelik for their support and contributions. The authors declare that they have no conflict of interest.

(Received 18th Jul 2018; accepted 20th Sep 2018)

Abstract. The preliminary aim of the study before future breeding program was to reveal usability of ISSR markers to assess genetic diversity and relatedness within raspberry genotypes wildly grown in Northern Turkey. In this study, 19 wild raspberry genotypes collected from Black Sea region in Turkey were used. ISSR PCR analyses were carried on the DNA of genotypes isolated using mini CTAB extraction method. The levels of polymorphism between genotypes were determined using the UBC ISSR primers. A total of 111 bands were obtained from 15 UBC ISSR primers. Out of 111 bands, 101 bands were polymorphic. The number of bands obtained per primer ranged between 3 and 10, the average number of bands were determined as 7.4. The average number of polymorphic bands per primer was 6.73. Similarities and differences between genotypes have been studied at the molecular level. The data used for statistical analysis were obtained by the evaluation of ISSR bands. Similarity coefficient and UPGMA dendrogram were built using the Basic Coordinates Analysis. According to the dendrogram, the genotypes have been divided in two main groups, one small and other large group. While the small group was only comprised of three (A8, A10 and A14) genotypes, the large group included the rest of the genotypes studied.
Keywords: *molecular, polymorphism, dendrogram, raspberry, Turkey*

Introduction

Anatolia is one of the gene resources of the world with its natural flora of hundreds of wild plant forms, and wild forms of strawberry is also very common in most parts of the Turkey, especially in Black Sea coast and on the mountains through the sea cost. The wild ancestors of many plants which now provide staples for mankind still grow this region. Turkey is also the home of wild form of many soft fruits such as raspberry, blackberry. These species are mainly originated from the foothills of the Mountains on Black Sea coast. The wild forms have so much contribution to improve new cultivars. That is why it is so important to describe the wild forms and to establish collection gardens with them (Davis, 1982; Jennings, 1988).

As an important commercial fruit crop, red raspberries (*Rubus idaeus* L.: Rosaceae) are widely grown in all temperate regions of the world and are consumed by local people. Many of the most important modern commercial red raspberry cultivars derive from hybrids or selections from the wild. Black Sea region in northern Turkey is one of the important germplasm centers of this species (Davis, 1982). They grow naturally in high elevations and require moist, rich soils. The plants are usually seen as small, spatially discrete populations over 1000 m altitude, mostly along roadsides, in woodland clearings. *Rubus idaeus* has been an important source of genes for breeding new raspberry varieties (Alice et al., 2001; Marshal et al., 2001). In the development of improved varieties, the main qualities selected for are hardiness, productivity, disease resistance, fruit size, and

© 2018, ALÖKI Kft., Budapest, Hungary

firmness. Scientists have also started using *R. idaeus* as a model plant to develop and apply genetic techniques in the study of perennials, particularly members of the family *Rosaceae* (Graham et al., 1996).

Very few recent studies have attempted to quantify the genetic variation present in raspberry germplasm in Turkey. Ercisli et al. (2008) examined genetic diversity in 11 wild selections with one red raspberry using Amplified Fragment Length Polymorphism (AFLP) markers. There are also several reports on genetic diversity in raspberries from all over the worlds and modern molecular marker techniques are essential in effectively evaluating this germplasm collection as a source of useful genetic material for raspberry breeding programs (Howell et al., 1994; Chwedorzewska et al., 2002; Lund et al., 2003).

The development of molecular biology has resulted in DNA based marker procedures that should lead to a greater understanding of relationships between species and more accurate taxonomic classification. These techniques should also allowed more effective understanding of crop plant's genetic architecture and utilization of genetic diversity by breeders and identification of species and cultivars by means other than morphological characteristics (Graham et al., 1996).

Inter simple sequence repeats (ISSRs) have been shown to provide a powerful, rapid, simple, reproducible and inexpensive means to assess genetic diversity and identify closely related cultivars in many species (Gonzalez et al., 2002) The ISSR technique has been extensively used for several applications in molecular taxonomy, conservation and breeding. ISSR PCR has since been applied for cultivar identification (Charters et al., 1996; Cekic et al., 2001; Haritha et al., 2015; Ayesh, 2017), to detect geneflow and introgression (Allainguillume et al., 1997; Kalyani et al., 2014) and for mapping purposes (Kojima et al., 1998) and genetic diversity analysis (Cekic and Özmen, 2016). Further, ISSR PCR is useful in fingerprint and characterization of accessions and identification of cultivar and varieties (Wolf et al., 1995; Hardik et al., 2016). Against this backdrop, the present work was taken up with an objective to assess the level of genetic variation among 19 raspberry genotypes from Black Sea region in North Anatolia based on ISSR PCR before future breeding program.

Material and methods

Plant material

For research purposes, a total of 19 different raspberry genotypes from Black Sea region in North Anatolia were used. Observed observations showed wild raspberry plants spread from 1200 m above sea level of Turkey, where the forests end and the open fields begin, and on the northern slopes facing the Black Sea, where foliage is common where water leaks from the ground. Coordinates and elevation of the place where the samples are taken are recorded by specifying with Global Positioning System (GPS) (*Table 1*) and these coordinates marked on the map (*Fig. 1*) In addition, plants and surroundings are photographed in terms of ease of identification of the region and plant sample taken in the field.

DNA extraction

Total genomic DNA was extracted according to the cetyltrimethylammonium bromide (CTAB) method (Doyle and Doyle, 1987). DNA sample concentration was determined using a fluorometer employing a Hoechst dye (Hoefer Inc., San Francisco, CA, USA),

and the DNA samples were diluted to a final concentration of 10 ng/µl with 1 × TE buffer and stored at -20 °C prior to polymerase chain reaction (PCR) amplification.

ISSR amplification

15 primers that produced clear and reproducible fragments were selected out of a hundred UBC primers, which were previously tested for further analyses. ISSR amplification was performed in a 20 µl volume containing 20 ng genome DNA, 1 × Taq buffer, 2.0 mM $MgCl_2$, 0.2 mM dNTPs, 0.75 µM primer, 0.5 units of Taq DNA polymerase. The amplification reaction consisted of an initial denaturation step at 94 °C for 5 min, followed by 45 cycles of 45 s at 94 °C, annealing at 50 °C–56 °C for 45 s, extension at 72 °C for 90 s, and ended with extension at 72 °C for 7 min. The amplified products were resolved electrophoretically on 2.0% agarose gels run at 100 V in

1.0 × TBE buffer, visualized by staining with ethidium bromide (0.5 μg/ml), and photographed under ultraviolet light (Charters et al., 1996; Rafalski et al., 1996) The amplifications were repeated twice and only clear repetitive bands were used in data analysis, and molecular weights were estimated using a 100 bp DNA marker (Vivantis).

Data analysis

Alleles were designated on the basis of fragment size; bands were scored as diallelic (1 = band present, 0 = band absent). To assess the genetic variation among the genotypes, the eighteen ISSR markers were analyzed using NTSYS-pc (Rohlf, 2002). The coefficients of genetic similarity for all pair-wise comparisons were computed using Jaccard's coefficient. A similarity matrix was used to create a dendrogram using the unweighted pair group method with arithmetic mean (UPGMA). The observed number of bands, polymorphic band number, polymorphic band ratio per primer, Resolving power (RP value) and Polymorphic information content (PIC) were calculated with the POPGENE software version 1.31 (Yeh et al., 1997) to estimate genetic variation. Polymorphic information content (PIC), the probability in detecting polymorphism by a primer or primer combination between two randomly drawn genotypes was calculated using the formula PIC = 1 - Σpi2, where pi is the frequency of the ith allele (Sehgal et al., 2009); Resolving power (Rp) which is the ability of each primer to detect level of variation between individuals was calculated according to Prevost and Wilkinson (1999): Rp = ΣIb where Ib (band informativeness) takes the values of: $1 - [2|0.5 - p|]$, where p is the proportion of individuals containing the band, and marker index (MI) for each primer was also calculated as a product of two functions - the polymorphic information content and effective multiplex ratio (EMR) (Varshney et al., 2007). Group constellations were also independently developed by using principal component analysis (PCA) to verify the grouping obtained through the dendrogram. PCA further helped in depicting the variation among the genotypes in a three-dimensional mode (McVean, 2009).

Results and discussion

ISSR polymorphism

On the basis of the number, intensity and reproducibility of ISSR bands 15 primers were selected out of a hundred UBC primers, which were previously tested (Cekic et al., 2001). Bands with the same mobility were treated as identical fragments. Weak bands with negligible intensity and smear bands were both excluded from final analysis (*Fig. 2*). Each primer was evaluated for total band number (TBN), polymorphic band number (PBN) and the ratio of polymorphism (PR = PBN/TBN × 100). The amplification of ISSR markers was consistent between repeat PCR runs. The number of polymorphic bands produced ranged from 3 (for primer 889) to 10 (for primers 881 and 888). The number of scored bands varied from four to ten with an average of 7.40 bands per primer and an average of 6.73 polymorphic bands per primer. In total, 101 bands out of 111 derived from 15 primers were polymorphic (*Table 2*). Cao et al. (2000) reported that 50 polymorphic bands were sufficient for determination of differences and similarities between genotypes. With our 101 polymorphic band obtained in our study, it appears to have exited. So that this variability allowed raspberry genotypes to be distinguished on their genetic bases. The polymorphism level with 90% was higher than

© 2018, ALÖKI Kft., Budapest, Hungary

the findings with 69% polymorphism level of Ercisli et al. (2008), where 12 raspberry genotypes in eastern Turkey were analysed by AFLP markers. The average PIC and RP values were 0.25 and 0.41, ranging according to primers from 0.0729 to 0.3515, and from 0.08 to 0.57 for PIC and RP values, respectively (*Table 2*). Chesnokov and Artemyeva (2015) reported that the maximum PIC value is 0.5 for the dominant markers like ISSR, and for the markers with equal distribution in the population the PIC values are higher.

Cluster analysis

Genetic similarity among varieties was estimated using dissimilarity coefficient matrix based on ISSR bands scored. Pair wise values of dissimilarity coefficients ranged from 0.57 for genotypes with the same scored bands to 0.83 for the most similar genotypes. The dendrogram was constructed based on the similarity matrix, using the unweighted pair group method with arithmetic mean (UPGMA) method (Rohlf, 1992). The 19 raspberry genotypes were divided into two main clusters (*Fig. 3*), in which three genotypes in one group and the rest of the genotypes falling under the other group. While the first major group contained only one subgroup, the second major cluster was further separated into several subgroups. The coefficient values in first subgroup ranged from 0.74-0.83. On the other hand, the similarity of the second varied 0.62 to 0.75 (*Fig. 3*).

Group constellations were also independently developed by using principal component analysis (PCA) to verify the grouping obtained through the dendrogram. PCA further helped in depicting the variation among the genotypes (Asif et al., 2015). The principle component analysis roughly also put the genotypes into two different

clusters as parallel to the dendrogram of the raspberry genotypes. The small main group consists of the A8, A10 and A14 genotypes which form a different cluster in the PC1-PC2 and PC1-PC3 planes (*Fig. 4a, b*). Although, A8 and A14 were found to be 100% similar in same group of dendrogram, these two genotypes were still apart from each other by the different dimensional view of PCA analysis. On the other hand, while A18 and A19 were differentiated around 26% level in the dendrogram, PCA analysis put these two genotypes very close each other in both PC1-PC2 and PC1-PC3 dimensions (*Fig. 4a, b*).

Figure 4. *The principle component analysis with three components of raspberry genotypes according to 15 ISSR primers*

Conclusion

Screening of the 19 genotypes of different raspberry genotypes revealed that banding profiles obtained with fifteen ISSR primers were enough to distinguish the diversity among the wild raspberry genotypes. The fifteen ISSR primers we used on 19 raspberry genotypes resulted 101 polymorphic bands, which is much higher than the reports of Cao et al. (2000), where 50 polymorphic bands were sufficient for determination of differences and similarities between genotypes. The results indicated that the ISSR technique is effective to develop genotype specific banding patterns valuable for genotype identification. Since ISSR PCR technique does not require previous DNA sequence information and uses very small quantity of DNA, it is considered as one of the most widely used techniques for genotype identification and genetic diversity studies. The study also revealed that the dendrogram created using UPGMA method and the PCA analysis were complementary, and were useful to use together in diversity studies.

Although no scientific data was recorded regarding the morphological characters of genotypes, the observation of morphologies of genotypes during in collection parcel did not reveal obvious correlation with morphological characters. This work was the first attempt to use ISSR markers to assess genetic diversity and relatedness within raspberry genotypes wildly grown in Norhern Turkey, and the information generated herein may be useful for the improvement of this crop and could serve a promising future for breeding programs in our genetic collection. Further studies examining new molecular markers correlating morphological and pomological characters could explain more completely the diversity within this species.

Abstract. In this study, impact on the fruit characteristics of different pollinators used on the Osmanli strawberry cultivar, which is male sterile and therefore necessarily needs foreign pollination, was studied. In the trial three foreign cultivars, as well as three local varieties obtained from farmers in Northeast of Turkey, where these local varieties were grown with the Osmanli strawberry, were used as pollinators on Osmanli strawberry cultivar. Before pollination, pollen viability and pollen germination capability of pollinator cultivars were determined; and then, the physical properties, photochemical and aroma components of the hybrid fruit of strawberry, as well as the fruits of six parent cultivars used as pollinators, were analyzed. The study showed that the pomological and phytochemical characters as well as aroma components of fruits in Osmanli strawberry can be influenced by the pollinators of its flower. Since the highest aroma components were obtained from Sweet Charlie as pollinator, this cultivar with its well aroma can be used as pollinator on the Osmanli strawberry cultivar.
Keywords: *male sterility, phytochemicals, pollinator, pomology, metaxenia*

Introduction

Strawberries grown in many countries of the world in the soft fruit group are preferred due to their unique aroma, taste and rich nutritional content. There are diploid species *Fragaria vesca* and *Fragaria viridis* in the flora of Turkey. These wild species, together with local and old octoploid F. X ananassa varieties which have been used for many years, constitute the strawberry genetic resources of the country. Local varieties such as the Osmanli (Ottoman) and Arnavutkoy have narrowed and limited production areas by the growing use of more efficient commercial strawberry varieties. Cultured strawberry species have bigger fruits and give higher yields than the wild species, but the local or wild species have better aroma than the commercial varieties in use. Concentration of taste and aroma compounds generally decreases in commercial varieties with increasing fruit size (Zebatakis and Holden, 1997). Quantities of sugars and organic acids are qualitative and quantitative in essence of qualities in fruit. Sugar / acid balance is also a very important issue for breeders. In strawberry fruit, sugar and organic acids are important factors in determining the harvest time and the taste of fruit (Mina et al., 2017). There are many genetic and environmental factors in the formation of strawberry aroma, such as genes controlling some aroma compounds (Jetti et al. (2007), or cultural applications to plants (Loughrin and Kasperbauer, 2002). Osmanli strawberry cultivar which comes to foreground in terms of very good flavor of the local strawberry varieties decreases day by day and faces the danger of disappearance. This local cultivar is morphologically male sterile and a pollinator strawberry is necessary for fruiting.

On the other hand, pollens have effects on endosperm and embryo development (xenia), on the developing maternal tissues of seed or fruit outside the embryo and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

endosperm (metaxenia), or on the carpel tissue (carpoxenia) in foreign-pollinating species. Since pollen sources totally come from outside in self-incompatible and infertile species, fruit quality attributes may vary based on pollen source. The variations in aroma and other fruit quality attributes of Osmanli strawberries may also result from either variation in climate parameters or pollinating species. Therefore, there is a need for a research to elucidate such variations. Various researchers reported effects of pollinator on fruit quality attributes (Gercekcioglu, 1997).

The aroma of strawberry fruit is composed of various esters, alcohols, aldehydes and sulphur compounds and it is originated from degradation of carbohydrates, proteins and fats throughout ripening period (Samykanno et al., 2013).

In this study, in order to determine the effects different pollinators on the fruit characteristics of Osmanli strawberry cultivar, which is male sterile and therefore necessarily needs foreign pollination, three local ('Karacilek', 'Tuylu', 'Deli') and three commercial ('Cabarla', 'Sweet Ann' and 'Sweet Charlie') strawberry varieties were used as pollinators for Osmanli local cultivar. Morphological, phytochemical composition and aroma compounds of the fruits by different pollinators were investigated. Another objective was to determine the role of pollinator and to select proper pollinator or pollinators for Osmanli strawberry cultivar.

Material and method

In the trial, as well as three commercial cultivars ('Cabarla', 'Sweet Ann' and 'Sweet Charlie'), three local varieties ('Karacilek', 'Tuylu', 'Deli') obtained from farmers in North west of Turkey, where these local varieties were grown with the Osmanli strawberry, were used as pollinators on Osmanli strawberry cultivar. Before pollination, pollen viability and pollen germination power of pollinator cultivars were determined; and then, the physical properties, photochemical and aroma components of the hybrid fruit of Osmanli strawberry, as well as the fruits of six parent cultivars used as pollinators, were analyzed. The plants Osmanli seedlings used as mother parent were moved to a temperature-controlled greenhouse into tulle-covered cages and ten Osmanli seedlings were left for open pollination. The flowers over mother parent were emasculated and the flowers were covered with parchment paper. Then throughout following three days, pollinations were performed. Ten pots were used for each pollinator and ten flowers were pollinated for each plant. The non-pollinated fruits were plucked and removed. Pomological measurements such as appearance of calyx flowers, position of calyx with respect to fruits, position of achenes over the fruit, width of the sections without achenes over the fruit, achenity and achene depths were analyzed in accordance with UPOV (The International Union for the Protection of New Varieties of Plants 2012) criteria, which is used for the definition of morphological and pomological characteristics within the species. Fruit mass, fruit width and length was measured and fruits were grouped based on length/width ratio in accordance with Cekic et al. (2003). Fruit external color (cheek and tip), fruit firmness, water soluble dry matter (WSDM) content, pH, titratable acidity, ascorbic acid (vitamin C) content (%), fruit aroma compounds were determined.

Fruit mass was determined through weighing with a precise balance (±0.01 g). Fruit width and length was measured with a digital caliper (±0.05 mm); fruits were grouped based on length/width ratio in accordance with Çekiç et al. (2003). Fruit external color (cheek and tip) was measured with Minolta CR400 color-meter and L, a, b, *Chroma* (C) and Hue (h) values were determined. Fruit firmness was measured in kg/mm^2 with a

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

penetrometer vertically penetrating 10 mm into the fruit. Water soluble dry matter (WSDM) content was measured with a portable hand-refractometer. The pH values were measured with a digital pH meter. Titratable acidity was measured with potentiometric titration method. Ascorbic acid (vitamin C) content (%) was measured by using Kromasil (250 × 4.6 mm 100-5C18 5 µm) HPLC column and Perkin Elmer (Series-200) UV detector at 215 nm wave length.

All the observations and analyses were performed in three replications, and carried out in this study were considered as the average of 10 fruits. All the resultant data were subjected to variance analyses and means were compared with LSD multiple comparison test. SAS software was sued in statistical analyses.

Results and discussion

Pollen vigor tests

Before hybridization works, pollen vigor levels of local and standard cultivars to be used as a pollinator for Osmanli cultivar were determined with tri-phenyl tetrazolium chloride (TTC) test. The greatest vigor was observed in Cabarla cultivar (74.4%) and the lowest vigor was observed in Tuylu cultivar (6.7%).

Eti et al. (1995) in a study used 8 different strawberry cultivars and reported pollen vigor levels through TTC test as between 5.07-73.71%. Present values varied between 6.7-74.4% and the present range of vigor was higher than the one reported by Eti et al. (1995).

Success of hybridization and fruit set

From a total of 321 hybridizations, 253 plants were obtained. The most successful hybridization was achieved in Sweet Charlie cultivar (91.4%) and the worst yield was observed in Tuylu cultivar (14.4%). About 78.8% of hybridizations yielded a fruit.

Appearance of calyx leaves and position of calyx with respect to fruit

Appearance of calyx leaves and their position with respect to the fruit are provided in *Table 1* based on UPOV criteria. Since calyx leaves were taken out during emasculation process from the fruit samples obtained from hybridizations with Osmanli cultivar, data about the appearance of calyx leaves were not available for these fruits. Considering the position of calyx with respect to the fruit, it was observed that Cabarla, Sweet Charlie and Karacilek cultivars at the end of hybridization did not presented their own criteria and reflected the characteristics of Osmanli cultivar (buried within the fruit).

Position of achenes over the fruit

Position of achenes over the fruit is provided in *Table 1*. In Sweet Ann and Sweet Charlie cultivars used as pollinator, achenes lost their characteristics of being within the fruit surface and reflected the characteristics of the parent Osmanli cultivar.

Width of the sections without achenes over the fruit

The width of the sections without achenes over the fruit is provided in *Table 1*. In Cabarla and Sweet Ann cultivars, the width of sections without achenes lost their characteristics of being ‘narrow’ and turned into ‘absent or very narrow’ characteristic of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_68456855
© 2018, ALÖKI Kft., Budapest, Hungary

parent Osmanli cultivar. Besides in Sweet Charlie, Tuylu and Karacilek cultivars, width of the sections without achenes had 'absent or very narrow' characteristics of themselves and parent Osmanli cultivar.

Table 1. *Fruit characteristics of parents and hybrids according to UPOV criteria*

Parents and hybrids	Attitude of sepals	Position of calyx attachment	Position of achenes	Width of band without achenes
Cabarla	Upwards	Level with fruit	Below surface	Medium
Sweet Charlie	Upwards	Level with fruit	Below surface	Absent or very narrow
Sweet Ann	Upwards	Inserted	Below surface	Narrow
Tuylu	Downwards	Inserted	Below surface	Absent or very narrow
Deli	Downwards	Inserted	Below surface	Absent or very narrow
Karacilek	Upwards	Level with fruit	Below surface	Absent or very narrow
Osmanli	Downwards	Inserted	Below surface	Absent or very narrow
Osmanli x Karacilek	X	Inserted	Below surface	Absent or very narrow
Osmanli x Tuylu	X	Inserted	Below surface	Absent or very narrow
Osmanli x Sweet Ann	X	Inserted	Below surface	Absent or very narrow
Osmanli x Cabarla	X	Inserted	Below surface	Absent or very narrow
Osmanli x Sweet Charlie	X	Inserted	Below surface	Absent or very narrow

X: calyx and corolla were totally removed from mother plants while emasculation of stubborn anthers

Fruit mass (g/fruit)

Mean fruit mass values are provided in *Table 2*. Significant differences were observed in fruit mass of strawberry genotypes used in this study at 5% level. The fruits of Osmanli x Tuylu hybrids had the lowest fruit mass values and other hybrids were not significantly different from each other with regard to fruit mass.

Fruit length and width (mm)

Fruit length and widths of strawberry genotypes were measured in accordance with Cekic et al. (2003) (*Table 2*). The greatest fruit length and width were observed in Sweet Ann cultivar. The lowest fruit width was seen in Osmanli x Tuylu hybrid and the lowest fruit length was observed in Tuylu cultivar. The fruits obtained from the pollination of Osmanli cultivar with Karacilek cultivar had the greatest length and width scale.

Length/width ratio

Length/width ratio is one of the pomological characters of strawberry fruits, where the fruit shapes can be like sphere, flattened or cylindrical depending of the ratio. Although the ratio was over 1 in the fruits of cabarla, sweet charlie and sweet ann cultivars, the fruits of Osmanli pollinated with them were flattened with the ratio lower than 1. So, it can be said that pollinators had no effect on the fruit shape of Osmanli cultivar (*Table 2*).

Number of achenes per fruit

Number of achenes per fruit is provided in *Table 2*. The greatest number was observed in Sweet Charlie (301.8) and the lowest number was observed in Osmanli cultivar (59.6). After hybridization with Osmanli cultivar, the greatest number was observed in Osmanli x

© 2018, ALÖKI Kft., Budapest, Hungary

Cabarla hybrids (147.5). With regard to achenity according to 1 (less achenes) – 9 (highly achenes) scale, 'Sweet Charlie' was expressed with 9 and 'Osmanli' was expressed with 1.

Table 2. *Pomological characteristics of fruits*

*The difference between the values indicated by different letters in the same column is significant at the 0.05 probability level

Achene number and Achene number/fruit size

In the strawberry, one component of yield is fruit size, which we have shown to be determined by the number of fertilized ovules (achenes) on the surface and the degree of receptacle expansion associated with each achene. Berry weight is highly correlated with achene spacing and achene number, so that for each value of achene spacing there is a linear relation between berry weight and achene number (Abbot and Webb, 1970). This data was taken to determine the success of fertilization by the different pollinators and the effect of pollinators on the achene numbers. While number/fruit size ratio in the open pollinated Ottoman cultivar was 68.86, this ratio varied between 91.50 (Tuylu) and 229.35(Sweet Charlie) in the pollinators. On the other hand, this ratio ranged from 68.08 to 177.66 on the fruits of Osmanli pollinated with Tuylu and Cabarla, respectively.

Fruit firmness

Fruit surface and flesh firmness are significant factors for transport and storage of strawberries. Fruit firmness values are provided in *Table 2*. Values were significant at 5% level. The greatest firmness was observed in Cabarla cultivar (1.47 kg) and the lowest value was seen in Tuylu cultivar (0.59 kg).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_68456855
© 2018, ALÖKI Kft., Budapest, Hungary

Özdemir et al. (2007) carried out a study with 7 different strawberry cultivars and reported the greatest firmness for Cabarla cultivar (0.63 kg). Gündüz and Özdemir (2012) also reported Cabarla cultivar as prominent with its fruit firmness. In another study, Osmanli cultivar was reported as the softest cultivar (Özuygur, 2005).

Water soluble dry matter (WSDM) content

WSDM is among the most significant quality criteria for strawberries and it is mostly related to sugar content of the fruits. WSDM directly influences fruit taste. Therefore, high WSDM values are preferred in strawberry fruits. Among the main plants, the greatest WSDM content was observed in Osmanli cultivar. Among the hybrids, Osmanli x Tuylu (12.1%) had the greatest WSDM content. The Sweet Ann cultivar and Osmanli x Sweet Charlie (9.1%) hybrids had the lowest WSDM contents (*Table 3*).

Besides plant genetics, environmental factors also influence WSDM content of the fruits (Shaw, 1988; Galletta and Bringhurst, 1990; Abeytilakarathna et al., 2013). Özdemir et al. (2007) and Macit et al. (2011) reported that 'Cabarla' cultivar had lower WSDM content than the other cultivars.

pH

The pH values of strawberry cultivars are provided in *Table 3*. Gelling of jellies, marmalades and jams, color, taste and aroma of foodstuff and taste, aroma and odor development are closely related to fruit pH levels. Present values were not able to be subjected to statistical analyses because of insufficient number of fruits. Among the hydrides, Osmanli x Tuylu (3.79) had the greatest pH and among the main cultivars, Osmanli (3.67) had the greatest pH value. The lowest pH (3.33) was obtained from Karacilek cultivar.

Sürücü (2010) reported the pH value of Osmanli cultivar as 3.65 and such a value was parallel to the present value.

Table 3. *Phytochemical characteristics of fruits*

Titration acidity

Titratable acidity values of strawberry cultivars are provided in *Table 3*. A single value was obtained from each cultivar because of insufficient number of fruits from the cultivars. Therefore, results were not subjected to statistical analyses. The greatest acidity was observed in Osmanli x Sweet Charlie (1.34%) hybrid. Among the main cultivars, the greatest acidity was observed in Tuylu cultivar (1.26%). The lowest acidity was observed in Osmanli x Tuylu (1.07%) hybrid. Among the entire cultivars used in this study, Cabarla (0.69%) had the lowest titratable acidity.

Özuygur (2005) in a study reported the lowest titratable acidity for Sweet Charlie (0.75%) cultivar. In that study, titratable acidy of Osmanli cultivar was reported as 0.92% and the value was measured as 1.08% in present study.

WSDM/Acid ratio

The WSDM/acid ratios for experimental cultivars are provided in *Table 3*. The greatest ratio was observed in Karacilek (13.29) and the lowest ratio was observed in Osmanli x Sweet Charlie (6.79) hybrid.

Schöpplein et al. (2002) reported WSDM/acid ratio of 11 strawberry genotypes as between 8.7-12.4. The WSDM/acid ratios varied within a larger range (6.79-13.29) in present study.

Özuygur (2005) in a study reported the WSDM/acid ratio of Osmanli cultivar as 11.12 and such a value was quite close to the present value. Özuygur (2005) reported WSDM/acid ratio of Sweet Charlie as 10.21 and the cultivar had the second greatest ratio after Osmanli cultivar.

Ascorbic acid (vitamin C) content

Ascorbic acid values of parents and hybrids are provided in *Table 3*. The values were found to be significant at 5% level. The greatest value was obtained from Osmanli (27.97 mg/100 g), it was followed by Tuylu cultivar and the lowest value was obtained from Cabarla (16.77 mg/100 g) cultivar. Ascorbic acid values were not able to be obtained from Osmanli x Tuylu and Osmanli x Sweet Ann hybrids because of insufficient number of fruits from these hybrids. The differences in ascorbic acid values of the other three hybrids were not found to be significant.

Hakala et al. (2003) reported vitamin C content of strawberry cultivars as between 32.4-84.7 mg/100 g, but indicated that vitamin C contents of the years were significant. Özuygur (2005) reported the lowest average ascorbic acid content for Osmanli cultivar (26.22 mg/100 g) and reported ascorbic acid content of Sweet Charlie cultivar as 50.88 mg/100 g. Although present values of Osmanli cultivar were close to the ones reported by Özuygur (2005), present values for Sweet Charlie were significantly different. Eti (2006) reported the greatest ascorbic acid content for Sweet Charlie (57.29%) cultivar. Sürücü (2010) reported vitamin C content of Osmanli cultivar as 59 mg/100 g.

Aroma compounds

Mass spectroscopy (MS) library of NIST and WILEY was used for the identification of aroma substances. With regard to number of aroma substances, 15 different substances were identified in Cabarla, 10 in Sweet Charlie, 9 in Tuylu, 7 in Deli, 11 in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_68456855
© 2018, ALÖKI Kft., Budapest, Hungary

Karacilek, 11 in Osmanli, 8 in Osmanli x Cabarla hybrid and 9 substances in Osmanli x Sweet Charlie hybrid. Data were not able to be obtained for Sweet Ann cultivar.

The greatest lactone content was observed in Deli cultivar, it was respectively followed by Cabarla, Sweet Charlie, Osmanli x Sweet Charlie and the lowest value was seen in Osmanli cultivar. Furaneol (2,5-dimethyl-4-OH-3(2H)-furanone) was identified only in Cabarla (6.65%) cultivar. Furaneol has quite low threshold detection value (10 µg/L; Schieberle and Hoffmann, 1997) and with caramel aroma provided to strawberries, it is a significant aroma substance. The 2,5-dimethyl-4-metoxy-3(2H)-furanon (mesifurane) is a lactone compound with great contributions to strawberry aroma. The greatest amount of this compound was respectively observed in Cabarla, Osmanli and Sweet Charlie cultivars. Schieberle and Hoffmann (1997) reported detection threshold for mesifurane as 25 µg/L and indicated that this compound contributed a fragrance to strawberries.

Acids with high detection thresholds have quite low contributions to general aroma of the fruits. The greatest 'trans cinnamic acid' was observed in Osmanli (29.24%) cultivar, the greatest 'hexanoic acid' was observed in Sweet Charlie (28.39%) cultivar and the greatest 'succinic acid' was observed in Osmanli x Cabarla (20.96%) hybrid. Cinnamic acid was identified only in Osmanli cultivar (1.10). Palmitic acid was identified in Sweet Charlie (2.81) and Osmanli (2.18) cultivars.

Fruit color parameters

Multiple color spaces are often used to define color parameters of fruits. Among them, CIE L*a*b* (CIELAB) specified by International Commission on Illumination is the most common one (Fairchild, 2013) were used to evaluate the skin color parameters (L*, a*, and b*). L* represents lightness (100: white, 0: black), a* indicates the difference between red (+a*) and green (-a*), and b* represents the difference between yellow (+b*) and blue (-b*). Hue angle (h^o) and Chroma (C*) values were derived from a* and b* values. Mean color parameters (L, a, b, *Chroma* and h^0) were measured from the cheeks and tips of the fruits using a Minolta Chroma Meter CR-400 (MinoltaKonica, Japan) on the basis of CIE L*a*b* color space. Equations in the scientific literatures (Viscarra Rossel et al., 2006; Kus et al., 2017) were used for calculations. The differences in color parameters of strawberry genotypes were found to be significant at 5% level. A decrease was observed in 'L' values of all hybrid fruits. The greatest cheek L value was observed in Osmanli x Sweet Ann (49.0) hybrid and the greatest tip L value was observed in Osmanli x Tuylu (50.7) hybrid. As compared to Osmanli cultivar, an increase was observed in 'a' values of all hybrids. Hybrids had greater 'b' values than Osmanli cultivar. Osmanli x Cabarla (30.9) hybrid had the greatest cheek measurement and Osmanli x Karacilek (30.7) hybrid had the greatest tip measurements. *'Chroma'* values of hybrid fruits were higher than Osmanli fruits. While cheek 'h' values of all hybrids were greater than Osmanli cultivar, a decrease was observed in tip 'h' values of Osmanli x Sweet Ann and Osmanli x Sweet Charlie hybrids as compared to Osmanli cultivar. The differences in cheek and tip values of hybrid fruits and Osmanli fruits were not found to be significant (*Table 4*). Özuygur (2005) reported the greatest 'L' and 'h' (60.7 and 81.2) and lowest 'a', 'b' and 'C' (7.2; 47.8 and 48.5) values for Osmanli cultivar and the second greatest 'C' value (78.0) for Sweet Charlie cultivar. Parallel to present findings, Skupien and Osmianski (2004) in a study reported L values as between 35.32 and 41.11. Nunes et al. (1995) indicated high correlations of 'a' values with anthocyanin content of strawberries. Skupien and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

Osmianski (2004) reported negative correlations of 'a' value with pelargonidin-3-glucozid and total pelargonidin contents. Gündüz and Özdemir (2012) observed the brightest fruit external color on 'Osmanli' cultivar and indicated that Sweet Charlie had also sufficient brightness. Kafkas (2004), Serçe et al. (2004), Kıyga (2009), Yılmaz (2009) and Gündüz and Özdemir (2012) reported the greatest 'h' values for 'Osmanli' cultivar.

Conclusion

Osmanli strawberries morphologically infertile, but they have stubborn anthers. Therefore to improve the reliability of hybrids, calyx and corolla were totally removed from mother plants while emasculation of anthers. Then, calyx was not observed in hybridized plants. Variation was not observed in achenes over the fruits obtained through all pollinators and thus all fruits reflected achene characteristics of open-pollinating Osmanli cultivar. A similar case was also observed in widths of sections without achenes. In all fruits with controlled pollinators, width of sections without achenes reflected the fruit characteristics of Osmanli cultivar. Fruit size of pollinators did not reflect over the fruits obtained through controlled pollination. Among the pollinators, Tuylu cultivar reduced fruit size as compared to open-pollinating ones and large-fruit pollinators did not increase their fruit size.

Among the Osmanli cultivar and pollinators, Tuylu had the lowest fruit firmness, but the fruits of pollinated Osmanli cultivar had the greatest firmness values. The fruits pollinated by firm-fruits also had soft fruit flesh. Therefore, it was concluded that pollinator had adverse effects on fruit firmness. With regard to pH values of the fruits, there were not significant differences between the fruits of pollinator cultivars and controlled-pollinated Osmanli cultivar. While Osmanli cultivar was the richest in ascorbic acid content, pollinators decreased ascorbic acid contents of Osmanli strawberries. Since Osmanli cultivar is male-infertile and needs a pollinator, Karacilek with the greatest ascorbic acid content may be recommended as a pollinator. The greatest number of aroma compounds was observed in fruits pollinated with Sweet Charlie cultivar, therefore Sweet Charlie may be recommended as a pollinator for Osmanli cultivar prominent with its own aroma.

© 2018, ALÖKI Kft., Budapest, Hungary

As to conclude, pollinator selection is a significant issue for male-infertile Osmanli strawberries. The present study proved that some characteristics of pollinators relatively passed into Osmanli strawberries at different levels in the same year and the effects of pollens on fruits in foreign-pollinating cultivars (metaxenia) were also observed in Osmanli strawberries. Pollinator resulted in changes in fruit pomological and phytochemical characteristics and aroma characteristics which are significant attributes for Osmanli strawberry varied based on pollinators. Although a common known knowledge these terms (xenia, metaxenia, carpoxenia), there is not enough scientific literature on this area. Our study serves some preliminary data about the first effects of pollinators on the fruit. Based on this study, in depth studies should be done on strawberries and other species.

(Received 28th Jul 2018; accepted 26th Sep 2018)

Abstract. This study was carried out to determine the factors affecting the cold tolerance of cotton genotypes and to determine the relationships between cold tolerance and some seed characteristics in 2017. Fourteen cotton varieties belonging to *G. hirsutum* L. were used as material. Cold (15 °C) and normal (30 °C) germination condition parameters and fatty acid composition of the cotton varieties were investigated. Resulting, genetic structure and environmental conditions were effective in terms of fatty acid composition and cold tolerance parameters in addition to need of 21 days which is the time to germinate in cold conditions. Varieties Fantom and Stoneville-453 were the highest mid-tolerant, followed by BA-119, Sayar-314 and Deltapine-499, second degree mid-tolerant, and Berke, Deltaopal, SureGrow-125 and Deltapine-332 were medium tolerant in the third grade while Carmen, Gloria, Flora and Teks varieties were sensitive. Positive relationship was observed between cold tolerance and linolenic acid, stearic acid, saturated fatty acids, saturated/unsaturated fatty acid ratio, 100 seed weight, and seed density while negative relationship was between cold tolerance and oleic acid, linoleic acid, palmitic acid, unsaturated fatty acids, unsaturated/saturated fatty acid ratio, oleic/linolenic acid ratio, oleic/palmitic acid ratio, and linoleic/palmitic acid.
Keywords: *cotton, chilly, stress, fatty acids, correlation*

Introduction

Many ecological factors are involved in the growth and development of cotton plants. The main factors of these are temperature (high and low temperature), humidity, drought, wind and salinity. Germination in cotton seeds begins with water intake and continues with many biochemical and physiological changes such as softening of seed husk, seed swelling and cracking of seed husk by the effect of water (Khan, 2003). Temperature and humidity are very important factors in the germination of cottonseed. If the temperature is insufficient, germination cannot occur and cotton germination is known to be inhibited at low temperatures (Haigh and Barlow, 1997). The optimum germination temperature in cotton seeds is 30-34 °C (Lauterbach et al., 1999; Cole and Wheeler, 1974). For many cotton varieties, the physiological level of zero for germination is 15 °C (Marani and Dag, 1962; Wanjura and Buxton, 1972; Speed et al., 1996). If temperature falls below 15 °C during germination or if the cotton plant remains at temperatures of 10 °C or lower for several hours, long-term irreparable damage to cotton seeds can occur. The most important quality criteria in the seed are high viability and seed vigor (resistance to stress conditions, germination rate, etc.) (McDonald, 1999). Low temperatures cause irregularities and delays in germination and emergence of cotton seeds, resulting in the inability to obtain the desired plant populations in the field.

According to data, from 1970-2016 averaged for many years in Turkey from May to September period (hot period), soil temperature decreases from 5 cm to 10 cm soil depth while in other periods (cold/cool periods) it increases (*Fig. 1*). Cotton is grown between April 15 and May 15 in Diyarbakir/Turkey ecological conditions as a main

crop. The most important factor affecting the sowing date is the temperature of the air and the soil. According to long years average (1970-2016), temperature changes at 5 cm soil depth were 8 °C, 14 °C, 20.5 °C (MGM data) in March, April and May, respectively (*Figs. 1* and *2*). In addition, especially in April and May, low night temperatures in addition to rainfall causing low temperatures in this period are great disadvantages for cotton seeds germination and emergence.

One of the biggest obstacles to early planting and possibility to extent vegetation duration is the problem of germination and emergence at low temperatures. Especially after midnight, there are serious decreases in air temperatures. This affects cotton germination, emergence and seedling growth negatively. The second (re) planting should be done with the low temperature period that occurs after early planting and the lack of sufficient plant population, as well as with stand deficiencies and poor seedling growth in field conditions. The ability of cotton seeds to germinate at low temperatures will ensure that cotton sowing occurs earlier. This will lead to cotton vegetation time to be longer as well as positive development for cotton fiber yield (Sharma et al., 1998; Norfleet et al., 1998; Porter et al., 1997; Tomar et al., 1991; Raju and Kharache, 1994) and quality characteristics (Porter et al., 1997). Also, it will prevent the adverse effects of cotton development due to the low temperatures that occurs after the date of planting in the spring.

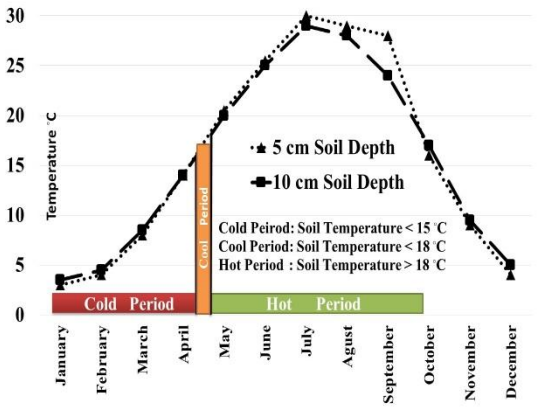

Figure 1. *Temperature change averaged for many years (1970-2016) at 5 cm and 10 cm soil depth (MGM data)*

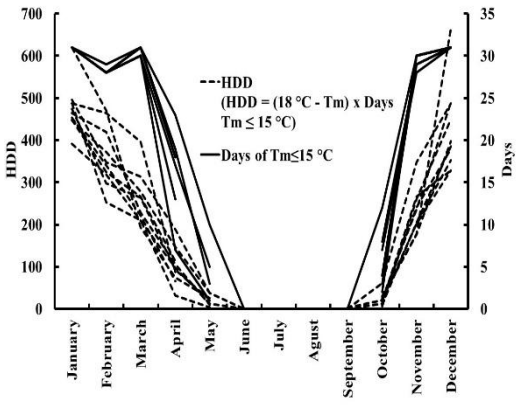

Figure 2. *Change of HDD and T < 15 °C days between 2008-2017 by months*

Germination tests on cold conditions are also a stress test. When seed is subjected to cold stress conditions, this way, its performance against cold stress is examined. Many tests and parameters related to cold tolerance have been explored and used. Germination percentage, germination coefficient, speed of germination index, cold warm vigor index, high cold stress index, vigor index and germination index are the primaries. The cold- warm vigor index developed by Hopper is a very good colt tolerance test (Hopper et al., 1994; Metzer, 1987; Kerby et al., 1989).

Cotton fatty acid composition which is not always constant can vary respect to species, variety and environmental factors (Genter et al., 1957; Zimmerman et al., 1959; Ramey, 1984; Baydar and Turgut, 1999; Karaca and Aytaç, 2012). Temperatures of 15 °C or higher causes phase transition at fatty acid composition of cottonseed and membrane lipids. When the temperature is below 15 °C, the oil crystallizes and the cell membrane loses its fluidity and selective permeability (Hall, 2003). Fatty acid composition in cottonseeds is manifested by low membrane function at low temperatures.

This study was carried out to determine the factors affecting the germination of cotton seeds in cold conditions and to determine the relationship between cold germination tolerance and some seed characteristics of cotton.

Materials and methods

The field study was carried out in the research area of Faculty of Agriculture at Dicle University, in the year of 2016 with 14 cotton (*G. hirsutum* L.) varieties (Teks, Stoneville-453, Stoneville-468, Deltaopal, Deltapine-499, Deltapine-332, BA-119, Carmen, Sayar-314, SureGrow-125, Fantom, Berke, Flora and Gloria).

The experimental area is located (37°890075 N, 40°275785 E) at 670 m above sea level. This region generally is characterized by a semiarid continental climate. The soil temperature change of 5 and 10 cm for long-term (1970-2016) have been presented in *Figure 1*. Change of day degree units (HDD) and T < 15 °C days period 2008-2017 by months have been presented in *Figure 2*. The average relative humidity is about 29.8% and total rainfall is 495 mm. The soil is low in organic matter and phosphorus. It has adequate calcium, potassium, and high clay content (48% to 68%) in the 0 to 160 cm profile. The sowing of cotton seeds was made by machine on 5 May (2016). All plots were treated with 20-20-0 (N-P-K) composite fertilizer to provide 75 kg N ha^{-1} and 75 kg P_2O_5 ha^{-1}. All plots were furrow irrigated regularly. A total of 9 irrigations were applied. Plots were harvested twice by hand. Yield of four rows of plot were weighed and calculated for seed cotton yield. First harvest was done on 20 October (2016); second harvest was done on 12 November (2016).

The germination tests at 15 °C and 30 °C temperatures were carried out in the test laboratories of the Science and Technology Research and Application Center at Dicle University in 2017 with 4 replications according to randomized blocks design. Fatty acid composition of cotton seeds was analyzed with gas chromatography (GC).

Germination tests in cold (CC_{15C}) and normal (standard) conditions (NC_{30C}) were carried out in a temperature controlled growth cabinet having 80-100% humidity. Fifty seeds with 3 replications were placed in a wet paper towels and placed into growth cabinet. Counts were made on days 4, 7, 14 and 21 in both germination tests. At each count, a moist towel was opened and healthy developing seedlings having hypocotyl length of 3.8 cm or more was counted and recorded. The counted seedlings were

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/…..1605_68576872
© 2018, ALÖKI Kft., Budapest, Hungary

removed then the towel rewound and left in the growth cabinet again (Edmisten, 2000; Smith and Varvil, 1984; Tolliver et al., 1997). The parameters of germination coefficient (GC), speed of germination index (SGI), cold warm vigor index (CWVI) and high cold stress index (HCSI) were calculated with the following equations in cold and normal germination conditions.

GC can be calculated as *Equation 1* (Maguire, 1962):

$$GC = \frac{\sum G}{\sum GT} x100 \quad \text{(Eq.1)}$$

SGI was calculated as *Equation 2* (AOSA, 1983, 1990):

$$SGI = \sum \frac{G_n}{T_n} \quad \text{(Eq.2)}$$

where, G represents the number of germinated seeds counted on T day (4, 7, 14 and 21 days).

CWVI was calculated as *Equation 3:*

$$CWVI = GP_{NC7} + GP_{CC21} \quad \text{(Eq.3)}$$

GP represents germinated percentage, NC represents normal condition (30 °C) at 7 day, CC represents cold condition (15 °C) at 21 day. The obtained CWVI value is considered to be excellent over 160, good between 140 and 159, moderate between 139 and 120 and weak if below 120 (Stauss and Hopper, 1983; Baughman et al., 1994, 2011).

HCSI was determined as *Equation 4* (Fischer and Maurer, 1978):

$$HCSI = \frac{\frac{G_{GPNC14} - G_{GPCC14}}{G_{GPNC14}}}{\frac{M_{GPNC14} - M_{GPCC14}}{M_{GPNC14}}} \quad \text{(Eq.4)}$$

where, G: Genotype; M: Means; GPNC14: normal condition (30 °C) germination percent at 14 day; GPCC14: cold condition (15 °C) germination percent at 14 day. HCSI < 0.50 highly cold stress tolerant, 0.50 < HCSI < 1.00 moderately cold stress tolerant and HCSI > 1.00 susceptible.

The values obtained for each parameter were analyzed using JMP 7.0 (Copyright © 2007 SAS Institute Inc.) statistical package program. Means were grouped according to the LSD (0.05) test.

Results

Ratios for oleic acid (C18:1) (%), linoleic acid (C18:2) (%), linolenic acid (C18:3) (%), palmitic acid (C16:0) (%), stearic acid (C18:0) (%), saturated fatty acids (%), unsaturated fatty acids (%), unsaturated/saturated fatty acids, saturated/unsaturated fatty acids, oleic/linoleic acid, oleic/linolenic acid, linoleic/palmitic acid and means for 100

seed weight (g) and seed density (g.ml^{-1}) were given in *Tables 1*, *2*, and *3*. In terms of all the traits examined, varieties were statistically (1%) different than each other.

The ranges and the mean values for oleic acid 14.75-21.90% (18.70%), linoleic acid 36.99-48.95% (44.01%), linolenic acid 0.26-0.50% (0.37%), palmitic acid 20.75-27.75% (24.21%), stearic acid 2.05-3.58% (2.80%), saturated fatty acids 23.76-30.84% (27.00%), unsaturated fatty acids 54.37-70.47% (63.10%), unsaturated/saturated fatty acids ratio 2.05-2.69 (2.35), saturated/unsaturated fatty acids ratio 0.37-0.49 (0.43), oleic/linoleic acid ratio 0.31-0.50 (0.43), oleic/linolenic acid ratio 29.12-78.99 (52.73), oleic/palmitic acid ratio 0.58-1.00 (0.78), linoleic/palmitic acid ratio 1.61-2.06 (1.83) 100 seed weight 9.96-13.30 g (11.34 g), and seed density 1.01-1.15 g.ml^{-1} (1.06 g.ml^{-1}) were measured (*Tables 1, 2* and *3*).

In terms of oleic acid trait, Carmen and Teks varieties; in terms of linoleic acid trait, Carmen, Flora, and Gloria varieties; in terms of linolenic acid and stearic acid traits, Fantom, and Stoneville-453 varieties; in terms of palmitic acid trait, BA-119, Berke, and SureGrow-125 varieties were the group in which the highest values were obtained (*Table 1*).

Discussion

When the germination rate at 30 °C, considered as the normal germination temperature for cotton plant, was examined, it was determined that the maximum germination occurred on the 7th day, whereas the germination count at 21 day determined to be the maximum germination time at 15 °C, which was considered as the cold condition (*Figs. 3* and *4*). This suggests that low temperature causes delayed of germination time and a significant reduction of germination rate.

Results of the germination coefficient (GC_{15}), speed of germination index (SGI_{15}), cold-warm vigor index (CWVI) and high cold stress index (HCSI) values that are indicative for cold tolerance were parallel to each other. The high values of the GC_{15}, SGI_{15} and CWVI were confirmed by the low HCSS. Our findings had similarity with Tuck et al. (2006).

It is desirable that the CWVI values are high and the HCSI value is low for tolerance to cold. No HCSI value < 0.50 was obtained from the varieties forming the material, and so no cold-tolerant variety was detected. Since 0.50 < HCSI < 1.00 was detected in

Stoneville-453, Fantom, Sayar-314, BA-119, Stoneville-468 and Deltapine-499 varieties, they were called as mid-tolerant but other varieties were susceptible to cold. However, Fantom (0.86) and Stoneville-453 (0.87) varieties were found to be the highest mid-tolerant varieties with the lowest HCSI values (*Table 4; Fig. 8*). BA-119, Sayar-314 and Deltapine-499 varieties showed themselves as medium tolerant varieties at the second level (*Fig. 8*).

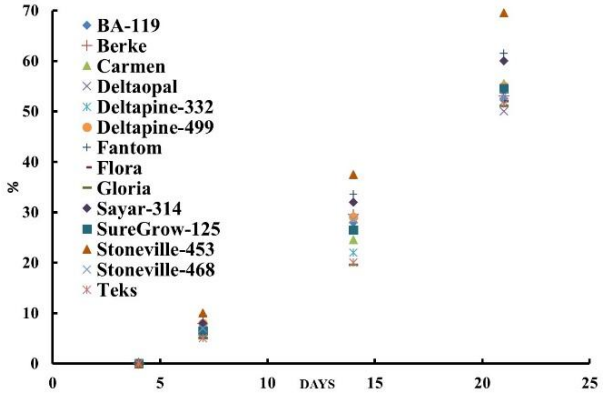

Figure 3. *Germination percentage at cold (15 °C) conditions on days 4, 7, 14 and 21*

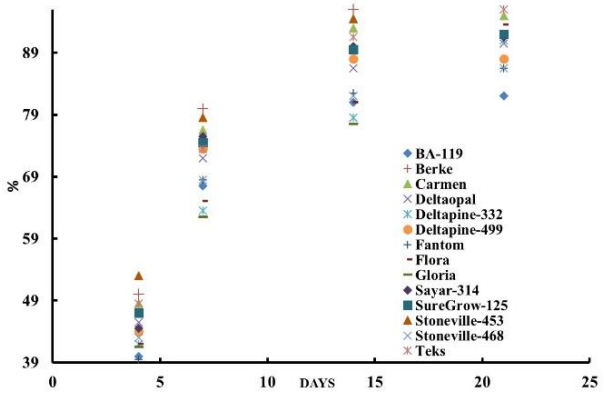

Figure 4. *Germination percentage at standard (30 °C) conditions on days 4, 7, 14 and 21*

Values of CWVI > 160 were not determined, while values of Fantom, Stoneville-453 and Sayar-314 ranged from 140 to 160 that were indicated as *good*. On the other hand, Stoneville-468, BA-119, Deltapine-499, Berke, Deltaopal, SureGrow-125 and Deltapine-332 varieties were found to be *medium* because CWVI values were between 120-140 while Carmen, Gloria, Flora and Teks varieties were *weak* because of values were smaller than 120 (*Table 4; Fig. 8*). Similar results have been obtained with varieties in terms of CWVI and HCSI characteristics.

Among the cotton varieties used were Fantom and Stoneville-453, the highest mid-tolerant, BA-119, Sayar-314 and Deltapine-499 varieties, secondly medium tolerant, Berke, Deltaopal, SureGrow-125 and Deltapine-332 medium tolerant with 3th grade, Carmen, Gloria, Flora and Teks varieties were thought to be sensitive to cold. Our findings are similar to the results of Bartonkowski et al. (1978), Maluf and Tifchelaar (1982), Hailstones and Smith (1988), Speed et al. (1996), Borth (1997), Al-Bahrain and

Khary (2000), Sheikh et al. (2002), Down et al. (2010), Özbek (2011), Karaca and Aytaç (2012), Kaya (2014), Kazmi et al. (2015), Bolek et al. (2016), while those of Dogras et al. (1977) and Lukonge et al. (2007) are different. This difference may be due to the difference in genotype or environmental conditions.

The cold-tolerant genotype in cotton seeds is characterized by high CWVI and low HCSI. It is seen that Fantom and Stoneville-453 varieties where the highest values for linolenic acid, stearic acid, 100 seed weight and seed density traits are obtained are also the highest varieties in which CWVI values are obtained (*Fig. 8*). This suggests that linolenic acids, stearic acids, 100 seed weight and seed density are important properties for CWVI (*Figs. 11* and *13*). The positive correlation between linolenic (r = +0.54**), stearic acids (r = +0.43**), 100 seed weight (r = +0.52**) and seed density (r = +0.77**) with the CWVI supports this situation (*Table 5*). In this case, the amount of high linolenic acids, stearic acids, 100 seed weight and seed density cottonseed, is more tolerant to high cold stress, reveals the result. This suggests that linolenic acids, stearic acids, 100 seed weight and seed density are important properties for CWVI and HCSI (*Figs. 6, 7, 11* and *13*). However, significant positive correlation was found between cold tolerance in the cottonseed and saturated fatty acids (r = +0.22), saturated/unsaturated (r = +0.32), but this was not statistically significant (*Table 5; Figs. 5–14*).

On the other hand, our findings, oleic acid, linoleic acid, palmitic acid, unsaturated fatty acids, unsaturated/saturated, oleic/linoleic, oleic/linolenic, oleic/palmitic, and linoleic/palmitic should be low for high cold tolerance in the cottonseed (*Figs. 9, 10, 12* and *14*). Correlations between CWVI and oleic (r = -0.23), linoleic (r = -0.71**) and palmitic (r = -0.31*) acids, unsaturated fatty acids (r = -0.66), unsaturated/saturated (r = -0.32), oleic/linoleic (r = -0.20), oleic/linolenic (r = -0.42**), oleic/palmitic (r = -0.01), and linoleic/palmitic (r = -0.30*) support this (*Table 5*). All results obtained for CWVI are also supported by HSCI results. The existence of a positive relationship (r = +0.78 **) between HCSI and CWVI confirms this similarity (*Table 5*). Our findings are similar to those of Judith and Christiansen (1976), Carmichael (2007), Özbek (2011), but differ from the findings of Edmisten (2000).

100 seed weight and seed density traits can vary significantly depending on the conditions of growing the cotton plant. As 100 seed weight and seed density increases in favorable growing conditions, it decreases in unfavorable conditions. It is also an indicator of the maturity of the cotton seed. While mature cotton is high in seed density, low value is obtained in immature cotton seeds. This suggests that cold tolerance is influenced not only by the genetic structure of the cotton seed, but also by the environmental conditions and seed maturity of the cotton seed. This reveals the fact that the conditions for growing cotton seeds are of great importance for cold tolerance. Our findings showed similarities with the findings of Bartee and Krieg (1974), Tripathi and Khan (1990), Bolek (2006, 2010) and Pahlavani et al. (2008).

Conclusion

Genetic structure and environmental conditions are very effective factors in terms of fatty acid composition and cold tolerance parameters. The cold condition for germination of cotton seed is 15 °C that prolongs the duration up to 21 days which brings with many negativity. There were not cold tolerant variety used in this experiment but cultivars could be ordered as Fantom and Stoneville-453 were the highest medium-tolerant, BA-119, Sayar-314 and Deltapine-499 were the second medium-tolerant, Berke, Deltaopal, SureGrow-125 and Deltapine-332 varieties were medium-tolerant at the third level, while Carmen, Gloria, Flora and Teks varieties were sensitive. In future studies, it is recommended to use Stoneville-453 and Fantom cotton varieties as highest medium-tolerant genotypes and Carmen, Gloria, Flora and Teks cotton varieties as sensitive genotypes. It is recommended that the properties of linolenic acid, stearic acid, saturated fatty acids, saturated/unsaturated fatty acids ratio, 100 seed weight and seed density are high in cotton seeds to reduce cold stress during germination. The CWVI and HCSI features are ideal indicators for cold tolerance.

Abstract. Nanotechnology, as the source of new industrial materials, has been widely used in recent years and has appeared in almost every field. Nowadays, nanoparticles are used in many areas like textiles, cosmetics, pharmaceuticals, automotive and defense (military) industries. The usage of nanoparticles has increased in recent years, but their effects on the environment are not exactly known. In this study, TiO_2 nanoparticle (TiO_2-NP) was applied at increasing concentrations (0, 5, 10 and 20 mg L^{-1}) to maize (*Zea mays* L.) plant grown in hydroponic culture at 16 h light/8 h dark, 25/20 °C temperature, 60% humidity and 10 Klux light intensity for 20 days. Application of TiO_2-NP on biomass production, nitrogen (N), phosphorus (P), potassium (K), zinc (Zn), iron (Fe), manganese (Mn), copper (Cu) and chlorophyll contents were investigated. The results showed that the plants' shoot and root biomass and leaf chlorophyll contents were significantly reduced with increasing TiO_2-NP applications. On the other hand, TiO_2-NP applications positively affected macro- (N, P, K) and micronutrients' (Zn, Mn, Cu) concentration except for Fe. Compared to the control treatment, the concentration of Zn, Mn, Cu, N and P significantly increased with the application of TiO_2 nanoparticles. Consequently, TiO_2-NPs treatments have increased nutrient uptake of maize excluding iron while decreased the dry biomass of maize at high doses.
Keywords: *chlorophyll, nanoparticle, maize, phytotoxicity, TiO_2 nanoparticles*

Introduction

Nanotechnology, one of the most popular scientific disciplines, has been widely used in different branches of science and technology in recent years (Siddiqui et al., 2015; Reddy et al., 2016; Cox et al., 2017). Although today nanotechnology has a billion-dollar industry around the world, ongoing comprehensive research shows that this technology is still in the discovery stage and that technology is expected to grow even further (Reddy et al., 2016; Cox et al., 2017).

Nanoparticles, rare in nature and being used in nanotechnology are widely used in cosmetics, agriculture, industry, technology, transportation, pharmaceutics, and energy due to their different properties (Kavaz, 2011; Rafique et al., 2014; Rastogi et al., 2017). The nano is a word from the Greek and it means very small, tiny. The size of these particles are less than 100 nm and they have unique chemical and physical properties (Du et al., 2011; Doğaroğlu and Köleli, 2017a; Rastogi et al., 2017). These properties of nanoparticles depend on their size, shape, morphology and properties of surface area.

Nanoparticles (NPs) are widely produced to supply increasing industrial demands. Enormous and unlimited use of NPs in recent years has led researchers to investigate this issue, regarding the problems that may arise in practice, and the environmental impact of these problems (Gottschalk et al., 2015; Tolaymat et al., 2015; Reddy et al., 2016).

Metallic nanoparticles such as TiO_2, ZnO, CuO etc., are the most common nanoparticles used in agriculture and industry. TiO_2-NP is the oxide of the metal titanium (Ti) and belongs to the family of transition metal oxides (Samadi et al., 2014; Lyu et al., 2017). Titanium dioxide is the most-produced nanoparticle (88.000 metric tons/year) after silicon dioxide (SiO_2) in the world (Medina-Velo et al., 2017) and it is used quite wide range areas such as cosmetics, pharmaceuticals, paints, coatings, antibacterial products, textiles (Da Costa and Sharma, 2015; Cox et al., 2017). Because of its intensive usages, its entry into the environment, concentration of soil and water is increasing day by day. There is no data directly published about the toxic concentration of TiO_2 and other metallic nanoparticles in soil and water (Da Costa and Sharma, 2015). But the knowledge about the toxic effect of TiO_2-NPs on the environment is limited and not well known. However, the researches done to evaluate the effects of TiO_2-NPs on the plant are not much. Several studies reported TiO_2 impact on plant development and physiology (Lyu et al., 2017). According to some reports, TiO_2-NPs are beneficial to some organisms and have positive effects on plant growth, chlorophyll synthesis and photosynthesis (Lyu et al., 2017). For instance, in spinach, TiO_2-NPs increased chlorophyll synthesis, photosynthesis and plant dry weight (Zheng et al., 2005; Hong et al., 2005). On the other hand, some investigations have reported that TiO_2-NP has an adverse impact on seed germination and plant growth and may lead to phytotoxicity (Samadi et al., 2014; Ruttkay-Nedecky et al., 2017).

Maize is a cereal plant that has been the most-cultivated crops in the world after wheat and rice. According to the Food and Agriculture Organization (FAO), the world maize harvested area was 1.8 billion hectares with an approximately billion tones production in 2016 (FAO, 2018). For these reasons, maize was used in the current experiment to investigate the effects of TiO_2-NP on growth and development of maize and the possible participation of TiO_2-NP in the food chain.

The toxic effects of nanoparticles such as TiO_2, ZnO, CuO, etc. on the plant were tested in petri-dishes (Lee et al., 2010; Castiglione et al., 2011; Doğaroğlu and Köleli, 2017a, b) or in the agar medium (Lee et al., 2008; Nair and Chung, 2014). These experiments could give very limited information. However, a hydroponic experiment gave more information about the uptake, accumulation of NPs in a different part of plants (shoot and root) and also the impact of these NPs on plants (such as chlorophyll content, plant growth, etc.) in a short time (Pošćić et al., 2016). After seedlings, plants would need essential mineral nutrients in growing media for healthy growth. Because of that reason, hydroponics systems with nutrient supply would be useful for phytotoxicity testing (Song et al., 2013). Because of these advantages, a hydroponic experiment was conducted under controlled climate chamber condition. The effect of TiO_2-NPs on growth, chlorophyll content, and mineral nutrient uptake of maize was investigated.

Materials and methods

The TiO_2 (<100 nm) nanoparticles, used for the hydroponic experiment, were synthesized by Dr Birol Karakaya in Gebze MAM institute.

The identification of TiO_2 nanoparticle as one of the primary nanomaterials by the Organization for Economic Co-operation and Development (OECD) is the most important criterion in selecting the nanoparticles to be used in this study (OECD, 2013). Maize, a widely grown plant, was used as plant material in this study. KERMESS (FAO 600-630) hybrid maize seeds were obtained from the KWS Seed Company.

The synthesized and characterization of nanomaterials

Titanium dioxide (~30-60 nm) nanoparticles were synthesized by Dr. Birol Karakaya through using a combination of Sol-Gel and hydrothermal synthesis with small changes in traditional methods at a research centre (BME-Kocaeli/Turkey) (Doğaroğlu and Köleli, 2017a). In this study, Variable Pressure Field Emission Scanning Electron Microscope (VP FE-SEM) (Carl Zeiss Supra 55) was used to characterize TiO_2-NPs coated with platinum-palladium. Titanium dioxide nanoparticles coated with platinum-palladium were imaged in SEM and elemental analysis was performed with EDX.

Hydroponic experiment

The maize seeds were germinated in a mixture of peat and perlite (1:1 w/w). When seedlings were getting 2-3 leaves and hairy rooted, they were transferred into the 4.5 L polyethylene pots supplied with the Hoagland nutrient solution medium (Hoagland and Arnon, 1950). The composition of the nutrient solution was as follows; the macronutrients (1 mM KH_2PO_4, 3 mM KNO_3, 0.25 mM $MgSO_4.7H_2O$, 2 mM $Ca(NO_3)_2.4H_2O$ and $2.5x10^{-2}$ mM KCI) and micronutrients (1 µM $MnSO_4.H_2O$, 1 µM $ZnSO_4.H_2O$, 0.25 µM $CuSO_4.H_2O$, 0.25 µM $(NH_4)_6Mo_7O_{24}$, and 0.125 µM H_3BO_3), pH was 5.2. Freshly prepared 0.1 mM Fe EDTA solution was added to each pot for the supply of the iron requirement of the maize plants. The nutrient solution was continuously aerated with a pump (KNF vacuum pump No.22.AN.18). Five maize plants were transferred to the pots and TiO_2-NP was applied with increasing dose 0, 0.5, 10, 20 mg L^{-1} to the nutrient culture. The nutrient solution was changed every 2-3 days. The plants were grown under controlled conditions (16/8 h light/dark period, 25/20 °C, 60% humidity and 10 Klux light intensity) for 20 days. The experiment design was a randomized block method with tree replication.

The effects of TiO_2-NP application on leaf chlorophyll contents were determined by the Konica Minolta SPAD-502 (Konica-Minolta, Japan, 0.06 cm^{-2} measurement area and its accuracy is 1.0 SPAD units) chlorophyll meter. The SPAD-502 calculates the chlorophyll content as soil Plant Analysis Development value (SPAD value). After the chlorophyll measurements, the plants were harvested as shoots and roots part and then washed with distilled water. After that, all samples were dried at 65°C in an oven until reaching a constant weight. The dry weights of plant samples were taken, and then ground in the mixer mill (Retsch MM301) for plant analysis. Plant samples were digested with HNO_3 and H_2O_2 in microwave oven (MarsXpres CEM). Total K, P, Zn, Fe, Cu, and Mn concentrations of the samples were determined by Inductively Coupled Plasma Mass Spectrometry (ICP-MS) (Agilent 7500ce Model). All results were given based on dry plant matter at 65 °C. The nitrogen concentrations of shoots were analyzed according to Bremner and Mulvaney (1982). Certified reference materials (SRM 1573A, SRM 1547) were also analyzed in order to check the accuracy of the extraction technique used in this study.

Statistical analysis

The variance analysis of the results was statistically analyzed by using the IBM SPSS-20 statistical analysis package program. The difference between the averages was grouped by applying the Least Significant Difference (LSD) test.

Results and discussion

The characterization of TiO_2-NP

The SEM image of synthesized TiO_2-NPs is shown in *Figure 1* and the average size of nanoparticles was found about 30-50 nm^{-1}. The SEM image showed that the TiO_2-NPs tend to agglomerate and this might be based on its hydrophobic surface properties (Nia et al., 2015; Doğaroğlu and Köleli, 2017a). In addition, SEM-EDX showed that Ti, O and C were identified using SEM-EDX (*Fig. 1*).

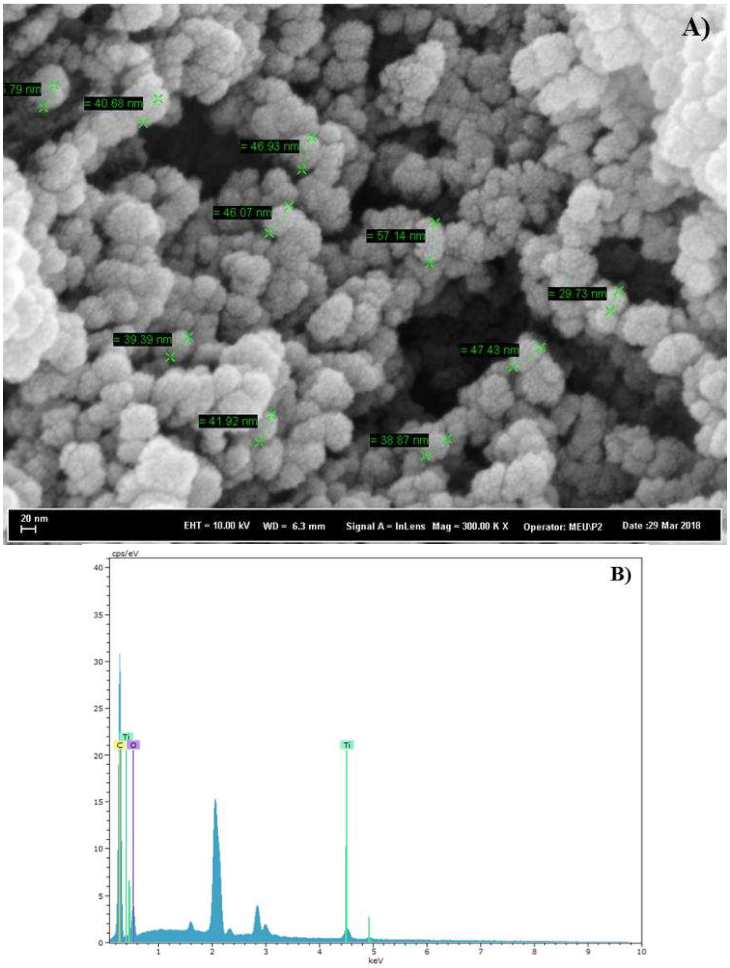

Figure 1. *SEM image and EDX spectrum of synthesized the TiO_2-NPs. Scanning Electron microscopic image of TiO_2-NPs (A) and elemental analysis of the TiO_2-NPs (B)*

Hydroponic experiment

The effects of increasing doses (0, 5, 10 and 20 mg L^{-1}) of TiO_2-NP treatment on maize plants were investigated in hydroponic culture experiment.

Morphological observations and chlorophyll content

Chlorophyll does not only give plants green color, it is also vital for plants. It produces energy and carbohydrates for physiological processes, plant growth, and development (Tan et al., 2017). If chlorophyll damage with any phytotoxicity, plant

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_68736883
© 2018, ALÖKI Kft., Budapest, Hungary

growth also reduces. Generally, the phytotoxicity of nanoparticle negatively affects the physiology and growth of a plant. Physiologically, the chlorophyll content leads to a decrease and this cause decrease in biomass production. The phytotoxic effects of NP-TiO_2 are related to the size, concentration, surface properties of the particles and their effects on germination and chlorophyll content, biomass production and other parameters (Samadi et al., 2014; Doğaroğlu and Köleli, 2017a; Yaqoob et al., 2018). Very slight chlorosis at 5 and 10 mg TiO_2 L^{-1} doses, and moderate chlorosis at 20 mg TiO_2 L^{-1} dose on the leaves of maize were observed (*Fig. 2*). The roots of plants had no significant visual symptoms.

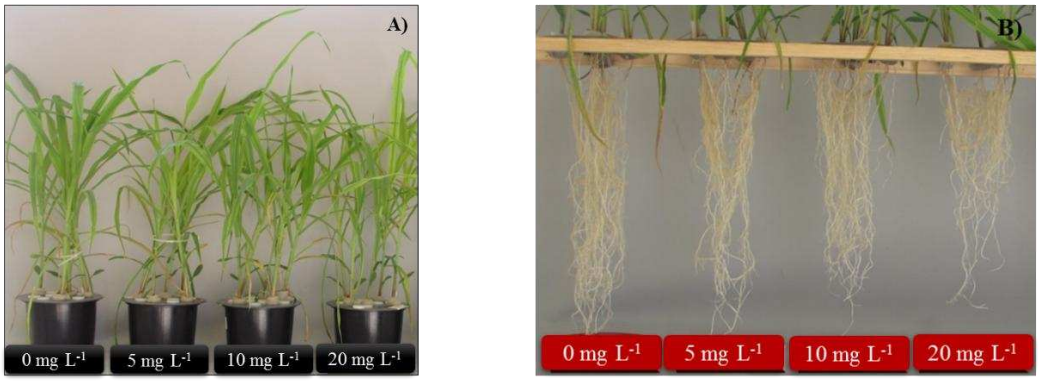

Figure 2. *TiO_2-NP application effects on shoot (A) and root (B) growth of maize*

Increasing TiO_2-NP applications has significantly reduced the chlorophyll contents of old and young leaves (*Fig. 3*). While the highest chlorophyll contents (SPAD Unit) were measured in old and young leaves of the control plants (24.2 and 30.4 respectively) and the lowest chlorophyll content (14.2 SPAD Unit) was measured on old leaves at 20 mg TiO_2 L^{-1} dose ($p \leq 0.01$). Doğaroğlu and Köleli (2017a) had the similar results. They have reported the chlorophyll contents of barley decreased at 20 mg kg^{-1} ZnO-NP and TiO_2-NP treatments. On the contrary to our result, many studies reported that TiO_2-NPs treatments increased photosynthetic activity and chlorophyll content of plants such as spinach (Hong et al., 2005), cucumber (Servin et al., 2012, 2013), Arabidopsis (Lenaghan et al., 2013), rapeseed (Li et al., 2015).

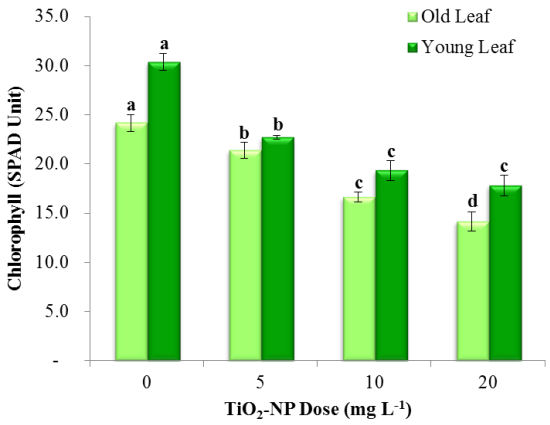

Figure 3. *TiO_2-NP application effects on chlorophyll contents of maize. Letter(s) on each bar show significant level ($p < 0.01$)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_68736883
© 2018, ALÖKI Kft., Budapest, Hungary

Dry weight (DW)

The dry weights (DWs) of the shoot and root decreased with the increasing TiO_2-NP application compared to the control treatment plant (*Fig. 4*). Controlled plant was has produced the highest shoot (2.13 g) and root (0.192 g) DWs. The lowest shoot (1.50 g) DW was obtained at 20 mg L^{-1} TiO_2-NP application dose. The root DW decreased up to 10 mg L^{-1} TiO_2 doses; however, DW production increased at 20 mg L^{-1} TiO_2 doses. Because of chlorophyll inhibition, the phytotoxicity of TiO_2-NPs application may be reduced with shoot and root DWs of the plant. In addition, these decreases may depend on the TiO_2-NPs size and surface properties with the application of increasing doses of TiO_2-NPs.

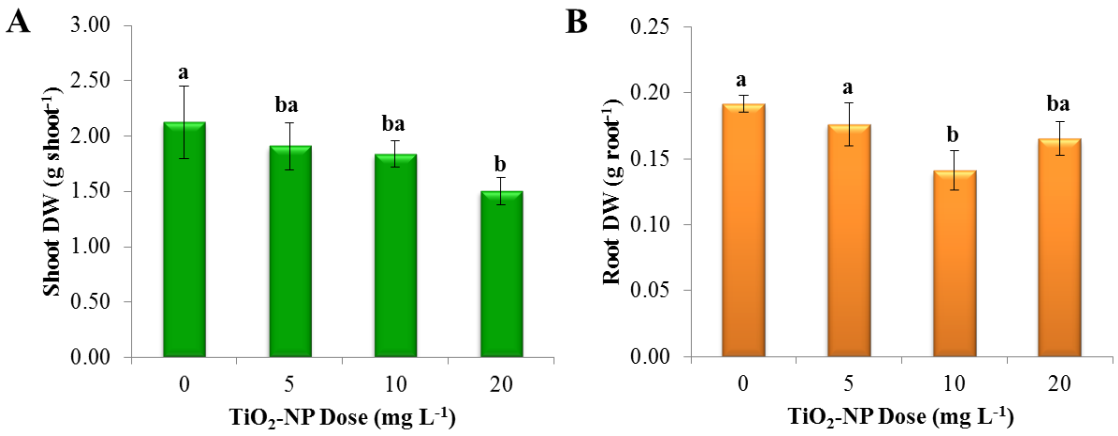

Figure 4. *TiO_2 application effects on shoot (A) and root (B) DWs of maize. Letter(s) on each bar show significant level ($p < 0.05$)*

Asli and Neuman (2009), that the plant leaf growth was inhibited by 300 mg TiO_2 L^{-1} treatment in maize, reported similar finding. Du et al. (2011) reported that the application of TiO_2 and ZnO nanoparticles (10 g TiO_2-NPs and 5 g ZnO-NPs mixed with 110 kg soil separately) reduced wheat growth and enzyme in field conditions. Feizi et al. (2012) investigated the effect of increasing doses of TiO_2-NPs (0, 5, 20, 40, 60 and 80 mg L^{-1}) on the fennel seed germination and early growth. On the contrary, they reported that the total germination percentage increased at 60 mg L^{-1} TiO_2 application after 14 days of seed incubation. The germination of *Zea mays* L. and *Vicia narbonensis* L. seeds were delayed by TiO_2-NPs applied at concentrations ranging from 0.2% to 4.0% for the first 24 hours (Castiglione et al., 2011). Kumar and Udayasoorian (2014) investigated the effect of three different types of nanoparticles (ZnO, TiO_2, and Al_2O_3) on growth parameters (germination percentage, vigor index, shoot and root length) of maize. They found that the highest toxic effect on growth parameters of the 2000 mg L^{-1} dose of the all three nanoparticles suspensions in the order of $ZnO > TiO_2 > Al_2O_3$.

Mineral nutrient concentrations

Unfortunately, many scientists have not analyzed or reported the nutrient concentration of plant after nanoparticle exposure. In fact, the relationship of toxicity (such as heavy metal, NPs, salt etc.) and plant nutrient uptake can be synergistic, antagonistic or neutral. Because of this reason, when the phytotoxic effect of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_68736883
© 2018, ALÖKI Kft., Budapest, Hungary

nanoparticles is investigated, the mineral nutrient concentration should also be also measured. In this study, the effects of increasing TiO_2-NP doses on macro (N, P and K) and micro (Cu, Fe, Mn and Zn) nutrient element concentrations of the shoot were investigated (*Table 1*) and root (*Table 2*).

Table 1. *The effects of increasing TiO_2-NP application on mineral nutrient concentrations (N, P, K, Zn, Fe, Mn, Cu) in shoots*

Cultivar	TiO_2-NP (mg L^{-1})	N	P	K	Zn	Fe	Mn	Cu
		(%)			(mg kg^{-1})

The shoot nutrient (N, P, K, Zn, Cu, Mn) concentrations were increased with TiO_2-NP applications except for Fe (*Table 1*). The highest N (3.24%), P (0.64%), K (7.69%), Zn (44.5 mg kg^{-1}) and Mn (84.2 mg kg^{-1}) were recorded at the shoot of TiO_2 treatment plants compared to control plant. However, the highest Fe (64.3 mg kg^{-1}) and Cu (6.49 mg kg^{-1}) concentrations were obtained from control plant. While TiO_2-NP applications were positively affecting N, P, K, Zn and Mn uptake, negatively affecting Fe and Cu uptake to the shoot of the plant. All results were significantly important ($p < 0.05$) except for K and Cu concentrations result.

The highest Fe (4618 mg kg^{-1}) concentration was obtained in the roots of maize plant ($p \leq 0.01$) (*Table 2*). However, the highest concentrations of P (1.23%), K (4.80%), Zn (119 mg kg^{-1}), Mn (71.2 mg kg^{-1}), and Cu (48.2 mg kg^{-1}) were obtained at 20 mg L^{-1} TiO_2-NP dose in plant roots. All results were significantly important ($p < 0.01$) except for the Mn concentration result.

Table 2. *The effects of increased TiO_2-NP application on mineral nutrient concentrations (P, K, Zn, Fe, Mn, Cu) in roots*

Tan et al. (2017) reported that increasing amount of three different TiO_2-NPs particles (unmodified, hydrophobic, and hydrophilic TiO_2-NPs) affected plant growth

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_68736883
© 2018, ALÖKI Kft., Budapest, Hungary

and mineral nutrition concentration of basil plants. Compared with the control, hydrophobic and hydrophilic TiO_2-NPs significantly reduced seed germination (41% and 59%, respectively); while unmodified and hydrophobic TiO_2-NPs significantly decreased shoot biomass (31% and 37%, respectively). On the other hand, they reported that the unmodified particles increased Cu (104%) and Fe (90%); hydrophilic particles increased Fe (90%); while hydrophobic increased Mn (339%) but reduced Ca (71%), Cu (58%), and P (40%) at 500 mg kg^{-1} soil treatment. Servin et al. (2013) reported that TiO_2-NPs (27 ± 4 nm) treatment (250, 500, and 750 mg kg^{-1}) to the soil were enhanced K and P concentration of cucumber fruit.

Pošćić et al. (2016), studied the application of increasing doses (0, 500 and 1000 mg kg^{-1}) of cerium oxide ($nCeO_2$) and titanium dioxide ($nTiO_2$) nanoparticles effects on the nutrient concentration of barley (*Hordeum vulgare* L). They were obtained significantly increased Ca and significantly decreased sulfur (S) in both $nTiO_2$ treatments. Potassium concentration was decreased at 1000 mg kg^{-1} $nTiO_2$. Manganese and Zn concentrations were increased at 500 mg $nTiO_2$ kg^{-1} treatment.

All these results indicated that there was a relation between TiO_2-NPs and mineral nutrient uptake. On the other hand, NPs size, concentrations, application medium (soil, hydroponic, agar, etc.) are also related to the plant nutrient uptake and toxic effects of NPs on plant physiology and growth.

Concluding remarks

The TiO_2-NP application decreased chlorophyll and plant growth, while interestingly, it enhanced some of the mineral nutrient uptakes such as N, P, and K. This study showed possible toxic effect of TiO_2-NPs on maize growth and physiology. Still, some uptake and toxic effect mechanism of NPs in maize plant is unknown. In the future study, it will be necessary to investigate the effects of phytotoxicity mechanisms, the size distribution of nanoparticles in plant and possible effects of uptake and translocation of nanoparticles by plants.

However, the potential impacts of nanoparticles on agricultural and environmental systems, their transport and mobility in the ecosystem, accumulation and toxicity on plants and the risk of entry of these particles into the food chain need to be investigated in the future especially plants grown in natural environments or in the field.

Abstract. In the study, resistance analyses were performed on pepper lines and genotypes (60 genotypes) of mainly common local genotypes found in the gene pool by classical testing methods. Classical tests were first applied in seedling stage. Second inoculation (the last) was carried out (in the stage of fruit retention) on resistant genotypes determined in the first inoculation. Varieties resistant to *phytophthora capsici* (CM 334 and partially resistant P1, P2 and P4) were also included in the study. Peroxidase and catalase enzyme contents of plant materials have been determined. Scale of 0-5 was applied to inoculated plants. Five pepper properties were measured and used as original variables. The first two principal components accounted for 74% of total variance. Score plots of the first two principal components were used to map genotypes according to their morphological properties. Some relationships between genotypes and their morphological traits were obtained. The results revealed that genotypes of P1, 13 (Urfa), 25 (UKST), 38 (UI), 48 (UKDT), 57 (ANKSB) were partial resistant genotypes while CM334 was fully resistant. To conclude, principal component analysis was shown to be a useful tool for mapping the pepper genotypes in terms of *phytophthora capsici* resistance.
Keywords: *pepper, biotic stress, resist, peroxidase, catalase, PCA*

Introduction

Pepper is one of the species of genus *Capsicum* in the family *Solanaceae*. The genus *Capsicum* is divided into twenty-five different species (Baral and Bosland, 2002). *Capsicum* originates from Mexico, South Peru and Bolivia. Almost all *Capsicum* species are diploid with 12 chromosome pairs (Moscone et al., 1996). *Capsicum annuum*, *Capsicum frutescens*, *Capsicum chinense*, *Capsicum baccatum* and *Capsicum pubescens* were cultured (Pickersgill, 1997). These species are the most important species in terms of economic and nutritional status (Djian-Caporalino et al., 2006).

Phytophthora capsici Leonian (*P. capsici*), is one of the most important soil born plant pathogens in the world and first was found by Fernandez-Pavia and his friends; of the 26 isolates, only 7 were pathogenic on the cucumber. While 24 of them were virulent in pepper, no stable condition was observed in tomato (Pavia et al., 2004). *Phytophthora capsici* causes damages on tissues of root, fruit and leaves of various vegetables (Manohara and Rizal, 2002). Phytophthora species secrete a large number of effectors during the infection of host plants (Stam et al., 2013). Bell pepper succumbed to disease in particularly humid and humid conditions. Only some partially resistant pepper cultivars are commercially available (Candole et al., 2010; Gisbert et al., 2010). Also *Phytophthora blight* caused by *Phytophthora capsici* is a very important disease in vegetable production (crop losses exceeding 50%) on worldwide and selective use of

DOI: http://dx.doi.org/10.15666/aeer/1605_68856901
© 2018, ALÖKI Kft., Budapest, Hungary

fungicides is the main part of disease management programs (Jackson et al., 2012; Sanogo et al., 2012; Yin et al., 2012). *Phytophthora capsici* is an oomycete that causes reductions in the production of capsicum (*Capsicum annuum* L.) worldwide. Nowadays, there are no chilles varieties that are resistant to this pathogen and the fungicides used for its struggle increase the resistance of disease races and increase the environmental damage (Garcia-Rodriguez et al., 2010).

Identification of initial symptoms of disease is very difficult and usually cannot be detected by the producers. Yellowing, fading and falling of leaves on the upper part of pepper plants are the most important and obvious signs of the disease (Ton et al., 2005). When these symptoms were observed, the infection has already reached to the advanced stage and caused root rot. *P. capsici* is very difficult to be controlled and causes a marked decline in pepper yields at pepper producer countries. For example, in Indonesia, root rot reduces 30 to 40% pepper yield in some gardens while in others it may cause 100% loss of yield (Nam, 2012). In Malaysia, more than 95% of pepper production areas have been similarly infected with *P. capsici*, resulting in a 5 to 10% reduction in productivity (Kueh, 1990). Yield loss in India was around 30% (Anandaraj, 2000). Successful management with *P. capsici* cannot be made due to the insufficient biologic information on *P. capsici*. According to the majority of scientists, A1 and A2 are the pathogen reproduction types (Ton, 2005; Hausbeck and Lamour, 2004; Ristaino and Johnston, 1999).

Plant enzymes are involved in defense mechanisms of plants against diseases caused by pathogens. Plant enzymes include antioxidants, such as peroxidase that enhance the cell structure and contribute to the formation of inhibitors in defense and catalyze the formation of lignin and other oxidative phenols. Studies conducted with plants such as pepper, tomato and wheat revealed a significant relationship between enzymes and protection against pathogens (Mohammadi and Kazemi, 2002). Catalase (CAT) enzyme is found in vertebrates, invertebrates, plants, fungi and all aerobic organisms (Bergmeyer and Grassl, 1982). The CAT enzyme has the highest conversion rate among all enzymes (Koç and Üstüm, 2016). The CAT enzyme is inhibited at high light intensity and by H_2O_2 which occur at high concentrations in stressed plant cells (Fridovich, 1986). Peroxidase (POX) is a part of the enzyme complex in the superoxide dismutase and CAT containing plant cell that regulates the level of harmful oxygen radicals formed under unfavorable external conditions. The POX enzyme has been isolated and characterized many times and the amino acid sequence of the enzyme has been revealed (Koç, 2011). The CAT and POX enzymes take part in purification of ROS (cell reactive oxygen species) from toxins. The enzymes disintegrate H_2O_2 and regulate the concentration of H_2O_2 in the cells. The CAT enzyme and different types of POX enzymes catalyze the disintegration of H_2O_2 (Chang et al., 1984). Since the catalase enzyme is not involved in chloroplasts, the breakdown of H_2O_2 in chloroplasts takes place by specific peroxidases (Asada, 1992). Principal component analysis (PCA) is a multivariate analysis technique and is also known as eigenvector analysis. The main objective of a PCA is to reduce the dimensionality of a set of data. This is particularly advantageous if a set of data with many variables lies, in reality, close to a two-dimensional subspace. In this case the data can be plotted with respect to these two dimensions, thus giving a straight forward visual representation of what the data look like, instead of appearing as a large mass of numbers to be digested (Jolliffe, 2002). The PCA is usually applied in environmental and agricultural studies (Panishkan et al., 2012; Yılmaz et al., 2017). The PCA was used to cluster patterns of 60 pepper

genotypes based on their morphological properties. The aims of this study were to study classification of pepper genotypes according to their morphological and chemical properties by using PCA.

Materials and methods

Materials

Fifty-nine pepper lines in the pepper gene pool of the Siirt University/Turkey, Department of Horticulture and CM334 (Criollos de Morelos 334) resistant to *P. capsici* were used in the experiment (*Table 1*). Fungal material was obtained from Van Yüzüncü Yıl University/Turkey, Faculty of Agriculture, Plant Protection Department. The isolate used is the most aggressive isolate of the strain.

Methods

Experimental design and treatments

Field studies were carried out in research and application fields of the Department of Horticulture, Faculty of Agriculture, Siirt University, Turkey. The effects of *P. capsici* on pepper varieties/lines have been investigated in two stages. At the first stage, resistance or sensitivity status of varieties/lines were determined at seedling period. After that, the resistant varieties/lines were selected and the effect of pathogen on plants was investigated in field conditions following the seedling period.

Prior to planting, the pepper seeds were placed in 2% sodium hydroxide solution for 5 min, subjected to surface disinfection, and washed twice using sterile distilled water. Peat was used as seedling growing medium. The experiment was designed with 3 replicates and each replicate included 10 plants.

The seedlings at 3-4 leaf stage were infected with spore solution containing zoospores of *P. capsica*. Seven-day cultures of *P. capsica* (in 9 cm petri dishes) grown in an incubator purely under dark at 25 °C within Potato Dextrose Agar medium were used for this purpose.

Fungi incubation

The petri dishes were left under the light for 2 days to allow sporulation. Twenty mL of sterile distilled water was added in each petri dish and incubated in the refrigerator at 4 °C for 40 min and then kept at room temperature for 30 min. Thus, zoosporogenesis of the fungus has been promoted. The zoospores of *P. capsici* were collected by filtration through two layers of cheesecloth. The zoospores of the fungus were then adjusted with hemocytometer at a concentration of 2×10^6 zoospor ml^{-1}.

Three ml of this solution was taken and inoculated to the surrounding of seedling roots to be inoculated with pathogen. After the first inoculation, the surviving seedlings were inoculated second time as indicated in the first stage. Peroxidase and catalase enzymes of samples taken from the sensitive varieties/lines in the uninoculated control group were also determined.

Enzyme activity assay

Catalase and peroxidase enzyme activities were determined by using Thermo Scientific UV-VIS instrument at Siirt University Science, Technology Application and Research Center. The plant leaf samples taken in accordance with the cold chain rules were broken into pieces with homogenate buffer for 5 min within a homogenizer and centrifuged at 15000 rpm for one hour at + 4°C. Both enzyme activities were measured in 100 µl homogenate of the substrate added to the buffer solution.

Catalase enzyme activity was determined using the method outlined by Jebara et al. (2005). Enzyme activity and enzyme calculation formula are given in *Table 2*. The measurement was performed at 240 nm in a quartz cuvette with 3 repetitions following the calibration of the instrument. The EU / ml values were obtained by calculation.

The activity measurement of peroxidase enzyme was determined spectrophotometrically according to the procedure applied by Şişecioğlu et al. (2010). This procedure is based on the oxidation of guaiacol chromogenic substrate by H_2O_2 and the monitoring the increase in absorbance resulted from colored compound at 470 nm (Şişecioğlu et al., 2010). The enzyme activity and enzyme calculation formula are

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_68856901
© 2018, ALÖKI Kft., Budapest, Hungary

given in *Table 3*. After device calibration, the measurement was made at 470 nm in a quartz cuvette with 3 repetitions. The EU/ml values were determined by calculation.

Table 2. *Catalase enzyme mechanism and enzyme calculation formula*

Catalase: $2H_2O_2 \longrightarrow 2H_2O + O_2$ Calculation of Catalase: EU/ml = 3.45 (pure) Catalase/min (V_E) 3.45 = 240 nm which corresponds to degradation of 3.45 µm dead caused by hydrogen peroxide produced in 3 ml of reaction for absorbance decline from 0.45 to 0.40. df = dilution factor min = time required to decrease absorbance at 240 nm from 0.45 to 0.40. V_E = The amount of enzyme used

Table 3. *Peroxidase enzyme mechanism and enzyme calculation formula*

Peroxidase mechanism: 2Guaiacol + $2H_2O_2 \longrightarrow$ 2oxide guaiacol + $2H_2O$ Calculation of Peroxidase: EU/ml = (Peroxidase, absorbance difference occurs in 1 min) * df / 1*(0.01) df: dilution factor 1: per enzyme / increase in 1 min 0.01: amount of enzyme homogenant used Unit/mg protein: (Unit / ml enzyme) / (mg protein / ml enzyme)

0-5 scale

Disease severity of plants was determined using 0-5 scale after 4, 8, 12 and 16 days of pathogen inoculation. In this evaluation; 0 = no sign of disease; 1 = brown lesions began to appear on lightly faded leaves and body; 2 = disease indication in 30-50% of the plant; 3 = disease symptoms at 50-70% of the plant; 4 = disease symptoms at 70-90% of the plant; 5 = dead plant (Sunwoo et al., 1996; Ozgonen and Erkilic, 2007).

Principal component analysis

The first principal component (PC), y_1 is a linear combination of x_1, x_2, …, x_p (*Eq. 1*):

$$y_1 = a_{11}x_1 + a_{12}x_2 + \cdots + a_{1p}x_p = \sum_{i=1}^{p} a_{1i}x_i \quad \text{(Eq.1)}$$

such that the variance of y_1 is maximized given the constraint that the sum of squared (SS) weights is (*Eq. 2*):

$$\sum_{i=1}^{p} a_{1i}^2 = 1 \quad \text{(Eq.2)}$$

The random variables x_i, can be either deviation from mean scores or standardized scores. If the variance of y_1 is maximized, then so is the SS correlations of y_1 with the original variables x_1, x_2, …, x_p (*Eq. 3*):

$$\sum_{i=1}^{p} r_{y_i x_i}^2 \quad \text{(Eq.3)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_68856901
© 2018, ALÖKI Kft., Budapest, Hungary

PCA finds the optimal weight vector $(a_{11}, a_{12}, \ldots, a_{1p})$ and the associated variance of y_i which is usually denoted by λ_i. The second PC, y_2, involves finding a second weight vector $(a_{21}, a_{22}, \ldots, a_{2p})$ such that the variance of (*Eq. 4*)

$$y_2 = a_{21}x_1 + a_{22}x_2 + \cdots + a_{2p}x_p = \sum_{i=1}^{p} a_{2i}x_i \quad \text{(Eq.4)}$$

is maximized subject to the constraints that it is uncorrelated with the first PC and (*Eq. 5*)

$$\sum_{i=1}^{p} a_{2i}^2 = 1 \quad \text{(Eq.5)}$$

the results in y2 having the next largest SS correlations with the original variables. The first two PCs together have the highest possible SS multiple correlations (Dunteman, 1989).

Statistical analysis was performed using MINITAB 14 Software.

Results and discussion

Enzymatic component of antioxidative enzymes are important for the formation of antioxidative reactions in plants and in obtaining cell homeostasis for defense system. Antioxidative enzymes are being frequently used in recent transgenic studies to increase the resistance of plants to different stressors. The fruit shape and hotness of peppers may also be an indicative of resistance. The resistance of capia, half-capia-pointed pepper or bell peppers was different. The capia peppers showed resistance to *phytopthora capsici*, while the genotypes or varieties with semi capia-pointed peppers were included in the partially resistant or sensitive or even very sensitive group. The bell pepper genotypes and varieties did not show any resistance to the disease and were found as sensitive or even very sensitive.

The highest peroxidase activity among genotypes investigated was obtained with line 10 (0.0744), and followed by genotypes 3 (0.0568), 38 (0.0540), 57 (0.0533) and 11 (0.0482), respectively. The genotype 10 showed a similar profile (2.9571429) in terms of catalase activity and followed by genotypes 8 (1,5525), 56 (1,5525), 9 (1,514,6341) and 11 (1,444186), respectively (*Tables 4* and *5*). Similar to our findings, Lamour et al. (2012) also showed that CM 334 genotype had resistance to all *P. capsici* isolates.

Seven of the 60 genotypes (genotypes 3, 10, 13, 25, 38, 48 and 57) survived after the first inoculation. Significant disease symptoms were observed in other 53 genotypes and these genotypes died in a short time after the inoculation. Different genotypes resistant to *P. capsici* may be developed when early symptoms are not ignored (Black et al., 1991; Ortega et al., 1995; Pochard et al., 1983). Similar to the findings of Kim et al. (1989), resistance to *P. capsici* increased during 12-leaf period. All other genotypes except 10 genotypes died after the second inoculation. The highest peroxidase enzyme activity was obtained with the seven genotypes survived following the first inoculation (*Tables 4* and *5*). The seedlings were not significantly affected from *P. capsici* at the beginning of their developments. However, when seedlings reached to 4 true leaf stage, the initial symptoms started to appear, and the resistance mechanism was different for the different parts of plants (Bosland and Lindsey, 1991; Sy et al., 2005). The peroxidase enzyme activity was low in very sensitive genotypes, while enzyme activity

was very high in very resistant genotype (genotype 10-CM 334) and partially resistant genotypes (3, 13, 25, 38, 48 and 57).

Although catalase enzyme content was different in some genotypes, similar results were obtained for peroxidase. The peroxidase (POX) content of genotypes that sensitive in the early stage of inoculation had generally high but catalase content significantly varied among these genotypes. The POX enzyme content can be used as a determinant because POX is an oxide-reductive enzyme which stimulates oxidation and suberization of phenols participating in cell wall polysaccharide processes, lignification of host plant cells during defense and provides a reaction against pathogenic substances (Ray et al., 1998). The POX content is very high in stable plant tissues (Breusegem et al., 2001; Lin and Kao, 2001). Lignin accumulation and phenolic compounds have been correlated with the disease. Similar results were also obtained in wheat-*Fusarium graminearum* (Mohammadi and Kazemi, 2002) and cucumber-*Pythium aphanidermatum* (Chen et al., 2000) treatments. The POX is believed to participate in cell wall metabolism (Welinder,

1993) and production of anti-microbial compounds (Kobayashi et al., 1994) that play a role in healing of wounds. The POX content was tended to increase in resistant variety/line/genotypes (Jung et al., 2006).

The scale of 0-5 was used to identify the disease (*Table 6*). Zero stands for no disease symptoms and 5 represents the highest symptoms of disease. The disease was very vigorous and continuous in genotypes with a 5-scale value. Distinction of symptoms required great attention in genotypes received scores between 0 and 5. Some of the genotypes (3, 25 and 38) received high values at the initial assessment whereas their scores were lower at later observations and included in resistant genotypes. Sixteen days after the inoculation, the differences between susceptible and resistant and partially resistant genotypes started to be apparent. The enzyme (peroxidase and catalase) contents were also compatible with the resistance of genotypes. Some genotypes were classified within the sensitive group at initial assessments, whereas they scored lower in the later evaluations, meaning less disease symptoms (i.e. Gayoso et al., 2004; Ray et

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

al., 1998; Ponmurugan et al., 2007). Resistance or sensitivity did not follow a linear trend in some genotypes. Genotypes of 28, 35 and 45 were finally determined as susceptible, and despite the deaths at the first inoculation they were classified among the genotypes that responded as if the disease symptoms had improved. The genotypes 3, 25 and 38 received higher scale values at the beginning and followed by lower values at the subsequent observations. The genotype 10 had a 0-scale value in every observation and it was identified as the most resistant plant material without any signs of disease. The genotype 33 showed initial disease symptoms even at the fourth observation following the first inoculation. The enzyme activity content of sensitive genotypes with no stabilized score values do not have also sufficient values for enzyme activity. Inconsistent differences in the scale values may be due to enzyme activity, and this may also a sign of morphological clarification and genetical impurities.

Significant correlation between POX activity and content of phenolic compound of plants with different families in which pepper is included has been reported (Candole et al., 2012). The peroxidase and similar enzymes trigger the formation and enhancement of the phenolics in the plant cell wall during defense against pathogens (Gayoso et al., 2004).

In some studies, approximately one week after the infection of disease, the increase in peroxidase, as well as phenol contents especially in the stem and leaves of plant, was reported and even the increase reached to the maximum level (Gayoso et al., 2004). The CM334 is a worldwide known resistant genotype (partial wild) against *P. capsica* and has been defined as a resistant genotype in our study based on both peroxidase and catalase contents. The peroxidase activity of resistant CM334 genotype was higher compared to the sensitive genotypes.

Inadequate enzyme activity in sensitive varieties may have caused these genotypes defeating against the disease. Living in a certain period of time for sensitive genotypes despite the disease may be attributed to the consumption rate of phenolic substances. Ponmurugan et al. (2007), it is predicted that it may be aimed at producing some metabolites which may cause the metabolism of the pathogens to be distributed and balanced. The overproduction of ROS (free radicals) and the consumption of antioxidant defenses may cause disruption of oxidant–antioxidant balance and occurrence of oxidative stress in the cells (Koç and Üstün, 2016).

Three morphological (resistance, hotness and fruit shape) and two chemical (peroxidase and catalase) characteristics of pepper genotypes were investigated in this study. The descriptive statistics (mean, standard deviation, minimum, maximum and median) for characteristics were presented in *Table 7*. The relationships among genotypes in terms of characteristics studied were evaluated by principal PCA. The mean and standard deviation values revealed that resistance had the lowest variability and peroxidase and catalase had the highest variability. High coefficient of variability is an indication of the differences in genotypes.

Table 7. *Descriptive statistics of pepper genotypes*

Traits	N of obs.	Mean	Std. dev	Minimum	Median	Maximum	CV (%)
Resistance	60	2.9833	0.5365	1.0000	3.0000	4.0000	17.98
Hotness	60	1.6000	0.7178	1.0000	1.0000	3.0000	44.86
Fruit shape	60	1.5333	0.7003	1.0000	1.0000	3.0000	45.67
Peroxidase	60	0.0274	0.0165	0.0030	0.0260	0.0740	60.22
Catalase	60	0.7389	0.4278	0.0360	0.6435	2.9570	57.90

Each component in the table explains a certain portion of the variability in the data. The higher the proportion, the more variability is explained by the PC. Cumulative proportion is the variability explained by the consecutive PCs. The PCs with the largest eigenvalues were retained to explain the variability. A PC with eigenvalues greater than 1.0 is kept for further analyses. The scree plot enables visual comparison of the eigenvalue sizes (*Fig. 1*). The first two PCs have eigenvalues greater than 1.0 and explain 74% of the variation in the data. The eigenvalues start to form a straight line after the second PC. The amount of variability explained by the two PCs is sufficient hence the first two PCs will be used to explain the variability.

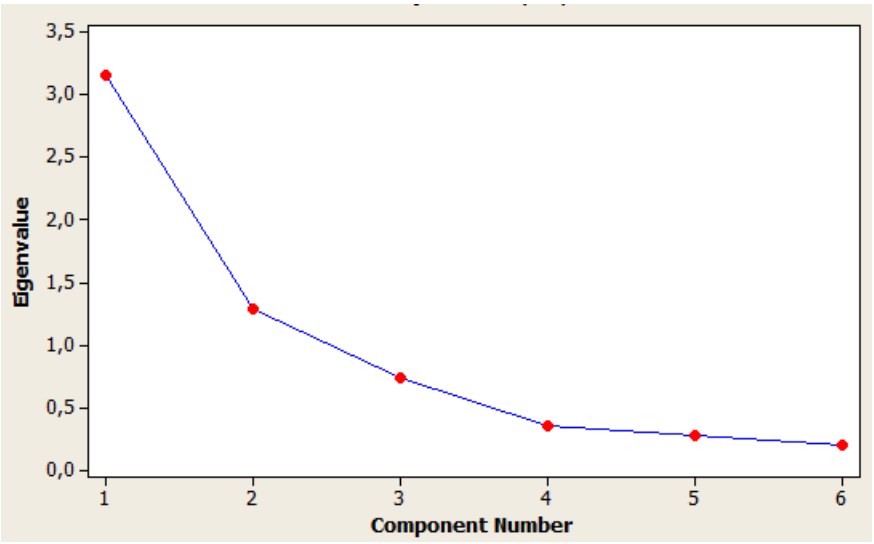

Figure 1. *Scree plot of the eigenvalues*

The PCs are the linear combinations of the original variables that account for the variance in the data. The coefficients indicate the relative weight of each variable in the component. Peroxidase, resistance and fruit shape had the highest influence in PC1 (*Table 8*). The peroxidase and resistance had positive effects in PC1, while fruit shape had negative effect (the effect on ingredient increases as the fruit gets more pointed).

Table 8. *Results of principal component analysis*

Trait	PC1	PC2	PC3	PC4	PC5	PC6
Resistance	0.491860	0.197271	-0.067553	-0.131608	0.491860	0.197271
Hotness	0.440223	-0.051902	0.545261	0.648487	0.440223	-0.051902
Shape of fruit	-0.480311	0.259828	-0.171691	0.208326	-0.480311	0.259828
Genotype	0.116054	-0.718223	-0.580743	0.343676	0.116054	-0.718223
Peroxidase	0.501997	-0.050420	-0.153561	-0.512774	0.501997	-0.050420
Catalase	0.260977	0.610322	-0.554803	0.371071	0.260977	0.610322
Eigenvalues	3.1560	1.2860	0.7356	0.3548	0.2705	0.1972
Proportion %	52.6	21.4	12.3	5.90	4.50	3.30
Cumulative proportion %	52.6	74.0	86.3	92.2	96.7	100.0

The second PC had a large negative association with genotype (71.8%) and positive associations with catalase (61.0%) and fruit shape (25.9%) (*Fig. 2*).

There are a number of variants of the biplot idea, but all give a simultaneous display of n observations and p variables on the same two-dimensional diagram. In one of the variants, the plot of observations is identical to a plot with respect to the first two PCs, but the biplot simultaneously gives graphical information about the relationships between variables. The relative positions of variables and observations, which are plotted on the same diagram, can also be interpreted (Jolliffe, 2002). High positive effects of resistance, peroxidase and hotness on PC1 are seen in biplot figure (*Fig. 2*). In other words, the first component focuses on the hotness, peroxidase and catalase

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

contents of plants and resistance to phytophthora disease. The second component is more related to the fruit shape of the plant. The relationships among genotypes grouping based on fruit shape, hotness and resistance are illustrated in the score plots (*Figs. 3–5*).

Figures 3 and *4* show that the genotypes form groups according to these morphological characteristics. Based on resistance parameter, genotypes could be grouped absolutely independently (*Fig. 5*).

The first PC accounts 52.4% and the second PC explains 21.6% of total variation. A model based on the first two principal components accounts for 74.00% of total variance.

the leaves of the partially endogenous genotypes P1, 13 (Urfa), 25 (UKST), 38 (UID), 48 (UKDT), 57 (ANKSB)] showed weak symptoms. New shoot formation was detected in these genotypes. In the second inoculation, however, these genotypes have also been found at high rates since the first week after the inoculation of the disease indications. Deaths in these genotypes were observed in approximately 2 weeks. The first week after inoculation is important for breeders. As a result of our observations that the genotypes started to show resistance in the first week after inoculation may be breeding material. The yield and fruit qualities of genotypes found to be resistant or very resistant are not available in commercial pepper cultivation. CM 334 genotype has lower fruit quality and yield values. Partly resistant genotypes (deaths in the first two weeks and deaths after second inoculation due to disease) should be used at breeding program because according to Hwang et al. (1996), resistance against *P. capsici* occurs during the last stages of plant development. The genotypes that are resistant (genotype 10 /CM 334) or part-resistant (genotypes 3, 13, 38 and 48) all have the shape of capia fruit. Again, the genotypes listed above have bitter fruits. It was found that the fruits of the fruit-shaped capia and hot were likely to be resistance (*Table 1*). The PCA helped to reveal some relationships between genotypes and morphological properties. The PCA has proved to be a useful approach in characterization of genotypes based on their morphological properties.

Abstract. This study was carried out in Iran to determine the effect of foliar application of Selenium and plant density on oil quality and quantity and fatty acid composition of canola cultivars. The experiment was laid out in a factorial split plot arrangement based on a complete blocked design with three replications at Karaj Seedling and Seed Breeding Institute, Karaj, Iran during 2015 and 2016. Treatments were plant density (40, 60 and 80 plants/area) and foliar application of selenium (0 and 30 $g.l^{-1}$ sodium selenite) in main plots and varieties (Sarigol, Hyola 401, Jacomo, Jerome, and Dalgan) in sub-plots**.** The results showed that year, plant density, selenium, variety treatments, and interaction effect of density*year and cultivar*density had a significant effect on seed yield, oil yield, oil percentage, and fatty acid composition, such as palmitic, linolenic, linoleic, oleic and erusic acids ($P \leq 0.01$). The Dalgan variety had the highest seed and oil yield in 40 plants per square meter (m^2) density (4817.41 and 2134.83 $kg.ha^{-1}$ respectively). Maximum seed oil content (43.78%) was obtained in 40 plants per square density treatment. However, the maximum rates of seed oil yield, palmitic acid, and linoleic acid were observed in Hyola-401 variety, and Jerome variety had the highest linolenic and erusic acid. The palmitic and linolenic acids in Dalgan variety at 40 plants per square treatment had the maximum rate. The findings showed that with increasing of plant density decreased grain yield, oil content and fatty acid compositions. However, application of selenium increased them especially in Dalgan variety. Also the highest seed yield, seed oil content and palmitic acid and lowest amount of linolenic and erusic acids was obtained in Dalgan variety. The maximum linoleic and erusic acid was obtained in Jermco variety. The lowest erusic acid was obtained in 40 plants per square treatment. The results also showed that foliar application of selenium increased seed yield, seed oil yield, palmitic, linolenic and erusic acid compared to non-application of it. In final the present study indicated that increased seed yield, oil content, oil yield and fatty acid quality in 40 plants/area treatment, specially Dalgan variety in Golestan province, Iran.
Keywords: *erusic acid, fatty acids, foliar application, sodium selenate, yield*

Introduction

Canola (*Brassica napus* L.) is an oilseed plant that has a wide range of adaptation to different climates, and has two autumn and spring types and is utilized in the crop rotation programs in different regions (Angadi et al., 2003). In terms of oil production canola is locate after soybean (FAO, 2017). Various canola cultivars' capability to germinate and grow at low temperatures resulted in increasing development of its cultivation in cold regions of the world, including Canada, northern Europe and the cold parts of Asia. This issue has caused several studies to be conducted on this product in

© 2018, ALÖKI Kft., Budapest, Hungary

the cold regions. Following soybean, canola is the second most important source for production of edible oil in the world (FAO, 2017).

The canola seed oil content, quality and components have always been the concern of plant breeders. Fatty acid compounds and unsaturated fatty acids levels controlled genetically controlled but also affected by environmental conditions (Bellaloui et al., 2013). Studies have shown that some environmental factors, such as the temperature and shading (Ruuska et al., 2004), for example, at high plant density per unit area, change the composition of fatty acids. They state that the oil seed produced under shade conditions has less fatty acids than those produced in full sunlight. Today, the canola yield and oil quality have rapidly increased in order to mechanize harvesting, higher yield cultivars introduction, and better agronomic practices (Shahbaz et al., 2018). However, further studies are needed to increase canola oil yield and quality.

Plant density is the most important factor to reach the maximum crops yield. Along with the use of suitable cultivars adapted to the climatic conditions of each area, as well as the maximum use of environmental resources such as light, water, and nutrients, it can allow the result to achieve higher crop yields (Chavan, 1989). However, increasing the plant density reduces the number of stems per plant due to the increase of inter-plant competition, which decreases the number of stems or lateral branches by decreasing the allocated space per plant (Vega et al., 2000). Increasing the plant density results in the single plant yield reduction by reducing the number of sub-branches and the number of pods per plant, but the appropriate increase of plant density will result in compensation of sub-branch and plant yield components' reduction by increasing the number of plants per area (Onofri et al., 1996). In high density rape seed, plant bedding and chlorophyll degradation in the plant increased, resulting in the loss of yield due to inter and intra-plant competition (Morrison et al., 1990). They argued that the reduction of light in the plant community is a major cause of the early leaves senescence, and appropriate density can delay their senescence by having an effect on the leaves emitted radiation. It was reported that with the increasse in plant density, the number of pods per square increased, but the number of seeds per pod and 1000 grain weight linearly decreased that resulted in the decrease of grain yield (Ozer, 2003). Also, Bilgili et al. (2003) and Lythgoe et al. (2001) concluded that the plant density plays a major role in rapeseed grain yield. Canola can adjust its grain yield in a wide range of density. The ability of a plant to compensate of below optimal level density depends on available resources, such as light, water, and nutrients (Angadi et al., 2004). The scores of higher plant density are prevention of the large number of branches and the number of pods in branches that leads to uniform maturity of canola (Malhi and Gill, 2004).

Due to an impact on the growth and development of plants and its presence in antioxidant systems, selenium is recognized as one of the vital elements for human and animal health. While beneficial elements are not involved directly in the metabolism of plants and completing their life cycle, they play a role in improving the vegetative and reproductive growth, especially in environmental or biological stress conditions (Hajibolan, 2012). Recent findings reveal that selenium at low concentrations can enhance oxidative stress resistance by increasing antioxidant capacity, which has a positive effect on the decrease of lipid peroxidation. This indicates the positive impact of selenium in reducing lipid peroxidation and increasing the activity of anti-oxidative enzymes (Seppanen et al., 2003; Xue et al., 2001). Low concentration of selenium has a beneficial impact on the plants' growth and stress resistance through their antioxidant capacity (Turakainen, 2000). The use of selenium leads into an increase in plant height,

© 2018, ALÖKI Kft., Budapest, Hungary

number of pods, number of seeds per pod, biological yield, harvest index and oil percentage and reduced respiration, proline and malondialdehyde (Bybordi, 2016). Seppanen et al. (2003) reported that selenium prevents chlorophyll degradation in environmental stress conditions. Other beneficial impacts of selenium are increasing metabolism of carbohydrates and the stress resistance (Zhu et al., 2004). Haji Boland et al. (2014) showed that the impact of selenium in increasing drought resistance and improving the water relations in canola was related to increasing the water absorption due to development of root, which increased the photosynthesis and forming the soluble sugars. By conducting the studies on the methods of increasing the yield under density conditions, we can provide an appropriate mechanism for improving product yields.

However, information on selenium foliar application and plant density on fatty acid composition changes and oil quality are limited in canola. Therefore, this study was conducted to examine the application of selenium on the seed oil quantity and quality in various winter-planted canola cultivars, in order to reduce the adverse effects of stress resulting from density.

Material and methods

Research location: the present study was conducted in two years of 2015 and 2016 in a 400-ha farm of Karaj Seedling and Seed Breeding Institute, Karaj, Iran (35°49'). The latitude of the location is 35°49'N and its longitude is 51°6'E and its height from sea surface is 1321 m.

Meteorological information: this region is considered among the hot and dry Mediterranean climate regions based on the climate data and amberthermic curve, due to having 150 to 180 dry days in a year. It is also considered a dry humidity regime, due to having cold and wet winters and hot and dry summers. According to the 30-year Karaj meteorological information, the average rainfall is 243 mm per year. In this region, rainfall occurs often in the late fall and early spring. The average annual maximum temperature is seen in July with 28 °C and the average annual minimum temperature is seen in January with 1 °C. The average temperature of this region in a 30-year period is 13.5 °C and the soil temperature is 14.5 °C.

Soil characteristics of the region: according to *Table 1,* soil texture of the region is loamy and clay (*Table 1*).

Table 1. *Soil characteristics in experimental location*

Characteristics	Electrical conductivity (dS/m)	pH	Percentage of neutralized materials	Humidity percentage of saturated clay	Organic carbon (%)	Nitrogen (%)	Phosphorus (Mg/kg)	Potassium (Mg/kg)	Percentage of clay	Percentage of silt	Percentage of sand
Sampling depth (0-30 cm)	1.45	7.9	8.56	36	0.91	0.09	14.7	197	28	47	25
Sampling depth (30-60 cm)	1.24	7.2	8.68	38	0.99	0.07	15.8	155	25	49	26

According to the results of soil analysis and fertilizer recommendation, we applied fertilizer (a part of the N fertilizer and all of the P and K fertilizer required). We also applied Treflan herbicide (2.5 l/ha) laid uniformly in field. Fertilizer and herbicide were mixed with soil using disk. For the optimal usage of nitrogen, the rest of the required nitrogen fertilizer was used at the beginning of the stem generation and the emergence of the first flower buds. After conducting the experiment, the feeding operation including the control of pests, especially wax aphid, was performed using metasystoxpesticide in accordance with the planting plan and seedling emergence, which was approximately 1.5 l/ha.

Statistical design: the experiment was laid out in a factorial split plot arrangement based on completely randomized block design with three replications. Here, we would plot the plants to the maximum capacity in terms of density and would separate and single out the plants to reach an ideal amount for this experiment. In this experiment, treatments were plant density at three levels of 40, 60 and 80 m^2 and with selenium in two levels of control (lack of foliar application (water) and foliar application with selenium at amounts of 30 $g.l^{-1}$ sodium selenate were placed as a factorial in main plots, and five cultivar such as Sarigol, Hyola 401, Jacomo, Jerome, and Dalgan was placed at sub-plots. Each experimental plot included 6 rows with 30 and 4 cm row to row and plant to plant distance respectively. Middle rows were harvested to seed yield to determination. Irrigation was performed in accordance with the plant requirement using siphon. Foliar application of selenium (30 $g.l^{-1}$ sodium selenite per hectar) applied in two stages, 15 $g.l^{-1}$/ha before rosette and 15 $g.l^{-1}$/ha in the fast stem growth stage and foliar application of water as control. After treatments, a 5 grams seed sample was selected from each plot to determine the amount of the seed oil content using an NMR device. After determining the seed oil percentage, the seed yield was calculated in $kg.ha^{-1}$. Gas chromatography method was used to measure and determine the seed oil fatty acid and its composition (Yang et al., 2009). Statistical analysis was also performed using the SAS 9.1 software. In order to compare the means of the traits, Duncan statistical method was used at the level of 5%.

Results

Seed yield: according to the analysis of variance table, the effect of year, density, variety, and selenium, the interaction effect of variety * density were significant on seed yield ($P \leq 0.01$). Also, the effect of year, block and density were significant on seed oil content, while the interaction of the studied treatments had no significant effect on this trait (*Table 2*). The effect of year, block, density, variety, selenium and interaction effect of variety * density were significant on seed oil yield ($P \leq 0.01$). The results of present study showed that the year, block, density, selenium, variety treatments were significant on fatty acid composition, such as palmitic, linolenic, linoleic, oleic and erusic acids ($P \leq 0.01$). However, the interaction effect of variety * density were significant on all fatty acid composition, except linolenic and oleic acids (*Table 2*).

The results showed that the highest seed yield was obtained in Dalgan variety cultivated in 40 plants per m^2 density (4817.41 $kg.ha^{-1}$), and the lowest seed yield was obtained in Sarigol variety at 80 plant per m^2 density (1519.91 $kg.ha^{-1}$) (*Fig. 1*). Based on the results, the Jerome variety had the lowest seed yield in 40 and 60 plant per m^2 density treatment (3895 and 2541 $kg.m^{-2}$ respectively) (*Fig. 1*). Increasing the plant density decreases seed yield significantly in all varieties.

