(Received 9th May 2018; accepted 11th Jul 2018)

Abstract. Two-year experiments were conducted to determine optimum tillage time to improve soil compaction and hydro-thermal properties for maize growth. Two tillage treatments: no-tillage (NT), and subsoiling (SS) were performed in correspondence to eight tillage times from March 25 to July 20 (I: March 25, II: April 10, III: April 25, IV: May 10, V: May 25, VI: June 10, VII: July 5, and VIII: July 20) at 15 days interval, synchronously with eight sowing times. SS significantly decreased soil bulk density (0-30 cm) by about 0.13 g cm^{-3} at times of I–V, and about 0.08 g cm^{-3} at VI–VIII. Increment in total soil porosity due to SS was about 3.88% during I–V and about 2.27% at VI–VIII. SS significantly increased soil moisture content by 1.60% in 10-30 cm soil profile. Soil minimum temperature significantly increased by about 0.58 °C (0-20 cm) for I–V, while an increase of 1.06 °C (0-10 cm) was seen for maximum soil temperature due to SS. Greater seedling dry matter coupled with higher growth, and yield improvement was achieved with SS. Dry matter accumulation and grain yield was maximum for May 25 to June 10 sowing as compared to early (22%, 43.5%) and late (60%, 41%, respectively) sowing due to SS versus NT. Initial SS intervals could alleviate soil compaction and low temperature stress for spring maize, with improved soil hydrothermal properties.
Keywords: *subsoiling time, soil bulk density, soil moisture, soil temperature, maize growth*

Introduction

No-tillage in maize (*Zea mays* L.) is the dominant agricultural practice in Huang-Huai-Hai (HHH) maize growing region in China, and the long-term no-tillage is often unfavorable for the growth of maize. Soil compaction has been a major limiting factor for soil environment and plant growth (Zheng and Yan, 2006). To improve soil environment and health, subsoiling tillage as an effective measure is getting popular for maize growth (Ji et al., 2013). Normally, soil tillage and seed sowing are always conducted in June with low precipitation and high temperature in HHH region. Although, no-tillage is practiced for maize sowing in HHH region, except a little soil disturbance at the time of sowing, under winter-wheat and summer-maize cropping system. However, intensive tillage could cause serious soil surface water evaporation during this period, especially with high temperature (Yu and Zhang, 2005), and intensive tillage over longer periods also alters the chemical and physical properties of soil (Lozano-García and Parras-Alcántara, 2014; Jabro et al., 2009). This could lead to a severe drought stress for maize seedling growth (Zhou et al., 2009). Especially under the recent scenario of climate change, in which air temperature is increasing and causing irregular rainfall flashes in northern China (Zafar et al., 2018; Piao et al., 2010; Guo et al., 2010). To avoid the negative effects of soil problems and external micro and macro climate on maize growth and development, the time of soil tillage and sowing date considering the external environment should be given greater attentions (Noor,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_60076023
© 2018, ALÖKI Kft., Budapest, Hungary

2017; Yin et al., 2017). Therefore, identifying an effective tillage time to decrease soil compaction level and improving soil hydro-thermal properties is very important for the maize seedling growth (Nath and Lal, 2017; Lu et al., 2016).

Recently, great progress has been made through soil tillage management in reducing soil bulk density and increasing soil moisture storage. Subsoiling tillage is reported as conservation tillage practice, by improvement of soil characteristics for maize sowing and seedling growth (Liu et al., 2009; Hou et al., 2012; Hoffmann and Kismányoky, 2001). Many studies indicated that subsoil deep tillage could break the soil plough pan and reduces soil bulk density to a proper soil compaction in northeast China (Wang et al., 2014). Soil structure and hydro-thermal characteristics are not only influenced by soil tillage management, but also highly sensitive to the external environmental conditions such as temperature and precipitation (Karandish and Shahnazari, 2016; Hartmann et al., 2012; Bhaduri et al., 2017).

Therefore, studying the effects of subsoiling tillage implemented at different time intervals has practical guiding value for selecting optimal soil tillage management in maize. Our objectives in present study were, in the process of soil improvement, (1) to find the differential effects of subsoiling tillage on soil compaction and hydro-thermal properties at different subsoiling tillage times; (2) to evaluate the specific subsoiling tillage time alleviating the soil compaction stress at maize seedling growth; (3) to identify optimum time for subsoiling tillage for improving soil compaction problem and minimizing drought stress effects encountered by maize at the seedling stage in HHH region.

Materials and methods

Site description

The field experiments were conducted in Xinxiang Experiment Station of Chinese Academy of Agricultural Sciences, Henan Province, China (35°18áN, 113°54áE). Soil textural class for studied site is classified as clay loam (ISSS Classification, International Soil Science Society), with percentage composition of sand, silt and clay as 32.95, 34.2 and 32.85%, respectively (saturation: 38.5%). Soil bulk density was 1.29 g cm^{-3}, 1.34 g cm^{-3}, 1.55 g cm^{-3} and 1.52 g cm^{-3} at 0-10 cm, 10-20 cm, 20-30 cm and 30-40 cm soil depth, respectively. Major soil nutrient contents analyzed were: organic matter 12.55 g kg^{-1}, total nitrogen 1.13 g kg^{-1}, available phosphorus 16.15 mg kg^{-1}, and 109.95 mg kg^{-1} available potassium (pH = 8.21, EC = 1.2 dSm^{-1}, slope gradient with negligible risk of soil erosion). Usual crop rotation for this area is double cropping system with winter-wheat and summer-maize, in that rotary tillage (15-20 cm) is practiced for wheat and no-tillage farming for maize crop is followed usually.

Annual mean temperature and accumulated precipitation conditions from March to July during 1990 to 2012 are shown in *Figure 1*. From year 1990 to 2012, annual accumulated precipitation had a decline trend, whereas annual mean temperature gradually increased.

Experimental design and soil tillage management

The experiment was conducted from 2011 to 2012. Randomized complete block design was used with split plot arrangement and three replications. Main plots were assigned to tillage times correspondingly with eight sowing intervals starting from

March 25 to July 20 (I: March 25, II: April 10, III: April 25, IV: May 10, V: May 25, VI: June 10, VII: July 5, and VIII: July 20). Whereas, in subplots two soil tillage treatments just before the maize sowing were conducted viz. SS: subsoiling tillage management involved complete soil inversion and burial of crop residues to a depth of 30 cm using a stripe deep loosening machine (Hehuinong machine Co. Ltd., Beijing, China)., NT: no tillage for two consecutive years. The experimental plots were 30 m long and 3.6 m wide and consisted of 6 rows. Maize sowing and soil tillage were conducted at the same day, so the experiment had eight sowing dates correspondingly. There was no deep soil tillage management for the rotational crops and the plough pan lies at the depth of 20-30 cm of soil profile. The maize variety Zhengdan-958 was planted at the density of 67500 plants ha^{-1} with an 80-40 cm wide/narrow row spacing pattern. N fertilizers at 225 kg N ha^{-1} (Urea: 46% N) were applied in two split applications: 1/3 as basal application before planting, and the remaining 2/3 as side-dressing at the V8-V9 growth stage. Phosphate (P_2O_5) and Potassium (K_2O) fertilizers were applied at 75 kg/ha and 150 kg/ha before sowing, respectively.

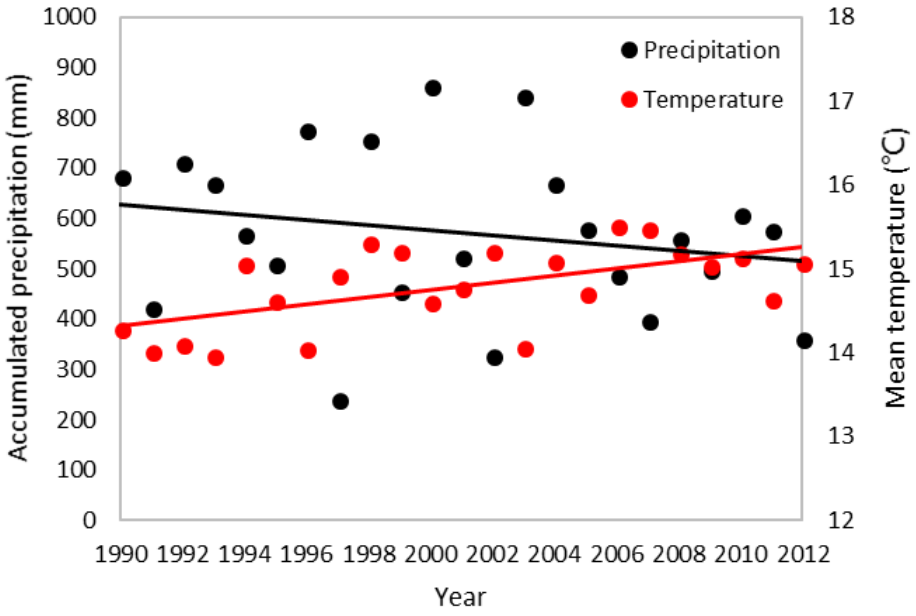

Figure 1. *Changes of annual mean temperature and accumulated precipitation from 1990 to 2012*

Sampling and measurement

Soil samples were collected from four soil depths (0-10 cm, 10-20 cm, 20-30 cm, and 30-40 cm) for each tillage treatment 20 days after soil tillage implementation. In each plot, soil sample was obtained to determine soil bulk density, soil porosity, soil moisture content and soil temperature. For plant samples plant shoots were cut manually at the ground level to determine the shoot dry weight, and plant roots were dug out from soil profile of 40 cm depth to determine the root dry weight for 3 plants per plot at 20 days after soil tillage management.

Soil bulk density was determined by weighing method (*Eq. 1*) with cutting-ring which had a fixed volume of 100 cm^3 to sample the soil maintaining the soil physical structure at the same time. Then weighing the soil fresh weight and dry weight:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_60076023
© 2018, ALÖKI Kft., Budapest, Hungary

$$\text{Soil bulk density (g/cm}^3) = \frac{\text{soil dry weight (g)}}{\text{cutting-ring volume (cm}^3)} \quad \text{(Eq.1)}$$

The measurement was made at four depths of soil (0-10, 10-20, 20-30, and 30-40 cm) at seedling stage of maize. The measurement was repeated three times in each plot. Total soil porosity was calculated (*Eq. 2*) from soil bulk density as follows:

$$\text{Total soil porosity (100\%)} = \frac{(\text{soil density} - \text{soil bulk density})}{\text{soil density}} \quad \text{(Eq.2)}$$

where soil density is 2.65 g cm^{-3}. For soil moisture content (*Eq. 3*), soil samples were taken from the 0-40 cm soil profile at 10 cm intervals and oven-dried to constant weight in an aluminum container.

$$\text{Soil moisture content (100\%)} = \frac{(\text{fresh soil weight} - \text{dry soil weight})}{\text{dry soil weight}} \quad \text{(Eq.3)}$$

The measurement was repeated three times in each plot at 20 days after sowing of maize. For soil temperature measurement, thermistor temperature probes were buried at three points in each plot and four depths in the 0-20 cm soil profile (0-5, 5-10, 10-15, and 15-20 cm). Daily soil minimum and maximum temperatures were measured at consecutive 20 days after sowing of maize.

Sampling was done from each plot by cutting three adjacent plants in a row at ground level to determine leaf area and dry matter accumulation at V3, V6, VT and R3 growth stages. Leaf area index (LAI) was calculated by multiplying leaf area with plant density per m^2. Already sampled three plants were oven dried at 105 °C for one hour initially and then at 71 ± 1 °C to measure dry matter accumulation. Twenty days after sowing of maize, five whole plants were randomly sampled from each sub-plot and then plant shoot and roots were separated and dry matter was determined. At harvest stage, maize ears were hand harvested in the two central rows (the length of each row was 20 m) of each plot, dried and shelled. Dry matter and yields were obtained according to standard procedures. The maize yield potential (YP) in HHH area was obtained by the Hybrid-Maize simulation model (Yang et al., 2004).

The effect of soil tillage time on all analyzed parameters was tested using a one-way analysis of variance (ANOVA) (SPSS 13.0 for Windows; SPSS Inc., Chicago, USA). Tukey's HSD method was used as post hoc test for multiple comparisons of means. Mean data was presented for both years (2011 and 2012) for all the studied parameters except for some growth attributes (LAI, dry matter accumulation), due to non-significant year effect for the studied period.

Results

Soil and external environment before soil tillage

The values of soil temperature and soil moisture were significantly lower at initial soil tillage time intervals than later tillage intervals (*Table 1*). Soil mean temperature at different soil tillage times were recorded as the sequence of I<II<III<IV<V<VI<VII<VIII.

The values of soil mean moisture content at different soil tillage times were recorded in the sequence of I<II<III<IV<VII<V<VI<VIII. The values of effective accumulated temperature for different soil tillage times were as the sequence of IV>III>V>II>VI>VII>I>VIII during whole crop growth period (*Fig. 2*).

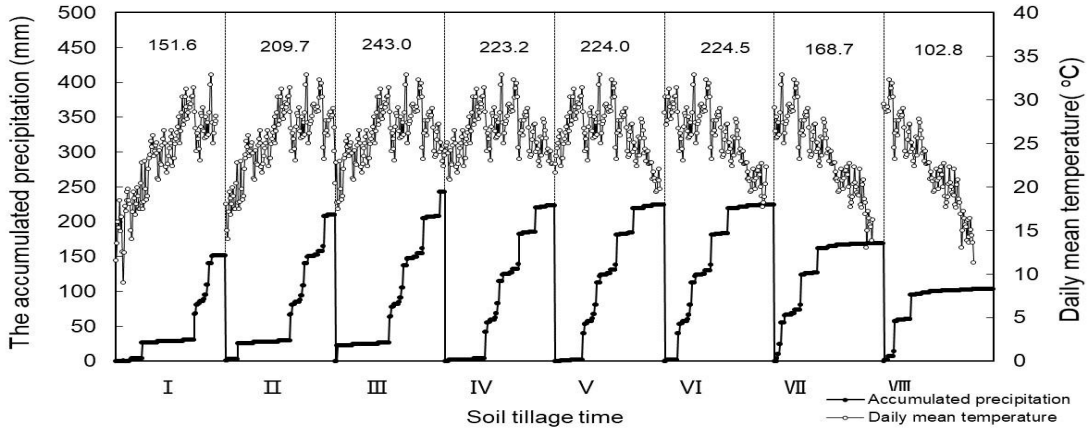

Figure 2. *Effective accumulated temperature (top word in figure), daily mean temperature (center line in figure) and accumulated precipitation (bottom line in figure) during growth cycle of maize at different soil tillage time. I: March 25, II: April 10, III: April 25, IV: May 10, V: May 25, VI: June 10, VII: July 5, and VIII: July 20*

Soil bulk density

In 0-10 cm soil layer, SS significantly decreased soil bulk density by about 0.13 g cm^{-3} ($P < 0.01$) at former tillage time of I–V, and the decrease was about 0.04 g cm^{-3} ($P < 0.05$) at later soil tillage intervals of VI–VIII, compared to NT (*Fig. 3*). In 10-20 cm soil layer, soil bulk density significantly decreased by about 0.07 g cm^{-3} ($P < 0.05$) at each soil tillage time under SS treatment compared to NT. Because of the destruction of soil hard plough pan, SS significantly decreased soil bulk density by about 0.15 g cm^{-3} ($P < 0.01$) at each soil tillage time compared to NT in 20-30 cm soil layer.

Soil porosity

Because of the decrease in soil bulk density, soil total porosity was therefore increased significantly (*Fig. 4*). In 0-10 cm soil layer, SS significantly increased soil total porosity by 4.18% ($P < 0.01$) at initial tillage intervals of I–V, and the increment was 2.38% ($P < 0.05$) at later soil tillage time of VI–VIII compared to NT. SS significantly increased soil porosity with average of 3.75% ($P < 0.01$) in top (0-30 cm) soil layer at initial tillage intervals of I–V, while the increment was 2.26% ($P < 0.05$) at tillage intervals VI–VIII, as compared to NT.

DOI: http://dx.doi.org/10.15666/aeer/1605_60076023
© 2018, ALÖKI Kft., Budapest, Hungary

Soil moisture content

In 0-10 cm soil layer, SS significantly decreased soil moisture content by 2.06% ($P < 0.01$) at later soil tillage time of VI–VIII, because of the soil disturbance coincidence with high soil evaporation (*Fig. 5*). In 10-20 cm soil layer, SS significantly increased soil moisture content by 2.24% ($P < 0.01$) at intervals I, II, III, V, and the increment was 1.13% ($P < 0.05$) at later intervals of IV, VI, VII, VIII. In 20-30 cm soil layer, soil moisture content significantly increased by 2.26% ($P < 0.01$) at I, II, V, VI intervals, and the increment was about 1.13% ($P < 0.05$) at later intervals of III, IV, VII, VIII.

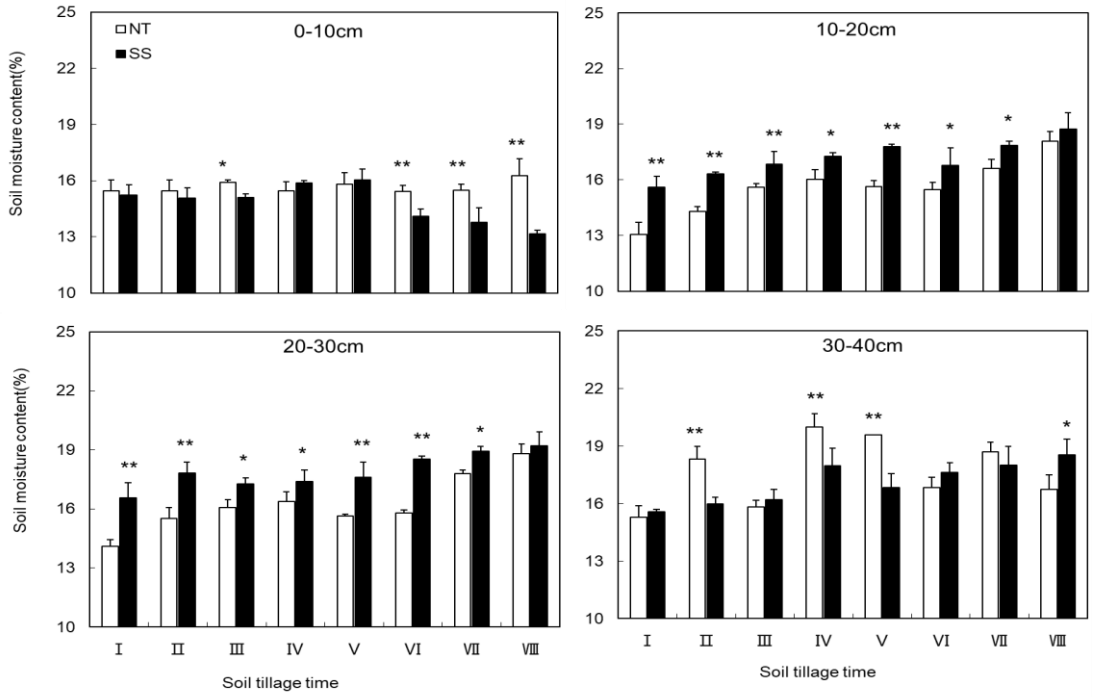

Figure 5. *Soil moisture content in 0–40 cm depth at different soil tillage. NT: no tillage, SS: subsoiling tillage; I: March 25, II: April 10, III: April 25, IV: May 10, V: May 25, VI: June 10, VII: July 5, and VIII: July 20; ** above the column indicate statistical significance at the P = 0.01 level within the same soil tillage time; * above the column indicate statistical significance at the P = 0.05 level within the same soil tillage time*

Soil temperature

In 0-10 cm soil layer, SS was able to increase soil minimum, maximum and mean temperatures as compared to NT (*Table 2*). For soil lowest temperature, the significant increment was 1.29 °C ($P < 0.05$) at tillage time of I, II, while it was 0.51 °C at intervals III, IV, V, VI. For soil maximum temperature, the increment was about 1.06 °C ($P < 0.05$) at each soil tillage time. For soil mean temperature, the increment recorded was 1.12 °C ($P < 0.05$) at former soil tillage intervals of I, II, while it was 0.65 °C at intervals III, IV, V, VI, VII, VIII. In 10-20 cm soil layer, SS just increased soil lowest temperature compared to NT, the increment was 0.43 °C for tillage intervals of I–V, while it was -0.28 °C at later soil tillage time of VI–VIII, as compared to NT.

Relationship of soil temperature and soil moisture content

Soil moisture content influences the range of soil temperature under different tillage treatments. For the soil lowest temperature, it showed increasing trend with the soil moisture content increasing at tillage time of I, II, III, IV, and V when the soil temperature was low (*Fig. 6*). For soil maximum temperature and daily mean temperature, it showed decreased tendency with the soil moisture content increasing at tillage time of IV, V, VI, VII, and VIII. Hence, the soil lowest temperature was easily affected by soil moisture when the soil temperature was very low.

Growth

Among tillage treatments, SS performed better in improving LAI over the all soil tillage intervals as compared to NT, for both the years (*Table 3*). During 2012 year, an increasing trend for LAI was recorded for the intervals I–V, whilst a decrease was

observed after that for the intervals VI–VIII. This decreasing trend is significantly visible for both the years during VT and R3 growth stages, because of delayed sowing time as compared to initial sowing intervals of I–V.

From *Figure 7,* we could see that SS caused a significant increase in dry weight of shoot and root at 20 days after sowing of maize. For shoot dry weight, the highest value was obtained at soil tillage time of VIII, while the highest increment was obtained at soil tillage time of I under SS (*Fig. 7*). SS significantly increased shoot dry weight by 13.85% ($P < 0.01$) at initial tillage intervals of I–IV, and by 7.83% ($P < 0.05$) at later soil tillage time of V– VIII compared to NT. For root dry weight, the highest value was obtained at soil tillage time of VI, while the highest increment was obtained at soil tillage time of I under SS. Similar to LAI, dry matter accumulation varied across different sowing intervals as well as sampling stages of crop growth period (V3–R3) (*Table 4*). Maximum value for dry matter was found for SS during sowing interval VI (2011) and V (2012) at R3 sampling stage.

NT: no tillage, SS: subsoiling tillage; I: March 25, II: April 10, III: April 25, IV: May 10, V: May 25, VI: June 10, VII: July 5, and VIII: July 20; Values between NT and SS for each tillage date followed by different letters are significantly different at $P < 0.05$

Regardless of soil tillage time, the grain yield of maize was significantly higher under the SS management than no-tillage treatment (*Fig. 8*). In terms of tillage intervals, the yield of maize was highest in the SS tillage management implemented at VI, but the highest increment of yield was recorded at SS tillage implemented at I. The highest yield potential (YP) of maize was recorded at soil tillage time of V. The potential equivalent was in the range of 71.89–85.10% at SS, while it was 67.08-81.78% (range) at NT for tillage times I, II, III, IV, V, VI, and VII, respectively.

Discussion

Soil bulk density is an important indicator for soil stiffness (Carter, 1990). Liang et al. (2010) and Liu et al. (2010) found that subsoiling tillage could break the soil hard plough pan and loosen the compacted soil, thereby reducing soil bulk density. Meanwhile because of the dryness and reduced soil viscosity with low soil moisture and temperature, the soil structure could easily be altered (Yang et al., 2013). Our results indicated that SS significantly reduced soil bulk density in 0-30 cm soil layer, especially at the former soil tillage time of I–V, when compared to no-tillage treatment (*Fig. 3*). These results are in disagreement with that of Gürsoy et al. (2011). Whereas, Ozpinar and Ozpinar (2015) found a significant decrease in soil bulk density, confirming our results, in top soil due to tillage practices in a five-year experiment at enhancing maize productivity. In 20-30 cm soil layer, because of the destruction of hard plough layer, soil bulk density showed a much significant decrease in present case, promising for sustainable field maize production in China.

Assouline (2006) suggested that, soil can be significantly loosened and the proportion of large pores can be increased significantly under SS tillage. The level of soil porosity is related to intensity of soil tillage (Chen et al., 2009). In present study, the implementation of SS tillage significantly increased soil total porosity in 0-30 cm soil depth compared with no-tillage treatment (*Fig. 4*). This improvement can be attributed to the reason that the level and distribution of soil total porosity were significantly affected by the soil bulk density (Raczkowski et al., 2012; Wang et al., 2017).

Soil moisture content is a basic characteristic required for optimum crop growth. Appropriate soil moisture contents could support uptake of crop root and can regulate the dynamics of soil temperature and heat (Karandish and Shahnazari, 2016; Tsironi and Taoukis, 2017). Assouline (2006) showed that SS could improve soil moisture infiltration and storage attributed to the decrease in soil bulk density and increased soil total porosity. Meanwhile the SS tillage could break the continuity of soil pores to prevent the evaporation and reduction of deep soil moisture (Osunbitan, 2005), thereby significantly increasing deep-layer soil moisture contents. However, the SS tillage involves excessive soil ploughing, resulting in relatively higher surface soil moisture evaporation due to more exposure to sunshine (Debaeke and Aboudrare, 2004). And the high soil and air temperature accelerate the surface soil moisture evaporation (Wang et al., 2007). Our study showed the same results that SS significantly increased soil moisture content in 10-30 cm soil depth, while the soil moisture content decreased in 0-10 cm soil depth compared with no-tillage (*Fig. 5*). In 10-20 cm soil depth, soil moisture content showed a much significant increase at soil tillage intervals of I, II, III, V, and VI because of the relevant decrease in soil bulk density and increase in soil total porosity due to SS, compared to NT.

In field, seed germination and seedling growth of maize are closely related to soil temperature (Ahmad et al., 2016; Lopushinsky and Max, 1990). Fu et al. (2005) suggested that SS tillage could balance and improve the status of soil temperature through the function of heat preservation on minimum soil temperature conditions and may cause decrease in maximum soil temperature and it could keep the stability of soil temperature, beneficial for the crop growth. In this study, SS tillage increased soil minimum temperature in 0-20 cm soil depth at soil tillage time of I–VI. For soil maximum temperature and daily mean temperature, the increments were only occurred in 0-10 cm soil depth at each tillage time (*Table 2*). Soil temperature jointly determined

© 2018, ALÖKI Kft., Budapest, Hungary

with atmospheric temperature and soil heat conditions are reported to be regulated by soil moisture content and soil porosity (Lakshmi, 2003). Higher soil porosity and moisture content could contribute to heat transfer and storage (Zhang et al., 2009; Wu et al., 2017). For these reasons, the soil minimum temperature showed an increased tendency with increase in soil moisture content, especially at intervals III, IV and V. While the soil maximum and daily mean temperature showed an decreased tendency with increasing soil moisture at later soil tillage time of V, VI, VII and VIII (*Fig. 6*).

Anand et al. (2012) reported that the decrease in soil penetration resistance, increase in soil moisture and temperature could improve the seedling emergence and growth during early spring under low temperature conditions. Tolon-Becerra et al. (2011) showed that better seedling emergence and growth were achieved under soil with lower compaction, and the relationship between root dry matter and maize yields was strongly positive. In our study, SS significantly increased shoot and root dry matter of maize seedling. Though the highest maize seedling dry matter was obtained at SS tillage time of VI, VII and VIII, which are contrary to the findings of Ge et al. (2013). The reason can be described by effective accumulated temperature, daily mean temperature and accumulated precipitation at respective growth stage of maize (*Fig. 2*), the maximum increase in maize seedling matter was obtained at tillage intervals of I, II, III, IV and V (*Fig. 7*). The decrease during former tillage intervals plausibly because of the soil high compaction and low temperature, which may be attributed as main limits for maize seedling growth at March, April, and May (*Fig. 1*). The improvement in soil compaction and temperature significantly enhanced the maize seedling growth, corroborating the findings of Hoffmann and Kismányoky (2001). The increase in maize yield was significantly improved at SS tillage compared with no-tillage management, which is against the results reported earlier by Mohammadi et al. (2013), and SS also decreased the yield gap between yield and yield potential in our case. Though the highest maize yield was harvested at SS tillage time of V, VI and VII, whilst the highest increment in maize yield was harvested at subsoiling tillage time of I, II, III and IV (*Fig. 8*), which are contrary to the results of Zhang et al. (2009). Recently, Moinoddini et al. (2017) also found significant positive effects of deep tillage on maize grain yields as compared to no-tillage during the evaluation of different tillage practices and N application rates under corn-based rotation system. In present case, SS tillage significantly increased soil moisture storage and soil temperature, and improved seedling growth of maize at subsoiling tillage time of I, II, III and IV, as compared no tillage.

Our results indicate that in no-tillage maize growing areas of HHH, soil hydro-thermal properties can be improved by implementing the SS in the month of May and June. This improvement reflects in terms of increased soil temperature, moisture content, porosity and the significant decrease in soil bulk density, which in turn is attributed to better seedling growth and early stand establishment with higher shoot/root parameters, and the succeeding plant growth and final dry matter accumulation. The reason can be explained through the maximum accumulated temperature, precipitation (*Fig. 2*) and the sunshine hours during these months (May, June), which were favorable to improve soil environment and the plant growth under SS tillage implementation, as compared to no-tillage.

Conclusion

In Huang-Huai-Hai area of China, SS tillage proved effective in improving soil physical and hydro-thermal properties, and improving maize seedling growth and grain yield, especially when implemented at early time (March, April and May). Compared with no-tillage, subsoiling tillage significantly decreased soil bulk density, and greatly increased soil porosity. SS tillage at early time (especially for May and June) significantly increased the soil moisture storage in 10-30 cm soil depth. Soil minimum temperature (0-20 cm) and soil maximum temperature (0-10 cm) significantly increased at SS tillage time of March, April and May. The SS tillage produced maximum dry seedling matter in maize and grain yields compared to no-tillage management, especially when implemented at early time. Because at early sowing of maize, low soil temperature and Spring seasonal drought cause serious hindrance for early stand establishment in HHH. We can conclude that SS tillage could alleviate the soil high compaction and low temperature stress for spring maize, and can alleviate the soil high compaction stress for summer maize. Dry matter accumulation and grain yield was maximum for sowing from May 25 to June 10. It will be of great significance in improving soil environment, seedling growth and grain yield of maize at early sowing with low precipitation and temperature.

(Received 3rd Jun 2018; accepted 2nd Aug 2018)

Abstract. The study was conducted to determine the effect of fermented extruded corn stover on nutrient digestibility and milk composition in colostrum of pregnant sows. A total of 48 pregnant sows (24 Landrace and 24 Yorkshire) were randomly assigned into four experimental treatment groups (0, 10%, 15%, 20% fermented extruded corn stover). The results of nutrient digestibility (*Table 2*) showed that in crude protein and neutral detergent fibre, there were no significant differences between the control group and 10% fermented extruded stover ($P > 0.05$). However, these results in energy and acid detergent fibre showed a significant differences between control group and all the experimental groups ($P > 0.05$), respectively. In fat, lactose and non-fat solids, there were no significant differences between control group and experimental groups ($P > 0.05$), respectively. There was a significant difference in protein between control group and experimental group ($P < 0.05$). Our findings suggest that with the increase of fiber content in feed, protein and lactose content are increased in colostrum of pregnant sows and there is little effect on digestibility.
Keywords: *dietary fiber, corn stover, pregnant sows performance, digestibility, lactation*

Introduction

Dietary fiber is well recognized to affect digestive functions in the small intestines with result of digestion and absorption of nutrients, also in pigs it is the main substrate for bacteria in the gastro-intestinal tract and its inclusion has shown to promote bacterial growth resulting in higher fecal excretion (Metzler and Mosenthin, 2008). The high interest to use dietary fiber in pig's diets is an economical point and animal welfare perspective, also feedstuff with high content of dietary fiber could be supplied as cheap by products as roughage (Banino, 2012). Kim et al. (2018) stated that during pregnancy, sow feed intake is not adequate to meet the nutrient requirements for maintenance, fetal growth and lactation which leads to mobilization of body reserves. According to Krogh et al. (2015) high fiber diets that are greater than 7% crude fiber, during sow's gestation period have increased growth performance of new born piglets, also increased sow feed intake during lactation and reduced constipation. Sows performance has been improved over the last decades by which energy and nutrients intake has become critical and nutritional factors such as metabolic status, energy supply during lactation may affect the milk production while feed intake and dietary fibre content may affect heat energy of reproductive sows (Theil et al., 2004). Ngalavu et al. (2018) recommended that supplementation is required for feeding during sow's gestation period to improve

performance. There is little information on dietary fiber supplementation on milk composition in colostrums of pregnant sows. Hence, we hypothesized that the dietary fiber supplementation such as fermented corn stover might be the supplement to improve nutrient digestibility and milk composition of pregnant sows.

The objective of the present study was to investigate the effects of dietary fiber supplementation on nutrient digestibility and milk composition in colostrums of pregnant sows. This study will provide basic scientific knowledge of dietary fiber such as fermented corn stover as supplement during the pregnant stage of sows.

Materials and methods

Study site

This experiment was conducted in a research area of Jilin Agricultural University, Changchun city of the People's Republic of China. Jilin Province is located at latitude 43° 42' N and longitude 126° 12' E whereas Changchun city is found at latitude 43° 88' N and longitude 125° 35' E. The average annual rainfall ranges between 350-1000 mm during rainy seasons between March and August, while the dry season is between September and February. Average daily temperatures in winter (Nov- Mar), ranges between -8 °C (17 ºF) to -20 °C (-4.6 °F, and in summer (May-July) between 16 °C (61.4 °F) and 28 °C (81.2 °F) respectively.

Corn stover preparation and fermentation

Corn stover leaves were removed and dried at a temperature of 70 °C until the constant weight was achieved. Corn stover was completely dried and further cut into 10 cm, thereafter crushed into fine powder to allow passing through a 3.5 mm mesh mini laboratory sieve to determine the level of dry matter. Corn stover fermentation for the current study was prepared using the method indicated by Chang et al. (2012) and Ngalavu et al. (2018). In the current study, the Commercial baking yeast was used as *Saccharomyces cerevisie* for the microbial fermentation process. The yeast was then inoculated into medium, containing glucose 50 gL^{-1}, peptone 5 gL^{-1}, MgSO4.7H2O 1 gL^{-1}, K2HPO2 and 5gL^{-1} of yeast. The medium was autoclaved at 121 °C (249 °F) for 15 min. After autoclaved, the yeast was inoculated on the orbital shaker for a period of 18 h at 30 °C, 50 rmp.

Experimental design and sows feeding management

Experiment was conducted in completely randomized design; forty eight pregnant sows (24 Landrace and 24 Yorkshire) were randomly assigned into 4 experimental treatment groups (0%, 10%, 15% and 20% fermented extruded corn stover) for with 12 replicates per group and were selected on the basis of genetics, weight and parity similar to binary hybrid sow (long x large). In addition, pigs live body weights were ranged between 17.5-20.5 kg (average 19 kg). Daily feed intakes, health conditions of pigs and free access to drinking water were carefully checked and recorded. The duration of the trial included 3 days of pre-feeding; from mating to sow delivery 114 days, sows 7 days after delivery to 28 days after weaning, up to a to a total number of 145 days. Pigs' immunization and disinfection of piggery and experiments were according the conventional method of pigs.

Nutrient digestibility and milk composition analysis

Total of 300 g fecal samples were collected from each pen every morning (9:00 am) for seven days and stored at -20 °C immediately after collection. Frozen dried samples of feces were ground through 1 mm screen in a Wiley Mill model 4; Thomas Scientific, Swedesboro, NJ. The chromium concentration in fecal samples was determined using an ICP procedure (Method 990.08, AOAC Int., 2007). Samples were prepared using nitric acid. Colostrum samples were collected in a 50 ml centrifuge tube immediately after sows had delivered, and the stored at -40 °C refrigerator for cryopreservation tests. The samples were analysed using FOSS multi-functional milk composition analyzer for milk fat, milk protein and non-fat solids.

Chemical analysis and statistical analysis

The procedure of AOAC (2005) was used to analyze the digestible energy (DE) and crude protein (CP). Van Soest (1994) method was followed to analyze the acid detergent fibre (ADF) and neutral detergent fibre (NDF). All the experimental diets including Calcium (Ca), phosphorus (P), Sodium (Na) and Chloride (Cl) were analyzed according the procedure explained by Chang et al. (2015). One-way analysis of variance (ANOVA) was used for data analysis with Duncan multiply range test for comparing difference among the means using statistical package for social sciences (Version 10.0 for windows, SPSS Inc., Chicago, IL). All the results were expressed as mean ± standard deviation (mean ± SD). Alpha 0.05 was the significance level of the study.

Results and discussion

Effects of fermented extruded corn stover on digestibility

The results of nutrient digestibility (*Table 2*) showed that in crude protein and neutral detergent fibre, there were no significant differences between the control group and 10% fermented extruded stover ($P > 0.05$). However, these results in energy and acid detergent fibre showed a significant differences between control group and all the experimental groups ($P > 0.05$), respectively. It can be seen that with the increase of fiber content in diets, the apparent digestibility of fiber level showed a significant decrease trend. The apparent digestibility of energy and the apparent digestibility of protein decreased with the increase of fiber content. Through the results of this experiment, it can be seen that the addition of fermented extruded stover during pregnancy to improve the level of fiber in sow diets will reduce the apparent digestibility of its energy without affecting the sow during pregnancy. Digestibility, apparent digestibility of acidic detergent fibers, and apparent digestibility of neutral detergent fibers were negatively correlated with increased fiber levels in diets. Sows have high utilization capacity for high fiber diets, mainly because adult sows have a relatively complete intestinal digestion environment. The fiber can be in the intestine through the role of micro-organisms, resulting in short-chain fatty acids (acetic acid, propionic acid, butyric acid) and other volatile fatty acids to supply energy for the sow and other energy needs (Jha and Berrocoso, 2015). The energy digestibility of the test group was not significant, mainly due to the longer metabolic time of the fiber, due to the structural characteristics of the fiber, resulting in sow satiety, thereby reducing the sow physical activity so as to reduce the need to maintain the purpose. The mechanism of protein digestion and absorption in the sow is mainly due to the physical properties of the fiber, to prevent the digestive enzymes in the intestine as well as to digest the nutrient, so that parts of the nutrients are not absorbed by the fiber composition of a membrane and material, which is wrapped up by the sow through the form of feces discharged. Johnston et al. (2003) stated that fibrous feed typically have not been used for non-ruminants due to the reported depression of digestibility, however, some type of fiber do not apply such negative effects on nutrient digestibility. Recent study (Jiang et al., 2016) on Acid Detergent Fibre (ADF) and Neutral Detergent Fibre (NDF) digestibility was improved and Gross Energy (GE) digestibility was improved, which may be the reason for an improved Average Daily Feed Intake (ADFI) compared with pigs fed control diets. Declining Metabolic Energy (ME) intake plus observation that dietary fibre decrease digestibility of energy and other nutrient (Renteria-Flores et al., 2015).

Effects of fermented extruded stover on milk components and composition in sows' colostrum

Effect of corn stover on pregnant sow's colostrum ingredients is portrayed on *Table 3*. The results discovered that in fat, lactose and non-fat solids, there were no significant differences between control group and experimental groups ($P > 0.05$). There was a significant difference in protein between control group and experimental group ($P < 0.05$), respectively. In addition, Devillers et al. (2004) indicated that piglet body weight gain increases concurrently with colostrum intake during the first 24 h after birth and a weight gain of 50 g during the weaning on average is allowed by 250 g of colostrum ingested.

Table 3. *Effects of fermented extruded corn stover on milk components in sows' colostrum*

Milk components	Experimental groups			
	Control	**10% fermented extruded straw**	**15% fermented extruded straw**	**20% fermented extruded straw**
Protein	16.73±0.55[c]	17.79±1.12[ab]	18.53±0.07[ab]	16.38±0.03[a]
Fat	5.18±0.96[a]	5.29±0.56[a]	4.98±0.06[a]	5.37±0.06[a]
Lactose	2.53±0.01[a]	2.61±0.04[a]	2.55±0.06[a]	2.80±0.01[b]
Non-fat solids	21.35±1.43[a]	22.37±0.97[a]	22.41±0.46[a]	20.53±0.54[a]

[a, b]Means in rows with same superscripts are the same significantly ($p \leq 0.05$)

As shown in *Table 4,* there was no significant difference in the total solid content between the control group and the colostrum ($P > 0.05$). There was significant difference between the control group and the experimental groups in colostrum composition ($P < 0.05$). There was no significant difference between the control group and the 20% fermented extruded stover group ($P > 0.05$). The control group and 10% fermented extruded stover group had no significant difference ($P > 0.05$). The results has shown that the amount of protein and lactose in the milk composition of the colostrum of each group increased with the increase of the fiber content in the sow diets, and the difference was significant. Similar results were also reported by Kim et al. (2018), who found that sows fed high energy diet had higher concentration of lactose in milk. The content of free fatty acid (FFT), non-fat solid (NFS), freezing point (FP) and total solid (TS) were not significantly different; however, there was a difference in the decrease free fatty acids. Studies have shown that feeding high-fiber diets can increase the content of volatile fatty acids in sows, while some of the volatile fatty acids play an

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_60256031
© 2018, ALÖKI Kft., Budapest, Hungary

important role in the milk production of sows, and therefore have a higher effect on milk fat content in milk. Quesnel et al. (2009) study have shown that high-fiber diet than the control group increased milk production, but the difference was not significant, no significant difference in milk composition, which is slightly different from the current study results, which may be related to the type of feeding fiber inconsistencies. According to Quesnel et al. (2009), the great appetite of lactating sows fed a high fiber diet during gestation may be slightly indicated by decreased secretion of leptin and does not seem to have connection with change in glucose and insulin metabolism. The reduction in part of the milk composition in the 20% fermented puffed straw group may be related to excessive fiber intake. This also shows that the fiber cannot rely too much on the low energy use effect. Feed ingredients, such as fermented liquid and yeast extracts has shown to cause change in colostrum composition (Farmer and Quesnel, 2009).

Table 4. *Effects of fermented extruded corn stover on milk composition in sows' colostrum*

Milk composition	Experimental groups			
	Control	**10% fermented extruded straw**	**15% fermented extruded straw**	**20% fermented extruded straw**
Total solids	30.43±0.15[a]	28.96±0.08[a]	27.35±0.12[a]	27.10±0.17[a]
Freezing point	1.50±0.03[a]	1.24±0.12[ab]	1.24±0.11[b]	1.26±0.01[b]

[a, b]Means in rows with different superscripts differ significantly ($p \leq 0.05$)

Conclusion

Fermented extruded corn stover which is a dietary fiber supplement can be used to slightly improve performance of pregnant sows. Our findings suggest that with the increase of fiber content in feed, protein and lactose content are increased in colostrum of pregnant sows and there is little effect on digestibility. There is great potential to develop different methods of feed processing that will increase the effect of fiber supplementation in pig's performance.

Abstract. Decontamination of heavy metal polluted soil and water by plants is called phytoremediation. Succulent plant species such as *Aloe vera* (L.) are considered for the current study to investigate their ability to accumulate heavy metals and their uptake rate of different heavy metals are tested. This study aimed to measure the concentration of toxic heavy metals (As, Cd, Cr, Cu, Pb, Hg, and Ni) in arid contaminated soils of Saudi Arabia. The soil was contaminated with 1500 ppm of each element. During a year of the experiment, 4 samples were taken on a trimester basis. All samples were digested to measure heavy metal content in soil and plant. Metal Transfer Factor (MTF) and Translocation Factor (TF) were calculated from the examined data. This study showed that the *A. vera* has the ability to decontaminate heavy metals from polluted soil. The greatest accumulation was detected from As but the accumulation was declined after 9 months. Hg accumulation showed no significant results of heavy metal uptake by *A. vera*. The greatest MTF was of Cd elements and counted for 1.3404 and the lowest was of Cr and counted for 0.1292. Cd TF was the maximum (2.8538) but Pb TF was the minimum (1.2191).
Keywords: *accumulation ability, metal transfer factor, succulent plant, soil treatment, translocation factor*

Introduction

The medium for plant root growth and waste disposal is the soil. Moreover, it is a transmitter of different contaminants in water, air, and food. Soil pollution has effects on the natural quality of agricultural crops and water resources. Subsequently, it may menace human health and may affect the quality of the atmosphere. Some attention has gone to soil pollution linked to crops in the past (Wong, 1996). Also, the polluted soil affecting the functions of soil and the environment has been gradually confirmed by environmentalist (Tiller, 1992).

Heavy metals are physical constituents of the soil's profile. Human industrial activities, as well as extensive agricultural practices, have hardly changed the stability and biological cycles of many heavy metals (Elhag and Bahrawi, 2016; Elhag et al., 2017a). An assessment of the ecological danger due to the polluted soil is of importance for agricultural zones, because of heavy metals that are potentially harmful to all organisms not only human, persist in soils for many years (Grzebisz et al., 2001).

The riskiest hazards affecting both rich and poor countries are heavy metal pollution. Industrialization, fossil fuel consumption and the production of a variety of chemical compounds has led to the worldwide deterioration of the quality of the environment (Chakravarty et al., 2010). All trace elements at the high level of concentrations have

intense poisonous effects and are viewed as pollutants of the environment (Rashed and Niyazi, 2017).

Phytoremediation is a sustainable, cost-effective, green technique to decontaminate the environment from pollutants such as heavy metals, insecticides, thinners, explosive material, petroleum, polycyclic aromatic hydrocarbons, and landfill leachate in the soil, water, and sediments. It involves the use of plants to take off, move out, balance and control pollutants in soil and water (Hughes et al., 1996). It is a weak entered approach depending on biological attenuation by biodegradation and physiochemical devices that decrease the concentration of the contaminant (Parrish et al., 2005; Schwab and Banks, 1993).

The implementation of phytoremediation approach in arid regions requires special plant selection and is anticipated to be less feasible than in humid regions with more favorable climate for plant growth. The arid climate considered by low annual rainfall and high wind make the phytoremediation research challenging in the Middle East. For phytoremediation in arid and semiarid areas, it is necessary to set up a varied phytocoenosis, including plants that can accumulate, stabilize or degrade contaminants (Piha et al., 1995). Phytoremediation is very hopeful for the removal of pollutants from the soil and water (Garbisu and Alkorta, 2003).

Phytoremediation of metal contaminants falls within four different phytoremediation strategies, each of which includes several techniques of actions for remediating heavy metal pollution: Phytostabilization is the restraint of pollutants in the soil by plants, through uptake by roots, adsorption onto roots or precipitation within the root of the plant grows under soil and maintain the physical balance of soils (Padmavathiamma and Li, 2007), Phytofiltration means that plants use roots or seedlings to accumulate contaminants, heavy metals, from water and aqueous waste streams (Prasad and Freitas, 2003), During the process of phytovolatilization plants absorb these heavy metals in elemental forms from the polluted soil, and their biologically convert them into gaseous forms that are finally emitted into the air (Thangavel and Subbhuraam, 2004). Phytoextraction is the uptake of heavy metals from the polluted soil by plants and their translocation to harvestable green parts of the plant where they accumulate (Padmavathiamma and Li, 2007).

Phytoremediation can involve grasses, shrubs as well as trees. Grasses can run a groundcover and limit wind dispersion which plants provide a wide canopy and develop a deep network of plant root to prevent soil erosion. (Williams and Twine, 1960). The roots of plants in the soil play a chief role in metal removal by purification, uptake and cation exchange, and plant induced chemical changes in the narrow region of soil (Dunbabin and Bowmer, 1992). A heavy metal will only become toxic if its concentration in the plants exceeds the allowable threshold. Plants have been divided into three groups based on their acceptance to accumulate metals: Excluders are plants insensitive for absorption and accumulation of heavy metals, Indicators are plants that content of heavy metal linearly responds to increasing availability of heavy metals in contaminated soil and Accumulators are plants accumulating higher contents of heavy metals in their tissues per their rise in the soil than others (Peer et al., 2005).

Some plants in the group of accumulators called hyperaccumulators, which it can accumulate 100 times higher levels of a specific heavy metal in their shoot tissues compared with regular, non-accumulator plants (Reeves and Baker, 2000). A hyperaccumulator is a plant that can grow in polluted soil with very high concentrations of heavy metals, and uptake these heavy metals through their roots, and accommodate

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_60336045
© 2018, ALÖKI Kft., Budapest, Hungary

very high levels of metals in their tissues. The ability to hyperaccumulate toxic heavy metals compared to other plant species has been exposed to be due to several gene expressions and regulations of the same genes in different plants. (Ali et al., 2013).

There are 41 species of Aloe recorded from the Arab region which encompass the countries of Saudi Arabia (Newton, 2001), Yemen (including Socotra) and Oman. The aloes are principally restricted to the areas in the west and south-west of the peninsula (Walker, 2005).

The main objective of the current study is to investigate the ability of *A. vera* in phytoremediation practice of soils polluted with heavy metals in Saudi Arabia. Metal Transfer Factor and Translocation Factor are the evaluation criteria which used to conduct the designated research study.

Materials and methods

Study area description

The Kingdom of Saudi Arabia is influenced by several natural factors, the most important of which is the Astronomical Observatory. The Kingdom is located between 16 degrees and 33 degrees North and 34 and 56 East longitudes, making it the largest part of the dry tropical desert region in South Asia (Sen et al., 2017). The climate of the Kingdom is characterized by drought throughout the year and by high temperatures especially in the summer (Elhag and Bahrawi, 2014a). The geographic location of Saudi Arabia and its varied geological composition and different surface and climatic features from one region to another led to the existence of many natural environments that differ in the components of the vegetation cover (Elhag et al., 2015) from one place to another. Most of the Kingdom's regions are located in dry areas except the Empty Quarter and the Sarawat Mountains within the semi-arid regions. Much of the Kingdom's soil is calcareous because of insufficient rainfall to wash calcium carbonate. Because of these conditions, the Kingdom's environment is fragile and sensitive (Elhag and Bahrawi, 2014b). Saudi Arabia is located in a geographical area lacking fresh water and has no natural resources such as springs, rivers, and lakes with scarcity or lack of rainfall in some areas. Natural resources in the Kingdom are limited to some wells, rainwater pools, and floods that have not been sufficient to meet the essential needs (Elhag et al., 2017b).

Experimental design

The experiment was designed in a tinplate tank with dimensions of 100 × 50 × 75 cm, length, width, and height, respectively. Four tanks were prepared to implant *A. vera* juveniles in PittMoss soils. *A. vera* is a stemless plant growing to 50 Inch, spreading by offsets. The leaves look thick and pulpy, different shades of green, with some species showing white flecks on their upper and lower stem surfaces. The margin of the leaf is serrated and has short and small thorns. The flowers are produced from June to September on a spike up to 120 cm, and each yellow tubular corolla flowers are droopy. Healthy and intact plants were collected with equal in length of 24 cm which is considered to be the optimum plant condition to be examined (Yates, 2002). Prior to the experiment, the juveniles of *A. vera* were planted in tanks for 3 months to adapt to the experimental environment.

Experimental process

Aloe vera was selected for this study because it is not part of the food chain of humans or animals, it can grow in dry arid climates and it is naturally occurring in Saudi Arabia. The growing juveniles of *A. vera* were irrigated with a solution containing inorganic compounds of heavy metals. Aqueous solutions of 15 g/l were prepared from the soluble form of each heavy metal. The polluted solution was prepared according to O'Connell et al. (2008). Consequently, the juveniles were irrigated once a month with one liter of clean water in each experimental tank.

The samples were taken from one tank at a time 4 times on a trimester basis. Leaves area was calculated for all samples. Shoots and roots were weighed before air drying. Root and shoot samples were dried in the air than dried in an oven at 60 °C for two days. Mixed acid digestion procedure was used for preparing the extracts of plant materials. $HClO_4$ (60%), concentrated HNO_3 and H_2SO_4 were mixed in 1:3:1 ratio by volumes. 5 ml was used for the digestion of 0.2 g of fine powdered dry root and shoot. After digestion on a hot plate is completed as indicated white fumes developed and the solutions became colorless, the volume was completed to 50 ml with distilled water (Allen, 1989; Wade et al., 1984). Experimental design and experimental process are illustrated in *Figure 1*.

Figure 1. *Experimental design and experimental process*

MTF and TF calculation

Metal Transfer Factor (MTF) and Translocation Factor (TF) were calculated from the sample's analysis' data. The calculations of using heavy metal concentration in the extracts of samples were carried out according to the following formulae (Cluis, 2004; Barman et al., 2000; Gupta et al., 2008):

$$MTF = \frac{metal\ concentration\ in\ plant}{metal\ concentration\ in\ soil}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_60336045
© 2018, ALÖKI Kft., Budapest, Hungary

$$TF = \frac{metal\ concentration\ in\ shoot}{metal\ concentration\ in\ root}$$

Heavy metals analysis

20 g of plant materials were dried in the air than dried in the oven at 100 °C for two days. 5 ml of acids were used for digestion of 0.2 g of plant material (Krumbein and Pettijohn, 1938). In atomic absorption spectroscopy, a liquid sample is aspirated and mixed as an aerosol with combustible gasses (acetylene and air). The mixture is ignited in a flame of temperature ranging from 2100 to 2800 °C. During combustion, atoms of the element of interest in the sample are reduced to the atomic state. A light beam from a lamp, that cathode is made of the element being determined, is passed through the flame into a monochronometer and detector. Free, unexcited ground state atoms of the element absorb light at characteristic wavelengths; this reduction of the light energy at the analytical wavelength is a measure of the amount of the element in the sample (Lindsay and Norvell, 1978).

Results and discussion

Different heavy metals absorption by *A. vera* showed a different accumulation behavior along with the experimental time demonstrated in *Figure 2*. Cd accumulation decreased by the time. The highest accumulation of Cu was after 6 months but it was dropping off after 9 months. Cr, Ni, Pb and Hg accumulation increased but it dropped after 9 months. The least heavy metal accumulation was detected in the case of Hg. The highest accumulation was As accumulation but it decreased after 9 months.

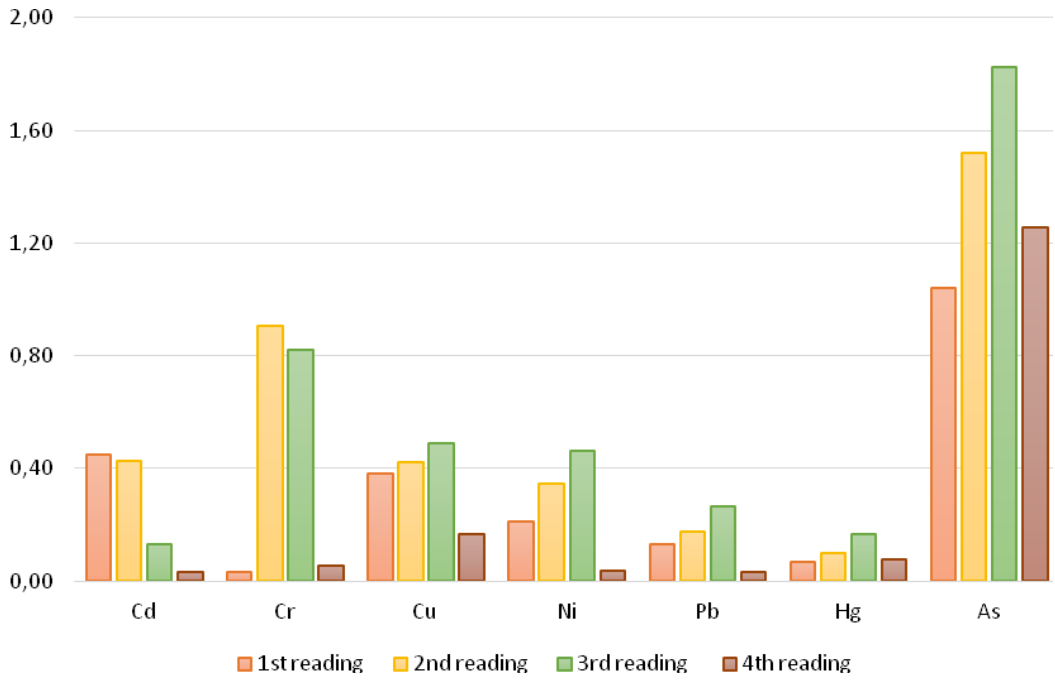

Figure 2. *Heavy metal accumulations in the root (mg/l)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_60336045
© 2018, ALÖKI Kft., Budapest, Hungary

Meanwhile, the heavy metal accumulations in the shoot system of *A. vera* showed fewer accumulation rates in general but with less significant behavior in particular with the case of Cr and Cu heavy metal accumulation (*Fig. 3*). Cd accumulation decreased by the time. The highest accumulation of Cr was after 3 months but it was retreating after that and continued decreasing till the end of the experimental period. Cu, Ni, Pb, and Hg accumulation increased by the time. The least accumulation was detected in the case of Hg. The highest accumulation was As accumulation but it decreased after 9 months.

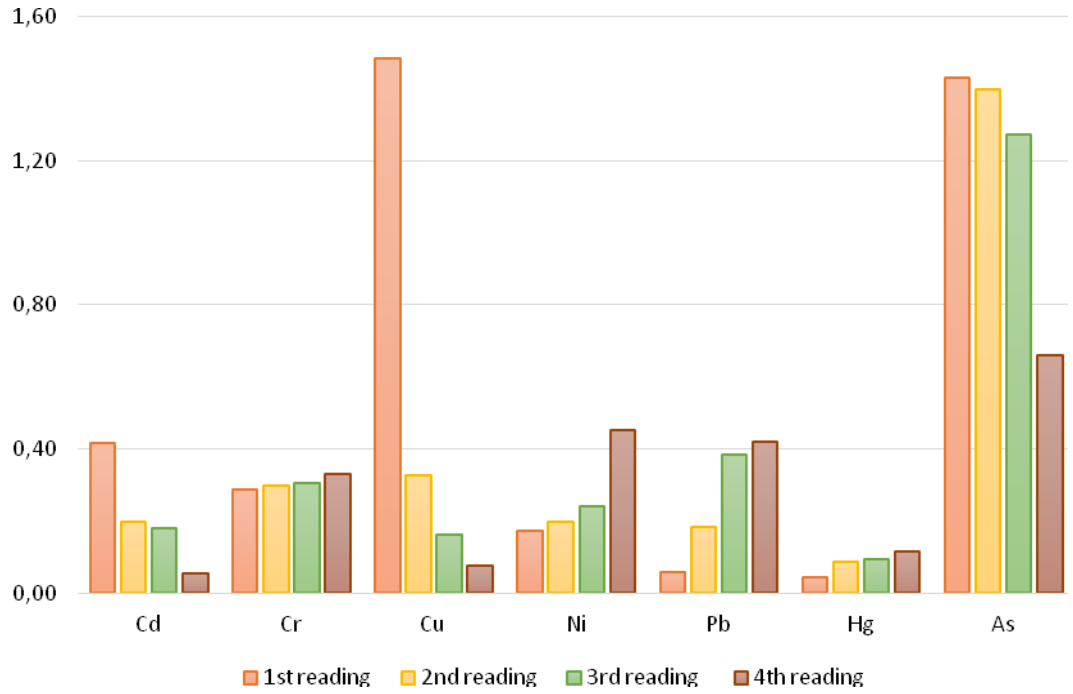

Figure 3. *Heavy metal accumulations in the shoot (mg/l)*

Heavy metal accumulations in both roots and shoots are demonstrated in *Figure 4*. Cd accumulation decreased over time. The least accumulation was Hg accumulation. The highest accumulation was As accumulation but it decreased after 9 months. As, Cu, Ni, Pb and Hg accumulation decreased after 9 months. The concentrations of all heavy metals decreased after 9 months.

The plants for phytoremediation should be rather indigenous to the zones where the contaminants are found, as they have developed adaptation and survival strategies suitable to the hard climate in arid and semiarid areas (Piha et al., 1995). Environmental concerns about the use of exotic species and their threat to the indigenous plant communities are of great importance.

For phytoremediation practices, attention should be given to the use of nonpalatable species before efforts are made to grow these plants. This should contain discussions with concerned regulatory agencies and common organizations about the suitability of the plant species as well. However, non-native species may be an acceptable option provided the climatic conditions are the same and the introduced species do not build a new ecological risk (Radwan et al., 1998).

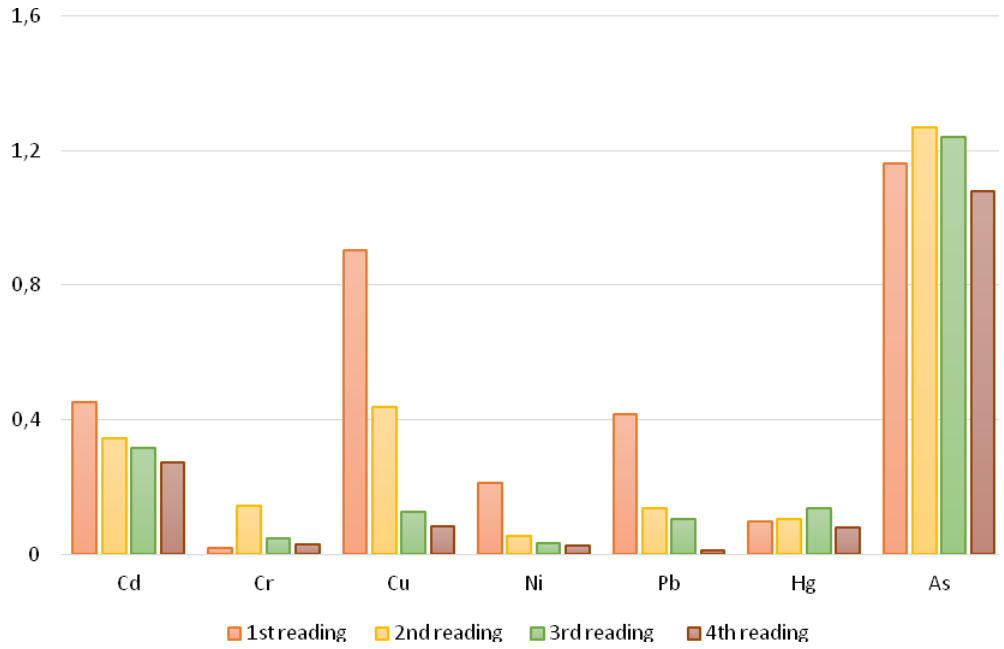

Figure 4. *Heavy metal accumulations in Aloe vera (mg/l).*

The allocation of heavy metals in plant tissues is demonstrated in *Figure 5a–g*. The concentration of Cu and Pb are more in shoot than in root. The concentration of Cd, Cr, Hg and As are more in shoot than in root. The concentration of Ni in root and in the shoot is equal.