The findings of the present study showed that the highest seed oil content was obtained at the 40 plants per square density treatment (43.78%), compared to 80 plants per square density treatment (41.71%) ($P \leq 0.05$) (*Table 3*). However, in 40 plants per square density treatment, the highest seed oil yield, palmitic, linoleic acid, linolenic, oleic and erusic acids were obtained and with increasing the plant density it reduced them significantly (*Table 3*). There are significant reductions in seed yield, seed oil yield, palmitic, linoleic acid, linolenic, oleic and erusic acids by the increase in plant densities (*Table 3*).

Foliar application of selenium increased seed yield significantly compared to control (3679.63 $kg.ha^{-1}$) (*Table 4*). Also, The results of the present study showed that application of selenium increases seed oil yield (1358.81 $kg.ha^{-1}$), palmitic (5.21%), linolenic (5.93%) and erusic (0.32%) acids (*Table 4*).

The results showed that the highest amount of seed oil yield (1521 $kg.ha^{-1}$), palmitic acid (5.452%) and linoleic acid (19.62%) were obtained in Hyola-401 variety but the highest linolenic acid (6.17%) and erusic acid (0.33%) were obtained in Jerome variety (*Table 5*). However, the erusic acid, as a negative factor in fatty acid composition in the Dalgan variety, was lower than other varieties (0.29%). There are no significant differences between Jacomo and Jerome varieties in seed yield, seed oil yield, palmitic, linolenic, linoleic and erusic acids. However between Hyola-401 and Dalgan there are no significant differences in palmitic and linoleic acids.

The results showed that the Dalgan variety had the highest oil yield in 40 plants per m^2 density treatment (2134.83 $kg.ha^{-1}$), while Jerome variety had the lowest oil yield at the same density (1686.75 $kg.ha^{-1}$) (*Fig. 2*). However, in 80 plants per square density treatment the Sarigol variety had the lowest seed oil content (628.08 $kg.ha^{-1}$). Based on the results in all varieties, oil yield decreased significantly by the increase in plant density.

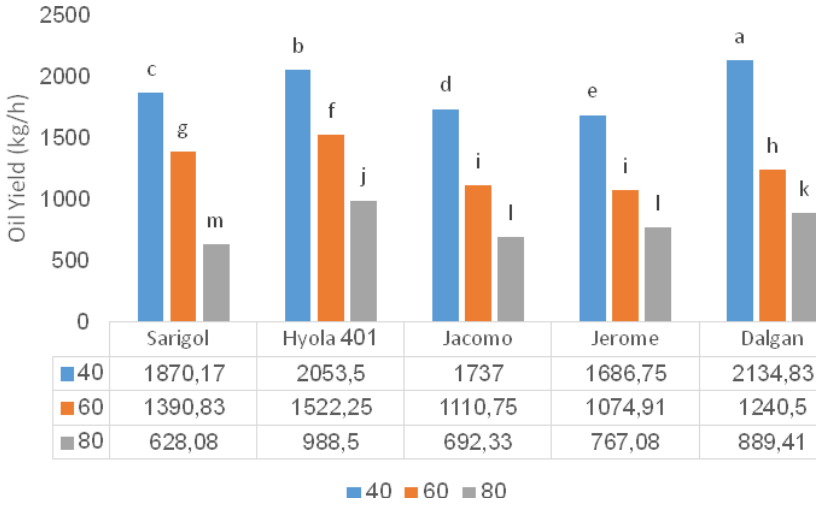

Figure 2. *The interaction effect of different densities on oil yield of canola varieties. (Columns by uncommon letters had significant differences)*

The 40 plants per square treatment had the highest fatty acid composition. The highest palmitic and linolenic acids was observed in Dalgam cultivar at 40 plants per square density treatment with amounts of 6.08 and 66.06, respectively. In addition, the lowest amount of erusic acid (0.18) was obtained in this cultivar with the same density conditions (*Table 6*). The oleic, linolenic and linoleic as three unsaturated fatty acids that oleic and erusic acids significantly decreased with increasing plants density (*Tables 3* and *6*), reaching a a maximum reduction in 80 plant per square density treatment compared with the 60 plant per square treatment. Interaction effect of plant density*variety shows that the highest palmitic acid (6.08%) and oleic acid (66.06%) were obtained in Dalgan variety in 60 plant per square density treatment (*Table 6*). The decrease of these fatty acid compounds result to oil quality reduction. The 40 plants per square density treatment had the lowest erusic acid and in this plant density treatment erusic acids percent in Dalgan, Hyola-401, Sarigol, Jacomo and Jerome varieties were 18, 19, 23, 24 and 25%, respectively (*Table 6*)

The palmitic acid content in 2016 was higher than 2015 due to the lower temperature at the grain filling period. In both years, the palmitic acid as a saturated fatty acid decreased linearly with increasing of plant density. The results also showed that palmitic acid decreased significantly by the increase of plant density in both years (*Fig. 3*).

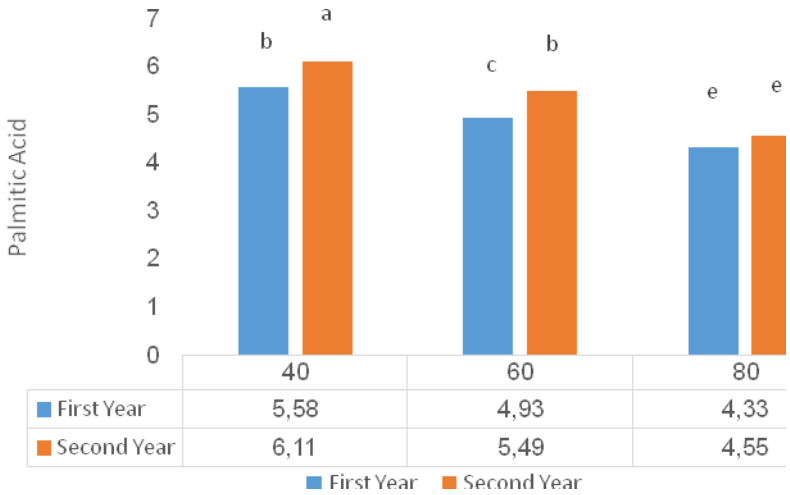

Figure 3. *The effect of different plants density on palmitic acid in canola varieties during 2015-2016. (Columns by uncommon letters had significant differences)*

Discussion

In the present study there are significant differences between varieties in the seed yield. Rezadoost and Rashidi (2003) reported that cultivar had a significant effect on the seed yield ($P \leq 0.01$). Increasing the plant density from 40 to 80 plants per square decreases the seed yield of canola genotypes from 6337 kg.ha^{-1} to 2741 kg.ha^{-1} (Nasiri et al., 2017). Looking at the yield components, including the number of pods per plant, number of seeds per pod and 1000-seed weight, it is seen that all of these traits are affected by factors such as the optimal use of light, nutrients, appropriate density, efficient photosynthesis and the adequate uptake of assimilate materials by plant, which all of them are effective in increasing the seed yield (Wales, 1991). Onofri et al. (1996) found that seed yield per hectare increased with increasing plant density, but an extreme

DOI: http://dx.doi.org/10.15666/aeer/1605_69036916
© 2018, ALÖKI Kft., Budapest, Hungary

increase in the plant density reduced seed yield. The seed yield was reduced in this study as density was increased from 40 to 80 plants per square meter that is in line with findings of Chavan et al. (1989); Patel et al. (1980) and Tanveer et al. (1998) in canola. Increasing the plant population per square in high density plants result in increasing of the inter-plant competition for water and nutrients, and the reduced grain number and weight per plants that laid to the grain yield reduction. Vega et al. (2000) concluded that plant density forced a strong competition for water and nutrient absorption during the grain filling period. This means that the process distributed lower nutrient between grains, therefore allocating less dry matter to physiological sinks at grain filling period. The Jerome variety had the lowest seed yield in 40 and 60 plant per m^2 density. Similarly, Naseri et al. (2012) reported that the thicker density plans (80 plants per m^2) reduced canopy sunlight absorption, assimilation, and transformed them to reproductive sinks that laid to the increasing of competition among plants and seed yield reduction. Chavan et al. (1989) reviled that higher plant densities resulted in seed yield reduction due to the increase of plant elongation and competition. However, in an appropriate density, environmental factors were optimum for higher assimilation then achieving higher seed yield.

Different results have been observed on the effect of plant density on the changes in oil content of oil-seed plants. Danesh-Shahraki et al. (2008) held that the plant density had a significant effect on oil content of canola. The seed oil content was reduced associated with increasing of plant density in canola (Onofri et al., 1996), sunflower (Vega, 2000) and soybean (Wells, 1991). It seems that the low and uniform distribution of plants in a lower plant density reduces the plant competition and better photosynthetic system performance that results in increasing of the seed oil content (Wells, 1991). Onofri et al. (1996) attributed the increasing of oil percent in lower plant density per unit area to the increasing number of pods per plant and the relative grain size reduction.

With regards to this fact that the application of selenium increased grain yield, some researchers founded that the application of selenium increases yield in rapeseed (Zahedi et al., 2009), potato (Turakainen et al., 2004; Germ et al., 2007), lettuce (Ramos et al., 2010) and buckwheat (Ozbolt et al., 2008). Kopsell et al. (2000) founded that foliar application of selenium increases chlorophyll content of *Brassicaoleracea* due to positive effects of leaves' Mg content that led to the increase of the photosynthesis and yield. Selenium delayed leaf senescence (Hawrylak-Nowak et al., 2009), increased plant growth and yield due to the increase of starch storage in chloroplasts (Xue et al., 2001). They also told that the selenium had a protective role for cell water status and adjusted it in a water deficit condition. Germ et al. (2003) holds that the selenium consumption by plants compensate the water deficit that results to increasing of grain yield. Even though selenium is not an essential element for plant growth (Djanaguiraman et al., 2005), the present study indicates that the foliar application of selenium increased the grain yield of canola at 30 $g.l^{-1}.ha^{-1}$. Zahedi et al. (2010) argued that the increase of rapeseed grain yield by foliar application of selenium is due to the increase of number of pods per plant and the number of grain per pods, which are in line with these findings. The application of selenium reduced the water deficit stress damages in potato (Germ et al., 2007) and rapeseed (Valadabadi et al., 2010) and that laid to the increase of biological yield.

The seed oil yield and fatty acid composition increased with the application of selenium. Other researchers such as Davoodi et al. (2016) founded that fatty acid

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

composition such as palmitic acid oleic acid, were increased by the foliar application of selenium in canola. Since Linoleic acid is an essential fatty acid for photosynthetic activity (Hugly et al., 1989) and canola pollen development (Mc-Conn and Browse., 1996), selenium application seems to increase the linoleic acid synthesis and the improvement of photosynthetic conditions, which lead to the increase of plant grain yield. However, the increase of seed oil yield might be the result of supply assimiliation at grain filling period which linked with the increase of silique photosynthesis (Shahbaz et al., 2018). They also find that canola oil quality is depended on quantity of oleic, linoleic, and linolenic acids as fatty acid composition. The composition of canola fatty acid has 60–65% oleic acid, 18–20% linoleic acid, 10–10.5% linolenic acid, and less than 3% erusic acid (Rathke et al., 2006). However, it should be noted that the erusic acid is an important indicator for rapeseed oil quality and its edible consumption (Gesgel et al., 2007), and in this study, foliar application of selenium increases erusic acid content.

The Hyola-401 variety had the highest seed oil yield. Naseri et al. (2012) founded the Hyola-401 hybrid had the highest seed yield than Hyola 308, Zarfam and Sarigol cultivars. They argued that the seed yield difference may be due to their genetic properties. Pasbaneslam (2015) evaluated 23 spring and autumn genotypes of canola in terms of seed yield, oil, and seed oil percentage, and he reported a significant difference among the cultivars. They found that there are significant differences between the different genotypes in this state. However differences between varieties in seed yield can be found because of genetic differentiation. The variation of seed yield among the rapeseed varieties may be attributed to their genetic potential (Sana et al., 2003). There are significant differences for seed yield between 29 genotypes of *Brassicanapus* L. (Khehra and Singh, 1988). It seems that the Dalgan variety may be tolerant to environmental factors while others may be susceptible. The amount of seed yield, seed oil content, palmitic acid, linolenic acid, linoleic acid anderusic acid in Jerome variety are equal to Jacomo, and their differences were not significant (*Table 5*). Some researchers such as Das (1998), Baranyk and Zukalova (2000) and Gentent et al. (1996) reported the differences in oil yield and oil content of *brassica* species. The variation in genetic variety make up and genetic background of each variety is the main reason for different amount of seed oil content (Sana et al., 2003). Adaptation characteristics of different varieties to environmental condition are another reason for this phenomenon.

The Dalgan variety was better than other varieties in oil yield at 40 plants per m^2 density. The Sarigol variety had the lowest seed oil content compared to other varieties. The seed oil yield had a negative correlation with seed size (Onofri et al., 1996). High oil yield in 40 plants per square density treatments could be due to the high seed yield (Nasiri et al., 2017). It was reported that the thin density leads to the increase in pod per plant and the reduction of seed size and the increase of seed oil content in thin density (Onofri et al., 1996). Two main factors that affected the canola oil content are genetic and environmental factors (Ozoni and Davaji, 2007). However the higher seed oil yield in Dalgan variety is due to the smaller seed size and the higher number of seed per plant compare to other varieties. In the present study, the seed oil yield reduced at high plant population treatments was due to the reduction of seed yield. The changes of seed yield result correlate to the same direct change of oil yield (Ali and Zhou, 2018). Ozer (2003) reviled that the lower seed size is associated with higher seed oil yield that is in line with these findings. Based on the results, the increase in plant density results in the increase of plant vegetative growth of seedlings, which reduced photo assimilation of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

translocation to reproductive grain sinks then seed oil percentage. Also, increasing of vegetative growth coincide the grain filling period to high temperatures of July and August, which negatively affects the plant metabolism and oil synthesis.

The palmitic and linolenic acids in Dalgam variety were higher than others mainly in 40 plants per square density. The oleic, linolenic and linoleic as well decreased in higher plant densities. The decrease of these fatty acid compounds is the result of oil quality reduction. Nasiri et al. (2017) holds that the highest erusic acid was founded in 80 plants per square that was in line with present findings. Also Fathy et al. (2009) founded that highest palmitic acid and linoleic acid increased by plant density increase, which was in line with present results too. Shahbaz et al. (2018) holds that the content of rapeseed erusic acid was significantly reduced at high plant density compared with to the low plant density. Our study in 2015-2016 indicated that Palmitic acid influenced by plant density and year treatments. The palmitic acid decreased in higher plant density compared to lower densities. However, seed filling period is a crucial stage in oilseed growth, and during grain filling period plant density effects on oil quality, stability, and content. Decreasing the oil content and oil yield in the higher plant density is the main reason for reduction of fatty acid compounds, such as the saturated and unsaturated fatty acids. The higher plant densities result in increasing of vegetative growth and late pod formation in the field condition. The pod shattering due to the nonuniformed pods maturity at higher plant densities leads to seed damage, resulting in low oil quality. Shahabaz et al. (2018) concludes that changes in conversion of carbohydrates into lipids as photosynthetic function negatively affect biosynthesis and accumulation of fatty acids that is founded in higher canola plant density. The unsaturated fatty acids, oleic acid for example, were strongly influenced by environmental changes. The linoleic acid is an important and essential fatty acid for the photosynthetic activity of the plant (Hugly et al., 1989) and the development of canola pollen (Mc-Conn and Browse, 1996). However, because the synthesis of fatty acids is a light-dependent process (Suresha et al., 2013), the increase in plant density reduced their biosynthesis due to the increase of shading in the canopy. The canola grain filling period is one of the most sensitive stages that changes in temperature and sunlight in this period, and it directly affects the fatty acid composition, accumulation of assimilates, and their modification of the source-sink ratio (Gauthier, 2017). Based on Ruuska et al. (2004) seeds produced in shade conditions have a lower fatty acids compared to the seeds of plants fully exposed to the sunlight. Therefore, in this study, the increase of shading in higher plant density treatments led to a decrease in seed oil content and composition of saturated and unsaturated fatty acids in canola.

Conclusion

This study was laid out in order to study the effect of foliar application of selenium on seed yield, quality and quantity of seed oil of canola varieties in three 40, 60 and 80 plant/area treatments. Based on the results, plant density and foliar application of selenium was significant on seed yield, oil production, and fatty acid compositions of canola varieties. The maximum seed yield in canola was founded in foliar application of selenium and low plant density. The amount of two beneficial fatty acids in canola oil including linoleic acid (Omega 6) and oleic acid (Omega 9) was reduced by increasing of plant density treatments. In addition, the application of selenium element reduced harmful fatty acids, such as erusic acid, while it increased the beneficial fatty acids such

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

as oleic acid and linoleic acid. Our results showed that the Dalgan had a highest seed yield compared to other varieties. However, these findings suggest that, the Dalgan variety with 40 plant/area along with foliar application of selenium is better treatment to achieving the highest canola seed yield and oil quality in the Golestan province, Iran.

Abstract. SOM (soil organic matter) and N (nitrogen) are important ecological factors in coastal wetland ecosystems. A specific area in Yancheng coastal wetlands was chosen and monitored on the spot in April 2012, spatial distribution characteristics of SOM and N and the relationship between them were analysed. The results showed that the content of SOM and N differs significantly in various vegetation types, their content in *Spartina* marshes is the highest, followed by *Reed* marshes, *Suaeda* marshes and the mudflat. The average content of SOM and N in them were 1.138%, 1.103%, 0.851%, 0.399% and the average value of total nitrogen were 489.935 mg/kg, 369.811 mg/kg, 365.491 mg/kg, and 95.542 mg/kg respectively. Furthermore, SOM and TN (total nitrogen), TN and ammonia nitrogen (NH_3-N) in the coastal wetlands are closely related and fit perfectly for linear regression equation, however, the correlation coefficient for OM (organic matter) and NH_3-N is low and fits well for the cubic curve equation. The specific value of carbon and nitrogen are the highest in the mudflat, followed by *Reed* marshes, *Spartina* marshes and *Suaeda* marshes. The specific value of NH_3-N and TN are the highest in the mudflat and in S*partina* marshes, *Reed* marshes and *Suaeda* marshes are close to it. Vegetation coverage conditions and physiological characteristics of plants are important factors affecting spatial distribution of SOM/N in coastal wetlands.

Keywords: *soil ecological elements, spatial differences, relationship, coastal wetlands, Yancheng National Nature Reserve*

Introduction

Coastal wetlands, in the transition zone of the terrestrial ecosystem and marine ecosystem, is an ecologically sensitive area of fragility (Zhang et al., 2005). Nutrient elements such as OM and N, are not only important components of wetland soil, but also extremely important ecological factors in the wetland ecosystem (Mitsch and Gosselin, 1986). Soil is a space-time continuum with high variability and there are obvious variations in the soil properties at the same time in different space positions (Sun et al., 2010). SOM is an important component of the soil. On the one hand, it shows fertility status of the soil; on the other hand, it also reflects the improvement of soil conditions and climate changes (Li and Wang, 2000; Wang et al., 2002). N as an important indicator of wetland soil nutrient levels (Judith and Jeffery, 2001), can not only reflect nutrient supply situation of the wetland soil and, to some extent, its level of availability; but also strongly correlates with the growth of plants.

Yancheng coastal wetland is one of the few typical coastal wetlands in China and the world, but under the bidirectional action of nature and human, the structure and function

© 2018, ALÖKI Kft., Budapest, Hungary

of ecosystem changed greatly (Liu et al., 2003) and has raised wide attention of scholars. Real-time monitoring and diagnosis of ecosystem health are scientific preventive measures for maintaining the wealth of coastal wetland ecosystem (Zhu et al., 2010). The study of the biodiversity, accumulation and distribution of SOM, chemical processes of P (phosphorus) and N and soil water characteristics in the coastal wetlands had accumulated a series of achievements. (Gao et al., 2004, 2008; Liu et al., 2005; Shen et al., 2005; Mao et al., 2009; Ren et al., 2010). But study on the relationship between soil OM and N in coastal wetlands needs to deepen and expand. In this paper, one typical case area of Yancheng coastal wetlands is selected to reveal the spatial distribution characteristics of SOM and N in coastal wetlands and further elaborate the relationship of OM and N, NH_3-N and TN. It is of scientific and practical significance for deeply understanding the evolution law of the coastal wetland ecosystem, revealing the environmental change of coastal wetlands and promoting the natural exploitation and utilization of coastal wetlands.

Materials and methods

Study area

Yancheng Nature Reserve lies in the middle of Jiangsu coastal area. It is located between 32°20' and 34°37'N latitude and 119°29' and 121°15'E longitude and is bordered by the Yellow Sea to the east. It crosses 6 counties (cities, areas): Dongtai, Dafeng, Tinghu, Binhai, Sheyang and Xiangshui with a coastline of 582 km and a beach wetland area of 45.33 × 104 hm^2, which is the largest western Pacific coast muddy tidal flat wetland. With Xinyanggang River to the north, Doulonggang River to the south, seawall to the west, the core area of Yancheng national natural reserve is the typical long silted wet beach in Jiangsu province and its total land mass is 1.92 × 104 hm^2. The reserve is divided into northern and southern parts by Zhonglugang Road (*Fig. 1*). The northern part, with an area of about 0.52 × 104 hm^2, is a typical artificial management area and is planted a large area of r*eed* marshes. The southern part, with an area of about 1.10 × 104 hm^2, is a typical natural condition control area, whose landscape patterns and ecological processes are mainly affected by the climate, topography, hydrology, soil, vegetation and other natural factors, and it became the typical wetland areas under the control of natural conditions. This paper chose the coastal wetlands under southern natural conditions (Zhonglugang Road to the north, Doulonggang River to the south) as the research area, whose vegetation is from land to sea, in turn is *Reed*, *Suaeda*, *Spartinas* and mudflat.

Data sources and processing

This paper was based on analysis data of research in April 2012. On the south side of Zhonglugang Road in the study area, 17 sample plots are arranged along the direction of land-to-sea. From sea to land were numbered by S1-S17. S1 and S2 are mudflat. S3, S4, S5, S6, S7 are *Spartina* marshes. S8, S9, S10, S11, S12, S13 are *Suaeda* marshes. S14, S15, S16, S17 are *Reed* marshes. The sample is distributed zonally in *Figure 1*. The sample area covered all the vegetation types and the equidistant distribution was basically adopted in each vegetation zone. Each sample plot set three sample points and used the soil collector to collect soil samples of 0-20 cm depth. Each sample column was 10 cm in diameter and 20 cm in height, and three sample columns were taken for mixing. A total of 17 mixed samples were mixed. We brought the samples back for laboratory analysis and recorded the vegetation types of each sample at the same time. After being brought to the laboratory and drying for 7 days, the samples were put into the oven. Under the condition of 50℃ drying to constant weight, further grind the dried sample to make the particle size less than 0.149 mm. The experimental procedures were using the samples to measure the content of organic matter through hydrate thermo - accretion potassium oxidation - colorimetric method. The total content of nitrogen in soil was measured by using concentrated sulfuric acid-indophenol blue colorimetric method. And Ammonia nitrogen in the soil was measured by using indophenol blue colorimetric method. Analyze the field monitoring data with statistic package for social science (SPSS) 19.0 software and single factor variance analysis. Conduct the significant test of difference on the soil OM, TN and NH_3-N. Then, we studied the relationship between OM and TN, OM and NH_3-N, TN and NH_3-N by using the regression analysis method.

Results

The characteristics of SOM\N in the coastal wetland

In the study area, the vegetation zonation is obvious. *Reed* marshes are located above the high tide of spring tide with high vegetation and the average height is above 1.5 m and the coverage is above 90%. *Suaeda* marshes is located in the upper part of the intertidal zone. The plants between the high tide and the average high tide are short, with a height of 0.5-1.2 m and a coverage of about 50%. The *Spartina alterniflora* is located between the mean high tide and the neap tide, with dense vegetation and average height of 2 m, covering degree of 100%. The mudflat is located between the high tide and low tide of the neap tide, almost no vegetation nearly.

The value of the soil OM, TN, NH_3-N is tested by the normal distribution testing in the SPSS 19.0. The data show an approximately normal distribution and are statistically significant. It can be seen from *Table 1:* the content of SOM is between 0.365% and 1.547% and the average level is 0.942%. Its maximum value is in *Spartina* marshes and its minimum value is in the mudflat. There is a moderate degree of variation and the variation coefficient is 36.075%. The content of TN is between 92.316 mg/kg and 908.710 mg/kg, with a mean value of 371.350 mg/kg. Its maximum value is in *Spartina* marshes and its minimum value is in the mudflat. There is a moderate degree of variations and the variation coefficient is 56.314%. The content of NH_3-N is between 3.510 mg/kg and 22.136 mg/kg. Its maximum value is in *Spartina* marshes and its minimum value is in the mudflat as well. Its mean value is 9.101 mg/kg, with a moderate degree of variation and the variation coefficient is 45.872%.

Table 1. *Characteristics of SOM, TN, NH_3-N in coastal wetlands*

ITEM	MAX	MIN	AVG	SD	CoV
OM/%	1.547	0.365	0.942	0.340	36.075%
TN/mg/kg	908.710	92.316	371.350	209.123	45.872%
NH_3-N/mg/kg	22.136	3.510	9.101	4.175	56.314%

The distribution pattern of SOM\N in coastal wetlands

It can be concluded from the single factor variance analysis of SOM and N in different vegetation types that: the test results of the three indicators are all F > P (alpha = 0.05), which shows that the content of SOM and N differs greatly between different vegetation. It can be seen from *Figure 2* that the content of coastal wetland SOM and TN is characterized by s-type fluctuation from land to sea. That is to say, it shows the characteristic of "high - low - high – low" from *Reed* marshes, *Suaeda* marshes, *Spartina* marshes to the mudflat. The average content of OM is 1.103%, 0.851%, 1.138% and 0.399% respectively and that of TN is 369.811 mg/kg, 365.491 mg/kg, 489.935 mg/kg and 95.542 mg/kg respectively. In addition, the soil NH_3-N turns out to be of the same characteristic of OM and TN in space after being analyzed and the mean values from *Reed* marshes, *Suaeda* marshes to mudflat is 8.731 mg/kg, 7.635 mg/kg, 12.419 mg/kg, 5.943 mg/kg respectively. Overall, differences in SOM and N in vegetation are reflected: *Spartina* marshes>*Reed* marshes> *Suaeda* marshes > the mudflat.

The content of SOM and N is closely related to vegetation types in coastal wetlands. SOM in coastal wetlands is closely related to the sources of SOM like plankton, benthos and plants. Variations in the content of nutrients like soil nitrogen, in a large degree, is mainly related to the factors such as climate, the soil parent material, etc. While in a small degree, it is mainly affected by the differences of vegetation and terrain without taking the differences of climate and soil plant material into consideration. SOM of the mudflat mainly comes from plankton and humus produced by benthos for lack of vegetation growth and the accumulation of nutrients is inferior to the vegetated areas. Not only *Spartina* marshes are affected by the sea, but also *Spartina* plants are tall in height and rich in density and have developed root system, which makes both the ground and underground biomass larger and the OM and N contribution rate high. In non-growing seasons, a lot of litter accumulates on the surface before large amounts of OM and N return into soil for decomposition. What is more, the good expansion ability of *Spartinas* contributes to the obvious increase in the sedimentary rate on the beach surface, the continuous acceleration of the beach face and accumulation of OM and N. On the other hand, the accumulation of SOM in *Spartina* marshes is affected by sea plankton and benthos. Therefore its capacity of enriching OM is much higher than *Reed*, *Suaeda* and the mudflat. While *Suaeda* marshes have lower content of the OM and N because the alkaline lotus have short plants, small and thin roots with low biomass on both the ground and underground and relatively weak accumulation for the OM and N. *Reed* marshes are less affected by seawater and SOM mainly comes from the metabolism and the litter form of humus of reed roots. Compared to *Spartina* marshes, the biomass and expansion ability of reeds is weaker. Furthermore, *Reed* marshes are located in top area of the coastal wetlands, which results in that their underground water level is lower than that of *Spartina* marshes and *Suaeda* marshes and weak soil peat

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_69176925
© 2018, ALÖKI Kft., Budapest, Hungary

accumulation ability. So the OM and N content in general is lower than that of *Spartina* marshes.

On the other hand, studies show that the soil particle size is closely related to the content of OM and N. Because *Spartina* marshes and *Suaeda* marshes have smaller particle size, they have greater chance of hummifications product and root secretions and higher content of OM and N. While where is smaller particle size, there is worse ventilation and water permeability, which affect soil respiration and soil in anaerobic condition for a long time and go against the decomposition of OM andNH_3-N. And that does be good to the fixation of C and N. Meanwhile, the particle size of mudflat and *Suaeda* is large, so the content of SOM and NH_3-N is less (Wang et al., 2013; Hou et al., 2011; Oades, 1998).

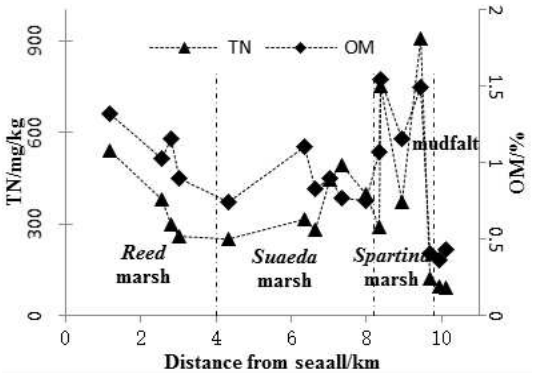

Figure 2. *The OM and TN content of soil in different vegetation*

The relationship between SOM and N in coastal wetlands

By using the SPSS correlation analysis, the conclusion can be drawn that: under the significance level of 0.01, OM and TN, TN and NH_3-N are very close, whose correlation coefficient is 0.825 and 0.858. By using linear regression to analyze the relationship between them, it shows good fitting effect as is shown in *Equations 1* and *2,* while the correlation of SOM and NH_3-N is poorer and its coefficient is 0.688 (the significance level of 0.01). It changes for the reason that NH_3-N in the soil can be directly absorbed by plants in the use of N and easily affected by hydrothermal conditions and biological activities (Deng et al., 2015). So we can use the cubic curve simulation method to express the relationship between them rather than simply using linear regression analysis. The cubic curve simulation method also shows a better fitting effect (*Eq. 3*).

$$OM = 0.444 + 0.001TN \quad \text{(Eq.1)}$$

$$TN = -19.866 + 42.986(NH_3\text{-}N) \quad \text{(Eq.2)}$$

$$OM = 0.905 - 0.125(NH_3\text{-}N) + 0.019(NH_3\text{-}N)^2 - 0.01(NH_3\text{-}N)^3 \quad \text{(Eq.3)}$$

where OM = organic matter; TN = total nitrogen; NH3-N = ammonia nitrogen.

The accumulation and decomposition of SOM directly affect the storage and transformation of N in the soil and play a leading role in the nitrogen content (Xu et al.,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_69176925
© 2018, ALÖKI Kft., Budapest, Hungary

2015). The distribution characteristics of soil carbon (hereafter referred to as C) and N and SOM and N are entirely different in coastal wetland. As can be seen from the C/N value, The C/N value of the mudflat is the highest whose mean value is 24.326. And the C/ N value in *Spartina* marshes and *Suaeda* marshes are highly close and their averages are 15.986 and 14.350 respectively. The C/ N value in *Reed* marshes, whose average value is 18.115, is higher than that of *Spartina* marshes and lower than that of the mudflat. Studies have shown that (Ge et al., 2010), C and N can reveal the conversion relationship between soil C and N in the process of biological decomposition. If the soil C/ N value is higher than 25, it will indicate that the soil N content cannot meet the needs of the bacteria and bring the accumulation of N content. In addition, the rapid propagation of soil spoilage bacteria can accelerate the decomposition of SOM. The C/ N value of all samples of C and N in this study are less than 25 except one point 27.190 in the mudflat. As can be seen from the mean of different vegetation zone average, only the point 24.326 of mudflat is closest to 25. Therefore, the OM and N accumulation of the mudflat is the weakest. The average value of C/N of *Reed* marshes, *Suaeda* marshes and *Spartina* marshes is lower than 20. This indicates that the degree of humification of coastal wetland soil is the highest, which easily causes the decomposition of OM and the mineralization of organic nitrogenous and it leads to the reduction of C and N value.

NH_3-N is one of the main forms of soil inorganic nitrogen and effective N which can be absorbed directly by the plant. By analyzing the ratio of NH_3-N/TN, it can be concluded that the mudflat has the highest ratio and its average value is 6.141. Besides, the content of NH_3-N/TN in the soil of *Spartina* marshes, *Reed* marshes and *Suaeda* marshes are closer. Their average values are 3.052, 2.161 and 2.399 respectively and it has much to do with the absorption of plants. *Spartina* root system is well-developed and may reach several meters deep underground, so the surface of 0~20 cm soil absorb less HN3-N. Therefore, the NH_3-N/TN in *Spartina* marshes is highest; *Reed* marshes take the second place. The root system of *Suaeda* marshes is undeveloped and its roots are short and mainly concentrated in the 15 to 25 cm soil layer. However, it absorbs much more NH_3-N on a scale of 0-20 cm soil layer. So the value of NH_3-N/TN is the lowest. On the other hand, the vegetation coverage and biomass of *Suaeda* marshes are low, which results in more barren soil under the eluviations (*Fig. 3*).

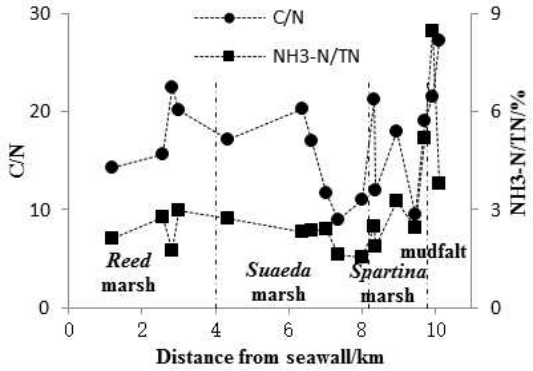

Figure 3. *The NH3-N and C/N of soil in different vegetation*

Discussion

The spatial differences and processes of the soil ecological elements is the basis of exploring the evolution mechanism of in the coastal wetlands. Many studies have

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_69176925
© 2018, ALÖKI Kft., Budapest, Hungary

revealed the response relationship between plant community and environmental factors at the scale of ecosystem (Cui and Yang, 2001; Mao et al., 2009; Yao et al., 2009), which showed that SOM and TN are the main factors that affect the spatial differences of the plant communities in wetlands (Zhang et al., 2009). The spatial differences of the soil ecological factors such as nitrogen, phosphorus, salinity and organic matter were the main content in Yancheng coastal wetlands. There were a series of common achievements, while some were still controversial aspects. Studies on SOM and N are not controversial, the lowest level was in the mudflat, but there were disagreements on whether the highest level was in *Reed* marshes or *Spartina* marshes (Shen et al., 2005; Yao et al., 2009; Zhong et al., 2010). Some studies had showed that the content of OM and N in the surface soil with vegetation distribution is higher than that in the mudflat and the highest value appears in *Spartina* marshes. In the vertical direction, the content decreases gradually from the table down (Mao et al., 2009; Ren et al., 2011). On this basis, the variation of SOM and N in the coastal wetland under natural conditions was further analyzed. The results confirmed that the highest content of the soil OM and N in *Spartina* marshes, and the areas covered by vegetation were higher than the mudflat. The positive correlation between the soil OM and TN was verified, the results showed there was obvious liner relation between them. On the other hand, it was found that the distribution characteristics of the specific value of soil carbon and nitrogen in the coastal wetlands were totally different from them of the soil OM and N. However, some studies showed that the highest C/N ratio appeared in the place where the growth time of *Spartina* was the longest, and the lowest value was the mudflat (Mao et al., 2009). In this paper, the ratio of the soil OM and N in the mudflat was the highest, followed by *Reed* marshes, *Spartina* marshes and *Suaeda* marshes. The ratio of NH_3-N and TN in the mudflat was the highest and the specific value in *Spartina* marshes, *Reed* marshes and *Suaeda* marshes were close. The results indicated that vegetation cover conditions and plant physiological characteristics may be the reasons for the differences of the soil C/N and NH_3-N/TN ratios in the coastal wetlands. However, how SOM, N and vegetation interact and how they are coupled remains to be further studied.

Conclusion

Based on analysis data of research in April 2012, this paper analyzed the spatial distribution features of soil organic matter and nitrogen in Yancheng coastal wetlands under the natural condition and the relationship between soil organic matter, total nitrogen and ammonia nitrogen. The results showed that there were significant differences among different vegetation types. It shows the tendency of decrease from *Spartina* marshes, *Reed* marshes, *Suaeda* marshes to the mudflat. The soil TN and NH_3-N, TN and OM in the coastal wetland were (significance level of 0.01) closely related, the correlation coefficient were 0.825 and 0.858 respectively. The soil OM and NH_3-N correlation was poor, but the fitting effect of the third-order curve equation was good, the curve equation of OM and NH_3-N was as *Equation 3*. The specific value of carbon and nitrogen in the mudflat was the highest and the average value was 24.326. The C/N value in *Spartina* marshes and the *Suaeda* marshes were very close, with the average of 15.986 and 14.350 respectively. The average C/N in *Reed* marshes was only 18.115. The specific value ratio of NH_3-N/TN was the highest in the mudflat, with an average value of 6.141, while the average value of the *Spartina* marshes, *Suaeda* marshes and *Reed* marshes was close, with the average value of 3.052, 2.161 and 2.399 respectively.

Abstract. Sesame is a source of excellent vegetable oil (35-63%). The present study aimed to evaluate the effect of phosphorus nano-chelate and chitosan application under end-season drought stress conditions based on split plot-factorial in three replications in the research field of Shahed University in Tehran, Iran during 2015-16 on the cultivation of sesame during summer. Main plots included drought stress in three levels including full irrigation as control (non-stress), irrigation cut-off at 50% seed ripening (75 BBCH), and 50% flowering (65 BBCH) as mild and severe stress levels, respectively. Subplots consisted of spraying treatments at four levels including non-spraying (control), phosphorus nano-chelate (2 ppt), chitosan (3 $g.L^{-1}$), and a combination of phosphorus nano-chelate + chitosan, as well as two cultivars such as sesame Oltan and Naz. Based on the results, the effects of drought stress, foliar application, and cultivar were significant on seed yield, oil and protein contents, peroxidase activity, and palmitic acid content. The highest seed yield was achieved by using phosphorus nano-chelate in Naz cultivar under full-irrigation condition (2114.7 $kg.ha^{-1}$). Severe drought stress caused a decrease in more than 60%, compared to the control treatment. Regarding foliar treatments, the highest percentage of oil was observed in using phosphorus nano-chelate, as well as the integrated use of phosphorus nano-chelate and chitosan, which increased by 12.39 and 14.97%, respectively, compared to the control treatment. Oil content in the seed of Naz cultivar was 7.22% higher than that of Oltan cultivar seed. In addition, the severe drought stress and Naz cultivar had the highest seed protein percentage (23.43 and 22.49%, respectively). The activities of catalase and superoxide dismutase antioxidant enzymes were directly related to an increasing drought stress. Further, Oltan cultivar had the highest activities of SOD and POX enzymes. The highest saturated fatty acids (palmitic and stearic) content were achieved in the non-foliar application (control treatment) in Oltan cultivar. Regarding the interaction effects of foliar treatment and cultivar, the lowest linoleic percentage was achieved in Oltan cultivar under non-foliar treatment and the highest percentage of the acid was observed in other treatments. In conclusion, the foliar application of phosphorus nano-chelate and chitosan improved the quantitative and qualitative yield of sesame and increased the growth and quality under drought stress condition.
Keywords: *enzyme activity, linoleic, oil, palmitic, protein, seed yield, nano fertilizer*

Introduction

Drought is a major environmental stress affecting plant morphology, physiology, and biochemistry (Shao et al., 2008). Plants can avoid the harmful effects of drought in several ways such as stomata closure, leaf rolling, osmotic adjustments, a reduction in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_69276944
© 2018, ALÖKI Kft., Budapest, Hungary

the cellular expansion, and alterations of various essential physiological and biochemical processes which can affect growth, productivity, and quality (Farouk and Amany, 2012). Traits are correlated with drought tolerance such as yield components and physiological traits, which are suitable indicators for selecting drought tolerant genotypes in breeding programs in order to reduce the impact of water deficit on crop yield (Almeida et al., 2008). Biochemically, water deficit was observed to stimulate the accumulation of the ROS (Dossa et al., 2017). In order to prevent or alleviate injuries from ROS, plants have evolved an antioxidant defense system including non-enzymatic compounds like ascorbate, glutathione, tocopherol, carotenoids, flavonoids, and enzymes such as SOD, CAT, POX, ascorbate peroxidase, glutathione reductase, and polyphenol oxidase (Agrwal and Pandey, 2004). Yousefzadeh Najafabadi and Ehsanzadeh (2017) reported that the drought stress in the sesame plant led to an increase in carotenoid concentration, CAT, SOD, and POX activities. A large number of studies have focused on the effects of drought stress on sesame yield, yield components, and oil content (Kadkhodaie et al., 2014). However, few studies emphasized the available information regarding the effects of drought stress on the fatty acid compositions of sesame genotypes. For example, Kim et al. (2006) planted 18 cultivars withholding irrigation for only 15 days at flowering and maturity stages and determined the seed oil yield and composition, compared with the well-watered plants as a control. Based on the results, the seed oil content was not significantly affected by drought stress while the oleic acid content increased. However, the linoleic acid content decreased under drought conditions. In another study, Abedi and Pakniyat (2010) reported that drought stress results in increased protein content, phosphorus content, CAT activity, and SOD activity. Jouyban and Moosavi (2012) concluded that an increase in the irrigation interval led to an increase in the protein content of sesame.

Chitosan, known as elicitors, is considered as a natural biopolymer modified from chitin, which is the main structural component of squid pens, cell walls of some fungi and crab shells. They were introduced as a material to improve grain yield under unfavorable conditions due to their bioactivities to plants such as inducing the plant resistance against a wide range of diseases through antifungal, antibacterial, antivirus activities (Wang et al., 2006), stimulating the growth of plants and seed germination (Chandrkrachang, 2002), improving soil fertility and enhancing the mineral nutrient uptake of plant (Dzung, 2007), increasing the content of chlorophylls, photosynthesis, and chloroplast enlargement (Limpanavech et al., 2008), escalating nitrogen fixing nodes related to the species of leguminous plants and reducing the effects of abiotic stress on plants (Dzung et al., 2011).

Nanotechnology provides new interdisciplinary venture into agriculture and food sciences by converging science and engineering. In addition, nanoparticles have potential applications in agriculture system, viz., the detection of pollutants, plant diseases, pests, and pathogens, controlled delivery of pesticide, fertilizers, nutrients, and genetic material, and can act as nano architects in forming and binding soil structure (Ghormade et al., 2011). The excess use of chemical fertilizers causes an irreparable damage to the soil structure, mineral cycles, soil microbial flora, plants, and even more on the food chains across ecosystems leading to heritable mutations in future generations of consumers. Considering the abovementioned issues, the use of nano-fertilizers in agriculture is considered as one of the solutions to the problems (Solanki et al., 2015). Jan et al. (2014) reported that the application of phosphorus plays a vital role

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_69276944
© 2018, ALÖKI Kft., Budapest, Hungary

in forming and translocating carbohydrates, root development, crop maturation, and resistance to disease pathogens.

Sesame (*Sesamum indicum* L.) is an ancient oilseed crop mainly grown in drought-prone environments, which is highly valued due to its high oil yield (~55%), as well as quality and stability (Pathak et al., 2014). Although sesame is considered as drought tolerant crop, the productivity is heavily affected by severe drought stress mainly when it occurs during anthesis (Dossa et al., 2017). Resistance to water stress in sesame is important in many countries with low rainfall (Golestani and Pakniyat, 2015). The fatty acid composition of sesame seed oil determines its commercial value, and drought stress and genotype may affect both the quality and quantity of oil which is extractable by sesame seed processors (Kadkhodaie et al., 2014).

Restricted water resources are considered as a limiting factor for irrigation applications around the world. Therefore, the present study aimed to evaluate the changes in the quality and biochemical traits of two sesame genotypes under drought stress and foliar application of chitosan and phosphorus nano-chelate in second cultivation.

Materials and methods

Plant material and growth conditions

The present study was conducted to investigate the changes in the quality and biochemical traits related to two sesame genotypes under drought stress and foliar application in chitosan and phosphorus nano-chelate in the second cultivation at research field of Shahed University in Tehran, Iran, during 2016. The experiment was conducted during a one-year factorial split plot experiment based on completely randomized block design with three replications. The research farm is located at geographical characteristics of latitude 31° and 36' and longitude 48° and 53' and the height of this area from sea level is equal to 1050 m. The place soil was tested and recognized as silty loam clay soil with pH about 8.10 (*Table 1*).

Table 1. *Some physical and chemical properties of soil in the experimental area (depth of 0-30 cm)*

	Texture	**pH**	**Electrical conductivity ($dS.m^{-1}$)**	**Organic matter (%)**	**Total nitrogen ($mg.kg^{-1}$)**	**Phosphorus ($mg.kg^{-1}$)**	**Potassium ($mg.kg^{-1}$)**	**Iron ($mg.kg^{-1}$)**
Experiment farm	Silty loam clay	8.10	2.00	1.11	1100	16.6	303.6	7.0
Optimum range	Loam and silty loam	6.5-7	1.51	2.00	2000	16.0	350.0	6.6

The experimental factors including drought stress at full irrigation as control (non-stress), mild stress (irrigation cut-off at 50% seed ripping equivalent 75 BBCH) and severe stress (irrigation cut-off at 50% flowering equivalent 65 BBCH) were in the main plots and spraying treatments including non-spraying (control), phosphorus nano-chelate (2 ppt), chitosan (3 $g.L^{-1}$), and the combination of phosphorus nano-chelate + chitosan and Oltan, and Naz single branch sesame cultivars were in the subplots. Based on the available documents, 75 BBCH is equivalent to seed about 50% of the final size

Regarding each experimental plot, six 3.5-m lines with 50 × 10 cm spacing, and main and subplots were 2 and 1 m, respectively. The seed was planted in late May after harvesting the wheat. Field preparation operations such as plowing, disc and the like were conducted before planting. Then, the first irrigation was given after sowing and the second was performed after 3 days. Accordingly, the irrigation time was determined by using Class A evaporation pan (in 70 mm evapotranspiration) (Shakeri et al., 2015). In the next procedure, irrigation treatments such as irrigation up to 50% flowering and seed ripening were performed after foliar use of nutrients. As for chitosan, chitosan-poly (D-glucosamine) prepared from SIGMA-ALDRICH was 3 $g.L^{-1}$, and a combination of the Khazra nano fertilizer (17% of phosphorus) was used at 2 ppt concentration for phosphorus nano-chelate. Then, spraying with these compounds was conducted at the beginning of flowering and seed ripping. In addition, drought stress treatments were conducted by irrigation at 65 BBCH (severe stress) or 75 BBCH (mild stress).

The extended Biologische Bundesantalt and Chemische (BBCH) scale and its associated decimal code were used to describe the different growth stages of *Sesamum indicum* L.

Seed yield

Seed harvest was done after physiological maturity, which occurred at the beginning of November by considering the browning about 75% of the capsules on the main stem in 50% of the plants. First, the grain yield was calculated based on the unit area and harvesting one square meter of each experimental plot and measuring grain weight (Mehrabi and Ehsanzadeh, 2011).

Seed oil and protein contents

Grain protein measurements were performed using the Bradford method (1976). In addition, the grain oil percentage was conducted by the method proposed by Leiboritz et al. (1987). Oil and protein percentages were multiplied in the seed yield in order to calculate the oil and protein yield.

Seed phosphorous contents

In order to measure the seed, phosphorus percentage was used based on the method proposed by Badigannavar et al. (2015). Finally, the obtained number was included in the standard equation and calculated as the concentration in the plant dry matter.

Protein and antioxidant enzyme assay

Before the leaves became yellowish, ten leaves of each plot were sampled for biochemical traits at the end of the seed ripping. In order to determine the total protein content and enzyme activity, 1 g of plant material was homogenized in 1 M Tris-HCl buffer (pH 6.8). The homogenate was centrifuged in a refrigerated centrifuge at 13000 g for 20 min (SIGMA 3-30K), and the obtained supernatant was used for determining protein assaying and enzyme. All the steps were conducted at 4 °C. Then, the protein content of the extracts was determined according to Bradford's (1976) method by using bovine serum albumin as the standard (Fazeli et al., 2007).

Catalase assay

The total CAT (EC 1.11.1.6) activity was measured according to the method proposed by Beers and Sizer (1952). The reaction solution consisted of 50 µL of the enzyme extract, 100 mM phosphate buffer (pH 7.0), 0.1 µ M EDTA, and 20 mM H_2O_2 in a total volume of 1.5 mL. Then, the enzyme activity was estimated by decreasing the absorbance of H_2O_2 at 240 nm due to H_2O_2 consumption. In addition, the decrease in H_2O_2 was monitored by reading the absorbance at the latter wavelength through using a UV-visible spectrophotometer (model Lambda 25, PerkinElmer, USA), and quantified by its molar extinction coefficient (36 mM^{-1} cm^{-1}). Finally, the enzyme activity was expressed as µmol H_2O_2 min^{-1} g^{-1} FW.

Peroxidase assay

Peroxidase (POX; EC 1.11.1.7) activity was assayed as described by Aghighi Shahverdi et al. (2018). The reaction mixture consisted of 4 cm3 of 0.2 M acetate buffer (pH 4.8), 0.4 cm^3 of H_2O_2 (3%), 0.2 cm^3 of 20 mM benzidine, and 0.05 cm^3 of enzyme extract. The rate of benzidine oxidation was measured at 530 nm.

Superoxide dismutase assay

The total SOD (EC 1.15.1.1) activity was determined by measuring the ability to inhibit the photochemical reduction of nitroblue tetrazolium (NBT) as described by Beauchamp and Fridovich (1971). The reaction mixture consisted of 0.1 cm^3 enzyme extract, 50 mM potassium phosphate buffer (pH 7.8), 13 mM methionine, 75 µM NBT, 0.1 mM EDTA, and 2 µM riboflavin. First, the test tubes were shaken and placed 30 cm from three 30 W fluorescent lamps. Then, the reduction in NBT was measured by reading absorbance at 560 nm. In the next procedure, blanks and controls were run similarly without any illumination and enzyme, respectively. One unit of SOD was defined as the amount of enzyme which produced a 50% inhibition of NBT reduction under the assay conditions (Fazeli et al., 2007).

Fatty acid compounds

In order to determine the amount of fatty acids, the oil should be extracted without high temperature in order to avoid possible changes in the fatty acid composition. Consequently, 50 g seed (after grinding) was mixed with hexane (1:4 ratio) and placed on a shaker (160 rpm) for 48 hours (Farhoosh et al., 2009). After separating the solvent, it was added to 7 mL methanol potassium 2 M. Then, each sample was injected into a gas chromatography (GC\MASS; Acme 6000, YOUNG LIN, Korea) with a 100 m-length column, an inner diameter of 0.25 mm, and 0.2 µm thickness. By comparing the peak of samples with standard peak and based on the RRT pick (relative retention time), the type of fatty acids was identified and its values were determined through calculating the surface area under the resulting peak curves.

Statistical analysis

ANOVA was used for analyzing the results of total traits by using the SAS 9.4 procedure PROC GLM. The mean comparison of data was done by Duncan's multiple range test at 5% probability level. Finally, correlation coefficients were calculated for each of the traits with the SAS 9.4.

Results

Seed yield

As shown in *Table 3*, the effect of drought, foliar application, cultivar, and interaction effect of drought × foliar application × cultivar on seed yield was significant. The highest seed yield was achieved by using phosphorus nano-chelate and control treatment in Naz cultivar and full irrigation condition (2114.7 and 2120.3 kg.ha^{-1}, respectively). According to the *Figure 2,* severe drought stress in Naz cultivar had the lowest seed yield (659.4 kg.ha^{-1}). Furthermore, an integrated application of phosphorus nano-chelate and chitosan under severe stress condition caused 4.76 and 10.85% increase in the seed yield of Oltan and Naz cultivars in compared to the mild stress, respectively.

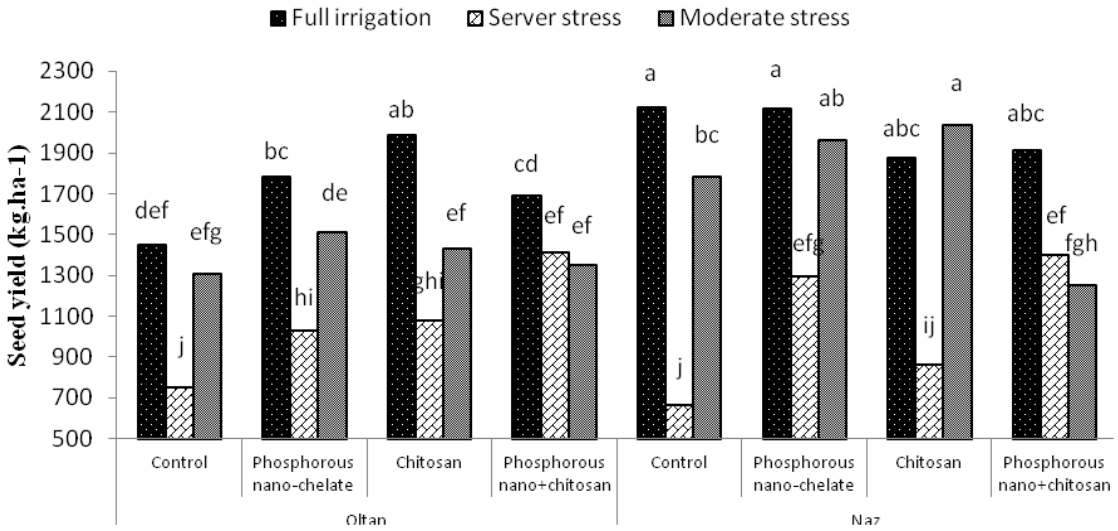

Figure 2. *Interaction effect of drought stress × foliar treatments on the seed yield of sesame. (Means in each column followed by at least one similar letter are not significantly different at 5% probability level by Duncan multiple test)*

Seed oil

The results of ANOVA indicated that the effect of drought stress, spraying and cultivar was significant on oil percentage and oil yield. In addition, the effect of drought × foliar application and drought × cultivar was significant on yielding seed oil (*Table 3*). As shown in *Table 4*, irrigation up to 50% flowering caused the least amount of seed oil. In foliar treatments, the highest oil percentage was observed in using phosphorus nano-chelate as well as the integrated application of phosphorus nano-chelate and chitosan, which increased 12.39 and 14.97%, respectively, compared to the control treatment (*Table 5*). Further, the oil content in the seed of Naz cultivar was 7.22% higher than that of Oltan cultivar seed (*Table 6*). Furthermore, as illustrated in *Figure 3,* based on the mean comparison of interaction effects of drought stress and foliar application, the highest seed oil yield was observed in full irrigation (control) with foliar application of phosphorus nano-chelate (922.3 kg.ha^{-1}) and the lowest mean was achieved in severe drought stress and none-sprayed treatment. Regarding the interaction effect of drought stress in cultivars, the highest oil yield was obtained in Naz cultivar

under full irrigation (924.03 kg.ha^{-1}). The results indicated that the severe drought stress could reduce oil yield by more than 50%, compared to the control treatment in both cultivars (*Fig. 3*).

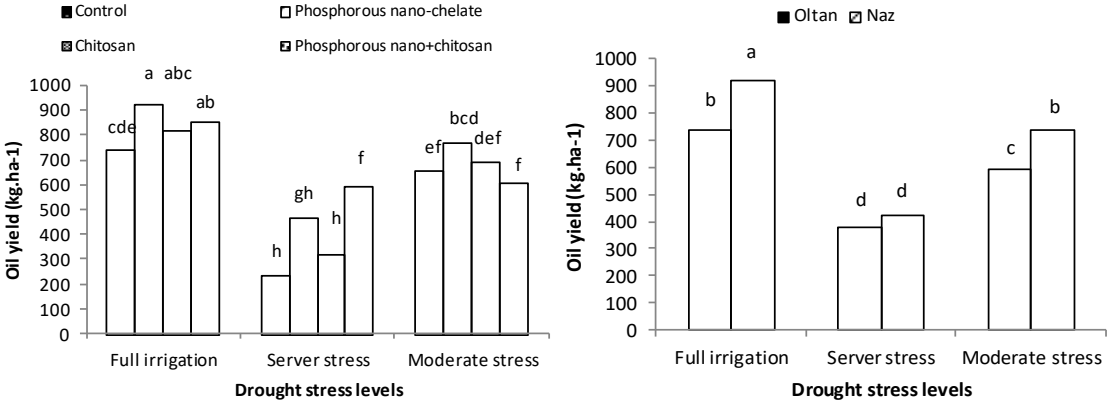

Figure 3. *Interaction effects of drought stress × foliar treatments and drought stress × cultivars on oil yield of sesame. (Means in each column followed by at least one similar letter are not significantly different at 5% probability level by using Duncan multiple test)*

Seed protein

As shown in *Table 3*, drought stress and cultivar could play a role in the percentage and yield of protein. In addition, foliar application, drought × foliar, drought × cultivar, and foliar × cultivar significantly affected protein yield. The severe drought stress level and Naz cultivar had the highest seed protein percentage (23.43 and 22.49%, respectively) (*Tables 4* and *6*). In addition, full irrigation treatment under the foliar application of phosphorus nano-chelate and chitosan (alone and integrated application) resulted in increasing seed protein yield. On the other hand, severe drought stress and non-sprayed treatment had the lowest seed protein yield, which decreased 57.21%, compared to the control treatment (*Fig. 4*). Further, based on the mean comparison interaction effect of drought stress in cultivar, the highest mean was observed in full irrigation in Naz cultivar (*Fig. 4*). The results showed that increasing the level of drought stress caused a significant decrease in seed protein yield.

Seed phosphorous

As indicated in *Table 3*, the results of ANOVA indicated that drought stress and foliar application could significantly influence on seed phosphorous content. In addition, drought stress caused a 7.14% decrease in seed phosphorous content, compared to the control treatment (*Table 4*). Further, the use of phosphorous nano-chelate had the highest seed phosphorous content (0.43%) while control treatment had the lowest mean in this regard (*Table 5*).

Antioxidants activity

Based on the results in *Table 3*, drought stress played a significant effect on CAT and SOD activities. The activities of these two antioxidant enzymes are consistent with an increase in drought stress. Thus, severe drought stress had the most activity. Regarding the comparison between the spraying treatments, the most catalase activity was related to chitosan application (*Table 5*). Furthermore, a significant difference was observed between cultivars in terms of POX and SOD activities. In addition, Oltan cultivar had the highest activities of SOD (0.79 U.mg protein.min^{-1}) and POX (0.64 U.mg protein.min^{-1}) enzymes (*Table 6*).

Fatty acid composition

Oleic, linoleic, palmitic, and stearic acids are the most important fatty acids measured in the experiment. The results indicated that the effects of cultivar, as well as the interaction of foliar application in cultivar, were significant on the contents of linoleic, palmitic, and stearic acids (*Table 3*). As illustrated in *Figure 5* and *6,* the highest content of saturated fatty acids (palmitic and stearic) was achieved in the non-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

foliar application (control treatment) in Oltan cultivar. In addition, the interaction effect of drought stress and the foliar application was significant on palmitic acid percent (*Table 3*). Further, as shown in *Figure 5,* the highest palmitic acid percent achieved full irrigation treatment under foliar application in chitosan and compound of phosphorous nano-chelate and chitosan. Regarding the interaction effects of foliar treatment and cultivar, the lowest linoleic percentage was achieved in Oltan cultivar under non-foliar treatment and the highest percentage of the acid was observed in other treatments (*Fig. 6*).

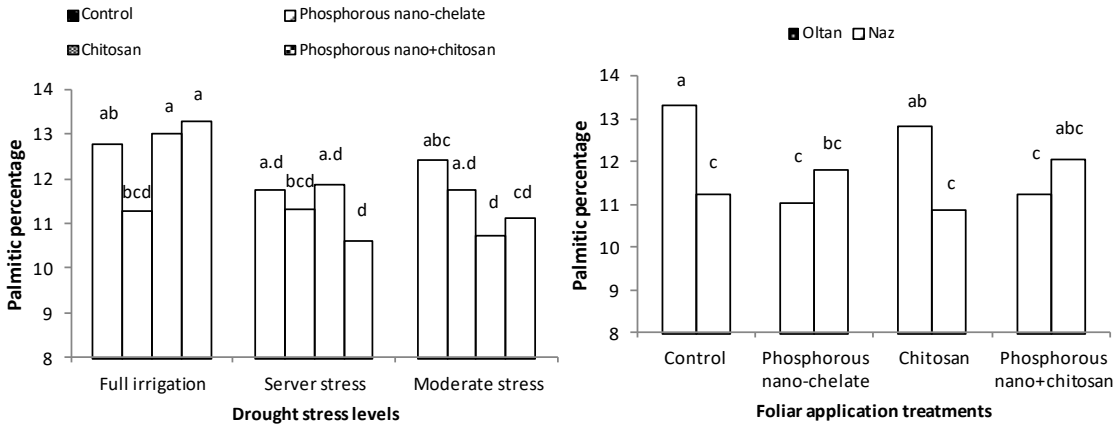

Figure 5. *Interaction effects of drought stress × foliar treatments and foliar treatments × cultivars on palmitic acid percentage. (Means in each column followed by at least one similar letter are not significantly different at 5% probability level, using Duncan multiple test)*

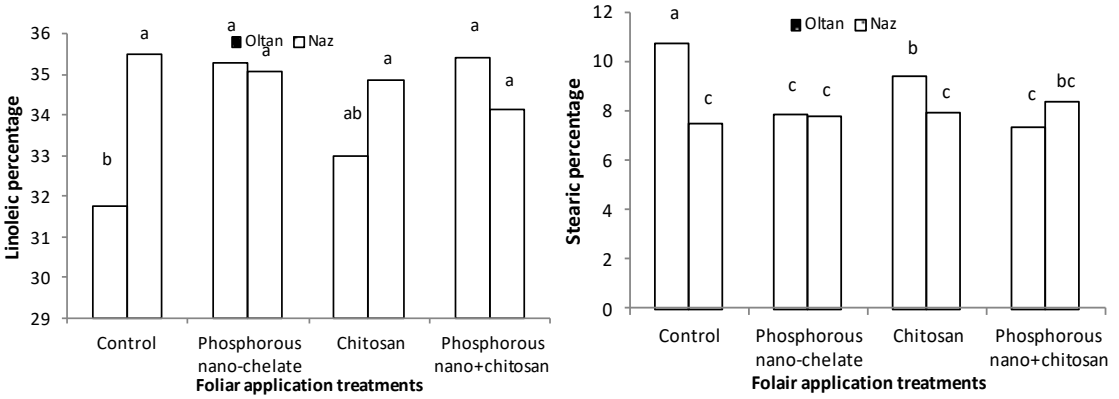

Figure 6. *Interaction effects of foliar treatments × cultivars on linoleic and stearic acids percentage. (Means in each column followed by at least one similar letter are not significantly different at 5% probability level, using Duncan multiple test)*

Correlations among traits

Tables 7 and *8* represent the results of simple correlation in non-drought stress (control) and drought stress conditions, respectively. As shown, qualitative traits such as seed yield, oil content, oil yield, protein content, protein yield, and phosphorous content were positively correlated in both conditions. However, a weak correlation was reported between oil content and protein content although the correlation among grain yield with

Discussion

Plants are exposed to environmental stresses during their growth. Drought stress is considered as one of the major abiotic stresses which causes a high reduction in plant growth and yield, which can affect the absorption and transfer of nutrients to the plant (Askari et al., 2018). Thus, the response of two sesame genotypes for lasting drought stress was emphasized in the present study. In addition, the originality of the present research resides in the fact that it is used as an integrated approach by combining agro-morphological, physiological, biochemical and seed quality traits to identify useful genotypes and interesting traits efficiently for planting in drought-prone environments in the south of Tehran, Iran. Based on the results, the severe drought stress led to a decrease in seed yield, oil percentage, oil yield, and plant phosphorus content. In line with the results of the present study, severe or prolonged drought plays a significant role in the productivity by affecting the number of capsules per plant, grain yield and oil yield and quality despite its relative tolerance to drought stress (Kadkhodaei et al., 2014; Dossa et al., 2017). Drought stress through chlorophyllase and peroxidase enzymes activities in plants resulted in reducing the content of chloroplast destruction and chlorophyll. In addition, these physiological changes lead to a reduction in plant growth and yield (Misra and Sricastatva, 2000; Askari et al., 2018).

Sesame seed quality (oil and protein contents) are adversely affected by environments severe drought (Menshah et al., 2006). The results of this study indicated that opposite responses to the changes in the oil content and protein content were found in response to drought stress as severe drought stress led to an increase in protein content and a decrease in the seed oil content (*Table 4*). According to Akinoso et al. (2006), the oil percentage varies with genetic and environmental influences.

The saturated fatty acid such as palmitic (C16:0) and stearic (C18:0) acids and unsaturated fatty acid such as linoleic acid (C18:2) were insignificantly influenced by cultivar and interaction effect of foliar application in cultivar while the effect of drought stress on fatty acids composition, except palmitic acid content, was insignificant (*Table 3*). As illustrated in *Figures 5* and *6,* non-application of nutrient treatment (control) in Oltan cultivar had the highest palmitic and stearic acid contents. In addition, drought stress resulted in decreasing the oil percentage, oleic acid and linoleic acid concentrations of the seeds and increasing the protein percentage, palmitic acid, and stearic acid in safflower seeds (Mohsennia and Jalilian, 2012). Further, genetic, climatic and agronomic factors indicated a significant effect on oil content and composition of sesame. However, oil content and composition are considerably different within different varieties (Yoshida et al., 2007). Fatty acid composition and oil content are exposed to variation by different physiological, ecological and cultural factors. The composition of sesame oil relies on the climatic conditions, soil type, as well as the maturity of plant and variety (El-Khier et al., 2008). Furthermore, the proximate analysis showed a significant variation among the different sesame genotypes which implies that genetic diversity is available among Nigerian sesame (Alege and Mustapha, 2013). Alege et al. (2011) studied three species of sesame from Nigeria by using morphological markers and reported a significant genetic diversity.

The mechanisms of absorption and transfer of nutrients in plants such as mass flow, emission or absorption, and transfer by osmotic phenomena are regarded as all functions of the moisture content of the soil and the expansion of the absorbing root. Regarding the reduced moisture or root expansion, intensity and amount of nutrient uptake undergo some changes (Taiz and Ezeiger, 1998). In the present study, the plant phosphorus

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_69276944
© 2018, ALÖKI Kft., Budapest, Hungary

content decreased by increasing drought stress (*Table 4*). Askari et al. (2018) reported that sever and mild drought stress can reduce phosphorus concentration to 15.96 and 6.96%, respectively, compared to optimal irrigation. The modulation of root development is considered as one of the drought stress effects. On the other hand, root growth is closely related to the absorption of phosphorus and nitrogen from the soil. In such a case, foliar application of phosphorus nano-chelate can compensate for the deficiency of this element and improve the growth, which was consistent with the results of the present study (Askari et al., 2018).

In addition, supplying the plant with its needed nutritional sources could increase its protein and oil percentage. Further, as shown in *Table 5*, practicing the phosphorus nano-chelate fertilizer increased the oil content in this experiment. Furthermore, phosphorus plays a role in increasing the formation of more capsules, and eventually, the formation of more seeds since it can enhance shooting and flowering (Safari Arabi et al., 2018). As a result, an increase in seeds leads to an increase in the oil content. In addition, it can affect the percentage and the yield of sesame oil since better nutrition leads to better photosynthesis during sesame growth and supplying the needed phosphorus fills the pod and seed.

The production of ROS appears to be involved in stress resistance induction (Gill and Tuteja, 2010; Pongprayoon et al., 2013). In order to prevent or alleviate injuries from ROS, plants have evolved an antioxidant defense system including non-enzymatic compounds like ascorbate, glutathione, tocopherol, carotenoids, flavonoids, and enzymes such as SOD, CAT, POX, ascorbate peroxidase, glutathione reductase, and polyphenol oxidase (Agarwal and Pandey, 2004). Based on the results of this study, the higher activity of SOD and CAT in the severe drought stress level indicated that they have a stronger ability to remove ROS (*Table 4*). Increased SOD, POX and CAT activities in response to water stress were reported in some studies (Kukreja et al., 2005). Further, Fazeli et al. (2007) and Kadkhodaie et al. (2014) concluded that more increase of antioxidant enzymes in leaves was related to drought resistance of some sesame genotypes. Furthermore, Cho et al. (2008) reported an improvement in the quality of sunflower by increasing the free radical scavenging activity. In general, the higher POX and SOD activities in Oltan leaves than may suggest the higher efficiency of Oltan under drought condition, compared to those of Naz.

Chitosan is a biopolymer with multiple agricultural applications, which has been shown to enhance plant growth and production yield in many species such as rice (*Oryza sativa* L.), pearl millet (*Pennisetum glaucum* L.), maize (*Zea mays* L.) and many orchid species (Pornpienpakde et al., 2010; Kananont et al., 2010). Furthermore, it was proposed as one potential chemical which can induce drought resistance via improving water use efficiency in the plant, as well as inducing drought resistance (Bittelli et al., 2001; Dzung et al., 2011). The same results were observed in the present experiment.

In addition, based on the results of the present experiment, the highest CAT activity was observed in the foliar application of chitosan which an increase of 33.33%, compared to the control treatment (*Table 5*). The chitosan response in plants is involved in inducing the reactive oxygen species (ROS) scavenging system. The enzyme activity and/or transcript levels of several antioxidant enzymes such as CAT, SOD, and POX were found to be induced by chitosan treatment (Yang et al., 2009; Povero et al., 2011). Further, the application of chitosan prior to drought stress can enhance the antioxidant activities of the SOD and CAT enzymes and decrease electrolyte leakage and production of malondialdehyde (Yang et al., 2009).

Regarding the results of correlation between traits, more negative correlation was observed between antioxidant enzyme activities (CAT and SOD) and qualitative traits (seed yield, seed oil and protein contents, and phosphorous content) in drought stress conditions, compared to non-drought stress conditions (*Tables 7* and *8*). Dossa et al. (2017) reported a high correlation within the different antioxidative enzyme activities and morphological traits of sesame which is in line with the results of the present study.

Conclusion

In conclusion, the exposure of sesame cultivars to drought resulted in decreasing seed yield, percentage and yield of seed oil, increasing seed protein percentage, CAT and SOD activities, and changing the fatty acids composition. In addition, foliar application of phosphorus nano-chelate and chitosan caused an increase in the seed yield, seed oil yield, and phosphorous content. Further, Naz cultivar was superior to most of the studied traits, compared to Oltan cultivar. Furthermore, the results indicated that sesame planting in warm and dry conditions could produce the appropriate grain yield and oil yield, due to the improvement of the physiological traits including the synthesis of oil and protein, the activity of antioxidant enzymes, and the like. Due to an increase in the content of phosphorus seeds and the improvement of oil and protein content of seeds, phosphorus nano fertilizer increased the quantitative and qualitative attributes of sesame. Finally, planting Naz cultivar under irrigation limited to the foliar application of phosphorus nano-chelate and chitosan is highly recommended to achieve higher performance in warm and dry climates. Study of changes in the quality of fatty acids and their relationship with physiological traits for future research is recommended.

(Received 27th Jun 2018; accepted 28th Sep 2018)

Abstract. The wastes of *Myoporum laetum* and *Livistona chinensis* leaves were utilized for removal of malachite green dye (MG) from solution. The highest removal for dye was observed with *M. laetum* biomass at pH: 6, temperature: 35 °C, biomass dose: 0.3 g L^{-1} and contact time: 120 min. The different concentrations of MG (5-35%) were highly removed by *M. laetum* (99.28% to 79.31%, respectively) as compared with *L. chinensis* (95.48-69.67%, respectively) at the optimum conditions. The sorption data were represented by Langmuir, Freundlich and Temkin isotherms. Adsorption was established well with isotherms of Langmuir and Freundlich. The study of thermodynamic suggested that the adsorption reaction was endothermic and the sorption of dye onto the biomass proceed in the forward direction and greatly promising process. The removal of dye was characterized by FT-IR analyses and the results confirmed that the groups responsible for the process of dye binding were hydroxyl or amino, and carboxylate or amide. The *M. laetum* cell wall showed a great porosity which permits the passage of dye molecules. The *M. laetum* biomass was more efficient than that of *L. chinensis.* The efficiency of the plant waste for a decolorizing solution containing dye, their abundance in nature and less processing requirements may lead to the emergence of low-cost adsorbents.
Keywords: *dye, plant leaves, equilibrium isotherm, thermodynamic, IR, SEM*

Introduction

Dyes are used in many industries and their extensive use causes pollution. Dyes are more difficult to degrade because they have a complex aromatic structure which makes them more stable (Seshadri et al., 1994). Dyes are toxic, mutagenic and difficult to be analyzed (Hammud, 2011). Thus, when the dye is discharged into waters it can affect the ecological system and human health. Dyes are dangerous to the aquatic living organisms (Vijayaraghavan and Yun, 2008). It causes problems to aquatic groups due to decreasing of light penetration and photosynthesis. The total amount of dyes generated in the world was found to be over 10,000 tons per year (Forgacs et al., 2004).

Malachite green is a dark green and belongs to triphenylmethane family. It is a water-soluble dye and can enter the cells due to their high lipid solubility (Albert, 1979). Malachite green dye is greatly used as a fungicide, bactericide, and antiprotozoal and for staining of cell and tissue samples (Hecht and Endemann, 1998). Malachite green play an important role as a food additive and in the process of paper coloring, silk, cotton, wool, leather, anthelmintic, and detergent (Srivastava et al., 2004). Its oral consumption is carcinogenic so that it is applied externally on ulcers

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_69456962
© 2018, ALÖKI Kft., Budapest, Hungary

and wounds (Clifton-Hadley and Alderman, 1987). Therefore, the presence of malachite green dye in animal milk, fishes, and other foodstuff is very dangerous to the human being (Srivastava et al., 1995). The products formed from degradation of malachite green are not safe and have a carcinogenic effect (Srivastava et al., 2004). Previous studies confirmed that malachite green induced hurts to bones, skin, eyes, liver, kidney, heart, and spleen in animals (Sundarrajan et al., 2000).

In many parts of the world, the dye is still being used. Accordingly, it is important to find methods to eliminate dye from ponds or wastewater. It is important to eliminate dye from the water before its discharging to stream by using an effective treatment technique. The industrial separation method used for the purification of wastewater is the adsorption technique. As compared with other methods, adsorption is the first in terms of cost, ease of design, flexibility, the simplicity of procedure and insensitivity to toxic pollutants (Laxmi and Ahmaruzzaman, 2010). Lately, the use of biomass for removal of dye has been seriously studied as another economical, and feasible technique. The biological treatment is a superior technique for the adsorption due to their ability to remove dyes in a highly concentrated form. Recently, attention has been concentrated on algae (Deokar and Sabale, 2014), bacteria, fungi (Gupta et al., 2015) and plants (Kadirvelu et al*.,* 2003). Adsorption of wastewater dyes by plant material or biomass is an eco-friendly and emerging process for removal of dyes in industrial effluents. The biomass is easy to be removed and can be stored for a long time without decomposition.

It is useful to understand and predict the mobility of toxic substances in the environment. Langmuir model is a common sorption isotherm and depends on reaction hypotheses (Langmuir, 1918). All the sites of adsorption are assumed to be identical, keep one molecule of the compound, energetically, and independent on the quantity of adsorbed. The model of Freundlich is empirical and based on the relation between the quantity of adsorbed and the concentration of remained solute (Freundlich, 1909).

The trees of *Myoporum laetum* and *Livistona chinensis* are found abundantly along streets of Jeddah city in Saudi Arabia. These trees are pruned annually making a huge accumulation and create great environmental problems. Therefore, economic utilization of these trees will be beneficial. The plant leaves can be dried and used as available biomaterials for the elimination of dye from solutions. The present study aimed to evaluate the efficiency of *Myoporum laetum* and *Livistona chinensis* leaves for removal of malachite green from solution. The effect of pH, contact time, dye concentrations, and temperature were determined to optimize the sorption conditions. The data of equilibrium biosorption was explained by Langmuir, Freundlich, and Temkin adsorption isotherm equations. The thermodynamic study, infrared spectroscopy, and scanning electron microscopy were investigated.

Materials and methods

Dye solution

Malachite green ($C_{52}H_{54}N_4O_{12}$) with a purity of 90% and molecular weight of 927.02 was attained from Merck, Germany. One gram of malachite green was dissolved in one liter of deionized water (1 g L^{-1}) to prepare the stock solution. Different concentrations (5, 10, 15, 20, 25, 30 and 35 mg L^{-1}) were prepared from the stock dye solution.

Preparation of biomass

The waste of *Myoporum laetum* and *Livistona chinensis* leaves were gathered from the streets of Jeddah, during the trimming season of trees in Saudi Arabia. The plant leaves were washed with water and then air dried at the Chemistry Lab., Faculty of Science, King Abdulaziz University. The dry constant was milled and sieved by using a standard sieve of 1.0 mm. The biomass was treated with 0.2% $CaCl_2$, dried at 45 C and then kept until use.

Removal of dye

The bioremoval study was performed for 5 mg L^{-1} dye solution using 0.5 g L^{-1} biomass of leaves in Erlenmeyer flasks. The dye solution and biomass were agitated at 150 rpm for 1 h to detect the optimum factors of temperature, pH, contact time, and weight of biomass for removal of dye. The absorbance of the removed dye was measured by UV-1800 spectrophotometer at 616 nm. The dye removal percentage was represented by *Equation 1*.

$$\text{Removal of dye } (\%) = \frac{Ci - Ce}{Ci} \times 100 \qquad \text{(Eq.1)}$$

where C_i represents the initial dye concentration and C_e is the concentration of dye at equilibrium.

Solution pH, temperature, and contact time

Dye solutions with different pH (2, 4, 6, 8, and 10), temperature (25, 35, 45 and 55 °C), and contact time (ranged from 0.0 to 180 min) were prepared. The optimum conditions of pH, temperature, and contact time for the uptake of dye were estimated by the dry biomass.

Weight of biomass

To obtain the ideal weight of biomass for removal of malachite green from solution, different weights of dry biomass (0.5, 1.0, 1.5, 2.0, 2.5 and 3.0 g L^{-1}) were prepared. At the optimal conditions of pH, temperature, and contact time, the removal of dye from solution was estimated.

Dye concentration

At the optimal condition of pH, temperature, contact time, and biomass, different concentrations of dye (5, 10, 15, 20, 25, 30, and 35 mg L^{-1}) were used to evaluate the efficiency of dry plant leaves for removal of dye from solution.

Adsorption isotherms

The different adsorption isotherms were evaluated at the optimal conditions of pH, temperature, contact time, biomass and dye concentration. The monolayer adsorption was represented by the model of Langmuir isotherm. The Langmuir model (Langmuir, 1918) was stated in *Equation 2*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_69456962
© 2018, ALÖKI Kft., Budapest, Hungary

$$\frac{1}{q_e} = \frac{1}{q_m} + \frac{1}{bq_m}\left(\frac{1}{C_e}\right) \quad \text{(Eq.2)}$$

where q_e is the amount dye absorbed onto the biomass (mg g^{-1}), q_m is the Langmuir constant that clarifies the highest capacity (mg g^{-1}), and b is the constant of Langmuir and represent the affinity of binding site (L mg^{-1}), C_e is the concentration of dye in the solution at equilibrium (mg L^{-1}), $1/bq_m$ is the intercept, and $1/q_m$ is the slope.

The affinity of biomass (adsorbent) to dye (adsorbate) was obtained from the factor of dimensionless separation (R_L). The R_L was discussed by Malik (2004) in *Equation 3*.

$$R_L = \frac{1}{1+bC_i} \quad \text{(Eq.3)}$$

The shape of isotherm was found to be favorable ($0 < R_L < 1$), linear ($R_L = 1$), irreversible ($R_L = 0$), or unfavorable ($R_L > 1$),

The unfavorable sorption on dissimilar surfaces and multilayer sorption was described in the Freundlich model (Freundlich, 1906). The Freundlich model was represented in *Equation 4*.

$$\ln q_e = \ln K_F + \frac{1}{n} \ln C_e \quad \text{(Eq.4)}$$

where q_e is the dye adsorbed onto the biomass (mg g^{-1}) at equilibrium, K_F Freundlich isotherm constant (mg g^{-1}), n is the sorption intensity constant, and C_e represents the concentration of dye at equilibrium (mg L^{-1}).

The interactions of indirect adsorbent-adsorbate and the behavior of the adsorption systems on the heterogeneous surfaces was represented by the model of Temkin isotherm (Temkin and Pyzhev, 1940). The model of Temkin was found in *Equation 5*.

$$q_e = \frac{R_T}{b_T} \ln A_T + \frac{R_T}{b_T} \ln C_e \quad \text{(Eq.5)}$$

where R is the gas constant, T is the absolute temperature, b_T is the Temkin isotherm constant (J mol^{-1}), A_T is the Temkin equilibrium constant (L g^{-1}), R_T/b_T is a constant related to the heat of adsorption (J mol^{-1}), and C_e is the concentration of dye (mg L^{-1}) at equilibrium. A_T and b_T were determined from the slope and intercept obtained by plotting q_e versus ln C_e.

Thermodynamic study

The values of thermodynamic were assessed by studying the temperature changes with an equilibrium constant. The following equation illustrates the free energy of the sorption reaction (*Eq. 6*):

$$\Delta G^\circ = -R_T \ln K_c \quad \text{(Eq.6)}$$

where ΔG° represents the variation in free energy (kJ mol^{-1}), R declares the gas constant (8.314 kJ mol^{-1}), T indicates the absolute temperature, and K_c is the equilibrium constant.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_69456962
© 2018, ALÖKI Kft., Budapest, Hungary

The thermodynamic values were estimated by the change of temperature with the equilibrium constant as found in *Equation 7*.

$$\ln K_c = -\frac{\Delta H^\circ}{R_T} + \frac{\Delta S^\circ}{R} \quad \text{(Eq.7)}$$

where ΔH° represents the enthalpy, and ΔS° is the entropy of the equilibrium process.

Infrared spectroscopy (IR)

The functional groups on the surface of the biomass were characterized by infrared spectrophotometer (Tensor 27, Netherlands).

Scanning electron microscopy (SEM)

Scanning electron microscopy (JEOL, JSM-5200 LV) was used to study the surface of the biomass before and after the treatment with dye.

Results

Influence of pH

As shown in *Figure 1,* the removal of malachite green (5 mg L^{-1}) onto 0.5 g L^{-1} biomass of *Myoporum laetum* and *Livistona chinensis* was increased with increasing the pH values. The removal of dye increased gradually from pH 2 (94.46%) up to pH 6 (99.01%) and then remained constant up to pH 10 by using the biomass of *M. laetum.* However, the removal of dye increased slowly at pH ranged from 4 to 8 (89.73% to 90.62%, respectively) and then highly increased at pH 10 (96.78%) by using *L. chinensis* biomass.

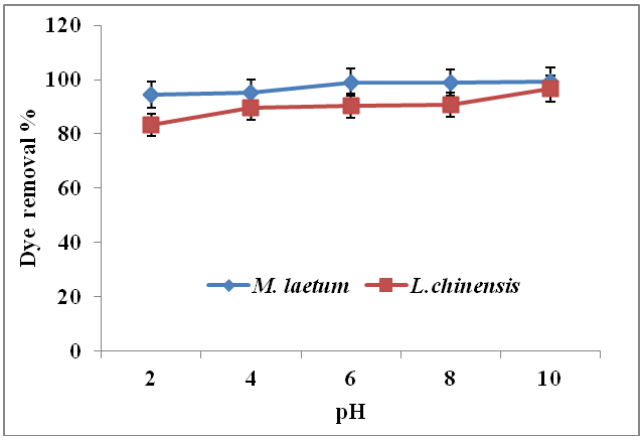

Figure 1. *The effect of different pH values on the removal of malachite green (5 mg L^{-1}) by using the biomass of M. laetum and L. chinensis leaves. The data are the mean of three values ± SD*

Influence of temperature

Figure 2 represents the removal percentage of MG onto the plant biomass (0.5 g L^{-1}) at different temperatures (25, 35, 45, and 55 °C) after 1 h. The results showed that the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_69456962
© 2018, ALÖKI Kft., Budapest, Hungary

removal of MG increased with increasing temperature up to 35 °C for both biomasses of *M. laetum* (97.67%) and *L. chinensis* (92.32%). With increasing the temperature up to 55 °C, the removal of dye still constant with the biomass of *M. laetum* (97.67%) and decreased with *L. chinensis* biomass (89.46%). It can be noticed that the removal efficiency of MG onto the biomass of *M. laetum* was higher than *M. laetum.* The temperature of 35 °C was chosen as the optimum temperature for the uptake of MG from solution.

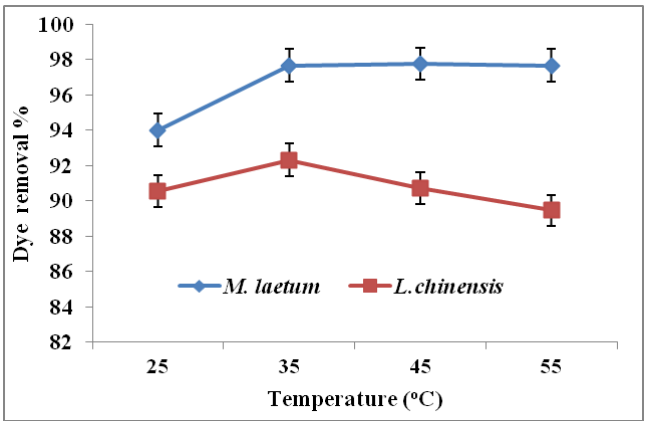

Figure 2. *The effect of different temperatures on the removal of malachite green (5 mg L^{-1}) by using the biomass of M. laetum and L. chinensis leaves. The data are the mean of three values ± SD*

Influence of contact time

The removal of dye (5 mg L^{-1}) at a different time (0.0-180 min) by tested biomass (0.5 g L^{-1}) was explained in *Figure 3*. As shown in the results, the uptake of dye increased with increasing the contact time up to a certain extent. After this point, the removal percentage of MG is not affected. The removal of dye quickly increased through the first 10 min (57%) and then slowly increased until equilibrium at 120 and 160 min for *M. laetum* and *L. chinensis,* respectively. The maximum removal percentages were 96% and 88% by *M. laetum* and *L. chinensis,* respectively.

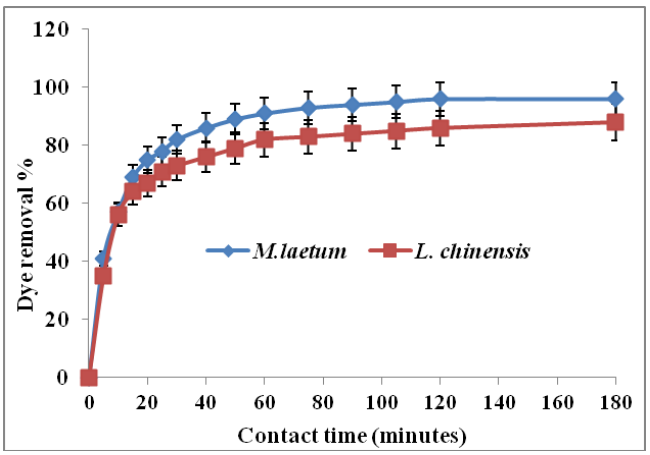

Figure 3. *The effect of contact time on the removal of malachite green (5 mg L^{-1}) by using the biomass of M. laetum and L. chinensis leaves. The data are the mean of three values ± SD*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_69456962
© 2018, ALÖKI Kft., Budapest, Hungary

Influence of weight of biomass

The removal of MG from solution by 0.1-0.7 g biomass was illustrated in *Figure 4*. The results revealed that the removal of dye was greatly increased with increasing dose of biomass up to 0.3 g of *M. laetum* (99.11%) and 0.4 g of *L. chinensis* (95.98%) and then remained constant. As clear from the results, the biomass of *M. laetum* was more efficient than *L. chinensis* for the uptake of MG.

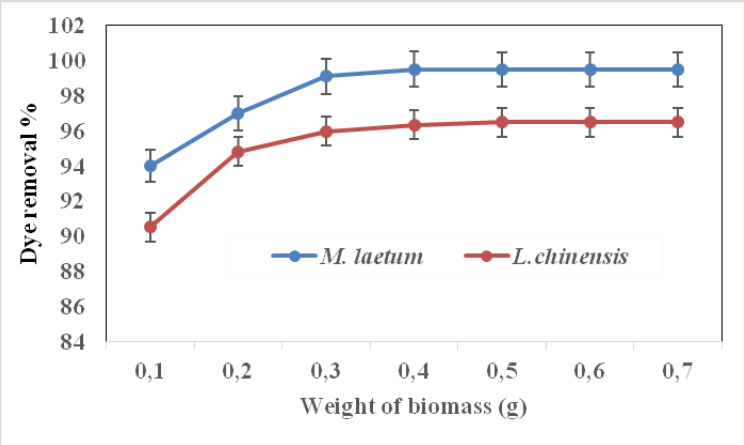

Figure 4. *The effect of different weights of M. laetum and L. chinensi biomasses on the removal of malachite green (5 mg L^{-1}). The data are the mean of three values ± SD*

Influence of dye concentration

The influence of 5-35 mg L^{-1} dye on the uptake of MG was investigated for both biomasses at the optimum conditions (*Fig. 5*). As shown from the above results the most favorable conditions for the removal of MG by using *M. laetum* were observed at pH: 6, temperature: 35 °C, 0.3 g L^{-1} biomass dose and 120 min contact time. However, pH: 10, temperature: 35 °C, 0.4 g L^{-1} biomass dose and 160 min contact time were the optimum condition for the removal of MG by using *L. chinensis*. The results presented that the percentage of MG uptake decreased with increasing the dye concentration from 5 to 35 mg L^{-1}. The maximum uptake of dye (99.28% and 95.48%) was attained at 5 mg L^{-1} by the biomass of *M. laetum* and *L. chinensis*, respectively. However, the biomass of *M. laetum* and *L. chinensis* showed the minimum removal percentage (79.31% and 69.67%, respectively) at 35 mg L^{-1} MG concentration.

Adsorption isotherms

It is important to design the most adsorption system for removal of MG dye. Thus, the equilibrium experimental data for adsorbed MG onto *M. laetum* and *L. chinensis* biomasses were studied using different isotherms of Langmuir and Freundlich and Temkin (*Table 1*). According to Langmuir isotherm, the values of intercept ($1/bq_m$) and slop ($1/q_m$) were attained from the plot of $1/q_e$ against $1/C_e$ for adsorption of MG onto the biomasses of *M. laetum* and *L. chinensis* (Fig. 6a, b). The results in *Table 1* revealed that the maximum capability (q_m) was found to be 50.065 and 42.212 mg g^{-1} for the biomass of *M. laetum* and *L. chinensis,* respectively. It can be noticed that the greatest capacity of adsorption of MG dye was recorded with *M. laetum.* Regarding to the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

results of Langmuir isotherm, the highest binding site affinity (*b*) for MG was observed with *M. laetum* biomass (0.242 L mg^{-1}). The R_L values for both *M. laetum* and *L. chinensis* were found to be 0.176 and 0.106, respectively suggesting that the process of dye sorption is favorable (*Table 1*).

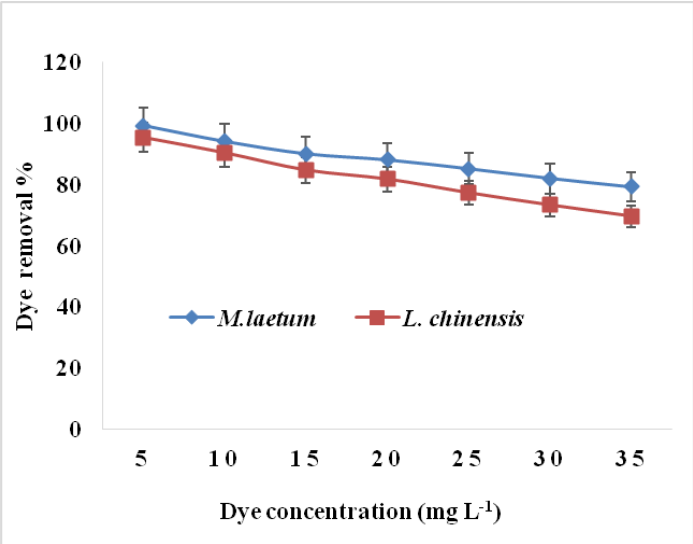

Figure 5. *Removal of different concentrations of malachite green by using the biomass of M. laetum and L. chinensis leaves under the optimal conditions. The data are the mean of three values ± SD*

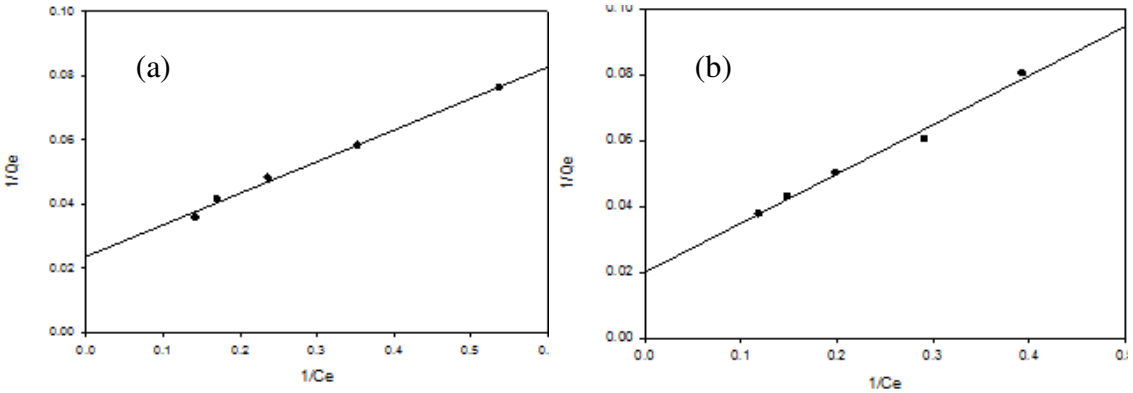

Figure 6. *The linear plots of Langmuir isotherm for adsorption of malachite green onto the biomass of M. laetum (a) and L. chinensis leaves (b)*

With regard to Freundlich isotherm, the results showed that the plotting of ln *qe* versus ln *Ce* give a straight line with a slope of 1/n and intercept of ln K_F for adsorption of MG onto the tested biomasses (*Fig. 7a, b*). The values of *n* were found to be 1.839 and 1.655 for *M. laetum* and *L. chinensis*, respectively (*Table 1*). As a general, MG is favorably adsorbed onto the tested biomass where $n > 1$. The adsorption capacity (K_F) for *M. laetum* (9.497 mg g^{-1}) was higher than that of *L. chinensis* (7.419 mg g^{-1}). Therefore, *M. laetum* biomass obtained the greatest binding affinity and adsorption capacity for MG as compared with the biomass of *L. chinensis*.

Table 1. *Parameters of Langmuir, Freundlich and Temkin isotherms for adsorption of malachite green onto the biomass of M. laetum and L. chinensis leaves*

Isotherm		*M. laetum*	*L. chinensis*
Langmuir	q_m (mg g^{-1})	50.065	42.212
	b (L mg^{-1})	0.242	0.134
	R_L	0.176	0.106
	R^2	0.97	0.97
Freundlich	K_F (mg g^{-1})	9.497	7.419
	n	1.839	1.655
	R^2	0.97	0.99
Temkin	A_T (L mg^{-1})	1.791	1.590
	b_T	233.34	246.33
	R^2	0.86	0.94

q_m: Langmuir constant, b: affinity of binding site, R_L: dimensionless separation factor, R^2: linear correlation coefficient, K_F: Freundlich isotherm constant, n: sorption intensity constant, A_T: Temkin isotherm equilibrium binding constant, b_T: Temkin isotherm constant

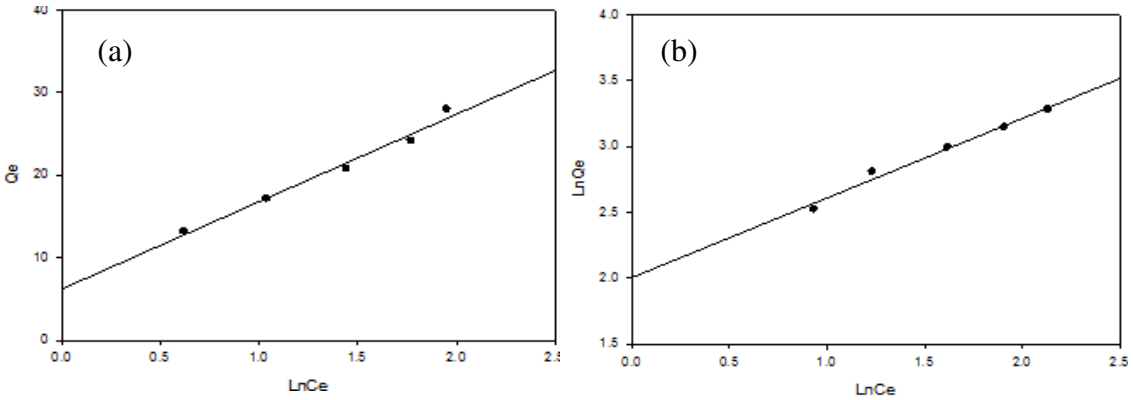

Figure 7. *The linear plots of Fruendlich isotherm for adsorption of malachite green onto the biomass of M. laetum (a) and L. chinensis leaves (b)*

According to the Temkin isotherm, the constant of A_T and b_T for sorption of MG by *M. laetum* and *L. chinensis* dry leaves were attained from the slop of q_e against ln C_e (*Fig. 8a, b*). The results demonstrated that A_T was 1.791 and 1.590 L mg^{-1} for *M. laetum* and *L. chinensis* biomass, respectively (*Table 1*). The b_T values were 233.34 and 246.33 for *M. laetum* and *L. chinensis* biomasses, respectively.

The results showed that the Langmuir isotherm for *M. laetum* biomass was linear within the entire studied concentration of dye with a linear correlation coefficient ($R^2 = 0.97$), suggesting that the data fit quite well with Langmuir model. The Langmuir isotherm confirms the monolayer sorption of MG by *M. laetum* biomass and heterogonous active sites distribution on the adsorbent. Depending on the great values of the correlation coefficient ($R^2 = 0.97$), the Freundlich model was also established to be a favorable model for explanation of the adsorption performance of MG by *M. laetum* biomass. Based on these results, it can be noticed that the adsorption of dye was well fitted by both Langmuir and Freundlich models for the biomass of *M. laetum.* It

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_69456962
© 2018, ALÖKI Kft., Budapest, Hungary

can be concluded that both homogenous and heterogonous adsorption takes place throughout the process.

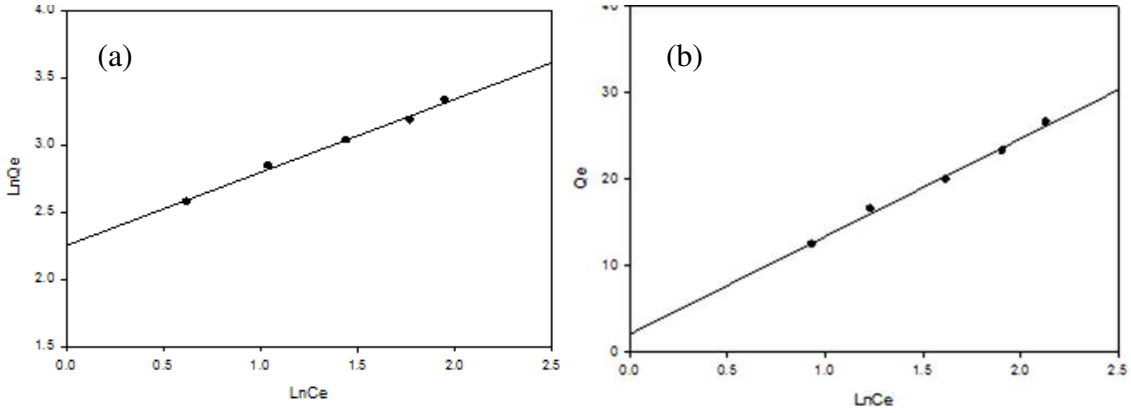

Figure 8. *The linear plots of Temkin isotherm for adsorption of malachite green onto the biomass of M. laetum (a) and L. chinensis leaves (b)*

As compared with other isotherms, the highest value of the correlation coefficient ($R^2 = 0.99$) was observed with the biomass of *L. chinensis*. This result clarified that the Freundlich model was the most favorable to describe the adsorption equation data for *L. chinensis* biomass.

According to Temkin isotherm, the correlation coefficients (R^2) of *M. laetum* and *L. chinensis* biomasses were ranged between 0.86 and 0.94, respectively (*Table 1*). This result elucidated that Temkin equation represents the poor fit as compared with the other isotherms for both biomasses.

Thermodynamic study

In the present study, the values of thermodynamic were given in *Table 2*. The ΔG° was determined as -6.3 kJ mol^{-1} and -4.8 kJ mol^{-1} for *M. laetum* and *L. chinensis*, respectively. The highest affinity for removal of MG by the biomass of *M. laetum* may be returned to the highest value of $-\Delta G^\circ$ as compared with *L. chinensis* biomass. The sorption process of MG by the tested biomass was spontaneous and highly favorable due to the negative values of ΔG°. The values of ΔH° and ΔS° were represented by 8.5 kJ mol^{-1} and 49 kJ mol^{-1}, respectively for *M. laetum* and 7.3 kJ mol^{-1} and 40 kJ mol^{-1}, respectively for *L. chinensis* (*Table 2*).

IR spectral analysis

The IR spectral analysis of raw biomass of *M. laetum* showed different functional groups at 3435 cm^{-1} due to –OH and –NH stretching, at 2923 cm^{-1} attributed to C-H stretching vibration, at 1627 cm^{-1} assigned to $–COO^-$ stretching or amide I and amide II and finally at 1035 cm^{-1} due to N-H bending vibration or C-OH stretching vibration of alcohol (*Fig. 9a*). However, the IR spectrum of *M. laetum* biomass after dye sorption (*Fig. 9b)* exhibited change in the position and intensity of adsorption bands at 3435, 1627 and 1037 cm^{-1} due to hydroxyl or amino groups, and carboxylate or amide groups. These results showed the contribution of these groups in the biosorption of MG dye by *M. laetum* biomass.

Table 2. *Parameters of thermodynamic and activation energy for adsorption of malachite green onto the biomass of M. laetum and L. chinensis leaves*

Plant	ΔG° (kJ mol^{-1})	ΔH° (kJ mol^{-1})	ΔS° (kJ mol^{-1})
M. laetum	-6.3	8.5	49
L. chinensis	-4.8	7.3	40

ΔG°: variation in free energy, ΔH°: enthalpy of equilibrium, ΔS°: entropy of equilibrium

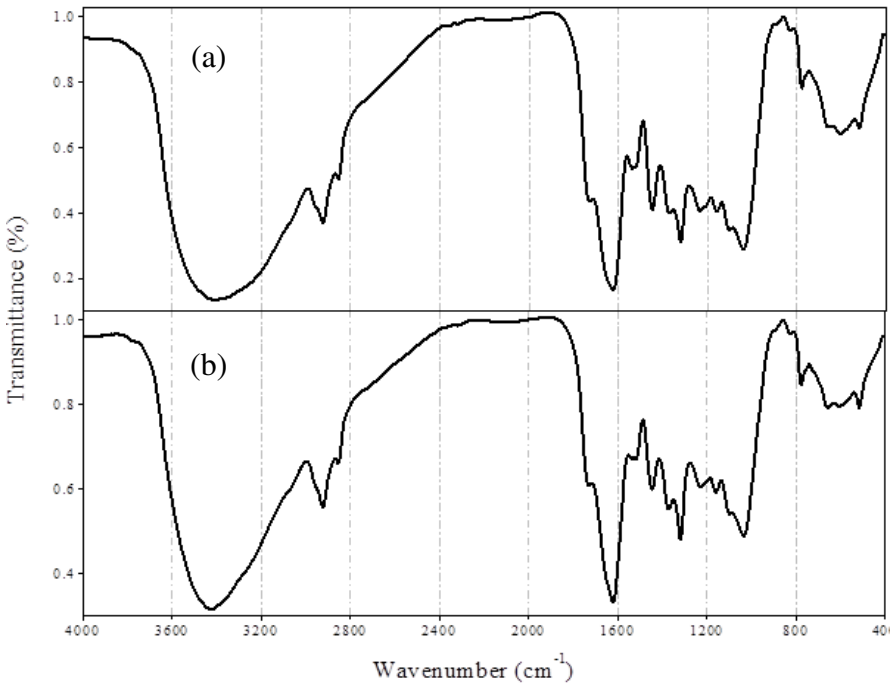

Figure 9. *FTIR spectrum of M. laetum biomass before (a) and after (b) adsorption of malachite green*

The IR spectrum of raw biomass of *L. chinensis* (*Fig. 10a*) exhibited a broad peak for adsorption at 3436 cm^{-1} attributable to -OH and -NH stretching vibration, 2923 cm^{-1} due to stretching vibration of C-H, 1631 cm^{-1} caused by COO^{-} group or amide group and 1034 cm^{-1} assigned to N-H bending or stretching vibration of C-OH. The adsorption bands after dye treatments revealed some changes in the position and intensity of the above absorption bands especially at 1631 cm^{-1} due to carboxylate or amide groups which confirm the participation of these groups in dye biosorption by *L. chinensis* biomass (*Fig. 10b*).

Scanning electron microscopy micrographs (SEM)

Evaluation of the morphological changes on the surface of *M. laetum* biomass, which is the most efficient for sorption of MG dye adsorption, was performed by using scanning electron microscopy. Before the removal of MG by the biomass, the cells were rich with high porous structure exhibited hole-like (*Fig. 11a*). The surface of the biomass cells became rough and meanders after the removal of dye ions, due to precipitation of dye ions around the cell surface (*Fig. 11b*).

Discussion

The waste materials of the dry leaves of the plant can be used for the removal process of dye. The removal process was found to be affected by the pH values of the dye solution. In agreement with the current result, Anbia and Ghaffari (2011) showed that the uptake of malachite green from solution using adsorbent was found to increase at high pH. They reported that the pH effects on the charge, functional groups, and ionization degree on the biomass active sites, in addition to the chemistry of dye solution. The MG is a cationic basic dye and contains a negatively charged chloride ion,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

a positive charged organic ion, and a positive nitrogen ion. The color intensity and stability of MG structure were found to be affected by the pH value (Mall et al., 2006). They showed that the pH range 3-7 made the color of MG stable, and the reduction of color increased with increasing pH from 7 to 11 in the solution of MG.

The pH value of the solution effect on the functional groups on the active sites of the biomass and the degree of ionization of dye which effects on the process of uptake (Nandi et al., 2009). MG is protonated in the acidic medium and deprotonated at high values of pH. The low removal of MG at acidic pH may be related to the competition between the abundant hydrogen ions, adsorption sites on the biomass and the dye cations. In our study, the great adsorption of MG at pH 8-10 may be related to the changes in the structure of MG molecules as mentioned by Sun and Tomkinson (2001). Maurya et al. (2006) found that deprotonating of different functional groups of the biomass lead to an increase in the removal dye.

The results showed that the removal of MG by the tested biomass increased with increasing temperature. This result indicates that high temperature is favorable for the removal of MG from aqueous solution. The rate of diffusion of the dye molecules is a temperature dependent process. In accordance with the present result, Demierege et al. (2015) showed that the biosorption of dye by using mushroom stump wastes increased with increasing temperature from 20 °C to 50 °C due to the increase in surface activity and kinetic energy of dye molecules. Increase in temperature may increase the mobility of the large dye ion and consequently increase the adsorption process (Singla et al., 2016). A sufficient energy is required for a number of molecules to make an interaction with the active site at the surface (Doğan and Alkan, 2003). An increase in temperature causes fast diffusion of dye molecules across the internal pores of the adsorbent particles and the external boundary layer due to the less resistance of viscous forces in the aqueous solution (Banerjee and Chattopadhyaya, 2017). The increase in adsorption capacity may be due to the enlargement of the pore size of adsorbents at high temperature (Demirbas et al., 2008).

The present result indicated that removal of MG dye by using the tested biomasses showed an increase with increasing contact time through the first minutes and then slowly increased until equilibrium. The uptake of dye does not increase with more increase in contact time as a result of the accumulation of dye on the available sites of adsorption on biomass material (Eren, 2009; Singla et al., 2016). The biomass of *M. laetum* reached equilibrium earlier than and that of *L. chinensis.* This result suggests that there are a higher affinity and stronger electrostatic force of attraction between MG dye and the binding-sites and functional groups on the wall surface of *M. laetum* biomass as compared with that of *L. chinensis.* The uptake of dye returned to the great number of active and vacant sites on the adsorbent surface at equilibrium time (Vijayaraghavan et al., 2008). Ashish et al. (2017) showed that the removal of MG dye occurs at the high-speed rate by *Limonia acidissima* (98.87%) after 3.30 h of equilibrium time. Malik et al. (2007) suggested that a monolayer of dye is formed on the surface of the biomass, and the rate of the dye uptake is controlled by the rate of transported dye from the exterior to the interior site of the biomass. This result suggests that there are a higher affinity and stronger electrostatic force of attraction between MG dye and the binding-sites and functional groups on the wall surface of the biomass.

As shown in the results, the removal of dye was greatly increased with increasing the weight of biomass up to certain limits and then remained constant. At first, the rate of dye removal has been found to be rapid and slowed down as the biomass dose increased

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_69456962
© 2018, ALÖKI Kft., Budapest, Hungary

(Salleh et al., 2003; Omar et al., 2018). This can be explained depending on the fact that, at a lower weight of biomass the dye is more available and due to this, the removal of dye per unit weight of biomass is higher. In addition, the increase in the adsorbent dose leads to an increase in the adsorbed dye due to increases in the number of available adsorption sites and the surface area of adsorbent (Mane et al., 2007). As clear from the results, the biomass of *M. laetum* was more efficient than *L. chinensis* in the removal of dye. This may be returned to the availability of more binding sites on the surface of *M. laetum* biomass.

The removal of dye decreased gradually with increasing dye concentration at the optimum condition as shown in the present study. This result may be returned to the increase in the gradient pressure between solution and biomass which drive the dye molecules from the solution to the surface of the biomass (Rasool and Lee, 2015). The decrease in the removal capacity with increasing dye concentration may be due to the higher quantity of adsorbate than the adsorbent dose (Chen and Zhao, 2009). At high concentration of dye, the available sites of sorption became fewer as compared to the concentration of dye and so the uptake of dye is associated with the initial concentration of dye.

Equations of equilibrium isotherm were used to illustrate experimental absorption data. These equations parameters and the thermodynamic properties explain both the mechanism of sorption and adsorbent affinity. Graphically it is likely to elucidate the isotherm of equilibrium adsorption by plotting liquid phase concentration against solid phase concentration. It is necessary to determine the foremost acceptable correlation for the equilibrium curve, to enhance the design of an adsorption system to eliminate dyes from effluents. Consequently, the association of equilibrium data using theoretical and experimental equation is essential for the sorption interpretation and expectation of the adsorption range.

According to the Langmuir isotherm results, the *M. laetum* biomass recorded the greatest affinity of the binding site (b) to MG. In addition, the R_L low values elucidated that the removal of MG was favorable by the biomass. The low value of R_L means high adsorbent to adsorbate affinity (Jelinek et al., 2015). Depending on the high values of linear correlation coefficient (R^2), the models of Langmuir and Freundlich were found to be more favorable for explaining the sorption MG onto *M. laetum* and *L. chinensis* biomass. In addition, homogeneous and heterogeneous adsorption energy occurred throughout the removal of MG by the biomass. Hii et al. (2011) confirmed that the high values of the linear correlation coefficient ($R^2 > 0.95$) of each model of Langmuir and Freundlich are favorable for a description of the sorption of the dye by *Aristaeomorpha foliacea*. The confirmation of Langmuir and Freundlich isotherms to the sorption study showed that the tested biomass may exhibit monolayer adsorption and heterogeneous surface conditions (Kumari and Abraham, 2007). The results of Temkin isotherm proposed that the heat of molecule adsorption decreased linearly in the layer. Fil (2016) reported that the negative value of $\Delta G°$ for all temperatures proposed that the adsorption process was spontaneous. The ΔH° within the range of 0.5-20.9 kJ mol^{-1} means that the removal of MG by tested biomass was physical biosorption (Ahmet and Mustafa, 2008). The positive ΔS° values represent the decrease in the degree of freedom on the adsorbent surface during MG sorption process.

The IR analysis explained that the interaction between the biomass and MG were ionic between MG and carboxylate group, and coordinate bond was found between MG and the lone pair of electrons on the -OH or $-NH_2$ groups. In addition, forces of van der

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

Waals between nonpolar groups of biomass and MG, and ion-dipole interaction between the negative dipole end of the carbonyl group and MG. According to the results of IR, the changes in the position of functional groups on the tested biomass after treatment with MG confirmed the contribution of these groups in the dye removal as suggested by Jayaraj et al. (2011). Zhai et al. (2014) explained that the plant cell walls consist of carbohydrate, protein, lignin, hemicellulose, cellulose microfibrils and aromatic compounds. These molecules on the surface of the cell have carboxyl, amino, phosphate, thiol, and sulfhydryl functional groups (Tüzün et al., 2005).

The surface of the tested biomass became rough and meanders after exposure to the ions of MG because of the precipitation of dye at the surface of the biomass cell. This result may be due to the linkage of dye ions with the functional groups of cell surface and replacement of the ions for some of the cations in the cell wall matrix. The differences in the morphology and the structure of the biomass cell wall lead to the presence of differences in the efficiency of dye removal. The increase of dye removal may be related to the pores on the surface of plant biomass which allow the free passage of dye molecules (Deokar, 2016). The irregular surface of biomass cells, make the sorption of solution ions possible on different parts of these materials.

Conclusions

The color removal of dye from wastewater is a matter of concern due to its toxicity. The easily available and low-cost biomass such as the waste of *M. laetum* and *L. chinensis* leaves were found to have the unlimited capacity for the removal of MG and thus decrease the toxic effect of dye in the solution. The efficiency of *M. laetum* biomass was higher than *L. chinensis* biomass for adsorption of MG. The present study confirmed that the plant biomaterial which is discarded as a waste can be used for the removal of dyes from wastewater and make the water cleaner for various uses. This is an economical and environmentally-friendly alternative to various other methods that use a large number of chemicals to treat wastewater.

NEXUS OF AGRICULTURE, GDP, POPULATION AND CLIMATE CHANGE: CASE OF SOME EURASIAN COUNTRIES AND TURKEY

DOĞAN, H. G.

Department of Agricultural Economics, Agricultural Faculty, Kirsehir Ahi Evran University
40100 Kirsehir Province, Turkey
(e-mail: hg.dogan@ahievran.edu.tr; phone: +90-386-280-4869)

(Received 7th Jul 2018; accepted 20th Sep 2018)

Abstract. Climate has an important role in the life processes of living creatures economically, socially and biologically. It affects several sectors and is affected by several sectors. Climate events are known to have changed since the second millennium and today it stands out as a problem that humanity has to face. Climate change has to be evaluated together with the global warming phenomenon. The most important factor causing global warming is the CO_2 concentration. This study examines the effects of variables including the share of the agricultural fields within total area, agricultural added value, GDP and population on the CO_2 release within the scale of the Eurasian Region and Turkey. The study covers the period between 1993 and 2016 years. Econometric models like ADF unit square test, ARDL and VECM were used. According to the obtained results, the effect of population was determined to be greater than that of the other variables in both regions. All of the variables under study had an increasing effect on CO_2 release in the long term in the Eurasian Region, while the share of the agricultural areas within total area and the GDP variables had an effect to reduce CO_2 release. This different situation is directly related to the size of the agricultural production in the Eurasian Region and Turkey and to the awareness level of the people. As a result, awareness of the individuals as well as of the state rulers on environmental destruction or environmental cost in particular in all works is considered to be important. On the other hand, it is necessary to plan agricultural production system within an environmental dimension and this needs to become a state policy. However, when creating these policies, one should avoid practices causing any difficulty in meeting the food demand of the population or causing excessive increases in food prices, such as the results when agriculture was affected by the climate events. Otherwise, there may be undesired consequences like food deficiency and corresponding deterioration of the macroeconomic balances of countries.
Keywords: *CO_2, ARDL, VECM, Eurasia, Turkey*

Introduction

Climate is an important environmental element affecting life on Earth (Carson, 1999). However, it has significantly changed in recent years. The change process started with the industrial revolution continued with the burning of fossil fuels and with human activities. It leads to the phenomenon of global warming. Climate change affects every stage of our lives, especially physical and natural environment (Özdemir et al., 2017). Global warming and climate change have important effects on the economies of developed and developing countries. It is stated that the concerned economic effects may reach to enormous levels if the necessary measures to reduce release and measures for compliance are not taken. The global warming and climate change have directly or indirectly affected all regions of the world in recent years. The sensible effects are more visible in the last few decades. These effects are expected to increase further in years to come. In other words, global warming and climate change is a global phenomenon at present (Gafari et al., 2014). The primary accountable element of the said phenomenon is human activity. Human activities cause global warming and increase the greenhouse gas release that leads to great changes in global climate. Several extreme events may occur due to climate change. These include irregular precipitation periods, irregular wind directions, increased level of drought,

© 2018, ALÖKI Kft., Budapest, Hungary

desertification, and changes in underground and surface water levels (Angel, 2008). Technological development and welfare increase have been an important factor in greenhouse gas release. The basic sources for the greenhouse concentration can be defined with the use of fossil fuels in sectors like electricity generation, agricultural production and transportation. It is stated that the result may have huge negative regional, country based and global effects (Janjua et al., 2014). These effects occur with the accumulation of the greenhouse gases. Scientists agree on the fact that the basic cause of this problem is due to greenhouse gases like CO_2.

According to the present calculation, it is estimated that only a 1 °C increase in global warming will lead to an annual economic cost of 2 trillion dollars in 2050. According to a study conducted in EU, the cumulative global economic cost of global warming may reach to Euro 74 trillion (Bayraç and Doğan, 2016). It has been a significant increase in the amount of greenhouse gas in the atmosphere since the industrial revolution. Since 1750, the CO_2 level in the atmosphere increased nearly by 30% and reached from 280 ppm to 380 ppm. Today, CO_2 concentration increases around by 1.5 ppm every year. Therefore, it is necessary to keep the atmospheric greenhouse concentrations under control through various methods (Bayraç and Doğan, 2016). There are main sectors causing greenhouse gas release. *Figure 1* includes sectoral greenhouse gas releases at a global scale. As shown in *Figure 1,* the greenhouse gas releases are caused by industry (21%), transportation (14%), buildings (6%), agriculture and forestry and other field uses (24%), power and heat generation (25%), and other energy generation (10%) (IPCC, 2014a).

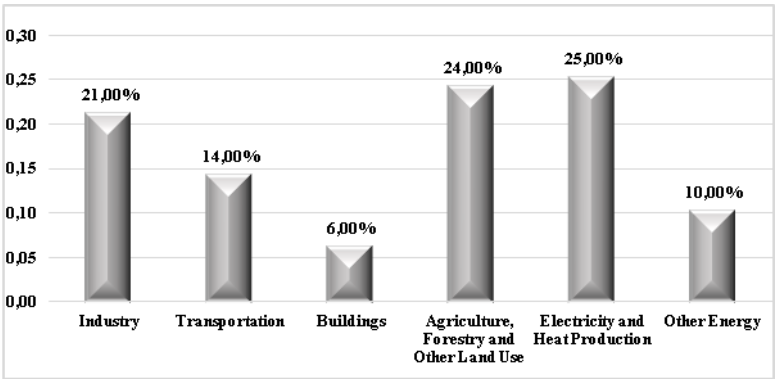

Figure 1. *Sectoral greenhouse release (IPCC, 2014a)*

Sectoral greenhouse releases stated by IPCC are in one aspect directly related to the energy consumption. It is estimated that the total global energy supply will double between 2004 and 2020 (Kaygusuz, 2009). On sectoral basis, energy sources may vary and substitute each other. It is stated that the 24% coal share in 2004 will increase to 36% in 2020 and substitute oil in certain extent. After such a substitution, the CO_2 release is expected to increase three times between 2004 and 2020 (Kaygusuz, 2009).

Climate change affects various economic sectors including agriculture, forestry, water, industry, tourism, energy and even finance and insurance markets with agriculture being the most sensitive to these changes (Hosseini et al., 2013). Agricultural sector is affected more by the climate events than the others. It is a high risk sector as it is inherently based on natural conditions. Agricultural sector has dynamics causing climate change and it has a decisive role for production and sustainability in both short term and long term (Gafari et al., 2014). It is proportionally

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/160569636976
© 2018, ALÖKI Kft., Budapest, Hungary

the second biggest sector contributing to the greenhouse release (IPCC, 2014b). The greenhouse gas emission in the agriculture sector contributing by 24% is caused by soil processing during production process and animal activities, heat and electrical energy generation, agricultural equipment, inorganic manure, agricultural chemicals and fossil fuels used in tractors and other transportation vehicles. ABD emission statistics report that the agricultural sector is directly responsible for greenhouse release. Soil management is defined to be the most important dynamic in the sector (Holly, 2015). Reynolds and Wenzlau (2012) reported that the agriculture sector has a 14 to 30% contribution to the total greenhouse emission due to irrigation and nitrogen rich fertilizers. In another aspect, agriculture is a sector that is affected by climate change. That is, it both causes and is significantly affected by climate change and global warming. The agricultural sector is highly dependent on climate events. This dependency directly affects food supply, agricultural food products and sectoral economic performance (Holly, 2015; Sakurai et al., 2014; Kang et al., 2009; Magadza, 2000).

As stated by World Bank (2016a, b), global agricultural sector produces CO_2, CH_4 and N_2O. However, the CH_4 and N_2O concentration are lower than the CO_2 concentration. CO_2 concentration had a 40% increase from 1750 to 2014 (IPCC, 2014b). United Nations Food and Agriculture Organization (FAO) states that the agricultural sector has a potential to reach an 80 to 88% reduction in the CO_2 emissions it causes at the moment (Reynolds and Wenzlau, 2012). Based on this result, it can be considered that environmental damage is not a must for economic and agricultural growth. Several attempts have been made to find a scientific answer to this question. It is emphasized that growth increase depends on various factors including energy consumption, food demand and land usage and leads to increases in CO_2 emissions. However, the agricultural sector contributes to the greenhouse release by producing CO_2 and causes global warming while it helps to reduce the CO_2 level by producing more O_2 through plantation (Khasman et al., 2016). It is clear that proper approaches are necessary for the organization of this two-way action-reaction process.

Humanity faces increasing threats with respect to global warming and climate change every day on one hand, and food demand and economic growth quests on the other. When we take a liveable world as a priority, energy consumption, considered among the main contaminants, becomes a focal point in this matter. Therefore, there has been a demand for empirical studies on energy consumption, economic growth and their environmental costs. When we look at the results obtained from the said studies, we notice the presence of strong relation between these variables that are studied. Since the last quarter of the second millennium, that is within period of oil wars and thereafter, scientific studies happened to have different dimensions with the Kyoto Protocol. These research studies indicate the fact that the studies on energy economy and environment economy cover a very important field. However, the results highlight the necessity to increase the energy consumption to ensure the targeted growth rates despite the potential environmental cost (Tiwari, 2011). The present study intends to bring a perspective from the agricultural dimension to the greenhouse effect, which is one of the main causes of global warming and climate change. Eurasian countries and Turkey were selected as the study region. It is intended to compare two regions with different population growth and economic structures. Despite these differences, it is aimed to study the comparative conditions of the two regions that are within the same geopolitical frame. The variables that are studied include two important variables.

Because, agriculture has an effect to reduce both global warming and climate change while it has also an effect to increase global warming and climate change by greenhouse gas release (Bayraç and Doğan, 2016). In addition, the variables including population and national income per capita were examined in the study as the other important determinants. As it was already mentioned, the main reason of the global warming and climate change process has a human root.

Figures 2 and *3* include the development trend of the Eurasian countries and Turkey between the years 1993 and 2016 years with respect to the variables under the study.

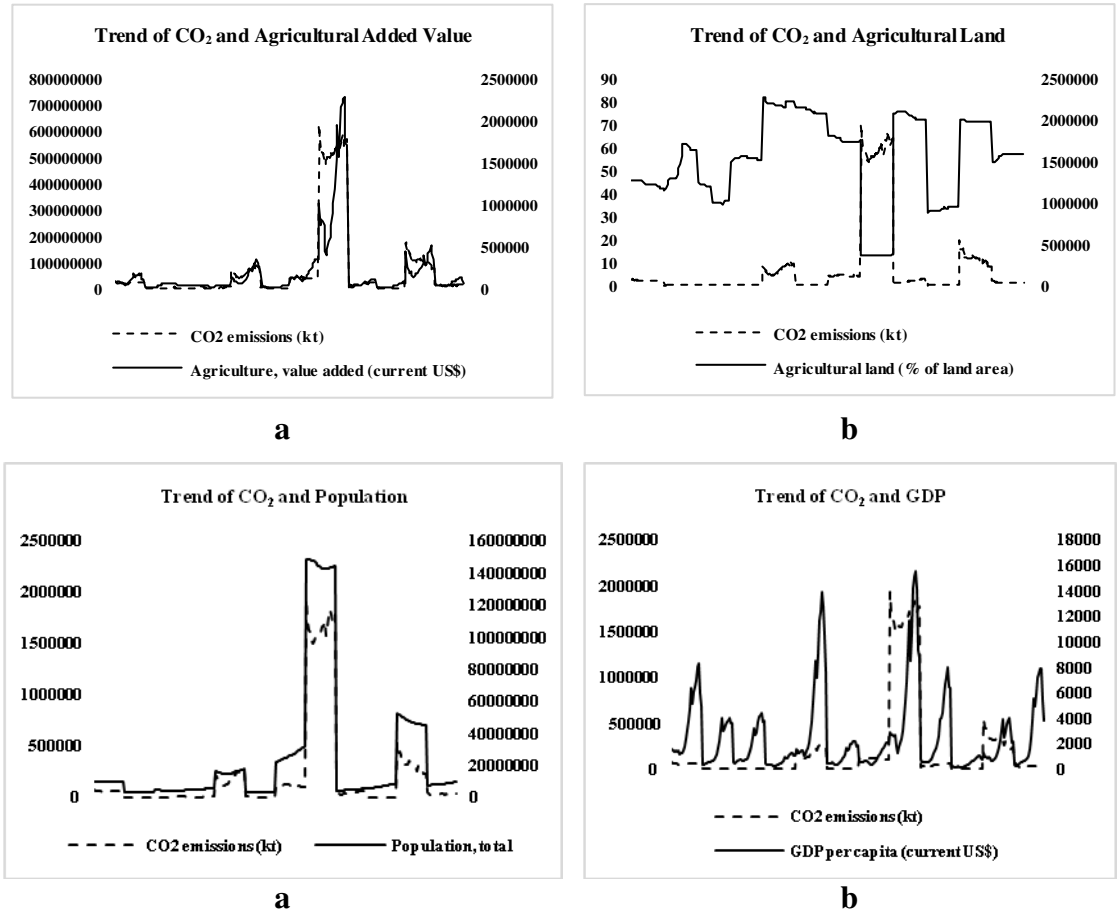

Figure 2. *The interaction among agricultural added value (a), agricultural land (b), population (c) and GDP (d) and CO_2 in Eurasian countries (Wolrdbank, 2017). Note: X-axis represents the Eurasian countries (12 countries) between 1993 and 2016 years*

When we examine the trend of variables in the Eurasian countries between 1993 and 2016 years, the trends of CO_2 and other variables are similar with the direction of the coefficients obtained from the econometric results. It is possible to see in *Figure 2* that agricultural added value, population and GDP have movements in the same direction. This simultaneous trend differs only in the Russian Federation within the panel addressed with respect to agricultural field. The reason is that agricultural production is very low in the Russian Federation (average share of the agricultural added value within GDP between 1993 and 2016 years is 4.88%; the lowest among 12 countries within the Eurasian region (World Bank, 2017). It can be said that the other factors increasing the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

CO_2 level in the Russian Federation are more effective. However, it cannot be said that this is valid for all of the panel.

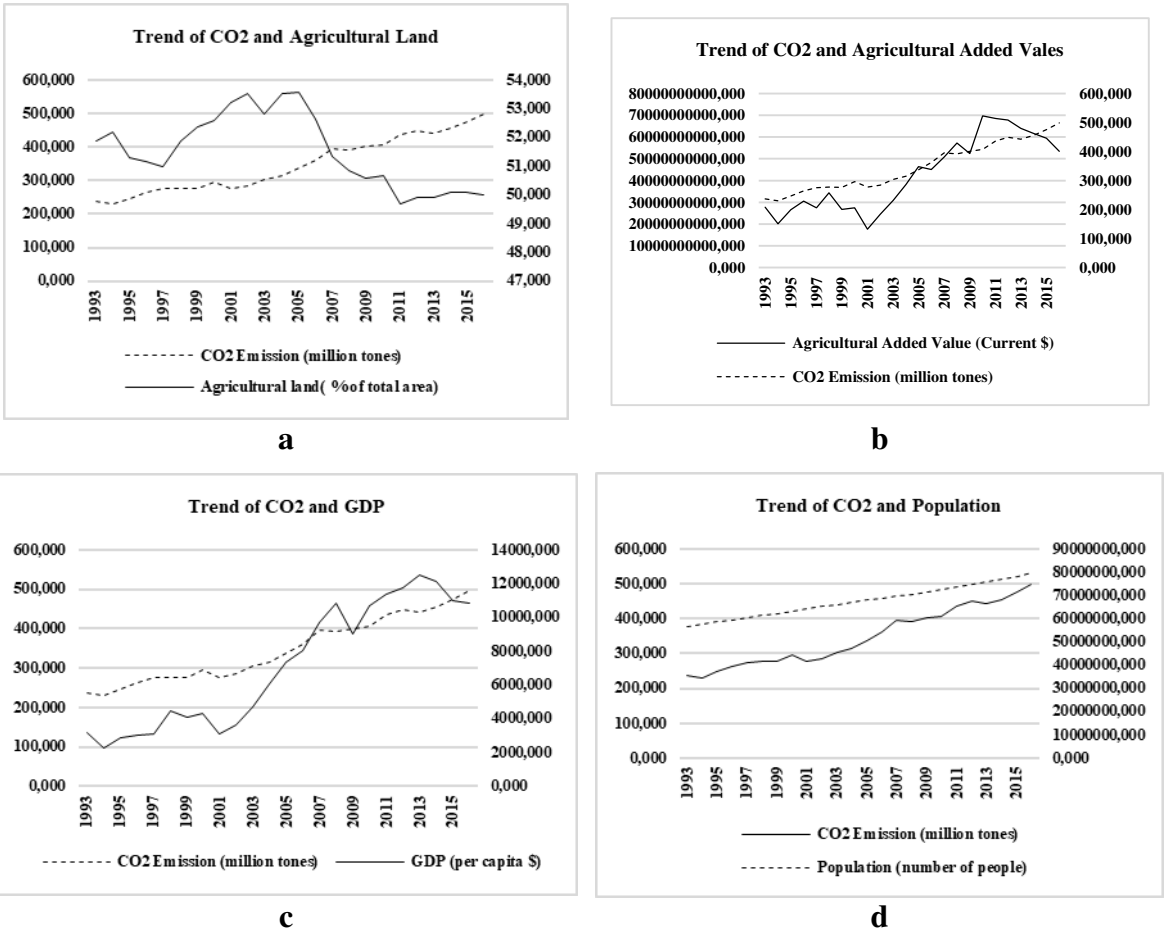

Figure 3. *The interaction among agricultural land (a), Agricultural added value (b), GDP (c), population (d) and CO_2 in Turkey (World Bank, 2017). Note: X-axis represents between 1993 and 2016 years*

Figure 3 indicates the interaction between CO_2 release in Turkey and agricultural area, agricultural added value, population and GDP. Accordingly, the long time trend of the variables develops in the same trend as CO_2. However, the interaction of agricultural fields and CO_2 should be kept different from this framework because the increase in CO_2 release continues even if the share of the agricultural fields has a decreasing trend after 2005. This can be linked to the fact that the agricultural fields in Turkey face urbanization and housing despite they are under the status of agricultural production.

Materials and methods

In the study, factors affecting CO_2 release in Eurasian countries and Turkey were investigated. The study involved the years between 1993 and 2016 years. These factors are the share of agricultural areas in total area, agricultural added value, GDP and population. Eurasia is defined from United Kingdom to Japan in the literature. It includes 103 countries (Anonymous, 2018). This concept was firstly used by Alexander

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/160569636976
© 2018, ALÖKI Kft., Budapest, Hungary

von Humbolt in 1849 (İşyar, 2013). Although there is no consensus on the scope of this concept, there are many approaches that cover various countries. Countries emerging after the dissolution of the Soviet Union are also located within this region. It can be said that they are intensely related to each other in terms of culture, politics and economics. Therefore, in this study, 12 countries with similar characteristics were named as the Eurasian region. These are Belarus, Armenia, Georgia, Kazakhstan, Kyrgyzstan, Moldova, Uzbekistan, Russia, Tajikistan, Turkmenistan, Ukraine and Azerbaijan. Panel data analysis was used for the modelling of 12 countries while time series analysis was used in the econometric modelling for Turkey. *Table 1* includes the symbols and data sources of the variables.

Table 1. *Symbols and data sources of the variables used in the study*

Name of the variable	Symbol	Unit	Data source
CO_2	Y	For Eurasia; kgtonnes/for Turkey; million tones	World Bank, Turkstat
Share of agricultural fields within total area	χ	% of land area	World Bank
Agricultural added value	σ	current US$	World Bank
GDP per capita	λ	current US$	World Bank
Population	δ	Total number of people	World Bank

Full logarithmic form was chosen in the study for the variables used in the model. The functional relation between the CO_2 level and other variables can be expressed as follows in *Equation 1:*

$$\ln Y = f(\ln \chi, \ln \sigma, \ln \lambda, \ln \delta) \quad \text{(Eq.1)}$$

The factors causing the long term greenhouse gas effect in both the Eurasian Region and Turkey were analysed by means of the following economic models:

- Unit root test (ADF)
- Autoregressive distributed lag bound test (ARDL)
- Vector error correction model (VECM)

Unit root test is used to carry out the stability studies of the series. Stability tests are carried out to avoid the spurious regression problem. Several studies in the literature revealed the necessity to carry out the unit root tests (Maddala and Shaowen, 1999; Kao and Chiang, 2000; Hadri, 2000; Choi, 2001; Levin et al., 2002; Im, 2003). There are several types of the unit root test. However, basically the unit root tests are based on the ADF principle. This study also used the ADF unit root test. The notation of the ADF test statistics can be stated as follows in *Equation 2:*

$$\Delta X_t = \beta_0 + \beta_1 t + \beta_i X_{t-1} + \sum_{j=1}^{n} Y_i \Delta X_{t-j} + e_t \quad \text{(Eq.2)}$$

In *Equation 2,* $\beta 0$ refers to fixed term; t refers to deterministic trend; n refers to lag length and e_t refers to stochastic term. The results of the ADF test statistics are

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/160569636976
© 2018, ALÖKI Kft., Budapest, Hungary

compared by means of the MacKinnon critical value. Stability of the series is decided by accepting/rejecting according to the importance levels of 1%, 5% and 10% (MacKinnon, 1996).

Autoregressive distributed lag (ARDL) and vector error correction model (VECM)

The frequently used models in the literature are the Engle-Granger model (1987) based on the error term in the co-integration tests, Johansen model (1988) and Johansen & Jesilius model (1990) based on system approach (Altıntaş, 2013). However, stability approach at the I(0) level of all variables provides validity of these methods (Pesaran and Shin, 1995; Pesaran et al., 2001). The advantage of the ARDL approach is that it can carry out the co-integration test without considering the integration levels of the variables. There are basically 3 important points to pay attention to in the method. I-limit test procedure is easy and it is possible to carry out co-integration relation test after determining the lag length contrary to the multivariable co-integration methods like Johansen and Juselius (1990). II-limit test procedure does not require the preliminary tests of the variables included in the unit root test model, which is different from the co-integration techniques of Johansen and Juselius (1990). The limit test can be applied regardless of the fact that the models in the series are at the I(2) level, I(0) level and I(1) level or mutually co-integrated at the same level. III-limit test is very effective for small or limited sample clusters.

Equations 3, 4, 5, 6 and *7* include the limit test models of the 4 independent variables that were adapted to the study and the notations based on the estimation of the unlimited error correction model by the OLS method.

$$\Delta \ln Y = \beta_0 + \sum_{i=1}^{m} \beta_{1i} \Delta \ln Y_{t-i} + \sum_{i=0}^{m} \beta_{2i} \Delta \ln \chi_{t-i} + \sum_{i=0}^{m} \beta_{3i} \Delta \ln \sigma_{t-i} + \sum_{i=0}^{m} \beta_{4i} \Delta \ln \lambda_{t-i} + \sum_{i=0}^{m} \beta_{5i} \Delta \ln \delta_{t-i} + a1 \ln Y_{t-1}\, a2 \ln \chi_{t-1} + a3 \ln \sigma_{t-1} + a4 \ln \lambda_{t-1} + a5 \ln \delta_{t-1} + u_t \quad \text{(Eq.3)}$$

$$\Delta \ln \chi = V_0 + \sum_{i=1}^{m} \beta_{1i} \Delta \ln \chi_{t-i} + \sum_{i=0}^{m} \beta_{2i} \Delta \ln Y_{t-i} + \sum_{i=0}^{m} \beta_{3i} \Delta \ln \sigma_{t-i} + \sum_{i=0}^{m} \beta_{4i} \Delta \ln \lambda_{t-i} + \sum_{i=0}^{m} \beta_{5i} \Delta \ln \delta_{t-i} + a1 \ln Y_{t-1}\, a2 \ln \chi_{t-1} + a3 \ln \sigma_{t-1} + a4 \ln \lambda_{t-1} + a5 \ln \delta_{t-1} + u_t \quad \text{(Eq.4)}$$

$$\Delta \ln \sigma = K_0 + \sum_{i=1}^{m} \beta_{1i} \Delta \ln \sigma_{t-i} + \sum_{i=0}^{m} \beta_{2i} \Delta \ln Y_{t-i} + \sum_{i=0}^{m} \beta_{3i} \Delta \ln \chi_{t-i} + \sum_{i=0}^{m} \beta_{4i} \Delta \ln \lambda_{t-i} + \sum_{i=0}^{m} \beta_{5i} \Delta \ln \delta_{t-i} + a1 \ln Y_{t-1}\, a2 \ln \chi_{t-1} + a3 \ln \sigma_{t-1} + a4 \ln \lambda_{t-1} + a5 \ln \delta_{t-1} + u_t \quad \text{(Eq.5)}$$

$$\Delta \ln \lambda = Z_0 + \sum_{i=1}^{m} \beta_{1i} \Delta \ln \lambda_{t-i} + \sum_{i=0}^{m} \beta_{2i} \Delta \ln \chi_{t-i} + \sum_{i=0}^{m} \beta_{3i} \Delta \ln \sigma_{t-i} + \sum_{i=0}^{m} \beta_{4i} \Delta \ln Y_{t-i} + \sum_{i=0}^{m} \beta_{5i} \Delta \ln \delta_{t-i} + a1 \ln Y_{t-1}\, a2 \ln \chi_{t-1} + a3 \ln \sigma_{t-1} + a4 \ln \lambda_{t-1} + a5 \ln \delta_{t-1} + u_t \quad \text{(Eq.6)}$$

$$\Delta \ln \delta = Q_0 + \sum_{i=1}^{m} \beta_{1i} \Delta \ln \delta_{t-i} + \sum_{i=0}^{m} \beta_{2i} \Delta \ln \chi_{t-i} + \sum_{i=0}^{m} \beta_{3i} \Delta \ln \sigma_{t-i} + \sum_{i=0}^{m} \beta_{4i} \Delta \ln \lambda_{t-i} + \sum_{i=0}^{m} \beta_{5i} \Delta \ln Y_{t-i} + a1 \ln Y_{t-1}\, a2 \ln \chi_{t-1} + a3 \ln \sigma_{t-1} + a4 \ln \lambda_{t-1} + a5 \ln \delta_{t-1} + u_t \quad \text{(Eq.7)}$$

In *Equations 3, 4, 5, 6* and *7* Δ refers to the difference processor, and m refers to lag length. Information criteria like AIC, SC, FPE and HQ are used to determine the lag

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/160569636976
© 2018, ALÖKI Kft., Budapest, Hungary

length. Here, the lag length providing the smallest critical value is determined to be the lag length of the model. The process continues by passing to the next lag value like the first smallest value, the second smallest value … etc until reaching to the model without autocorrelation. The significance of the one-lag level values of the variables is tested to determine the presence of long term co-integration between the variables by using the F-test. H_0 hypothesis indicates that there is no co-integration between the variables in the Equations 3-7 and it is formed as follows: H_0: a1 = a2 = a3 = a4 = a5. The alternative hypothesis H_1 which indicates the presence of co-integration is formed as follows: H_1: a1 ≠ a2 ≠ a3 ≠ a4 ≠ a5. In the study, co-integration between series was searched and then the long term ARDL model on the greenhouse release and error correction model (VECM) was estimated.

The VECM model allows the estimation of the short and long term flexibilities as well as the deviation coefficient from the balance taking place between the variables (Enders, 2008). In addition, the VECM analysis allows the removal of the spurious regression problem that may occur between the dependent and descriptive variables. *Equations 8, 9, 10, 11* and *12* include a corresponding VECM model (Granger, 1988).

$$\Delta \ln Y = \beta_0 + \sum_{i=1}^{m} \beta_{1i} \Delta \ln Y_{t-i} + \sum_{i=0}^{m} \beta_{2i} \Delta \ln \chi_{t-i} + \sum_{i=0}^{m} \beta_{3i} \Delta \ln \sigma_{t-i} + \sum_{i=0}^{m} \beta_{4i} \Delta \ln \lambda_{t-i} + \sum_{i=0}^{m} \beta_{5i} \Delta \ln \delta_{t-i} + \Psi ECM_{t-1} + \varepsilon_t \quad \text{(Eq.8)}$$

$$\Delta \ln \chi = V_0 + \sum_{i=1}^{m} \beta_{1i} \Delta \ln \chi_{t-i} + \sum_{i=1}^{m} \beta_{2i} \Delta \ln Y_{t-i} + \sum_{i=1}^{m} \beta_{3i} \Delta \ln \sigma_{t-i} + \sum_{i=1}^{m} \beta_{4i} \Delta \ln \lambda_{t-i} + \sum_{i=1}^{m} \beta_{5i} \Delta \ln \delta_{t-i} + \Psi ECM_{t-1} + u_t \quad \text{(Eq.9)}$$

$$\Delta \ln \sigma = K_0 + \sum_{i=1}^{m} \beta_{1i} \Delta \ln \sigma_{t-i} + \sum_{i=1}^{m} \beta_{2i} \Delta \ln Y_{t-i} + \sum_{i=1}^{m} \beta_{3i} \Delta \ln \chi_{t-i} + \sum_{i=1}^{m} \beta_{4i} \Delta \ln \lambda_{t-i} + \sum_{i=1}^{m} \beta_{5i} \Delta \ln \delta_{t-i} + \Psi ECM_{t-1} + v_t \quad \text{(Eq.10)}$$

$$\Delta \ln \lambda = Z_0 + \sum_{i=1}^{m} \beta_{1i} \Delta \ln \lambda_{t-i} + \sum_{i=1}^{m} \beta_{2i} \Delta \ln \chi_{t-i} + \sum_{i=1}^{m} \beta_{3i} \Delta \ln \sigma_{t-i} + \sum_{i=1}^{m} \beta_{4i} \Delta \ln Y_{t-i} + \sum_{i=1}^{m} \beta_{5i} \Delta \ln \delta_{t-i} + \Psi ECM_{t-1} + z_t \quad \text{(Eq.11)}$$

$$\Delta \ln \delta = Q_0 + \sum_{i=1}^{m} \beta_{1i} \Delta \ln \delta_{t-i} + \sum_{i=1}^{m} \beta_{2i} \Delta \ln \chi_{t-i} + \sum_{i=1}^{m} \beta_{3i} \Delta \ln \sigma_{t-i} + \sum_{i=1}^{m} \beta_{4i} \Delta \ln \lambda_{t-i} + \sum_{i=1}^{m} \beta_{5i} \Delta \ln Y_{t-i} + \Psi ECM_{t-1} + k_t \quad \text{(Eq.12)}$$

Equations 8, 9, 10, 11 and *12* are analyzed and interpretation is possible depending on the fact that the ECM coefficient is both statistically significant and negative or positive.

Empirical results

The presence of unit root in the series was searched first before evaluating the relation between CO_2 and other variables in short and long term. *Table 2* includes the unit root test results related to the variables that were examined.

*, ** and *** mean significant, respectively, at 1%, 5% and 10%. According to SIC. Y: CO_2, χ: share of agricultural fields within total area, σ: agricultural added value, λ: GDP per capita, δ: population

According to the unit root test results which reveal whether the variables are affected by the past values, all of the variables are not stable at I(0) level per Individual Intercept in the Eurasian countries. However, they are stable at I(1) level.

Individual intercept and trend are stable at the CO_2 and population I(0) level while the other variables are not stable. At I(1) level, all variables were determined to be stable. A similar case can also be stated for Turkey. According to Intercept, all variables are not stable at I(0) level. And they are all stable at I(1) level. According to Intercept and Trend, population is stable at I(0) level, while all variables are stable at I(1) level.

According to the results of the unit root test, the ARDL test can be applied if one of the variables under study is stable at I(0) level, the other is stable at I(1) level. *Table 3* includes the results of the ARDL model established for the Eurasian countries and Turkey.

Table 3. *ARDL long run results*

ARDL maximum lags were specified as automatic selection. *, ** and *** mean significant, respectively, at 1%, 5% and 10%. Y: CO_2, χ: share of agricultural fields within total area, σ: agricultural added value, λ: GDP per capita, δ: population

According to the results of ARDL, all variables examined in the Eurasian countries were considered to be statistically important in the long run. The share of the agricultural fields within the total area, agricultural added value, 1% increase in GDP

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/160569636976
© 2018, ALÖKI Kft., Budapest, Hungary

and population increase the CO_2 level by 0.53 %, 0.15 %, 0.06 % and 1.34 % respectively. All variables studied in Turkey were considered to be statistically important. It was determined that the CO_2 level decreases by 1.83% as the share of the agricultural fields within the total area increases by 1%. In fact, this is related with the decreasing size of the agricultural fields in Turkey in recent years. As shown in *Figure 3,* the share of the agricultural fields within the total area decreased gradually after 2005. However, the forest areas in Turkey had an 11% increase during the study period despite the decreasing agricultural fields (Turkstat, 2018). The basic cause of this negative relation was dimensioned in this aspect. The positive relation between the agricultural added value and the CO_2 level gives the idea that the wrong practices in the agricultural production activities create environmental pressure. However, the negative relation between the agricultural added value and the CO_2 level can be explained with the environmentally improving effect of the agricultural sector (Khashman et al., 2016). That is, it can be said that the increase in agricultural fields may contribute to the decrease of the greenhouse effect and the destruction created thereby. A similar reverse directional relation is also seen in GDP. GDP is one of the most important parameters used to express the development levels of countries. The trend of GDP has significantly increased in recent years under the conditions of Turkey. According to the result, a 1% increase in GDP causes a decrease of 0.04% in the CO_2 level. It can be considered to be a result in line with the reverse relation appearing after the peak point of the Environmental Kuznets Curve (EKC) suggested by Simon Kuznets in 1958. As known, the peak point of EKC is stated as the level of awareness of the individuals (Kuznets, 1955). Under the conditions of Turkey, a 1% increase in population can be explained by a 1.98% increase in the CO_2 level.

Short and long term causalities were determined with the Vector Error Correction Model for the variables affecting the CO_2 level for the Eurasian countries and Turkey. Suitable lag length was determined before conducting the VECM causality analysis. Suitable lag length is given in *Table 4*.

Table 4. *Lag length criteria for VAR model*

	Lag	**LogL**	**LR**	**FPE**	**AIC**	**SC**	**HQ**
Eurasia	1	1745.681	NA	8.29e-14	-15.93224	-15.54158	-15.77441
	2	2103.077	681.6993	3.82e-15*	-19.00997*	-18.22866*	-18.69432*
	3	2124.706	40.25422*	3.94e-15	-18.97876	-17.80679	-18.50528
	Lag	**LogL**	**LR**	**FPE**	**AIC**	**SC**	**HQ**

According to the results of the VECM approach Short Run Causality relation, a causality relation was determined in the Eurasia countries in the short term from the agricultural fields to population and from the agricultural added value to GDP. In the long term, it is possible to see the effect of the agricultural added value and GDP. It can be said that the 0.014% difference between the observed value and realized value of the CO_2 level would disappear within a period. In other words, the relevant imbalance can only disappear after 71 years if the conditions are maintained this way. When we look at the situation in Turkey, a causality relation was determined in the short term from the CO_2 level to population, from the agricultural fields to GDP, from the agricultural added value to population, from population to CO_2, agricultural fields and agricultural added value, and from GDP to population. Long term effect of agricultural added value and GDP are determined. It can be said that the 1.325% difference between the observed value and the realized value of the CO_2 level will disappear after a period. In other words, the CO_2 level will be balanced every 9 months if the conditions in Turkey are maintained this way.

Discussion and conclusion

There is an increasing trend in the global release of greenhouse gas. This increase is contributed by the countries of the world by various rates. The condition in the Eurasian region which is examined in the present study is different. Overall a decrease is observed in the region despite countries among the Eurasian countries showed increases and decreases between 1993 and 2016 years. This decrease is at the level of 13.91% (World Bank, 2017). In Turkey, there was an increase of 110% during the period of the study (Turkstat, 2018). The share of the agricultural fields within total area, agricultural added value, effect of GDP and population were analyzed by means of ARDL and VECM in order to determine this increase and decrease.

Accordingly, all variables studied in the Eurasian region have an effect increasing the CO_2 level in the long run. Population was determined to be the most effective variable. Similarly, population is considered to be the primary cause affecting the CO_2 level under the conditions of Turkey. According to the results of the VECM analysis, in the Eurasian Region, the long-term deviations are eliminated in the short term, albeit with a very small proportion. As it can be seen from the results of the VECM analysis, it can be said that long term deviations in Turkey is not balanced in any way. When we consider the population increases in the period under study, a population increase of 2.16% took place in the whole Eurasian region, while this increase was 40.22% in Turkey in the same period (World Bank, 2017). Another effective variable determined after population was the share of agricultural fields within the total area. A linear relation was determined between the share of the agricultural fields and CO_2 release in the Eurasian region while there was a negative directional relation in Turkey. However, the share of the agricultural fields within the total area of the Eurasian region was 55.09% between 1993 and 2006 while this value was 51.53% in Turkey. However, the cultivation status of the total agricultural fields, ratio of the forest lands and the product patterns in the agricultural fields are different in the Eurasian region and Turkey. Mostly the product group of grains are cultivated in the Eurasian region with intensive agriculture every year. However, the share of the agricultural fields within total area during the period of the study has gradually decreased in Turkey despite heavy agricultural activities. Soilless agriculture, environment friendly production systems and corresponding policy actions were taken as well. This is totally related to the intention of agriculture to reduce greenhouse gas release. While a one-way causality was determined between the agricultural fields and population in the Eurasian region in the short run, there was no such causality in Turkey. When we look at long term causality, long term deviation in the Eurasia Region does not appear to be reversible in the short run. With regards to the agricultural added value, effects increasing CO_2 release were determined in both regions, and balancing long term deviations in the short run was considered to be statistically important. GDP is another variable with differences between regions. There is a positive directional and linear relation between GDP and environmental destruction in the underdeveloped countries while it is possible to see a negative directional relation in the developing or developed countries. This can be explained by the presence of the individuals in the country under the study and the policies implemented for that purpose. Turkey consists of a structure which is, even partly, more developed, has higher income level and possesses social awareness. This difference can be seen in the reports of the United Nations development plans.

In summary, the quality and sustainability of the world we live in and the life conditions in the world are dependent on humans. Human-induced deterioration is also expressed in scientific studies (Kadıoğlu, 2002; Türe, 2003). For example, every year, a result of human activities CO_2 level increases by 3 billion tons (Bozoğlu et al., 2003; Karakaya and Özçağım, 2004). Environmental cost should definitely be taken into consideration while carrying out both agricultural activities and other income generating activities. All countries of the world should ensure conscientious individuals and informed development processes. Contributions should be made to raise awareness and improve education in underdeveloped countries and regions. States and policy makers should implement the laws on environmental issues and make them enforceable. All relevant ministries and organizations should be extremely sensitive and definitely take

steps in their action plans to protect environmental plans. In conclusion, a destructed environment, polluted water and atmosphere affect all humans.

Abstract. Transhumance is a very old form of pastoralism where livestock is moved seasonally between higher and lower pastures. The historical sheep track represents a valuable ecological asset that needs to be maintained. This study consisted in the agro-ecological characterization of the sheep tracks landscape and the detection of areas having higher conservation value. A planning framework was arranged and the sheep track system of the Apulia region (Italy) was characterized with the support of a Geographic Information System. Plain areas, mainly associated with transhumance in the past, are today much less involved in the residual presence of these sheep tracks; conversely, the most abundant presence and the best conservation status was detected in the hilly and marginal agricultural areas. Moreover, those biotopes having prevailing semi-natural traits closely associated with transhumance are today under-represented in the landscape and largely surpassed in extent by biotopes pertaining to agricultural land use. This work is a preliminary step in detecting the traits of the residual sheep track network in Apulia. Actions are required converging in a preservation plan that supports the recovery of the sheep track system according to an integrated land management perspective. Therefore, a new dimension in the sheep track conservation should be accomplished, not related to pastoralism, but able to deliver ecological services and promoting rural development in marginal areas.
Keywords: *agroecological planning, analytic hierarchy procedure (AHP), corine biotopes; geographical information system (GIS), high nature value farmland (HNV), land ecological network (LEN)*

Introduction

Transhumance is a very old form of pastoralism consisting in the seasonal movement of livestock and herders between higher pastures, in summer, and lower pastures, during winter (Ruiz and Ruiz, 1986). In Southern Italy, since the 15th century, long and grassy paths were connecting Abruzzo and Molise (in the Central Apennines) to the Southern Apulia region (down to the Tavoliere plain), and then in the reverse way (de Iulio and Biscotti, 2015). *Figure 1* provides a general representation of all the historical sheep tracks once traceable in Southern Italy. This practice dates back to time immemorial, but a long documented history is also available. In the middle of the 15th century, no less than 3.0 million sheep and 30 thousand shepherds travelled annually along the transhumance paths, while in the 17th century the sheep were about 5.5 million (de Iulio and Biscotti, 2015). Transhumance was practiced until the 1950-1960s, and abandoned

later, at least according to the original model, while much shorter trips of herds are still observed (between higher pastures in summer and lower valleys in winter), albeit quite rarely.

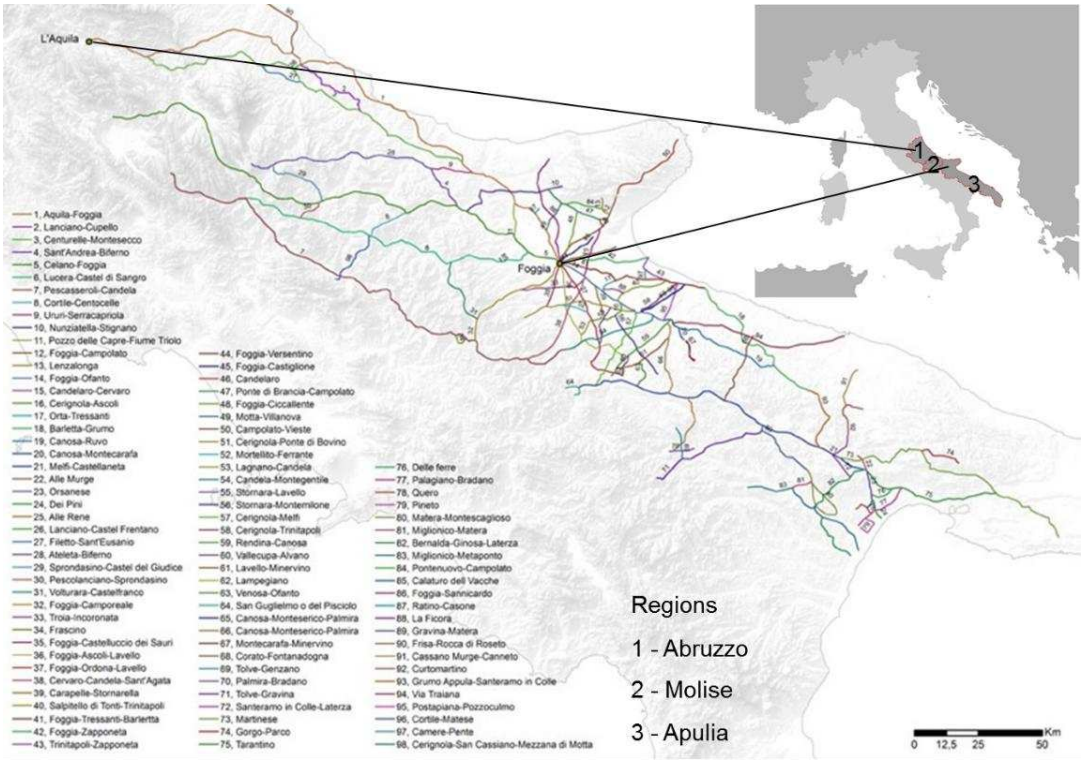

Figure 1. *Comprehensive map of the historical South Italian transhumance network. The name and dislocation of the most important sheep tracks in the three involved Italian regions (Abruzzo, Molise and Apulia, respectively) are displayed. (Adaptation from: I tratturi (n. d.): http://www.leviedeitratturi.com/i-tratturi/)*

Transhumance took place in several areas of the world and in almost every continent, particularly in Europe and Western Asia. These grassy routes travelled by drovers and herds assumed specific names in the language of various regions: *tratturi* in Italy, *cañadas* in Spain, *carraires* in France and *drumul oierilor* in Romania, all having the same features and functions (Paone, 2006).

The main *tratturi* (the so-called "royal" paths) have a precise width of 111 m, and are generally longer than 100 km, crossing longitudinally the southern part of the Italian peninsula. Secondary paths (named *tratturelli*) and lower order "branches", connecting the higher order paths, complete the dense and intricate sheep track network (*Fig. 1*).

Over the centuries, flocks, but also herds, were following this complex network of sheep tracks that developed progressively, adapting to the natural shape of the landscape. This provided the environmental "warp" to a "weft" made of relevant historical and cultural heritage. Natural environment and human culture, affecting each other, are closely interconnected and represent the two main landscape dimensions driving the coevolution processes. A vast scientific literature highlights the strategic importance of this landscape heritage, also with respect to the Mediterranean regions, including the relevant remaining of historical rural infrastructures, such as routes and lanes, stone-made terraces, field enclosures, ancient buildings and architectures, and

much more (Moreira et al., 2006; Brown et al., 2007; Cullotta and Barbera, 2011; Petanidou et al., 2008). Historically, transhumance has created a truly peculiar agricultural landscape, as clearly demonstrated by Melini et al. (2014) who presented an interesting case study in Molise, a southern region of Italy. Large open fields, lean (steppic) pastures, *maquis* and *garrigue* shrubland, animal resting places, woods and glades, single or clustered trees with broad and shadowing canopies, dry stone walls serving as land ownership boundaries, etc. are all elements jointly characterizing this landscape systems. One of the key features of this type of landscape is its strong semi-natural trait, resulting from the limited human interference, apart grazing management. Both over- and under-grazing may represent degrading factors leading to ecological disruption, but when grazing was well managed, semi-natural ecosystems resulted from a dynamic equilibrium between wildlife and human activities (Pykälä, 2000; Sutherland, 2002). Today, these landscapes are recognised as key habitats for maintaining biodiversity in the European agricultural areas (Bakker, 1989; Poschlod and Bonn, 1998; Pykälä, 2000).

Semi-natural ecosystems, with specific reference to permanent pastures, are a treasure chest of exceptional biodiversity and are the source for the majority of the environmental public goods generated by European farming (EC, 2014). This considering, they are fundamentally different from pastures under more intensive agricultural use (Beaufoy et al., 2011) and need to be protected from land use change due both to intensification, with the consequent conversion into arable land, and abandonment, frequently followed by natural afforestation. Indeed, the rapid technological changes experienced by more intensive agricultural practices proved to be one of the major threats to biodiversity in the last decades (Luoto et al., 2003; Butler et al., 2007), thereby altering the composition, structure and function of these valuable agro-ecosystems (Vitousek et al., 1997; Kremen and Ostfeld, 2005). On the other hand, a widespread agricultural land abandonment due to extra-marginal economic conditions can result in forest transition (Kauppi et al., 2006). Land intensification and land dereliction are the combined, double-sided process largely explaining the current agricultural land-use changes. Therefore, halting the loss of these semi-natural ecosystems, and specifically permanent pastures, is a key action for stopping the decline of biodiversity in Europe as a whole.

Transhumance, being connected to pasture maintenance and utilization, particularly along the sheep track network, largely contributed in forming a valuable set of pastoral landscapes and associated habitats. Some of these habitats are crucial, today, for the conservation of many “endangered” animal and vegetal species (Garzon, 2001), i.e. species which has been categorized as likely to become extinct.

The importance played by the sheep track system formed with transhumance in the conservation of semi-natural ecosystems and its associated biodiversity have been rarely analysed (Olea and Mateo-Tomás, 2009). Despite being present in many European countries, from Balkans to Scotland, this practice is currently a declining activity in Europe (Ruiz and Ruiz, 1986; Liberatori and Penteriani, 2001) due to the shift from old and traditional breeding practices to modern ones.

Although transhumance, today, is no longer carried out, Mediterranean countries retain significant traces of these sheep tracks, together with historical and cultural artefacts linked to transhumance. Therefore, the legacy of such a peculiar resource should be considered a valuable regional asset that needs to be properly maintained and relaunched through a systemic strategy, made of both conservation and valorization,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

altogether promoting new or renewed forms of rural development in those involved areas.

Generally, *tratturi* have the juridical status of public property and are preserved thanks to specific regulations protecting cultural heritage. After the 1930s, they were included in the enfranchisement law. Agriculture thus began to occupy the space of the traditional greenways that, until then, were under protection by numerous national regulations (Russo, 2002). In 1977, with the Presidential Decree n. 616 (Art. 66), sheep routes and tracks passed under the authority of the regional governments.

The management of this asset in the Apulia region is, today, in charge of the Regional Land Property Department that recently endorsed a new regulation framework (L.R. 4/2013) through which the entire regional sheep track system should be characterized and classified in order to promote, soon after, integrated actions of recovery and development. The first need (preliminary to every other kind of analyses and measures) was to consider the current conservation status of the sheep track system, discerning those portions still able to be recognized and not yet impaired from those stretches degraded by now and irremediably lost.

As part of a more general planning procedure on the sheep track network in the Apulia Region, the present study was specifically focused on the agroecological analysis and landscape characterization. This task was assigned to the University of Foggia (Department of Agriculture, Food and Environment) in collaboration with other institutional entities, forming a panel that included experts from the public administration of the Apulia Region (Land Property Department), the Foggia Province (Planning Department), the National Ministry of Cultural Heritage (Department of archaeology, fine arts and landscape). Colleagues from the Polytechnic University of Bari, specialized in architectural design (Department of Engineering and Architecture) and from the University of Foggia, specialized on cultural anthropology (Department of Humanistic Studies, Letters, Cultural Heritage) coordinated the team and contributed to the work, financially supported by the Apulia Regional Administration.

In parallel with the agroecological analysis, other studies and investigations were performed, involving this wide range of experts and scholars, mostly considering the current territorial arrangement of the land ownership, a survey of historical records and remaining, traditions and cultural heritage, arts and historical buildings, and much more.

The specific objective of the present study was to identify, characterize, classify and select land areas pertaining to the sheep track regional network, having higher conservation value according to agroecological criteria, still in good status of maintenance, and featuring less intensive farming practices or semi-natural conditions, similar (at least approximately) to the original landscapes at the times of transhumance.

The purpose of collecting a significant amount of information and defining a coherent and comprehensive framework of knowledge was considered a precondition, the final goal being developing an effective planning model to address the establishment of a protected natural area (called “Sheep track regional park”) to be connected to the regional ecological network and the “Natura 2000” (Habitat Directive 92/43/CEE) biodiversity system.

The study area

The study area is the Apulia region, placed in the Southeast of Italy and about 20.000 km^2 wide. It can be divided into 11 sub-regions according to the Regional

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

Landscape Plan (PPTR, 2013). This subdivision takes into account the geo-morphological, hydrological, environmental, as well as the anthropic and cultural traits of the region. Over the centuries, all these assorted characteristics contributed to the development of a landscape heritage consisting of a wide range of natural and semi-natural environments (habitats and species), as documented by several national and regional publications (ISPRA, 2013; PPTR, 2013). The typical climate is Mediterranean, although several peculiar local conditions can be detected. Altitude varies from 0 to about 1,200 m above the sea level. The region is mostly characterized by plain areas (53%), while hilly and mountainous surface covers the remaining part (47%). *Figure 2* displays the 11 sub-regions together with the Apulian sheep track network.

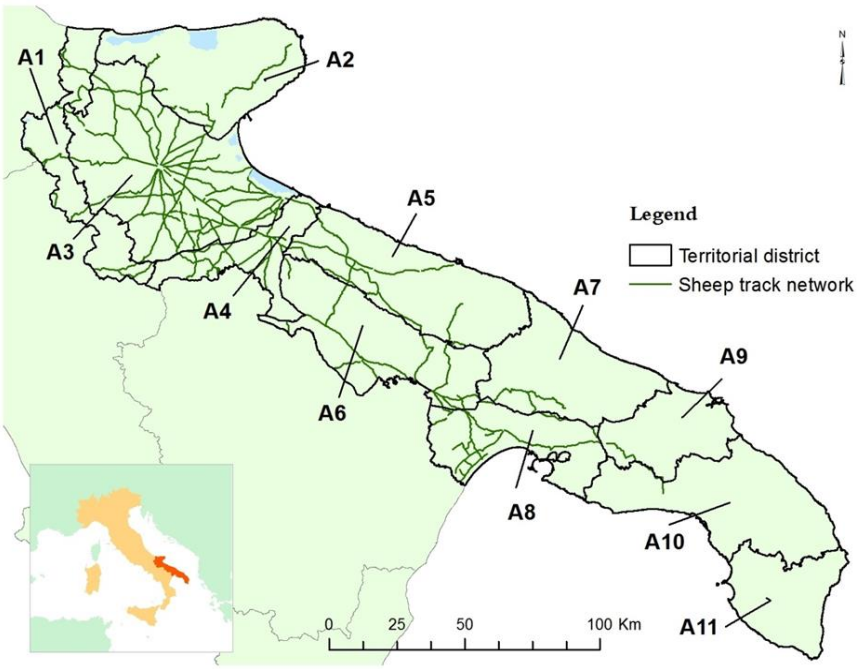

Figure 2. *Map of the Apulian sheep track network. Sub-regions according to the Apulian Landscape Plan are also represented. Monti Dauni (A1), Gargano (A2), Tavoliere (A3), Ofanto (A4), Puglia Centrale (A5), Alta Murgia (A6), Murgia dei Trulli (A7), Arco Ionico Tarantino (A8), Campagna Brindisina (A9), Tavoliere del Salento (A10), Salento delle Serre (A11)*

Material and methods

A landscape planning procedure is the methodological approach carried out in this work. It was applied to a peculiar set of agriculture, natural and semi-natural ecosystems (defined "biotopes"). A Geographic Information System (GIS) supported the analysis and allowed the processing of georeferred information, thus obtaining properly designed thematic maps. The software "ArcGis 10.1" was used for these purposes.

After a survey of the land use/land cover databases available from both regional and national digital cartographic portals, the Apulian Biotope Map (ISPRA, 2013) was the one selected to be used in the analysis. This database is focused on the spatial representation of the ecological and naturalistic traits of lands, specifically considering the range of ecosystems and biotopes detected in the region. This kind of information was judged particularly fitted to the scope of the considered land planning procedure.

Schematically, the applied methodology is composed of a sequence of steps, as represented in *Figure 3*. Starting from the historical sheep track network (step 1), the spatial analysis was restricted to a buffer zone of 1 km outlined around each path of the network (step 2).

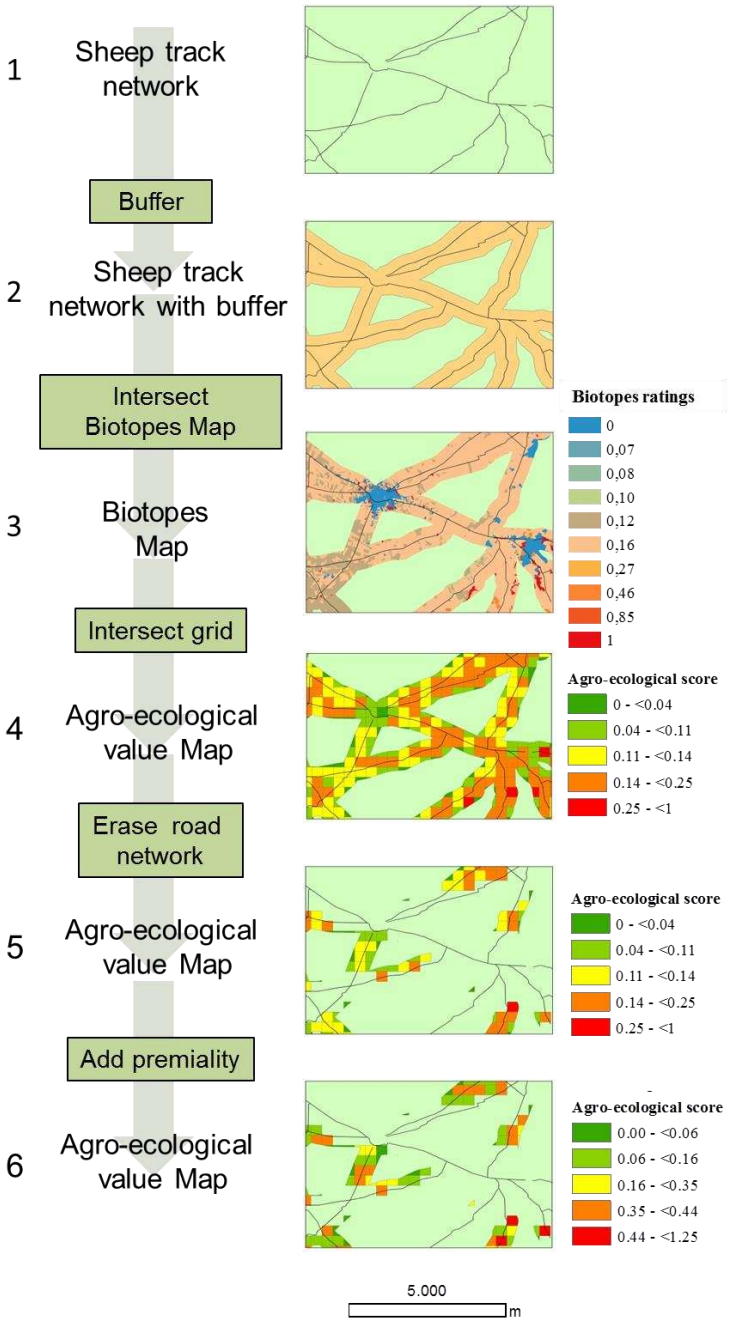

Figure 3. *Flow chart explaining the six consecutive steps of the applied methodology: identification of sheep track network (step 1); creation of a buffer area around the sheep paths (step 2); spatial intersection between the buffer area and the biotope map (step 3); overlapping with a grid to define the agro-ecological score for each mesh (step 4); erasing of the modern road network (step 5); adding premiality for those meshes belonging to protected areas (step 6). Concerning step 3, the exact rating assigned to the 11 biotope categories is reported (see the legend), while about steps from 4 to 6, the agroecological scores (see the legends) are partitioned according to a quintile distribution*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_69777000
© 2018, ALÖKI Kft., Budapest, Hungary

The biotope units within the buffer areas were selected. Then, an aggregation of the original biotope categories was performed, thus identifying 11 biotope categories (or biotope "categories"), in total. Each cluster was ranked with respect to all the others by assigning an "agroecological rating", ranging from 0 to 1, according to the opinion of experts who have adopted a set of shared criteria. The applied ranking procedure is a rearrangement of the methodology by Berthoud et al. (1989) originally developed to define the environmental naturalness value for conservation priorities.

The Biotope Map was obtained accordingly (step 3). A grid with a squared mesh of 1 km by side was overlapped to the Biotope Map. The surface fraction of each biotope occurring in every cell of the mesh was determined. Then, the "agroecological score" of every cell was computed as the average rating of all the featuring biotopes, each weighted by its corresponding surface fraction. A quintile classification of the cell-scores was performed (each class having 20% of the total number of cells), and 5 consecutive score-classes were therefore identified. In this way, the Agroecological Value Map was obtained (step 4). Those stretches of the sheep tracks currently no longer physically recognizable or irrecoverably impaired were discarded and consequently removed from the map (step 5). This occurred when a complete overlapping between a sheep truck path and a modern road segments was detected. Finally, the "agroecological score" was increased only for those cells placed inside protected natural areas. A score re-classification (according to the same quintile breakdown) was consequently performed (step 6).

Some critical methodological features of the applied procedure probably need to be better clarified. The following are further explanations, by bullet points, about these issues:

(A) *Biotope data source and their aggregation*. The Apulian Biotope Map (ISPRA, 2013) was obtained at 1:50.000 scale, it accounts for 80 detected habitats, arranged according to the European classification system called CORINE Biotopes. In the CORINE system, each habitat is classified within a hierarchical structure made of several embedded levels. The Apulian Biotope Map reached the 6th hierarchical level of habitat classification. Considering all the habitats featured in the sheep track network, a clustering of them was arranged, according to similarity criteria. In this way, 11 aggregated biotope categories were defined, each with a larger or smaller number of habitats. *Table A1* (see *Appendix*) reports this clustering. The categories "woods and forests" is the one with the larger number of habitats (16), followed by "meadows and pastures" (7), "dunal vegetation" (7), "bush and garrigue" (6), "riparian vegetation areas" (6). For the sake of simplicity, the habitats listed in *Table A1* are reported only with their CORINE Biotope code, while the specific name assigned to each habitat is reported in *Table A2* (see *Appendix*), according to the CORINE biotopes (Version 2000) database. A detailed description of these habitats can be found in ISPRA (2013).

(B) *Spatial scale of the analysis* (reason why a 1 km mesh-size). The appropriate size of the landscape analysis may vary according with the objectives of the work. The main advantage of using a grid of regular mesh superimposed to the regional digital map in the GIS assisted procedure is represented by the equal area of each cell, thus creating statistically similar units across the area being analysed. The choice of 1 km as the mesh size of the grid overlapped to the Biotope Map was associated to the corresponding size of 1 km of the buffer applied to both sides of each sheep track. Considering that the largest *tratturo*, the first order sheep track, was originally 111 m width, the buffer dimension is about nine time larger. This should be considered a proper dimension to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_69777000
© 2018, ALÖKI Kft., Budapest, Hungary

perform a planning analysis at regional scale, an optimal trade off allowing capturing both good amount of internal variability as well as heterogeneity of biotopes among adjacent cells of the grid.

(C) *Biotopes ranking procedure* (how coherently evaluating the rating distance between pairs of biotope categories). An Analytic Hierarchy Procedure (AHP) was applied (Saaty, 2008) with the main goal of estimating the correct rating to be assigned to each biotope category or, in other words, valuing the distance, in terms of a quantitative rating, between the agroecological values of all possible pairs of biotope categories. In this kind of analysis, expert judgement played a key role in estimating the relative importance of a biotope category with respect to another (Delivand et al. 2015). Therefore, a panel of 10 experts belonging to the "Regional Committee on the Sheep track Network" and mostly composed by naturalists, ecologists and agronomists, was asked to perform the AHP under the coordination of the Authors. In other words, each single expert was asked to compare the biotope categories two by two, according to the following set of criteria (Spitaleri et al. 1991):

a) Level of naturalness (fully artificial, semi-artificial, semi-natural; fully natural although of secondary origins)
b) Degree of diversity (low, medium, high richness of species)
c) Rarity status (low, medium, high number of species demanding protection or precious biocenosys)
d) Biotope representativeness (presence of endemic species or species associations characterizing the Mediterranean type of environment)

Consecutive pairwise comparison between criteria produced a resulting symmetric matrix of judgment (Delivand et al. 2015). In this way, the AHP generates a "weight" for each evaluation criterion: the higher the weight, the more important the corresponding criterion. Then, for each criterion, a "value" to every biotope category was assigned, again according to the AHP expert pairwise comparisons: the higher the "value", the better the performance of the biotope category with respect to the considered criterion. Finally, the AHP combines the criteria "weights" and the biotope "values", thus determining a global "rating" for each biotope category, and a consequent ranking. Saaty (2008) presents a complete description on how to lay out and solve AHP analysis (matrix operations, eigenvalue extraction and normalization). When many pairwise comparisons are performed, some inconsistencies may typically arise. The AHP incorporates an effective technique for checking the consistency of the evaluations made by the experts when building each of the pairwise comparison matrices. The technique relies on the computation of an index called "consistency ratio" (CR). A perfectly consistent expert should always obtain CR = 0, but small values of inconsistency may be tolerated. If CR is smaller or equal to 0.1 the combination of weights or the combination of biotope values should be considered satisfactory. Differently, some pair comparisons have to be revised (Saaty, 2008; Ying et al., 2007).

(D) *Reason why long stretches of the sheep track network were discarded*. By using the geo-referred database and comparing the historical sheep track system with the modern road network it was observed that, today, not only secondary roads but also highways and main national roads of intense motorized traffic are overlaid to the original sheep paths. Roads have physically occupied the original settlement of the sheep paths and roadside facility services their adjacent areas. This happens both quite often and for long distances, thus representing a very serious impairment, almost

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_69777000
© 2018, ALÖKI Kft., Budapest, Hungary

irreversible, to the integrity of the sheep path system. Therefore, whenever such conditions were detected and stretches of the sheep track were no longer physically discernible, it was determined not to consider them furthermore in the analysis and to remove them from the processing map.

(E) *Reward assigned to cells inside natural protected areas*. Those cells of the mesh whose surface was inside protected natural areas (both National and Regional Parks, as well as SCI and SPA of "Natura 2000" network) were rewarded by increasing of 0.25 their "agroecological score". The total score of each cell was therefore re-classified into new 5 intervals, according to the corresponding quintile.

Having conveniently prepared the comprehensive set of spatial data useful for the analysis, the final step of the analytical procedure was the following: cells belonging to the upper score class (i.e. those corresponding to the highest agroecological scores) were selected and further examined. These cells were appropriately mapped at a smaller scale, and studied, more in detail, in their biotope composition. Considering those remaining cells, the percentage of land assigned to each biotope categories was determined as well as the percentage of land attributed to each Apulian sub-region; a combination of the two factors (biotope category and sub-region) was also analysed in terms of surface fraction allotted to each biotope category in each sub-region. A double entry table was then obtained and the corresponding matrix was processes through a factorial analysis. The outcomes of this multivariate statistical procedure were very useful in detecting the main characters of the agricultural landscape of the region with respect to the areas pertaining to the sheep track network.

Results

The main findings related to the ranking of the biotope categories, the selected areas to be preserved and their characteristics and distribution among the territorial districts are presented below.

Ranking of biotope categories

Figure 4 reports the 11 clustered biotope categories ranked according to their agroecological "rating" assigned by the expert panel as the result of the AHP.

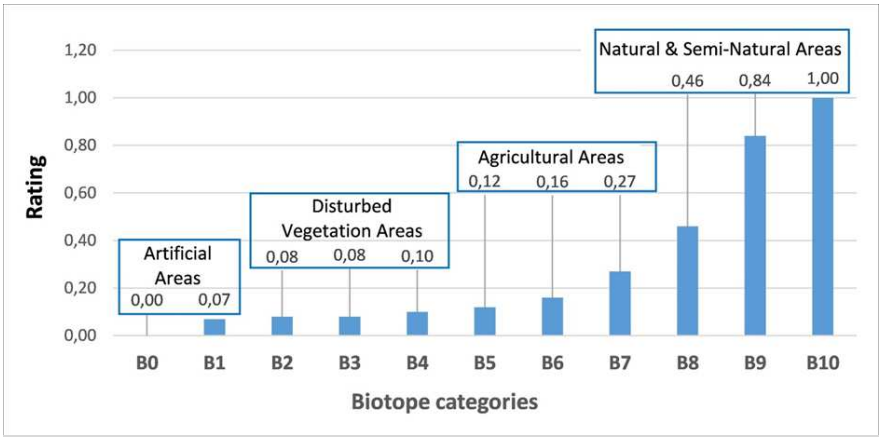

Figure 4. *Rank of the agroecological "rating" assigned to biotope categories by the expert panel as a result of the Analytic Hierarchy Procedure (AHP). More details about the applied procedure and the list of biotopes are available in the Appendix*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_69777000
© 2018, ALÖKI Kft., Budapest, Hungary

As a general outcome, lower ratings were assigned to artificial biotope categories, while higher ratings were associated to natural and semi-natural biotopes. Finally, the ratings of farmland biotopes are placed in a central position along the ranking (the complete list of the detected biotopes in reported in *Tables A1* and *A2* in the *Appendix*).

However, the main interesting comment to *Figure 4* is not the ranking *per se*, but the relative rating distance between biotope categories. The highest agroecological rating, indeed, was attributed to "meadows and pasture" (B10), followed by "bush and garrigue" (B9). Those biotope categories (such as permanent pasture, grassland and other semi-natural vegetation types) are clearly associated to transhumance. Their remarkable rating (1.00 and 0.84, respectively) is considerably higher than that of other natural or semi-natural biotopes, represented by "woods and forests" (B8), whose rating was estimated equal to 0.46, i.e. approximately half the values of B10 and B9. This impressive difference, detected by the joint expert evaluation, can be justified in the light of the so called "forest transition" process. Land abandonment (especially in traditional agricultural landscapes) and forest expansion often lead to lower landscape heterogeneity with negative effects on biodiversity, particularly for those species benefitting from open habitats and edge environment (Giampietro, 1997; Marull et al., 2010 and 2014). Biotope B10 is characterized by the presence of priority habitat types (i.e. habitat types in danger of disappearance) with single species or plant associations that, according to the Directive 92/43/CEE, need special protection. These species are represented by *Brachypodium retusum*, *Brachypodium ramosum*, *Trachynia distachya*, *Bromus madritensis* e *Lagurus ovatus*. Moreover, these species are often associated with the presence of rare wild orchids. Biotope B9 is frequently present in 'Natura 2000' areas (Habitat Directive 92/43/CE) that are part of an ecological network of protected zones, safeguarded against potentially damaging developments.

These considerations, largely prevailing among the experts, motivated the biotope ranking, and the lower ecological rating attributed to wood and forest as compared to pasture, garigue, maquis and meadows.

Moreover, among biotope categories associated to farmland, a higher rating was credited to "complex cultivation patterns" (B7), agricultural systems characterized by higher heterogeneity as compared to "tree crops" (B6) and "annual crops" (B5), more specialized farming systems. B7, indeed, is a traditional form of agricultural land utilization, marked by a rich assortment of crop patterns and diversified cultivation managements, strictly associated with higher biodiversity degrees, preserving and attracting wild species, both animals and plants. Finally, lower ratings were assigned to other biotope categories considered of poorer agroecological relevance, being artificial habitats, or habitats frequently subjected to human disturbance, or in any case habitats difficult to correlate with pastoral use, although natural or semi-natural.

Selected fractions of the original sheep track network

Figure 5 represents the outcome of the overall analytical procedure. The results obtained consist in the selection and location on the map of those areas characterized by the highest agroecological value within the sheep track network of the Apulia region (identified as "red" colored spots on the map). The geographical distribution of these areas appears self-evident and leads to make further assessment about the most involved sub-regions as well as about the most represented biotope categories (see the following sub-sections).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_69777000
© 2018, ALÖKI Kft., Budapest, Hungary

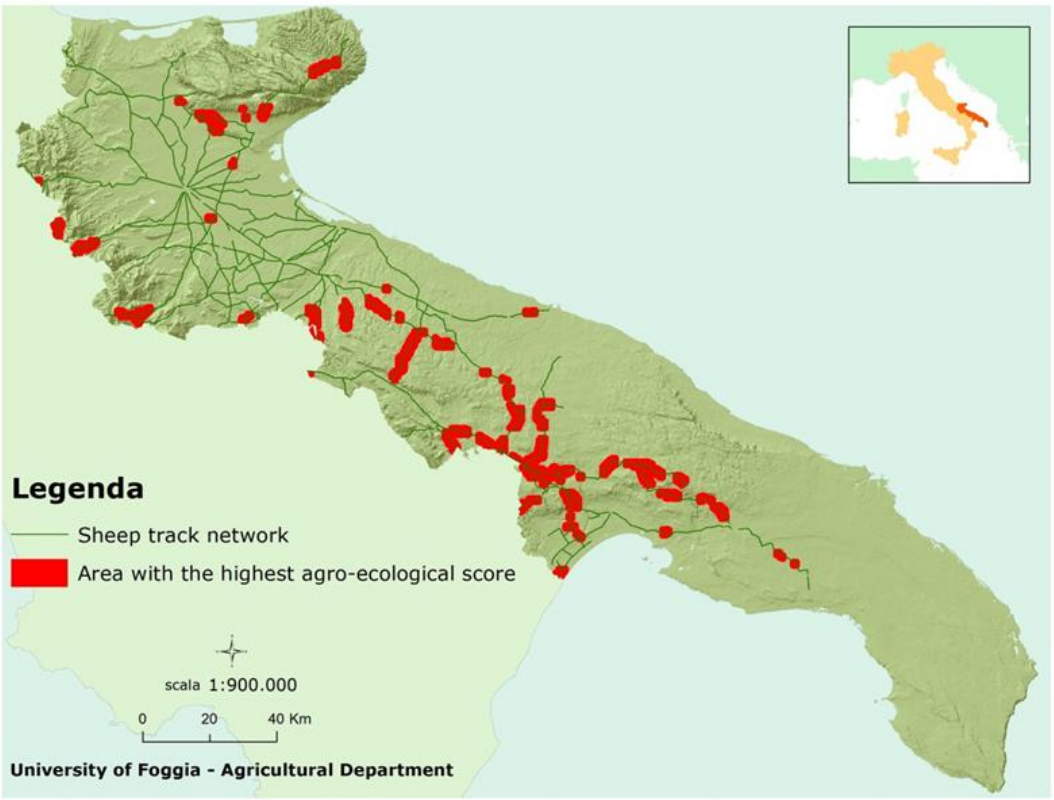

Figure 5. *Outcome of the planning analysis. Geographical dislocation of the selected portions of the sheep track network of the Apulia region credited with the highest agroecological score*

Considering the total historical sheep track network in the region, approximately 51% of the pertaining areas were excluded from the original system due to irreversible impairments and loss of physical integrity of the paths. Approximately, another 38% was discarded considering that these areas showed lower agroecological value (below the upper quintile assumed as benchmark). Therefore, the remaining 11% is the relative amount of the original network that was considered deserving specific attention through protective policies and development strategies. From about 350 thousand hectares originally assigned to the network, roughly 170 thousand hectares are still functional and clearly detectable, while 40 thousand hectares are the surfaces in the best agroecological conditions (totals reported in *Table 1*).

Surface breakdown by sub-regions

Table 1 reports the absolute and relative surface coverage of the sheep track network by sub-regions. Column TA1 accounts for the total area pertaining to the buffer zone considering the historical sheep track network, while column TA2 reports its breakdown percentages. Column RA1 offers the remaining areas of the buffer zone after the exclusion of the impaired and degraded lands that showed overlapping stretches with the road network (highways and main national roads), while Column RA2 reports its breakdown percentages. Finally, Column SA1 represents the selected areas of the buffer zone, i.e. those lands belonging to the class with the highest agroecological score, while Column SA2 reports its breakdown percentages.

Arco Jonico Tarantino	A8	34,604	9.79	16,542	9.54	4,849	12.07
Campagna brindisina	A9	5,834	1.65	3,336	1.92	9	0.02
Tavoliere Salentino	A10	2,708	0.77	1,661	0.96	265	0.66
Salento delle Serre	A11	-	-	-	-	-	-
Total (Apulia Region)		**353,358**	**100.00**	**173,420**	**100.00**	**40,180**	**100.00**

With reference to the historical areas of the network, about 40% of the overall buffer area falled within Tavoliere (*Table 1,* A2). Only other three sub-regions showed quite high percentages, approximately in the range 9-11%, i.e. Alta Murgia, Puglia Centrale and Arco Jonico Tarantino. About the remaining not degraded areas of the network (*Table 1,* RA2), Tavoliere significantly decreased its surface contribution to approximately 38% of the total, while Alta Murgia increased its contribution reaching about 13%; approximately the same was observed considering Murgia dei Trulli, with a percentage that increased to 5%. Radically different are the percentages that marked the best agroecological areas of the network, i.e. those finally selected (*Table 1,* SA2). In this case, Tavoliere collapsed to 1% only, while Alta Murgia impressively increased its allocation to roughly 43%; quite remarkable are the percentages contributed by Murgia dei Trulli and Arco Jonico Tarantino (approximately 12%), together with Monti Dauni that reached the 10% of the total surface of the network. The most important transformation to be considered in comparing the sheep track initial condition (i.e. the historical network) with the final one (the selected agroecological network) is the drastic overturning in the surface contribution of Tavoliere and Alta Murgia. The former almost disappeared in its contribution, while the latter became unconditionally the most relevant. What was observed, indeed, is part of a wider "modernization" process also involving the transformation of the agricultural landscapes from several decades until now. Agricultural intensification and the expansion of built areas rarefied the agroecological zones of higher value in the plains (Tavoliere) and concentrated these residual but valuable agro-ecosystems in the inner areas of the region (Alta Murgia), more hilly and mountainous. These latter areas, mostly characterized by marginal agricultural systems, show still suitable conditions for the persistence of such extensive ecosystems. The same kind of transformation was observed also considering other internal and marginal sub-regions, such as Monti Dauni and Gargano, whose surface

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_69777000
© 2018, ALÖKI Kft., Budapest, Hungary

contribution has shown an increase from the initial condition (the historical network) to the final one (the selected network). Other two sub-regions showed similar surface fraction increases, i.e. Murgia dei Trulli and Arco Jonico Salentino, respectively.

Table 2 was derived from *Table 1,* but is useful to highlight other specific traits about the agricultural landscape dynamic and its transformation processes over the last decades. Having fixed equal to 100, in each sub-region, the total surface of the sheep track network, *Table 2* gives the share of "land losses" (Column LL) in consequence of degradation processes due to the road network entirely covering the sheep paths, together with the share of "land discarded" (Column LD) in consequence of agroecological impoverishment due to farmland intensification. The residual share, pertaining to the "land selected" (reported in Column LS), account for the relative extent of the sheep track network still in good ecological conditions (and therefore selected in the course of the planning procedure).

Two different dimensions of the comprehensive process of landscape deterioration were considered:

i) Land "consumption" (LL) related to human settlements and infrastructures (expansion of built-up area and road constructions, in particular), on the one hand;
ii) Degraded land (LD) due to over-exploitation for agricultural intensive use, on the other hand.

Table 2. *Shares of land surface pertaining to the sheep track network by sub-regions. The following classes are considered: buffer area losses due to road network overlapping (LL); buffer area discarded due to lower agroecological score (LD); buffer area selected because of higher agroecological conditions (LS)*

Apulian sub-regions	**Code**	**Land losses LL (%)**		**Land discarded LD (%)**		**Land selected LS (%)**	
Tavoliere	A3	53.96	*	45.72	*	0.32	
Ofanto	A4	53.86	*	41.35	*	4.79	
Puglia centrale	A5	52.30	*	39.63	*	8.07	
Alta Murgia	A6	43.11		13.51		43.38	*
Murgia dei trulli	A7	32.60		30.46		36.94	*
Monti Dauni	A1	47.06		34.32		18.62	*
Gargano	A2	55.57	*	26.99		17.44	*
Arco Jonico Tarantino	A8	52.20	*	33.79		14.01	
Campagna brindisina	A9	42.82		57.03	*	0.15	
Tavoliere Salentino	A10	38.65		51.56	*	9.79	
Salento delle Serre	A11	-		-		-	
Average (Apulia Region)		**47.21**		**37.44**		**15.35**	

Percentages marked by a star are higher than the average value of the class

The sub-regional areas of the network where the two landscape degradation typologies jointly occurred (both LL and LD), resulted in very limited percentages of areas still ecologically valuable to be selected (LS). This condition was detected in sub-regions such as Tavoliere (A3), Ofanto (A4) and Puglia Centrale (A5). It is worth

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_69777000
© 2018, ALÖKI Kft., Budapest, Hungary

noting that these sub-regions are flat areas marked by intensive agriculture and large and expanding urban centers. The opposite was shown in the case of Alta Murgia (A6) and Murgia dei trulli (A7), where the two degradation processes limitedly affected the agricultural landscape (neither LL, nor LD) or, their incidence was below the average regional value. Murgia, indeed, is one of the inner and marginal areas of the Apulia region, today largely included into a National Natural Park. The same trend, but somewhat lower, is observed also considering Monti Dauni (A1), another inner area of the Apulia region. This double effect explains the highest (in A6 and A7) and relatively high (in A1) surfaces selected at the end of the planning procedure in the mentioned sub-regions. Intermediate conditions also occurred, such as Gargano (A2) and Arco Jonico Tarantino (A8), marked by higher landscape degradation due to road infrastructures rather than agricultural intensification (LL, but not LD). Campagna Brindisina (A9) and Tavoliere Salentino (A10), conversely, showed a higher degradation level related to agriculture intensification coupled with a lower than average damage to the sheep track network due to road construction (not LL, but LD).

Surface breakdown by biotope categories

Considering the selected areas of the sheep track network (the areas represented as "red spots" in *Fig. 5*), the most abundant biotope category, in terms of covered surfaces, corresponds to "Complex cultivation patterns" (B7), accounting for 47% of the total considered network (*Table 3*). Far behind, that is to say much less represented than the former, are biotopes such as Tree crops (B6), about 18%, then followed by "Woods and forests" (B8), together with "Meadows and pastures" (B10), both around 15% of the total surface. The other biotope categories showed very limited diffusion and can be considered negligible in this discussion.

Table 3. *Biotope categories with codes, their corresponding surface coverage and percentage breakdown with respect to the total selected area*

Biotope categories	Code	Biotope areas (ha)	Biotope percentages (%)
Complex cultivation patterns	B7	18,937	47.13
Tree crops	B6	7,055	17.56
Woods and Forests	B8	6,232	15.51
Meadows and pastures	B10	5,986	14.90
Annual crops	B5	1,087	2.70
Bush and garrigue	B9	648	1.61
Riparian vegetation areas	B4	235	0.58
Total		**40,180**	**100.00**

The ranking process and the selection procedure assigned the maximum rating to "Meadows and pastures" (B10 = 1.00) as compared to other biotope categories (B8 = 0.46; B7 = 0.27; B6 = 0.16), in order to get the presence of these semi-natural ecosystems as much as possible, considering their strict relevance in association with transhumance. The supposed consequence was to include this biotope category, with all its inherent habitats, within the selected portion of the sheep track network, the one with the best agroecological value. The outcomes of the analysis were both unexpected and worrisome. B10, indeed, is much less represented in terms of surface, while agricultural

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

land use (B7 and B6) and forest cover (B8) are the most abundant biotope categories observed along the sheep track network, and specifically in that fraction of the network selected because of the best agroecological conditions. The presented data confirmed, from a different perspective, the well-known progressive trend in pasture rarefaction and forestry expansion, together with farmland. Considering farmland, however, the ecosystem quality is significantly increased due to the large surface fraction of "Complex cultivation patterns" (B7) as compared to "Tree crops" (B6) and "Annual crops" (B5).

Surface breakdown by sub-regions and biotope categories

Table 4 shows the percentage breakdown of the surfaces allocated to every biotope featuring within each sub-regions. These data arrangement allows an accurate characterization of the Apulia region, specifically concerning the "red spots" of higher agroecological value.

Table 4. *Breakdown of relative surface coverage allotted to every biotope category (Bi) within each sub-region (Ai). All the reported values are expressed in percentages*

Apulian sub-regions	Code	B4	B5	B6	B7	B8	B9	B10
Monti Dauni	A1	0.11	3.51	1.42	67.77	19.39	0.00	7.79
Gargano	A2	0.03	11.66	10.08	5.80	46.14	2.27	24.02
Tavoliere	A3	1.88	65.73	3.28	0.00	3.10	0.00	26.01
Ofanto	A4	11.29	13.81	21.03	26.90	0.44	0.36	26.17
Puglia Centrale	A5	0.00	0.00	64.48	20.92	1.67	0.67	12.26
Alta Murgia	A6	0.05	0.00	11.56	62.39	5.93	0.00	20.06
Murgia dei Trulli	A7	0.00	0.00	5.73	46.38	46.27	1.41	0.21
Arco Jonico Tarantino	A8	0.59	0.00	39.34	36.27	7.74	9.71	6.36
Campagna Brindisina	A9	0.00	0.00	60.05	0.00	0.00	0.00	39.95
Tavoliere Salentino	A10	0.00	0.00	51.77	5.96	0.00	0.00	42.27
Salento delle Serre	A11	0.00	0.00	0.00	0.00	0.00	0.00	0.00

The same double entry table (reported in *Table 4*) was also the matrix employed in performing a "factor analysis" based on variables correlations. The first two independent and uncorrelated factors were selected, considering that their corresponding eigenvalues were higher than 1. This multivariate procedure accounted for 60% of the total variance (F1 35% and F2 25%, respectively). The resulting "biplot" is shown in *Figure 6*.

Very clearly, Tavoliere (A3) is predominantly associated to Annual crops (B5), confirmed by the high percentage of B5 in A3 (62%) in *Table 4*. Alta Murgia (A6) and Monti Dauni (A1) are the territorial districts where Complex cultivation patterns (B7) is the dominant biotope (B7 > 60%). Murgia dei Trulli (A7) presents a hybrid condition, with a similar share of "Complex cultivation patterns" (B7), on one hand, and "Woods and forest" (B8), on the other one (B7 = B8 = 46%). Gargano (A2) is mainly characterized by a larger occurrence of "Woods and forest" (B8 = 46%). Puglia centrale (A5) is characterized by a considerable prevalence of "Tree crops" (B6 = 64%), while Arco Jonico Tarantino (A8) showed a remarkable combination between "Tree crops" (B6 = 39%) and "Bush and garrigue" (B9 = 10%), respectively. Campagna Brindisina

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

(A9) and Tavoliere Salentino (A10) are characterized by a combination of Tree crops (B6 = 52 and 60%, respectively) together with "Meadows and pasture" (B10 = 42 and 40%, respectively). Ofanto (A4) is strictly associated with "Riparian vegetation areas" (B4 = 11%), although shows a high incidence of "Complex cultivation pattern" (B7 = 27%) and "Meadows and pasture" (B10 = 26%). Lastly, Salento delle Serre does not present any significant portions of the sheep track network within its land.

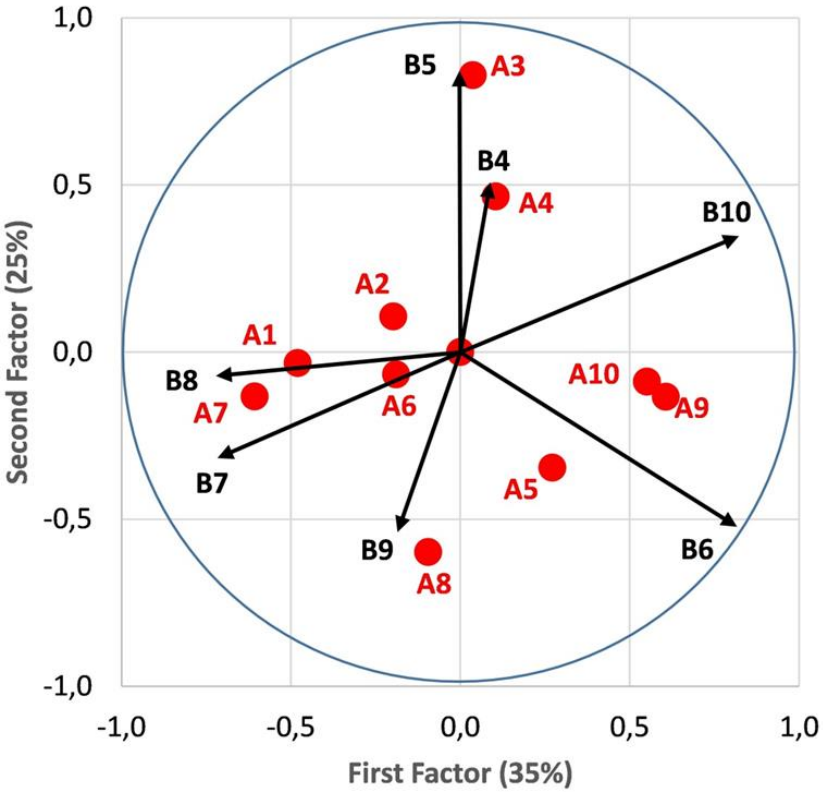

Figure 6. *Biplot of the factor analysis representing both the scores (points) and the factorial weights (arrows). Each point in the graph corresponds to one of the Apulian sub-regions (11 in total). A11 is not represented in the plot because scored zero (see Table 4)*

Discussion

This study performed an agroecological characterization of the sheep track landscape of the Apulian region and the identification of areas with higher conservation value was the subsequent goal.

Two overturning results came out from the analysis of the selected sheep track network: the first pertains to geography, while the second is related to biotopes.

1) The best conservation status of the sheep track network was detected in Alta Murgia (a hilly and marginal agricultural area), whereas sub-regions such as Tavoliere, but also Monti Dauni and Gargano, that were the geographical areas historically associated with transhumance and pastoralism are, today, much less involved in the conservation of these ancient sheep and shepherd paths. Unfortunately, in these latter sub-regions, large portions of the network are fragmented, hidden, covered, impaired and partially ruined by road construction and roadside infrastructures. Alternatively,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_69777000
© 2018, ALÖKI Kft., Budapest, Hungary

land conversion to intensive agricultural systems is the other factor affecting the ecological integrity of the lands along the sheep tracks.

2) Despite a higher agroecological rating was attributed to those biotope categories with prevailing semi-natural traits and in strict association with transhumance, the biotopes with the highest occurrence and the largest extents were those pertaining to agricultural systems and, in particular, "Complex cultivation patterns" (B7). Surprisingly, "Meadows and pastures" (B10) as well as "Bush and garrigue" (B9) are under-represented in terms of surface and outnumbered in terms of units by "Woods and forests" (B8) and "Tree crops" (B6).

Among agricultural systems, B7 should be considered very valuable in preserving a high degree of biodiversity, strongly connected to cultivation practices and strictly dependent on farming management, this latter being clearly based on extensive agricultural systems. The agricultural traits shown by B7 are very similar to "type 2" High Nature Value Farmland (HNVF), sensu Andersen et al. (2003). This type of HNVF, indeed, are characterized by a farming landscape with a large proportion of semi-natural vegetation (wood, forests, meadows and pastures) which insists in a rich mosaic of arable and/or tree crops. Such inherently biodiversity and rich farming systems, including livestock, arable, permanent crop or mixed farming, usually rely on traditional low intensity practices (Andersen et al., 2003; Beaufoy et al., 1994; EEA, 2004; Pedroli et al., 2007; Van Doorn and Elbersen, 2012). Low grazing densities of livestock, the use of fallow inserted in a sequence of arable crops, low inputs of fertilizing nutrients per unit of cultivated area, reduced use of agrochemicals and rainfed condition in arable and permanent crop systems are the main features (Beaufoy et al., 1994; Van Doorn and Elbersen, 2012). Such farming systems are referred to as HNVF since they contribute to maintain natural habitats and viable populations of wild species of the highest conservation value, together with the diversity of the land cover types (Beaufoy et al., 1994; Bignal and McCracken, 1996, 2000; Henle et al., 2008; Plieninger and Bieling, 2013).

The conservation of the sheep track landscapes is just one *tessera* of a complex mosaic that relates to the need of preserving the agricultural landscape as a whole. A socio-geographical double bound is observed: agricultural abandonment in marginal, hilly sub-regions (and the consequent forest expansion), on the one hand; agricultural intensification on flat, alluvial and fertile areas (and the consequent competition with urban expansion), on the other hand. They shall be considered the two sides of the same coin. The sheep track landscape is affected by exactly the same risks and the same threats.

The abandoning of pastures at higher altitudes has led to an expansion of woodland areas, and the loss of open spaces, which are important not only for the landscape itself, but also for biodiversity conservation. Conversely, the areas on the plain have been affected by urban expansion and the loss of traditional crop and inter-cropping, with a notable worsening of the landscape quality (Agnoletti et al., 2011).

With respect to agricultural abandonment, some authors suggest that forest expansion should be favored given their potential for slowing down soil erosion, improving water quality, and mitigate climate change through carbon sequestration (Rudel et al., 2005). Similarly, some authors judge land abandonment an opportunity for biodiversity conservation. While American ecologists and naturalists are commonly more focused on the conservation of post-abandonment ecosystems, European landscape ecologists generally consider land abandonment, and the consequent secondary naturalization

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_69777000
© 2018, ALÖKI Kft., Budapest, Hungary

process, mainly as a threat (Marull et al., 2015). The uncontrolled expansion of unmanaged forests leads to social and ecological negative impacts, causes damages to biodiversity (Marull et al., 2015) and increases wildfire hazard (Pausas et al., 2008).

Concerning agricultural intensification/extensification dynamics, depending on the cultivation management, farming systems may entail either a decrease or an increase in biological diversity (Marull et al., 2015). It is generally recognized, today, that farm systems may provide environmental services as well as productive goods. In this respect, ensuring both agricultural production and ecological services might trigger the well-known "sparing" vs. "sharing" opposite strategies (Marull et al., 2015):

i) The land-sparing approach is based on increasing agricultural intensification in some areas so as to devote the others to nature conservation and forest transition (Green et al., 2005; Matson and Vitousek, 2006); conversely:
ii) The land-sharing approach is based on a wildlife-friendly farming able to provide complex agroecological matrices connected with natural sites that jointly maintain high species richness at landscape level (Bengston et al., 2003; Marull et al., 2010; Perfecto and Vandermeer, 2010; Tscharntke et al., 2012).

This latter strategy (i.e. the land sharing approach) can be seen allied with the strategy of HNVF identification and protection; extensive farmland and semi-natural ecosystems are the most important indicators in selecting HNVF. Sound ecological sheep tracks can be considered the very first candidate to be identified as HVVF, thus providing very useful ecological services, including regulatory, support, cultural and aesthetic functions (Lomba et al., 2014), i.e. positive externalities and environmental benefits. Preserving at least some selected portions of the sheep tracks implies keeping farming systems that use traditional agricultural practices.

Another relevant dimension pertaining to the protection of the sheep track network is related to the cultural heritage it represents and the historical legacy that should be transmitted to future generations.

According to Oppermann et al. (2012), the characteristics of HNVF landscapes make them central to the European identity and culture. Following these characteristics, HNVF landscape are considered, at least throughout Europe, "cultural" landscape (Plieninger and Bieling, 2012). If this is true with respect to HNVF (and no doubt, it is), then, even more this applies to the sheep track landscapes.

Considering the historical and cultural values of the agricultural landscape, the Italian Ministry of Agricultural Food and Forestry Policies recently started a survey for the compilation of a National Catalogue of Historical Rural Landscapes. It aims at creating a list of landscapes having historical importance in terms of significance, integrity and vulnerability (www.reterurale.it). A valuable site ("Pasture of Northern Alta Murgia") linked to transhumance was identified in Apulia, characterized by the presence of large, open, semi-grazed pastures and small rural buildings, remains of the *tratturo* "Melfi-Castellaneta" that crossed the area. Another relevant example concerns the Molise region that applied the *tratturi* system to the UNESCO world heritage, considering them a combined work of nature and man, areas including outstanding value from the historical, aesthetic, ethnological and anthropological point of view.

One of the main problems with the conservation and valorization of the Italian rural landscapes, is the lack of perception of their importance, both among the public administrators and civil society. Anyway, their protection should not to be postponed any longer. Above all, what is needed is to promote their active but sustainable

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_69777000
© 2018, ALÖKI Kft., Budapest, Hungary

utilization, i.e. their original function as well as alternative forms of development. This means that the key to a sustainable future for semi-natural farmland (including the sheep tracks) is their socio-economic viability and the possibility to find a stable or growing market for local products and services. Nature, history, culture are important component of the product panel.

Conclusion

Maintaining the sheep track network areas and the ecosystem services they can offer is a way to preserve, synergistically, not only relevant biotopes but also a complex and long lasting cultural system, traditionally linked to transhumance. The analysis worked out in this paper was performed at regional scale, in the frame of a planning assignment by the Apulian Land Property Department. The work achieved its target: an agroecological characterization of the sheep track landscape connected to transhumance was carried out and the selection and location on the map of those portions of the network characterized by the highest agroecological value was thus obtained.

This work should be considered a preliminary, although essential step to promote further actions, mostly in terms of policy measures, to encourage the recovery and requalification of the sheep track system in a perspective of both integrated land management and rural development.

Acknowledgements. The Apulia Regional Administration - Land Property Department, supported this research. The authors are very grateful to the Regional Administration for the coordination of the activity performed by the "Regional Committee on the Sheep Track Network". Heartfelt thanks are also addressed to all the colleagues of the same Committee.

(Received 10th Jul 2018; accepted 20th Sep 2018)

Abstract. Vermicompost helps soil to retain water, regulate soil temperature and structure, and helps solve the soil's nutrient problem. The aim of our study was to compare chemical fertilization with different rates of vermicompost treatments in terms of growth properties, yield, and nutrient element content of spinach (*Spinacia oleracea* L.). We also determined the appropriate rate of vermicompost application for spinach. The experiment was repeated in two successive seasons with five treatments in the experiment: (1) control, (2) 1 ton vermicompost/ha, (3) 2 tons vermicompost/ha, (4) 3 tons vermicompost/ha, and (5) chemical fertilization. To assess the effect of the treatments in spinach, soil analysis (soil texture, pH, EC (Electrical Conductivity), percent of calcium carbonate, organic matter, and macro and micro elements), plant height and yield of spinach plants, and plant nutrient element analysis of spinach leaves were performed. Evaluation of the results indicated that vermicompost had positive impacts on the soil and the plant; the best treatment rate was 3 t/ha. This vermicompost application rate resulted in a 149% yield increase compared with the chemical fertilizer treatment.
Keywords: *earthworm, vermicompost, Spinacia oleracea, organic fertilizers, yield, nutrient elements content*

Introduction

The main objective of agricultural production is to provide food enough to meet requirements of population in good quality that will not harm health of human beings. For this purpose, it requires the development and application of new inputs and technologies. New agricultural technologies, including agrochemicals (fertilizers, pesticides, etc.) and intercropping, are being randomly used to improve the success of modern agriculture. Some of these technologies are causing our soils to become ill, environmental pollution, increased pest resistance in weeds, insects, and pathogens, and toxic residue in our food (Narwal, 2010). Fertilizing and irrigation are the main inputs in agricultural production. Prior to any kind of agricultural production, artificial fertilizer is applied to eliminate nutritional deficiencies in the soil. For an effective fertilizing process, improving the availability of the nutrients supplied by fertilizers is equally significant as the fertilizer treatment. Nowadays, human and public health and environmental protection is becoming more important and in this case, using of organic manure is getting higher. Organic matter has a fairly high importance on soil productivity and soil serves several functions. For this reason, farmers preserve resources to minimize the artificial inputs from outside the farm, and manage pests (weeds, insects, nematodes, and pathogens) via internal regulating mechanisms based on ecological principles and processes (Stinner and House, 1987). Organic agriculture is often proposed as a solution for producing food with reduced environmental impact

(Tilman, 1998; Scialabba and Hattam, 2002). Even though it constitutes less than 1% of global agricultural land and less than 5% of retail sales in most high-income countries (Willer and Lernoud, 2015), it represents one of the fastest growing food sectors (Seufert et al., 2017).

Vermicompost, the excreta of the earthworm, can improve the health and nutrients of the soil. Vermicompost helps manage waste as a valuable compost and biocontrol agent. In soil quality improvement, using vermicompost waste is better compared to traditional compost and landfill (Joshi et al., 2015). Vermicompost helps with soil water retention, regulation of soil temperature and structure, enhances the soil with nutrient elements, and increases the biomass and community structure of the microbial population (Vivas et al., 2009).

Vermicomposting consists of a simple biotechnological composting process. Here, certain earthworms were used to improve the waste conversion process to yield a better product. This mesophilic process used microorganisms and earthworms that are active between 10 and 32 °C, which are not ambient values; however, these are the values in moist organic material. This process is faster than composting. The reason for this is that the material passes through the earthworm's gut, then a transformation occurs that results with earthworm's castings (worm manure) that are rich in microbial activity and plant growth regulators and fortified with pest repellence attributes. Briefly, earthworms can transform garbage into "gold" (Gandhi et al., 1997; Julka, 2001). Vermicompost has 1.5–2.2% nitrogen (N), 1.8–2.2% phosphorus (P), and 1.0–1.5% potassium (K) on average. The organic carbon content is between 9.15 and 17.98%, and has micronutrients such as sodium (Na), calcium (Ca), zinc (Zn), sulphur (S), magnesium (Mg), and iron (Fe) (Adhikary, 2012).

Spinach (*Spinacia oleracea* L.) is a significant source of organominerals, such as vitamin B complex, ascorbic acid, vitamin A, and carotin (Bhattacharjee et al., 1998). Spinach is used in a variety of meals, such salad and with cooked meat and vegetable dishes (Molerock and Correll, 2008). Spinach best grows in cool climates, in an optimum temperature range of 7 and 24 °C. The minimum temperature for spinach seed germination is 2 °C (Molerock and Correll, 2008).

Crop yield quality and size are mostly affected by fertilization (Jablonska-Ceglarek and Rosa, 2001), so fertilizers with different mineral constituents create differences in the yield and nutritional quality of the crop. Nitrogen is the nutrient that most strongly affects nutritional quality differences in crops. Simultaneously treatment with organic and inorganic fertilizer has been found to be the most effective at improving crop production (Chaoui et al., 2003). Organic foods are often seen as healthier and more nutritious and better in quality compared with conventionally grown foods (Kansal et al., 1981).

Due to its short vegetation period and high market demand during winter, the amount of spinach production increases each year. Spinach is a vegetable whose leaves are eaten, thus the treatment of fertilizers and pesticides used during its growth requires special attention. This study was performed to determine the impacts of different rates of vermicompost application on soil properties, yield, and some growth properties and nutrient element contents in the leaves of spinach. Also, vermicompost treatments with and without artificial fertilizers were compared in terms of the properties mentioned above. We believe that this is a healthy and environment-friendly production technique for both the soil and crop, and especially in leafy vegetables such as spinach.

Materials and methods

Experiment location

The experiment was performed at the research station belonging to Turgut Ozal University, Agriculture Faculty, Department of Horticulture, Battalgazi, Malatya, Turkey (38°25'22" N and 38°21'30" E) in two consecutive years: spring (from March to May) and fall (from October to April) 2015. The study area is located 790 m above the sea level. The soil of the study area has an A-Bw–C1-C2 horizon with a soil temperature typical of mesic soil, an acidic moisture regime, and is classified as Aridisol Ordo, Orthid sub Ordo, and Camborthid big group. The soils in the experimental area were clean with no pesticide residues as no planting had occurred in the experimental area for a long time. For the second growing period in the experiment, a location that was not cultivated in the first year was used. Soil analyses were performed both prior to seed sowing (no treatment) and also after harvesting for V300 (3 tons vermicompost/ha) treatment in the first (spring) season.

Plant material

As plant material, the Sprinter F_1 spinach cultivar with high market quality, flat leaf surface, wide oval shape, bright green color, bump foliar, medium stem with high yield potential, and fast growth was used in the experiment (*Fig. 1*).

Figure 1. *Sprinter F_1 is spinach cultivar that used in the experiment*

Experimental layout

In spring 2015, two months elapsed from sowing the spinach seeds to the harvest time; the time elapsed in fall was around six months. In this study, the experiment was repeated in two successive seasons: the first experiment covered the spring season from March 19 to May 14, 2015, for a total of 56 days, and the second experiment covered the autumn-winter-early spring seasons from October 8, 2015 to April 17, 2016, for a total of 192 days. The Malatya climate data during the spinach growing season in the field are provided in *Table 1*.

Table 1. *Average climate data in Malatya, Turkey during the 2015 and 2016 growing season*

	October	November	December	January	February	March	April	May	June
Average temperature (°C)	15.4	7.8	2.0	−0.4	1.4	6.7	13.0	18.1	23.2
Average highest temperature (°C)	21.3	12.5	5.4	3.1	5.3	11.5	18.3	23.9	29.5
Average lowest temperature (°C)	9.8	3.9	−0.9	−3.4	−2.2	2.1	7.5	11.9	16.1
Average sun bathing time (hour)	7.3	5.2	3.1	3.2	4.2	5.4	7.2	9.2	11.4
Average rainy days	6.7	8.6	10.8	10.9	10.7	11.0	10.7	10.0	4.7
Monthly total rainfall amount (mm)	35.9	42.0	39.9	42.1	40.7	48.9	54.7	44.5	17.1

Experimental design

The experiment had a random block design with five treatments and three replications. For each replication, treatment size was 5 × 5 m = 25 m^2 and the total area used in the experiment excluding edge effects was 375 m^2. Since the experimental area is small, spinach seeds were planted by spreading, and the space between the rows and over rows was 30 cm and 2–3 cm, respectively, by rarefying the plants after emergence. Seeding density was 375 g seed in each area (10 kg per ha).

Fertilizer treatments in the experiment were as follows: (1) control without fertilizer (WF), (2) 1 ton (1000 kg) vermicompost/ha (V100), (3) 2 tons (2000 kg) vermicompost/ha (V200), (4) 3 tons (3000 kg) vermicompost/ha (V300), and (5) chemical fertilization (CF). The CF treatment included a mixture of pure N 1 kg/ha, 1 kg/ha phosphorus (P_2O_5), and 1.2 kg/ha potassium (K_2O), by calculating chemical fertilizers (Şalk et al., 2008). Vermicompost was produced in our faculty and is not commercial. After the production, pre-experiments were carried out to determine the dose in pepper, tomatoes, lettuce and spinach growing. In the results of spinach; we were not found significant difference between 3 tons of vermicompost treatment per hectare and 4 tons of vermicompost treatment per hectare in terms of plant growth and yield. For this reason, we preferred 3 tons of vermicompost/ha dose at the highest level in vermicompost treatments in this study.

In the spring growing period (Experiment 1), fertilizer treatments were applied into the soil two days prior to sowing as base fertilizer. In the fall growing period (Experiment 2), fertilization was performed in two parts: the first treatment was two days before sowing and the second treatment occurred during the first week of March after the cold winter days. Vermicompost was applied in solid form at the same time as chemical fertilization. In spring, all treatments were applied before sowing once as base fertilizer and in the fall season, it was split into parts: half prior to planting and the rest in the first week of March.

Vermicompost preparation

In the experiment, solid vermicompost produced at Turgut Ozal University was used. Vermicompost was produced by *Eisenia foetida* worms called Red California worms. We also used farm manure. We placed the worms inside the farm manure. Vermicomposting is a mesophilic process where the farm manure passes through the earthworm gut, and changes the physical and chemical structures of the farm manure occurs through this process, which results in earthworm castings (worm manure). The worm gut activity is similar to a small composting tube that mixes conditions and inoculates residues (Abbot and Parker, 1981). A synergistic relationship exists between moisture, pH, and microbial populations in the gut, creating an excellent byproduct appears (Becker, 1991). Every day, worms swallow large soil amounts that have organic substances (germs, plants, and animal debris). They then grind these in their gizzard and digest them in intestine with the help of enzymes (Scheu, 1987). Then, solid forms of vermicompost were applied to the spinach-growing soil. The properties of vermicompost used in the experiment are outlined in *Table 2*.

Table 2. *Some selected physical and chemical properties of the vermicompost used in the experiment (Durak et al., 2017)*

Property	Value
pH	8.89
$CaCO_3$	11.30%
Organic matter	55%
EC	0.009 mmhos /cm
Total nitrogen	2.55%
P (combustion)	9376.46 ppm
P (Olsen method-plant available phosphorous)	2193 ppm
K (Dry combustion method)	11263.10 ppm
K (Soluble in ammonium acetate)	4635 ppm
Ca (Combustion method)	24366.60 ppm
Ca (Soluble in ammonium acetate)	2072.25 ppm
Mg (Dry combustion)	4894.80 ppm
Fe (Dry combustion)	3797.45 ppm
Mn (Dry combustion)	275.08 ppm
Zn (Dry combustion)	94.95 ppm

Soil analyses

Soil analyses were performed both prior to planting and after harvesting. Soil texture analyses was performed according to the Bouyoucos hydrometer method (Gee and Bauder, 1986). pH and electrical conductivity (EC) were measured in soil water solution (1:2.5) using a pH meter with glass electrode and EC meter, respectively (Richards, 1954). Calcium carbonate ($CaCO_3$) (%) was measured using a Scheibler Calcimeter (Allison and Moodie, 1965). Soil organic matter was measured according to the modified Walkley-Black method with the soil available in terms of phosphorous (mg kg^{-1}) by measuring P in the extracts after $NaHCO_3$ extraction using a spectrometer (Olsen and Dean, 1965). Extractable potassium (mg 100 g^{-1}) was determined in a flame

© 2018, ALÖKI Kft., Budapest, Hungary

photometer in the extracts obtained after soils were shaken and centrifuged with 1 N (Normality) ammonium acetate three times (Knudsen et al., 1982). Total and extractable Fe, Zn, Cu, and Mn (mg kg^{-1}) in the extracts were determined by shaking soil HNO_3 and HCI mixtures (Baker and Amacher, 1982) and diethylenetriaminepentaacetic acid (DTPA) solution using an Atomic Adsorption Spectrometer and filtered using Whatman 42 filter paper (Lindsay and Norvell, 1978).

Plant analyses and measurements

Plant heights of 10 randomly selected plants from each replicate were measured and averaged. The roots of the spinach were separated from the aboveground biomass when determining fresh matter yield. For yield measurements, plants at harvesting time were harvested with their roots and weighed after roots were washed and separated from the aboveground biomass. The final yields were obtained as kg m^{-2}. For the analyses of the nutrients in plant leaves, 10 mature leaves were randomly selected from each replication and were first washed with tap water, later with pure water, and left for air drying. Dried leaves were grinded in a mill and prepared for analyses (Kacar, 1995; Kacar and Inal, 2008).

For nitrogen analyses, a modified Kjeldahl method was used (Kacar, 1995; Kacar and Inal, 2008). Phosphorous, in dried and grinded plant samples, was measured in the extracts prepared according to dry combustion. P in the extracts was determined with the Vanado Molibdo Phosphoric Yellow Color method using a spectrophotometer. For measurement of K content, a flame photometer was used to measure K in the extracts obtained by extracting the plants burned in ash furnace using 3 N HCI as previously described (Plank, 1992). Fe, Mn, Mg, and Zn contents in the plant were determined using an Atomic Adsorption Spectrometer after the plants were burnt according to the dry combustion method (Kacar, 1995; Kacar and Inal, 2008; Karaman et al., 2012).

Data analyses

Experiments were performed over two successive seasons according to a randomized block design with three replications. The data obtained each season were subjected to analysis of variance (ANOVA) using the SPSS statistical program (SPSS version 20). The data were subjected to factorial analysis of variance, and means were separated by a Duncan's Post Hoc Test with a 5% level of significance ($p < 0.05$).

There were no significant interactions and differences between two growing season; therefore, the data belongs to Experiment 1 and Experiment 2 were pooled. Accordingly, the results have not presented separately.

Results

The results of both soil and also plant analyses in two successive growing seasons (spring and fall growing period) were very close to each other. For this reason, the results presented in the study were obtained by averaging the values of both.

Soil analyses results

The results of soil analyses performed both prior to sowing (no treatment) and after harvesting in V300 treatment area (3 tons/ha) are presented in *Table 3*.

BS: Before sowing (no treatment); AH: After harvesting

Differences in the results of the analyses performed in soil samples obtained before planting and after harvesting were observed and pH decreased within the short growing period. Similarly, a decline was observed in salt content. Due to plant uptake, potassium and phosphorous contents of the soils decreased whereas organic matter levels increased (*Table 3*).

Plant height and yield production of spinach

We observed that spinach height and yield were better in the vermicompost treatments compared with both the control and chemical fertilizer treatments (*Figs. 2* and *3*). Total spinach yield was statistically different at a $p < 0.01$ significance level in V200 and V300 vermicompost treatments compared with the control (*Fig. 3*). According to the evaluation of plant heights, V300 treatment was found statistically different at the $p < 0.05$ significance level (*Fig. 2*). V300 treatment had higher values recorded than other treatments.

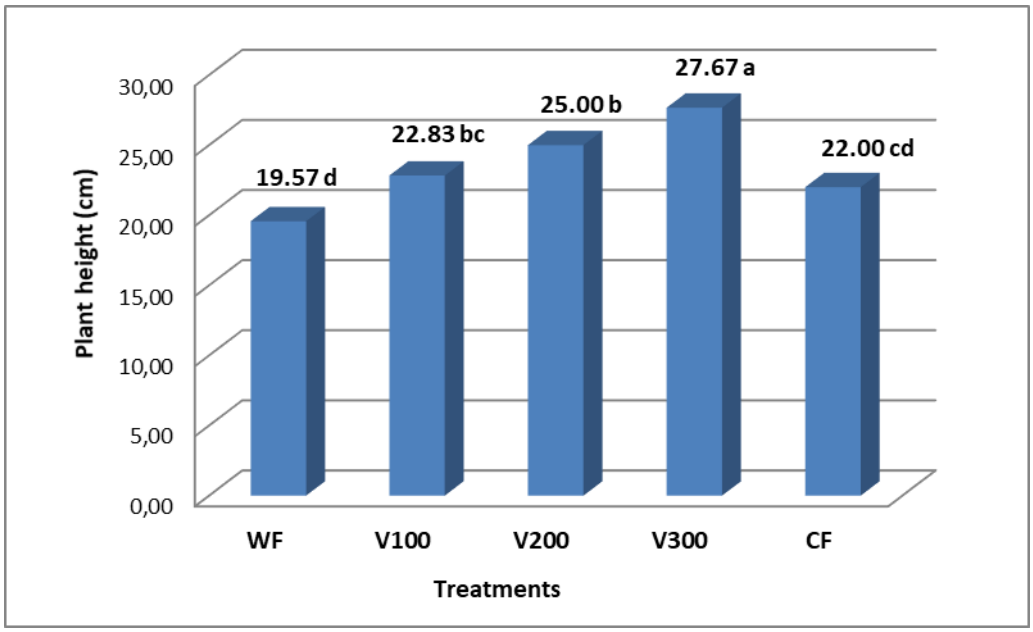

Figure 2. *Average plant heights of the control treated with chemical fertilizer and vermicompost at different application rates. The means followed by different letters are significantly different ($p < 0.05$). WF: control without fertilizer, V100: 1 ton vermicompost/ha, V200: 2 tons vermicompost/ha, V300: 3 tons vermicompost/ha, and CF: chemical fertilizer*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

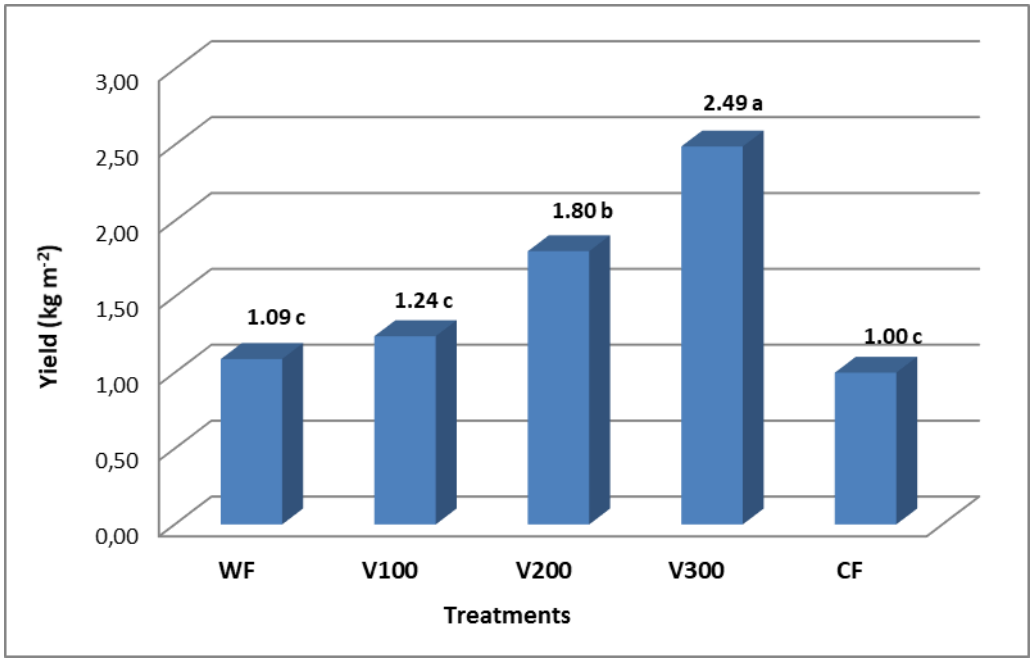

Figure 3. *Crop yields of vermicompost and chemical fertilizer at different rates and control areas. The means followed by different letters are significantly different ($p < 0.01$). WF: control without fertilizer, V100: 1 ton vermicompost/ha, V200: 2 tons vermicompost/ha, V300: 3 tons vermicompost/ha, and CF: chemical fertilizer*

The highest yield was obtained with the V300 treatment followed by the V200 treatment. The yields obtained with V100, CF, and WF treatments were closer to each other, and therefore, they were grouped together (*Fig. 3*).

Nutrient contents of plant leaves

As seen in *Table 4,* all nutrients except Fe were within the adequate limits for spinach. The main reasons for the high Fe content were that the experimental area had not been used for agriculture for a long time, and the higher Fe uptakes from vermicompost. In terms of N content, no difference was observed among the treatments. The lowest nitrogen content was recorded in the controls with no fertilizer treatment. In statistical evaluation, the V100 treatment was grouped with the treatment with no fertilizer. The highest nitrogen content was determined in the chemical fertilizer treatment areas, followed by the V300 then V200 treatments.

P content ranged between 0.23 and 0.36%. The lowest P content was recorded in the treatments with no fertilizer, whereas the values in other treatments were found close to each other. There were no statistically significant differences among treatments.

The K content of the leaves ranged between 2.12 and 6.03%. These differences were found to be statistically significant. The lowest K content was found in the treatments with no fertilizer, whereas the highest values were determined in the treatments where only chemical fertilizers were applied. V100 treatment was grouped with the WF treatment. V200 and V300 treatments were also grouped together.

Ca content of different fertilizer treatments were not found to be statistically significant and they ranged between 0.68 and 0.81% in the study.

Table 4. *Average nutrient contents of plant leaves treated with Vermicompost, chemical fertilizer at different doses and the controls*

Treatments	N (%)	P (%)	K (%)	Ca (%)	Mg (%)	Fe (ppm)	Mn (ppm)	Zn (ppm)	Cu (ppm)
WF	2.76 c	0.23	2.12 b	0.68	0.49 b	201.3 c	42.5	23.9	5.6
V100	3.28 c	0.32	3.21 b	0.80	0.57 ab	434.9 b	48.9	40.2	5.8
V200	4.01 b	0.36	4.77 ab	0.78	0.75 a	561.5 a	64.5	45.6	6.9
V300	4.86 ab	0.36	4.97 ab	0.81	0.79 a	534.3 a	68.2	53.8	7.3
CF	4.93 a	0.32	6.03 a	0.76	0.65 a	496.4 a	58.7	44.4	7.5
Adequate range for spinach	4.0–6.0	0.3–0.6	5.0–8.0	0.7–1.2	0.6–1.0	60–200	30–250	25–100	5–25

The means in the columns followed by different letters are significantly different ($p < 0.05$). WF: control without fertilizer, V100: 1 ton vermicompost/ha, V200: 2 tons vermicompost/ha, V300: 3 tons vermicompost/ha, and CF: chemical fertilizer

According to nutrient analyses results of the leaves, the Mg content of the leaves differed among fertilizer treatments and these differences were statistically significant. The highest Mg content (0.79%) was found in V300 treatment, followed by V200 and CF (0.75–0.65%), and these three treatments were grouped together. The lowest Mg content (0.49%) was determined in the WF treatment, whereas the V100 treatment with 0.57% was the intermediate group.

The evaluation of the results of the micronutrients in spinach leaves showed that the V300 and V200 treatments provided better results than other treatments. Among the micronutrients, the Fe content impacted the micronutrients significantly ($p < 0.05$) in the treatments. Fe content was the highest in the V200, V300, and CF treatments followed by the V100 treatment, whereas the lowest values were recorded in the WF treatment. In the spinach leaves, the Mn levels ranged between 42.5 and 68.2 ppm, Zn content from 23.9 to 53.8 ppm, and Cu content from 5.6 to 7.5 ppm, depending on different treatments. Differences in the contents of the Mn, Zn, and Cu were not found to be statistically significant ($p < 0.05$).

Discussion

Vermicompost treatment enhanced the quality parameters of the soil in this study. Castings slow-released nutrients that were ready for the plants. Castings include plant nutrients, which dissolve slowly instead of immediate nutrient leaching, as they are encased in a mucus membrane secreted by the worms. The product has excellent soil structure, porosity, aeration, and water retention capabilities, which may insulate plant roots against extreme temperature values, decrease erosion, and control weeds (Suhane, 2007). According to the results of the soil analysis in our study, the pH was reduced in the soil and the organic matter was increased by vermicompost application. Spinach plants had uptake potassium and phosphorus more with vermicompost treatments, so the amount of phosphorus and potassium in the soil was decreased.

Red worm castings have high humus content, which causes soil particles to be converted into clusters to form a channel for air by improving the capacity to retain water. When there are worms, the compacted soil is regenerated and the water

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_70017016
© 2018, ALÖKI Kft., Budapest, Hungary

penetration is enhanced at a rate of more than 50% (Ghabbour, 1973; Capowiez et al., 2009). In this study, vermicompost has provided nutrients to be better uptake by the spinach plant by increasing the proportion of humus in the soil. The humic acid in humus forms binding sites for plant nutrients like calcium, iron, potassium, sulfur, and phosphorus. Humic acid also enhances the plant growth although at a slower rate (Canellas et al., 2002), and is essential for plants from three aspects: (1) enabling the plant to extract nutrients from soil, (2) helping the plant to dissolve minerals that were not dissolved for delivering organic matter to plants for use, and (3) stimulating root growth. Even the chemical fertilizers are more effective when humus is present in the soil (Li and Li, 2010). Bacteria, enzymes, and remnants of plant materials not digested by worms exist in worm castings, which are actually biologically active mounds. The microbial activities of useful microorganisms in the castings are considerable, with rates 1–20 times greater than in normal soil (Edwards, 1995). Nitrogen-fixing and phosphate solubilizing bacteria, known as the actinomycetes and mycorrhizal fungi, are among useful soil microorganisms stimulated by earth worms (Scheu, 1987). Castings also slow-release nutrients ready for plants and include plant nutrients encased in mucus membranes (Edwards, 1995).

In this study, macro and micro nutrient contents of spinach leaves were found to be higher in vermicompost treatments than WF and CF treatments. The micro and macro nutrient contents of spinach in the areas treated with vermicompost were always higher compared with those treated with mineral components, which can be explained by the release and availability of the micronutrients after mineralization of organic materials. Additionally, microorganisms in the rhizosphere area provided by vermicompost treatment increased the availability of nutrients, such as N and K, by improving nitrogen fixation and biological solubilization of P (Mackey et al., 1982). Fe content was determined high when compared with reference values for spinach, which may be attributed to the fact that no agricultural activity had been performed in the study area.

According to the results of previous studies, vermicompost treatments were increased nutrient element contents in the leaves of plants. Pant et al. (2009) reported relatively higher micro nutrient (B, Zn, Fe, Mn, and Cu) content in the tissues of pak choi (*Brassica rapa*) in the areas treated with non-treated vermicompost tea than those treated with aerated vermicompost tea and vermicompost tea combined with microbial enhancer and controls. Vermicompost treatment increased nutrient content in different parts of other plants, such as N, P, K, Zn, Fe, Mn, and Cu content in geranium (*Pelargonium* species); average N, P, K, and Mg content of plant tissue of *Amaranthus* species; and N, P, K, and Ca content of groundnut (*Arachis hypogaea*) and marigold (*Tagetes*) plant; K, Zn, Ca, and Fe content in the stem and root tissues of Lilium plant; K and Ca content of marigold (*Tagetes*) plants; total N (%) of spinach; and P content in the leaves of maize (*Zea mays*) (Peyvast et al., 2007; Uma and Malathi, 2009; Shadanpour et al., 2011; Chand et al., 2011; Mycin et al., 2010; Gutie'rrez-Miceli et al., 2008; Moghadam et al., 2012). Uptake of P and K by African marigold (*Tagetes*) and uptake of K, Ca, and Mg by Setaria grass plants increased with vermicompost treatment (Jaworska and Kmiecik, 1999; Mackey et al., 1982). Increases in uptake and availability of nutrients were explained by improved soil environment and humic acid released after vermicompost treatment (Mycin et al., 2010; Stevenson, 1991; Nardi et al., 2002).

In our study, the reason for the improvement of soil properties and increase of nutrient element contents in the spinach leaves due to vermicompost treatments; it can be said that the increase of soil humus and microbial activity in vermicompost

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_70017016
© 2018, ALÖKI Kft., Budapest, Hungary

applications is the result of decrease of pH value. Hence, the plant height and yield of the plants in the vermicompost treatments were found to be higher than control and chemical treatments.

According to the results of this study, with the highest plant height values obtained in V300 treatment in mind, the treatments of V200, V100, CF, and WF followed these values, in decreasing order. The plant height results for V300 treatment were determined to be 29% higher than WF treatment and 20% higher than CF treatment.

In similar study results, vermicompost treatments were found to increase plant height. Peyvast et al. (2008) investigated the effect of four different application rates (0, 10, 20, and 30%) of vermicompost obtained from cattle dung on spinach (*Spinacia oleracea*) under greenhouse conditions. The highest and the lowest plant heights in spinach were obtained with the 10% and 0% vermicompost treatments, respectively, and the plant heights of 14.30 and 14.16 cm were obtained with 20% and 30% vermicompost treatments, respectively. Although the treatments of all three vermicompost rates compared to the control increased the plant heights, these increases were not statistically significant. In potato (*Solanum tuberosum*), the highest plant height was obtained through incorporating a mixture of vermicompost and 100% NPKS (chemical fertilizers) into soil (Alam et al., 2007). Taller plants in *Abelmoschus esculentus* were obtained with vermicompost prepared from *perithecium* compared to control (only soil) and soil treated with the recommended dose of chemical fertilizers (Vijaya et al., 2008). Crossandra (*Crossandra undulaefolia*) had higher plant heights when it was grown in pots treated with water and hyacinth vermicompost compared to when grown in the control pots and in pots treated with water hyacinth compost (Gajalakshmi and Abbasi, 2002). A six t/ha vermicompost treatment improved the plant height of eggplant (*Solanum melongena*) compared to control without vermicompost (Moraditochaee et al., 2011).

In some of the previous studies, the growth responses of plants in vermicompost was claimed to resemble hormone-induced activity, which is related to high nutrient levels, humic acid, and humate in vermicompost (Edwards and Burrows, 1988; Atiyeh et al., 2000a). A positive vermicompost effect includes stimulated seed germination in some plants like green gram (Karmegam et al., 1999), tomato (Atiyeh, 2000b; Zaller, 2007), petunia (Arancon et al., 2008), and pine trees (Lazcano et al., 2010). Also, vermicompost enhances vegetative growth by stimulating shoot and root development (Edwards et al., 2004) and the morphology of the seedling by increasing leaf area and root branching (Lazcano et al., 2009) Vermicompost has been demonstrated to stimulate plant flowering and increase the number and biomass of flowers (Arancon et al., 2008; Atiyeh et al., 2002) and increase fruit yield (Singh et al., 2008; Atiyeh et al., 2000b; Arancon et al., 2004a, b).