The biological effects of heavy metals in plants depend on many ecological factors: the absorptions in the environment, biotic and abiotic factors, exposure time, plant growth, uptake techniques, the affinity of heavy metals for the uptake sites and metals speciation (Mazej and Germ, 2009). Although phytoremediation of contaminated sites in arid and semiarid areas has been attempted by many organizations, the remediation technologies are not properly documented and appear in published literature occasionally. In this study, the current information on phytoremediation for organic and inorganic contaminants in arid and semiarid areas, as well as the potential problems that have an impact on the longstanding practice, are investigated.

According to Deng and Wong (2004), Aloe vera can be considered to have a normal accumulation ability according to its Translocation Factor mentioned in *Table 1*. Different plant species have different TF values based on their affinity to accumulate heavy metals in plant tissues. According to the accumulation ability, phytoremediation plants are categorized into three groups. The first group involves plants with high accumulation ability, like *Typha angustifolia* and *Leersia hexandra*. The second group involves plants with normal accumulation ability, like *Acorus calamus* and *Eleocharis valleculosa*. The third group involves plants with low accumulation ability, like *Neyraudia reynaudiana* and *Phragmites australis* (Deng et al., 2004).

TF and MTF values are demonstrated in *Table 1*. Cu, Ni and Pb concentrations are higher in shoot than in root. Cd, Cr, Hg and As concentrations are higher in root than in shoot. *A. vera* has a high ability to As accumulation, a normal ability to the accumulation of Cd, Cr, Cu, Ni and Pb, and low abilities to accumulate Hg (*Fig. 6*).

Table 1. *Translocation factor and metal transfer factor*

	TF	MTF
Cd	0.820116	2.21934
Cr	0.676804	2.477533
Cu	1.402193	1.713169
Ni	1.00759	1.992467
Pb	1.728856	1.578417
Hg	0.835766	2.196508
As	0.844858	2.183631

TF of Cd, Cr, Hg and As < 1
TF of Cu, Ni and Pb ≥ 1
MTF of Cd, Cr, Hg and As > 2
MTF of Cu, Ni and Pb < 2

In plants, succulence is defined as the presence of thickened tissues in plant organs that the primary function is water-storage and, consequently, drought avoidance (Gibson, 1982; Gibson and Nobel, 1990; Willert, 1992). Because they store water, organs with succulent tissues tend to have a large volume to surface area ratios compared with non-succulent organs in the same plant (Gibson and Nobel, 1990; Rowley, 1987). Such increases in volume result in surface areas with relatively large cross-sectional areas, which leads to greater resistance of bending stresses (Niklas, 1992).

Phytoremediation can be used along with other cleanup techniques. (Padmavathiamma et al., 2014). In general, the use of phytoremediation is confined to sites with low to medium contaminant concentrations, and contamination in the top profile of soils, where phytotoxicity does not occur and the root of the plant can readily access the contaminants (Pivetz, 2001).

Conclusion

This study showed that the *Aloe vera* has the abilities to be a phytoremediators to heavy metals from contaminated soil polluted with metals such as (As, Cd, Cr, Cu, Pb, Hg, and Ni) due to the great reduction of these metals in the contaminated soils which demonstrates a significant level of affinity to these metals. The results confirm that the cultivation of *A. vera* is favorable in soils contaminated with Arsenic (As). Moreover, the optimum lifespan of *A. vera* is nine months after its plantation before its affinity to accumulate heavy metals declines. However, *A. vera* is not recommended for soil polluted with Mercury (Hg). Soil nutrients and soil moisture content among other climatic factors shall be considered in future utilization of *Aloe vera* in phytoremediation. Further investigation needs to be directed towards using *A. vera* under several drought conditions instead of regular irrigation to compare the accumulation ability of *A. vera* in different irrigation schedules.

(Received 17th Jun 2018; accepted 22nd Aug 2018)

Abstract. Green marketing has rapidly emerged as a global phenomenon around the world .As a result, some companies have responded to environmental challenges by applying green marketing strategies. However, with the increasing importance of environmental and health issues and the concept of social responsibility among consumers, recognizing behavior by actors and companies related to green products marketing is necessary. Therefore, this study helps to improve the understanding of green marketing behavior, which plays an important role in improving community health and economic growth. This study aims to design a green marketing behavioral pattern focusing on poultry products. The statistical population of this study is 145 actors who are involved in the production, distribution, promotion and pricing of green poultry products in Iran (Gilan Province). The findings indicate that attitudes toward green marketing (β: 0/94), subjective norms in relation to green marketing (β: 0/90) and feasibility (β: 0/67) had significant positive influences on intention toward green marketing. In addition, the results of green marketing behavior revealed that intention toward green marketing (β: 0/48), feasibility (β: 0.28) and government support (β = 0.56) were the three variables that influenced green marketing behavior, with government support having the greatest impact.
Keywords: *attitudes, subjective norms, feasibility, self-efficacy, decomposed theory of planned behavior, planned behavior theory, green products*

Introduction

In conventional marketing, the needs of customers are identified and satisfied (Kotler, 2003) in the most profitable manner (CIM, 2011) without accounting for social welfare and environmental issues .In other words, conventional marketing focuses on the economic desires of the company and the direct benefits of the products (Khan and Rafat, 2015). In Iran, conventional marketing methods for agricultural production are associated with high costs and are incompatible with sustainable development goals. Among the major problems that Iranian traditional marketing faces in relation to agricultural products are price instability, the high cost and inadequacy of transportation, lack of producer knowledge of market situations due to the inadequacy of the market information system, lack of facilities such as warehouses, high cost of production and waste during the various stages of production, the existence of brokers and the inadequacy of government support in market development and marketing policies. In addition to the lack of green marketing options, information and targeted advertising, the lack of public interest in environmental programs is another challenge in Iran (based on interviews with experts from the Jahad Agricultural Organization).

Since traditional marketing techniques no longer address all of the issues of modern markets, the implementation of green marketing is expected to improve marketing strategies not only by providing long-term financial performance for companies, but also by improving their environmental performance (Kotler et al., 2010; Luchs et al.,

© 2018, ALÖKI Kft., Budapest, Hungary

2010; Liu et al., 2012; Malhotra et al., 2012). Thus, green marketing incorporates a wide range of activities, including product modifications, changes to the production process and, packaging changes, and also modifies the advertising approach (AMA, 2015; Polonsky, 2007). Additionally, Pride and Ferrell (1993) and Grove et al. (1996) noted that the term "green marketing" refers to an organization's efforts to design, promote, price and distribute goods that will not cause damage to the environment. Polonsky (1994) identified several reasons for companies to adopt alternative marketing: (1) social responsibility, i.e., a company understands that it is a members of a wider community and therefore should behave in an environmentally friendly manner and achieve both environmental and profit-related objectives; (2) opportunity, i.e., as people become increasingly concerned about the environment, the benefits of adopting alternative marketing strategies increase, and companies that have incorporated green marketing into their corporate strategy may enjoy a sustainable competitive advantage over companies that have not; and (3) governmental pressure, i.e., governments are attempting to establish regulations that control the amount of dangerous waste produced by companies and are issuing environmental licenses to control those wastes.

Ottman (2011) believes that the companies' product marketing function may be useful for two reasons. First, when a company adopts a program of environmentally friendly products, its distribution, pricing and promotion of the company image and reputation among customers can improve. Second, implementation of a green marketing plan may increase sales by giving a company access to new market segments.

In organic poultry production, the number of birds, nutritional factors, lighting, environmental conditions and even labor force prices and packaging are involved in the quality of the product. In general, the entire production cycle from corn and millet to the final ring of the slaughterhouse should be conducted without chemical interference. Due to the complexity of the production process, organic poultry production in Iran requires a suitable foundation that may take several years to establish. However, the first step in organic poultry in Iran is producing poultry without the use of antibiotics, meaning that during the breeding period, no antibiotic agent is injected into or consumed by poultry that are labeled as green. The northern provinces of Iran, due to their geographical location and the availability of appropriate physical resources, are potentially suitable for the poultry industry (Suri, 2014). Therefore, Gilan province was selected as a northern province in Iran with a high safety factor in the production of green poultry. Research in this field indicates that producers and actors in Gilan province have undergone a positive trend toward green marketing and organic farming because of the competitive and health advantages of such products. However, in recent years, early efforts at green marketing in Iran have focused only on the production; due to the lack of information, no serious efforts have yet been made in the areas of packaging, distribution and pricing. In addition, because of the high cost of organic production and the lack of specialized staff and government policies, this tendency has not led to the associated behavior. Therefore, this study aimed to examine green marketing behavior (GMB) predictors by designing a behavioral pattern.

According to market researcher Mintel, approximately 12% of the U.S. population can be identified as true greens, that is, consumers who seek out and regularly buy so-called green products. Another 68% can be classified as light greens, consumers who sometimes buy green products (Hanas, 2007). Research has also shown that the market grew by approximately 41% from 2004 to 2009 (Mintel, 2010). According to a new survey, most Europeans would be prepared to change their purchasing habits and buy

© 2018, ALÖKI Kft., Budapest, Hungary

more environmentally friendly products, but many feel that they lack information and distrust manufacturers' environmental claims (European Commission, 2013).

A change in agricultural practices is equivalent to changing the culture and mindset of farmers, which can be achieved only by prolonged interaction. Nongovernmental organizations (NGOs) have demonstrated capabilities to this effect (Shenoy, 2003). In Iran, due to the dispersion of active actors in the field of green production and green marketing as well as the lack of government support, official and accurate statistics regarding those who are engaged in green marketing are not available. With the emergence of the phenomena of social responsibility and green marketing, the private sector and NGOs play an important role in promoting and advertising organic farming activities; however, there is still little consumer participation in these activities (Sabori, 2009).

Academic studies on green marketing began in the 1990s and focused on concepts and approaches (Polonsky, 1994; Peattie, 2001; Peattie and Crane, 2005; Rex and Baumann, 2007), the evaluation of green marketing strategies (Polonsky and Rosenberger, 2001; Rivera Camino, 2007), the relationship between green marketing and consumers (Laroche et al., 2001; Ginsberg and Bloom, 2004; D'Souza et al., 2006; Lee, 2008) and the application of green marketing (Johri and Sahasakmontri, 1998; Teisl et al., 2002; Gurau and Ranchhod, 2005). Other researchers reported that there is a significant relationship between green product features, promotion, pricing and distribution and consumers' green behavior (Shahlaee Bagheri, 2014; Boztepe, 2012). Therefore, higher levels of green consciousness lead to greater influence by the mediating factors of attitude, subjective norm, and behavioral control on behavioral intention and the consequent actual behavior. Many studies applied the theory of planned behavior (TPB) to explore consumers' attitude, intention and actual buying behavior with regard to green products (Arvola et al., 2008; Smith and Paladino, 2010; Tanner and Wölfing Kast, 2003; Tarkiainen and Sundqvist, 2005).

The theoretical model of GMB is a set of factors. To better understand these factors, the most important are described in *Table 1*.

Table 1. *Constructing the research model factors*

Factors	Definition	
Attitude	H1	The degree to which the individual favors the behavior being examined (Ajzen, 1991)
Perceived risk	H2	An actor's perceptions of the uncertainty and adverse consequences of engaging in an activity (Bauer, 1960; Taylor, 1974)
Perceived usefulness	H3	The degree to which the individual believes that a technology would improve his or her job performance (Davis, 1989)
Ease of use	H4	The degree to which an innovation is easy to understand and operate (Rogers, 2003)
Subjective norms	H5	An individual's perception of social normative pressures, or relevant others' beliefs that he or she should or should not perform a behavior (Ajzen, 1991). Subjective norms are decomposed into injunctive norms and descriptive norms
Injunctive norms	H6	People's beliefs about what ought to be done (Cialdini et al., 1990; Lapinski and Rimal, 2005)
Descriptive norms	H7	Beliefs about what is actually done by most others in one's social group (Cialdini et al., 1990; Lapinski and Rimal, 2005)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_60476061
© 2018, ALÖKI Kft., Budapest, Hungary

Feasibility (PBC)	H8	Beliefs regarding access to the resources and opportunities needed to perform a behavior or, alternatively, the internal and external factors that may impede the performance of the behavior (Ajzen, 1985, 1991; Ajzen and Driver, 1992; Ajzen and Madden, 1986; Madden et al., 1992)
Self-efficacy	H9	An individual's self-confidence in his/her ability to perform a behavior (Bandura, 1977)
Facilitating conditions	H10	The availability of resources needed to engage in a behavior, such as time, money or other specialized resources (Taylor and Todd, 1995). In other words, the person believes that this behavior is in his or her control
GMI	H11	An indication of an individual's readiness to perform a given behavior. It is assumed to be an immediate antecedent of behavior (Ajzen, 2002)
GMB	H12	The actors offer an environmentally friendly product that is not deleterious to health, the environment and society (based on qualitative research). Therefore, the term "behavior" is calculated with a mixture of green marketing aspects, including green product, green price, green promotion and green location

Surprisingly, there are few studies on Iranian agriculture in general, and none specific to green marketing that provides a behavioral pattern. For this study, a green marketing behavioral pattern was designed for actors in green poultry production in Gilan province. The author of this article had the following aims:

1. Describe certain personal and professional characteristics of actors in green poultry production.
2. Determine the effects of attitude, subjective norms, feasibility (perceived behavioral control), governmental support, and knowledge and intention toward green marketing (GMI) in green poultry production on GMB.
3. Provide a path analysis model of the green marketing behavioral pattern of actors in green poultry production.

Materials and methods

This is an applied study based on quantitative research, and the method of analysis used is correlation. This study focused on Gilan province, which has the potential capacity to serve as a poultry production zone in northern Iran .Due to the lack of sufficient facilities, most Iranian poultry farms are not used to produce green poultry. The production and marketing of this product are controlled by private companies that are responsible simultaneously for production, monitoring and marketing; therefore, accurate statistics regarding the amount of green poultry production and those engaged in it in Gilan were not available. However, information was informally obtained from experts. The sample in this study is 145 people who are involved in the production, distribution, promotion and pricing of green poultry in Gilan province; they are referred to as the actors (n = 145). The study was conducted as a census study because of the small size of the population of experts, and 128 usable questionnaires were obtained from interviews with the actors.

The main instrument used for data collection was a questionnaire, which was developed from a review of the related literature, in 8 sections (present status of GMB, intention toward green marketing (GMI), attitude toward green marketing, review of the actor's subjective norms, green marketing feasibility, review of government support, assessment of the actor's knowledge and description of the actor's personal and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_60476061
© 2018, ALÖKI Kft., Budapest, Hungary

professional characteristics). The evaluations were based on two 5-point Likert scales ranging from 1 (strongly disagree) to 5 (strongly agree).

The content and validity of the questionnaire were established and revised with the help of experts, including faculty members and a few specialists in green marketing. A pretest study was conducted with 20 experts randomly chosen from these populations; the reliability of the questionnaire was verified (calculated Cronbach's alpha was 87.3 and ordinal theta coefficients were 81-94%), confirming the suitability of the items.

This study contained two types of variable: 1) GMB (Y2) as the final dependent variable, which was measured by the respondents' answers to 19 items, and 2) GMI as an intermediate dependent variable, which was measured by 5 items on the Likert scale. Independent variables included governmental support, actors' knowledge of green marketing, actors' attitude, actors' subjective norms and feasibility of green marketing.

The hypotheses were measured by studying the relationships between the variables and their direct and indirect effects. Structural equation modeling (SEM) is a general approach to data analysis that can accommodate either observable or latent variables (or factors) within structural models. This study used descriptive statistics and SEM. Following data mining, descriptive statistics and SEM analysis were conducted with SPSS20 and AMOS20 software, respectively.

Although some authors support the TPB model, whether it can predict all the determinants of human behavior has been questioned (Ajzen, 1991). Therefore, many researchers have proposed revised models to predict behavior accurately (Bond et al., 2009; He, 2012; Läpple and Kelley, 2010; McCarthy, 2007; Wauters and Mathijs, 2010). Many studies have applied the TPB to explore attitude, intention and actual behavior with regard to green products (Arvola et al., 2008; Smith and Paladino, 2010; Tanner and Wölfing Kast, 2003; Tarkiainen and Sundqvist, 2005). Additionally, influential studies have focused on green purchasing and green consumers, but none have provided an exhaustive study integrating all the effective elements from several viewpoints in the form of an individual study. In this study, the theoretical basis of the model is the planned behavior theory by Icek Ajzen and the decomposed theory of planned behavior described by Taylor and Todd. To better predict the green marketing behavioral pattern of actors in green poultry production and to evaluate the model performance, related variables used by other authors were also used to develop this model (*Fig. 1*).

Results

Personal characteristics

The results showed that of the 128 respondents, 4 (3.1%) were female and 124 (96.9%) were male; the average age and average work experience of the respondents were 40 and 9 years, respectively. Of the actors, 35.2% had an associate's degree. The actors' knowledge of green marketing was measured by a test (correct or wrong answers); the results indicated that their average level of green marketing knowledge was 65%.

Significance test

SEM was used to verify the research model. As shown in *Table 2,* some paths are significant and others are not significant.

Table 3. *Standardized regression weights of significant paths*

Path	Estimate
Attitude of actors ⟶ GMI	0.94
Subjective norms of actors ⟶ GMI	0.90
Feasibility ⟶ GMI	0.67
Feasibility ⟶ GMB	0.28
Governmental support ⟶ GMB	0.56
GMI ⟶ GMB	0.48
Knowledge of actors ⟶ self-efficacy	0.12

Structural analysis and measures of fit

Model evaluation is one of the most unsettled and difficult issues of structural modeling. SEM was used to verify the research model with a covariance relationship among antecedents. The following goodness-of-fit measures were used to confirm the appropriateness of the research model for this study: P = 0.213, CMIN/DF = 1.431, GFI = 0.830, AGFI = 0.820, CFI = 0.980 and RMSEA = 0.037. These indices suggest a good model approximation to the sample data, and regression models are shown below:

1. GMB = 0.28 × feasibility + 0.48 × GMI + 0.56 × governmental support
2. GMI = 0.94 × attitude + 0.9 × subjective norms + 0.67 × feasibility

Figure 2 shows latent variables that influence GMB and GMI. The effect of knowledge of green marketing and government support on intention is not significant. The final model of the green marketing behavioral pattern of actors in green poultry production in Gilan province is shown in *Figure 3*.

Discussion

The purpose of this study was to design a green marketing behavioral pattern focusing on poultry products. It was predicted that certain elements would affect GMB. The results show how the TPB can increase our understanding of the factors that influence and determine GMB. In this regard, political (government support) and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_60476061
© 2018, ALÖKI Kft., Budapest, Hungary

educational (knowledge of green marketing) elements were also used to better predict the results of this model.

According to the analysis of the results, it can be deduced that:

- The attitude of the actors has a significant positive effect on their GMI. Our finding is consistent with the findings of Ing Wul and Yi Chen (2014), Knabe (2012), Lin et al. (2010), Arvola et al. (2008), Smith and Paladino (2010), Tarkiainen and Sundqvist (2005) and Asadollahpour et al. (2016).
- The subjective norms of the actors have a significant positive effect on their GMI. This finding is in accordance with the findings of Ing Wul and Yi Chen (2014), Knabe (2012), Lin et al. (2010), Arvola et al. (2008), Smith and Paladino (2010), Tarkiainen and Sundqvist (2005), Soonthensmai (2001) and Asadollahpour et al. (2016).
- Feasibility has a significant positive effect on the actors' GMI. This finding supports the findings of Ing Wul and Yi Chen (2014), Knabe (2012) and Asadollahpour et al. (2016).
- Feasibility has a significant positive effect on the actors' GMB. This finding supports the findings of Ing Wul and Yi Chen (2014) and Asadollahpour et al. (2016).
- Governmental support has a significant effect on the actors' GMB. This finding is consistent with the findings of Chen and Chai (2010), Mei et al. (2012), Diekmeyer (2008) and Punitha and Rahman (2011).
- GMI has a significant positive effect on the actors' GMB. This finding is in accordance with the findings of Ing Wul and Yi Chen (2014), Knabe (2012), Lin et al. (2010), Arvola et al. (2008), Smith and Paladino (2010), Tarkiainen and Sundqvist (2005), Asadollahpour et al. (2016), Soonthensmai (2001) and Che Hsu et al. (2016).
- The knowledge of the actors has a positive effect on their self-efficacy.
- The effect of the actors' knowledge on their GMI is not significant. This finding confirms the results of Maichum et al. (2016).

The results indicated that first, the three components of intention, actors' attitude (0.94), actors' subjective norms (0.90), and feasibility (0.67), had significant positive effects on GMI. Additionally, the three variables GMI (0.48), governmental support (0.56) and feasibility (0.28) each contributed to the prediction of perceptions of GMB and were found to have significant positive effects on GMB. Attitude (0.94) had the most significant influence on GMI and thus was the strongest predictor of GMI, followed by subjective norms (0.90) and feasibility (0.67). Additionally, governmental support (0.56) had the greatest effect on GMB. The overall results confirmed that the TPB model and its measures were suitable for the studied group.

The reason that knowledge of green marketing was not a strong predictor of GMB and GMI in this study may be that most of the actors had no education in green marketing. The results indicated that knowledge of green marketing had a small effect on self-efficacy (0.12) and an indirect effect on feasibility. These findings are consistent with those of Ing Wul and Yi Chen (2014), Asadollahpour et al. (2016), Chen and Deng (2016) and Maichum et al. (2016).

Conclusion

Although levels of analysis are not necessarily mutually exclusive, there are three general levels into which social science research may fall: microlevel; mesolevel, or middle range; and macrolevel (Blalock, 1970). Based on the results of this study, the following recommendations are presented at these three levels:

Macrolevel: The macrolevel is the national policy governing these activities in the country, including legislation and regulations. The analysis focuses on how these national policies influence activities in an institution or organization or at the field level. International influences on laws and policies may also be examined (ITCILO, 2009).

Among the variables constructing the GMB factor, governmental support was identified as the most important. In Iran, due to the lack of specific government policies related to organic products, there is little potential for organic poultry production; thus, government agencies and policy makers should consider specific policies such as:

- Allocating funds to develop organic production infrastructures
- Preparations and government support to attract foreign investors
- Allocating targeted funds to the construction of modern slaughterhouses in accordance with European standards
- Increasing government support to increase the ability of actors to produce organic products

Mesolevel: At the mesolevel, the focus is on how institutions such as NGOs and development organizations operate in terms of service provision and implementation and how they influence national policy. At this level, the focus is on education services, the role of the public and private sectors, the level of decentralization and the level of expertise in the institutions (ITCILO, 2009).

The importance of the variable subjective norms among the variables that construct the GMB factor has been explained by Montaño and Kasprzyk (2008). Montaño and Kasprzyk (2008) believe that if a person realizes that the result is a positive behavior, he or she will have a positive attitude toward performing that behavior; in addition, if others are positive about the behavior and the individual is motivated to satisfy others' expectations, a positive subjective norm is expected. Studies have shown that individuals' subjective norms affect GMI, and the results of this study confirmed the positive relationship between these two variables. As a result, it is recommended that institutions and service organizations use modern methods of information and advertisement, such as social media and the Internet, to develop green marketing campaigns to create positive subjective norms.

Microlevel: At the microlevel, the focus is on female and male consumers. The analysis should focus on how to identify the contexts-related specific needs and priorities of consumers and examine the extent to which gender roles, relationships and cultural issues are key (ITCILO, 2009).

Among the variables that construct the GMI factor, attitude was identified as the most important. Montaño and Kasprzyk (2008, p. 71) believe that "Attitude is determined by the individual's beliefs about outcomes or attributes of performing the behavior weighted by evaluations of those outcomes or attributes." In Iran, green marketing is related mostly to production, and no serious action has been taken for green packaging, distribution and pricing. Due to high production costs and the risk of customer distrust of green products, there is the possibility of financial losses for the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_60476061
© 2018, ALÖKI Kft., Budapest, Hungary

actors. As a result, there is no positive attitude toward green marketing, and the impact of this variable on GMI is known to be the most important. Therefore, justifying the profitability of green products due to increased consumption of these products in the coming years and managing production, pricing, promotion and distribution plans in the framework of export standards may be fruitful for companies.

In sum, the results of this study showed that positive attitudes, appropriate subjective norms, and the feasibility of green marketing improve actors' GMI, and this positive intention will have an impact on GMB for organic production. In addition, government policies and support for the development of organic agriculture will significantly influence the process of GMB. Therefore, with a view to highlighting the financial and commercial aspects of organic agriculture, the agricultural extension as an educational institution can play an important role in this field with facilities and activities for educational and cultural promotion and the implementation of incentive policies.

The novelty of this study is its consideration of political, social, cultural, economic and educational dimensions in the hope that the results will be useful to managers, researchers, practitioners, and policy makers and contribute to future research as a reference. Also in this study, the theoretical basis of the model is combination of the planned behavior theory by Icek Ajzen and the decomposed theory of planned behavior described by Taylor and Todd, on the other hand to better predict the green marketing behavioral pattern of actors in green poultry production and to evaluate the model performance, related variables (governmental support, knowledge of green marketing and perceive risk) were also used to develop this model based on interviews with actors and the researchers' view.

There are some recommendations for future studies in this area. First, other aspects of the marketing mix that are considered substitutes for the 4 Ps, such as the 4 Cs (consumer, cost, communication, and convenience), and are more customer-oriented should be studied. Additionally, the limitations of the present study include the small size; therefore, future research should include a more comprehensive sample. In this study, based on some interviews and literature review, a questionnaire was developed. For further studies, using Delphi technique and grounded theory, will be suggested.

Acknowledgements. Thanks are expressed to Gilan Veterinary Organization and Jahad Agricultural Organization for their constructive comments.

Abstract. The present study reveals preliminary lepidological results in a critically endangered species, Petzea rudd (*Scardinius racovitzai* Müller 1958) from Petea Spring Natural Reservation, Bihor county, Romania. Study of scales morphology in Petzea rudd was performed by use of light microscopy. This is the first attempt to reveal some scale features such as: scale type, shape, arrangement and number of radii and position of focus on scale on Petzea rudd. The geometric morphometric analysis has been applied in order to identify the characteristics for a reliable discrimination between Petzea rudd and its related species from Romanian inland waters, common rudd, *Scardinius erythropthalmus* (Linnaeus, 1758). The comparative analysis of scales shape in *S. racovitzai* and *S. erythrophthalmus* highlighted the statistically significant discrimination among two sets of observations and the significant variation of focus position and shape of scales among these two species.
Keywords: *Petzea rudd, scales, morphology, geometric morphometrics, light microscopy*

Introduction

Petzea rudd, *Scardinius racovitzai* Müller 1958, is a critically endangered fish species (Freyhof and Kottelat, 2008) that is endemic in Ochiul Mare Thermal Lake from the Petea Spring Natural Reservation, Bihor county, from Western part of Romania (Müller, 1958; Bănărescu; 1964; Kottelat and Freyhof, 2007). The present-day status of thermal ecosystem is strongly deteriorated and exposed to extinction because the over exploitation of the thermo-mineral underwater springs and decreasing of thermal water flow (Telcean an Cupșa, 2013; Grigoras et al., 2014; Müller et al., 2014b).

The taxonomic status of *S. racovitzai* was differently approached by ichthyologists, after first description as specific taxon by Müller (1958). Thus, *S. racovitzai* was described as subspecies of the cosmopolite common rudd, *S. erythrophthalmus* (Linnaeus, 1758) by Bănărescu (1964) while further studies revealed specific morphological, physiological and ethological patterns of Petzea rudd (Crăciun, 1998, unpublished PhD dissertation quoted by Bănărescu, 2002; Crăciun, 1997; Müller et al., 2014a; Grigoras et al., 2014, 2015). The species is indexed with specific rank, as *S. racovitzai* by Kottelat and Freyhof in 2007. Bănărescu (2002) supposed *S. racovitzai* could be a recent isolated species from Central European common rudd and he considered that molecular techniques are necessary for clarifying the taxonomic status of Petzea rudd.

The present study provides preliminary results regarding morphology of the *S. racovizai* scales. To the best of our knowledge, this is the first attempt to study the scales morphology in thermal rudd from Natural Reserve of Petea Spring.

A second objective of the paper is to assess the scales morphometric patterns that can be used for discrimination of Petzea rudd from its congener species from Romanian inland waters, *S. erythrophthalmus*. The disruption of the thermal barrier which separated in the past the Petzea rudd from the related species (Telcean and Cupșa, 2013) raises the question of continuity for thermal population under the conditions of cohabitation with a more opportunistic species with hybridisation potential (Nico et al., 2015). We have applied principal components analysis for examination the particularities of shape variation in scales samples (Klingenberg, 2011). Canonical variate analysis (CVA) provides information that maximizes the separation of species (Klingenberg, 2011). We also used the discriminant analysis (DA) for reliability testing of groups dissimilarity (Klingenberg, 2011).

Literature review

Research of fish scales represents a useful tool for identifying the fish at genus or species levels and also in studies of fish phylogeny, sexual dimorphism, age determination, evaluation of the habitats impact on development etc. (Cărăușu, 1952; Esmaeili et al., 2007, 2009; Esmaeili and Gholami, 2011; Ibáñez et al., 2007, 2016; Jawad, 2005a, 2005b; Jawad and Al-Jufaili, 2007; Masood et al., 2015; Miranda and Escala, 2000; Poulet et al., 2005; Renjith et al., 2014).

Shape, size and number of scales are characters used in the taxonomy of fish (Bănărescu, 1964). Since the beginning of the 19th century, Agassiz used a classification system of the fish into four groups, based upon scale morphology (Esmaeili et al., 2009; Renjith et al., 2014). Likewise, the presence or absence of the denticles as well as their shape, size and the distances between them can be utilised as taxonomy analysis criteria in various fish species (Esmaeili et al., 2007, 2009; Jawad, 2005a, b; Delmater et al., 1974; Lippitsch, 1990; Jawad et al., 2007 cited by Esmaeili and Gholami, 2011).

Scale morphology is frequently applied as an instrument of analysis of the differentiation between populations, species or assessment of the phenotypic plasticity of fishes in relation with the habitat conditions and effect of toxic chemicals (Cărăușu, 1952; Jindal and Jha, 2005; Pillay, 1950; Taylor, 2012).

Deviation from pattern of circuli disposal or discontinuities of circuli, breakage or loss of interradial denticles, deformations or losses of tubercles provide conclusions regarding the past environment under which were exposed the fish, including the effect of pollutants on organism during its development and growth (Esmaeili and Gholami, 2011). Lippitisch (1990) and Pou and Gallego (1990), both quoted by Jawad (2005a) show different environment factors may have an effect on some scales morphological characters. Taylor (2012) mentions the fish populations display different growing characteristics in relation with various external factors, e.g. seasonal or habitat variability, availability of feeding resources etc. and therefore, the scales, that also are the first contact barrier with surrounding environment, represent an important phenotypic particularity in relation with all these factors.

In the same, way, the researches of Cadrin (2000) cited by Taylor (2012) pointed out the geographical isolation may lead to occurrence of some morphological patterns of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

fish scales at population level as a result of environment influence or selection over ontogenetic development, inducing morphometric differentiation between species.

There are studies that highlight the influence of intrinsic factors on the intraspecific differences of scale characters in fish. The lepidological researches of Sire (1986) quoted by Mekkawy et al. (2011) in cichlids as well as the studies of Mekkawy et al. (2011), Mahmoud et al. (2005) and Harabawy et al. (2007) in various wide-spread fresh water and marine species, sustain the genetic determinism of scales morphology, invalidating environment control.

In the research of Müller et al. (2014a), on morphology of scales in *S. racovitzai,* authors discriminate Petzea rudd population from its congeneric species, common rudd, *S. erythrophthalmus,* by using geometric morphometrics of scales. Several references regarding the lepidological studies in various cyprinids have been used in the interpretation of our results; Gursoy et al. (2005) in *Scardinius erythrophthalmus,* Miranda and Escala (2000) and Jawad (2005a) in species of *Barbus* genus, Poulet et al. (2005) in *Leuciscus burdigalensis* Valenciennes, 1844, Jindal and Jha (2005) in *Cyprinus carpio* var. *communis* Linnaeus, 1758, Esmaeili et al. (2007) in *Capoeta damascina* (Valenciennes, 1842), Esmaeili and Gholami (2011) in *Rutilus frisii kutum* Kamenskii 1901, Staszny et al. (2012) in *Carassius gibelio* (Bloch, 1782).

Statistical tools used in our study for shape variability analysis with the help of shape coordinates (geometric morphometrics) is largely applied in biology researches (Ibáñez et al., 2007; Klingenberg, 2011; Miranda and Escala, 2000; Moneva et al., 2012; Poulet et al., 2005; Staszny et al., 2012).

Materials and methods

The *S. racovitzai* specimens have been sampled in August and September, 2013 from the "Ochiul Mare" Lake, Natural Reserve Petea Spring, Bihor county, North-Western Romania (*Fig. 1 left)*. The fish sampling was approved by Order no. 1231/2013 of the Environment and Climate Changes Ministry. Different methods have been used for fish capture: a cast-net and a fishing net with 10–16 mm mesh sizes *(Fig. 1 right)*.

Figure 1. *"Ochiul Mare" Lake, Natural Reservation Petea Spring, Bihor county, Romania. The natural habitat of Petzea rudd (left). Fish sampling with fishing net (right)*

The scales were removed from the left side of the body, in the area between the dorsal fin insertion and the lateral line (*Fig. 2*) from thirteen specimens. The small

DOI: http://dx.doi.org/10.15666/aeer/1605_60636076
© 2018, ALÖKI Kft., Budapest, Hungary

number of fish used for this study is linked to the special conservation status of the species and special law of exemption for capture. Around 3–5 scales taken from each specimen have been preserved in dry state and pressed in paper envelopes, after the removal of the epithelium cells and mucus.

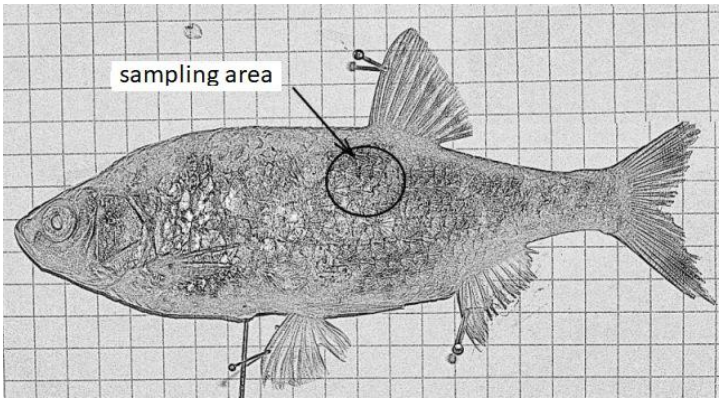

Figure 2. *S. racovitzai and the emphasised area of the scales sampling from the fish body*

The analysis of scales morphology was carried out between 2 microscope glass slides, under microscope (Olympus CH2), magnification up to 1500x, for the identification of the structure details.

Scales morphometric patterns (shape and size variation) were used for discrimination between *S. racovitzai* and its congener species from Romanian inland waters. Similar operations of sampling/processing scales where applied in the case of common rudd, *S. erythrophthalmus*. Atotal of fourteen specimens of common rudd have been captured from Lower Danube River in the confluence area with Prut and Siret rivers (Mm80).

A stereo-microscope (Olympus SZ 40-CTV), 10x ocular and 4x maximum focus has been used for images collecting of scales from both species. The images of the scales enlarged through stereomicroscopy where digitised with the camera (Canon A590 IS).

Seven markers were attached on every digital image of the scales using the TPS Digitize (Rohlf, 2016a) (*Fig. 3*).

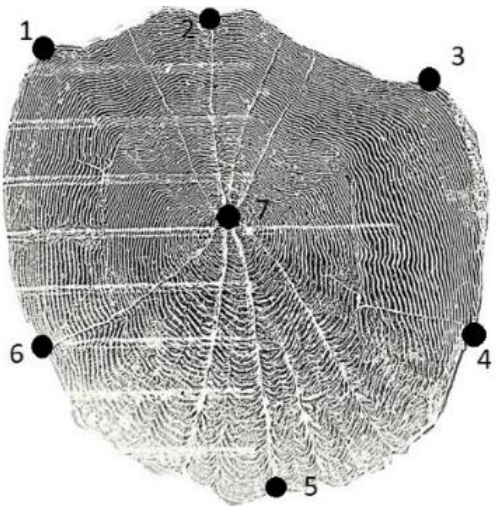

Figure 3. *Landmarks data collection on Petzea rudd scale*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_60636076
© 2018, ALÖKI Kft., Budapest, Hungary

The digital images were processed with and TPS Utility (Rohlf, 2016b) software before statistical analyses.

The geometric morphometric analysis of the scales of two congener species where processed with MORFOJ 1.05f software (Klingenberg, 2011). Data regarding the scales shape was obtained by Procrustes superimposition that excludes the variation of size, position and orientation of landmarks. Several statistical tools: the principal component analysis (PCA), discriminant analysis (DA) and canonical variate analysis (CVA) were applied in order to draw conclusions regarding the two groups separation.

Results and discussions

Preliminary results regarding the scales morphology in S. racovitzai.

The type of scales from the lateral side is elasmoid cycloid, with general particularities of a cycloid scale (*Fig. 4*): anterior field (rostral), posterior field (caudal), the focus, radii, circuli, denticles of circuli, tubercles in posterior zone of the scale.

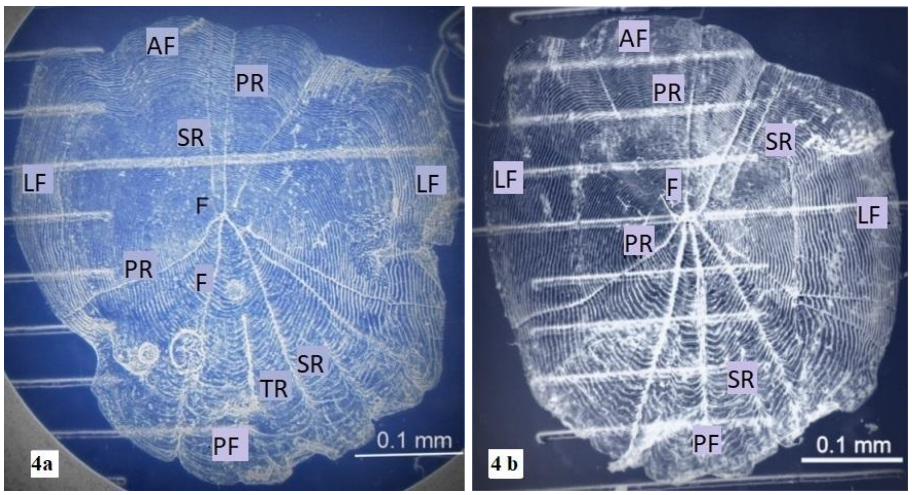

Figure 4. *Stereomicroscope images of normal scales from the lateral side of Petzea rudd (10 x 3). a – scale with all three radii types, b – scale with primary and secondary radii. AF – anterior field, PF – posterior field; LF – lateral field, PR – primary radii, SR – secondary, TR – tertiary radii; F – focus (nucleus)*

The focus or nucleus of the scale (*Fig 4, 5a*), that occurs during ontogenetic development of fish, can represent a taxonomic criterion (Jawad, 2005a). In *S. racovitzai*, the focus is slightly displaced to front of the scale and divides the scale in anterior field (cephalic towards focus) and the posterior one (caudal towards focus). The focus area appears as a reticulate structure, with a not clear shape delimitation, with or without pore mucus. This aspect is recorded in other fish species scales. Jawad (2005a) mentions similar focus characteristics in another cyprinid, *B. arabicus* (Trewavas, 1941).

There are interspecific differences regarding the position and shape of scale focus. A pointed shape is observed by Esmaeili et al. (2011) in *Rutilus frisii* (Nordmann, 1840), a round shape focus in *Labeo niloticus* (Linnaeus, 1758) by Jawad (2005a), translucent or with mucus pores in *Capoeta damascina* according to Esmaeili et al. (2007).

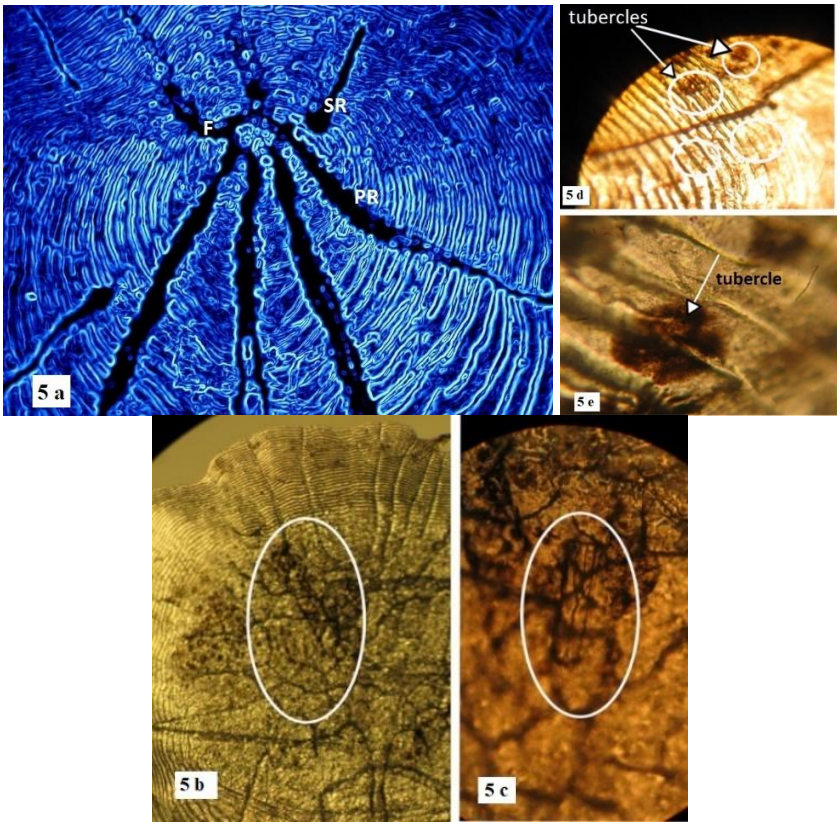

Figure 5. *Microscope images of normal scales and lateral lines scales. a – normal scale with reticulate focus (nucleus) and radii that cross the focus and circuli (15 x 40), b – lateral lines scale image revealing the lack of focus and the disposal of lateral line canal along the anterior – posterior axis (10 x 3.5), c – the lateral lines channel with previous pore and posterior pore (15 x 10), d – normal scale with tubercles, e – normal scale with tubercle with circular shape from the posterior field (15 x 40)*

The scales from the vicinity of the lateral line have the focus slightly outlined and covered by reticular structures shaped like honeycomb. Hagerman (1952) noted the scale focus of some fish species may gain a diffused appearance as the age increasing.

The same reticulate structures of the focus of scales from the vicinity of the lateral line in Petzea rudd is revealed by Esmaeili et al. (2007) for other cyprinids as *Catla catla* (Hamilton–Buchanan, 1822) and *Tor putitora* (Hamilton–Buchanan, 1822).

Microscopic observation in Petzea rudd scales from lateral line revealed the lack of focus (*Fig. 5b, c*). The same feature is mentioned by Esmaeili et al. (2007) in cyprinid *C. damascina*. Conversely, other species display the focus in the lateral line scales as is highlighted by Masood et al. (2015) on some mugilid species.

The lateral line canal (*Fig. 5b, c*) is positioned on the anterior-posterior axis of the scale, slightly oblique and crossing about a half from the anterior scale field, with two pores, the anterior one in a „V" shape and the posterior pore in a „C" shape. The electronic microscopy studies regarding the lateral line scales of various teleost species reveal an increased structural variability of the lateral line canal, which can take different form as straight or oblique simple perforations (Delmater et al., 1973 quoted by Esmaeili et al., 2007) till the wide canals protected by complex structures covering

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_60636076
© 2018, ALÖKI Kft., Budapest, Hungary

two-thirds of the scale on which focus is present (e.g. in *Barbus arabicus, Lates niloticus*, according to researches of Jawad, 2005a).

Primary radii (*Figs. 4, 5a*) reach the focus and there are 1–4 radii in the anterior field and 1–4 radii in the posterior field. The similar results have been reported in other species such as genus *Barbus* studied by Jawad (2005a). These radii type can converge to the nucleus without crossing it, e.g. in Tripterygiidae as it is shown by Jawad study (2005b). Lateral body scales also have secondary radii, more numerous than the primary ones (0–2 secondary radii in the anterior field of scale, 1–8 secondary radii in the posterior field) and even less tertiary radii (0–1 tertiary radii in the posterior field of scale) (*Figs. 4, 5a*). We have not identified a significant relationship between the scales size and the number of radii. The studies of Esmaeili et al. (2007, 2009), Esmaeili and Gholami (2011) reveal the number of radii depends upon the location of scales in different body areas and represents a line of scale flexibility. According to these authors as well as Jawad (2007) quoted by Esmaeili et al. (2007), in some teleost fish, there is a proportional relation between the radii number and body length, the radii number could being used as a taxonomic tool for a reliable species identification.

The presence of primary, secondary and tertiary radii could also provide information regarding the growing conditions of fish (environment factors, feeding resources) (Lippitsch, 1990 quoted by Esmaeili and Gholami, 2011). This scale pattern is considered as being linked to quantity and quality of trophic resources, available during development and growing period (Johal et al., 1984 and Tandon and Johal, 1996 cited by Esmaeili et al., 2007; Esmaeili and Gholami, 2011).

Concentric circuli (*Figs. 4, 5* and *6*) start near the focus area, being interrupted by radii and represent concentric distinctive growth lines, formed through sclerite sedimentation and separation through inter circular space (*Fig. 6*).

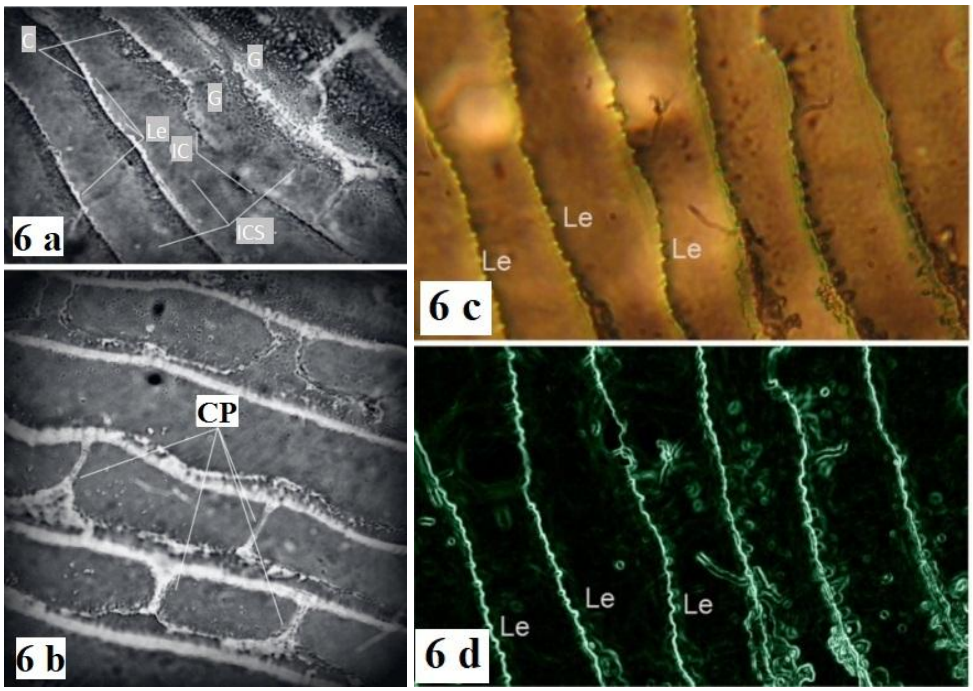

Figure 6. *Microscope images of the scales from the lateral side in S. racovitzai (15 x 40). a – scale with circuli (C), hyaline intercircular spaces (ICS), interrupted circuli (IC) and inter circular granulations (G); b – scales with calcium projections (CP); c, d – scales with denticles or lepidonts on the interradial circuli (Le)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_60636076
© 2018, ALÖKI Kft., Budapest, Hungary

Inter circular spaces are in general really narrow in the anterior field of scale as a result of the focus position, and wider in the lateral and posterior fields. Similar observations are mentioned by Esmaeili (2011) at Rutilus frisii kutum, the posterior circuli could being less distinctive (Moneva et al., 2012), covered by tubercles or missing in other species such as a cyprinid fish, Capoeta damascina (Esmaeili et al., 2007).

The anterior and lateral interradial circuli are almost rectilinear while these structures are convex in the posterior field. According to Lippitsch (1990) cited by Esmaeili et al. (2007), the shape of the first interradial circuli (rectilinear, convex or concave) could be used in the determination of some cichlid species and can suffer changes under environment factors influence.

The concentric annuli formed around the nucleus, typical for the fish species from temperate zones (Bănărescu, 1964; Cărăușu, 1952; Hagerman, 1952; Ilieș et al., 2014) are difficult to detect in the Petzea rudd, which is not subjected to the same seasonal temperature variation. Appearance false annuli in some observed scales could be linked to other extrinsic or intrinsic factors that can can lead to a variable growing rhythm, e.g. reproduction period (Hagerman, 1952; Gursoy et al., 2005), but this aspect should be further investigated.

The circuli have calcium projections (*Fig. 6b*), radii bifurcations and specific structures called denticles (lepidonts) (*Figs. 5c, d*), the last ones being identified in the lateral field of scale and oriented towards the focus. The presence or absence of the denticles, their shape, size and the distances between them can be utilised as taxonomy analysis criteria in various fish species (Esmaeili et al., 2005, 2009; Jawad, 2005a, b; Delmater et al., 1974; Lippitsch, 1990; Jawad et al., 2007 cited by Esmaeili and Gholami, 2011).

The posterior field of the scales possesses pigmentary granules (tubercles) with regular shape or formless contour (*Figs. 5d, e*). The tubercles are formed by crowding of the epithelial cells of epiderma. According to researches of Esmaeili et al. (2007), Esmaeili and Gholami (2011), Ibáñez et al. (2007), these tubercles contribute to the rigour of the scales and represent a useful tool for taxonomic research as well as habitat condition assessment. We noted a poor distribution of the tubercles on the scales. This aspect must be further investigated in order to verify the origin of this observed particularity (genetical or medial effect).

Geometric morphometric analysis of scales in S. racovitzai

The principal components analysis (PCA) has enabled conclusions regarding the shape variation between fish samples. and was performed by use of the covariance matrix of Procrustes coordinates (Klingenberg, 2011) for each group of the two congener species, *S. racovitzai* and *S. erythrophthalmus*. The data of the landmarks were superimposed through a full Procrustes fit.

According to PCA analysis, the first three components sum 70.459% from total variance (*Fig. 7*) that reveal significant variation in shape of scales sampled from two rudd groups.

The shape changes of lateral body scales in both species are illustrated in *Figure 7*. The focus position (represented trough the L7 landmark, *Fig. 8*) in S. racovitzai, is displaced prior from the centre of the scale compared with the S. erythrophthalmus focus disposal and the entire shape is more elongated in Petzea rudd (*Fig. 8*). One the other hand, the axis represented by the L4–L6 landmarks (which delineates the field

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_60636076
© 2018, ALÖKI Kft., Budapest, Hungary

with tubercles) does not show significant variation of position, being connected with the adaptive phenotypic response of the two related species to similar hydrodynamic feature (Ibáñez et al., 2007; Sudo et al., 2002 cited by Ibáñez et al., 2007).

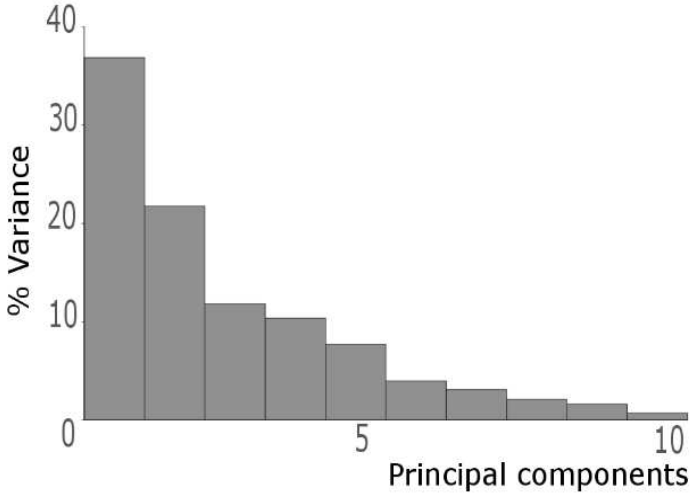

Figure 7. *The percentage of total variance for each principal component (PC) of the fish scales analysis of S. racovitzai and S. erythrophthalmus*

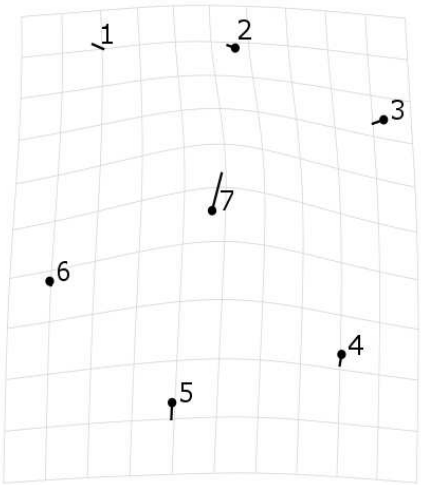

Figure 8. *Transformation grid illustrating the scale shape changes associated with PC, between the S. racovitzai and S. erythrophthalmus. The lines point in the direction of the shape change for each landmark*

The relationships between observations carried out on scales geometric morphometric analysis and the disposal of the specimens of two species in the multivariate analysis morphospace is shown in *Figure 9*. The scatter plot of PC scores reveals the two clear groups separated by PC1.

CVA provides extra information in data interpretation that maximise the separation between groups (species/ecotypes, Klingenberg, 2011). The histogram of canonical variate scores covers the shapes particularities which denote the dissimilarities between the two species (*Fig. 10*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_60636076
© 2018, ALÖKI Kft., Budapest, Hungary

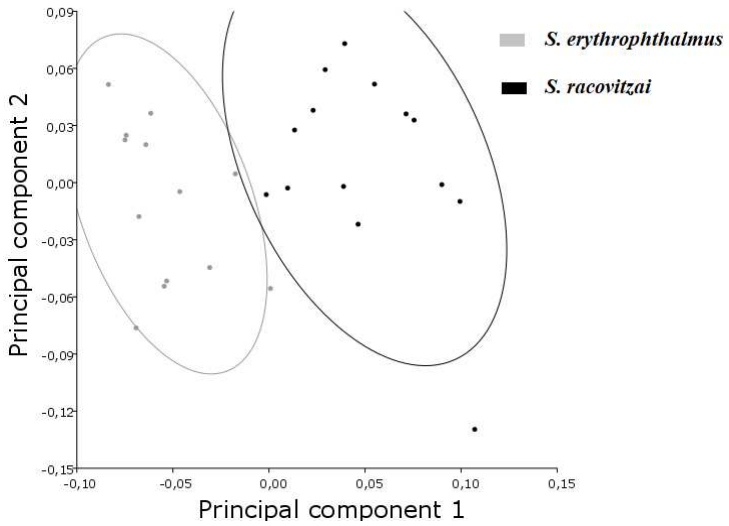

Figure 9. *The tolerance limits (90% confidence level) of the scores distribution of the first two principal components (PC) of the scales shape analysis of fish from two groups. The species disposal in the morphospace of the multivariate analysis (PC1 36.865%, PC2 21.766%)*

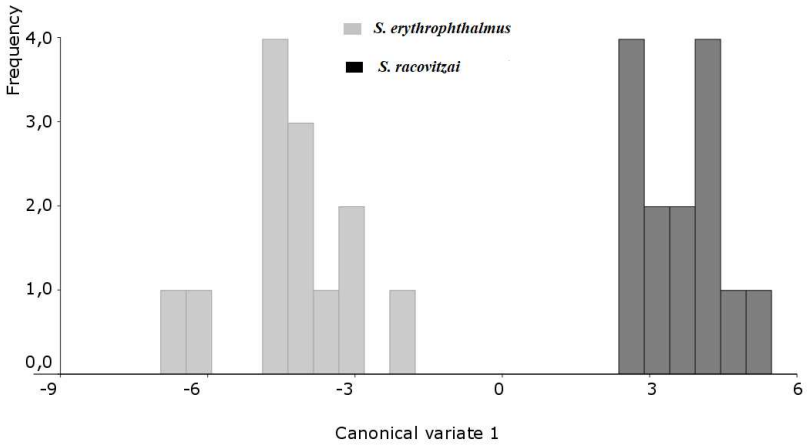

Figure 10. *Scatter plot of CV scores for scales shape of two congener species (S. racovitzai and S. erythrophthalmus)*

Mahalanobis distance (7.5872) reveals a significant separation between groups ($P < 0.0001$ from 10 000 permutation tests). The same result is obtained by permutation test for Procrustes distances ($P = 0.1067$, $P < 0.0001$).

The discriminant analysis (DA) of scales shape of fish from the two groups allows the examination of reliability of separation between groups.

The histogram of distribution of eigenvalues discriminant scores highlighted the separation among the two congener species (*Fig. 11*).

The parametric P-value (<0.0001) for null hypothesis test of similarity between means of observations groups sustains the reliable distinguish between the rudd species. The results for Procrustes distance (0.10672500), Mahalanobis distance (7.5872) and associated parametric P-values could also be in connection with anisotropy of scales samples (Klingenberg, 2011).

Conclusions

The microscopic analysis of scale morphology reveals that lateral scales in *S. racovitzai* are of elasmoid cycloid type, with following particularities: anterior field (rostral) and posterior field (caudal), focus, radii, circuli, denticles on the circular radii and tubercles.

Some scale features on Petzea rudd as: the reticulate structure of the normal scale focus, the lack of the focus on lateral line scale, the primary radii crossing the focus, the presence of toward oriented denticles in the lateral fields of scale, displaying of tubercles with regular or formless shape in the posterior field of scale are common with other cyprinids species.

The focus position, slightly displaced to front of scale represents a reliable criterion that discriminate the *S. racovitzai* from the congener species, *S. erythrophthalmus.*

Taking into consideration our preliminary results regarding the morphology of Petzea rudd scales and the pattern that discriminate *S. racovitzai* from *S. erythrophthalmus*, futur comparative works will develop in order to define which scale features clearly distinguish Petzea rudd from other related cyprinids species.

Acknowledgements. The present study was supported by The Mohamed bin Zayed Species Conservation Fund, Abu Dhabi (project no. 13255722 "Captive breeding and maintaining ex situ populations of *Scardinius racovitzai* and *Melanopsis parreyssii*"). The authors gratefully acknowledge the following individuals for their support: the anonymous reviewers and the editors of Applied Ecology and Environmental Research for the valuable, critical and helpful comments on the manuscript.

(Received 26th Jun 2018; accepted 31st Aug 2018)

Abstract. Two-spotted red spider/red spider mite is an important pest of cultivated crops. Resistance is one of the most important problems in the intensive chemical control used in traditional management methods. Therefore, researchers have been using alternative control methods in pest management to overcome resistance problem. This study was conducted between 2015 and 2017 to investigate the effects of entomopathogenic fungi (EPF) *Beauveria bassiana* and *Purpureocillium lilacinum* TR1 on *Tetranychus urticae* (Koch) (Acarina: *Tetranychidae*). The doses used for *P. lilacinum* were 10^4, 10^5, 10^6, 10^7, 10^8 and 1.6 10^8 conidia ml^{-1} and for *B. bassiana* 10^4, 10^5, 10^6, 10^7, 10^8, 10^9 and 3.7×10^9 conidia ml^{-1}. After five days the results showed that mortality of *T. urticae* adults were started with 10^5 conidia ml^{-1} concentration of *B. bassiana* and after seven days 10^4 conidia ml^{-1} concentration of *P. lilacinus.* At the end of the trial, the mortality rate recorded by the highest doses, 10^8 conidia/ml, of both EPFs were 28.3 and 66.6% with *P. Lilacinus and B. bassiana*. Since many EPF fungi are thought to be epizootic, *B. bassiana* and *P. lilacinum* can be effectively used against *T. urticae* control as biological agents.
Keywords: *two spotted spider mites, entomopathogenic fungi, control, Turkey*

Introduction

The polyphagous pests are among the most harmful pest groups of agricultural products (Vacante, 2016). *Tetranychus urticae* is also an important pest of cultivated crops. Hatched two-spotted spider mites ((TSSM) mostly fed on the lower surface of leaves. The TSSM causes destruction in leaves by feeding in approximately 18-22 plant cells in a minute. After inserting the stylet like mouthparts into leaf cells, secretes the enzyme and absorbs the cell contents. Consequently, leaves are turned on pale, yellowish, gray or bronze-colored spots and causing drying and defoliation. In addition, adults cause damage by spinning tight and silk webs on the plants (Anonymous, 2008). Approximately 4000 different host plant species of *T. urticae* have been identified in worldwide (Migeon and Dorkeld, 2010, 2017) as well as in different studies conducted in Turkey (Yabaş and Ulubilir, 1995; Bulut, E., 1999; Yeşilayer, 2009).

The most preferred method in TSSM management is chemical control which is inexpensive and easy to adapt. However, one of the most important disadvantages of continuous use of chemical control is the resistance of *T. urticae* to the pesticides over time (Keena and Granett, 1987; Herron and Rophail, 1998; Van Leeuwen et al., 2004). New methods which can be alternative or complementary to chemical control of pests have recently been studied and especially importance of biological control is increasing as a suitable alternate method. Biological control is an appropriate method to sustainable agricultural techniques and sensible to human and animal health. The main components of this method used in pest control are parasitoids, predators and entomopathogens (Kılınçer et al., 2010; Dermauw et al., 2013). Studies conducted to date have reported approximately 500 fungi species as pathogenic in insects The

entomopathogenic fungi species of *Lagenidium, Entomophaga, Neozygites, Entomophytora, Erynia, Aschersonia, Lecanicillium, Nomuraea, Hirsutella, Metarhizium, Beauveria* and *Isaria* have gained importance in the field of plant protection (Erkılıç and Uygun, 1993; Kılıç and Yıldırım, 2008). *P. lilacinus* is known as a nematophagus fungi and used to control mites and insects. In addition, EPN activity of entomopatogen fungus *B. bassiana* against *T. urticae* and insects has also been demostrated (Örtücü and Albayrak İskender, 2017).