According to the results of this study, the highest yield was obtained in V300 treatment. The V300 treatment was followed by V200, V100, WF and CF respectively. The yield results for V300 treatment were determined to be 56% higher than WF treatment and 60% higher than CF treatment.

In previous similar studies, yield was determined higher in vermicompost treatments. Earlier research reported that vermicompost treatment increased the total yield of potato (Alam et al., 2007), two cultivars (Sultan and Storm) of cucumber (*Cucumis sativus*) (Azarmi et al., 2009; Singh et al., 2008), strawberry (*Fragaria X ananassa*) (Singh et al., 2008), *Abelmoschus esculentus* (Vijaya and Seethalakshmi, 2011), lettuce (*Lactuca sativa*) (Papathanasiou et al., 2012), and *Amaranthus* species (Uma and Malathi, 2009),

the fruit yield of eggplant (*Solanum melongena*) (Alam et al., 2007), in marketable yields of tomato (*Lycopersicum esculentum*) (Uma and Malathi, 2009), fruits of okra (*Abelmoschus esculentus*) (Ansari and Sukhraj, 2010), and increased the harvest index of crossandra (*C. undulaefolia*) (Gajalakshmi and Abbasi, 2002). In addition, vermicompost treatments improved the oil yields of geranium (*Pelargonium* species) (Chand et al., 2011) and *Matricaria chamomilla* (Hadi et al., 2011).

Conclusions

Ecological agriculture, which is synonymous with sustainable agriculture, improves the fertility of the soil and creates a secondary income source for farmers, while focusing on total food protection and on the farm–human ecosystem. Vermicompost has potential to be applied in ecological agriculture systems. We believe that plant growth, yield and soil properties are enhanced by the application of vermicompost given our study results. In this respect, vermicompost could be applied in the near future as an alternative agriculture supplement combined with inorganic fertilizers. Spinach (*Spinacia oleracea* L.) is a unique crop as a vegetable with a relatively short growing period with high yield potential. In the present study, vermicompost positively impacted spinach yield and other plant parameters, as well as soil organic matter, as supported by the results of soil analyses, and plant analyses and measurements. Evaluation of the results indicated that vermicompost had positive impacts on the soil and the plant. The best treatment application rate was 3 tons vermicompost/ha. The study results suggest that the use of vermicompost for commonly consumed vegetables would increase the parameters and future experiments should be conducted for other vegetable species.

Abstract. *Anoectochilus* genus is a precious Chinese medicinal plant. High temperature is among the critical factors that threatens plant growth in the *Anoectochilus* genus. The experiment was conducted at Key Laboratory of Crops Genetics and Improvement of Guangdong Province, Guangzhou, China. Two lab experiments were conducted to evaluate the high temperature tolerance of different *Anoectochilus* germplasm resource and the physiological responses of high-temperature-resistant and sensitive *Anoectochilus* to high temperature. Heat injury index, recovery index, soluble protein contents, proline content, malondialdehyde (MDA) content, relative electrical conductivity (REC), superoxide dismutase (SOD) activity, and catalase (CAT) activity were investigated. The results showed that, the recovery index was strongly negatively correlated with the heat injury index. The mean heat injury index at 6 h, 12 h, 24 h, 30 h and 36 h under high temperature were 5.17%, 16.90%, 39.96%, 53.70% and 70.61%, respectively. Five high-temperature-resistant species of *Anoectochilus* were selected. Compared with high-temperature-sensitive species of *Anoectochilus* germplasm, the high-temperature-resistant *Anoectochilus* germplasm had higher SOD activity, proline content and lower REC, CAT activity, MDA, and soluble protein content. REC, SOD activity and soluble protein content were strongly related to heat injury index. In conclusion, REC, SOD activity and soluble protein content are important attributes that could help to screen out the high temperature tolerant varieties of *Anoectochilus*.
Keywords: *Anoectochilus, high temperature stress, heat injury index, physiological indexes, enzymatic activity*

Introduction

Anoectochilus is an important medicinal plant species in China and recognized as ‘golden grass’ and/or ‘the king of medicine’ due to its high medicinal value. It has notable anti-inflammatory effects (Zhang et al., 2007; Du et al., 2008). *Anoectochilus* plants generally have substantial concentrations of polysaccharides, alkaloids, flavonoids, amino acids and organic acids etc. (Zheng et al., 2013; Shao et al., 2014). The extracts of *Anoectochilus* had been reported to cure diabetes, hypertension, tumor, nephritis, fever, snakebite, chest and abdominal pain etc. (Du et al., 2003; Fang et al., 2008). Therefore, *Anoectochilus* was endowed with high edible, medicinal as well as ornamental value.

The *Anoectochilus* species required cool, humid, low-light environment for its optimum growth. Generally, most of the *Anoectochilus* species were sensitive to high temperature. The optimum temperature for the growth of *Anoectochilus* was ranging from 18 °C to 25 °C, and ≥ 70% relative humidity whereas temperature over 30 °C inhibited the growth of *Anoectochilus*. So, it was important to enhance the heat resistance for the introduction and breeding of new *Anoectochilus* varieties. However, the high-temperature-resistance ability of the different *Anoectochilus* species are still unknown. Moreover, no study has yet been reported the evaluation of the high-temperature-resistance ability of the different *Anoectochilus* species.

How does the *Anoectochilus* respond under high temperature? Like other plants, the *Anoectochilus* plant might activate some physiological and biochemical responses to avoid high temperature damage (He et al., 2004). MDA, proline and soluble protein are important osmoregulator substances in plants under stress conditions. Enhancement in the activities of antioxidants such as superoxide dismutase (SOD) and catalase (CAT) improved plant stress tolerance. For example, Wang et al. (2018) indicated that amino acids and soluble proteins are important for Hard Fescue to resist heat stress. For lettuce seedlings, the malondialdehyde (MDA), proline and soluble sugar contents in leaf were associated with heat stress (Han et al., 2013). The activities of SOD, CAT and peroxidase (POD), as well as the contents of MDA in *Rhododendron lapponicum* leaves were assumed as key physiological indexes in response to heat stress (Li et al., 2018). Rivero et al. (2015) reported that high temperature stress on tomato plants would cause the increase of SOD whilst decrease in CAT activities. Zhang et al. (2017) suggested that *C. nitidissima* plants might have some level of tolerance to high temperature period that might be related to the growing period of the plants. Chen et al. (2016) showed that the leaves of gerbera cultivars had a phenotypic response to heat treatment, as a consequence of increased relative electrical conductivity (REC), decreased soluble protein, and accumulated MDA and proline in leaves. Tian et al. (2011) reported that the marigold cultivars increased SOD, POD and CAT activities, and increased MDA contents and REC in response to high temperature stress. To date, very few studies had been conducted to investigate the physiological responses of *Anoectochilus* under high-temperature stress. Therefore, present study was aimed to establish a method to evaluate high-temperature-resistance of *Anoectochilus* species by evaluating the heat injury index and recovery index of different *Anoectochilus* species, and to investigate the physiological responses of *Anoectochilus* under high-temperature stress.

Materials and methods

Plant materials and growth

Thirty-two *Anoectochilus* genus species were collected from different provinces of China (*Table 1*) by the Southern Medicine Research Group of Crop Research Institute, Guangdong Academy of Agricultural Sciences. The plant samples were grown under greenhouse conditions for 6 months. Uniform seedlings with 8~9 cm height, 3~4 leaves, and 2~3 healthy roots were selected. The seedlings were then transplanted to a 6 cm × 6 cm × 6 cm plastic planting container, 1 plant per container. For high temperature treatment, the container was filled with cultivation substrates (peat: vermiculite = 1:2 (V:V)).

Experiment 1: High temperature treatment for thirty-two Anoectochilus genus species

High temperature treatment stress was imposed at Key Laboratory of Crops Genetics and Improvement of Guangdong Province, Crop Research Institute of Guangdong Academy of Agricultural Sciences. The high temperature treatment processes were as follows: before high temperature treatment, all plants were grown in an artificial climate incubator with a day/night temperature of 25 °C /18 °C, light intensity of 2000 Lx 12 h day/night cycle, and relative humidity of 80% for 15 days. The plants were watered

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_70177031
© 2018, ALÖKI Kft., Budapest, Hungary

once per day at 20 ml per plant. Then, the plants were transferred to incubator with day/night temperature of 43 °C /38 °C, illumination intensity of 2000 Lx 12 h day/night cycle, and relative humidity of 80%. The heat injury index of different species of *Anoectochilus* were determined at 6 h, 12 h, 24 h, 30 h, and 36 h as described by Li et al. (2009). After that, all the plants were subjected to incubation with a day/night temperature of 25 °C /18 °C, light intensity of 2000 Lx 12 h day/night cycle, and relative humidity of 80% for 15 days and the recovery index was investigated according to Jia and Chen (2005). The heat injured plants were separated into five levels: level 0, no injured leaves, green; level 1, drooping leaves, leaves' color were normal; level 2, the tip of the leaves wilted; level 3, 50% of the leaves wilted; level 4, almost all the leaves wilted; level 5, the whole plant died. The calculation of heat injury index was according to the following formula: heat injury index = ∑(number of plant at different injury level × injury level) injury level / (the highest injury level × total number of plants) × 100%. For calculation of recovery index, the plants were separated into different levels: level 0, the whole plant died; level 1, stems kept erecting, dry leaves, plants were unable to recover; level 3, the whole plant recovered and grew well. The recovery index was calculated as the following formula: recovery index = ∑(number of plant at different recovery level × recovery level) injury level / (the highest recovery level × total number of plants) × 100%.

Experiment 2: Physiological responses of high-temperature-resistant and sensitive Anoectochilus

The fresh plant sample (5.0 g) of all the plant species was collected at 6 h, 12 h, 24 h, 30 h, and 36 h under high temperature treatment, soaked in liquid nitrogen for 1 min, and then immediately stored at -80 °C for the determination of physiological indexes. The physiological indexes, i.e. soluble protein contents, proline content, malondialdehyde (MDA) content, relative electrical conductivity (REC), and the activities of superoxide dismutase (SOD) and catalase (CAT) were determined to test the high-temperature-resistance and sensitivity of *Anoectochilus*.

Measurement of soluble protein contents

Soluble protein contents were estimated according to the methods devised by Bradford (1976) using G-250, the absorbance was read at 595 nm and the concentration was expressed as $mg \cdot g^{-1}$.

Determination of proline content

Proline contents were determined according to the method of Bates et al. (1973) by evaluating the absorbance of the red chromophore in the toluene fraction at 520 nm and the amount of proline was estimated by comparing with a standard curve and expressed as $\mu g \cdot g^{-1}$.

Determination of malondialdehyde (MDA) content

The malondialdehyde (MDA) content was measured by the method of Chen and Wang (2006). MDA reacted with thiobarbituric acid (TBA), the absorbance of the reaction solutions were recorded at 532 nm, 600 nm, and 450 nm. The final result of MDA was expressed as nmol·g.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_70177031
© 2018, ALÖKI Kft., Budapest, Hungary

Determination of relative electrical conductivity (REC)

The plant leaves were thoroughly washed with deionized water. The leaf sample was then put into a clean beaker with 30 ml of deionized water and kept under vacuum for 15 min. The electrical conductivity was measured and marked as EC1. The leaves were then heated in boiling water for 20 min and then cooled at room temperature. The electrical conductivity was investigated again and marked as EC2. The formula for the calculation of the relative electrical conductivity (REC) calculation was: REC = (EC1/EC2) × 100%.

Determination of superoxide dismutase (SOD) activity

The superoxide dismutase activity was measured by using Nitro blue tetrazolium (NBT) method, after the reaction, the color change was measured at 560 nm, and one unit of SOD activity was equal to the volume of extract needed to cause 50% inhibition of the color reaction. The enzyme activity was expressed as $U \cdot g^{-1}$ (Wang et al., 2009).

Determination of catalase (CAT) activity

Catalase activity was determined by the method of Wang et al. (2009), 50 μl of enzyme extract was added to the reaction solution system containing 1 ml 0.3% H_2O_2 and 1.95 ml H_2O, the absorbance change at 240 nm was recorded for calculating CAT activity. The enzyme activity was expressed as $U \cdot g^{-1}$.

Statistical analysis

The data were analyzed using statistical software SPSS V 18.1; the differences amongst means were separated by using least significant difference (LSD) test at 5% probability level. Microsoft Excel was used for graphical representation.

Results

Experiment 1

Heat injury index and recovery index

The heat injury index investigated at 6 h, 12 h, 24 h, 30 h and 36 h, under high temperature treatment and the recovery index at 15 d after high temperature treatment was shown in *Table 2*. The heat injury index in different species of *Anoectochilus* was different, a wide range of heat injury index was detected at 6 h (0. 00%- 15.33%), 12 h (0. 00%- 58.00%), 24 h (2.00%- 74.67%), 30 h (2.00- 78.00%) and 36 h (37.33-94.00%) under high temperature. The mean heat injury index at 6 h, 12 h, 24 h, 30 h and 36 h under high temperature were 5.17%, 16.90%, 39.96%, 53.70% and 70.61%, respectively. At 30 h of high temperature treatment, over 75% of the *Anoectochilus* species had a heat injury index higher than 50%. At 36 h of high temperature treatment, over 80% of the *Anoectochilus* species had a heat injury index higher than 60.00%. The recovery index at 15 d after recovery was ranging from 0.00% to 74.44%, with a mean of 23.85%. Over 80% of the *Anoectochilus* species had a recovery index lower than 40.00%. Overall, the *Anoectochilus* species, like NYJ2, NYJ6, NYJ14, NYJ21 and NYJ24 were high-temperature-resistant species of *Anoectochilus*, and others were high-temperature-sensitive species of *Anoectochilus*.

Relative electrical conductivity (REC)

Before high temperature treatment, the two species had similar levels of REC. With high temperature treatment, NYJ2 had lower REC than NYJ18. At 6 h, 12 h, 24 h, 30 h and 36 h under high temperature treatment, the REC was significantly higher than CK for NYJ2. For NYJ18, at 6 h under high temperature treatment, the REC level was slightly higher than CK, while at 12 h, 24 h, 30 h and 36 h under high temperature treatment, the REC increased rapidly and significantly and it was higher than CK (*Fig. 1*).

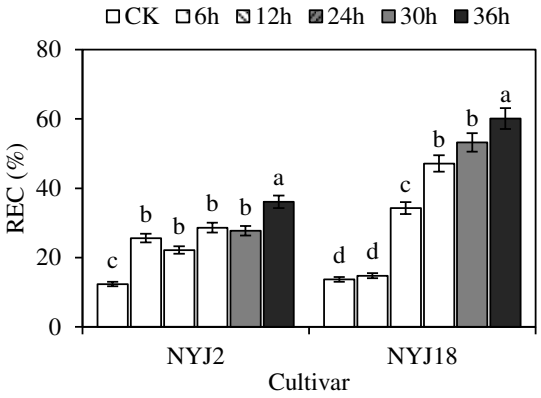

Figure 1. *Effect of high temperature stress on the relative electrical conductivity (REC) in high-temperature-resistant Anoectochilus germplasm (NYJ2) and high-temperature-sensitive Anoectochilus germplasm (NYJ18). Vertical bars with different lower case letters above are significantly different at P = 0.05 by LSD tests. Capped bars represent SD*

Superoxide dismutase (SOD) activity

For NYJ2, the SOD activity at 6 h, 12 h, 24 h and 30 h under high temperature treatment was significantly higher than CK. At 36 h under high temperature treatment, the SOD activity was similar to that in CK. For NYJ18, compared with CK, the SOD activity at 6 h, 12 h, 24 h and 36 h under high temperature treatment was significantly decreased. The SOD activity at 36 h under high temperature treatment was slightly decreased. The SOD activity in NYJ2 was higher than in NYJ18 (*Fig. 2*).

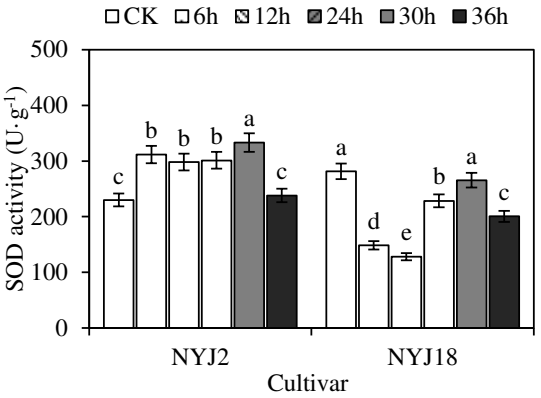

Figure 2. *Effect of high temperature stress on SOD activity in high-temperature-resistant Anoectochilus germplasm (NYJ2) and high-temperature-sensitive Anoectochilus germplasm (NYJ18). Vertical bars with different lower case letters above are significantly different at P = 0.05 by LSD tests. Capped bars represent SD*

Catalase (CAT) activity

The CAT activity in NYJ2 was lower than in NYJ18. The CAT activity at 6 h, 12 h under high temperature treatment was slightly decreased for NYJ2, whilst the CAT activity at 24 h, 30 h and 36 h under high temperature treatment was dramatically decreased. For NYJ18, short time high temperature treatment (6 h) did not affect CAT activity, but at 12 h, 24 h, 30 h, and 36 h high temperature treatment, the CAT activity was decreased linearly (*Fig. 3*).

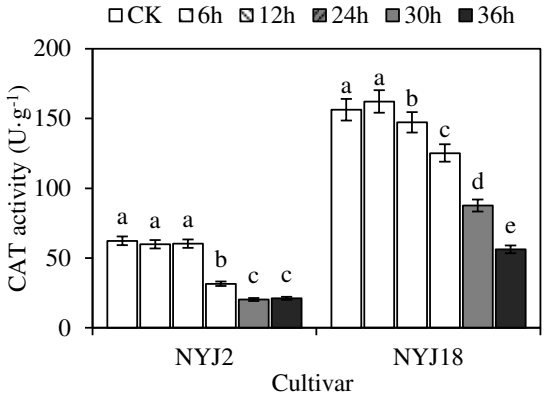

Figure 3. *Effect of high temperature stress on CAT activity in high-temperature-resistant Anoectochilus germplasm (NYJ2) and high-temperature-sensitive Anoectochilus germplasm (NYJ18). Vertical bars with different lower case letters above are significantly different at P = 0.05 by LSD tests. Capped bars represent SD*

Malondialdehyde (MDA) content

The MDA content in NYJ2 was lower than in NYJ18. As temperature increased, the MDA content in the plant was increased. For NYJ2, in the 6 h high temperature treatment the MDA content was slightly increased, in the 30 h high temperature treatment the MDA content reached a peak, then decreased in the 36 h high temperature treatment. For NYJ18, the MDA content increased gradually when high temperature treatment time increased (*Fig. 4*).

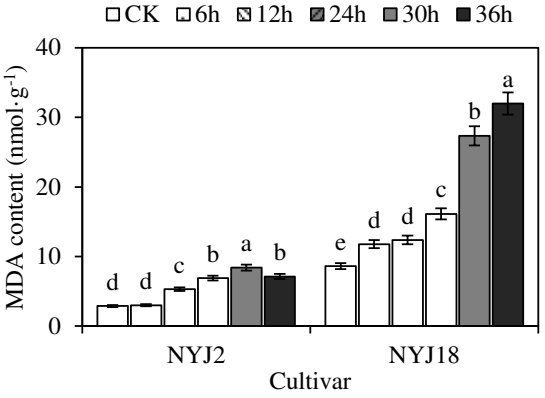

Figure 4. *Effect of high temperature stress on malondialdehyde (MDA) content in high-temperature-resistant Anoectochilus germplasm (NYJ2) and high-temperature-sensitive Anoectochilus germplasm (NYJ18). Vertical bars with different lower case letters above are significantly different at P = 0.05 by LSD tests. Capped bars represent SD*

Proline content

With increase in temperature, the proline content in NYJ2 increased gradually, and was significantly higher than CK. For NYJ18, the proline content was significantly decreased in the 6 h high temperature treatment only. At 12 h, 24 h 30 h, and 36 h under high temperature treatment, the proline content was substantially improved (*Fig. 5*).

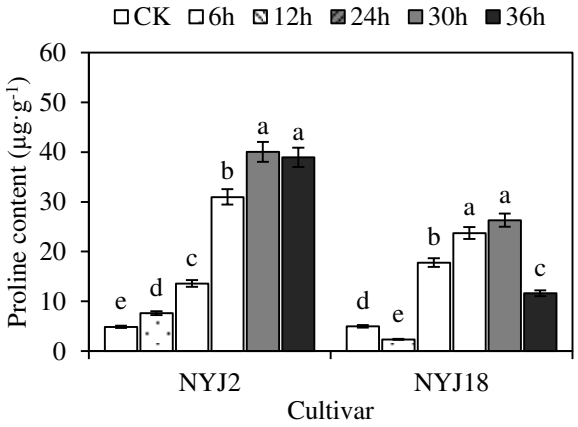

Figure 5. *Effect of high temperature stress on proline content in high-temperature-resistant Anoectochilus germplasm (NYJ2) and high-temperature-sensitive Anoectochilus germplasm (NYJ18). Vertical bars with different lower case letters above are significantly different at P = 0.05 by LSD tests. Capped bars represent SD*

Soluble protein content

Exposure of high temperature stress for short duration (6 h, 12 h and 24 h) did not significantly affect soluble protein content in NYJ2. At 30 h and 36 h high temperature treatment, the soluble protein content was significantly increased in NYJ2 whereas, for NYJ18, at 6 h high temperature treatment, the soluble protein content was decreased significantly. With increased duration of high temperature, the soluble protein contents were increased (*Fig. 6*).

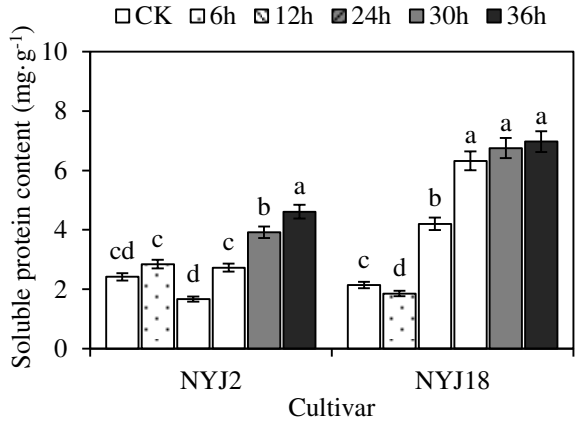

Figure 6. *Effect of high temperature stress on soluble protein content in high-temperature-resistant Anoectochilus germplasm (NYJ2) and high-temperature-sensitive Anoectochilus germplasm (NYJ18). Vertical bars with different lower case letters above are significantly different at P = 0.05 by LSD tests. Capped bars represent SD*

Correlation analysis

The recovery index showed a significant negative correlation relationship with heat injury index at 6 h (-0.7675**), 12 h (-0.6687**), 24 h (-0.8566**), 30 h (-0.8894**), and 36 h (-0.9291**), respectively (*Table 3*). The heat injury index was significantly associated with REC (0.9186**), SOD activity (0.8699**), and soluble protein content (0.9442**) for both high-temperature-resistant and sensitive *Anoectochilus* germplasm (*Table 4*). For high-temperature-resistant *Anoectochilus* germplasm (NYJ2), a significant positive correlation relationship between heat injury index and soluble protein content (0.8741*) was investigated (*Table 5*). For high-temperature-sensitive *Anoectochilus* germplasm (NYJ18), the heat injury index was significantly associated with REC (**0.9783****), MDA content (-0.8241*), and soluble protein content (**0.9695****) (*Table 6*).

Discussion

In this study, we applied the high temperature treatment method to evaluate the high-temperature-resistance of *Anoectochilus* species. In this method, the recovery index was strongly negatively correlated with heat injury indices for *Anoectochilus* species (*Table 3*). The mean heat injury index at 6 h, 12 h, 24 h, 30 h and 36 h under high temperature were 5.17%, 16.90, 39.96%, 53.70% and 70.61%, respectively. Over 80% of the *Anoectochilus* species were high-temperature-sensitive, five high-temperature-resistant species of *Anoectochilus* (NYJ2, NYJ6, NYJ14, NYJ21 and NYJ24) were identified (*Table 2*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

The REC and MDA content of the two species of *Anoectochilus* genus were apparently increased with the increase of high temperature stress. Han et al. (2013) indicated that high temperature could lead to increased membrane permeability and membrane lipid peroxidation. The REC increased as a consequence of increasing membrane permeability which led to extracellular electrolyte leakage. In our study, REC and MDA content of the high-temperature-sensitive NYJ18 increased more than that of high-temperature-resistant NYJ2.

In addition, when both high-temperature-resistant *Anoectochilus* germplasm resource (NYJ2) and high-temperature-sensitive *Anoectochilus* germplasm resource (NYJ18) were pooled together, the heat injury index significantly associated to REC (0.9186**). For high-temperature-sensitive *Anoectochilus* germplasm resource (NYJ18), the heat injury index significantly associated to REC (0.9783**) and MDA content (-0.8241*). It could be seen that the heat injury index of different breedings of *Anoectochilus* were significantly positively correlated with REC. The high-temperature-sensitive species had strong negative relation to MDA content (Peng et al., 2012). Therefore, by comparing the increase range of REC and MDA content of two species to identify their high-temperature-resistant ability, which was consistent with the conclusions of most research on other plants (Lin et al., 2014; Li et al., 2015).

For anti-enzyme activity, SOD could reduce superoxide radicals into hydrogen peroxide, while CAT could trigger the conversion of hydrogen peroxide into water and oxygen (Xu et al., 2006). In this study, the results showed that CAT activity in both species of *Anoectochilus* decreased under heat stress, and in high-temperature-sensitive NYJ18 it decreased more rapidly than in high temperature tolerant NYJ2. The SOD activity of the high-temperature-sensitive NYJ18 decreased rapidly at the beginning of stress treatment; while the SOD activity for high temperature tolerant NYJ2 increased. Moreover, when both high-temperature-resistant *Anoectochilus* germplasm resource (NYJ2) and high-temperature-sensitive *Anoectochilus* germplasm resource (NYJ18) were pooled together, the heat injury index significantly associated with SOD activity (0.8699**). SOD was resistant to membrane lipid peroxidation and maintenance of membrane structure integrity, and these were great significance (Lin et al., 2014). The changes of SOD and CAT activity with high temperature treatment time in this study were consistent with other researches (Jiang et al., 2008; Peng et al., 2012; Can et al., 2016).

Soluble protein and proline in leaves act as osmotic adjustment substances, and are beneficial to the maintenance of cell structure and function under stress. Previous study suggested that soluble protein and proline were active oxygen scavengers, which had a protective effect on plant cells (Can et al., 2016). With time and stress level increased, within a certain temperature range, the accumulation of free proline was positively correlated with the stress intensity (Liu et al., 2001; Sun et al., 2006). In this study, the proline content of the high-temperature-resistant NYJ2 was significantly higher than that of high-temperature-sensitive NYJ18 in the late stress stage and the proline content in the high-temperature-sensitive NYJ18 significantly decreased. In addition, the soluble protein content of NYJ2 and NYJ18 decreased in a certain range at the beginning of stress treatment (before 12 h), and then increased with the prolongation of stress time. The soluble protein content of high-temperature-resistant NYJ2 was significantly lower than that of high-temperature-sensitive NYJ18. Moreover, when we pooled both high-temperature-resistant *Anoectochilus* germplasm resource (NYJ2) and high-temperature-sensitive *Anoectochilus* germplasm resource (NYJ18) together, the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_70177031
© 2018, ALÖKI Kft., Budapest, Hungary

heat injury index significantly associated with soluble protein content (0.9442**). For high-temperature-resistant *Anoectochilus* germplasm resource (NYJ2), the heat injury index significantly associated with soluble protein content (0.8741*). For high-temperature-sensitive *Anoectochilus* germplasm resource (NYJ18), the heat injury index significantly associated with soluble protein content (0.9695**). Thus, soluble protein content might be important for identifying high-temperature-resistance of *Anoectochilus* species.

Conclusion

In conclusion, the recovery index was strongly negatively correlated with the heat injury index. The mean heat injury index at 6 h, 12 h, 24 h, 30 h and 36 h under high temperature were 5.17%, 16.90, 39.96%, 53.70% and 70.61%, respectively. Over 80% of the *Anoectochilus* species were high-temperature-sensitive, five high-temperature-resistant species of *Anoectochilus* (NYJ2, NYJ6, NYJ14, NYJ21 and NYJ24) were identified. Compared with high-temperature-sensitive species of *Anoectochilus* germplasm, the high-temperature-resistant *Anoectochilus* germplasm had higher SOD activity, proline content and lower REC, CAT activity, MDA, and soluble protein content. The heat injury index was significantly associated with REC, SOD activity, and soluble protein content for both high-temperature-resistant and sensitive *Anoectochilus* germplasm. For high-temperature-resistant *Anoectochilus* germplasm, heat injury index was significantly related to soluble protein content. For high-temperature-sensitive *Anoectochilus* germplasm, the heat injury index was significantly associated with REC, MDA content and soluble protein content. This study is important to understand the heat-resistant mechanism and the breeding of new varieties of *Anoectochilus*. Further studies on molecular basis regarding heat-resistance of *Anoectochilus* is needed.

Abstract. The aim of the paper is to study the effects of auxin and cytokinin, synthetic growth regulators, on selected parameters of hybrid alfalfa and red clover nutritional value. The experiment was conducted at the experimental facility of Siedlce University of Natural Sciences and Humanities between 2014 and 2016. In the autumn of 2014 plastic cylinders with no bottom, 40 cm high and with the diameter of 36 cm, were sunk 30 cm deep into the ground, with spacing of 0.8 × 0.8 m. They were filled with the soil of the anthropogenic order. Experimental factors: plant species - hybrid alfalfa and red clover, growth regulator - control (distilled water), indole-3-butric acid (auxin), 6-benzyloaminopuryn (cytokinin), indole-3-butric acid + 6-benzylaminopuryn. After plants in each cylinder were harvested their chemical analysis was carried out. Dry matter digestibility (%) and total protein, crude fibre concentration in dry matter (g kg^{-1}) was determined with the NIRS method using the Buchi NIRFlex N-500 spectrometer. The results of the multi-factor experiment with 24 experimental units were processed statistically using repeated measures analysis of variance. Growth regulators affected the content of protein and crude fibre in plant matter in different wayes. Cytokinin and a mixture of hormones reduced the concentration of protein relative to the control, but fibre share increased. Auxin had no significant effect on these features.
Keywords: *auxin, cytokinin, Fabaceae, total protein, crude fibre, dry mater digestibility*

Introduction

Auxin and cytokinin are important plant hormones regulating such important physiological processes as nutrient transport (Jenik and Barton, 2005). Additionally, according to many authors (Jenik and Barton, 2005; Cheng et al., 2006, 2007; Weijers et al., 2006), natural plant hormones take part in root elongation, which, in turn, affects the rate of nutrient absorption from the soil. It was confirmed by other studies that plant growth regulators containing synthetic hormones stimulate root system growth too, increasing nutrient uptake form the soil (Hwang and Sakakibara, 2006). Ali et al. (2008) reported that auxins are leading factors in this process, acting as signals informing about the state of physiological processes in cells and about growing demand for nutrients, this way attracting them. Thus, high quantities of soil nutrients are absorbed by the roots, and big amounts of them are transported from vegetative to generative parts.

According to Nowak and Wróbel (2010a, b) chemicals and mineral fertilizers can no longer be used in rising quantities to increase agricultural productivity, which is why there is a need to look for other substances affecting plant growth. The authors' opinion is that such growth regulators should increase production potential in unfavourable climatic and in other adverse conditions, not conducive to the growth and development of a particular plant species. Von Richthofen (2006) pointed out that those products would be very important in the case of *Fabaceae* plants, with their unstable growth and

© 2018, ALÖKI Kft., Budapest, Hungary

sensitivity to weather conditions. Among growth regulators there are synthetic plant hormones that have been used both in agriculture and horticulture for quite a few years (Czapla et al., 2005; Nowak and Wróbel, 2010a, b; Wierzbowska and Bowszys, 2008)

For economic and environmental reasons *Fabacea* plants like lucerne (*Medicago* x *varia* T. Martyn) and clover (*Trifolium pratense* L.) are worth considering for cultivation in larger areas. Those plants make it possible to limit mineral fertiliser use, and, besides, they contribute to activation and movement of many nutrients in the soil (Wilczek et al., 2006). Additionally, *Fabaceae* plants grown together with grass species as mixtures improve physical and chemical properties of the soil, positively affecting its structure, fertility, biological activity of microflora, and movement of nutrients from lower to upper layers (Gaweł and Żurek, 2003). Wild growing clover (*Trifolium pratense* L.) has been known for a long time, mainly as a medicinal plant (Booth et al., 2006). High content of polyphenols and isoflavones belonging to the group of phytoestrogens such as daidzein, genistein, formononetin and biochanin makes it an antioxidant plant (Surh et al., 2006). Present in *Fabaceae* plants Polyphenol compounds positively affect human health, for example, mitigating menopause symptoms, preventing development of cardiovascular disease, and lowering a risk of some cancer forms (Thompson et al., 2007). High-protein PX (protein-xanthophyll) concentrate is an alfalfa product which may become widely used in animal nutrition, while EFL (extract fleur lucerne) produced form concentrated alfalfa juice is used in human nutrition. For their yield to be high and to contain high protein content, plants used to produce PX should be grown in good conditions, without weeds. All chemical treatments should be applied according to the withdrawal period, to maintain high standards of health and safety (Plaza et al., 2003; Karwowska et al., 2010). Both of the above substances are produced by extracting proteins, macronutrients, and vitamins from alfalfa juice, with indigestible elements removed earlier (Brito et al., 2007).

The aim of the paper is to study the effects of auxin and cytokinin, synthetic growth regulators, on selected parameters of *Medicago* x *varia* T. Martyn and *Trifolium pratense* L. nutritional value. The purpose of the experiment was to assess the impact of indole-3-butyric acid (synthetic auxin), 6-benzyloaminopuryn (synthetic cytokinin), and their mixture on total protein and crude fibre content, and dry mater digestibility of selected plants.

Material and methods

Experimental conditions

The experiment was conducted at the experimental facility of Siedlce University of Natural Sciences and Humanities (52°10’03”N; 22°17’24”E; Poland) between 2014 and 2016. In the autumn of 2014 plastic cylinders with no bottom, 40 cm high and with the diameter of 36 cm, were sunk 30 cm deep into the ground, with spacing of 0.8 × 0.8 m. They were filled with the soil of the anthropogenic order, culture earth type, hortiolse subtype, and the granulometric composition of loamy sand. Before the experiment was set up, organic carbon (C_{org}) concentration in the soil was 13.50 g kg^{-1} DM, with total nitrogen concentration of 1.30 g kg^{-1} DM. The ratio of C:N was 10.4:1, and soil pH of 6.8 was close to neutral. The soil had high content of phosphorus and magnesium, while available forms of potassium were of medium quantities. Because of relatively high content of nutrients mineral fertilizers were not used.

Plastic sheeting was spread between the plants to prevent weeds from sprouting. Next, 10 seeds were planted into each cylinder. After germination, when seedlings had 3-10 leaves, three best looking plants were selected for further research, while the others were removed. In the growing seasons of 2015 and 2016 plants reached their full potential to be harvested three times when 30-40% alfalfa and clover plants were in the bloom stage. The experiment was set up in a split-plot design with three replications (*Fig. 1*).

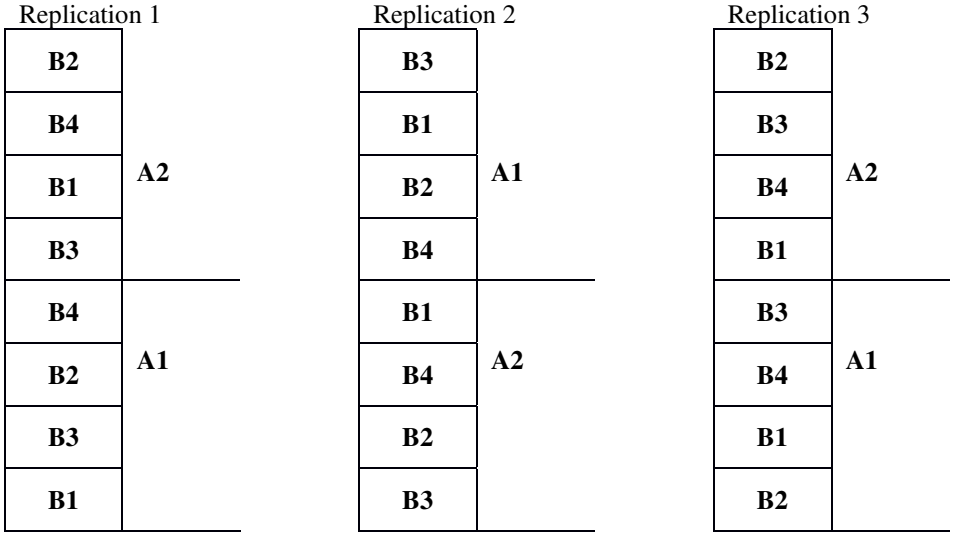

Figure 1. *The outlay of the experiment. Plants: A1 - hybrid alfalfa, A2 - red clover. Treatments: B1 - control, B2 - auxin; B3 - cytokinin, B4 - auxin + cytokinin*

Experimental factors:

- Plant species: hybrid alfalfa (*Medicago* x *varia* T. Martyn) var. Kometa and red clover (*Trifolium pratense* L.) var. Krynia;
- Growth regulator (applied as a spray): K – control (distilled water), A – indole-3-butric acid (IBA – synthetic auxin), C - 6-benzyloaminopuryn (BAP - synthetic cytokinin), AC - indole-3-butric acid + 6-benzylaminopuryn (IBA+BAP at a rate of 1:1).

Plants were treated twice during each growing cycle:

- Hybrid alfalfa – the first treatment after the development of the first internode, the other when the first flower buds were visible outside leaves;
- Red clover – the first treatment after the appearance of the first branches, the other when the first florescence emerged.

For the plants to be thoroughly covered, 0.2 dm^3 of spraying liquid was used per one cylinder with growth regulator concentration of 30 mg dm^{-3}. The control unit was treated with the same amount of distilled water.

After plants in each cylinder were harvested their chemical analysis was carried out. Dry matter digestibility (%) and total protein, crude fibre concentration in dry matter (g kg^{-1}) was determined with the NIRS method using the Buchi NIRFlex N-500 spectrometer.

Weather conditions

Sielianinov's hydrothermal coefficient was calculated in order to determine temporal variation of meteorological conditions and their effects on vegetation. The hydrothermal coefficient (K) was calculated on the basis of monthly sums of precipitation (P) and a sum of monthly air temperatures (t), using the following formula (Skowera and Puła, 2004):

$$K=P/0.1\sum t$$

Values of Selianinov's hydrothermal coefficient (K) are presented in *Table 1*. It was assumed that extreme conditions took place when its value was below 0.7 and above 2.5 (Skowera and Puła, 2004).

Table 1. *The value of Sielianinov's hydrothermal coefficient (K) in the growing season*

Years	Months						
	April	**May**	**June**	**July**	**August**	**September**	**October**
2014	1.36 (o)	1.87 (mw)	1.64 (mw)	0.59 (sd)	1.92 (mw)	0.64 (sd)	0.12 (ed)
2015	1.22 (md)	2.63 (sw)	0.87 (d)	1.08 (md)	0.18 (ed)	1.46 (o)	1.94 (mw)
2016	1.89 (mw)	0.82 (d)	1.02 (md)	2.15 (w)	1.05 (md)	0.36 (ed)	7.65 (ew)

$K \leq 0.4$ extreme drought (ed). $0.4 < K \leq 0.7$ severe drought (sd). $0.7 < K \leq 1.0$ drought (d). $1.0 < K \leq 1.3$ moderate drought (md). $1.3 < K \leq 1.6$ optimal (o). $1.6 < K \leq 2.0$ moderately wet (mw). $2.0 < K \leq 2.5$ wet (w). $2.5 < K \leq 3.0$ severely wet (sw). $K > 3.0$ extremely wet (ew)
2014 - the year in which the experiment was established, 2015 and 2016 - years of full use of experience

Optimal temperature and moisture conditions were only in April 2014 and in September 2015. In the remaining months of the growing periods they were not as favourable, varying from extremely dry in August 2015 to extremely wet in May 2014. Throughout the experiment the best conditions were at the beginning of each growing season. It can be concluded that the most difficult situation for plants was in 2015, when, apart from May and the end of the growing season, the weather ranged from moderately dry to extremely dry. The growing season of 2016 was characterized by a lack of a period with optimal conditions for plant growth. A high level of precipitation in July (K = 2.15) and drought in most of the remaining months hindered proper growth and development of plants.

Statistical analysis

The results of the multi-factor experiment with 24 experimental units were processed statistically using repeated measures analysis of variance; the same forage parameters were measured during each growing cycle. The Fisher-Snedecor test was done to determine the significance of the effect of experimental factors on the parameters. Tukey's test was used to compare differences between means at the $LSD_{0.05}$ significance level. All the calculations were made with the Statistica 13 – 2017 program. In tables

© 2018, ALÖKI Kft., Budapest, Hungary

homogenous groups are marked with letters. Means in lines and columns marked with the same letters are not significantly different.

Results and discussion

Total protein concentration (*Table 2*), an average for treatments, was in a statistically significant way higher in hybrid alfalfa (199 g kg^{-1}) than in red clover (176 g kg^{-1}). The concentration in red clover was lower but at close levels during both growing seasons; similar results were recorded by Ćwintal and Kościelecka (2005) in their experiment on diploid and tetraploid red clover agricultural value. Throughout the experiment protein concentration was the highest in the second year, also in alfalfa, with 203 g kg^{-1}.

Table 2. *The effect of growth regulators on total protein concentration (g kg^{-1} DM)*

K - control (distilled water), A - synthetic auxin, C - synthetic cytokinin, AC - synthetic auxin + synthetic cytokinin

Growth regulators diversified total protein concentration in dry matter. It was the highest in plants from units treated with auxin and from the control, with the identical value of 189 g kg^{-1}. Cytokinin and a mixture of auxin with cytokinin resulted in statistically significant reductions of protein content in the biomass. Average annual protein content values were similar throughout the experiment, but there were some differences between harvests (see below). Gaweł and Żurek (2003) studying protein content in three varieties of alfalfa demonstrated opposite results, with its decrease in consecutive years. Low total protein content in the present experiment resulted from longer growing cycles, which was a consequence of three harvests instead of four. Andrzejewska et al. (2013) found that delaying alfalfa harvest time from the beginning of the flower budding stage to the flowering stage resulted in a decrease in protein content by, on average, 20 g kg^{-1}. In addition, the authors discovered that this delay caused an increase in the amount of fibre.

In the present experiment there was some diversification of total protein content in plants caused by an interaction between the effect of a regulator and a harvest (*Table 3*). The highest average total protein content for both species was in the first harvest (202 g kg^{-1}), and it was lower in the second (188 g kg^{-1}) and third (172 g kg^{-1}).

The above differences were statistically significant. Those findings were comparable with results provided by Wilczek et al. (2005a). Wilczek et al. (2005a, b) examined selected varieties of hybrid alfalfa and alfalfa (*Medicago sativa* L.) and found total protein content in those plants at the level of 170-220 g kg^{-1} DM. In turn, Stochmal et al. (2000) identified general protein content in legume plants as190 g kg^{-1} DM.

Hybrid alfalfa had higher average concentration of crude fibre (239 g kg^{-1}) than red clover (*Table 4*). This concentration in red clover was in a statistically significant way similar in both growing seasons (2015 – 214 g kg^{-1}; 2016 – 216 g kg^{-1}). Crude fibre content was diversified by growth regulators, and it was on average the highest in forage from units treated with cytokinin (234 g kg^{-1}) and with a mixture of auxin and cytokinin (231 g kg^{-1}). In the control unit and in the one with auxin there was statistically significant reduction of crude fibre concentration, by, on average, 5.1%.

As an average for both species crude fibre content underwent substantial variation as a result of regulator and harvest interaction (*Table 5*). In the first and second harvests auxin caused a statistically significant decline in fibre concentration, to 207 and 231 g kg^{-1}. In the third harvest the regulator also caused a decrease, but this trend was not statistically significant. The experiment confirmed the view of differences in fibre content between consecutive harvests. Forage from the first and third harvests had a better nutritional value because fibre content was in a statistically significant way lower than in the second one. This tendency in consecutive harvests was confirmed by other authors (Wilczek et al., 2005a, b).

According to Gaweł (2009) proper digestibility of plant material should be around 65%. Dry matter digestibility (*Table 6*), i.e. percentage of nutrients absorbed by the digestive system, was significantly higher in red clover (52.7%) than in alfalfa hybrid (50.5%), with a statistically significantly increase in the latter plant in the second year. This result was confirmed by the research of Gaweł (2012), when digestibility of alfalfa mixtures with grasses was also the highest in the second year.

Generally, throughout the research growth regulators did not affect red clover and hybrid alfalfa digestibility, with its average annual values remaining similar with no statistically significant differences. However, there were differences between harvests during the same growing season (*Table 7*). The lowest value, average for the species and the regulator, was in the biomass of the second harvest (48.2%), while plant material from the first and third ones had statistically significantly higher digestibility, 53% and 53.6%, respectively. The highest digestibility of all samples was in alfalfa treated with growth regulators in the third harvest (55.5%), and the lowest in the second (45.2%). In red clover dry-matter digestibility in the second and third harvests remained at a similar level and was significantly lower than the values in the first one.

According to Gaweł and Żurek (2003) the number of growing cycles in a growing season had a marked effect on plant digestibility. This was closely related to the development stage at the harvest time and the pace of plant senescence. Overall, low digestibility of hybrid alfalfa and red clover in the present study resulted from the three

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

harvests in the growing season. Gaweł (2009, 2012) reported that with four harvests read clover had dry matter digestibility of 72%, and growing this species in a mixture of grasses raised it to 75%.

In the first harvest of the first and second years (*Fig. 2*) the highest dry matter digestibility was on units treated with auxin, but the values were not significantly higher than those obtained on units with other treatments.

In the second harvest of the second year (2016) it was highest on the control and on units with cytokinin. Other treatments decreased this value. In turn, in the third harvest of the second year the highest dry matter digestibility was on the unit treated with a mixture of auxin with cytokinin, and it was statistically significantly higher than the

values on other units. It should be noted that that growing season was characterized by extreme weather conditions. September 2016 was extremely dry and October extremely wet (*Table 1*). Such a large diversity of weather conditions could have impacted the effect of hormone mixtures on plants. It can be concluded that because of the September drought in 2016 a mixture of auxin with cytokinin stimulated total protein accumulation in plants, limiting accumulation of fibrous substances. The consequence of this was a big increase in plant dry matter content. In turn, extremely wet October (monthly rainfall of 161.2 mm) with low temperatures (daily average temperature of 7.2 °C) slowed down accumulation of protein and of non-digestible substances.

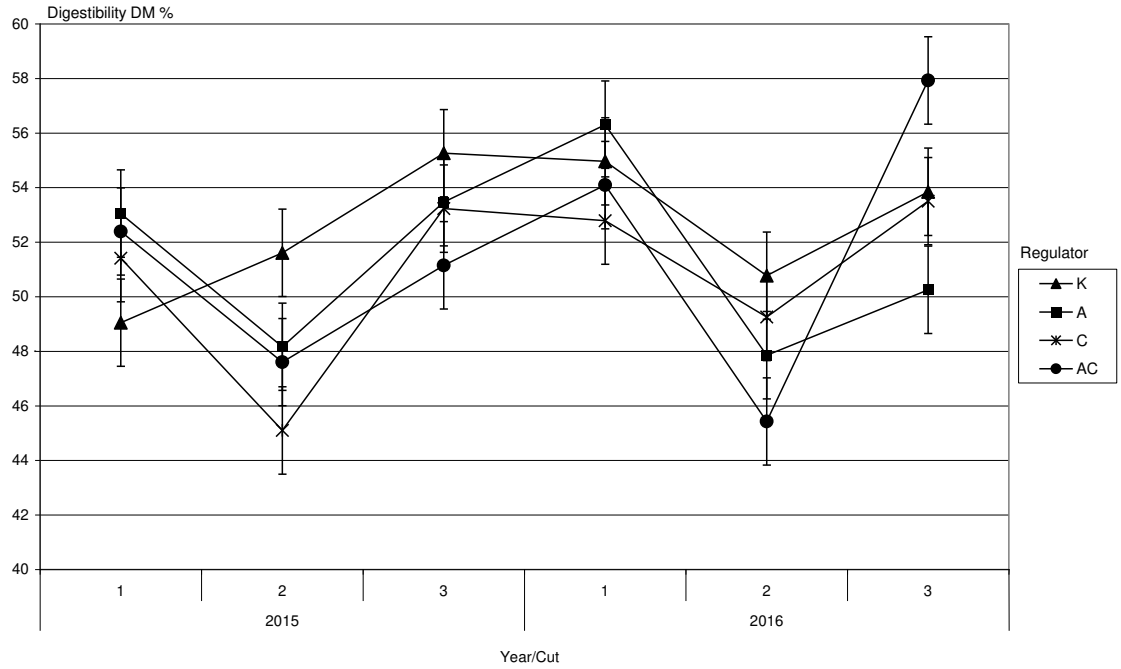

Figure 2. *The effect of growth regulators on digestibility of forage in individual harvests (%)*

Conclusions

1. Exogenous growth regulators in different ways affected the content of protein and crude fibre in plant dry matter.
2. Cytokinin and a mixture of hormones reduced the concentration of protein relative to the control, but fibre share increased. Auxin had no significant effect on these features.
3. Overall, growth regulators did not change dry matter digestibility, but there were differences between harvests.
4. The experiment did not prove that the quality of plant material improved as a result of the application of synthetic auxin, cytokinin, and mixtures of these compounds.

Abstract. Sexual reproduction plays an important role in the maintenance of the genetic variability of plant species. In the case of entomophilous species (like *Pulsatilla grandis*) pollinators are needed to this way of propagation. It is important to have complete knowledge on the pollinators to understand the biology of plant species. Our aim was to collect information about the pollinators of *P. grandis*, as there is no available data on the pollinators of this endangered species. We studied the flower-visiting species in 2017 and 2018 on the Csatár Hill near Veszprém (Hungary) in a population of about 2000 individuals of *P. grandis*. The number of collected *Apis mellifera* individuals (239) was the highest followed by *Bombus* (31 individuals) and *Andrena* (15 individuals) species. *Lasioglossum, Polistes* and *Priocnemis* species were collected as well. We collected 5 male insects which visit the flowers only for nectar but they can help the self-pollination as they are searching for nectar in the flower. We recorded the most intense flower visitation between 10-11 a.m. Our new results can help to develop the conservation strategy of *P. grandis*.
Keywords: *flower-visiting insects, Apis mellifera, Bombus, pollen, nectar*

Introduction

The frequency and intensity of grazing is decreasing due to the decline in livestock farming. As a result the diversity of semi-natural grasslands is decreasing as well. The species number of plants and insects is dwindling in these habitats (Walker and Pinches, 2011). Biodiversity influences ecosystem services in some semi-natural landscapes (Lowenstein et al., 2015). Having enough information about the pollination strategy of rare and endangered species is a key factor to develop protection and management strategies. However, our knowledge is imperfect even in the case of intensively studied species (Denisow et al., 2014a; Gostin, 2011). In the case of metapopulations it is especially important to know the plant-pollinator interactions and the requirements of effective gene flow to maintain healthy populations of rare and endangered species (Schemske et al., 1994). Sexual reproduction is essential from genetic and evolutional aspects. It contributes to the inter- and intrapopulation genetic variability of individuals (Charlesworth and Charlesworth, 1987). Fructification rate and seed set depends on fertilization which is the result of pollination, so the effectiveness of pollination is a key factor in the reproduction success of entomophilous species (Larson and Barrett, 2000). The plant-pollinator interactions are very complex and can be influenced by many factors in addition to environmental ones (Denisow et al., 2014a). In the temperate climate zone about 80% of plant species is pollinated by insects. Both cultivated and wild species are important elements of pollination systems (Strzałkowska et al., 2016). In

the case of early spring flowering species the number of pollinators is low. The number of flower-visitations by insects is limited due to unfavourable weather conditions (Kratochwil, 1988). In early spring pollen is an especially important protein source for insects (Moquet et al., 2015). The demand for nectar and pollen increases quickly in early spring by bee-like insects (Denisow, 2006). The pollen is needed to forage the brood to reach the proper family size. *Pulsatilla grandis* is a valuable and threatened species of semi-dry grasslands. This species is a significant pollen source for bees as it is flowering in early spring. The morphology and ecology of *Pulsatilla* species also promote the pollination by insects (Zimmermann, 1935). They attract insects with their bell-shaped, actinomorphic flowers and lots of yellow stamens (Walker and Pinches, 2011; Essl, 2005). In the case of partly opened flowers the pollinators first touch the pistils so they can be fertilized with the pollen carried from another plant. While in the case of older, fully opened flowers the bees land on tepals, so they first touch the stamens and after that the pistils (Zimmermann, 1935). Some authors classified *Pulsatilla* species as pollen producing plants, having a lot of stamens but producing no nectar, similar to other species of the *Ranunculaceae* family. Although Weryszko-Chmielewska and Sulborska (2011) proved that the staminodes of *Pulsatilla* flowers produce nectars, so they function as nectaries. Staminodes are much smaller than stamens and have a simple structure. They can be found on the basis of the androecium. The nectar is produced when the pistil is ready for fertilization. Insects have to reach the basis of androecium to reach the nectar. Meanwhile they support fertilization as they touch the stigma. The pollen production of *Pulsatilla* species is 4.22-9.16 g/m^2, so they are significant pollen sources. These species produce more pollen than other early spring perennials (Strzałkowska-Abramek et al., 2016). *Pulsatilla grandis* has different strategies to ensure the efficient pollination. It can close its flowers in the case of unfavourable weather conditions (rain, wind) until the flowers are not pollinated (Sauberer and Panrok, 2015). Most anthers of *Pulsatilla* flowers open in the warmest hours of the day, which is typical of many other early spring species as well (Denisow et al., 2014b, 2015). Pollen emission round midday is advantageous for early spring plants and increases the number of insect visitations (Strzałkowska et al., 2016). The anthers open one after the other. So the flower produces pollen during a long period of time and the ratio of fertilization is higher. This long period of pollen emission is important from population genetic aspect. The number of pollinators, carrying pollen from other individuals, increases as well, so the genetic variability of the next generation multiplies (Kratochwil, 1988). Because the flying distance of pollinator insects is about 10 km, the gene flow between distant populations is not probable (Walker, 2011). *Pulsatilla vulgaris* Mill. is a related species occurring in Western Europe. The success of its reproduction is considerably influenced by the pollination of insects and the spread of pollen depends on the flying distance of pollinators. There is a positive correlation between the foraging distance and the size of pollinator species. Bumblebee species which also visit its flowers has longer foraging range and provide gene flow between distant populations as well (Hensen et al., 2005; Walther-Hellwig and Frankl, 2000; Osborne et al., 2008). It was observed that besides bumblebees honey bees have longer flying distances as well (Steffan-Dewenter and Kuhn, 2003), therefore these insects have significant role in the pollination of populations living in fragmented habitats.

Insects visit *Pulsatilla* species both for nectar and pollen (*Table 1*). However, the visiting *Apoidea* species do not fertilize the flowers in every cases, some of them are nectar robbers (Kratochwil, 1988).

Our aim was the collect information about the pollinators of *P. grandis*, as there is no available data on the pollinators of this endangered species.

Table 1. *Pollinators of the Pulsatilla genus and Pulsatilla vulgaris*

Taxon	Pollinator	Comment	Reference
Pulsatilla genus	*Apis mellifera* Linnaeus, 1758 *Bombus terrestris* (Linnaeus, 1758)	Mainly visited by honey bees (*Apis mellifera* Linnaeus, 1758) for pollen and nectar	Zimmermann (1935)
Pulsatilla genus	Honey bees and bumble bee species	Pollen and nectar collection	Weryszko-Chmielewska and Sulborska (2011)
P. vulgaris		Nectar collecting bees	Weryszko-Chmielewska and Sulborska (2011)
P. vulgaris	*Lasioglossum lineare* (Schenck, 1869), *Andrena bicolor* Fabricius, 1775	Solitary bees are the main pollinators	Kratochwil (1988)
P. vulgaris	*Halictidae* family, *Andrena* genus		Sauberer and Panrok (2015)
P. vulgaris	*Apis* and *Bombus* species		Walker (2011), Walker and Pinches (2011)
P. vulgaris	*Halictus fulvicornis* (Kirby,1802), *H. tumulorum* (L.1758), *H. albipes* (Fab. 1781), *H. flavipes* (Fab. 1787), *H. leucopus* (Kirby, 1802), *Osmia bicolor* (Schrank, 1781), and *Bombus agrorum* (Fab. 1787) [=*B. pascuorum* (Scopoli, 1763)]	Great Britain	Wells and Barling (1971)

Materials and methods

Study species

Pulsatilla grandis Wender. is a Natura 2000 species, wich is listed in the Annex II and Annex IV of the Habitats Directive of the European Commission (Council Directive 92/43/EEC) (Randic et al., 2013). Its range is Pannonian type, i.e. distributed from Western Ukraine to Austria and the Czech Republic (Sauberer and Panrok, 2015). It is listed as a threatened species, e.g. in Germany, Czech Republic, Slovenia, Slovakia and Ukraine (Dostalova and Király, 2013).

This perennial species of dry grasslands is flowering in early spring. Its attractive flowers are pollinated by insects.

Its flowers open in late February or early March. The leaves develop at the end of flowering. After flowering the peduncle elongates bearing the fruit over the layer of other plants which helps the dispersion of seeds by wind (Kaligaric et al., 2006; Sauberer and Panrok, 2015).

DOI: http://dx.doi.org/10.15666/aeer/1605_70457062
© 2018, ALÖKI Kft., Budapest, Hungary

Flowers are mainly cross-pollinated but in the lack of allogamy self-pollination is also possible (Walker and Pinches, 2011; Zimmermann, 1935; Lindell, 1998).

Study area

The pollinators of *P. grandis* were studied on the calcareous rocky steppes of the Csatár Hill (N47.107830, E17.848507) (*Figs. 1, 2* and *3*), near Veszprém in Southern Bakony (Hungary). The summit of this dolomite hill is 340 metres above sea level. This population of *P. grandis* contains more thousand individuals. The botanical values of the area are threatened by the expansion of weekend houses.

Measuring pollinators

The pollinators were studied in the spring of 2017 and 2018. The methods were different in the two years. On the 25 March 2017 we observed three fully-opened flowers of an individual and one fully-opened flower of another one. On the 28th March 2017 three fully-opened flowers of an individual were studied (no other flower visitation was recorded). The flower-visitations were recorded through 18 h from between 9 a.m. and 5 p.m. on both days. The weather was sunny and windless on both days.

Photos were taken about the flower visiting insects to identify them and record the time of visitation. With this method it was possible for pollinators to visit the flowers more times. However this method was not effective enough. Only a little ratio of visitations was recorded and identified. At the same time only these results show that some pollinators visit the same plant individuals repeatedly. Those individuals that were not identified reliably are not included in the results of this study. In 2018 we studied a 3800 square metres area. The number of *P. grandis* individuals was about 2600. The pollinators were collected in glasses every hour. An insect collecting nest (30 cm in diameter) was used to collect the insects individually and then put them in the glasses. We studied the area through 20 h on 2-10 April (1-3 people collected simultaneously). The length of observation (25 h) and sampling (20 h) were different as there were periods when no pollinators visited the plants (*Table 2*). The study days were sunny and windless, excepting 4 April which was a sunny but very windy day. The individuals were identified with a binocular microscope by Zs. Józan. The collected individuals were identified according to following literature: Andrenidae species: Schmid-Egger and Scheuckl (1977), Apis mellifera and Bombus species: Móczár (1957), Halictidae species: Móczár (1967) and Ebmer (1970), Osmia species: Móczár (1958), Vespidae species: Móczár (1995), Pompilidae species: Wolf (1972) and for all species: Schmiedeknecht (1930).

Table 2. *Flower visitations of Pulsatilla grandis (2018)*

Date	Length of observation (h)	Length of sampling (h)
2 April	3 p.m.-6 p.m.	3 p.m.-6 p.m.
3 April	9 a.m.-4 p.m.	10 a.m.-4 p.m.
4 April	9 a.m.-4 p.m.	10 a.m.-3 p.m.
8 April	9 a.m.-4 p.m.	10 a.m.-3 p.m.
10 April	11 a.m.-12 a.m.	11 a.m.-12 a.m.
Total:	**25**	**20**

a.m. = before noon, p.m. = after noon

Besides the cited publications distribution data of species are based on the unpublished studies of Zs. Józan who studied and collected pollinators through 5 decades in the Bakony Hills, Western and Southern Transdanubia. Flower-visitation data was collected by the author and Jenő Papp. The specimens of collected insects are preserved in the Rippl-Rónai Museum (Kaposvár, Hungary) and in the Natural History Museum of the Bakony Hills (Zirc, Hungary).

Results

In 2017 we recorded 31 flower-visitations of *Aculeata* (6 species) species (*Table 3*). *Apis mellifera* was the most frequent (80% of all visitations) pollinator of *P. grandis*. The *Bombus* genus was the second most frequent with 12%. The flower-visitations of *Andrena* and *Lasioglossum* species were not significant, both representing 3%.

We recorded the most visitations between 10-11 a.m., followed by the period between 11-12 a.m. *Apis* species visited the flowers between 9 a.m and 3 p.m., the *Bombus* species between 10 a.m. and 3 p.m., the *Andrena* species between 11-12 a.m.,

while the *Lasioglossum* species between 12-1 p.m. There was no visitation between 1-2 p.m.

Table 3. *Aculeata pollinators of Pulsatilla grandis in decreasing frequency (2017)*

Species	Sex	Number of flower-visitations (during 18 h)	Time of flower visitation
Apis mellifera Linnaeus, 1758	Worker	25	9 a.m.-1 p.m., 2-3 pm.
Bombus lapidarius (Linnaeus, 1758)	♀	2	11-12 a.m., 2-3 p.m.
Bombus pascuorum (Scopoli, 1763)	♀	1	10-11 a.m.
Andrena bicolor (Fabricius, 1775)	♀	1	11-12 a.m.
Lasioglossum fulvicorne (Kirby, 1802)	♀	1	12-1 p.m.
Bombus haematurus (Kriechbaumer, 1870)	♀	1	12-1 p.m.
Total:		**31**	

♀ = female, a.m. = before noon, p.m. = after noon

In 2018 23 species (299 individuals) were collected (*Table 4*). *Apis mellifera* was the most frequent (80% of all visitations) pollinator of *P. grandis*. It was followed by the *Bombus* genus with 10%. The ratio of *Andrena* species was only 5% (*Table 5*).

Table 4. *Aculeata pollinators of Pulsatilla grandis in decreasing frequency (2018)*

Species	Number of individuals	Sex	Time of flower visitation
Apis mellifera (Linnaeus, 1758)	239	Worker	10 a.m.-6 p.m.
Bombus lapidarius (Linnaeus, 1758)	8	♀	11 a.m.-1 p.m., 2-3 pm.
Andrena bicolor (Fabricius, 1775)	6	5 ♀ + 1 ♂	10-11 a.m., 12-2 p.m.
Bombus pratorum (Linnaeus, 1761)	6	♀	12-5 p.m.
Bombus haematurus (Kriechbaumer, 1870)	5	♀	10-12 a.m., 3-4 p.m., 5-6 p.m.
Bombus hypnorum (Linnaeus, 1758)	5	♀	10-11 a.m., 12-2 p.m.
Osmia cornuta (Latreille, 1805)	5	4 ♀+1 ♂	12-2 p.m.
Bombus terrestris (Linnaeus, 1758)	4	♀	10 a.m.-2 p.m.
Andrena gravida (Imhoff, 1832)	3	2 ♀+1 ♂	12-2 p.m., 3-4 p.m.
Bombus pascuorum (Scopoli, 1763)	2	♀	11-12 a.m., 1-2 p.m.
Lasioglossum laterale (Brullé, 1832)	2	♀	11 a.m-1 p.m.
Osmia bicolor (Schrank, 1781)	2	♀	12-12 p.m.
Polistes nimpha (Christ, 1791)	2	♀	12-1 p.m.
Andrena bimaculata (Kirby, 1802)	1	♂	2-3 p.m.
Andrena bluethgeni (Stöckhert, 1930)	1	♀	11-12 a.m.
Andrena dorsata (Kirby, 1802)	1	♀	11-12 a.m.
Andrena jacobi (Perkins, 1921)	1	♂	4-5 p.m.
Andrena nitida (Müller, 1776)	1	♀	12-1 p.m.
Andrena vaga (Panzer, 1799)	1	♀	1-2 p.m.
Bombus ruderarius (Müller, 1776)	1	♀	12-1 p.m.
Lasioglossum bluethgeni (Ebmer, 1971)	1	♀	2-3 p.m.
Lasioglossum xanthopus (Kirby, 1802)	1	♀	11-12 a.m.
Priocnemis mimula (Wesmael, 1851)	1	♀	2-3 p.m.

Table 5. *Aculeata pollinators (genus) of Pulsatilla grandis in decreasing frequency (2018)*

Genus	Number of individuals	Ratio of all flower visits (%)
Apis	239	79.9
Bombus	31	10.4
Andrena	15	5.0
Osmia	7	2.3
Lasioglossum	4	1.3
Polistes	2	0.7
Priocnemis	1	0.3
Total:	**299**	**100**

We observed the most flower-visitation between 10-11 a.m., followed by the period between 12-1 p.m. (*Table 6*). *Apis* and *Bombus* species visited the flowers between 10 a.m. and 6 p.m., while *Andrena* species between 10 a.m. and 5 p.m.

Table 6. *Temporal distribution of Pulsatilla grandis pollinators (2018, daylight saving time)*

Time	Number/hour	Ratio (%)
10-11 a.m.	66	22.0
11-12 a.m.	55	18.4
12-1 p.m.	60	20.1
1-2 p.m.	40	13.4
2-3 p.m.	25	8.4
3-4 p.m.	16	5.3
4-5 p.m.	26	8.7
5-6 p.m.	11	3.7
Total:	**299**	**100**

a.m. = before noon, p.m. = after noon

We collected the most number of insects (34 individuals) on 8 April between 10-11 a.m., while we collected the fewest (1 individual) on 10 April between 10-11 a.m. There was no visitation before 10 a.m. We recorded visitations between 4-6 p.m. only on the first few days. Later no visitation was observed after 4 p.m.

We found 5 males besides the females and workers (*Andrena bicolor, A. gravida, A. bimaculata, A. jacobi, Osmia cornuta).*

Three quarters of bee-like species collected from *P. grandis* have a wide range (Palearctic, Western Palearctic and Eurosiberian). One quarter of the species occurs in certain regions of Europe, and only 15% lives in the Mediterranean with a range extending to Central Europe.

The ratio of species preferring warm habitats (eremophil) was only 20%. The species of cool and wet habitats represented 35%. Most of the species (45%) are eurytopic.

The species are polilectic, except *Andrean vaga* which is an oligolectic species. According to the studies of Zs. Józan in the Bakony Hills, Western and Sothern Transdanubia 45% of species visited less than 25 plant species, 30% visited 26-50 species, 10% visited 51-75 species, while 15% visited more than 76 plant species for pollen or nectar.

Collected species

Apidae

Apis mellifera Linnaeus, 1758

It was the most dominant pollinator species. Our only social bee species that has perennial colonies. It is a eurytopic species (Móczár, 1957), its subspecies can be found worldwide (Móczár, 1957). The workers visit practically the flowers of every plant species that produce pollen or nectar (unpublished data of the author). In early spring they visit the catkins of *Salix* species (*Salix caprea, Salix cinerea*) which produce a high amount of pollen. *P. grandis* seems to be a good source of pollen and nectar as well. The pollen baskets of specimens collected from its flowers were full of pollen. After winter the workers feed the first larvae generation with this protein rich forage. From the end of March they start to visit the flowers of fruit trees, so the visitation of other plants become less significant. It has economic and ecological significance (Rand et al., 2015).

Bombus haematurus Kriechbaumer, 1870

This bumblebee species has Ponto-Mediterranean range (Móczár, 1957). Its number has been increasing rapidly in Hungary in the last decades. The species was first observed in Hungary in 1990 in the Mecsek Hills. Later about 40 occurrences have been recorded in the Bakony Hills, Transdanubian Hills, Mecsek Hills, Villányi Hills, furthermore in Vas County and near Bősárkány (North Hungary) (Józan, 1995, 1996b, 1998, 2000a, 2003, 2006, 2009, 2016, 2017). Sárospataki et al. (2004) classified the species as rare and highly threatened. However, the studies of recent years show it is not so rare. It is also supported by the fact that the species was observed together with other common species on the Csatár Hill. Visited plant species: *Rubus idaeus, R. fruticosa, Geum urbanum* (Rosaceae), *Vicia grandiflora* (Fabaceae), *Galeobdolon luteum, Lamium purpureum, L. maculatum* (Labiatae), *Symphytum officinale* (Boraginaceae), *Corydalis cava, Lonicera* sp., *Philadelphus coronarius* (other plant families) (Józan, 2009, 2017).

Bombus hypnorum (Linnaeus, 1758)

B. hypnorum is a Eurosiberian bumblebee which prefers habitats with cool and humid microclimate (Móczár, 1953, 1957). It is moderately rare in Hungary (Móczár, 1953; Sárospataki et al., 2004). The species has been observed in 30 localities in Hungary from Bősárkány through the Bakony Hills, the Transdanubian Hills, the Mecsek Hills until the Villányi Hills (Józan, 1990, 1992a, 1995, 1996a, 1998, 2000a, 2000b, 2001, 2006, 2016, 2017). Visited plant species: *Rubus idaeus, Rosa sp.* (Rosaceae), *Lamium maculatum* (Labiatae), *Calendula officinalis, Cirsium arvense* (Asteraceae), *Anchusa officinalis, Echium vulgare* (Boraginaceae), and *Berberis vulgare, Epilobium montanum, Knautia drymeia, Lycium barbarum, Salix cinerea, Symphoricarpus albus, Philadelphus coronarius* (other plant families) (Józan, 2017).

Bombus lapidarius (Linnaeus, 1758)

It is a common eurytopic species living in the Western-Palearctic range (Móczár, 1953, 1957; Sárospataki et al., 2004). It is common everywhere in Hungary. It has been found in lots of localities during our studies (Józan, 1985, 1992a, 1992b, 1995, 1996a, 1996b, 1998, 2000a, 2000b, 2001, 2002, 2003, 2006, 2009, 2016, 2017). Its pollination

© 2018, ALÖKI Kft., Budapest, Hungary

was recorded on 50 plant species of 23 plant families. Most of the species belong to the Fabaceae, Labiatae and Asteraceae families (Józan, 2009, 2016, 2017).

Bombus pascuorum (Scopoli, 1763)

It is a eurytopic Eurosiberian bumblebee species (Móczár, 1953, 1957; Sárospataki et al., 2004). *B. pascuorum* is the most common bumblebee species in Hungary according to our studies (Józan, 1990, 1992a, 1992b, 1995, 1996a, 1998, 2000a, 2000b, 2001, 2006, 2009, 2014, 2016, 2017). It has been collected from 70 plant species of 22 plant families (Józan, 2009, 2016, 2017).

Bombus pratorum (Linnaeus, 1761)

B. pratorum lives in habitats with cool and humid microclimate. Its range is of Eurosiberian type (Móczár, 1953, 1957). *B. pratorum* was classified as moderately rare in Hungary (Sárospataki et al., 2004). During our faunistic studies it has been collected from 40 localities in Transdanubia (Józan, 1990, 1992a, 1996a, 2000b, 2001, 2002, 2006, 2017). Visited plant species: *Rubus idaeus* (Rosaceae), *Astragalus onobrychis, Trifolium pratense* (Fabaceae), *Aegopodium podagraria, Anthriscus sylvestris* (Apiaceae), *Ajuga reptans, Galeobdolon luteum, Marrubium peregrinum, Salvia nemorosa* (Labiatae), *Centaurea jacea, C. micranthos, Taraxacum officinale* (Asteraceae), *Stellaria* sp. (Caryophyllaceae), *Echium vulgare, Pulmonaria officinalis, Symphytum officinale, S. tuberosum* (Boraginaceae), other plant families: *Allium ursinum, Berberis vulgaris, Cerinthe minor, Geranium* sp., *Knautia arvensis, K.. drymeia, Melampyrum nemorosum, Ribes rubrum, Solanum nigrum, Symphoricarpus albus* (Józan, 2017).

Bombus ruderarius (Müller, 1776)

It is a eurytopic bumble bee species with a Western Palearctic range (Móczár, 1957). It is moderately common in Hungary (Móczár, 1953; Sárospataki et al., 2004). We have found this species in many different localities during our faunistic studies (Józan, 1990, 1992a, 1992b, 1995, 1996a, 1996b, 1998, 2000a, 2000b, 2001, 2002, 2006, 2009, 2016, 2017). It has been collected from more than 40 species of 14 plant families (Józan, 2009, 2017).

Bombus terrestris (Linnaeus, 1758)

It is a eurytopic bumble bee species that occurs in the Palearctic region (Móczár, 1957). It is very common in every part of Hungary (Józan, 2001; Móczár, 1953; Sárospataki et al., 2004). It has been collected from 110 localities (Józan, 1985, 1990, 1992a, 1992b, 1995, 1996a, 1996b, 1998, 2000a, 2000b, 2001, 2002, 2003, 2006, 2009, 2014, 2015, 2016, 2017). Its pollination has been observed on nearly 100 species of 35 plant families. Most significant families were the Fabaceae, Labiatae and Asteraceae (Józan, 2009, 2016, 2017).

Andrenidae

Andrena bicolor Fabricius, 1775

This Eastern Palearctic mining bee species prefers cool and humid habitats (Dylewska, 1987; Móczár, 1957). *A. bicolor* is moderately common in Hungary (Móczár and Warncke, 1972). It has two generations per year, the first being on the wing in spring and the second in summer (Schmid-Egger and Scheuchl, 1977). It has

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_70457062
© 2018, ALÖKI Kft., Budapest, Hungary

been found in nearly 100 localities during our faunistic studies (Józan, 1990, 1992a, 1992b, 1996a, 1996b, 1998, 2000a, 2000b, 2001, 2002, 2003, 2006, 2009, 2014, 2016, 2017). It has been collected from 35 species of 15 plant families. The summer generation visits mainly the flowers of *Campanula* species (Schmid-Egger and Scheuchl, 1977; Józan, 2009, 2016, 2017).

Andrena bimaculata (Kirby, 1802)

A. bimaculata is an eurytopic mining bee species that is widespread in the Palearctic region. It has two generations per year (Dylewska, 1987; Schmid-Egger and Scheuhl, 1977). It is common in Hungary (Móczár and Warncke, 1972; Józan, 2011). It has been collected from more than 130 localities (Józan, 1985, 1990, 1992a,1992b,1995, 1996a, 1996b, 1998, 2000a, 2000b, 2001, 2003, 2009, 2014, 2016, 2017). It has been observed on 36 species of 13 plant families. The spring generation swarms mainly on the catkins of *Salix* species (Schmid-Egger and Scheuchl, 1977; Józan, 2009, 2016, 2017).

Andrena bluethgeni Stöckhert, 1930

The range of this species is not well-known. It has been found in Central and Northern Europe (Schmid-Egger and Scheuchl, 1977). It is very rare in Hungary. In the last century it was collected only from 4 localities near Budapest and from one locality in the North Hungarian Mountains (Móczár and Warncke, 1972). In the last decades we have observed it in six localities of the Balaton Uplands, near Esztergom, in the Zákány Hills and in Külső-Somogy (Józan, 1992a, 2000b, 2016). Visited plant species: *Amygdalus communis, Cerasus vulgare, Prunus cerasifera, P. spinosa* (Rosaceae)*, Capsella bursa-pastoris* (Cruciferae)*, Acer platanoides* (Aceraceae) (Józan, 2016).

Andrena dorsata (Kirby, 1802)

A. dorsata is a eurytopic Western Palearctic mining bee species with two generations (Dylewska, 1987). It is common in Hungary. It has been collected from more than 200 localities during our faunistic studies (Józan,1985, 1990, 1992a, 1992b, 1995, 1996a, 1996b, 1998, 2000a, 2000b, 2002, 2003, 2006, 2009, 2014, 2016, 2017). It has been noted on nearly 100 species of 27 plant families. Most of them belong to the Rosaceae, Cruciferae and Asteraceae families (Józan, 2009, 2016, 2017).

Andrena gravida Imhoff, 1832

A. gravida is a widespread mining bee species in Europe (Dylewska, 1987). Its only generation flies from early spring until May. It is common in Hungary (Móczár and Warncke, 1972). It has been found in nearly 150 localities (Józan, 1990, 1992a, 1992b, 1995, 1996a, 1996b, 1998, 2000a, 2000b, 2001, 2002, 2003, 2006, 2009, 2016, 2017). It has been collected from more than 50 species of 25 plant families. Most of them are members of the Rosaceae and Cruciferae families (Józan, 2009, 2016, 2017).

Andrena jacobi Perkins, 1921

It is a Western Palearctic species with one generation swarming in spring (Dylewska, 1987). It is moderately common in Hungary (Móczár and Warncke, 1972). We have found it in 84 localities during our studies (Józan, 1990, 1992a, 1992b, 1995, 1996a, 1996b, 1998, 2000a, 2000b, 2001, 2017) It has been collected from 24 species of 12 plant families. It has mainly visited the species of Rocaseae family (Józan, 2017).

DOI: http://dx.doi.org/10.15666/aeer/1605_70457062
© 2018, ALÖKI Kft., Budapest, Hungary

Andrena nitida (Müller, 1776)

A. nitida has the same range as the former species (Dylewska, 1987). Its only generation flies in the spring months. It is quite common in Hungary (Móczár and Warncke, 1972). It has been found in nearly 130 localities (Józan, 1990, 1992a, 1992b, 1995, 1996a, 1996b, 1998, 2000b, 2001, 2002, 2003, 2009, 2015, 2016, 2017). It has visited more than 50 species of 25 plant families. Most of them are members of Rosaceae and Cruciferae families (Józan, 2016, 2017).

Andrena vaga Panzer, 1799

A. vaga is a mining bee species that lives in Southern Europe (Dylewska, 1987). It flies in early spring. It is not rare in Hungary but not abundant (Móczár and Warncke, 1972). It has been collected from 60 localities in the last decades (Józan, 1985, 1990, 1992a, 1995, 1996a, 1996b, 1998, 2000b, 2001, 2003, 2006, 2015, 2016, 2017). Visited plant species: *Prunus spinosa, Sorbus intermedia* (Rosaceae), *Lamium purpureum* (Labiatae), *Salix cinerea, S. rosmarinifolia* (Salicaceae) (Józan, 2016, 2017).

Halictidae

Lasioglossum bluethgeni Ebmer, 1971

L. bluethgeni is a Pontomediterranean sweat bee species (Ebmer, 1988; Móczár, 1967). It has two generations. The spring generation contains only of females. It has been observed in many locations in Hungary, but it is not common. It has been collected from 35 Transdanubian localities in the last decades (Józan, 1992b, 1995, 1996a, 1998, 2000b, 2006, 2009, 2015, 2016, 2017). It has visited the flowers of the following species: *Anthriscus cerefolium, A. sylvestris, Daucus carota, Pastinaca sativa* (Apiaceae), *Capsella bursa-pastoris, Rorippa amphibia, Lepidium draba* (Cruciferae), *Hieratium* sp. (Asteraceae), *Echium vulgare, Lithospermum purpureo-coeruleum* (Boraginaceae), other families: *Cotinus coggygria, Dictamnus albus, Scabiosa ochroleuca* (Józan, 2009).

Lasioglossum fulvicorne Kirby, 1802

It is a eurotypic species with a Palearctic range (Ebmer, 1988; Móczár,1967). It is rare in Hungary. It has been collected only from Nagybajom (Józan, 1992a), Tótújfalu (Józan, 1995), Kővágószőlős (Józan, 1996a) and Zics (Józan, 2000b). Visited plant species: *Anthemis austriaca, Berteroa incana, Capsella bursa-pastoris, Dorycnium germanicum, Ficaria verna, Orlaya grandiflora.*

Lasioglossum laterale (Brullé, 1832)

This sweat bee species occurs in the Northern part of the Mediterranean (Ebmer, 1988; Móczár, 1967). It has two generations. The spring generation contains only of females. It is moderately common in Hungary (Móczár, 1967). It has been collected from more than 70 localities in the Bakony Hills and in the southern part of Transdanubia (Józan, 1990, 1992a, 1995, 1996a, 1996b, 1998, 2000a, 2000b, 2003, 2006, 2009, 2017). It has been collected from 20 species of 10 plant families.

Lasioglossum xanthopus (Kirby, 1802)

L. xanthopus is a Wester Palearctic species (Ebmer, 1988; Móczár, 1967). It also has two generations. The spring generation contains only of females. It is moderately common in Hungary (Móczár, 1967). We have found it in less localities than the former

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_70457062

species (Józan, 1992a, 1995, 1998, 2000a, 2000b, 2003, 2016, 2017). According to our observations it does not occurs abundantly in any type of habitat. It has been recorded on 24 species of 13 plant families. The distribution of species was quite equal between families (Józan, 2016, 2017).

Megachilidae

Osmia bicolor (Schrank, 1781)

It is a widespread species in Europe. It swarms in spring and nests in snail shells (Móczár, 1958). It is moderately common in Hungary (Móczár, 1958). It has been collected from 75 Transdanubian localities (Józan, 1985, 1990, 1992a, 1992b, 1995, 1996a, 1996b, 1998, 2000b, 2003, 2006, 2009, 2015, 2016). It has been recorded on 22 species of 15 plant families. Most of them are member of the Rosaceae family (Józan, 2009, 2014, 2016, 2017).

Osmia cornuta (Latreille, 1805)

It is a widespread species ranging from the northern part of the Mediterranean to Central Europe. It is common in Hungary (Móczár,1958). It nests in hollow stems or other holes. The cells are separated with mud (Móczár, 1958). The males are often on wings in early March foraging on *Salix* catkins (author's observation). It rarely can be seen in May. It was collected from 16 species of 14 plant families. Most of them are member of the Rosaceae family (Józan, 2009, 2016, 2017).

Pompilidae

Priocnemis mimula Wesmael, 1851

It is a Palearctic pompilid species. It is distributed mainly in the hilly and mountainous regions of Hungary. It is common but not abundant (Móczár, 1956). It is a parasitoid species. It visits the flowers for nectar (Móczár, 1956). It has a limited role in pollination due to the lack of body hairs.

Vespidae

Polistes nimpha (Christ, 1791)

It is a Palearctic Vespidae species. It is very common in Hungary. First it feeds the larvae with nectar and other sweet saps. Later the larvae feed on chopped insects (Móczár, 1995). Its role in pollination is similar to the former species.

Discussion

Apis mellifera was the main pollinator of *P. grandis* in both years of our study. It was followed by *Bombus* species. The high number of *Apis mellifera* can be partly explained by the fact that an apiary can be found 300 meters from the population of *P. grandis*. The fruit trees of the Csatár Hill were not blossoming at the time of early *P. grandis* flowering, so the studied flowers were the only pollen sources for *Apis mellifera*. The significant role of honey bees in successful fructification was observed in the case of later flowering orchid species as well (Biró et al., 2015).

Apis and *Bombus* species had the longest collecting period in both years, which can be explained with the fact that both genus contains eurytopic species.

In 2018 early spring was cold, so a large number of insects visited the flowers of *Pulsatilla* on 4 April even in windy weather.

In 2018 the mornings were quite cool so the flowers were not visited before 10 a.m. In the first days of our study the insects collected pollen until 6 p.m. but later their activity decreased in late afternoon which is the consequence of the long winter as well.

Males visit the flowers only for nectar. They do not have special collecting hairs, so the probability of carrying pollen from a flower to another is lower. In the lack of allogamy *P. grandis* can reproduce with self-pollination as well (Walker and Pinches, 2011; Zimmermann, 1935; Lindell, 1998). As a consequence, male insects can help the pollination of this species too. They can carry the pollen of the same plant to the stigma as they searching for nectar in the flower.

It is normal that the ratio of eremophil bee species was low (20%) in the early spring aspect.

In comparison with the observations of Kratochwil (1988) on *P. vulgaris* we found mainly social bee species (*Apis mellifera, Bombus*), while *Andrena* and *Osmia* species were the most frequent among solitary species. *Andrena bicolor* was the most frequent species of the genus in our study as well. We did not collect *Lasioglossum lineare*, but we found *L. fulvicorne*, *L. laterale* and *L. xanthopus*. Two non-*Apoidea Hymenoptera* species was collected: *Priocnemis mimula* and *Polistes nimpha*.

Our results support the observations of Weryszko-Chmielewska and Sulborska (2011) on *Pulsatilla* species as Bee-like species were the main pollinators of *P. grandis*.

The studies of Sauberer and Panrok (2015) on *Pulsatilla* species showed different results from our observations on *P. grandis*. We collected only 1-2 individuals of 4 Halictidae species (*L. fulvicorne, L. laterale and L. xanthopus*) and the number of individuals of *Apis* and *Bombus* species was significantly higher than the number of individuals of the *Andrena* genus.

Our results meet the observations of Zimmermann (1935), Walker (2011) and Walker and Pinches (2011): *Apis mellifera* and *Bombus* species were the most frequent pollinators. However, in our case *B. lapidarius* was the most frequent species of the genus instead of *Bombus terrestris* (Zimmermann, 1935).

Compared to the results of Wells and Barling (1971) we collected only 1-2 *Bombus pascuorum* and *Osmia bicolor*.

Pulsatilla species produce pollen in early spring when the activity of Aculeata species is starting as well. They attract the insects with a huge amount of pollen and some nectar.

Pulsatilla species have many strategies to ensure the success of allogamy, especially in the case of early flowering species.

As the seed dispersal distances are short the gene flow ensured by pollination plays an important role in the maintenance of the genetic variability of populations. Therefore, the significance of pollinators is high (Hensen et al., 2005).

In our former studies we found significant differences between the number of fruits in the different *P. grandis* populations in the southern part of Bakony Hills (Mészáros T. in prep.) which can indicate the important role of pollinators as well. According to our studies a large number of pollinators have visited the flowers of *P. grandis*. The success of fructification can depend not only on the number of pollinators but on habitat parameters or weather conditions as well. As a consequence, further studies are needed to determine the role of the studied insects in the success of fructification.

Conclusion

No special plant-pollinator relation was found between the studied species and its pollinators. This result is not surprising as only 1-2% of bee species are specialists. Most of the bee species feed on more plant species and most of the plant species are visited by many insects.

The number of bees has decreased considerably in the last decades which can be caused by the changes in landscape structure and the retreat of visited plant species, so the pollination crisis is becoming more obvious (Potts et al., 2010; Biesmeijer et al., 2007). Besides the retreat of food plants the increasing presence of dangerous chemicals reduces the number of pollinators as well (Dainese et al., 2018).

The early flowering of *P. grandis* is very important for bees appearing in early spring as these flowers are the first food sources for them after the pupa stage. In this period of the year only a few plant species produces pollen. After the flowering of *P. grandis* its pollinators (which have longer life cycle than the flowering period of *P. grandis*) visit other plant species occurring in increasing number, so the bees can choose from more food sources. We can speak about mutual dependency as pollinators are necessary for successful fertilization (and with that for the maintenance of genetic diversity of populations), and the flowers *P. grandis* are food sources for early pollinators. Either the decrease of pollinators or early flowering plant populations influences the relation negatively.

With our study we filled the gap of missing information about the pollinators of *P. grandis* and would like to draw attention to the key role of early flowering plant species in the maintenance of bee diversity. In the lack of these species even the non-specialist pollinators can not maintain their populations. Therefore it is important to conserve and maintain the populations of early flowering plant species.

Acknowledgements. We would like to thank Mrs. Józan, Dénes Péteri and Gábor Barad for their help in insect collection. We would like to thank Judit Bódis and István Galambos for their comments on the manuscript. The publication is supported by the EFOP-3.6.3-VEKOP-16-2017-00008 project. (Received 24th Jul 2018; accepted 5th Oct 2018)

Abstract. In order to evaluate the effect of using super-absorbent polymer (SAP) on quantitative yield and growth indices of potato in autumn sowing, an experiment was conducted in Hamedan city, Hamedan province, Iran during two crop years. The experiment was conducted as split split plot based on randomized complete block design (RCBD) with three replications. Treatments include sowing depth (10, 15, 20 and 25 cm), potato cultivars (Sante, Fontane, and Agria) and SAP (non-application and application). The use of SAP in all three cultivars led to an increase in stem diameter, crop height and tuber yield and resulted in a decrease in the percentage of tuber dry weight. The results of growth indices showed that in all three cultivars, the use of SAP led to an increase in leaf area index (LAI), in leaf area duration (LAD) and in crop growth rate (CGR). The LAI and LAD increased with increasing depth and use of SAP. The highest LAI and LAD were obtained under conditions of using SAP at three depths. At all sowing depth, the use of SAP resulted in an increase in *CGR* relative to the non-use of SAP.
Keywords: *Agria, Sante, superabsorbent polymer, tuber yield, Fontane*

Introduction

Drought is one of the biggest challenges in the agricultural sector of Iran. Almost 90% of the regions in Iran are considered to have arid and semi-arid climates (Bannayan et al., 2010). In this respect, we must apply methods that can improve better water use efficiency (WUE) and do not damage the sustainable production of potato (*Solanum tuberosum* L.) as important crop in these regions (Parvizi and GhadamiFiroozabadi, 2015). Reports showed that drought stress induces a wide range of physiological and biochemical changes in crops (Garg et al., 2012; Maksup et al., 2014). In general, dehydration in crops increases cell volume, cell division, cell growth and crop dry weight, and reduces them relatives to non-stress conditions (Sirousmehr et al., 2014).

Potato is currently the fourth most important food crop in the world after wheat, rice, and corn (FAO, 2008). The area under potato cultivation in Iran in 2013 was 190,000 hectares and its yield in area under potato cultivation in Iran was reported as over 29,2623 kg/ha in 2013 (FAO, 2013). Several studies indicated that potato is sensitive to drought stress in all growth stages, especially the tuber formation stage due to the shallow roots with limited expansion and its inability to absorb water from lower depths (Ayas, 2013; Shock et al., 2013). Increasing the use of this crop in the food industry in

© 2018, ALÖKI Kft., Budapest, Hungary

line with the growing world's population made the farmers and agricultural specialists to approach the production of this product to its genetic potential by eliminating nutrient deficiencies and managing the correct use of water and fertilizers (Haase et al., 2007).

In terms of total tuber yield, the early-season to mid-season cultivars of Marfona, Arinda, Fresco and Sante are superior to other cultivars. In general, the early-season to mid-season cultivars of Sante and Faresco and the late-season cultivars of Agria, Columbus, Timothy, Satina and Julianus are more suitable for potato cultivation and production in Hamedan Province (Parvizi, 2008).

The use of superabsorbent polymers (SAP) is one of the strategies to reduce the effect of drought stress especially in semi-arid regions of Iran. SAP are water-friendly gels which the water inside it is slowly evacuated and the soil remains moist for a long time after water absorption and drying the environment gradually (Ghooshchi, 2015). SAP in agriculture reduce the number of irrigation up to 50%, increase the water and nutrition storage capacity of the soil for a long time, make the uniform use of water for crops, cause the faster and more favorable root growth, decrease the soil nutrient leaching, reduce the irrigation costs, increase the cationic exchange capacity of the soil, maximize the production potential of crop production, provide moisture in the upper layer of the soil, and increase the faster and more healthy growth of crops, especially in very hot and dry areas (Yazdani et al., 2007; He and Zhang, 2005). In a study, the use of SAP led to the increase of crop height, stem diameter, grain yield and biomass yield (Islam et al., 2011). In another study, the effect of organic and SAP on leaf chlorophyll index and their interaction effect on stomatal and nitrogen conductivity were statistically significant. In this study, the use of SAP increased the percentage of phosphorus in potato tubers (Rashidi et al., 2015).

Another method of management of potato yield increase is determining the appropriate sowing depth playing an essential role in forming the number of stolons and potato aerial stem and ultimately the final yield of potato (Ezekiel, 1992). The sowing depth determines the status and changes in the soil heat and moisture and is a criterion for soil resistance to the primary bud exit from the soil. Abducting the suitable sowing growth causes a delay in the rate of emergence or weakness of the seedlings (Acquaah, 2005). Several research results showed the significant effect of sowing depth on potato yield (Esehaghbeygi, 2010; Arab et al., 2011). Although in the autumn sowing, there will be a risk of frozen tubers under the soil if there is a severe cold weather but this possibility will decrease if the tubers are sown deeply. Thus, the autumn sowing of potato in temperate and semi-temperate regions is of great importance for some reasons such as reduced water consumption, higher sales prices, optimal utilization and maximum utilization of fall and winter precipitation resources and can be appropriate to change the pattern of sowing (Hassanpanah, 2016). The present study aimed at evaluating the effect of using moisture superabsorbent on growth and yield indices of autumn potato with different depths to reduce the adverse effects of drought stress.

Materials and methods

This experiment was carried out during two crop years of 2015-2016 and 2016-2017 at Ekbatan Research Station, Hamedan Agricultural and Natural Resources Research Center, Hamedan city, Hamedan province, (34° 88' North, 48° 53' West and 1731 m above sea level) which is located in the west of Iran (*Fig. 1*).

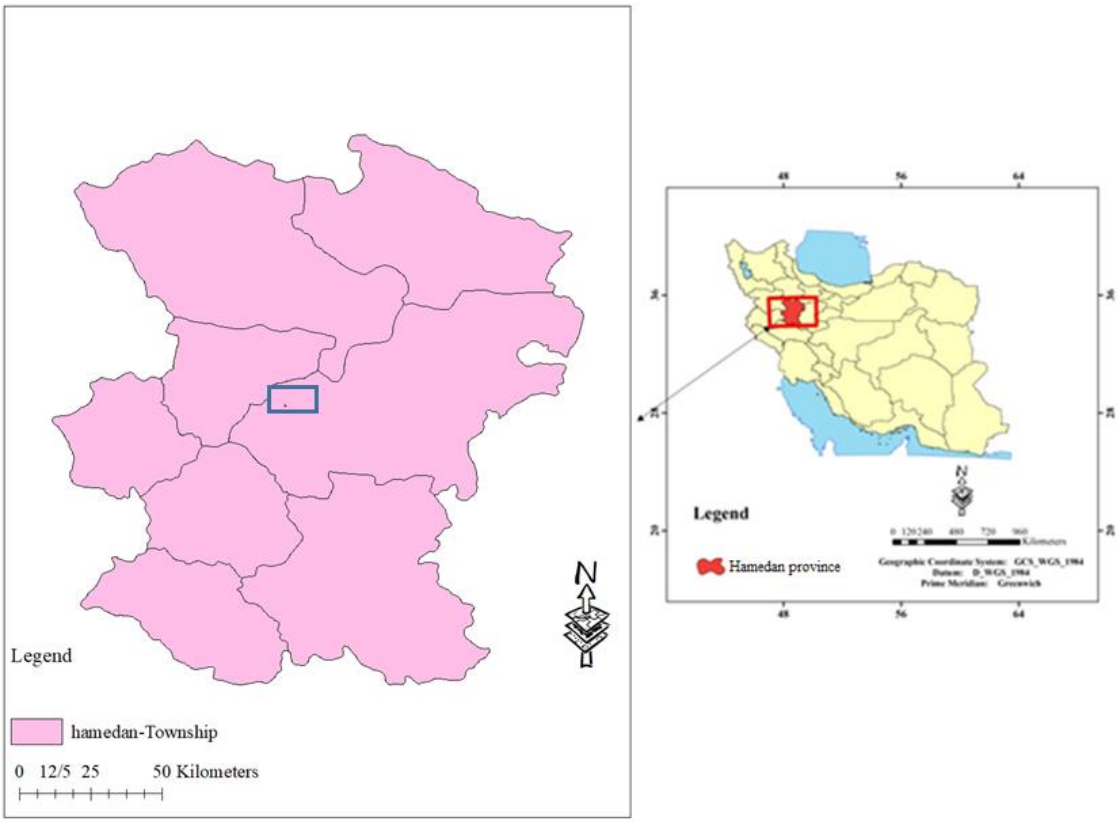

Figure 1. *The location of the experiment area, Hamedan city, Hamedan province, Iran*

The experiment was conducted as split plot based on randomized complete block design (RCBD) with three replications. The main factor included the sowing depth at four levels (10, 15, 20 and 25 cm), the subplots included the potato cultivar at three levels (early-season Sante, mid-season Fontane, and late-season Agria) and the sub-subplot included the use of SAP as 80 kg / ha and at two levels (without using (control) and using SAP). Before the cultivation, sampling was carried out with a depth of 0-30 cm to determine the physical and chemical characteristics of soil in the test site and the full specifications are presented in *Table 1*. Tillage was carried out in the autumn. After land levelling, a plot of 14 m^2 was started. Each plot included 3 rows of planting at a distance of 75 cm and a length of 6 m, the block spacing was one meter and the crop spacing in each row was 25 cm.

Table 1. *Experimental farm soil specification*

Soil depth	Soil texture	pH	EC	Nitrogen percentage	Absorbable phosphorus (mg/kg)	Absorbable potassium (mg/kg)
0-30	Clay loam	7.8	1.8	0.35	4.8	386.3

Fertilizer application was performed based on soil analysis. Accordingly, 250 kg of ammonium phosphate and 150 kg of potassium sulfate per hectare were used. Before sowing, the seed tubers were disinfected by Rural T. S fungicide (52.5% wettable

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

powder). The SAP was distributed to 80 kg/ha at the time of sowing the tubers in cultivation grooves. Sowing the tubers was carried out on November 20th and the tubers were under the soil and in sleep throughout the winter. In the spring and before the buds leave the soil, the first turn of the weed control was carried out with paraquat (Gramaxone) herbicide (3 liters per hectare). Then, the weed control was carried out manually by observing the first weed and continued until the product was ripe. Irrigation was carried out as droplets and tapes. When the crop height reached 10-15 cm, the cultivator and soil were carried out at the foot of the crops. During the grazing time, the complete fertilization of Humex micro fertilizer (at 3,000) was carried out in one turn while Urea fertilization was carried out as topdressing in two turns (mobbing and flowering stages). In flowering stage, the traits such as number of stems per crop, crop height and stem diameter were measured.

At the time of harvesting after random sampling from a square meter, the marginal effect was removed and the resulting tubers were weighed to obtain the tuber yield in kilograms per square meter. In order to calculate the percentage of tuber dry matter from each plot, three tubers were randomly weighed thoroughly after washing, then they were cut into thin chips and placed in an oven at 70 °C for 48 h. Then, they were weighed again and the percentage of tuber dry matter was calculated by dividing the dry weight of the tubers by their initial weight multiplied by 100. For measurements of growth indices, 1 m^2 of each plot were randomly selected from the central rows in plots. The remaining rows (except the border rows) were used for taking periodic plant samples. The sampling was done at 185, 192, 199 and 205 days after sowing. Then, the crops were dried in an oven at 75 °C for 48 h to be weighed. The rate of leaf area index (*LAI*), crop growth rate (*CGR*) and leaf area duration (*LAD*) were obtained from the *Equations 1– 3,* respectively (Taiz and Zeiger, 2006):

$$LAI = \frac{LA_1 + LA_2}{2} \times \frac{1}{GA} \quad \text{(Eq.1)}$$

$$CGR = \frac{W_2 - W_1}{GA(t_2 - t_1)} \quad \text{(Eq.2)}$$

$$LAD = \left(\frac{LAI_1 + LAI_2}{2}\right)(t_2 - t_1) \quad \text{(Eq.3)}$$

where $LA_2 + LA_1$ is total leaf area, GA is ground area $W_2 - W_1$ is dry weight changes, $t_2 - t_1$ is sampling time interval and $LAI_1 + LAI_2$ is total leaf area at time interval of $t_2 - t_1$.

The data obtained from the experiment were analysed by SAS statistical program (v.9.12) and the averages ere compared by Duncan's multiple range test at the 5% level. The charts were drawn by Excel (2010) software.

Results

The number of days up to 50% germination

The results of compound analysis indicated the significant effect of year (Y), sowing depth (D), cultivar (C), superabsorbent application use (S) and interaction between cultivar, depth and SAP in cultivar and depth at 1% level on the number of days up to 50% germination (*Table 2*). The results showed that number of days up to 50% germination was significantly affected by years (*Table 3*).

© 2018, ALÖKI Kft., Budapest, Hungary

of sowing depth and SAP, cultivar and sowing depth, cultivar and SAP and interactions of sowing depth, cultivar and SAP were at 1% level (*Table 2*).

The number of stems per crop

The results of variance analysis showed the significant effect of year (Y), sowing depth (D), cultivar (C), use of super adsorbent (S) at 1% level, and interaction of cultivar and SAP on the number of stems per crop at 5% level (*Table 2*).

Tuber yield

The results of compound analysis showed the significant effect of year (Y), sowing depth (D), cultivar (C), use of super adsorbent (S) and interaction of sowing depth and cultivar and SAP, cultivar and sowing depth at 1% and interaction between SAP and sowing depth at 5% level on the tuber yield (*Table 2*). The results showed that tuber yield was significantly affected by years (*Table 3*).

Percentage of dry matter

The results of compound analysis showed that the dry matter percentage of the tuber was significantly ($P < 0.01$) affected by year (Y), sowing depth (D), cultivar (C), and superabsorbent use (S). Meanwhile, the interaction effect of cultivar and sowing depth as well as the interaction effect of sowing depth, cultivar and SAP were significant at 1% level (*Table 2*).

Discussion

The number of days up to 50% germination

The results of comparing the three-sided interaction between sowing depth, cultivar and SAP showed that the maximum number of days to 50% germination in Agria cultivar was obtained with a depth of 25 cm with a SAP use (165 days). The use of SAP with sowing depths of 10, 15 and 25 cm resulted in significant increase of days to 50% germination in Agria cultivar while this situation did not occur in two other cultivars (*Fig. 2*). It should be noted that the survival rate of tubers and their germination percentage were insignificant at 10 cm depth of all cultivars especially Agria cultivar due the frozen tubers.

Crop height

The results of mean comparison showed that the highest crop height in Agria cultivar was obtained at a depth of 15 cm with a SAP use (46 cm), which increased 9.5% than the use of SAP at the same depth and cultivar (Agria). In general, the use of SAP in all three cultivars resulted in a significant increase in crop height relative to non-use of SAP (*Fig. 3*).

The decrease in stem height with water deficit during the growing season and in the absence of SAP use is consistent with the results of research by Motalebifard et al. (2014). Cell growth is the most sensitive stage under the influence of water stress. The size of organs is limited by decreasing cell growth and the first palpable effect due to water deficiency in the crops is shown by decreasing leaf size and crop height (Kirank et al., 2003). The results of studies by Jahan et al. (2013) and Islam et al. (2011) showed

the positive effect of SAP on crop height which is consistent with the results of this research.

Stem diameter

With the significance of the interaction of sowing depth, cultivar and SAP, it was found that the highest stem diameter was Sante cultivar at a depth of 10 cm with the use of SAP (1.55 cm) and Agria cultivar at a depth of 20 Cm with the use of SAP (1.57 cm). In general, the use of SAP in all three cultivars resulted in a significant increase in stem diameter (*Fig. 4*).

The number of stems per crop

The significance of interaction between cultivars and SAP showed that in Sante and Agria, the use of SAP resulted in a significant increase in number of stems per crop. However, the use of SAP had no significant effect on number of stems per crop in Fontane cultivar (*Fig. 5*).

Tuber yield

The highest tuber yield was in the Fontane cultivar at a depth of 25 cm with SAP use. In general, the use of SAP in all three cultivars and different sowing depths resulted in a significant increase in tuber yield relative to non-use of SAP (*Fig. 6*). In this regard, the potato yield under the sowing depth (greater than 20 cm depending on the sowing conditions) was increased (Ezekiel, 1992). The results of Esehaghbeygi's study (2010) indicated that cultivar and sowing depth had a significant effect on the yield of potato and dry matter.

Extreme leaf area reduction of radiation absorption, as well as the reduction of photosynthetic yields result in the loss of dry matter and yield under drought stress conditions.

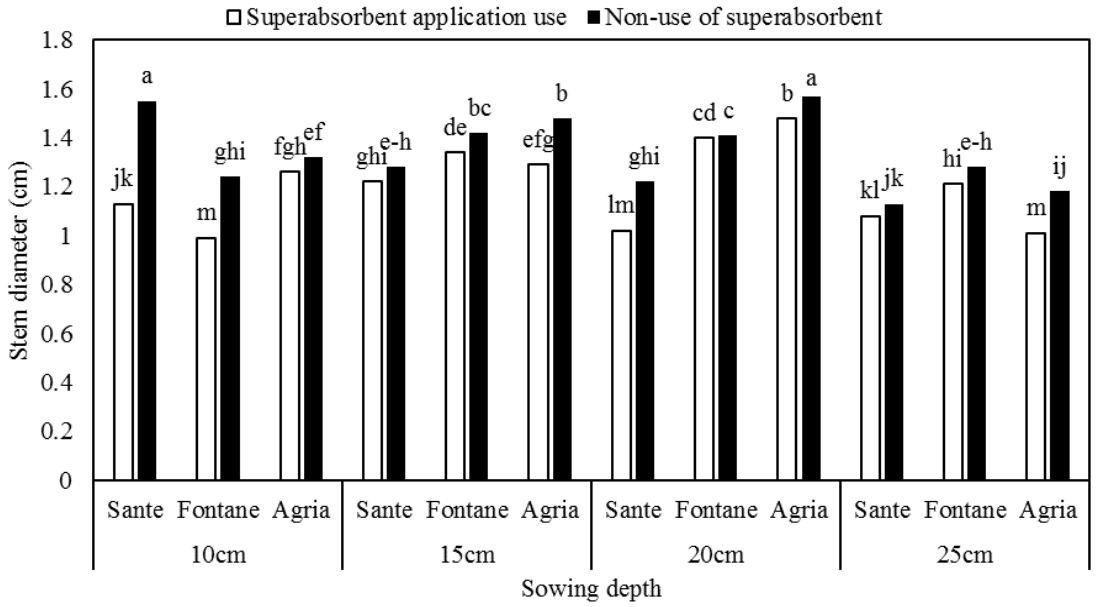

Figure 4. *The interaction of cultivar (Sante, Fontane and Agria), sowing depth (10, 15, 20 and 25 cm), and superabsorbent (application and non-application) on stem diameter of potato at flowering time. © 2018, ALÖKI Kft., Budapest, Hungary

In this relation, King et al. (2004) stated that the soil water deficit in the mid and late stages of potato tuber yield could reduce the tuber yield. SAP can increase the growth and yield of crops by increasing the absorption and maintenance of water in soil, storage of nitrogen, phosphorus, sulfur and exchangeable cations, as well as increasing ventilation by improving soil structure (Nazarli et al., 2010). Other researchers reported a decrease in yield, yield components including number of tubers per crop, and the average weight of the tuber per crop, as well as reduced water use efficiency due to the application of water stresses (Alva et al., 2012; Liu et al., 2006; Ayas, 2013).

Percentage of dry matter

With significance of interaction between cultivar, sowing depth, use of SAP, it was determined that the highest percentage of dry matter in Sante and Fontane cultivars was cultured at 10 cm depth without using SAP. In general, the use of SAP and increasing the sowing depth in all three cultivars resulted in a significant decrease in the percentage of dry matter, while their variation was not uniform (*Fig. 7*).

Several studies showed that the percentage of dry matter of the tubers increases with decreasing irrigation, drought stress, and reducing yield (Ayas and Korukcu, 2010; Ayas, 2013; Porter et al., 1999). It seems that the reason for increasing dry matter percentage due to drought stress is to reduce the potential of water around the root and water deficit of the crop resulting in less water being directed to the tissues of the crop while the percentage of dry matter of the tubers increased (Bagheri et al., 2016).

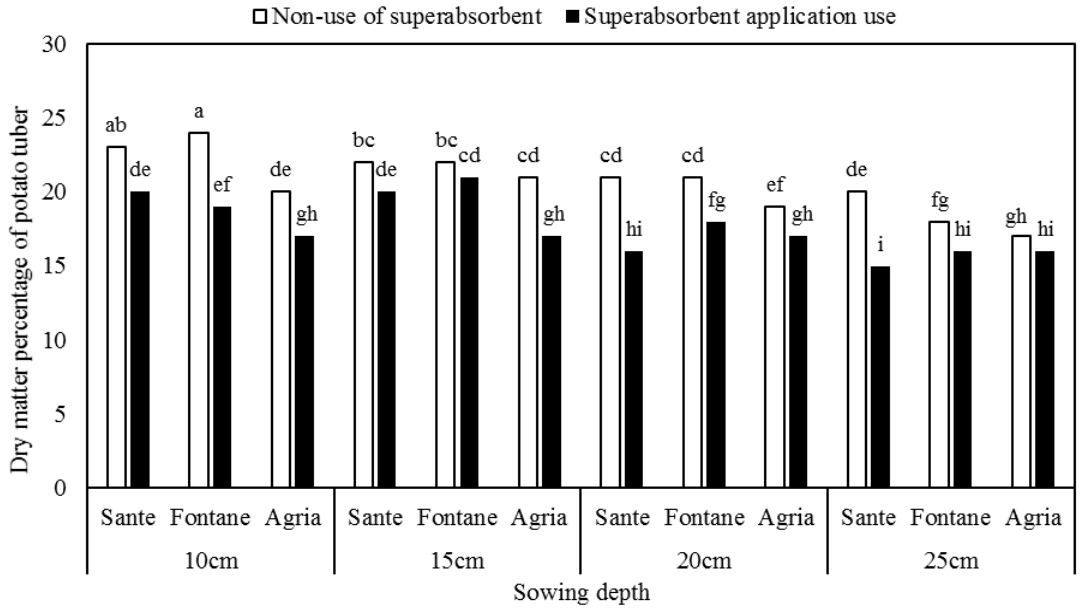

Figure 7. *The interaction of cultivar (Sante, Fontane and Agria), sowing depth (10, 15, 20 and 25 cm), and superabsorbent (application and non-application) on dry matter percentage of potato tuber. At each treatment, values with the different letters are significantly different according to Duncan's multiple range test at $P < 0.05$*

Leaf area index (LAI) and leaf area duration (LAD)

The results showed that in all three cultivars, the use of SAP led to an increase in leaf area index and leaf area duration. The highest leaf area index in Sante and Agria

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_70637078
© 2018, ALÖKI Kft., Budapest, Hungary

cultivars was obtained with SAP use (*Figs. 8* and *9*). In Sante cultivar at 10 cm depth, leaf area index and leaf area duration were lower than other treatments. Increasing the sowing depth to 20 cm in Sante cultivar resulted in an increase in leaf area index. In other treatments, this trend was the same (*Figs. 10* and *11*). *LAI* and *LAD* levels increased with increasing SAP depth and use. The highest rate of these two traits was obtained under the conditions of SAP use at three depths of 15, 20, and 25 cm. The amount of *LAI* and *LAD* at sowing depth of 10 cm was less than three other depths (*Figs. 12* and *13*).

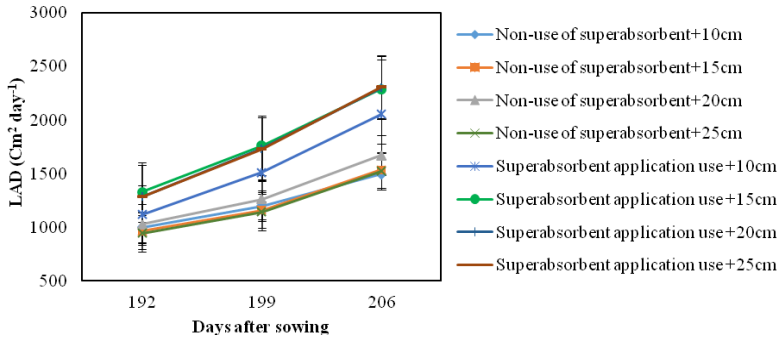

Figure 13. *The effects of superabsorbent use and sowing depth on the leaf area duration of potato (LAD). Bars represent standard errors of three replicate*

Drought stress can reduce leaf area and photosynthesis (Ierna and Mauromicale, 2006). The study results of FazeliRostampour (2013) showed that the use of SAP and supply of needed water up to 80% increased the leaf area index and leaf area duration.

Crop growth rate (CGR)

The effects of cultivar and SAP use indicated that in all three cultivars, the use of superabsorbent n led to an increase in *CGR* (*Fig. 14*). In Sante cultivar at 10 cm depth,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_70637078
© 2018, ALÖKI Kft., Budapest, Hungary

CGR was less than other treatments during the growing season. Increasing the depth of cultivation in the Sante cultivar led to an increase in *CGR* (*Fig. 15*). In each of the four depths, the SAP use resulted in an increase in *CGR* compared with the absence of SAP use. The highest *CGR* was obtained under the conditions of SAP use at three depths of 15, 20 and 25 cm (*Fig. 16*).

Higher the LAI and the adequate absorption of radiation results in higher production rates and higher growth rates. Reducing the leaf water potential results in the reduced growth rate of the product due to the increase in respiration rate associated with the increase in plant temperature and reduction of the intensity of photosynthesis (Evans, 1978).

Conclusion

In conclusion, increasing the sowing depth to 25 cm resulted in increasing the number of days to 50% germination, number of stems per crop, and tuber yield. However, increasing the sowing depth resulted in the reduced tuber dry weight. In general, the use of superabsorbent in all three cultivars and at different sowing depths resulted in a significant increase in tuber yield relative to the non-use of superabsorbent. The results of growth indices showed that in all three cultivars, the use of superabsorbent led to an increase in leaf area index, in leaf area duration, and in crop growth rate. Based on the results of this study and durability of superabsorbent polymer in soil, we can say that using superabsorbent under different sowing depth conditions can increase the potato yield and productivity.

Abstract. Potassium (K) as a macro nutrient governs important physiological mechanisms ensuring optimum plant growth and produce quality. An experiment was conducted during the summer of 2017 to study the effects of potassium application on maize under high nitrogen (N) nutrition with optimum and reduced irrigations. The experiment was comprised of three factors, viz. two irrigation levels (optimum, reduced), three potassium levels (80, 120 and 160 kg ha^{-1}) and four nitrogen levels (100, 150, 200 and 250 kg ha^{-1}). Two separate trials were carried out in randomized complete block design (RCBD), one under optimum (five irrigations) and another under reduced irrigation (three irrigations). One control plot (0K, 0N) was used under each replication for both trials. Optimum irrigation had resulted in maximum days of tasseling, silking, physiological maturity, crop growth rate (CGR), net assimilation rate (NAR), absolute growth rate (AGR), plant height, grains ear^{-1}, thousand grains weight, biological yield, grain yield, chlorophyll contents and shelling percentage. High N (250 kg ha^{-1}) delayed tasseling, silking and physiological maturity and resulted in maximum growth, physiological traits and biological yields. However, 150 kg N ha^{-1} had resulted in maximum number of ears m^{-2}, number of grains ear^{-1}, thousand grains weight and grain yield. While 100 kg N ha^{-1} had resulted in early tasseling, silking and physiological maturity. Potassium fertilization at the rate of 160 kg ha^{-1} delayed phenology and recorded with maximum growth rates, improved physiology and maximum yield traits and grain yield. However, the treatment 120 kg K ha^{-1} remained almost statistically similar to the 160 kg K ha^{-1} for most of the parameters. In the case of control vs rest, generally the performance of the control plot was poor. Hence, 150 kg N ha^{-1} with 120 kg K ha^{-1} under optimum irrigation is recommended for optimum productivity of maize crop.

Introduction

Maize (*Zea mays* L.) is the third most important cereal crop in Pakistan after wheat and rice and ranks second in Khyber Pakhtunkhwa province after wheat. Maize is cultivated in Pakistan on 64% irrigated and 36% on rainfed land (Ahmad and Rashid, 2003). Implementation and adoption of the new production technologies had increased the maize production per unit area due to balance use of agriculture inputs and new methods (Amanullah, 2004).

Improper application of the synthetic fertilizers in Khyber Pakhtunkhwa is the main cause of low yield of maize (Amanullah et al., 2014). In Pakistan only tobacco crop receive potassium due to industrial requirement while farmers do not apply potassium to wheat and maize in general. Deficiency of potassium is reported in most of the Pakistani soils due to multiple cropping systems (Ahmad and Rashid, 2003). Potassium is used by the crops in large amounts (Mengel et al., 2001; White and Karley, 2010). A soil deficient in potassium results in reduced plant photosynthesis (Wang et al., 2015a), which is the main cause of low yield of maize (Amanullah and Khalid, 2016), sunflower (Amanullah and Khan, 2010) and brassica (Amanullah et al., 2011).

Potassium is the primary major nutrient which is a non-structural component of the plant body. After nitrogen it is the second most abundant nutrient in plant tissues generally 1-3% by weight. It is very important for the transport of assimilates in plant cells and activates more than 60 different enzymes. Potassium increases plant tolerance to frost and heat injuries, droughts and enhances the resistance to diseases, different pest incidence and keeps anion balance in plants (Wang et al., 2013). The most important role of K^+ in plants is the osmoregulation which maintains turgor pressure in the cell, crucial for cell elongation and hence the growth and regulation of stomatal opening and closing, affecting carbon dioxide intake by photosynthesis process and transpirational cooling (Marschner, 1995). Potassium is a macro nutrient which is important for the growth of plants. Comparatively the large amounts of mineral potassium are present in the Pakistani soil which is non-soluble, and only a small amount is available to plants. Optimum amount of potassium in the soil in case of water scarcity comparatively enhances deposition of total dry matter in the crops compared to soils with less potassium regimes (Rosenstock et al., 2016). Potassium regulates stomata which in turn enhance photosynthesis (Marschner, 2012). Moreover, the root growth is supported by the crucial role of potassium in the transportation of photosynthetic products (Romheld and Kirkby, 2010).

Being a macro-nutrient, nitrogen is essential for the plant health and acts as a growth-limiting nutrient (Noor, 2017; Wang et al., 2018). Nitrogen is the major part of several essential organic compounds such as amino acids, proteins, coenzymes, nucleic acids, chlorophyll, cytochrome, ribosomes and many vitamins (Noorka et al., 2009, 2011). Among various grasses, maize is the grass whose nitrogen requirements for optimum grain yield is very high (Noor, 2017). Certain metabolic processes of the plants depend on the role of nitrogen in plants (Wang et al., 2015b). During the whole grain-filling stage, it aids to keep the kernels active, affecting the size and number of improved kernels (Huber et al., 1994). Usually nitrogen demand of maize is very different, and approximately 0-250 kg N ha^{-1} is the range for economically optimal nitrogen rates (EONR) (Scharf et al., 2006). Therefore, it is imperative to manage nitrogenous fertilizers accurately (Noor, 2017), but the capacity to determine the exact EONR had been kept comparatively elusive.

A sufficient amount of water in the soil is important for the growth and development of crops, recovery of water loss through transpiration and as a transport medium for nutrients to roots (Wang et al., 2018). Scarce availability of water to crops in the soil leads to drought. Acute water deficiency reduces water use and hence crop yield. There are three big processes by which maize yield is limited by water scarcity in the soil: (i) decreased absorption of the incident photosynthetically active radiation by canopy, (ii) reduced radiation use efficiency, (iii) decreased harvest index (Earl and Davis, 2003).

To know and keeping in mind the importance of potassium, in case of high nitrogen nutrition impact on maize lodging under optimum and reduced irrigations, the present experiment was designed and conducted to find out optimum level of potassium for improved growth and yield traits by minimizing lodging losses, enhancing resistance to drought and to figure out the best nitrogen level for higher maize productivity in the agro-climatic conditions of Peshawar, Pakistan.

Materials and methods

Site description

Field experiments were conducted to study the response of spring planted maize hybrid, at Agronomy Research Farm, The University of Agriculture Peshawar, Pakistan, during the summer of 2017. The research farm is located at 34.01°N, 71.35°E, at an altitude of 350 m above sea level in the Peshawar valley (*Fig. 1*). Peshawar is located about 1600 km north of the Indian Ocean and has semiarid climate. The research farm is irrigated by the Warsak canal from Kabul River. The soil of the farm is clay loam in texture, alkaline (pH 8.2), and calcareous, with a low organic matter content of 8.7 (g kg^{-1}) and low concentrations of extractable phosphorus of 6.57 mg kg^{-1} and exchangeable potassium (AB-DTPA) of 121 (mg kg^{-1}). The climate of the area is semiarid where the mean annual rainfall is very low (300 to 500 mm), 60–70% rainfall occurs in summer, while the remaining 30–40% rainfall occurs in winter.