Thee fungi do not develop resistance in mites, insects and like other pesticides, have absence of any toxic effects on ecology and have potential for future biotechnological developments. The longtime control, infecting the development period of their hosts, applicability with many insecticides and easiness in for mass production are also other advantages of these fungi (Demirbag, 2008). Fungi directly enter from the cell wall. The spores on cuticle settle here and germinate. The germinating spores enter due to the appressorium (penetration peg). The hyphae in epidermis and hypodermic grow, continue to proliferation in the insect body and blood cells and cause the death of insect (Ortiz-Urquiza, 2013). Commercial preparation of some entomopathogenic fungi as mycoinsecticides (*B. bassiana*, *Metarhiz anisopliae, Hirsutell thompsoni*) are available in the world and Turkey (Kılınçer et al., 2010). Recent studies have recorded the efficiency of some EPFs such as B. *bassiana*, *Verticillium lecanii* and *M. anisoplia* against two spotted spider mites (Chandler et al., 2005). The aim of this study was to evaluate the efficiency of two different entomopathogenic fungi, *Purpureocillium lilacinum* and *Beauveria bassiana* against *Tetranychus urticae*.

Material and methods

Plant and mites culture

Bean used as host plant *Phaseolus vulgaris* L. (Fabaceae) was grown in production cabinets at 25 ± 2 °C, 65 ± 5% relative humidity and 16 h lights: 8 h darkness photoperiod in the Plant Protection Department of Faculty of Agriculture, Gaziosmanpaşa University in Tokat-Turkey. The plants, at 5-6 leaves stage were transferred to the production cabin to be used in the production of two-spotted red spiders. Cultures of *Tetranychus urticae* were reared in climate chambers of Plant Protection Department, Faculty of Agriculture, Gaziosmanpasa University. The infected bean plant leaves with mites were cut and placed on non-infected plants to infect.

Cultures of entomopathogenic fungus

The EPFs used in the study, *Purpureocillium lilacinum* (syn: *Paecilomyces lilacinus* (Thom) Samson) TR1 and *Beauveria bassiana* (Balsamo) Vuillemin were obtained from the stock cultures of Prof. Dr İlker KEPENEKÇİ (Department of Plant Protection, Faculty of Agriculture, Gaziosmanpasa University) and from Prof. Dr. Fikret DEMİRCİ (Department of Plant Protection, Faculty of Agriculture, Ankara University), respectively. The fungus was produced at the PDA medium to obtain sufficient spore suspension. Pure entomopathogenic isolates were planted using with glass hokey stick. After 4 weeks, 5 ml of 0.02% Tween 80 solution was added to the petri dishes containing the cultures and homogenous mixing of fungi spores was achieved by spreading with glass hokey stick. The resulting suspension was then filtered through a sterile material to remove particulates, and transferred to 15 ml and 50 ml centrifuge

© 2018, ALÖKI Kft., Budapest, Hungary

tubes. The centrifuge tubes were shaken for 5 min on a Vortex shaker to separate the clustered fungi spores in the fungi suspensions. The spore intensity was determined using Thoma slide and light microscopy (Gabarty et al., 2014). Afterwards, each fungi isolate was diluted and the number of spores was adjusted.

Bioassay

Total of 13 different conidial concentrations were prepared to study the efficiency of entomopathogenic fungi on *T. urticae*. The conidial concentrations included 7 different doses of *B. bassiana* (1×10^4, 1×10^5, 1×10^6, 1×10^7, 1×10^8, 1×10^9 and 3.7×10^9 conidia ml^{-1}) and 6 different intensities of *P. lilacinum* (1×10^4, 1×10^5, 1×10^6, 1×10^7, 1×10^8 and $1 \times 1.6\ 10^8$ conidia ml^{-1}). For each application, 10 ml suspensions of different spore-density solutions were shaken for 2-3 min on the Vortex shaker. The EFPs, then, were sprayed to the leaves using a hand sprayer (2.5 ml). For each application, 10 *T. urticae* adults were used. Fungi solutions were sprayed to the down side of bean leaf disc and placed on a moist cotton in Petri dishes. Adult mites were transferred with a fine brush to the surface of leaf disc. Sterile distilled water (dH_2O) containing 0.02% Tween 80 was sprayed onto the leaves in the control. Mortality values were counted on days 1, 3, 5, 7 and 9 after the application, and mycosis rates observed on days 7, 11 and 19 were recorded. Mites, mortality in mycosis experiment were placed on a moist filter paper in 9 cm sterile glass petri dishes and fungal development was observed.

Daily maintenance and humidity control were carried out during the experiments. The experiment was set up with three replicates and repeated twice.

Statistical analyses

Data was subjected to the one-way analysis of variance (One-Way ANOVA), and mean values were compared by Tukey's test at P = 0.05 significance level (SPSS, 2011).

Results

Total of 13 concentrations of two different entomopathogenic fungi were applied to the adults of *T. urticae* under the laboratory conditions. Mortality using single dose of 10^5 started to occur on days 3 and 5 after applications of *P. lilacinum* and *B. bassiana*, respectively. Mortality of *T. urticae* adults among the application of other concentrations after the single dose experiment, were observed from day 5 at 10^6 concentration of *P. lilacinum*. The mortality rate at 10^6, 10^7 and 10^8 conidia ml^{-1} doses on day 9 was 28.3% and the mortality rate at the highest concentration ($1 \times 1.6\ 10^8$ conidia ml^{-1}) on day 11 was 76.6%. The mortality rates were linearly increased with increasing the doses and days (*Table 1*). The counting results in day 3 of *P. lilacinum* application in controlling the adult mites was not significantly different ($P > 0.05$). The mortality rates counted on days 5, 7 and 9 at 10^7 conidia/ml dose were statistically significant ($P < 0.05$) and the mortality rate ranged from 20 to 61.6% (*Table 1*).

The deaths of two-spotted adult mites at the highest concentration (3.7×10^9 conidia ml^{-1}) of *B. bassiana,* the second EPF used in the study, started on day 3 and mortality rate reached to 20%. The mortality rate was recorded as 91% on the last day (*Table 2*).

The mortality rates on days 5 (13.3%) and 7 (16.6%) at 10^7 and 10^8 conidia ml^{-1} concentrations of *B. bassiana* were statistically significant ($P < 0.05$). In contrast to *B.*

bassiana, the difference between mortality rates obtained with *P. lilacinum* starting from 10^8 conidia ml^{-1} concentration on day 3 was significant ($P < 0.05$). The differences between mortality rates on days 5 and 7 were similar, though statistically significant ($P < 0.05$). Mortality has not been observed after 3 days treatment with 10^4 but mortality was 48.3% at end of the day 9.

Mycosis study with EPF fungus

Mycosis observations were conducted on days 7, 11 and 19 within the efficiency study against *T. urticae* adults included the different concentrations of the two EPF fungi. The mycosis rate on the end of day 7 at the lowest concentration (10^4 conidia ml^{-1}) was 10% and it was 51.6% at the end of the 19th day. The mycosis development rates of six different *P. lilacinum* concentrations on various days showed mycosis development on day 7 at 1×10^5, 1×10^6 and 1×10^7 conidia/ml concentrations, but the difference was not statistically significant ($P > 0.05$). The rate of mycosis development at 1×10^8 and $1 \times 1.6\ 10^8$ conidia ml^{-1} concentrations on day 7 was statistically significant ($P < 0.05$) (*Table 3*).

Similar to *P. lilacinum* (*P. lilacinus*), the mycosis development rates conducted at different concentrations of *B. bassiana* started to be observed from the day 7. The mycosis development rate at the highest concentrations of 1×10^7, 1×10^8 and $1 \times 1.6\ 10^8$ conidia ml^{-1} ranged from 20 to 45% and it was statistically significant ($P < 0.05$). The rate of mycosis development, which increased to over 50% at the highest

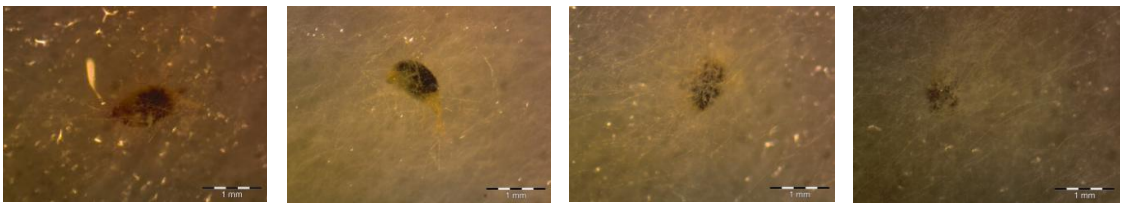
Means followed in the same column by different letters are significantly different $P < 0.05$, Tukey test

The difference between observed mycosis rates of both EPF applications was statistically significant ($P < 0.05$). The mycosis development rate at the lowest concentration on the day 11 varied from 21 to 60% for *P. lilacinum* and from 28 to 78% for *B. bassiana*. The mycosis development rates of two different EPFs at different concentrations on days 7, 11 and 19 are presented in *Figure 1a-d*.



a **b** **c** **d**

Figure 1. *The mycosis development rates a- P. lilacinus 10^5, b- P. lilacnius 10^7, c- B. bassiana 10^5, d- B. bassiana 10^7 micosis*

© 2018, ALÖKI Kft., Budapest, Hungary

The mycosis rates at 10^4 conidia ml^{-1} concentration of *B. bassiana* and *P. lilacinum* were recorded on days 7, 11 and 19. The mycosis development at 10^4 conidia ml^{-1} concentration in both fungi application was similar at the end of day 19 day. The lowest mycosis rates at 10^4 conidia ml^{-1} concentration on day 7 were 13.3 and 15% for *P. lilacinum* and *B. bassiana*, respectively. The mycosis rate on day 19 was lower in *P. lilacinum* than in *B. bassiana*. The lowest mycosis rates at 10^6 conidia ml^{-1} concentration on day 7 were 13.3 and 16% for *P. lilacinum* and *B. bassiana*, respectively. The mycosis rate of *P. lilacinum* from day 11 at 10^7 conidia ml^{-1} concentration was 45% while that of *B. bassiana* was over 50%. The mycosis rate at the highest common concentration (10^8 conidia ml^{-1}) on day 11 was recorded over 50% for both fungi while a mycosis rate of 100% was recorded on day 19.

Discussion

The lowest mortality rate for both fungi, *P. lilacinum* and *B. bassiana*, used in the study at the lowest concentration of 10^4 conidia ml^{-1} on day 9 was 20% and 48.3%, respectively. The mortality rate at the highest concentration on day 5 was found to be 28.3% for *P. lilacinum* and 45% for B. *bassiana*. The mortality and mycosis rates in the *B. bassiana* treatment were higher than that of *P. lilacinum* and the mortality rate of *T. urticae* at 7 different concentrations ranged from 10 to 100% between days 3 and 9. Similarly, Shi et al. (2008b) reported that *B. bassiana* application caused 31.9 to 87.7% mortalities of *Tetranychus cinnabarinus*, a red spider, in a study with three different EPFs. In laboratory conditions, application of two different isolates of *B. bassiana* caused mortality between 22.1 and 82.6 of adult females of *T. evansi* mites (Wekesa et al., 2005). In another study conducted with four different EPFs, *M. anisopliae* V275 and *M. anisopliae* led to quite high mortality on adult stages of *T. urticae*. In the same study, *M. flavoviride*, *L. lecanii* and *B. bassiana* were found effective in the adult stage by 57.8, 50 and 45.8%, respectively, and the differences in adult mortality rates caused by entomopathogenic fungi were statistically significant (Doğan, 2016). Shi and Feng (2009) and Wekesa et al. (2006) reported that entomopathogenic fungus applications resulted in deaths in *T. urticae* mites and also reduced their reproductive potentials. Tamai et al. (2002) investigated the effects of 45 isolates belonging to *Aschersonia aleyrodis* (1), *Beauveria bassiana* (32), *Metarhizium anisopliae* (10), *Hirsutella* sp. (1) and *Paecilomyces farinosus* on *T. urticae*. The concentration of entomopathogenic fungi were 5×10^7 conidia ml^{-1} except for *Hirsutella* sp. which was 1.7×10^7 conidia ml^{-1}. *B. bassiana, Hirsutella sp*. and *M. anisopliae* were found more pathogenic than other fungi used in the study, and these fungi have been reported causing mortalities of mites from the third day after inoculation. Similar to the findings of others, the mortality of mites in this study started after the third day of 10^8 and 10^9 conidia ml^{-1}. *B. bassiana* application.

The highest mortality rate of *B. bassiana* at 1×10^7 conidia ml^{-1} concentration in this study was 58.3%, while Doğan et al. (2017) reported 80% mortality on *T. urticae* at 1×10^7 concentration of the same fungus. Wu et al. (2016) reported 37 to 49% adult mortality at 1×10^7 concentration of different *B. bassiana* strains, and fungal virulence was attributed not only to strains but also to the concentration, frequency of application and formulation. Therefore, 80% mortality was reported from *T. evansi* and *T. cinnabarinus* strains of *B. bassiana* (Wekasa et al., 2005; Shi et al., 2008a). Bugeme et al. (2014) found that 1×10^7 conidia ml^{-1} concentration of *B. bassiana* and *M.*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_60776086
© 2018, ALÖKI Kft., Budapest, Hungary

anisopliae increased the mortality rates of *T. urticae* nymphs and adults and both EPFs were found effective.

The *P. lilacinum*, in the experiment, was very effective in two-spotted spider mites. The mortality rate linearly increased with the increase in concentrations. The mortality rate at 1×10^6, 1×10^7 and 1×10^8 conidia ml^{-1} concentrations ranged from 80 to 100%. Amjad et al. (2012) applied three different doses (1×10^6, 1×10^7 and 1×10^8 conidia ml^{-1}) of *Metarhizium anisopliae*, *Paecilomycis fumosoroseus* (Wize) and *Verticillium lecanii* against *T. urticae* and reported 90% mortality with *P. fumoroseus* application. In this experiment, the mortality rate at $1 \times 1.6\ 10^8$ conidia ml^{-1} *P. lilacinum* application was %66.3. In addition, development of mycosis was observed on day 7 of *P. lilacinum* applications against mites tested. Amjad et al. (2012) have also observed mycosis development on adult female mites from day 7 of *P. lilacinus* application against *Tetranychus kanzawai*.

The results of efficacy study conducted in Tokat province of Turkey revealed that *B. bassiana* and *P. lilacinum,* entomopathogenic fungi, caused effective mortality of mites at the end of 72 h (3 days) and 120 h (5 days), respectively. The development of mycosis has been intense from the day 7 at both fungi application. The *B. bassiana*, comparing the mortality and mycosis rates, was more effective against red spider mites than *P. lilacinum*.

In conclusion, we may conclude from the laboratory results that *B. bassiana* and *P. lilacinus* can be successfully used in controlling *T. urticae*. However, greenhouse and field trials are needed to support the findings of this study and to obtain more effective control against *T. urticae*. The use of entomopathogens in management of two-spotted red spiders has more advantageous to practice in terms of human, environment, benefices and predators. In addition, mass production, formulation development, licensing and further research efforts are required on entomopathogens fungi.

Acknowledgements. The authors thank Prof. Dr. İlker Kepenekci (Gaziosmanpaşa University, Turkey) and *B. bassiana* Prof. Dr Fikret Demirci (Ankara University, Turkey) for providing *P. lilacinum*. This study was funded by Research Foundation (BAP-2015-137) of Gaziosmanpaşa University

(Received 26th Jun 2018; accepted 31st Aug 2018)

Abstract. The aim of this research is to examine the effects of chemical and organic fertilizer applications on the forage yield and quality of smooth brome. The research was conducted in two separate experiments under irrigated and non-irrigated conditions in a randomized complete blocks design with three replications. Ammonium sulphate was used as chemical fertilizer, manure and poultry manure as organic fertilizer and *Vicia sativa* L as green manure. Under irrigated and non-irrigated conditions, the impacts of different fertilizer applications on the smooth brome's height of plant, crude protein rate, crude protein yield, green grass yield and dry matter yield were evaluated. According to the results of the research, while the average dry matter yield was obtained to be 3.94 t ha^{-1} under irrigated conditions, it was obtained as 1.70 t ha^{-1} under non-irrigated conditions. The peak values under irrigated conditions were obtained from chemical fertilizer application. However, under non-irrigated conditions the highest values were obtained from organic fertilizer applications. Consequently, considering the impacts of using organic fertilizers on the ecological properties of the soil in the long term, it was concluded that the yield difference between chemical fertilizer and organic fertilizer under irrigated conditions was at tolerable level.
Keywords: *manure, poultry manure, chemical fertilizer, dry matter yield, organic forage*

Introduction

Plant production methods not damaging the natural resources and ecosystem should be preferred, while it is aimed to obtain maximum yield in unit area from plant production. One of the most frequently used methods in increasing productivity is fertilization. Especially, with the use of chemical fertilizers, the importance and value of organic fertilizers were ignored. The most applied method in improving the physical properties of soil and maintaining its sustainability is the addition of organic matters (Bender et al., 1998). Organic fertilizer improved the physical, chemical and biological properties of the soil (Shiralipour et al, 1992; Carpenter-Boggs et al., 2000; Marinari et al., 2000) as well as increasing the plant yield and quality Yolcu (2011). Sonmez et al. (2008) emphasized that the use of chemical fertilizer was essential in agricultural production despite some of its adverse effects, but that the arising problems could be reduced by paying attention to the amount and time of application and by supporting with organic fertilizer. The sustainability and profitability of plant production shall only be achieved by increasing chemical fertilization and organic fertilization made

according to the available nutrient content of our soil that was exposed to intensive chemical fertilizer use. With the use of organic fertilizer, organic matter of the soil increases, and thus the physical, chemical and biological properties of the soil improve. Manure, poultry manure, compost and green fertilizer are used for organic fertilization purpose.

According to the researches, it is seen that the effects of chemical fertilizers on the increase of forage yield are higher, whereas the advantages of organic fertilizers in terms of productivity, cost and ecology decrease the attractiveness of chemical fertilizers. Nazli et al. (2014) found that the use of organic fertilizers and chemical fertilizers met the forage need, while at the same time it could reduce the dependence on inorganic fertilizers in agricultural areas. Thus, it was reported that it had positive impact on both the soil productivity and the environment. Bulluck et al. (2002) examined of the effects of the organic and synthetic fertility amendments on the soil in organic and conventional farm. The researchers reported that the yield is not affected by the fertilizer applications within the first year, but the organic production yield is higher than the conventional production yield within the second year. Furthermore, the researchers emphasized that the useful microorganisms in the soil increase, the pathogen population decrease, the soil organic substance, the total carbon and the cation exchange capacity (CEC) increase and thus the soil quality is improved with the alternative fertilizer applications. Emerenciano Neto et al. (2016) concluded that manure was lower than chemical fertilizer as a nitrogen source but that manure was available to be used in order to reduce cost and environmental impacts. Razec et al. (2009) stated that through fertilization made with manure, more economic efficiency was obtained, the yield increased by 75-123% and vegetation density and seed formation capacity increased.

Among the forage legumes, the smooth brome is one of the plants that can be included in the planting pattern under arid and semi-arid conditions due its temperature-tolerance and drought-tolerance. In addition, smooth brome is the leading forage plant that can be used alone or in mixtures with legumes under irrigated and arid conditions (Serin et al., 1998).

In the last decade, organic animal production has been rapidly increasing in many countries around the world. In fourteen countries of the European Union, Cereals and forage crops are cultivated on more than 80% of arable under organic farming (Golijan, 2017). The most important need for organic livestock farming is the production of organic forage plants (Yolcu, 2011). The production of organic forage crops plays an important role in organic livestock farming especially in terms of the ecological and economic sustainability of the farms (Will, 2012). As in conventional agriculture, the forage plant cultivation constitutes about 70% of production costs in organic livestock farming. Organic meadow-pasture areas constitute 62% of total organic agricultural areas in the world and organic forage plants production areas constitute 5%. In total, organic roughage production areas constitute 67% of the world's organic agricultural production areas. Organic roughage production in our country is 44206 tonnes in organic meadows and 315 053 tonnes in organic forage plants (Yolcu et al., 2014). Moreno-Resendez et al. (2017) reported that in the organic forage crops production, organic fertilizer increases the forage yield and quality of corn.

Smooth brome can be considered as alternative forage plant especially in the regions where stiff winters are dominant due to its resistance to cold and semi-arid ecologies. Researchers conducted in different locations on yield and quality of smooth brome.

© 2018, ALÖKI Kft., Budapest, Hungary

Albayrak and Ekiz (2005) obtained the dry matter and crude protein yields of smooth brome under arid conditions as 1.28 t ha^{-1} and 0.142 t ha^{-1}, respectively. Karakurt and Ekiz (2000) obtained the highest dry matter and crude protein yields of smooth brome, which was subjected to nitrogen fertilizer and manure under arid conditions, from 120 kg ha^{-1} of nitrogenous fertilizer 3 t ha^{-1} applications. Serin et al. (1998) stated that the highest dry matter yield of smooth brome was obtained in the first year and that the yield decreased in the 2nd and 3rd years. Hongrong et al. (2000) reported that the smooth brome aboveground yield increases with the sewage-sludge application.

The aim of this research is to determine the effects of chemical and organic fertilizer applications on the forage yield and quality of smooth brome. In addition, the effectiveness of different fertilizer applications under irrigated and dried conditions were also determined. The data obtained shall be of importance in terms of applications that have gained importance in recent years such as sustainable agriculture, low-input agriculture, good agricultural practices and organic agriculture.

Materials and methods

Locations, soil and climate

This research was conducted in 2003 and 2004 in the smooth brome experiment field that was established in 2002 in Field Crops Department of Faculty of Agriculture, Ankara University, Turkey. The geographical coordinates of the experiment field are within 39° 57' northern latitude, 32° 52' eastern longitude and 860 m altitude. The soil properties of the experimental field have clayed-loamy texture, with pH = 7.88, 1.15% of organic matter, 0.061% of total salt, 10% of lime and with phosphorus and potassium of 6.6 and 140 kg/ha, respectively. The long-term average of total precipitation was determined as 384.9 mm, 308 mm in 2003 and 272.4 mm in 2004 (*Fig. 1*). The average temperature in the experimental years was high in 2003, but it was similar to the long-term average in 2004.

Materials and treatments

The experiment was conducted complete blocks design with three replications in 2003-2004 years. Within the second and third year of the experiment established in 2002, the effects of the fertilizer applications applied to smooth brome plant were examined within the following years. This research was conducted in two separate experiments under irrigated and non-irrigated conditions. Smooth brome (*Bromus inermis L.*) (15 kg ha^{-1}) seed populations characteristic was used as seed material. Ammonium sulphate, manure, poultry manure and as a green manure common vetch (*Vicia sativa* L.) were used as fertilizer materials in the experiment. The applications were determined as smooth brome (control), smooth brome + ammonium sulphate, smooth brome + barnyard manure, smooth brome + poultry manure, smooth brome + green manure. In the experiment, the parcels were at the length of 4 × 2.4 m and smooth brome and vetch were planted as 12 rows at the row interval of 20 cm in alternative orders in the parcels where vetch is planted (100 kg ha^{-1}) for the purpose of green manure to 6 rows at the row interval of 40 cm. The vetch was mixed into the soil by being harvested from the surface of the soil when it reached to 50% blooming period (Karatas, 2004). In the fertilizer applications, barnyard manure of 20 tons ha^{-1} and poultry manure of 10 tons ha^{-1} were mixed into the depth of 0-20 cm of the soil in the spring ploughing. Ammonium sulphate manure was applied as 100 kg ha^{-1} within the seedling period after planting. In the experiment conducted under irrigated conditions, the decision was taken according to the precipitation condition of traditional flood irrigation. Traditional flood irrigation was made for once in March 2003 and for twice in March and April due to the precipitation decrease in March and April 2004.

In the irrigated and non-irrigated plots, harvesting was performed at the beginning of flowering. The harvested plant samples were dried until reaching a constant mass to obtain dry matter yields at 70 °C (Martin et al.,1990). After the weed samples were ground, the nitrogen ratio was determined by the Kjeldahl method. The determined nitrogen ratios were multiplied by a coefficient of 6.25 and the crude protein ratio was calculated in the dry weeds. The crude protein yields were determined by proportioning the crude protein ratios obtained with dry matter yields.

Statistics

Variation analyses of the obtained data were conducted separately according to significance levels of 5% and 1% based on the General Linear Model of Statistical Analysis Systems (SAS) program. LSD test was used to compare treatment means at a 5% significance level, when differences emerged between fertilizer applications.

Results and discussion

The mean values and variance analysis results of effects of chemical and organic fertilizer on the examined properties in the smooth brome cultivated under irrigated and non-irrigated conditions are given in *Table 1*. The height of the plant was not affected by the application during the years when the research was conducted. Considering the two-year average, the highest plant height was obtained by application of ammonium sulphate and manure under irrigated conditions. Under the non-irrigated conditions, the highest plant height was obtained from green fertilizer application with 70 cm. Karakurt

© 2018, ALÖKI Kft., Budapest, Hungary

and Ekiz (2000) reported that different nitrogen and manure applications in Ankara conditions did not affect the plant height of the smooth brome.

In statistical evaluation regarding the crude protein ratio, the difference between the applications in 2003 and 2004 was found to be significant at a level of 1% under irrigated conditions and 5% under non-irrigated conditions (*Table 1*). Under irrigated conditions, the highest crude protein ratios in 2003 and 2004 were obtained from ammonium sulphate with 13.93 and 14.16%, respectively. The values we obtained regarding the crude protein ratio under irrigated conditions are similar to those of Serin (1996b). The crude protein ratio values in the non-irrigated conditions according to the two years average were obtained between the ranges of 11.8-14.2%. The values obtained by Serin (1996a) and Karakurt and Ekiz (2000) are similar to the values of crude protein ratio we obtained from our research. Albayrak et al. (2011) and Albayrak and Ekiz (2005) obtained crude protein ratio in smooth brome as 10.79% and 10.30%, respectively. It was determined that while the crude protein ratio values were affected by different fertilizer applications in both years, they were not affected by irrigation.

In the first year of the research, the highest crude protein yield was obtained from the ammonium sulphate application under irrigated conditions and this was followed by manure and poultry manure applications. The highest average crude protein yield was obtained from the application of chemical fertilizer with 0.69 t ha^{-1} and this was followed by poultry manure application with 0.52 t ha^{-1}. Yolcu (2011) reported that the highest crude protein yield was obtained from manure and chemical fertilizer applications. In the second year of the research, yields of crude protein decreased significantly due to the decrease in dry matter yields. Ozaslan et al. (2011) stated that there was an increase in the amount of sod-boinding by the increase in precipitation and that the same problem was encountered again 3-4 years after the year of establishment. The crude protein yields of smooth brome decreased in the research due to irrigation and the fact that it was the 3rd year of establishment.

Under non-irrigated conditions, it was found that there was a significant decrease only in the application of manure in the second year, but there was no significant decrease in other applications and accordingly the difference between the years was not significant (*Table 1*). In the first year, the highest crude protein yield was obtained from manure application with 0.31 t ha^{-1}. In the second year, values close to each other were obtained from all other applications except manure. Considering the two-year general average, the highest value was obtained from the application of poultry manure with 0.26 t ha^{-1}. Karakurt and Ekiz (2000) obtained the highest crude protein yield from 120 kg ha^{-1} of nitrogen application and this was followed by manure application with 3 t ha^{-1}. The difference between applications and years may be caused by the amount of precipitation of that year, and thus the fertilizer efficiencies (*Fig. 1*).

Irrigation improves the effectiveness of chemical fertilizers. The highest dry matter yield in smooth brome was obtained from ammonium sulphate application in both years under irrigated conditions. In organic fertilizers, values close to each other were obtained in manure and poultry manure and values close to the control value were obtained in green fertilizer. The highest dry matter yield was obtained from chemical fertilizer application with 4.93 t ha^{-1}. This application was followed by poultry manure application with 3.99 t ha^{-1}. The dry matter yield values obtained in 2003 decreased by half in 2004, the third year of the research (*Table 1*). The decrease in yield may be caused by the sod-boinding occurred in the smooth brome due to irrigation and the fact that the field was in its third year. The values we obtained in our research for the dry matter yield of smooth brome cultivated under irrigated conditions are consistent with the values obtained by Serin (1996b) and Tukel et al. (2001). Serin et al. (1998) reported that and that smooth brome yield decreased in the 2nd and 3rd years compared to the first year under irrigated conditions.

The highest dry matter yield of smooth brome cultivated under non-irrigated conditions was obtained from the manure in the first year of the research, from poultry manure and green fertilizer in the second year and from poultry manure in the two-year average. These results show that organic fertilizers have more effect on plant yields in arid and semi-arid conditions. According to the consolidated years average, the highest dry matter yield was obtained from the application of poultry manure with 2.03 t ha^{-1}. The lowest dry matter yield was obtained from control and chemical fertilizer applications.

Conclusion

According to the research results, it was determined that crude protein ratio, crude protein yield and dry matter yield were affected by different fertilizer applications under both irrigated and non-irrigated conditions. It was found that the efficiency of chemical fertilization was higher under irrigated conditions, but that the sod-boinding problem observed in smooth brome was higher due to the effect of irrigation. This situation significantly decreased the dry matter yields. It was determined that organic fertilizers were more efficient than chemical fertilizers under arid and semi-arid conditions. This result is of importance for producers carrying out conventional agriculture. Also, it is a known fact that the use of organic fertilizer is more profitable in the long term, despite the fact that there is a difference between chemical fertilization applications and organic fertilizers in irrigated agricultural lands.

(Received 29th Jun 2018; accepted 22nd Aug 2018)

Abstract. Sudden changes in influent organic carbon (OC) and ammonia nitrogen (AN) concentrations were performed to evaluate the resistance of A^2O process against shock loadings. The influent organic loading rate was increased from 11 gCOD/(gMLSS·d) to 48 gCOD/(gMLSS·d) with low OC shocking loading and to 125 g COD/(gMLSS·d) with high OC shock loading. The influent NH_4^+-N was increased from 55 mg/L to 110 mg/L as AN shock loading. The results showed that the augmented OC concentration was beneficial for nitrogen removal and high AN concentration had slight influences on COD removal, but was detrimental to nitrogen removal in the A^2O system. The performance of the A^2O system restored rapidly from the shock loadings once the normal influent conditions were provided. The loosely bound extracellular polymeric substances (LB-EPS) and total extracellular polymeric substances (EPS) increased at the initial stage of shock loadings and then declined with the prolonged shock loading, whereas the tightly bound EPS (TB-EPS) experienced smaller variations. The SVI value varied in a similar trend with LB-EPS and total EPS and their low values indicated a good settleability of the activated sludge. In conclusion, the A^2O process produced high-quality effluents once the shock loading ceased.

Introduction

Excessive nitrogen inflow from industrial and municipal wastewater is strictly controlled due to severe eutrophication and environmental pollution (Chang et al., 2006; Yang et al., 2008; Chen et al., 2011). A variety of nitrogen removal processes had been developed and extensive researches have been conducted on the nitrogen removal mechanisms. Over the past several decades, biological nitrification-denitrification processes have been widely applied for their cost-effective and eco-friendly features compared with chemical treatment methods (Guo et al., 2005; Bassin et al., 2012; Seifi

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_60956112
© 2018, ALÖKI Kft., Budapest, Hungary

and Fazaelipoor, 2012; Tanabene et al., 2018). The biological nitrogen removal processes developed include the five-stage Bardenpho process, the University of Cape Town (UCT) process, the sequencing batch reactor (SBR) and the anaerobic–anoxic–oxic (A^2O) process, etc. (Peng et al., 2006; Chen et al., 2011). Based on these biological processes, strategies for realizing short-cut nitrification denitrification, anaerobic ammonium oxidation (ANAMMOX) and simultaneous nitrification and denitrification (SND) were widely investigated in order to lower the construction investment and energy requirements (Zhang et al., 2008; Walters et al., 2009; Park et al., 2010; Yong et al., 2017). The most commonly used process was the anaerobic-anoxic-oxic process (A^2O process) due to its convenient operation and management and high biological nitrogen removal efficiency (Pai et al., 2010). The A^2O process is a sludge suspended growth system incorporating separate anaerobic, anoxic and aerobic stages in sequence to satisfy the requirement of oxygen in the nitrification and the absence of oxygen in the denitrification. Under aerobic stages, NH_4^+-N was oxidized, first to NO_2^--N and then, to NO_3^--N. Furthermore, the residual NO_2^--N and NO_3^--N in the reflux were then denitrified to gaseous nitrogen compounds under the anaerobic and anoxic conditions.

The nitrogen removal performances of the A^2O process under various environmental conditions were widely investigated in the previous literature. Ma et al. (2006) indicated that the nitrogen removal efficiency increased when the dissolved oxygen (DO) concentration in the aerobic stage rose from 2 mg/L to 3 mg/L, and almost no improvement was observed when the DO was further enhanced to 4 mg/L. The reflux ratio of the mixed liquid and carbon source type could also influence the performance of A^2O process (Xu et al., 2009; Zhu et al., 2014). However, a very limited number of investigations were reported in terms of the performances of the A^2O process under shock loadings. The sudden changes of influent constituents or shock loading could eventually destabilize the performance of the biological treatment system (Wang et al., 2006). As the biological systems were frequently under shock loadings as a result of wastewater quantity and quality fluctuations, it is necessary to understand the performance of the A^2O process under shock loadings.

In the biological wastewater treatment reactors, the bio-flocculated microbial aggregates, known as activated sludge flocs, are the essential components of the process. It is, therefore, an undisputed fact that the physicochemical characteristics of activated sludge flocs play an important role in the performance of the process (Ye et al., 2011). Indeed, almost all the performances of the activated sludge process are related to or dependent on the physicochemical properties of the flocs, including flocculation, sludge settling and sludge dewatering. Extracellular polymeric substances (EPS) are one of the representative components of the flocs and are considered to have significant influences on the physicochemical properties of microbial aggregates, including structure, surface charge, flocculation, settling properties, dewatering properties, and adsorption ability (Sheng et al., 2008; Shou et al., 2018). They came from molecules in wastewater or from cell lyses, which consisted of various organic substances mainly including polysaccharides, proteins, and nucleic acid, etc. (Li et al., 2008). EPS in sludge flocs could be stratified into loosely bound EPS (LB–EPS) and tightly bound EPS (TB–EPS) based on the extraction methodology (Zhang and Wang, 2014). LB-EPS could diffuse into mixed liquid and had a loose structure at the outer layer of EPS. However, TB-EPS had a stable structure between LB-EPS and cell. And TB-EPS could be tightly combined with the cell surface and stick to the cell wall (Sheng et al., 2008). EPS are involved in the formation of microbial aggregates and are

© 2018, ALÖKI Kft., Budapest, Hungary

closely connected to their mass transfer, surface charge, adhesion ability, flocculation ability, settleability and stability (Sheng et al., 2010). The nature and content of EPS are sensitive to the operational and environmental conditions (Ye et al., 2011). However, few data were available concerning the effects of the organic loading rate (OLR) on the EPS. The resistant ability to shock loading and nitrogen removal properties can be comprehensively understood when the characterization of EPS was comprehended under different OLRs in the activated sludge of the A^2O process.

The shock loadings were carried out by varying the influent sodium acetate as the carbon source and the influent ammonia chloride as the nitrogen source in synthetic municipal wastewater of the A^2O process. The carbon and nitrogen removal efficiency were evaluated under organic carbon (OC) and ammonia nitrogen (AN) shock loadings. Meanwhile, the variations of EPS and sludge volume index (SVI) were also investigated under various levels of OC and AN shock loadings. The objective of this study is to investigate the ability of the A^2O process to withstand the shock loadings that were applied to the reactors and to evaluate the corresponding characteristics of the activated sludge represented by EPS amount and SVI value. The results obtained in this study could provide guidance for the operation of the A^2O process encountering shock loadings; for example, whether the system could survive the shock loadings without additional installations or measures should be performed to alleviate the passive influences of the shock loadings.

Materials and methods

Operation of the reactor

A bench-scale anaerobic-anoxic-oxic (A^2O) reactor with a working volume of 60 L was used in this study (*Fig. 1*) and it was constructed refer to the reference (Zeng et al., 2010; Li et al., 2014; Zhang et al., 2017). A^2O reactor was operated from April 2016 to November 2017 in the waste treatment lab of Northeast Electric Power University, Jilin, China. There were eight zones in the reactor, separated by baffles to achieve anaerobic/anoxic and aerobic conditions. The first two zones were typically operated as anaerobic reactors, and the following two zones as anoxic reactors, while the remaining four as aerobic zones with separate aeration facilities. The raw wastewater and the recycled sludge flowed into the first zone of the anaerobic reactor and the mixed nitrate liquid was recycled from the last zone of the aerobic reactor to the first zone of the anoxic reactor. The flow rates of the influent, recycled sludge and nitrate recirculation were controlled together by peristaltic pump and regulating valve and the regulating valve was located at the outlet of the influent water tank. Internal recycle was the recycle of nitrification liquid to anoxic stage and external recycle was the recycle of sludge to anaerobic stage.

Recycle ratios of internal recycle and external recycle were 100% and 80%, respectively, with an influent flow rate of 43.44 L/d. Stirrers provided the mixture of sludge in the anaerobic and anoxic zones and kept the biomass in suspension. Aeration was provided in each aerobic zone when the pressurized air passed through long stone diffusers. The diffusers used in the lab-scale A^2O system were stone material with micro pores that could transfer the compressed air into the mixed liquid. The treated wastewater was settled in a vertical sedimentation basin with a total volume of 5 L. The design and operational parameters of the A^2O configuration are listed in *Table 1*.

Table 1. *The design and operational parameters of A^2O reactor*

Design parameters			
Stage	**Number**	**Volume (L)**	**HRT (h)**
Anaerobic zone	2	15	4.34
Anoxic zone	2	15	4.34
Aerobic zone	4	30	8.70
Total	8	60	17.38
Settler	1	5	2.48
Operational parameters			
$Q_{Influent}$ (L/d)		43.44	
Internal recycling ratio (%)		80	
External recycling ratio (%)		100	
DO (mg/L)	Anoxic reactor	≤1	
	Oxic reactor	5–7	
ORP in the anaerobic reactor		≤–100 mv	
T (°C)		15±2	
pH		7.0–8.0	
MLSS (mg/L)		1500±200	

During the start-up period, the system was operated and fed with the synthetic wastewater with chemical oxygen demand (COD) of approximately 400 mg/L and NH_4^+-N of approximately 55 mg/L. Samples were collected regularly from the influent and different zones of the reactor in order to analyze NH_4^+-N, NO_2^--N, NO_3^--N, total nitrogen (TN), COD and mixed liquid suspended solids (MLSS), respectively. Temperature, DO, ORP and pH were measured online. After two-month operation, the removal efficiency of COD, NH_4^+-N and TN were respectively higher than 95%, 95% and 85%, which could indicate the successful start-up of the A^2O system and

achievement of the steady-state as the effluent water quality meet the Level I (B) criteria of the Discharge Standard of Pollutants for Municipal Wastewater Treatment Plant (GB18918-2002) of China. COD, NH_4^+-N and TN were lower than 60 mg/L, 15 mg/L and 20 mg/L, respectively, in the Discharge Standard of Pollutants for Municipal Wastewater Treatment Plant (GB18918-2002). And then the operation of the A^2O process was divided into four different phases to investigate the influences of the OC and AN shock loadings on the performance of the system and the variations of the EPS and SVI. The arrangement of the organic and nitrogen shock loading experiment was illustrated in *Table 2*.

Table 2. *The arrangement of the shock loading experiments*

Operation	Influent conditions	Days
Phase I (Normal operation)	Organic loading rate of 11 gCOD/(gMLSS·d); NH_4^+-N concentration of 55 mg/L	0–60
Phase II (Low OC shock loading)	Organic loading rate increased from 11 gCOD/(gMLSS·d) (3 days) to 48 gCOD/(gMLSS·d) (7 days) and then recovered to 11 gCOD/(gMLSS·d) influent (5 days); NH_4^+-N concentration of 55 mg/L	61–75
Phase III (High OC shock loading)	Organic loading rate increased from 11 gCOD/(gMLSS·d) (3 days) to 125 gCOD/(gMLSS·d) (7 days) and then recovered to 11 gCOD/(gMLSS·d) (5 days); NH_4^+-N concentration of 55 mg/L	76–90
Phase IV (High AN shock loading)	Organic loading rate is 11 gCOD/(gMLSS·d); NH_4^+-N concentration increased from 55 mg/L to 110 mg/L (10 days) and then recovered to 55 mg/L (10 days)	91–110

Synthetic wastewater and sludge

The bench-scale A^2O reactor was fed with synthetic wastewater when sodium acetate was used as carbon source. The synthetic wastewater was prepared as follows (per liter): CH_3COONa, 0.48–4.8 g; NH_4Cl, 0.2±0.02 g; K_2HPO_4, 0.03 g; $MgSO_4 \cdot 7H_2O$, 0.05 g; $CaCl_2 \cdot 2H_2O$, 0.01 g. The pH was controlled at 7.0–8.0 by adding $NaHCO_3$ and HCl solution. Excess sludge, which collected from the secondary settling tank of a municipal wastewater plant located in Jilin, China, was used as inoculum. The major influent characteristics are shown in *Table 3*.

Table 3. *The major characteristics of the influent*

Parameters (mg/L)	Min/Max
COD	360–4300
NH_4^+-N	55–110
NO_2^--N	0-2
NO_3^--N	0
TN	53–59

Analytical methods

COD, BOD, MLSS, NH_4^+-N, NO_2^--N, NO_3^--N and TN were measured according to the Standard Methods for the Examination of Water and Wastewater (APHA, 1998). Temperature, pH, ORP and DO were analyzed online with a WTW pH/ORP sensor (WTW, pH 3310) and a DO sensor (WTW, OXi340i). 50 mL of activated sludge collected from Aerobic 4 of the A^2O reactor was used to analyze the EPS amount. The extraction and quantification of LB-EPS and TB-EPS were performed according to the protocol described by Liang et al. (2010).

Results

The influences of OC shock loading on COD removal performance

Unexpected industrial wastewater was often discharged into the sewage and resulted in the high COD surge of the municipal wastewater treatment plant. In addition, the biological wastewater system often experienced higher pollutants surge when there was an equipment failure. In order to investigate the effects of high COD surge on the performance of the municipal wastewater treatment plant, high OLRs of 48 gCOD/(gMLSS·d) and 125 gCOD/(gMLSS·d) were applied.

The COD removal performances under OC shock loading were shown in *Figure 2*. The effluent COD was below 60 mg/L and more than 95% of COD was removed in the first 3 days when the influent OLR was elevated from 11 gCOD/(gMLSS·d) to 48 gCOD/(gMLSS·d). The effluent COD was higher than 100 mg/L when the low OC shock loading continued. An average of 95% COD removal efficiency was achieved though the effluent COD concentration was higher than 100 mg/L, which indicated that the A^2O system could remove more organic carbon at higher OLR. When the influent OLR returned to 11 gCOD/(gMLSS·d) on the 71th day, the effluent COD concentration was stable and below 30 mg/L. It is suggested that the A^2O process had strong resistant ability to low organic shock loading and the system could restore rapidly when the organic shock loading stopped.

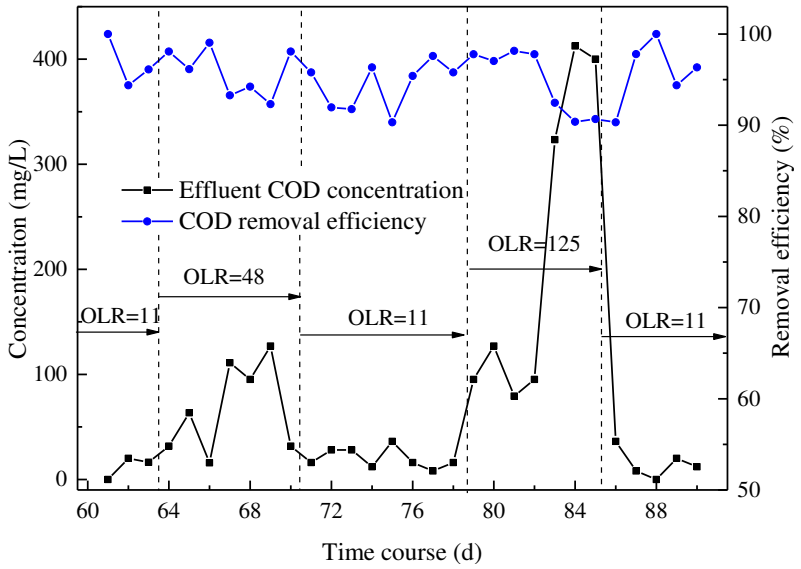

Figure 2. *The COD removal under OC shock loadings*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_60956112
© 2018, ALÖKI Kft., Budapest, Hungary

The effluent COD concentration was greater than 100 mg/L and then increased to more than 500 mg/L when there was a sudden increase of OLR from 11 gCOD/(gMLSS·d) to 125 gCOD/(gMLSS·d). However, when the influent OLR declined to 11 gCOD/(gMLSS·d), the effluent COD concentration dropped rapidly and restored to the original level, which demonstrated that the A^2O system could remove high loads of carbon and recover low carbon concentration in the effluent after high shock loading.

The influences of OC shock loading on nitrogen removal performance

The nitrogen removal performances of the A^2O process under organic shock loading were plotted in *Figure 3*. As the influent OLR increased sharply from 11 gCOD/(gMLSS·d) to 48 gCOD/(gMLSS·d), negligible variations of the NH_4^+-N removal efficiency and the effluent NH_4^+-N concentration were detected and their average values were 96.57% and 1.93 mg/L, respectively. Satisfactory TN removal was also achieved when the influent OLR increased. And meanwhile, NO_3^--N concentration in the effluent reduced compared with that under normal OC feeding condition. The effluent NO_3^- was between 14.50 mg/L and 15.45 mg/L and the average value was 14.86 mg/L under normal OC feeding condition, however, the effluent NO_3^--N was between 11.13 mg/L and 13.15 mg/L and the average value was 12.19 mg/L when influent OLR increased. In the aerobic zones, NH_4^+-N was converted into NO_3^--N by nitrifiers with the presence of DO. Nitrifiers are autotrophic microorganisms and efficient nitrogen removal could be achieved if there is enough hydraulic retention time and sufficient DO. The total nitrogen (TN) removal efficiency was up to 91% with an effluent TN concentration of 4.6 mg/L, which was improved when the A^2O system encountered low organic shock loading. The TN removal efficiency declined with an effluent concentration of 10 mg/L when the influent OLR was recovered from 48 gCOD/(gMLSS·d) to 11 gCOD/(gMLSS·d). Since variations of effluent NH_4^+-N and the corresponding NH_4^+-N removal efficiency under low organic carbon surge were small under low organic carbon surge when compared with that of the TN, the improved TN removal efficiency was thus attributed to the instantaneous improvement of denitrification rate when the system encountered OC surges.

During the high OC shock loading, the NH_4^+-N concentration in effluent ranged from 1.68 mg/L to 3.87 mg/L with an average value of 2.53 mg/L, which was comparable to that before shock loading. The removal efficiencies of TN exceeded 85% with an average effluent TN concentration of 10.5 mg/L. The removal efficiencies of TN decreased when the OLR returned from high value to low value because of the absence of carbon sources.

Nitrification and denitrification rate were two key indexes for the evaluation of the nitrogen removal efficiency. The variation of NH_4^+-N concentration between influent and effluent was used to calculate the nitrification rate (Mino et al., 1995; Li and Irvin, 2007). The equation was as follows (*Eq. 1*):

$$r_N = \frac{dc_{NH_4^+-N}}{dt}\left(\frac{mg \cdot N}{L.h}\right) \quad \text{(Eq.1)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_60956112
© 2018, ALÖKI Kft., Budapest, Hungary

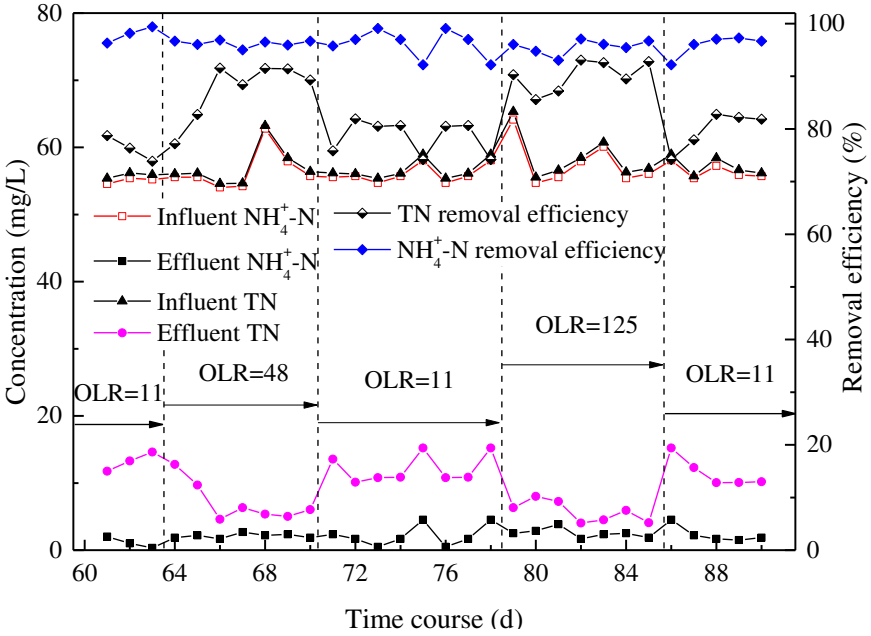

Figure 3. *Nitrogen removal under OC shock loadings*

The variations of nitrification rate under different OLR were shown in *Figure 4*. Initially, the nitrification rate showed an arising trend when the OLR of influent increased from 11 gCOD/(gMLSS·d) to 48 gCOD/(gMLSS·d) and then declined as the shock loading continued. The figure increased to the original level at the end of the shock loading. The nitrification rate increased from 1.20 mg/(L·h) to 1.26 mg/(L·h) and then slightly reduced to 1.25 mg/(L·h) when the A^2O system was subjected to a OLR of 125 gCOD/(gMLSS·d). The variation of the nitrification rate was small when the A^2O system suffered high OLR.

Two steps are involved in the denitrification process, of which NO_3^--N is reduced to NO_2^--N and then NO_2^--N is further reduced to N_2. The difference between the sum of influent NH_4^+-N, NO_2^--N and NO_3^--N in the anoxic zones and the sum of effluent NH_4^+-N, NO_2^--N and NO_3^--N was utilized to calculate the denitrification rate (Liu et al., 2014; Shen et al., 2016). The calculation equation was as follows (*Eq. 2*):

$$r_N = \frac{d(c_{NH_4^+-N} + c_{NO_2^--N} + c_{NO_3^--N})}{dt}(\frac{mg \cdot N}{L.h}) \quad \text{(Eq.2)}$$

As shown in *Figure 4*, the denitrification rate was improved with the increase of influent COD concentration. The denitrification rate increased from 1.17 mg·N/(L·h) to 2.11 mg·N/(L·h) when the influent OLR ascended from 11 gCOD/(gMLSS·d) to 125 gCOD/(gMLSS·d). Consequently, OLR increases were beneficial for the denitrification process by providing sufficient carbon source.

The influences of AN shock loading on the COD removal performance

As shown in *Figure 5*, the effluent COD concentration was below 30 mg/L and the corresponding removal efficiency was greater than 95% when high influent AN concentration (110 mg/L) was provided. The COD removal performance of the A^2O

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_60956112
© 2018, ALÖKI Kft., Budapest, Hungary

system was not influenced by the increase of influent NH_4^+-N concentration as sufficient HRT was provided and the influent OLR was 11 gCOD/(gMLSS·d). It is indicated that in the biological system, the removal of organic pollutants was started ahead of the nitrification process as the nitrification reaction was slower and more sensitive to environmental conditions than carbon oxidation by heterotrophs in the biological system (Liang et al., 2010). Hence, the influence of NH_4^+-N concentration variation on the COD removal of the A^2O process was very small and could be neglected under the condition of a relative high AN concentration in the A^2O process.

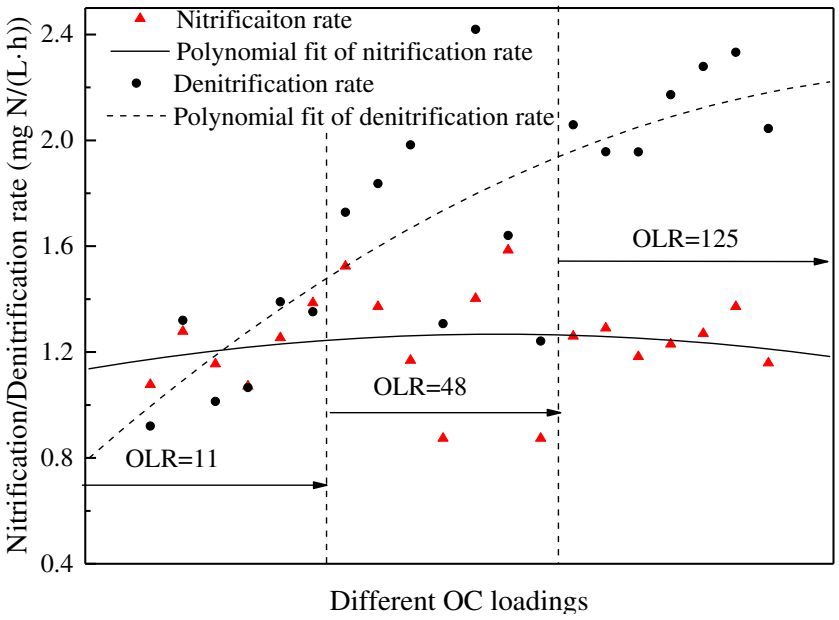

Figure 4. *Variations of nitrification and denitrification rate under OC shock loadings*

The influences of AN shock loading on the nitrogen removal performance

As shown in *Figure 6*, the nitrogen removal efficiency of the A^2O process under high influent NH_4^+-N concentration (110 mg/L) was evaluated by the removal performance of NH_4^+-N and TN. The effluent NH_4^+-N concentration was below 5 mg/L with a removal efficiency of 95% on the first day. The effluent NH_4^+-N concentration began to increase along with the duration of the AN shock loading and was higher than 60 mg/L at the end of the AN shock loading. It was assumed that at the initial stage of the AN surge, high NH_4^+-N concentration was buffered by the remaining reactor contents within the range that the nitrifiers could effectively convert NH_4^+-N to NO_2^--N and NO_3^--N. Gradually, the effluent NH_4^+-N concentration increased as the continuous feed of excessive NH_4^+-N exceeded the nitrifying ability of the microorganisms in the A^2O process. The effluent NH_4^+-N concentration declined to 29 mg/L when the AN shock loading ceased. Then the effluent NH_4^+-N concentration gradually returned to the original level before the occurrence of AN shock loading.

The removal performance of TN was similar to that of NH_4^+-N. The effluent TN was 8 mg/L and 90% removal efficiency was obtained on the first day of the AN shock loading. The effluent TN concentration increased to more than 70 mg/L at the end of the AN shock loading possibly due to the accumulation of nitrite and nitrate.

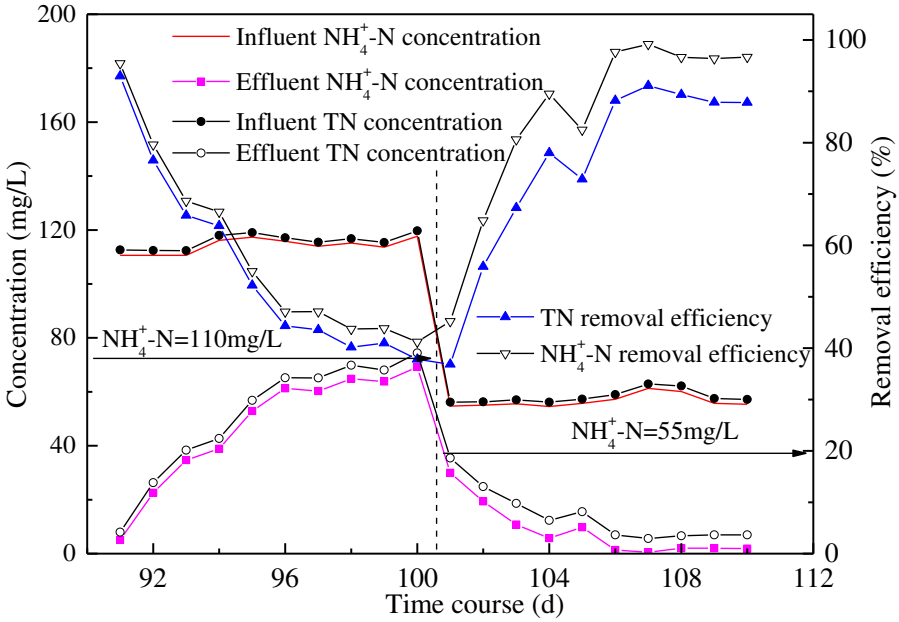

Figure 6. *Nitrogen removal performance under AN shock loading*

As shown in *Figure 7*, the nitrification rate ranged from 1.36 mg·N/(L·h) to 0.58 mg·N/(L·h) under the AN shock loading, whereas the denitrification rate varied in a range between 0.57 mg·N/(L·h) and 2.46 mg·N/(L·h). It was demonstrated that high nitrogen-loading rate can provoke the inhibition of nitrification and consequently the BNR instability (Jubany et al., 2008; Torà et al., 2011). In the present study, the variation of the denitrification rate were more remarkable than that of the nitrification rate, indicating that the AN shock loading interference with the nitrification process and the denitrification process was further influenced as the former provided the reaction source for the latter.

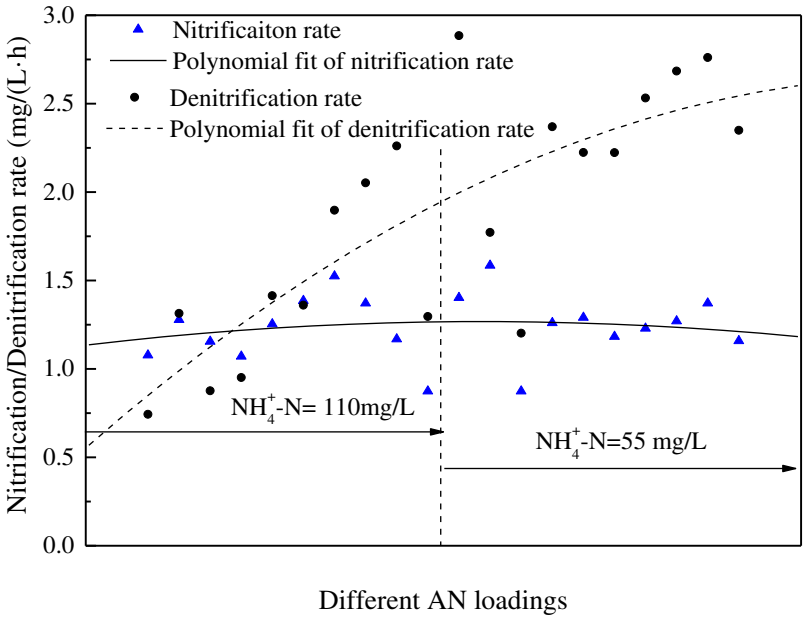

Figure 7. *Variations of nitrification and denitrification rate under AN shock loadings*

The influences of shock loading on EPS amount and SVI value

The daily variations of LB-EPS, TB-EPS, the total EPS amounts and effluent COD were observed during OC and AN surges in the discharged mixed liquid from the last aerobic zone (shown in *Fig. 8*). The average values of different types of EPS, VSS (Volatile Suspended Solids) and SVI were summarized in *Table 4*.

Table 4. *EPS amounts and SVI values during different shock loadings*

Experiment	LB (mg/L)	TB (mg/L)	EPS (mg/L)	SVI (mL/g)	VSS (mg/L)	Effluent appearance
Phase I	161.8	252.1	413.9	100	1210	Clean
Phase II	99.4	297.9	397.3	87	1176	Clean
Phase III	194.5	278.7	473.2	200	1290	Turbid
Phase IV	83.4	231.0	314.5	80	1105	Clean

During the low OC shock loading, the LB-EPS amount showed a dramatic reduction and then stabilized at approximately 60 mg/L, whereas the variations of TB-EPS amount fluctuated at a range of 265.1–343.2 mg/L with an average value of 297.9 mg/L. The amount of total EPS increased in the first 3 days and then dropped in the following days. Meanwhile, the effluent COD increased when there was an influent OC shock loading at the initial stage and then decreased with prolonged shock loading, which might be due to the acclimation of microorganisms to shock loadings. VSS was decreased from 1201 mg/L to 1176 mg/L, and furthermore, the sludge volume index (SVI) descended from 100 mL/g to 87 mL/g and the effluent quality was affected as indicated by the variations of effluent NH_4^+-N, TN and COD concentrations. Gentle variations of the LB-EPS amount were observed when the influent OLR increased sharply from 11 gCOD/(gMLSS·d) to 125 gCOD/(gMLSS·d). The TB-EPS amount

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_60956112
© 2018, ALÖKI Kft., Budapest, Hungary

increased to an average value of 297.9 mg/L and then became constant with the proceeding of high OC shock loading. The total EPS amount and VSS were up to 473.2 mg/L and 1290 mg/L, respectively, which were much higher than situation without shock loading. An average SVI value of 200 mL/g was obtained when the A^2O system suffered high OC shock loading. During AN shock loading, the LB-EPS amount increased to 167.2 mg/L and then showed a sharp reduction from the 3rd day. The TB-EPS and LB-EPS amounts showed a similar trend. The average SVI value and VSS were 80 mL/g and 1105 mg/L, respectively, and the effluent had a clean appearance.