Experimental treatments and management practices

Two trials, one with optimum irrigation (I) (I = 5 irrigations) and another with reduced irrigation (I_2 = 3 irrigations) were carried out in randomized complete block design (RCBD). Nitrogen (N_1 = 100, N_2 = 150, N_3 = 200 and N_4 = 250 kg ha^{-1}) and potassium (K_1 = 80, K_2 = 120 and K_3 = 160 kg ha^{-1}) were applied in combination to both experiments with three replications. Each replication was added with an unfertilized plot (0N, 0K). CS-220 variety of maize was sown on 18th May 2017 with a sub-plot area of 3 m × 4 m, which was consisted of 70 cm apart 3 m long 5 rows. Seeds were planted at the rate of 35 kg ha^{-1}. Before seed bed preparation, presoaking irrigation of 100 mm was given. When the soil reached at field capacity, seedbed was prepared. Subsequently, five irrigations (75 mm each) were applied at VE, V6, V12, V18 and R1 stages of maize for optimum irrigation treatment. For the reduced irrigation, three irrigations (75 mm each) were applied at VE, V12 and R1 stages of maize. Muriate of potash (MOP) was used as a source of potassium which contains 60% K_2O, Similarly N was applied as urea (46% N). Source of phosphorus was triple super phosphate (TSP) at the rate of 90 kg ha^{-1}. Potash and phosphorus were applied as a whole at the planting time, whereas half split of nitrogen was applied at planting and the other half at V6 stage (knee height). Weeds were controlled by applying herbicide Primixtra gold (S-

Metolachlor 400 g/L, Atrazine 320 g/L) at rate of 2000 ml ha^{-1} two weeks after sowing maize crop. On the basis of calibration for experimental area, 250 l ha^{-1} water was used for the herbicide application. Furadan (Carbofuran) was applied at rate of 10 kg ha^{-1} with second irrigation and 10 kg ha^{-1} with the third irrigation. During the whole growing season, uniform agronomic techniques were performed in all sub plots.

Figure 1. *Location of the study site in the Peshawar city of Pakistan. (Modified from the source: www.surveyofpakistan.gov.pk)*

Harvesting of whole plots was done manually on 15th August 2017. After harvesting, plants were kept in the field for three days and then tied into bundles and stacked in the sun light for 3 weeks for sun-drying. After 3 weeks the ears of the whole plot were husked and allowed to dry in sunshine for two days. After sun-drying, husked ears were threshed by maize sheller and subsequent calculations were done to determine grain yields.

Measurements

Phenological parameters

Days to tasseling data were recorded by counting days from planting date to the date when 50% plants had produced tassels in each plot. Days to silking data were figured out in each plot by counting the number of days from sowing date to the date when 50% silks

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_70797097
© 2018, ALÖKI Kft., Budapest, Hungary

were appeared. Data on days to physiological maturity were recorded by counting the number of days between sowing date and the date when 50% plants in each plot get matured. The sign of physiological maturity i.e. dark brown/black abscission layer appearance in the base of seed was considered. For recording plant height (cm) with the help of meter rod, five plants were randomly chosen at silking stage in each sub-plot and then averaged.

Physiological traits

For calculating CGR (Crop Growth Rate, g m^{-2} d^{-1}), one meter long row from side rows in each experimental unit was harvested and plants were oven-dried for 72 h at 70 °C to calculate their dry weight at, (1) V6 leaf stage, (2) Blister stage, and (3) R6 (Physiological maturity) stage. Formula used was:

$$CGR\ (g\ m^{-2}\ d^{-1}) = [(W_2 - W_1) / (T_2 - T_1) \times (1 / GA)]$$

where, W_1 = Initial weight at 27th day after sowing; W_2 = Last weight at 98th day after sowing; T_1 = Initial date 18th May 2017 (Sowing); T_2 = 30th August 2017 (Harvesting); GA = Row to row distance (0.75 cm) × plant to plant distance (20 cm) × number of plants (five plants)

Similarly, for absolute growth rate (AGR) one meter long row was selected from each plot was harvested and oven-dried for 72 h at 70 °C and then dry weight was determined at various growth stages viz. (1) V6 leaf stage, (2) Blister stage, and (3) R6 stage. AGR was figured out by the following formula:

$$AGR\ (g\ m^{-2}\ d^{-1}) = W_2 - W_1 / T_2 - T_1$$

where, W_1 = weight at 27th day after sowing; W_2 = weight at 98th day after sowing; T_1 = date 18th May 2017 (sowing); T_2 = 15th August (harvesting).

Net assimilation arte (NAR) was calculated similarly as for CGR in each sub plot by selecting one meter long row from border rows, and harvested and oven-dried at 70 °C for 72 h. Dry weight was found out at two growth stages, (1) V6 stage, and (2) R6 stage (physiological maturity). The following formula was used for NAR:

$$NAR\ (g\ m^{-2}\ d^{-1}) = [W_2 - W_1 / T_2 - T_1] \times [\ln L_2 - \ln L_1 / L_2 - L_1]$$

where, W_1 = weight at 27th day after sowing; W_2 = weight at 98th day after sowing; T_1 = date 18th May 2017 (sowing); T_2 = 15th August 2017 (harvesting); L_1 = Initial leaf area at 18th May 2017; L_2 = final leaf area at 15th August 2017.

Chlorophyll contents at different stages

From each experimental unit, five plants and three leaves per plant were randomly selected and sampled. The chlorophyll contents were measured out on three locations per leaf with chlorophyll meter (Model: SPAD-502, Minolta, Japan) and then averaged.

Yield and yield attributes

Ten ears were randomly chosen and sampled from each experimental unit and grains were counted and averaged. From these sampled ears, 1000 grains were randomly

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_70797097
© 2018, ALÖKI Kft., Budapest, Hungary

selected and weight was measured by electronic balance. At R6 stage, three central rows in each experimental unit were harvested manually by keeping sufficient border plants, fresh weight was measured and then sun-dried for 7 d and after that their dry weight was recorded. For calculating grain yield, all the ears from sun-dried plants of three central rows for each plot were threshed and weighed for calculating grain and biological yields, and for ear characteristics. The grain yields were adjusted to 15.5% grain moisture content and then presented. For each treatment, shelling percentage was estimated with the following formula:

$$\text{Shelling percentage} = \text{Grain weight of 10 ears} / \text{Total weight of 10 ears} \times 100$$

Statistical analysis

Data were statistically analyzed by analysis of variance (ANOVA) procedure suitable for randomized complete block design. Means were compared using least significant difference (LSD) test at 0.05 probability level, when F-values were significant (Steel et al., 1996). Interaction graphs were made through Sigma plot software (version 12.5).

Results

Phenological parameters

Irrigation, nitrogen, potassium and control vs rest significantly affected number of days to tasseling of maize, whereas all the interactions were found non-significant (*Table 1*). Means values of the data indicated that optimum irrigation significantly enhanced days to tasseling compared with reduced irrigation. Results revealed that lower N (100 kg ha^{-1}) resulted in early tasseling. Days to tasseling were delayed with increase in nitrogen and maximum days to tasseling were noted with 250 kg N ha^{-1}. Potassium fertilization at the rate of 120 kg ha^{-1} showed maximum days to tasseling which were statistically same to 160 kg K ha^{-1} treatment, while less days to tasseling were recorded with 80 kg K ha^{-1}. Fertilized plots resulted in more days to tasseling compared with control plots.

Results revealed that days to silking were significantly influenced by nitrogen, potassium and control vs rest comparison, whereas irrigation and all the interactions were found non-significant (*Table 2*). Mean values for nitrogen showed that lower N (120 kg ha^{-1}) resulted in early silking, while delayed silking was observed with nitrogen application at the rate of 250 kg ha^{-1}. Maximum days to silking were noted with 160 kg K ha^{-1} while less days to silking were recorded with potassium fertilization at the rate of 80. Data regarding physiological maturity was also effected by all treatments, while all the interactions were non-significant (*Table 1*). Optimum irrigation resulted in late physiological maturity compared to reduced irrigation. Mean values for nitrogen reported that minimum days to physiological maturity were observed with lower N (100 kg ha^{-1}) which were statistically identical to 150 kg N ha^{-1}. Increase in N had delayed the maturity and more days to physiological maturity were recorded for 250 kg N ha^{-1}. Potassium fertilization at the rate of 160 kg ha^{-1} delayed physiological maturity while early maturity was observed with 80 kg K ha^{-1}.

Plant height was also affected significantly due to irrigation and N treatments, whereas potassium and all the interactions were found non-significant (*Table 1*). Taller plants were produced by optimum irrigated plots. Mean values of the data revealed that nitrogen application at the rate of 100 kg ha^{-1} resulted in shortest plants. Plant height increase with each increment of N and significantly tallest plants were recorded with 250 kg N ha^{-1}. The tallest plants were produced with 160 kg K ha^{-1} treatment. Fertilized plots produced taller plants as compared to control plots.

Growth parameters

All the treatments had significantly affected the growth parameters at different stages, while all the interactions were found non-significant (*Table 2*). Results showed that S1 (1st sampling stage) recorded with higher crop growth rate than S2 (2nd sampling stage). Mean values of the data indicated that optimum irrigation significantly increased the crop growth rate compared to reduced irrigation treatment. Mean values for nitrogen revealed that lower N (100 kg ha^{-1}) resulted in less crop growth rate. Crop growth rate increased with increase in N and significantly higher crop growth rate was recorded for 250 kg N ha^{-1}. Potassium application at the rate of 160 kg ha^{-1} resulted in more crop

growth rate while less crop growth rate was observed with 80 kg K ha^{-1}. The treatment 120 kg K ha^{-1} was statistically similar to the highest K application treatment. Fertilized plots resulted in more crop growth rate compared to control plots.

All treatments and stages significantly affected absolute growth rate (AGR) of maize, while all the interactions were found non-significant (*Table 2*). Results showed that S1 produce more AGR than S2. Mean values of the data indicated that optimum irrigation significantly produced more AGR. AGR increased with increase in N and significantly more values were recorded with 250 kg N ha^{-1}. Potassium application at the rate of 160 kg ha^{-1} was found with maximum AGR, and was similar to 120 kg K ha^{-1}.

Almost same trend was found for net assimilation rate (NAR) of maize (*Table 2*). Results showed that S1 produce more NAR than S2. Amongst N treatments, 250 kg N ha^{-1} was found maximum and K application at the rate of 160 kg ha^{-1} resulted in maximum NAR, and was to 120 kg K ha^{-1}.

Chlorophyll contents at different stages

All the treatments and the control vs rest significantly affected chlorophyll contents at tasseling stage of maize, while all the interactions were found non-significant (*Table 3*). Lower N (100 kg ha^{-1}) resulted in less chlorophyll contents at tasseling stage. Whereas, 250 kg N ha^{-1} produced maximum chlorophyll contents at tasseling stage. Optimum irrigation and the potassium application at the rate of 160 kg ha^{-1} resulted in more chlorophyll contents at tasseling stage.

Almost the same results pattern for treatments were found for the SPAD values at later stages of silking and grain formation, as recorded for tasseling stage. We observed that silking stage was recorded with maximum SPAD values (chlorophyll contents) as compared to other two stages (*Table 3*).

Yield and yield attributes

Data concerning grains ear^{-1} of maize showed that all the treatments (I, N, K) significantly influenced grains ear^{-1}, whereas all the interactions were found non-significant (*Table 4*). More number of grains ear^{-1} were produced by optimum irrigated plots. N fertilization at the rate of 100 kg ha^{-1} produced less grains ear^{-1}. Grains ear^{-1} increased with increase in nitrogen up to 150 kg ha^{-1}. Thereafter, no increase in grains ear^{-1} were observed with further increase in N level. Maximum number of grains ear^{-1} were produced when potassium was applied at the rate of 160 kg ha^{-1} which was statistically similar with 120 kg K ha^{-1}. Fertilized plots produced more grains ear^{-1} in contrast to unfertilized plots.

weight was noted with increase in N level. Potassium application at the rate of 120 kg ha^{-1} resulted in more thousand grains weight which was statistically similar to 160 kg K ha^{-1}.

Irrigation (I), nitrogen (N), potassium (K), control vs rest and K × N interaction significantly affected biological yield of maize (*Table 4*). Optimum irrigation remained superior in this regard. Mean values for nitrogen revealed that lower N resulted in less biological yield. Biological yield increase with increase in N and significantly more biological yield was recorded with 250 kg N ha^{-1} which was statistically similar with 200 kg N ha^{-1}. Potassium application at the rate of 120 kg ha^{-1} resulted in more biological yield which was statistically similar to 160 kg K ha^{-1}. K × N interaction represented that application of K at the rate of 80 kg ha^{-1} × 100 kg N ha^{-1} produced less biological yield. Biological yield increased up to 80 kg K ha^{-1} × 150 kg N ha^{-1}. Thereafter, no increase in biological yield was noted with increase in N level. In case of 120 kg K x N, biological yield increased linearly with increase in N up to 200 kg N ha^{-1}, thereafter a slight decrease in biological yield was noted with increase in N level up to 250 kg ha^{-1}. Similarly in case of 160 kg K x N, biological yield increased linearly with increase in N up to 150 kg N ha^{-1}, thereafter a slight increase in biological yield was noted with increase in N level up to 250 kg ha^{-1} (*Fig. 2*).

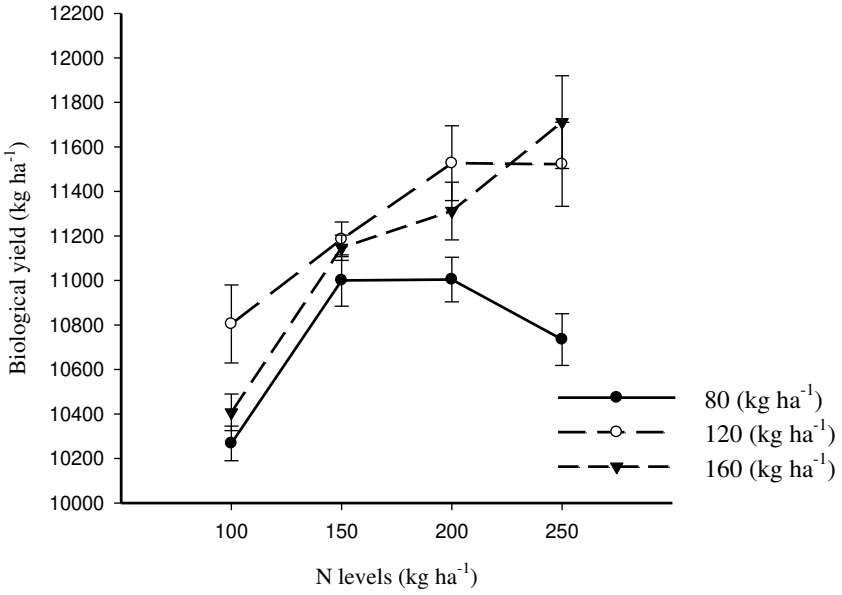

Figure 2. *Interactive response of K and N on biological yield (kg ha^{-1})*

Irrigation (I), nitrogen (N), potassium (K), control vs rest and K x N interaction significantly affected grain yield of maize, whereas other interactions were found non-significant (*Table 4*). K × N interaction represented that application of K at the rate of 80 kg ha^{-1} × 100 kg N ha^{-1} produced less grain yield. Grain yield increased up to 80 kg K ha^{-1} × 150 kg N ha^{-1}. Figure 3. *Interactive response of K and N on grain yield (kg ha^{-1})*

Irrigation (I), nitrogen (N), potassium (K) and control vs rest significantly affected shelling percentage of maize, while all the interactions were found non-significant (*Table 4*). Optimum irrigation significantly recorded with maximum shelling percentage. Shelling percentage increased with increase in N and significantly more shelling percentage was recorded with 250 kg N ha^{-1}. Potassium application at the rate of 160 kg ha^{-1} resulted in more shelling percentage while less shelling percentage was observed with 80 kg K ha^{-1}. Fertilized plots resulted in more shelling percentage compared with control plots.

Discussion

Effect of N and K on phenology of maize under optimum and reduced irrigation

Delayed tasseling was observed with higher levels of nitrogen and potash. This delayed phenology with increasing N levels could be attributed to the impact of N on vegetative growth of maize crop, and photosynthetic performance (Ma et al., 2015), that might had increased leaf longevity and ultimately phenological development (Wang et al., 2017). These results are in full accordance with that of Peng et al. (2017) who observed delayed phenology with higher levels of N. Likewise, delayed tasseling under high level of potassium could be attributed to the role of potassium in stomata regulation and photosynthetic activity (Shah et al., 2017). These results were supported by Zamir et al. (2015) who observed delayed tasseling from plots having higher levels of potash. The optimum irrigation level had delayed days to tasseling in comparison with reduced irrigation which could be attributed to hormonal changes and greater availability of N and K (Alfredo and Setter, 2000). Delayed silking in plots treated with higher levels of N might be attributed to vigorous vegetative growth in response to higher nitrogen use efficiency that might had delayed the silking (Sharifi and Namvar, 2016). These results are also supported by Muller et al. (2017), as they observed delayed silking with increasing levels of N. Delayed silking with higher levels of K are further evidenced by Aslam et al. (2014).

Delayed maturity in plots treated with higher levels of N could be attributed to prolonged vegetative growth. This prolong vegetative growth might be attributed to retention of green leaf, higher chlorophyll contents, and greater photosynthetic performance (Zhang et al., 2014). Higher rates of N delayed leaf senescence and uphold extended photosynthetic performance that might have delayed the maturity (Arif et al., 2012). These results are in line with that of Ali et al. (2012), who observed delayed physiological maturity from plots treated with higher N levels. The delayed maturity under higher K levels could be attributed to improved water use efficiency and higher uptake of nutrients that extended the vegetative growth and delayed maturity (Hati et al., 2006). These results are in line with Iqbal et al. (2016), who observed delayed physiological maturity with higher K levels. Although plant height is genetically controlled character however, it is also influenced from environment and management practices (Achieng et al., 2010). Taller plants in plots treated with higher levels of N might be related to impact of N on enzymatic and photosynthetic activities as well as cell division and stem elongation (Cechin and Fumis, 2004). The report of Achieng et al. (2010) are in full accord with our finding. The taller plants obtained from optimum irrigation could be attributed to better physiological activities and improved plant growth (Gaveh et al., 2011). Our results are also in line with that of Cakir (2004).

Effect of N and K on growth indices of maize under optimum and reduced irrigation

The higher crop growth rate in response to optimum nitrogen application is attributed to higher leaf area and leaf area index and higher chlorophyll contents (Azarpour et al., 2014). The higher level of nitrogen promotes hormonal activities in plants that enhance the vegetative growth and leaves enlargement (Azarpour et al., 2014). The higher crop growth rate in early stages compared to later stages of plant development is supported by Peng et al. (2017). The higher CGR means greater dry matter is accumulated by plants per unit area per unit time as a result of enhanced photosynthetic efficiency which might increase in response to higher levels of potassium application and optimum irrigation (Inthichack et al., 2012). These results are supported by Antony and Singandhupe (2004) who observed greater plant growth and final yield in response to optimum irrigation regime. Al-Omran et al. (2010) reported that optimum water supply is essential for higher crop growth, which is in accordance with our findings.

The higher net accumulation rate and absolute growth rate of maize crop was observed from application of higher levels of N and K as well as optimum irrigation. The higher concentration of nitrogen and potassium might had increased enzymatic activities responsible for translocation of assimilates towards the economic portion (Zhong et al., 1997). The higher rates of N and K had increased the dry matter of plants through increased photosynthates production that might had increased the net accumulation rates. Likewise optimum irrigation might had improved the leaf longevity that might results in optimum NAR compared with reduced irrigation (Amanullah and Khalid, 2016). These results are in line with that of Azizian and Sepaskah et al. (2014). The maximum shelling percentage of maize crop was observed from higher levels of nitrogen and potash as well as optimum irrigation treatment was due to optimum leaf area and chlorophyll contents that might had increased the physiological parameters i.e. CGR, NAR and AGR, thus resulting in maximum translocation of assimilates towards the economic portion. This higher translocation of assimilates might had improved the shelling percentage. These results are further supported by the findings of Shah et al. (2017).

Effect of N and K on chlorophyll contents of maize under optimum and reduced irrigation

The increased chlorophyll contents of maize leaf in response to increasing levels of nitrogen might be attributed to the impact of nitrogen on leaf growth and leaf area (Bojovic and Markovic, 2009). The same authors reported a high correlation between nitrogen application and leaf chlorophyll contents. It was reported that nitrogen is the structural element of protein and chlorophyll molecule, and its higher concentrations had proved to increase the chloroplast formation and leaf photosynthetic efficiency (Shah et al., 2017). Hokmalipour and Darbandi (2011) reported that nitrogen fertilization activates the enzymes associated with chlorophyll formation thus results in higher concentration of chlorophyll than control plots. These results are in full accordance with that of Ciompi et al. (1996) and Zhao et al. (2005). The higher chlorophyll contents in plots treated with higher levels of potassium might be associated with better nitrogen uptake under higher N levels (Peng et al., 2017). Potassium is essential for chlorophyll formation, stomatal conductance and RuBP case activities, thus it had great impact on photosynthesis (Liu et al., 2009). These results are further supported by Shah et al. (2017). The maximum chlorophyll content in response to optimum irrigation is supported by Liu et al. (2005).

Effect of N and K on agronomic traits of maize under optimum and reduced irrigation

Number of grains ear^{-1} was significantly affected by N, K and irrigation levels. Optimum number of grains ear^{-1} was recorded from plots having 180 kg N ha^{-1}. This increase could be attributed to greater seed row ear^{-1} and number of grains row^{-1} (Hokmalipour and Darbandi, 2011) and maximum dry matter accumulation. These results are supported by Shah et al. (2017). The K fertilization has likely to increase the water use efficiency of crops under water limited conditions and hence increased the dry matter production and its ultimate partitioning towards the reproductive part of the plant, that might had increased the number of grains ear^{-1} (Iqbal et al., 2016). These results are supported by Shah et al. (2017) who observed higher number of grains ear^{-1} from increasing K levels.

Higher thousand grains weight and grain yield from plots treated with 180 kg N ha^{-1} might be attributed to higher chlorophyll contents associated with higher leaf area, that might had increased the photosynthetic efficiency and assimilates production and its availability during grains filling stage (Manzoor et al., 2006). The higher assimilates production through photosynthesis and its efficient partitioning towards the grain might had increased the yield and yield components of maize (Khan et al., 2014b). These results are fully supported by the results reported by Hokmalipour and Darbandi (2011). The increased yield and yield components of maize in response to higher levels of K might be attributed to the role of K in increasing water use efficiency that might had increased the cell division, improved plant growth and efficiently translocate the photosynthates towards the grains (Shah et al., 2017). However Enujeke (2013) reported that accumulation of proteins and other reserves food might be the cause for increased yield. The probable reason for optimum yield with higher K levels could be more leaf area, delayed maturity and improved yield attributes (Iqbal et al., 2016), due to stabilized stomatal regulation, greater carbon dioxide assimilation and the more carbohydrate production (Zeidan and Kramany, 2001). The increase in grain yield with

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_70797097
© 2018, ALÖKI Kft., Budapest, Hungary

optimum irrigation have also been reported by Pandey et al. (2000) and Khan et al. (2014a). The combination of N and K had boosted 1000 grains weight and grain yield than their sole use. This increase in grain yield is also supported by the study of Shah et al. (2017).

The maximum biological yield in response to increasing levels of nitrogen might be attributed to better vegetative growth, greater leaf area and dry matter production (Keivanrad and Zandi, 2012) probably due to lower completion of plants for N and more even distribution of assimilates (Zangani et al., 2006). These results are in line with that of Imran et al. (2015), who observed maximum biological yield from higher doses of N fertilizer. Likewise the stover and biological yield was increased with increasing levels of potassium which might be attributed to the better plant growth due to the possible role of potassium in water balance, maintenance of turgor pressure, transportation of assimilates and disease resistance (Brar and Tiwari, 2004). The report of Hosinkhani et al. (2013) was also found in accordance with our findings. Shah et al. (2017) also reported similar results as ours. The optimum irrigation had increased the biological yield in comparison with reduced irrigation which might be explained with proper plant growth and better development due to moisture availability at sensitive stages of phonological development (Ngwako and Mashiqa, 2013). These results are supported by Hussain et al. (1996). The increase in biological yield with integrated use of N and P was supported by Khan et al. (2014a). Brar and Tiwari (2004) also observed the increase in biological yield of maize from integrated use of N and P, and attributed this increase to greater nitrogen use efficiency.

Conclusion

On the basis of findings obtained in present work, it is concluded that optimum irrigation produced optimum plant growth, yield and yield attributes in maize. Application of 120 kg K ha^{-1} had resulted in higher grain yields and yield components. Whereas, application of 150 kg N ha^{-1} boosted maize yield and yield components to their optimum levels. Based on the results, application of 120 kg K ha^{-1} along with 150 kg N ha^{-1} is recommended for obtaining optimum growth, yield and yield attributes under optimum irrigation (five irrigations) for maize in agro-climatic conditions of the Peshawar, Pakistan. To strengthen our results, future studies should focus on optimizing the fertilizer (N, P, K) rates by estimating the nutrient use efficiencies, with special emphasis on agronomic- and physiological-use efficiency for the maize hybrids being cultivated in major areas of Pakistan. In addition to nutrient recovery analysis, the data pertaining to the plant organ nutrient analysis for N, P and K under different planting densities are vital for the Pakistani maize production system.

(Received 31st Jul 2018; accepted 28th Sep 2018)

Abstract. This study explores the relationship between environmental factors and the main essential oil components in the leaves of Crimean juniper (*Juniperus excelsa* M. Bieb.), which is commonly distributed in rocky and stony land with shallow soil conditions in the Mediterranean region of Turkey. After the leaf samples collected from 20 plots were dried, essential oil components were detected by GC-MS method. α-Pinene (81.3%), myrcene (5.2%) and limonene (4.5%) were found to be the major components, respectively. Relations between these major components and environmental factors (physiographic, climatic and soil factors) were questioned by Pearson correlation analysis, cluster analysis and principal component analysis. According to statistical analysis results; α-pinene bio18, altitude and pH were found to have a negative relationship. The limonene component showed a negative relationship with latitude and clay, but showed a positive correlation with pH.
Keywords: *environmental factors, climate, principal component analysis, major components, Mediterranean region*

Introduction

Due to various biochemically active substances contained by their miscellaneous organs such as leaves, cones, bark, roots and flowers, the taxa of juniper are amongst the important medicinal and aromatic plant species distributed in forests (Topçu et al., 2005). Therefore, it has been used by people not only as food and spice but also for multiple purposes such as beverage, perfumery, cosmetics, aromatherapy and medicine for treatment of some diseases since ancient times (Ložienė and Venskutonis, 2016). With the development of new technologies in recent years, juniper species just like many other medicinal and aromatic plant species can now be processed with more modern techniques and they can be used more comprehensive in different forms, e.g. such as food, medicine, pharmaceuticals and cosmetics (Faydaoğlu, and Sürücüoğlu, 2011).

It is possible to explain properties of the medical and aromatic plants with the biochemical substances they contain. Juniper species are characterized by intense essential oils they contain in different organs, and several volatile components in the essential oils. Therefore, many studies have been conducted in the scientific literature regarding the essential oil yield and components of juniper species in recent years (Bakkour et al., 2013; Höferl et al., 2014; Fejér et al., 2018).

In Turkey's forests, which cover an area of around 22.3 million hectares, juniper species are represented by 11 different taxa in 7 species belonging to 3 different sections (Fakir, 2014). In Turkey, out of these taxa, *Juniperus excelsa* M. Bieb. (Crimean juniper) has the widest distribution area (Göze et al., 2017). Around the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_70997113
© 2018, ALÖKI Kft., Budapest, Hungary

world, it is distributed in Macedonia, Aegean and Greek Islands, Asia Minor and Caucasia; while it has the widest distribution especially in the Mediterranean Region and Western Taurus range in Turkey. The distribution range of Crimean juniper extends through the steppe areas into the inner parts of Anatolia. The anthropogenic impacts throughout the history resulted in the destruction of this species in the Mediterranean forest (Fontaine et al., 2007). On the other hand, the seed dormancy and germination problems which are considered to be a general juniper-related issue has led to challenges in the regeneration of Crimean juniper in natural habitats until recently (Gülsoy and Özkan, 2013).

Crimean juniper is of ecological importance for Turkey's forests and has been used in food, pharmaceutical, medicine, preservation and perfume industries due to several chemical substances they contain in their cones, leaves and barks such as other juniper species. It is known that especially the essential oils this species contains in its organs, add value to the plant in medicinal and aromatic terms. The products such as juniper oils and juniper essence that are obtained through distillation from various organs are reported to add industrial value to this species. In particular, the extracts of the species is expressed to be the effect of anti-inflammatory, anti-microbial, antiseptic, anti-termite, insecticide, hypotensive, diuretic, antioxidant, antibacterial and antispasmodic (Moein et al., 2010; Orhan, et al., 2012; Adams et al., 2013; Göze et al., 2017).

As one can understand from the abovementioned information, Crimean juniper is an important forest tree species but also a crucial plant with its biochemical substances. Therefore, there are many studies in the literature regarding various biochemical substances of the species and its medicinal-aromatic properties. However, there is no study that explores the relationship between the ecology of the species and the main essential oil components it contains. Nevertheless, it is argued that the biochemical properties of plants vary depending on different methods applied, which part of the plant is used, maturity period, growing method and genetic factors as well as ecological conditions (Gende et al., 2010). This study aimed to identify the ecological habitat conditions of this species distributed in the Lakes District in the Mediterranean Region of Turkey. Another important intention of the study was to introduce the interactions between the environmental factors and the major essential oil components. Thus, the study aimed at obtaining significant information about the impacts on the essential oil components in the leaves depending on the ecological site conditions of this species. It is suggested that the results of this study will lead to further scientific studies on this topic.

Material and methods

Study area

This study was conducted at 20 Crimean juniper sites selected is located within the Lakes District extending from 38°25'-36°06 northern latitudes and 29°30'-32°34' eastern longitudes in the southwest of Turkey (*Fig. 1*).

The predominant bedrock formations in the study area are mainly limestone and dolomite. The main soil types are red, brown or reddish-brown forest soils of the terra-rossa type developed on karst landforms that lead to variations in soil characteristics in the district (Sandler et al., 2015). Soil depth is generally thin with a thickness of 0-40 cm on slopes and rarely deep a thickness of up to 100 cm in depressions. According to the data recorded for many years in the region, the average annual rainfall is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_70997113
© 2018, ALÖKI Kft., Budapest, Hungary

approximately 600-1300 mm and the average annual temperature varies between 12-20 °C. A subtropical Mediterranean climate generally characterized by hot and dry summer months and warm wet winter months prevails in coastal zones near the Mediterranean Sea, low-altitude locations and the sea-facing slopes of the mountains, while the transition climate from Mediterranean climate to continental climate is observed in areas distant from the sea and at higher elevations (Benli, 2016).

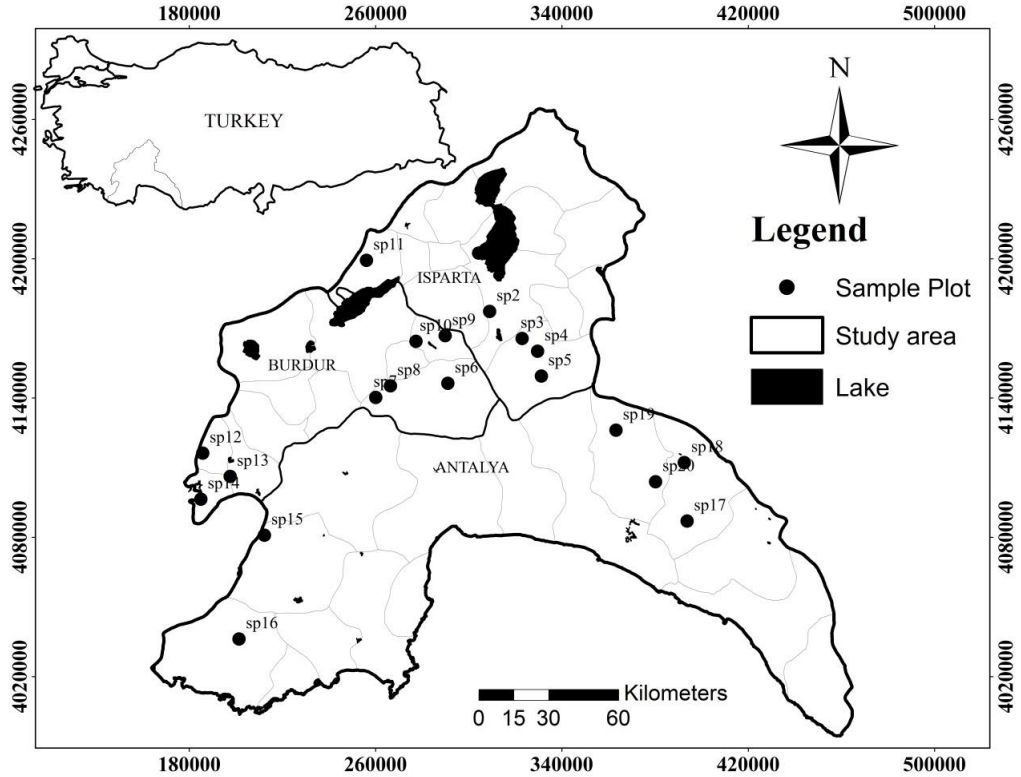

Figure 1. *Location map of the sample plots in the study area*

Data collection

Crimean juniper leaves used in this study were obtained from 20 sampling plots in the Lakes District of Turkey. These plots were selected from the sites free from human impact, fungal and insect damage. Leaves samplings were collected from the last year's shoots on the northern aspects of the plants. In addition to leaf sampling, several ecological measurements were conducted in each sampling plot in order to find the associations of the essential oil components to be derived from the leaves with environmental factors. First, latitude, longitude and elevation (m) values were recorded using GPS while the aspect of hillside (°) was recorded using a compass and the slope (%) was measured with a clinometer. The surface stoniness (%) of the land was estimated using the iron rod penetration method at 10 points randomly selected within each sampling plot (Eriksson and Holmgren, 1996). Furthermore, landform and slope position were recorded through observations in the sampling plots. The depth of the mineral soil was measured in hand-excavated pits and bedrock formations were determined from geological maps compiled by General Directorate of Mineral Research and Exploration.

© 2018, ALÖKI Kft., Budapest, Hungary

The climate maps were obtained from the database developed by Fick and Hijmans (2017) at global scale and edited with the Global Mapper at the local scale. The boundaries of the sampling plots were matched with the pixels of the maps of climate variables according to the GPS coordinates, climate data for each plots were obtained from these maps.

Before the statistical assessments, a digital elevation model (DEM) was created from the topographic database. Radiation index, heat index and topographic position index for each sampling plot were calculated using this DEM. At this stage; the radiation index equation (*Eq. 1*)

$$RI = \frac{[1-\cos((\pi/180)(Q-30))]}{2} \quad \text{(Eq.1)}$$

that can be applied to intermediate distance from equator line to 60° north latitude, slope degree less than 90°, and all aspects of hillsides was used (McCune and Keon, 2002). RI varies between 0 and 1, and the approximation of this value to 1 indicates the long duration of sunshine in the plot. Then, heat index values with *Equation 2:*

$$\text{HI} = 1 + \cos((45°\text{-aspect degree})/\text{slope degree}) \quad \text{(Eq.2)}$$

were calculated (Beers et al., 1966). HI varies between -1 and 1, and the approximation of this value to 1 indicates hotter points in the field.

The elevation value of the pixel on which the sampling plot is located on the map and the elevation differences of the other pixels adjacent to that sampling plot were used to calculate the topographic position index (TPI) values for each sampling plot (Weiss, 2001). Last, the distance between the sampling plots and the borders of the lakes and sea located in the study site was calculated on the basis of the distance that would result from the landform on DEM. For this step, ArcMap 10.2 software was used. For both measurements, "distance point to line/polygon" command was used for measurements in each sampling plot on the basis of the closest polygon and line to the points (Mert et al., 2013).

The soil samples (0-5 cm) were taken among of the trees from which leaf samples were collected in the field. After the soil samples were air-dried and ground, they were passed through the sieve (2 mm). The soils were analysed at the Laboratory of Süleyman Demirel University Faculty of Agriculture - Soil Department. Particle size of the soils was determined by using Bouyoucos's hydrometer method (Bouyoucos, 1951). Field capacity was measured by a pressure plate device (Cassell and Nielson, 1986). Soil pH level was determined through pH metre with glass electrode according to Jackson (1958). In addition, organic matter content in soils was determined by modified Walkley-Black method according to Jackson's procedure (1958). The carbonate contents ($CaCO_3$) in soil samples were measured with a Scheibler Calcimeter using volumetric method (Bush, 1970). Finally, after saturating soils with Na-acetate, they were extracted with ammonium acetate and the extracted sodium was read in the atomic absorption spectrophotometer and their cation exchange capacity was found (Chapman, 1965).

As a result 42 different environmental variables were identified and codes with maximum 6 characters were assigned to these variables for statistical assessment (*Table 1*).

The leaves collected from the field were stored to air-dry for 2 months under laboratory conditions in summer period of 2015. Then, the air-dried samples were placed in metal containers and dried in oven at 35 °C until reaching a constant weight. The adsorption of essential oil components was carried out using Solid Phase Microextraction Technique (SPME) by a fibre (Spietelun et al., 2013). For desorption of essential oil components, fibre was immersed onto injection port for 5 more minutes. The percentage of the essential oil components were determined by Gas Chromatography-Mass Spectrometry (GC/MS) analysis. In the GC/MS device, the column temperature was started at 40 °C for 2 min. It was then heated to 250 °C with an increase rate of 4 °C per minute and kept at 250 °C for 5 min.

Statistical analysis

During statistical assessments, factor analysis was firstly performed for the bio-climate variables considered to have a high correlation probability**.** In order to determine the bilateral relationships between the environmental variables and major essential components, Pearson Correlation Analysis was applied. To determine how the sampling plots were grouped in terms of the major components, cluster analysis was performed (Sarstedt and Mooi, 2014). Finally, Principal Components Analysis (PCA) was applied to identify the direction of the relationships between the major essential oil components that were the dependent variables and the environmental factors that were the independent variables (Bro and Smilde, 2014). SPSS Version 21.0 and PC-ORD Version 6.0 software were used in statistical analysis process.

Results and discussion

The mean elevation of 20 sampling plots selected at different locations was 1273 m, while the elevation of the highest sampling plot was 1920 m and that of the lowest sampling plot was 475 m. The mean inclination of the sampling plots was 27 degrees with plots consisting of both flat and steep inclination. The radiation index values ranged from 0.005 to 0.999. The topographic position index of the sampling plots varied from -0.438 to 0.954. The heat index values ranged from 0.013 to 2.00. As for the

© 2018, ALÖKI Kft., Budapest, Hungary

landforms of the sampling plots, 40% had flat terrain while 60% had undulating terrain. 55% of the sampling plots were located on upper slopes, 20% were located on medium slopes, 15% were located on lower slopes and 10% were on bottom lands. According to the landform characteristics, 2 different types of data were recorded in the study site, out which 90% were rocky and stony while 10% were flat. The mean stoniness percentage of the sampling plots was found to be 47.8%. With regard to the bedrock characteristics, limestone was dominant (80%) in the areas where *J. excelsa* was distributed.

Depth of the sampling plots ranged from 4 cm to 120 cm with a mean soil depth of 46 cm. The results of the chemical analysis conducted on topsoil (0-5 cm) samples revealed that the percentage of sand in the sampling plots ranged from 16.5% to 54.4%, percentage of clay ranged from 4.7% to 44.2%, while the dust percentage ranged from 25.9% to 52.9% according to the texture analysis. As for the acidity-alkalinity of the soils sampled from the sampling plots, pH value ranged from 7.1 to 8.5. With regard to the lime content ($CaCo_3$) of the soil, it was found the highest with 68.9% in one of the sampling plots, while it ranged from 1.29% to 6.72% at the other sampling plots. The amount of organic matter ranged from 2.7% to 13.4%. The mean cation exchange capacity (CEC) of the soils collected from 20 sampling plots was found to be 55.8 me/100 g. The lowest cation exchange capacity was found to be 19.5 me/100 g, while the highest was 102.8 me/100 g. Average field capacity of the soils collected from the sampling plots was 36.8%. The lowest field capacity was found to be 21.7%, while the highest was found 56.7%. The exchangeable cations from the biggest to the smallest in the soils collected from the sampling plots were Ca^{++} (85.5 me/100 g), Na^{+} (16.2 me/100 g), Mg^{++} (9.3 me/100 g) and K^{+} (8.9 me/100 g).

With regard to a total of 41 essential oil components obtained from the leaves of *J. excelsa*, α-pinene was the component with the highest amount with a mean value of 81.3% v/w. α-pinene was followed by myrcene with 6.2% v/w and limonene with 4.5% v/w (Gülsoy and Merdin, 2017). The total percentage of the remaining 38 component was 8.0% v/w, therefore, α-pinene, myrcene and limonene were defined as the primary essential oil constituents in the leaves of Crimean juniper.

If there is a very high correlation between the independent variables, explaining the relations in the environment becomes a complex. The bio-climate data used in this study are highly correlated with each other. By applying factor analysis, climate variables with the highest correlation coefficient with the components can be determined. As a result of this process, relationships are made through these representative variables. Other climate parameters are evaluated with an indirect interpretation. For this purpose, factor analysis was applied among the bio-climate variables in this study.

The factor analysis applied to bio-climate variables revealed that bio12 and bio18 variables had the highest correlation coefficient. Therefore, only these two variables were used in the subsequent statistical assessment as they had the highest explanation capacity instead of using all bio-climate variables (*Table 2*).

The correlation analysis applied to the relationship between the environmental variables and major essential oil components revealed that α-pinene had a negative correlation with elevation (r = -0.505) and bio18 (r = -0.451). Limonene, however, had a negative correlation with latitude (r = -0.526). Myrcene did not have any statistically significant correlation with any environmental factors. Finally, α-pinene that was subjected to correlation analysis with soil variables had a statistically significant negative correlation with pH (r =-0.444) while limonene had a negative correlation with

© 2018, ALÖKI Kft., Budapest, Hungary

clay (r = -0.475) and a positive correlation with pH (r = 0.448). Myrcene showed no significant relationship with any of the soil variables.

Table 2. *The correlation coefficients of the variables according to the factor analysis applied to the bio-climate variables on component 1 and component 2*

Variables	Component 1	Component 2

bio13	0,714	0,690
bio14	-0,921	-0,012
bio16	0,715	0,691
bio17	-0,902	-0,048
bio18	**-0,954**	-0,098
bio19	0,715	0,691

After the correlation and factor analyses, cluster analysis (according to Jacard index and Flexible Beta (= 0.25) Cluster Group Linkage Method) was performed in order to find out how the amount of major components were grouped on the basis of the sampling plots. The dendrogram showing the groups of sampling plots according to the cluster analysis is presented in *Figure 2*.

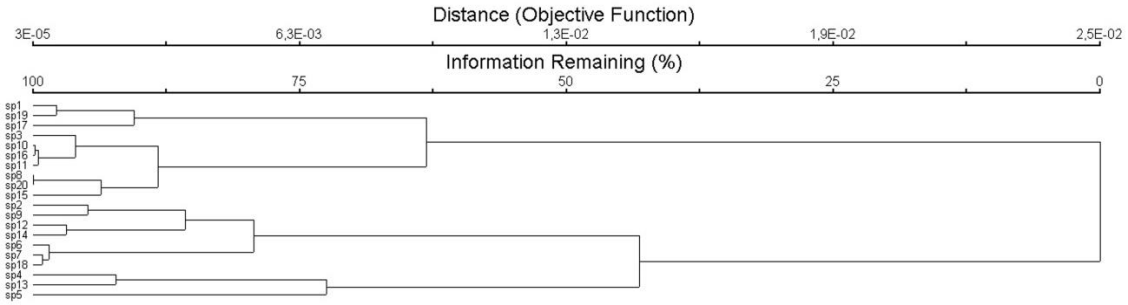

Figure 2. *Dendrogram showing the cluster analysis applied to the major essential oil components (sp: sample plot)*

The dendrogram shows that division starts at the division line of 40%, after which the sampling plots were clearly divided into 2 groups. 10 sampling plots were in cluster group 1 (sp1, sp3, sp8, sp10, sp11, sp15, sp16, sp17, sp19, sp20), while the other 10 sampling plots were in cluster group 2 (sp2, sp4, sp5, sp6, sp7, sp9, sp12, sp13, sp14, sp18). This suggests that this might be due to the different effects of locations on major essential oil components. Therefore, in order to determine to what extent this difference between the locations was represented by the environmental variables of the sampling

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_70997113
© 2018, ALÖKI Kft., Budapest, Hungary

plots, PCA was conducted. Through the analysis, the eigenvalues of the axes, variance percentages and percentage values of cumulative variance were calculated (*Table 3*).

Table 3. *Eigenvalues of the axes and variance percentages in the PCA applied to major essential components*

Eigenvalue	% of variance	Cumulative% of variance	Broken-stick eigenvalue	Eigenvalue
Axis1	**1,807**	**60,249**	**60,249**	**1,833**
Axis2	0,886	29,531	89,780	0,833
Axis3	0,307	10,220	100,00	0,333

The prerequisite to interpret the axis values found through the PCA analysis is that the eigenvalue coefficient of the relevant axis is smaller than the Broken-stick eigenvalue coefficient. *Table 3* shows that Axis1 which explains 60.2% of the total variance fulfils this criterion. In Axis 2, however, the Broken-stick eigenvalue coefficient explains 29.5% of the total variance although its numerical value is higher than the eigenvalue. These two axes together explain 89.7% of the total variance. Therefore, it would be right to make an interpretation principally over Axis 1 and partially over Axis 2 in order to explain the associations during the PCA applied between the major components and environmental variables.

The correlation coefficients of Principal Component Axes with major essential oil components (Pearson and Kendall correlations) are presented in *Table 4.*

Table 4. *Eigenvalues of the axes and variance percentages in the PCA applied to major essential components*

Major components	Axis1	Axis2
	r	**r**
α-pinene	**0.710**	**0.648**
Myrcene	**-0.684**	**0.682**
Limonene	**-0.914**	-0.007

The table shows that α-pinene (r:0.710) which was the most intense components in the leaves of Crimean juniper had a significantly positive correlation with Axis 1, limonene (r:-0.914) and myrcene (r:-0.684) had a negative correlation with the same axis. On the other hand, α-pinene (r:0.648) and myrcene (r:0.682) had a positive correlation with Axis 2.

Data matrixes regarding the physiographical-climate and soil variables developed to determine the correlations between the essential oil components and environmental factors were transferred to the PCA separately. First, the correlation between the physiographical-climate variables and major components was determined (*Table 5*).

The results showed that latitude (r:0.506) had the highest correlation with PCA Axis 1, while topographic position index (r:-0.499), elevation (r:-0.469) and precipitation of the hottest quarter (r:-0.457) had the statistically highest correlation with Axis 2. A simple interpretation on Axis 1 reveals that α-pinene's intensity increased in the plants in areas where latitude rose, while to the contrary myrcene and limonene decreased. The interpretation made on Axis 2 showed that myrcene and α-pinene decreased in areas

As shown in *Figure 4,* a statistically significant correlation was found between PCA Axis 1 and clay only (r = 0.430) and between Axis 2 and potassium only (r = -0.480). Clay percentage had a positive correlation with α-pinene out of the essential oil components in the Crimean juniper leaves on Axis 1, which was the most explanatory one, and a negative correlation with myrcene and limonene.

In this study, the essential oil components in the leaves of Crimean juniper which has a considerable distribution area both in Turkey and across the world and the environmental variables were associated. Ecological site conditions in areas where the species is distributed at elevations between 500-2000 m in moderately and highly mountainous parts are that limestone is dominant with rocky-stony landform, mainly on upper slopes and undulating terrain. The mean radiation index and temperature index of the sampling plots show that the species is found mainly on the very shadowy and humid aspects but also prefer sunny aspects as soon as it finds the appropriate site conditions at the combination of other ecological factors. In general, these areas are very inclined, steep and precipitous and had shallow or moderately deep soils in terms of absolute soil depth. In a study conducted to explore the ecology of the species in the region, it was found that its distribution increased at an elevation of 800-1800 m where the surface stoniness intensified under dry climate conditions, while the ecological tolerance of Crimean juniper was higher especially on the shady aspects of these environments compared to *Cedrus libani* A. Rich and *Pinus nigra* Arnold (Özkan et al., 2010). In general, it was stated that Crimean juniper that is referred to as a cold and drought tolerant species (Sarangzai et al., 2015) preferred mainly the humid environments in the northern and western aspects of the inner parts of the Mediterranean Region of Turkey (Fontaine et al., 2007). On the other hand, it was also underlined that especially higher elevations and areas with valley characteristics were more appropriate for the distribution of this species compared to the lower elevations and flat terrains (Fisher and Gardner, 1995). Furthermore, it is known that Crimean juniper trees could adapt to areas with typical Mediterranean climate with hot summers and frost in winter under shallow soil conditions in the rocky and stony terrains of the very inclined or steep lands without suffering from any damage. That is because Crimean juniper is known to convert the restricted absolute depth conditions into physiologically appropriate forms by taking advantage of the cracked structure of the bedrock which is mainly dominated by limestone in these types of environments (Gülsoy and Özkan, 2013). Therefore we can conclude that the findings of this study regarding the distribution of this species are in accordance with other published studies.

The dominant soil type of the topsoil included in this study (0-5 cm) was loam and its derivatives, while they were classified as rich and humic soils in terms of organic matter content. In direct proportion to the rich humus content, the field capacity of these soils and wilting point were found to be high and the soils have a granular structure in general. Moreover, with respect to lime content, nearly all of these soils were classified as carbonated, poorly alkaline and saline-free soils. The pH of the soils collected from juniper sites were found to be mildly alkaline and the most common cation in the soils was Ca^{++}, which can be explained by the high lime percentage depending on the limestone bedrock (Gülser et al., 2012).

In the study, forty one compounds were identified from the leaves of Crimean juniper and quantified, with α-pinene (81.3%), myrcene (5.2%) and limonene (4.5%) being the major components. All major components identified belonged to the monoterpene class. Topçu et al. (2005) found that the major essential components in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_70997113
© 2018, ALÖKI Kft., Budapest, Hungary

leaves of Crimean juniper consists of α- pinene (29.7%), cedrol (25.3%) and α-murolene (4.4%), respectively. Furthermore, in another studies conducted in Iran and in south-east of R. Macedonia, α-pinene (32.3%, 33.8%) and cedrol (13.1%, 24.4%) were found as major components in the leaves essential oil of Crimean juniper (Emami et al., 2011; Sela et al., 2015). On the contrary, Sela et al. (2015) found that sabinene and thujone were the predominant essential oil components in the samples from south-western part of R. Macedonia. In a different study, α-pinene (36.0%), β- pinene (30.2%) and limonene (12.6%) were found as the major components in the leaves of the species (Nadir et al., 2013). It is clear that α-pinene was found to be the major component in almost all of these studies, while differences were observed between the percentages of α-pinene and those of the other components. This difference is considered to be due to the location where the samples were collected, harvest season, maturity stage and genetic factors (Salehi et al., 2010; Adams et al., 2013). As a matter of fact, it has been stated that these types of factors are also effective in the several chemical properties such as the phenolic content, antioxidant and sugar levels of plants (Ali et al., 2011; Skrovankova et al., 2015).

Finally, with regard to the association between the percentages of major essential oil components in the sampling plots and the environmental factors, the cluster and principal component analyses showed that primarily latitude as well as clay percentage and secondarily topographical position index, elevation and climate factors might have an effect. Adams et al. (2013) reported a partial effect of geographical variations in the essential oil components of Crimean juniper leaves sampled from Greece, Bulgaria, Turkey and Cyprus. No other study was found in the literature that explored the association between the essential oil properties of Crimean juniper leaves and environmental factors.

Conclusions

In conclusion, the findings of this study exhibited that environmental factors can have an impact on the essential oil components of the plants, whereas they are not so explanatory. The reason is that factors such as especially genetic variation of plant species, time of sample collection and methods applied have an impact on the type and percentage of these components in addition to the environmental factors as mentioned before. Therefore, there is a need for further studies with established standards on this matter in order to obtain clearer and precise results. It is possible that some secondary metabolites, such as volatile oils, can be assessed in some cases, such as climate change, environmental pollution etc., if clearer information is obtained from these studies.

Acknowledgements. We would like to thank Süleyman Demirel University Scientific Research Projects Coordination Unit for supporting our study under the project number SDÜ-BAPKB-4116-YL1-14. Moreover, the soil data were obtained simultaneously with the project numbered TUBİTAK-112O814, for which we would also like to thank the relevant institutions and persons.

(Received 1st Aug 2018; accepted 5th Oct 2018)

Abstract. Few studies have reported about the diversity and distribution of picoeukaryotes in the ecosystem of reservoir bay. In this study, Sanger-based clone libraries of 18S rRNA gene were used to determine the picoeukaryotic diversity of three sampling sites; these sites were located across the Xiangxi Bay of Three Gorges Reservoir, China. The sampling sites were monitored across all four seasons in 2013. We identified 13 phyla in Xiangxi Bay. In this experimental survey, we found that picoeukaryotic community was dominated by three main phyla, namely, Cryptophyta, Chlorophyta, and Ciliophora (69.9% of clones in all). Moreover, the remaining 10 phyla showed a relative abundance of less than 6%. In Xiangxi Bay, the seasonal variability of communities overwhelms spatial patterns; upper reaches exhibited highest species diversity, whereas middle reaches exhibited lowest species diversity. The community temporal stability had decreased from upstream to downstream. Primary producers were dominant in all the sample sites, irrespective of the season. In Xiangxi Bay upstream, terrestrial microbes may be integral components of the microbial community assembly. In Xiangxi Bay, the distribution pattern of picoeukaryotes might have been affected by the mainstream of Three Gorges Reservoir.
Keywords: *picoeukaryotes, microbial diversity, 18S rDNA, tributary bay, distribution pattern*

Introduction

Picoeukaryotes are widely distributed in aquatic environments, contributing significantly to biomass and primary production (Li, 1994; Caron et al., 2012). They are core members of aquatic microbial food webs and play a fundamental role in biogeochemical cycling (Massana et al., 2011). This indicates that they play an important role in maintaining the balance of water ecosystems (Biegala et al., 2003; Vaulot et al., 2008). Many studies have reported about the unexpected diversity of picoeukaryotes in Open Ocean, coastal areas, and estuaries (Massana et al., 2011; Wu et al., 2014; Farnelid et al., 2016).

Some studies have determined the diversity of picoeukaryotes in freshwater systems. In oligotrophic systems, picoeukaryotes are very important primary producers of biomass (Stenuite et al., 2009). Moreover, a high level of picoeukaryote diversity was recorded in mesotrophic lakes (Lepère et al., 2008; Lefèvre et al., 2008). Recent studies have reported that picophytoplankton is an important primary producer in eutrophic

© 2018, ALÖKI Kft., Budapest, Hungary

estuaries, contributing significantly to the total phytoplankton biomass (Murrell and Lores, 2004; Gaulke et al., 2010). In another study, researchers found that pico-phytoplankton abundance was quite high in rivers; it was almost equivalent to that in lakes and oceans (Contant and Pick, 2013). Currently, molecular techniques are used for surveying the diversity of picoeukaryotes that inhabit rivers (Thomasa et al., 2012), freshwater lakes (Zhao et al., 2011), and shallow aquatic environments (Simon et al., 2015a, b). However, we have little information about the diversity and distribution of picoeukaryotes, which thrive in an ecosystem of reservoir bay.

The Three Gorges Reservoir is located in the lower section of the upper reaches of Yangtze River in China (Han et al., 2015). The Xiangxi River is one of the longest rivers in the Three Gorges Reservoir region. After constructing the Three Gorges Dam, the Xiangxi River was transformed into Xiangxi Bay (Holbach et al., 2015). In this study, we used Sanger-based clone libraries of 18S rRNA gene to determine the picoeukaryote diversity of three sampling sites, which were present along the Xiangxi Bay of the Three Gorges Reservoir; the picoeukaryote diversity was monitored across all the four seasons in 2013. We addressed the following basic questions: what is the picoeukaryotic diversity in the bay of a large reservoir? Does the mainstream reservoir affect the distribution pattern of picoeukaryote in the bay?

Materials and methods

Sample collection and environmental data

Water samples were collected from downstream (XX01, 30°97'32.28"N, 110°75'80.59"E), midstream (XX04, 31°11'06.06"N, 110°77'57.14"E) and upstream (XX07, 31°18'96.64"N, 110°75'33.75"E) of Xiangxi Bay of the Three Gorges Reservoir of China in February (winter), April (spring), August (summer), and October (autumn) of 2013 (*Fig. 1*). The linear distance between the XX01 and XX07 sample sites was approximately 26 km.

Water samples were collected at a depth of 0.5 m beneath the water surface using a 5-L sampler and pre-filtered through 5 μm pore-size polycarbonate filters (Millipore) followed by filtration onto GF/F filters (0.7 μm, Whatman) for molecular analyses. Samples were immediately frozen in liquid nitrogen and stored at -80 °C until analysis.

Physical and chemical factors, such as water temperature (WT), dissolved oxygen (DO), pH and turbidity, were measured in situ. Concentrations of total nitrogen (TN), orthophosphate (P-PO_4, PO43-), nitrate (N-NO_3, NO3-), total phosphorus (TP), Chemical Oxygen Demand (COD), Oxidation-Reduction Potential (ORP), water transparency (SD) and ammonium (N-NH_4, NH4+) were measured using standard methods, as described previously (Huang et al., 1999). The trophic states of the Xiangxi Bay in different sample sites and seasons were determined by comprehensive nutritional status index (trophic level index, TLI) using the values of TN, TP and SD (Tian et al., 2017). Trophic states are set as follows: $TLI \leq 30$, oligotrophic; $30 < TLI \leq 50$, mesotrophic; $50 < TLI \leq 60$, slightly eutrophic; $60 < TLI \leq 70$, moderately eutrophic; $TLI > 70$, highly eutrophic (Meng and Zhao, 2007).

DNA extraction and clone library construction

DNA was extracted from filters using a previously described method (Countway et al., 2005). Near full-length 18S rDNA fragments were amplified by polymerase chain reaction （PCR） using the eukaryotic-specific primers Euk328f/Euk329r (Euk328f: 5'-ACCTGGTTGATCCTGCCAG-3', Euk329r: 5'-TGATCCTTCYGCAGGTTCAC-3') (Moon-van der Staay et al., 2000). PCR was carried out under the following conditions: 35 cycles (denaturation at 94 °C for 30 s, annealing at 55 °C for 45 s, extension at 72 °C for 2 min) proceeded by 3 min denaturation at 94 °C and followed by 8 min extension at 72 °C. 18S rDNA clone libraries were constructed using the pGEM®-T Easy Vector Systems (Promega) following the instructions provided by the manufacturer.

Amplified ribosomal DNA restriction analysis (ARDRA)

Positive clones from each library were screened by re-amplifying the 18S rDNA by PCR as described above, except that 0.1 μl of the culture of *Escherichia coli* containing the insert was used as a template. Positive PCR product was digested with *Hae*III (Fermentas). Gel electronic images were visualized by means of ChemiDoc XRS (Bio-Rad), images were analyzed with Image Lab software v. 3.0 (Bio-Rad). Clones with the same ARDRA pattern were grouped and considered as the same operational taxonomic unit (OTU).

Statistical analyses

Based on the result of ARDRA analysis, a library coverage value was computed according to the literature (Dang et al., 2008). Diversity indexes (Shannon and Pielou evenness) were also calculated. The Shannon diversity index is an index that is commonly used to characterize species diversity in a community. Pielou's evenness refers to how close in numbers each species in an environment are. The Kruskal-Wallis test was used for comparison between multiple groups. Bray-Curtis (temporal) dissimilarity based on relative abundance data OTUs was used as indices of the temporal turnover of community. The community structures were compared with non-metric multidimensional scaling (NMDS) using Bray-Curtis distances. The significance of the observed differences was determined by permutational multivariate analysis of variance (PERMANOVA) based on Bray-Curtis distance measurements with 999 permutations. NMDS and. the Bray-Curtis dissimilarity between pairwise samples was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_71157128
© 2018, ALÖKI Kft., Budapest, Hungary

calculated on the basis of OTU abundances. All these analyses were done using the R package vegan.

Analysis based on sequence

One or several representative clones of each ARDRA pattern were partially sequenced (Majorbio, China). Colonies were sequenced using the Euk 528F primer (5'-GCGGTAATTCCAGCTCCAA-3') (Elwood et al., 1985). All sequences obtained were edited to exclude the primer sequence using Lasergene.v7.1 (DNAStar Inc), and checked for chimerical structures using the CHECK-CHIMERA program on the Ribosomal Database Project (http://rdp.cme.msu.edu/html/). In order to determine the phylogenetic affiliation, all non-chimeric sequences were aligned using the online automatic SILVA Incremental Aligner SINA v1.2.11 (http://www.arb-silva.de/aligner/) to identify known sequences with a high degree of similarity. Phyla that differed significantly ($q < 0.05$) for two groups were identified using White's non-parametric t-test with Storey's multiple testing correction in the STAMP software version 2.1 (Parks et al., 2014). Similarity percentage analysis (SIMPER) was used to assessing which taxa are primarily responsible for an observed difference between groups. SIMPER were carried out using PAST 3.18 (Hammer et al., 2001).

Correlations between picoeukaryotic communities and environmental factors were analyzed using the canonical correlation analysis (CCA) using R package vegan. CCA was performed using the relative abundance data of phyla (except rare phyla) and environmental factors. Significant environmental variables were chosen by the manual forward selection procedure, followed by Monte Carlo permutation tests (1000 iterations).

Nucleotide sequence accession number

The 18S rRNA gene sequences determined have been deposited in the GenBank database under accession numbers KX998709 - KX998893.

Results

Environmental characterization

The physicochemical parameters of water samples were present in *Table A1* in the *Appendix*. Among these parameters, statistically significant difference was observed in only TN values of the three sample sites ($p = 0.036$, Kruskal-Wallis tests). On the whole, the concentration of TN had increased gradually from upstream to downstream. Except for autumn, the TLI of the three sampling sites was greater than 50 through the year (*Table A1, Fig. A1*). The median TLI of three sampling sites (XX01, XX04, and XX07) was 51.57, 57.74, and 57.54, respectively (*Fig. A1*).

18S rDNA clone libraries

In total, 12 clone libraries were constructed for the three sample sites. Approximately 85–105 clones were isolated from each clone library; these clones were then subjected to ARDRA analysis. In total, ARDRA analysis was performed on 1116 clones; these clones were clustered into 240 OTUs. In each sample, the number of OTUs ranged from 18 to 59. The coverage of respective libraries ranged from 63% to 91% (*Table 1*). The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_71157128
© 2018, ALÖKI Kft., Budapest, Hungary

distribution of OTUs varied according to seasons or different sample sites. Only 31 OTUs appeared at all sites. Furthermore, only 6 OTUs appeared throughout the year (*Fig. A2*).

Table 1. *Summary of ARDRA analysis of the 12 clone libraries*

Season	Sample sites	No. of RFLP types	Coverage	Shannon-Wiener	Pielou evenness
Spring	XX01	40	78.70%	4.65	0.87
	XX04	18	90.00%	3.17	0.76
	XX07	59	68.47%	5.52	0.94
Summer	XX01	36	68.42%	4.64	0.89
	XX04	44	71.27%	4.94	0.90
	XX07	35	72.50%	4.47	0.86
Autumn	XX01	29	90.76%	3.54	0.71
	XX04	48	68.13%	5.29	0.85
	XX07	55	63.16%	5.51	0.95
Winter	XX01	42	71.59%	4.93	0.93
	XX04	23	80.00%	4.10	0.91
	XX07	48	78.99%	5.04	0.90

The Shannon index and Pielou evenness index of 12 clone libraries were calculated (*Table 1*). The Shannon index peaked in upstream (XX07 site), and they were least in the middle reaches (XX04 site) of Xiangxi Bay (*Fig. A1*). No statistically significant difference was observed in the diversity index of the three sample sites; moreover, no statistically significant difference was observed for the four seasons of the year (all $p > 0.09$, Kruskal-Wallis test).

Picoeukaryotic community composition

We obtained 185 high-quality sequences after removing all low-quality, unassembled, and potentially chimeric sequences. We performed phylogenetic analyses on 12 samples; the analyses results indicate that there were 13 phyla in these 12 samples (*Fig. 2*). Moreover, analyses results indicate that these libraries were dominated by Cryptophyta and Chlorophyta (32.4% and 21.5% of the total 910 clones respectively), followed by Ciliophora (16%) and Bacillariophyta (5.9%), Chrysophyta (3.3%). Telonemia, Pyrrhophyta, and Cercozoa were the three groups of picoeukaryotes, which were present in extremely low proportions. Besides, we also detected a very small amount of Haptophyta (1 sequence, 1 clone). Moreover, some kinds of fungi (Chytridiomycota, Cryptomycota, and Basidiomycota) and fungus-like (Oomycota) taxa were also detected in this study. The relative abundance of these fungi and fungus-like taxa was very low at the three sample sites. In these libraries, a significant number of sequences (37 sequences, 16.5% of the total 910 clones) were not affiliated with any formal taxa.

Among the Cryptophyta, an overwhelming majority belonged to Cryptomonadales (39 sequences); we also identified six sequences that were affiliated to uncultured Kathablepharidae. The Chlorophyta sequences were grouped into four taxa:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_71157128
© 2018, ALÖKI Kft., Budapest, Hungary

Chlorophyceae, Chlorodendrophyceae, Mamiellophyceae, and Trebouxiophyceae. Among them, Chlorophycea was the most abundant taxon (26 of 35 Chlorophyta sequence). The Ciliophora sequences were grouped into three taxa: uncultured Choreotrichia, Litostomatea, and Prostomatea. Among them, uncultured Choreotrichia was the most abundant taxon (20 of 40 Ciliophora sequence). All the six sequences of Bacillariophyta belonged to the taxon Mediophyceae. Chrysophyta contained different types of sequences: three sequences were affiliated to the taxon Chrysophyceae, while one sequence was affiliated to Nannochloropsis. Telonemia consisted of four sequences, which were affiliated to the taxon Telonema (Shalchian-Tabrizi et al., 2006).

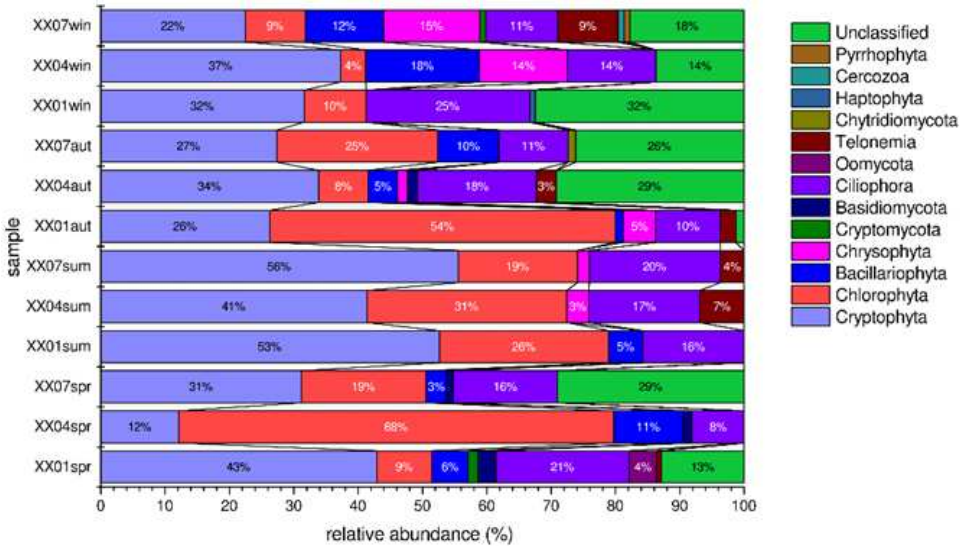

Figure 2. *Distribution of the phyla in all samples. Spr: spring, sum: summer, aut: autumn, win: winter*

Community structure across space and time

From winter to spring, the structure of picoeukaryotic communities changed slightly; a different picoeukaryotic community structure was observed from summer to autumn, with slight variation in composition. Seasonal patterns were detected by NMDS analyses (*Fig. 3*). By performing PERMANOVA analyses, we found that the composition of picoeukaryotic communities was significantly different across all the four seasons (p = 0.0011); however, there was no significant difference between the composition of picoeukaryotic communities of three sample sites (p = 0.9937). By SIMPER analysis, we observed the seasonal differences were mainly attributed to appreciable seasonal fluctuations in the relative abundance of dominant phyla. The seasonal differences were mainly observed in following phyla: Chlorophyta (24.41%), Cryptophyta (20.3%), and Ciliophora (12.25%).

In Xiangxi Bay, picoeukaryotes were unevenly distributed across the three sample sites; moreover, the distribution of picoeukaryotes also changed across the four seasons. By determining the Bray-Curtis dissimilarity matrix of all the samples, we found that the community temporal stability decreased from upstream to downstream (*Fig. 4*). By STAMP analysis, we found that Basidiomycota has a significantly higher abundance in spring than in summer ($q < 0.01$) (*Fig. 5*). No significant variations were observed in the composition of the phyla, regardless of the sample site.

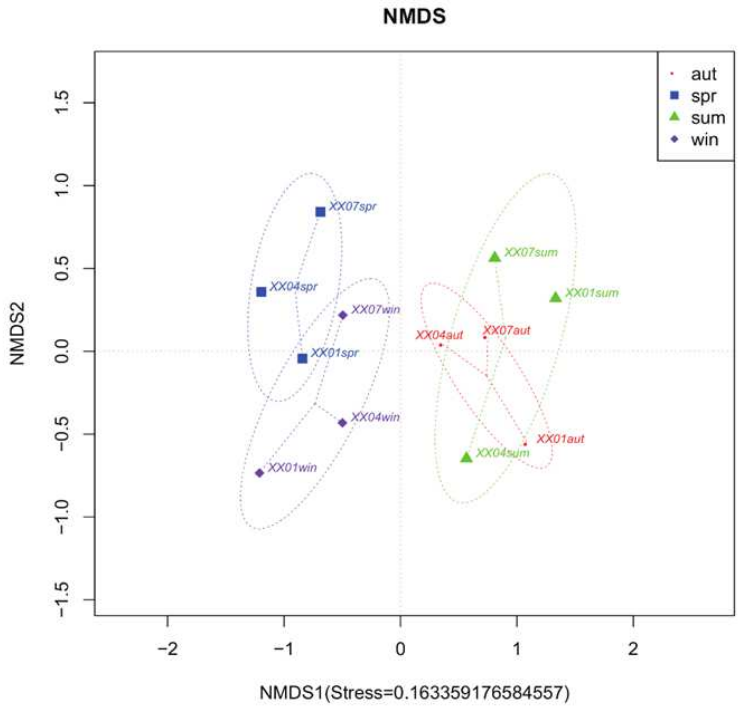

Figure 3. *Non-metric MultiDimensional Scaling (NMDS) plot based on Bray-Curtis distances*

Picoeukaryotic communities in relation to environmental variables

The results of CCA analysis indicate that abundances of specific taxa depended upon environmental variables (*Fig. 6*). The first two axes accounted for 35.3% of the variance. The abundances of Chrysophyta and Bacillariophyta were negatively related to pH and turbidity. The distribution of Bacillariophyta was greater in the area with higher concentration of N–NH_4. The distribution of Chrysophyta was concentrated in the least turbid area, which had lower values of N–NH_4.

Discussion

In this study, we found that TLI was the highest in middle reaches (XX04 site) and least in the downstream (XX01 site) of Xiangxi Bay (*Fig. A1*). There is water exchange between the Three Gorges Reservoir mainstream and its tributaries (Liu et al., 2012; Huang et al., 2014). Owing to water exchange, nutrients are supplied from the Three Gorges Reservoir mainstream to the Xiangxi Bay (Yang et al., 2015). Water exchange occurs frequently at the river mouth; however, the time of water retention is short (Liu et al., 2012). Consequently, the middle reaches of Xiangxi Bay were replenished with several nutrients (Ji et al., 2010). Therefore, middle reaches of Xiangxi Bay have the highest TLI.

Previous studies have reported that the diversity of species decreases with eutrophication (Baho et al., 2017; Cook et al., 2018). Therefore, the diversity index was lowest in middle reaches of Xiangxi Bay (*Fig. A1*). Surprisingly, the diversity index was highest at the upstream (XX07 site) of Xiangxi Bay, but its trophic level was higher than the downstream of Xiangxi Bay. With the flows of water, soil, litter, and anthropogenic materials were transported in and around rivers. These materials got easily mixed with the resident microbial communities (Mansour et al., 2018). Recently, several studies have been carried out on different water ecosystems; these studies have reported that terrestrial microbes show significant abundance in the microbial communities of headwater ecosystems (Crump et al., 2012; Besemer et al., 2013; Ruiz-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_71157128
© 2018, ALÖKI Kft., Budapest, Hungary

González et al., 2015). In the upstream sampling site, microbial diversity could be structured by inoculating the microbes from terrestrial sources; these microbes would contribute to community assembly. This may be the reason for the differences in the diversity of picoeukaryotic communities, which are found in the down and upper reaches of Xiangxi Bay.

The upstream of Xiangxi Bay had the highest diversity index, while the midstream of Xiangxi Bay had the lowest diversity index (*Fig. A1*). Before the construction of the Three Gorges Reservoir, the diversity index of Xiangxi River was lower down-stream (Kuang et al., 2004). This implies that the distribution pattern of plankton diversity has changed to some extent after the construction of the Three Gorges Reservoir. Furthermore, our results indicate that diversity indices of summer and winter were greater than those of spring and autumn (*Fig. A3*). Similar results have been presented by researchers in previous studies (Zhang et al., 2017). Previous studies have proved that the mainstream of Three Gorges Reservoir significantly influences its tributaries in spring and autumn seasons: this is because water is discharged from the mainstream of Three Gorges Reservoir during spring season; moreover, water is impounded into the same reservoir during autumn (Li et al., 2012). After analyzing the diversity indices and temporal turnover of picoeukaryotic communities, we infered that the Three Gorges Reservoir does impact plankton diversity of its tributaries.

The concentration of $N–NO_3$ is much higher than that of $N–NH_4$ in Xiangxi Bay (*Table A1*). The results of ordination analysis prove that Bacillariophyta had a positive relationship with $N–NH_4$. In the presence of sufficient nutrients, diatoms are generally $N–NO_3$ opportunists (Donald et al., 2011; Glibert and Wilkerson, 2014). Some studies have reported that diatoms are distributed in the area, which has higher concentration of $N–NH_4$ values (Zhao et al., 2013). Therefore, further studies must be conducted to determine whether elevated levels of $N–NH_4$ favor the growth of pico-diatoms in Xiangxi Bay. Chrysophyta often grows in highly transparency water, which has low organic content (Lin et al., 2003). In this survey, Chrysophyta appear in less turbid areas, which have comparatively lower concentration of $N–NH_4$. The relative abundance of Chrysophyta was much greater in oligotrophic lakes than in Xiangxi Bay. This indicates that eutrophication affects the composition of plankton communities in different water bodies.

In summary, water exchange between Xiangxi Bay and Three Gorges Reservoir mainstream may affected the distribution pattern of biodiversity and nutritional state of Xiangxi Bay. So, middle reaches of Xiangxi Bay have the highest TLI. Furthermore, upper reaches exhibited highest species diversity, whereas middle reaches exhibited lowest species diversity. In Xiangxi Bay, the seasonal variability of communities overwhelms spatial patterns. The community temporal stability had decreased from upstream to downstream. In the upstream sampling site, microbial diversity could be structured by inoculating the microbes from terrestrial sources.

Abstract. The increase of human activities in recent years has led to many adverse effects and accelerated climate change at an important level. Therefore, it is very important to know how species will be affected by climate change. This study aimed to determine how the distribution of Gray wolf (*Canis lupus*), one of the most important predator species in the ecosystem, will be affected by climate change. The study was carried out using presence data of this species in the Lake District and the changes in the habitats and distribution of Gray wolf according to the RCP 4.5 and RCP 8.5 (HADGEM2-ES) climate scenarios. We conducted mapping and modelling of the current habitat preferences of Gray wolf using MaxEnt method based on the bioclimatic features derived from the Worldclim. 4 bioclimatic variables (BIO12, BIO13, BIO16 and BIO19), and 3 environmental variables (slope, ruggedness, topographic position index) were used in the study. The model and maps of the Gray wolf were compared with the future climate scenarios. In conclusion, it is projected that habitats which are determined as suitable for Gray Wolf will decline significantly due to climate change.
Keywords: *climate change, GIS, Canis lupus, HADGEM2-ES, MaxEnt*

Introduction

Adverse effects of global climate change on ecological systems are increasing day by day. One of the most striking results of global climate change is that Earth's climate has warmed by about 0.6°C over the past century and it is estimated that it will increase by 1.4-5.8°C in the next century. Regional changes have also been observed in rainfall and humidity levels in the proportion to the rising global temperature (Bellard et al., 2012; Collins et al., 2013; Trenberth et al., 2014).

Changes in the climate are presented in the report prepared by the IPCC (Intergovernmental Panel on Climate Change) and made available to researchers. The data is updated by the IPCC periodically and different scenarios for the future are presented. The last of these reports (IPCC 5th Assessment Report) was announced to the world in Sweden in September 2013 (IPCC, 2013). A report on climate change in Turkey was also prepared by Turkey's State Meteorological Service. In this report, regional climate projections produced by downscaling methods for Turkey were based on global models in the CIMIP5 (Coupled Model Intercomparison Project Phase 5) project and the RCP (Representative Concentration Pathways) scenarios created for the IPCC 5th Assessment Report. RCP 4.5 (which we can describe as moderate) and RCP 8.5 (which we can characterize as pessimistic) were selected. According to the temperature and rainfall projections obtained using HadGEM2-ES (Hadley Centre

Global Environment Model version 2- Earth System) based on RCP 4.5 scenario for Turkey, it is estimated that temperatures in 2050 will have limited to rise approximately 2 C and precipitation will have decreased by nearly 20% throughout the whole country. It is also expected that in 2070 temperatures will have increased by 4 C and precipitation will have decrease decreased by 40% especially in summer. According to the temperature and rainfall projections produced using HadGEM2-ES based on RCP 8.5 scenario for Turkey, it is predicted that in 2050, temperatures will have increased by about 5 C and precipitation will have decreased by about 50%, in 2070 temperatures will have increased by 6°C, especially in the summer, and rainfall will have decreased by 50% especially in summer (Akcakaya et al., 2013; Demir et al., 2013; Demircan et al., 2017).

The changes in precipitation and temperatures will affect all living organisms. Most of the research on this subject has focused on plant species and wild animals because these species can easily be affected by climate change challenges and respond in different ways to this situation (Bellard et al., 2012; Gamfeldt et al., 2013). Therefore, the reactions of all species in the food chain to climate change need to be evaluated for sustainability of ecosystems. For this reason, conservationists and researchers need to detect species that are likely to be most affected by the impacts of climate change in order to minimize biodiversity losses due to climate change and the most appropriate approaches should be selected. Therefore, many recent studies have concentrated on modelling species based on ecological needs and projecting those needs onto modelled future climate regimes to predict future potential distributions (Braunisch et al., 2013; Domisch et al., 2013; Porfirio et al., 2014; Pacifici et al., 2015).

Large predators which constitute the top of the food chain are among the most affected species by changes in precipitation and temperature (Gilman et al., 2010). Gray wolves (*Canis lupus*) may be the most affected large mammalian carnivore by the mentioned negative factors in Turkey.

In addition, these species are in a wide range of motion, especially for searching for food. It is thought that these behaviours often lead them to conflict with humans and livestock, thereby increasing extinction risk (Behdarvand et al., 2014; Ripple et al., 2014). When previous studies on this species in Turkey are examined, it is seen that these studies are limited and generally were carried on population estimates. In these studies, it is stated that the number of individuals belonging to this species is about 5000-7000 (Can, 2008; Akbaba and Ayas, 2012). Contrary to traditional studies, species distribution maps created using modeling techniques for protection of these species are an important basis for conservationists (Guisan et al., 2013; Fourcade et al., 2014). The MaxEnt method, which is one of the modelling techniques used to identify high-quality habitats and determine the ecological factors that are effective in the distribution of species, is a widely preferred modelling and mapping method (Phillips et al., 2004; Barbet-Massin et al., 2012; Mesler, 2015). In this study, it is thought that this method will be useful in estimating the potential distribution of Gray wolf under climate change and monitoring the differences that may occur in future distribution.

The aims of the present study carried out in Lake District are as follows: i) to take inventory of Gray wolf in this area, ii) to determine the climatic factors and environmental variables affecting the distribution of Gray wolf for the present iii) to determine the appropriate habitats for the species by creating the current potential distribution map, and iv) to determine the future potential distribution of species taking future climate scenarios into account (RCP 4.5 and RCP 8.5 scenarios).

Materials and methods

Site description

The study area, Lake District, is located in the Western Mediterranean Region between 38°25'-36°06' N latitudes and 29°30'-32°34' E longitudes according to the UTM coordinate system in Turkey (*Fig. 1*). In terms of climate characteristics, the study area has a very high variation, especially depending on elevation differences. It is possible to say that the average annual precipitation values in the region are between 600-1300 mm and the annual mean temperature values vary between 12°C and 20°C. The summer drought period in the region lasts for approximately 2-4 months. In general, the area has a transitional climate between the Mediterranean climate and the continental climate. Red pine (*Pinus brutia* Ten.), Black pine (*Pinus nigra* Arnold.), various oak species, and juniper species are dominant forest trees in the region.

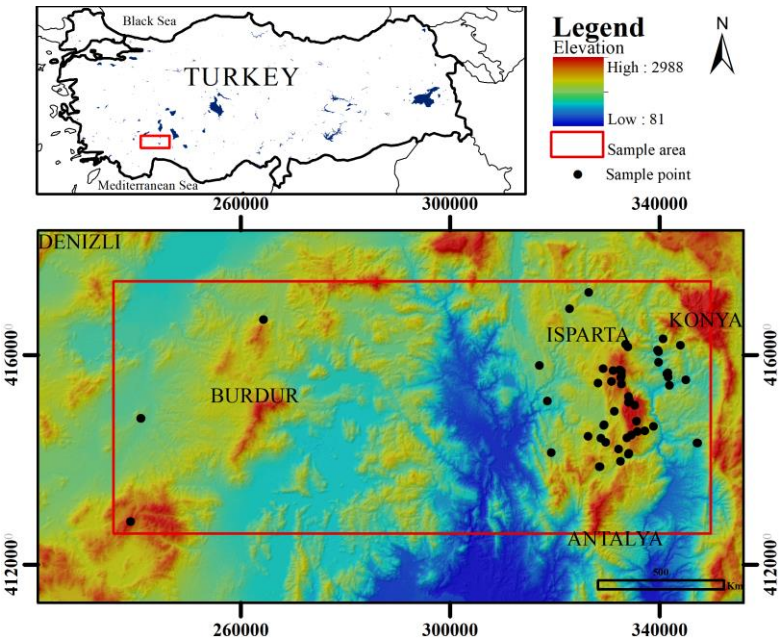

Figure 1. *Geographical location of the study area and presence data of Gray wolf*

Sampling method

Tracks and signs of Gray wolf were recorded on field cards by using indirect inventory techniques during the field study. Thus, from 2014 to 2016, feeding signs, footprints, faeces, burrows, and signs of predation belonging to Gray wolf were recorded as presence data at 59 sample points by using absence-presence inventory techniques (Baddeley, 1985).

Data and statistical evaluation

Scenarios and projections (*Table 1*) updating at regular intervals were presented in the report prepared by the IPCC and made available to researchers (IPCC, 2013). In this study, 2 of 4 different scenarios, namely RCP 4.5 (which we can describe as moderate) and RCP 8.5 which we can characterize as pessimistic, were selected to create habitat suitability maps of Gray wolf for future scenarios.

Table 1. *Types of representative concentration pathways (RCP's) (based on IPCC, 2013)*

Name of RCP's	Radiative forcing	Time	Pathway shape	Concentration (ppm)	Emissions (Kyoto Protocol's greenhouse gases)
RCP 8.5	>8.5 W/m2	In 2100	Rising	> ~1370 CO2-eq in 2100	Rising continues until 2100
RCP 6.0	~6.0 W/m2	At stabilization after 2100	Stabilization without overshoot	~850 CO2-eq (at stabilization after 2100)	Decline in the last quarter of century
RCP 4.5	~4.5 W/m2	At stabilization after 2100	Stabilization without overshoot	~650 CO2-eq (at stabilization after 2100)	Decline from the mid-century
RCP2.6-PD*	~3.0 W/m2	Peak at before 2100 and then decline	Peak and decline	Peak at ~490 CO2-eq before 2100 and then decline	Decline in the first quarter of century

Climate maps were obtained primarily for modelling and mapping. In order to create these maps, 19 different bioclimatic data (available at http://www.worldclim.org) generated by Hijmans et al. (2005) was downloaded in ascii format on a world scale, and then was cut according to the scale of the study area and made ready for use. In the same way, the bioclimatic data to be used in future scenarios (2050, HadGEM2-ES RCP 4.5 and 8.5 scenarios; 2070, HadGEM2-ES RCP 4.5 and 8.5 scenarios) were prepared.

In the next step, maps of environmental variables were created with ArcMap 10.2 software. Firstly, slope, aspect, and elevation maps were created by digital elevation model (DEM) of the study area. Topographic position index, landform position index, ruggedness index, roughness index, topographic convergence index, hill shade index, solar illumination index (6am, 8am, 10am, noon, 2pm, 4pm, 6pm, 8pm), and solar radiation index were then created. Finally, aspect suitability index (ASI) (*Eq. 1*), radiation index (RI) (*Eq. 2*) and heat index (SI) values are calculated and mapped. Finally, using different equations; aspect suitability index (ASI), radiation index (RI) and heat index (HI) (*Eq. 3*) values are calculated and mapped using different equations. The equations for these indices are as follows:

$$\mathrm{ASI} = \cos(Amax - A) + 1 \quad \text{(Eq.1)}$$

$$\mathrm{RI} = \frac{[1 - \cos((\pi/180)(Q - 30))]}{2} \quad \text{(Eq.2)}$$

$$\mathrm{HI} = \cos(A - Amax) * \tan\left(radian(slope)\right) \quad \text{(Eq.3)}$$

where the value of Amax is 202.50. A, refers to the radian value of aspect. Q refers to aspect. The value of π was taken as 3.14159265.

Bioclimatic variables have a high correlation with each other (Süel, 2014). If there is a high correlation between the variables, accuracy and reliability of obtained models decrease. For this reason, Pearson correlation analysis and factor analysis were applied to bioclimatic variables by SPSS software.

MaxEnt 3.4.1 software was used for the determination and modelling of the variables that are effective in the distribution of Gray wolf. For the analysis, the data matrix consisting of bioclimatic variables and environmental variables was recorded as "ascii" file. The presence data of Gray wolf was saved as "csv" file. The data was analyzed via cross validation with 90% training data of the model, 10% test data, and 10 replications. The success of the obtained models was assessed according to area under the curve

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_71297137
© 2018, ALÖKI Kft., Budapest, Hungary

(AUC) values in the receiver operating characteristic (ROC) curve. If the model's AUC value is close to 1, the model is perfect. If it is closer to 0.7, it is descriptive; however, if it is 0.5, the model is invalid (Phillips et al., 2004).

As a result of this analysis, the current potential distribution model of the Gray wolf was obtained and the variables affecting the distribution were determined. This model was then simulated for 2050 (HadGEM2-ES RCP 4.5 and 8.5 scenario) and 2070 (HadGEM2-ES RCP 4.5 and 8.5 scenario).

Results

Presence data of Gray wolf was recorded in 59 sampling points. Pearson correlation analysis and factor analysis were applied to climatic variables due to high correlations among them.

As a result of the factor analysis, four different bioclimatic variables with the best representation ability were obtained: BIO12 (Annual Precipitation), BIO13 (Precipitation of Wettest Month), BIO16 (Precipitation of Wettest Quarter) and BIO19 (Precipitation of Coldest Quarter).

13 different current potential distribution models were obtained for the Gay wolf and the 13th model was chosen as the most suitable model according to AUC values in the ROC curve. The training data AUC value is 0.937 and the test data AUC value is 0.920 for this model (*Fig. 2*). When the variables affecting the distribution of Gray wolf in the conclusion model were examined, BIO12 (23%), BIO13 (18.5%), and BIO16 (21.3%) were determined as bioclimatic factors and heat index (14%), aspect (12.4%), and topographic position index (10.8%) were determined as environmental variables.

As a result of simulating the variables obtained in the current habitat suitability model for Gray wolf into the future scenarios, a model with AUC training value of 0.942 and AUC test value of 0.939 was obtained (*Fig. 3*).

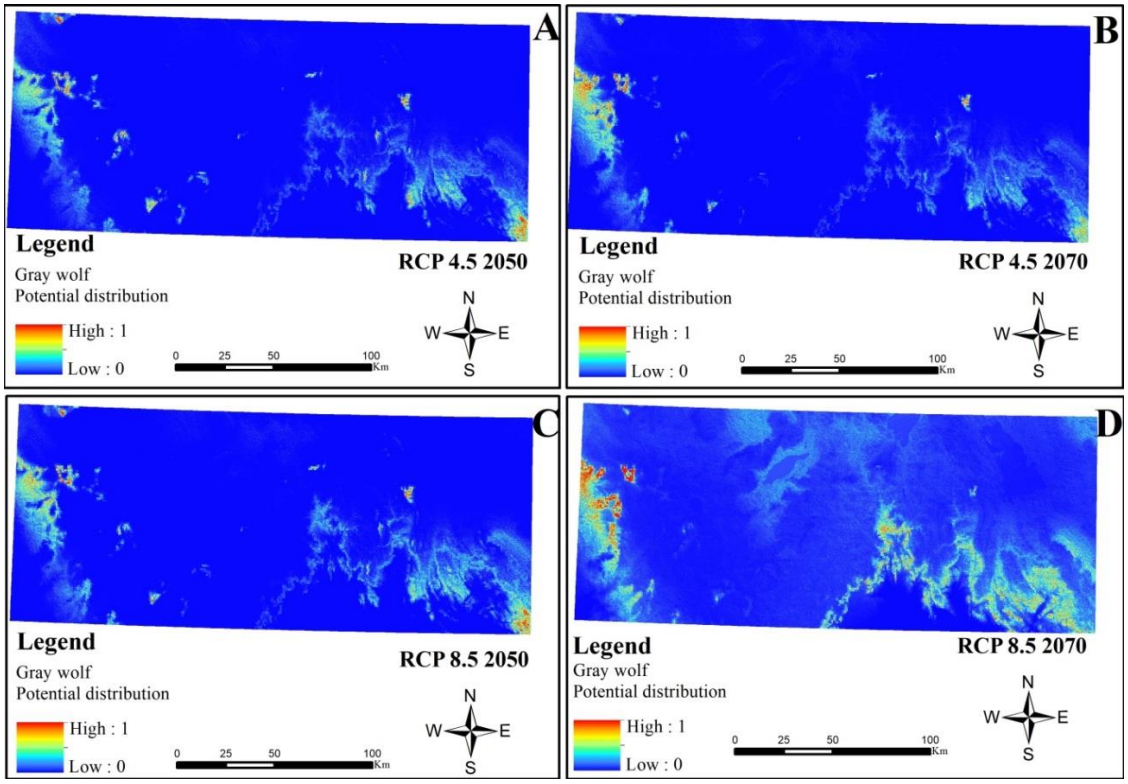

Figure 3. *Habitat suitability maps of Gray wolf for future scenarios. A: HADGEM2-ES RCP 4.5 2050, B: HADGEM2-ES RCP 4.5 2070, C: HADGEM2-ES RCP 8.5 2050, D: HADGEM2-ES RCP 8.5 2070*

Discussion

When the current habitat suitability model for Gray wolf is examined using variables ((BIO12 (23%), BIO13 (18.5%), BIO16 (21.3%), heat index (14%), aspect (12.4%), topographic position index (10.8%)) which formed the model, it is determined that precipitation and temperature are the most important factors limiting the distribution of this species According to *Figure 2*, high zones and the eastern part of the study area are more preferred by this species (red coloured areas in maps). However, when the habitat suitability maps (*Fig. 3*) generated for HADGEM2-ES RCP 4.5 (2050; 2070) and HADGEM2-ES RCP 8.5 (2050; 2070) are examined, it is seen that there would be a significant change in distribution. In other words, depending on climate change, the distribution of the Gray wolf will be affected and the species will migrate in search of a different habitat.

According to the scenario RCP 4.5 2050 (HADGEM2-ES), there is a decrease in the distribution of the wolves, a deviation towards the interior and coastal areas at the same time. A similar change is also observed in the habitat suitability map created for the RCP 4.5 2070 (HADGEM2-ES) scenario (*Fig. 3*). However, according to the scenario RCP 4.5 2070 (HADGEM2-ES), this distribution is concentrated towards the western part of the area, whereas the current habitat suitability map shows a distribution in the eastern part of the area. It is thought that the rise in temperature and the decrease in precipitation will cause these changes (Larsen and Ripple, 2006). At the same time, prey species, which are preferred by target species in the field, should be taken into account as to how they will react to possible changes in the future climate. When

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

studies on feeding behaviour of the target species in literature are examined, it is stated that they move seasonally by following migratory prey species in their region due to nutritional needs despite being a non-immigrant species (Hof et al., 2012; Metz et al., 2012). In view of this information, it is thought that the hunting species in the area may be another important factor for the change in the distribution of the target from east to west according to the HADGEM2-ES RCP 4.5 scenarios. Diet types of this species vary depending on age, sex, and season. There are also several conditions (weather conditions, the vulnerability of prey species, and wolf density in the region etc.) limiting food availability of Gray wolf (Stahler et al., 2006; Metz et al., 2012).

When habitat suitability maps created according to the scenarios of HADGEM2-ES RCP 8.5, 2050, and 2070 are examined, it is predicted that the potential distribution of goal species in the region will reduce considerably and the distribution will shift to the west and north-west. It is seen that in studies conducted on the general behavior of the species, before setting a new territory or joining any wolf pack, the male wolf can move about 113 km and their females can move about 78 km. In some cases, they can even show a distribution over 840 km. It is also known that the species prefer to habitat as high as possible, avoiding human influence (Treves and Karanth, 2003).

It is estimated that Gray wolf with high metabolic demand and long distance mobility (Walker and Churchill, 2014) can use coastal areas of the region for any reason such as diet and reach up to Central Anatolia. As can be seen from the HADGEM2-ES RCP 8.5 scenarios, especially in the habitat conformity map created for 2070, it is proven that coastal area is suitable for distribution of this species. However, it is also probable that human activity which is increasing in coastal areas especially in summer months will limit the movement of the species. To sum up, Gray wolf has to be able to force itself to more movement in order to reduce the effect of negative conditions that will occur in the climate and to be able to return to higher parts where it will feel safe and secure after satisfying its basic needs. According to the habitat suitability maps obtained for both scenarios, it is seen that the results support each other and the distribution of Gray wolf in the region will be affected negatively.

Conclusion

In conclusion, it is predicted that Gray wolf's habitats will be affected by climate change in the future; however, this situation can be tolerated by the high mobility of this species. Nevertheless, it is clearly seen that there are significant differences between the current potential distribution areas shown in *Figure 2* and the potential distribution areas determined for the future scenarios in *Figure 3*. Due to decreases in the suitable habitats, it is expected that the conflict of this species with human and other animal groups will increase. To sum up, present study should be supported by more detailed studies performed by determining all the variables affecting the habitat in order to prevent the extinction of this species.

Abstract. This study was conducted to determine forage quality characteristics of duo (alfalfa + one grass) and trio (alfalfa + two grasses) mixtures of some warm season perennial grass species such as dallis grass (*Paspalum dilatatum* Poir.), Rhodes grass (*Chloris gayana* L.), Bermuda grass (*Cynodon dactylon* (L.) Pers.) Guineae grass (*Panicum maximum* Jacq.), blue couch grass (*Digitaria didactyla* Willd) and finger grass (*Digitaria milanjiana* (Rendle) Stapf) with alfalfa as well as their pure sowings under irrigated conditions in the Mediterranean region of Turkey during 2010-2012 growing seasons. In the study, crude protein contents, crude protein yields, acid detergent fiber contents (ADF), neutral detergent fiber contents (NDF), digestible dry matter contents (DDM) and relative feed values (RFV) of the mixtures and pure sowings were determined. The experimental design was completely randomized block design with three replications. The results of the study showed that there were significant differences among mixtures and pure sowings in the forage quality characteristics. The highest crude protein yield (3948.5) kg ha^{-1}) was obtained from the mixture of dallis grass + alfalfa. The highest crude protein ratio (20.5%), DDM ratio (68.3%) and RFV (170.88) was obtained from the pure alfalfa. The highest ADF (40.2%) and NDF (70.9%) was obtained from the pure Guinea grass. From the results of the study, it was concluded that Bermuda grass, Rhodes grass, blue couch grass and dallis grass could be used to establish of duo and trio pasture mixtures with alfalfa, having long grazing season and giving high hay quality. Before the establishment of such pasture mixtures, it is needed to search for proper mixture ratios and proper management techniques of the mixtures.
Keywords: *warm season perennial grasses, alfalfa, mixture, forage quality, ADF, NDF, RFV*

Introduction

Quality forage for livestock is produced from natural pastures and forage crops grown under field conditions worldwide. Legume–grass mixtures are easily established in degenerated pasture or field conditions. Legumes are rich in terms of protein contents, whereas grasses have higher carbohydrate contents and can benefit from the nitrogen fixed by legumes when they are grown together. Thus, legume–grass mixtures

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_71397154
© 2018, ALÖKI Kft., Budapest, Hungary

may be more productive than monoculture grasses. Alfalfa (*Medicago sativa* L.) is grown under both irrigated and dry conditions and it may be more productive in mixtures with grasses. Several studies reported that alfalfa–grass mixtures resulted in higher yields and higher nutritional quality as compared with grasses alone (Albayrak and Turk, 2011).

The advantages of cool season legumes in cool season pastures and hay lands have been well documented, but there is little information on mixing legumes with warm season grasses. Some researchers reported that growing warm-season grasses with legumes resulted in higher dry matter yields than pure sowings (Aganoglu, 1985; Blanchet et al., 1995; Larbi et al., 1995; Gettle et al., 1996; Tessema and Baars, 2006; Cinar and Hatipoglu, 2014).

Mediterranean region of the Turkey experiences long periods of drought, especially in mid-summer. High temperatures and low precipitation are detrimental to production of cool season forages. Lack of productivity of cool season pastures during the summer months often results in overgrazing. Perennial warm season grasses produce their yields in midsummer, which could provide forage production during that period (Jung et al., 1978).

Methods to effectively establish and manage some warm season grasses for yield have been characterized for Mediterranean conditions (Cinar and Hatipoglu, 2014). Using the potential of these species to provide a dependable pasture forage supply during summer months warrants investigation of options to enhance their quality.

Rhodes grass is one of the main sub-tropical grasses and is widely grown in Africa, Australia, Japan and South America as well as in the Middle East under irrigation for both forage and soil conservation purposes. Dallis grass is a summer-active perennial grass native to the humid sub-tropics of southern Brazil, Argentina and Uruguay. It is now widespread in many areas of the world, and is capable of very high production under suitable conditions. Bermuda grass has been widely used in tropical and warm temperate regions as a pasture grass and is one of the major turf grasses in the world. Blue couch grass is similar to Bermuda grass. It differs from Bermuda grass in its shorter, broader leaf and its distinctive bluish colour (Skerman and Riveros, 1990).

Guinea grass is widely distributed in the tropical and sub-tropical areas of the world. It can produce over 20 tons dm ha^{-1} but suffers from drought when dry matter production can be reduced to as low as 40% of its yield potential. Guinea grass responds well to cutting and grazing, and is fairly pest resistant (Nung and Binh, 2014).

Finger grass is a native of tropical Eastern and Southern Africa, from Ethiopia down to South Africa. It is found in semiarid to wet equatorial areas, with average annual rainfall between 450 to 1700 mm. It grows in grasslands on sandy loam soils and in open woodlands on heavy black or sandy soils. An annual dry matter yield of up to 15 t/ha has been achieved from well fertilized finger grass. It is very palatable to all types of stock as green feed, dry feed or as hay. It can be used in mixed pastures or as a hay crop. It should not be grazed in the wet season of establishment (Cameron et al., 2010).

This study was conducted to determine forage quality of duo (one grass + alfalfa) and trio (two grass + alfalfa) mixtures of some perennial warm season grass species such as dallis grass (*Paspalum dilatatum* Poir.), Rhodes grass (*Chloris gayana* L.), Bermuda grass (*Cynodon dactylon* (L.) Pers.) Guineae grass (*Panicum maximum* Jacq.), blue couch grass (*Digitaria didactyla* Willd) and finger grass (*Digitaria milanjiana* (Rendle) Stapf) with alfalfa (*Medicago sativa* L.) as well as their pure sowings under irrigated conditions in the Mediterranean region of Turkey.

This paper was prepaired from a part of data obtained from the research conducted to determine the forage yields and qualities of duo (one grass + alfalfa) and trio (two grass + alfalfa) mixtures of some perennial warm season grass species such as dallis grass (*Paspalum dilatatum* Poir.), Rhodes grass (*Chloris gayana* L.), Bermuda grass (*Cynodon dactylon* (L.) Pers.), Guineae grass (*Panicum maximum* Jacq.), blue couch grass (*Digitaria didactyla* Willd) and finger grass (*Digitaria milanjiana* (Rendle) Stapf) with alfalfa (*Medicago sativa* L.) as well as their pure growings under irrigated conditions in Mediterranean region of Turkey. A paper from data related to the yields and some other characteristics of the mentioned mixtures as well as pure growings had been published (Cinar et al., 2014).

Materials and methods

Materials

The study was carried out during 2011 and 2012 years in Adana province (36°51'N, 35°20'E, elevation 12 m), located in the Mediterranean region of Turkey (*Fig. 1*).

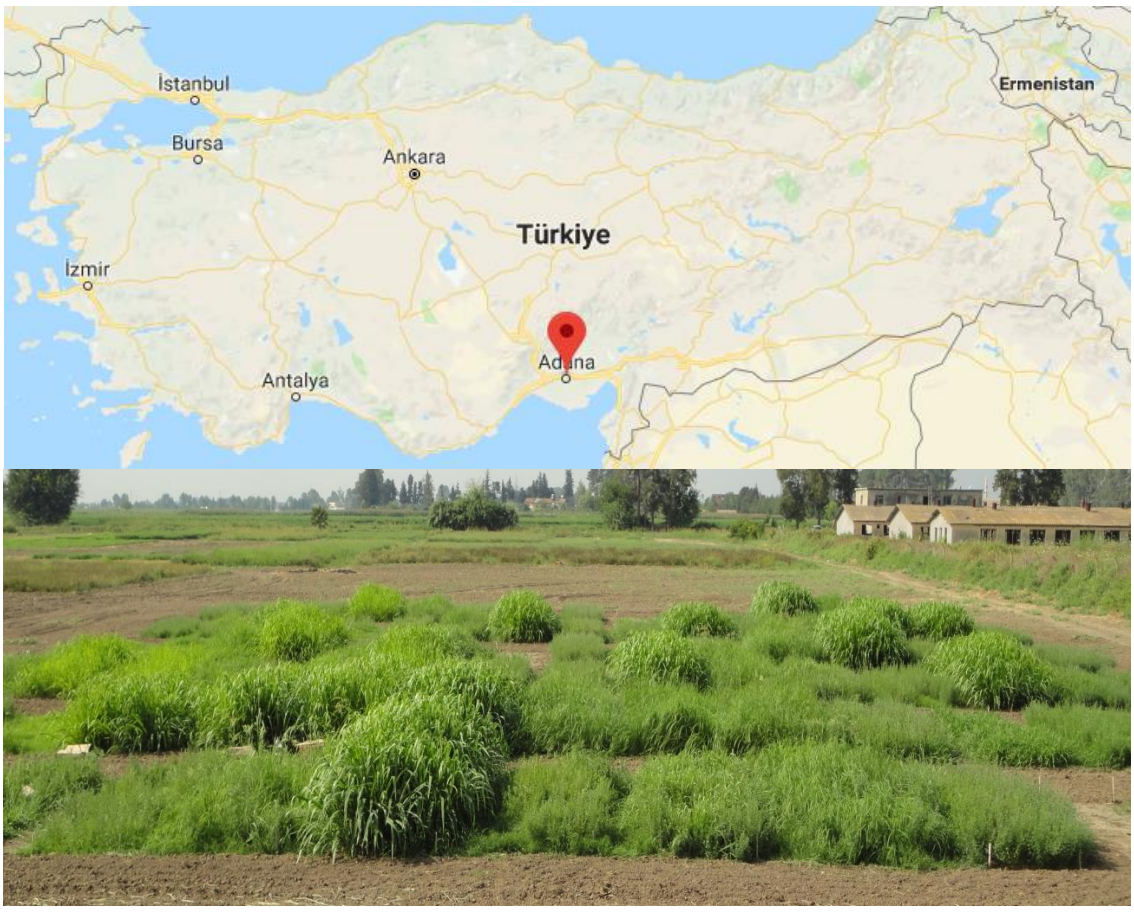

Figure 1. *The map of Turkey and picture of study area*

The experimental area has typically Mediterranean climate with hot and dry summer and heavy precipitation during winter. According to the average of long years, the coolest month is January with a monthly mean temperature of 9.9 °C and the hottest

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_71397154
© 2018, ALÖKI Kft., Budapest, Hungary

month is July with 29.7 °C. The total precipitation was higher in 2011 (687.7 mm) and in 2012 (1048.8 mm) compared with the longterm precipitation mean (647.1 mm). The means of the temperature and relative humidity during the experimental period were close to the long-term means (Anonymous, 2013).

The research area has a flat land; its soil texture is classified as silty clay with slightly alkaline, which contained medium organic matter, poor phosphorus (P), zinc (Zn) and calcium (Ca) contents (Anonymous, 2011).

Dallis grass (*Paspalum dilatatum* Poir.), Rhodes grass (*Chloris gayana* L.), Bermuda grass (*Cynodon dactylon* (L.) Pers.) Guineae grass (*Panicum maximum* Jacq.), blue couch grass (*Digitaria didactyla* Willd), finger grass (*Digitaria milanjiana* (Rendle) Stapf) and alfalfa (*Medicago sativa* L.) were used as experimental material. In the research, duo and trio mixtures of the mentioned grass species with alfalfa as well as their pure sowings were studied.

Methods

The experiment was established according to the randomized complete block design with three replications. There were 28 treatment plots in each block. Each plot consisted of 6 rows each 5 m in length. The row spacing was 25 cm. The seeding rates for dallis grass, Rhodes grass, Bermuda grass, Guineae grass, finger grass, blue couch grass and alfalfa in pure sowing were 11 kg ha^{-1}, 4 kg ha^{-1}, 10 kg ha^{-1}, 6 kg ha^{-1}, 8 kg ha^{-1}, 8 kg ha^{-1} and 10 kg ha^{-1}, respectively. Seed mixtures consisted of 30% alfalfa and 70% grasses. Seed ratio of each grass species in trio mixtures was 35%. The seeds of alfalfa and grass species were sown in the same rows. Sowing was done by hand on May 28th 2011. Plots were fertilized with 100 kg ha^{-1} N and 100 kg ha^{-1} P at sowing (Avci, 2000). The plots were irrigated once after each harvest. The harvest time was based on the 10% flowering stage of alfalfa (Cinar et al., 2014). The plots were harvested at 5 cm cutting height. The plots were harvested 3 and 5 times during the growing season of 2011 and 2012, respectively.

All samples were dried at 70 °C for 48 h and weighed. The samples from the mixture plots were hand-separated to the mixture components before the drying. Dry matter content was determined from ground samples dried at 105 °C for 24 h (Sleugh et al., 2000).

Contents of crude protein, acid detergent fiber (ADF) and neutral detergent fiber (NDF) of samples were determined using Infrared Reflectance Spectroscopy (NIRS) (Hoy et al., 2002; Aydin et al., 2010). NIRS was calibrated using software program coded IC-0904 FE hay and fresh forage.

Crude protein yield (CPY), digestible dry matter yield (DDMY), dry matter intake (DMI), digestible dry matter (DDM) and relative feed value (RFV) were estimated according to the following equations adapted from Sheaffer et al. (1995) (*Eqs. 1–4*):

$$DMI = 120 / (NDF\%) \text{ dry matter basis} \quad \text{(Eq. 1)}$$

$$DDM = 88.9 - (0.779 \times ADF\% \text{ dry matter basis}) \quad \text{(Eq. 2)}$$

$$RFV = (DDM\% \times DMI)/1.29 \quad \text{(Eq. 3)}$$

$$CPY = \text{Crude protein content } (CP\%) \times \text{dry matter yield } (DMY) \quad \text{(Eq. 4)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_71397154
© 2018, ALÖKI Kft., Budapest, Hungary

Relative feed value (RFV) was calculated by multiplying digestible dry matter by dry matter intake and then dividing by 1.29 (Schroeder, 1994).

Statistical analyses

The experimental design was completely randomized block design with three replications. Data were analyzed by using MSTATC software program (V.1.2, Michigan State University, USA). The differences between means were separated by Duncan multiple range test ($P \leq 0.05$) (Steel and Torrie, 1960).

Results

Crude protein ratio and crude protein yield

The results of the variance analysis showed that the crude protein ratio was influenced by pure sowings and mixtures as well as years. Year x treatment (pure sowings and mixtures) interaction was also statistically significant. Average crude protein ratios in the second year were significantly higher than that in the first year (*Table 1*). The alfalfa sown in April, normally sown in November under Mediterranean conditions, produced lower hay yield than that sown in November in the first year. Therefore contribution of the alfalfa on the yield of the mixtures was significantly lower than those in the second year. Lower alfalfa ratio in the hay yields of mixtures in the first year resulted in the lower averaged crude protein ratio than those in the second year.

In the first year, crude protein content of alfalfa dry matter was statistically significant higher than those of the other pure sowings and all of the mixtures (*Table 1*). The mixtures GG+A gave significantly lower crude protein ratio than pure sowings and other mixtures.

In the second year, the mixture of RG+FG+A produced dry matter with statistically significant higher crude protein content than the all of the pure sowings with the exception alfalfa and all of the other mixtures with the exceptions of RG+GG+A, GG+A, A, FG+A, BG+A, DG+A, RG+A, GG+FG+A, GG+BCG+A and RG+BCG+A. On the other hand, pure sowing of Guinea grass gave significantly lower crude protein content than the pure sowing of Rhodes grass and all of the mixtures. All of the pure sowings of the grasses gave the dry matter with statistically significant lower crude protein content than the pure sowing of alfalfa and all of the mixtures.

According to the averaged values over two years, the highest crude protein ratio was obtained from pure sown alfalfa. Pure sowings of Guinea grass produced the dry matter with significantly lower crude protein content than the other pure sowings and mixtures.

The results of the variance analysis showed that the crude protein yield was influenced by pure sowings and mixtures as well as years. Year x treatment interaction was also statistically significant. The averaged crude protein yield in first year was significantly lower than those in the second year (*Table 2*). The variation in the crude protein yield of the pure sowings and mixtures depending on the years was due to the variation in dry matter yield and crude protein ratio (Cinar et al., 2014; *Table 1*).

In the first year of the experiment, the mixture of RG+A gave statistically significant higher crude protein yield than the pure growings of Bermuda grass and blue couch grass and the mixtures of GG+A, BCG+A, GG+BCG+A and GG+FG+A. In the second year, the mixture of alfalfa + dallis grass gave significantly higher crude protein yield

ADF and NDF ratios

The results of the variance analysis showed that ADF and NDF contents of the dry matter were statistically significant influenced by pure sowing and mixtures as well as the years. Interaction of the years and treatments was also statistically significant. The averaged ADF content over the pure sowings and mixtures in the first year was significantly higher than those in the second year (*Table 3*). In the first year, contribution of the warm season grasses on the hay yield of the mixtures was higher than those in the second year. The grasses contain generally higher ADF than alfalfa

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_71397154
© 2018, ALÖKI Kft., Budapest, Hungary

(Linn and Martin, 1999). Therefore averaged ADF content of the dry matter in the first year was significantly higher than those in the second year.

In the first year and as the averaged values over the two years, alfalfa gave the dry matter with significantly lower ADF content than the other pure sowings and all of the mixtures. In the second year, alfalfa was the treatment among the treatments producing dry matter with low ADF content. In contrast to this, Guinea grass produced the dry matter with significantly higher ADF content than the other pure sowings and all of the mixtures in the second year and as the averaged values over the two years. It was among the treatments with high ADF content in the first year.

Digestible dry matter content

The results of the variance analysis showed that the digestible dry matter ratio was influenced by pure sowings and mixtures as well as years. Year x treatment interaction

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_71397154
© 2018, ALÖKI Kft., Budapest, Hungary

was also statistically significant. Averaged digestible dry matter ratios in the second year were significantly higher than that in the first year (*Table 5*).

The digestible dry matter ratio is calculated using the ADF values and is inversely proportional. ADF ratios are higher in the second year than in the first year. Therefore, the rate of digestible dry matter in the second year is higher than in the first year.

In the first year, digestible dry matter ratio of alfalfa was significantly higher than those of the other pure sowings and all of the mixtures with the exception of BCG+A and BG+DG+A (*Table 5*). Pure sowing of Guinea grass produced dry matter with significantly lower digestibility ratio than the other pure sowings and all of the mixtures with the exceptions of the mixtures containing Guinea grass.

In the second year, the mixture of RG+GG+A produced the dry matter with significantly higher digestibility ratio than all of the pure sowings with the exception of alfalfa and all of the mixtures with the exceptions of GG+A, GG+FG+A, BCG+A, BG+GG+A, DG+GG+A and RG+FG+A All of the pure sowings of the grasses gave the dry matter with significantly lower digestibility ratio than the pure sowing of alfalfa.

Some of our findings are consistent with those above mentioned, some of them are incompatible. The differences between our finding and that of previous studies could be due to the ecological differences, varieties, mixes, practices applied.

Relative feed value (RFV)

The results of the variance analysis showed that RFV was statistically significant influenced by pure sowings and mixtures as well as years. Year x mixture interaction was also statistically significant. The averaged RFV over the pure sowings and mixtures significantly changed depending on the years. The averaged RFV in the second year was significantly higher than those in first year (*Table 6*). The higher alfalfa contribution to the hay yield of the mixtures in the second year as compared to the first year resulted in higher RFV in second year. RFV is inversely proportional to the ADF and NDF. Therefore higher averaged RFVs were obtained in the second year in which ratios of NDF and ADF were lower than those in the first year.

In the first year of the experiment and as averaged value over the years, pure sown alfalfa produced the dry matter with significantly higher RFV than the other pure sowings and all of the mixtures. In the second year, the mixtures of DG+A, RG+A, GG+A, BCG+A, RG+GG+A, RG+FG+A and GG+FG+A gave dry matters with RFVs being not statistically significant different from that of Alfalfa dry matter.

Discussion

It was determined that crude protein content of pure growing alfalfa was significantly higher than those of pure growing grasses and generally higher than the mixtures of grasses with alfalfa. Previous studies have also shown that alfalfa contains significantly more protein than grasses and that grass+legume mixtures contain more crude protein than the pure sowing grasses (Spandl and Hesterman, 1997; Avci, 2000; Albayrak and Ekiz, 2005; Cinar and Hatipoglu, 2014).

Nutrient value of a mixture forage relatively depends on the botanical composition and harvesting time. The results indicated that CP contents of dry matter of the mixtures were generally lower than 16-18% which requires supplementary feeding to obtain high performance from milk cows (Baytekin and Gul, 2009).

According to the two years averaged values, alfalfa gave significantly higher crude protein yield than the pure growing grasses. Conrad and Martz (1985), Rohweder and Keuren (1985), Spandl and Hesterman (1997) reported also that alfalfa has higher dry matter and crude protein yield than grasses. Some of the duo mixture of grasses with alfalfa such as BG+A, DG+A and FG+A produced significantly higher crude protein yield than pure growing alfalfa. This was due to the higher dry matter yields of those mixtures. This result was consistent with that of Albayrak and Turk (2011).

In the study, alfalfa gave the dry matter with significantly lower ADF and NDF contents than the other pure sowings and generally lower than those of all of the mixtures. In contrast to this, Guinea grass produced the dry matter with significantly higher ADF and NDF contents than the other pure sowings and all of the mixtures. The reasons of the higher ADF and NDF contents of Guinea grass could be development stage of the plant at the harvest (Anonymous, 2012) as well as the lower leaf- stem ratio (Pinkerton and Cross, 1992). The ADF concentration refers to the cell wall portion of the forage. The portion consist of cellulose and lignin. The ADF value is important because it describes the ability of an animal to digest the forage. As the ADF increases, the digestibility of the forage usually decreases. The NDF value refers to the total cell

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_71397154
© 2018, ALÖKI Kft., Budapest, Hungary

wall, composed of the ADF fraction plus hemicellulose. NDF value is important in ration formulation because it reflects the amount of forage that the animal can consume. As the NDF percentage increases, the dry matter intake will generally decrease (Joachim and Jung, 1997; Albayrak et al., 2011). Horner et al. (1985) determined ADF content of alfalfa as 35.3 - 41.1% while Cassida et al. (2000) reported it as 29.7 - 33.5%. ADF content of the mixture of Rhodes grass + white sweet clover was reported by Corletto et al. (2009) as 37.0%. Horner et al. (1985) determined NDF content of alfalfa as 46.0% while Cassida et al. (2000) reported it as 37.8 - 42.0%. Jeranyama and Garcia (2004) reported a NDF value of 54% for the mixture of alfalfa + grasses of mixtures. Tessema and Baars (2006) determined NDF values for Rhodes grass and for the mixture of alfalfa + Rhodes grass as 55.7% and 46.9%, respectively. Lemus (2009) reported a NDF value of 67.2 - 67.6% for dallis grass. Cinar et al. (2014) reported a ADF, NDF value of the 40.2%, 70.9% for dallis grass respectively.

Some of our findings are consistent with those above mentioned, some of them are incompatible. Differences between the findings may be due to differences in climatic conditions, under which researches were conducted, and management techniques applied in the experimental plots (Linn and Martin, 1999; Belyea et al., 1999; Bani et al., 2007).

According to the averaged values over two years, the highest digestible dry matter ratio was obtained from pure sown alfalfa. It was significantly higher than those of all of the other pure sowings and all of the mixtures with the exception of the mixture BCG+A. Pure sowings of Guinea grass produced the dry matter with significantly lower digestibility ratio than the other pure sowings and mixtures. Alfalfa's ADF content is lower than those of grasses. As the proportion of alfalfa in the mixture increases, the ADF ratio decreases and the digestibility increases (Joachim and Jung, 1997; Cinar and Hatipoglu, 2014). Felicity et al. (1996) determined DDM content of dallis grass as 63.6% while Cook et al. (2005) 57.0-63.0%. Cinar and Hatipoglu (2014) reported DDM ratio values of alfalfa, dallis grass, Bermuda grass, Rhodes grass, DG+A, BG+A, RG+A, RG+DG+A, BG+DG+A, RG+BG+A 68.1%, 57.6%, 63.1%, 60.7%, 63.0%, 66.3%, 63.4%, 62.6%, 65.1%, 63.1% respectively.

Relative feed value (RFV) has been used for years to compare the quality of legume and legume/grass hays and silages. Having one index to price hay and predict animal performance has been very useful for livestock producers and hay farmers. Forages with an RFV value over 151, between 150-125, 124-103, 102-87, 86-75, and less than 75 are categorized as prime, premium, good, fair, poor and rejected, respectively (Kiraz, 2011; Uzun, 2010; Cinar et al., 2014). According to these index values, hay of pure sowing alfalfa is classified as prime while hays of the mixtures of Bermuda grass+alfalfa, dallis grass+alfalfa, blue couch grass+alfalfa, finger grass+alfalfa, Bermuda grass+dallis grass+alfalfa, Bermuda grass+blue couch grass+alfalfa, Bermuda grass+finger grass+alfalfa, dallis grass+blue couch grass+alfalfa, dallis grass+finger grass+alfalfa, Rhodes grass+finger grass+alfalfa, finger grass+blue couch grass+alfalfa are classified as premium.