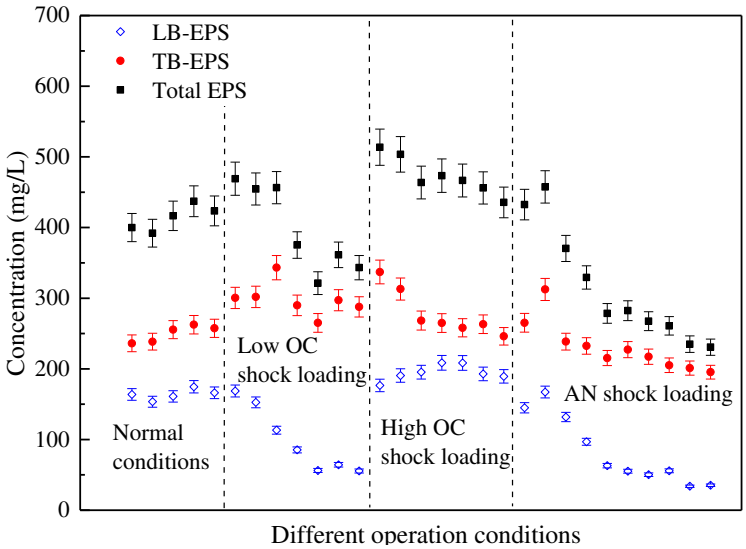

Figure 8. *Variations of LB-EPS, TB-EPS and the total EPS amounts*

It is indicated that low OC shock loading could lead to the temporary increase of the EPS amount, whereas the LB-EPS amount and VSS declined when the low OC shock loading continued. When the A^2O process was subjected to high OC shock loading, the amount of LB-EPS and VSS showed a milder variation compared with TB-EPS. The total EPS amount and VSS during high OC shock loading were the highest among all operational conditions. All types of EPS amount and VSS declined in the long-term operation when the A^2O process experienced the AN shock loading.

In this work, the SVI values were in good agreement with the LB-EPS (or total EPS) concentration and VSS. It is indicated that the LB-EPS had a negative effect on sludge flocculation and excessive EPS in the form of LB-EPS could weaken cell attachment and result in poor flocculation (Xu et al., 2016). Along with the increase of LB-EPS concentration and VSS, the presence of a large number of fine flocs significantly reduced the effluent quality and the activated sludge settleability. Zhang and Yang (2015) also found that LB-EPS had a negative effect on the sludge settleability as an increase in LB-EPS content might bring more bound water into the aggregates, and therefore produced highly porous flocs with a low density.

Discussion

As a widely applied biological wastewater treatment process, the A^2O process was resistant to all the shock loadings and produced high quality effluents once the shock

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_60956112
© 2018, ALÖKI Kft., Budapest, Hungary

loading ceased. However, the effluent deteriorated when the system was subjected to high-strength or prolonged shock loadings. The use of real-time control systems were thus proposed to optimize processes under various effluent and environmental conditions (Li et al., 2016). The A^2O system was capable of removing more organic carbon at higher OLR and the elevated carbon source supply was beneficial for the removal of nitrogen compounds.

The heterotrophic microorganisms showed fast proliferation and became dominant in the anaerobic zones owing to the sufficient organic compounds in the influent. In the anoxic zones, heterotrophic facultative denitrifying bacteria could utilize the NO_x^--N as the electron acceptor and the denitrification rate was higher under a relative high influent OC. In the aerobic zones, the growth of heterotrophic microorganisms was restricted due to the low organic compounds from the anoxic zones and nitrifying bacteria became the dominant bacteria under sufficient DO. The COD in aerobic and anoxic zones was lower than 50 mg/L when the influent COD was 414 mg/L. The difference between effluent COD in aerobic zone and effluent COD in anoxic zone was slight. Therefore, a large portion of the organic substrate was consumed in the anaerobic and anoxic reactors of the A^2O process. Low concentration of organic compounds could not meet the demand of the growth of heterotrophic microorganisms in the aerobic zones. Previous literature indicated that the increase of COD concentration would induce the competition of the heterotrophic microorganisms and the nitrifiers for DO, nutrients, space or other ecological factors (Zhu and Chen, 2001; Tsuno et al., 2002). Ling and Chen (2005) also reported that the decrease of nitrification rate with the addition of OC and the nitrification rate was lower when the OC was higher. In this study, a large portion of organic substrate was already consumed in the anaerobic and anoxic zones of the multistage A^2O process. The level of COD in the aerobic zones was thus below the concentration to induce the competition between the heterotrophic microorganisms and the nitrifiers since sufficient HRT and DO concentration were provided for the growth and reproduction of heterotrophs and nitrifiers.

On the contrary, the denitrifiers in the anoxic zones demand external carbon source for denitrification. The denitrification step reduces nitrate to nitrogen gas by many species of heterotrophic facultative bacteria and require biodegradable organic carbon to perform metabolic processes. Enough carbon must be available for the complete denitrification of nitrate formed during the nitrification (Wunderlich et al., 2012; Xie et al., 2012; Xu et al., 2018). In our study, similar results were obtained and denitrification efficiency was improved in the anaerobic zones under high influent OLR. However, compared with high OLR shock loading, denitrification efficiency was lower in the anaerobic zones under the low OLR shock loading. An external carbon source addition was proposed to raise the denitrification rate when needed to compensate for high nitrogen loads or low seasonal temperatures (Han et al., 2010). The external COD addition was known as a feasible and flexible strategy to increase the denitrification rate when the COD concentration was low and could not cope with the current nitrogen load (Majumder et al., 2008). However, at a high C/N ratio, Michaud (Michaud et al., 2006) reported that heterotrophic bacteria outcompeted nitrifiers for available oxygen and space in the biofilter media, which deteriorated the nitrification process and led to nitrate deficiency for the denitrification. The present study showed that the majority of organic compounds were consumed in the anaerobic and anoxic zones. Therefore, the COD concentration was relative low in the aerobic zones, which resulted in low

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_60956112
© 2018, ALÖKI Kft., Budapest, Hungary

multiplication rate of heterotrophic bacteria and high multiplication rate of nitrifiers in the aerobic zones. Consequently, the nitrification rate was high in the aerobic zones.

High AN concentration had slight influences on COD removal, but was detrimental to the removal of nitrogen compounds. Greater fluctuations were observed on the denitrification rate than the nitrification rate when the A^2O was subjected to shock loadings. It was reported that the COD/N ratio of 5–15 in the bioreactor was suitable for nitrification and denitrification reaction (Ding et al., 2011). The deficiency of carbon substrate resulted in the unbalance of nitrification and denitrification reactions and finally led to low overall nitrogen removal.

The nature and content of EPS are sensitive to the operational and environmental conditions. The LB-EPS, TB-EPS and total EPS amount showed an increase at the initial stage of the shock loadings and then declined with the prolonged shock loading. The characteristics of EPS in the activated sludge were closely connected with its resistant ability to shock loading and pollutants removal properties. SVI was widely used for characterizing sludge settleability and SVI values below 100 mL/g were considered as an indication of good settling properties of the sludge (Satyawalia and Balakrishnan, 2009). The SVI value was changed in a similar trend with the variation of average LB-EPS and total EPS amounts. The amount of LB-EPS had great influences on the SVI value and VSS, and SVI increased with the increasing content of LB-EPS and VSS because LB-EPS was not bound tightly to the cell. Meanwhile, LB-EPS had open and loose structure, high moisture content, low density and large volume around the cell, which could result in the larger volume and smaller density of sludge flocs and furthermore weaken the compressibility of sludge flocs. On the contrary, the effect of the change of TB-EPS on the volume of sludge flocs was relative small because TB-EPS was bound tightly to the cell and had tight structure, low moisture content and high density (Ruan et al., 2013). A long-term high shock loading leads to high LB-EPS and total EPS, which could influence the settleability of sludge and SVI increased. Substrate type and concentration, bacterial growth phase, the presence of toxic substances, shear rate of the bioreactor and other external conditions could influence the quantity and nature of EPS (Badireddy et al., 2008; Janus and Ulanicki, 2010; Li et al., 2015). At the initial state of each shock loading, the amounts of all types of EPS were elevated to a different level and SVI was increased with the increasing EPS. The temporary increase of EPS could be consequence of the necessity to acclimate to the new conditions. Moreover, a decline tendency was observed with the prolonged shock loadings. On the one hand, the bacterial cells tended to produce more EPS to protect themselves against unfavorable conditions (Sheng et al., 2008), which could be a possible reason for the temporary increase of EPS at the initial stage of the shock loading (Laspidou and Rittmann, 2002). On the other hand, the microorganisms could not adapt to the prolonged high organic loadings. The activity of microorganisms decreased and their cells could not autolyze when there was high substrate concentration. Therefore, less EPS was released when the system was under long-term high organic loadings (Shao et al., 2017). However, the EPS production rate is not necessary proportional to the substrate consumption rate. Laspidou and Rittmann (2002) demonstrated that the relationship between EPS production and substrate consumption rate depended on the kind of microorganisms involved and the system conditions. Consequently, the EPS variation could be an indication of the flocculation in microbial community of the A^2O system. The LB-EPS amount declined dramatically during the low OC and AN shock loading, which was in accordance with the previous literatures that LB-EPS functioned

as the primary surface for cell interaction and attachment (Sheng et al., 2008). The LB-EPS increased initially when the biological system was under high OC loading and then its amount decreased. The temporarily increased LB-EPS may cover the surface or fill the interior of the activated sludge flocs. As a result, the mass transfer of the substrates and the export of metabolic products were significantly prevented as described in the previous literature (Mu et al., 2006; Zheng and Yu, 2007). Consequently, a high level of EPS was not beneficial for biodegradation, which could be the reason for the effluent deterioration during the high OC shock loading. The highest EPS amount was accompanied by elevated effluent COD concentration and turbidity. Therefore, the composition of the activated sludge flocs changed, followed by the alteration of the physiochemical characteristics of the activated sludge as a result of shock loading.

Conclusion

The A^2O process successfully withstood all the shock loadings and restored its performance once the shock loading ceased. The enhanced carbon source concentration was beneficial for the removal of nitrogen compounds in the A^2O system. High AN concentration had slight influences on COD removal, but was detrimental to the removal of nitrogen compounds. Greater fluctuations were observed on the denitrification rate than the nitrification rate when the A^2O was subjected to shock loadings. The LB-EPS, TB-EPS and total EPS amount showed an increase at the initial stage of the shock loadings and then declined with the prolonged shock loading. The SVI value varied in a similar trend with the variation of average LB-EPS and total EPS amounts. Smaller concentrations of LB-EPS and total EPS indicated a good settleability of the activated sludge.

(Received 3rd Jul 2018; accepted 31st Aug 2018)

Abstract. Length–weight relationships (LWR) were estimated for three main Songkhla Lagoon fish species occurring in the lower gulf of Thailand. Samples were collected monthly during monsoon and after monsoon season (September 2017 to April 2018). Fishes were captured by three methods: fishing gear, crab gear and shrimp gear. This study is the first reference on LWR equation parameters of *Pellona ditchella* (Valenciennes, 1847), *Sardinella gibbosa* (Bleeker, 1849) and *Alepes vari* (G. Cuvier, 1833) in the lower gulf of Thailand, this good document would be used to compare these fish condition with many coastal areas in the world. This work provides the important information of fish migration between lagoon and lower gulf of Thailand as well as for two species from which we present a wider size range in FishBase, *Pellona ditchella* (Valenciennes, 1847) and *Sardinella gibbosa* (Bleeker, 1849).
Keywords: *length–weight relationship, Pellona ditchella, Sardinella gibbosa, Alepes vari, fish migration, fish well-being*

Introduction

Songkhla Lagoon is one of the two lagoons in the world that has Irrawaddy dolphins (*Orcaella brevirostris*), which are endangered species. The lagoon is located in the southern part of Thailand and is divided into three distinct parts. The southern part of the lagoon is connected to the Gulf of Thailand through a 380 m wide strait Songkhla Lagoon. It is very rich regarding biodiversity and provides resources and livelihoods for local fishermen all year around. The livelihood of more than 1.9 million people of the 25 districts located in the three provinces of Southern Thailand rely on the lagoon's fishery resources. However, as in many other similar ecosystems elsewhere (Martínez et al., 2007; Satumanatpan and Pollnac, 2017), those resources have been declining sharply over recent decades. Many fishermen of Songkhla Lagoon are wondering

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

whether they can sustain themselves through fishing or if they must convert to another occupation. Many of them have already moved to other fishing areas or changed profession.

As part of the efforts to create policies for sustainable fishing in Songkhla Lagoon and improve the livelihoods of fishing communities dependent on the lagoon's resources, numerous studies were conducted in the past two decades on Songkhla Lagoon, focusing mostly on models of fish catch landing (e.g. Chesoh and Lim, 2008; Chesoh, 2009; Chesoh and Choonpradub, 2011; Hue et al., 2018) or the effects of chemical contamination (e.g. Pradit et al., 2013). Other research has dealt with the government-led shrimp restocking program (Xu et al., 1997; Davenport et al., 1999; Wang et al., 2006; Hamasaki and Kitada, 2013; Niamaimandi and Zarshenas, 2015).

Fish condition can be a very important parameter to the managers of fisheries. Plump fish may be an indicator of favorable environmental conditions (e.g., habitat, food availability), whereas thin fish may indicate a less favorable environment. Thus, monitoring fish well-being can be extremely useful for the biologists of fisheries to make management recommendations concerning fish populations and their management. There is evidence that length–weight relationships (LWR) plays an important role in estimating fish biomass based on length. These parameters can be compared between seasons, years or different areas using standardized sampling procedures (Correia et al., 2017), and data on the length and weight of fish are currently two of the most common and standardized parameters about the biology of fish (Le Cren, 1951).

Pellona ditchella (Valenciennes, 1847), *Sardinella gibbosa* (Bleeker, 1849) and *Alepes vari* (G. Cuvier, 1833) are present in most of the markets in Southeast Asia. Their current known distribution extends across the Indo-West Pacific: from Madagascar, and Durban, South Africa to the Gulf of Oman and the coasts of India; from the Andaman Sea to Indonesia and the Philippines, southeast to the Arafura Sea, northern and western Australia and Papua New Guinea (Russell et al., 1989). During the period 2003-2017, they were found frequently in the lower Gulf of Thailand, including Songkhla Lagoon. *P. ditchella* is found most often in coastal, marine waters, but also enters mangroves and river estuaries, and tolerates brackish water and freshwater. *S. gibbosa* is commonly found in marine, pelagic-neritic habitats, and forms schools in coastal waters. Alepes scads are marine, coastal predatory fish not found in the open oceans (Pauly et al., 1996; Riede, 2004; Fricke et al., 2011).

Information about the health of these fishes is important in all countries along their range of distribution where they are fished commercially. Previous research on these fishes focuses on *S. gibbosa* and includes a study on the genetics and morphology of cryptic species of *S. gibbosa* (Thomas et al., 2014); the confirmation of presence of *S. gibbosa* in the Red sea and documenting its introduction into the Eastern Mediterranean Sea (Stern et al., 2015); heavy metal contamination in *S. gibbosa* in the coast of Balochistan, Pakistan (Ahmed et al., 2015); and stock assessment of *S. gibbosa* in the Gulf of Thailand (Boonjorn et al., 2012). No studies are known of the ecology or the living conditions of these fishes, let alone of monthly or seasonal changes in those two aspects. This paper addresses this gap by studying monthly and seasonal changes in the length–weight relationship of the two species and one genus of fish. It provides an account of investigations carried out in both Songkhla Lagoon and Sathing Pra, in a context of sharp decline in fish catches in Songkhla Lagoon. This study concentrates primarily on the populations and general biology of those fishes, in particular growth

© 2018, ALÖKI Kft., Budapest, Hungary

and related aspects, thereby providing early findings to inform further research on measures to enhance fish populations in Songkhla Lagoon.

Material and methods

Study site

This study was conducted in the lower Gulf of Thailand, in the coastal area of Sathing Pra District, Thailand (*Fig. 1*). The climate of the lower Gulf of Thailand is governed by two monsoons the southwest monsoon from May to September, and the northeast monsoon between October and March. There are two seasons: (a) the rainy season, usually covering the period May to January, with the heaviest rains typically in November; and (b) the dry season, from February to April. April is normally the hottest month (ONEP, 2005).

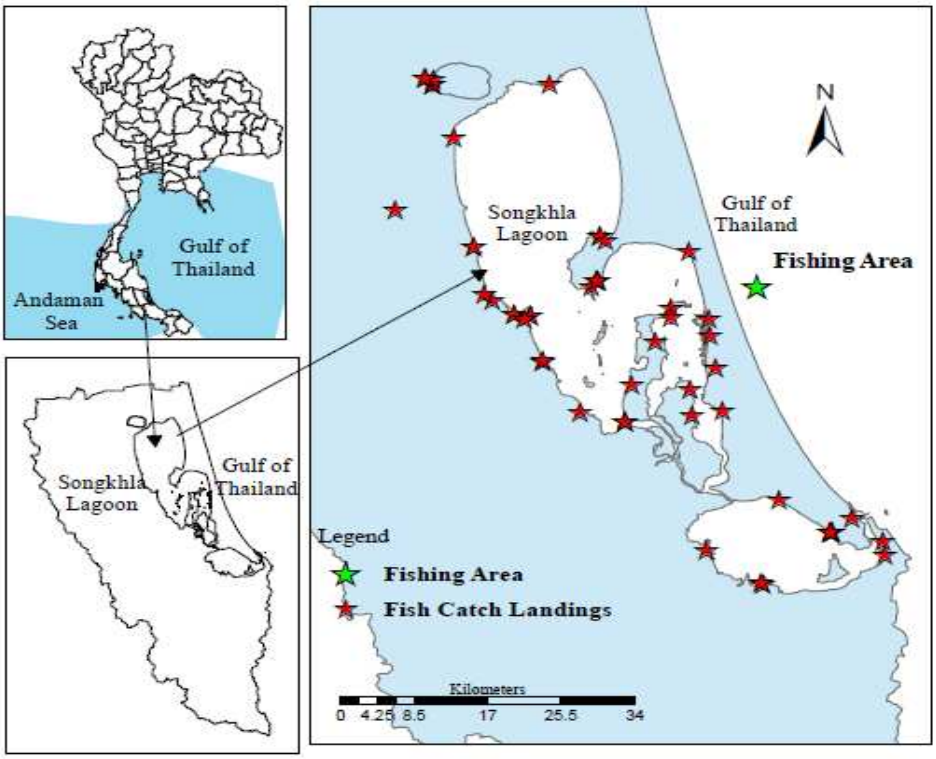

Figure 1. *The locations of sampling*

Data collection

Specimens used in this study were collected on a monthly basis from fishermen fishing in the coastal district of Sathing Pra during the period of September 2017 to April 2018, at the sampling sites indicated in *Figure 1* (07°31'24" N; 100°27'46" E). A list of 185 fish species found in Songkhla Lagoon during 2003-2017 issued by the Thai National Institute of Coastal Aquaculture (NICA) was used to identify the caught fish species. The list was first given to the head of Fisherman Association in Sathing Pra, through whom it was distributed to the fishermen contributing to the study, who did the first species identification themselves.

The fishing grounds where the specimens were caught are located approximately 3 km from the shores of the lagoon. Number Fish specimens were captured with two main fishing gears: fish nets (length: 180 m, mesh size: 4.5 × 4.5 cm) and shrimp nets (length: 30 m, mesh size: 3 × 3 cm), the only one fish specimen Sardinella gibbosa was caught with crab nets (length: 180 m, mesh size: 11 × 11 cm), at depths of approximately 80, 15 and 20 m, respectively. Fishing usually took place between 3 and 6 am, with some variation between months and seasons. The fishing boats in this coastal area are usually small boats with a length of 7-10 m length and a width of 1.8-2 m.

All specimens were bought from the fishermen, iced and transferred to the laboratory of the Marine and Coastal Resources Institute, Prince of Songkla University (MACORIN), where a verification of the species was carried out, followed by the measurement of the total length and weight. Total length of fish was measured from the tip of the premaxilla to the tip of the longest caudal fin ray stretched out posteriorly. Millimeter was used to be length measurements (Society, 2017). The total weight of fish specimens was recorded with an accuracy of 0.1 g using an Ohaus digital weighing balance (Ajani et al., 2013).

Data analysis

The purpose of this study is to assess the condition of commercially important fish found in Songhkla Lagoon by investigating their length–weight relationship, and monthly and seasonal changes in this parameter. The monthly data on length and weight was separated into two periods: the monsoon season (from September 2017 to January 2018) and after the monsoon season (dry season) (from February to April 2018).

Length–weight relationship analysis

Linear transformation of fish length and weight was made by using natural logarithm at the observed lengths and weights. The length–weight relationship (LWR) was calculated following Pauly (1983) and used to calculate the regression coefficient (slope of regression line of weight and length). The parameter "β" of the LWR was estimated using *Equation 1:*

$$W = aL^{\beta} \quad \text{(Eq.1)}$$

Here: W = the weight of the fish in grams, L = the total length of the fish in millimeters, a = constant, β = growth exponent.

A logarithmic transformation was used to make the relationship linear (*Eq. 2;* Le Cren, 1951):

$$\text{Log } W = \beta \log L + \log a \quad \text{(Eq.2)}$$

The LWR parameters *a* and β as well as the coefficient of determination (R^2) were derived by least squares regression (Ricker, 1973). The slope (β) also known as the allometry coefficient, has an important biological meaning, indicating the rate of weight gain relative to growth in length or the rate at which weight increases for a given increase in length.

© 2018, ALÖKI Kft., Budapest, Hungary

Inferences about slope (β)

If a fish grows without changing its shape or density, then it is said to exhibit isometric growth. In this case, the volume of the fish is proportional to any linear measure of its size and β = 3. Isometric growth in fish is rare (Bolger and Connolly, 1989; McGurk, 1985). If β > 3 the fish tends to become "plumper" with an increase in length, a situation called positive allometric growth (Blackwell et al., 2000). If β < 3 the fish tends to become "thinner" with a decrease in length, a situation called negative allometric growth (Froese, 2006).

A test of whether the fish from the lower Gulf of Thailand exhibits allometric growth or not and confidence interval for β can be obtained by fitting the transformed length–weight model. The slope is generically labeled with beta (β) such that the test for allometry can be translated into the following statistical hypotheses:

$$H_0 : \beta = 3 \text{ ("Isometric growth")}$$

$$H_1 : \beta \neq 3 \text{ ("Allometric growth")}$$

Regarding model parameters can be obtained with a t-test using *Equation 3:*

$$t = \frac{\hat{\beta} - \beta_0}{SE_{\hat{\beta}}} \quad \text{(Eq.3)}$$

where β, SE_β are from the linear regression result and β_0 is the specified value in the H_0. In this study, the hypothesis test that a linear model parameter is equal to a specific value. To test a parameter is equal to a value other than 0, hoCoef meets all the requires and was used to efficiently compute the t and corresponding P-value for non-default hypothesis (for H_0: $\beta = 0$ by default).

Predictions of fish original scale

The study used the result from the length–weight regression to predict the weight of the fishes at the mean length. The result was back – transformed to the original scale by exponentiation. Due to the fact that the geometric mean is always less than the arithmetic means and, thus, the back-transformed mean always underestimates the arithmetic mean from the original scale (Ogle and College, 2013), the final original scale was multiplied with a correction factor derived from analysis of normal and log – normal distribution theory, using *Equation 4:*

$$e^{\frac{(\delta_{Y/X})^2}{2}} \quad \text{(Eq.4)}$$

where $\delta_{Y/X}$ is calculated from summarizing model length–weight regression of fish.

Comparing length–weight regressions (between seasons)

Inter-seasonal variation in the LWR of the fish included in this study was assessed by means of an analysis of variance (ANOVA) of the regression models using the factor season. The statistical significance for the study was set at a P value < 0.05. The full

DOI: http://dx.doi.org/10.15666/aeer/1605_61136127
© 2018, ALÖKI Kft., Budapest, Hungary

model with indicator and interaction terms was then fit and stored in an object with the ANOVA table. All statistical analysis was performed using the FSA package (Ogle, 2018) from the R software (R Core Team, 2018).

Results

During the study period, 20 different Songkhla Lagoon species were captured in the coastal area of Sathing Pra, of which two species were crabs, three species were shrimps and 15 species were fish. The number of species varied markedly between months, but the fish species Indian pellona (*Pellona ditchella*), goldstripe sardinella (*Sardinella gibbosa*) and genus alepes (*Alepes vari*) appeared regularly, with sample sizes of 537, 162 and 49, respectively *(Table 1).* Among the samples, the total length of *P. ditchella* ranged from 103 to 183 mm, *S. gibbosa* from 102 to 175 mm, and *Alepes vari* from 122 to 216 (*Table 1*), whereas the ranges of the total body weight were 9 to 59 g, 6 to 43 g, and 11 to 93 g, respectively (*Table 1*).

Table 1. *Total length and weight for Pellona ditchella, Alepes vari and Sardineela gibbosa*

Common name	Scientific name	Sample size	Total length (mm)		Total weight (g)	
			Range	Mean	Range	Mean
Pellona ditchella	*Pellona ditchella* (Valenciennes, 1847)	537	103-187	143.9	9-59	30.81
Alepes vari	*Alepes vari* (G. Cuvier, 1833)	49	112-216	162.9	11-93	47.71
Sardinella gibbosa	*Sardinella gibbosa* (Bleeker, 1849)	162	102-175	130.8	6-43	19.93

Length–weight model

Figure 2 depicts the natural log-transformed total length and weight of *P. ditchella*, Alepes and *S. gibbosa* captured in the lower gulf of Thailand between September 2017 and April 2018, with the best fit regression line superimposed. *Table 2* gives the equations and other parameters of the length weight models for the three fish included in the study by using *Equation 2,* derived from those regression lines.

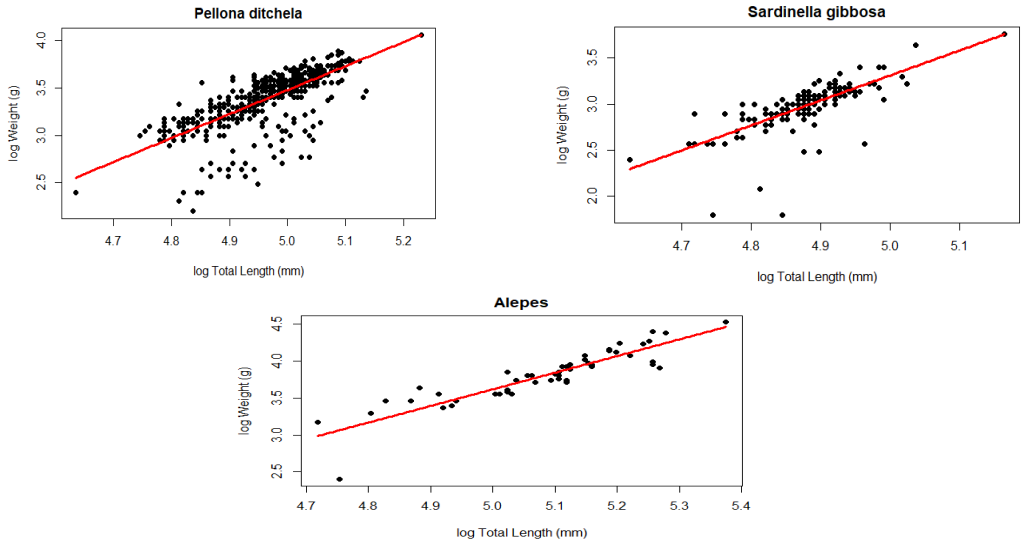

Figure 2. *Plot of natural log total length and weight of the three sampled fish*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_61136127
© 2018, ALÖKI Kft., Budapest, Hungary

Table 2. *Equation of the length weight models for P. ditchella, Alepes vari. and S. gibbosa*

Fish species	Equation (on the transformed scale)	Equation (on the original scale)	R^2	b range (95% confidence)	P value
P. ditchella	log(W) = -9.19+2.53log(L)	$W = 0.000102*L^{2.53}$	0.51	2.32 - 2.75	P = 0.00002
Alepes vari	Log(W) = -7.64+2.25log(L)	Log(W) = -7.64+2.25log(L)	0.81	1.93 - 1.93	P = 2.538096e-05
S. gibbosa	Log(W) = -10.25 + 2.71*log(L)	$W = 0.000035*L^{2.71}$	0.55	2.33 - 3.1	P = 0.1432605

With a value of R^2 between 0.5 and 0.6 the models for *P. ditchella* and *S. gibbosa* have a weaker fit to the data than the model for Alepes vari, with a value of R^2 of 0.81. The results for the slopes of the equations show that, according to the model, *S. gibbosa* exhibits isometric growth ($p > 0.05$) with an exponent parameter (β) between 2.33 and 3.1, with 95% confidence. The results for the other two fish show that, according to the respective models, both *P. ditchella* and Alepes vari exhibit allometric growth ($p < 0.05$) with values of β between 2.32 and 2.75 for *P. ditchella* and 1.93 and 2.27 for Alepes vari.

Predictions based on original scale

Table 3 presents the results for the predicted mean weight of the three fish included in the study, using the length–weight models presented in *Table 2* and *Equation 4*. With a mean length of 150 mm, *P. ditchella* was estimated to have a weight between 33.4 and 34.6 g. For *Alepes vari,* with the mean length is 160 mm, the weight predicted lies between 18.6 to 19.7, whereas for *S. gibbosa* the figures are 130 mm and 42.2 to 46.3 g.

Table 3. *Prediction of weight of P. ditchella, Alepes vari and S. gibbosa based on the mean length*

Fish species	Bias correction factor	Predicted weight (g)	Mean length (mm)
P. ditchella	1.097	33.4 - 34.6	150
Alepes vari	1.01	18.6 - 19.7	160
S. gibbosa	1.015	42.2 – 46.3	130

Monthly variation of length–weight relationship of the fish

Monthly length–weight relationship of the fish was calculated by using *Equation 1.*, where a = constant, β = slope (or allometry coefficient or growth exponent), n = number of fish sampled, R^2 = Coefficient of determination. The results are shown in *Table 4*.

Table 4 presents the monthly data for the length and weight of the three fish, for the entire study period (September 2017 to April 2018), and the parameters for the respective length–weight relationships. The value of β could not be determined for certain fish in the months of November 2017 and January, March and April 2018 due to the small size of the sample. No sampling was carried out in December 2017, as the heavy weather prevented all fishing activities.

There is a slight variation in the value of β (slope) between months for the three fish included in the study, with the majority exhibiting negative allometric growth ($\beta < 3$), and only Alepes vari exhibiting positive allometric growth during the month of October

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_61136127
© 2018, ALÖKI Kft., Budapest, Hungary

2017 (β = 3.14). This suggests that the majority of the fish sampled experiences poor growth and living conditions. Carlander (1969) showed that the coefficient β in the LWR of fish usually ranged from 2.5 to 3.5. In this study, there were 10 instances in which the value of β was outside this range, as depicted in *Table 4* and *Figure 3*. The same table and figure also show that the lowest value of β was obtained for *S. gibbosa* in October 2017, whereas the highest was for Alepes vari in October 2017 (β = 3.14), followed by that for *S. gibbosa* in January 2018 (*b* = 2.94).

In the majority of instances (76.9%) the value of the coefficient of determination (R^2) was equal or greater than 0.60, which indicates a moderately significant relationship between length and weight of the fish examined in the period of this study *(Fig. 4)*.

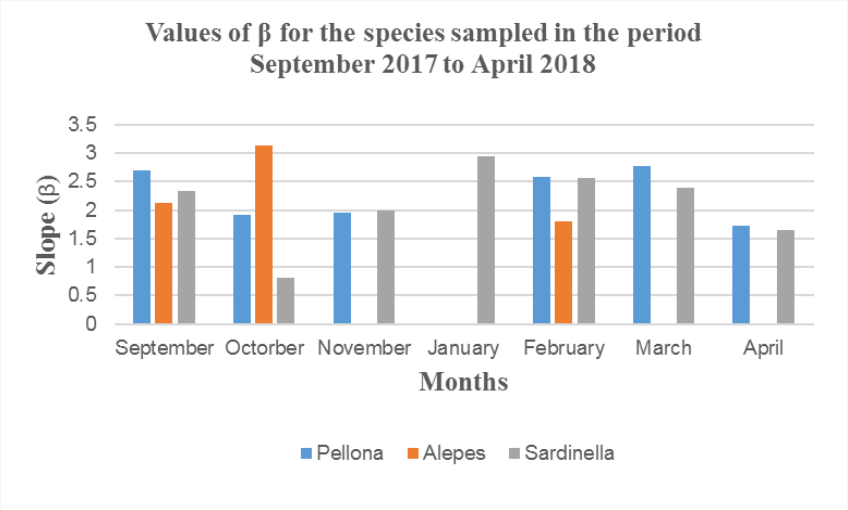

Figure 3. *Values of β for the species sampled in the period September 2017 to April 2018*

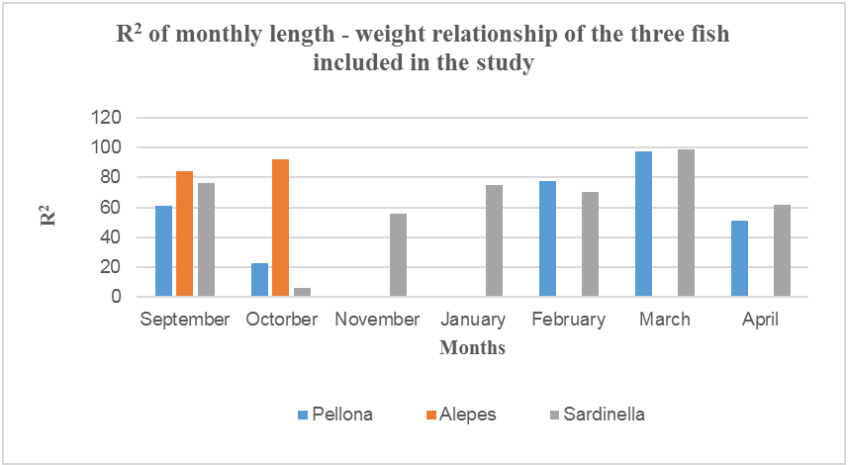

Figure 4. *R^2 of monthly length–weight relationship of the three fish included in the study*

Comparing length–weight regressions during and after the monsoon season

Table 5 presents the values of the ANOVA of the length–weight relationship for the three fish in two distinct periods, namely during and after the monsoon season.

These results show that for *P. ditchella* the interaction terms are significant (p = 0.02), which indicates that there is enough evidence of the difference in the slope in the length–weight relationship between the monsoon and after monsoon seasons. The p-value for the indicator variable also suggests that there is a difference in the intercepts between seasons (p < 0.05). There are statistically significant differences between the slopes and intercepts of the regressions for the two different seasons, and there is a constant difference between the log-transformed weights of fish from the two seasons regardless of the log-transformed lengths of the fish. This is confirmed by the plots *(Fig. 5)* and confidence intervals. This result states that, the growth of *P. ditchella* during monsoon and after monsoon seasons is different.

For *S. gibbosa Table 5* shows that the difference in the length–weight regression between seasons is not significant (p = 0.538), hence there is not enough evidence to draw any conclusions about inter seasonal differences in the length–weight relationship of this fish species. The p-value for the indicator variable suggests that there is a difference in the intercepts between the two seasons (p < 0.05).

The interaction term for Alepes vari is slightly significant (p = 0.04), suggesting that there is enough evidence to conclude that there is difference in the slopes in the length–weight relationship between the monsoon and after monsoon seasons. The p-value for the indicator variable suggests that there is no difference in the intercepts of the regressions for each of the two seasons (p = 0.53).

These results also show that *P. ditchella* and *S. gibbosa* captured during the monsoon season are smaller than those captured after the monsoon (dry) season, with differences in weight of 0.05 - 0.13 g and 0.03 - 0.14 g, respectively. The opposite was found for Alepes vari, in which case fish captured during the monsoon season was 0.14 to 0.25 g larger than the fish captured during the dry season. *Figure 5* portrays the final models for the length–weight regressions for the monsoon and dry seasons for the three fish, with the respective fit plots.

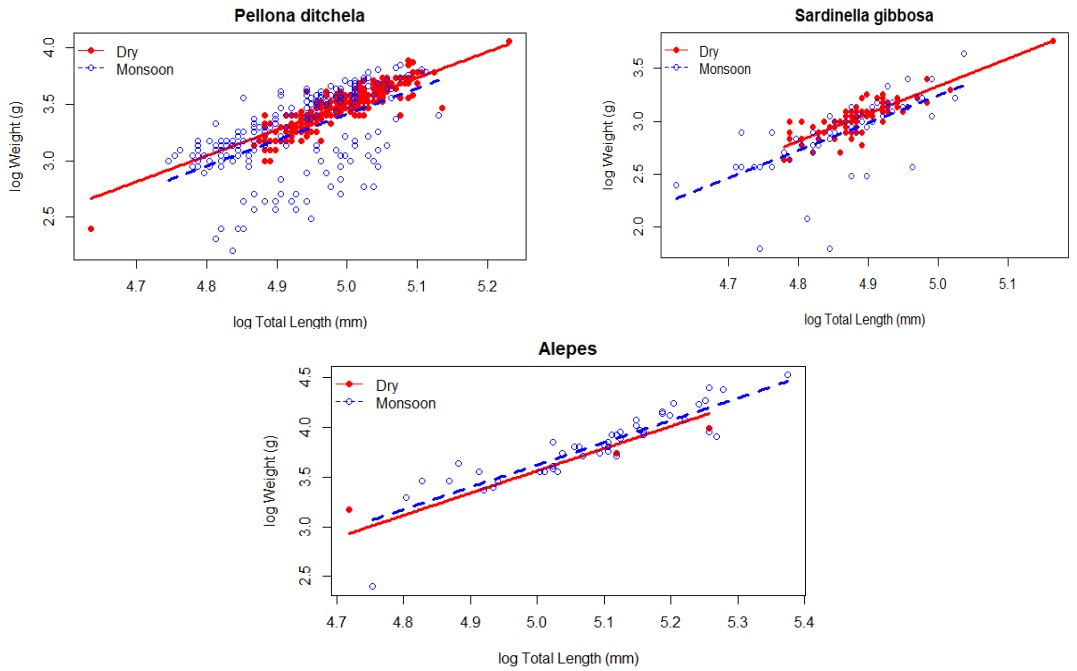

Figure 5. *Fit plot of the length–weight relationship for the three fish during the monsoon and after monsoon (dry) seasons*

Discussion

This paper provides the first monthly values for the length–weight relationship of three commercially important fish commonly found in Songkhla Lagoon and captured in the coastal areas of the lower Gulf of Thailand. It also contributes with revised values for the maximum length of two of the species studied in the online database FishBase (Froese and Pauly, 2018, *Table 1*): the maximum recorded length for *P. ditchella* (Valenciennes, 1847) and *S. gibbosa* (Bleeker, 1849) was previously 160 mm and 170 mm length (Whitehead, 1985), and this study determined new maximums at 187 mm and 175 mm, respectively.

With respect to the LWR, a value of 3 (three) for the slope of the regression (β) corresponds to the ideal growth of fish. However, such situation is seldom found (Allen, 1938) due to changes in the shape of fish during the growth period (Martin, 1949). That coefficient can be affected by factors such as the length and shape of the fish itself and the time of spawning; the fishing gear used (Farran, 1936; Deason and Hile, 1947); or environmental factors such as food supply and season changes in environmental parameters (Brosset et al., 2015). In this study, the average of the monthly values of β for the three fish studied fall below the standard interval of 2.5 to 3.5 as determined by Carlander (1969). The average values from this study are 2.277, 2.357 and 2.099 for *P. ditchella,* Alepes vari and *S. gibbosa*, respectively. This indicates that all three fish have negative allometry, which is interpreted as a sign of poor body condition. This is in line with the views of fishermen contacted for this study, most of whom were of the view that the amount and size of fish has decreased in the coastal area of the southern Gulf of Thailand, which they attribute to the oil drilling activities taking place offshore and the illegal fishing gear, such as: sai nang (sitting cage). 14.29% of the fishermen interviewed in this area said they are using sai nang, they knew that this fishing gear catches all small fishes, but they still have to use because the number of fishes are decreasing sharply (Source: Author). The results from this study are insufficient to establish such a causal relationship though, and a broader investigation would be needed to determine the effects of coastal water quality on the condition of fish in the lower Gulf of Thailand.

The study also found that two of the fish captured after the monsoon season (dry season), namely *P. ditchella* and *S. gibbosa* were on average fatter than when captured during the monsoon season. This is in line with the result from the author, only 13.6% amount of fish was caught during monsoon season, 39.98% was before monsoon season and 46.42% was after monsoon season (Source: Author). This may be due to the biology of these two species, as both migrate to the mangroves in the estuarine and freshwater environments of the lagoon (Hue et al., 2018), which affects their growth negatively compared to life in the marine environment of the coastal waters. Eventhough, Alepes was found thinner in the dry season, but due to its small sample size (N = 3), it is not appropriate for a correct statistical evaluation, to conclude about Alepes, it requires further study.

The main limitation of this study is the relatively short study period of seven months, which is insufficient for studying the biology of the fish included in the assessment. Despite this limitation, it has unveiled statistically significant differences in selected growth parameters between two seasons in the lower Gulf of Thailand. The fish studied are all of high commercial importance, yet are subject to increasing anthropogenic pressure from fishing, including the use of illegal gear such as sitting cage (Source: Author), offshore drilling for oil and habitat destruction (Satumanatpan and Pollnac,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_61136127
© 2018, ALÖKI Kft., Budapest, Hungary

2017). In view of these pressures and the need to improve the management of commercial fish stocks, the findings of this study are potentially very useful for current and future stock estimation and evaluation studies. Moreover, these findings could be useful for comparing the body condition of fish over time and between different regions. Further studies of similar nature and involving some elements of the biology of commercially important species are necessary to support the formulation of policies for the sustainable utilization and appropriate management of fisheries resources in the southern Gulf of Thailand and in the whole the country.

Conclusion

Seven months for studying the biology of fish may not be a long time but this is enough time to see the difference of growth parameters between two typical seasons in the lower gulf of Thailand for some fish species. In the investigated area, these species have high commercial value, however, high pressure on population caused by fishing, illegal fishing gear (trawl), oil drilling from human activities are destroying fish habitat. Findings of present research are very important for stock estimation and evaluation studies in the future. Moreover, they will give an opportunity to compare fish conditional living over the time and between regions.

Further studies of similar nature and involving some biological aspects of commercially important species are necessary to support the formulation of policies for sustainable utilization and appropriate management of fisheries resources in the country.

(Received 4th Jul 2018; accepted 14th Aug 2018)

Abstract. In this review data on parasitofauna of allochthonous fish species in the Danube River Basin in Serbia is presented. Up to now, 33 ecto- and endoparasites of seven examined allochthonous invasive fish species have been reported. Some of the identified parasitic species are new for fish parasitofauna in the Serbian waters (*Trichodina nobilis, Balantidium sp., Philometroides cyprini, Philometroides parasiluri, Eustrongylides* sp., *Ergasilus sieboldi, Lernaea cyprinacea, Sinergasilus polycolpus)*. In the open waters of Serbia (the Danube River Basin) a total of 26 non-indigenous fish species were recorded, of which 16 were the allochthonous invasive fishes. The major means of introductions and translocations were found to be the aquaculture, fish stocking and transportation. Habitat modification was found to be the factor that largely contributes to the capability of the water bodies to become a suitable recipient area. The large presence of alien fish species (27.66%) and its parasites creates a serious threat to the stability of freshwater ecosystems and the survival of the native ichthyofauna. The main environmental consequences of alien fish spreading are related to the alteration in fish community structure and function, as well as the introduction of the alien parasite species.
Keywords: *parasites, alien fish, alteration in fish community, Danube, Serbia*

Introduction

The introduction of fish specimens into aquatic ecosystems is common around the world. The main purpose of these introductions over the past three decades is for aquaculture, reinforcement of natural populations, biological control or recreation activities (exotic fish aquaria, angling, etc.) (Welcomme, 1981, 1988; Stewart, 1991). Ballast water of ships, deliberate fish stocking and introduction into aquaculture were pointed as prospective agents of dispersal of non-indigenous fish species in aquatic ecosystems (Gherardi et al., 2009).

Alien fishes have been introduced for many reasons in Europe: ornament, sport, improvement of wild stocks, aquaculture, biological control and accident (Elvira, 2001).

Aquatic introductions are made possible by a range of factors, including species-specific traits as well as by human activities such as river regulation, the connection of bordering basins by canals or ballast transport (Grigorovich et al., 2003). The success of introduction depends on the capability of species to avoid predators and parasites (Torchin et al., 2003). According to that, introduced species attain higher population densities and greater individual sizes in the recipient areas as compared to nonspecific

in their native range (Torchin et al., 2001). Non-indigenous species may affect indigenous species by competing for resources, transferring pathogens, or significantly altering the habitat. The introduction of non-indigenous species may work synergistically with some factors, such as water pollution, to alter the population and distribution of indigenous species (Elvira, 2001). The main environmental consequences of alien fish spreading are related to the alteration in fish community structure and function, as well as the introduction of the non-indigenous parasite fauna. Despite the importance of host manipulation by parasites for ecosystems and health, the effects of environmental changes on their ecological roles are largely ignored (Labaude et al., 2015). In contrast to other ecological effects, the importation of parasites, pathogens and diseases can be made via alien fish never intended to be released into the wild. Many diseases of salmonids that infect hatchery-reared fish and also occur in wild populations have been imported. Rainbow trout *Oncorhynchus mykiss* (Walbaum, 1792) from the western part of North America has carried furunculosis to Europe (Borno and Colquhoun, 2009). The importation of pathogens that are not group specific is a great risk associated with the introduction of exotic species (Elvira, 2001).

The consequences of biotic invasions are diverse and interconnected, since invaders can alter fundamental ecological properties such as dominant species in a community, productivity, nutrient cycling and thus can alter the structure and function of the ecosystem (Mack et al., 2000). Also, when present in sympatry, invasive species have the potential to amplify or diminish their ecological impacts through their trophic interactions, like it is tested for *Cyprinus carpio* and *Pseudorasbora parva* (Jackson and Britton, 2014).

Aquatic ecosystems in Serbia, especially those settled in north, lowland district, are influenced by biological invasion and contamination. The Danube River is an important invasion corridor, so called "Southern Invasion Corridor" (Galil et al., 2007) highly suitable for introduction of invasive fish species in Serbian waters (Jankovic et al., 1987; Hegedis et al., 1991; Cakic et al., 1996, 2004; Maletin et al., 1997; Simonovic and Nikolic, 1997; Simonovic et al., 1998, 2001). Also, the role of hydro-morphological alterations in aquatic invasions in this region has already been shown in the case of introduction and acclimation of invertebrate and fish species (Jankovic et al., 1987; Lenhardt et al., 2011). Thus, the Iron Gate area, downstream stretches of the main tributaries of the Danube River (the Sava, the Tisa and the Velika Morava River), that are under the influence of hydro-morphological changes, as well as artificial channel network Danube-Tisa-Danube, seemed to be suitable recipient areas for introduction and population establishment of non-native taxa.

Non-native ichthyofauna in Serbia has mostly been investigated as the part of ecological or taxonomical studies of particular areas. The data on alien fish fauna within the Serbian part of the Danube River originated from a number of studies and monitoring programs (Cakic and Hristic, 1987; Maletin et al., 1997; Jankovic, 1998; Simonovic et al., 1998, 2001; Lenhardt et al., 2011; Zorić et al., 2014). Introduction of allochthonous species into Serbian waters were made primarily in order to increase ichthyoproduction for weed control, sport fishing purposes and also accidentally (Lenhardt et al., 2011).

The aim of the present study is to report parasitic species of allochthonous fish species in the Serbian waters in the period of the last 31 years, and to investigate their contribution to diversity of fish parasitofauna.

Materials and methods

The study comprehends the data derived from several long-term investigations of freshwater fish species in the surface waters of the Danube River Basin in Serbia. During these studies, many allochthonous fish species have been identified and processed. Fish samples were collected using multi-mesh nets with mesh size of 10-60 mm, as well as by electrofishing (HONDA 1.2 kW, 6 A). After sampling, fish specimens were anesthetized in clove solution and sacrificed with a quick blow to the head. Fish species were identified according to Simonović (2006). The material of non-native freshwater fishes was analyzed for ecto- and endoparasites using standard parasitological procedure. Squash slides were taken from the skin and gills and observed under a light microscope (400 x magnitudes) within two hours. The slides were impregnated with silver-nitrate according to the modified Klein-Feussner method. The collected parasites were preserved in 4% formaldehyde (Acantocephala, Digenea/Trematoda, Cestoda, Bivalvia), in a mixture of ammonium picrate and glycerin (Monogenea) or in a mixture of glycerin and alcohol (Nematoda). Metazoan parasites were bleached, stained, prepared and fixed for determination and collection. Isolation, sorting and identification of parasite fauna have been done in the laboratory. Appropriate identification keys were used for the determination of parasite fauna representatives to the lowest taxonomic level (Bykhovskaya-Pavlovskaya et al., 1962; Banina, 1984; Shulman and Jankovsky, 1984; Stein, 1984; Bauer, 1987; Lom and Dikova, 1992; Moravec, 1994).

Results

In total, 26 non-indigenous fish species from nine different families have been reported from the Serbian part of the Danube River basin area (*Table 1*), contributing to the total species richness of ichthyofauna of Serbia 27.66%. Their parasitic species have been investigated and identified. In this paper, a total of 33 parasites (ecto- and endo-) are reported. The impact of those aliens on native fish is the topic for further research.

The list of allochthonous fish species, their status and occurrence in recipient area, pathway of introduction in our waters as well as their origin are presented (*Table 1*).

Discussion

The Danube River is one of the main target areas for invasive fish species, as well as one of the most convenient ways for their dispersal. In the Danube River drainage area in Serbia 26 non-indigenous fishes have been recorded (Maletin et al., 1997; Simonovic and Nikolic, 1997; Simonovic, 2006).

One of the most adverse effects of the introduction of non-indigenous fish species on the native ones is associated with the introduction of exotic parasitic species. The unfavorable consequences of parasitism related with introduction of non-native fish species and spreading of parasites to native taxa have already been reported in Serbia (Cakic and Hristic, 1987; Cakic et al., 1998, 2001, 2004; Nikolic and Simonovic, 1998a,b, 1999a,b; Nikolic et al., 2003, 2006, 2007, 2010).

According to previous investigations in Serbia, the fish parasite fauna was supplemented by *Trichodina nobilis (*Ciliata*), Triaenophorus nodulosus* (Pallas, 1781) (Cestoda) and *Philometroides cyprini* (Nematoda) after the deliberate introduction of Asian fish species, such as Grass carp *Ctenopharyngodon idella*, Bighead carp *Hypophthalmichthys nobilis (*Richardson, 1845), silver carp *Hypophthalmichthys*

mollitrix (Valenciennes, 1844) into fish farms (Nikolic and Simonovic, 1998a) and invasion by *Philometroides parasiluri* (Yamaguti, 1935) *and Eustrongylides* sp. (Jägerskiöld, 1909) from *P. glenii* (Nikolic et al., 2007). Comparing with the results reported for the last 70 years (Djikanovic et al., 2012), eight parasitic species found in allochthonous fish are new for parasitofauna in the Serbian open water.

Ectoparasites of allochthonous fish species in Serbian open waters are examined. They can be detected as an outcome of fish juveniles' introduction or together with alien fish species. With fish juveniles several Asiatic ectoparasitic species were imported from the family of *Trichodinidae*, as a consequence of fish introduction in fishponds without previous health condition control (Nikolic and Simonovic, 1998a,b; Nikolic et al., 2007).

Endoparasites of allochthonous fish species in Serbian open waters have been the subject of a few hydrobiological investigations (Cakic et al., 1998, 2001, 2004). In relation to the growing concern about biological invasions in the Serbian section of the Danube River and interconnected ecosystems (Cakic et al., 1998, 2001, 2004; Simonovic et al., 1998, 2001; Simonovic, 2006) this work provides worthy information on the parasitofauna of non-indigenous fish species.

Metazoan parasites of *Neogobius* fishes (monkey goby *Neogobius fluviatilis* (Pallas, 1814), bighead goby *Ponticola kessleri* (Günther, 1861) and round goby *Neogobius melanostomus* (Pallas, 1814)) have been investigated in the Slovak section of the Danube River. Thirteen parasite species were identified, and the most prevalent parasites were *Pomphorhynchus laevis* (Acanthocephala) and glochidia of *Anodonta anatine*. The maximum parasite diversity was found in *N. fluviatilis* (Ondračkova et al., 2005). These founds are common to parasites in the Middle Danube basin. Gobiid fish (*Neogobius melanostomus* and *N. fluviatilis*) from the north-western Black Sea were analysed for presence of helminth species, and representatives from Cestoda (1), Trematoda (6), Nematoda (6) and Acanthocephala (3) have been reported (Kvach, 2005). In Serbian open waters no parasites for *Neogobius* fishes were observed. Parasitofauna of gobiid species in the Serbian part of the Danube River has not been investigated yet.

In the brown bullhead *Ameiurus nebulosus* some Trematodes from family Allocreadiinae and a few helminth parasites were found in the USA (Arnold, 1934; Krueger, 1954), while in the Serbian section of the Danube ectoparasites from the group Cliophora and *Acanthocephalus anguillae* (Acanthocephala) (Cakic and Hristic, 1987; Kiskaroly and Tafro, 1988; Nikolic and Simonovic, 1998b, 1999a,b; Nikolic et al., 2003) have been recorded. *Piscicola geometra* (Hirudinea) was recorded in Prussian carp *Carassius gibelio* (Bloch, 1782) from a lake in Turkey (Arslan and Emiroglu, 2011). Prussian carp from the Srebarna Biosphere Reserve was infected with two trematode species (*Posthodiplostomum cuticola* and *Diplostomum rutili)* and two nematode species (*Contracaecum microcephalum* and *Raphidascaris acus*) (Shukerova, 2005). In the Serbian open waters, Prussian carp have been infected by *Posthodiplostomum cuticula* and *Philometroides cyprinid* and some ectoparasites (Ciliophora) (Cakic and Hristic, 1987; Nikolic and Simonovic, 1998a,b; Cakic et al., 2001; Nikolic et al., 2003, 2006).

Some Monogenean parasites (*Dactylogyrus suchengtai, D. hypophthalmichthys* and *D. scrjabini*) were recovered from the silver carp at a fish farm in Hungary (Molnar, 1984). In our study, one Ciliophora and two crustaceans were found for this fish (Cakic and Hristic, 1987; Cakic et al., 1998; Nikolic and Simonovic, 1998a). Intestinal lesions

in the Grass carp caused by infection of *Balantidium ctenopharyngodonis* (Protozoa: Ciliophora) were reported by Molnar and Reinhardt (1978). Species *Trichodina nobilis, Ergasilus sieboldi* and *Triaenophorus nodulosus* have been detected in this alien fish species in the Serbian section of the Danube River Basin (Nikolic and Simonovic, 1998a).

During the survey in Denmark, the Rainbow trout *Oncorhynchus mykiss* has been examined and 12 protozoans and 10 metazoan species were found (Buchmann and Bresciani, 1997). In Serbian surface waters, a diverse parasitofauna of rainbow trout has been detected (Babic, 1935; Cakic, 1992; Nikolic and Simonovic, 1999a,b; Nikolic et al., 2006, 2010). Helminth fauna of the Chinese sleeper (*Nippotaenia mogurndae*, *Asymphylodora* sp.) and *Lepomis gibbosus* (*Triaenophorus nodulosus, Proteocephalus percae*, Echinorhynchidae) have been reported (Košuthová et al., 2009). Two monogenean parasites were found on the gill filaments of the pumpkinseed *Lepomis gibbosus* (Linnaeus, 1758) (Sterud and Jorgensen, 2006). Some monogenean parasites of pumpkinseed from the Slovak part of the Danube River Basin have been collected (*Gyrodactylus sp., Onchocleidus similis, O. dispar* and *Actinocleidus recurvatus*) (Ondračková et al., 2011). Monogenea *Urocleidus similes,* Nematoda *Schulmanela petruschewskii,* two crustaceans *(Ergasilus sieboldi*, *Lernaea cyprinacea*) as well as one species from Ciliophora (*Trichodinella epizootica)* were identified for *Lepomis gibbosus* in our study (Cakic and Hristic, 1987; Kiskaroly and Tafro, 1988; Cakic et al., 1998; Nikolic and Simonovic, 1999a).

The cestode *Nippotaenia mogurndae* is reported for the Chinese sleeper *Perccottus glenii* (Perciformes: Odontobutidae) (Košuthová et al., 2004; Reshetnikov et al., 2011). Except this cestoda species, the parasite community consisted of *Trichodina domerguei* and of 3 species, *Diplostomum spathaceum* (metacercaria), *Echinochasmus spinosus* (met.), and *Eustrongylides excisus* (larvae) (Mierzejewska et al., 2012). The parasites of the *Perccottus glenii* were studied in different parts of Ukraine and 15 taxa of parasites were registered; among them were 1 species of Microsporidia, 5 species of ciliates, 2 species of cestodes, 2 species of trematodes, 2 species of nematodes, 1 species of acanthocephalan, 1 species of parasitic crustacean and 1 mollusk (glochidia) (Kvach et al., 2013). For this alien fish, two Nematodes have been recorded in Serbian open waters (*Philometroides parasiluri, Eustrongylides* sp.) (Nikolic et al., 2007; Moravec, 2008).

Generally, the helminth fauna of invasive fish species reported from the new territories is less rich than their native areas (Drake, 2003; Torchin et al., 2003).

The consequences of introducing pathogens or hosts into new geographical zones where certain parasites exist can affect the healthiness of native fish population (Blanc, 2001; Pegg et al., 2015). The impacts of alien fish introduction on the fish populations in open waters are several: Demographic impacts (the impacts on the survival of fish populations are rarely quantified, except in the particular case of lake ecosystems, or populations targeted for fishing or long-term scientific studies); Genetic impacts (genetic differences of the hosts could play a critical role in the nature and outcome of helminthiasis – Wakelin (1978, 1992), hybridization was also considered with introgression of the resistance character or selective rearing of the survivors of a given population (Blanc, 2001). One of the negative impacts of alien species on freshwater ecosystems is the introduction of alien infectious agents, representing one of the greatest risks associated with ecological implications of introduction of species (Britton, 2013; Britton et al., 2011). As such, topmouth gudgeon in Europe is a carrier of several

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

pathogens (Gozlan et al., 2005), posing a risk not only to freshwater aquatic species, as this threat has also expanded to marine fishes.

Usually, invasive species have less parasite richness than in their native habitats (Torchin et al., 2003). The release of parasites and pathogens is one of the conditions of successful invasion (Kvach et al., 2013).

Conclusion

The large presence of alien fish species and its parasites creates a serious threat for the stability of freshwater ecosystems and the survival of the native ichthyofauna. In the Serbian surface waters contribution of allochthonous fish species to the total species richness of ichthyofauna is 27.66%. Invasive species are often superior competitors in relation to the evolutionary isolated native species populations (Mills et al., 2004). Negative impacts on native species include predation, trophic competition, behavioural interference, hybridization, spread of novel parasites and diseases, alteration of food webs and modification of biochemical cycles (Mills et al., 2004; Cucherousset and Olden, 2011; Kalogianni et al., 2014).

Invasion of allochthonous fishes in the Danube River Basin in Serbia caused important changes in the native fish fauna composition and also enriched the fish parasite fauna.

(Received 4th Jul 2018; accepted 3rd Sep 2018)

Abstract. This research aimed to inspect the influence of khapra beetle (*T. granarium* Everts, 1898) onto marketing price and relevant traits in the controlled conditions in the laboratory of department of field crops of Faculty of Agriculture in the University of Harran in the south-east Anatolia. Laboratory experiment including larvae production was carried out employing 10 bread wheat advanced lines derived from CIMMYT (International Wheat and Corn Improvement Center) from 22 November 2017 and 29 April 2018. A split plot experimental design where the larval infestation levels are main plots and entries as sup plots with 3 replications was employed. Various physical, grain quality characteristics and marketing prices were scored initially and at nearly 40, 80 and 120 days after starting date. The results revealed that quality parameters declined significantly at the end of study. Geometric mean of weight loss was 8 kg ton^{-1}. This was 32.7 kg ton^{-1} at the end of study. Comparing ceiling prices at the local commodity market, marketing price loss of khapra damaging grains excluding parity loss of Turkish Lira against US dollar for 120 days was 30.8 USD ton^{-1}. It was concluded that there were response differences to khapra beetle among the entries regarding quality characteristics and marketing prices. Entry number of 9, 6 and 10 were the least weight loosing genotypes and 9, 1, and 10 were the least affected genotypes from marketing price declines due to khapra damaging.
Keywords: *khapra damage, common wheat, weight and quality losses, economical loss*

Introduction and literature review

Khapra beetle, *Trogoderma granarium* Everts (Coleoptera: Dermestidae) is one the worst pest of cereals and many other stored products (Ahmedani et al., 2011, 2009, 2007). Its undeniable economic importance relies on its ability to cause huge physical and quality losses in the stored grains by feeding and increasing temperature of storage environment making them liable to be invaded by some other pests including fungi and bacteria (Sayed et al., 2006; Ahmedani et al., 2009, 2007). It has tough larval ability to withstand starvation as long as three years under very low relative humidity (Ahmedani et al., 2009). Larvae feed from embryo initially and later consume the whole grain. This results in a hollow in the grain and only the seed coat remains (Ahmedani et al., 2009). The youngest larvae cannot feed on whole grain and is able to survive utilizing from deteriorated grains. Elderly larvae cannot eat whole grains. Rate of population increase may reach to 12.5 times in a month at 37 °C (Anonymous, 2005). Adults have no long life span and do not result in significant damage in grains (Ahmedani et al., 2007).

Parameters of grain quality reduce due to ending up of nutrients such as, total carbohydrates, crude fat, sugars, real protein content and sedimentation. Contrary, damaging khapra beetle increases grain moisture, total protein and crude fiber (Jood et al., 1993, 1996; Jood and Kapoor, 1993). Moreover anti nutrient polyphenol and phytic acid increase significantly (Kumar and Srivastava, 2017). Khapra beetle occurs in large scale in Northern hemisphere including Europe, Middle East, Central and Southern Asia (Ahmedani et al., 2007).

Post-harvest losses due to the storage pests were guessed to be up to 9% in developed countries whereas it could reached up to 20% in developing countries (Yadav et al., 2018). Post-harvest losses for grains in India were 7-10% of total production from field to purchasers and 4-5% at marketing (Yadav et al., 2018). In Pakistan, estimated storage loss for food grains due to pests was 4-10% (Hugue et al., 1969), 5.08% (Chaudhry, 1980), 5% (Ahmad, 1984), and 3.5-25.5% (Irshad and Baloch, 1985). Varietal differences were also detected in response to khapra beetle damage (Ahmedani et al., 2011, 2009). Average weight loss at 36 °C and 15% infestation level may reach to 2.6% with a 24% viability loss (Prasad et al., 1977). Weight loss may rise to 16.36% in wheat (Girish et al., 1975). Turkey is an important grain producer among top-ten countries in the world (FAO Stat, 2009) and host for many storage pests (Ekmekçi and Ferizli, 2000). Citing the last ten year average, wheat acreage varies from 7.5 to 8.5 mil ha and the annual production varies from 17.2 to 22.6 mil tons (TMO, 2016). 14.3% of total bread wheat production was met by southeastern Anatolia in 2016. Khapra beetle damage can reach high infestation levels in the region (Işıkber et al., 2014) and may vary from 10% (Ekmekçi and Ferizli, 2000) to 25-35% (Kalkan,1963). Weight loss in durum wheat for an 8 months storage period was 4.075% with a 103 USD ton^{-1} marketing price loss (Özberk et al., 2017). Downgrading factors mostly referred by purchasers in local commodity market are the presence of sunn pest damaged grains (%), barley grain contaminations (%), protein (%), energy value (Joule) and sedimentation (ml), thousands kernel weight (g) and hectoliter weight (kg) (Macca and Özberk, 2012; Özberk et al., 2005). Impact of khapra beetle deteriorated grains onto marketing price has not been assessed systematically in bread wheat. This study aimed to assess some physical traits, quality and marketing price of khapra beetle damaged grains under increasing larval infestations and various genotypes.

Material and methods

This laboratory experiment was carried out between 22 November 2017 and 29 April 2018 in the laboratory of department of field crops of Faculty of Agriculture in the University of Harran in Sanliurfa in Turkey. Ten advanced lines (Entry numbers of 2, 3, 4, 5, 6, 7, 8, 9, 10 and 13) from 35 th ESWYT (Elite Selection Wheat Yield Trial) 2014-15 (*Table 4*) were tested employing a split plot experimental design with three replications where larval infestation rates, i.e. 5, 10 and 15 and entries were assigned as main and subplots respectively. Losses in TKWs (g) (Uluoz, 1965), hectoliter weight (kg), sample weight (g) and marketing prices (cents kg^{-1}) were scored at 11.01.2018, 16.02.2018 and 29.03.2018 respectively. Except for marketing price scoring, all rest of experimental material (90 jars) was subjected to above analysis. At above given dates, first replication of experiment (30 jars) were presented to randomly selected 4 purchasers in local commodity market (as replications) for marketing price estimations holding on split plot experimental design. Initial marketing price estimations of all entries with non-damage grains were scored by presenting randomly selected 4 purchasers at the same commodity market employing randomized complete block design with 4 replications (purchasers). Some of grain quality analysis of entries at the beginning such as TKW (g) (Uluoz,1965), HLW (kg) (AACC 2000 method 55-10), protein (%) (AACC 2000 method 46-10.01), wet gluten (%) (AACC 2000 method 38-12.02), dry gluten (g) (AACC 2000 method 38-12.02), gluten index (%) (AACC 2000 method 38-12.02), grain hardness (kg m^{-2}) (AGW) and sedimentation (ml) (AACC 2000

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_61436153
© 2018, ALÖKI Kft., Budapest, Hungary

method 38-10.01) were both scored at the beginning and at the end of study and a paired 't' test was performed for statistical significance. Geometric means of weight loss and marketing price reductions due to increasing khapra beetle damage were calculated and rank stability performance of entries for weight loss and marketing price punishments were scored and graphical illustrations were drawn (Huen, 1990). JMP-5 statistical software was used for all types of analyses including graphics.

Implementations for laboratory trial

Larvae were grown in corn a month prior to study start day. Grain samples were subjected to high temperature (5 hours at 45 °C) to omit the possibility of early infestations. Relative humidity (RH) (%) after heat treatment was 10% for all experimental material. Nine samples (100 g grain in each) of healthy grains from each entry were placed into 250 mL glass jars. Then jars were covered by muslin cloth with rubber bunds. 5, 10 and 15 neonate khapra beetle larvae were put into 3 jars of each entry (replications). Jars were placed into incubator calibrated to 32±2 °C and 55±5% RH for 120 days. Damaging grains in each jar were subjected to sieving to isolate the grains dust and other residues prior to scoring for various traits. All larvae and pupae in jars were kept alive and returned to jars after scoring traits.

Results

Thousands kernel weights, hectoliter weights, sample weights and marketing prices

Above given characteristics for all entries were scored at the three consecutive dates of study. A split plot ANOVA for all traits was performed individually and the statistically significant components of variation excluding larval intensity x entries interactions were grouped through LSD (Least significant differences). Joint effects of major factors may result in complications in interpretations. Therefore this was avoided. Grain samples of all entries free from Khapra damage were presented to local purchasers for initial marketing price estimates and purchasers (replications) were non-significant ($F = 3.13^{ns}$ $p > 0.05$). Entries were found to be significant ($F = 3.38^{**}$ $p < 0.01$). Entries 8, 3 and 2 were at top three ranks giving 30.893, 30.806 and 30.675 cents kg^{-1} respectively. Average marketing price of all entries was 30.50 cents kg^{-1}.

First scoring date (10.01.2018)

Individual analysis of variance revealed that the response of entries against khapra beetle infestation for TKW, sample weights and marketing price were statistically significant giving $F = 77.36^{***}$ ($p < 0.001$), $F = 3.829^{**}$ ($p < 0.01$), $F = 16.97^{**}$ ($p < 0.01$) respectively (*Table 1*). No significant differences were found among larval infestation levels for TKW, HLW and sample weights. But this turned out to be significant for marketing price ($F = 46.05^{***}$, $p < 0.001$). Except HLW, CV's (%) for above given characteristics seemed to be reliable giving low values. A 13.28% CV for HLW was found to be higher than expected one. The means of statistically significant entries for TKW, sample weights and marketing price were grouped by LSD test. Entry number of 6, 8 and 7 ranked at top three giving 49.238, 44.988 and 44.539 g of TKW values. Entry numbers of 6, 8 and 10 for sample weight ranked at first three presenting none weight losses. Entry numbers of 3, 9, and 4 for marketing price placed at the first

three ranks giving 27.530, 27.504 and 27.496 cents kg^{-1} respectively. Larval infestations of 5, 10 and 15 for same characteristics gave 27.632, 26.965 and 26.376 cents kg^{-1}as expected.

Second scoring date (16.02.2018)

Individual analyses of variances (*Table 2*) were also performed for same traits given above. $F_{entries}$ turned out to be significant for all characteristics giving F = 53.57*** (p < 0.001), F = 5.87** (p < 0.01), F = 3.02** (p < 0.01) and F = 19.98** (p < 0.01) respectively. F values for larval infestation levels for all traits also turned out to be significant giving F = 20.94** (p < 0.01), F = 45.75*** (p < 0.001), F = 28.55** (p < 0.01) and F = 102.53*** (p < 0.001) respectively. CV's (%) for all traits under study were also quite low presenting reliability of the results. Entry numbers of 6, 8 and 9 for TKW ranked at top three giving 48.24, 43.53 and 43.50 g respectively. For HLW, entry numbers of 9, 5 and 4 placed at the first three ranks with 81.12, 81.06 and 80.95 kg respectively. For the sample weight, entry numbers of 10, 9 and 6 were the first three ranking entries with 99.08, 99.06 and 98.53 g presenting to be the least

affected genotypes from khapra beetle infestation. For the marketing price estimates, entry numbers of 1, 9 and 3 were the higher marketing price offer receiving genotypes with 26.910, 26.779 and 26.354 cents Kg^{-1} respectively. When the larval intensity increased from 5 to 15, TKW declined from 42.47 to 40.10 g, HLW from 81.62 to 78.25 kg, sample weight from 98.97 to 96.918 g and marketing price from 26.918 to 25.389 cents kg^{-1}.

Table 2. *Means and LS D groups of varieties and larval infestation levels for the TKW, HLW, weight loss and marketing price from 100 g of initial sample weight in second scoring date (16.02.2018)*

Third scoring date (29.03.2018)

Analysis of variance for each traits was performed (*Table 3*) and $F_{entries}$ and $F_{larval\ intensities}$ were all found to be significant giving either $p < 0.01$ or $p < 0.001$ significance. CV's (%) obtained from ANOVA's ranging from 1.307 to 3.47% indicated the reliability of the results. Entry numbers of 6, 9 and 8 were the first three ranking genotypes giving 46.66, 43.59 and 43.31 g of TKW's respectively. For the hectoliter weight, entries 5, 6 and 9 were the highest ranking entries giving 81.72, 81.19 and 80.03 kg respectively. For the sample weight, entry numbers of 9, 6 and 10 were the top ranking and least affected genotypes with 98.30, 98.28 and 97.86 g respectively. Finally

in marketing price, entries 9, 1 and 10 were found to be less affected genotypes from khapra beetle infestation giving 25.755, 24.792 and 24.450 cents kg^{-1} respectively. As the larval intensity increased from 5 to 15, TKW decreased from 42.95 to 39.43 g, HLW from 81.14 to 77.26 kg, sample weight from 98.68 to 94.18 g and marketing price from 25.542 to 22.803 cents kg^{-1} respectively.

Comparison of initial and final quality parameters

Some of the major quality traits of all entries scored as the average of three reads at the beginning and at the end of study were given in *Table 4*. For the final quality analysis, all three replicates of each infestation level were joined prior to analyzing quality. Statistical significance between grand means of various characteristics at the beginning and at the end of study was investigated through paired 't' test. Except grain hardness, grand mean differences for all scored traits were found to be significant. Final means were always lower than those of initials. In grain hardness, non-damaged kernels were employed for scoring both at the beginning and at the end of study. Final grand means for TKW (g), HLW (kg), protein content (%), wet gluten (%), dry gluten (g), gluten index (5) and sedimentation (ml) were significantly lower than those of initials.

Ranks stability analysis for sample weight and marketing price

A rank stability analysis for sample weight (*Fig. 1*) and marketing price (*Fig. 2*) was performed employing average rank and rank standard deviations of all entries. Entry numbers of 6, 10, 9 and 8 were the least weight loosing genotypes. Especially entry number of 6 had also lower standard deviation than grand mean of all standard deviations. Entry numbers of 9, 1, 3 and 10 were the highest marketing price offer receiving genotypes respectively. Entry numbers of 9, 1 and 10 were also found to be more stable than that of 3 with relatively lower standard deviation than that of grand mean of all entries. Geometric mean of weight loss during 120 days was 8 kg ton^{-1} and the loss was 32.7 kg ton^{-1} at the final scoring date. Ceiling marketing prices and grands mean of marketing prices of all entries at the scoring dates were given in *Figure 3*. Taking into account initial and final marketing prices and excluding parity loss of Turkish Lira against US Dollar, a 30.08 USD ton^{-1} genuine marketing price loss was detected for 120 days.

Discussion

Apart from initial and final scoring, TKW and HLW were scored regularly during the course of study. There was only 1.544 g reduction between grand means of all entries at the beginning (42.79 g) and that of at the end (41.246 g). Same trend was detected for HLW. There was only 1.46 kg decline at the beginning (80.96 kg) and at the end of study (79.45 kg). Özberk et al. (2017) obtained a 3.96 g reduction in TKW for 8 months in durum wheat. Weight loss of jars with 100 g of grain sample initially increased during the course of a 120 day period. Geometric mean of weight loss for study period was 8 kg ton^{-1} whereas at the final date, weight loss was 32.7 kg ton^{-1} (3.27%). Grand mean of weight loss in durum wheat was 4.075% in 8 months (Özberk et al., 2017). Varietal differences to khapra beetle infestation were detected for above given characteristics. Entry number of 6, 7, 8 and 9 for TKW and entry numbers of 6, 9 and 10 for HLW were the least affected genotypes. These results matched those of Ahmedani et al. (2009, 2011), Sayed et al. (2006) and Khattak et al. (2000). In which Mehran-89 and Wafaq-2001 were the least affected cultivars against khapra beetle infestation. Physio- chemical and biochemical structure of grains were proved to be properties for resistance mechanism (Warchalewski et al.,1993; Dobbie, 1991; Baker, 1986). The effects of larval intensities for all traits given above were significant. When the larval intensity increased, TKW, HLW and initial weight decreased confirming the results of Özberk et al. (2017), Ahmedani et al. (2011), Khattak et al. (2000) and Navarro et al. (1978). They proved the presence of high degree positive and significant correlations between progeny development vs. damage ratio and weight loss. Some of quality analysis such as wet (%), dry gluten (g), gluten index (%) and sedimentation (ml) at initial stage vs. final resulted in lower values for latter significantly. For the final analysis, all replications were joined to avoid any biased estimation. Non-significant grain hardness may be due to employment of only healthy grains for both scoring. Non-significant protein content (%) between initial vs. final seemed to be insect inclusion to flour and this results in some increase in protein (%). Marketing price estimations were received from randomly selected 4 purchasers (replications) at the local commodity market employing first replication of laboratory experiment. As shown by *Figure 3,* ceiling prices decreased gradually toward end of study due to the parity loss of Turkish Lira against US dollar (30.84 - 27.51 = 3.33 cents kg^{-1}). Whereas marketing price of khapra beetle infested grains reduced from 30.50 to 24.09 cents kg^{-1} for 120 days. A 6.41 cents kg^{-1} marketing price loss can be attributed to khapra infestation and parity loss. A 3.08 cents kg^{-1} marketing price loss (6.41- 3.33 cents kg^{-1}) was genuine due to khapra damage. This means a 30.8 USD ton^{-1} marketing price loss for 120 days. This was a 103 USD ton^{-1} for durum wheat in 8 months (Özberk et al., 2017).

Varietal differences to khapra beetle attack were genuine and entry numbers of 9, 1, 3 and 10 were the least marketing price loosing and stable genotypes. Increasing larval intensity reduced marketing price as detected by Özberk et al. (2017) in durum wheat. Economic loss of grain grower countries suffering Khapra beetle damage seem to be huge (Sayed et al., 2006; Ahmedani et al., 2007; Özberk et al., 2017). Hence, taking into account for zero tolerance trends of some countries such as Canada (Canada Grain Act, 1975) to stored grain insects, control measures and resistance mechanism of grains against Khapra beetle must be the focused of such researches.

Conclusions

It was concluded that even a short duration of storage such as 120 days, khapra beetle affected all quality parameters negatively and resulted in as much as 3.27% weight loss and a 30.8 USD ton^{-1} marketing price loss. The presence of varietal response to khapra beetle attack should also be stressed.

Acknowledgements. Many thanks for the purchasers (M. Satıs, B. Koc, H. Aslan, O. Gok, H. Salgu) in local commodity market for their help in marketing price estimates, K. Ayıkgoz for quality analysis and marketing price scoring, H. Ayhan for grain hardness analysis, D. Izol for larvae development, incubation and scoring. I declare my deep respects to I. Ozberk for his encouragement, comments, critics and helps for statistical analysis and M/s preparation.

(Received 6th Jul 2018; accepted 31st Aug 2018)

Abstract. The alterations in *F. graminearum* due to tetraconazole (TCZ) have been investigated in this study. The minimum inhibitory concentration (MIC), and inhibitory concentrations 50% and 25% (IC_{50} and IC_{25}) were obtained by adding different concentrations of TCZ to potato dextrose agar (PDA). MIC, IC_{50} and IC_{25} values were detected as 32, 16 and 8 µg/mL TCZ. Epigenetic changes have been evaluated via genomic template stability (GTS) by the RAPD and CRED-RA methods. GTS values were recorded as 86.73% and 85.71% in IC_{50} and IC_{25} sets. A total of 157 bands were obtained via RAPD. The average % polymorphism values of *HapII* and *MspI* digested samples were detected as 5.72 and 5.37 with 4.68 and 2.6% for IC_{25} and IC_{50} groups, respectively. The expression levels of genes related to apoptosis (*Hog1*), cell stability (*Mgv1*), oxidative stress (*POD*) and deoxynivalenol production (*tri5*) in the control and the experiment sets were investigated by qPCR. Increased concentrations of TCZ lead to upregulation in *Hog1, Mgv1* and *POD* genes whereas down regulation was recorded in *tri5* expression. The late apoptosis and oxidative stress were detected via the acridine orange-ethidium bromide (AoEb) and the DCF-DA staining assays. The findings showed that TCZ could lead to damage on phytopathogenic fungi at genomic, epigenetics, transcriptomics and apoptotic levels.
Keywords: *apoptosis, epigenetics, fungicide, genomic stability, oxidative stress*

Introduction

Fusarium graminearum species complex is a worldwide important phytopathogenic species. *F. graminearum* is predominating causal agent of fusarium head blight (FHB) disease in humid and semi-humid areas. The FHB results in destructive affects in fields related to economically important cereals such as wheat, barley and maize (Goswami and Kistler, 2005; Miedaner et al., 2008). Annual economic losses reach up to millions of dollars only in the USA and China (Lori et al., 2009; Matny, 2015). Epidemics result in products with reduced quality and quantity. Also, deoxynivalenol, zearalenone and some other minor mycotoxins contamination of cereals have been detected in the fields related to FHB worldwide (Miedaner et al., 2008; Pasquali et al., 2016). FHB and the related mycotoxins lead to several kinds of negative effects on human health and struggle with major agent of FHB*, F. graminearum,* is a preliminary step in disease management.

F. graminearum is a homothallic fungus with asexual (*F. graminearum*) and sexual (*Gibberella zeae*) stages (Kerényi et al., 2004). High levels of genotypic and morphological diversity have been reported for *F. graminearum*. 16 members for this species complex have been identified by the morphological and multiloci genotyping analysis (Aoki and O'Donnell, 1999; O'Donnell et al., 2004; Miedaner et al., 2008; Sarver et al., 2011; Przemieniecki et al., 2015). The species also shows high levels of variation in host, chemotype and aggressiveness worldwide (Pasquali and Migheli, 2014). These and some features of *F. graminearum* make it popular phytopathogen and also allow it to become a model organism in molecular plant pathology research area.

© 2018, ALÖKI Kft., Budapest, Hungary

The genome of *F. graminearum* PH-1 strain has been sequenced and annotated. Up to 14.000 genes are identified by bioinformatics analysis and comparative data for ESTs, DNA markers, gene clusters related to mycotoxin production or genes associated with secondary metabolite biosynthesis pathways have been well characterized (King et al., 2017). The knowledge on genome structure of *F. graminearum* shows that it would facilitate further molecular genetics studies about FHB.

Struggle with FHB and *F. graminearum* have been maintained by different approaches worldwide. The development of disease-resistant plant cultivars or genetically modified plants, the antagonistic microorganisms' usage and the fungicide treatment are currently the most popular strategies. However, the development of resistant plants or antagonistic microorganism usage have some possible disadvantages such as prolonged periods, laborious assays, non-cost-effective processes, low agronomic traits and poor results (Dal-Bello et al., 2002; Anand et al., 2003; Bai and Shaner, 2004; Bernardo et al., 2007). However, the usage of fungicides has become the most popular and the most effective strategy in fighting with FHB worldwide. Several common types of fungicides including benzimidazole class and demethylation inhibitors have been used in disease management worldwide. However, the fungicide application does not present successful results in the fields, where they have been used. Particularly, the antifungal resistant development has been reported for those chemical compounds in many regions of the world. The logic behind the poor results in disease management and fungicide resistance development have been related to high level of genetic diversity among the populations of *F. graminearum* species complex. The failure in fungicide application and fungicide resistance have been shown by genetic and phenotypic analysis. Isolates with MIC values higher than 10 µg/mL for azole derivatives have been detected in *F. graminearum* species complex isolates by the agar dilution technique. The point mutations in *β-tubulin* and *cyp51* genes leading to the fungicide resistance have been detected. Time management and climatic changes in agro-ecological regions where FHB present have also become related to failure related to fungucide application (Chung et al., 2008; Talas and McDonald, 2015; Qian et al., 2018; Yang et al., 2018). However, investigations associated with alterations in molecular levels in fungicide treated fungi could provide additional and extra point of view for disease management. In this study, it was aimed to detect the effects of tetraconazole (TCZ; one of the most common azole derivative used in disease management worldwide) on *F. graminearum* have been evaluated at epigenetics, transcriptomics and cellular levels by different approaches..

Materials and methods

Fungal material and phenotypic tests

F. graminearum H-11 strain which is isolated from the diseased rice sample was provided from Dr. Theresa Lee from Seoul National University (Lee et al., 2001). The experimental steps of this study were carried out in Turkey. The fungal control sets were grown on potato dextrose agar/broth (PDA/PDB) for 7 days at 26 ± 2 °C (PDA: Hi-Media, India) at controlled growth chamber (Nüve, Turkey). Experimental groups were grown on PDA/PDB amended with different concentrations of TCZ (2, 4, 8, 16 and 32 µg/mL) (Sigma, U.S.A.). The 0.25 cm^2 mycelial plugs were used for obtaining fresh cultures. Minimum inhibitory concentration (MIC), inhibitory concentration 50% and 25% (IC_{50} and IC_{25}) values were detected by the agar dilution technique and the

© 2018, ALÖKI Kft., Budapest, Hungary

linear growth rates (LGR) were calculated by the measurement of radial growth of fungal cultures as mm day^{-1} at 4th and 7th days of incubation.

Genomic DNA (gDNA) extraction, RAPD (random amplified polymorphic DNA) and CRED-RA (coupled restriction enzyme digestion-random amplification) analysis

gDNA was extracted from the 7-day-old *F. graminearum* cultures of experiment sets. 100 mg mycelia was homogenized with liquid nitrogen, sterile pestle and mortar. 500 µL of lysis buffer (100 mM Tris HCl, 100 mM EDTA, 1 M NaCl, 1% SDS and 1/500: v/v: β-mercaptaethanol) was added and the homogenization was completed. Then, the sodium dodecyl sulphate-based protocol was followed (Niu et al., 2008; Yörük et al., 2016). Qualitative and quantitative analyses were performed via 1% agarose gels and spectrophotometer (Thermo, U.S.A.).

RAPD and CRED-RA methods were used in the genomic template stability and epigenetic profiling of TCZ treated and non-treated *F. graminearum*. A routine RAPD protocol (Yörük and Albayrak, 2013) was used in GTS assays of non-digested control, *MspI*-digested, *HapII*-digested experiment sets by using thermal cycler (Hi-Media, India). The total of 20 RAPD primers were used in this study (*Table 1*).

gDNA digestion was carried out in 20 µL mixture including: 1X digestion buffer, 20 U of digestion enzyme (Takara, Japan) and 250 ng/µL gDNA. The incubation for digestion was carried out at 37 °C for 1 h in the thermal cycler. The digested (and also non-digested) samples were used in CRED-RA assays. PCR bands were

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

electrophoresed on 1.7% agarose gels and captured via UV light using a transilluminator (Hi-Media, India). The genomic template stability (GTS %) and the polymorphisms % for methylation was calculated as reported previously (Nardemir et al., 2015). The amplified bands were scored according to their presence (1) or absence (0). A similarity matrix and dendrogram were obtained from Nei-Li's coefficient (Nei and Li, 1979) and the unweighted pair group method with arithmetic average algorithm (UPGMA) by using MVSP 3.1 software, respectively.

Total RNA extraction and cDNA synthesis

Total RNA molecules were extracted using Tri-Pure reagent (Roche, Switzerland) from seven days old culture. 50 mg of mycelium was homogenized with 0.5 mL Tri-Prure reagent by using sterile mortar and pestle. The manufacturer's recommendations were then followed in the binding, washing and elution steps (Thermo, USA). The RNAs were evaluated as described as in gDNA analysis.

After RNA isolation, total RNAs were immediately converted to cDNA molecules. 2 µg total RNA was used as starting amount. cDNAs were obtained by using one step commercial kit (Takara, Japan) by using the thermal cycler. The manufacturer's recommendations about thermal cycling and reaction mixtures were used in cDNA synthesis. cDNA molecules cDNAs were diluted as ¼ for gene expression analysis and used in the qPCR (quantitative polymerase chain reaction; real time PCR) analysis.

Gene expression assays

qPCR assays were used in the expression analysis of the *Hog1* (apoptosis related putative MAP kinase; DQ065608.1), *Mgv1* (MAP kinase; AF492766.1), *POD* (peroxidase; XM_011329011.1) and *tri5* (Trichodiene synthase; EF661664.1) genes. The housekeeping gene was the *β-tubulin* (AY303689.1). Primers (*Table 2*) were designed via Primer 3 software and checked via the olygoanalyzer tool of the Integrated DNA Technologies.

Table 2. *Primers related to gene expression analysis used in this study*

In qPCR assays, the target gene expressions were normalized according to the housekeeping gene expression by using the $2^{-\Delta\Delta CT}$ formula (Livak and Schmittgen, 2001). The Cp (crossing point), ΔCT, ΔΔCT, $2^{-\Delta\Delta CT}$ values were recorded and calculated using the software provided by Roche LightCycler 480 II system (Roche, Switzerland). The one step Sybr Green I master mix kit (Takara, Japan) was used in qPCR assays. qPCRs were carried out in 12 µL reaction volume with 1X Sybr Green I mix, 0.5 pmol primers and 2 µL of cDNA corresponding to 0.5 µg total RNA. Cycling

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

conditions, standard dilutions of 4 log phases and the melting curve analysis were carried out as described by Yörük et al. (2018a). Experiments were replicated at least three times. Statistical analyses were performed via One Way ANOVA Analysis with Tukey's post-hoc test (GraphPad Prism 5.0, USA).

Acridine orange/ethidium bromide (AO/EB) fluorescent staining

The apoptotic and oxidative stress stemming from alteration in *F. graminearum* which is related to the TCZ treatment was evaluated via fluorescent microscopy. The determination early and/or late apoptosis and potential oxidative stress/reactive oxygen species (ROS) were investigated using Acridine Orange/Ethidium Bromide (AO/EB) and 2′,7′-Dichlorofluorescin diacetate (DCF-DA) staining, respectively. *F. graminearum* cultivated on PDB supplemented with TCZ (IC_{50} and IC_{25} concentrations) were used in the fluorescence detection.

In AO/EB dual staining assays, mycelia were obtained in 1X Phosphate buffered saline buffer (PBS) of 2 mL (Leiter et al., 2005). The mycelia were then fixed with 4% paraformaldehyde and 0.1% Triton X-100 at least 30 min at 25 °C. The cells were centrifuged at 14.000 rpm for 5 min. The cells were washed with 1.5 mL 1X PBS twice. 5 µL AO/EB (60 µg mL^{-1} / 100µg mL^{-1}) was added onto cells. The mixture was incubated at 25 °C for 5 min. After staining, the cells were washed with 1 mL of 1X PBS twice and then the cells were solved in 100 µL 1X PBS. Dual staining was managed with fluorescence microscope (Carl Zeiss, Germany) with green fluorescent protein (GFP; AO 502ex/526em nm, EB 510ex/595em nm) and Texas RED (595ex/613em nm).

In ROS detection assays, TCZ treated and non-treated cells were suspended in PDB including 5 µg/mL DCF-DA for 15 min. The cells were washed with 1X PBS and the fluorophore was excluded as mentioned above. ROS detection was carried out via the FITC filter (494ex/518em nm). The significant differences for fluorescence analysis were evaluated as described in qPCR assays.

Results

TCZ resistance

F. graminearum H-11 showed both mycelial and also conidial growth in PDA media supplemented with 2, 4, 8 and 16 µg/mL TCZ. MIC concentration was detected as 32 µg mL^{-1} TCZ. The IC_{50} and IC_{25} values were detected as 16 and 8 µg/mL TCZ. These concentrations of TCZ were used in the further analysis.

GTS and epigenetics profiles

The total of 20 primers were used in both RAPD and CRED-RA analysis. Three of these primers (OPA-04, OPA-05 and OPA-06) yielded no amplicon. Remaining 17 primer gave PCR bands in nine experiment sets comprising non-digested, *HapII*-digested and *MspI*-digested groups of TCZ untreated, TCZ treated with IC_{25} and TCZ treated with IC_{50} sets.

In GTS analysis, 108 bands were obtained from the non-digested sets of IC_{50}, IC_{25} and control groups by using 17 primers. The minimum and maximum band numbers were obtained from OPB19 with 3 bands and OPA07 with 13 bands (*Fig. 1*). The GTS values were detected as 86.73% and 85.71% for the IC_{25} and IC_{50} groups. These data

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_61556167
© 2018, ALÖKI Kft., Budapest, Hungary

showed that the TCZ treatment (with increased concentrations) lead to a potential decrease in genomic stability.

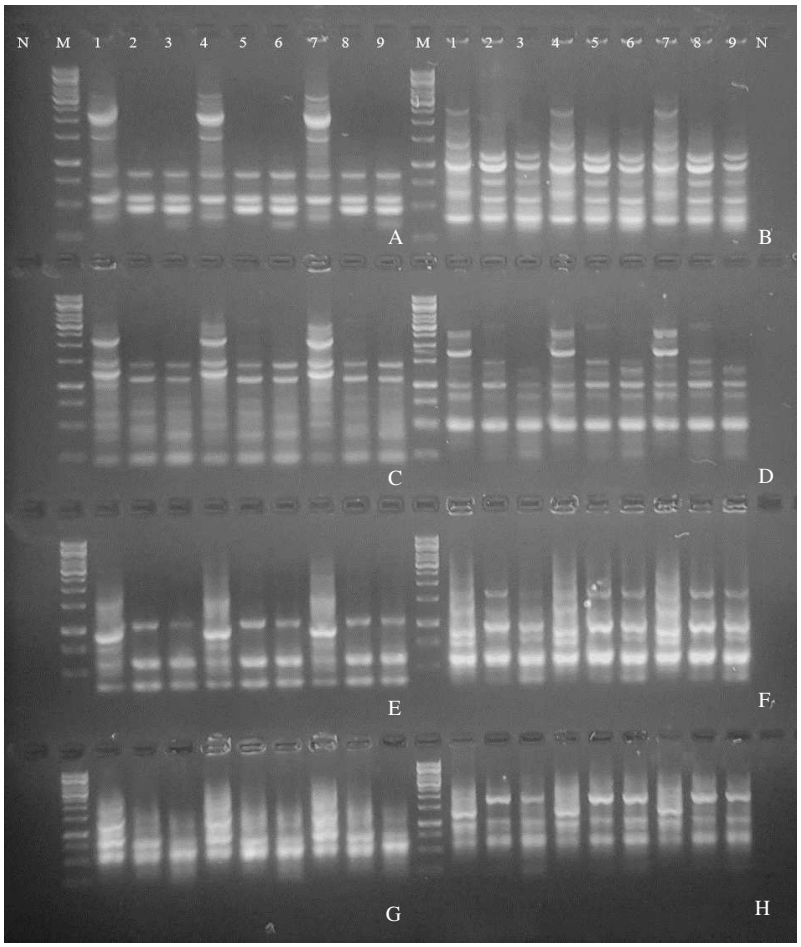

Figure 1. *RAPD and CRED-RA profiles obtained from primers OPA01 (A), OPA03 (B), OPA07 (C), OPA08 (D), OPA09 (E), OPA02 (F), OPA13 (G), and OPAC7 (H), M: 1 kb DNA ladder (Genemark, Taiwan), 1: control non-digested, 2: control HapII digested, 3: control MspI digested, 4: IC25 TCZ-treated non-digested, 5: IC25 TCZ-treated HapII digested, 6: IC25 TCZ-treated MspI digested, 7: IC50 TCZ-treated non-digested, 8: IC50 TCZ-treated HapII digested, 9: IC50 TCZ-treated MspI digested samples. N: no template control*

As well as in GTS analysis, 17 RAPD primers gave amplicon from each experiment set in CRED-RA analysis. Results showed that there were Type II and Type III epigenetics alterations due to TCZ treatment. The epigenetic alterations related to *HapII* and *MspI* digestion profiles of IC*50* and IC*25* groups were given in *Table 3*.

The average polymorphisms for epigenetic alterations were ranged from 2.6 to 5.72% for *HapII* and *MspI* analysis. Polymorphic changes based on epigenetics alterations were characterized by the band intensity and the loss or addition of a band. Additionally, the conventional band presence/absence analysis of Nei & Li's coefficient showed that the minimum and the maximum genetic similarity values were as 40.86% and 97.98% in nine experimental groups. Genetically the most similar samples were belonged to the same enzyme digestion or the non-digestion sets for each experimental sets (*Table 4*).

Gene expression analysis

cDNA molecules were converted from total RNAs of high quality and quantity and then used in qPCR. In qPCR analysis, mean E values and melting scores (important markers for efficient qPCR experiments) were in the ranges of 2 ± 0.2 and $90 \pm 10\%$,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

respectively. Minimum and maximum Cp values for the control and the experiment sets of *b-tubulin, Hog1*, *Mgv1, POD,* and *tri5* genes were as 19.86 and 26.174, 19.53 and 24.7, 21.61 and 27.1, 20.19 and 24.8 with 21.58 and 26.74, respectively. Fold changes in *Hog1*, *Mgv1, POD, tri5* expressions were recorded as 1.57 ± 0.13 ($p > 0.05$), 1.44 ± 0.28 ($p > 0.05$), 1.56 ± 0.27 ($p > 0.05$) and 0.32 ± 0.09 ($p < 0.001$) for IC_{25} set, respectively (*Fig. 2*). Similarly, these values for *Hog1*, *Mgv1, POD* and *tri5* genes were as 2.31 ± 0.55 ($p < 0.001$), 2.08 ± 0.33 ($p < 0.01$), 2.08 ± 0.33 ($p < 0.01$) and 0.033 ± 0.01 ($p < 0.001$) for IC_{50} set (*Fig. 2*). Significant changes in gene expression was found in each gene for IC_{50} sets where as only in *tri5* expression showed significant differences in IC_{25} set.

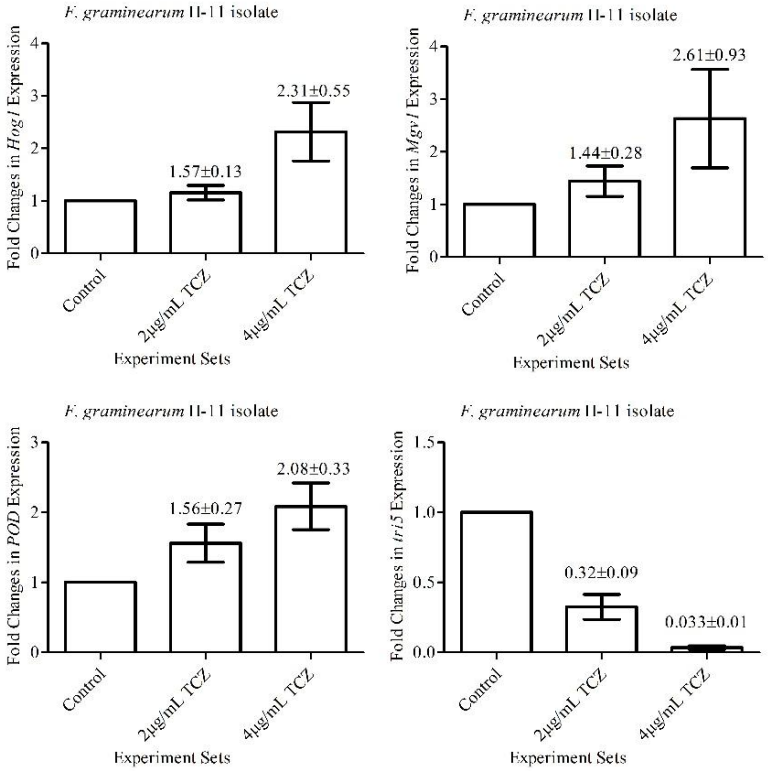

Figure 2. *qRTPCR data of four target genes in the control and two experiment sets*

Fluorescence staining analysis

The late apoptotic cells and the presence of oxidative stress were evaluated via the AoEb dual staining and the DCF-DA staining. In AoEb staining, both experiment sets showed apoptotic profiles while no yellow or orange painted cells were present in the control set. The fluorescence intensity of EB was higher (%50) than AO in the experiment sets. The healthy cell percentages in IC_{25} and IC_{50} groups were 86.38 ± 5.54 and 77.19 ± 9.91, respectively (*Fig. 3A, B*). Significant differences in apoptotic cell levels were detected for IC_{25} ($p < 0.05$) and IC_{50} ($p < 0.01$) experimental sets.

Similarly, control set showed no fluorescent dye effect whereas the ROS activity was detected in the IC_{25} and IC_{50} groups via the DCF-DA staining (*Fig. 3C, D*). The healthy cell percentages were detected as 79.25 ± 5.13 ($p < 0.01$) and 72.2 ± 3.81 ($p < 0.001$) in IC_{25} and IC_{50} experimental sets, respectively.

Discussion

The alterations due to the TCZ on *F. graminearum* was investigated at different molecular levels in this study. TCZ is one of the major fungicide worldwide for many phytopathogenic species (Cools and Hammond-Kosack, 2013). MIC value for *F. graminearum* was recorded as 32 µg/mL. It can be easily said that this level of fungicide could provide a powerful strategy to overcome the *F. graminearum* infections in the fields. Especially, if and when the MIC value is compared to the potential antifungal agents, the MIC values which could reach up to 1 mg/mL (Sefer et al., 2017; Yörük et al., 2018a), TCZ could be considered as a strong antimicrobial agent.

The common and powerful fungicides could lead to an antifungal resistance in the fields where they have been applied (Chung et al., 2008; Arif et al., 2009; Cools and Hammond-Kosack, 2013). The resistance to the common fungicides has been generally related to the genotypic variation, crop rotation, climatic conditions and some other characteristics related to the fungus and the host. However, the molecular basis has not been explained clearly and comprehensively. Responses of several phytopathogens to the specific antifungals have been investigated by several molecular genetics approaches such as the gene expression analysis, the oxidative stress and the apoptosis determination (Agus et al., 2018; Yörük et al., 2018a). However, those investigations present only limited data for antifungal resistance. In this study, the responses of *F. graminearum* to TCZ (which is harmful to the human health indirectly by feeding and drinking water supplies) have been evaluated at different molecular levels. The GTS and the CRED-RA analysis showed that this common antifungal could lead to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_61556167
© 2018, ALÖKI Kft., Budapest, Hungary

alterations at the genomic and epigenomics levels. The long-term usage of TCZ could lead to more changes in GTS which can be a sign of genotypic diversity. Additionally, the transposable elements movement could be triggered by TCZ usage. GTS changes could result in high level of genomic variations, might lead to differentiation of novel species complex members. However, this kind of a suggestion needs further investigation. Epigenetics alterations have also been detected in this study. These results could serve as the turn on/off genes which could have a critical role in the fungal life cycle. Genetic engineering based tools such as the gene silencing and the gene replacement analysis could be used in further studies to support these findings.

TCZ usage led to the significantly important changes in the gene expression in *F. graminearum*. Upregulation of *Hog1*, *Mgv1* and *POD* genes in TCZ treated experiment set showed that the TCZ application could result in apoptosis like cell death and oxidative stress. Similarly, significant decrease in *tri5* expression was detected in TCZ treated groups. Findings showed that TCZ could inhibit mycotoxin biosynthesis in addition to decrease in the fungal radial growth capacity. These genes or homologues have been used in different studies related to the apoptosis mechanism, downregulation of mycotoxin synthesis and the novel antifungal resistance etc. (Ponts et al., 2007; Sharon et al., 2009; Shlezinger, Goldfinger and Sharon, 2012; Sefer et al., 2017; Yörük et al., 2018b). However, in this study, it was claimed that the alterations in *Hog1*, *Mgv1*, *POD* and *tri5* genes could be used as markers in revealing the detailed antifungal effects of any specific chemical compound. These antifungal effects could include a programmed cell death, oxidative stress, toxin inhibition, an abiotic stress response etc. Oxidative stress and programmed cell death like processes were also verified by the fluorescence microscopy analysis. Ethidium bromide penetrates into the cells with lost integrity and stains the cell as orange to red (McGahon et al., 1995). Similarly, the cells subjected to oxidative stress turn into green since DCF-DA is rapidly oxidized with ROS, and turn into the fluorescent DCF dye (Jou et al., 2004). The TCZ treated experimental sets showed that yellow-tan and green colored profiles with AoEb and DCF-DA, respectively. Both gene expression analysis and cellular display assays showed that TCZ is a potential abiotic stress factor for *F. graminearum* at different molecular levels.

The investigation of the effects of this TCZ on *F. graminearum* at molecular levels would provide useful data for the studies related to phytopathology. *F. graminearum* is hemi-biotrophic fungus with an asexual and a sexual reproduction. The species is accepted as major causal agent of head blight and crown rot of some economically important cereals worldwide (Miedaner et al., 2008; Matny, 2015). This popular enemy of field crops seem to be lose the against TCZ or some other common fungicides in many regions of the world. However, since resistance to common antifungals could be improved in the coming years, molecular responses of phytopathogens to antifungals should be clearly investigated. In this study, it was shown that TCZ could lead to alterations in *F. graminearum* at different molecular processes. However, the effects of TCZ on plant tissue cultures and the mammalian cell cultures should also be investigated in further studies.

Conclusion

The struggle with *F. graminearum* diseases have different approaches including the fungicide treatment as the most common protocol. The resistance to common

antimicrobials has been known for many different microorganisms so far. In this study, it was shown that TCZ lead to mycelial growth inhibition, GTS changes, methylation alterations, oxidative stress and apoptosis like process. These changes at molecular processes could be responsible for the development of a resistance against common or specific antifungal compounds. However, further studies could include necrotrophic species, the plant tissue culture test, the mammalian cell culture tests, and genetic engineering confirmation etc. which also provide additional and supportive data related to plant pathology research area.

(Received 7th Jul 2018; accepted 31st Aug 2018)

Abstract. Agriculture in arid areas with inadequate water supply enquires the right cognition of evapotranspiration related to water application. In this research a single-cross hybrid of maize (S.C. 704), under the split plot experiment based on randomized complete block design was selected for cultivation in 2015 and 2016 years. The experimental treatments were set up in three planting dates: 21st April, 11th May and 31st May, and four irrigation regimes: I_{100} (100%), I_{80} (80%), I_{60} (60%) and I_{40} (40%) of the estimated evapotranspiration (ET). The results showed a drastic reduction by 44 to 49% in grain yield under low irrigation regime (I_{40}) compared with full irrigation regime (I_{100}), respectively. Irrigation water use efficiency based on grain yield (1.39 and 1.20 kg/m^3) and biological yield (4.79 and 4.53 kg/m^3) was the highest in I_{40} for each year, respectively. Corns planted earlier fulfilled silking-maturity duration faster than corns planted at the end of planting window as a result of reducing final yield potential. Under drought stress situation of this experiment it was shown that with long season hybrid, grain yield and irrigation efficiency can be improved by timely applications of planting dates and irrigation levels.
Keywords: *drought stress, evapotranspiration, grain yield, silking-maturity duration, water use efficiency*

Introduction

In many parts of the world where agriculture is important, crops usually encounter a large variation in water supply during their growing seasons. Thus water deficit is a major constraint to crop production, even in humid environments (Soltani and Sinclair, 2012). Corn biomass can be reduced with deficit irrigation and any loss in biomass can result in the final yield reduction. When water for irrigation is limited the goal should be integrated to maximize net income per unit water used rather than per land unit. Thus, the limited irrigation strategy meets this concept by establishing water economy as well as achieving efficiencies (Fereres and Soriano, 2007).

Many crops have lower yield in response to water stress at vegetative and reproductive stages. Deficit irrigation involves an appropriate scheduling of irrigation because crop sensitivity to water deficit changes with the phenological stages (Istanbulluoglu, 2009). Water stress affects crop growth and productivity in many ways. Most of the responses have negative effect on production but crops have different and often complex mechanisms against water scarcity (Kirda et al., 1999). Many results implied that crop water use efficiency was an intrinsic system sensitive to climate change. These findings indicated that crops had the resilience by adjusting water use

© 2018, ALÖKI Kft., Budapest, Hungary

efficiency (Zhang et al., 2015). Planting date analysis showed that a delayed planting date caused a decrease in average yield of 55% for the rainfed and 21% for the irrigated conditions for all hybrids (Soler et al., 2007).

Weather conditions that are optimal for maize production are likely to be less predictable in future due to variability in weather conditions and may have infrastructural effects on the stage of maturity at harvest (Blignaut et al., 2009). Manipulations that increase carbohydrate supply to developing grains during drought stress not only decrease abortion but can also increase grain yield (Morison et al., 2008). Anthesis-silking interval is a predictor of seed set in many maize cultivars when affected by stresses at flowering (Edmeades et al., 2000). Grain yield can be reduced by decreasing yield components like ear size, number of kernel per ear and kernel weight. Claassen and Shaw (1970) observed that water stress at silking stage and pollination process resulted in kernel number reduction, while stress during or after silking reduced kernel weight.

Whether or not, one of the confrontational challenges for us is how we can adapt the crop system processes to the future environmental changes. However the challenge still remains of low crop yield and sometimes crop failure due to poor choice of planting date. Thus with the aim of optimizing water and corn productivities in relevant to optimum ET maintenance, this research explores the key agronomic practices such as taking right planting dates and well-apprised water requirements at critical stages of corn growth cycle.

Materials and methods

Study area

The arid and semi-arid region of Karaj in Alborz province, Iran (35° 50’ N, 51° 0’ E, 1312 m a.s.l.) is demarcated as one of the most important area for both food and forage crops cultivation. Maize production is possible only under irrigated condition (*Fig. 1*). The average rainfall of this site is less than 250 mm per annum. Such diversity of geographical features plays a dominant role in determining the topography, climate and plant species present in the region.

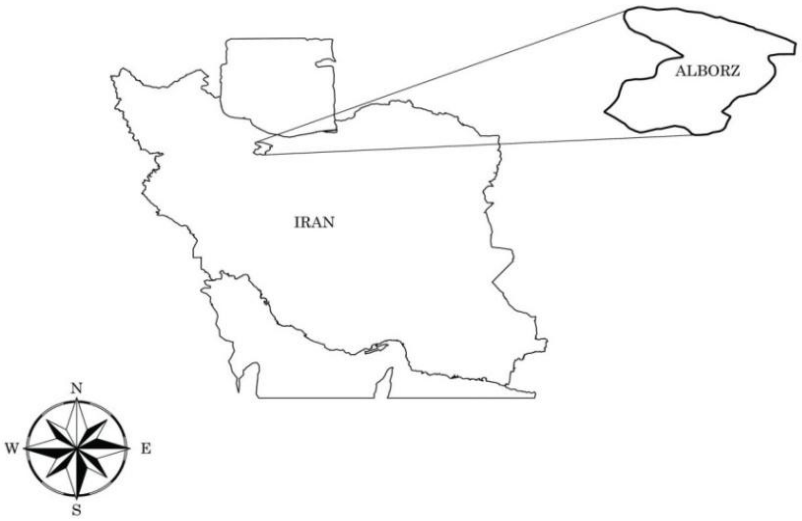

Figure 1. *Geographical location of Alborz province in Iran map*

Soil characteristics and agronomic management

Primarily the research field plowed and disked regularly to pulverize the clods. Thereafter, a Hiller-Furrower was employed to create planting furrows in the seedbed. According to the United States Department of Agriculture classification (USDA), the territory soil of the site is classified as a Typic Haplocambid (Mirkhani et al., 2010). The soil samples were tested for some physical and chemical compositions in both successive years (*Table 1*). The soil texture was determined as clay loam throughout the experiment.

Table 1. *Some physical and chemical compositions of soil in the experimental site*

Year	Soil depth	EC (ds/m)	Sp (%)	pH	N (%)	P (mg/kg)	K (mg/kg)	O.C. (%)
2015-16	0-30	2.53	39.8	8.3	0.08	6.3	203	0.71
2016-17	0-30	1.58	38.2	8.5	0.09	7.0	207	0.75

The field of research site was arranged in three blocks of 12 plots each, with an even space between them so that each plot involved six rows of 5 m in length and 75 cm spacing apart. After testing the seeds with fungicide (Tebuconazole), applying dry method, three-four seeds spaced in created grooves on the top of the furrows. The plots were kept weed-free by hand weeding and Rotavator applying between rows. Nitrogen application in the form of urea at a rate of 150 kg/ha, top-dressed at two stages of corn life cycle. Ultimately, thinning at five-leaf stage of seedlings was down up to a final density of 8 plants per square meter.

Experimental layout and crop assessment

The field experiments took place in the research farm of the College of Agriculture and Natural Resources, University of Tehran, located in Karaj, Iran (35° 48' N, 50° 57' E, 1293 m a.s.l.). The split-plot experiment based on a randomized complete block design with three replicates carried out in 2015-16 and 2016-17 cropping seasons. The experimental treatments in three planting dates in main plots were scheduled for 21st April, 11th May and 31st May, and four irrigation levels consisting of 100%, 80%, 60% and 40% of (ET) in sub plots were summarized as I_{100}, I_{80}, I_{60} and I_{40}. The amount of evaporated water through transpiration was estimated by *Equation 1* (FAO, 1977).

$$ET_c = K_c \times ET_o \quad \text{(Eq.1)}$$

where, ET_c is crop evapotranspiration (mm/d), ET_0 is reference evapotranspiration (mm/d) and K_c is crop coefficient. The calculation of ET_0 was determined in mm by recording weekly evaporation data obtained from the class A evaporation pan, located in synoptic weather station of Karaj. The amount of water evaporated during a period corresponds with the decrease in water depth of the pan in that period. On the basis of FAO Penman-Monteith Method, K_c values (0.3, 1.2 and 0.3-0.6) for three corn growth stages were defined as $K_{c\ ini}$, $K_{c\ mid}$, and $K_{c\ end}$, under the given condition (Allen et al., 1998). Water requirements for individual plots measured in gallon weekly then converted to liter per week. The final volume of water application for irrigating each plot was computed using *Equation 2:*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_61696180
© 2018, ALÖKI Kft., Budapest, Hungary

$$In = \frac{0.623 \times A \times Kc \times ET0}{IE} \quad \text{(Eq.2)}$$

where, I_n denotes the volume of irrigation water in gallons per week, 0.623 is the equation constant, A stands for plot area (sq. ft.), Kc represents crop coefficient, ET_0 is the reference evapotranspiration in (mm) per day. IE at the rate of 80 percent is the indicator of irrigation efficiency that finally expressed in decimal i.e. (0.80) (Howell, 2003). The total of irrigation volumes that computed for two consecutive years are presented in the following timetable (*Table 2*). All plots were irrigated uniformly until the plants were completely established. The irrigation treatments started when the plants were at the 6-7 leaf growth stage using water flow meter.

Table 2. *The weekly reference evapotranspiration (ET_o) and water volumes applied after starting irrigation regimes*

Year	Total weekly ET_0 (mm)	Number of irrigations	Total water volume applied for irrigation regimes (m^3/ha)			
			I_{100}	I_{80}	I_{60}	I_{40}
2015-16	27.1	7	7482	5986	4489	2993
2016-17	29.5	8	7490	5992	4494	2996

When the ears were at full physiological maturity stage with an evident black layer of the grains, whole plants from two adjacent rows in each plot including ears were harvested near the ground level to determine total dry matter. The plants separated into leaf, stem and ear fractions. Then leaf and stem samples separately put into a labeled paper bag and were placed in a dehydrator to dry at 75 °C until constant mass. For grain yield, 10 plants from the remaining half-plot were harvested and measured for weight of ears per plant and number of grains per ear. Finally, irrigation water use efficiency (IWUE) based either on grain yield (GY) or biological yield (BY) was calculated by *Equations 3* and *4:*

$$IWUE = (GY/I) \quad \text{(Eq.3)}$$

$$IWUE = (BY/I) \quad \text{(Eq.4)}$$

where, GY is grain yield (kg/ha), BY is biological yield (kg/ha), and I is the amount of applied irrigation water (m^3). It is important to emphasize, in the case of precipitation the amount of added water to the evaporation pan was measured daily during pan readings to account for estimating reference evapotranspiration. Also harvest index (HI) estimated by the ratio of harvested grains to total shoot dry matter by *Equation 5:*

$$HI = (GY/BY) \times 100 \quad \text{(Eq.5)}$$

Statistical analysis

average of the maximum (T-Max) and minimum (T-Min) temperatures (°C) for the day, minus the base temperature (T-Base) which is established as 10 °C for corn development. T-Max and T-Min are limited to 30 °C and 10 °C, respectively. All tables and graphs were designed by excel software. Significant differences among means were compared by Duncan's multiple range test.

Results

Weather conditions during corn life cycle

The maximum and minimum air temperatures, rainfall and relative humidity data were prepared based on Karaj auto weather station reports in the vicinity of the research site. The seasonal maximum and minimum air temperatures were approximately the same for both cropping seasons (*Fig. 2*). The total rainfall of 12.1 mm in 2016-17, was remarkably less than of 33.5 mm which mainly occurred in April during 2015-16. Therefore, due to more rainfall and wetter condition in 2015-16, the number of irrigations and the rates of estimated water volume in various irrigation regimes in 2016-17 were slightly greater than in 2015-16.

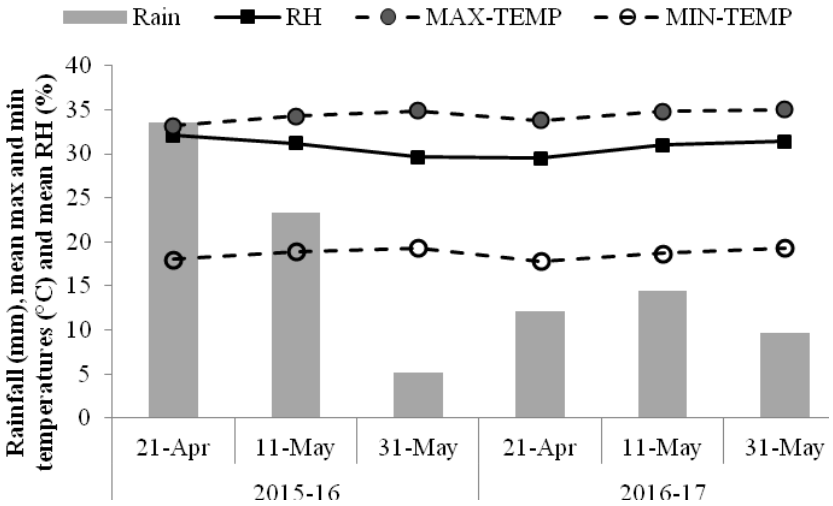

Figure 2. *Seasonal average of climatic data during corn maturity in 2015-16 and 2016-17*

Silking-maturity interval across various planting dates

Silking-maturity interval varies when crops are planted either early or late. Grain yield is in direct contact with kernel weight and GDD requirements. As planting delays, temperature and radiation levels become increasingly critical for yield determination. Hence, if corn is stressed during silking to maturity period, inadequate GDD levels can form prematurely preventing additional dry matter accumulation (*Table 3*).

Corn growth stage development can vary according to planting date. An early-planting corn may develop through growth stages slower than a late-planting corn. However, apart from early or late planting date, there is a transition between silking to physiological maturity time during which kernels are filled. In addressing the results of *Table 3,* silking to maturity duration by late-planted corns occurred at a slower pace (42 and 43 days) after the accumulation of 684 and 621 GDDs in each year, respectively

(*Fig. 3*). In contrast, early-planted corns with longer vegetative growth stage fulfilled silking to maturity period rapidly (40 and 39 days) after the accumulation of 739 and 711 GDDs in both years, respectively (*Fig. 4*).

Mean comparisons and significance level of interactions

As planting date (PD) delayed and water amount restricted from non-stress treatment (I_{100}) to full-stress treatment (I_{40}), there was a drastic reduction by 44 and 49% in GY during both 2015-16 and 2016-17, respectively (*Tables 4* and *5*). However the reduction of GY in response to late-planting date was more evident in the second year. Incidentally, the same tragedy occurred with BY which made a reduction by 17 and 22% in I_{40} compared to I_{100} in both years, respectively. There was also a decrement in the range of 32 to 35% for harvest index (HI) against irrigation levels in both years, respectively.

Irrigation water use efficiency (IWUE) at high irrigation level (I_{100}), was the lowest and at low irrigation level (I_{40}), was the highest. In consequence, the highest values of $IWUE_{GY}$ (1.39 and 1.20 kg/m^3) and the greatest values of $IWUE_{BY}$ (4.79 and 4.53 kg/m^3) were recorded at I_{40} compared with I_{100} in both years, respectively. Early-planting date was prominent for holding the highest values of each trait except kernel abortion.

Effect of water variability and planting date on grain yield

Planting dates and irrigation levels interaction (PD × IR) had significant effect ($p < 0.01$) on grain yield (GY) in 2016-17 (*Fig. 5*). Corns that planted later under effect of limiting factors such as drought stress, poor levels of radiation as well as irrepressible changes in temperature and assimilate supply, formed kernels poor in size and quality. Whereas, early-planting corns (PD_1), produced more nutrient levels than PD_2 or PD_3 in exchange of full water application of 100% ET_c. Consequential effects of these responses can find in bigger kernels which have been set during grain-fill stage as a result of grater final yield potential.

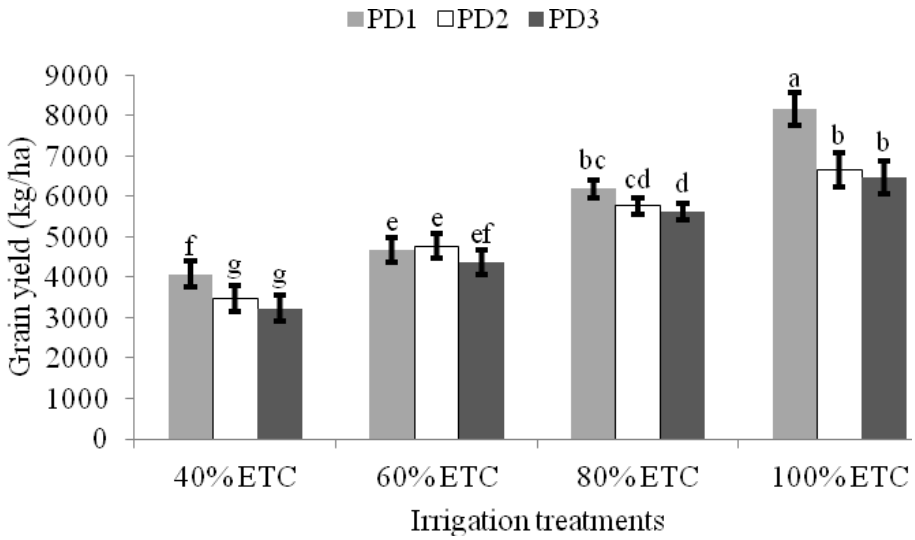

***Figure 5**. The interaction of planting dates and irrigation levels on grain yield in 2016-17. Different letters indicate significant difference ($p < 0.01$) based on DMRT test*

ET- function and management considerations of relevance

The effects of the various weather conditions are incorporated into the reference evapotranspiration (ET_0) estimates. ET_0 represents an index of climate demand and K_c varies, predominately with the specific crop characteristics and only to a limited extends with climate (Allen et al., 1998). In particular, crop ET demand can vary according to the location, time of planting, soil texture and corn growth period. The values of ET_0 and ET_c were quite low at the initial period due to the less evaporation from the soil and plant surfaces and subsequently from transpiration through stomata in the early of the corn life cycle. Initially, the ET_c values virtually followed constant trend at low fixed rates of K_c (0.3), then peaked at 70-80 days after planting at the higher K_c ranges (1.2 and 0.6) in mid and last terms of corn life cycle, respectively (*Fig. 6*).

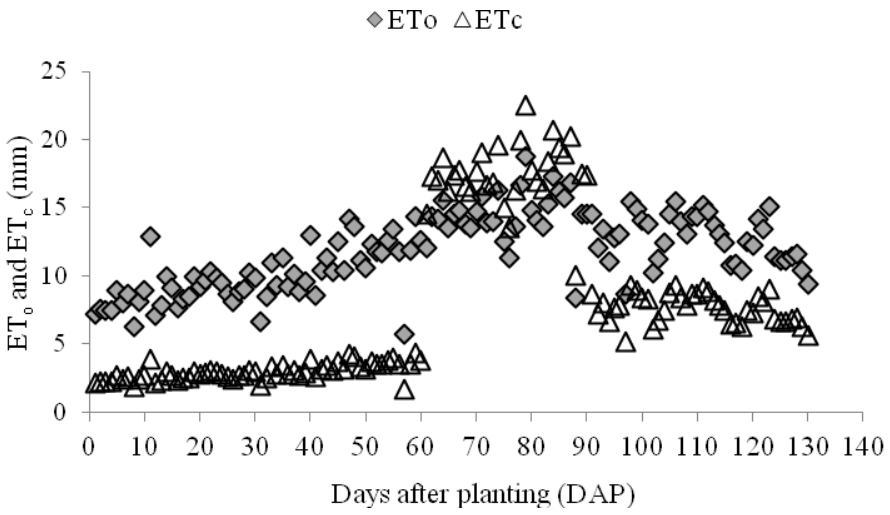

Figure 6. *Reference and crop ET estimations based on FAO (K_c) during corn maturity as a function of days after planting. ET_0 is a climatic parameter expressing the evaporation power of the atmosphere; ET_c refers to the evaporative demand from crops that are grown under the given climatic conditions*

Crop ET-value was the highest at silking stage (R1) which occurred around 80-82 days after planting (*Fig. 7*).

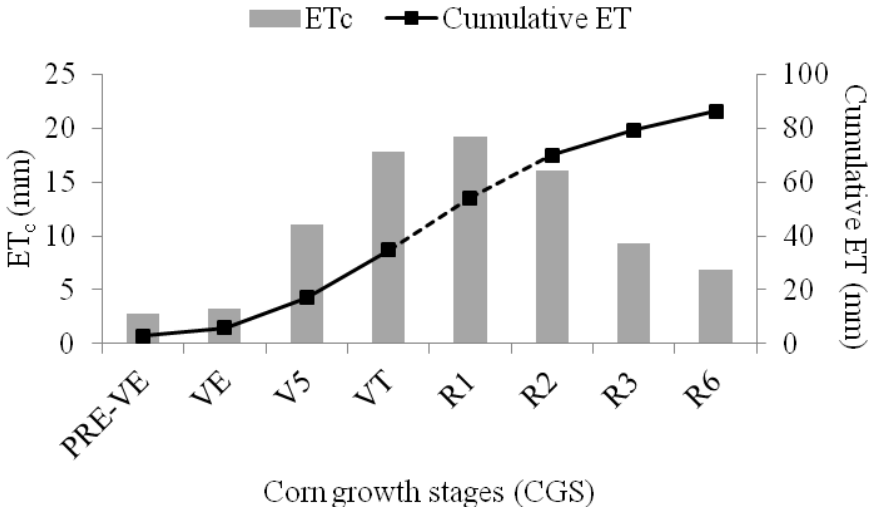

Figure 7. *Crop ET and cumulative ET (mm) variations in different corn growth stages, the dotted part represents the most critical time to water stress. PRE-VE = Pre emergence, VE = Emergence, V5 = Fifth leaf visibility, VT = Tasseling stage, R1 = Silking stage, R2 = Beginning grain fill, R3 = Milk stage and R6 = Physiological maturity*

Regionally when irrigation applied in the common rate of ET demand, grain yield reduction is not directly related to ET and biomass reduction. When ET demand cumulatively increases from what is needed for crop longevity and substantially deficit irrigation occurs below the optimum ET level, it can be more devastating at tassel to grain-fill stage (VT to R2). Although overall grain yield will decline as biomass

© 2018, ALÖKI Kft., Budapest, Hungary

declines, effective deficit irrigation management can allow corn water stress to be managed so that HI does not decline. For this reason, planting corn early in the season with sufficient water supply in the soil and less water loss by evaporation can avoid irrigations which are surplus to requirements. In this experiment, irrigation efficiency based on GY was improved by 23% and 16% in PD_1 compared to PD_3 for both years, respectively. These results underlined the advantage of water management at certain growth stages to minimize corn negative physiological responses.