Conclusions

It was concluded that, the mixtures of Bermuda grass+alfalfa, dallis grass+alfalfa, blue couch grass+alfalfa, finger grass+alfalfa, Bermuda grass+finger grass+alfalfa, dallis grass+blue couch grass+alfalfa, dallis grass+finger grass+alfalfa, Bermuda

grass+dallis grass+alfalfa, Rhodes grass+finger grass+alfalfa and finger grass+blue couch grass+alfalfa could be grown for the feeding of high yielding dairy cows in Mediterranean climatical conditions. On the other hand, additional researches on the seed mixture ratios, fertilization and harvest time should be conducted in order to increase the forage quality of the mentioned mixtures.

Abstract. In order to study the variability of the upper sea temperature in the tropical Pacific and Indian Oceans and reveal their coupling relationship with East Asian summer monsoon circulation, the singular value decomposition is employed to reveal the variation of 120 m sea temperature in the tropical Pacific and Indian Oceans, the main modalities of anomalous activities of the East Asian summer monsoon, and their mutual relation. The results show that during the summer of years with strong summer monsoon, the western Pacific subtropical high is weak and its location is northerly. In years with strong summer monsoon, the sinking movement of vertical velocity anomalies in East Asia weakens the Meiyu front and vice versa. When the 850 hPa east trade winds in the equatorial central and eastern Pacific Ocean are enhanced, the middle Indian Ocean and the western Pacific Ocean show westerly anomalies. Meanwhile, if the meridional wind anomalies on both sides of the equator in the central Indian Ocean/ eastern Pacific and East Asia show a clear convergent and divergent pattern, respectively, the corresponding 120 m sea temperature shows a La Niña state and is easy to trigger the strong East Asian summer monsoon.
Keywords: *singular value decomposition, 850 hPa wind filed, the tropical Pacific, El Niño state, 120 m sea temperature*

Introduction

Located in the East Asian monsoon region, China shows a typical monsoon climate. The monsoon in China shows large interannual variability leading to frequent droughts and floods (Hao et al., 2016). Therefore, it is of great practical significance to study the variability and main impacting factors of East Asian summer monsoon (EASM). The strength of the EASM is closely related to the subtropical high, the atmospheric circulation in tropics and mid-high latitudes, and the thermal effects of the Tibetan Plateau (Duan et al., 2008; Li et al., 2016). The anomaly of sea temperature is the most important for the prediction of EASM among the above factors (Zhang and Li, 2004). It impacts the precipitation in the monsoon region by impacting the monsoon circulation (Zhang et al., 1999). In the tropical oceans, the El Niño-Southern Oscillation (ENSO) is a strong signal of air-sea interactions. Studies have shown that the ENSO has an important impact on the EASM as well as the climate of China. The warming period of El Niño affects the strength and the burst time of the EASM, thereby affecting the amount of summer precipitation in East Asia (Feng et al., 2011; Zhou et al., 2012; Zhang et al., 2017). Many studies about the variability of the EASM have been conducted based on the sea surface temperature (SST). However, the subsurface sea temperature is less affected by the sea-air interface and has more significant interannual variation compared to the SST, thus, it has a large impact on the continued development of the climate. Chen et al. (2011, 2012) studied the interannual and interdecadal

© 2018, ALÖKI Kft., Budapest, Hungary

variability of subsurface ocean temperature anomalies in the tropical Pacific and their impacts on the climate anomalies in China using the variation of sea temperature in the thermocline. They found that the subsurface sea temperature affects the variation of EASM by affecting the subtropical high and the trough-ridge system in mid-high latitudes. Recent studies also show that there is a mutual interaction between the subsurface sea temperature anomalies in the western Pacific warm pool and the ENSO cycle (Li and Li, 2014; Shan et al., 2016; Li et al., 2017).

The above studying areas are mostly in the tropical Pacific Ocean, which cannot reveal the characteristic that the cold and warm center from the tropical Eastern Indian Ocean to the western Pacific Ocean is an integral system (Cai et al., 2005). The direct relationship between the EASM circulation field and the tropical subsurface sea temperature field is also rarely discussed. Therefore, the aim of this study is to reveal the general pattern of forecasting the EASM and the ENSO. Considering the areas from the tropical Indian Ocean to the Pacific Ocean, a singular value decomposition (SVD) method is employed to study the variation of tropical subsurface sea temperature and the EASM and discuss the coupling relationship between them.

Data and method

The data used in this study is the monthly anomalies of global upper sea temperature (1955-2003) produced by Scripps/NODC Joint Environmental Data Analysis Center (JEDAC) and downloaded from the Nanjing Atmospheric Data Service Center. It is a 5° × 2° dataset covering 60°S-60°N with 11 vertical layers at depths of 0, 20, 40, 60, 80, 120, 160, 200, 240, 300, and 400 m. The data from 30°S-40°N in the Indo-Pacific region is selected for this study. The 2.5° × 2.5° 850 hPa monthly mean data from the National Centers for Environmental Prediction/ National Center for Atmospheric Research (NCEP/NCAR) reanalysis are also selected.

The methods employed here include the synthetic analysis and the SVD. SVD is a method for analyzing the correlation between two element fields, that is, several pairs of correlative spatial distributions of the two element fields. Such spatial distribution can explain the cross-covariance of the two fields to the greatest extent (John et al., 1992). Its main advantage is that it is universal in the diagnostic analysis of the time-space coupled signals in meteorological fields. It is more effective than the natural orthogonal function and the typical correlation method when analyzing the connection between two different element fields and is a powerful tool to study the spatiotemporal relationship between two sequences of element fields (Ding and Jiang, 1995).

Circulation characteristics in years with strong/weak EASM

An Index of EASM (IEASM) defined by Zhang et al. (Zhang et al., 2003) is the difference between the anomalies of 850 hPa zonal wind in East Asian tropical monsoon trough (10°~20°N, 100°~150°E) and East Asian subtropical zone (25°~35°N, 100°~150°E) in June, July, and August. That is, IEASM = U850 hPa (10°~20° N, 100°~150°E) - U850 hPa (25°~35°N, 100°~150°E). A higher IEASM means a stronger summer monsoon and vice versa. This paper selected the data from 1955 to 1998. After standardizing, the years with the normalized IEASM > 1 are defined as the years with strong EASM and those with normalized IEASM < -1 are defined as the years with weak EASM. The years with strong/weak EASM are calculated by the above method,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_71557170
© 2018, ALÖKI Kft., Budapest, Hungary

which are listed in *Table 1*. The rest of years are considered as the years with normal EASM.

Table 1. *The years with strong/weak EASM defined by IEASM*

Strong/weak	Years					
EASM	1967	1972	1974	1978	1981	1984
Strong	1985	1986	1994	1997	2001	2002
EASM	1955	1956	1959	1969	1980	1983
Weak	1988	1995	1998			

In order to understand the variation characteristics of circulation in years with strong/weak EASM, a synthesis analysis is conducted using the years of strong and weak EASM to explore the variation of atmospheric circulation field during the EASM. *Figure 1a* and *b* are the summer (July) 850 hPa anomalous wind field for years with strong and weak EASM, respectively. In *Figure 1a,* the western Pacific subtropical high in the northern hemisphere (corresponding to the cyclonic circulation anomaly) is weaker than normal and its location is more northerly with the axis at 25°N. The Australia high in the southern hemisphere (corresponding to the anti-cyclonic circulation anomaly) is also weaker than normal, but its weakening intensity is far less than that of the western Pacific subtropical high. This corresponds to an air pressure anomaly field which has high and low values in the south and north, respectively, which forms a strong southeast and southwest anomalous airflow across the equator strengthening the EASM circulation. At 45°E, the northward Somalia jet across the equator further strengthens the EASM circulation. Therefore, the easterly airflow from the south side of the western Pacific subtropical high, the cross-equatorial southerly airflow from 105°~120° E in the southern hemisphere, and the westerly airflow from the Indian Ocean come together and form the southeasterly and southwesterly airflows. The southeasterly airflow is a subtropical monsoon airflow while the southwesterly airflow is a tropical monsoon airflow, both providing the warm and wet southerly airflow for East Asian monsoon zone. East Asia to the east of 100°E, the Korean peninsula, and Japan are all affected by these airflows, and they are also the main water vapor source for the summer precipitation in Eastern China. When this northward warm wet airflow meets the cold air from the circulation of mid-high latitude, a type of subtropical monsoon called Meiyu front is formed (Qin and Wang, 2015). In *Figure 1b,* the anomaly of the circulation field is almost opposite to that in *Figure 1a*. The western Pacific subtropical high in the northern hemisphere (corresponding to the anti-cyclonic circulation anomaly) is stronger than normal and is more southerly with the axis at 20°N, while the Australia high in the southern hemisphere (corresponding to the cyclonic circulation anomaly) is stronger than normal, but its strengthening intensity is far less than that of the western Pacific subtropical high. This corresponds to an air pressure anomaly field with high and low values in the north and south, respectively, which forms a strong northeast and northwest anomalous airflow across the equator weakening the EASM circulation. Therefore, the years with strong and weak EASM have significant differences in the tropospheric low-level circulation field: In the summer of years with strong/weak EASM, the tropical region in East Asia-Pacific shows a closed cyclonic/anti-cyclonic circulation anomaly corresponding to a weaker/stronger western Pacific subtropical high. Gong and He (2002) and Liu and Guo

(2005) found that the geo-potential height field in East Asia shows negative anomalies during the period when EASM is stronger while the situation is opposite when EASM is weak. Zhang and Wang (2006) and Wu and Zhang (2011) pointed out that the EASM circulation is stronger/weaker when cyclonic/anti-cyclonic circulation anomalies occur in the tropical monsoon region of East Asia, which is in line with the results in this study.

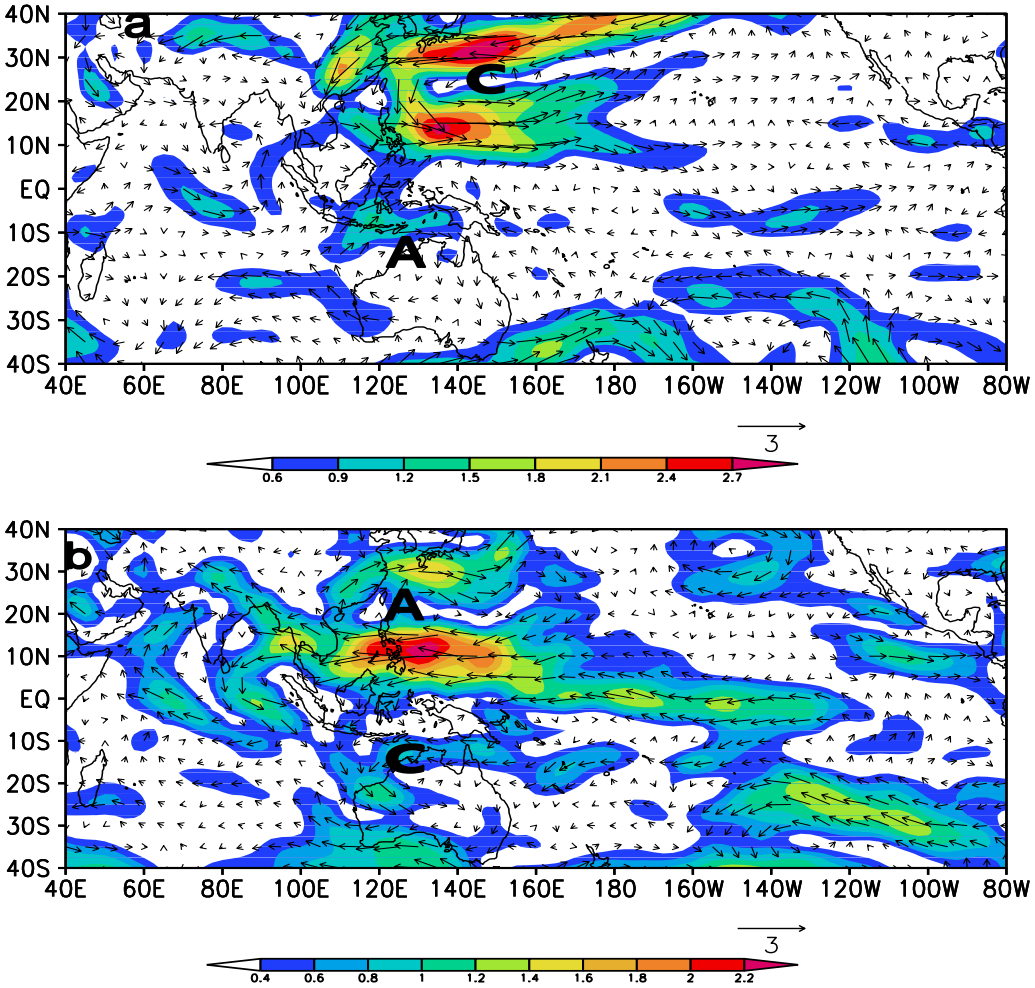

Figure 1. *The anomalies of the 850 hPa wind field (unit: m/s) in the summer of years with (a) strong and (b) weak EASM. A: anti-cyclone; C: cyclone*

In order to further understand the characteristics of circulation in the East Asian monsoon region during the summer of years with strong and weak EASM. *Figure 2a* and *b* show the mean longitude-height profiles of the vertical velocity anomalies in 25°~35°N in the East Asian monsoon region during the summer of years with strong and weak EASM, respectively. In the years with strong EASM (*Fig. 2a*), the vertical velocity from the near ground to the upper level in 110°~140°E shows anomalies of sinking movement, and the upward movement in the summer Meiyu front area (25°~35°N, 110°~140°E) is weakened, indicating the weakening of the Meiyu front intensity in East Asia. In the years with weak EASM (*Fig. 2b*), the vertical velocity from the near ground to the upper level in 110°~140°E shows anomalies of upward

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

movement, and strong upward movement appears in the Meiyu front area (25°~35°N, 110°~140°E), leading to the of strengthening of the Meiyu front intensity in East Asia. Thus, the vertical velocity anomalies in East Asia are significantly different in the summers of years with strong and weak EASM. In the years with strong/weak EASM, the vertical velocity anomalies in East Asia are downward/upward, weakening/strengthening the Meiyu front.

Results

Coupling relationship between subsurface sea temperature and 850 hPa wind field

According to Li et al. (2018), the 120 m layer in the equatorial region from the central Indian Ocean to the western Pacific Ocean and the 40 m layer in the equatorial eastern Pacific Ocean have the highest correlation with the IEASM. Since the distributions of the correlation field in the eastern Pacific are roughly the same in the layers of 40 m and 120 m, the relationship between the 120 m sea temperature and the summer monsoon reflects the relationship between subsurface sea temperature and the EASM in most regions from the tropical Pacific to the Indian Ocean. Meanwhile, in order to analyzing the Pacific as a whole system without splitting the east and the western Pacific, the 120 m layer sea temperature in winter (January) is selected to discuss the coupling relation between 120 m layer sea temperature and the 850 hPa wind field using SVD in order to understand the covariation of the sea temperature field

and the wind field during the same period. *Figure 3* shows the left and right heterogeneous correlation graphs and time coefficients of the first mode of SVD selecting the winter 120 m normalized sea temperature anomalies as the left field and the normalized 850 hPa zonal wind anomalies as the right field. *Table 2* shows the corresponding main information of the first three modes of SVD. It can be seen from *Table 2* that the first mode interprets 39.98% of the total covariance, reflecting the main coupling characteristics between the 120 m layer sea temperature field and the 850 hPa zonal wind field. For the first three modes, the correlations between time coefficients of the left and the right singular vectors are high and this correlation is significant at 0.001 confidence level. Therefore, a detailed analysis is conducted on the heterogeneous correlation field of the first mode.

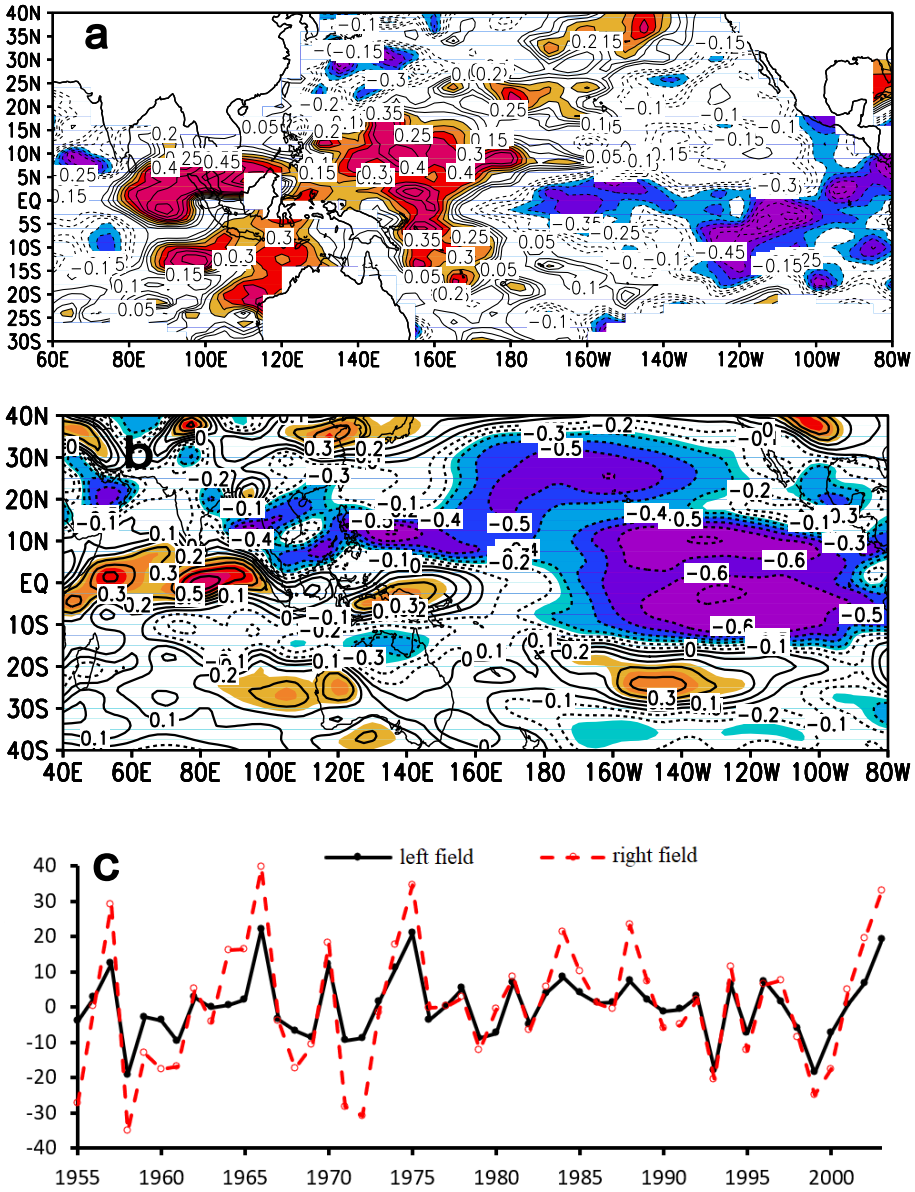

Figure 3. *Heterogeneous correlation graphs between winter 120 m sea temperature field and 850 hPa zonal wind field: (a) left field, (b) right field, and (c) time coefficient. The shadow means the values significant at 0.1 confidence level*

Table 2. *Information of the first three modes of SVD between sea temperature field and zonal wind field*

Sequence number	Correlation coefficients	The sum of squares of the interprets covariance%	Accumulation of the sum of squares of the interprets covariance%
1	0.91	39.98	39.98
2	0.90	8.71	48.69
3	0.92	5.59	54.28

In *Figure 3a,* the region from the equatorial eastern Indian Ocean to the western Pacific shows positive anomalies of sea temperature, with the center of the positive values located in 10°S~10°N, 80°~170°E. The correlation coefficient in the southern part of the Bay of Bengal, the region from Sumatra to the southern part of the South China Sea, and the equatorial ocean near 160°E reach 0.5 (significant at 0.001 confidence level). Most of the equatorial eastern Pacific shows negative anomalies. The absolute value of the maximum correlation coefficient is comparable with the corresponding values from the equatorial eastern Indian Ocean to the western Pacific. The absolute value of the correlation coefficient of the negative anomalies in the equatorial central Indian Ocean is lower. In *Figure 3b,* the zonal wind in the equatorial central and eastern Pacific shows easterly anomalies and the eastward trade wind is enhanced. Its negative center is located in 10°S~10°N, 150°~100°W with the maximum correlation coefficient of 0.7 (significant at 0.001 confidence level). The region from the equatorial central Indian Ocean to the western Pacific Ocean shows westerly anomalies indicating the existence of westerly jets (Ke et al., 2015). The positive center of this region is in 5°S~5°N, 50°~100°E with the maximum correlation coefficient of 0.5 (significant at 0.001 confidence level). As the modal correlation coefficient is positive, the time coefficients of the left and right fields share the same positive and negative phase on average (*Fig. 3c*). When the time coefficient is strongly positive, the trade wind in the equatorial central and eastern Pacific Ocean is enhanced. The region from center Indian Ocean to the western Pacific Ocean shows westerly anomalies. Meanwhile, the sea temperature in the region from the equatorial eastern Indian Ocean to the western Pacific Ocean becomes higher while the sea temperature in the central Indian Ocean and the eastern Pacific becomes lower, showing a La Niña state. On the contrary, when the time coefficient is strongly negative, the trade wind in the equatorial central and eastern Pacific Ocean is weakened. The region from center Indian Ocean to the western Pacific Ocean shows easterly anomalies. Meanwhile, the sea temperature in the region from the equatorial eastern Indian Ocean to the western Pacific Ocean becomes lower while the sea temperature in the central Indian Ocean and the eastern Pacific becomes higher, showing an El Niño state. Besides, the time coefficients show that the trends of the two fields are in generally consistent and both of them show clear characteristics of interannual variability.

Figure 4 shows the left and right heterogeneous correlation graphs and time coefficients of the first mode of SVD selecting the winter 120 m normalized sea temperature anomalies as the left field and the normalized 850 hPa meridional wind anomalies as the right field. *Table 3* shows the corresponding main information of the first three modes of SVD. It can be seen from *Table 3* that the first mode interprets

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

38.45% of the total covariance, reflecting the main coupling characteristics between the 120 m layer sea temperature field and the 850 hPa meridional wind field. For the first three modes, the correlations between time coefficients of the left and the right singular vectors are high. Therefore, an analysis is conducted on the heterogeneous correlation field of the first mode. In *Figure 4a,* the equatorial eastern Pacific shows positive anomalies of sea temperature. The center of the positive values located in 10°S~5°N, 170°~110°W with the maximum correlation coefficient of 0.4 (significant at 0.01 confidence level) while the correlation coefficients in the region of positive anomalies in the equatorial central Indian Ocean are low. The region from the equatorial eastern Indian Ocean to the western Pacific shows negative anomalies of sea temperature, with the center of the negative values located in 5°~15°N, 110°~150°E. The maximum of the correlation coefficient is comparable with that in the equatorial eastern Pacific Ocean. In *Figure 4b,* the meridional wind in the eastern Pacific Ocean to the north of the equator shows northerly anomalies with the maximum correlation coefficient of 0.6 (significant at 0.001 confidence level) while that to the south of the equator shows southerly anomalies. Therefore, the meridional wind anomaly is convergent from both hemispheres to the equatorial eastern Pacific Ocean, which is conducive to the accumulation of the warm water near the equatorial eastern Pacific Ocean. Similarly, the meridional wind in the equatorial central Indian Ocean shows northerly and southerly anomalies to the north and south of the equator, respectively, which is also conducive to the accumulation of the warm water near the central Indian Ocean. East Asia (110°~130°E) shows southerly and northerly anomalies to the north and south of the equator, respectively, which is divergent and is not conducive to the accumulation of the warm water near the equatorial western Pacific Ocean. As the modal correlation coefficient is positive, when the time coefficients of the left and right fields are strongly positive, the meridional wind anomalies on the two sides of the equator are convergent in the central Indian Ocean and eastern Pacific Ocean but divergent in East Asia. In this condition, the sea temperature in the central Indian Ocean and eastern Pacific Ocean increases while the sea temperature in the region from the eastern Indian Ocean to the western Pacific Ocean decreases, showing an El Niño state. On the contrary, when the time coefficients of the left and right fields are strongly negative, the meridional wind anomalies on the two sides of the equator are divergent in the central Indian Ocean and eastern Pacific Ocean but convergent in East Asia. In this condition, the sea temperature in the central Indian Ocean and eastern Pacific Ocean decreases while the sea temperature in the region from the eastern Indian Ocean to the western Pacific Ocean increases, showing a La Niña state. The time coefficients (*Fig. 4c*) show that the trends of the two fields are in generally consistent and both of them show clear characteristics of interannual variability.

Coupling relationship between subsurface sea temperature in tropical Pacific-Indian Ocean and EASM circulation

The correlation coefficients are calculated between the IEASM and the sea temperature anomalies in the region from the tropical Pacific Ocean to the tropical Indian Ocean. The calculation is conducted month by month and layer by layer from 0 to 400-m depth. It is found that the IEASM has high correlations with the sea temperature anomalies in the equatorial region from the central Indian Ocean to the eastern Pacific Ocean and these correlations change with time. The correlation is the highest when the sea temperature field leads and lags the monsoon for six months and four months, respectively, and the distribution characteristics are significant (Li et al., 2018; Guo et al., 2018). It can be seen that the tropical subsurface sea temperature affects the intensity of EASM by affecting the atmospheric circulation in East Asian,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_71557170
© 2018, ALÖKI Kft., Budapest, Hungary

while the variation of EASM also affects the distribution of the sea temperature field. To further understand the coupling relationship between 120 m sea temperature field and EASM circulation field, the SVD is conducted between these two fields for the conditions that the sea temperature field leads and lags the EASM circulation field for six months and four months, respectively.

Coupling relationship when subsurface sea temperature field leads wind field

Figure 5 shows the left and right heterogeneous correlation graphs and time coefficients of the first mode of SVD selecting the winter (January) 120 m normalized sea temperature anomalies as the left field and the summer (July) normalized 850 hPa wind field anomalies as the right field. *Table 4* shows the corresponding main information of the first three modes of SVD. It can be seen from *Table 4* that the first mode interprets 37.92% of the total covariance, reflecting the main coupling characteristics between the 120 m layer sea temperature field and the 850 hPa wind field. For the first three modes, the correlations between time coefficients of the left and the right singular vectors are high (significant at 0.001 confidence level). Therefore, an analysis is conducted on the heterogeneous correlation field of the first mode.

Table 4. *Information of the first three modes of SVD between sea temperature field and wind field*

Sequence number	Correlation coefficients	The sum of squares of the interprets covariance %	Accumulation of the sum of squares of the interprets covariance %
1	0.92	37.92	37.92
2	0.90	10.03	47.95
3	0.91	7.45	55.40

In the right field in *Figure 5a,* the region from the equatorial eastern Indian Ocean to the western Pacific shows westerly anomalies. The region locates in 0°~15°N, 70°~180°E, and the highest correlation is found around 80°~150°E with the maximum correlation coefficient of 0.8 (significant at 0.001 confidence level), which is in line with the latitudinal band and eastward stretch of the westerly jet in summer during the years with strong EASM. Meanwhile, the western Pacific subtropical high in the northern hemisphere (corresponding to the anti-cyclonic circulation anomaly) is weaker than normal, indicating that the EASM circulation is strengthened. In the corresponding left field in *Figure 5b,* the region from the equatorial eastern Indian Ocean to the western Pacific shows positive anomalies of sea temperature centered in 10°S~10°N, 100°~170°E. The correlation coefficients in the south of the Bay of Bengal and the equatorial ocean near 160°E are 0.4 which is significant at 0.01 confidence level. Most regions in the equatorial central Indian Ocean and the equatorial eastern Pacific Ocean show negative anomalies, and the absolute value of the maximum correlation coefficient is lower than that in the region from the equatorial eastern Indian Ocean to the western Pacific. According to *Figure 5c,* when the time coefficient is strongly positive, the sea temperature in the region from the equatorial eastern Indian Ocean to the western Pacific Ocean becomes higher while the sea temperature in the central Indian Ocean and the eastern Pacific becomes lower in winter, showing a La Niña state.

As the sea temperature leads the monsoon for six months, the EASM in La Niña years will be stronger than normal. On the contrary, when the time coefficient is strongly negative, the sea temperature in the region from the equatorial eastern Indian Ocean to the western Pacific Ocean becomes lower while the sea temperature in the central Indian Ocean and the eastern Pacific becomes higher in winter, showing an El Niño state and leading to a weaker EASM. Besides, the time coefficients show that the trends of the two fields are in generally consistent and both of them show clear characteristics of interannual variability.

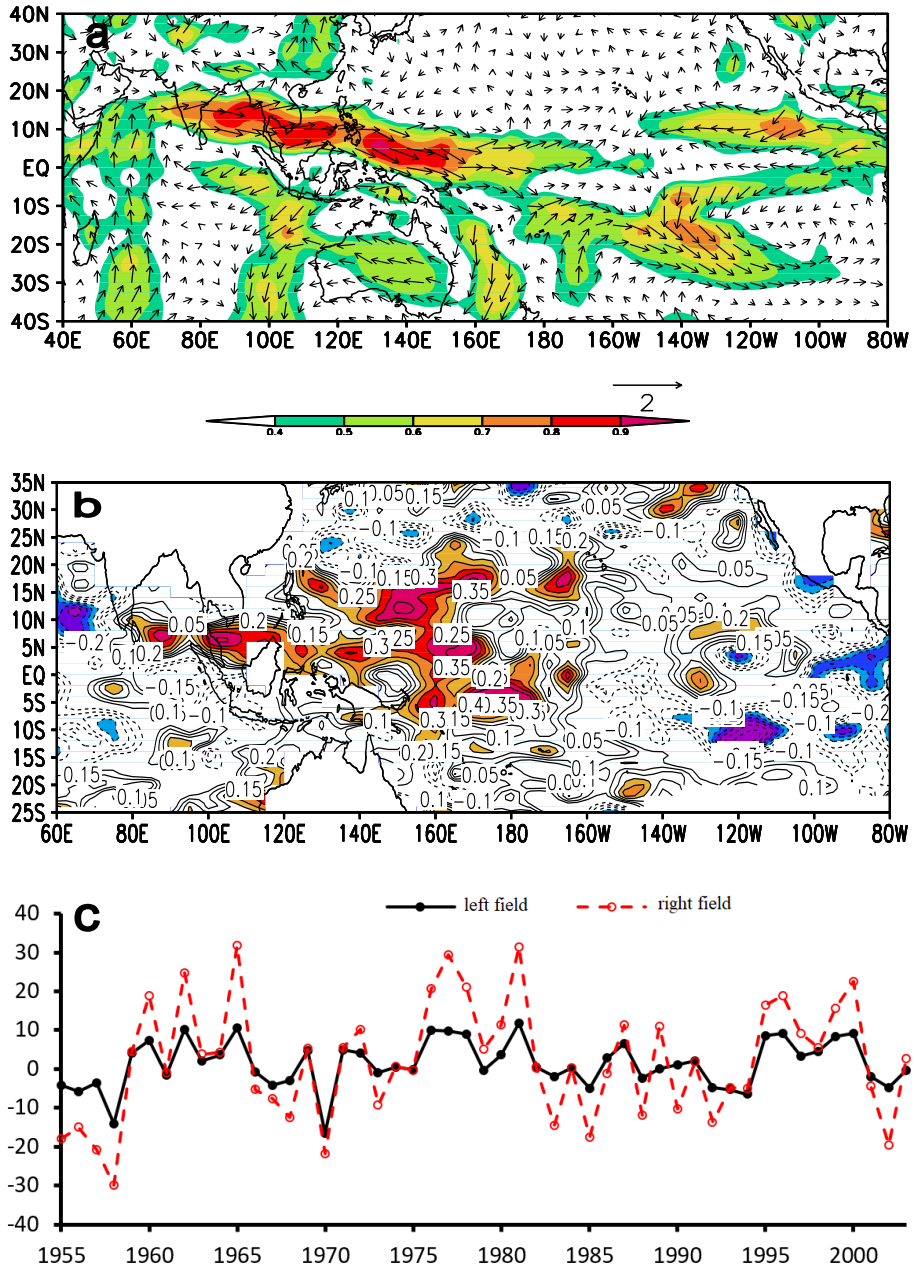

Figure 5. *Heterogeneous correlation graphs between 120 m sea temperature field and 850 hPa meridional wind field when sea temperature leads the wind for six months: (a) left field, (b) right field, and (c) time coefficient. The shadow means the values significant at 0.1 confidence level*

Coupling relationship when subsurface sea temperature field lags wind field

Figure 6 shows the left and right heterogeneous correlation graphs and time coefficients of the first mode of SVD selecting the winter (November) 120 m normalized sea temperature anomalies as the left field and the summer (July) normalized 850 hPa wind field anomalies as the right field. *Table 5* shows the corresponding main information of the first three modes of SVD. It can be seen from *Table 5* that the first mode interprets 40.15% of the total covariance, reflecting the main coupling characteristics between the 120 m layer sea temperature field and the 850 hPa wind field. For the first three modes, the correlations between time coefficients of the left and the right singular vectors are high. An analysis is conducted on the heterogeneous correlation field of the first mode. The distribution of the right field in *Figure 6a* is similar to that in *Figure 5a,* indicating the strengthening of EASM circulation. In the corresponding left field in *Figure 6b,* the equatorial eastern Pacific Ocean shows positive anomalies in sea temperature while the positive anomalies in the equatorial eastern Indian Ocean are relatively low. The highest correlation is found in 5°S~5°N, 160°~120°W with the maximum correlation coefficient of 0.4 (significant at 0.01 confidence level). The region from the equatorial eastern Indian Ocean to the western Pacific shows negative anomalies, with the absolute value of the maximum correlation coefficient similar to that in the equatorial eastern Pacific Ocean. According to *Figure 6c,* when the time coefficient is strongly positive, the EASM is stronger than normal. As sea temperature lags monsoon for four months, the sea temperature in the region from the equatorial eastern Indian Ocean to the western Pacific Ocean becomes lower while the sea temperature in the central Indian Ocean and the eastern Pacific becomes higher in autumn and winter, showing an El Niño state. On the contrary, when the time coefficient is strongly negative, the EASM is weaker than normal. The sea temperature in the region from the equatorial eastern Indian Ocean to the western Pacific Ocean becomes higher while the sea temperature in the central Indian Ocean and the eastern Pacific becomes lower in autumn and winter, showing a La Niña state. The time coefficients show that the trends of the two fields are also in generally consistent and both of them show clear characteristics of interannual variability.

Table 5. *Information of the first three modes of SVD between sea temperature field and wind field*

2	0.91	12.49	52.64
3	0.88	7.88	60.52

Discussion

The covariation of the sea temperature field and the wind field can be summarized as follow: When the 850 hPa trade wind in the equatorial central and eastern Pacific Ocean increases/decreases, the region from the central Indian Ocean to the western Pacific Ocean shows westerly/easterly anomalies, or the meridional wind anomalies on the two sides of the equator are convergent/divergent in the central Indian Ocean and eastern

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_71557170
© 2018, ALÖKI Kft., Budapest, Hungary

Pacific Ocean but divergent/convergent in East Asia. The corresponding 120 m sea temperature in the region from the eastern Indian Ocean to the western Pacific Ocean increases/decreases, and the sea temperature in the central Indian Ocean and eastern Pacific Ocean decreases/ increases, showing a La Niña/El Niño state.

From the lead-lag SVD above, it is found that: When the sea temperature in the region from the central Indian Ocean to the western Pacific Ocean is higher/lower than normal and the sea temperature in the central Indian Ocean and the eastern Pacific Ocean is lower/higher than normal, a La Niña/El Niño state will be shown. After that, the EASM is stronger/weaker than normal, and the increase/decrease of EASM circulation leads to an El Niño/La Niña state in the tropical Pacific and Indian oceans in autumn and winter. This result is consistent with (Ke et al., 2015) and (Guo et al., 2018), further verifying the relationship between the subsurface sea temperature and the EASM.

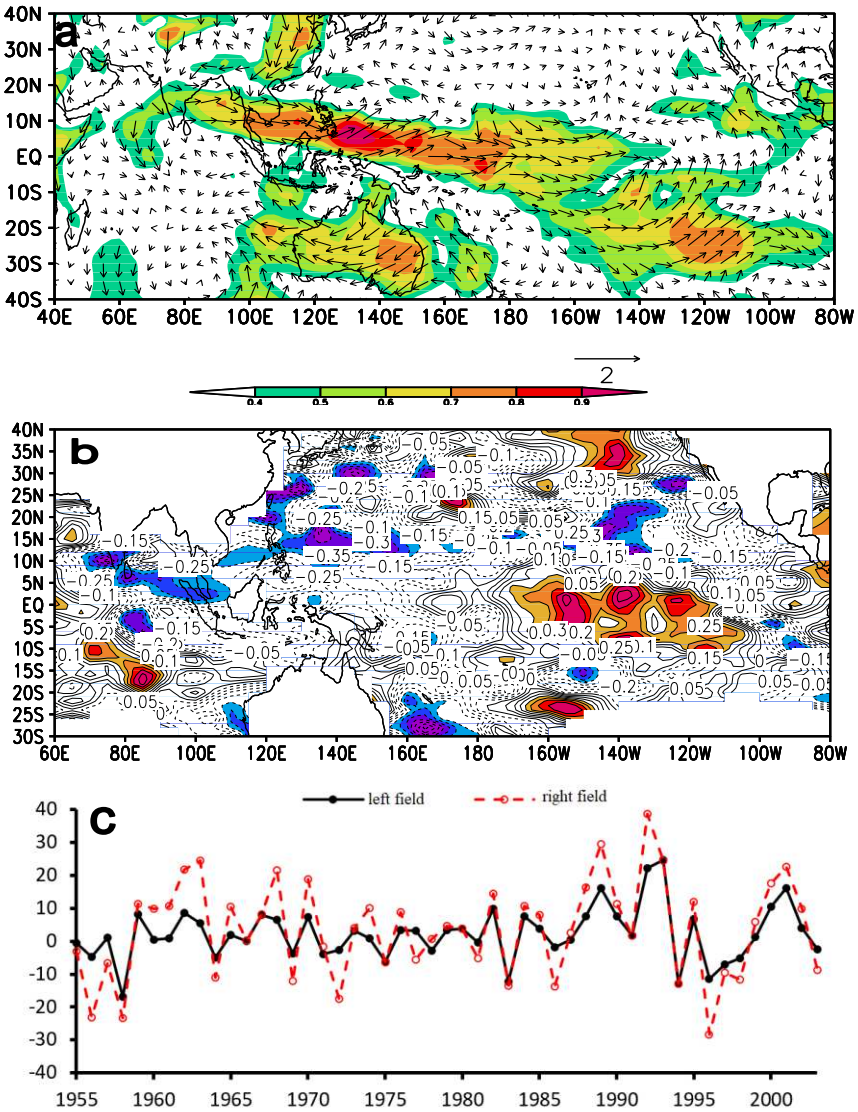

Figure 6. *Heterogeneous correlation graphs between winter 120 m sea temperature field and 850 hPa meridional wind field when sea temperature lags the wind for four months: (a) left field, (b) right field, and (c) time coefficient. The shadow means the values significant at 0.1 confidence level*

In summary, the distribution of tropical subsurface sea temperature anomalies has an impact on the interannual variation of the EASM while the anomalies of EASM change the thermal state of the ocean. There is a mutual interaction between the EASM and the subsurface sea temperature in the tropical region from the Pacific Ocean to the Indian Ocean. The tropical subsurface sea temperature anomalies are an important reference for predicting the variation of EASM. However, this study only focuses on the subsurface sea temperature of the tropical ocean. More parameters which are representative of the ocean characteristics (such as heat capacity and salinity) (Yang et al., 2017) are needed for the future work. Meanwhile, the mechanism of interaction between the EASM and the subsurface sea temperature in the tropical Pacific and Indian Ocean needs to be further explored.

Conclusions

This study analyzes the interannual variation and circulation characteristics of the IEASM. The characteristics of the subsurface sea temperature anomaly field and the EASM anomaly field in the tropical Indian and Pacific Ocean are investigated, and their coupling relationship is discussed in this study. It turned out that:

The intensity of the EASM has obvious interannual variability. The IEASM defined by Zhang et al. (2003) during the years with strong/weak EASM are analyzed, and the result shows that the tropospheric low-level circulation is significantly different in the years with strong and weak EASM. In the summer years with strong/weak EASM, the western Pacific subtropical high is located more north/south than usual, and the tropical region in East Asia and the Pacific Ocean shows closed cyclonic/anti-cyclonic anomaly circulation, and the western Pacific subtropical high is weak/strong than normal.

The characteristics of the integral circulation in the EASM region during the years with strong and weak EASM show that the vertical velocity anomalies in the EASM region are significantly different during the summer of the year with strong and weak EASM. The vertical velocity anomalies in East Asia are downward/upward during the years with strong and weak EASM leading to a weaker/stronger Meiyu front.

The covariation of the sea temperature field and the wind field is: When the 850 hPa trade wind in the equatorial central and eastern Pacific Ocean increases/decreases, the region from the central Indian Ocean to the western Pacific Ocean shows westerly/easterly anomalies, or the meridional wind anomalies on the two sides of the equator are convergent/divergent in the central Indian Ocean and eastern Pacific Ocean but divergent/convergent in East Asia. The corresponding 120 m sea temperature in the region from the eastern Indian Ocean to the western Pacific Ocean increases/decreases, and the sea temperature in the central Indian Ocean and eastern Pacific Ocean decreases/ increases, showing a La Niña/El Niño state.

When the winter 120 m sea temperature in the region from the equatorial eastern Indian Ocean to the western Pacific is higher than normal and that in the central Indian Ocean and the eastern Pacific Ocean is lower than normal, which means the distribution of the sea temperature is a La Niña state, it is easy to be with strong EASM, and the distribution of the sea temperature tends to turn into an El Niño state during the autumn and winter. In contrast, when the winter 120 m sea temperature in the region from the equatorial eastern Indian Ocean to the western Pacific is lower than normal and the that in the central Indian Ocean and the eastern Pacific Ocean is higher than normal, which means the distribution of the sea temperature is an El Niño state, it is easy to be with

weak EASM, and the distribution of the sea temperature tends to turn into a La Niña state during the autumn and winter.

(Received 3rd Aug 2018; accepted 28th Sep 2018)

Abstract. The study empirically investigates the relationship between financial development, sustainable economic opportunity and ecological footprint in Southern African Development Community (SADC) countries. The research was carried out utilizing time series data on financial access (bank branches per 100,000 adults), financial depth (private credit by deposit money banks to GDP), financial efficiency (bank return on equity percentage, after tax), financial stability (bank Z-score), composite index for financial development, ecological footprint indicator and sustainable economic opportunity. Bootstrap panel causality procedure based on meta-analysis in heterogeneous mixed panels was employed to test causal effects. The empirical results indicate the following; (i) causality between financial development, sustainable economic opportunity and ecological footprint varies across countries with different conditions, which leads to the conclusion that SADC countries are heterogeneous in nature, (ii) for the entire panel, financial development causally affects both sustainable economic opportunity and ecological footprint, and (iii) for the entire panel, sustainable economic opportunity causally affects ecological footprint. The findings suggest introduction of modern financial institutions, especially depository and investment institutions that will stimulate financial services and not only provide funds for investments in human and physical capital required to improve sustainable economic opportunity in SADC countries, but also make funds available for research and development of more efficient ecofriendly technologies.
Keywords: *Africa, bootstrap panel Granger causality test, environment, funds, growth*

Introduction

The main aim of this research is to empirically analyze and find answers to the following questions in relation to Southern African Development Community (SADC) countries; (i) is there any statistically significant causal relationship between financial development, sustainable economic opportunity and ecological footprint in the regional bloc? (ii) is there any statistically significant causal relationship between financial development, sustainable economic opportunity and the ecological footprint in the individual member countries?

The authors believe that finding answers to these questions will aid policy makers in these countries in economic planning, positioning of the countries for opportunities that are sustainable without losing sight of environmental degradation issues.

Crucial to the development of economically sustainable livelihoods strategies is an in-depth understanding of markets and the facilitation of stronger, fairer relationships between government policies in creating development opportunity, for citizens and corporations. A financially viable enterprise should therefore benefit local communities

today without entirely sacrificing the future environment (Rousseau and Wachtel, 2011; Feng et al., 2018).

Variables of socio-economic growth in recent times generally include two basic components–sustainability and inclusiveness of opportunity (Acemoglu and Wolitzky, 2015). Sustainable economic opportunity is about being commercially viable and attractive to development today, bearing the future in mind. It is the aggregation and transformation of various capitals, from human, natural, produced, and social capital into financial capital as a means of achieving economic development and growth (Mo Ibrahim Foundation, 2018).

Financial development is advancement of financial systems (financial markets, banks and various financial intermediaries) in quality, quantity and efficiency. It is the output of the depth, access and efficiency of the financial sector (Ang and McKibbin, 2007; Huang and Wang, 2017). Countries always put in place policies, institutions, and measures that create, widen and deepen effective financial markets and intermediaries so that capital and financial services can be easily available (World Economic Forum, 2012). Financial capital is often utilized to the detriment of sustainability which is long term. Most financial and commercial activities are usually aimed at short term gains and immediate profit (Sofia et al., 2011).

Ecological footprint is a measurement of how much nature still exists, and how much has been used up. It measures the ecological assets that a given population requires to produce the natural resources it consumes. It is an extensive detailing of demand and supply of nature, in supporting commercial activities. The ecological footprint is an instrument of projection to track the consumption of land and/or living resources and the carbon-based waste of human populations (Baabou et al., 2017; Global Footprint Network, 2018).

Over the past two decades, extant literature has revealed that financial sector activities and environmental resources have significant impact on economic performance of societies (Li et al., 2016). Unsurprisingly, research interest in this area continues to grow. An extensive body of literature exists on the inter-relations between financial development and economic activity. They are grouped into 4 broad categories; (i) those that provide evidence in support of the supply-leading theory which states that economic growth is preceded by financial development. The theory suggests that financial development induces improvements in savings and investment efficiency which in turn drives economic growth (Ang, 2008; Körner and Schnabel, 2009; Bojanic, 2012; Pradhan et al., 2014; Li et al., 2015), (ii) those that support the demand-following theory which states that economic growth drives the demand for financial services. The theory asserts that growth in the real sector of an economy raises the demand for supporting financial services and this in turn induces growth in the financial sector (Liang and Jian-Zhou, 2006; Ang and McKibbin, 2007; Panopoulou, 2009), (iii) those that are in alignment with the neutrality hypothesis. This group of literature posits that there is no significant relationship between the financial sector and economic growth (Al-Yousif, 2002; Mukhopadhyay et al., 2011), and (iv) the group of studies that affirm the existence of a feedback relationship (feedback hypothesis). The feedback hypothesis argues that improved financial sector performance positively affects economic growth and increased economic growth in turn causes an increase in demand for financial services (Wolde-Rufael, 2009; Pradhan et al., 2013).

The economic activity-environment nexus has mostly been tested within the environmental Kuznets curve (EKC) framework which examines the impact of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

economic growth on single pollution indicators such as CO_2, SO_2, NO_X and CO and asserts that there is an inverted U-shaped relationship between economic performance and pollution. The hypothesis suggests that pollution increases alongside industrialization during the early stages of economic growth up to a point beyond which higher economic growth leads to the introduction of more efficient technologies, better environmental regulations and higher environmental expenditures (Acar and Asici, 2017). Recent examples of such EKC studies include Lau et al. (2014), Onafowora and Owoye (2014), Al-Mulali et al. (2015), Apergis and Ozturk (2015), Chang (2015), Tang and Tan (2015), Azam and Khan (2016), Kang et al. (2016), Li et al. (2016), and Gill et al. (2017).

Overall, studies on economic activity, financial development and the environment display the following limitations. First, many of them only investigate the effect of either financial development or economic growth on environmental quality. They do not examine all 3 variables within a unified framework. Second, most of the studies only carry out one-way examinations of the effect of either financial development or economic growth on environmental quality. They mostly neglect the possibility of feedback relationships. Third, most of them adopt very narrow measures of these 3 variables. For example, financial development is mostly proxied with these three measures: domestic credit to private sector, banking sector credit and financial domestic credit. These measures of financial development are indicators of financial depth. They ignore other important aspects of financial sector performance such as financial access, financial efficiency and financial stability. Similarly, environmental quality is mostly measured with degree of pollution. However, the impacts of economic activities are wide-ranging and multidimensional, such that it cannot be sufficiently accounted for using one-dimensional pollution indicators (Wackernagel et al., 2002). Also, economic performance is most commonly measured through economic growth which largely ignores economic opportunities that contribute to a prosperous and equitable society. Finally, previous studies also mostly neglect the issues of cross-sectional dependency and cross-country heterogeneity. According to Chang et al. (2013), the importance of cross-country heterogeneity and cross-sectional dependency cannot be over emphasized. Although each country may sustain its own dynamics in economic development, economic or financial instability in one country often spreads to other countries through economic integration and trade.

In this context, this study's contributions to literature are as follows. First, the relationship between financial development, economic performance and the environment is examined via bootstrap panel Granger causality tests of Emirmahmutoglu and Kose (2011) in SADC countries. With this test, it is possible to detect Granger causality in the entire panel as well as in each of the individual countries contained in the panel. Furthermore, with this test, the pre-test bias associated with testing for stationarity and co-integration is avoided. Second, panel causality modeling which controls for country-specific differences and cross-country dependency is followed. Third, various dimensions of financial development–financial access, financial depth, financial efficiency and financial stability–as well as an aggregate index of these 4 measures is considered. Moreover, ecological footprint, a multidimensional indicator of environmental state, is used in this study. Furthermore, rather than adopt economic growth as the measure of economic performance, the degree of sustainable economic opportunity is used instead.

SADC countries

Southern African Development Community (SADC) consists of 15 countries whose main objectives are; achievement of development and economic growth, poverty alleviation, enhancement of standard and quality of life through regional integration, evolution of common political values, systems and institutions, promotion of peace and security, promotion of self-sustaining development on the basis of collective self-reliance and interdependence among Member States, achievement of complementarity between national and regional strategies and programmes, maximization of productive employment and utilization of resources of the Region, achievement of sustainable utilization of natural resources and effective protection of the environment, and consolidation of the long standing historical, social and cultural affinities and links among the people of the Region.

The sources of GDP in SADC are industry (32%), agriculture (17%), and service sector, with the largest share (52%). This regional bloc has shown signs of economic improvement over the past decade. The regional bloc includes four countries officially classified as middle-income countries–Botswana, Mauritius, Namibia and South Africa (www.sadc.int/about-sadc/overview/sadc-facts-figures).

The rest of this study is structured as follows: data and empirical methodology, results, discussions and conclusion.

Data and empirical methodology

Data

The study sample consists of time series data on 13 of the 15 SADC countries over the period 2000-2016. Seychelles and Zimbabwe are left out of the sample due to insufficient data. In the analysis, data on financial access (bank branches per 100,000 adults), financial depth (private credit by deposit money banks to GDP), financial efficiency (bank returns on equity %, after tax) and financial stability (bank Z-score) provided by the World Bank and accessed at http://www.worldbank.org/en/publication/gfdr/data/global-financial-development-database are used. These 4 measures are then further aggregated into a single composite index for financial development using principal component analysis (PCA) given as (*Eq. 1*):

$$p_i = \sum_{i=1}^{n} a_{ij} x_i \quad \text{(Eq.1)}$$

where: $p_i = p_1, p_2, \ldots, p_k$ represent the principal Components, a_{ij} stand for component loadings and x refers to the original measures. Differences in measurement units were controlled for by using the variables in their standardized forms. The composite index is constructed with the formula (*Eq. 2*):

$$CI = \sum_{i=1}^{n} a_{ij} \frac{x_{ij}}{\sigma(x)_i} \quad \text{(Eq.2)}$$

where: CI is the composite index for financial development and σ is the standard deviation.

The ecological footprint indicator provided by (Global Footprint Network, 2018) is used as the measure of environment condition. Ecological footprint sums the use of six categories of productive surface areas: cropland, grazing land, fishing grounds, built-up land, forest area, and carbon demand on land and land area. It is expressed in units of global hectares (gha).

Data on sustainable economic opportunity is from the Ibrahim Index of African Governance (IIAG) online database. The sustainable economic opportunity index consists of four sub-categories (public management, business environment, infrastructure and rural sector), made up of 29 indicators, from 18 different data sources.

The descriptive statistics for the SADC countries included in the analysis are presented in *Table 1*.

Table 1. *Summary statistics*

Panel A: Financial development index				
Country	**Mean**	**Std. Dev**	**Minimum**	**Maximum**
Angola	11.589	1.237	9.278	14.155
Botswana	9.136	1.545	6.150	11.260

Panel C: Ecological footprint				
Angola	0.600	0.191	0.410	0.980
Botswana	1.702	0.174	1.360	2.040
DR Congo	0.465	0.015	0.430	0.480
Lesotho	0.903	0.046	0.830	0.990
Madagascar	0.594	0.026	0.540	0.640
Malawi	0.444	0.046	0.360	0.510
Mauritius	1.754	0.212	1.400	2.080
Mozambique	0.486	0.049	0.430	0.600
Namibia	2.829	0.979	1.898	5.702
South Africa	1.957	0.141	1.660	2.170
Swaziland	1.216	0.254	0.660	1.450
Tanzania	0.722	0.066	0.660	0.870
Zambia	0.495	0.057	0.430	0.590
Panel	1.094	0.782	0.360	5.702

In *Table 1,* the lowest mean financial development value (2.252) reported for Zambia shows the country has the least developed financial sector over the period considered, and the highest mean financial development value (18.184) reported for Mauritius indicates the country has the best developed financial sector for the period considered. Mauritius again turns out as the best performing country in terms of sustainable economic opportunity (72.380) while Angola has the poorest performance (28.093). Average demand of nature is highest in Namibia (2.829) and lowest in Malawi (0.444).

Methodology

Bootstrap panel Granger casualty test

This study applies the bootstrap panel causality procedure based on meta-analysis in heterogeneous mixed panels proposed by Emirmahmutoglu and Kose (2011). The test is an extension of the Toda and Yamamoto (1995) approach to testing coefficient restrictions in a level VAR model for an integrated or cointegrated process. The test does not require the variables in the underlying VAR system to be stationary. It may therefore be applied to panels consisting of stationary, non-stationary, cointegrated and non-cointegrated series (Seyoum et al., 2014). Pre-test bias associated with testing for stationarity and cointegration is therefore avoided. The method employs a modified Wald (MWALD) test in a lag augmented VAR (LA-VAR) which has a conventional asymptotic chi-square distribution when a VAR (p + dmax) is estimated, where p is the lag order and dmax is the maximal order of integration suspected to occur in the process. The system of equations for the panel causality tests include two sets of equations specified as follows:

$$Y_{1,t} = \alpha_{1,1} + \sum_{i=1}^{ly_1+dmax_j} \beta_{1,1,i} Y_{1,t-i} + \sum_{i=1}^{lx_1+dmax_j} \delta_{1,1,i} X_{1,t-i} + \sum_{i=1}^{lz_1+dmax_j} \gamma_{1,1,i} Z_{1,t-i} + \varepsilon_{1,1,t} \quad \text{(Eq.1a)}$$

$$Y_{2,t} = \alpha_{1,2} + \sum_{i=1}^{ly_1+dmax_j} \beta_{1,2,i} Y_{2,t-i} + \sum_{i=1}^{lx_1+dmax_j} \delta_{1,2,i} X_{2,t-i} + \sum_{i=1}^{lz_1+dmax_j} \gamma_{1,2,i} Z_{2,t-i} + \varepsilon_{1,2,t} \quad \text{(Eq.1b)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_71717190
© 2018, ALÖKI Kft., Budapest, Hungary

$$Y_{N,t} = \alpha_{1,N} + \sum_{i=1}^{ly_1+dmax_j} \beta_{1,N,i} Y_{N,t-i} + \sum_{i=1}^{lx_1+dmax_j} \delta_{1,N,i} X_{N,t-i} + \sum_{i=1}^{lz_1+dmax_j} \gamma_{1,N,i} Z_{N,t-i} + \varepsilon_{1,N,t} \quad \text{(Eq.1n)}$$

$$X_{1,t} = \alpha_{2,1} + \sum_{i=1}^{ly_2+dmax_j} \beta_{2,1,i} Y_{1,t-i} + \sum_{i=1}^{lx_2+dmax_j} \delta_{2,1,i} X_{1,t-i} + \sum_{i=1}^{lz_2+dmax_j} \gamma_{2,1,i} Z_{1,t-i} + \varepsilon_{2,1,t} \quad \text{(Eq.2a)}$$

$$X_{2,t} = \alpha_{2,2} + \sum_{i=1}^{ly_2+dmax_j} \beta_{2,2,i} Y_{2,t-i} + \sum_{i=1}^{lx_2+dmax_j} \delta_{2,2,i} X_{2,t-i} + \sum_{i=1}^{lz_2+dmax_j} \gamma_{2,2,i} Z_{2,t-i} + \varepsilon_{2,2,t} \quad \text{(Eq.2b)}$$

$$X_{N,t} = \alpha_{2,N} + \sum_{i=1}^{ly_2+dmax_j} \beta_{2,N,i} Y_{N,t-i} + \sum_{i=1}^{lx_2+dmax_j} \delta_{2,N,i} X_{N,t-i} + \sum_{i=1}^{lz_2+dmax_j} \gamma_{2,N,i} Z_{N,t-i} + \varepsilon_{2,N,t} \quad \text{(Eq.2n)}$$

and

$$Z_{1,t} = \alpha_{3,1} + \sum_{i=1}^{ly_3+dmax_j} \beta_{3,1,i} Y_{1,t-i} + \sum_{i=1}^{lx_3+dmax_j} \delta_{3,1,i} X_{1,t-i} + \sum_{i=1}^{lz_3+dmax_j} \gamma_{3,1,i} Z_{1,t-i} + \varepsilon_{3,1,t} \quad \text{(Eq.3a)}$$

$$Z_{2,t} = \alpha_{3,2} + \sum_{i=1}^{ly_3+dmax_j} \beta_{3,2,i} Y_{2,t-i} + \sum_{i=1}^{lx_3+dmax_j} \delta_{3,2,i} X_{2,t-i} + \sum_{i=1}^{lz_3+dmax_j} \gamma_{3,2,i} Z_{2,t-i} + \varepsilon_{3,2,t} \quad \text{(Eq.3b)}$$

$$Z_{N,t} = \alpha_{3,N} + \sum_{i=1}^{ly_3+dmax_j} \beta_{3,N,i} Y_{N,t-i} + \sum_{i=1}^{lx_3+dmax_j} \delta_{3,N,i} X_{N,t-i} + \sum_{i=1}^{lz_3+dmax_j} \gamma_{3,N,i} Z_{N,t-i} + \varepsilon_{3,N,t} \quad \text{(Eq.3n)}$$

In the system of *Equations 1, 2* and *3,* $Y_{i,t}$, i = 1,…,N denotes financial development (access, depth, efficiency, stability and overall index, respectively), $X_{i,t}$, i = 1,…,N denotes sustainable economic opportunity and . N represents the number of countries included in the panel (j = 1,…, N), $Z_{i,t}$, i = 1,…,N is ecological footprint. t refers to the time period (t = 1,…,T), l is the lag length and $dmax_j$ stands for the maximal order of integration.

The possible alternative causal relations that could be detected for each country and the entire panel are (i) One-way Granger causality from X to Y when all $\beta_{2,j,i}$s are zero, but not all $\delta_{1,j,i}$s are zero. (ii) One-way Granger causality from Y to X when all $\delta_{1,j,i}$s are zero, but not all $\beta_{2,j,i}$s are zero. (iii) Two-way Granger causality between X and Y if some of the $\delta_{1,j,i}$s and $\beta_{2,j,i}$s are not zero. (iv) One-way Granger causality from Z to Y when all $\beta_{3,j,i}$s are zero, but not all $\gamma_{1,j,i}$s are zero. (v) One-way Granger causality from Y to Z when all $\gamma_{1,j,i}$s are zero, but not all $\beta_{3,j,i}$s are zero. (vi) Two-way Granger causality between Z and Y if some of the $\gamma_{1,j,i}$s and $\beta_{3,j,i}$s are not zero. (vii) One-way Granger causality from Z to X when all $\delta_{3,j,i}$s are zero, but not all $\gamma_{2,j,i}$s are zero. (viii) One-way Granger causality from X to Z when all $\gamma_{2,j,i}$s are zero, but not all $\delta_{3,j,i}$s are zero. (ix) Two-way Granger causality between Z and X if some of the $\gamma_{2,j,i}$s and $\delta_{3,j,i}$s are not zero.

The Emirmahmutoglu and Kose (2011) Granger causality test employs the Fisher (1932) meta-analysis statistical procedure. It conducts N number of separate time series tests, and combines the significant individual p-values in a single panel test statistic. The test statistic has a chi-square distribution with 2N degrees of freedom. The Fisher test statistic (λ) is specified as (*Eq. 4*):

$$\lambda = -2 \sum_{i=1}^{N} ln_{(pi)} \;\; i = 1,2, \ldots, N \quad \text{(Eq.4)}$$

pi denotes the p-value for the Wald statistic of the ith cross section.

In the presence of cross sectional dependency, the limit distribution of the Fisher test statistic becomes invalid. The test deals with this problem through the bootstrap approach. Readers are referred to Emirmahmutoglu and Kose (2011) for the detailed

© 2018, ALÖKI Kft., Budapest, Hungary

bootstrap procedure. In line with Emirmahmutoglu and Kose (2011), *Equations 1, 2* and *3* are estimated and the panel Granger causality tests with bootstrap critical values are executed (*Eq. 5*).

$$LM = \sum_{i=1}^{N-1}\sum_{j=i+1}^{N} T_{ij}\hat{p}_{ij}^2 \rightarrow \chi^2 \frac{N(N-1)}{2} \quad \text{(Eq.5)}$$

where $\hat{p}_{ij}^2$ = correlation coefficients from residuals

Pesaran (2004) Scaled LM test: Pesaran (2004) developed a scaled version of the LM test which is more efficient than the Breusch-Pagan (1980) LM test for data series with large N. Under the null of no cross-sectional dependence, the LM statistic is as follows (*Eq. 6*):

$$LM_s = \sqrt{\frac{1}{N(N-1)}}\sum_{i=1}^{N-1}\sum_{j=i+1}^{N}(T_{ij}\hat{p}_{ij}^2 - 1) \rightarrow N(0,1) \quad \text{(Eq.6)}$$

Pesaran (2004) CD test: a major flaw of the previous tests is that they suffer from size distortion especially when N is large and T is small. To deal with this limitation, Pesaran (2004) developed a more general alternative test statistic that provides valid results for large panels by averaging pairwise correlation coefficients $\hat{p}_{ij}$. For the null of no cross-sectional dependence, the LM test statistic for dependence is given as (*Eq. 7*):

$$CD_p = \sqrt{\frac{2}{N(N-1)}}\sum_{i=1}^{N-1}\sum_{j=i+1}^{N} T_{ij}\,\hat{p}_{ij} \rightarrow N(0,1) \quad \text{(Eq.7)}$$

Tests for slope homogeneity

Cross-country heterogeneity is also an issue of importance when employing bootstrap panel causality tests. Presence of slope heterogeneity in the data series is an indication that economic occurrences observed in one of the SADC countries are not necessarily replicated in the other SADC countries. The Pesaran and Yamagata (2008) standardized version of the Swamy (1970) homogeneity test was applied. The modified version of the Swamy (1970) test is computed as (*Eq. 8*):

$$\tilde{S} = \sum_{i=1}^{N}(\hat{\beta}_i - \hat{\beta}_{WFE})' X_i' \frac{M_T X_i}{\tilde{\sigma}_i^2}(\hat{\beta}_i - \hat{\beta}_{WFE}) \quad \text{(Eq.8)}$$

where $\hat{\beta}_i$=Pooled OLS estimator, $\hat{\beta}_{WFE}$ = weighted fixed effect pooled estimator and $\tilde{\sigma}_i^2$ is the estimator. The standard dispersion statistics is computed as (*Eq. 9*):

$$\tilde{\Delta} = \sqrt{N}\left(\frac{N^{-1}\tilde{S} - k}{2k}\right) \quad \text{(Eq.9)}$$

Alternatively, the bias adjusted version of the standard dispersion statistics may be computed (*Eq. 10*):

$$\tilde{\Delta}_{Adj} = \sqrt{N}\left(\frac{N^{-1}\tilde{S} - E(\tilde{z}_{it})}{\sqrt{var}(\tilde{z}_{it})}\right) \quad \text{(Eq.10)}$$

Both statistics are tested under the null of slope homogeneity.

Results

Table 2 reports the results of cross-sectional dependence tests (LM, LM_S and CD_P) obtained from estimating *Equations 6, 7* and *8*. The results from LM and LM_S tests clearly show that the null hypothesis of no cross-sectional dependence is rejected for all variables at ($p < 0.01$) significance level, whereas the results from CD_p test show that the null of no cross-sectional dependence is rejected for depth, stability, financial index and sustainable economic opportunity at ($p < 0.01$) level of significance, and for access at ($p < 0.1$) level of significance. Both efficiency and ecological footprint turn out as insignificant under the CD_p test. The results overwhelmingly indicate that there is cross-sectional dependence among the SADC countries. Therefore, shocks are transmitted across the SADC economies. *Table 2* also reports the results from the slope homogeneity tests ($\hat{\Delta}, \hat{\Delta}_{adj}$). Based on the delta and the bias adjusted delta statistics, the null hypothesis of slope homogeneity is rejected for financial depth, financial efficiency, overall financial index, ecological footprint and sustainable economic opportunity. This suggests that individual SADC countries possess unique economic characteristics. The bootstrap panel Granger causality approach can thus be applied.

Table 2. *Cross-sectional dependence and homogeneous test results*

Tables 3–7 below report the test statistics for the causality tests between financial development (overall index, access, depth, efficiency and stability, respectively) and sustainable economic opportunity for each SADC country, and for the entire panel. The main focus is on the outcomes involving the overall financial index. The test results indicate that at country level, the causality between financial development and sustainable economic opportunity varies across countries with different conditions. For example, significant Granger causality from overall financial development index to sustainable economic opportunity exists in Botswana, Mauritius and Namibia. Significant Granger causality in the other direction exists in DR Congo, Malawi and Mozambique. A significant feedback relationship only exists in South Africa. At the panel level, significant one-way causality is detected running from the overall financial development index to sustainable economic opportunity.

When the overall index is disaggregated into its components, at the country level, the following results are found. Significant one-way causality from; financial access to sustainable economic opportunity in Botswana, DR Congo, Mauritius, Mozambique, Namibia and South Africa, from sustainable economic opportunity to financial access in Angola, from financial depth to sustainable economic opportunity in Mozambique, South Africa and Swaziland, from sustainable economic opportunity to financial depth in Angola, DR Congo and Tanzania, from financial efficiency to sustainable economic opportunity in Angola, Namibia, South Africa and Swaziland, from sustainable economic opportunity to financial efficiency in Lesotho and Madagascar, from financial stability to sustainable economic opportunity in Botswana, DR Congo, Mauritius, Namibia and South Africa, and from sustainable economic opportunity to financial stability in DR Congo, Lesotho, Malawi, Mozambique and Zambia. Bidirectional causal relationships are however detected between financial access and sustainable economic opportunity in Lesotho, between financial depth and sustainable economic opportunity in Madagascar, Malawi, Mauritius and Namibia, between financial efficiency and sustainable economic opportunity in Malawi and Mozambique, and between financial stability and sustainable economic opportunity in Madagascar, South Africa and Tanzania. At the panel level, significant one-way causality from financial access and financial efficiency to sustainable economic opportunity is found, whereas a significant feedback relationship is detected between financial depth and sustainable economic opportunity and between financial stability and sustainable economic opportunity.

In *Tables 8–12* below, the causality results for the relationship between financial development (overall index, access, depth, efficiency and stability, respectively) and ecological footprint at country and panel levels are reported. Again, the focus is on the outcomes from the overall financial development index. At country level, it is discovered that causality varies with different conditions. Significant Granger causality from overall financial development index to ecological footprint exists in DR Congo, Namibia and Swaziland. Significant one-way causality in the other direction exists in Mauritius and Mozambique. Significant feedback relationship exists in Lesotho, Madagascar, Malawi and South-Africa. At the panel level, one-way causality from overall financial development index to ecological footprint is found.

When the overall financial development index is disaggregated into its components, at country level, one-way causal effect is detected from financial access to ecological footprint in Angola, Mozambique, Namibia, Swaziland and Zambia, from ecological footprint to financial access in DRC, Mauritius and South Africa, from financial depth to ecological footprint in Botswana, DRC Congo, Madagascar and Mauritius, from ecological footprint to financial depth in Angola, Tanzania and Zambia, from financial efficiency to ecological footprint in Malawi, Mauritius and Tanzania, from ecological footprint to financial efficiency in Namibia and Swaziland, from financial stability to ecological footprint in DR Congo, Namibia, South Africa and Zambia, and from ecological footprint to financial stability in Lesotho. Bidirectional causal effects are also detected between financial access and ecological footprint in Madagascar and Malawi, between financial depth and ecological footprint in Lesotho, Malawi, Mozambique, Namibia and Swaziland, and between financial stability and ecological footprint in Malawi, Mauritius, Swaziland and Tanzania. At the panel level, causality is found running only from financial access to ecological footprint.

With respect to the causal relations between sustainable economic opportunity and ecological footprint, as reported in *Table 13,* one-way causal effect from sustainable economic opportunity to ecological footprint is detected in Madagascar, Mozambique, Namibia and Tanzania at the country level. One-way causality in the opposite direction is however detected in Mauritius while a feedback relationship between both variables is uncovered in Angola, South Africa and Swaziland.

Discussion

Findings from this study bring to the fore some interesting issues. First, the very ambitious agenda set by the SADC at inception include amongst others; regional integration, evolution of common political values, systems and institutions, achievement of complementarity between national and regional programmes and strategies, interdependence among member states, and strengthening and consolidation of historical, social and cultural affinities and links among people of the region. The presence of cross-sectional dependence in the region shows that the regional bloc has succeeded to a great extent in achieving these goals. The presence of country-specific heterogeneity however suggests that the region still has a long way to go before full integration is achieved. This is further confirmed by the dissimilar patterns of causality noticeable across the SADC.

Second, the dissimilar patterns of causality also suggest that a one size fits all approach to dealing with issues surrounding the interaction between financial development, sustainable economic opportunity and ecological footprint is not feasible in the SADC. In places where causality runs from financial development to sustainable

economic opportunity, the financial system is able to stimulate the economy (supply-leading theory). As for countries where causality runs in the opposite direction, the financial system simply responds to improvements in the economy (demand-following theory). In countries where causality runs in both directions, a vicious cycle in which financial development triggers improvements in the economy which in turn further triggers financial development is experienced. In countries where no significant causality is detected, the neutrality theory holds. The economy cannot be improved through financial development neither can better economic performance drive financial development.

Third, it is also quite significant that the dimensions of financial development (access, depth, efficiency and stability) that are causally related to sustainable economic opportunity vary from country to country.

Fourth, concerning the relationship between sustainable economic opportunity and ecological footprint, the energy-led growth hypothesis holds true in countries where causality is detected from ecological footprint to sustainable economic opportunity. In such countries, energy is a necessary production factor and expansion of energy use will improve the economy, whereas in countries where causality is from sustainable economic opportunity ecological footprint, the conservation hypothesis holds true. In such places, energy plans may be implemented without the impacts on the economy.

Conclusion

In this paper, causal relationship between financial development, sustainable economic opportunity and ecological footprint in SADC countries during the period during the period 2000–2016 was examined. The use of bootstrap panel Granger causality tests of Emirmahmutoglu and Kose (2011), the adoption of ecological footprint, a multidimensional indicator of environmental condition, the introduction of sustainable economic opportunity and the consideration of various dimensions of financial development–financial access, financial depth, financial efficiency and financial stability–as well as an aggregate index of these 4 measures represent the main contribution of this paper. The empirical results indicate the following; first, that causality between financial development, sustainable economic opportunity and ecological footprint varies across countries with different conditions, and leads to the conclusion that SADC countries are heterogeneous in nature.

Second, that financial development causally affects sustainable economic opportunity. This supports the findings of Liang and Jian-Zhou (2006), Ang and McKibbin (2007), Panopoulou (2009), and Li et al. (2015). All these researches have revealed that financial development supports economic growth through channeling of credits. For example, Li et al. (2015), while investigating the relationship between financial development, environmental quality and economic growth in 102 countries, clearly indicated that financial development has an effect on economic growth and could be used in the production function of economic models, with sustainable economic opportunity being a measure of economic performance.

That financial development causally affects ecological footprint aligns with the position of Tamazian et al. (2009) and Charfeddine and Khediri (2016). Extant literature suggests that financial sector and the environment may be positively or negatively correlated. On one hand, a well-developed financial sector may assist the energy sector in adopting more efficient, ecofriendly technologies that help lower environmental

© 2018, ALÖKI Kft., Budapest, Hungary

degradation (Charfeddine and Khediri, 2016). Financial development may also cause improvements in the environment through funding of environmental projects at reduced funding costs (Tamazian et al., 2009).

Third, that sustainable economic opportunity causally affects ecological footprint. This is in agreement with the conclusions reached by Jensen (1996) that economic activity affects environmental conditions. Economic activities may also lead to increase in manufacturing activities, resulting in greater industrial pollution and environmental degradation (Jensen, 1996). The findings of Jensen (1996) is hung on the pollution haven hypothesis that industries that produce increased pollution are most likely to move to environments with flexible regulations on environmental pollution.

Policy recommendations

On the basis of the findings made in this study, the following policy recommendations are made:

In SADC countries where the supply-leading theory is confirmed, policy makers need to give more attention to political, legal and regulatory determinants of financial development since financial development can be used as a tool for achieving sustainable economic development. It will be in the interest of such countries to introduce modern financial institutions, especially depository and investment institutions that will stimulate financial services in terms of access, depth, efficiency and stability. Furthermore, each country should focus mainly on improving the dimensions of financial development (access, depth, efficiency or stability) that causally affect their sustainable economic opportunity.

Policy makers in SADC countries where the demand-following theory is confirmed need to quickly come to the realization that all efforts directed towards financial system development will not be worthwhile in the long-run, and more effort should instead be directed toward achieving a better economy.

In SADC countries where the energy-led hypothesis is confirmed, energy conservation policies designed to reduce greenhouse gas emissions to combat global warming may be counterproductive because they harm the economy. On the other hand, in SADC countries where the conservation hypothesis holds, energy conservation policies may be implemented without significant impact on economic performance.

Abstract. Aster flowers belong to the Asteraceae family which has approximately 1.000 genera, and a number of species approaching 25.000. It is the largest family of the flowering plants and has spread to almost every region of the world, except for Antarctica. Considering the relatively low number of studies in the literature regarding the subject, this study was conducted to determine the shading requirements of the *Dahlia* spp. The experimental tests were conducted in the facilities of the "Agricultural Applications and Research Directorate" of Gaziosmanpasa University in the city of Tokat. Observations and measurements were made regarding the yield, flower diameter, plant height, plant stem diameter, pedicle length, pedicle width, number of buds, bud diameter, and lifetime-in-pot properties of the *Le Castel, Seattle, Babylon Purple*, and *Gloriosa* genera of the *Dahlia* spp. The results obtained indicate that the tested shading practices (35% and 55%) have resulted in increased performances compared to the control group in terms of yield and quality. Between the genera, *Le Castel* genus has given better results compared to others in terms of yield in both 35% and 55% shading. In pedicle length, *Babylon Purple* genus has given better results with 35% shading, while *Gloriosa* was the best in that regard with 55% shading. For the flower diameter property, the best results (249.05 mm) were obtained in the third measurement by *Babylon Purple* with 35% shading practice. As a result, the difference between plant diameters of the genera under the shading practices were found to be statistically significant, and that 35% shading practice was ideal for all the genera tested.

Introduction

Bulbous and tuber plants have attractive flowers with interesting shapes and colors, and they bloom relatively early (Yazici and Gülgün, 2016). Especially towards the end of winter months, their flowers bloom as soon as the snow melts away, which makes them a tell-tale sign of the spring. They are also grown with relative ease. All these reasons have made them one of the most commonly used plants in gardens and parks all around the world (Mathew, 1987; Mathew and Swindells, 1994; Leeds, 2000). In Turkey, around 700 flower bulb species grow naturally (Karagüzel et al., 2007). As the significance of the diversity and richness of Turkey's flora was recognized by authorities of other countries, the flower bulbs were gathered from the wilds with the purpose of exhibiting them in botanical gardens. This practice transformed into commercial purposes over time, and the level of destruction of their natural habitats increased.

Amongst bulbous plants, Aster flower of the Asteraceae family is especially preferred as an outdoor ornamental flower. Most of the plants in this family are annual or biennial flowers, and very few are in bush or tree forms. The flowers have the shape of stars, while the leaves are either simple or are compound leaves in the shape of badges (Kim et al., 1992; Villasenor and Martiez, 2018). Aster flowers have around 30 prominent species and around 20.000 breeds. The flower naturally grows in the Central America continent, especially in the high mountains of Mexico. The flowers bloom in summer and fall. The stems are of brier type, while the roots are tuberous. 27 species of it can be found in nature. Some of these species may reach up to 8-9 meters height, while others are scrubs (Brickell, 1992; Hessayon, 1993; Mc Claren, 2004; Alp, 2008). Starting in July, they continue to bloom flowers, until the arrival of the first cold-weather waves. In temperate regions, they bloom much earlier, and the variation of their plant height and flower shapes and sizes increase. Their flowers can be of many shapes: simple, lotus, anemone, powder puff, orb, semi-cactus, cactus, decorative, orchid, or peony. In addition to the shades of blue, the flowers also contain all of the warmer colors. There are very few literature studies in Turkey regarding the Aster flower. Since it is a plant that can be produced relatively easy due to its large bulb resembling a potato, it is a good candidate for commercial use in the ornamental plant sector.

This study aims to evaluate the adaptation capabilities of the ornamental plant known as the Aster flower (*Dahlia* spp) and to determine the shading practices most suitable for the plant under the ecological conditions Kazova plains of the city of Tokat. A secondary objective is to determine the suitability of the Aster flower (*Dahlia* spp.) for plant design. Hopefully, this study will be able to determine optimal shading practices for the plant and act as a precursor for the growers that want to grow ornamental plants as the city of Tokat. We believe a new plant can thus be introduced to the ornamental plant design patterns places similar to Tokat ecological conditions, and *Dahlia* spp. can become an important part of decorative flowers. In addition, it could also contribute to application appropriate shading, varieties and to develop different studies in similar climatic conditions areas.

Literature review

American Dahlia Society officially lists 15 colors for the Dahlia: bicolor, bronze, dark blend, dark pink, dark red, flame blend, lavender, light blend, orange, pink, purple, red, variegated, white, and yellow. It can be used as a cut flower, or as an ornamental plant for outdoor environments. Those grown from the tubers have large flowers, while those grown from seeds have smaller ones (Evans, 1998; Mc Claren, 2004; Önay, 2007; Romer, 2008).

Hertogh and Nard (1992) and Mc Claren (2004) state that Aster flowers have flat receptacles, and that while the flowers on the edge are tongue-like in form while the ones on inner areas are more tubular. The flowers have a wide variation of colors. The leaves are bilateral, are of single or three bodies, and have serrated edges. Aster flowers are quite varying both in flower form and in color. It is also possible that a layered type aster flower can transform into a semi-layered form, along with a change in its color. The ones with two colors may lose one color over time. It is also reported by these researchers that the same plant may grow flowers of a different color over different branches.

In another shading practice study, the effects of shading on the rooting properties of the "Choot Hashani", "Orpheo" and "Lavanta Perfection" genera of the Dahlia spp. were evaluated. Natural light density has caused about 50% rooting reduction in the "Orpheo" slips, while it had no effect on the rooting rate of the "Lavanta Perfection" slips (Brian and Halevy, 1973). Shading during daylight hours has caused longer internodes for the "Orhpeo" genus only, while it had no effect on the rooting rate. On the other hand, the same shading has caused increased rooting for the "Choot Hashani" genus. Shading the bases of the slips has caused rooting percentage and roots per slip to increase significantly. The variance in response to shading is still being discussed, and the shading practices for these genera were determined to have influence only when applied to the rooting area. It is being surmised that shading incentivizes the weedy character of the rooting area, resulting in improved rooting (Brian and Halevy, 1973).

According to another study; excessive sunlight, high temperature, low humidity and sunlight caused problems in *Dahlia* spp., but the amount and intensity of sunlight should be adjusted to increase the flower stalk length and flower color quality with shading applications (Lumpkin and Lumpkin, 2005). According to another study on dahlia; different levels and combination of bio fertilizers and organic manures was applied to assess the vegetative, floral and yield characteristics of dahlia. The experiment was laid out in randomised block design with ten treatments and three replications. The maximum plant height (65.07 cm), number of primary branches (9.67), number of leaves (33.67), plant spread (43.73 cm), number of flowers (8.13), duration of flowering (10.53), flower yield ha-1 (33.65), weight of tuber (56.67 g), number of tubers (4.87) and tuber yield (13.80 t ha^{-1}) were produced in the treatment. (Pandey et al., 2017). The experiment of Verma and Kulkarni (2017) was laid out in simple randomized block design with three replication and twenty treatments on dahlia. Significant differences for all growth and yield parameters were found among different genotypes of dahlia. Maximum plant height (122.38 cm), number of branches (13.15), stem girth (1.48 cm) plant spread (59.12 cm) and intermodal length (18.04 cm) were recorded in genotype Hiranmoyee whereas, maximum leaf area (1909.78 cm^2) was recorded in genotype Barakanchari. Maximum number of flowers per plant (25.30) was found in genotype Hiranmoyee whereas, maximum flower yield per plant (g) was found in Song of India (718.72 g).

Materials and methods

The study was conducted in the fields of Center of Agricultural Research and Applications in the city of Tokat (Turkey), under the ecological conditions of the Kazova plains in the year 2018. After harvest, the plants were left to pot life in the laboratories of Gaziosmanpaşa University Faculty of Agriculture Department of Garden Plants.

Materials

The plants which had the most commonly sought-after colors were used in the study: white and pink speckled yellow-red and yellowish-orange. The plant has great potential for use in ornamental plant sector, especially as an outdoor environment ornament. The plant materials for the study were obtained from Konya Asya Lale Production Company, which were mostly created by hybridization of *D. pinnata* and

Method

Dahlia spp. tubers were planted to the garden belonging to the GUTAM (Gaziosmanpaşa University Agricultural Application and Research Center) in three different shading applications (open, 35%, and 55% shading). The light intensities in the applications were measured by light meter (400,000 Lux / 40,000 FC) at 12:30 pm. Light intensities at three different points were measured and averaged. These averages were 97.6 Klux in open area, 66.8 Klux in 35% shading and 48.1 Klux in 55% shading. The growth environment was loamy-sand garden soil. Considering that the flowers are relatively large, the plants were seeded in a 50 × 50 cm grid, to a depth of 15 cm. Each repeat had 8 tubers and there were a total of three repeats, separated into two rows. A total of 288 *Dahlia* spp. tubers were thusly used. The tests were repeated three times with "parcels divided by randomized blocks" method, and each repeat had 8 tubers. After the variance analysis, the averages were compared using Duncan test (Düzgüneş et al., 1987).

Results

Phenological findings

Vegetation period

This period was defined as the time it takes for 50% of the tubers after seeding to grow into plants that reach the soil surface. The Aster flower tubers that were sown on May 26 vegetated on June 11, in 15 days.

Inflorescence period

This period was defined as the time it takes for 50% of the plants flowering after being sown. The non-shaded (control group) tubers that were sown on May 16 flowered 35 days later, in the 1st of July, while those under 35% shading flowered 40 days later in 6th of July and those under 55% shading flowered 44 days later, on July 10th.

Floral period

This period was defined as the time it takes for 50% of the plant flowers to wither and fall. The plants that were not shaded which bloomed in 6th of July kept their flowers for a period of 85 days, till the 29th of September, while those under 35% shading kept their flowers for 96 days and those under 55% shading kept them for 103 days.

Leaf coloration period (days)

The leaf coloration was observed on the flowers for a total of 141 days, from the day 50% of the plants reached their vegetation period (June 11) till October 30th.

Abscission period

This period was defined as the time it took for 50% of the leaves to fall and was determined as 158 days from the plants' vegetation (June 11) till November 16th.

Morphological observations

Yield (pcs)

Inspected independent from the type, the general averages indicate that shaded plants yielded more flowers in the first harvest, compared to the control group. Those under 35% shading yielded an average of 20.58 flowers and achieved better flower yields compared to those in the control group and the 55% shaded group. The plants under 35% and 55% shading yielded significantly more yields in second and third harvests, compared to non-shaded plants. When the interaction between the flower genera and the shading level are inspected, it can be seen that the Seattle and Babylon Purple flowers under 35% shading yielded more flowers (with 15.66 and 17.66 units respectively), compared to the control and 55% shaded plants *(Fig. 3a).*

Flower diameter (mm)

Inspected independent of plant type, the plants under shading achieved higher flower diameters compared to non-shaded plants. Inspection of interaction between the shading application and plant genera reveals that *Le Castel, Seattle*, and *Babylon Purple* plants in the control group bloomed flowers with a significantly lower diameter in the first

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

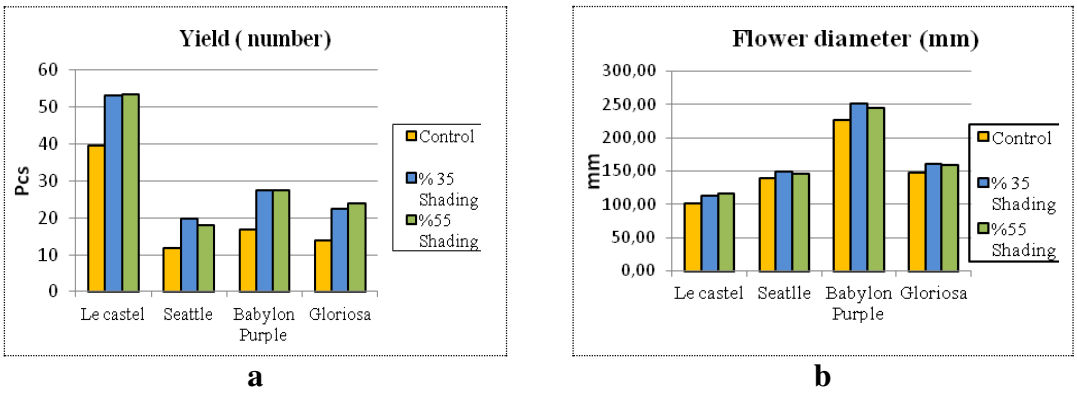
© 2018, ALÖKI Kft., Budapest, Hungary

control (25th of July) compared to shaded groups, with 121.25, 157.69, and 249.38 mm, respectively. In the third measurement (25th of September), the plants under shading application (*Le Castel, Seattle, Babylon Purple*, and *Gloriosa*) were found to have larger-diameter flowers compared to the control group. When the plant genera are compared to each other, Le Castel is found to be the one with the lowest flower diameter (121.25 mm), while Babylon Purple had the largest flower diameter (249.38 mm). The difference between *Seattle* and *Gloriosa* types were found to be insignificant (157.69 and 165.35 mm respectively). Le Castel plants under 35% and 55% shading had the smallest diameter flowers, while *Babylon Purple's* under shading had the largest (*Fig. 3b).*



a **b**

Figure 3. a. *The yied in Dahlia spp. some varieties.* ***b.*** *The flower diameter in Dahlia spp. some varieties*

Pedicle length (cm)

Inspected independent of plant type, the plants under 35% and 55% shading were found to have significantly longer pedicles in all three harvests compared to the control group plants. When the interaction between the flower genera and shading levels are inspected in this regard, it can be seen that *Le Castel* and *Seattle* type flowers of the control group had significantly shorter pedicles (23.5 and 20.92 cm, respectively) compared to shaded plants. The *Babylon Purple* plants under 35% shading, and *Gloriosa* plants under 55% shading achieved significantly longer pedicle lengths compared to the plants in the control group, with 34.24 and 32.35 cm, respectively. Regarding the shading application's effect on the plant genera, 35% and 55% shaded *Babylon Purple* flowers, and 55% shaded *Gloriosa* flowers were found to have significantly longer pedicles overall, with 34.24, 30.97, and 32.35 cm, respectively (*Table 1*).

Pedicle width (mm)

Inspected independent of plant type, the plants under 55% shading had significantly wider pedicles (6.56 mm) compared to the plants in 35% shading and control group. In the second harvest measurement, the plants under 55% shading had wider pedicles compared to the control group as well (5.15 and 4.86 mm, respectively). No significant difference was found between the pedicle widths of the flowers in the third measurement. Inspection of shading application with the plant genera reveals that Le Castels under 35% shading had thinner pedicles (3.77 mm) compared to those under no

shading, or under 55% shading. Babylon Purple plants under 55% shading, on the other hand, were found to have wider pedicles (8.60 mm) compared to control and 35% shaded groups in the first measurement in 25th of July. The Babylon Purple plants also had wider pedicles (6.22 mm) in the second measurement (25th of August) compared to other groups as well. In the third measurement, Le Castel plants of the third measurement under 35% and 55% shading were found to have significantly thinner pedicles compared to other types as well (*Table 1*).

Bud (gemma) count (pcs)

When the average bud count is inspected independent of the plant type, the first harvest's plants under 35% shading had more buds (4.45) compared to the control and 55% shading groups. In the second and third harvests' measurements, the plants in the control group developed significantly fewer buds compared to 35% and 55% shaded plants. The inspection of interaction between shading practices and the plant types reveals that *Seattle* and *Babylon Purple* plants developed more buds (2.54 and 3.20 respectively) compared to the control and 55% shading group plants in the first harvest's measurements made in 25th of July. Le Castel plants in the first harvest measurement developed more buds (7.62) compared to others (*Fig. 4a).*

Bud diameter (mm)

Type-independent inspection of the averages reveal that 35% and 55% shaded plants have developed larger flower buds compared to the control group. The 35% shaded

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

plants of the second harvest have developed significantly larger buds compared to the 55% shaded plants. The inspection of interaction between plant types and shading practices reveals that the control group *Babylon Purple* plants of the first harvest of 25th of July have developed smaller flower buds (28.75 mm) compared to the 35% and 55% shaded plants. 35% shaded *Le Castel* and *Gloriosa* plants of the second harvest of 25th of August, on the other hand, developed larger buds (19.45 mm and 27.44 mm respectively) compared to others. The plants under 35% and 55% shading of the third harvest (*Le Castel, Seattle, Babylon Purple* and *Gloriosa*) have developed significantly larger buds compared to the control group plants. For plant types, the largest buds were developed by the 35% shaded *Babylon Purple* plants of the first harvest (31.70 mm), while *Le Castels* developed the smallest buds (21.79 mm) (*Fig. 4b).*

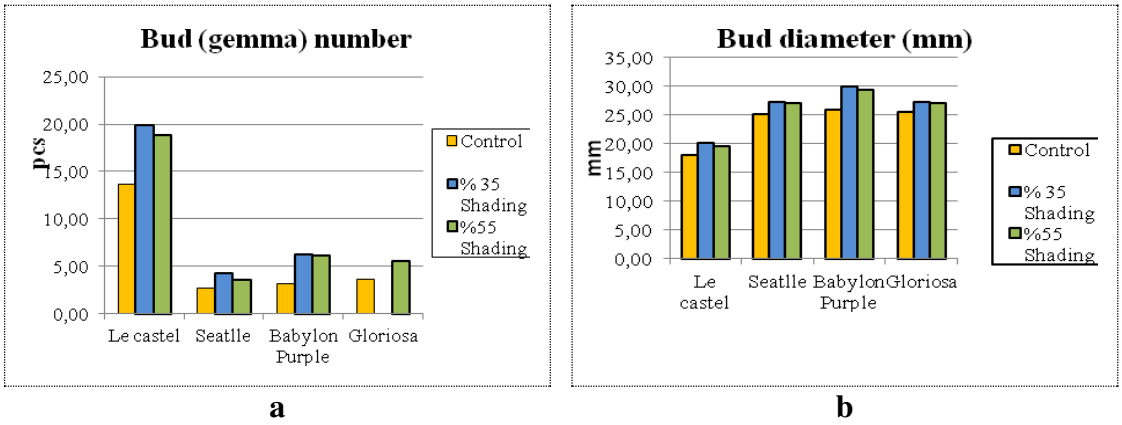

Figure 4. a. *The bud number in Dahlia spp. some varieties.* ***b.*** *The bud diameter in Dahlia spp. some varieties*

Plant height (cm)

When the averages are inspected independent of plant type, 35% shaded plants were found to have developed higher (77.14 cm) compared to the control and 55% shaded groups in the first harvest. In the second harvest, shaded plants reached a higher size compared to the control group. In the third harvest, the longest plants were developed by the 35% shaded plants (133.54 cm), while the smallest ones were developed by the control group (110 cm). The analysis of type-shading interaction reveals that the *Le Castel* plants of the control group in the second harvest of 25th of August developed shorter plants (96.37 cm) compared to the ones in the 55% shaded group (111.66 cm.) *Seattle* plants under 55% shading developed to be longer (92.27 cm) compared to the control group plants (64.56 cm). *Babylon Purple* and *Gloriosa* plants of the control group were shorter (120.93 cm and 113.53 cm, respectively) compared to the shaded ones. *Le Castel* plants developed longer (111.66 cm) compared to *Seattle* plants (92.27 cm). The *Gloriosa* plants of the third harvest under 35% shading grew to be longer (151.55 cm) compared to the *Le Castels (Fig. 5).*

Stem diameter (mm)

Type-independent evaluations reveal no significant variation in terms of stem diameter. When the effects of shading application on various types of plants are inspected, it can be seen that *Gloriosa* plants under 35% shading in the first harvest of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

25th of July have developed larger stems (15.60 mm) compared to the *Le Castel* (11.29 mm) plants. No significant differences were observed between 55% shaded *Seattle* (18.23 mm) and *Babylon Purple* (18.39 mm) plants. The second harvest's (25th of August) Le Castel plants developed thinner stems (12.11 mm) compared to the Seattle plants (18.01 mm). *Gloriosa's* under 35% shading developed larger stems (17.94 mm) compared to the *Le Castel's* (11.55 mm). No significant difference was observed between 55% shaded *Babylon Purple* and *Gloriosa* plant stem diameters (22.23 mm and 18.72 mm respectively). The Seattle plants of the third harvest (25th of September) developed larger stems (20.26 mm) compared to the Le Castel plants (13.83 mm). Le Castel plants under 35% shading developed thinner stems (13.31 mm) compared to other plants. No significant difference was observed between 55% shaded Babylon Purple and Gloriosa plants (23.94 mm and 22.79 mm, respectively) (*Fig. 6a*).

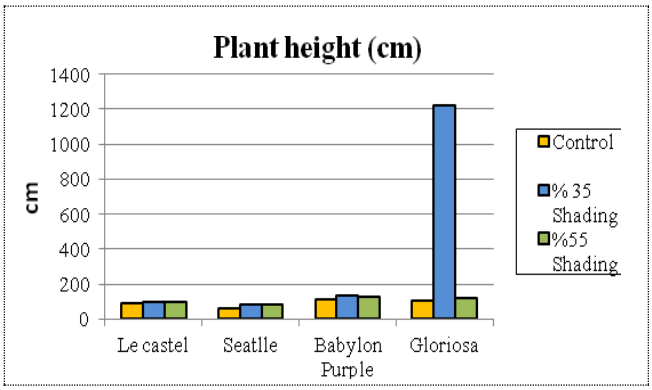

Figure 5. *The plant height number in Dahlia spp. some varieties*

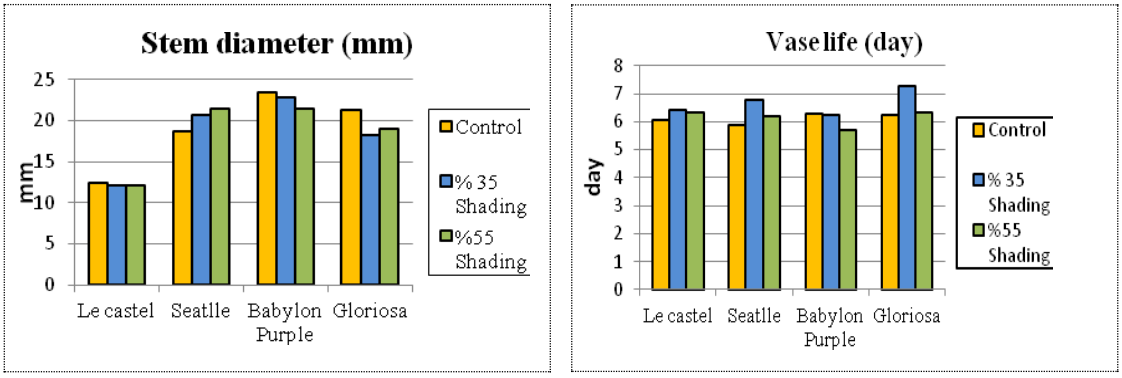

a **b**

Figure 6. a. *The stem number in Dahlia spp. some varieties.* ***b.*** *The vase life in Dahlia spp. some varieties*

Vase life (day)

The vase life of flowers is commercially important because of storage. After the harvest, fading time of flower was examined in pure water. Type-independent inspection reveals that 35% shaded plants had significantly more vase lifetimes compared to control and 55% shaded groups in the first and second harvests, and in total average. Type and shading based inspection reveal that 35% shaded *Le Castel* and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

Gloriosa flowers of the first harvest of 27th of July have survived longer in the vases (6.58 and 7.41 days respectively) compared to control and 55% shading groups. Amongst the flowers of the second harvest of 27th of August, the Seattle flowers of 35% shading survived longer in a vase (6.91 days) compared to other groups. On average, Seattle and Gloriosa flowers under 35% shading were found to survive longer in a vase (6.79 and 7.29 days respectively) compared to control and 55% shading (*Fig. 6b*).

Discussion

The evaluations on the collected data reveal that shading practices (35% and 55%) have resulted in positive developments regarding total yield and some quality criteria compared to the control group. In terms of yield, the inspection of shading practices reveals that the plants of second and third harvests have developed more flowers compared to the control group when 35% and 55% shading was applied. Evaluation of the plant types in terms of yield (*Le Castel*, *Seattle*, *Babylon Purple*, *Gloriosa*) reveal that Le Castel plants were significantly yielding compared to other plants in all three harvests. Amongst the third harvest plants, Le Castels under 55% shading yielded the highest amount of flowers (85.33). According to the study of Akçal (2016), plants subjected to 16 h of photo-period under 40% shading displayed a more uniform development and resulted in more compact flowers suitable for decorations. Similarly, the results of our study indicate that 14-15 h of photo-period under 35% shading result in more uniformly developed plants which were more suitable for use as outdoors ornamentals.

The results also indicate that 35% and 55% shading practices also increase the plant height and flower diameter. This is similar to the findings of Yanming Dent et al. (2012), which indicates that 20-50% shading for Jasmine (*Jasminum sambac Aiton*) plants have resulted in increased vegetative growth and yield. Similarly, both the 35% and 55% shading practices in our study resulted in better vase lifetime, stem diameter, plant height and yield. The study of Malta (2016) also report similar results, in which 35% and 55% shading practices for tulips (*Tulipa gesneriana L.*) have resulted in better properties in terms of flower lifetime, pedicle length, flower diameter and corm size.

Pedicle length is an especially important property for the cut flower sector. In terms of pedicle length, the plants under 35% and 55% shading were found to have developed longer pedicles compared to the control group plants in general. Even though *Babylon Purple* and *Gloriosa* types have similar properties in this regard, the *Babylon Purple* type flowers have developed the longest pedicles (32.24 cm) in the first harvest under 35% shading.

When all these criteria are evaluated together, it can be surmised that shading practices of 35% and 55% result in increased yields for the Aster flower overall. In some climate-related events like rainfalls, the 55% shaded plants were found to have developed form irregularities towards their centers. Considering all of these, we report that the ideal point lies in 35% shading for the Aster flowers in places such as Tokat Kazova conditions.

Conclusion

Although it is known that the Dahlia's need shadow what kind of dahlia to how much shadow (Klux) are important. As shown in this study, the responses of the varieties to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

shadow applications were found to be significant. After this study, the amount of shade should be taken into consideration in landscaping applications for Dahlia's. In addition, the use of varieties (*Bayblon purple Seattle, Glorissa, Le castel*) should be evaluated according to their development in the shade in the light of the obtained data.

CROP LOAD REGULATION WITH CHEMICAL THINNERS IN DEVECI PEAR (*PYRUS COMMUNIS* L.)

KAÇAL, E.

Department of Fruit Breeding and Genetic, Fruit Research Institute, 32500 Eğirdir, Isparta, Turkey
(e-mail: emel.vural@gmail.com; phone: +90-246-313-2420-112; fax: +90-246-313-2425)

(Received 3rd Aug 2018; accepted 28th Sep 2018)

Abstract. The efficacy of three different doses of ammonium thiosulfate (ATS), potassium thiosulfate (KTS) and BA (6-benzyladenine) on fruit quality, yield and return bloom was evaluated in this present experiment on 'Deveci' pear (*Pyrus communis,* L.). All treatments were compared to an unsprayed control and hand fruit thinning. The highest fruit set was achieved with BA treatments. It was significantly reduced in KTS rates compared to control and other thinning treatments. KTS sprays create a statistically significant increase in fruit diameter and fruit weight, while ATS and BA have had no dramatic effect. Hand fruit thinning has resulted in heavier fruit at harvest similar to KTS with 2%. Thinners increased the percentage of fruit to ≥75 mm in diameter and proportions to 250-500 g fruit weight. In the control trees, the ratio of fruit to ≥75 mm diameter was 57%, the 75% or more of which was in hand thinning and chemical thinners. The proportion of fruits within 250-500 g fruit weight group was found in the highest KTS doses. No physiological disorder as bitter pit, water core, and aging disorder and phytotoxicity were observed in fruit samples. Study results show that 2% KTS significantly reduce crop load and increased fruit quality in 'Deveci' pear. Therefore, it can be used as an alternative to hand fruit thinning in the 'Deveci' pear to achieve high fruit quality. But, neither flower nor fruit thinners induced return bloom in 'Deveci' pear.
Keywords: *alternate bearing, 6-BA, blossom thinners, fruit quality, yield efficiency*

Introduction

Turkey is among the top 10 pear producers in the world with 420.000 tons of pear production. Although pears are grown throughout the country, production is mainly focused around the Southern Marmara, Northern Mediterranean and Central Anatolia Regions. Many different varieties of pears are grown in Turkey. Most popular pear varieties are 'Santa Maria', 'Deveci', 'Akca', 'Mustafabey', 'Williams', 'Kieffer', and 'Ankara'. 'Deveci', which is an Anatolian origin, is one of the major pear varieties produced in Turkey. It constitutes 20% of production (Atalaysun, 2016) and is very popular among consumers because of having large fruit and high consumption quality. 'Deveci' is a variety with biennial bearing. If there is no thinning in the "on year", no flower may be in the next year. Alternate bearing or biennial bearing is common in temperate fruit trees such as apple, pistachio, pear and olive. Genetic predisposition has an important role in the occurrence of alternate bearing, but it is possible to reduce it with plant nutrition practices and crop load management. Crop load management is one of the most important horticultural practices for sustainable fruit quality and quantity (Yıldırım and Koyuncu, 2004). Thinning applications can be performed in different phenological periods such as buds, flowers and fruits by different methods. Flower thinning is practiced to maximize crop value and promote return bloom when compared to fruitlet thinning. Early thinning will conserve photosynthetic reserves by reducing competition between all organs throughout the tree. Flower thinning can be conducted mechanically or chemically. But in practice, the most common method is the use of chemical thinners. Chemical blossom thinners are caustic and reduce fruit set by

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_72037212
© 2018, ALÖKI Kft., Budapest, Hungary

damaging different parts of the flower and prevent fertilization (Fallahi and Willemsen, 2002). Several chemicals like ATS, KTS, armothin, etc. have been identified to reduce fruit set when applied at the flowering time. Chemical fruit thinning is achieved by plant growth regulators such as BA, NAA, NAD when the fruits reach a certain size. Hand fruit thinning, one of the applications in crop load management, is not economical for industrial countries since it increases labour costs and is a time-consuming practice (Bangerth and Quinlan, 2000). Therefore, the interest in chemical thinners has also increased steadily.

Apple is the main fruit species in which thinning studies are widely performed due to high expectation of fruit quality and the tendency to alternate bearing. Many apple varieties have been tested for their response to chemical thinners in different ecologies. However, limited studies are available in the literature on pear. Crop load studies with chemicals have been conducted on 'Nijisseiki', 'Hosui', 'Conference', 'Forelle', 'Bartlett', 'Williams', 'Abbate Fetel', 'Williams Bon Chretien' and 'Packams Triumph' pears (McArtney and Wells, 1995; Maas and van der Steeg, 2011; Kirstein, 2015; Greene, 2012; Theron, 2011; Bound, 2015). The effects of Ethephon, NAA, BA, ABA, Metamitron, and ATS have been investigated in these studies. In the present work, it was evaluated the efficacy of three rates of ATS, KTS, and BA on fruit quality, crop load and return bloom in 'Deveci' pear grown on the Quince A rootstock.

Materials and methods

Study area and plant material

This study was conducted on the Fruit Research Institute (37°49'1"9N, 30°52'23"E), Eğirdir, Isparta, Turkey in 2017-2018 vegetation periods. Isparta has favourable conditions for temperate fruit growing. It is very important apple production region within Turkey; it leading producer with about 25% of total. The Institute is located between Eğirdir and Kovada Lakes. The location is the transitional zone between the Mediterranean and the continental climate. The study area is 917 m above sea level. The average temperature is 12.2 °C and the annual rainfall is 564.3 mm (1929-2017). Some of the meteorological data recorded in the study area (37°48'52"N, 30°52'30"E) are presented in *Table 1*.

'Deveci' pear tree, 16-year-old, at a spacing of 4.0 x 2 m in north-south rows on Quince A rootstock, was selected as experimental trees. 'Deveci' trees grow semi-vigour and are semi-spreading. The number of days between full bloom and harvest is 150-160. Ripening season is around 15-20 October. Eleven applications including

unsprayed control (no thinning), hand fruit thinning (HFT) just after June drops (one fruitlet left per cluster), ammonium thiosulfate (ATS) (1.0%, 2.0%, 3.0%), potassium thiosulfate (KTS) and BA (6-benziyladenine) (Exilis®) (100, 125 and 150 mg l^{-1}) were designed. The applications were performed by spraying on the predetermined healthy trees by handgun sprayer. All sprays were applied to the whole tree and no surfactant was used. Detailed information about experiments is given in *Table 2*.

Table 2. *Thinning practices, application time and date*

Treatments	Doses	Application period	Application date
Control	-	-	-
HFT	-	After June drop (one fruit was left in each flower cluster)	06.06.2017
ATS	1% 2% 3%	Full bloom (70-80%)	19.04.2017
KTS	1% 2% 3%		
BA	100 mg l^{-1} 125 mg l^{-1} 150 mg l^{-1}	10-12 mm fruit diameter	12.05.2017

The experimental area was irrigated twice a week by drip irrigation and the fertilizers were given based on the soil analysis results. The soil of the experimental area was loamy-clay. It contains 2.8% organic matter. During the trial, orchard management practices were carried routinely and spray program was followed for plant health.

Measurements

Fruits were harvested at commercial harvest time in 16.10.2017. Ten fruits were selected randomly per tree for fruit quality measurements such as fruit length (mm), fruit diameter (mm), fruit weight (g), fruit flesh firmness (N), soluble solid contents (SSC) and titratable acidity (TA). A total of 120 fruits were analysed in each application. Fruit samples were also assessed for physiological disorders. They were graded into various sizes and weight classes. Different groups were formed between 100-500 g for fruit weight and 65-90 mm for fruit diameter.

All flower clusters were counted to determine fruit set ratio at pink bloom stage and the number of fruits per tree. The yield was recorded in each tree at harvest. During the winter period, the stem diameter was measured at a height of 15 cm from the graft union and the trunk cross-sectional area (TCSA) as calculated (πr^2).

A few days after application, macroscopic observations were made for phytotoxic effects of thinners on tree organs. This trial was planned for two vegetation years and no thinning applications could be made because of alternate bearing in 2018. Thus, flowers were only counted for return bloom in 2018. During the spraying period, meteorological data were taken in order to determine the effects of temperature and relative humidity on thinning mode of chemicals (*Fig. 1*).

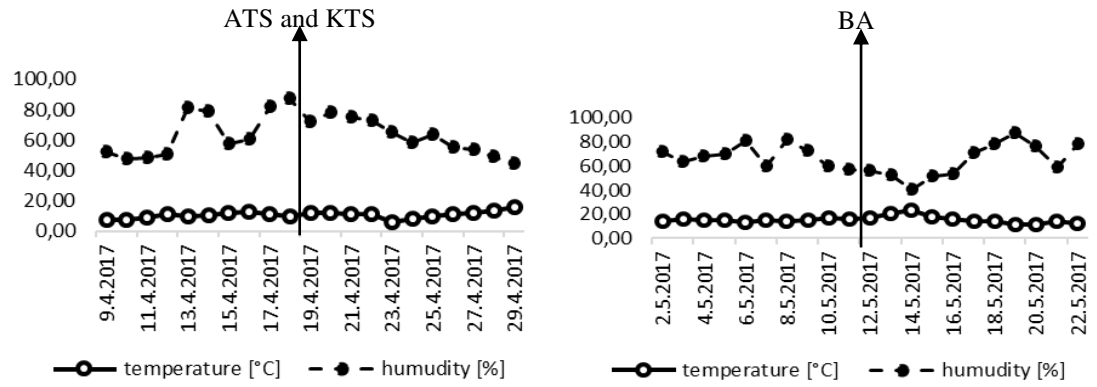

Figure 1. *Temperature and relative humidity in the application period*

Statistical analysis

Experiments were arranged in a randomized complete block design with four replicates, three trees were used for each replicate. Statistical procedures were performed using statistical analysis systems SPSS software. Duncan's multiple range test was used for means separation at a significance level of 5%.

Results and discussion

Fruit set and cropping

In this study, fruit set was affected by treatments. Differences among treatments on fruit set and cropping were significantly at 5% level. It is tended to decline with increased rates of KTS. ATS at 3% and KTS at 3% spraying significantly reduced fruit set, whereas BA did not. This data is not overlapping with findings of Chabikwa (2008), Bound and Mitchell (2002), Curetti et al. (2011) and Bertelsen (2002) on 'Early Bon Chretien', 'Packam's Triumph', 'Williams' and 'Clara Frijs' pears for BA. But these results are similar to Greene (2012) who works on 'Bartlett' pear. Low temperatures at application time could reduce BA efficiency. The highest ATS rate caused approximately 42.86% reduction in fruit set in comparison with untreated control. That was 52.29% compared to 125 mg l^{-1} BA. In BA and ATS, yield was higher than KTS doses and the highest yield was obtained from ATS as 2%. ATS and KTS reduced yield at harvest as 3% and 1% respectively. But, the lowest fruit yield with the 30.89 kg $tree^{-1}$ was taken from hand fruit thinning trees. 100 mg l^{-1} BA was the best practice for yield efficiency compared to untreated control and others (*Table 3*).

Fruit quality

Significant differences were found among treatments on fruit quality parameters in comparison with the unsprayed control. All thinning practices increase fruit quality statistically ($P \leq 0.05$) at varying rates compared to control. KTS sprays increased fruit diameter and fruit weight, while ATS and BA had no significant effect. Hand fruit thinning has resulted in heavier fruit at harvest similar to KTS as 2% (*Table 4*). ATS doses used in this study, being a promising thinner for 'Packham's Triumph' (Bound, 2015) and 'Clara Frijs' (Bertelsen, 2002) pears, were not as effective as hand fruit thinning and KTS doses on the fruit quality.

*Means in columns followed by the same letters are not significantly different at 5% level

ATS increased fruit diameter and fruit weight 3% relative to other ATS rates. Multiple applications of the ATS may also have a better thinning effect on the 'Deveci' variety, such as 'Packham's Triumph' (Bound and Mitchell, 2002). Compared to ATS and unsprayed control, KTS doses gave good results on fruit quality. However, the 2% KTS was more effective than the 1% KTS and 3% KTS. BA applications were made when the fruit diameter was 8-12 mm. Although the doses of 50-200 mg l^{-1} have been used in practice, the thinning effect of 100-150 mg l^{-1} BA has been found promising for some varieties. Theron et al. (2011) reported that the application of 100-150 mg l^{-1} BA on 8-12 mm fruit diameter in 'Early Bon Chretien' pear greatly reduced fruit set and that the thinning effect of 150 mg l^{-1} BA was higher. In the literature, although the positive effects of BA on fruit thinning in pear are mentioned, it is reported that some pear varieties do not respond to fruit thinning applications. Reactions of varieties to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_72037212
© 2018, ALÖKI Kft., Budapest, Hungary

chemical thinners may differ. Greene (2012) informed that BA was not effective in 'Bartlett's' pear, while Maas and Van der Steeg (2011) in 'Conference', Bound (2015), in 'Packham's Triumph' and Bertelsen (2002) in 'Clara Frijs' pear could be recommended for thinning. In 'Forelle' pear variety, BA + NAA applications reduced fruit set more than single applications of BA (Kirstein, 2015). In our study, although BA treatments increased fruit quality compared to control, they did not exceed KTS, ATS and hand fruit thinning with regards to efficacy. It is thought that this situation may be related to the climatic conditions at the time of application with the variety response. This is because the air temperature in the application period was around 15 °C, which is the limit value for BA. Low temperatures during the application period may have overshadowed the effectiveness of the BA. In contrast, Bregoli et al. (2006) stated that the effect of BA may be related to the king fruit size rather than climatic conditions. In this study, BA treatments were made 24 days after full bloom when the fruit diameter reached 10-12 mm. It is also possible that the phenological period at the time of application may not be suitable for BA in Deveci, or BA alone may be inadequate for a good thinning effect. As a matter of fact, Kurnaz et al. (1992) suggested that NAA and Carbaryl applications in 'Deveci' pear are not enough alone to be as effective as hand fruit thinning on fruit weight and size.

The fruit flesh firmness in ATS reached the highest value of 2%, but it was significantly ($P \leq 0.05$) reduced in control and hand fruit thinning fruits. It is thought that the fruits of this application have more cells, but these cells do not reach sufficient size because of high crop load. The positive effect of ATS on fruit flesh firmness has also been reported in previous studies in apples (Bound and Wilson, 2007). SSC values obtained in the current study were classified according to the applications. As a result of a yield decrease, SSC was higher in 3% ATS and hand fruit thinning. Reductions in SSC with high crop load may have been the result of reductions in soluble carbohydrates, increased competition for assimilate between plant organs resulting from increased crop load. Similar findings were reported by Coneva and Cline (2006) in 'Redhaven' peaches. SSC is increasing due to the increase of ATS doses. Titratable acidity was unaffected by thinning (*Table 5*).

Table 5. *Effects of treatments on soluble solids content and titratable acidity*

Treatments	Doses	SSC	TA %
Control	-	12.4bc*	0.2ns

Fruit size in 'Deveci' pear is an important trait, and it is linked to eating quality. Fruit juiciness and crispness reduce when fruit size decreases. It was determined that in control trees where no application was made, the fruit diameter and weight, as well as the fruit flesh firmness, decreased (*Table 4*). The eating quality of these fruits is also lower relative to large fruits. The effect of thinners on fruit diameter distribution was different. The chemical thinners increased the percentage of fruit to ≥75 mm in diameter. In control trees, the ratio of fruit to ≥75 mm was 57%, where ATS 2% and KTS 3% were 69%. In KTS 2%, 80% of the fruits have ≥75 mm. Fruit rate of to ≥85 mm was found to be higher in hand fruit thinning and KTS at 2% (*Fig. 2*). The effect of KTS sprays on fruit size was the greatest.

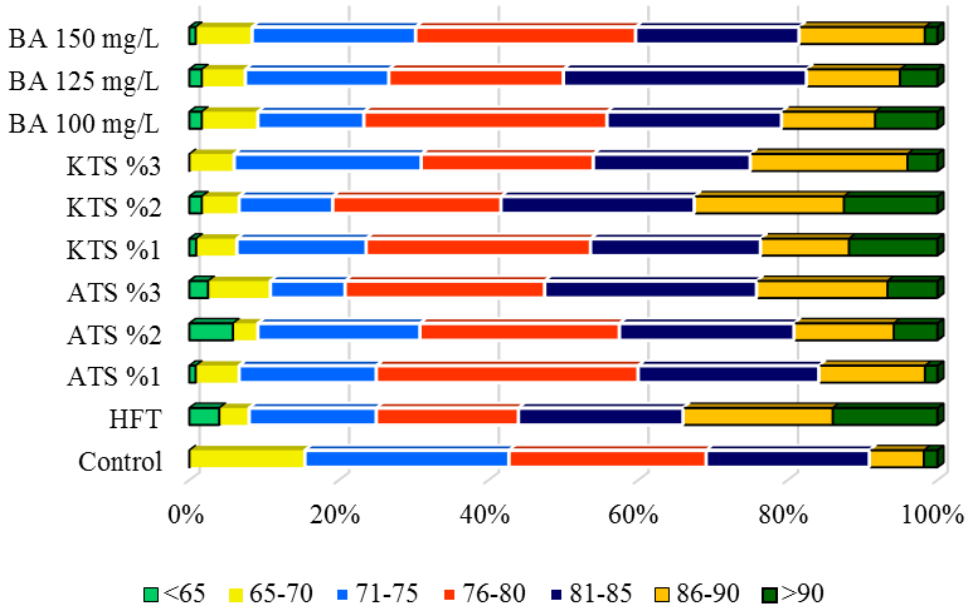

Figure 2. *Effects of thinners on fruit size distribution (mm)*

'Deveci' pear can produce fruit up to 1500 g depending on the nutrition conditions and crop load. Although fruit size is an important factor for 'Deveci', over a certain size, it is not preferred by consumers. Ideal fruit weight for 'Deveci' is approximately between 250 and 450 g. The fruits above 450 g are not demanded. The fruit weight of 250 g and above in KTS was higher than the other. Among the KTS doses, 2% KTS was the most effective with 59.2%. Hand fruit thinning was followed with 57% to KTS. The lowest fruit rate was found in control with 32.7%, while doses of ATS 1% and BA 150 mg l^{-1} were beyond all applications, except control trees. In BA applications, 50% of the fruits reached to 100-250 g fruit weights (*Table 6*). The reduction of fruit size in 'Deveci' following application of BA contradicts the findings of Curetti et al. (2011) for 'Williams'.

Return bloom

Early thinning before seed development could increase return bloom. Also, crop load significantly affects it (Melan and Gjerde, 1993). This is particularly important for varieties showing alternate bearing. However, thinners positively affected the fruit quality in 'Deveci', they reduced return bloom dramatically in the second year of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_72037212
© 2018, ALÖKI Kft., Budapest, Hungary

experiment. Similar findings were found by Bound and Mitchell (2002) in 'Packham's Triumph' pear with ATS at 2%. According to Forshey (1986), varieties showing alternate bearing generally do not respond to chemical thinners. In 2017, the highest number of flowers was recorded in the KTS 3%. This was followed by ATS 2% and ATS 3%. The number of flowers in the hand fruit thinning and BA 100 mg l^{-1} was lower, but the highest flower number was obtained from these applications in 2018 (*Fig. 3*). However, the efficiency of BA on return bloom was not at optimum level. This response is likely to be related to dose, application time, varietal characteristics or weather conditions. Additionally, spur leaf damage might be prevented to the formation of flower buds (Luckwill, 1970).