Discussion

Based on the findings, the effect of deficit irrigation on GY was greater than on total biomass, as reflected in low HI under deficit irrigation treatments. Our observation corroborated by those of (Payero et al., 2009; Chaichi et al., 2015). According to Fereres and Soriano (2007), as biomass production is tightly associated with ET, it represents that in the case of deficit irrigation plant capability in converting per unit of water to biomass will be improved through transpiration due to the proximity of wetter condition and cooler temperatures in the early of the growing season. Early-planted corns via earlier shading of soil surface with unrestricted accessibility to water resources have higher irrigation efficiency. In contrast late-planted corns due to loss of moisture increasingly below the optimum ET level and less demand for assimilate; produce smaller grains in relation to per mm of water application. Lower GYs were largely occurred as total biomass and harvest index decreased with delayed plantings (Tsimba et al., 2013). Instead, in cereals it may also result in beneficial redistribution of assimilate from storage to developing grains to increase HI under scarcer water condition (Yang et al., 2002). In spite of improving irrigation efficiency with water deficit in this experiment, AL-Kaisi and Xinhua (2003) reported that drought stress reduced the water use efficiency for the production of biological yield but somewhat increased it for the production of economical yield in maize. In general, there is not inordinate demand for water during corn developmental stages due to proximity of rainy season and minimal weed competition in the early stage of corn life cycle. As plant population increase, an early-planting date becomes more important. Thus in a water-limited situation, planting long duration hybrids early in the season when the cumulative seasonal ET demand is low induced less yield penalty (Tsimba et al., 2013). Based on the soil type and ET demand, avoiding water stress around two weeks prior to pollination entering into two weeks after silking, can assure economical yields as a result of better seed set and less barren tips. The results obtained are in agreement with the ex-reports (Doorenbos and Kassam, 1979; Hatfield et al., 2015). Vegetative growth is strongly affected by water stress at different developmental stages. Short-duration irrigations during the rapid vegetative growth period caused 28 to 32% loss of final dry matter weight (Cakir, 2004). Fundamentally, GDDs are used to account for corn growth relative to temperature. Normally, corn requires approximately 600 to 800 GDDs to accomplish silking to maturity period. If unfavorable conditions exist it may take more time for late-planted corns to achieve this period with less GDDs accumulation than early-planted corns. Additionally, as planting delayed, radiation abatement and low GDDs accumulation became increasingly critical for kernels setting. Water stress during this time can delay silking, reduce pollination and lead to kernel abortion. These remarks compared with those who addressed silking to pollen shed or anthesis-silking

interval responses to water stress (Herrero and Johnson, 1981; Westgate, 1994; Bolaños and Edmeades, 1996).

Conclusion

In conclusion, when corn planting occurs later in the season the source-sink limitations can avert loading and substantially grain yield losses in response to drought stress. Instead, corns that are planted earlier in the season tend to develop more gradually under more abundant of water supplies with definite number of GDDs accumulation. Reasons for this can help greater overall productivity with early-planting date. In the case of being in trouble for water supply, early planting date via holding optimum ET level and accelerating silking to maturity interval can avoid irrigations that are surplus to requirements. The irrigation water use efficiency and overall productivity of corn in this research improved through the assignment of early-planting date and deficit irrigation to the environmental and crop physiological limitations. Consequently, shifting planting date from common-planting date (PD_2) to an earlier date as well as deficit irrigation were integrated as the best adaptive strategies for Iran climate and other regions in the world with high evaporative ranges. Other adaptation strategy can prioritize by producer to select diverse hybrids of maize with high drought tolerance ratings.

GENOME-WIDE IDENTIFICATION AND CHARACTERIZATION OF THE SBP GENE FAMILY IN *EUCALYPTUS GRANDIS*

BUYUK, I.

Department of Biology, Faculty of Science, Ankara University, Ankara, Turkey
(e-mail: buyuki@ankara.edu.tr; phone: +90-312-212-6720 (1390); fax: +90-312-223-2395)

(Received 9th Jul 2018; accepted 6th Sep 2018)

Abstract. SQUAMOSA promoter binding proteins (SBP) are a group of plant transcription factor (TF) families that play an important role in plant development and defence response. Genome-wide investigations of *SBP* genes have been carried out in many plant species, however this is the first comprehensive report on the identification and characterization of *SBP* genes in *Eucalyptus grandis* (*E. grandis*). According to the results herein, 16 *SBP* genes from *E. grandis* were identified and SBP proteins were clustered in eight clades. 16 *SBP* genes were presented to distribute 7 out of 11 chromosomes and three segmental duplicated gene couple were found throughout the entire genome of *E. grandis*. A total of 15 conserved motifs were described and 3 out of 15 were found to be conserved among all Egrandis_SBP proteins, due to forming of SBP domain which is essential for the function of SBP proteins. Gene structures of all *Egrandis_SBP* genes were investigated and the estimated number of exons among all genes extended from 2 to 11. According to the synteny analysis, it was seen that homologs of *E. grandis* genes were found in corresponding syntenic blocks of *Arabidopsis thaliana* and *Vitis vinifera*. Digital gene expression analyses showed that most of the *Egrandis_SBP* genes were highly expressed in shoot tips, young leaf, xylem, mature leaf, immature xylem and phloem tissues of *E. grandis*. Taken all together, the results of this study will provide an important source for literature and further works.
Keywords: *bioinformatic approach, phylogeny, RNAseq, digital gene expression*

Introduction

Squamosa promotor binding proteins (SBPs) are transcription factor (TF) genes that are only found in plants, their presence have not been verified in animals and prokaryotic organisms thus far (Klein et al., 1996; Hou et al., 2013). One common feature in members of the SBP TF family is the presence of 76 aa DNA-binding domain which have been called: SBP domain containing two zinc fingers (Cys-Cys-His-Cys and Cys-Cys-Cys-His) (Klein et al., 1996; Yamasaki et al., 2004; Pan et al., 2017).

They were first discovered in *Antirrhinum majus* (Klein et al., 1996) and their first comprehensive characterization was performed in *A. thaliana* (Cardon et al., 1997) in order to explore their exact function in plants. Like all TFs that have been discovered up to date, SBP proteins were indicated to play crucial roles in the expressional regulation of genes that are involved in many important processes related to plant development and defence response (Unte et al., 2003; Zhang et al., 2007; Wu and Poethig, 2006).

Genome-wide characterization and expression studies of *SBP* genes have been conducted on a number of plant species including *Betula pendula, Chlamydomonas, Oryza sativa, Zea mays, Populus trichocarpa, Lycopersicon esculentum* L.*, Malus* × *domestica* Borkh., *Salvia miltiorrhiza, Gossypium hirsutum, Arachis hypogaea* L., *Petunia*, *Capsicum annuum* L., and *Phyllostachys edulis* (Chuck et al., 2010; Kropat et al., 2005; Lannenpaa et al., 2004; Li et al., 2013, 2016; Lu et al., 2011; Pan et al., 2017; Preston et al., 2016; Salinas et al., 2012; Xie et al., 2006; Zhang et al., 2016, 2014; Zhang et al., 2015). Nonetheless, the SBP proteins in *Eucalyptus grandis,* a tall forest tree in the *Myrtaceae* known as the flooded gum or rose gum, have not been identified and characterized despite the fact its genome was sequenced in 2014 (Myburg et al., 2014).

Eucalyptus grandis (*E. grandis*) is a plantation crop which spreads widely in tropics and subtropics areas. It is commonly found in nature in Australia, and it is considered an important plant for plant scientist because, of its extreme ability to adapt to both climate and soil (Robinson et al., 2006). Moreover, there is a wide range of uses for *E. grandis* in farm; specialty products (flowers generate nectar for honey production), urban (used for ornamental purposes), wildlife value (its flowers attracts birds) and wood products including: pulpwood, boat building, boxes, flooring, heavy construction, fuelwood, industrial charcoal, panelling and timber for furniture etc (dos Santos et al., 2004; Nautiyal and Couto, 1984; Hardie and Wood, 1973; Dye, 2013).

Due to its importance in a wide range of use for the industry, and its ability to adapt to extreme soil and climate conditions, our aim was to identify and characterize SBP proteins in *E. grandis* which are important TF family for the plant developmental processes. Accordingly, 16 Egrandis_SBP members were identified and comprehensive analyses of the sequence phylogeny, genomic organization, exon-intron region of gene, conserved protein motifs, gene duplication events, and expression analysis were performed.

Materials and methods

Identification of SBP genes in E. grandis genome

E. grandis of SBP protein sequences were retrieved from Phytozome database v12.1 (www.phytozome.net) using keywords in the search with Pfam Accession Number (PF03110) obtained from Pfam Database (http://pfam.xfam.org). BLASTP and BLASTX searches (National Center for Biotechnology Information [NCBI]: http://www.ncbi.nlm.nih.gov) were used to confirm Egrandis_SBP proteins. Non-redundant sequences were obtained using decrease redundancy tool (http://web.expasy.org/decrease_redundancy/). SBP domains in non-redundant sequences were checked by HMMER (http://www.ebi.ac.uk). The solid and chemical traits of SBP proteins in *E. grandis* were identified using the ProtParam tools (http://web.expasy.org/protparam/) such as: the theoretical isoelectric point (pI), number of amino acids, and molecular weight (Da).

Phylogenetic analysis, physical location, conserved motifs of Egrandis_SBP genes, gene structure and gene duplication events

Chromosomal locations and CDS sizes (bp) were identified by using Phytozome database v12.1. The *Egrandis_SBP* genes were mapped with MapChart (Voorrips, 2002). Multiple sequence alignment of aminoacid sequences of Egrandis_SBP proteins was conducted with ClustalW Phylogenetic analysis were performed using MEGA v7 (Tamura et al., 2013; Buyuk and Aras, 2016) and Neighbor-joining (NJ) algorithm with 1000 replicated-bootstrap value.

Egrandis_SBP protein sequences of the conserved motifs were identified using MEME (Multiple Expectation Maximization for Motif Elucidation; http://meme-suite.org/) (Bailey et al., 2006; Buyuk et al., 2016; Inal et al., 2017; Ilhan et al., 2018). The limits for maximum number of motifs and minimum/maximum width were adjusted to; 20 and 2, 50, respectively. Motif sites were among 2 and 300. Site distribution was set as any number of repetitions. The described conserved motifs were examined in InterProscan with default adjusting (Quevillon et al., 2005).

DOI: http://dx.doi.org/10.15666/aeer/1605_61816193
© 2018, ALÖKI Kft., Budapest, Hungary

Gene Structure Display Server program tool (GSDS; http://gsds.cbi.pku.edu.cn/) was used (Guo et al., 2007) to predict the exon/intron organization of the *Egrandis_SBP* genes. Genomic DNA sequences and coding sequences of *Egrandis_SBP* genes were utilized.

Segmental duplicate gene pairs were examined on the Plant Genome Duplication Database server (http://chibba.agtec.uga.edu/duplication/index/locus), with a display range of 100 kb. The nonsynonymous rates (Ka), synonymous rates (Ks) and developmental constraints (Ka/Ks) with the duplicated pairs of *Egrandis_SBP*s were evaluated using CODEML program in PAML (Yang, 2007).

Synteny analysis

E. grandis and *A. thaliana*, *E. grandis* and *V. vinifera* of orthologue *SBP* genes were identified with Plant Genome Duplication Database (PGDD; http://chibba.agtec.uga.edu/duplication/) (Lee et al., 2013). Then, the protein sequences of orthologue were retrieved from Phytozome v12.1. The obtained synteny map was created using iTAK - Plant Transcription factor & Protein Kinase Identifier and Classifier (http://itak.feilab.net/cgi-bin/itak/index.cgi) (Zheng et al., 2016).

Gene expression analysis in silico

The expression levels of *Egrandis_SBP* genes were examined in special tissue libraries of plants at different stages of; shoot tips, young leaf, xylem, mature leaf, immature xylem and phloem. They were retrieved from Phytozome Database v12.1 (http://phytozome.jgi.doe.gov/pz/portal.html#!info?alias=Org_Pvulgaris). FPKM (expected number of fragments per kilobase of transcript sequence per millions base pairs sequenced) units were used for the expression levels in silico. FPKM values were log2 transformed and the heatmap was produced with the algorithm CIMMiner (http://discover.nci.nih.gov/cimminer).

Results and discussion

Identification of SBP gene family in E. grandis

Sequences of *SBP* proteins in the *E. grandis* genome were downloaded from Phytozome database v12.1 (www.phytozome.net) using keywords in the search with Pfam Accession Number (PF03110) retrieved from Pfam Database (http://pfam.xfam.org/). Subsequently, SBP domains were analyzed by performing a search in the HMMER and Pfam databases in candidate Egrandis_SBP proteins, and the redundant sequences were discarded after obtaining confirmation. A total of 16 candidate *SBP* genes in *E. grandis* genome were discovered and given in *Table 1* which includes information about chromosomal location, amino acid (length), molecular weight, number of isoelectric point (pI) and instability index.

As shown in *Table 1* and *Figure 1*, all of the non-redundant *Egrandis_SBP* genes were distributed on 7 out of 11 chromosomes of *E. grandis*. While the lowest number of *Egrandis_SBP* genes was observed on chromosome 4 (one *Egrandis_SBP* gene), the highest number was found on chromosome 11 (4 *Egrandis_SBP* genes) (*Fig. 1*). The length of Egrandis_SBP proteins extended from 147 (Egrandis_SBP_8) to 1078 (Egrandis_SBP_10) amino acids (aa). PI values of Egrandis_SBP proteins were among 5.77 (Egrandis_SBP_9) and 9.50 (Egrandis_SBP_5) ranging from acidic to alkaline

while the molecular weight of Egrandis_SBPs was between 21.277 kDa (Egrandis_SBP_11) and 119.285 kDa (Egrandis_SBP_10) (*Table 1*). SBP, which is a plant specific transcription gene family, was detected and classified in various species thus far, such species include: *A. thaliana* (Rhoades et al., 2002), *Orzya sativa* (Xie et al., 2006), *Lycopersicon esculentum L.* (Salinas et al., 2012), *V. vinifera* (Hou et al., 2013), *Citrus* (Shalom et al., 2015), *Triticum L.* (Wang et al., 2015), *Zea mays* (Mao et al., 2016), *Gossypium raimondii* (Ali et al., 2017), *Petunia* (Zhou et al., 2018), *Fragaria vesca*, *Pyrus bretschneideri*, *Prunus persica* and *Prunus mume* (Abdullah et al., 2018). Nevertheless, this is the first comprehensive report on identification and characterization of *SBP* genes in *E. grandis.*

Based on the importance of gene duplications in the evolution of gene families in plants, the gene duplication events of putative *SBP* genes in *E. grandis* genome have been examined in this study. Our analysis identified three duplicated gene couple (Egrandis_SBP_2/ Egrandis_SBP_4, Egrandis_SBP_8/ Egrandis_SBP_13, Egrandis_SBP_11/ Egrandis_SBP_13 and Egrandis_SBP_3/ Egrandis_SBP_15) among eight identified *Egrandis_SBP* genes (*Fig. 1*). The Ka/Ks ratios between these duplication gene couples were found to be lower than '1' which suggests that: natural selection has occurred during segmental duplication events (Juretic et al., 2005).

Likewise, many segmental duplications of SBP genes have been detected in *A. thaliana* (*AtSPL10*/*AtSPL11*, *AtSPL4*/*AtSPL5*, *AtSPL1*/*AtSPL12*) and *O. sativa* (*OsSBP10*/*OsSBP5*, *OsSBP11*/*OsSBP4*, *OsSBP12*/*OsSBP3*) (Blanc and Wolfe, 2004; Bowers et al., 2003; Paterson et al., 2004; Wang et al., 2005). Besides segmental duplication events, some plant species including *Malus* × *domestica Borkh* (Li et al., 2013), *V. vinifera* (Hou et al., 2013), *F. vesca, Pyrus bretschneideri, P. persica* and *P. mume* (Abdullah et al., 2018) have demonstrated to have tandem duplication events either.

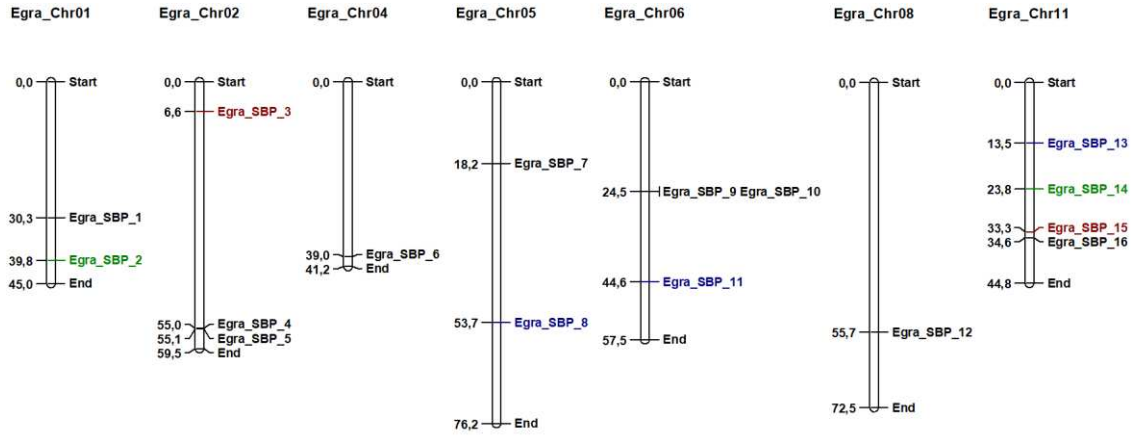

Figure 1. *Distribution of Egrandis_SBP genes on chromosomes of Eucalyptus grandis*

Phylogenetic analysis, gene structure and conserved motifs of Egrandis_SBPs

To discover the relationships between Egrandis_SBP proteins, a phylogenetic tree of SBP proteins in *E. grandis*, *A. thaliana* and *V. vinifera* was constructed using neighbor-joining (NJ) method with bootstrapping 1000 times (*Fig. 2*). Egrandis_SBPs were clustered into eight groups from A to D4 (*Fig. 2*). Group C2 was the largest group containing 18 SBP members, that is almost 34% of the total SBP proteins in the tree. And a minimum of one member of Egrandis_SBP proteins have made a contribution to each group, except for the Group A which has only one SBP protein from *V. vinifera* (*Fig. 2*). Egrandis_SBP proteins were clustered with the same number (7 from each) of *A. thaliana* and *V. vinifera* SBP proteins in Group C2. In contrast, any of *A. thaliana* were clustered with SBP proteins of *E. grandis* and *V. vinifera* in Group C1 suggesting that these genes may have been lost during evolution in *A. thaliana.* As previously declared by Abdullah et al. (2018), this kind of loss and birth of SBP genes which are specific to species might cause divergence in these genes in terms of functionality (Abdullah et al., 2018). In addition, similar coding and exon-intron sequences were observed in *SBP* genes which were found in the same subgroup of the phylogenetic tree (*Fig. 2*).

Similarly, phylogenetic trees of SBP proteins from several plant species including rice (Xie et al., 2006), *A. thaliana* (Guo et al., 2008), *Z. mays* (Chuck et al., 2010), *L. esculentum* (Salinas et al., 2012), *Malus slyvestris* (Li et al., 2013) and *Phyllostachys edulis* (Pan et al., 2017) were also divided into eight groups in accordance with the phylogenetic tree of SBP proteins from *E. grandis.*

To investigate conserved motifs in Egrandis_SBP proteins, MEME (v4.12.0) were used, and a total of 15 conserved motifs were described (*Fig. 3* and *Table A1* in the *Appendix*). The lengths of identified motifs were between 11 and 50 amino acids and all identified Egrandis_SBP proteins were found to have Motif 1, 2 and 3, which constitute the SBP domain (*Fig. 3*). Some of the other SBP motifs were only found in some Egrandis_SBP proteins, suggesting that these motifs may be provide by a specific function of these proteins (*Fig. 3*).

The SBP domain were shown to form two zinc fingers in all *Egrandis_SBP* proteins and zinc finger 1 (Cys-Cys-His-Cys) was composed of Motif 1 while Motif 2 and 3 were involved in the construction of zinc finger 2 (Cys-Cys-Cys-His) as shown in *Figure 4*. These zinc binding sites were shown to be essential for SBP domain however they have been reported as having different structures than other zinc binding structures by Yamasaki et al. (2004) and thus, they are known as a novel zinc-binding motif (Yamasaki et al., 2004).

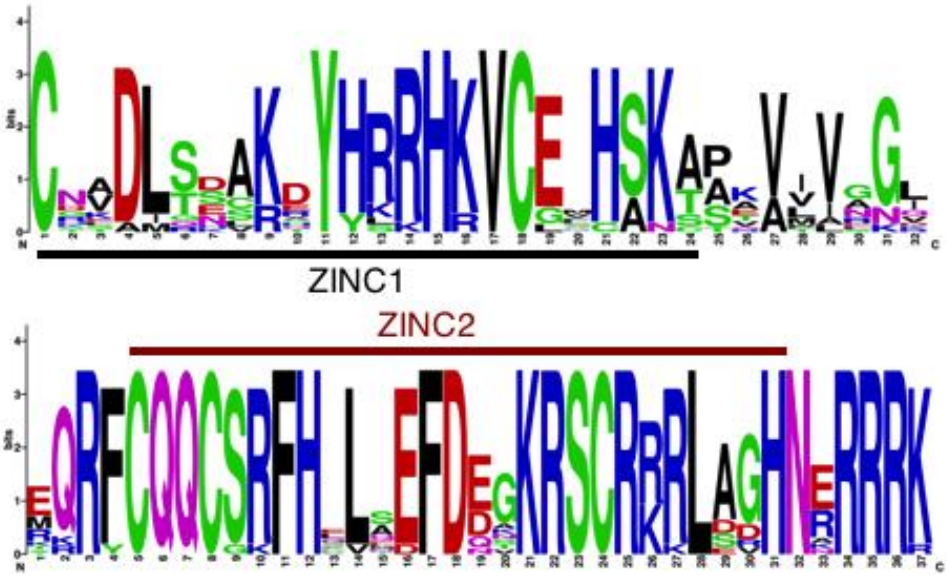

Figure 4. *Domain compositions of Egrandis_SBP genes. Thirteen Egrandis_SBP genes have both the characteristics of ZINC1 (Cys-Cys-His-Cys) and ZINC2 (Cys-Cys-Cys-His). The bit score represents the information content for each position in the sequence*

Gene structures of 16 *E. grandis* SBP gene were investigated and the estimated number of exons among all genes extended from 2 (*Egrandis_ SBP_8*) to 11 (*Egrandis_ SBP_1*) (*Fig. 5*). This varied numbers of exons in *E. grandis SBP* family genes by gain or loss of exon(s)/intron(s) might have occurred during evolution of *Egrandis_SBP* genes.

Comparative and synteny events among SBP genes of E. grandis, A. thaliana and V. vinifera

SBP protein sequences from *E. grandis*, *A. thaliana* and *Vitis vinifera* were subjected to comparative synteny analysis, to calculate evolutionary relationship of the SBP gene family between these species (*Fig. 6*). A total of 16 SBP proteins from *E. grandis*, 12 from *A. thaliana,* and 10 from *V. vinifera* was used to perform the synteny analysis. According to the synteny analysis results, homologs of *E. grandis* genes were found in corresponding syntenic blocks of *A. thaliana* and *V. vinifera* (*Fig. 6*). In terms of co-evaluation of gene duplications and synteny analyses of *Egrandis_SBP* genes, we can conclude from here, that both of these events might contribute to the evolutionary expansion of SBP genes in *E. grandis* genome (*Figs. 1* and *6*).

Expression profiles of Egrandis_SBPs in different tissues

In this study, a common mRNA analysis of *Egrandis_SBP* genes were performed via publicly available expression data in Phytozome v12.1 online plant genomics resource (https://phytozome.jgi.doe.gov). The heatmap shows the expression variance of identified 16 *Egrandis_SBP* genes in different plant tissues (*Fig. 7*).

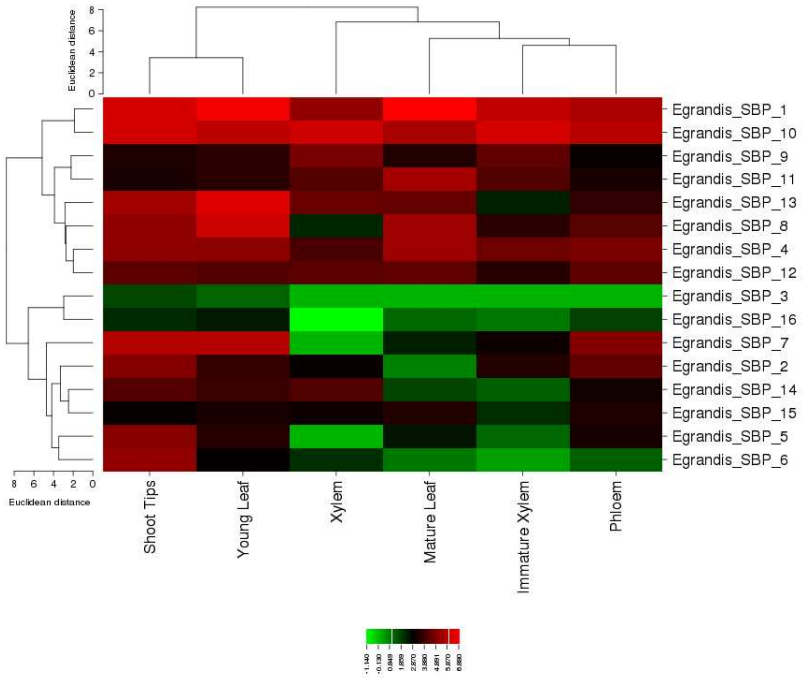

Figure 7. *Expression profiling of E. grandis SBP genes in shoot tips, young leaf, xylem, mature leaf, immature leaf and phloem tissues. Green and red colors indicate low-expression and high-expression, respectively*

As seen in the *Figure 7, Egrandis_SBP_1, -10, -9, -11, -13, -8, -4* and *-12* genes revealed relatively high expression levels in almost all tissues including shoot tips, young leaf, xylem, mature leaf, immature xylem and phloem. However, *Egrandis_SBP_2, -3, -5, -6, -7, -14, -15* and *-16* genes constituted relatively low expression levels in all tissues except for: shoot tips and young leaf (*Fig. 7*). In short, a conclusion can be drawn from the heatmap, that most of the *Egrandis_SBP* genes were highly expressed in all examined tissues of *E. grandis.*

Conclusions

The study herein, provides a comprehensive genome-wide identification of SBP genes in *E. grandis.* A total of 16 SBP genes were identified and were labelled as: *Egrandis_1* to *Egrandis_16*. They were sorted based on their chromosomal locations. To get insight into their biological functions in the genome of *E. grandis,* several analyses were conducted using many online and offline bioinformatic tools and genome databases. This study being the first study regarding the identification of SBP genes in *E. grandis*, it can be considered as a useful resource for the future studies regarding SBP genes in either in *E. grandis* or comparative different plant species.

ASSESSMENT OF RELATIONSHIP BETWEEN LOCATIONS AND DISTANCES TO ROADSIDE OF FOREST FIRES IN ISTANBUL, TURKEY

SENTURK, N.

Department of Forest Construction and Transportation, Faculty of Forestry, Istanbul University-Cerrahpasa, 34473 Bahcekoy, Istanbul, Turkey
(e-mail: nsenturk@istanbul.edu.tr)

(Received 16th Jul 2018; accepted 22nd Aug 2018)

Abstract. Forest fires have negative effects on human health, ecosystems and climate change. One way to fight and prevent forest fires is formation of risk maps based on Geographical Information Systems (GIS). This study created a GIS-based database that contains information on forest fires that took place in Istanbul, Turkey in the period of 2013-2016 such as location, reason, burned area, etc. According to the spatial analysis maps that were obtained based on the initial location of the fires in 2013-2016, a large part of the fires took place in the zone in the south of the city between forests and settlement areas. It was also aimed in this study to reveal the relationship between the initial locations of forest fires and their distance to forest roads. For this purpose, spatial and temporal distribution maps were crated for the fires that took place in 2013-2016 with buffer zones that were created in distances of 0-25 m, 25-50 m, 50-75 m and 75-100 m from forest roads. According to the results of this analysis, among the total of 427 forest fires that took place within 0-100 m from forest roads, 186 (43%) took place within 0-25 m, 99 (23.19%) took place within 25-50 m, 90 (21.08%) took place within 50-75 m and 52 (12.18%) took place within 75-100 m. As it may be understood from the analysis results, numbers of fires decrease when the distance from forest roads increases.
Keywords: *forest road, forest fire, spatial analysis*

Introduction

Forest fires occur due to natural and anthropogenic effects (Adab et al., 2013; Demir et al., 2009) and affect human health, ecosystems and climates negatively (Sukitpaneenit and Oanh, 2014; Arganaraz et al., 2015). In a time less than the last 200 years, about six million square kilometers (600,000,000 ha) of the forests in the world were damaged due to forest fires (Dimopoulou and Giannikos, 2004).

Reducing the severity of losses related to forest fires is largely dependent on precautions such as fire prevention, detection and elimination (Kucuk et al., 2017). One of the most important precautions in question is formation of fire risk maps. Fire risk maps, which are created for determining areas with high fire risk, are a significant prevention tool that will help plan firefighting and fire prevention work (Aricak et al., 2014).

In forming fire risk maps, GIS-based spatial analysis results provide significant basis in fighting fire (Jaiswal et al., 2002; Erten et al., 2004).

Based on their cause of occurrence, forest fires may be divided into six groups as natural fires, fires with no known cause, accident fires, deliberate fires, voluntary fires and rekindle fires (San-Miguel-Ayanz et al., 2012). The FAO report dated 1998 stated that the vast majority of the fires in Turkey were anthropogenic. While the ratio of anthropogenic fires in Turkey is 97%, only 3% occurred due to lightning. Among anthropogenic fires, 23% occur due to arson and deliberation, 27% occur due to neglect

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_61956204
© 2018, ALÖKI Kft., Budapest, Hungary

and carelessness, and 50% occur without a known cause (Mol and Kucukosmanoglu, 1997; FAO, 1998).

As Mol and Kucukosmanoglu stated in 1997, people cause the majority of forest fires in Turkey. Again, a significant part of these occurs due to fires that are lit during picnics with recreational purposes. There are areas for building controlled fires in recreational areas.

However, especially in large metropolitan cities where there is intense anthropogenic pressure on forests such as Istanbul, recreational areas may be insufficient, and people may build picnic fires in forests outside controlled picnic areas. The majority of the places where these fires in question are built are near forest roads as they are easily accessed. In addition to all forestry operations, forest roads are also used for recreational needs (Akgul et al., 2016).

In the scope of the study, GIS-based spatial analyses were used to map the fires that took place in the forest areas within the border of the province of Istanbul in the period of 2013-2016 based on the causes of fires and the distances of the fires to forest roads, and the initial locations and intensities of the fires were analyzed.

Material and methods

Study area

The research area was selected as Istanbul city which is located in the north-west Marmara region of Turkey, in the coordinates of 28°10’ and 29°40’ East longitudes and 40°50’ and 41°30’ North latitudes (*Fig. 1*).

Figure 1. *Location map of the study area*

About 46.6 (251,716 ha.) of Istanbul is covered with forests, and these areas are distributed in the north of the city. Within the forest areas, there is a total of 4414-km-long forest roads. There are also 36 recreational areas with different sizes within the forest areas in Istanbul. These areas are popular among the citizens (*Fig. 2*).

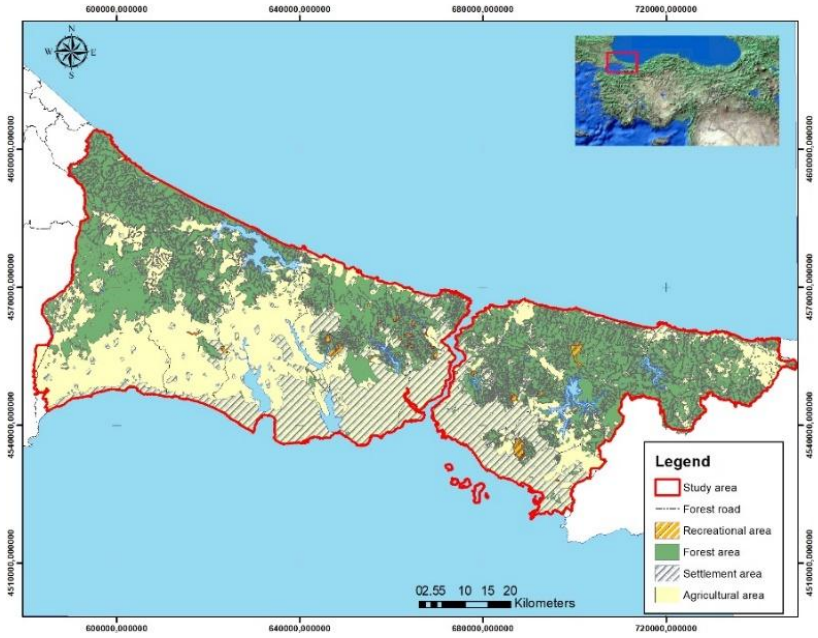

Figure 2. *Location map of the study area*

Methods

This study investigated the fires that took place in 2013-2016 in forests within the provincial borders of Istanbul according to General Directorate of Forestry Turkey (GDF, 2017). Where these fires mostly occurred and the distances of these fires were determined. For this, a database was created using the ArcGIS 10.3 GIS software to analyze the locations of these fires. In the database, the date of the forest fires, forest fire occurrence locations (in the ITRF 96 coordinate system), total burnt areas (ha) were defined.

Forest fire density analysis was conducted with the database that was create within the scope of the study. In addition to the density analysis, spatial analysis of the fires that took place in 2013-2016 was carried out using the Kernel Density method. Kernel density method is commonly used in several engineering disciplines it provides to calculates the density of features in a neighborhood around the features.

Within the main purpose of the study buffer zones were defined in distances of 0-25 m, 25-50 m, 50-75 m and 75-100 m from forest roads. This is how the zone where the fires mostly occurred was determined. The buffer zones were overlapped with the forest fire locations in the ArcGIS 10.3 software. The overlapping process was carried out based on the years.

Results and discussion

Numerical and spatial distribution of forest fires according to main reason of fires

In the study, according to fire reasons, forest fires were investigated in five groups as lightning, carelessness, sabotage, electrical fault and unknown cases. In order to determine the relationship between the locations of fire and numbers of fire with fire reasons, the number of fire over the years is also shown in *Table 1* depending on the fire reasons. According to spatial distribution analysis results for 2013 it was calculated that

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_61956204
© 2018, ALÖKI Kft., Budapest, Hungary

the minimum number of fire occurred by lightning as one while maximum number of fire caused carelessness was calculated as one.

According to the distribution analysis of main reason of fires (*Table 1*);

Considering the total of 243 fires that took place in 2013;

- Most (87) of the fires occurred due to carelessness,
- Following this, 78 fires occurred without a known cause,
- The least of the fires (1) occurred due to lightning.

Considering the total of 100 fires that took place in 2014;

- Most (46) of the fires occurred due to carelessness,
- Following this, 28 fires occurred without a known cause,
- The least of the fires (2) occurred due to lightning.

Considering the total of 121 fires that took place in 2015;

- Most (53) of the fires occurred due to carelessness,
- Following this, 45 fires occurred without a known cause,
- The least of the fires (2) occurred due to electrical fault.

Considering the total of 196 fires that took place in 2016;

- Most (141) of the fires occurred due to unknown causes,
- Following this, 38 fires occurred due to carelessness,
- The least of the fires (17) occurred due sabotage.

As understood from the results of the spatial distribution analysis and seen in *Figure 4,* a large part of the fires took place in the zone in the south of the city between forests and settlement areas. It is also seen that the forest areas and northern parts where forest fires took place the least frequently had high numbers of recreational areas (*Fig. 3*).

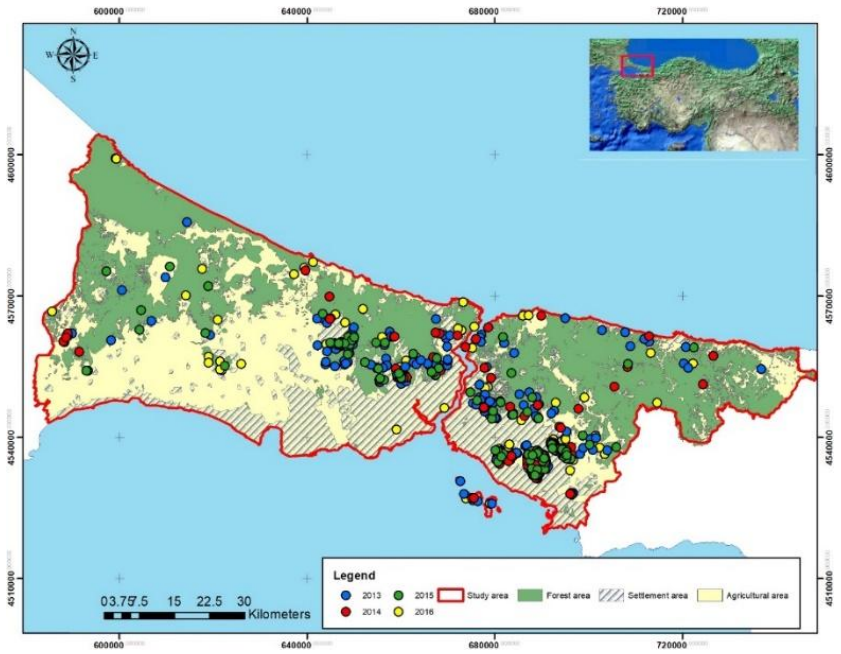

Figure 3. *Fire locations by year*

Table 1. *Distribution of fires according to main reason of fires*

Fire reason	2013	2014	2015	2016	Total
Lightning	1	2	0	0	3
Carelessness	87	46	53	38	224
Sabotage	72	24	21	17	134
Electrical fault etc.	5	0	2	0	7
Unknown cases	78	28	45	141	292
Total	**243**	**100**	**121**	**196**	**660**

According to the results of the spatial distribution analysis on the causes of fires;
Within the total of 50.46 ha of burnt areas in 2013;

- The smallest area (0.02 ha) was burnt due to lightning,
- The largest area (26.05 ha) was burnt due to sabotage.

Within the total of 14.13 ha of burnt areas in 2014;

- The smallest area (0.03 ha) was burnt due to lightning,
- The largest area (6.60 ha) was burnt due to carelessness.

Within the total of 24.20 ha of burnt areas in 2015;

- The smallest area (0.09 ha) was burnt due to electrical fault,
- The largest area (9.52 ha) was burnt due to sabotage.

Within the total of 33.78 ha of burnt areas in 2016;

- The smallest area (1.77 ha) was burnt due to sabotage,
- The largest area (28.83 ha) was burnt due to unknown reasons (*Table 2, Fig. 4*).

Spatial distribution of forest fires by distance to road

It was aimed to reveal the relationship between the initial locations of the fires and their distance to forest roads. For this purpose, spatial and temporal distribution maps were crated for the fires that took place in 2013-2016 with buffer zones that were created in distances of 0-25 m, 25-50 m, 50-75 m and 75-100 m from forest roads (*Fig. 5*).

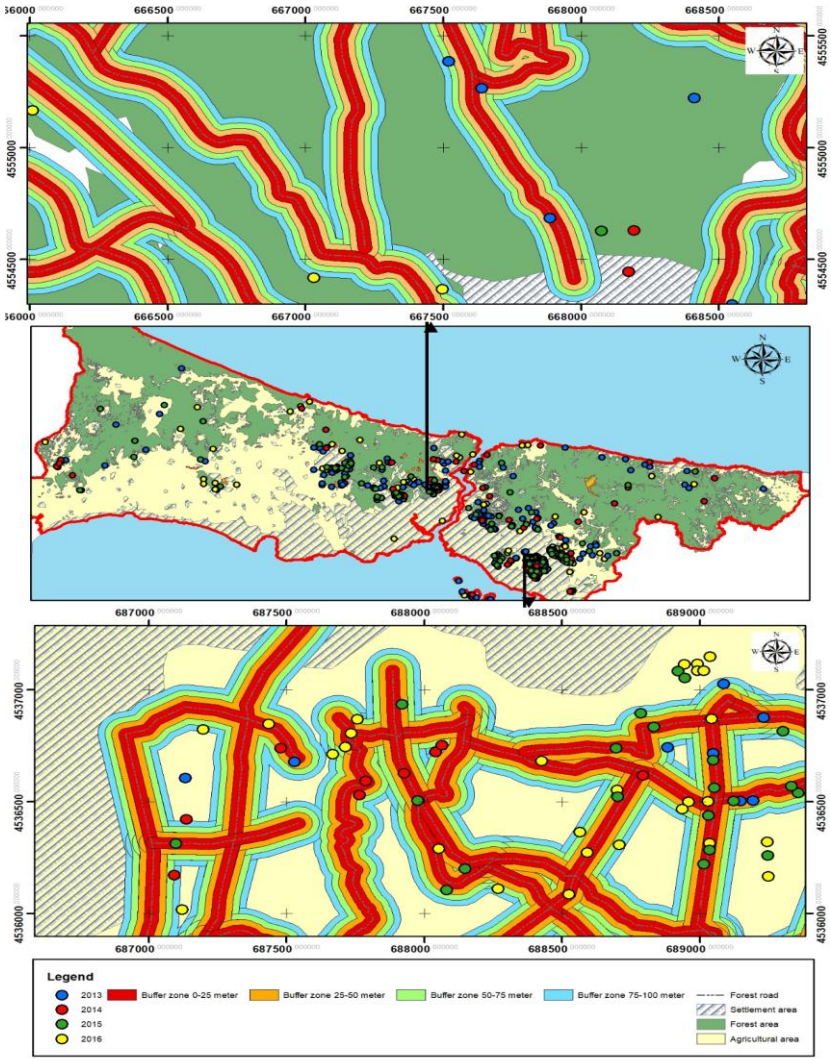

Figure 5. *Spatial distribution of forest fires by distance to forest road*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_61956204
© 2018, ALÖKI Kft., Budapest, Hungary

According to the spatial and temporal distribution analysis results, within 100 m from forest roads, there were

- 197 fires in 2013,
- 42 fires in 2014,
- 76 fires in 2015,
- 112 fires in 2016,

constituting a total of 427 fires. This number represents 64.6% of the total number of fires that took place in Istanbul in 2013-2016 (*Table 3, Fig. 6*).

Additionally, considering the distances of the fires that occurred in 2013-2016, 186 (43%) took place within 0-25 m, 99 (23.19%) took place within 25-50 m, 90 (21.08%) took place within 50-75 m and 52 (12.18%) took place within 75-100 m.

In the study by Eskandari (2017) that aimed to reveal forest fire risk using the fuzzy Analytic Hierarchy Process (AHP) and GIS methods, it was found that the distance from the road and the distance from settlements were the most important risk factors among anthropogenic risk factors. Moreover, Narayanaraj and Wimberly (2012) determined that reduction of closure near the roads, increase of wind and temperature and forest management activities impact burning. It was also emphasized by several authors that proximity to roads increases risk of fire (Pourtaghi et al. 2016; Vinod et al., 2016; Ajin et al., 2016).

Table 3. *Distribution of forest fires by distance to road*

Years	Buffer zone (m)								Total
	0-25 m		25-50 m		50-75 m		75-100 m		
	Number	%	Number	%	Number	%	Number	%	
2013	81	41.12	48	24.37	43	21.83	25	12.69	**197**
2014	21	50.00	6	14.29	8	19.05	7	16.67	**42**

As it may be understood from the analysis results, numbers of fires decrease when the distance from forest roads increases. Furthermore, when the ratios of the locations of the fires are considered, it is seen that 97.13% of the fires in Istanbul occurred in the southern parts of the city. It is understood that most of the fires were found near the settlement areas as can be seen from *Figure 4*.

This may be interpreted as the following. When the recreational purposes of the citizens in large metropolitan cities like Istanbul and the distance of residential areas to green spaces are considered, the numbers of forest fires are higher in the southern parts of Istanbul where green spaces are lacking. The fire density analysis based on the initial locations of forest fires that is shown in *Figure 7a* and the area size and fire density analysis that is shown in *Figure 7b* which were carried out to test this hypothesis also confirmed that the highest density of the forest fires was in the southern parts.

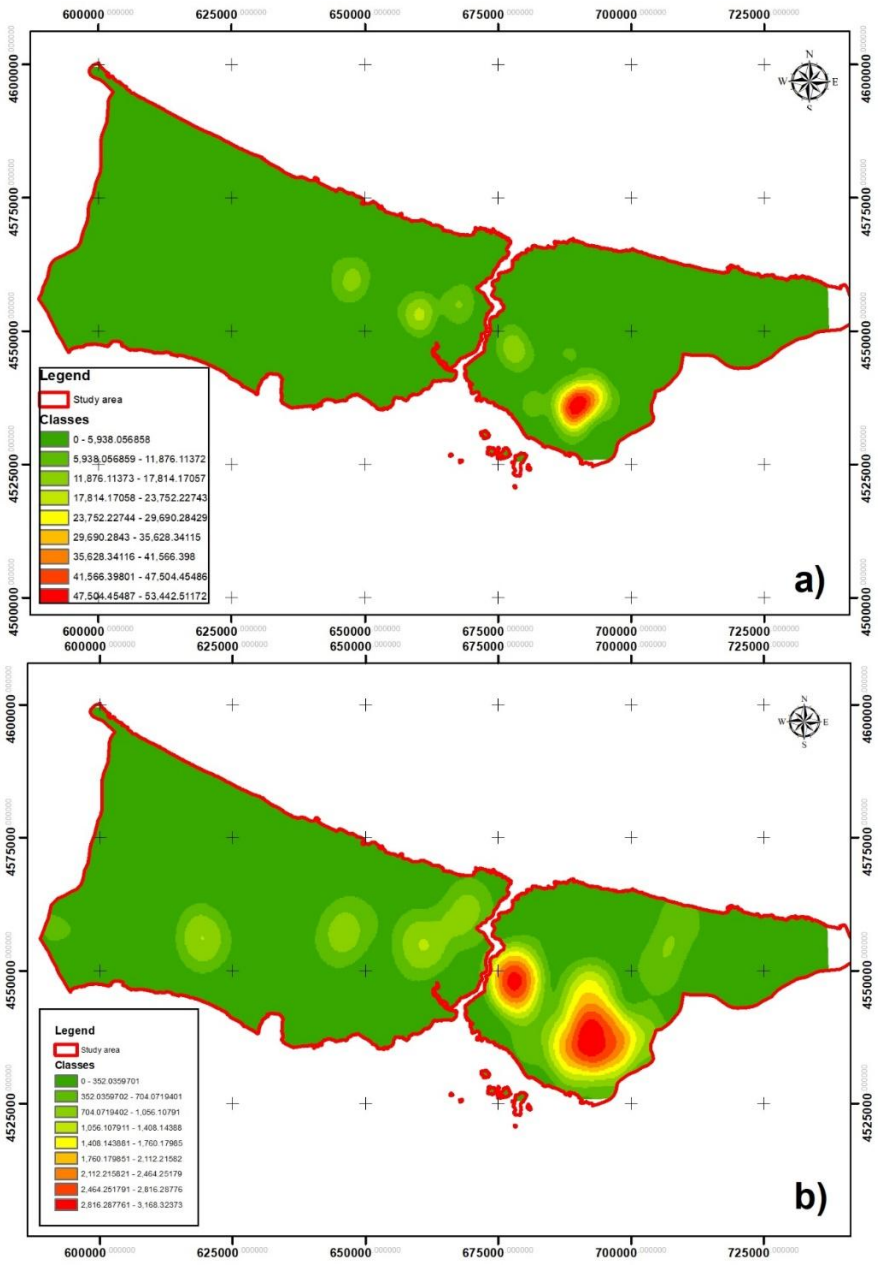

Figure 7. *Results of intensity and area fire intensity analysis according to fire exit points*

In agreement with this situation, Dong et al. (2005) stated that as the distance from roads, residential areas and agricultural lands increases, risk of fire would decrease. Moreover, other studies by Suryabgavan et al. (2016) and Matin et al. (2017) observed that forest fires are more frequent in relation to anthropogenic factors in places that are close to residential areas.

Furthermore, considering the distances of the fires from forest roads, in the southern parts of Istanbul where there is a dearth of recreational spaces, it is seen that people park their vehicles on the side of roads and take part in picnic activities with fire due to lacking and/or uncontrolled picnic and recreational needs.

Additionally, the reason for reduced numbers of fires as one gets further away from forest roads may be that people carry out picnic activities with fire at locations close to their vehicles to keep a line of sight for security.

Conclusions

With this study, the relationship between the locations of fires and their distances to roads and other areas (residential and agricultural land) was determined with the help of GIS. Based on the analyses that were carried out within the scope of the study, it was found that proximity to such locations increased the number of fire. Accordingly, proximity to these places should be kept in mind and planning should involve information on this within the scope of fighting and taking precautions against forest fires. The results of the study are important especially in terms of reducing forest fires that occur due to anthropogenic reasons as people access recreational areas with these roads in large metropolitan cities.

Moreover, it is believed that this study will allow determination of priority and importance of firefighting and precautions against fires, as well as detection and ranking of risk zones. In addition to all these precautions, protective activities in forests and zones between forests and settlements where anthropogenic pressure is high should be carried out intensely, and green spaces (picnic areas and parks) that will reduce the pressure of the citizens on the forest should be planned and built in suitable locations and with suitable space.

(Received 18th Jul 2018; accepted 22nd Aug 2018)

Abstract. This study was undertaken to investigate the effects of single and double girdling applications on the fruit yield, commercial size, quality, photosystem II (PSII), leaf chlorophyll and leaf nutrition content of 22-year-old Robinson mandarin (*Citrus reticulata*). Girdling treatments were performed at anthesis (when 60% of the flowers were opened) with approximately 5 mm trunk diameter in 2014. The fruit was harvested in 2014 at the optimum harvest time (in December) for fruit yield, properties and size. Evaluations of leaf mineral content, chlorophyll concentration and fluorescence measurements were performed at monthly intervals. Leaf samples were taken in eight periods for analysis of plant nutri-elements. It was determined that double girdling was the best application in terms of fruit yield and percentage of marketable fruit. The treatments did not significantly affect fruit internal quality. Girdling reduced PSII and leaf chlorophyll concentration but did not affect leaf mineral content. However, we observed a tendency toward a decrease in nitrogen levels in the girdled trees. According to the results of the present study, girdling treatments significantly affected fruit yield and size together with several macro-micro plant nutri-elements.
Keywords: *citrus, chlorophyll concentration, fruit yield, cultural practices, plant nutri-elements*

Introduction

Due to the steady increase in citrus production in Turkey, 3,781,359 million tons of citrus fruits were produced in 2014. Of the citrus produced in Turkey, 1,779,675 tons were oranges (FAO, 2015). The main varieties of mandarin (*Citrus reticulata*) grown in Turkey are satsumas, such as 'Okitsu Wase',' Owari' and 'Dobashi Beni'; the rest include 'Nova', 'Robinson', 'Fremont', Clementine 'Murcott' and 'Minneola' (Tuzcu et al., 2001). Robinson is an early-ripening mandarin cultivar with high fruit quality; this variety is also productive and has low tendency for alternate bearing. However, fruit size in the citrus fruit market is very important, and small fruit size is one of the main factors limiting the sales of citrus fruit; large fruits bring higher prices in the export market. Consumers prefer large fruits; thus, there is a significant price difference between large and small fruits (Agustí et al., 1994; Guardiola and García Luis, 2000; Erner et al., 2004). In terms of determining profitability, the size of citrus fruit has become as important as the yield. This phenomenon is readily apparent for small mandarin fruits as well as lemons, sweet oranges and large grapefruit species (Guardiola and García Luis, 2000). Fruit size is affected by many factors, including irrigation management, soil type, rootstock, as well as ecological variables that cannot be controlled by the producer. Moreover, fruit size is inversely proportional to yield and fruit number (Guardiola, 1997). Bevington (2003) demonstrated that region, cultivar, rootstock, soil type, microecology

DOI: http://dx.doi.org/10.15666/aeer/1605_62056218
© 2018, ALÖKI Kft., Budapest, Hungary

and plant age all affect fruit size. The availability of carbohydrates (increases fruit size), flower intensity (decreases fruit size), competition between flowers/fruitlets (decreases fruit size) and abiotic stressors (decrease fruit size) are the most important factors affecting the final size of citrus fruits (Guardiola et al., 1982; Patrick, 1993; Agustí et al., 1995; Goldschmidt and Koch et al., 1996; El-Otmani et al., 2000). Cultural treatments such as pruning, irrigation and fertilization can be optimized to increase fruit size. For instance, techniques such as girdling (Cohen, 1984) and thinning (Hirose, 1981; Wheaton, 1981; Zaragoza et al., 1992; Guardiola and García Luis, 2000) are used in citrus production to increase fruit size.

Girdling applications are important and have been used worldwide for centuries in citrus and other fruit tree crops, especially to increase flowering, fruit set and fruit size (Tuzcu et al., 1992; Mostafa and Saleh, 2006). Girdling consists of the removal of a strip of bark from the trunk or major limbs of a fruit tree, which blocks the downward translocation of photosynthates and metabolites through the phloem, thus reducing fruit drop and enhancing fruit growth and yield (Zhao et al., 2013; Raveh, 2013; Mostafa and Saleh, 2006). Girdling applications at different times are used to increase the yield of fruit in some varieties, such as Robinson, Nova, Dancy, Osceola, Klemantin, Minneola, Orlando and Ortanique, which are self-sterile. The fruit set process is complex because photosynthetic activity and, thus, the production of photosynthetic compounds, can be altered by sink demand. Girdling effect has been related to the accumulation of photoassimilates in the canopy as a result of the interruption of the downward transport of soluble sugars resulting increases in fruit set in Citrus (Rivas et al., 2007). It has been reported that girdling treatments increased yield by 125% in mandarins (Rivas et al., 2006).

Girdling has also been shown to alter the partitioning of photosynthates, mineral nutrients and plant growth regulators in the tree (Rivas et al., 2006). On the upper line of girdling, leaf nitrogen (N) content and Carbon (C)/N ratio are improved, and as a result, flowering and fruit set are increased (Mostafa and Saleh, 2006). However, the effects of girdling on the translocation of various mineral nutrients in leaves are still unclear (Wang et al., 2010). Exactly how girdling functions in this way is still unknown, but the immediate effect of this technique is to break the phloematic flow toward the roots, thereby modifying the nutritional and hormonal balance of the plant (Vaio et al., 2001). In addition to single girdling, double girdling had, in most cases, a much greater effect than a single girdle. The greater efficiency of the double girdling may be due to this treat- ment keeping the girdling wound open for longer than with single girdles (Cohen, 1984).

The aim of this work was to study the effects of girdling on yield, fruit size and quality in the Robinson mandarin. Another objective was to determine the effects of trunk girdling on the quantum yield efficiency of PS II and the mobility of the mineral elements in Robinson mandarin leaves.

Materials and methods

Plant materials

The experiments were conducted on 22-year-old Robinson mandarin trees planted on sour orange rootstock at 6 × 6 m intervals at the Research Station of Cukurova University, Agricultural Faculty Citrus Experiment Station, Adana, Turkey (latitude 35° 23' N; longitude 36° 50' E; altitude 27 m) in 2016. The trees were managed and selected for uniformity and crop load. In the experimental area, the soil was clay loam (55% clay, 22% silt and 23% sand containing 11% $CaCO_3$), and the soil pH was between 7.20 and

© 2018, ALÖKI Kft., Budapest, Hungary

7.29 at a depth of 0-90 cm. The area has mean maximum and minimum temperatures of 26 and 14.5 °C, respectively, and an average annual rainfall of 465 mm (*Fig. 1*). The trees were irrigated weekly from May to October using drip irrigation. Nitrogen (N) was applied at a rate of 1.5 kg N/tree (2/3 in mid-February and 1/3 in mid-May), phosphorus (P) was applied at a rate of 1 kg P/tree (December), and potassium (K) was applied at a rate of 1 kg K/tree (January).

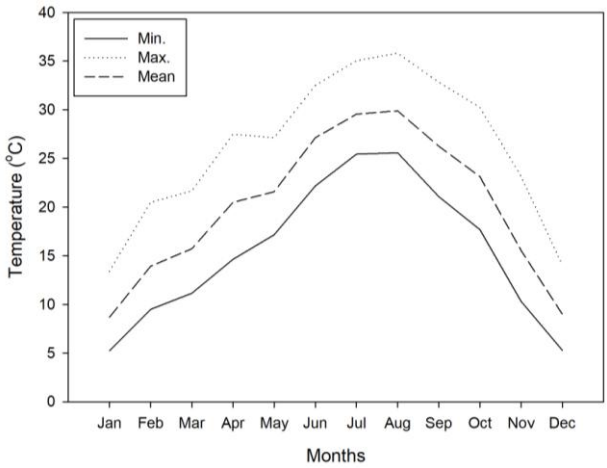

Figure 1. *Minimum, maximum and mean temperature data of the experimental field in 2016*

Girdling treatments

Girdling treatments were performed at anthesis (when 60% of the flowers were opened) with an approximately 5 mm diameter trunk using a girdling knife without injuring the wood layers. The experiment utilized a randomized complete block design with ten replicates for each treatment. Ten trees of each treatment were selected for similarity in size, vigor and flowering intensity. The girdling treatments were conducted on three plots with single girdling (SG), double girdling (DG) or without girdling (control). Single girdling (SG) was undertaken at 15 cm under the scaffold branch junction level. In the double girdling (DG) treatment, the first girdling was taken at 15 cm under the scaffold branch junction level and the second girdling at 5 cm above it (*Fig. 2*).

Figure 2. *Single (left) and double (right) girdled 'Robinson' trees from examined orchard*

Leaf chlorophyll concentration and photosystem II efficiency

The leaf chlorophyll concentration was estimated using a portable SPAD meter (Minolta, Japan), and the chlorophyll fluorescence parameter ((*Fv' / Fm'*) = quantum yield in light-adapted leaves) was measured with a portable fluorometer (FluorPen FP100, Photon System Instruments Ltd, Drasov, Czech Republic). The evaluations of the chlorophyll concentration and fluorescence measurements were taken in six periods between 2015 and 2016. The same leaves were used to estimate the leaf chlorophyll (Chl) concentrations and PSII efficiency, based on the quantum yield of light-adapted leaves (*Fv' / Fm'*), The chlorophyll concentration and maximum chlorophyll fluorescence efficiency readings for the light-adapted leaves were measured on 10 fully expanded young leaves (third and fourth leaves from the shoot apex) of each replicate at the four chosen time points. Measurements were performed before midday (08.00-11.00).

Fruit yield, properties and size measurements

The fruit was harvested in 2014 at the optimum harvest time (in December) from each plot. The yield per tree (kg/tree) was obtained by weighing the harvested fruit. A random sample of 25 grapefruits was evaluated for rind thickness, percent juice, juice soluble solids (SSC), acidity and soluble solid/acid ratio. Fruits from each of the plots were measured at the fruit equatorial diameter and graded according to commercial categories as follows: >78 mm (extra), 71-78 mm (class 1), 65-70 mm (class 2), 59-64 mm (class 3), 53-58 mm (class 4), 47-52 mm (class 5) and <47 (discard). The 25 fruits were weighed and juiced using a standard juicer; then, the juice was weighed and expressed as a percentage of the total fruit weight. The fruit rind thickness was measured with a digital caliper (Mitutoyo CD-15CPX, Mitutoyo America Corporation, USA). Soluble solids were determined with a portable refractometer (FG-103/113) using a few drops of juice. The total acidity of the juice was determined by titrating 5 ml of the juice sample with 0.1 N sodium hydroxide (NaOH) using phenolphthalein as the indicator.

Leaf chlorophyll concentration and fluorescence measurements

The leaf chlorophyll concentration was estimated using a portable SPAD meter (Minolta, Japan), and the chlorophyll fluorescence parameter ((*Fv' / Fm'*) = quantum yield in light adapted leaves) was measured with a portable fluorometer (FluorPen FP100, Photon System Instruments Ltd, Drasov, Czech Republic). Evaluations of leaf mineral content, chlorophyll concentration and fluorescence measurements were initiated 15 d before girdling (in April) to ensure that there were no differences among trees at the beginning of the trial. Subsequent measurements were performed at monthly intervals as follows: 30 d after girdling (d.a.g) (in May), 60 d.a.g (in June), 90 d.a.g (in July), 120 d.a.g (in August), 150 d.a.g (in September), 180 d.a.g (in October), and 210 d.a.g (in November). Readings of chlorophyll concentration and maximum chlorophyll fluorescence efficiency in the light-adapted stage were measured on 10 fully expanded young leaves (third and fourth leaves from the shoot apex) of each replicate at the eight chosen time points. Measurements were performed before midday (08.00-11.00).

Leaf mineral concentrations

Leaf samples were taken at each of the eight time points for analysis of plant nutri-elements in 2014 according to Chapman (1960). The leaves were washed in a detergent

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_62056218
© 2018, ALÖKI Kft., Budapest, Hungary

solution, rinsed several times in distilled water, and then dried at 70 °C for 48 h using a thermo-ventilated oven. The dried leaves were ground (<0.5 mm) and ashed in a muffle furnace at 550 °C for 8 h. The ash samples were digested in HNO_3-$HClO_4$ (3:1 v/v) and filtered through a blue band paper filter (Kacar, 1972). In the extract solutions, sodium (Na), potassium (K), magnesium (Mg), iron (Fe), manganese (Mn) and copper (Cu) concentrations were determined by inductively coupled plasma-atomic emission spectrometry (ICP-AES, Varian Liberty Series II), and the concentrations of phosphorus (P) were determined by UV-VIS spectrophotometry (Barton, 1948). Leaf total nitrogen (N) content was determined by the semi-micro-Kjeldahl method (Less, 1971).

Statistical analysis

Data were subjected to two-way analysis of variance (ANOVA), and significant differences between means were evaluated using Tukey's multiple range test at $p \leq 0.05$ and $p \leq 0.01$. All statistical analyses were performed by using SAS v9.00 statistics software procedures (SAS, 2006), and SigmaPlot® version 11.00 was used for the data presentation.

Results

Effects of girdling on fruit yield and fruit size

The effects of girdling treatment on the distribution of the crop within the commercial fruit size classes were presented in *Figure 3A*.

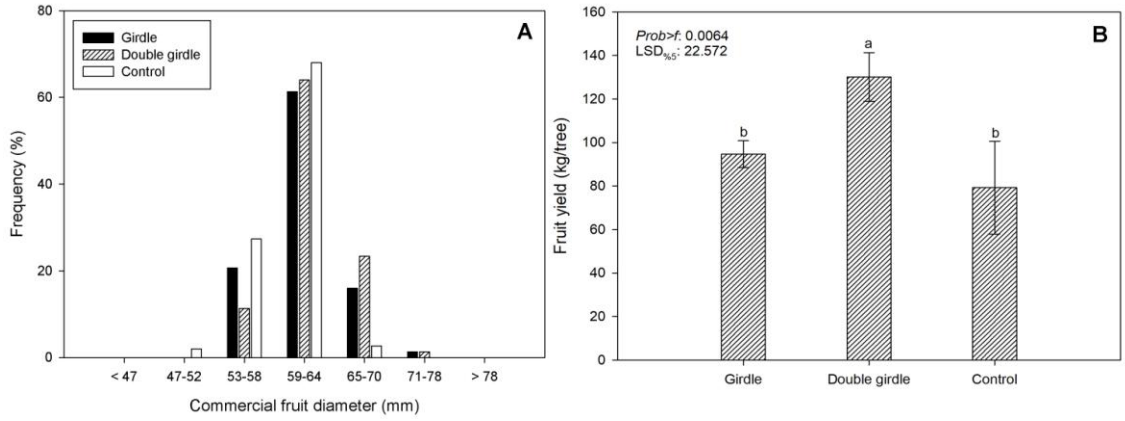

Figure 3. *Effects of girdling treatments on the frequency distribution of the diameter (A) and fruit yield (B) of the Robinson mandarin*

The results indicated that the frequency distribution of the fruit shifted toward larger sizes when the trees were girdled. The highest percentage of large, commercially valuable Robinson fruits (71.00-78.00 mm and 65.00-70.00 mm; classes 1 and 2, respectively) was obtained from trees with DG followed by those with SG. The control trees yielded no commercially valuable Robinson fruits (71.00-78.00 mm) and had the lowest percentage of large fruits (fruit sizes 65.00-70.00 mm). Moreover, compared with trees that were girdled, control trees produced a higher percentage of class 3 (59.00-64.00 mm) and class 4 (53.00-58.00 mm) fruits. Alternatively, the highest

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_62056218
© 2018, ALÖKI Kft., Budapest, Hungary

percentage of commercially unacceptable fruits (47.00-52.00 mm) was obtained from the control trees, even though in the girdled trees, there were no commercially unacceptable fruit sizes (47.00-52.00 mm and <47 mm). Girdling treatments had a significant effect on the yield of Robinson mandarin (*Fig. 3B*). Compared with the controls, the girdling treatment led to an increase in the fruit yield. As shown in *Figure 3B,* the highest fruit yield per tree was obtained in the DG treatment followed by SG. Control trees produced a low yield compared with the treatment trees.

Fruit internal quality

Data in *Table 1* show the effect of the girdling treatments on fruit internal quality in the Robinson mandarin. Girdling did not affect fruit internal quality, and no significant differences in the rind thickness, SSC content, acidity, SSC/acid ratio and juice content were observed. The girdling treatments decreased the rind thickness, although not significantly compared to the control. There were no trends observed for internal fruit quality due to girdling.

Table 1. *Effects of girdling treatment on the rind thickness, total soluble solids (TSS), total acidity (TA), juice content and TSS/TA ratio*

Treatment	Rind thickness (mm)	TSS (%)	TA (%)	Juice content (%)	TSS/TA
SG	4.37	11.27	0.96	49.42	11.92
DG	4.25	11.87	1.14	48.70	10.49
Control	4.60	11.87	1.01	47.74	11.72
Prob>f	*0.6953*	*0.2014*	*0.2226*	*0.8058*	*0.2334*

Leaf chlorophyll concentration and fluorescence measurements

Girdling significantly affected the leaf chlorophyll (Chl) concentration. A two-way ANOVA indicated a significant main effect of girdling and sample date and of their interaction ($P \leq 0.01$) on Chl concentration (*Table 2*).

Table 2. *Results of two-way analysis of variance (ANOVA) testing for effects of sampling date (SD) and girdling (G) and their interaction (SD×G) on the dependent variables*

Leaf chlorophyll concentrations ranged between 52.13 and 68.84 (*Fig. 4A*). The highest Chl concentration was obtained from the leaves of control plants, whereas the lowest was obtained from trees with SG followed by DG. In terms of Chl measurements, statistically significant differences were found between the sample time points. The lowest Chl was observed in June (60 d.a.g) and 15 d before girdling (in April). The highest Chl was found at 150 d.a.g (in September) (*Fig. 4A*). Girdling significantly affected on PSII efficiency in the Robinson mandarin (*Table 2*). A two-way ANOVA indicated a significant main effect of girdling and sampling time point ($P \leq 0.01$). However, interactions were not observed between girdling treatment sampling points. In the present study, there was a tendency toward a decrease in PSII in girdled trees, especially in the DG treatment in comparison with controls. In terms of the PSII measurements, statistically significant differences were found between time points (*Fig. 4B*). The lowest chlorophyll fluorescence was observed in July (90 d.a.g) followed by 15 d before girdling (in April) and 30 d.a.g. (in May). The highest chlorophyll fluorescence levels were observed in October (180 d.a.g) and November (210 d.a.g).

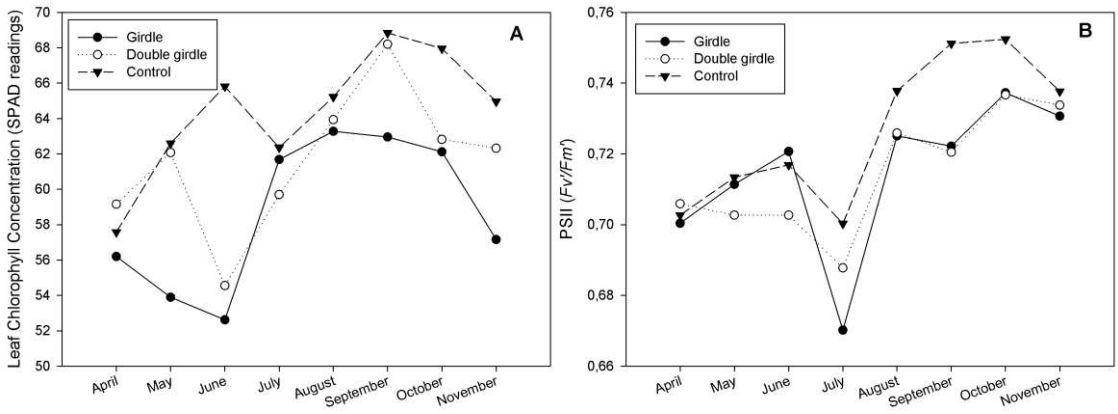

Figure 4. *Effects of girdling treatments on the leaf chlorophyll concentration (A) and PSII efficiency (B) in Robinson mandarins*

Leaf mineral concentrations

In the present study, leaf mineral content was not affected by girdling treatment (*Table 2*). A two-way ANOVA indicated a significant effect of sample date and the interaction on the concentrations of some leaf minerals (N, P, Na, Mg, Fe) (*Table 2*). It can be argued that the significant differences among sample dates in mineral elements are a natural result because plant nutrients are used at different rates in different periods. Although not significantly, the leaf N levels were reduced in the girdled trees compared with non-girdled trees. There was a decrease in leaf N content until 30 d.a.g (in May) in girdled trees, while an increase was observed in untreated trees (*Fig. 5A*). In all treatments, a rapid increase was observed in the 60 d.a.g (June), but it was lower in girdled trees, especially after double girdling. The values of the control and girdled trees (except double girdling) showed a similar tendency after 120 d.a.g. (August) and remained more or less constant throughout the measurement periods. The potassium (K) percentage in the leaves was not affected by any treatment (*Fig. 5C*).

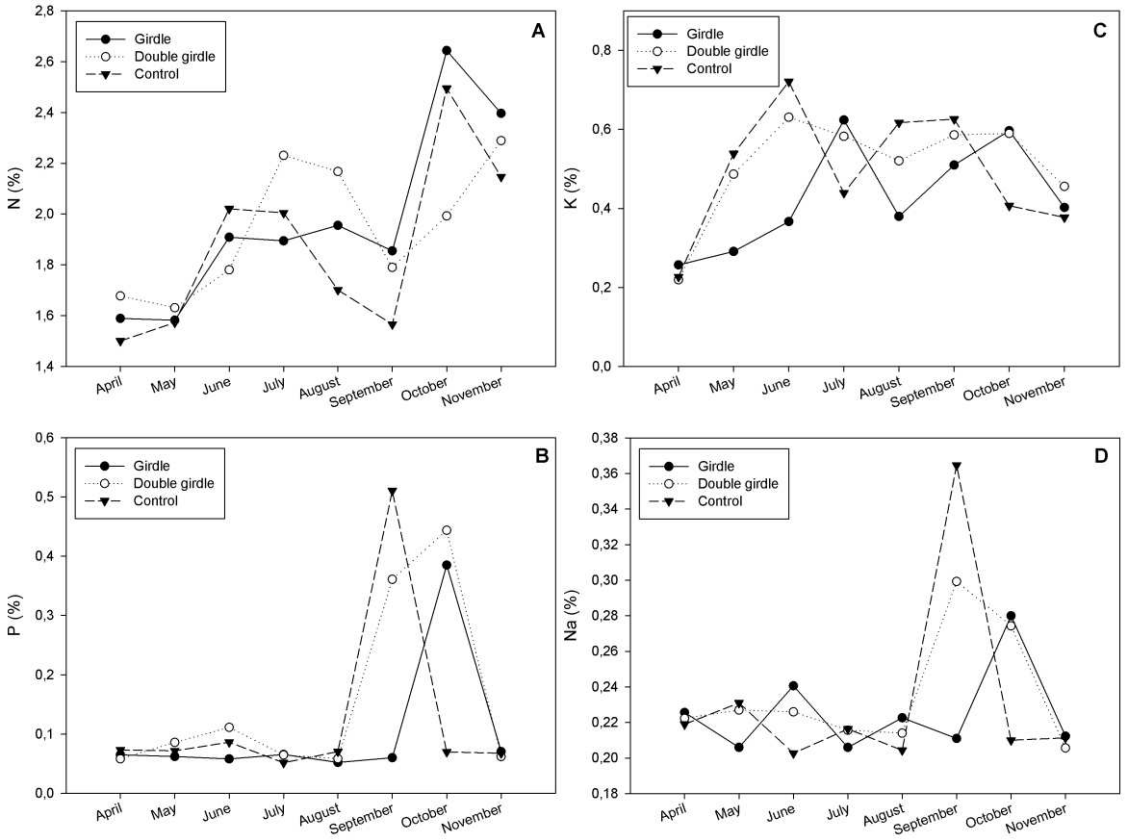

Figure 5. *Effects of girdling treatments on the leaf N (A), P (B), K (C) and Na (D) concentrations in Robinson mandarins*

The K value in the DG trees increased up to the 60 d.a.g (June) in all applications, though not as much as in the control trees. Similar trends were observed in other measurement periods in all treatments. Leaf P, Na and Mg contents we not affected by the treatments and no trend was determined among the treatment in the different sample periods (*Figs. 5B-D* and *6A*). However, in terms of these values (P, Na and Mg), a significant increase was observed in both control and girdled trees from the 120 d.a.g. (August), and these increases were more prominent in the control trees than in girdled trees. For all the measured micronutrients, similar trends were found (*Fig. 6 A-D*).

Discussion

According to the results obtained in this study, girdling application significantly affected fruit set, and the most effective treatment was DG followed by SG. The most favorable effect of girdling was the improvement of fruit set and growth, especially after DG treatment. In previous studies, a significant increase in the fruit yield of the Balady mandarin was obtained when a girdling treatment was applied before blossoming (Mostafa and Saleh, 2006). Additionally, according to Rivas et al. (2007), girdling delayed fruitlet abscission in all shoot types and leafy flowering shoots had increased fruit set in Loretina and Nova mandarin cultivars. According to Rivas et al. (2006), the productivity of Fortune and Clausellina mandarins can be improved by girdling. Moreover, Tuzcu et al. (1992) found that the application of double girdling at

© 2018, ALÖKI Kft., Budapest, Hungary

the beginning of flowering increases the yield of the Algerian tangerine (clementine/mandarin) compared to the control. Similarly, trunk girdling has been shown to increase fruit set in many crops, including apple (*Malus domestica* Borkh.) (Hoying and Robinson, 1992), lychee (*Litchi chinensis* Sonn.) (Roe et al., 1997), kiwifruit (*Actinidia chinensis* Planch.) (Boyd and Barnett, 2011) and Fuyu persimmon (*Diospyros kaki* L.) (Choi et al., 2010).

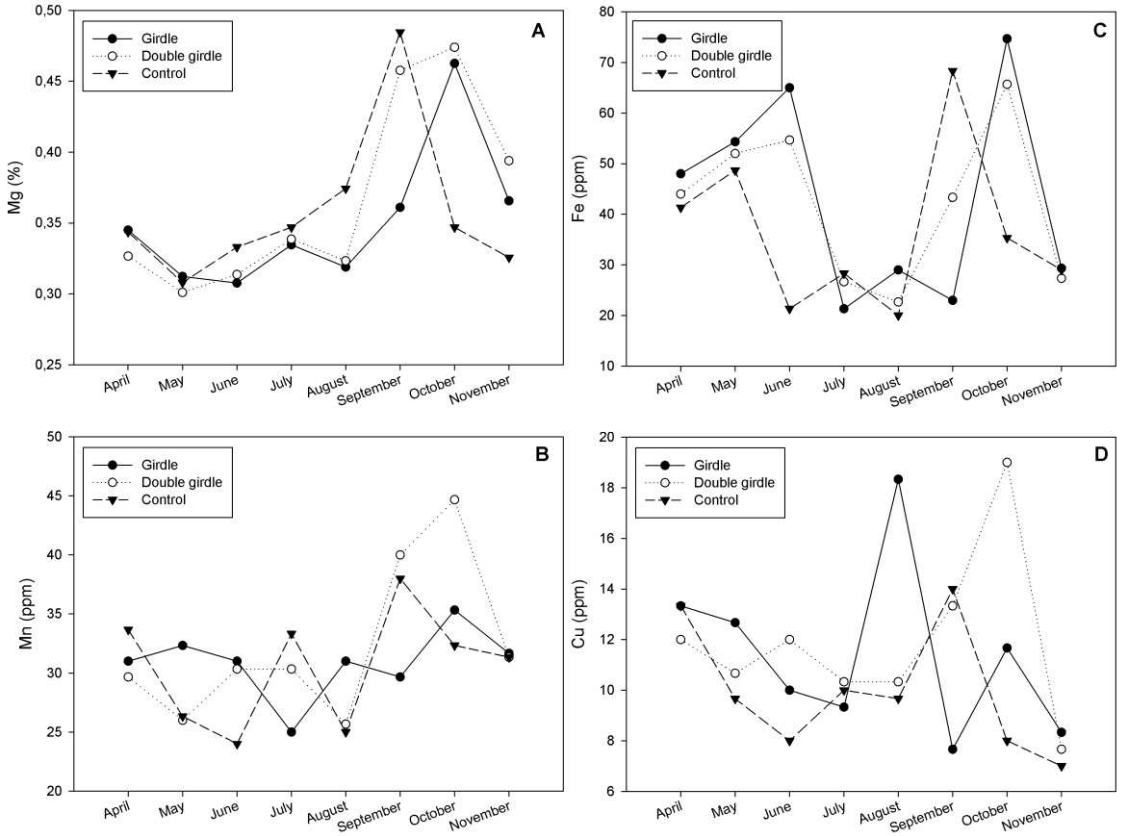

Figure 6. *Effects of girdling treatments on the leaf Mg (A), Mn (B), Fe (C) and Cu (D) concentrations in Robinson mandarins*

Fruit size is one of the most important factors affecting the marketing of fresh citrus fruits. Thus, techniques such as girdling, thinning and synthetic auxin application are commonly used to increase the size of fruit for fresh consumption. Girdling applications often promote fruit set and increase the size of fruit. In addition, Agustí et al. (2002) demonstrated that girdling can be used to increase final fruit size. In the present study, fruit diameter was significantly affected by the application of girdling treatments. Specifically, treatment with girdling increased the number of large fruits and reduced the number of fruits with a diameter <65 mm. In previous studies, fruits harvested from trees treated with girdling were significantly larger than fruits from control trees, which indicated that the application of girdling increased fruit size (Tuzcu et al., 1992; Mostafa and Saleh, 2006; Rivas et al., 2007). Moreover, Cohen (1984) found that the application of summer girdling increased fruit size of the Marsh seedless grapefruit. Similarly, Khandaker et al. (2011) indicated that fruit size of wax jambu was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

significantly influenced by different girdling treatments and that girdled branches produced the highest fruit length and diameter compared to the control branches.

Girdling treatments resulted in no marked effects upon the fruit quality. The results obtained in the present study are in concordance with those of previous studies that reported that girdling increases SSC in navels (Church, 1993) and satsumas (Peng and Rabe, 1996). However, the increased SSC due to girdling was not always significant. The results obtained in the present study are in agreement with those described in a previous report by Verreynne et al. (2001), who studied the effects of trunk girdling on the internal fruit quality of the "Marisol" clementine and found no significant differences in fruit quality due to girdling. According to Peng and Rabe (1996), girdling did not have any significant effect on juice volume; however, Mostafa and Saleh (2006) reported lower juice volume after girdling. In addition, Roussos and Tassis (2011) demonstrated that the titratable acidity, pH and maturity index of the Nova mandarin were not significantly affected by girdling.

Our results demonstrate that girdling has a significant effect on the quantum yield of PSII (*Fv/Fm*), especially with DG. In addition, the differences in PSII between girdled trees tended to decrease in comparison with controls. The results obtained in the present study are in agreement with those described in a previous report by Rivas et al. (2007), who studied the effects of girdling on fruit set and quantum yield efficiency of PSII in two *Citrus* cultivars and indicated that girdling reduced the quantum yield efficiency of PSII in the leaves of vegetative shoots. Similar results were reported in mango (Urban et al., 2004), and *P. canariensis* (López et al., 2015). Additionally, according to Quentin et al. (2013), leaves on girdled trees had a reduction of A_{net} compared to leaves on control trees. Similar results have also been reported for wet tropical rainforest trees (Asao and Ryan, 2015). Similarly, no significant differences in photosynthetic activity between the control and girdled shoots were observed until the day after girdling. However, the photosynthesis activity of the control tree then increased until harvest, while the girdled shoots showed a significant reduction (Vaio et al., 2001). The most well-known effect of girdling is the increase in carbohydrates above the girdle (Fishler et al., 1983; Mataa et al., 1998; Urban et al., 2004). However, girdling reduces leaf net photosynthesis in numerous fruit trees (Inglesias et al., 2002; Zou and Quebedeaux, 2003; Urban et al., 2004; Frank et al., 2006). According to Quentin et al. (2013), the photosynthetic activity of leaves might be restricted by feedback control in the absence of adequate sinks or upregulated where sink demand is increased. Recent studies have shown that the decline in leaf net photosynthesis due to sink demand is independent of a direct feedback effect of the end products (DaMatta et al., 2008; Cheng et al., 2008). In addition, López et al. (2015) demonstrated that the accumulation of carbohydrate can explain the reduction in the quantum yield efficiency of photosystem II through feedback loops.

Regarding chlorophyll concentration in the leaves, we found that chlorophyll concentrations decreased in girdled plants. The values of the control trees increased continuously until 60 d.a.g (in June), while the girdled trees showed a marked decrease. The values of control and girdled trees showed a similar tendency after 90 d.a.g (July) and remained more or less constant throughout the measurement periods. The results obtained in the present study are in agreement with those described in a previous report by López et al. (2015), who studied the effects of stem girdling on photosynthesis and chlorophyll in *P. canariensis* and found that they progressively decreased in girdled plants but that the effect was rapidly reversed when the phloem was reconnected. Rivas et al. (2007) demonstrated that girdling had no effect on foliar Chl concentrations

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_62056218
© 2018, ALÖKI Kft., Budapest, Hungary

between control and girdled trees in two *Citrus* cultivars. In addition, Mostafa and Saleh (2006) indicated that all treatments significantly increased both total chlorophyll and Ch_a compared to untreated trees, but no significant differences in leaf Ch_b were detected among the treatments.

Our results showed that girdling did not affect leaf mineral content. However,, we observed a tendency toward decrease in nitrogen level in the girdled trees. Similar trends were observed in the other measurement periods in all treatments. According to Cimó et al. (2013), girdling treatments decreased N, P, K, Ca and Mg concentrations in the leaves of citrus and reduced the levels of all measured micronutrients. Davies et al. (1995) reported that N, K and Ca levels were lower in avocado leaves in girdled branches compared with those of control branches. Similarly, trunk girdling decreased N levels in the leaves of several crops, including lychee (*Litchi chinensis* Sonn.) (Wang et al., 2010) and pistachio (*Pistacia vera L.*) (Vemmos, 2005). Mostafa and Saleh (2006) also demonstrated that the P percentage in the leaves of the Balady mandarin was not affect by girdling. Moreover, Jasrotia et al. (2014) found that leaf N and P in olive were not affected by girdling.

Conclusion

In conclusion, girdling significantly increased fruit set; especially when girdling was performed at the onset of cell enlargement stage, it increased the final fruit size and improved the commercial fruit size distribution. According to our results, girdling treatments increased the yield and commercial fruit size of the Robinson mandarin variety so that the girdling as one of the cultural practices can be applied for higher fruit size and fruit yield. We determined that girdling has a significant effect on both the PSII and leaf chlorophyll concentration as both decreased in girdled trees. This decrease may be related to carbohydrate accumulation in upper site of the girdling zone as reported in previous studies.

Abstract. Non-point source (NPS) pollution is an important source of lake eutrophication, the phosphorus (P) is one of the main elements of NPS pollution, and land use change has an important influence on NPS pollution load. Most previous studies focused on a single phase and did not analyze the internal structure of land use. In this study, six natural river basins such as the Hangbu River Basin were selected as the study area in Chaohu Basin, China. Based on the Sediment Delivery Distributed (SEDD) model, the NPS P load was simulated from 2000 to 2015, and the characteristics of land use change were depth analyzed at the same time to discuss the mechanism of land use pattern on NPS P load under long-term sequence. The main result are as follow: the NPS P load intensity was positively correlated with FL (forest land) area, in the whole study area, the correlation coefficient between NPS load intensity and FL area was 0.67, and the NPS P load intensity was negatively correlated with arable land (AL), construction land (CL) and wetland (WL) area, and the correlation coefficients were 0.56, 0.26 and 0.14 respectively. On the other hand, the internal structure of land use is also affecting NPS P load, the Fractal Dimension Index Mean (FRAC) was positively correlated with NPS P loss intensity, and the correlation coefficient is 0.56. Compared to the AL, FL and CL are more easily affected by FRAC. The optimization of land use spatial layout plays an important role in alleviating NPS pollution particle state.
Keywords: *sediment delivery distributed model, landscape index, long-term sequence, wetland, arable land, construction land, forest land*

Introduction

Phosphorus (P) is one of the main nutrients in inland lakes (Naramngam and Tong, 2013; Norton et al., 2012). As the main reason of eutrophication, Non-point source (NPS) P has been proven to be an important cause of bloom (Delpla et al., 2011; Dong et al., 2014; Hoffmann et al., 2009). The surface P is mainly lost by soil erosion in the adsorbed state (Wang et al., 2012). Under the influence of the dramatic change of land use, the ground surface conditions changed significantly, leading to changes in surface runoff characteristics and soil erosion (Hollis, 1975; Hundecha and Bardossy, 2004),

© 2018, ALÖKI Kft., Budapest, Hungary

Furthermore, the temporal and spatial evolution of NPS pollution loads is influenced (Ahearn et al., 2005). Therefore land use change is an important factor of NPS pollution and lake nutrient enrichment (El-Khoury et al., 2015; Haggard et al., 2001). It can be seen that the improvement of lake water environment must be based on optimizing the spatial distribution of the river basin and reducing the NPS pollution. And exploring the internal relation and the influence mechanism between them has become the hot spot in the academic circles together with river basin environmental management department (Ouyang et al., 2013; Recanatesi et al., 2013; Wu et al., 2012b).

There are two types of estimation models for NPS pollution. The first is physical model, such as the Soil Water Assessment Tool (SWAT) and the Annualized Agricultural Non-Point Source model (AnnAGNPS). This kind of model can accurately simulate NPS P loads (Bingner et al., 2003; Kim et al., 2013; Wilson and Weng, 2011), but the model parameters are complicated, and strongly depending on the plot experiment and observation. Therefore, this model is not suitable for large space scale and long time series, and unfavorable to the comparative analysis between different watershed (Bechmann et al., 2009; Yang et al., 2012). Another kind is empirical model, such as the Sediment Delivery Distributed (SEDD) model and the Pollution Loads (PLOADS) model. Empirical model, by contrast, have characteristics of simple data acquisition, wide applicable scope, strong operability and easy to operate. Therefore, it is very suitable for assessing and simulating NPS P loads in the large space scale and long time series (Borrelli et al., 2014; Bu et al., 2008; Lin et al., 2016).

There have been some studies on the relationship between land use and NPS P loads. In the early stage, Garnier et al. (1998) overlaid USLE model and land use type, results show that, compared to other areas, the NPS pollution loads is significantly higher than other area in the animal husbandry and agriculture concentration areas. Later, urban construction land surface runoff is considered to be one of the important reasons to the NPS pollution (Li et al., 2008; Tang et al., 2005). In addition, some scholar's studies found that the bare surface type, like cultivated land and plantation, is an important source of NPS P loads (Ahearn et al., 2005; Catherine et al., 2013). Recently, with the further research, there are different conclusions about the influence of forest land, construction land, and cultivated land on NPS P loads. Jiang et al. (2014) found NPS P loads was negatively correlated with cultivated land and construction land, while it was positively correlated with forest land. However Tasdighi et al. (2017) suggested that phosphorus loads was positively correlated with construction land, was negatively correlated with agricultural land. Kim et al. (2016) found that the phosphorus loads intensity of cultivated land is highest, followed by forest land.

There are many conclusions which have shown that the change of land use caused by human activities affects NPS P loads. However, previous studies have focused on a single phase and did not analyse the internal structure of land use. This leads to differences between the various scholars, particularly, there is a disagreement about the effects of cultivated land, forest land, and construction land on NPS P loads. Therefore, in this paper, the Chaohu Lake Basin, which has the most serious NPS P loads in China, is selected as the study area (Jiang et al., 2014; Kong et al., 2015), and 6 regions were determined according to the main natural rivers into the lake. The SEDD model (Fu et al., 2006; Lin et al., 2016; Taguas et al., 2011) was used to estimate the NPS P loads in Chaohu Lake Basin from 2000 to 2015, and the spatial analysis methods and indicators, which focus on the diversity of spatial and temporal changes of land use and internal structure, are used in the study to analyze the changes of NPS P loads and land use

pattern under long-term sequence, and then reveals the mechanism of land use mode on the NPS P loads. First, we confirmed the main land types that affect the NPS P loads, and then discussed the effects of different land use types on NPS P loads. Finally the response mechanism of different land use change patterns to NPS P loads is determined, and it can be used to provide scientific and technical support, and data base for spatial optimization of land use for NPS pollution control.

Materials and methods

Study sites

Chaohu Lake is one of China's five major fresh water lake, the lake area is 769 km^2, normal hydrological year average water depth is 2.69 m, the maximum water depth of 3.77 m (Wang and Dou, 1998). Chaohu Lake basin is located in central Anhui Province and north of the Yangtze River Delta, the area is 13350 km^2, the terrain is mainly plain, mountain is located in the southwest of the basin. Average annual rainfall is 1215 mm, which flood season for 5 ~ 8 month, precipitation accounts for 51% of annual precipitation. The agricultural economy is developed in Chaohu Lank basin, which is the main commodity grain production base in China, agricultural land area accounted for 60% of the basin area, and the agricultural NPS pollution is serious (Yan and Wang, 1998; Zhou and Gao, 2011). According to remote sensing inversion results and river water quality monitoring data, the west lake area water quality serious pollution (Pan et al., 2011; Shang and Shang, 2007), Nanfei River and Pai River total phosphorus input accounted for 60% of the total pollution loads of rivers into the lake (Wang et al., 2011).

Natural river basin mainly based on the terrain, and the artificial river is less affected by the terrain, so the main six natural rivers into the lake were selected: ①Zhegao River, ②Tongyang River, ③Nanfei River, ④Pai River, ⑤Hangbu River, ⑥Baishitian River. Six river basin range preliminarily determined through the analysis of the hydrological Arc SWAT function, counterclockwise number R1 ~ R6 from east to west, and further subdivided is 55 sub-basins (*Fig. 1*), the study area partition and its basic information such as shown in *Table 1*.

The land use data source and land use indices

Land use is divided into six types: ① forest land (FL); ② construction land (CL); ③ grass land (GL); ④ wetland (WL); ⑤ arable land (AL); ⑥ unutilized land (UL). According to 55 sub-basin, the area and spatial distribution of six land types were analyzed respectively. In order to evaluate the change of landscape characteristics of each sub-basin with time, four landscape indices that can reflect the spatial structure characteristics are selected, included: ① Contagion index (CONTAG); ② Fractal Dimension Index Mean, (FRAC); ③ Shannon`s Diversity Index (SHDI); ④ Shannon`s Evenness Index (SHEI). CONTAG is used to measures the degree of aggregation of the same type of patches and is influenced by the number of landscape homogeneity and type. High value shows that the greater the landscape connectivity of the advantages of plaque type exist. FRAC is a fractal pattern index, is obtained by calculation complexity area ratio, the greater the value the more complex landscape shape. SHDI is used to measure the diversity of land use in a given area. The SHDI value increases with the increase of land use type. SHEI indicates the uniformity of the land use type distribution in the area, the closer the value 1, and distribution more uniform. All landscape indices

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

are calculated in Fragstats3.3 (Lin et al., 2015; McGarigal and Marks, 1995). To show the change of land use structure and distribution in sub-basin, according to the landscape index changes over time to classify it into five types: ① gradually increased (GI); ② gradually decreased (GD)); ③ first increased and then decreased (ID); ④ first decreased and then increased (DI); ⑤ fluctuation type (FT).

Quantitative evaluation of NPS P loads

The calculation method of surface phosphorus loads is based on the fundamental form of Revised Universal Soil Loss Equation (RUSLE), the sediment delivery ratio (SDR) and the phosphorus content in the soil, to estimate watershed NPS P loads (*Eq. 1;* Lin et al., 2016; Yang et al., 2012).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_62196238
© 2018, ALÖKI Kft., Budapest, Hungary

$$W = A_i \times P \times SDR_i \quad \text{(Eq.1)}$$

where W is the surface loads of the nutrient substance per unit area per unit area ($kg \cdot km^{-2} \cdot yr^{-1}$); A_i is the soil erosion amount; P is the soil phosphorus content ($g \cdot kg^{-1}$); SDR_i is the sediment delivery ratio of the grid i (Stefano and Ferro, 2007; Yang et al., 2012; Zhou and Wu, 2008), the equation is (*Eq. 2*):

$$SDR_i = \exp(-\beta t_i) \quad \text{(Eq.2)}$$

where t_i is the time required for the loss from the grid i point to the nearest water system, and β is a constant. The soil erosion estimation model uses RUSLE as the prototype, and uses the satellite remote sensing technology to provide the data for the model. Therefore, the model calculates the spatial resolution consistent with the satellite remote sensing image, with a 30 * 30 m grid as the minimum evaluation unit. The model equation is expressed as (*Eq. 3*):

$$A_i = R_i \times LS_i \times P_i \times C_i \times K_i \quad \text{(Eq.3)}$$

where R_i is rainfall erosivity factor ($MJ\ mm \cdot (ha\ h\ yr)^{-1}$); LS_i is slope length and steepness factor; P_i is conservation support practice factor based on land use; C_i is cover management factor; K_i is soil erodibility factor. R_i is based on the monthly rainfall calculation, the calculation method is (*Eq. 4*):

$$R_i = \sum_{n=1}^{12} 1.735 \times 10^{(1.5 \times \lg(\frac{P_i^2}{P}) - 0.8188)} \quad \text{(Eq.4)}$$

P_i is the average monthly rainfall (mm), and P is the average annual rainfall (mm). LS_i reflects the topographic factors on the driving force of soil erosion, according to the related literature (Onyando et al., 2005), the calculation method is (*Eqs. 5–7*):

$$L = (\lambda/22.13)^m \quad \text{(Eq.5)}$$

$$m = \begin{cases} m = 0.2 & \theta < 0.5° \\ m = 0.3 & 0.5° \le \theta < 1.5° \\ m = 0.4 & 1.5° \le \theta < 3° \\ m = 0.5 & \theta \ge 3° \end{cases} \quad \text{(Eq.6)}$$

$$S = \begin{cases} 10.8\,sin(\theta) + 0.03 & \theta \le 5° \\ 16.8\,sin(\theta) - 0.5 & 5° < \theta < 10° \\ 21.9\,sin(\theta) - 0.96 & \theta \ge 10° \end{cases} \quad \text{(Eq.7)}$$

where θ is the slope (°) of the grid I and λ is the slope length (m) of the grid in. P_i reflects the influence of regional soil and water conservation measures on soil erosion, and its assignment is determined by different land use patterns. The P was taken on Xu et al. (2013).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_62196238
© 2018, ALÖKI Kft., Budapest, Hungary

C_i reflects the effect of vegetation on soil erosion, according to Cai et al. (2000) and (Wu et al., 2012a), the calculation method is (*Eq. 8*):

$$C = \begin{cases} 1, & c = 0 \\ 0.6508 - 0.3436\ lgc, & 0 < c \leq 78.3\% \\ 0, & c > 78.3\% \end{cases} \quad \text{(Eq.8)}$$

where c is plant coverage (%), K_i is the soil erodibility, many of the research on the literature research in the study area, assignment of each soil type, interal (0, 1). Because the soil types will not change with the passage of time, so we cannot reflect the change characteristics of soil erodibility. In order to reflect the temporal and spatial variability of soil erodibility, the K_i values were directly assigned by literature research in 2000 and 2005 (Bu et al., 2002; Zhang et al., 2007), The K_i values for 2010 and 2015 are calculated using the initial measurement method specified in the RUSLE equation guide (*Eq. 9;* Sharpley and Williams, 1990):

$$K = \left\{0.2 + 0.3 \times \exp\left[-0.0256 \times Sd \times \left(1 - \frac{Sl}{100}\right)\right]\right\} \times \left[\frac{Sl}{Cl + Sl}\right]^{0.3} \times \left\{1.0 - 0.25 \times \frac{Coc}{Coc + \exp\left(3.72 - 2.95 \times Coc\right)}\right\} \times \left\{1.0 - \frac{0.7 \times \left(1 - Sd/100\right)}{1 - Sd/100 + exp - 5.51 + 22.9 \times \left(1 - Sd/100\right)}\right\} \quad \text{(Eq.9)}$$

The model is a function of soil organic matter and mechanical composition, where Sd, Sl, Cl, and Coc correspond to the percentage of soil sand, granule and clay and soil organic carbon.

Sample collection and data acquisition

Land use classification data sets in 2000, 2005, 2010 and 2015, are provided by the Lake-Watershed Science Data Center, National Earth System Science Data Sharing Infrastructure, National Science & Technology Infrastructure of China (http://lake.geodata.cn). Land use data supported by the "Strategic Priority Research Program - Climate Change: Carbon Budget and Related Issues" of the Chinese Academy of Sciences, Grant No. XDA05050106.

The soil's physical and chemical properties data were obtained from the laboratory testing which were collected in field (*Fig. 1*). Surface soil samples (0~10 cm depth) were collected from July 22 to 24, 2016, using four points method according to different land use types: FL, CL and AL. A total of 43 samples were collected and brought back to the laboratory to analyze the physical and chemical properties of the critical soil. The soil total phosphorus (TP), soil organic matter (SOM) and soil particle composition (sand (0.05~2 mm), silt (0.002~0.05 mm) and clay (0~0.002 mm)) were analyzed after air drying and grinding. TP were measure with inductively coupled plasma-atomic emission spectrometry (ICP-AES). SOM measure with potassium dichromate method.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_62196238
© 2018, ALÖKI Kft., Budapest, Hungary

The contents of soil particle composition were measured with the pipette method (Lin et al., 2008; Lin et al., 2016). The test results are shown in *Table 2*.

Table 2. *Statistic of soil properties*

	Min	Max	Mean	Std	CV/%
TP (g/kg)	0.25	2.95	0.76	0.53	70.76
SOM (g/kg)	7.41	128.77	36.08	21.94	60.80
Clay (%)	10.63	29.88	19.43	3.76	19.34
Silt (%)	42.39	81.91	72.14	7.94	11.00
Sand (%)	0.41	45.15	8.43	9.80	116.19

The spatial representation of each factor of the SEDD model depends on the plot test and the data extraction of the satellite remote sensing image. The basic data needed for each factor are shown in the *Table 3*.

Table 3. *The data source for NPS P loads calculation*

Data type	Data source	Description
Precipitation data	Meteorological monitoring stations in Chaohu Basin	The Chaohu Lake Basin has a total of 14 meteorological monitoring stations, which can get the monthly rainfall data from 1970 to the present. After the monthly average and spatial interpolation, the spatial and temporal distribution of rainfall erosivity is estimated
Digital elevation model (DEM)	ASTER global DEM	Downloads the 30 m spatial resolution DEM data from the USGS site, to calculate the slope length, steepness factor and SDR
Soil physical and chemical properties	Laboratory test	All chemical tests are done in the Key Laboratory of Watershed Geographic Sciences, Institute of Geography and Limnology, Chinese Academy of Sciences
Vegetation coverage	Landsat 5/8 Satellite imagery	Data were downloaded from the USGS website to obtain 30 m spatial resolution remote sensing images in four years, and extract the corresponding year vegetation index
Soil types	National soil type distribution map	After digitizing the national soil type distribution map, according to the soil type, assigned the soil erodibility factor

Results

Characteristics of land use change

According to the time series, six typical types of land use in the study area were classified. The spatial distribution characteristics of each land use type were shown in *Figure 2*. The main land use type in the whole basin is the arable land. Forest land is mainly distributed in the southwest mountainous area. The forest land area increased rapidly during 2010~2015 in R4 and R5. In 2000, the most of construction land was distributed in R3. Construction land expanded rapidly over time, constantly occupying arable land, gradually covered the entire R3 and expanding to the R4 in 2015.

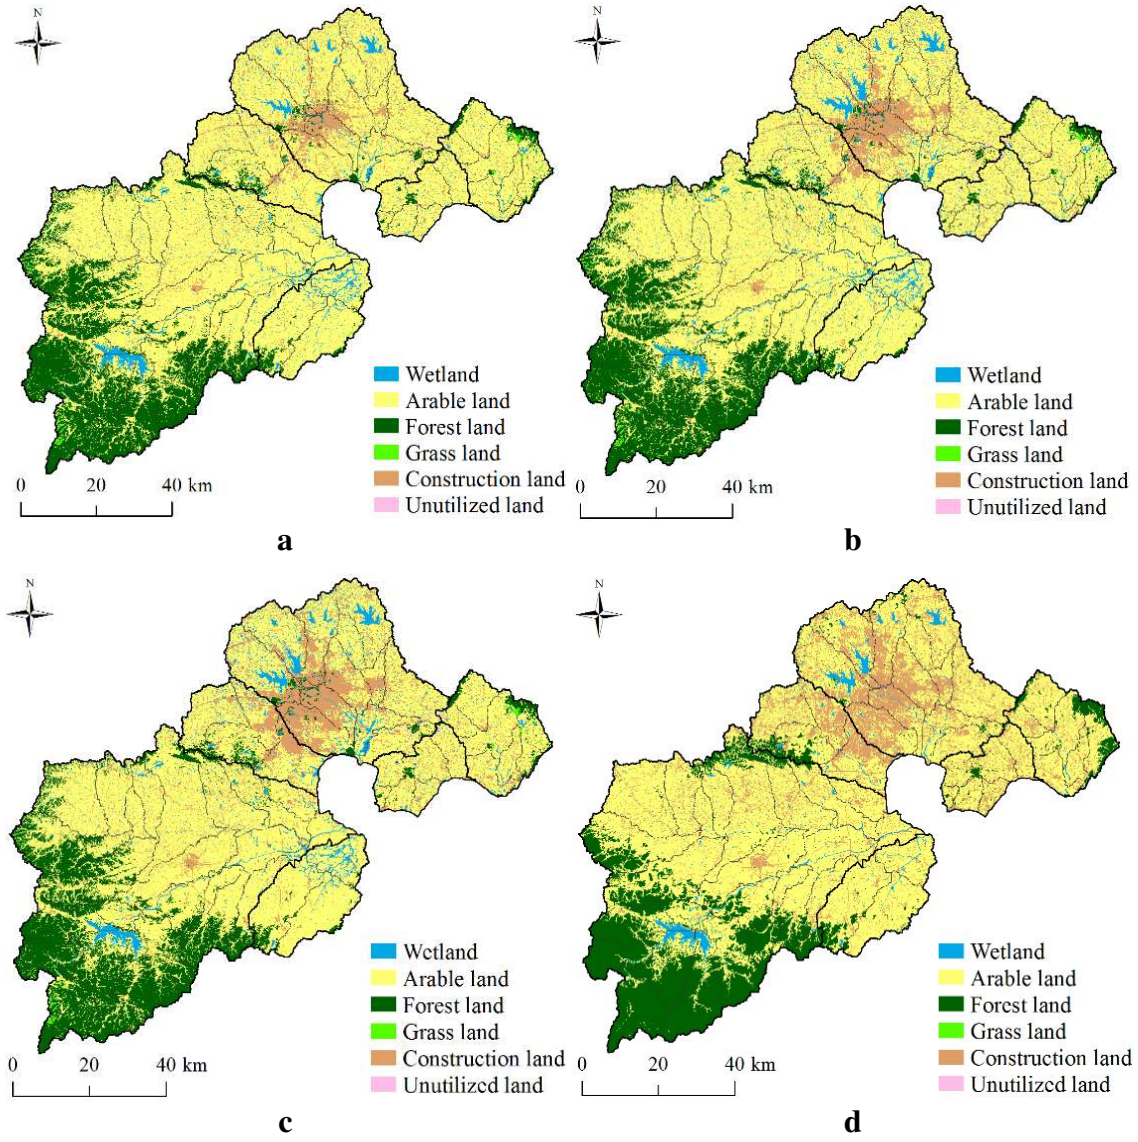

Figure 2. *The tendency of land use/cover change (LUCC) over of each sub-basins.* ***a.*** *2000;* ***b.*** *2005;* ***c.*** *2010;* ***d.*** *2015*

In addition to the spatial distribution characteristics of different land use types, the spatial structure and landscape characteristics also changed significantly with time. To show the change of land use structure and distribution in sub-basin, according to the landscape index changes over time to classify it into five types: ① gradually increased (GI); ② gradually decreased (GD)); ③ first increased and then decreased (ID); ④ first decreased and then increased (DI); ⑤ fluctuation type (FT). As shown in *Figure 3,* the land use patterns of most sub-basins were regular, and the sub-watersheds with exponential fluctuation are few.

The mainly type of change in CONTAG is GD. Except the sub-basin 20 is GI, the other sub-basins show the DI and FT characteristics, because the 20th sub-basin is the city center of Hefei, the land use types are mainly composed of construction land. In the latest decade, the construction land expands rapidly with urbanization process, so CONTAG showed a gradual increased trend. It is notable that half of the sub-basins in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_62196238
© 2018, ALÖKI Kft., Budapest, Hungary

R3 show a trend of DI, because these sub-basins construction land expanded rapidly, the occupation of cultivated land has led to the decline of connectivity and advantage of cultivated land, so CONTAG decrease. In the later period, the cultivated land became the main land use type in the sub-basin, and the connectivity of construction land increased, so do the CONTAG increase.

The main types of FRAC are GI and DI. The land use pattern in the study area showed a tendency of fragmentation over time. In the six regions, all the sub-basins in R1, R2 and R4 showed a trend of DI, and the GI is mainly in the R5 region.

The trends of SHDI in each sub-basin were different. The sub-basins in the R1, R2 and R3 show the trend of ID, and the other sub-basins are GI and FT. Only 20 and 52 sub-basin are GD, because the 20 sub-basin is the city center of Hefei, construction land gradually replaced the other land use types, so SHDI showed a trend of GD, and 52th sub-basin forest area gradually increased to replace other land types, resulting in SHDI decreased.

The main change of SHEI was GI, few sub-basins showed the ID and FT characteristics. The distribution of different land use types in the study area were more uniform over time, and the dominant position of cultivated land was decreasing gradually.

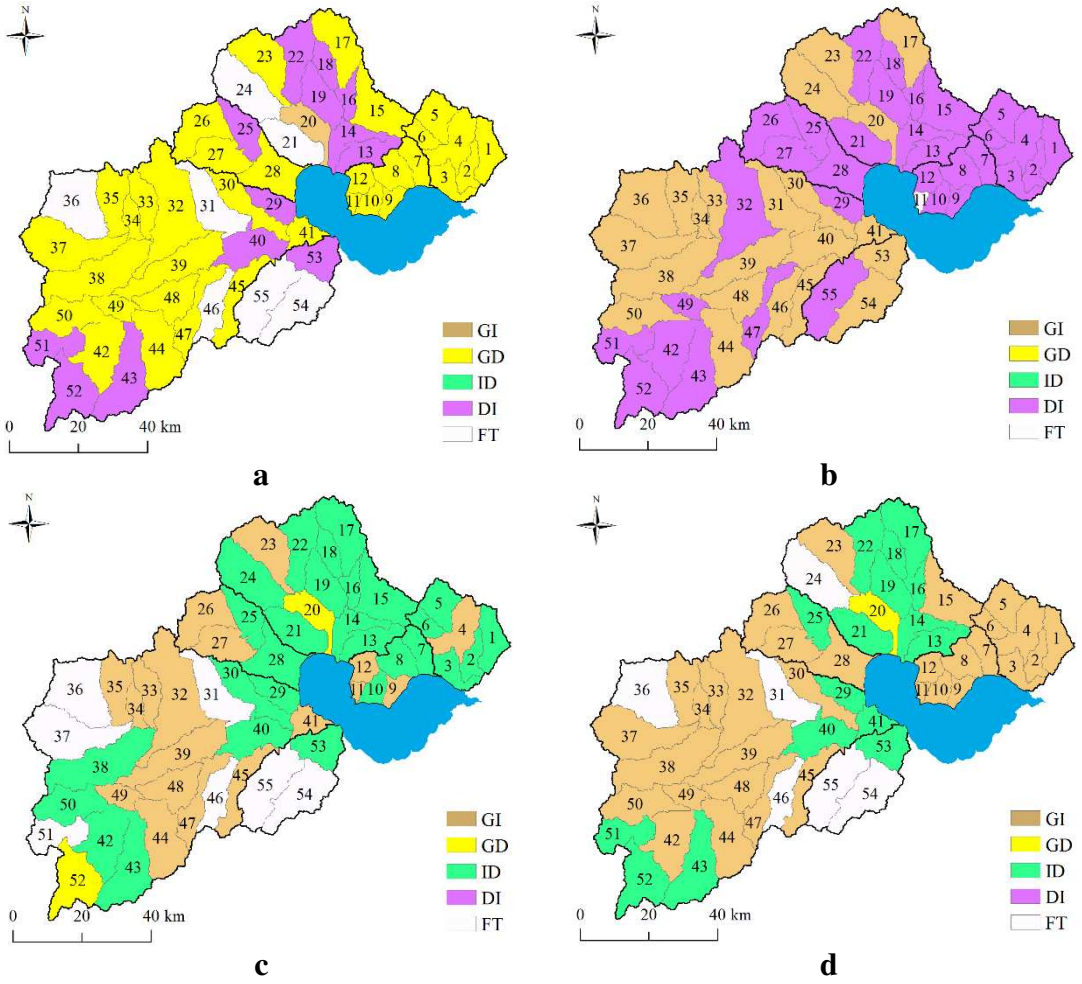

Figure 3. *Landscape index changes in each sub-basin.* ***a.*** *CONTAG;* ***b.*** *FRAC;* ***c.*** *SHDI;* ***d.*** *SHEI*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_62196238
© 2018, ALÖKI Kft., Budapest, Hungary

The main land use types in Chaohu Lake Basin was AL, and the area of CL increased rapidly. The CONTAG was decreasing, and the FRAC and SHEI show an increasing trend.

Characteristics of NPS P loads change

According to SEDD model, 2000, 2005, 2010 and 2015 NPS P loads estimated. In order to analysis the NPS P loads intensity in each sub-basin, the 55 sub-basins NPS P loads intensity was divided into seven grades (*Fig. 4*). On the whole, the change of NPS P loads changes was not obvious from 2000 to 2005, part of sub-basins showed an increasing trend during 2005~2010, all sub-basins showed a rapid increase trend during 2010~2015. The most obvious change area is R5, the spatial distribution characteristics are obvious that the high loads area is concentrated in the southwest mountain area. In 2000, the NPS P loads was low, the highest value was 1.11 $t \cdot km^{-2} \cdot yr^{-1}$, and all the sub-basins NPS P loads were below 40 $kg \cdot km^{-2} \cdot yr^{-1}$, and nearly half of the sub-basins NPS P loads is less than 5 $kg \cdot km^{-2} \cdot yr^{-1}$. In 2005, the highest value is 1.67 $t \cdot km^{-2} \cdot yr^{-1}$, shows a slow increasing trend, most of the sub-basins NPS P loads change is not obvious, except No. 1, No. 3 and No. 4 sub-basin NPS P loads decreased in R1, No. 38, No. 47 and No. 50 sub-basin NPS P loads increased in R5. In 2010, the NPS P loads showed a rapid increase trend, the highest value reached 11.66 $t \cdot km^{-2} \cdot yr^{-1}$, NPS P loads changes is different in different sub-basins, 22th sub-basin is the only sub-basin with descending trend, nearly half of the sub-basins NPS P loads showed an increasing trend. In particular, No. 43, No. 44, No. 51 and No. 52 sub-basins NPS P loading in R5 showed a rapid upward trend, more than 100 $kg \cdot km^{-2} \cdot yr^{-1}$. In 2015, the highest value of the NPS P loads decreases to 5.42 $t \cdot km^{-2} \cdot yr^{-1}$, but most of the sub-basins NPS P loads present increased. A total of 22 sub-basins NPS P loads is higher than 20 $kg \cdot km^{-2} \cdot yr^{-1}$. In addition, it is necessary to note that, when the most of the sub-basins in R5 are showing an increasing trend, especially after 2010 sub-basins NPS P loads is more than 100 $kg \cdot km^{-2} \cdot yr^{-1}$ in the southwest, the No. 40 and No. 41 sub-basins NPS P loads remained below 5 $kg \cdot km^{-2} \cdot yr^{-1}$.

© 2018, ALÖKI Kft., Budapest, Hungary

In summary, NPS P loads did not change significantly before 2005, and increased rapidly after 2005. The spatial distribution of the high loads zone was closely related to the terrain, so it concentrated in the southwest mountainous area.

Relationship between NPS P loads and land use change

The correlation coefficients between the NPS P loads and the different land use area and land use index in the whole study area and the six region are shown in *Table 4*.

On the whole, NPS P loads intensity was positively correlated with FL area and FRAC, negatively correlated with AL, CL and WL area. Verify the Jiang et al. (2014) conclusions on the cultivated land, construction land and forest land. The correlation coefficient of the whole study area was clear, but the correlation coefficients in each region were different. For example: (1) Although the NPS P loads was significantly positive correlated construction land area, but only in R5 was significantly positive correlated, and it was opposite in R2 and R6; (2) Although, on the whole, CONTAG, SHDI and SHEI were not significantly correlated with NPS P loads, there was a significant correlation in both R1 and R2.

Table 4. *Correlation coefficients (r) between NPS P loads intensity and LUCC area and indices*

*Correlation is significant at the 0.05 level (2-tailed)
**Correlation is significant at the 0.01 level (2-tailed)
.[b] indicates that there is no such land use type in this region

Some conclusions can be drawn from the simple correlation coefficient, but the relationship between the NPS P loads and the land use pattern cannot be generalized. There were differences in different regions, especially the relationship, in particular the relationship between the land area and NPS P loads.

Discussion

Effects of land use change on NPS P loads in different regions

The land use change statistics for the six regions are shown in *Figure 5,* AL was a major land use type in Chaohu Lake basin, and the second was followed by construction land. Except the R5, the region includes the Dabie Mountain, the FL area was larger than the CL area, become the second largest land area after cultivated land. Land. CL area showed an increasing trend in all basins, especially in R2, R3 and R4, CL area increased rapidly, AL area decreased rapidly, indicated that the expansion of construction land is based on the occupation of cultivated land. During 2000~2010, the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_62196238
© 2018, ALÖKI Kft., Budapest, Hungary

wetlands in the six regions had different trends, such as R3 increased, while the R6 decreased, but during 2010~2015, WL area decreased in all regions. GL and UL area were small, almost replaced by other land in 2015

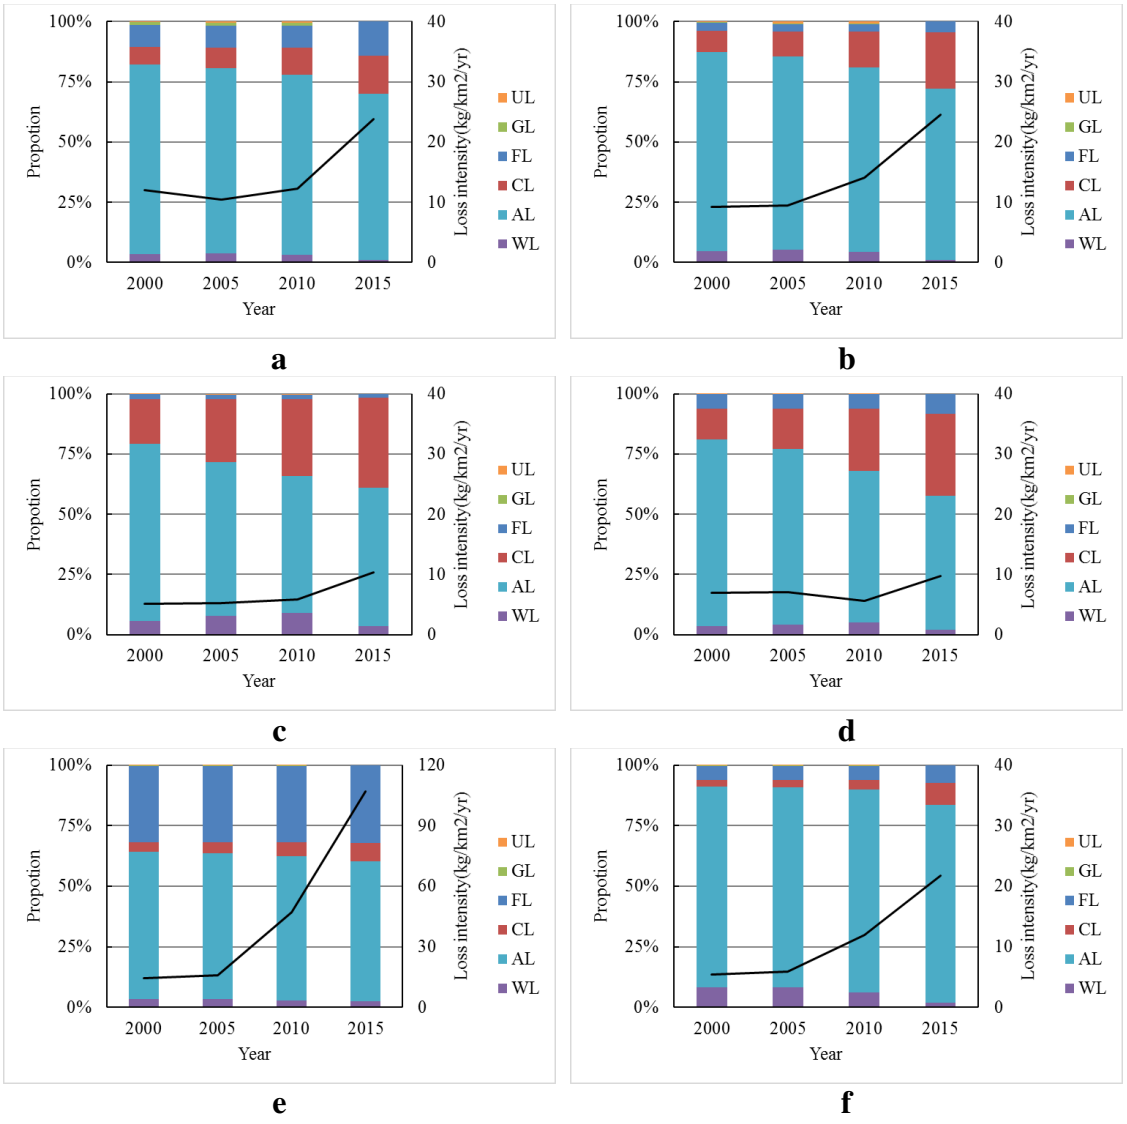

Figure 5. *Statistical data of each land use proportion and NPS P loss intensity in different region.* ***a.*** *R1;* ***b.*** *R2;* ***c.*** *R3;* ***d.*** *R4;* ***e.*** *R5;* ***f.*** *R6*

NPS P loss intensity showed an increasing trend, the highest intensity areas in R5. During 2000~2005, NPS P loss intensity growth slowly. During 2005~2010, loss intensity increased rapidly, but the change is different in different regions, for example, in R5, NPS P loss intensity have trebled, while R4 is decreased. During 2010~2015, NPS P increased rapidly, the loss intensity in all regions have doubled. Chaohu Lake Basin NPS P loads estimation results are comparable with other scholars. On the spatial distribution, Jiang et al. (2014), calculated the three periods of Chaohu Lake Basin NPS P loads, the results of 2001 to 2008 show that the high value of NPS P is concentrated in the southwest mountainous area, and there is a small amount in the northeast, which is consistent with the results of this study. Wang et al. (2015) simulated the spatial

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_62196238
© 2018, ALÖKI Kft., Budapest, Hungary

distribution of NPS pollution in the Chaohu Lake Basin in 2010, and the spatial distribution of the NPS P loads was also the same. Kong et al. (2015) estimated the surface loads of the Chaohu basin from 1953 to 2012, NPS P loads are showing an increasing trend in 2000, 2000 and 2010 three periods, consistent with the trend of this research. Therefore, this study of NPS P loads estimation has a certain credibility.

During 2005~2010, R1 and R3 NPS P loads changed not obviously, R5 and R6 increased quickly, because the proportion of CL in R1 and R3 was significantly higher than that in R5 and R6, indicating that the CL can slow down the growth rate of the NPS P loads. During 2000~2010, NPS P loads intensity was not increasing in all regions, but during 2010~2015, all regions NPS P increased rapidly. During this period, the most obvious change of land use was the WL area decreased dramatically, illustrate the WL area was small, but played an important role in NPS P loads. This was consistent with the findings of Chescheir et al. (1992) and Braskerud (2002).

In summary, the WL and CL area had an important influence on the NPS P loads, WL area decreasing lead to NPS P loads intensity increase rapidly, the increase of CL area can slow down the growth rate of NPS P loads. On the other hand, FL and AL were not only the main land use types in the study area, but also the land classes that many scholars have paid attention to over the years. Therefore, we are going to discuss the effect of land use change on NPS P loads in WL, CL, FL and AL.

Effects of land use change on NPS P loads in different land use types

Because the proportion of WL area was small, and it had a very important impact on NPS P loads, so the WL was discussed separately. And the influence of WL area on the basin NPS P loads, as well as to the three main land use types NPS P loads. In recent years, many scholars have different opinions about the influence of AL, CL and FL on the NPS P loads (Jiang et al., 2014; Kim et al., 2016; Tasdighi et al., 2017). These three land use types are not only the main land use types in basin, but also would influence each other between the three land use types, so these three land use types are discussed together.

Wetland

According to *Table 4*, sub-basin was the evaluation unit, the correlation coefficient between WL area and NPS P loads is only 0.14, and not all regions have significant correlation. Taking the region as the evaluation unit, the NPS P loads intensity and WL area of 6 regions in 4 years were shown in *Figure 6*. The results showed that the WL area was negatively correlated with the NPS P loads intensity, R^2 was only 0.17, and the highest point of the loads intensity belongs to the R5. When the 4 points in the R5 area were removed (*Fig. 6b*), R2 reached 0.55. It indicated that there was a strong negative correlation between WL area and NPS P loads intensity, the change of WL area had a significant effect on the NPS P loads. In the R5, compared with other regions, the influence of WL area on the NPS P loads was different. As the area was affected by the mountain, the surface phosphorus loads intensity was significantly higher than other regions, causing the regional NPS P loads intensity beyond the adjustment ability of WL. On the other hand, it indicated that in different spatial scales, the WL area influence on NPS P loads approach was different, it still need further study in the future.

Table 5 is the correlation coefficient between WL area and the NPS P loads intensity of the three main land types. In the whole study area, the wetland area was negatively

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

correlated with the NPS P loads intensity in AL, and there was no significant correlation with the other two land use types. However, there were differences in different areas and land use types. For example, in R1 and R6, WL area was significantly negative correlated with NPS P loads intensity in three land use types, but in R2 and R5, there was no significant correlation between WL area and NPS P in three land use types. It indicated that the change of WL area plays a role in the NPS P loads intensity in the whole area.