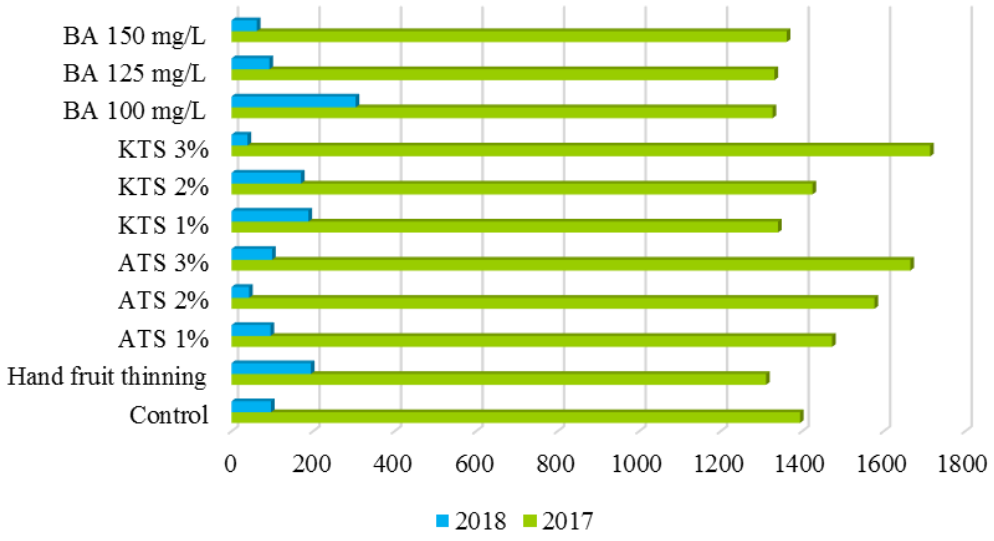

Figure 3. *Effects of thinners on flower number in 2017 and 2018 years*

Phytotoxicity and physiological disorders

Blossom thinners as ATS and KTS are caustic and they can cause damage on the development of spur leaves or other parts of the tree (Webster, 2002; Grenee, 2002).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_72037212
© 2018, ALÖKI Kft., Budapest, Hungary

Factors such as weather conditions, high concentrations and variety characteristics often affect the thinners' response and damage ratio on the flower, spur leaves, young branches and fruits (Forshey, 1986; Kaçal and Koyuncu, 2012). Previous studies reported that high doses of ATS result in serious damage (Sanders and Looney, 1993; Janoudi and Flore, 2005). Phytotoxic effect of ATS than high doses, the previous day from the time of application occurred in cool, humid, and rainy weather (Schupp and Greene (2002). However, Bound and Jones (2004) performed that rates of 3% ATS or higher doses caused foliar damage and bud death. KTS and ATS doses showed symptoms of leaf burning and chlorosis on spur leave a few days after application in this study resulting from low temperate and high humidity, but they did not affect fruit size. This damage has increased with increasing doses. No phytotoxicity was found in BA applications.

BA can cause russet on the fruit skin. This condition was observed by Greene (2002) on Bartlett pear. But in the case of excessive thinning, physiological disorders such as bitter pit and water core in fruits are likely to occur when the increase in fruit size and nutritional conditions are taken into account. However, during the experiment, no physiological disorder as bitter pit, water core, and aging disorder and phytotoxicity were observed.

Conclusion

Efficacy of ATS, KTS, and BA on the fruit quality and return bloom in 'Deveci' pear was evaluated in this experiment. Flower thinners reduce fruit set and yield and increase fruit quality. But neither flower nor fruit thinners induced return bloom. There is no record about what is the optimum fruit number for next year cropping and high fruit quality in 'Deveci'. Further detailed crop load studies should be done on 'Deveci' pear. Dose, application times, chemicals and combined use of either flower or fruit thinners, single applications or the sequential use of ATS and KTS should further be tested to create a thinning schedule for pear growers.

(Received 4th Aug 2018; accepted 4th Oct 2018)

Abstract. Land degradation is already one of the major problems affecting the world. Land degradation by soil erosion is one of the most serious ecological problems and environmental issues in many sites of arid and semiarid regions. There has been an increasing concern regarding the semiarid highlands of Turkey that degradation of these ecosystems results in excessive soil erosion, ecosystem degradation, and loss of natural resources. This paper, therefore, explores the impact of land cover in a linkage to the soil erodibility indices and some soil properties of Koruluk (Gümüşhane-Turkey) dam watershed. Soil samples were taken from soil profiles opened in 78 sample pilots among the lands which border each other in the same altitude levels and same slopes on the andesite-basalt bedrock in the southern aspect group according to 0-10 cm and 10-20 cm depths. Sand, silt, clay, soil organic matter, dispersion ratio, erosion ratio, structural stability index, aggregate stability, clay dispersion ratio, field capacity, available water capacity, bulk density, total porosity, soil pH and electrical conductivity analyses were performed in soil samples. The results obtained about land cover were tested by variance analysis. The relationships between the selected soil characteristics were determined by correlation analysis. Degraded scotch pine forest soils were observed to be more susceptible to erosion compared to degraded oak forests and open space areas. Consequently, it was revealed that soils that developed from similar parent material in semi-arid ecosystem and under all land covers were susceptible to erosion. The fact that the watershed supplies Koruluk dam built for irrigation water production makes these results quite significant. Agricultural activities are very important in the protection and continuity of the socio-economic situation of local people. The continuity of agricultural activities, in one respect, is associated with the availability of irrigation in this semi-arid region. Therefore, priority should be given to the necessary rehabilitation, planning and management studies in Koruluk dam watershed, and the results of this study should be considered.
Keywords: *Koruluk dam, degraded forests, semi-arid, erodibility indices, soil properties*

Introduction

Soil erosion is an ecological, environmental, economic, social and serious problem. This not only causes land degradation and reduction of soil fertility but also significantly affects the public health and sustainable development in rural areas (Tang, 2004; Zheng et al., 2004; Jing et al., 2005). Soil erosion is a natural process that continues depending on physiographic and climatic factors. However, it is the accelerated erosion that reduces soil fertility, decreases its quality, adversely affect water quality and management. Erosion can be accelerated through human activities. Surface mining, forestry, agriculture and construction are the major activities (Lal, 2001).

The trigger for accelerated erosion in arid and semi-arid areas is loss of vegetation cover. This exposes soils to wind and water erosion, loss of soils decreases the potential for vegetation production. The end result is a decrease in the carrying capacity of the rangeland and productivity of forests. Despite being in arid and semi-arid areas the

erosion is largely a result of infrequent but heavy rainfall events. The erosion of soils exacerbates soil degradation. Soil quality decreases along with the erosion, especially structural units become weakened. In others, erosion may lead to decline in soil quality and set in motion the degradative trend. Soil erosion can be a manifestation of soil degradation because it involves physical removal of soil in a vertical and/or horizontal direction and degrades soil quality (Lal, 2001). Soil physical processes involve decline in soil structure leading to an increase in bulk density, decrease in total and macroporosity reduction in infiltration, increase in runoff, and exacerbation in erosion by water and wind.

Turkey is one of the countries that are most affected by erosion and are susceptible to land/soil degradation and drought because of its geomorphological structure, physiographic, edaphic and climatic characteristics. Sediment occurring in active erosion areas leads to major flooding, drainage and deposit losses in stream beds, base-agricultural lands, dams and reservoirs by accumulating. The reservoirs and dam built with big investments lose their function due to the runoffs and the soil material moved by the rivers and are in danger of being inactivate before their economic life. About 65 of the total area of Turkey has a semi-arid and arid characteristic (ÇEM, 2011). Drinking and potable water needs in arid and semi-arid regions are met by the dams and reservoirs. Arid and semiarid areas are considered fragile environments where vegetation cover is scarce and where soil erosion processes occur rapidly and severely after rainfall events fall in these areas. However, even under those conditions, the importance of native vegetation is very significant in the regulation of surface hydrological processes.

Land cover affects the occurrence and the intensity of runoff and soil erosion (Chen et al., 2001; Wei et al., 2007). Proper management of land cover patterns may greatly improve soil properties, leading to reduced soil erosion to the recommended threshold limits (Fu, 1989; Chen et al., 2003). Improved physical soil characteristics can also positively affect the establishment of vegetation (Kosmas et al., 2000). Land cover systems might lead to changes in a number of soil characteristics and soil erosion processes (Bao-hua et al., 2003; Costa et al., 2003).

Four dams and four reservoirs were established in Gümüshane region where the study was conducted. Koruluk dam watershed, one of these dams, has become susceptible to erosion and deterioration by the destruction of vegetation cover by local people as well as the effect of geomorphological and climatological characters. Being aware of erosion trends, physical and chemical characteristics of watershed soils is quite important for the rehabilitation works to be conducted in these areas and measures to be taken.

The aim of this study is to investigate the hydro-physical characteristics and some erosion trends of Koruluk Dam watershed soils in Gümüşhane-Şiran region which is located in semi-arid region in Turkey's Eastern Black Sea Region depending on land cover changes.

Material and method

Study area

Study area is located in Gümüşhane province in northeast of Turkey. Koruluk dam, which was built for irrigation, is located in the northern part of Gümüşhane-Şiran district and is 7 km away from there (*Fig. 1*).

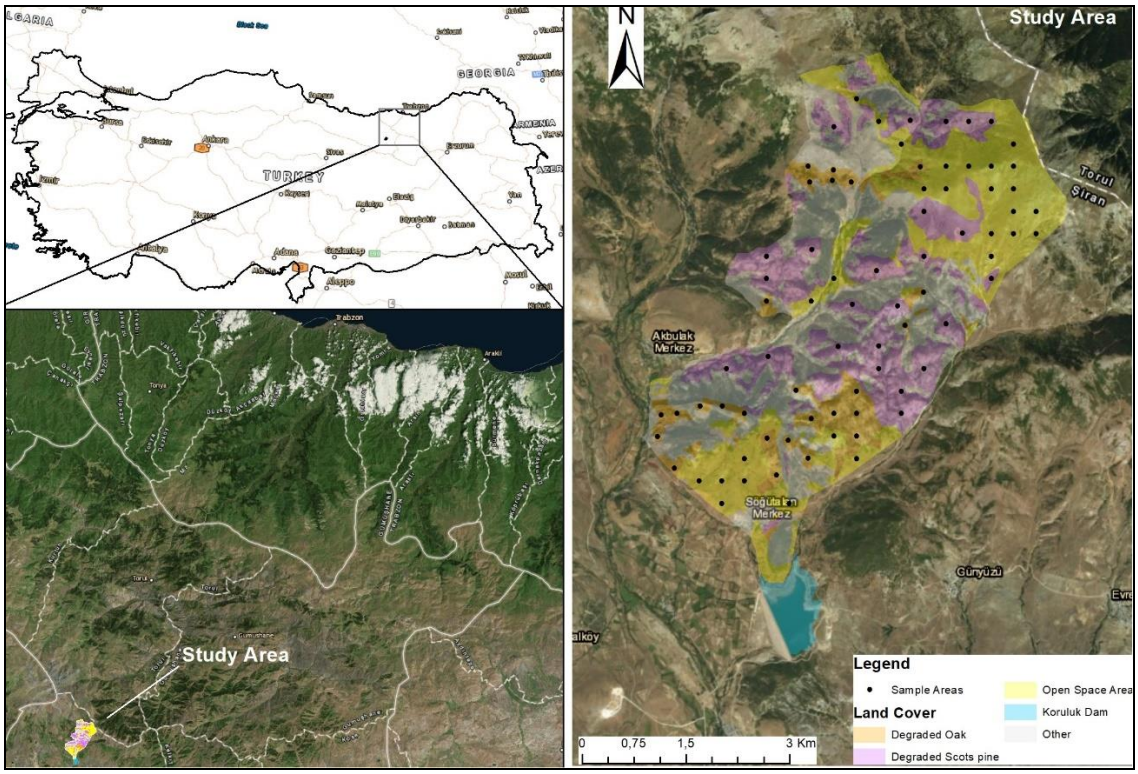

Figure 1. *Location of study area*

The construction of the dam was carried out between 1990-2005. The lake area is 0.7 km^2 in normal water elevation. Total irrigation area of the dam used for for the irrigation of agricultural areas near the dam is 3447 ha. Erenkaya, Şiran, Çal, Söğütalan, Örenkale, Sarıca, Koyunbaba, Günbatur and Bilgili villages benefit from Koruluk dam fed by Ceviz stream for irrigation.

In the study area, eocene aged andesite-basalt volcanic rocks are surfaced (Baykal, 1952). The data of Kelkit meteorological station (1965-1989) close to Şiran district were used in determining the climatic type of the study area. According to Thornthwaite climate analysis, the study area has a climatic type which is "close to the continental climate with little or no excess water semi-arid at low temperature (microthermal) indicated by DC'2db'2" symbol". Some climate data according to Thornthwaite method were given in *Table 1*.

Soil sampling and analyses

Sample pilots were taken from on soils developed from volcanic rocks and from south aspect. Average slopes and altitudes of the sample pilots are close to each other (*Table 2*).

Table 2. *Geomorphological characteristics of the areas under different land cover*

	Degraded oak forest	**Open space area**	**Degraded scotch pine forest**
Average slope (%)	31	35	38
General aspect	South	South	South
Average altitude (m)	1770	1820	1815
Parent material	Andesite-basalt	Andesite-basalt	Andesite-basalt

Sample pilots in the study area were determined by the selection sampling method as 26, 28 and 24 pieces, respectively, including degraded oak forest, open space area and degraded scotch pine forest. Total of the 78 sample plots, 25 of them were received in Işık (2016). The soil was sampled at two different depths: 0–10 cm (surface layer) and 10–20 cm (subsurface layer). Statistical analyses and assessments were carried out for surface layer, subsurface layer and average of profile (0-10 cm, 10-20 cm depths and 0-20 cm depth).

Particle size distribution (2-mm) and soil organic carbon (0.5 mm) were determined using disturbed soil samples using the Bouyoucos hydrometer method (Bouyoucos, 1962; Gülçur, 1974) and the modified Walkley-Black wet oxidation procedure, respectively. Soil organic matter (SOM) was calculated by multiplying soil organic carbon by 1.72 (Nelson and Sommers, 1982; Arp, 1999). Soil pH were measured using the procedures outlined by Arp (1999) and Page et al. (1982), for bulk density (BD) and total porosity (TP) by Blake and Hartge (1986) and Danielson and Sutherland (1986). Dispersion ratio (DR) was determined according to the methods described by Middleton (1930). The clay and silt fractions obtained by chemical dispersion were taken as total clay (TC) and total silt (TS), while water dispersible clay (WDC) was obtained as above except that no chemical dispersant was used. Colloid-moisture equivalent ratio (C-MER) and erosion ratio (ER) (Özhan, 2004), available water capacity (AWC) (Karaöz, 1989), aggregate stability (AS) (Le Bissonnais, 1996) and structure stability index (SSI) (Leo, 1963) were also determined.

Statistical analyses

Analyses of variance (ANOVA) were performed to determine the effects of land cover on the chemical and hydro-physical properties of the soil. Significant differences between variables were determined by Student-Newman-Keuls test. Correlation analysis was used to determine relationships between erodibility indices and hydro-physical properties of soils. Statistical analyses were performed using SPSS (2011).

Results

The change of average of the soil samples taken from two depth levels of soil profiles (0-10 cm and 10-20 cm and 0-20 cm) according to land cover was tested by

analysis of variance. The selected soil characteristics of Koruluk dam watershed soils are statistically different compared to land cover ($p < 0.05$ and $p < 0.001$) (*Tables 3, 4, 5*).

Different letters indicate significant differences ($p < 0.05$).

The soils collected from different land covers showed significant difference ($p < 0.001$) with respect to average SOM content open space areas had the highest content of soil (2.22%) followed by degraded oak forest (2.01%), while the level of SOM in degraded scotch pine forest was very low (1.30%) (*Table 5*).

There is no difference between land covers in terms of BD values. Degraded scotch pine forest soils have the highest average BD values (1.18 g/cm^3) in terms of BD average values (*Table 5*). Total porosity values of Koruluk dam watershed are statistically different according to land cover ($p < 0.001$). The average AS value is minimum in degraded scotch pine forest soils and maximum in degraded oak forest soils. AS values are statistically different according to land cover ($p < 0.001$). The highest silt content of soils presents in open space area soils (11.0%) and is different from degraded oak forest and degraded scotch pine forest soils. While open space area and degraded oak forests are in the same group in the average sand contents of soils, the habitats dominated by degraded scotch pine forests are different with the highest values. The lowest average sand content was found in open space areas. There are significant differences in the soil fractions by percentage among land covers ($p < 0.05$, $p < 0.001$). The clay content in environments in which degraded oak exists is higher than open

space area and degraded scotch pine forests, degraded oak forest soils are similar with open space area soils and different from degraded scotch pine forest soils. DR from erodibility indices is greater than the limit value of 15 in soils under every three land covers. The highest DR values were found in degraded scotch pine forest soils and also the soils under this land cover are susceptible to erosion. However, degraded scotch pine forest soils are more susceptible to erosion. The study area soils vary according to land cover in terms of average DR values (*Table 5*).

ER values of soils are greater than the limit value of 10 in areas under all land cover, and soils were observed to be more susceptible to erosion in terms of this erosion index value. The highest average ER value was found in degraded oak forest soils (*Table 5*). No statistical difference was found according to land cover types in terms of the average ER values of soils. Although there was no difference in soils taken from the surface layer, ER values of subsurface layer were statistically different. All land covers are susceptible to erosion because its C-MER values are lower than the limit value of 1.5. C-MER values are statistically different; and open space area soils are present in two groups as separately with degraded scotch pine forest soils and degraded oak forest soils (*Table 5*). DR values are at the highest level in degraded scotch pine forest soils with the lowest clay+silt amounts (%17.5), and at the lowest level in open space area soils with high clay+silt amounts (%22.7) (*Table 5*).

Different letters indicate significant differences ($p < 0.05$).

Relationships between some soil properties of 0-20 cm depths as the average of two depths (0-20 cm, 10-20 cm) and hydro-physical characteristics were tested by correlation analysis. In the correlation analysis carried out among soil properties selected in the study area which was susceptible to erosion, significant positive relationships were observed between SSI values and soil pH, SOM, C-MER, silt and clay amounts, and significant negative relationships were observed between DR, ER, BD and sand amounts (*Table 6*).

Statistically significant and important relationships were found between the aggregate stabilities of the study area soils and some soil characteristics (*Table 6*). There are positive correlations between AS values of the soils and C-MER, SSI, pH, SOM, Clay and FC values; and there are negative correlations between DR, ER, BD, sand values.

Discussion

SOM values of open space areas and degraded oak forest top soils are higher than degraded scotch pine forest. SOM values in open space areas and degraded oak forests are statistically similar and different from degraded scotch pine forest soils ($p < 0.001$). In degraded oak forests, while SOM values showed a decrease of approximately 37% in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_72137229
© 2018, ALÖKI Kft., Budapest, Hungary

subsurface layer compared to surface layer, there is a decrease of 19% in degraded scotch pine forests. This decrease in the value of the SOM will reduce erosion resistance (Wu and Tiessen, 2002). DR, ER values of open space areas with high SOM content are lower, and SSI values are higher. The average FC and AWC are also high in open space area soils with high average of SOM content (*Table 4*). The easier weathering of meadow grass and annual plants in open space areas raised the SOM content compared to Oak and Scotch Pine litters. Increased SOM improves aggregation, water-holding capacity, nutrient-retention capacity and ion exchange capacity in soils. SOM is one of the most important factors that determine the soil structural properties (Abdollahi et al., 2014), an important criterion in terms of susceptibility to erosion (Boix-Fayos et al., 1998; Marti et al., 2001; Castro et al., 2002; Sarah, 2005; Le Bissonnais et al., 2007). The presence of SOM by 2% is an important threshold in terms of soil erosion due to AS (Oades, 1988; Cerda, 1996). Indeed, organic matter content of 60% of soil samples which is the subject of the research is lower than 2%, and the aggregate stability of this land is relatively low. Therefore, it can be said that watershed soils are quite susceptible to erosion.

Open space area and degraded scotch pine forest soils are similar in terms of soil reaction and more acidic than degraded oak forest soils. This situation may have emerged as a result of further leaching of open space area and degraded scotch pine forest soils. This will be understood when soil pH at surface layer and subsurface are compared (*Tables 3, 4,* and *5*). Reasonably higher pH of the degraded scotch pine forests was primarily due to presence of base cations (Ca^{++}, Mg^{++}, K^{+} and Na^{+}) associated in the soils. The fact that the oak litter had a slightly acid character and that the clay colloids in the soil (the average clay content is higher in degraded oak forest soils) adsorbed the base cations affected the high soil pH in degraded oak forests compared to other lands. Because the potential evaporation in the region is higher than the amount of rainfall, the water entering the soil during rainy season moves downwardly for a while (*Table 1*). With the start of the arid period, the deep water moves the dissolved salts to topsoil layers by evaporating and can increase the pH of the topsoil. This is even more evident in degraded oak forests where the average land slope and altitude are low. Acidity increases in the top layer in open space area soils as a result of root respiration of intense herbaceous plants. Soil pH is lower in degraded scotch pine forest soils due to acidic origin litter compared to degraded oak forest soils.

Although soil texture is not as effective as SOM on AS (Tisdall and Oades, 1982; Metzger et al., 1987; Roberson and Firestone, 1991; Canton et al., 2009), the clay fraction of soil is an important criterion on the aggregate strength (Balcı, 1996) and has a considerable impact on erosion trends. Clay content of the soils checks the structural stability of the soil (Gollany et al., 1991; Payne, 1992). In case of a decrease of structural stability and structural strength of the soil, soils undergo physical degradation (Sahani and Behera, 2001). The average clay content of Koruluk dam watershed are in degraded scotch pine forest, open space areas and degraded oak forest soils, respectively, including 9.6%, 11.6% and 13.2%. It is reported that land cover is effective on the clay content (Okatan et al., 2010; Yılmaz et al., 2015) and that the soils with clay content ranging between 9-30% are more susceptible to erosion (Nkana and Tonye, 2003). The clay content of the majority of soils in the research area remains in these ranges (2.7–36.0%), and soils under all land covers were found to be susceptible to erosion. All land covers showed more clay in the lower depth (10-20 cm) compared to the upper soil. While passing from top depth to lower depth, clay content increased in degraded oak forests by 20% and in open space areas by 35% (*Tables 3* and *4*). It decreased in degraded scotch pine forest by about 8%. The increase in clay content in open space area and degraded oak forests and decrease in degraded scotch pine forest when going down from land cover on the same parent material and the same aspect to the lower depth levels in soil profiles can be explained in two ways. Firstly, litter decomposition is slow as the average altitude of degraded scotch pine forests is higher. In this case, lesser amount of water can enter the soil, and the movement of fine material in the soil could not take place. Second one is the decrease of decomposition reactions in the soil depending on the altitude as going down to soil depths. In open space areas and degraded oak forests, the presence of a layer that can transmit the soil by absorbing water that can reach on the soil especially in winter and spring seasons with abundant precipitation allowed the movement of clay from top soil to the lower soil in these areas, even if just a bit. Again, in the areas on these two land covers, SOM amount in the topsoil facilitated the movement of clay to sub soils by increasing soil permeability. The fact that the slope degrees of degraded oak forests and open space

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_72137229
© 2018, ALÖKI Kft., Budapest, Hungary

areas are less than degraded scotch pine forests is effective in increasing the amount of water that can enter into soil.

In semi-arid and arid regions with low degree of coverage of the vegetation such as the research area, soil erosion trends can significantly be affected by physiographic-topographical features which are effective in the formation and development of soil, and the land cover. Within the scope of the study, the erosion trend values of soils developing under similar climatic conditions in the same parent material were found to be different. Probably, these differences resulted from the factors such as land cover type, altitude and land slope degree. These factors changed the other soil characteristics such as pore volume, BD and AS of the soil due to the mechanical composition of the soil. Pore size distribution and connectivity together with BD, aggregation and AS is important soil property that can be to a great extent influenced by the land degradation and soil erosion.

Degraded scotch pine forest soils had higher BD than the adjacent soils under degraded oak forests and open space areas for the average of two different depths. BD was generally higher in subsurface than surface soils (*Table 5*). This situation is more obvious in soil profiles taken from open space areas and degraded oak forests. A decrease occurred in BD with the accumulation of clay moved from top soil in sub soil horizons (10-20 cm). In degraded scotch pine forests, the BD remained approximately same as there was no significant change between the clay and silt content, amount of SOM, total porosity of the top soils with sub soils.

Many researchers reported that there are strong relationships between BD of soil and SOM content (Aşkın and Özdemir, 2003; Morisada et al., 2004; Leifeld et al., 2005; Perie and Ouimet, 2008). Curtis and Post (1964) stated a negatif correlation between SOM and BD. Sharma and Qahar (1989) and Gupta et al. (2010) determined the strongest correlation between BDs and SOM among the data attained from the analysis results. We obtained similar results with strong negative correlation ($r = -0.757$, $p < 0.001$) between SOM and BD of soil samples. In the research area, it was observed that DR, ER values were high, SSI, AS and C-MER values were lower in degraded scotch pine forest where SOM content was low, and BD was high. The increase in BD values increased the erosion sensitivity indices and decreased the endurance indices. Significant positive relationships were observed between BD values and DR and ER values as $r = 0.630$, $p < 0.001$ and $r = 638$, $p < 0.001$, respectively. Chaudhari et al. (2013) determined strong positive relationships in BD values and DR and ER values in their study ($r = 0.792$, $p < 0.001$ and $r = 0.663$, $p < 0.001$). Along with the increase of BD of soil, SSI, AS, C-MER and TP values decreased, and this decrease was statistically significant (*Table 6*).

The total porosity of degraded scotch pine forest soils that was more susceptible to erosion remained the lowest. Water erosion and soil loss are expected to be less in open space area and degraded oak forest soils with high pore volume, and soil losses are expected to be more in degraded scotch pine forest soils with low pore volume. The low total porosity and low amounts of organic material of degraded scotch pine forest top soils (0-10 cm) may increase soil loss. The highest pore volume values were found in open space area soils where the average SOM is high. Dense rooting system of the open space areas grasses may account for the difference in TP of the 10–20 cm layer between the degraded scotch pine forest, degraded oak forest and open space areas soils. Vegetation increases SOM, TP, and reduces BD and soil erodibility (Igwe, 2003). In

© 2018, ALÖKI Kft., Budapest, Hungary

open space areas soils, high total porosity and amounts of SOM could reduce soil erosion by facilitating the entry of water into the soil with infiltration.

The main soil characteristics of soils affecting the aggregate stabilities are soil texture, clay mineralogy, SOM content, type and concentration of cations and sesquioxide contents (Le Bissonnais, 1996). However, general soil properties most closely correlated with soil AS are the contents of clay and SOM (Canasveras et al., 2010; Jozefaciuk and Czachor, 2014; Waruru et al., 2016). Clay particles are considered as cementing agents for aggregation because of their high specific surface area, cation exchange capacity, and consequently, high physical and chemical activity. SOM content can affect soil structure as well as soil AS various ways (Besalatpour et al., 2013). The topography and vegetation characteristics indirectly affect the aggregate stability (Canton et al., 2009). Furthermore, slope and aspect may influence the rate of weathering and erodibility of soils and thus soil aggregate stability (Bronick and Lal, 2005). The study area soils are susceptible to erosion under all land covers, and the erosion trends of open space area soils are lower in terms of DR, ER, WDC values. The average AS values were observed to be 49.6% in open space area soils, and the erosion trend values were higher in open space area soils and were 55.6% in degraded oak forest soils.

In other words, it is remarkable that the aggregate stability of degraded oak forest soils with higher erosion potential in terms of some parameters than open space area soils was found to be higher. It is thought that the fact that soil reaction (soil pH) was higher in degraded oak forest soils influenced high AS values. The increase in soil reaction decreases the clay dispersion (Amezketa and Araqües, 1995; Lipiec et al., 2018), therefore, increases the aggregate stability. The main factors affecting the clay dispersion and clay clotting in the soil are the electrolyte concentration (EC), solution pH and sodium adsorption ratio (Shainberg and Letey, 1984; Suarez et al., 1984). Low electrolyte concentrations increase the clay dispersion and adversely affect the soil structure. It is well known that low electrolyte concentrations have adverse effects on hydraulic conductivity and infiltration ratio (Shainberg et al., 1987; Quirk, 1986; Abu-Sharar et al., 1987; Shainberg and Singer, 1990; Rengasamy and Olsson, 1991). The fact that the electrical conductivity values, a measure of the electrolyte concentration in soil solution, are maximum in degraded oak forest soils have an effect on high average aggregate stability values in these soils. When *Tables 2, 3* and *4* are analyzed, it can be seen that the average SSI values of degraded oak forest soils with the highest average AS values are high.

The erosion trends values of soils vary depending on the soil's mechanical composition, infiltration capacity, the soil structure and the organic and chemical characteristics of the soil (Wishmeier and Smith, 1978; Canga, 1998). Texture is an important factor affecting erodibility values, but structure, SOM, and permeability also contribute (Mitchell and Bubenzer, 1980; Goldman et al., 1986). The change of sand, silt and clay fractions ratios forming the mechanical composition of the soils is very important because it changes the erosion trend values of the soils. High amount of sand and low amount of silt and clay increase the erosion trends of soils (Yılmaz et al., 2015). There are positive correlations between erosion trend values and the coarse fractions in the soil (Korkanç, 2003; Erol, 2004; Koiter et al., 2017). Soils under all land cover are susceptible to erosion in terms of DR, ER and C-MER values (*Tables 3, 4 and 5*).

The clay+silt amounts of soils affect the erosion resistance since they are effective on SOM and water holding capacity. DR, one of the most important erodibility indicators, varies between 13.1 and 71.7. There are studies in which the DR values change between 13-69 (Igwe, 2003) and 26-95 (Korkanç, 2003).

Results of this study indicated that dispersion ratios varied according to the land cover ($p < 0.05$). Soils of the open space area had a smaller and significant DR than rest of the soils developed from the other land covers, which had statistically similar values. On the other hand, having DR on greater than %15, all land covers produced soils susceptible to water erosion.

In addition to these erodibility indices, SSI values are also used for the structural stability of soils. SSI values is an indicator of stable soil aggregates and thus higher SSI values, better will be the soil structure and higher will be the stable soil aggregates (Rudramurty et al., 2007). Structural stability has been used to evaluate the sensitivity of soils to erosion (Darboux and Le Bissonnais, 2006). The soils with the structural stability value of less than 40% are classified as strongly erodible soils, and the soils with higher structural stability value are classified as moderately erodible soils (Leo, 1963). Based on these erosion indices values, the study area soils are in the strongly erodible soils. SSI value is maximum in open space area soils by 15.43 and minimum in degraded scotch pine forest soils by 10.54. SSI values were found to be statistically different according to land covers. Open space area and degraded oak forest soils are similar, and degraded scotch pine forest soils are different (*Tables 3, 4* and *5*). It is well established that addition of SOM can not only reduce BD and increase water holding capacity and soil structure stability (Mikha et al., 2006). The fact that the structural stability index values of soils were found to be very low may be due to the low organic matter and clay content of the soil. SOM and clay content are the main abiotic binding agents in the formation and stabilization of aggregates (Tisdall and Oades, 1982; Chenu et al., 2000; Duchicela et al., 2012; Portella et al., 2012; Carrizo et al., 2015). The SOM of 60% of study area soils were found to be lower than 2%. These low values in SOM may adversely affect the AS. Kay and Angers (Kay and Angers, 1999) stated that a minimum of 2% SOC was necessary to maintain SSI and observed that if SOC content was between 1.2-1.5%, stability declined rapidly. In case of higher amounts of SOM, an increase can be expected in the SSI. Boix-Fayos et al. (2001) showed that a threshold of 3-3.5% SOC had to be attained to achieve increases in AS; no effects on AS were observed in soils below this threshold.

The clay contents of the soil are considered to be more effective on the increase or decrease of structural stability index in soils with higher amount of organic matter than this threshold value. In the studies carried out by Yılmaz et al. (2015, 2008), the structure stability indices of the soils with clay amount ranging from 8.5% to 15.7% varied between 14.5 and 25, the structure stability indices of the soils with clay amount ranging from 40.6% to 47.8% varied between 41.0 and 50.9. It is reported that SSI values of the soils of different land covers with average amount of clay ranging from 17.8% to 22.9% vary between 22.3 and 29.3 (Yılmaz et al., 2008).

Conclusions

The land cover has been destroyed in Koruluk dam watershed which was built to meet the irrigation water needs of the local community on Ceviz stream (Gümüşhane-Şiran). It was determined that degraded oak forest, degraded scotch pine forests and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

open space areas were susceptible to erosion in sub watershed close to the dam reservoir.

In all study area, watershed lands are faced with effective erosion because they lack the protective vegetation cover. Active erosion in watershed lands threatens the economic life of dam reservoir and surrounding irrigation reservoirs. Protective vegetation cover should be created in areas close dam reservoir and residential areas by means of performing afforestation with the types such as rose hip and mayflower that will yield money for the local people and with oak in higher altitudes, and by grassing open spaces with appropriate types (such as *Trifolium repense, Trifolium pratense, Dactylis glomerata, Festuca drymeja, Onobrychis sativa, Lolium perenne, Lotus corniculatus and Bromus inermis*). If lands susceptible to erosion in the dam watershed are not restored with a continuous vegetation cover, dam reservoirs will complete their economic life in a shorter time due to the soil erosion that will occur. This study scientifically revealed that natural vegetation has significant effects on local water, soil conservation and ecological restoration management in a semi-arid ecosystem.

Further research is needed to determine the degree of improvement that vegetation can play an important role on soil porosity, bulk density, soil infiltration, soil structural properties (structural and aggregate stability) and soil erodibility indices. In this study area, the relationship between the function and the structure of the artificial vegetation should also be one of the focus points of future research.

Abstract. Volunteer rice is a global problem in rice production, especially conservation tillage. Here volunteer rice from four rice cultivars viz. *Xiangyaxiangzhan*, *Meixiangzhan*, *Changnongjing 1* and *Yliangyou1173* was treated with different flooding treatments. Two weeks of water flooding were applied at four depths: 2.0-2.5 cm (F1), 3.0-3.5 cm (F2), 4.5-5 cm (F3) and 6.0-6.5 cm (F4). A control was set by maintaining the soil wet as normal farmer practice of this region. It was found volunteer rice germination was more reduced with increased submergence levels, while treatments F3 and F4 both decreased the germination index and germination energy greatly for all rice varieties. Flooding treatments also reduced the seedling rate and inhibited the growth of volunteer seedling. Treatments F3 and F4 decreased seedling rates of *Changnongjing 1* and *F2 generation of Yliangyou1173* to zero, while the flooding treatment induced the malonaldehyde accumulation and altered the activities of peroxidase, superoxide and catalase in seedlings for all rice varieties. Hence, we suggest 2-week flooding at soil depth 6 cm after the harvest of early-season rice in South China in order to prevent the harvest loss in late-season rice caused by volunteer rice.
Keywords: *rice, flood, seed germination, rice seedling, anti-oxidative enzyme*

Introduction

Oryza sativa L. (Rice), one of the main crops and a staple food, contributes to 35%-75% of caloric intake by about 3 billion people worldwide. During the rice production, the primary considerations are the yield and grain quality, which can be affected by many factors, especially volunteer rice. As a common problem in paddy field, volunteer rice emerges from the previous crop (Gealy and Gressel, 2005; Warwick et. al., 2005; Street et al., 1995) because of shattered seeds or harvest loss. The severity of this global problem in rice production differs depending mostly on the region, cultivating measures and cultivars planted. Volunteer rice in temperate regions germinates either before winter (October-November) or in spring (April-May) (Sudianto et al., 2013). Seeds of volunteer plants could be harvested with the cultivated rice. The grains of volunteer rice from a different variety or plant type that matures earlier or later would reduce the overall milling quality (Singh et al., 2016a).

In tropics and subtropics, since volunteer rice germinates after the harvest, farmers take mechanical or chemical control measures to eliminate or lower the interference with the succeeding or ratooned rice. Volunteer rice is regarded as a weed phenologically and morphologically different from the planted cultivar and has lower yield and grain quality. Furthermore, volunteer rice from hybrid rice is a segregating plant that competes with crop and reduces grain yield and rice quality, thus decreasing the final productivity of paddy field and the overall level of grain quality. Thus, volunteer rice from conventional varieties is considered less influential than that from hybrid or weedy rice. Moreover, volunteer seeds from herbicide- resistant rice such as Clearfield rice^{TM} could even become the agent for resistant gene flow between rice cultivars and natural weedy rice by outcrossing (Shivrain et al., 2007; Gressel and Valverde, 2010; Gealy et al., 2003. Normally, less than 1% cross pollination happens between cultivars and weedy populations (Cao et al., 2006), but introgressed crop genes are able to persist in weedy population indefinitely (Ellstrand et al., 1999). Therefore, the outcrosses can promote the rise to weedy type population, which then competes with the rice cultivar and contaminates the rice, inducing economic losses.

In recent years, conservation tillage is increasingly recognized and accepted since tranditional tillage is faced by many limitations, such as poor soil structure and negative effect on soil organism. Organic farmers in Europe have great interest in conservation tillage (Peigné et al., 2018). There are many practices, including direct seeding without any tillage, or tillage at depth down to 15-20 cm. The rice root system and soil nitrogen can accumulate in the surface soil layer in zero-tillage compared with conventional tillage (Triplett and Dick, 2008; Huang et al., 2016). During rice production in China, zero-tillage has become increasingly popular for its benefits of saving fuel, labor and equipment and conserving soil (Huang et al., 2011). However, conservation tillage is still limited by many urgent problems, including volunteer rice. In South China, rice normally grows twice each year, in March (early season) and in July (late season) (Kong et al., 2017). In conservation tillage, the volunteer rice from early season easily germinates and seedlings in late season because the paddy fields are not ploughed. As a result, the volunteer plants would compete with the rice cultivar for nutrients and sunshine. Meanwhile, because of the commensalism between volunteer plants and the rice cultivar, the rice population becomes denser and prone to inducing various diseases and insect pests, which will complicate rice management and reduce the yield and grain quality of late season rice.

As reported, winter-flood reduced the germination rate of volunteer rice (Singh et al., 2016a), indicating flood treatment could be an effective means to deal with volunteer rice in double-cropping rice in South China. Under the hypothesis that flood treatment can reduce the germination of volunteer rice and the growth of volunteer seedlings, we conducted experiments in artificial weather boxes.

Materials and methods

Seed materials

Seeds from two fragrant rice cultivars (*Meixiangzhan*, *Xiangyaxiangzhan*), one japonica rice cultivar (*Changnongjing 1,* Yangtze University, Hubei, China) and the F2 generation of hybrid rice (*Yliangyou1173*) were used as the experimental

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_72317242
© 2018, ALÖKI Kft., Budapest, Hungary

materials (Those cultivars were well-known and widely grown in South China). Seeds of early season rice were collected from College of Agriculture, South China Agricultural University, Guangzhou, China. All seeds were obtained from the upper parts of panicle.

Flood treatment and growth conditions

Normally, there was about two weeks between the harvest of early season and transplantation of late season rice in South China. Hence, after sowing seeds into soil-containing plastic pots (100× 80 × 20 cm^3; 500 seeds in each pot), we began the 2-week flood treatments as follows:

CK: soil was contained wet without any water layer at soil surface.

F1, *F2*, F3, F4: 2.0-2.5, 3-3.5, 4.5-5, 6-6.5 cm water layer were maintained at soil surface, respectively.

After the treatments F1, F2, F3 and F4, the water layers were drained off and all the pots contained wet soil without any water layer for a week in order to determinate the seedling rate and some biochemical indicators. The temperature for germination and growth was 33 °C in the day and 27 °C at night under 1200X yellow light. The experimental soil was sandy loam containing 1.443% total nitrogen, 24.56% organic matter, 0.927% total phosphorous and 18.220% total potassium at pH 6.54.

Seed bioassay

After sowing, the germination of each treatment was observed daily for 7 days according to the Association of Official Seed Analysis (Wiesner, 1990). The number of days to reach 50% germination (T_{50}) was calculated by a devised method with modification (Farooq et al., 2013):

$$T50 = ti + \frac{\left(\frac{N}{2} - ni\right)(tj - ti)}{nj - ni}$$

where N is the final number of emerged seeds; n_i and n_j are the cumulative numbers of emerged seeds at time t_i and t_j respectively when $n_i < N/2 < n_j$.

Mean germination time (MGT) was calculated as follows (Ellis, 1981):

$$MGT = \Sigma Dn / \Sigma n$$

where n is the number of emerged seeds on day D, which is counted from the beginning of emergence.

Germination index (GI) was calculated according to the equation of Association of Official Seed Analysis:

$$GI = \frac{\text{No. of emerged seeds}}{\text{Days of first count}} + \ldots\ldots + \frac{\text{No. of emerged seeds}}{\text{Days of final count}}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_72317242
© 2018, ALÖKI Kft., Budapest, Hungary

The energy of germination (*GE*) was observed on the 3rd day after sowing. This percentage of germinating seeds 3 d after sowing is relative to the total number of seeds tested (Ruan et al., 2002).

The radicle and plumule lengths of twenty seedlings randomly selected from each experimental unit were measured 7 d after sowing. Three weeks after sowing, seedling rate was recorded while 30 seedlings randomly selected from each experimental unit were measured for fresh weight and then oven-dried at 80 °C for 48 h to determine the dry biomass.

Biochemical analyses

After malonaldehyde (MDA) reacted with thiobarbital acid, absorbance of solutions was recorded at 532, 600, and 450 nm. The MDA content (μmol/L) was determined as = 6.45(OD532 −OD600) − 0.56OD450 (Pan, 2013), and final result was expressed as μmol/g FW.

The superoxide (SOD, EC 1.15.1.1) activity was detected according to Zhang (Zhang et al., 2008). The reaction mixture contained 1.75 ml of sodium phosphate buffer (SPB, pH 7.8), 0.3 ml of 130 $mM \cdot l^{-1}$ methionine buffer, 0.3 ml of 750 $\mu mol \cdot l^{-1}$ nitroblue tetrazolium (NBT) buffer, 0.3 ml of 100 $\mu mol \cdot l^{-1}$ ethylene diamine tetraacetic acid disodium (EDTA-Na_2) buffer, 0.3 ml of 20 $\mu mol \cdot l^{-1}$ lactoflavin and 0.05 ml of enzyme extract. The color change was measured at 560 nm after the reaction. One unit of activity was equal to the volume of extract needed to inhibit 50% of the color reaction. The peroxidase (POD EC1.11.1.7) activity was examined according to Yu (Xia et al., 2009). Enzyme extract (50 μl) was added to the reaction solution which contained 1 ml of 0.3% H_2O_2, 0.95 ml of 0.2% guaiacol, and 1 ml of 50 $mM \cdot l^{-1}$ SPB (pH 7.0). The absorbance was read at 470 nm. One unit of POD activity was expressed as the absorbance increase because of guaiacol oxidation by 0.01 (U/g FW). Catalase (CAT, EC 1.11.1.6) activity was measured according to Aebi (1984). An aliquot of enzyme extract (50 μl) was added to the reaction solution containing 1 ml of 0.3% H_2O_2 and 1.95 ml of SPB and, the absorbance was recorded at 240 nm. One unit of CAT activity was expressed as the absorbance decrease by 0.01 (U/g FW).

Statistical analyses

Data were analyzed using Statistix 8.1 (Analytical Software, Tallahassee, FL, USA) while differences among means were separated by using least significant difference (LSD) test at the 5% probability level. Graphical representation was conducted via Sigma Plot 14.0 (Systat Software Inc., California, USA).

Results

Germination rate

Flooding treatment significantly affected the emergence of volunteer rice. The germination of seeds started after 3 days in both treatments F3 and F4 for all rice varieties (*Fig. 1*). For *Xiangyaxiangzhan*, the speeds of germination were not significantly different among treatments CK, F1 and F2, but were significantly slowed down after treatments F3 and F4. Similar trend was found in *Meixiangzhan*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_72317242
© 2018, ALÖKI Kft., Budapest, Hungary

For both *Changnongjing 1* and *F2 generation of Yliangyou1173*, the trend of speed germination was recorded as: CK > F1 > F2 > F3 > F4.

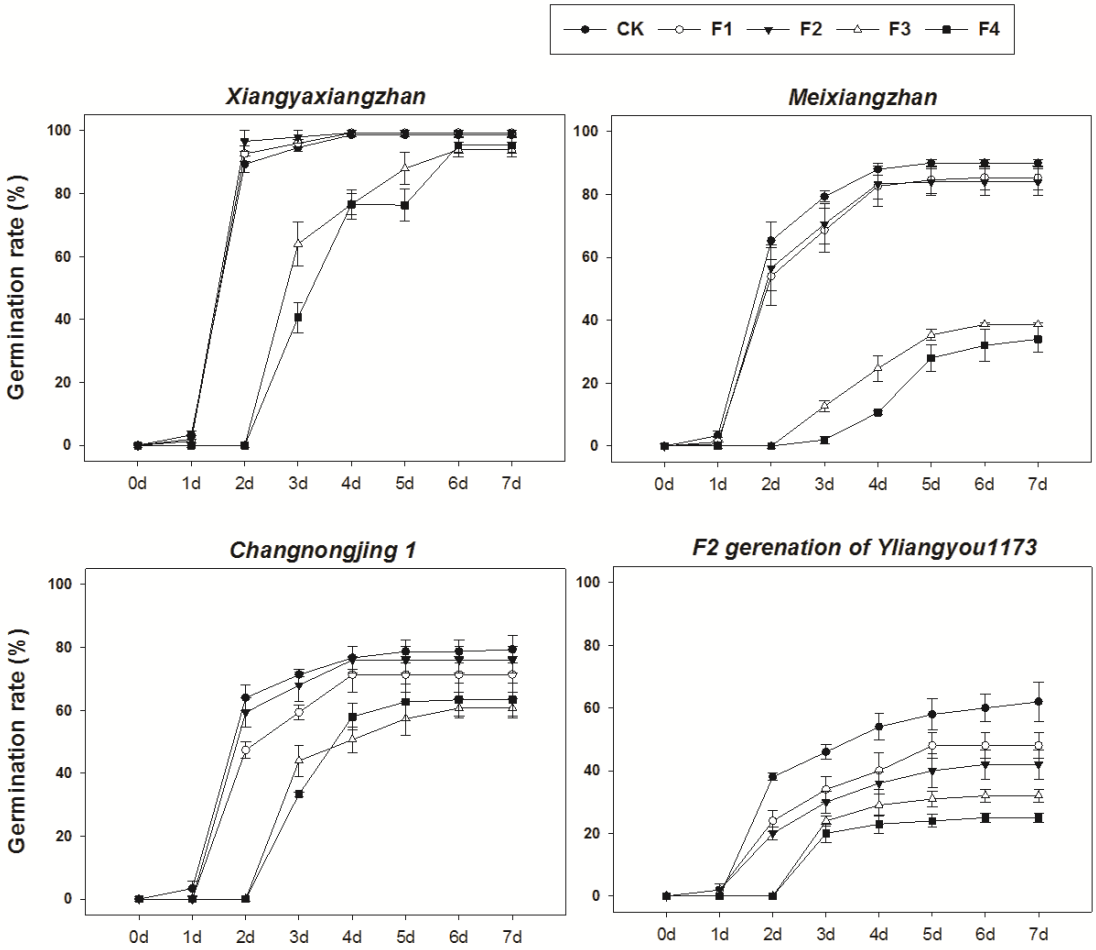

Figure 1. *Effects of flood treatments on germination rate of volunteer rice*

Emergence attributes

Flooding treatments influenced germination vigor significantly (*Table 1*). Treatments F3 and F4 both decreased the GI, GE, lengths of radicle and plumule, but increased the MGT and T_{50} significantly for all rice varieties. For *Xiangyaxiangzhan*, GIs in F3 and F4 declined by 43.56% and 47.72%, respectively, and GEs in F3 and F4 decreased by 22.29% and 22.37%, respectively, compared with CK. For *Meixiangzhan*, the lowest GI, GE and FGP were found in F4; Compared with CK, GIs in F3 and F4 decreased by 77.42% and 85.32%, respectively, while 71.97% and 87.88% lower were recorded in F3 and F4, respectively. For *Changnongjing 1*, no significant difference between treatments F3 and F4 was found in GI, GE or FGP, while GI, GE and FGP significantly all declined in F3 and F4. For *F2 generation of Yliangyou1173*, the changing trend of GI, GE and FGP was recorded as: CK > F1 > F2 > F3 > F4, while F3 and F4 prolonged MGT and T_{50} significantly. Furthermore, F1 and F2 treatments did not significantly affect FGP for *Xiangyaxiangzhan*, *Meixiangzhan* or *Changnongjing 1* whilst both F3 and F4 decreased the lengths of radicle and plumule for all 4 varieties compared with CK.

Seedling quality

Flooding treatments reduced the seedling quality of volunteer rice significantly. The trend of seedling rate was recorded as: CK > F1 > F2 > F3 > F4 for both *Xiangyaxiangzhan* and *Meixiangzhan* (*Table 2*). In treatments F1 and F2 compared with CK, seedling rate was 81.51% and 81.94% lower in *Changnongjing 1*, respectively, while 43.55 and 57.98 lower in *F2 generation of Yliangyou1173*, respectively. No seed could grow or develop into a whole seedling in F3 or F4 for either *Changnongjing 1* or *F2 generation of Yliangyou1173*. Moreover, dry weights were 5.2%, 10.09%, 45.15% and 39.58% lower in F1, F2, F3 and F4 respectively for *Xiangyaxiangzhan*, respectively. For *Meixiangzhan*, the trend of dry weight was recorded as: CK > F1 > F2 > F3 > F4. Both F1 and F2 decreased the dry weight in *Changnongjing 1* and *F2 generation of Yliangyou1173*.

MDA contents and anti-oxidant responses of seedlings

Flooding treatments influenced the anti-oxidative activities in terms of POD, SOD and CAT, and caused oxidative damage by increasing lipid per-oxidation (MDA content). For *Xiangxiangzhan*, MDA contents in F1, F2, F3 and F4 were 19.39%, 10.20%, 36.73% and 64.29% higher, respectively. POD and CAT activities in F1 and F2 all were higher than CK while lower in F3 and F4. Similar discussion was found in *Meixiangzhan*. For *Meixiangzhan*, MDA contents were 12.33, 11.53, 37.09 and 85.11% higher in F1, F2, F3 and F4, respectively. Highest and lowest SOD activity were recorded in F2 and F4, respectively. For *Changnongjing 1* and *F2 generation of Yliangyou1173*, both F1 and F2 treatments reduced the activities of POD, SOD and CAT while promoting the production of MDA (*Table 3*).

Correlation analysis

Seedling rate was significantly and positively correlated with dry weight, POD, SOD, CAT, GI, GE, and FGP (*Table 4*). Significant positive correlations were also observed among GI, GE and FGP, but negative correlations were found between MDA and seedling rate and between T_{50} and FGP.

Table 4. *Relationship between seedling rate, anti-oxidant responses and seed bioassay*

Discussion

Volunteer rice is a global problem of rice production, especially in conservation tillage. In the United States, areas of rice growing normally begin to be flooded from early autumn after the rice harvest until the tillage operations in spring (Fogliatto et al., 2010) because anaerobic environment could limit the germination and growth of abundant weeds such as weedy rice (Bird et al., 2002). The present study confirms this view by showing the decline of emergence properties of volunteer rice in flooding treatments. Specifically, the germination speed slowed as the water layer increased, especially F3 and F4. Once the water layer was over 4.5 cm, the time to start germination was extended and the quantity of eventually germinated volunteer rice was weakened. Flooding treatment significantly altered the germination characteristics of volunteer rice. Since the seed germination and seedling establishment phase is highly vulnerable to injury, disease and stress, we believe this phase is a key time period to prevent harvest loss caused by volunteer rice. Germination vigor is driven by the ability of plant embryos, embedded in seeds, to resume the metabolic activity in a coordinated and sequential manner (Rajjou et al., 2012). The germination vigor can be evaluated using many indexes. We observed that as water layer rose in flooding treatments, MGT and T_{50} were prolonged for most rice varieties while the GI and GE reduced. Both F4 and F3 significantly influenced volunteer rice germination by minimizing the germination rate, and drastically declined both radicle and plumule lengths for all rice varieties. These results agreed with Prakash (Rajjou et al., 2012) who found rice germination was further reduced with the rise of submergence levels. In addition, the volunteer rice from *Xiangyaxiangzhan* was strongly tolerant against submergence. The FGPs in F1, F2, F3 and F4 were all not significantly different from those in CK. Thus,

Xiangyaxiangzhan might be one of the tolerant genotypes against flooding stress. The flooding tolerance during germination is a complicated process involving many mechanisms. Ismail already identified several genotypes with higher flooding tolerance during germination (Ismail et al., 2009). However, the submergence tolerance during germination is associated with the flooding tolerance during the vegetative stage, as reported in the sensitivity of FR13A, a landrace that is most tolerant of complete inundation during this stage (Ella et al., 2003; Jackson and Ram, 2003).

We also noticed flooding treatment greatly reduced seedling rate and dry matter weight. As reported similarly, flooding treatments decreased root, shoot and total dry matter production in all rice cultivars and with more reduction in higher than lower flooding levels (5 vs. 1 cm) (Prakash et al., 2016a). These results indicate the seeds of volunteer rice even under the flooding environment could germinate successfully, but the chance of developing into whole normal seedlings was very low, which was greatly embodied by the zero seedling rates of both *Changnongjing 1* and *F2 generation of Yliangyou1173* in treatments F3 and F4. After 3 weeks of treatment, MDA production in volunteer seedlings was enhanced with the increasing submergence level. The MDA over-accumulation might be attributed to oxidation of polyunsaturated fatty acids (e.g., lineolenic acids, galacto- and phosphp-lipid components), which are critical in the functional and structural characteristics of thylakoid membranes and the arrangement of reaction centers of photosystems (Elshintinawy, 2000). MDA also reacts with free amino acids to even form ethylene in cellular membranes (Rakwal et al., 2003; Jiang and Zhang, 2002). Thus, MDA accumulation is a key indicator of oxidative stress, which is characteristic of intercellular and intracellular membranes and hence intensifies the ion leakage through cell membranes (Dash and Mohanty, 2002). In this study, the improvement of MDA content meant flooding treatment caused submergence stress and some oxidative damage to volunteer seedlings. Furthermore, the anti-oxidative enzymatic activities all differed maong the flooding conditions. Anti-oxidant plays an important role in quenching reactive oxygen species. For example, when superoxide radicals accumulate in organisms, SOD is responsible for breakdown and then POD and CAT are involved in scavenging H_2O_2 (Sairam et al., 2000). In the present study, treatments F1 and F2 both enhanced the activities of POD, SOD and CAT for both *Xiangyaxiangzhan* and *Meixiangzhan*, whilst F3 and F4 greatly decreased the anti-oxidative enzymatic activities. The main reason might be that lower flooding level (1.5-3.5 cm) already caused oxidative stress to rice seedlings, but the damage could be mitigated by the anti-oxidant regulation of seedlings. Thus volunteer seedlings under lower submergence level would activate the anti-oxidation mechanism in order to prevent the oxidant damage caused by flooding stress. However, under higher flooding level (4.5-6.5 cm), the submergence stress during germination and seedling development already caused irreversible damage and even destroyed the anti-oxidative system, so that the POD, SOD and CAT activities decreased while the MDA content increased greatly. Moreover, *Changnongjing 1* and *F2 generation of Yliangyou1173* were sensitive to flooding stress so that the anti-oxidative enzymatic activities declined in F1 and F2.

Conclusion

In conclusion, long-term (2 weeks) flooding treatment significantly limited or even prevented the germination and growth of volunteer rice, while treatment F4 (6.0-6.5 cm)

was the most effective because of the lowest seedling rate. In order to prevent the harvest loss in late season rice caused by volunteer rice and further investigation should be at the field trials, the possible effects of flooding on the late-season rice production should be studied before the real application.

(Received 8th Aug 2018; accepted 5th Oct 2018)

Abstract. Effects of pre-harvest calcium chloride and post-harvest UV-C (200–280 nm ultraviolet light) treatments on pepper fruits (*Capsicum annuum* L. cv. Mertcan F1) were investigated in this study. Calcium treatments usually delay softening in horticultural crops. UV-C treatments prevent decay on fruit surface. However, instead of these physical attributes, changes in the chemical composition of fruit were investigated in this study. Experimental treatments were arranged as control (without any treatments), UV-C, Ca and Ca + UV-C. Treated fruits were stored in a cold storage at 0 °C and 95% relative humidity for 10 days. Samples were taken in every 2 days of the storage and pH, titratable acidity (TA), soluble solids content (SSC), color change, total phenolic content (TPC) and total antioxidant capacity (TAC) were determined. All experimental treatments all increased SSC, titratable acidity, total phenolic content and total antioxidant capacity. Particularly, treatments containing Ca yielded the greatest increases in SSC and titratable acidity. UV-C + Ca treatment preserved the color intensity (chroma - C) the best (32.85). Total phenolic content and total antioxidant capacity had the least change with UV-C treatment. UV-C + Ca was recommended as the best treatment keeping quality attributes of 'cv. Mertcan F1' pepper throughout the cold storage for 10 days. Such 10-day extension is a significant criterion for pepper storage and marketing.
Keywords: *Capsicum annuum L., antioxidant, total phenolic content, postharvest*

Introduction

Turkey has ecologically quite available conditions for pepper farming. It is possible to grow peppers all year-long in Turkey. Annual productions, yield levels and quality attributes are all greater than world averages (Vural and et al., 2000; Gunay, 2005). Turkey produces 2,127,944 tons of pepper annually and such an amount constitutes about 7% of world production (32,324,345 tons). Following China and Mexico, Turkey has the third place in world pepper production (FAOSTAT, 2014). Despite high production volumes, deficiency in storage and packaging techniques causes significant losses in fresh peppers. As it is a quickly rotting product, storage and delivery to markets are vital issues for peppers (Erdogmus et al., 2015).

Pepper (*Capsicum annuum* L.) is originated from tropical and sub-tropical countries of America and it is an essential vegetable for healthy life. Fruits are quite rich in biological agents such as vitamins, antioxidants and other phytochemicals. Fruits are consumed in various ways; as fresh vegetable in salads, fried, cooked with meat or olive oil, as pepper paste, pickle and spice (Vural et al., 2000; Frank et al., 2005; Crosby, 2008). Peppers are also rich in antioxidants, ascorbic acid, carotenoid and vitamin E, thus used in prevention of some cancer cases, heart diseases and cardiovascular diseases (Simonne et al., 1997; Salk et al., 2008).

Peppers have non-climacteric fruits (Watkins, 2002) and thus they are not significantly influenced by post-harvest ethylene synthesis. Besides, fresh pepper fruits have quite high water contents shortening their shelf life and speeding up deteriorations. Especially when the pepper fruits were kept in room conditions, the physiological deterioration is most likely to be caused by water loss, congestion and wrinkles. Consumers prefer peppers with a firm and fresh appearance. Therefore, in order to maintain the quality of peppers, like other products, they must be kept in cold storages with high relative humidity and low temperatures. Fresh pepper fruits can be stored between 7 to 10 C° and 90-95% relative humidity for 1-3 weeks (Hardenburg et al., 1986; Snowdon, 1992). This time period can be extended up to 35-45 days by modified atmosphere packages (Rodov et al., 1995; Halloran et al., 2000; Demirdoven et al., 2006). Cold damage is the most important factor restricting the preservation of peppers in cold storages. Low temperatures below 7–10 C° cause softening, shrinkage, drying and pathological disorders in peppers, which severely reduce the quality and acceptability of the product (Mercier et al., 2001; Nyanjage et al., 2005).

Calcium facilitates calcium pectate formation on cell walls, thus increases fruit firmness. Such a case then facilitates the preservation of the product for a long period. Besides, as in many vegetables, calcium also prevents blossom-end rotting in peppers. Pre and post-harvest calcium treatments delay aging during the storage and marketing stages and these treatments do not have any negative effects on appearance (Lester and Grusak, 2000; Hernandez-Munoz, 2006; Chen et al., 2011). Ca treatments generally reduce respiration and metabolic activity in fruits. As a result, the breakdown of carbohydrates were delayed and increasing of soluble solids content (SSC) in peppers were decreased (Rao et al., 2011).

Erdogmus et al. (2015) reported that post-harvest application of 2% $CaCl_2$ to the 'cv. Yalova Yağlık 28' pepper at 0 C° and 90% relative humidity resulted in 11.6% weight loss after 30 days of storage and a decrease was the lowest as compared to the other applications. Rao et al. (2011) immersed fresh sweet 'Indra' peppers into 0.5, 1.0 and 1.5% calcium chloride solutions for 15 min and stored peppers at 10 °C and 25 °C for 18 days in polyethylene packages. Researchers reported that significant effects of 1.5% calcium chloride treatment on SSC, titratable acidity (TA) and pH ($p < 0.05$) and weight loss both during the storage and the shelf life. It was concluded that fruits could be stored for up to 71 days without significant losses in taste.

Ultraviolet-C (UV-C) is a technology commonly used in surface and water disinfection as well as in fruit juice pasteurization (Koutchma et al., 2016). Recent studies showed that UV-C light stimulated the formation of secondary metabolites when it was applied as an abiotic stressor to the plants (Alothman et al., 2009). UV-light treatments increased antioxidants and total phenolics of red peppers during the storage (Andrade-Cuvi, 2011; Perez-Ambrocio et al., 2018). Vicente et al. (2005) applied UV-C light to 'Zafiro' pepper with red color and stored peppers in a cold storage at 10 C° and 90% relative humidity for 18 days. The 7 kJm^{-2} UV-C treatments better preserved color parameters, carotenoid levels and fruit firmness and reduced decay rates, but did not affect the changes in SSC values. UV-C treatments had lower total phenolic content. Abbasi et al. (2015) applied UV-C (3 and 5 min at 254 nm), the edible coatings aleo gel, ginger oil and chitosan to 'Royal Wonder' bell pepper at different rates and stored treated fruits

© 2018, ALÖKI Kft., Budapest, Hungary

at 8-9 C° and 80-85% relative humidity for 24 days. Researchers reported that 5-min UV-C treatments better preserved fruit firmness, SSC, color parameters, ascorbic acid contents and titratable acidity. UV-C (short-wave ultraviolet radiation) is a chemical-free method and it provides longer-lasting, high-quality preservation of products by preventing or eliminating the development of pathogens.

This study investigated the effects of alternative environment-friendly methods (calcium and UV-C treatments) on preservation of quality attributes of fresh peppers throughout the cold storage. Shelf life of fresh peppers is quite short due to softening, water loss and decay. Extension of the shelf life for a few days is very important for the marketing of the product. Number of studies on calcium and UV-C treatments in peppers is quite limited. Thus, the primary objective of the present study was set as to extend shelf life of fresh peppers with calcium and UV-C treatments.

Materials and methods

Fruit material

The 'cv. Mertcan F1'(*Capsicum annum* L.) peppers used in this study were obtained from a producer farm in the Kazanlı distict in Mersin province, Turkey (36° 49' 14.5956" and 34° 45' 22.0536"), toward the end of the production period spanning October 2016 to January 2017. This pepper is a sweet and early type. It is cultivated in greenhouses at 40 cm × 50 cm spacing by fertilization and drip irrigation. Peppers were transported by air-conditioned vehicles to The Post-harvest Laboratory of Van Yuzuncu Yil University, Faculty of Agriculture, Department of Horticulture. Initially, pH, SSC, titratable acidity, color parameters, total phenolic content and total antioxidant capacity were measured before placing the peppers into cold storage.

Experimental plan

The pepper fruits to be used in experiments were packed due to the fact that it is cheap and lightweight in styrofoam packs of 0.5 kg, 30 fruits in each and 2 replications for each treatment, and then they were placed in cardboard boxes of 5 kg. Experimental treatments were arranged as; a-) Control, b-) UV-C, c-) Ca and d-) Ca+UV-C. For pre-harvest Ca treatments, 12.1% commercial calcium fertilizer (DRT speedfol calcium) was applied for 2 days and 1 hour per week at 500 cc/da rate of application.

UV-C was applied as specified by Vicente et al. (2005); 30 fruits were placed on a sterile plastic tray 30 cm below 4 sterile UV-C lamps (TUV G30T8, 30 W, Philips, Argentina) with 254 nm light emission and applied at 14 kJm^{-2}. In order to get better light during the application, the peppers were manually rotated around the surface three times. The radiation intensity was measured by a digital UV radiometer (Cole-Parmer Instrument Company, Vernon Hills, Ill.).

Fruits were stored at 0 °C and 95% relative humidity for 10 days and they were analyzed in every 2 days.

The SSC ratio was measured with a digital refractometer (Atago, Tokyo, Japan) and the results were expressed in Brix. Titratable acidity was measured as the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

quantity of 0.1 N NaOH solution consumed in titration until a pH values of 8.2 and the results were expressed as citric acid percentage. Fruit color changes were measured with a Minolta colormeter (Model CR-400; Osoka, Japan). L shows brightness (0 black, 100 white), 'a' shows green color change (60 green, +60 red), b bluish change (-60 blue, +60 yellow), C color intensity (low values indicate dark color) and h (hue) angle value (0 red-violet, 90 yellow, 180 blue-green, 270 blue).

In order to find the total phenolic content; 5 g fresh pepper tissue was extracted with 25 ml of 80% methanol and homogenized at medium speed in a homogenizer (Ika Ultra-Turrax T25 Basic, Germany) for 2 min. Then the mixture was kept in dark for 14-16 hours at 4 °C. Samples were filtered through filter papers and tubed. Samples were stored at -20 °C until the analyses. Total phenolic content was determined by a spectrophotometer (Varian Bio 100, Australia) in accordance with Swain and Hillis' method (1959), in which the Folin-Ciocaltaeu calorimetric method was modified. The absorbance of the samples in the spectrophotometer at wavelength of 725 nm was identified, and total phenolic content was expressed as Gallic acid equivalent (GAE) mg/100 g fresh weight (FW).

Antioxidant capacity specified by Benzie and Starin (1996), Ferric Reducing Antioxidant Power (FRAP), was used to determine the total antioxidant capacity. The absorbance of the samples in the spectrophotometer at a wavelength of 593 nm was identified and the total antioxidant capacity was expressed as μmol trolox equivalent (TE) / g FW.

Experimental data were subjected to variance analysis with SPSS 11.5 software in accordance with randomized sampling design. Means were compared with Duncan's multiple range test at $p < 0.05$. LSD (Least Significant Differences) test was used to analyze the differences between treatments and intervals.

Results and discussion

The titratable acidity values of the 'cv. Mertcan F1' pepper fruits increased slightly with Ca and post-harvest UV-C treatments during the 10-day storage period (*Table 1*). The effects of all treatments on TA were found to be insignificant ($p > 0.05$). It can also be stated that increase in TA and SSC was resulted from loss of water in fresh peppers in time. Despite the slight increases in TA, as stated by Rao et al. (2011), use of fruit organic acid in respiration slowed down the conversion of carbon dioxide and water. Parallel to present findings, Erdogmus et al. (2015) reported insignificant changes in 1% and 2% $CaCl_2$ – treated 'Yalova Yaglik 28' pepper fruits throughout the storage for 15 and 30 days at 7.5 °C with 90% relative humidity (RH). Likewise, Rao et al. (2011) found that 1.5% $CaCl_2$ treatments preserved TA of 'Indra' fresh sweet peppers during storage during 18 days at 10 °C and 25 °C shelf life as compared to the control fruits. Such slight changes in TA ensure that pepper taste could be preserved for a long time.

The pH values of 'cv. Mertcan F1' pepper fruits did not change much in the first 8 days of storage, while the values decreased in the last 2 days (*Table 1*). Similar to present study, Rao et al. (2011) applied calcium to peppers, Abbasi et al. (2015) applied UV-C to 'Royal Wonder' bell peppers and they both indicated insignificant effects of experimental treatments on pH values of the peppers

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

throughout the storage. In present study, slight increase in titratable acidity at the end of storage was effective in reducing the pH values.

The effects of treatments and storage periods on SSC ratios were also found to be insignificant ($p > 0.05$). There was a slight increase in SSC ratios in all treatments as compared to the initial values (*Table 1*). The UV-C applications of Vicente et al. (2005) to 'Zafiro' pepper and Abbasi et al. (2015) to 'Royal Wonder' bell pepper and $CaCl_2$ application of Rao et al. (2011) to 'Indra' sweet pepper preserved the SSC values as it was in present study. The SSC increase was high at the beginning due to water loss. With the progress of ripening throughout the storage, inherent sugar is used for respiration, thus increase in SSC slowed down toward to end of storage.

As compared to the initial values, color lightness (L*) values decreased in control and Ca treatments and brightness values increased in UV-C and Ca + UV-C treatments during the first 2 days and then decreased until the 4th day. At the end of the 10th day, the effects of all treatments on brightness was not found to be significant ($p > 0.05$). The change in brightness values was irregular in all treatments and they all had different results (*Table 1* and *Fig. 1*). Such changes in color parameters were attributed different maturity levels at harvest. Abbasi et al. (2015) reported that UV-C treatments did not have significant effects on L* values of 'Royal Wonder' bell pepper. In present study, despite fluctuations during cold storage, there was no significant change in the initial value of L* during the 10 days of storage. As indicated also by Abbasi et al. (2015), such insignificant effects of UV-C treatments were because of the chemical structure of the wax layer over the cuticle and its effects on the reflection of light.

Table 1. *Effects of Ca and UV-C treatments on pH, titratable acidity (TA), soluble solids content (SSC), pH, total phenolic content (TPC), total antioxidant capacity (TAC) and color parameters (L*, a*, b*, C and h^o) of pepper fruits stored at 0 °C and 90-95% relative humidity for 10 days*

The chroma (C*) values decreased in all treatments until the 6th day of storage, and then increased. At the end of the storage, the greatest chroma was observed in Ca treatments and the lowest value was observed in Ca + UV-C treatments with also the lowest initial chroma values. It can be stated based on present findings that Ca + UV treatments kept maturity going because had the least change and therefore in long-term pepper fruit storage, these treatments may be more effective than the other treatments. There is a decrease in h angle values in all treatments after the 6th day of storage (*Table 1* and *Fig. 1*). At the end of the 10-day storage, the lowest h angle value was obtained from Ca treatments and the greatest value was obtained from UV-C treatments. The effects of present treatments on a* values were not found to be significant ($p > 0.05$) throughout the storage period. Since a* values indicate the color change from green to red, control treatments were less effective than the other treatments. The effects of treatments on b* values were found to be significant only on 6th day of storage ($p < 0.05$) (*Table 1* and *Fig. 1*). Perez-Ambrocio et al. (2018) applied UV-C to Habanero chili pepper at various times and kept pepper fruits at 0 °C for 35 days. Contrary to present findings, researchers reported slightly increasing L* and a* values and decreasing b* values with UV-C treatments. Such differences were mainly resulted from differences in pepper types and harvest times.

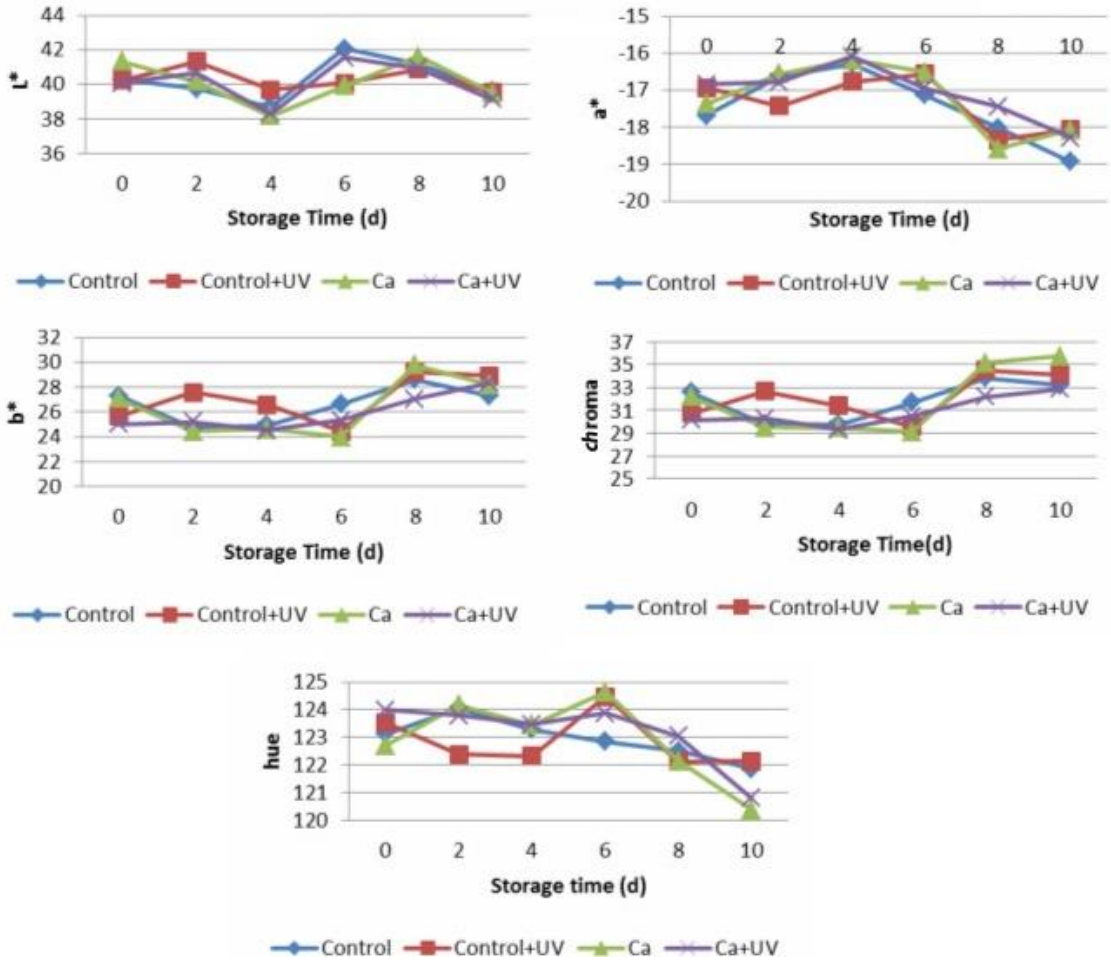

Figure 1. *Color parameters of pepper treated with Ca and UV-C light at the beginning and end of 10-day storage*

The effects of treatments and storage periods on total phenolic content and total antioxidant capacity of pepper were also not found to be significant ($p > 0.05$). In all treatments, a slight increase was observed in total phenolic content and total antioxidant capacity of the samples until the 6th day of storage, but afterwards a decrease was observed as compared to the initial values (*Table 1* and *Fig. 2*). Such an increase was an expected case as the physiological and pathological deterioration will increase with the prolongation of the cold storage period. Castro-Concha et al. (2014) investigated total phenolic content and antioxidant capacities of 'Habanero' (*Capsicum chinense*) peppers at different maturity levels and Perez-Ambrocio et al. (2018) applied UV-C to the same pepper cultivar for 0.5 and 3 min and both reported increased total phenolics and antioxidants. Such findings conflict with the present ones because of differences in pepper types and cultivation places. Researchers also indicated that 'Habanero' chili pepper had greater quantities of phenolics in research countries than in Mexico.

Conclusion

In general, Ca + UV-C treatments were found to be the most successful treatments for preservation of quality attributes throughout the cold storage. As compared to the initial values, Ca + UV-C treatments yielded the lowest changes in quality attributes after 10 days of storage. The Ca + UV-C treatments also reduced color changes and increased total phenolic content and total antioxidant capacity of the plants. Present findings revealed that UV-C treatments slowed the increase in total phenolic content and total antioxidant capacity. Therefore, it can be stated that Ca + UV-C treatments were quite effective in storage of peppers for longer periods and better quality.

As a result, since the post-harvest UV-C treatments do not contain any chemicals and pre-harvest Ca treatments have no adverse effect on human health, they can reliably be used in pepper storage for longer periods without significant losses in quality attributes.

Abstract. Climate smart agriculture is defined as a systematic and synergetic ingress for transformation and reorientation of agricultural development under constrained environment with climate risks. Enhanced plant productivity and reduced microbial respiratory C can potentially mitigate the rising of the atmospheric CO_2 however we are currently in shortfall of efficient routes to accomplish these objectives. Under future climate scenarios of exalted CO_2, rhizosphere microbes may serve important links in mediating plant productivity and soil C/N dynamics with optimization of root-soil interface mechanisms to achieve CSA goals. Study was undertaken to precisely quantify microbial biomass-carbon and microbial activity of rhizosphere region of cauliflower (*Brassica oleracea var. botrytis*) at two different agro-climatic zones. A native bacterial strain *Bacillus pumilus* isolated from cauliflower rhizosphere was employed that enhanced plant growth, nutrient uptake with improved soil nutrient status. Microbial biomass carbon (119.8 mg MB-C/ 100 g soil) was the highest with the application of *Bacillus pumilus* and 75% NP fertilizers at both locations. Moreover, the microbial activity was found to be the highest (0.18 mg CO_2/ g soil) with the same consortium up to 48 h and then followed a sudden decreasing trend. The results clearly suggest that *Bacillus pumilus* strains as bio-inoculants can be successfully employed for maintaining soil health being useful in context of climate smart agriculture goals.

Introduction

The hastily growing world population which is expected to be 8.9 billion by 2050 (UN, 2015), raised an alarming situation of increasing food demand. In a study done by Center for Study of Carbon Dioxide and Global Change revealed that about 70-100% increase in crop production is requisite to feed this consistently rising population (UN, 2015). Intensive farming, a tool of elevated yield however, promotes the use of chemical fertilizers and pesticides at peak levels with rapid existence of pests and diseases. When used frantically, these fertilizers and pesticides get accumulated in soil and in water leading to adverse impact on livestock and on human health, as well as on our ecosystem (Liu et al., 2012). Depletion of soil nutrients, diversification of croplands, genetic diversity and augmentation to global warming are the other well-known associated obstacles of intensive agriculture. Thus, considering long-term emphasis of soil quality and fertility there is an increasing interest in the use of climate smart agritechnology that can enhance crop yield as well as ensures sustainability and resilience (Hamilton et al., 2016). Climate smart agriculture (CSA) may be defined as a synergetic approach to transform and reorient agricultural development and security

under the horrified situation of climate change (Khatri-Chhetri et al., 2017). Sustainable productivity, enhanced resilience or adaptation and Green house gases (GHGs) mitigation are identified as the three interlinked pillars requisite to engender these agricultural food security goals. To achieve desired goals of food productivity, adaptation and GHG mitigation CSA approaches must involve the appropriate inclusion of beneficial bacteria. Revitalising soil quality is a major aspect of sustainable agriculture. Technologies like use of plant growth promoting microbes serves as a boon to crops with multifarious attributes. Despite of the restoration of soil fertility, rhizosphere microbes are lending with other perks such as stimulation of plant growth, boosting crop yield and resistance against diversified soil borne pathogens. Plant growth-promoting rhizobacteria (PGPR) can arouse plant growth by direct (fixation of nitrogen, solubilization of phosphorus etc.) or indirect (antibiosis, induction of systemic resistance etc.) mechanisms (Kaushal and Wani, 2016). Some of the common PGPR include genera *Acinetobacter, Alcaligenes, Arthrobacter, Azospirillum, Azotobacter, Bacillus pumilus, Beijerinckia, Burkholderia, Enterobacter, Erwinia, Flavobacterium, Rhizobium*, and *Serratia* (Anandaraj and Dinesh, 2008). Various studies have shown positive effects of PGPR on cereals (Shaharoona et al., 2006), fruits (Kavino et al., 2010) and vegetables (Kaushal et al., 2017) when either used alone or in combination with fertilizers for enhancing crop yields and have committed to the progress of sustainable agricultural systems. Impacts of PGPR on growth and yield parameters have been widely investigated, slight clue exists on the effects of PGPR on sensitive biochemical and microbial indices reflecting soil quality. Besides extra sensitive to environmental stress biochemical properties imparts rapid and authentic values on soil quality (Ding, 2010). The biochemical parameters comprise of the variables that are directly associated to microbial activity such as microbial biomass C and respiration. Microbial biomass C and respiration are considered as potential indicators of soil quality and management impacts (Dinesh and Ghoshal, 2013). Moreover, ameliorated microbial biomass C boosts plant productivity and reduced microbial respiratory C loss could potentially mitigate increasing atmospheric CO_2 concentrations. Nevertheless, our understanding of PGPR interactions with plants to regulate microbial biomass C and microbial respiration in the rhizosphere is still limited. We evaluated the effect of *Bacillus pumilus* inoculation with reduced applications of N and P on productivity of cauliflower and soil nutrient status under North Western Himalayas. *Bacillus pumilus* with 75% NP, improves cauliflower yield (by 27.65%) over recommended dose of fertilizers through several different mechanisms, such as enhancement of nutrient uptake and the suppression of plant diseases (Kaushal and Kaushal, 2015). Here, we hypothesized that use of PGPR along with reduced application of fertilizers (NP) would attenuate such negative impacts of sole NPK use on beneficial soil microbiota and their related functions.

Hence, the objective of the study was to figure out the impacts of *Bacillus pumilus* (native strains of PGPR isolated from cauliflower rhizosphere) applied with reduced application of NP fertilizers (urea and muriate of potash) on microbial biomass C and microbial activity (CO_2 evolution). Another objective was to determine the correlations between yield parameters of cauliflower, soil nutrient status and inoculated population of native strain impacting microbial biomass and activity.

Materials and methods

Site description

The study was conducted at two locations (Dr. Y. S. Parmar University of Horticulture and Forestry, Nauni, Solan and Regional Horticultural Research Station, Kullu) of Himachal Pradesh that belongs to North-Western Himalayan region of India as presented in *Figure 1*. Experiments was replicated twice at both locations in each year 2010 and 2011. Both locations differ slightly in geographical characteristics, physico-chemical and microbiological properties of soil as presented in *Table 1*. Rhizosphere soil sampling was done before sowing (Mar 2010 and 2011) and after harvest (May 2010 and 2011) of field trails at both locations replicated twice. Three randomized soil samples were collected from each plot to make one composite sample (100 g) with the help of a soil augur and up to a depth of 15-20 cm from all the treated plots and every replicated experiment.

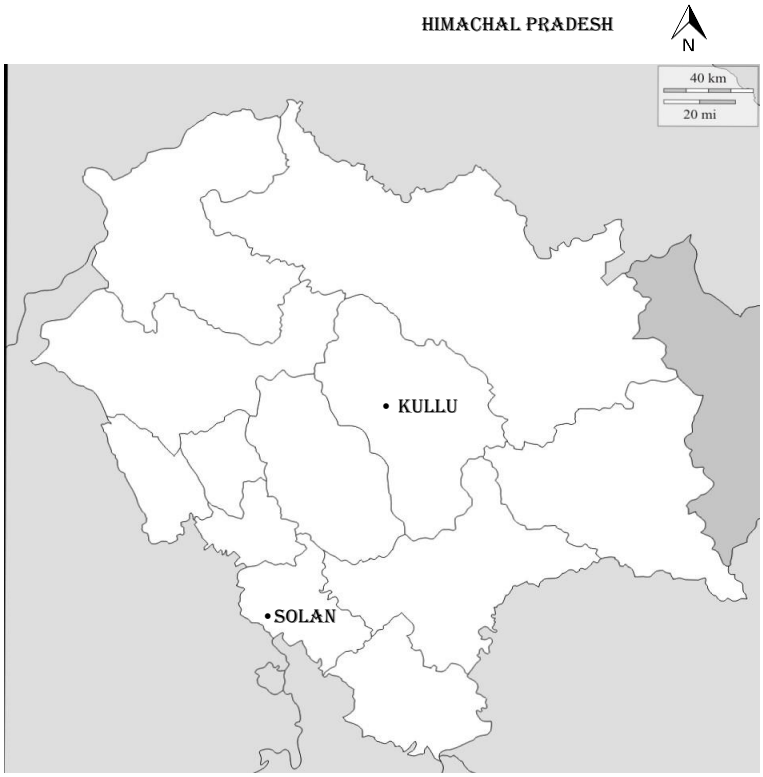

Figure 1. *Study area and sampling locations of rhizospheric soil samples*

Plant growth promoting rhizobacterial attributes of Bacillus pumilus

Isolated native bacterial strain from cauliflower (*Brassica oleracea var. botrytis*) was tested for its in vitro efficacy in ideal laboratory conditions before the field experimentations (Jan – Mar 2010) at Soil Microbiology Laboratory, Department of Soil Science and Water Management, Dr. Y S Parmar University of Horticulture and Forestry, Solan – India. Isolate was tested for major plant growth promoting attributes including P-solubilization, Indole acetic acid (IAA), siderophore and Hydrogen cyanide (HCN) production and antagonistic activities against phytopathogens (Kaushal et al.,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_72537270
© 2018, ALÖKI Kft., Budapest, Hungary

2016). Nitrogen fixation ability of native bacterial strain was also quantified indirectly by acetylene reduction assay (ARA) method and compared to standard strain (procured from the Institute of Microbial Technology, Chandigarh) of *Azotobacter chroococcum* (Hardy et al., 1968).

Table 1. *General characteristics of both locations (Solan and Kullu)*

Parameters/characteristics	Solan	Kullu
Longitude	77.0967° E	77.1095° E

Field efficacy of Bacillus pumilus inoculation

Based on in vitro plant growth promoting traits and N_2-fixing abilities, field studies were conducted twice at both locations with *Bacillus pumilus* and reduced application of N and P fertilizers (Kaushal and Kaushal, 2015). The treatments: T1 (Uninoculated control), T2 (*Bacillus pumilus* +25% NP), T3 (*Bacillus pumilus* +50% NP), T4 (*Bacillus pumilus* +75% NP), T5 (*Bacillus pumilus* +100% NP), T6 (100% NPK), T7 (75% NPK), T8 (50% NP), T9 (*Bacillus pumilus*-inoculation) and T10 (Recommended dose of fertilizers) were arranged in randomized complete block design (RCBD) and replicated thrice. Calcium ammonium nitrate (25% N) and single super phosphate (16% P_2O_5) were the sources of nitrogen and phosphorus, respectively. Bacterial cell suspension (at OD 540 nm 1.00) of 72 h old cultures, grown in 10% nutrient broth, was used as inoculum. Data were collected on the growth and yield parameters of cauliflower, soil nutrient status and rhizospheric as well as endophytic microbial population and analysed over recommended dose of fertilizers. We used 20 plants/treated plot for analysing the data and each plant is harvested manually and recorded for growth and yield parameters which includes number of non-wrapper leaves, curd diameter and curd weight.

Efficacy of Bacillus pumilus inoculation on soil microbial biomass and microbial activity (CO2 evolution)

We analysed the incremental growth of microbial biomass-carbon and microbial activity (CO_2 evolution) over time. The fumigation–extraction method was used to analyse soil microbial biomass-C (CMIC) (Vance et al., 1987). Microbial activity was measured as the CO_2 evolved from moist soil, adjusted to 55% water holding capacity, and pre-incubated for 7 days at 20 °C in the dark. The CO_2 evolution was then measured

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_72537270
© 2018, ALÖKI Kft., Budapest, Hungary

for the next 7 days using NaOH traps and titration with HCl and the metabolic quotient (qCO_2) was calculated (Salamanca et al., 2002).

Statistical analysis

All samples were measured in triplicate. The selected variables were compared between the tested soils using a one-way ANOVA. Significant differences were detected at the 0.05 level. Correlations between all measurable variables (plant, soil and microbial) were estimated using Pearson's r with $p < 0.05$ significance threshold. Principal components analysis (PCA) was conducted to determine and clarify the relationship between plant, soil and microbial parameters.

Results and discussion

Plant growth promoting rhizobacterial traits of Bacillus pumilus

Bacillus pumilus was the native bacterial strain isolated from rhizosphere of cauliflower. Our earlier published results confirmed that this strain displayed a very high ability towards most of the plant growth promoting attributes (Kaushal et al., 2017).

The isolate (*Bacillus pumilus*) produced a significantly higher concentration P-solubilization (664.33 µg/mL), IAA (29.67 µg/mL), maximum (51.36%) siderophore unit and HCN production (*Fig. 2*).

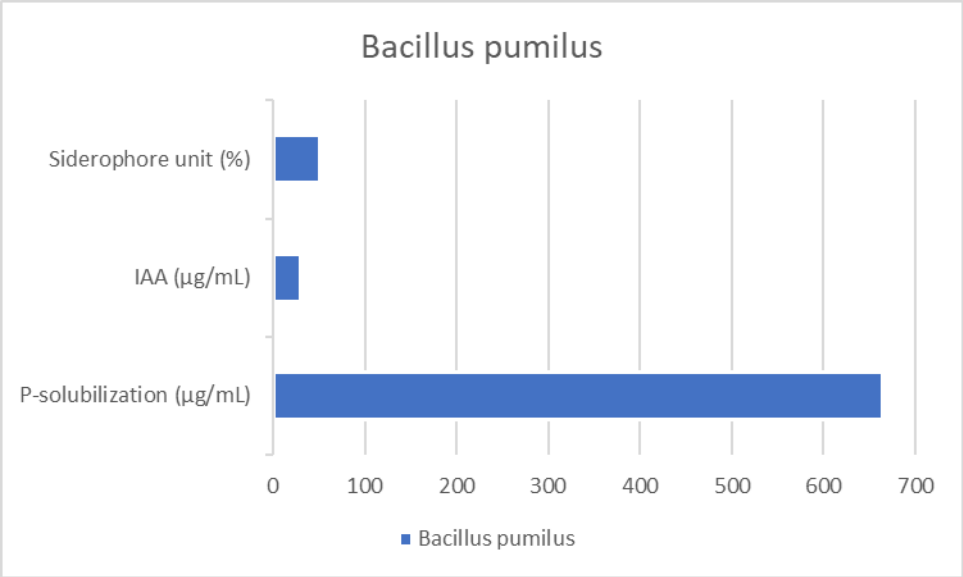

Figure 2. *Plant growth promoting activities of selected bacterial isolates (Bacillus pumilus). *Significance < 0.05*

Inorganic phosphate is solubilized by rhizosphere microbes with the production of organic acids and chelating oxo-acids from sugar (Cao et al., 2017). Thus, most quantitative analysis to evaluate the efficacy of phosphate-solubilizing bacteria due to the production of organic acids into surrounding medium are based on lowering pH (Bini et al., 2011). IAA produced by *B. pumilus* can enhance plant growth which was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_72537270
© 2018, ALÖKI Kft., Budapest, Hungary

the same as synthetic PGRs produced (Dasri et al., 2016). Siderophore and HCN production was also exhibited by *Bacillus pumilus* used as potential biocontrol agent of Fusarium in tomato (Heidarzadeh and Baghaee-Ravari, 2016). With regards to antagonistic activity against *Sclerotinia sclerotiorum*, culture filtrate of *Bacillus pumilus* exhibited very high antifungal antibiotic activity with an inhibition zone ranged from 20.2 to 22.4 mm. Our results are agreement with other researchers., who demonstrated that *Bacillus pumilus* strain is a promising biological control agent for control against Sclerotinia stem rot (Gao et al., 2014). *Bacillus pumilus* also showed higher nitrogenase activity, i.e., 437.26 ηmole C_2H_4 h^{-1} mg^{-1} protein (109 mg of N_2 fixed/ha/d), as compared to standard of *Azotobacter chroococcum*, i.e., 372.85 ηmole C_2H_4 h^{-1} mg^{-1} protein (93.0 mg of N_2 fixed/ha/d). In support to our results, a representative strain of *Bacillus pumilus* was identified that is also able to fix atmospheric N_2 as determined by the acetylene-dependent production assay (Castellano-Hinojosa et al., 2016).

Field efficacy of Bacillus pumilus inoculation

Our earlier published results confirmed that bio-inoculation of *Bacillus pumilus* at 75% of N and P fertilizers significantly enhanced all the growth and yield parameters of cauliflower such as number of non-wrapper leaves, curd weight and curd diameter (Kaushal and Kaushal, 2015).

Field experiment data of two years for both locations (replicated twice) revealed that bio inoculation of *Bacillus pumilus* along with 75% NP increased curd yield by 27.65% over recommended dose of fertilizers along with the saving of 25% NP (*Fig. 3*). Application of beneficial microbes to crop plants enhanced the fixation of atmospheric N, organic decomposition and augmented the soil properties by production of bioactive compounds such as vitamins, phytohormones which accelerated plant growth and yield (Upadhyay et al., 2012). The increase in levels of chemical fertilizers (NP) along with the bio-inoculation of *Bacillus pumilus* significantly enhanced NPK content in plants. Two years data (each replicated twice) revealed that N contents increased by 4.46% and 3.29%, P contents 0.49% and 0.57%, K contents 3.84% and 3.02% over uninoculated controls at Kullu and Solan, respectively. Uptake of N (77.14 kg/ha and 90.86 kg/ha) and P (35.28 kg/ha and 26.22 kg/ha) also boosted significantly with progressive increase in the supply of N and P nutrients along with bio-inoculation of *Bacillus pumilus* to the crop in both the years and locations. As far as ameliorations in plants nutrient status is concerned, enhanced nutrients like N, P and K might be due to enhanced vegetative growth and improved soil health leading to increased root formation. Studies reported enhanced N, P and K constituent of plant which might be attributed to presence of abundant number of soil microorganisms, microbial respiration and microbial biomass C and align with the findings of other researchers (Liu et al., 2012; Santibanez and Varnero, 2014). In addition, increased level of P might be due to presence of adequate organic acids which were released after organic matter decomposition and subsequently help in the solubilization of the indigenous phosphates. It was interesting to note that larger the total rhizosphere population, more is the accumulation of nitrogen, phosphorus and potassium contents in plants. Soil physico-chemical and nutrient status, i.e. pH, electrical conductivity (EC), bulk density (BD), organic matter (OM), N, P, K, was also assessed after harvest of crop (*Fig. 3*). Concentration of nutrients increased in soil with the combined use of *Bacillus pumilus* and NP fertilizers. The available nutrient contents N and P were increased by 2.56-32.00% and 6.66-40.72%, respectively over control. Bio-inoculation of *Bacillus*

pumilus not only improved the nutritional content particularly NPK of plants but also increased their uptake significantly over uninoculated control. This increase may be attributed to atmospheric nitrogen fixation, phosphate solubilization in the rhizosphere by *Bacillus pumilus*. The higher concentration of soil available nutrients with conjoint use of *Bacillus pumilus* and NP fertilizers may be attributed to well develop root system, significant improvement in soil physical properties and metabolic activity as well as rhizospheric and endophytic microbial population (Kaushal and Wani, 2016). The microbial analysis performed at the harvest of crop in each year at both the locations. The data revealed higher population of rhizospheric and endophytic bacteria in duly inoculated plots as compare to uninoculated control. The highest 162.5×10^8 cfu/g soil and 158.8×10^8 cfu/g soil rhizospheric population was recorded at Kullu and Solan, respectively. The lowest total bacterial counts were recorded under uninoculated control at both the locations. Also, endophytic bacterial population was highest 106.4×10^1 cfu/g root (Kullu) and 108.8×10^1 cfu/g root (Solan). At both the locations, the lowest endophytic bacterial counts were recorded with uninoculated control. The rhizosphere is a niche of beneficial microflora. Higher root exudation, OC, N and moisture content in amended organic fertilizers mechanized the microbes for their proliferation (Nagar et al., 2016). Decomposition of root tissue contribute ample energy in terms of C and N for the multiplication of bacteria enabling the growth of heavy microbial population (Singh et al., 2012). Moreover, increase in beneficial microbial population may be because of balanced water supply, particulate organic matter and presence of respirable substances (Majumdar et al., 2014). The study revealed that bio-inoculation of *Bacillus pumilus* supplied plots improved the cauliflower yield, physico-chemical properties of soil leading to enhanced soil microbiome (*Fig. 3*).

Efficacy of Bacillus pumilus inoculation on soil microbial biomass and microbial activity (CO2 evolution)

Soil microbial biomass-carbon (SMBC) was significantly higher in *Bacillus pumilus* + 75% NP plots (*Figs. 4* and *5*). This might be due to enhanced mineralization of organic leading to increased microbial activity (Nagar et al., 2016) as revealed in our studies also. SMBC at Kullu was 119.8 mg MB-C/ 100 g soil and Solan was 117.6 mg MB-C/ 100 g soil both with bio-inoculation of *Bacillus pumilus* + 75% of N and P fertilizers as presented in *Figures 4* and *5*. Similarly, various studies displayed that increased population of *Azotobacter*, PSB, soil enzymes, OC exhibited positive correlation with SMBC (Majumdar et al., 2014). Moreover, significiant improvement in SMBC in our experiments might be due to more stimulation in associated microbial populations. Treatments consisting of *Bacillus pumilus* bio-inoculation and chemical fertilizers (NP) increased the CO_2 evolution up to 48 h of incubation period and then followed a decreasing trend with the increase in incubation period at both the locations. However, the maximum CO_2-evolution was recorded 0.18 mg CO_2/ g soil (Kullu) and 0.17 mg CO_2/ g soil (Solan) with bio-inoculation of *Bacillus pumilus* + 75% of N and P fertilizers as presented in *Figures 6* and *7*. The basal soil respiration gives an estimate of total microbial activity, reflecting both the quantity and quality of the carbon sources (Liu et al., 2012). In present study, higher soil respiration sustained our notion that the rhizosphere soils had a dominant soil microbial activity, implying accelerated decomposition of organic residues that makes nutrients available for the consequent stimulation of heterotrophic microorganisms as observed by other researchers (Fall et

© 2018, ALÖKI Kft., Budapest, Hungary

al., 2012). Moreover, the lower soil microbial metabolic quotient (qCO_2) displayed lower soil chemical stress to microbes, more worthwhile C utilization ability, low energy demand in microbial biomass supply and improved soil quality (Gonzalez-Quinones et al., 2011). Our results also suggested that inorganic fertilization did not increase soil respiration. Similar effects on soil respiration due to inorganic fertilization has been found when N fertilizer was added, possibly from the elimination of the decomposition of soil organic carbon due to reduction in microbial biomass (Yang et al., 2010; Ge et al., 2012).

Correlations analysis

Pearson correlation matrix revealed that many plant, soil and microbial variables were significantly correlated with each other The plant parameters, i.e. number of non-wrapper leaves, curd diameter, curd weight, curd yield, curd depth, soil physico-chemical, i.e. pH, EC, BD, OM, N, P, K, rhizospheric and endophytic bacterial population was significantly correlated at 5% level of significance at Kullu as given in *Table 2*. Significant positive correlation exists between curd diameter-N, P ($r = 0.49$, 0.48 respectively), curd diameter-rhizospheric bacterial population ($r = 0.42$), curd diameter-endophytic bacterial population ($r = 0.38$), curd weight-N, P ($r = 0.65$, 0.73, respectively), curd weight-rhizospheric bacterial population ($r = 0.35$), curd weight-endophytic bacterial population ($r = 0.50$), curd yield-N, P ($r = 0.65$, 0.73 respectively), curd yield-rhizospheric bacterial population ($r = 0.35$) curd yield-endophytic bacterial population ($r = 0.50$), curd depth-N, P ($r = 0.50$, 0.51 respectively), curd depth-rhizospheric bacterial population ($r = 0.32$), curd depth-endophytic bacterial population ($r = 0.33$), N-rhizospheric bacterial population ($r = 0.42$), P-rhizospheric bacterial population ($r = 0.43$), P-endophytic bacterial population ($r = 0.32$) and between K-endophytic bacterial population ($r = 0.53$). The plant parameters, i.e. number of non-wrapper leaves, curd diameter, curd weight, curd yield, curd depth, soil physico-chemical, i.e. pH, EC, BD, OM, N, P, K, rhizospheric and endophytic bacterial population was significantly correlated at 5% level of significance at at Solan as given in *Table 3*. Significant positive correlation exists between number of non-wrapper leaves-N, P ($r = 0.32$, 0.52 respectively), number of non-wrapper leaves-rhizospheric bacterial population ($r = 0.41$), curd diameter-N, P ($r = 0.47$, 0.59 respectively), curd diameter-rhizospheric bacterial population ($r = 0.46$), curd diameter-endophytic bacterial population ($r = 0.35$), curd weight-N, P ($r = 0.76$, 0.84 respectively), curd weight-rhizospheric bacterial population ($r = 0.38$), curd yield-N, P ($r = 0.76$, 0.84, respectively), curd yield-rhizospheric bacterial population ($r = 0.38$), curd depth-N, P ($r = 0.52$, 0.68, respectively), curd depth-rhizospheric bacterial population ($r = 0.37$), P-rhizospheric bacterial population ($r = 0.47$) and between P-endophytic bacterial population ($r = 0.31$). In our results, positive correlation between plant, soil and bacterial variables was obtained which showed a considerably positive relationship. Enhanced SMBC might be one of the determinant factor of this positive relationship. Moreover, as predicted in our findings, MBC is the important source of C supplying higher energy to the microbes leading to enhanced metabolic activities (Liu et al., 2017). The rhizosphere microbial community is recognized to be closely related to soil health and quality (Raaijmakers and Mazzola, 2016). The positive correlation between N-rhizospheric bacterial population ($r = 0.42$), P-rhizospheric bacterial population ($r = 0.43$), P-endophytic bacterial population ($r = 0.32$) and between K-endophytic bacterial population ($r = 0.53$) revealed in the field experiments corresponds with many previous studies, suggesting that the soil quality is directly related to bacterial population occurrence and could therefore be used as an indicator for soil fertility prediction. Moreover, bio-inoculation of *Bacillus pumilus* significantly induce the community shift of culturable bacteria in the rhizosphere soil leading to improved soil microbial biomass. From a long-term perspective, appropriate application of *Bacillus pumilus* can improve the soil quality and fertility. This comprises both nutrients (e.g., aggregation of organic matter) and structure (e.g., aggregates accumulation), which is conductive to agricultural sustainable development. The results also suggested a positive effect of N application on microbial biomass-C. After N application, N

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_72537270
© 2018, ALÖKI Kft., Budapest, Hungary

availability increased and consequently microbes immobilized N, which subsequently increased microbial biomass-C (Chaparro et al., 2014). A clear positive effect of combined application of *Bacillus pumilus* and NP on microbial biomass and microbial activity was observed. Microbial activity also varies considerably among the treatments including control. The metabolic quotient (soil respiration per unit of microbial biomass) reflects the maintenance energy requirement of soil microbes and can be a relative measure of how efficiently the soil microbial biomass is utilizing C resources, as well as the degree of substrate limitation for soil microbes (Xun et al., 2016). The results in this study did show changes in the microbial pool that would suggest changes in microbial biomass-C and activity as well (*Tables 2* and *3*). In contrast, combined application of *Bacillus pumilus* and NP treatments indicated relatively highly efficient microbial community and better use of the available organic substrates. On the contrary, the Pearson's correlation indicated strongly positive correlation between microbial biomass and plant and soil parameters (*Tables 2* and *3*). All the soil factors controlling microbial biomass-C had significant effects on microbial respiration (CO_2 evolution) as described by the correlation analysis.

Principal components analysis was used to determine the factors related to soil microbial properties. The two components (PC1 and PC2) explained 63.54% and 12.82% of the total variance. The PC1 and PC2 were chosen to draw a biplot, because of explaining 76.36% of the total variance together as presented in *Figure 8*. PCA was weighted by physico-chemical (pH, EC, BD, OM, N, P and K), which exhibited a more powerful influence on discrimination in soil samples and microbiological (rhizospheric and endophytic bacterial population) variables together with growth and yield components. Thus, PCA allowed us to detect the subtle differences in plant, soil physical-chemical and microbial factors among the studied parameters. Additionally, the high soil organic matter (SOM) and N contents as material basis largely contribute to the high microbial biomass and basal respiration. Also, changes in SOM and N application affects soil microbial biomass (SOM/N ∝ SMBC). As far as soil quality is concerned, microbial diversity should be well considered when vast of N fertilizer was added to soils in agricultural practice.

Conclusion

The inference could be drawn that inclusion of rhizobacteria in CSA ensures win win results of enhanced sustainable productivity, resilience and reduced GHG emissions. The conjoint application of *Bacillus pumilus* + NP (75%) showed higher impacts on plant productivity as well as soil fertility. Plant nutrients (N, P and K) and microbial population registered manifold improvement in organically sound (*Bacillus pumilus* + NP) plots as compared to control. SMBC was found to be higher in *Bacillus pumilus* + 75% NP treated plots as compared to other treatment plots. Similar trends were recorded in the bacterial (rhizospheric and endophytic) populations. A significant reduction in CO_2 evolution was recorded after 48 h of incubation in the treatments receiving *Bacillus pumilus* bio-inoculation. Therefore, based on these findings it is concluded that this fertilization regime (*Bacillus pumilus* + NP) not only could produce a good yield but also offers an opportunity for savings of fertilizers and mitigation of soil pollution. Despite the information gained from this detailed study, other relationships needed to know turnover rates of microbial biomass and microbial activity for which detail work using isotope dating is in progress.

EFFECTS OF LOW TEMPERATURES ON ENZYME ACTIVITY, CHLOROPHYLL AND ION CONTENTS IN COMMON BEAN GENOTYPES

KABAY, T.

Ercis Vocational School, Van Yuzuncu Yil University, Van, Turkey
(e-mail: tkabay@yyu.edu.tr; phone: +90-532-205-1624; fax: +90-432-225-1104)

(Received 14th Aug 2018; accepted 15th Oct 2018)

Abstract. Low temperatures slow down plant growth and development and generate physiological damages on plants. Metabolism of largely produced and consumed common bean (*Phaseolus vulgaris* L.) plants decelerates at temperatures below 15 °C. This study was carried out at Van Yuzuncu Yil University in Van province of Turkey with limited vegetation period due to its cold climate in winter. In this study, the bean plants were subjected to low temperature stress and catalase (CAT), super oxide dismutase (SOD), ascorbate peroxidase (APX) enzyme activities, malondialdehyde (MDA), chlorophyll-a, chlorophyll-b and total chlorophyll, K, Ca, and Mg ion contents of low temperature stress-tolerant Yakutiye and Ç30 and low temperature stress-sensitive Zulbiye and Ç13 bean genotypes were measured on 25th, 30th, 35th and 40th days of low temperature stress. Four bean seeds were sown in 2-liter pots filled with 2:1 peat:perlite mixture as to have 2 plants in each pot. The pots were irrigated with Hoagland nutrient solution. Low temperature stress plants were sown on 15th of March with low outdoor temperatures. In control group, been seeds were sown on 25th of April and plant samples were taken in again 5-day intervals in 4 periods (25th, 30th, 35th and 40th days of growth). Significant differences were observed in enzyme activities, chlorophyll contents and ion contents of low temperature-tolerant and sensitive bean genotypes in 4 measurement periods.
Keywords: *abiotic stress, biochemical characteristics, nutrient, Phaseolus vulgaris, physiological characteristics*

Introduction

In terrestrial climate zones, low bean yields are generally attributed to prominent climate conditions of the regions. Seed germination in beans largely depends on genotypes and quite a few genotypes are able to well-germinate at temperatures below 10 °C. In vegetables, low temperatures at root zone generate a stress in water absorption of the roots (Sakamoto and Suzuki, 2015). Beans are generally sensitive to cold temperatures, thus germination rates and percentages decrease at low soil temperatures in spring. Water absorption damage increases because of rapid water intake and ultimately seedling formation greatly weakened. In cold climates, temperatures often go below 15 °C during the initial growth stages of the seedlings and such low temperatures then negatively influence seedling growth and development (Elkoca et al., 2005). Plants develop different mechanism against cold stress-induced damages and ultimate die outs or to provide cold-tolerance. Exothermic effects of inner and intra cell frost formation on plants are categorized as physical changes in cell membranes throughout cold-stress period, cold resistance and acclimatization and biochemical changes throughout the cold acclimatization (changes in some soluble substances in plant extract, lipid composition of cell membranes, protein contents, enzyme activity and antioxidant systems (Aslantaş et al., 2010).

Abiotic stress factors negatively affect several crops. Significant decreases were reported in photosynthesis rates and chlorophyll contents of pea plants when the plants were subjected to 45 °C temperature for 24 h (Georgieva et al., 2007). Decreasing

© 2018, ALÖKI Kft., Budapest, Hungary

chlorophyll, K and Ca contents and increasing MDA, CAT, SOD and APX activities were reported for bean and tomato plants under drought and high temperatures (Terzi et al., 2010; Kabay and Şensoy, 2016, 2017; Alp and Kabay, 2017).

It was reported in a previous study investigating the effects of low temperature stress on physiological characteristics of tomato genotypes that cold stress reduced chlorophyll and dry matter content of young and old leaves and wakened antioxidative systems of the plants (Gökmen, 2006). Low temperatures were reported to increase antioxidant enzyme and MDA content of rapeseed plants (Xian et al., 2017). Low temperatures increase chlorophyll and weight losses of cabbages and increased reactive oxygen species (Soengas et al., 2018).

It was indicated in another study carried out with cold stress-resistant and sensitive sugar cane cultivars that sensitive cultivar had greater root length and root volume than the resistant cultivar, but cell structure was destructed in both cultivars and cold stress-induced plants had greater MDA, proline, soluble sugar, soluble protein, POD and SOD activity than the control plants (Sun et al., 2017).

It was reported in another study investigating the effects of cold stress on rye and wheat seedlings that cold stress increased antioxidant enzyme activities, proline, sugar and anthocyanins contents of both species (Kolupaev et al., 2016).

Significant decreases were reported in malondialdehyde, proline, peroxidase and catalase activities of control and transgenic tomato plants under cold and low temperature stress (Yu et al., 2015). Xintaimici and Jinyan cucumber (*Cucumis sativus* L.) cultivars were subjected to two different temperature regimes (15/15 °C and 25/18 °C) under low light intensity and significant increases were reported in leaf superoxide dismutase and guaiacol peroxidase activities of both cultivars and less increases were reported in leaf catalase activity (Xu et al., 2008). Ogweno et al. (2009) reported different photosynthetic physiological responds of tomato leaves to moderate and low temperature stress. Huang et al. (2018) reported decreasing net photosynthetic rate and chlorophyll contents of Akihime and Benihoppe strawberry cultivars under cooling stress. Researchers also reported that foliar selenium (Se) sprays relieved the decrease in net photosynthetic rate and chlorophyll content and increased malondialdehyde and hydrogen peroxide content under stress conditions. Do et al. (2018) reported increasing ascorbate peroxidase (APX) and superoxide dismutase (SOD) activities of melon and pumpkin plants when they were subjected to 12/7 °C (day/night) low temperatures for 0–72 h. Li et al. (2018) reported that cold stress increased the accumulation of reactive oxygen species (ROS) and resulted in an oxidative stress, such a case then decreased photosynthetic processes of tea leaves, but melatonin treatments reduced antioxidant potential and oxidative stress and increased photosynthetic capacity. Bilska-kos et al. (2017) reported that low temperatures (14/12 °C) altered pectin content and osmatic potential of maize leaf cells and ultimately altered cell membrane composition. Zhou et al. (2017) reported significant decreases in fresh and dry weights, leaf areas and relative water contents of tomato cultivars under drought stress as compared to the control plants. While significant increases were reported in antioxidant compound quantities of tomato plants, decreases were reported in chlorophyll contents (Gökmen, 2006). It was reported in study carried out to determine yield and total temperature demands of bean plants at different growth stages that the greatest yield was obtained from early July sowings and yields decreased as the sowing time approached to autumn (Yoldaş and Eşiyok, 2009). High and low temperatures (15/8, 20/13, 28/21, 33/23 and 36/26 °C) were applied to tomato plants

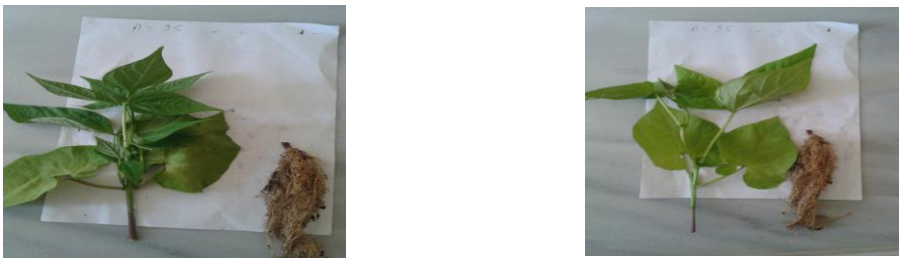
and it was observed that temperature stress negatively influenced plant growth and development and nutrient uptake (Sung et al., 2015).

This study was carried out to determine the effects of low temperature stress on enzyme activity, chlorophyll, K, Ca and Mg contents of low temperature tolerant (Yakutiye and Ç30) and sensitive (Zulbiye and Ç13) common bean (*Phaseolus vulgaris* L.) genotypes.

Materials and methods

This study was conducted to determine the effects of low temperature stress on common bean genotypes. The study carried out at the Greenhouses of Van Yuzuncu Yil University Erciş Vocational Collage of Turkey and the plant analyses were carried out at laboratories of the Agricultural Faculty of the same university. Catalase (CAT), super oxide dismutase (SOD), ascorbate peroxidase (APX) enzyme activities, malondialdehyde (MDA), chlorophyll-a, chlorophyll-b and total chlorophyll, K, Ca, and Mg ion contents of low temperature stress-resistant Yakutiye and Ç30 and low temperature stress-sensitive Zulbiye and Ç13 bean genotypes (*Fig. 1*) were measured on 25th, 30th, 35th and 40th days of low temperature stress. For low temperature stress, bean seeds were sown in 2-liter pots filled with 2:1 peat:perlite mixture on 15th of March with low outdoor temperatures in a plastic covered high tunnels. Four seeds were placed in each pot as to have 2 plants in each pot. Pots were irrigated with Hoagland nutrient solution. The initial samples were taken from 25-days old plants and high tunnel cover was removed. Plants were then exposed to outdoor conditions and plant samples were taken in 5-day intervals (25th, 30th, 35th and 40th days) in 4 periods. High-tunnel temperature was 16.76 °C in day time and 15.28 °C at night. When the tunnel cover was removed, day temperature was measured as 12.67 °C and night temperature was measured as 8.43 °C by Hobo temperature data loggers. In control group, bean seeds were sown on 25th of April into the pots placed in a high-tunnel and plant samples were taken in again 5-day intervals on 25th, 30th, 35th and 40th days of growth. Throughout the experiments, day temperature was measured as 27.44 °C and night temperature was measured as 16.87 °C. The analyses performed on plant samples are provided below.



Control Low temperature

Figure 1. *A view of control and low temperature stressed plant sample*

Mineral element analyses

At the end of 25th, 30th, 35th and 40th days after sowing, representative control and low temperature stress-treated plants were harvested, the shoot were initially dried at open places for two days and then dried in an oven at 65 °C for 48 h. About 200 mg of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_72717287
© 2018, ALÖKI Kft., Budapest, Hungary

dry shoot samples were ground and subjected to pre-digestion in ethyl alcohol and then burned to ash in an ash oven at 550 °C. Resultant ash was dissolved in 3.3% HCl, filtered through blue-band filter paper. K, Ca and Mg readings were performed in an atomic absorption device at Scientific Research and Implementation Center of Yüzüncü Yıl University (Kacar, 1994; Kacar and İnal, 2008).

Lipid peroxidation

Lipid peroxidation of the plants generally expressed as malondialdehyde (MDA) content. About 0.5 g leaf sample was homogenized in 10 ml 0.1% trichloric acid (TCA) and resultant homogenate was centrifuged at 15000 rpm for 5 min. About 1 ml was taken from the clear portion of the centrifuged sample and supplemented with 0,5% tiobarbituric acid (TBA) dissolved in 4 ml 20% TCA. The mixture was kept at 95 °C for 30 min and instantly cooled in ice-bath. Cooled sample was then centrifuged at 10000 rpm for 10 min and absorbance readings were performed in clear portion at 532 and 600 nm wave lengths. The following equation was used to calculate malondialdehyde (MDA) content of the samples (Heath and Packer, 1968; Sairam and Saxena, 2000):

$$\text{MDA (nmol ml-1)} = [(A532-A600)/155\ 000]\ 10^6$$

Antioxidative enzyme analyses

About 1 g frozen leaf sample was homogenized in 5 ml cold 0.1 M Na-phosphate, 0.5 mM Na-EDTA and 1 mM ascorbic acid mixture (pH: 7.5) and the resultant homogenate was centrifuged at 18000 rpm and 4 °C for 30 min. Ascorbate peroxidase (AP) activity of the resultant homogenate was instantly determined. For catalase (CAT) and superoxide dismutase (SOD) activities, 1 g frozen leaf sample was homogenized in 5 ml cold 0.1 M Na-phosphate and 0.5 mM Na-EDTA mixture (pH: 7.5). Resultant homogenate was centrifuged at 18000 rpm and 4 °C for 30 min. A portion of homogenate was used to determine CAT activity instantly and the remaining portion was kept at -20 °C for SOD activity (Jebara et al., 2005; Bagcı, 2010).

Catalase (CAT) activity

Catalase activity was determined through monitoring the inhibition of H_2O_2 at 240 nm. As the reaction solution, 0.05 M phosphate buffer (KH_2PO_4) and 1.5 mM H_2O_2 mixture was used (pH: 7.0). About 2.5 ml reaction solution was mixed with 0.2 ml plant extract. Readings were performed in a spectrophotometer at 0 and 60th seconds. Reaction was initiated with the addition of 0.1 ml enzyme extract. Assessments were made by taking the change in absorbance within a minute into consideration (Jebara et al., 2005; Bagcı, 2010).

Superoxide dismutase (SOD) activity

SOD activity was determined through monitoring te inhibition of nitroblue tetrazolium (NBT) at 560 nm wave length. As a reaction solution, 50 mM Na-phosphate buffer (Na_2HPO_4 x H_2O_2), 0.1 mM Na- EDTA, 33 µM NBT, 5 µM riboflavin and 13 mM methionine mixture was used (pH: 7.0). About 2.5 ml reaction solution was mixed with 0.1 or 0.2 ml plant extract. Reaction was performed by keeping at 25 °C

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_72717287
© 2018, ALÖKI Kft., Budapest, Hungary

under 75 µmol m-2 s-1 (40 W) light for 10 min. Control solution without enzyme supplementation was kept at dark for the same duration. Readings were performed in control and reaction solution at 560 nm. SOD activity was identified as the activity reducing 50% of NTB (Rahnama and Ebrahimzadeh, 2005).

Ascorbate peroxidase (APX) activity

Ascorbate peroxidase (APX) activity was measured through ascorbic acid-induced inhibition of H_2O_2 at 290 nm. As the reaction solution, 50 mM phosphate buffer (KH_2PO_4), 0.5 mM ascorbic acid, 0.1 mM EDTA and 1.5 mM H_2O_2 mixture was used (pH: 7.0). About 3 ml reaction solution was mixed with 0.1 ml plant extract. Readings were performed in a spectrophotometer at 290 nm in 0 and 60th seconds. Reaction was initiated with 0.1 ml enzyme addition. Assessments were made by taking the changes in absorbance within a minute into consideration (Sairam et al., 2005).

Chlorophyll

0.25 g samples from the third leaf of the plant were homogenized in 80% acetone in a place where the light does not directly come out, then the extract completed to 25 ml with acetone after filtering. Prepared samples were read at 663 nm and 645 nm wavelength and calculated by the following formula ((Lichtenthaler, 1983; Amira, 2011).

$$\text{Chlorophyll a (mg/g)} = (12.7 * 663\ \text{nm}) – (2.69 * 645\ \text{nm}) * V / W*10000$$

$$\text{Chlorophyll b (mg/g)} = (22.91 * 645\ \text{nm}) – (4.68 * 663\ \text{nm}) * V / W*10000$$

$$\text{Total Chlorophyll} = \text{Chlorophyll a} + \text{Chlorophyll b}$$

Statistical analysis

Experiments were conducted in randomized plots – factorial experimental design. Experimental data were subjected to variance analysis and significant means were compared with Duncan's multiple range test (Yesilova and Denizhan, 2016). Statistical analyses were performed by using SAS 9.4 software (SAS, 2018).

Results

In the present study, quite significant differences were observed between the control plants and cold stress-treated plants. Cold stress reduced chlorophyll a, chlorophyll-b and total chlorophyll contents and such decreases were greater in sensitive genotypes than in tolerant genotypes (*Tables 1–3*). Under low temperature stress, the greatest chlorophyll a, chlorophyll-b and total chlorophyll contents were obtained from the 1st period of Ç30 common bean genotype (chlorophyll-a: 0.468 mg g^{-1} FW, chlorophyll-b: 0.188 mg g^{-1} FW, and total chlorophyll: 0.657 mg g^{-1} FW) and the lowest chlorophyll-a (0.206 mg g^{-1} FW), chlorophyll-b (0.106 mg g^{-1} FW) and total chlorophyll content (0.312 mg g^{-1} FW) were obtained from the 4th period of Ç13 genotype (*Tables 1–3*). Considering the effects of low temperature on total chlorophyll content, the greatest total chlorophyll content of 0.697 mg g^{-1} FW in the 1st period of low temperature-tolerant Ç30 bean genotype decreased to 0.578 mg g^{-1} FW in the 2nd period and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_72717287
© 2018, ALÖKI Kft., Budapest, Hungary

decreased to 0.481 mg g^{-1} FW in the 4th period. In Yakutiye (Y) bean cultivar, total chlorophyll content of 0.616 mg g^{-1} FW in the 1st period decreased to 0.581 mg g^{-1} FW in the 2nd period and decreased to 0.460 mg g^{-1} FW in the 4th period. On the other hand, in low temperature-sensitive Ç13 bean genotype, total chlorophyll content of 0.633 mg g^{-1} FW in the 1st period decreased to 0.582 mg g^{-1} FW in the 2nd period and decreased to 0.312 mg g^{-1} FW in the 4th period. In low temperature-sensitive Zulbiye (Z) bean cultivar, total chlorophyll content of 0.631 mg g^{-1} FW in the 1st period decreased to 0.563 mg g^{-1} FW in the 2nd period and decreased to 0.326 mg g^{-1} FW in the 4th period (*Table 3*). In control plants, chlorophyll a, chlorophyll b and total chlorophyll contents increased in all 4 periods. The period-dependent differences in chlorophyll contents of the control and low temperature treatments were found to be significant (*Table 4*). Chlorophyll a+b values of the control treatments were identified as 0.731 mg g^{-1} FW for Ç30, 0.734 mg g^{-1} FW for Ç13, 0.727 mg g^{-1} FW for Yakutiye and 0.653 mg g^{-1} FW for Zulbiye. Chlorophyll a+b values of the low temperature treatments were identified as 0.562 mg g^{-1} FW for Ç30, 0.482 mg g^{-1} FW for Ç13, 0.541 mg g^{-1} FW for Yakutiye and 0.475 mg g^{-1} FW for Zulbiye (*Table 4*).

There were differences in ion contents of the 1st and the 4th period and K, Ca and Mg contents decreased at the end of 4th period as compared to the 1st period. Such decreases were greater in low temperature sensitive bean plants (*Tables 5–7*). Under low temperature stress, the greatest K content (1.530%) was obtained from the 1st period of Zulbiye been genotype and the lowest K content (1.170%) was obtained from the 4th period of Ç13 bean genotype. The greatest Ca content (3.365%) was obtained from the 1st period of Zulbiye bean genotype and the lowest Ca content (1.645%) was obtained from the 4th period of Zulbiye bean genotype. The greatest Mg content (0.410%) was obtained from the 1st period of Zulbiye bean genotype, the lowest Mg content was obtained from the 4th period of again Zulbiye bean genotype (*Tables 6–7*).

As compared to the 1st period, plant K, Ca and Mg ion contents of the control groups increased at the end the 4th period. The K contents of Ç30, Yakutiye, Zulbiye and Ç13 genotypes were found to be significant under low temperature stress. The K content of 1.467% in the 1st period of Ç30 genotype decreased to 1.420% in the 2nd period, but placed in the same statistical group as Yakutiye (Y) cultivar with a K value of 1.442%. K contents also decreased in the 3rd and 4th periods, Ç30 and Zulbiye (Z) bean cultivar were placed in the same statistical group. K content of Ç30 bean genotype decreased to

1.263% in the 4th period and K content of Zulbiye cultivar of the same statistical group decreased to 1.275%. The decreases in K content of Yakutiye bean cultivar in the 2nd and 3rd periods were not found to be significant (*Table 5*).

With regard to Ca content of bean genotypes under low temperature stress, Ç30 genotype and Yakutiye (Y) bean cultivar were placed in the same statistical group in the 1st period of stress (Ç30: 3.475%; Y: 3.502%). Ç13 genotype and Zulbiye (Z) bean cultivar were also placed in the same statistical group (Ç13: 3.665%; Z: 3.647%). There were decreases in Ca contents of the bean genotypes also in the 2nd period of the low temperature stress. Ç30, Ç13 and Yakutiye bean genotypes were placed in the same statistical group. As compared to the 1st and 2nd periods, Ca contents decreased in the 3rd period (Ç30: 2.842%; Y: 3.357%; Ç13: 2.900%; Z: 2.695%) and in the 4th period (Ç30: 2.635%; Y: 2.785%; Ç13: 1.865%; Z: 1.645%) (*Table 6*).

While the differences in magnesium (Mg) contents of Ç30, Y and Z bean (*Phaseolus vulgaris*) genotypes were not found to be significant in the 1st period (Ç30: 0.362%; Y: 0.380%; Z: 0.382%) and in the 2nd period (Ç30: 0.262%; Y: 0.280%; Z: 0.285%) and they were placed in the same statistical group, but Ç13 genotype was found to be significantly different from the other groups. Magnesium content of genotypes decreased in the 3rd period, but all genotypes were placed in the same statistical group. In the 4th period of low temperature stress, decrease in Mg contents of Ç30, Ç13 and Y bean (*Phaseolus vulgaris*) genotypes (Ç30: 0.195%; Y: 0.195%; Ç13: 0.190%) were not found to be significant and they were all placed in the same statistical group, but Zulbiye (Z) bean genotype with an Mg content of 0.182% was found to be significantly different from the other genotypes (*Table 7*). Period-dependent differences in K, Ca and Mg contents of control and low temperature treatments were found to be significant (*Table 8*). K contents of control groups were identified as Ç30: 3.41%, Ç13: 3.34%, Yakutiye: 3.29% and Zulbiye: 3.21% and K contents of low temperature treatments were identified as Ç30: 1.37%, Ç13: 1.29%, Yakutiye: 1.43% and Zulbiye: 1.40% (*Table 8*).

Significant differences were observed in MDA contents of the bean plants in 4 periods and increases were observed at the end of 4th period as compared to the 1st period. Such increases were greater in low temperature sensitive bean genotypes (*Table 9*). Similar changes were also observed in CAT, SOD and APX antioxidative enzyme activities. Increases were observed in CAT, SOD and APX activities of the bean genotypes in 4 periods. Increases were greater in the 4th period as compared to the 1st period and increases were also greater in low temperature-sensitive bean genotypes (*Tables 10–13*).

*Means in each column followed by the same letter are not significantly different (P < 0.05)

The changes in superoxide dismutase (SOD) activity of the bean genotypes under low temperature stress were not found to be significant in the 1st period and they were all placed in the same statistical group. In the 2nd period, Zulbiye (124.662 unit g^{-1} FW) and Ç13 (124.475 unit g^{-1} FW) bean genotypes were placed in the same statistical group and Yakutiye (116.510 unit g^{-1} FW) and Ç30 (116.015 unit g^{-1} FW) bean genotypes were placed in the same statistical group. In the 4th period of low temperature stress, greater increases were observed in the SOD activities of Ç13 (157.812 unit g^{-1} FW) and Zulbiye (157.873 unit g^{-1} FW) genotypes (*Table 10*). With regard to catalase (CAT) activity in the 1st period of low temperature stress, Ç13 (0.178 mmol g^{-1} FW) and Zulbiye (0.176 mmol g^{-1} FW) bean genotypes were placed in the same statistical group, but Yakutiye (0.176 mmol g^{-1} FW) and Ç30 (0.172 mmol g^{-1} FW) bean genotypes were significantly different from the other genotypes. A slight increase was observed in CAT activities of the genotypes in the 2nd period of low temperature stress, but differences in CAT activities of the genotypes, except for Ç13, were not found to be significant. In the 3rd period of stress, Ç30 and Yakutiye genotypes had a CAT activity of 0.203 mmol g^{-1} FW, Ç13 genotypes had a CAT activity of 0.216 mmol g^{-1} FW and Zulbiye genotype had a value of 0.215 mmol g^{-1} FW. The differences among the genotypes were not significant, thus they were all placed in the sme statistical group. In the 4th period of low temperature stress, the differences in CAT activities of the genotypes (Ç30: 0.217 mmol g^{-1} FW; Y: 0.224 mmol g^{-1} FW; Ç13: 0.244 mmol g^{-1} FW; Z: 0.245 mmol g^{-1} FW) were found to be significant (*Table 11*). With regard to ascorbate peroxidase (APX) activity of the 1st period, Ç13 (0.747 mmol g^{-1} FW) and Zulbiye (0.742 mmol g^{-1} FW) bean genotypes were placed in the same statistical group, thus the difference between them were not significant. Yakutiye (0.731 mmol g^{-1} FW) and Ç30 (0.759 mmol g^{-1} FW) bean genotypes were found to be significantly different from the other genotypes. In the 2nd period of stress, there was a slight increase in APX activity of the sensitive and tolerant genotypes and the differences in APX activity of sensitive and tolerant genotypes were found to be significant. There were significant differences in APX activity of the genotypes in the 3rd (Ç30: 0.903 mmol g^{-1} FW; Y: 0.873 mmol g^{-1} FW; Ç13: 1.124 mmol g^{-1} FW; Z: 1.116 mmol g^{-1} FW) and 4th (Ç30: 0.928 mmol g^{-1} FW; Y: 0.923 mmol g^{-1} FW; Ç13: 1.162 mmol g^{-1} FW; Z: 1.167 mmol g^{-1} FW) period of low temperature stress (*Table 12*).

Period-dependent differences in MDA, CAT, SOD and APX activity of control and low temperature treatments were found to be significant. Low temperature-tolerant Yakutiye cultivar had the values of MDA: 5.69 nmol g^{-1} FW, CAT: 0.187 mmol/g FW,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_72717287
© 2018, ALÖKI Kft., Budapest, Hungary

SOD: 110.16 unit g^{-1} FW, APX: 0.784 mmol g^{-1} FW in control treatments and had the values of MDA: 5.92 nmol g^{-1} FW, CAT: 0.197 mmol g^{-1} FW, SOD: 121.01 unit g^{-1} FW, APX: 0.824 mmol g^{-1} FW in low temperature treatments. Low temperature-sensitive Zulbiye cultivar had the values of MDA: 5.71 nmol g^{-1} FW, CAT: 0.190 mmol g^{-1} FW, SOD: 109.89 unit g^{-1} FW, APX: 0.788 mmol g^{-1} FW in control treatments and had the values of MDA: 6.13 nmol g^{-1} FW, CAT: 0.205 mmol g^{-1} FW, SOD: 127.36 unit g^{-1} FW, APX: 0.952 mmol g^{-1} FW in low temperature treatments.

Significant findings were obtained for investigated parameters of present study both in control and low temperature stress treatments. Among the investigated parameters, decreases were observed in chlorophyll and ion contents of the genotypes in 4 periods and increases were observed in MDA, CAT, SOD and APX activity of the genotypes. The differences between the genotypes and between the periods were found to be significant.

Discussion

Some significant recession is observed in plant growth and development under low temperatures. This recession is greater in low temperature-sensitive genotypes. In the present study, changes in chlorophyll, K, Ca, and Mg contents and lipid peroxidation (MDA), catalase (CAT), superoxide dismutase (SOD) and ascorbate peroxidase (APX) activities of low temperature-tolerant and sensitive bean (*Phaseolus vulgaris*) genotypes were investigated in four different periods of low temperature stress. Present findings were quite similar with the findings of the earlier studies.

There were decreases in chlorophyll a, chlorophyll b and total chlorophyll contents of tolerant and sensitive genotypes in four periods *(Tables 1–3)*. Such decreases were greater in low temperature sensitive Ç13 and Zulbiye (Z) genotypes than in low temperature-tolerant Ç30 and Yakutiye (Y) bean genotypes. There were also significant differences in investigated parameters of the control and low temperature treatments of four periods (*Table 4*). Decreases were reported in chlorophyll a, chlorophyll b and total chlorophyll contents of bean and tomato plants under abiotic stress conditions (Terzi et al., 2010; Kabay and Şensoy, 2016, 2017; Alp and Kabay, 2017). Similar findings were reported in literature about the effects of different low temperatures. It was reported in a previous study investigating the effects of low temperature stress on physiological characteristics of tomato genotypes that cold stress reduced chlorophyll and dry matter content of young and old leaves (Gökmen, 2006). Low temperatures increased chlorophyll and weight losses of cabbages (Soengas et al., 2018). Cold stress decreased photosynthetic processes of tea leaves, but melatonin treatments reduced antioxidant potential and oxidative stress and increased photosynthetic capacity (Li et al., 2018). Low temperatures (14/12 °C) altered osmatic potential of maize leaf cells and ultimately altered cell membrane composition (Bilska-kos et al., 2017).

In control groups, significant increases were observed in potassium (K), calcium (Ca) and Magnesium (Mg) content of bean (*Phaseolus vulgaris*) genotypes in four periods. The changes in K, Ca and MG content of bean genotypes under low temperature stress were also found to be significant and K, Ca and Mg contents decreased in four periods. Such decreases were greater in stress-sensitive genotypes (*Tables 5–7*). The decreases in K content of Yakutiye (Y) bean cultivar in the 2nd and 3rd periods were not found to be significant. The decreases in K content of cv. Zulbiye in the 3rd and 4th periods were also not found to be significant (*Table 5*). The changes in Ca and Mg contents were

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_72717287
© 2018, ALÖKI Kft., Budapest, Hungary

found to be significant in the 4th period of stress (*Tables 6* and *7*). Throughout 4 periods, changes in K, Ca and Mg content of bean genotypes in control and low temperature treatments were found to be significant and ion contents decreased under low temperature stress (*Table 8*).

It was reported that low temperature stress negatively influenced leaf cells of maize plants (Bilska-kos et al., 2017). Low soil temperatures in spring negatively influence seedling growth and development of sensitive bean plants (Elkoca et al., 2005). Low temperature stress was reported to have negative effects on cold stress-resistant and sensitive sugar cane cultivars (Sun et al., 2017). It was reported in study carried out to determine total temperature demands of bean plants at different growth stages that the greatest yield was obtained from early July sowings and yields decreased as the sowing time approached to autumn (Yoldaş and Eşiyok, 2009). High and low temperatures (15/8, 20/13, 28/21, 33/23 and 36/26 °C) were applied to tomato plants and it was observed that temperature stress negatively influenced plant growth and development and nutrient uptake (Sung et al., 2015). In vegetables, low temperatures at root zone generate a stress in water absorption of the roots (Sakamoto and Suzuki, 2015). Decreasing chlorophyll, K and Ca contents were reported for bean and tomato plants under abiotic stress (Terzi et al., 2010; Kabay and Şensoy, 2016; Zhou et al., 2017; Uzal and Yasar, 2017; Kabay et al., 2017; Alp and Kabay, 2017)

Significant differences were observed in MDA contents of the bean plants in 4 periods and increases were observed at the end of 4th period as compared to the 1st period. Such increases were greater in low temperature sensitive bean genotypes (*Table 7*). Similar changes were also observed in CAT, SOD and APX antioxidative enzyme activities. Increases were observed in CAT, SOD and APX activities of the bean genotypes in 4 periods. Increases were greater in the 4th period as compared to the 1st period and increases were also greater in low temperature-sensitive bean genotypes (*Table 9–12*). With regard to MDA activity, there were significant differences both between the bean genotypes and between the stress periods (*Table 9*). There were significant differences in superoxide dismutase (SOD) activity of the bean genotypes in the 4th period of stress. However, the differences in SOD activity of Ç13 and Zulbiye genotypes were not significant different in the 2nd and 3rd period of the stress (*Table 10*). There were significant differences in catalase (CAT) activity of both the bean genotypes and the stress periods (*Table 11*). The changes in CAT activity of Ç30 and Yakutiye bean genotypes were not found to be significant in 2nd and 3rd period of stress (*Table 11*). The differences in ascorbate peroxidase (APX) activity of both the genotypes and the stress periods were also found to be significant (*Table 12*). Both the control and the low temperature treatments yielded significant differences in MDA, CAT, SOD and APX activity of the bean genotypes. Significant increases were observed in MDA, CAT, SOD and APX activities under low temperature stress (*Table 13*). Xintaimici and Jinyan cucumber (*Cucumis sativus* L.) cultivars were subjected to two different temperature regimes (15/15 °C and 25/18 °C) under low light intensity and significant increases were reported in leaf superoxide dismutase and less increases were reported in leaf catalase activity (Xu et al., 2008). Increasing ascorbate peroxidase (APX) and superoxide dismutase (SOD) activities of melon and pumpkin plants were reported under low temperature conditions (Do et al., 2018).

In process of cold resistance, plants develop different mechanisms against cold stress-induced damages and ultimate die outs or develop such mechanisms to provide cold-tolerance such as physical changes in cell membranes, changes in some soluble

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

substances in plant extract, lipid composition of cell membranes, protein contents, enzyme activity and antioxidant systems and plant nutrients (Aslantaş et al., 2010). It was reported in a previous study investigating the effects of low temperature stress on physiological characteristics of tomato genotypes that young and old leaves of the plants were found to be insufficient in antioxidative systems (Gökmen, 2006). Low temperatures were reported to increase antioxidant enzyme and MDA content of rapeseed plants (Xian et al., 2017). Low temperatures increased chlorophyll and weight losses of cabbages and increased reactive oxygen species (Soengas et al., 2018). In a previous study carried out with cold stress resistant and sensitive sugar cane cultivar, cell structure was destructed and cold stress-induced plants had greater MDA, proline, soluble sugar, soluble protein, POD and SOD activity than the control plants (Sun et al., 2017). It was reported in another study investigating the effects of cold stress on rye and wheat seedlings that cold stress increased antioxidant enzyme activities, proline, sugar and anthocyanins contents of both species (Kolupaev et al., 2016). Significant decreases were reported in malondialdehyde, proline, peroxidase and catalase activities of control and transgenic tomato plants under cold and low temperature stress (Yu et al., 2015). While significant increases were reported in antioxidant compound quantities of tomato plants, decreases were reported in chlorophyll contents (Gökmen, 2006). In present study, significant decreases were observed in chlorophyll, K, Ca and Mg contents and increases were observed in MDA, CAT, SOD and APX activities of bean genotypes under low temperature conditions. Present findings were mostly well complied with the results of similar earlier studies.

Conclusion

Significant differences were observed in chlorophyll contents, enzyme activities and ion contents of low temperature-resistant and sensitive common bean (*Phaseolus vulgaris*) genotypes throughout cold stress treatments. The decrease in chlorophyll-a, chlorophyll-b, total chlorophyll, K, Ca and Mg contents were greater in low temperature-sensitive bean plants than in low temperature-tolerant plants.

With the progress of cold stress, the MDA content of sensitive genotypes were greater than the MAD contents of tolerant genotypes. On the other hand, tolerant genotypes had greater CAT, SOD and APX antioxidant enzyme activities than the sensitive genotypes. Present findings proved one more time the suitability of the parameters selected to determine the effects of low temperature stress for selection of drought stress-tolerant bean genotypes.

(Received 26th Aug 2018; accepted 11th Oct 2018)

Abstract. Drought is a main water-related natural hazard due to its features, sensitivities and effects to all sectors. According to climate change scenarios, drought hazards are expected to be more devastating, especially in arid and semi-arid regions. Drought characterization is essential to be aware of expected negative effects of droughts as well as to devise water management plans including possible mitigation measures. To this end, many drought indices have been developed for drought analysis, one of which is the Standardized Precipitation Index (SPI) that is widely used worldwide. In this study, a new drought index is proposed, namely the Drought Power Index (DPI), based on the SPI with orientation by reliability-resilience-vulnerability (RRV) concept. The use of the RRV approach with the SPI time series empowers the drought characterization by considering the frequency of drought event, drought recovery period as well as the severity of droughts-once a drought has occurred. Since the drought is identified as an unfavorable phenomenon, the DPI ranges from 0 to 1 where the higher values indicate higher drought devastating features (probability, duration and extremity of drought) and vice versa. The proposed approach is illustrated with reference to the Southeastern Anatolia Region, Turkey. The long-term (1970-2017) monthly precipitation data of eight meteorological stations under the operation of General Directorate of Meteorological Services of Ministry of Forestry and Water Affairs are used in the study. The 12-month SPI time series, which were later used for calculations of DPI, were obtained by the use of SPI_SL_6 software. The study revealed that there has been an increasing trend in DPI values in the basin, especially after 1993. It is concluded that the DPI is a valuable indicator for (i) spatially and temporally evaluating the drought characteristics, (ii) analysing meteorological, agricultural and hydrological drought severity with its coherent capability with SPI, (iii) ranking the regions in accordance with the drought vulnerability conditions.
Keywords: *drought power index (DPI), indicators, reliability, resilience, vulnerability*

Introduction

Drought is an important natural disaster, which has a wide range of negative impacts on the environment, agriculture and the economy (Man and Modra, 2008; Acikgoz, 2011; Konyali and Kiper, 2012; Gurel and Sener, 2012). It can be defined as a prolonged period of time beginning with a decrease in precipitation amount in a given region and a certain time interval; however, it is not possible to make a general definition due to its complexity, spatial and temporal variation and impacts (Heim, 2002; Wilhite and Glanz, 1985; Maracchi, 2000; Tate and Gustard, 2000; Tsakiris et al., 2007). The general approach to quantify the droughts is using indices. World Meteorological Organization (WMO) and Global Water Partnership (GWP) have given a wide and detailed literature and findings of drought indices for researchers in the domains of meteorology, hydrology, agricultural research and application, remote sensing, and water resources management (WMO and GWP, 2016). Depending on their structure, characteristics and their ability to fulfil certain criteria, some of them are used

© 2018, ALÖKI Kft., Budapest, Hungary

for a wide range of applications, while others are intended to address drought related issues in specific systems (Tigkas et al., 2018).

The Standardized Precipitation Index (SPI), suggested by McKee et al. (1993), is a broadly used drought index. In 2009, WMO recommended SPI as the main meteorological drought index that countries should use to monitor and follow drought conditions (Hayes et al., 2011).

Although it is considered as a meteorological drought index originally, it is also used in numerous studies related to hydrological and agricultural droughts. Within a broad perspective, the studies have shown that the SPI is a valuable tool to assess drought events (Ionita et al., 2016; Mishra and Desai, 2005; Szalai and Szinell, 2000; Panaitescu et al., 2014; Lloyd-Hughes and Saunders, 2002; Cancelliere et al., 2007), to detect spatial and temporal droughts (Vicente-Serrano, 2006; Livada and Assimakopoulos, 2007), to reveal recurrent floods (Seiler et al., 2002), to manage water resources in basin scale (Shokoohi and Morovati, 2011; Zhang et al., 2009) and to assess drought impact on crop production (Labudova et al., 2017; Chen et al., 2016).

On the other hand, the EPA (US Environmental Protection Agency) has proposed the use of integrated assessments of watershed health to assist managers with identifying healthy watersheds and prioritizing candidate watersheds for protection and restoration (EPA, 2014). Here, the use of performance indicators (PIs), which is a fundamental concept for developing new ways to assess and manage environmental resources, can help watershed managers to understand the behavior of the droughts.

In this study, a new drought index, the Drought Power Index (DPI), is proposed, based on the SPI with orientation by reliability-resilience-vulnerability concept (RRV), which is first used by Hashimoto et al. (1982) for evaluation of water resources system performance. The use of the RRV approach with the SPI time series empowers the drought characterization by considering the frequency of drought event, drought recovery period as well as the severity of droughts-once a drought has occurred. Additional PIs, namely maximum extent and maximum duration of drought are also added to the formulation of the DPI. These performance indicators are all valuable to judge the effects of climate change in a given watershed. Therefore, it differ from other indices (e.g. SPI) by its capability to reveal the increasing (decreasing) devastating potential of droughts, as well as the propensity of droughts in the watershed. In addition, the DPI serves to that EPA's proposition by its inherent hybrid approach. Since the drought is identified as an unfavorable phenomenon, the DPI ranges from 0 to 1 where the higher values indicate higher drought devastating features. The proposed approach is illustrated with reference to the eight different provinces in the Southeastern Anatolia Region, Turkey. By the use of DPI, it is aimed to provide a better identification of regional drought characteristic.

Materials and methods

Study area and data

The Southeastern Anatolia Region (SAR) covers 9 provinces (Adıyaman, Batman, Diyarbakır, Gaziantep, Kilis, Mardin, Siirt, Şanlıurfa and Şırnak) located on the Euphrates-Tigris Basin and upper Mesopotamia plains *(Fig. 1)*.

The SAR provinces constitute approximately 10.7% of Turkey's total population (80.8 million, in 2018), and covers 9.7 of country's surface area, 780.6×10^3 km^2 (GAP, 2018). In general, the summer season in the region is very hot and under the influence

© 2018, ALÖKI Kft., Budapest, Hungary

of dry and warm tropical air mass while the winter is warm and rainy. The average annual rainfall varies between 400 mm and 700 mm, and the mean annual temperature is about 18 °C, due to the high summer temperatures that approach 40 °C in daytime. The SAR holds 20% of the economically irrigable area of Turkey, while accounts for 28% of total water potential. In the fertile lands, the agriculture is the main activity, so the drought has vital importance on socio-economic development.

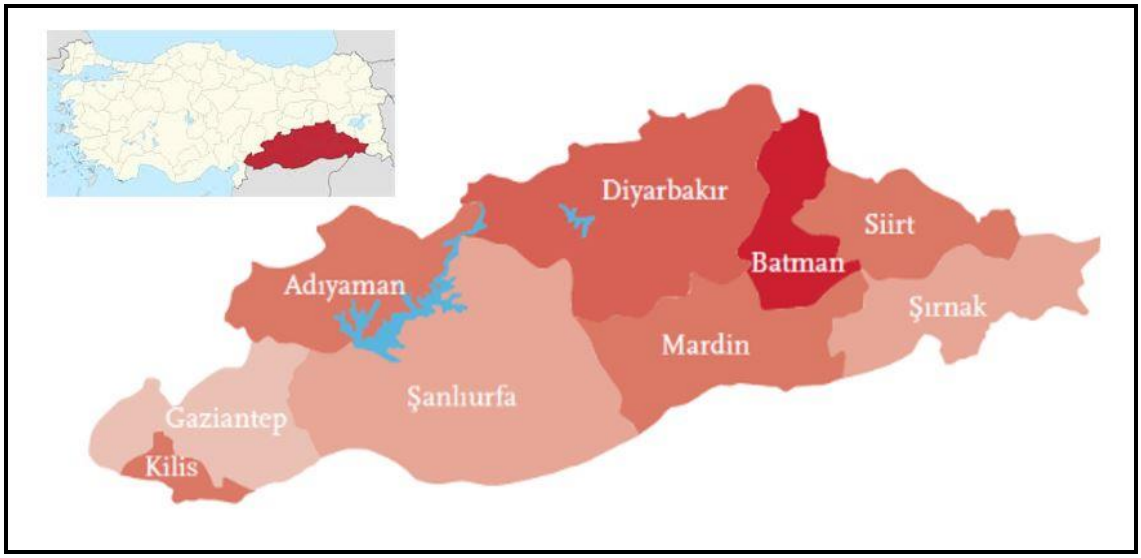

Figure 1. *Location of the Southeastern Anatolia Region (SAR) and provinces in the SAR*

In this study, although it was intended to calculate the DPI for the entire region, due to lack of adequate and reliable data for Şırnak, it is excluded from the analyses, and DPI values are calculated for the remaining eight provinces. *Table 1* shows the geographical co-ordinates of the meteorological stations chosen in the SAR. The precipitation data monitored in the meteorological stations between 1970 and 2017 were obtained from the General Directorate of Meteorological Services of Ministry of Forestry and Water Affairs. The statistical parameters of monthly precipitation at eight stations during the study period are presented in *Table 2*.

Standardized precipitation index (SPI)

The SPI is a powerful index with easy calculation steps as well as flexible time scales (e.g. 1, 3, 6, 12, 24 months). One of the main advantages of SPI is that it use only precipitation data. The index quantifies the precipitation deficit and surplus, taking into account the time series of cumulative precipitation for various reference periods. First, a Gamma distribution (two parametric) is fitted to precipitation data, and then it is transformed into a normal distribution. Therefore, the average of SPI values is 0, and the standard deviation is 1. For the studied area and studied period, one can identify the wet and dry conditions in accordance with the classification scale of SPI (*Table 3*).

It should be noted that, there has been studies which use different statistical distributions (Tsakiris and Vangelis, 2004; Angelidis, 2012), however Guttman (1999) showed that there are only minor differences in the results of SPI with respect to magnitude, duration and extent of drought. Since the SPI is a well-known index, the detailed calculation steps are not given here, however, it can be found in several papers (Mishra and Desai, 2005; Dashtpagerdi et al., 2015). In addition, the SPI software used in this study (SPI_SL_6.exe) could be download from the link given in the WMO (2012).

Table 3. *Classifications scale for SPI values (McKee et al., 1993)*

SPI values	Drought class
2.00 ≤	Extremely wet
1.99 to 1.50	Severely wet
1.49 to 1.00	Moderately wet
0.99 to (−0.99)	Near normal
(−1.0) to (−1.49)	Moderately dry
(−1.5) to (−1.99)	Severely dry
−2.00 ≥	Extremely dry

Performance indicators (PIs) for the SPI time series

The PIs are generally used to evaluate water management alternatives and/or to enable the comparison of decisions (Hashimoto et al., 1982). They can be simple averages (e.g. average of deficits), simple ratios (e.g. cost/benefit) and probability of time-based or volume based reliability.

In this study, the SPI-12 (12 month-SPI time series) were evaluated with five PIs defined as reliability, resilience, vulnerability, maximum extent and maximum duration. This procedure can be illustrated by considering any selected indicator C, whose time series of values is denoted as C_t, where the simulated period, t, extends to some future time, T (*Fig. 2*). To define reliability and resilience PIs, a single limit of unsatisfactory is assigned to SPI ≤ 0 for SPI-12 time series, which demonstrates the deficit from the mean amount of precipitation.

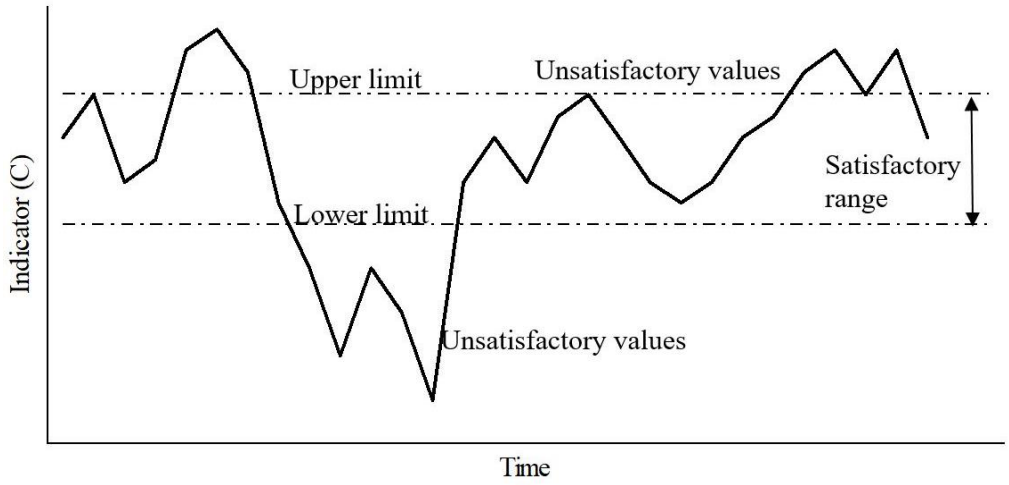

Figure 2. *Illustration for reliability, resilience and vulnerability concept*

Reliability (REL) is defined as the probability that any particular C_t value will be within the range of values considered satisfactory, and is calculated in accordance with *Equation 1*.

$$REL=\frac{(\text{Number of satisfactory } C_t \text{values, SPI>0})}{(\text{Total number of simulated period})} \quad \text{(Eq.1)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_72897303
© 2018, ALÖKI Kft., Budapest, Hungary

Resilience (RES) is an indicator describing the speed of recovery from an unsatisfactory condition. It is the probability that a satisfactory value C_{t+1} will follow an unsatisfactory Ct value, and is calculated according to *Equation 2.*

$$RES=\frac{(\text{Number of times a satisfactory } C_{t+1} \text{ value follows an unsatisfactory } C_t \text{ value})}{(\text{Total number of unsatisfactory values, SPI}\leq 0)} \quad \text{(Eq.2)}$$

Although several definitions are possible for the vulnerability (Sandoval-Solis et al., 2011), in this study it is expressed as the probability of exceeding a certain threshold. Here, VUL is obtained by using the following relation that accounts the *"drought events"* (SPI ≤ -1), and *"severe and extreme drought events*" where the SPI ≤ -1.50 (*Eq. 3*).

$$VUL=\frac{(\text{Total number of severe and extreme drought events, SPI}\leq -1.5)}{(\text{Total number of drought events, SPI}\leq -1.0)} \quad \text{(Eq.3)}$$

The maximum extent (ME) of the drought is calculated by dividing the minimum SPI that is experienced in the study period, by -4 (*Eq. 4*). Here, an assumption is made as the worst-case drought magnitude, SPI = -4.0. It should be noted that, it could be determined in accordance with the experts' and decision makers' opinions.

$$ME=\frac{(\text{min SPI that is experienced in time})}{(\text{worst-case drought magnitude , assumptive SPI}=-4.0)} \quad \text{(Eq.4)}$$

The maximum duration (MD) is considered as the ratio of maximum duration of continuous droughts to the worst-case drought duration (D), which is accepted as 3 years (36 months) long drought period in this study (*Eq. 5*). It is thought as a threshold after which the devastating socio-economic effects may occur in agriculture sector.

$$MD=\frac{(\text{max duration of continuous droughts})}{(\text{worst-case drought duration , assumptive D}=36 \text{ months})} \quad \text{(Eq.5)}$$

Drought power index (DPI)

The DPI can be calculated by combining the REL, RES, VUL, ME and MD indicators as suggested by various researchers (Hashimoto et al., 1982; Sandoval-Solis et al., 2011; Maity et al., 2013). In this study, the DPI is proposed as a geometric average of *M* performance indicator (C_m^i) for the ith province in accordance with Sandoval-Solis et al. (2011) as given in *Equation 6.*

$$DPI_i=\left[\prod_{m=1}^{M} C_m^i\right]^{1/M} \quad \text{(Eq.6)}$$

Here, since the drought is identified as an unfavorable phenomenon, the indicators have to be arranged in accordance to their criteria type (minimizing or maximizing). For example, the reliability indicator is a maximizing indicator even if we calculate sustainability (maximizing reliability is a desired situation). However, in this proposed index where the main aim is to determine the devastating effects of drought with a single numeric (the power of droughts), the reliability is considered as a minimizing indicator. Therefore, the REL indicator is added to the geometric average formula as (1-REL). The same approach is applied for all five indicators, and the DPI is defined by

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_72897303
© 2018, ALÖKI Kft., Budapest, Hungary

the following formula (*Eq. 7*) for the i^{th} province. The indicator (C_m^i) in the below equation must have a scale from 0-1, and undesirable criteria values tend to 1. In addition, more indicator can be included in DPI.

$$DPI_i=\left[(1\text{-}REL^i)*(1\text{-}RES^i)*VUL^i*ME^i*MD^i\right]^{1/5} \quad \text{(Eq.7)}$$

Decision scale of the DPI

The DPI is a valuable tool to demonstrate the drought character of the given region. However, a decision scale has to be proposed to evaluate the variations of drought character spatially and temporally. Since the drought power index does not mean the same thing for all water users, the proposed scale is flexible in accordance with the decision makers' preferences. To this end, the personal conversations with the water managers and crop yield experts in SAR are addressed the decision scale with the limits of indicators and the drought character (*Table 4*).

Table 4. *Indicator limits and decision scale*

Preferences of status	REL	RES	VUL	ME	MD	DPI range	Drought character
Very bad	0.40	0.40	0.80	0.80	0.80	0.71–1.00	Very strong (VS)
Bad	0.50	0.50	0.60	0.60	0.60	0.56–0.70	Strong (S)
Normal	0.70	0.70	0.40	0.40	0.40	0.36–0.55	Normal (N)
Good	0.80	0.80	0.20	0.20	0.20	0.20–0.35	Weak (W)
Very good	1.00	1.00	0.00	0.00	0.00	0.00–0.19	Very weak (VW)

Results and discussion

The assessment of the SPI-12 time series

The SPI-12 values obtained by the monthly precipitation data corresponding the eight provinces in the SAR are given in *Figure 3*. As can be seen, the most of year (approx. 70%) are counted in normal conditions, however the extreme droughts have occurred in 1973-1975 and 2007-2010 periods in almost all provinces. Generally, the basin has experienced severe droughts in 1990-1992 and 2000-2002. It leaps out that record extreme droughts (SPI-12 < -3.0) are monitored at Şanlıurfa, Batman and Gaziantep in 1973, at Kilis in 2014 and again at Batman in 2008. The year 1988 can be concluded as an extreme wet year in the basin. The percentile distributions of drought severities were analyzed by dividing the study period in two separate periods, 1970-1993 and 1970-2017 (*Table 5*). Although the SPI-12 time series is different from each other, it is possible to say that percentile of total droughts (total of moderate, severe and extreme droughts) has been increased in Mardin, Şanlıurfa and Kilis, due to the increasing number of severe and extreme droughts after 1993. Those results are in accordance with the slope of the regression line given in *Figure 3.*

Assessment of the DPI

To make an evaluation that base on the log-term drought conditions, the PIs and the DPI scores of each province were calculated (*Table 6).* The two different evaluation period constitute better understanding the variation in the drought character of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_72897303
© 2018, ALÖKI Kft., Budapest, Hungary

provinces. The REL scores are slightly decreasing in the SAR (except Batman and Diyarbakır) that means the annual total precipitation gets less since the time elapsed. The reduction in precipitation amount is more evident in Mardin, where the probability of getting more than average annual precipitation is decreased from 70 to 53%.

The RES is similar for reliability, so the number of continuous droughts is increasing while the individual droughts are decreasing. This is another important result for the region because continuous droughts are more devastating for the socio-economic development in an agricultural dominant region. Again, the decreasing in the resilience indicator is determined significantly for Mardin, and none of the provinces get an increment in that performance indicator.

In this study, the vulnerability measures the percentage of severe and extreme droughts in all drought events. Şanlıurfa, Batman and Adıyaman are in good status from the view of vulnerability. In other words, the severe and extreme droughts are in a shift towards moderate drought in these provinces; however, for the rest of the region, especially in Kilis and Siirt, the opposite is valid.

Şanlıurfa, Batman and Gaziantep have the worst scores for the ME due to the minimum SPI-12 values (-3.45), (-3.35) and (-3.31), respectively. Since the worst-case drought magnitude assumed as SPI-12 = -4.0, the maximum extent indicator results higher values 0.86, 0.84 and 0.83, respectively. As seen in *Figure 3,* the extreme droughts have observed in recent years in Batman, Kilis, Mardin and Diyarbakır, and that is why the significant increase in ME for the relevant provinces.

The MD is an important indicator in the proposed index since it detects the longest drought duration relatively. Siirt, Mardin and Diyarbakır has experienced the longest continuous drought durations 24, 22, and 21 months between 1970 and 2017, respectively. Excluding Adıyaman, it is clear from the increasing MD values that the longer droughts have experienced after 1993 for the other provinces.

Considering the end of 2017, the droughts were characterized as strong in seven provinces and normal in Adıyaman. When we compare the DPI values for 1970-1993 and 1970-2017, it is clear that there is an increase in the drought power generally. The DPI increase 43% and 25% for Mardin and Kilis, respectively. The ranking of provinces according to DPI scores for (1970-1993) and (1970-2017) revealed interesting results (*Table 7*). Due to the droughts after 1993, the orders of Mardin and Diyarbakır have moved from bottom to top in the ranking list. Adıyaman seems to lose drought power relative to the first period due to the environmental effects of Atatürk Dam, the biggest dam in Turkey with its 817 km^2 reservoir surface and under operation since 1992.

The results of the Southeastern Anatolia Region case which is in line with the findings of other researches (Sönmez et al., 2005; Oruç, 2017) are revealed that the region is under the threat of intense droughts. Moreover, it is obvious that the droughts have gained power after 1993. The increasing in drought power is more evident in Mardin, Diyarbakır, Siirt and Kilis, according to the DPI as well as the DPI rankings. Therefore, starting from these relevant provinces, the more efficient drought management plans integrated with water management policies are needed to overcome or reduce the negative effects of droughts in the region.

Table 7. *The DPI rankings of provinces*

Rankings	DPI (1970-1993)	DPI (1970-2017)
1	Şanlıurfa	Mardin
2	Adıyaman	Diyarbakır

Before concluding, it is worthwhile to mention here that the most critical factor in the RRV approach is the threshold selection process, as by using a different threshold, the results will be different. In the DPI formulation, a reasonable procedure (regional experts' opinions) is proposed to identify the failure thresholds and the performance limits to obtain the decision scale. More research is needed into choosing the threshold level for different hydroclimatic regions. Towards this aim, sensitivity analysis, which

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_72897303
© 2018, ALÖKI Kft., Budapest, Hungary

was beyond the scope of the present paper, is suggested as a tool to assess the sensitivity of the DPI to different SPI thresholds.

However, the DPI withstand the RRV framework approach, which has the ability to combine and quantify performance indicators. That is a key advantage of the DPI. Moreover, in recent years, more attention is given to the development of hybrid frameworks that could provide more reliable assessments with greater clarity and consistency. With its composite design, the DPI also fits well to that concept also, and can capture the long-term drought characteristics. Additionally, the DPI only needs the precipitation data that are relatively easy to obtain and process. In other words, the DPI also carries the advantages of the SPI.

Conclusions

In this study, the Drought Power Index (DPI), a modification of widely used SPI with performance indicators, is proposed. It aims to enhance the standardized precipitation index in characterizing drought's devastation power by logging the historical data. The DPI is a single metric to assess the historical drought characteristics base on the given performance indicators. It allows to evaluate the droughts by (i) considering the probability of occurrence, (ii) the speed of recovery once a drought occur, (iii) the relative frequency of severe and extreme droughts, (iv) maximum magnitude of experienced drought and (v) maximum duration of continuous droughts in a single metric. The selection of the time periods in SPI according to growing season of the main crops in the region as well as the decision makers' preferences on threshold values could make the DPI flexible and adaptable for the different drought management policies. Since it characterizes the drought power, it would provide additional insights for the studies dealing with socio-economic droughts, ecologic droughts as well as agricultural risk and insurance.

The presented case study is indicative to represent the DPI. It is noted that the use of the index in different watersheds should provide consensus on the effectiveness and the applicability of the proposed index. Moreover, the main recommendations on this approach include the application of the proposed approach to different time scales of SPI (e.g. monthly, seasonal or crop specific vegetation months for rainfed crops), investigation of the responses of the performance indicators to different SPI thresholds and application of this framework using other drought indices (e.g. Reconnaissance Drought Index). The further studies will reveal conclusions that are more comprehensive, and will help water authorities to assess existing situations, plan for future scenarios, implement processes and thus increase efficiency of the investments.

HERITABILITY OF END-USE QUALITY AND BIOFORTIFICATION CHARACTERISTICS IN LINE X TESTER BREAD WHEAT (*Triticum aestivum* L.) CROSSES

KUTLU, I.

Department of Biosystem Engineering, Faculty of Agriculture, Eskisehir Osmangazi University 26160 Eskisehir, Turkey
(e-mail: ikutlu@ogu.edu.tr; phone: +90-222-3242991; fax: +90-222-3242990)

(Received 29th Aug 2018; accepted 11th Oct 2018)

Abstract. Wheat (*Triticum aestivum* L.) is an important resource of dietary energy and protein for the growing world population and its potential to reduce micronutrient-related malnutrition can be increased via improving the genetically micronutrient-rich wheat varieties. The study aimed to evaluate "line x tester" bread wheat hybrids in terms of the physical quality criteria affecting wheat flour yield, protein and biofortification associated nutrient element contents. In addition, it was tried to determine the gene effects that play a role in the inheritance of biofortification and end-use quality traits. Twenty-eight F_1 hybrids which were obtained by crossing seven lines and four testers were evaluated along with parents in Eskisehir, Turkey during 2016-17 growing period for mentioned traits. It has been determined that the effects of non-additive genes are dominant in the inheritance of the traits examined. It would be wise to leave the selection for these properties to future generations. In addition, appropriate parents and promising crosses were identified by looking at their parents' general combination abilities and specific combination abilities and heterosis values of the crosses. The results obtained were also supported by the principal component analyses. Consequently, the DH22 line is appropriate for breeding programs for high end-use quality and biofortified capacity. "DH20xHarmankaya", "DH22xHarmankaya", "DH21xAltay" and "DH18xAltay" are promising crosses for biofortification and end-use quality.
Keywords: *zinc and iron concentration, kernel dimensions, protein rate, color values, gene action, malnutrition*

Introduction

Wheat (*Triticum aestivum* L.) is one of the cereals with the highest production worldwide and its traits such as easy marketing, transportation, storage and processing facilities encourage wheat cultivation. This intense and unending interest in wheat farming has also intensified plant breeding efforts to make the agricultural characteristics of wheat more suitable to consumer demands. Until today, major improvements in yield, processing and end-use quality of wheat has been obtained with agronomy and plant breeding. Despite this advancement, common food shortages maintain, there are a lot of undernourished people in the world today, predominantly in the developing countries. The changes in the yield potential of today's wheat varieties and the rapidly decreasing genetic potential, which are caused by the changing climatic conditions, make the breeding studies indispensable. Maintaining grain quality besides yield under climate change is critical for human nutrition, end-use functional traits and commercial value of wheat (Nuttall et al., 2017).

Grain quality is defined by a range of physical and compositional characters which are important end-use requirements and commercial value. Physical characteristics of the wheat kernel, including grain weight, dimensions, shape and hardness, influence the classification, milling, transportation, storage and market value of bread wheat (Maphosa et al., 2014). Grain color that can be included in physical quality characters of the kernel is also a frequently used parameter for the classification of wheat and quality

determination. Market classes of bread wheat are based in part on white or red kernel color. Color is of extensive significance in food preference, and it may be a guarantee of purity and trueness to the preferred type (Graham et al., 1999). The compositional characteristics include protein concentration and composition of other nutrients. Grain protein concentration and composition determine nutritional and end-use characters of dough mixing and rheological traits including loaf volume, dough strength, extensibility, breakdown and development time all of which influence the activity of the bread making process and product quality (Nuttall et al., 2017). Macro and micronutrient elements such as phosphor (P), potassium (K), copper (Cu), iron (Fe) and zinc (Zn) in the other nutrients constituting the grain composition are important components determining grain quality.

Cereal crops which are an important source of minerals and other nutrients for humans supply 44% of the daily intake of Fe (15% from bread), 25% of Zn (11% from bread) and 31% of Cu (14% from bread) (Henderson et al., 2003). Especially, high Zn and Fe concentrations in bread wheat are important quality characters because they could reduce micronutrient malnutrition-related problems in the developing world (Velu et al., 2012). Iron is an necessary element for nearly all alive organisms as it plays a role in a wide diverse of metabolic processes, including haemoglobin formation, deoxyribonucleic acid (DNA) synthesis, oxygen and electron transport (Abbaspour et al., 2014). In addition, Zn is one of the most important trace elements whose significance to health is increasingly appreciated. It has three major biological roles, as catalyst, structural, and regulatory ion in the organism and its deficiency may play an important role in the appearance of diseases (Chasapis et al., 2012). One of the minerals required for human nutrition is also Cu, which can create negative health effects in case both deficiency and excess (Stern et al., 2007). Potassium is one of the essential nutrients in the human body with the regulatory effect of blood pressure. It is important because of requiring in human nutrition, also it provide increased in quality of edible parts of crops and crop yield (He and MacGregor, 2008). Plant breeding to reduce the extent of mineral nutrient deficiencies and especially increase micronutrient concentrations such as Fe and Zn in cereal grain is named genetic biofortification and it is the most sustainable approach and a widely accepted strategy for this aim (Cakmak, 2008).

Grain quality is influenced by genotype, environment and agronomic practise. There is strong genetic control over physical kernel features like shape, thickness and volume just as functional properties of wheat such as grain hardness, protein content and composition (Ferreira et al., 2012). Grain color is also a simply inherited feature and can be easily combined with high-yielding traits (Graham et al., 1999). Over all, the understanding gene action play role in heritability of milling and end-use characteristics will provide a powerful tool for developing breeding strategies for overcoming the effects of climate change to grain quality. Knowing type of gene effect in the formation of a character is important to determine the breeding method to be able to improve the mentioned feature. In addition, improving biofortified wheat varieties which have desirable nutritional quality, protein content, processing quality and higher grain yield will provide reduction for undernourishment and malnutrition at developing countries.

It has been endeavored providing more crop yield and quality alternatives to farmers in developed varieties with conventional breeding. However, nutritional value of crop has been usually disregarded. Present genetic variation, heritability of characters, gene action, relationship among traits, and the availability of diagnostic tools and screening

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

techniques are criteria mostly used to define candidate characters and estimate potential genetic gains. Breeding for enhanced micronutrient content should performed basically depend on accompanying agronomic or end-use traits to be adopted by farmers and consumers. The availability of genetic variation for micronutrient density is necessary for determining the applicability of obtaining meaningful enhancement through conventional breeding. If there is adequate genetic variation, breeders can utilize transgressive segregation, additive gene effects and heterosis to develop micronutrient density (Pfeiffer and McClafferty, 2007). When the required genetic variation is not available, combining through hybridization is frequently used by plant breeders to create genetic variation. The breeder would like to recognize the parental and cross offspring in these newly developed cross populations in terms of desired characteristics in early generations and to choose those with superior characteristics. Knowing heritability and type of gene effect in the characters to be transferred, general and specific combination abilities of selected parents is important to determine breeding method and facilitate cultivar development studies. "Line x tester" analysis is frequently used as an easy and powerful statistical approach for determining combining ability of genotypes in plant breeding (Aslam et al., 2014).

The main purpose of the study was to identify the best parents and promising crosses according to general and specific combining ability of them for physical and chemical quality traits to determine the potential of desirable end-use quality and biofortification properties in bread wheat. In addition, determination of gene effects that play role in inheritance of these traits related to quality and biofortification was aimed.

Materials and methods

Plant material and experimental design

In the study, plant materials are seven doubled haploid (DH) wheat lines gained from the F_2 generation of hybrids between 33IBSWN-S-244, Tosunbey and Mufitbey, four registered cultivars (Altay 2000, Bezostaja-1, Harmankaya 99, Kate A-1) and twenty-eight crosses obtained from them. Hybridization method was line x tester mating design. The 39 genotypes were grown in randomized complete block design with three replications. The field experiment was conducted at Eskisehir Osmangazi University Agriculture Faculty research areas, Eskisehir, Turkey in 2016-17 growing season. The plots consisted of four rows which are 1 m long with 20 plants and distance between rows was 30 cm. Standard practices used by the breeding programs were applied as agronomic practices. Wheat grain was harvested at crop maturity and grain samples were analysed in terms of physical and chemical properties.

Physical kernel properties

Three principal kernel dimensions (length, width and thickness) were measured using a digital caliper (Neiko, 01409A, made in USA) reading to an accuracy of 0.01 (mm). Kernel length was accepted as the longest line through the grain, which almost always runs from the embryo to the distal end, and kernel width was the longest line through the grain at a 90° angle to the length, while kernel thickness was determined the longest line through the grain that is perpendicular to both the length and the width. Then, kernel sphericity (KS) and volume (KV) were calculated using the following equations:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_73057326
© 2018, ALÖKI Kft., Budapest, Hungary

$$KS = ((LWT)^{1/3}) / L * 100 \quad \text{(Mohsenin, 1986)}$$

$$KV = 4 / 3.\Pi.LWT \quad \text{(Weisstein, 2018)}$$

In these equations, L, W, T indicated length, width and thickness, respectively. Kernel hardness (KH) was determined as SKCS hardness index (HI) using the Single Kernel Characterization System 4100 (SKCS) (Perten Instruments, North America, Inc., Springfield, IL, USA). Similarly, kernel weight was measured using a sample of 300 kernels (Method 55-31) and then calculated thousand kernel weights (AACCI, 2000). The hectolitre weight was determined using a 250 ml volume hectolitre scale (Loyka H Hectolitre scales).

The kernel color of wheat genotypes was determined using Granular Attachment CR-A50 with Konica Minolta Chroma Meter CR-400 for each replicate. The CIE (Commission Internationale De L'eclairage) L (lightness), CIE a (red– green) and CIE b (yellow–blue) were read using a D65 light source and the observer angle at 2°. The tristimulus values of CIE L, a and b readings were calibrated against a standard white plate (Y = 84.8; x = 0.3199; y = 0.3377).

Chemical kernel properties

Kernel nitrogen (N) content was determined by the Kjeldahl method (Kirk and Sawyer, 1991), and then total protein content (%) calculated by multiplying the N percentage by 5.7. The ground samples were turned into ash at 500 °C in furnace for 5 h and then dissolved in 3.3% HCl and analyzed for K, Zn, Fe and Cu by using atomic absorption spectrometer (Analytic-Jena novAA 350, Germany) according to Balint et al. (2001). To check the related elemental measurements, reference tomato leaf samples from National Institute of Standards and Technology (Gaithersburg, MD, USA) were used. Phosphorus concentrations of these samples were measured colorimetrically according to the Barton (1948) method. The analysis results were confirmed by NIST Reference Material 8436 Status Wheat Flour.

Statistical analyses

The analyses of variance, general combining ability (GCA), specific combining ability (SCA), variance of additive and dominant gene effects based on variances of general and specific combination abilities and broad and narrow sense heritability were calculated according to Falconer (1980), using the TarPopGen Statistical Package Program developed by Ozcan (1999). The magnitude of heterosis over mid parent value and over better parent value (heterobeltiosis) was estimated according to the method suggested by Chiang and Smith (1967) and Fonseca and Patterson (1968), respectively.

The raw data of variables into distinct principal factors representing the different proportions of the data variability was transformed with principal component analysis (PCA). Thus, it was provided data reduction and transforming the raw data into principal components. PCA factors were equal to the number of studied variables which were 17 initial in this study, then these factors was transformed the raw data into six factors with the pattern that first factor contributed the most variability. The first six factors have effectively transformed the raw data, extracted significant variability and considerable for further data analysis due to having more than 1.0 eigenvector values. Maximum iterations for convergence were 25; and the variamax rotation method was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_73057326
© 2018, ALÖKI Kft., Budapest, Hungary

applied. The other factors had eigenvector value less than 1.0 not effective in order to interpret the results. However, evaluation of the first four factors instead of the first six factors resulted in a more meaningful grouping. Bi-plot was drawn by using principal factors, which have most of variability. Bi-plot was two dimensional scatter diagrams which depicted the scattering pattern of genotypes and traits. The maximum, minimum and mean values of genotypes for each trait were shown as box-plot. These analyses carried out with psych" R package (R version 3.3.1).

Results and discussion

End-use quality of parents and hybrids

The maximum, minimum and mean values of psychical kernel characteristic for "line x tester" bread wheat crosses were shown in *Figure 1*. For all genotypes, values of psychical kernel traits were ranged 5.97-7.12 mm for kernel length, 2.29-3.15 mm for kernel width, 2.86-3.45 mm for kernel thickness, 163.59-311.52% for kernel volume, 55.58-61.75% for kernel spherecity, 31.66-42.36 g for thousand kernel weights and 74.35-81.33 kg for hectolitre weight. The best parents among the testers were Harmankaya for kernel length while Bezostaja-1 for all psychical kernel traits. Among the lines, DH18 for kernel length, DH19 for kernel hardness and DH6 for hectolitre weight, while DH20 had the best performance for many of psychical kernel traits. Variation of crosses for these traits were quite small and mostly between their parents. "DH6 x Harmankaya", "DH22 x Harmankaya", "DH19 x Altay", "DH19 x Kate" and "DH20 x Bezostaja" were remarkable crosses for these traits (*Fig. 1*).

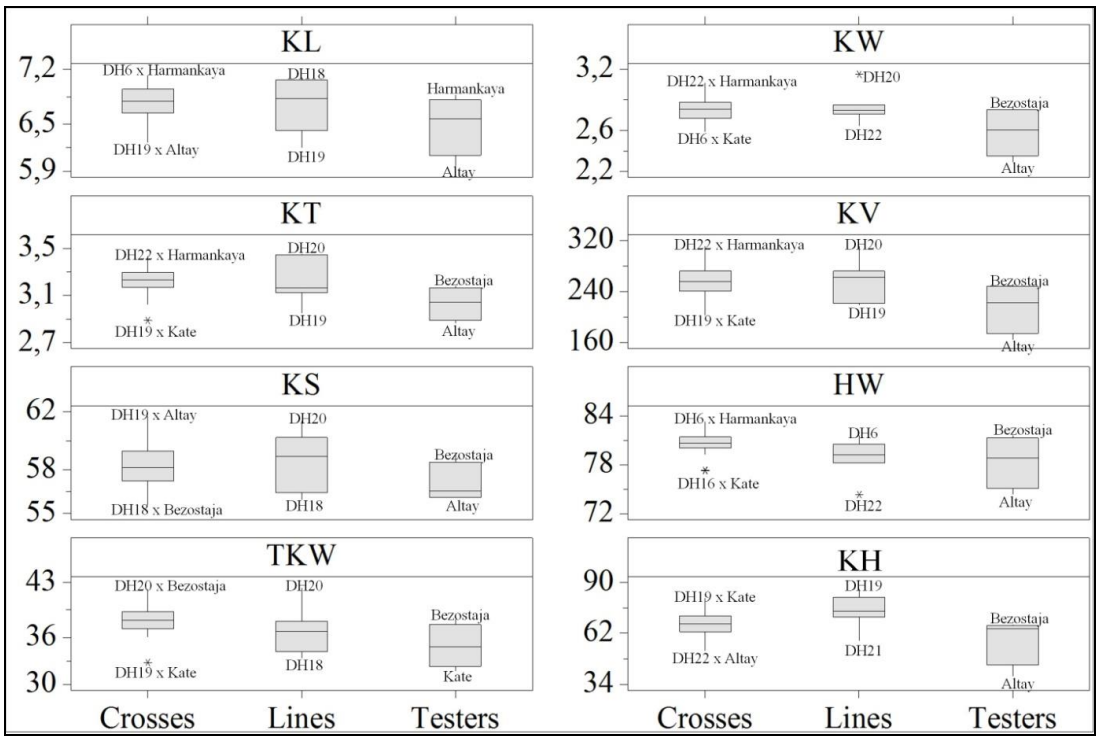

Figure 1. *Maximum, minimum and mean values of psychical kernel characteristic for line x tester bread wheat crosses. KL: kernel length (mm), KW: kernel width (mm), KT: kernel thickness (mm), KV: kernel volume (%), KS: kernel sphericity (%), HW: hectolitre weight (kg), TKW: thousand kernel weight (g), KH: kernel hardness (SKCS-HI)*

Kernel length, width, thickness, sphericity and volume affect the amount of flour. Because can be extracted in milling more flour, it is preferred with large, round and plump grain than small, thin and shrivelled grain (Maphosa et al., 2014). Thousand kernel weights that is an important component of grain yield is one of the physical factors that are indicative of grain size and determines grain quality and it is very important to focus on breeding studies (Korkut et al., 2001). Hectolitre weight is an important physical quality element used in wheat standards. As it increases, the amount of dry matter and flour increase (Schuler et al., 1995). If considered to the observed values, it is thought that the flour yield and milling quality of the mentioned genotypes and therefore the market values may be higher. Kernel hardness, in other words, the texture of wheat, has a great influence on the quality and general processing properties of bread wheat (Ponce-García et al., 2016). Hardness affects milling and if grain is harder, starch content is more damaged. Gas retention capacity, fermentation tolerance, water absorption, energy consumption in the mill increase (Hruskova and Svec, 2009). In the grain hardness measurements made with SKCS, hard wheat scores are around 75 and soft wheat scores 30 and below. According to this, genotypes DH6, DH16, DH19, DH22, "DH6 x Kate", "DH16 x Bezostaja", "DH19 x Harmankaya" and "DH19 x Kate" belong to the hard wheat class.

The L color value of the crosses, lines and tester measured in the kernel ranged from 43.93 to 56.94, with an average of 49.19. The line DH18, the tester Altay and their cross have the highest values (53.98, 56.94 and 56.73, respectively), it has been the lowest with the "DH21 x Harmankaya", Kate and DH19 (*Fig. 2*). In terms of a value in kernel, "DH20 x Altay" had the highest value (13.20), while "DH22 x Bezostaja" was the last value with 10.84 and the average of the genotypes was 12.01. The b value of the kernel was determined as the lowest 20.12 in "DH16 x Bezostaja", while as the highest 26.65 in "DH20 x Altay". The average of genotypes was 22.96 and the all lines were exceeding the average, while only one tester (Altay) exceeded it (*Fig. 2*).

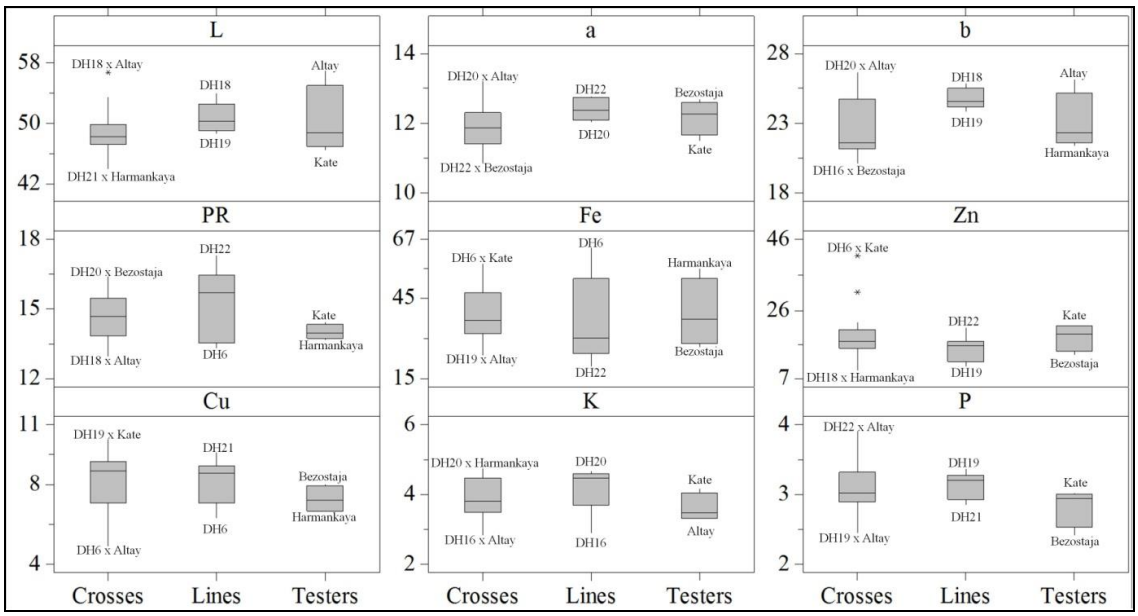

Figure 2. *Maximum, minimum and mean values of chemical kernel characteristic for line x tester bread wheat crosses. L: lightness, a: red-green, b: yellow-blue, PR: protein rate (%), Fe: iron (mg kg^{-1}), Zn: zinc (mg kg^{-1}), Cu: copper (mg kg^{-1}), K: potassium (mg kg^{-1}), P: phosphorous (mg kg^{-1})*

Kernel color serves as the basis for segregating wheat grain into classes. Wheat grains have white, yellow and red colors. These color differences are generally are caused by color materials present in different parts of the grain and genotypic differences. The fact that the grain is normal and light indicates that the grain is solid, thin-crusted and soft, and that it is normal and dark color indicates that the grain belongs to the hard wheat variety. When the observation values were examined, it was seen clearly that L value is low and a value is high for genotypes with high hardness and protein rate. Namely, dark colored and red grained genotypes had harder and higher protein. Although high protein contents and taking a long time pre-harvest sprouting resistance has been associated with red kernel color in wheat, white kernel color in wheat is preferred for the principal foods made from wheat in some countries (De Peuw and McCetc, 1988). Therefore, breeding programs are planned according to consumer demands for wheat kernel color.

Protein and mineral contents of genotypes

It is desirable that the amount of protein that plays a role in the occurring of wheat quality is least 11% for bread and 9% for biscuits. As shown in *Figure 2,* among parents, the highest protein content (17.30%) was found in the DH22 and the lowest protein content (13.30%) was detected in the DH6 line. Among the crosses, "DH20 x Bezostaja" had the highest value with 16.38%. McNeal et al. (1965) reported that F_1 crosses shown a lower mean value than parents in terms of protein content, while Perenzin et al. (1992) informed that they had higher protein content than their parents. In this study, cross combinations were usually among parental values.

Genetic variation for Zn and Fe is quite limited in registered wheat cultivars, so they are not useful for usage in breeding programs (Cakmak et al., 2004; Zhao and McGrath, 2009; Gomez-Becerra et al., 2010). However, the desired genetic diversity can be created by a suitable hybridization program. In this study, Fe (19.40-63.94 mg Fe kg^{-1}) and Zn (9.29-41.43 mg Zn kg^{-1}) had the largest variation among the examined micronutrients. Similar results were found by Gomez-Becerra et al. (2010). The highest Fe concentration was detected in DH6 line, the cross "DH6 x Kate" and tester Harmankaya followed it with 57.91 and 56.05 mg kg^{-1}, respectively. Zinc concentrations varied between 9.29 and 41.43 and mean values was 18.30 mg kg^{-1}. "DH6 x Kate" among the crosses, Kate between the testers and DH22 between the lines were remarkable genotypes (*Fig. 2*).

Copper concentrations of wheat genotypes ranged from 4.90 to 10.30 and the mean Cu concentration was 8.04 mg kg^{-1}. The best genotypes were "DH19 x Kate" and DH21, while the least Cu concentration was detected "DH6 x Altay". Mean values of K and P concentrations were around 4.0 and 3.0 mg kg^{-1} and there were narrow variations among genotypes. The highest K concentration was found "DH20 x Harmankaya" with 4.75 mg kg^{-1}, while the highest P concentration was 3.92 mg kg^{-1} in "DH22 x Altay". DH20 and DH19 were promising parents for high K and P concentrations (*Fig. 2*).

"Line x tester" variance analyses and estimates of genetic components

The results of "line x tester" variance analysis for each character of genotype and cross combinations are given in *Table 1*. In the analysis of the variance of the traits examined, the squares of all the genotypes (treatment) were found to be significant, while the parents had a statistically significant variation with respect to all other features except the a value.

When considering at the mean squares of the crosses; there were statistically significant differences according to 5% level of importance of kernel hardness and 1% of importance for other properties while thousand kernel weights was non-significant. Among the varieties used as a line, level of 1% statistically significant differences were found for kernel sphericity, kernel hardness, a value, protein ratio, Cu and K concentrations; and level of significant was 5% for kernel length, thousand kernel weight, L value and Fe concentration. Among the varieties used as tester, kernel width, kernel sphericity, kernel hardness and color values statistically significant variation was found. Among the variances belonging to the "line x tester" interaction, significant differences were found with respect to all examined traits except for kernel hardness, thousand kernel weight, a and b values.

When the proportional relations of the general and specific combination ability variance estimates of the examined properties and the variance components of the additive and dominance are examined, dominant gene effects were dominated in inheritance of b values; while "additive x dominant" gene interaction were prominent in inheritance of kernel hardness, thousand kernel weight, a value and Zn concentration. The selection efficiency is concerned with the magnitude of narrow sense heritability in the segregating populations. It was found very low narrow sense heritability degrees for the characters examined in the study (*Table 1*). This situation indicated that there is very low additive variance in this population and the selection should be postponed to further generations.

Previous researchers (Khan et al., 2010; Istipliler et al., 2015; Kumar et al., 2017) who have detected low narrow sense heritability and dominant gene effects for features such as thousand kernel weight, hectolitre weight, kernel hardness and protein rate, have indicated that the waiting of future generations for selection would be appropriate. Lines, testers, and "line x tester" interaction contributed to combinations' variances was found highly different in examined traits. The contributions of the lines to kernel sphericity, thousand kernel weight, protein rate, Cu and K concentrations were defined as highest, while to kernel length and Fe concentration were found closer to "line x tester" interaction. The contributions of testers were found in highest kernel hardness and color values. It is remarkable that there was much more variation in traits which had the highest "line x tester" interactions such as kernel width, kernel thickness, kernel volume, hectolitre weight, Zn and P concentrations.

General combining abilities of parents

General combining ability effects of the lines, testers or individual line performances are useful tools for selecting the cross parents in cross pollinated plants. GCA effects of the lines and testers used in the research can be seen at *Table 2* for observed traits. The negative GCA effects were generally observed for kernel dimensions. Genotypes DH22 and Harmankaya showed a positive and significant GCA for all kernel dimensions traits, while genotypes DH19 and Kate had negative and significant GCA effects. This situation showed that in the combinations which include these two genotypes had relatively small kernels. All parents had significant GCA effects for kernel volume. However, it can be realized that positive and significant GCA effects increasing the kernel volume are more than negative GCA effects. The DH22, which had the highest positive and significant GCA effect, increased the kernel volume in the combinations in which it took a place (*Table 2*). Therefore, the line Harmankaya and the tester DH22 were the most suitable parents for increasing this trait due to their high GCA effects.

GCA effects of kernel sphericity ranged from -1.24 to 1.37. The negative and significant was observed four parents while three parents had positive and significant GCA effects. When the GCA of parents were examined in terms of kernel hardness value, DH19 and Kate showed positive and significant GCA effect at 1% and 5% level, while Altay showed negative and significant GCA effect at 1% level. GCA effect of other parents was found to be insignificant. Negligible positive and negative effects were observed between lines and testers for thousand kernel weight. Besides, it can be seen that one of the lines called DH19 had negative and significant GCA effect for thousand kernel weight. The GCA effect, which reflects the additive gene effect, was found to be positive and significant in the DH6 and DH18 genotypes among the lines and in the Harmankaya variety as a tester, while the negative and significant GCA effect was observed in the DH16 line for hectolitre weight (*Table 2*). DH6, DH22 and Harmankaya genotypes having positive GCA effect on all of these properties are potential to be used as parents in breeding studies to improve flour yield and milling quality of bread wheat. For the L value affecting the lightness or darkness of grain color, the GCA effects were generally negative. Combinations of DH18 and Altay parents showing a positive and significant GCA value may be expected to be darker. The GCA values for a value, a indicator for red color, ranged from -0.47 to 0.72. Bezostaja had negative values, while two of the three parent significant GCA effects were found a positive value. None of the lines for b value had significant GCA effect, whereas three of the tester showed significant positive and negative GCA effect (*Table 2*). It would be appropriate to use DH21 to obtain darker and red kernels, and to use the Altay genotypes as a parent for light colored and white kernels.

When GCA values for protein rate are examined, it was seen that four parents have a positive, five parents have a negative GCA value and the DH20 had the highest GCA effect. While the lowest GCA effect was obtained from the DH18, the effect of the DH16 was calculated to be zero (*Table 2*). It can be concluded that parents with a positive GCA effect have the potential to increase the protein rate and transfer these characteristics to future generations. GCA values calculated for Fe and Zn contents were found statistically significant in almost all of the parents. DH18, DH20, DH21 and Altay genotypes showing a negative GCA value in terms of Fe content also had a negative value for Zn content. While DH6, DH16 and Kate with positive GCA values for both Fe and Zn contents may be suitable parents to improve these properties, DH19 and DH22 have the potential to increase Zn content and Bezostaja has the potential to be suitable parents for breeding programs to increase Fe content. Three of the four lines that detected the significant GCA effect for Cu content had a positive value, indicating that they had a Cu content enhancing effect. Among the parents with important GCA effect for P and K, DH22 and Kate had positive values for both elements (*Table 2*). Parent Kate was a good combiner for protein rate and biofortified crops indicating that this genotype could be the best candidate as one of the parental lines to improve any of these features.

Specific combining abilities and heterosis values of hybrids

Although specific combining ability (SCA) is generally suggested for cross pollinated species such as corn or rye (Longin et al., 2013; Istipliler et al., 2015), SCA effects can be used to select homozygous lines that show transgressive segregation. Significant SCA, heterosis and heterobeltiosis values of physical kernel properties were determined both positive and negative (*Table 3*). This condition indicates that the presence of adequate variation in this population and this cross population contains suitable materials that can be used in breeding studies.

The highest SCA values for kernel length, width, thickness, volume, sphericity and hardness were determined as 0.25 (DH19 x Harmankaya), 0.17 (DH16 x Bezostaja), 0.13 (DH21 x Kate), 32.24 (DH16 x Bezostaja), 1.50 (DH19 x Altay), 5.58 (DH20 x Harmankaya), respectively. Most of the cross combinations for these traits had a positive heterosis value indicating the presence of dominance in the direction of increasing these traits, while most heterobeltiosis values were negative. The heterosis express as percent deviation of cross from its mid-parental value, whereas heterobeltiosis was as percent superiority of cross in comparison to the best parent. Therefore, effective selection of desirable recombinants from crosses with significant high heterobeltiosis value is more likely to be. "DH22 x Kate" for kernel length, "DH22 x Harmankaya" for kernel width, "DH19 x Altay" for kernel thickness, "DH22 x Altay" for kernel volume, "DH6 x Altay" for kernel sphericity and "DH21 x Kate" for kernel hardness had the highest and desirable heterobeltiosis value. It was observed that "DH16 x Bezostaja", "DH20 x Harmankaya" and "DH21 x Kate" combinations had positive and significant SCA effects for all physical kernel properties (*Table 3*). Besides that, these combinations had the positive heterosis and heterobeltiosis values. Kernel size, volume, sphericity and hardness provide important information about flour yield. It was determined that the flour yield of large sized and hard kernel was higher and that the amount of grain protein was not decreased during milling (Dziki and Laskowski, 2005). In parents and crosses, those with positive and significant combination abilities, heterosis and heterobeltiosis values can be recommended for use in breeding studies to increase of kernel size, hardness and therefore to increase yield of flour.

"DH6 x Harmankaya", "DH18 x Altay" and "DH22 x Kate" crosses, which have a high SCA effect value, can be pursued for a thousand kernel weight, although all crosses have non-significant SCA effect. The heterosis values of the crosses for thousand kernel weight ranged from -4.02% (DH6 x Bezostaja) to 21.44% (DH18 x Altay) and the number of positive and significant heterosis value was detected thirteen. Four of the significant heterobeltiosis crosses were positive (*Table 4*). The highest heterobeltiosis was determined in the "DH18 x Altay" cross, followed in "DH18 x Harmankaya". Crosses showing positive heterobeltiosis can be considered as promising because heterobeltiosis is an indication of a performance exceeding both parents. For the hectolitre weight, the SCA effects of crosses varied between -1.80 (DH16 x Altay) and 1.89 (DH16 x Bezostaja). Half of the crosses showed a negative SCA effect while the other half showed a positive SCA effect. Only the DH16 cross series had statistically significant SCA effect. Two of the crosses (DH16 x Altay and DH16 x Kate) were found to be significant negative and the other two positive. When the heterosis values of the crosses were examined, significant values were calculated for 5% negative in a cross, 1% negative in a cross, and non-significant values in six crosses. All other crosses showed positive and significant heterosis. The heterobeltiosis values of the crosses were found to be statistically insignificant, and "DH22 x Altay" and "DH22 x Kate" combinations showed a positive significant value (*Table 4*). When the SCA values and heterosis-heterobeltiosis values of the crosses are considered together; the combination of "DH16 x Altay", "DH18 x Altay", "DH19 x Harmankaya", "DH20 x Kate" and "DH21 x Kate" should be followed as promising crosses in order to increase the hectolitre weight. Since, hectolitre weight and thousand kernel weight are one of the indicators of flour yield (Pomeranz, 1964); the wheat genotypes which have high thousand kernel weight and hectolitre weight are preferred in the flour industry. Hence "DH6 x Harmankaya", "DH18 x Altay", "DH19 x Altay", "DH19 x Harmankaya" and "DH22 x Kate" combinations are preferable for flour industry with their positive SCA, heterosis and heterobeltiosis values for both thousand kernel weight and hectolitre weight.

All SCA values calculated for kernel color values were statistically insignificant and mostly negative. For the L value, significant SCA value were detected as negative only for the "DH6 x Altay" cross and only the "DH22 x Kate" had positive and significant SCA value for the b value cross (*Table 4*). Similarly, the heterosis and heterobeltiosis values of the grain color had negative values for almost all crosses. This result pointed to the presence of colors that turned darker and turned from white to red in the examined population. Red and white kernel color is controlled by three independent, homoeologous genes. Red color is dominant to white, and a single locus containing the dominant allele is sufficient to result in red color. The degree of red color is additive, with genotypes homozygous dominant at all three loci having the darkest red color, and only those homozygous recessive at all three genes being white. Therefore, the genetics of kernel color makes problematic to conversion of red to white kernel color (Sherman et al., 2008). The "DH19 x Kate" cross has to be followed as a cross for lighter grain color, "DH20 x Altay" for increasing the redness and "DH18 x Altay", "DH20 x Altay" and "DH22 x Kate" crosses for increasing the yellowness.

When the SCA effects of protein rate were examined, it was seen that the values changed between -0.81 and 0.93 and that the SCA effects were positive and significant in 13 crosses, insignificant in 3 crosses, and negative and significant values in others (*Table 5*). Thirteen of the cross combinations had positive and significant, while 11 had negative and significant heterosis. The highest heterosis value was detected in "DH21 x Altay" cross with 10.15%. The heterobeltiosis values determined positively in 6 of the crosses were statistically significant in 4 crosses. It can be suggested DH20 and DH22 lines with a high observation average, positive GCA effect value for high protein bread wheat breeding. Within the crosses, "DH20 x Bezostaja", "DH22 x Kate", "DH22 x Harmankaya", "DH20 x Harmankaya", "DH21 x Altay", "DH21 Harmankaya", "DH6 x Altay" crosses showing high observation values, high positive SCA effect, high heterosis and heterobeltiosis can be considered as promising combinations. There were ten, nine, two, seven and one combinations relating to Fe, Zn, Cu, P and K which had positive and significant SCA effects, respectively. In terms of Fe content, the majority of the crosses have exceeded the mean of parents and have positive and significant heterosis values, while nine crosses exceeding the superior parent have been identified (*Table 5*). Twelve of twenty-two crosses which had significant heterosis values was detected positive value for Zn content, and the heterobeltiosis values of seven of them were also positive. Most of the crosses for Cu, P, and K content exceed mean of parents, while the crosses that detected significant heterobeltiosis were mostly negative. "DH19 x Kate" for Cu content, "DH21 x Bezostaja", "DH21 x Harmankaya", "DH22 x Altay", "DH22 x Harmankaya" and "DH22 x Kate" crosses for P content are combinations that should be considered with both positive SCA values and high heterosis and heterobeltiosis values (*Table 5*). Crop improvement activities focus, first, on exploring the available genetic diversity for Fe, Zn. At the same time (or during subsequent screening), agronomic and end-use features are characterized (Pfeiffer and McClafferty, 2007). The combinations "DH6 x Kate", "DH20 x Bezostaja", "DH21 x Bezostaja" and "DH22 x Altay" came into prominence as promising combinations in terms of the Fe and Zn content and it can be possible to obtain biofortified lines by carrying these combinations to next generations.

Selection of genotypes and breeding strategy for grain quality and biofortified capacity

Principal component analysis (PCA) is a method which defined plant properties which contributed most to the present variation within a group of genotypes. In addition, it helps breeders for genetic advancement of characters that have low heritability specifically in early generations via indirect selection, just as the selection of parental lines for breeding purpose (Golparvar et al., 2006; Ahmadizadeh and Felenji, 2011). Cumulative variability of four factors was 26.01%, 41.49%, 56.22% and 69.32%, respectively (*Table 6*). Different characters have different pattern of contribution for principal components. For PC1, all characters were positively contributing except L, b, Zn, P and Cu, whereas for PC2 only six component were positively contributing, also for PC3 and PC4, seven component were negatively contributing (*Table 7*).

Kernel length, kernel width, kernel thickness, kernel volume, thousand kernel weight and hectolitre weight constituted the first component so called physical kernel characters which had the highest factors loadings. Kernel hardness, L, a, b values which can be called as the color properties were the second component, and the third and fourth components included the kernel sphericity, protein rate and nutrient elements.

Bi-plot analysis was performed based on two principal components for relationships between variables and genotypes (*Fig. 3*). Genotypes and variables were presented in single bi-plot graph to further simplify the visualization. Physical kernel characters, protein rate, color values and Fe content contributed maximum towards the total variability present in the evaluated germplasm. Therefore, these traits might be considered selecting effectively of parents for hybridization program to improvement of genetic potential in bread wheat kernel quality in the population as well as to develop elite lines or new F_1 crosses. Moreover, selection of the genotypes had high kernel quality and biofortified capacity should be suggested as one of the best breeding strategy for genetic advancement of bread wheat. According to bi-plot graph, there was high variability in the examined genotypes. “DH20 x Altay”, “DH19 x Altay”, DH20, DH22, “DH21 x Altay”, “DH20 x Bezostaja”, “DH18 x Altay”, “DH22 x Harmankaya” and “DH20 x Harmankaya” can be identified as the best genotypes as these genotypes grouped in positive part as well as they can be easily identified as distinct or farthest from the rest of the genotype groups of the bi-plot (*Fig. 3*). Genotypes “DH6 x Harmankaya”, “DH20 x Harmankaya” and “DH22 x Harmankaya” were reflected much better performance compared to the rest of genotypes for physical kernel characters. The “DH6 x Kate” genotype, had high Fe and Zn content, can be specifically selected to breed biofortified variety.

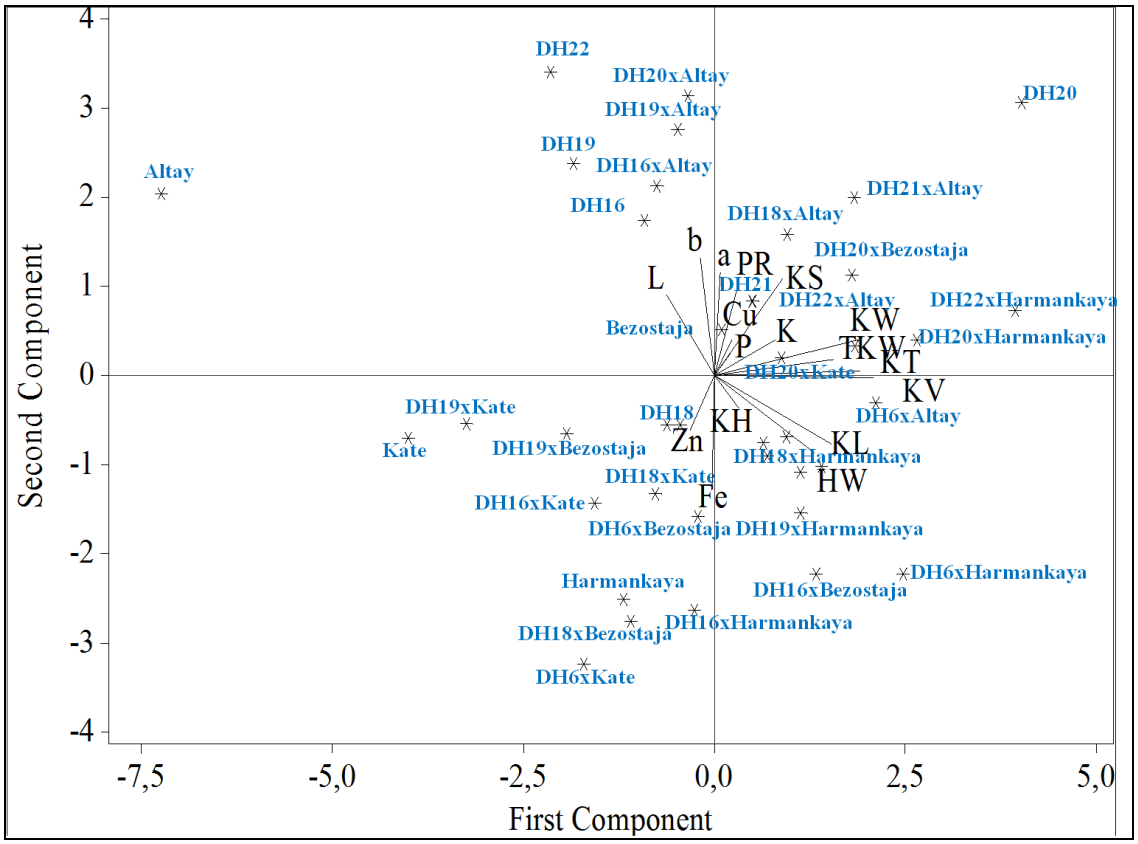

Figure 3. *Principal component bi-plot of 39 bread wheat genotypes between 17 kernel quality characters. (Contribution of first component = 26.01%, second component = 15.48%)*

Conclusions

The population examined in this study has sufficient variation to be assessed in breeding programs in terms of both end-use quality characteristics and biofortification. The predominance of non-additive type of gene actions clearly showed that selection of superior crops should be delayed to F_4 or F_5 generations. The lines DH6, DH22 and the tester Harmankaya were good combiners for the flour yield and milling quality. The lines DH21, DH22 and the tester Kate were good combiners for protein rate and biofortified crops. The DH22 line, in particular, is well-suited to be a favourite of breeding programs for this purpose with both end-use quality and biofortified capacity. "DH6 x Harmankaya", "DH20 x Harmankaya", "DH22 x Harmankaya", "DH6 x Kate", "DH20 x Altay", "DH19 x Altay", "DH21 x Altay", "DH20 x Bezostaja" and "DH18 x Altay" was found as the best crosses to all examined traits. Because "DH20 x Harmankaya", "DH22 x Harmankaya", "DH21 x Altay" and "DH18 x Altay" had both the best SCA and they grouped in positive part of the bi-plot, these crosses are particularly important as promising crosses for biofortification and end-use quality.

It is clear that genetic biofortification offer sustainable solutions to the escalating micronutrient-related malnutrition problems. However, biofortified crops must also be suitable for producers and consumer demands. Therefore, biofortification and end-use quality traits are highly complementary. This research provides general information about the inheritance of wheat quality, and plant breeding strategies for the bioavailability of micronutrients in modern cultivars. This information will light on the

molecular researches about genes controlled these properties, functional genomic analyzes and the creation of association maps in the future. In addition, examined wheat population has a potential occurring both high quality and nourishing candidate varieties for the countries with high malnutrition prevalence in the near future.

(Received 27th Aug 2018; accepted 15th Oct 2018)

Abstract. Transforming even-aged planted forests into uneven-aged, vertically diverse structures often implies that an equilibrium or sustainable condition will eventually be reached where the stand structure and species composition remains relatively constant over time. However, identifying the equilibrium condition is complicated by the complex dynamics of diverse forest structures. In this study four 'sustainability' indices—stand structure, stocking density, species diversity and increment—were applied over a 20 year period in a long-term permanent sample plot within an uneven-aged forest in Scotland to determine whether the equilibrium condition has been achieved. The Shannon Index of species diversity highlighted a gradual shift towards shade tolerating species. Transition periods (average time for all trees in one diameter class to move into next higher diameter class) of shade tolerating species declined with increasing diameter (trees growing more quickly), whereas the opposite trend was found with light demanding species highlighting competition pressures. However, evaluation of the q value, Lorenz curves, Gini coefficient and Stand Density Index revealed values comparable with those found in long-established Central European uneven-aged forests and suggests that, while subtle changes in species composition are occurring, the forest is within the range of parameters indicated for the equilibrium condition.

Keywords: *uneven-aged silviculture, Lorenz curves, Gini coefficient, Stand Density Index, Shannon Index*

Introduction

In many regions of the world, forest cover is dominated by even-aged plantation forests characterised by uniform canopies often of pure coniferous species. There has been increasing pressure in recent years to develop forest ecosystems that are more structurally and species diverse (e.g. Spiecker, 2003), and that are more adaptable to the potential threats of a changing climate (e.g. Millar et al., 2007). The move from predominately clear cutting management (removal of all trees from an area of forest) towards a more ecological or natural approach (i.e. 'uneven-aged', 'irregular', 'selection', 'plenter' or 'close-to-nature' forests) has required a better understanding of the mechanisms of regeneration and seedling/sapling development of species within structurally diverse canopies. Uneven-aged forests are generally described as having vertically varied structures usually comprising a mix of species ranging from new seedlings to mature stems growing within the same space and where a certain level of canopy cover is maintained in perpetuity. The expectation is that these forests will eventually reach a stage of development where, following each harvesting cycle, they revert to the same condition that is often defined as the 'equilibrium' (i.e. 'sustainable', 'stable' or 'balanced') state (e.g. Meyer, 1943; Smith, 1962; Bormann and Likens, 1994; Schütz, 2001). While no forest ecosystem can be regarded as being permanent as

© 2018, ALÖKI Kft., Budapest, Hungary

a result of climatic and human influences that impact over the long lifespans of most forest trees (von Denton, 2011), there remains a desire amongst foresters to achieve some form of equilibrium in uneven-aged forests. This is seen as being important if only to demonstrate that the silvicultural systems used are capable of maintaining a range of economic and environmental services and that these have some degree of permanence.

Determining the equilibrium condition within uneven-aged forests is complicated by the fact that it requires objective, easy-to-use measures that define ways in which management practices influence the relatively complex dynamics of diverse forest structures. O'Hara et al. (2007) pointed out that as forest stands move closer towards a vertically-diverse uneven-aged structure, variations in stand characteristics become more difficult to observe. They suggested four 'sustainability criteria'—stand structure, stand density, species diversity and increment—that they assert are capable of identifying subtle changes in the dynamics of uneven-aged forests. Maintaining the constancy of these measures should ensure that uneven-aged structures achieve a state that could be described as sustainable or in equilibrium, even accepting that some fluctuations are inevitable. Identifying the equilibrium condition would therefore require recurrent assessments of the same area of forest over a period of time to observe whether the equilibrium criteria have been realised.

Distribution of tree size is most commonly used to describe the condition of uneven-aged forests although it is not without its critics. The structure of uneven-aged forests was first objectively studied by de Liocourt (1898) through his negative exponential relationship between stem number and diameter (high number of small trees declining exponentially to a few large trees), and continues to be widely seen as a target for uneven-aged stands with the perception that it is both stable and creates 'natural' forest structures (Larsen, 1995). The shape of the negative exponential distribution is expressed by the ratio of decline in number of trees with increasing diameter known as the q value (Meyer, 1952). However, use of the q value and the underlying negative exponential relationship has been challenged by those who believe that it places too great an importance on the stem number-diameter distribution in decisions on uneven-aged stand structure and management (e.g. O'Hara, 1998; Schütz and Pommerening, 2013). A study of Central European uneven-aged stands by O'Hara and Gersonde (2004) indicated that there are more trees in the highest and lowest diameter classes than suggested by the q value due to the low growth of the small diameter classes requiring a high number of stems to allow diameter advancement. Once these small stems are released by canopy opening, their increment increases causing a sharp decline in the diameter distribution of the medium size classes. When the trees are larger, mortality declines while diameter class advancement continues to be high resulting in a slower decline in stem number. O'Hara et al. (2007) proposed that Lorenz curves (Lorenz, 1905) and related Gini coefficients (Gini, 1909) are more effective in analysing stand structure since they determine the equality of the population of trees in a stand rather than just the shape of diameter distributions (Weiner and Solbrig, 1984). Lorenz curves were originally developed to analyse economic data, but are widely used in studying forest structure. Lorenz curves define number and size as proportions of the tree population and make the method suitable for comparing stands of different size ranges and those that do not accurately follow the negative exponential distribution or reveal a variable q value; a situation common to most if not all uneven-aged stand structures. The Gini coefficient is a measure of the size of inequality in a stand (Weiner

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_73277344
© 2018, ALÖKI Kft., Budapest, Hungary

and Solbrig, 1984) and is considered to be better than other measures in analysing tree size diversity (Lexerød and Eid, 2006).

Stand density is an important measure of sustainability since successful regeneration and recruitment are dependent on the understorey light environment (Jenkins and Chambers, 1989; Philip, 1994; Mitchell and Popovich, 1997) and is usually represented as the number of trees or basal area per hectare. Foresters commonly adjust stocking density at harvesting interventions by altering basal area (cross-sectional area of all trees per hectare) as a means of effecting changes such as increasing levels of regeneration or to favour certain species in the regeneration mix. Successful regeneration in uneven-aged spruce-fir forests generally requires a basal area of no more than 27-33 $m^2 ha^{-1}$ (Schütz, 2002). A basal area no more than 27 $m^2 ha^{-1}$ has been found to be required for successful regeneration of both intermediate and shade tolerant species (Mailly and Kimmins, 1997; Drever and Lertzmann, 2003; Schütz and Pommerening, 2013), and a lower limit of around 20 $m^2 ha^{-1}$ has been suggested as the point at which competing vegetation inhibits regeneration (Ralston et al., 2004). Species diversity in the understorey, therefore, is strongly influenced by the direction of management in determining an appropriate basal area. An 'equilibrium' basal area and stocking density would have to be set at a level that permits continuous regeneration and recruitment into the canopy, ideally of the preferred species.

While basal area has been widely used to control level of canopy cover, it needs to be considered along with stocking density (number of trees per hectare) to provide a more accurate measure of 'site occupancy' since the maximum basal area that a forest stand can attain increases with tree diameter (Zeide, 2005). Site occupancy is usually expressed as the stand density index (SDI) (Reineke, 1933) and allows objective comparisons to be made between stands at different stages of development. Although SDI was originally developed as a stand density assessment method for single-species, even-aged stands, it has been adapted for use in uneven-aged stands with the aim of controlling stand density through balancing growth among the diameter classes (Sterba and Monserud, 1993; Woodall et al., 2005; Yang et al., 2018).

Many researchers argue that a better determinant of the equilibrium condition is increment, particularly within the saplings and lower diameter classes that will eventually become the future canopy trees (Meyer, 1952; Sterba, 2004; Schütz and Pommerening, 2013). It is suggested that the equilibrium state would require a similar number of trees growing into each diameter class from the next lower class and also trees growing out of the diameter class plus those that are harvested or die (Schütz, 1975). The problem with this approach is that data on tree removals are often unavailable or not recorded using a consistent method to estimate increment across the diameter classes (O'Hara et al., 2007). However, an indicator of the productivity of the standing trees in uneven-aged stands can be derived from increment cores to calculate 'transition periods', defined as the average number of years required for all trees in one diameter class to rise into the next higher diameter class (Čavlović et al., 2006). A feature of long established uneven-aged stands is that transition times decline (i.e. increment increases) with increasing diameter due to young trees in the partially shaded understorey emerging into the canopy where more light is available (Smith et al., 1997).

There have been very few investigations attempting to define the equilibrium condition in spite of the fact that it is a central premise of forest sustainability. The aim of the current study was to determine whether sustainability measures based on stem number and diameter, tree density, species diversity and increment (after O'Hara et al.,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

2007) can identify the equilibrium condition. These measures were applied to data collected over a 20 year period from a one hectare permanent sample plot in a rare example of an uneven-aged experimental forest comprising a geographically diverse range of native, Continental European, and North American species, located in Scotland. The stages of this study were analysed as follows: 1) examination of temporal changes in the stem number-diameter distributions, Lorenz curves and Gini coefficients; 2) analysis of increment across diameter classes using transition periods; 3) examination of temporal shifts in canopy and understorey species composition calculated using the Shannon Index of species diversity, and 4) examination of the relationship between stand density and understorey species composition.

Materials and methods

Study area and permanent sample plot

The research site is located within Faskally Research Forest, Perthshire, Scotland (56°42'39.4"N, 3°45'45.5"W) (*Fig. 1*). The research forest is at 120 m altitude and has a moist temperate climate with a mean annual precipitation of 900 mm. The geology comprises Dalradian mica schist parent material overlain with brown earth and ironpan soils. The conversion of the forest was started in 1953 in a mature mixed stand of planted Norway spruce (*Picea abies* (L.) Karst.), Scots pine (*Pinus sylvestris* L.), European larch (*Larix decidua* Mill.), Douglas fir (*Pseudotsuga menziesii* (Mirb.) Franco) and European beech (*Fagus sylvatica* L.). Gaps were opened in the canopy within a 25 hectare area of the forest and planted with Douglas fir, Norway spruce, western hemlock (*Tsuga heterophylla* (Raf.) Sarg.), European beech, Scots pine, European larch and silver birch (*Betula pendula* Roth). Further details on the background of the experimental site are reported in Cameron (2007).

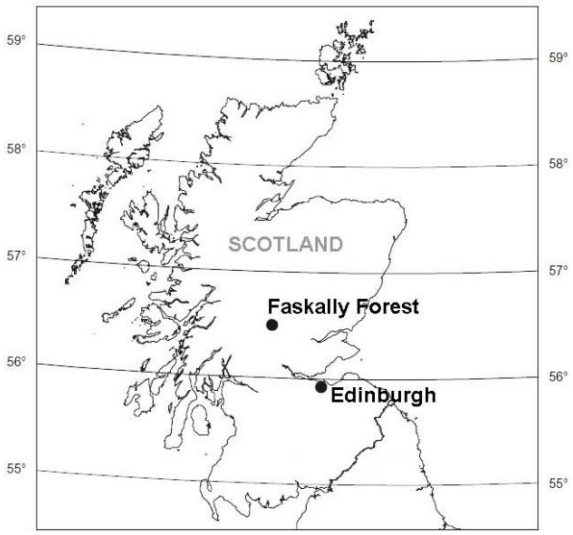

Figure 1. *Geographical location of study area*

A one hectare permanent sample plot was established in 1997 and complete inventories of the plot (all trees counted and measured) were carried out at this time and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_73277344
© 2018, ALÖKI Kft., Budapest, Hungary

subsequently in 2003, 2009 and 2015 corresponding with the six-year cutting cycles with the harvesting interventions occurring the year prior to the inventories. Permanent sample plots are favoured as a method of evaluating whether planned management objectives have been applied and whether management interventions have led to the intended structural changes towards a predefined target (Sterba and Ledermann, 2006). It is the principle of re-measuring exactly the same section of forest over time that gives this approach its precision in comparison with random plot surveys. The current study used data from all previous inventories of the one hectare permanent sample plot.

Diameter distributions

At each inventory, species and stem diameter (DBH – diameter at breast height measured at 1.3 m from ground level) of all the canopy trees (≥8 cm DBH) were recorded using diameter tapes based on methods described by Philip (1994). The diameter distributions of the canopy trees were recorded by five centimetre diameter classes based on the mid-point of the class, e.g. 10 cm class (8-12 cm), 15 cm class (13-17 cm) and so on (Philip, 1994). The average diminution quotient q for the canopy trees was calculated by dividing the number of trees in each diameter class by the number of trees in the next higher class.

Regeneration

A each inventory, a separate survey of seedlings and saplings (≥0.1 m tall, <8 cm DBH) was made using randomly set out 2 × 2 m sample grids (Cameron, 2007; Cameron and Hands, 2010; Cameron and Prentice, 2016). In the 2015 inventory, the regeneration was split into seedlings (≥0.1 m tall, <3 cm DBH) and saplings (3-7 cm DBH) to provide more detailed information on levels of recruitment into the canopy.

Seedlings and saplings were separated into shade tolerating (shade and intermediate tolerant) and light demanding species. Shade tolerating species have the capacity to germinate, establish, survive and grow in the shade of other plants, whereas light demanding species require full or nearly full light to achieve these attributes. Levels of shade tolerance of species used in this study were based on studies of relative shade tolerance (e.g. Mailly and Kimmins, 1997; Minore, 1979; Schütz, 2002; Drever and Lertzmann, 2003; Hale, 2004; Petritan et al., 2007; Schütz and Pommerening, 2013; Drössler et al., 2017). A summary of the data from the four inventories is shown in *Tables 1* and *2*.

Lorenz curves, Gini Coefficients and Stand Density Index (SDI)

Lorenz curves are derived by plotting cumulative relative number of trees against the corresponding cumulative relative diameter or basal area with the upper limit set by the largest tree. Lorenz curves were plotted from data from the full inventories. Curves are generated by ranking the trees by the cumulative proportion of number of trees (y-axis) against the cumulative proportion of both DBH class and basal area (x-axis) (*Eq. 1*).

$$L(F) = \frac{\int_0^F x(F_1)dF_1}{\int_0^1 x(F_1)dF_1} \quad \text{(Eq.1)}$$

where $L(F)$ = Lorenz curve, F = cumulative proportion of trees, $F(x)$ = cumulative distribution function and $x(F)$ = inverse cumulative distribution function.

The Gini coefficient measures the ‘bow’ of the Lorenz curve, and equals the area between the curve and the line of equality (45°) divided by the total area of the triangle

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_73277344
© 2018, ALÖKI Kft., Budapest, Hungary

below the 45° line. The Gini coefficient ranges from a minimum value of 0, where all values are equal, to a theoretical maximum of 1 representing total inequality (an infinite population where all individuals except one have a value of 0) (Weiner and Solbrig, 1984; *Eq. 2*).

$$G = 1 - \sum_{k=1}^{n}(X_k - X_{k-1})(Y_k + Y_{k-1}) \quad \text{(Eq.2)}$$

where G = Gini coefficient, X_k = cumulated proportion of diameter class variable for k = 0,…,n, with $X_0 = 0$, $X_n = 1.$, Y_k = cumulated proportion of stem number, for k = 0,…,n, with $Y_0 = 0$, $Y_n = 1$.

A high Gini coefficient indicates that the distribution of diameters or basal areas is very heterogeneous whereas a low Gini coefficient indicates more homogenous stands with a limited spread of tree sizes. Uneven-aged forest stands would expected to have higher and more stable values of Gini coefficient than even-aged stands (O'Hara et al., 2007).

Stand density index (SDI) is defined as the number of trees per hectare when the quadratic mean diameter of the stand is established at the index value of 25 cm (Reineke, 1933). SDI was determined for each inventory by calculating the index for each individual diameter class then summing for the whole stand (Woodall et al., 2005; *Eq. 3*):

$$SDI = \sum TPHi \left(\frac{DBHi}{25}\right)^{1.6} \quad \text{(Eq.3)}$$

where SDI = Stand Density Index, DBH_i = midpoint of the ith diameter class (cm) and TPH_i = number of trees per hectare in the ith diameter class.

Shannon Indices of species diversity

Shannon Indices (Spellerberg and Fedor, 2003) were calculated for the canopy trees and understorey regeneration using data of the broadleafs and conifers, and shade tolerating and light demanding species (from *Table 2*) using the formula (*Eq. 4*):

$$SI = -\sum_{i=1}^{n} p_i * \ln p_i \quad \text{(Eq.4)}$$

where SI = Shannon Index and p_i = proportion of the total number of trees. SI increases with increasing number of trees and increasing number of species. It is therefore sensitive to both species richness and species evenness.

Transition periods and annual recruitment

Transition periods (after Čavlović et al., 2006) were calculated from a sample of 90 trees randomly selected within the one hectare permanent sample plot in the spring of 2017. To ensure a representative sample of stem sizes, stratified random sampling was carried out across three size classes (small trees 8-25 cm DBH, medium trees 25-40 cm DBH, large trees >40 cm DBH). The species and DBH were recorded and increment cores removed from the outer 30 mm of each sample tree. Cores were taken at 1.3 m height on the north side of each tree and the number of annual rings in the first 25 mm from the bark were counted. Transition periods (years for all trees in a diameter class to move into the next diameter class) were calculated for each diameter class from the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_73277344
© 2018, ALÖKI Kft., Budapest, Hungary

increment cores. Transition period for the 10 cm class was calculated using the formula (*Eq. 5*):

$$T_{10} = \frac{10(DBH_{ul} - DBH)}{2(\frac{25}{N_{rings}})} \quad \text{(Eq.5)}$$

where T_{10} = transition period for the 10 cm DBH class, DBH_{ul} = upper limit of the DBH class and N_{rings} = number of rings in the outer 25 mm of each core. Pearson's correlations (r) were determined between transition period and DBH class. Annual recruitment into the 10 cm DBH class was calculated using the formula (*Eq. 6*):

$$R_{10} = \frac{(N_5 + N_{10})}{2T_{10}} \quad \text{(Eq.6)}$$

where R_{10} = annual recruitment into the 10 cm DBH class (trees per hectare), N_5 = number of trees in the 5 cm DBH class (3-7 cm), N_{10} = number of trees in the 10 cm DBH class (8-12 cm) and T_{10} = transition period for the 10 cm DBH class (years).

Results

Analysis of stand structure

The shape of the stem number-diameter distribution has changed over the four inventories of the permanent sample plot with a 'flattening' of the curve (*Fig. 2*) as a result of a reduction in tree density (*Table 1*) mainly in the smaller size categories.

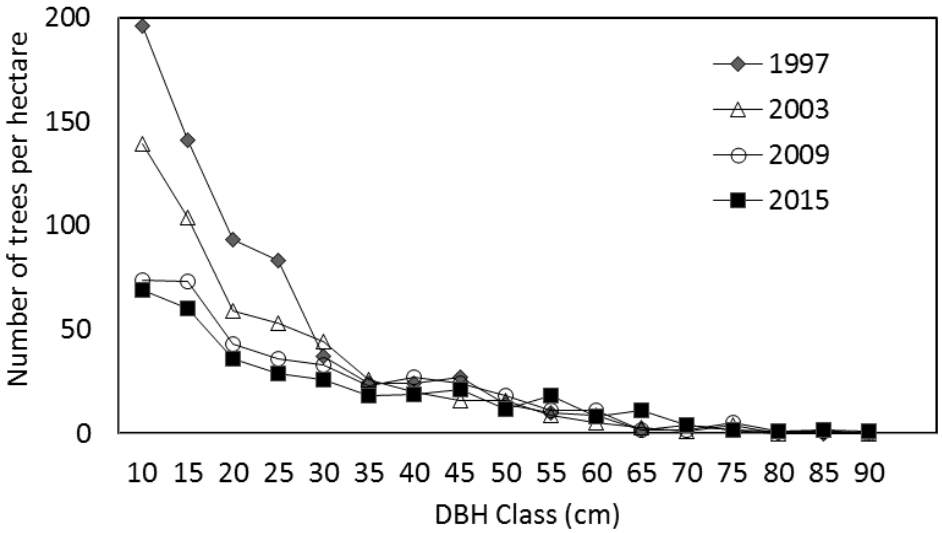

Figure 2. *Diameter distribution of canopy trees (≥8 cm DBH) recorded in the one hectare permanent sample plot in 1997, 2003, 2009 and 2015*

The current stem number-diameter distribution (2015 inventory) shows an approximate exponential relationship when compared with an 'idealised' negative exponential curve fitted to the data (*Fig. 3*).

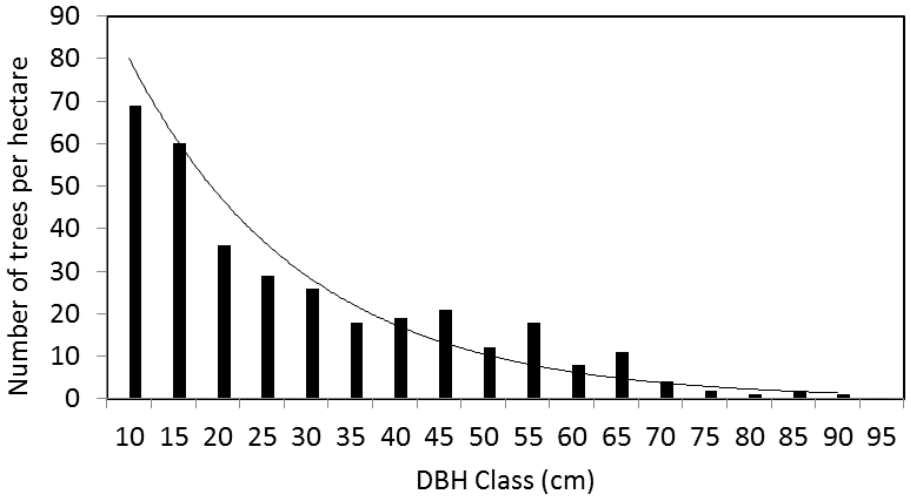

Figure 3. *Diameter distribution of canopy trees (≥8 cm DBH) measured in 2015 (fitted 'ideal' negative exponential curve* $y = 103.16e^{-0.253x}$*)*

The Lorenz curves indicate that a change in shape of the cumulative distribution of DBH and number of trees has occurred between 1997 and 2015 inventories (*Fig. 4*) with the curves becoming flatter particularly in the last two inventories of 2009 and 2015. The declining Gini coefficients (calculated from DBH) indicate that the heterogeneity of the stand has increased between 1997 and 2015 (*Table 3*). Lorenz curves derived from basal area and cumulative proportion of number of trees in the 2009 and 2015 inventories show a clear shift from one of side of the equality line (45°) to the other (*Fig. 4*) reflecting a shift in the impact of the smaller trees towards the larger trees in the basal area distribution. The movement of the Gini coefficients (calculated from basal area) towards zero highlights the greater balance between smaller and larger trees by the 2015 inventory (*Table 3*). SDI, a measure of the occupancy of the stand, shows a decline from 629 to 485 between the 1997 and 2015 inventories (*Table 3*), and reflects the overall reduction in 'site occupancy' by the canopy trees over this period.

Table 3. *Gini coefficients and Stand Density Indices (SDI) calculated from inventories of 1997, 2003, 2009 and 2015*

	Year of inventory			
	1997	**2003**	**2009**	**2015**
Gini coefficient (DBH)	0.66	0.64	0.53	0.50
Gini coefficient (basal area)	0.25	0.15	0.10	0.01
SDI (uneven-aged formula)	629	516	508	485

Proportion of shade tolerating and light demanding species in the canopy

An examination of the proportions of shade tolerating and light demanding coniferous and broadleaved species by diameter class from the 2015 inventory of the

© 2018, ALÖKI Kft., Budapest, Hungary

permanent sample plot indicates that nearly 80% of species in the 10 cm diameter class are shade tolerating and dominated by conifers (*Fig. 5*).

Species diversity

The Shannon Index (SI) for the understorey species diversity was at its lowest at the start of the study in 1997 (SI = 1.43), and has steadily increased by 2015 (SI = 1.91) (*Fig. 6*). The SI of canopy tree diversity has not varied greatly over the four inventories and this is evident when split by shade tolerance and by conifers and broadleafs. The SI of the understorey species (*Fig. 7b*) indicates that the diversity of shade tolerating species has increased in the understorey while the Index for light demanding species has remained relatively stable. Diversity of coniferous species in the understorey has gradually increased since 1997, whereas diversity of broadleaved species has fluctuated slightly although remaining relatively stable in 2009 and 2015.

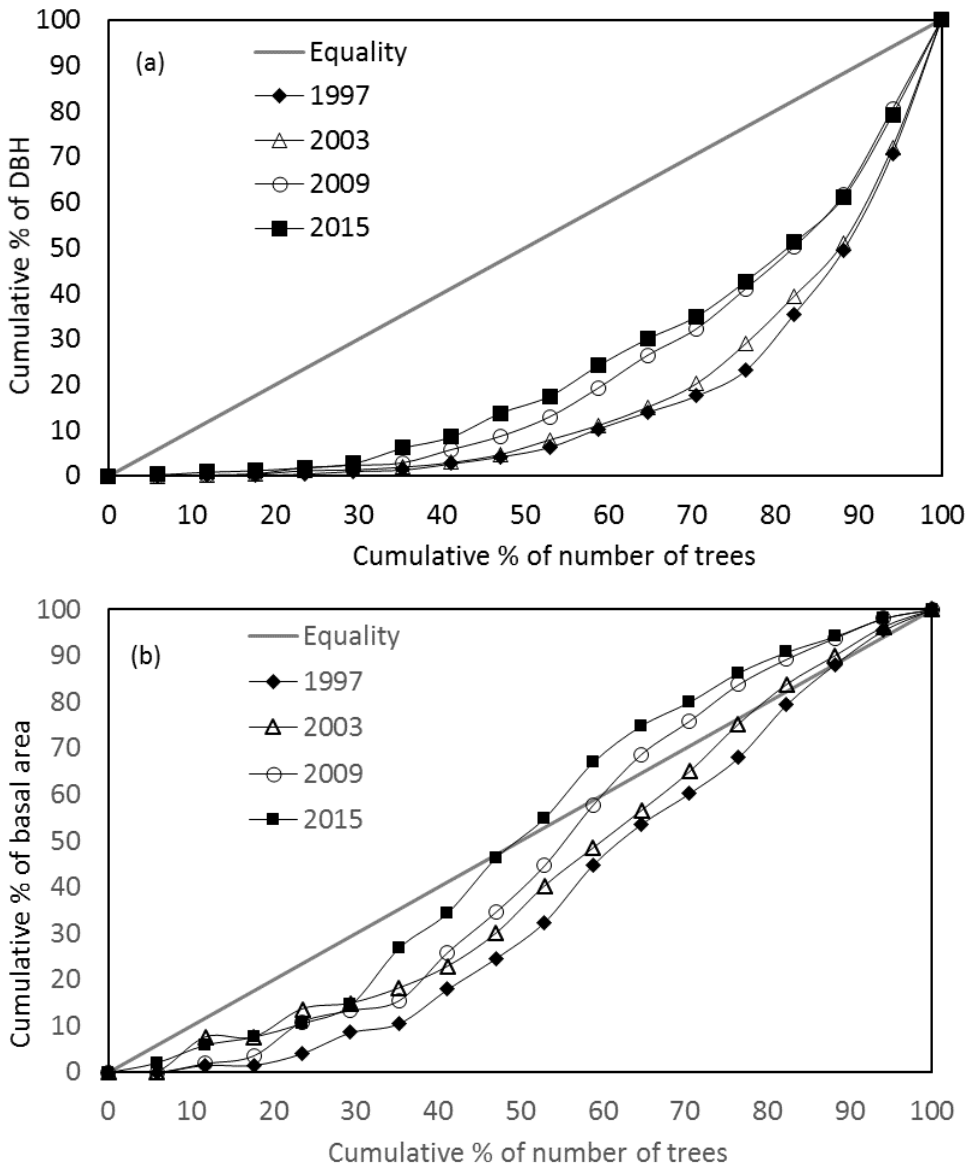

Figure 4. *Lorenz curves for cumulative % of DBH (diameter at 1.3 m)(a) and basal area (b) against number of trees measured in1997, 2003, 2009 and 2015*

Discussion and conclusion

While results indicate that the negative exponential relationship of the stem number-diameter distribution represents the all-aged, all-sized structure widely recognised in uneven-aged 'plenter' forests, Schütz (2002) pointed out that due to natural stand differentiation as a result of competition between species and individual trees, evidence of diameter variation is not on its own a valid indicator of age range or vertical structure. Using Lorenz curves based on stem diameter has highlighted a flattening of the stem number-diameter distribution with each inventory underlining the decline in the number of trees in the smaller diameter classes relative to the larger tree sizes. The associated decline in the Gini coefficients has shown that the diameter distribution has become less heterogeneous since the start of the study indicating a slight decline in the number of smaller trees. Nevertheless, the value of the Gini coefficient at the last inventory in 2015 (0.50) is in the middle of the range reported for uneven-aged boreal forests (0.44-0.57) (Lexerød and Eid, 2006) and within the range for plenter stands in Central Europe (O'Hara et al., 2007) (~ 0.4-0.7). These observations suggest that a Gini coefficient of around 0.50 is probably representative of a relatively stable uneven-aged stand structure. Significantly higher values would indicate greater inequality suggesting too many small or large trees or a diameter distribution deviating substantially from the negative exponential curve. Too small a Gini coefficient would indicate a substantial flattening of the negative exponential distribution that would result in too few trees in the smaller size classes for adequate recruitment into the higher classes and the stand may become unsustainable. When the Lorenz curves and Gini coefficients are calculated using cumulative basal area, the Lorenz curves representing the last two inventories have moved across the 'equality line' due to the greater effect of the bigger

© 2018, ALÖKI Kft., Budapest, Hungary

trees within the population as a direct result of the reduction of trees in the smaller size categories following the 1997 inventory. The associated Gini coefficient has been reduced to close to zero or equality indicating a relative balance in basal areas across the size classes, a distribution that has been suggested as potentially demonstrating a sustainable or equilibrium state (Cameron, 2007).

Since SDI (stand density index) has not been used widely in uneven-aged, mixed species forests (Woodall et al., 2005), comparable data are limited. Although there has been a decline in SDI, stocking density and basal area (representing a reduction in site occupancy) over the four inventories of this study, values from the 2015 inventory are surprisingly similar to those reported by Adamic et al. (2017) for managed, uneven-aged forests in Slovenia (values for current study in parentheses): SDI = 504 (485), stocking density (trees ha^{-1}) = 345 (337) and basal area (m^2 ha^{-1}) = 29 (26), indicating that site occupancy is probably within an acceptable range to maintain a steady stream of regeneration and recruitment into the canopy.

While species diversity of the canopy trees over the study period has not changed greatly, mainly due to the relatively small proportion of the canopy removed at each harvesting intervention, species diversity in the understorey has increased and this is entirely formed of shade tolerating species. This is a widely recognised feature of uneven-aged forests where the partially shaded conditions favour shade tolerance in the understorey species. These species are also growing faster than light demanding species with higher annual recruitment in all diameter classes, and further emphasises the favourable environment for shade tolerating species. The few light demanding species that do move into the canopy are subject to competition for crown development limiting their growth potential as observed through the increasing transition periods (trees growing more slowly with increasing size) whereas transition periods are declining (trees growing faster with increasing size) with shade tolerating species. This trend in the transition periods of shade tolerating species is consistent with the development of trees in uneven-aged stands where young trees emerge from the shaded understorey environment moving up into the canopy where higher light levels and more space permit canopy expansion and greater growth (Knuchel, 1953; Assmann, 1970; Smith et al., 1997).

The gradual shift towards shade tolerating species observed at the study site is unlikely to influence current stand structure if continuous regeneration and recruitment into the lower classes balance losses through competition and harvesting. It has been suggested that the dominance of shade tolerating species in uneven-aged forests is due to their greater resilience to changing environmental conditions within the understorey, with some species of *Abies* and *Picea* capable of surviving in a quasi-stationary state for a long time until they are released by the presence of small canopy gaps (Whitmore, 1989, Schütz, 2002). This allows the density of trees in uneven-aged stands to be relatively high (Schütz and Pommerening, 2013), which further increases the competitive pressure on light demanding species. In the longer term, what is lost from the population of light demanding species is likely to be balanced by an increase in shade tolerating species leaving overall species diversity largely unchanged.

Claiming that an uneven-aged forest has reached an equilibrium condition often implies that some optimum or target structure has to be first determined and that this structure remains in a relatively stable condition over some accepted period of time. However, deciding on a timescale over which a level of constancy in structure and function of uneven-aged stands indicating a sustainable state has never been

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_73277344
© 2018, ALÖKI Kft., Budapest, Hungary

satisfactorily resolved. It could be argued that the timescale over which the current study was carried out is too short to indicate an equilibrium condition; yet the longer the observation period becomes, the more likely that influences of climate and management direction will force change anyway (e.g. von Detten, 2011), and this raises the issue of whether it is realistic to set target equilibrium structures in the first place. O'Hara et al. (2007) found that long-term uneven-aged forests in Central Europe showed significant variation in stand structure, stocking density, species diversity and increment over periods of decades, and suggested that these forests are still evolving and that there is no single ideal structure. They stated that the resilience of uneven-aged forests may be due more to the flexibility of predominantly shade tolerant species in vertically diverse stands (Ibid.) than a rigorous approach to management with the aim of maintaining stable stand structures over time. Sterba (2004) suggested several equilibrium conditions are possible for uneven-aged stands and that there is no one ideal stand structure. Criticism of rigid definitions of optimal stand structures is not new and Henri Biolley, who was instrumental in the early development of selection systems, emphasised that uneven-aged stands should not be developed by reference to theoretical size-class distributions and instead should be managed on purely silvicultural grounds (Biolley, 1934). A flexible interpretation of the equilibrium condition would suggest that the current structure of the uneven-aged stand in this study is close to an equilibrium state even if it is accepted that a very gradual shift in species composition will inevitably take place; a view supported by Sterba (2004) who pointed out that stable diameter distributions do not necessarily show stable species distributions.

Unless there is a dramatic change in canopy cover that would influence the future passage of regeneration and recruitment into the canopy, there is no reason why the uneven-aged forest in this study under the current management regime will not continue long into the future as a relatively stable, vertically-structured, species-diverse stand. This study has also demonstrated that species from diverse geographic origins appear to be capable of forming relatively stable vertically-structured stands. This is important where foresters feel the need to diversify the species composition within their forests using a wide range of alternative species as a means of building resilience to a changing climate (Linder and Cramer, 2002; Woods, 2003; Pretzsch, 2003; Cameron, 2015). Future research will continue to focus on the gradual evolution of this forest in terms of structural diversity and tree species composition with the aim of determining whether a final stable forest structure can be achieved. The experimental site will also be used in future studies to estimate the net primary production of structurally diverse forests in terms of their potential to sequester atmospheric carbon, and how this compares with even-aged forest structures.