The WL area played an important role in NPS P loads intensity of the entire study area, and it was significantly negatively correlation with NPS P in AL, but the adjustment ability of the WL to NPS P loads was limited.

Arable land, construction land and forest land

The correlation coefficients between the NPS P loads intensity and the land area and landscape index were calculated for each of the three land use types (*Table 6*). It can be seen that the effect of land use change on the NPS P loads in different land use types was very complicated.

(1) The NPS P loads intensity in different land use types were affected by FRAC in different degrees, and FRAC impact on NPS P loads intensity in AL is minimal. There were only three regions that the NPS P loads intensity in AL were significantly correlated with FRAC, and there were five regions that the NPS P loads intensity in FL were significant correlated with FRAC. And the correlation coefficient of FRAC and the loads intensity in R2 was the highest, reaching 0.83. (2) Among the three types of land use, the NPS P loads intensity in CL was most affected by its own area. Except R4,

© 2018, ALÖKI Kft., Budapest, Hungary

CL NPS P loads intensity in all regions were significantly correlated with its area, the highest correlation coefficient was 0.75. (3) Overall, three kinds of land NPS P loads intensities were positively correlated with FRAC, negatively correlated with CONTAG, which indicates that when the land use fragmentation was higher and the contagion was lower, the NPS P loads intensity was higher.

	R5	0.52**	0	0.68**	0.03	0.06
	R6	0.67*	-0.42	0.19	0.58*	0.46

*Correlation is significant at the 0.05 level (2-tailed)
**Correlation is significant at the 0.01 level (2-tailed)

In R5, three land use types NPS P loads intensities were significantly correlated with the corresponding land area. Moreover, only in R5, the CL area negatively correlated with its NPS P loads intensity, and the NPS P loads intensity of the R5 region was hardly affected by the WL area (*Table 5*). This indicated that the NPS P load in mountainous area was mainly affected by terrain. In this case, the change of human activities on soil properties, and the blocking effect of artificial surface on rainfall erosion can lead to the decrease of NPS P load. Therefore, the effect of land use on NPS P load in mountainous and plain was different. In the future research, it is necessary to explore the mechanism of phosphorus loss in different slope conditions. In contrast to previous scholars' conclusions (Catherine et al., 2013; Tang et al., 2005), human activity does not only exacerbate the NPS P loads. In plain areas, human activities lead to NPS P loads intensity increased, while in mountainous areas, terrain plays a dominant role in NPS P loads intensity, human activities can reduce the NPS P loads.

In conclusion, three land use types, NPS P loads intensity in AL was the least affected by FRAC, NPS P loads intensity in CL was affected by its own area change most significantly. Human activities in the mountains may reduce the NPS P loads intensity.

Conclusion

In this study, six main natural rivers basin into the Chaohu Lake were chosen as the study area. The SEDD model was used to estimate the NPS P loads from 2000 to 2015, and a variety of typical land use types were selected to analyze the relationship between NPS P loads and land use change pattern, in order to explore the impact mechanism of land use on NPS P loads. The conclusions are:

(1) The NPS P loads intensity was positively correlated with FL area, and negatively correlated with AL, CL and WL area, and positively correlated with FRAC.

(2) Although the WL area was small, it played an important role in the NPS P loads in the basin, the WL area was significantly negative correlated with the NPS P loads intensity in AL. But its ability to adjust the NPS P loads was limited.

(3) Compared with AL, NPS P loads intensities of FL and CL were more susceptible to FRAC. The NPS P loads intensity of CL was more susceptible to its own area.

Land use patterns have an important impact on lake water quality through the impact of NPS pollution. Combining the basin and lake as a whole and analyzing the mechanism between land use, NPS pollution and lake water quality will be the focus of future research.

(Received 23rd May 2018; accepted 14th Aug 2018)

Abstract. Carbon sequestration needs to be accompanied by socio-economic enhancements, especially, in developing countries like Pakistan. Agroforestry has been considered as an ancient practice throughout the country but the knowledge about its impacts on tree and soil carbon storage is minimal. Growth, biomass, carbon stocks and CO_2 sequestration rate in three different age classes of *Populus deltoides* Bartr. Ex Marsh. planted in linear patterns along boundaries (bund planting) were estimated in three subdivisions (Tehsils) of district Chiniot (Bhawana, Chiniot and Lalian) of Punjab, Pakistan. For estimating tree biomass and carbon stocks, allometric equation was used and soil organic carbon (SOC) was assessed at two depths (0-15 and 15-30 cm). The diameter at breast height (DBH) and height of trees were higher at 4-6 years as compared to 2-4 years and the plant biomass was found the maximum (90.55 Mg ha^{-1}) in Tehsil Lalian at 6 years. Total carbon stocks and CO_2 sequestration rate varied from 0.89 Mg ha^{-1} and 1.63 Mg ha^{-1} yr^{-1} at 2 years to 43.54 Mg ha^{-1} and 26.58 Mg ha^{-1} yr^{-1} at 6 years, respectively, across all Tehsils. Total SOC stocks were maximum (43.73 Mg ha^{-1}) at 6 years in Tehsil Lalian while minimum 27.92 Mg ha^{-1} in Tehsil Bhawana at 2 years. Overall, soil + tree carbon stocks increased with age and was maximum at 6 years: 61.54 Mg ha^{-1}, 80.76 Mg ha^{-1}, and 87.27 Mg ha^{-1} in Tehsil Bhawana, Chiniot, and Lalian, respectively. The above results encouraged the establishment of *P. deltoides* planting along farm crops as an important possibility for increased carbon storage and mitigation of atmospheric accumulation of CO_2.
Keywords: *agroforestry, climate change, tree biomass, carbon capture, agriculture, environment*

Introduction

The agriculture sector of Pakistan is at risk and facing diverse challenges such as diminution of natural resources (agriculture, forests and water) and severe climatic changes due to increasing population pressure and growing needs of food, feed, fodder, pulp, fuel wood and timber (Saifullha, 2017). Being a less developed country, Pakistan is ranked 7th among the most vulnerable countries in the world (Kreft et al., 2017). Therefore, to ensure sustainability in agriculture and to fulfill the food requirements of the enormous population, suitable methods of climate change mitigation have to be adapted by the country (Nawaz et al., 2017b).

The contribution of agriculture in the anthropogenic emissions of greenhouse gases (GHGs) ranges from 10-12% around the globe (Smith et al., 2008). However, tree crop combination (agroforestry) has been documented by UNFCCC (United Nations

Framework Convention on Climate Change) as GHG mitigation opportunity because of its high carbon sequestering potential and fast growth rate of farm trees (Watson et al., 2000; Updegraff et al., 2004; Chauhan et al., 2009). Planting of trees and shrubs along crops or on grazed pastures on the same land area is known as agroforestry (Nair et al., 2009). In developing countries, like Pakistan, agroforestry has recently attained growing attention for mitigating GHG emissions. Agroforestry systems can store the higher amount of carbon as compared to conventional plantations (Hergoualc'h et al., 2012).

In recent years, agroforestry has got attention as a portion climate-smart-agriculture and is repeatedly declared as a prospective source to mitigate the adverse climatic conditions (Ajit et al., 2014). In Pakistan, agroforestry provides fuelwood, timber, fodder, fertilizer, fiber and contribute in the provision of food, maintain livelihoods, cope to overcome poverty and promotes the prolific and irrepressible cropping and agricultural environment, thus playing a vital role in the daily life of rural population of the country (Nawaz et al., 2016). Moreover, agroforestry has been getting noteworthy considerations by the researchers as well as by policymakers for its apparent ability to sequester carbon, alleviation of poverty, economic growth (DAC, 2014) and considered as an important part of 'Green Pakistan' movement in the country.

Poplar (*Populus deltoides* Bartr. Ex Marsh.) based agroforestry system has received a wide recognition throughout the globe, covering an area of 1.5 million ha (Kutsokon et al., 2015). The area is supposed to increase up to many folds in near future by planting the poplar in marginal agricultural lands to fullfil the needs of fuel and timber in developing regions of the world (Nielsen et al., 2014; Jha, 2018). Because of its fast growth rate, compatibility with crops and high industrial demand, poplar has got a wide acceptance by the farmers of Pakistan, especially, in Punjab during the last two decades. The branches, leaves and sometimes roots are used as fuelwood by the local dwellers while timber of the tree is used in plywood industries of the country. The tree has an enormous potential to store carbon and sequester CO_2 owing to its fast growth habit and wider adaptability throughout the country (Arora et al., 2014; Qureshi, 2005).

A number of studies have been documented on biomass, productivity, functioning, structure and carbon stocks of Poplar throughout the world (Das and Chaturvdi, 2005; Fang et al., 2007; Rizvi et al., 2011; Arora et al., 2014). Most of these studies were carried out in plantations and/or under different agroforestry systems, however, the studies in bund planting based agroforestry system under semiarid climate are rare. Moreover, in Pakistan, the information regarding biomass, productivity, carbon stock and rate of CO_2 sequestration of bund planted poplar based agroforestry by age under the set of local environmental conditions is scanty. Keeping in mind the above situation, the study was formulated to investigate the hypothesis that *P. deltoides* (poplar) planted linearly along field bunds (bund planting) store significant amount of carbon and thus mitigate CO_2 from the environment. The second hypothesis was that site factor can play a significant role in c sequestration owing to minor climatic differences and/or different agroforestry practices. The study was performed in three Tehsils of District Chiniot: Bhawana, Chiniot, and Lalian, with the major objective to estimate the growth, biomass, carbon storage and its dissemination in the various carbon pools (above ground biomass and belowground biomass + soil) among three different age classes of *P. deltoides*.

Materials and methods

Ethics statement

The current study was carried out in three administrative subdivisions (Tehsils) of District Chiniot (*Fig. 1*). Tree inventory and soil sampling were carried out in rural areas of these Tehsils with special permission from the farmers. It is confirmed that during sampling no harm was done to the farm crops and/or farm trees (*P. deltoides*).

Site description

The studied district shared boundary with four districts: Faisalabad on the south-east, Hafizabad on the north, Jhang on the south and Sargodha on the west. The whole district was comprised of three subdivisions (Tehsils): Bhawana, Chiniot, and Lalian, with a total area of 1,020 square miles. Geographically, this region is divided into two surface levels, i.e. low-level river valley in the center along river Chenab and old Sandal Bar area present along the extreme east. Areas near River Chenab experience severe floods during monsoon season. The region experiences very long summers and short severe winters. The dry period starts from early October and lasts until mid-July (Nawaz et al., 2016). The annual rainfall ranges from 345 mm (Tehsil Lalian) to 324 mm (Tehsil Bhawana). The mean annual temperature ranges from 24 to 24.3 °C with an average June high of 34.3 °C and January low of 11.8 °C among all three Tehsils of District Chiniot. (https://en.climate-data.org).

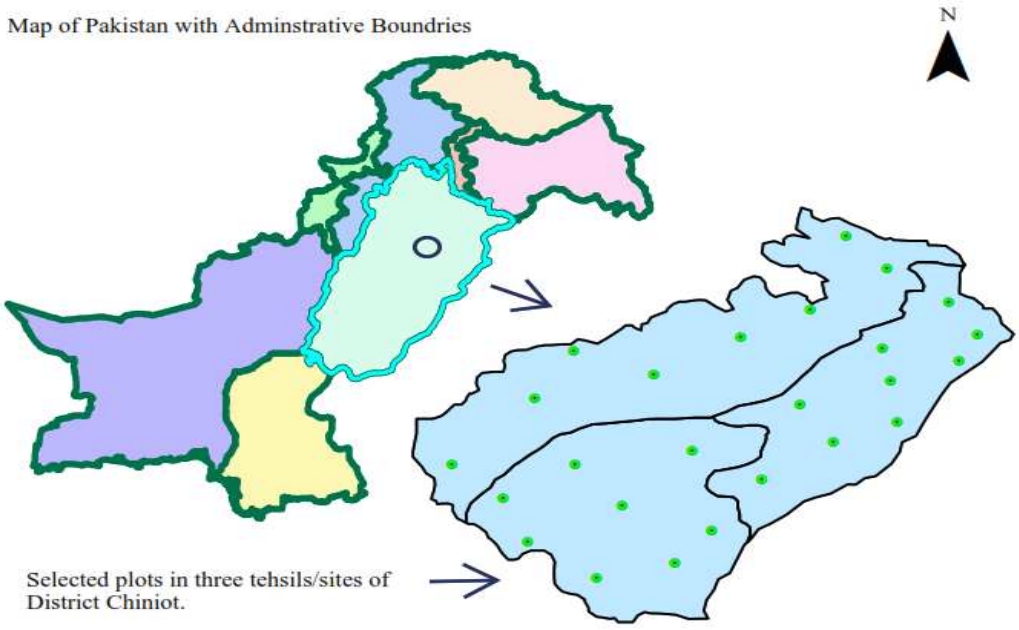

Figure 1. *Map of Pakistan with administrative boundaries and study area map showing the distribution of sampled plots in three Tehsils of District Chiniot*

Biomass sampling, carbon stocks, and CO_2 sequestration

A nondestructive approach was used to estimate the tree above and belowground biomass. Inventory data was collected from selected villages of each Tehsil. For that purpose, field visits were carried out during April 2016 and 2 plots of 0.405 ha (1 acre)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_62396252
© 2018, ALÖKI Kft., Budapest, Hungary

for each age group, which have *P. deltoides* planted linearly along croplands were randomly selected from each village (Nawaz et al., 2018; Murthy et al., 2013). The height and diameter at breast height (DBH) of all the *P. deltoides* trees planted by farmers on each plot were measured. The aboveground biomass was measured by using species-specific allometric equation from the literature (Arora et al., 2014). The belowground biomass was assumed to be 26% of the aboveground biomass (Cairns et al., 1997). Inventory parameters: DBH and height were then used to calculate the individual tree biomass of each age group which was then converted to biomass per plot. Carbon stock for each age group was calculated by assuming that the dry mass is 48.1% carbon of biomass (Thomas and Martin, 2012). The calculated weight of carbon content was then converted to CO_2 sequestered by trees of each age group by multiplying with 3.6663 (Afzal and Aqeela, 2013).

Soil sampling and soil carbon stocks

Soil sampling was done randomly at 5 places for each age group of *P. deltoides* at two depths (0-15 cm and 15-30 cm). Samples were collected in cardinal directions under the tree canopy as well as outside the tree canopy. To get a composite sample, these collected samples were then mixed together for each depth. Overall, 90 samples (3 ages × 3 Tehsils × 2 depths × 5 replicates), 10 for each age class and 30 from each Tehsil were collected. All of the soil samples within the same soil depth were pooled together and air dried. The Walkley Black method was used to calculate the soil organic carbon (Walkley and Black, 1934). Metal core having a height of 4 cm and an internal diameter of 5 cm was used to determine the bulk density at two depths (0-15 cm and 15-30 cm) by a procedure described by (Arora et al., 2014). Soil carbon per hectare was calculated by multiplying the values of bulk density, soil depth and %age of organic carbon content (Joa Carlos et al., 2001).

Statistical analysis

Descriptive statistics and the data regarding soil carbon and bulk density was analyzed for each age group by using two-way analysis of variance (ANOVA). The mean comparison was carried out by least significant difference test (LSD) at ($p \leq 0.05$) by using SAS 9.4 & Statistica 10 statistical softwares.

Results

Tree growth and biomass

The growth parameters indicated the increasing trend with increased age, a steady increase in DBH and height was noted among all three Tehsils of District Chiniot (*Table 1*). The DBH and height of *P. deltoides* increased from 1.98 cm and 1.83 m at the 2 years to 24.57 cm and 20.89 m at the 6 years, respectively. Among all the Tehsils, the maximum mean DBH (6.84 ± 1.58 cm, 12.46 ± 2.20 cm, and 20.43 ± 4.08 cm) was noted in Tehsil Lalian at the 2, 4 and 6 years, respectively. Whereas, for 2-year-old age, maximum mean height (5.52 ± 1.23 m) was calculated in Tehsil Bhawana and for 4 and 6 years, maximum mean height (9.28 ± 1.85 m and 13.45 ± 1.86 m) was estimated in Tehsil Lalian. Positive and significant relationship between tree age and DBH ($r = 0.92$, $p < 0.001$), tree age and Height ($r = 0.60$, $p < 0.001$) illustrate that both the parameters were responsible for biomass increment of *P. deltoides*. The AGB (aboveground

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

biomass), BGB (belowground biomass), and PB (plant biomass) recorded for different age classes of the *P. deltoides* viewed in the order: 6 > 4 > 2. Across all the three age classes of the *P. deltoides* bund agroforestry plantation, higher biomass proportion was noted in stem biomass as compared to the other parts. The AGB and BGB of the *P. deltoides* was increased with increasing age among all three Tehsils with maximum in Tehsil Lalian: 1.89 Mg ha^{-1} and 0.49 Mg ha^{-1} (2 years), 17.67 Mg ha^{-1} and 4.60 Mg ha^{-1} (4 years), and 71.85 Mg ha^{-1} and 18.68 Mg ha^{-1} (6 years), while minimum in Tehsil Bhawana 1.47 Mg ha^{-1} and 0.38 Mg ha^{-1} (2 years), 9.15 Mg ha^{-1} and 2.38 Mg ha^{-1} (4 years), and 37.80 Mg ha^{-1} and 9.85 Mg ha^{-1} (6 years), respectively. The plant biomass of the *P. deltoides* in the study district increased from 1.86 Mg ha^{-1} at the 2 years age to 90.55 Mg ha^{-1} at the 6 years plots, with the maximum increase found in the 4-6 years age (*Table 2*).

Tree carbon stocks and CO_2 sequestration

Tree carbon stocks and CO_2 sequestration was estimated at Tehsil level in three different age classes of the *P. deltoides* planted along the farm crops on bunds by farmers. Across all age groups, the aboveground carbon stocks (AGCS), belowground carbon stock (BGCS), total plant carbon stock (TPCS), CO_2 sequestration and CO_2

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

sequestration rate were highest at the 6-year-old plots and the lowest at the 2-year-old plots given in *Table 3*. A positive and significant linear relationship was found between plot-level tree carbon stock and tree basal area with R^2 = 0.98 as represented in *Figure 2*.

Table 3. *Carbon stock (Mg ha^{-1}), CO_2 sequestration (Mg ha^{-1}) and CO_2 sequestration rate ha^{-1} yr^{-1} in P. deltoides by age among three Tehsils of Distirct Chiniot*

Carbon stock (Mg ha^{-1}), CO_2 sequestration (Mg ha^{-1}) and CO_2 sequestration rate ha^{-1}yr^{-1}

AGCS, BGCS and TPCS refer to aboveground carbon stock, belowground carbon stock and total plant carbon stock, respectively

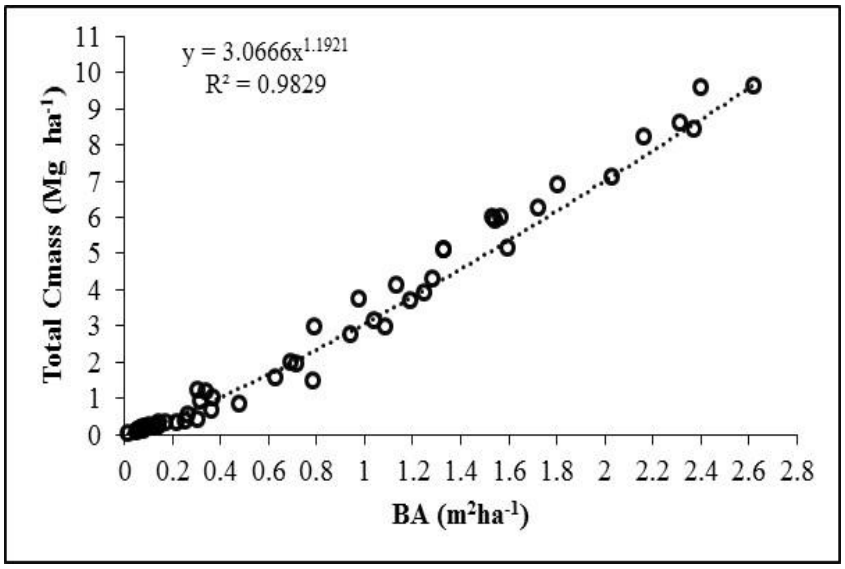

Figure 2. *Allometric model representing relationship between total carbon mass (Mg ha^{-1}) and tree basal area (BA m^2 ha^{-1}) for inventory plots of P. deltoides planted linearly along farm crops in District Chiniot*

Across all three Tehsils, the above and belowground carbon stocks at the 2-year-old plots were increased from 0.71 Mg ha^{-1} and 0.18 Mg ha^{-1} to 0.91 Mg ha^{-1} and 0.24 Mg ha^{-1}, with minimum values in Tehsil Bhawana and maximum in Tehsil Lalian. Similar trends were noted about the above and belowground distribution of carbon contents at the 4 and 6-year-old plots, maximum values accounted for Tehsil Lalian (8.50 Mg ha^{-1}, 2.21 Mg ha^{-1} and 34.56 Mg ha^{-1}, 8.99 Mg ha^{-1}), followed by Chinot (7.44 Mg ha^{-1}, 1.96 Mg ha^{-1} and 30.91 Mg ha^{-1}, 8.04 Mg ha^{-1}), while minimum carbon stocks were estimated in Tehsil Bhawana (4.40 Mg ha^{-1}, 1.14 Mg ha^{-1} and 18.23 Mg ha^{-1}, 4.74 Mg

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_62396252
© 2018, ALÖKI Kft., Budapest, Hungary

ha^{-1}), respectively. The total plant carbon stocks increased from 0.89 Mg ha^{-1} at the 2 years age class (Tehsil Bhawana) to 43.54 Mg ha^{-1} at the 6 years (Tehsil Lalian) with a maximum increase occurred in the 4-6 years age class. There was a positive and significant correlation was observed between biomass carbon and tree age ($r = 0.42$, $p < 0.001$). The CO_2 sequestration and CO_2 sequestration rate was increased from 84.13 Mg ha^{-1} and 14.02 Mg ha^{-1} yr^{-1} at 2 years of and reached up to a maximum of 159.50 Mg ha^{-1} and 26.58 Mg ha^{-1} yr^{-1} at 6 years in this study.

Soil organic carbon and carbon stocks

Soil organic carbon (SOC %) revealed a decreasing trend with the increase of soil depth across all age classes in the three Tehsils: SOC was higher in upper soil (0-15 cm) as compared to the sub-soil (15-30 cm). The difference in soil organic carbon because of age was significant (*Table 4*). SOC, in upper soil, was 36.97% greater in Tehsil Bhawana, 32.52% in Tehsil Chiniot and 38.28% in Tehsil Lalian in the 6 years as compared to the 2 years of *P. deltoides*. Bulk density (BD) showed antagonistic results as compared to SOC. However, BD increased with tree age across all the Tehsils. For all age classes, bulk density was more in the subsoil as compared to the upper soil surface (*Table 4*). It decreased from 1.50 g cm^{-3} at 2 years to 1.28 g cm^{-3} at 6 years in surface soil (0-15 cm).

Table 4. *Organic carbon (%) and bulk density (g cm^{-3}) in P. deltoides by age planted linearly among three Tehsils of District Chiniot*

Age (years)	Tehsils/sites	Organic carbon %		Bulk density (g cm^{-3})	
		0-15 cm	15-30 cm	0-15 cm	15-30 cm
2	Bhawana	0.75±0.07^{f}	0.51±0.03 ^{f}	1.47±0.02 ^{ab}	1.48±0.03 ^{bc}
	Chiniot	0.83±0.05^{e}	0.57±0.04 ^{def}	1.43±0.04 ^{bc}	1.51±0.02 ^{ab}
	Lalian	0.79±0.07^{ef}	0.53±0.06 ^{ef}	1.50±0.07 ^{a}	1.53±0.06 ^{a}
4	Bhawana	0.91±0.04^{cd}	0.59±0.03 ^{de}	1.31±0.04 ^{efg}	1.44±0.06 ^{cd}
	Chiniot	0.86±0.05^{de}	0.62±0.06 ^{cd}	1.40±0.04 ^{cd}	1.41±0.02 ^{cde}
	Lalian	0.95±0.06^{c}	0.66±0.05 ^{c}	1.37±0.05 ^{cde}	1.44±0.05 ^{cd}
6	Bhawana	1.19±0.04^{b}	0.78±0.06 ^{b}	1.28±0.04 ^{g}	1.34±0.06 ^{f}
	Chiniot	1.23±0.03^{ab}	0.86±0.05 ^{a}	1.31±0.03 ^{fg}	1.36±0.02 ^{ef}
	Lalian	1.28±0.03^{a}	0.85±0.06 ^{a}	1.35±0.03 ^{def}	1.39±0.03 ^{def}

n = 5 for each age class and values are mean with standard deviation. Means having same letters are not significantly different at a probability level of 5%

With the increase in tree age soil organic carbon stocks (SOCS) increased, regardless of soil depth across three Tehsils of District Chiniot (*Table 5*). In surface soil, SOCS were increased maximum 36.33% in Tehsil Chiniot while minimum 28.01% in Tehsil Bhawana at 6 years than in 2-year-old trees. At 15-30 cm depth, SOCS were decreased from 11.37 Mg ha^{-1} at the 2-year-old trees (Tehsil Bhawana) to 17.76 Mg ha^{-1} at 6-year-old trees. Tree age and SOC indicate a positive and significant correlation at both soil depths ($r = 0.86$ and $r = 0.80$, $p < 0.001$). The carbon sequestration rate (CSR) at 0-30 cm soil was greater in Tehsil Lalian (2.27 Mg ha^{-1} yr^{-1}) as compared to other two Tehsils at 6-year-old trees.

Total carbon stocks

Keeping in mind the guidelines of Intergovernmental Panel on Climate Change (IPCC), total carbon stock was (biomass + soil) calculated by considering the soil C up to 30 cm soil depth. The amount of total carbon increased with an increase of tree age in all three Tehsils (*Table 6*). The maximum total carbon stock at 2-year-old trees was estimated in Tehsil Chiniot (31.98 Mg ha^{-1} whereas at 4 and 6-year-old age trees higher total carbon stocks (44.75 Mg ha^{-1} and 87.27 Mg ha^{-1}) were estimated in Tehsil Lalian. Overall the total carbon stock increased from 28.81 Mg ha^{-1} at 2 years of age to 87.27 Mg ha^{-1} at 6 years of age among all three Tehsils. A significant and positive correlation was studied between total carbon stock and age of the *P. deltoides* trees ($r = 0.90$, $p < 0.001$).

Table 6. *Total carbon stock (tree + soil) in P. deltoides by age among three Tehsils of District Chiniot*

Age (years)	Tehsils/sites	Total carbon stock (Mg ha^{-1})

Discussion

The present study supports our hypothesis that biomass and carbon stocks in *P. deltoides* increased markedly in both above and belowground parts with tree age among

three Tehsils of District Chiniot. For example, Tehsil Lalian has the highest biomass than other two Tehsils because of higher tree density and greater DBH of all age classes. This can be attributed to better climatic conditions: slightly higher rainfall (345 mm annually) as compared to Tehsil Chiniot and Bhawana or there may be other factors such as agroforestry awareness and agroforestry practices. Similar trends of growth of *P. deltoides* planted in agroforestry and plantations have been reported in various studies (Jain et al., 2017; Chauhan et al., 2011; Kanime et al., 2013). Moreover, *P. deltoides* at 6 years age, accumulate more biomass in all Tehsils (47.75 Mg ha-1 to 90.55 Mg ha-1) than a 7 years old *E. camaldulensis* (62.35 Mg ha^{-1}) and 6 years old *S. siamea* (45.39 Mg ha^{-1}) described by Harmand et al. (2004). Though, the results of our study concerning aboveground biomass fall in line to those described by Rizvi et al. (2011) for *P. deltoides* in agroforestry systems. Overall, the findings of the biomass of the present study are comparable to other agroforestry trees such as *E. camaldulensis* hybrid, 95 Mg ha^{-1} at 7 years and *D. sissoo*, 50.3 to 122.7 Mg ha^{-1} (Negi and Sharma, 1985; Lodhiyal and Lodhiyal, 2003). The findings of the present study different as compared to previous studies might be because of climatic conditions, growth pattern, site quality, species density, age and cultural plus management practices.

In the present study we have quantified the above and belowground carbon stock in bund planted *P. deltoides* based agroforestry system at early growth stages. The findings of present study are based on bund planted agroforestry system while the previous studies were mostly carried out in different plantations and agroforetsry systems under different climatic conditions. For instance, mean carbon stock in a *P. deltoides* based agroforestry system in temperate region has been reported 15.1 t C ha^{-1} at 111 trees ha^{-1} (Peichl et al., 2006). The amount of carbon found by Fang et al. (2010) in 5 years old *P. deltoides* trees was only 7.8 t C ha^{-1}, far lesser as compared with our findings. The present estimates of total carbon stocks were maximum at 6 years of age across all Tehsils (22.7 Mg ha^{-1} to 43.54 Mg ha^{-1}), much higher as compared to the findings of Chauhan et al. (2010) for *P. deltoides*, Nawaz et al. (2017a) for *E. camaldulensis*. The potential of agroforestry systems to stock and sequester CO_2 are extremely inconsistent (0.29 to 15.21 t C ha^{-1} yr^{-1}) relying on several aspects including site characteristics, type of species, land use type, the age of trees and cultural practices (Nair et al., 2009). Traditional tree crop combination in Africa stock more carbon because of their greater DBH and height than the abandoned land and improved agroforestry systems which were comparatively young (Takimoto et al., 2008). Gera (2012) recommended that differences among carbon stocks can be credited to mean annual increment of trees which differed with nature of planting stock, site, age and tree density. In the present study, largest carbon amount was accounted for stem (about half) from above tree biomass, which is identical with different results for distinctive species (Redondo, 2007; Fonseca et al., 2012).

In agroforestry systems, the soil is considered as an important subsystem for lowering CO_2 levels in the atmosphere. Nair et al. (2009) compare SOC contents among different land use practices and found the trend in the order of forests > agroforestry > plantations > arable crops. A few studies from Africa demonstrated that tree carbon sequestration will not quickly hold soil carbon equivalent to the baseline level (Kaya and Nair, 2001). In the current study, higher organic carbon concentrations and SOC stocks were noted with increase in tree age at both depths. The higher SOC stocks in the upper soil surface are credited to more noteworthy carbon input from tree litter, dead roots, and root exudates (Kaushal et al., 2012; Nawaz et al., 2014; Yasin et al., 2016).

Poplar trees in agroforestry systems by and large increase 3.5 Mg ha^{-1} of litter fall each year (Kaushal et al., 2012). Higher SOC was observed with increase in tree age in upper soil layer 0-15 cm and was 18% higher under 3-year-old tree stand when compared with 1-year-old tree stand and it further increases by 18.5% at 0-15 cm layer of soil under 6-year-old tree stand (Gupta et al., 2009). The CSR (Carbon sequestration rate) in the soil across all Tehsils varied from 1.77 Mg ha^{-1} yr^{-1} to 2.27 Mg ha^{-1} yr^{-1} in 6-year-old trees which is slightly higher to the findings (1.18 Mg ha^{-1} yr^{-1} to 1.81 Mg ha^{-1} yr^{-1}) of Arora et al. (2014).

Conclusions

Carbon sequestration through woody vegetation is a sustainable and efficient approach. In the present study, it was found that the carbon sequestration ability of *P deltoides* increases with age and, when planted as bund planting in agroforestry systems, it differs from other patterns of tree planting such as compact plantations. The species is sequestering the exceptional amount of carbon in the limited span of time, thus creating an option for farmers to get extra revenue in terms of carbon credits. Moreover, *P deltoides* fulfill the demand of plywood industry and fuel because of its fast growth and higher biomass accretion of the country. Therefore, our study suggests planting *P. deltoides* in various agroforestry systems act as a feasible alternative for higher biomass production and carbon stocks to mitigate climate change. Along with carbon capturing and sequestration these systems could develop into technological alternative to reduce deforestation rates in the country. Therefore, further studies should be carried out to explore the potential impact of various bund planted tree based agroforestry systems in climate change mitigation through carbon sequestration.

Abstract. Compared to bays, coastal lagoons are more vulnerable to the effects of human activities. The continued deterioration of the Xincun and Li'an Lagoon ecosystems has affected habitat health in the region; therefore, the State Oceanic Administration has proposed the "Blue Bay Remediation Action Plan". To formulate a comprehensive, evidence-based remediation plan, a comprehensive assessment of ecosystem pressure that includes a quantitative spatial study of the cumulative impact intensity of human activities was conducted in the study region. The results showed that the Xincun Lagoon ecosystem pressure composite values have gradually decreased since 2012. Additionally, the area of extremely strong human activities accounted for only 6.67% of the sea area, most of which was distributed at the mouth of the lagoon. However, the ecosystem pressure composite value of the Li'an Lagoon continued to grow until 2014, at which time the area of extremely strong human activities accounted for 13.53% of the sea area, primarily in the Li'an town center region.
Keywords: *human activities, eco-environmental stress, impact assessment, spatial quantization, P-S-R model, coastal lagoons ecosystem*

Introduction

Coastal lagoons occupy 13% of the world coastline (Ana et al., 2018). Compared with bays, coastal lagoons are more actively affected by interactions between land, marine, and atmospheric processes and their environments and ecosystems are more prone to the dual effects of land and sea. Coastal lagoons are also more sensitive to fluctuations caused by changes in various natural processes and human activities, and their ecosystems are particularly vulnerable.

The deterioration of the ecosystems of the Xincun and Li'an Lagoons has affected many habitats (including coral reefs, mangrove forests, and seagrass beds) in the region. According to relevant data and preliminary surveys, large patches of coral reefs are no longer alive, and mangrove habitats are fragmented in the study site. Seagrass beds in the region have also exhibited reduced area and abundance and increased pollutants attached to seagrass.

In 2016, the State Oceanic Administration proposed the "Blue Bay Remediation Action Plan" to improve marine environmental quality, as well as coastal, marine and island ecosystem functions, and to protect marine ecological security. To formulate a scientific and comprehensive remediation plan, it is necessary to conduct a preliminary

survey and analysis of relevant pressure factors of the Xincun Lagoon ecosystem, diagnose the impact of pressure factors on the lagoon ecosystem, and propose a comprehensive remediation target system and measures for ecosystem conservation and utilization.

The academic community has conducted research into and put forward some indicators and methods for quantitative evaluation of ecosystem pressure. These include ecological footprint analysis (Leo et al., 2014), the green accounting method (Bartelmus, 1999), energy analysis (Brown and Ulgiat, 1991), the environment quality index (Cui and Li, 2014), pollutant emissions indicators, system dynamics (Château et al., 2015), input-output methods, and multivariate statistical analysis. These methods have made positive contributions to efforts to assess the power of economic development to the ecosystem, but there are still some problems. For example, the ecological footprint analysis method describes very little about the pressure from environmental pollution. The environmental quality method and the pollutant emission indicator method cannot describe the pressure caused by ecological damage, so they are not sufficiently comprehensive; the green nuclear algorithm and the energy (value) analysis method represent environmental pollution and ecological damage in the form of currency and energy, respectively, but they are not sufficiently reliable in terms of quantification; the system dynamics, input-output, and multivariate statistical methods are reasonably comprehensive and take into account more factors, but their calculation processes are more complicated than those of other methods, and the results are not intuitive.

In addition, the study of the cumulative impact of human activities has proceeded tortuously. Since the 1970s, the academic community has used environmental sensitivity indicators to identify marine areas sensitive and susceptible to human activities (Gundlach et al., 1978). In the late 1990s, scholars began to evaluate the cumulative effects of multiple pressures (Wiegers et al., 1998). But it was not until 2008 when Halpern et al. selected 17 human activities for the global marine ecosystem, quantified their cumulative impact on global marine ecosystem, and mapped out cumulative impact increments (Halpern et al., 2008), that related studies began to spring up like bamboo shoots after rain. Since then, the field has rapidly developed and gradually become one of the hotspots of basic research in marine spatial planning (MSP). According to a literature review analysis (Korpinen et al., 2016), the research method reported by Halpern et al. was used directly or indirectly in more than half of the papers in the relevant field (Micheli et al., 2013; Marcotte et al., 2015). Compared with the earlier methods, Halpern et al. combined and quantified human activity pressure with ecosystem state (simplified to a linear relationship), so that the research method forms a standardized model, and the results can be compared globally.

Preparation

Conceptual framework

This study aimed to combine data describing the current status of human activities (pressure) and ecosystem condition (state) in the study site and propose corresponding remediation measures (response). This process meets the definition of the pressure-state-response (PSR) framework.

The PSR framework was first proposed by Friends and Rapport (Friends and Rapport, 1979) to analyze the relationship between pressure, current state, and response

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_62536266
© 2018, ALÖKI Kft., Budapest, Hungary

in natural environments (Xu et al., 2017). In the 1970s, the Organization for Economic Co-operation and Development revised the PSR model and applied it to environmental studies. In the early 1990s, the OECD conducted applicability and efficacy analysis of the PSR model when used in analysis and studies of important ecosystem-associated indicators. Because the PSR model has an extremely clear causal relationship, it is widely used in studies of marine ecosystems and evaluation of wetland and lake resources.

Study region and area

The study site is located in the southeast portion of Lingshui Li Autonomous County, which is located on the southeast coast of Hainan Island, China (N18°22'-18°47', E109°45'-110°08'). This site is a classical tide-controlled natural lagoon composed of two lakes separated by a shoal in the middle. The southern portion of the study site is bounded by Nanwan Monkey Island and Niubai Mountain as natural barriers to the South China Sea. The waves are gentle in the lake, and the twin lakes are connected by the South China Sea through narrow mouths (*Fig. 1*).

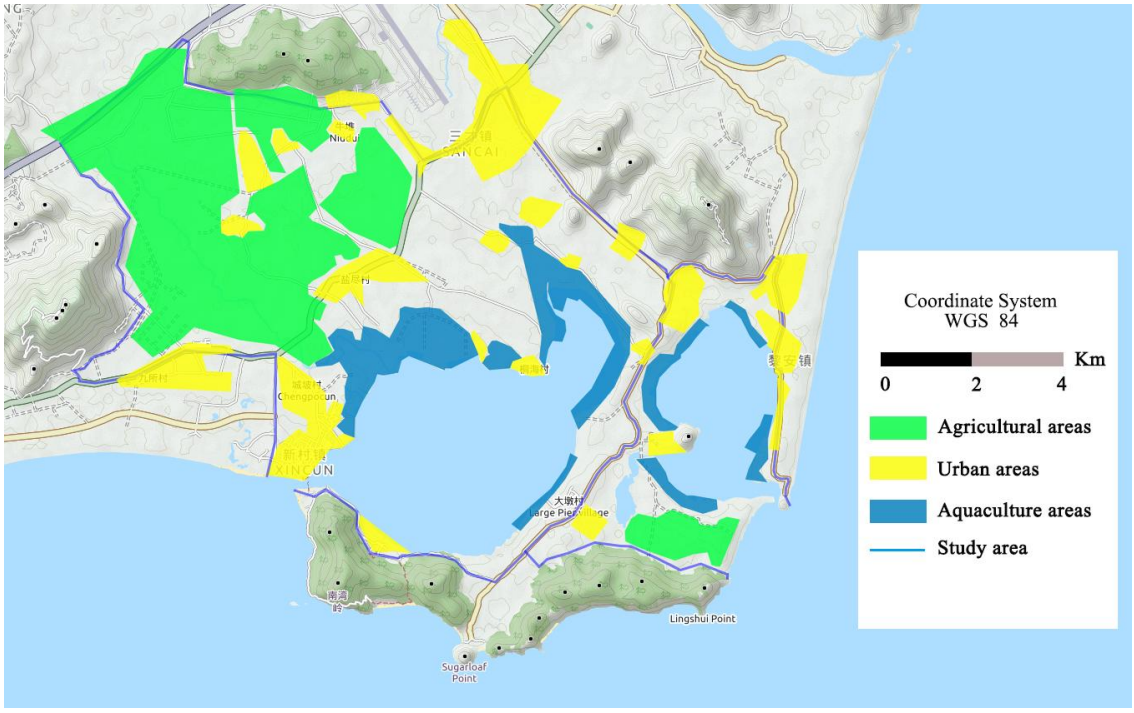

Figure 1. *Map of study region and area*

Lagoon pollution originates from water bodies, but land is also a major pollution source; therefore, water and land regions were included when determining the study site. The water region refers to regions that are formed by the water that curves inwards. The delineation of the land region boundary was based on an enclosed area formed by the watershed in the lagoon and the coastline of the lagoon.

However, for a large drainage basin, if the entire basin cannot be traced during estimation, tracing can be conducted to the part which is below the controlled section of the basin (i.e., the drainage basin only includes the region below the controlled section),

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

while that in upstream region will be estimated by using monitoring data for the controlled section. Therefore, the study area for this investigation was the water catchment area of the Qugang and Qugou rivers and their tributaries, which are bound by the G98 Hainan Island Ring Expressway, the China National Highway 223 and the surrounding mountains (region enclosed by the blue line in *Figure 1*.

Methods

Comprehensive assessment of lagoon ecosystem pressure

So far, there have been few studies on the evaluation of lagoon ecosystem pressure, and there is currently no standard evaluation indicator or method. We here report an optimized method on the basis of the Eco-environmental Stress Index (ESI) method proposed by Xu et al. (2004) of Peking University, rendering it able to adapt to the actual situation of the lagoon. This method has been validated in terrestrial areas (Hao et al., 2012; Song et al., 2014) and is a relatively new method that can intuitively indicate the pressure of socio-economic development on ecosystems and the change trend of the pressure.

This study analyzed the major stress factors of lagoon ecosystems to design an evaluation indicator system and then applied this system to the evaluation of the lagoon ecosystem. The specific evaluation steps were as follows: (i) determination of evaluation indicators and selection of year limit for evaluation; (ii) data standardization; (iii) determination of weight values; (iv) calculation of ecosystem pressure index.

Step i: We selected representative indicators (*Table 1*) based on the current status of the ecosystem in the study site for an evaluation period of 2011 to 2015.

Table 1. *Pressure evaluation indicator system for Xincun and Li'an Lagoon ecosystems*

Layer A		Layer B		Layer C		Layer D

© 2018, ALÖKI Kft., Budapest, Hungary

Step ii: As the evaluation indicators are not unified (*Tables 2* and *3*), a differential method was used for standardization of the ecosystem pressure indicators x_{ij} (*Tables 4* and *5*).

Table 2. *Annual representative Xincun Lagoon ecosystem pressure values*

	2011	2012	2013	2014	2015
Population density (people/km^2)	586	600	590	574	558

Total number of fishing vessels	0.57	0.51	0.47	0.43	0.48

Considering that the amount of evaluation indicators for ecosystem pressure assessment is generally large, the difference method was used to standardize the ecosystem pressure index. The specific calculation process is as described in *Equations 1* and *2*

Table 5. *Annual representative Li'an Lagoon ecosystem pressure standardization values*

	2011	**2012**	**2013**	**2014**	**2015**
Population density (people/km^2)	0.46	0.47	0.47	0.54	0.51
Population growth rate (%)	0.18	0.15	0.03	1.00	0.00
GDP per capita (RMB)	0.41	0.43	0.45	0.47	0.59
GDP growth rate (%)	0.37	0.69	0.68	0.66	0.63
Domestic wastewater discharge volume (tons)	0.46	0.47	0.47	0.54	0.51
High and low aquaculture pond area (km^2)	0.55	0.53	0.48	0.45	0.48
Nitrogen and phosphorus content in chemical fertilizers (kg)	0.70	0.69	0.67	0.66	0.30
Area of cultivated land (hectares)	0.70	0.69	0.67	0.66	0.30
Total number of livestock at year end (number of animals)	0.38	0.62	0.44	0.42	0.44

Total number of fishing vessels	0.51	0.47	0.53	0.49	0.53

Considering that the amount of evaluation indicators for ecosystem pressure assessment is generally large, the difference method was used to standardize the ecosystem pressure index. The specific calculation process is as described in *Equations 1* and *2*

The formula used for positive pressure indicators was (*Eq. 1*)

$$x_{ij}^{'} = \frac{x_{ij}}{\max(x_{ij}) + \min(x_{ij})}. \quad \text{(Eq.1)}$$

The formula used for negative pressure indicators was (*Eq. 2*)

$$x_{ij}^{'} = 1 - \frac{x_{ij}}{\max(x_{ij}) + \min(x_{ij})} \quad \text{(Eq.2)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_62536266
© 2018, ALÖKI Kft., Budapest, Hungary

Negative pressure is mainly targeted against economic pressure. This is because, under a specific environmental policy intervention, the overall environmental quality of a country or region will exhibit an initial deterioration followed by a subsequent improvement when economic strength increases.

Step iii: The analytic hierarchy process was used to determine weight values.

Step iv: Based on the determination of the weights (relative importance) at the corresponding layers of various single indicators and the total sorted weight (integrated importance) of the system layers, linear weighting was used to obtain the ecosystem pressure index further to evaluate pressure levels as follows (*Eq. 3*):

$$ESI = \sum_{i=1}^{m} W_i X_i \quad \text{(Eq.3)}$$

where ESI is the ecosystem pressure index; W_i is the indicator weight; and X_i is the standardized value of the indicator.

Spatial quantitative assessment of the impact of human activities on lagoon ecosystem

This study employed spatial quantization to investigate the relationship between human activities and marine ecosystems as described to evaluate the effects of human activities on the lagoon ecosystem and spatial visualization of the evaluation results was conducted (Li et al., 2015). The specific evaluation process for the model was as follows: (i) Determination of the study site, including the spatial range and rational layout of unit points; (ii) Identification of seas with human activities, i.e. determination of effect points, including spatial positions, effect strength, and maximum effect distance; (iii) Calculation of the effects of various human activities on the lagoon ecosystem; (iv) Superimposition of the aforementioned processes in (3) (e.g., comprehensive evaluation).

Step i: The study site consisted of the maritime areas of Xincun and Li'an Lagoons. If human land activities were present, they were represented by unit points concentrated in the coastal region. Estimation results from papers above were used as data. The grid was divided into 100 m×100 m (*Fig. 2*).

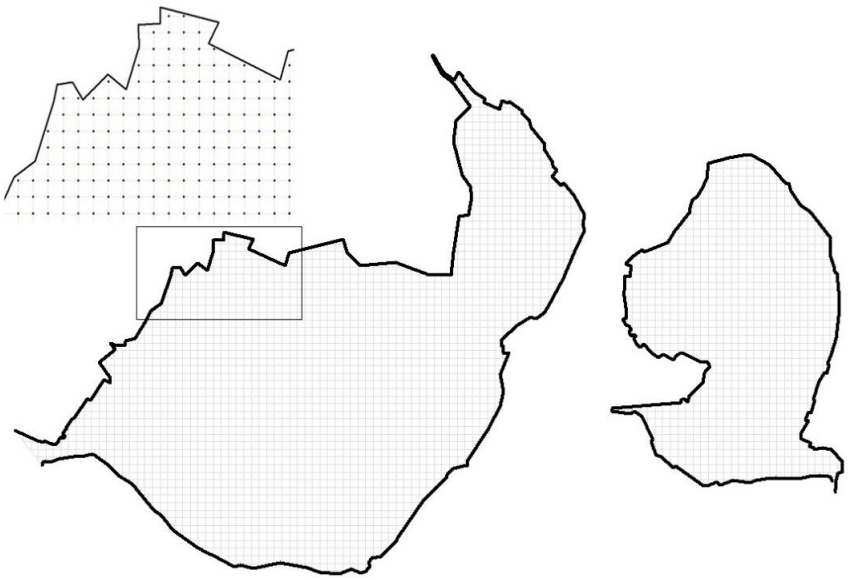

Figure 2. *Map of study region and spatial unit points*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_62536266
© 2018, ALÖKI Kft., Budapest, Hungary

Step ii: In this study, eight human activities were selected according to the characteristics of the studied sea and actual utilization status to construct an evaluation indicator system that was subsequently used to summarize various seascape human activities comprehensively.

A) Effect strength

Effect strength was expressed from 0 to 1, with 1 indicating the strongest impact and 0 indicating that the effect was negligible. The effect strength (F) of various effect points of human activities was directly assigned values according to the grade of the actual survey value in the standard range (Halpern et al., 2008).

B) Effect distance

Parravicini (Parravicini et al., 2012) used a geospatial model to evaluate the pressure status of eight seascape human activities on marine ecosystems. Their results showed that the effect of each type of human activity on marine ecosystems was about 50%. Therefore, this paper assumes that half the distance between any effect point and the furthest unit point is the maximum effective distance of that effect point (D).

C) Indicator weight

The indicator weights (W) of various human activities were determined according to the analytic hierarchy process. *Table 6* shows the calculated weights.

Table 6. *Evaluation indicator system and effect strength criteria for quantitative model*

Target layer	Factor layer	Indicator layer	Effect strength assigned value table					Weight
			1	0.75	<0.5	0.25	0	
Impact of human activities on marine ecosystems	Land-based human activities	Domestic wastewater discharge volume (10^4 tons)	>5	3–5	1–3	0–1	-	0.1787
		High and low aquaculture pond area (km^2)	>0.3	0.15–0.3	0.1–0.15	0–0.1	-	0.2148
		Nitrogen and phosphorus content in chemical fertilizers used (tons)	>5	3–5	1–3	0–1	-	0.0837
		Area of cultivated land (hectares)	>30	15–30	5–15	0–5	-	0.0837
		Total number of livestock at year end (number of animals)	>60	40–60	20–40	0–20	-	0.0837
	Marine human activities	Farming area of aquaculture raft (km^2)	>0.6	0.4–0.6	0.2–0.4	0–0.2	-	0.2148
		Fixed fishing area (km^2)	>0.3	0.2–0.3	0.1–0.2	0–0.1	-	0.0481
		Total number of fishing vessels	>75	50–75	25–50	0–25	-	0.0925

Step iii: The formula for calculation of the effects of certain human activities on unit points was as follows (*Eq. 4*):

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_62536266
© 2018, ALÖKI Kft., Budapest, Hungary

$$I = \sum_{i=1}^{m} F_i \times \frac{D_i - d_i}{D_i} \quad \text{(Eq.4)}$$

In *Equation 4, I* represents the effects of a certain human activity on a unit point. Human activity is present in *m* effect points; *i* represents the *i*th effect point; F_i is the intensity of the *i*th effect point of that human activity; D_i is the maximum effect distance of the *i*th effect point of that human activity; d_i is the distance between the unit point and the *i*th effect point of that human activity.

Step iv: The calculation formula for the integrated effects of various human activities on unit points was as follows (*Eq. 5*):

$$I_{Total} = \sum_{j=1}^{n} I_j \times W_j \quad \text{(Eq.5)}$$

where I_{Total} represents the integrated effects of various human activities on that unit point and there are *n* types of human activities; *j* represents the *j*th human activity; and I_j is the effect of the *j*th human activity on the unit point. W_j is the weight of the *j*th human activity in the comprehensive evaluation.

Results

Comprehensive assessment of lagoon ecosystem pressure

A) Xincun Lagoon

Table 7 shows the ecosystem pressure composite values for Xincun Lagoon, which peaked in 2012 before gradually decreasing. This occurred because population pressure is gradually decreasing, during which time growth has been negative. Also, economic pressure has been stable since 2014. This is because, although GDP is growing, the growth rate is decreasing significantly. However, human activity pressure is increasing annually because, although the number of aquaculture ponds is generally unchanged (due to aquaculture pond management policies), the quantity and area of aquaculture rafts are increasing.

Table 7. *Annual Xincun Lagoon ecosystem pressure composite values*

	2011	**2012**	**2013**	**2014**	**2015**
Pressure composite value	0.492	0.533	0.476	0.459	0.472
Population pressure	0.142	0.152	0.051	0.050	0.048
Economic pressure	0.067	0.089	0.122	0.104	0.109
Human activity pressure	0.283	0.293	0.304	0.305	0.315

Calculation explanation: On the basis of determining the weight (relative importance) of each individual indicator at its respective level and its total ranking weight (integrated importance) to the overall level of the system, the ecosystem pressure index can be further determined by the linear weighting method to evaluate the pressure level

B) Li'an Lagoon

Table 8 shows that the ecosystem pressure composite value for Li'an Lagoon increased continuously until 2014. This occurred because population pressure showed a sudden increase in 2014 because it increased from 408 people in 2013 to 467 people.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_62536266
© 2018, ALÖKI Kft., Budapest, Hungary

When compared with Xincun Lagoon, the GDP of Li'an Lagoon continued to increase, as did the rate of increase. Thus, economic pressure is still continuously increasing. However, human activity pressure started to decrease in 2012. Although the area of aquaculture rafts is increasing, and the area of high and low aquaculture ponds was generally unchanged (due to aquaculture pond management policies) the area of cultivated land shows an annual decreasing trend.

Table 8. *Annual Li'an Lagoon ecosystem pressure composite values*

	2011	**2012**	**2013**	**2014**	**2015**
Pressure composite value	0.448	0.489	0.466	0.569	0.462
Population pressure	0.064	0.062	0.051	0.154	0.051
Economic pressure	0.078	0.113	0.114	0.113	0.122
Human activity pressure	0.306	0.314	0.302	0.302	0.288

Calculation explanation: On the basis of determining the weight (relative importance) of each individual indicator at its respective level and its total ranking weight (integrated importance) to the overall level of the system, the ecosystem pressure index can be further determined by the linear weighting method to evaluate the pressure level

Cumulative impact intensity because of human activities

Based on the research results of Halpern et al. (2008) and Li et al. (2015), we combine the actual situation of the research area to conduct research and analysis. For the specific calculation process, see Step i-Step iv of spatial quantitative assessment of the impact of human activities on lagoon ecosystem in the Methods section above.

Spatial data analysis of the effects of human activities on the Xincun and Li'an Lagoon ecosystems was conducted using the ArcGIS10.2 software, with Kriging interpolation employed to process the effect values of human activities. *Figures 3* and *4* show the spatial quantitation results.

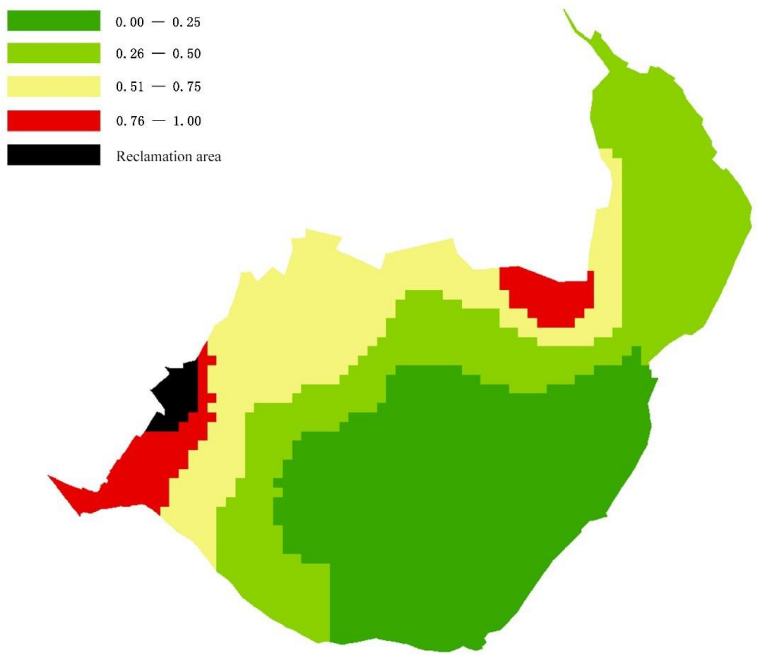

Figure 3. *Map of cumulative impact intensity due to human activities in Xincun Lagoon*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_62536266
© 2018, ALÖKI Kft., Budapest, Hungary

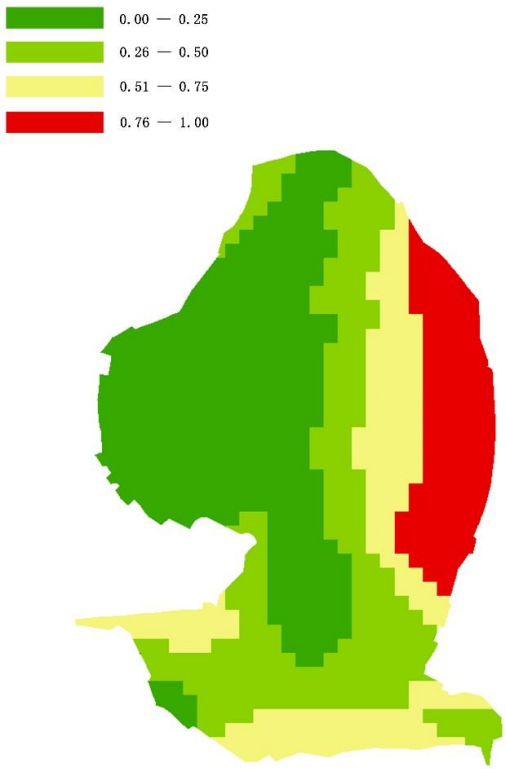

Figure 4. *Map of cumulative impact intensity due to human activities in Li'an Lagoon*

In Xincun Lagoon, extremely strong effect regions (effect values of 0.75–1.00) accounted for 6.67% of the entire sea space, while strong effect regions (effect values of 0.50–0.75) accounted for 21.63% of the entire sea space; moderate effect regions (effect values of 0.25–0.50) accounted for 32.32% of the entire sea space, and weak effect regions (effect values of 0.00–0.25) accounted for 37.75% of the entire sea space. Also, some reclamation sites were located outside the managed coastline (black lines in the figure). As shown in *Figure 3,* the area with the strongest human activity in Xincun Lagoon is located at the mouth of the lagoon and around Tonghai Village inside the lagoon, while the human activity in the southern sea of the lagoon is almost negligible. Therefore, the effect value for that region is less than 0.25.

In Li'an Lagoon, extremely strong effect regions (effect values of 0.75-1.00) accounted for 13.53% of the entire sea space; strong effect regions (effect values of 0.50-0.75) accounted for 19.74% of the entire sea space; moderate effect regions (effect values of 0.25-0.50) accounted for 26.75% of the entire sea space, and weak effect regions (effect values of 0.00-0.25) accounted for 39.98% of the entire sea space. As shown in *Figure 4,* the area with the strongest human activity in Li'an Lagoon is located in Li'an Village. Conversely, the human activity in the western sea of the lagoon is almost negligible; therefore, the effect value for that region is less than 0.25.

Analysis of remediation measures

According to the P-S-R model, after clarifying the pressure and status of Xincun and Li'an Lagoons, it will be necessary to combine the results of the studies above for analysis to effectively remediate the two lagoons. Generally, the response measures

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_62536266
© 2018, ALÖKI Kft., Budapest, Hungary

should be targeted against different aspects of pressure and status. Generally, the response measures should be targeted toward different aspects of pressure and status, as described below.

Pressure reduction measures

A) Optimization of aquaculture raft farming. The aquaculture capacity should be determined rationally. The specific measures are as follows. Aquaculture density should be controlled within the carrying capacity of the water body so that aquaculture pollutants do not exceed the self-cleaning capability of the water body. According to relevant studies (Hu et al., 2007), the presence of aquaculture raft farming causes the flow speed of some sea regions to significantly decrease, resulting in the reduced self-cleaning capability of the water body. Optimization of aquaculture raft layout should be conducted according to the unique hydrodynamic model of the study site. Adjustment and optimization of aquaculture structure should be conducted to develop the aquaculture of benthic economic species actively. Improvement of baitcasting techniques and improvement of feed quality will also greatly reduce water pollution.

B) Remediation of land-based pollution. According to the onsite survey and pollution calculations, domestic wastewater from the surrounding villages and towns of Xincun and Li'an Lagoons is an important source of land-based pollution. The specific measures to reduce this include the following. Sewage interception and treatment of domestic wastewater and solid waste of coastal villages and towns. Low aquaculture ponds, which are mariculture ponds that are below the surveyed coastline (State Oceanic Administration, 2012), not only occupy large amounts of valuable wetland but are usually accompanied by many mangrove forests. However, long-term immersion in aquaculture wastewater will threaten these habitats. Therefore, rapid pond reclamation and reforestation should be conducted to form a complete mangrove forest corridor. High aquaculture ponds are mariculture ponds that are above the surveyed coastline (State Oceanic Administration, 2012). Because it is difficult to remove these ponds completely, a wastewater treatment system of high aquaculture pond should be developed for centralized processing of the discharged wastewater.

Ecological improvement measures

A) Dismantlement of illegal facilities and garbage removal. The facilities to be dismantled and garbage to be removed include fixed fishing facilities and night-time fishing illumination equipment, utility poles that provide electricity for fishing and aquaculture rafts, and other fishing facilities that occupy and segment the sea. Also, floating public toilets and restaurants, as well as other fixed buildings that directly discharge excreta and solid waste into the sea should be removed. Finally, garbage thrown into the lagoons by tourists and villagers should be removed.

B) Sediment dredging. In the marine ecosystem, sediments are sinks and sources of nutrients, heavy metals, and persistent organic pollutants. Under conditions in which extrinsic pollutant sources are effectively controlled, biological or physical factors will promote the release of sediments. This can still result in maintenance of eutrophication in water bodies or deterioration of water quality for long periods of time. Sediment dredging can permanently remove contaminated sediment from aquatic systems and is widely used in the remediation of lakes, rivers, and bays (Zhong et al., 2007).

C) Bottom culturing and release of shellfish. Relevant studies have shown that shellfish are commonly used for ecological restoration and remediation of water bodies. Shellfish can decrease the concentration of particulate organic matter (seaweeds and organic debris) in the water body, indirectly control the concentration of nitrogen and phosphorus salts, couple with the aquatic benthic environment, and protect biodiversity and create biological habitats. Also, shellfish play an important role in carbon fixation in the oceans. Specifically, shellfish can remove particulate carbon in the sea by filter feeding, absorb carbon during formation of calcium carbonate shells and sequester large amounts of marine carbon.

Conclusion

This study not only identifies the pressure categories of human activities on the lagoon but can also be used to determine the ecosystem pressure index; it is also possible to spatially quantify the cumulative impact intensity.

The calculation model introduced in the paper is suitable for coastal lagoons that are little affected by the outer seas, have relatively weak water exchange capacity, and have relatively flat seabed topography. The model not only quantifies the impact results to a value of 0–1 in order to indicate the impact degree, but also displays the distribution of the impact results in the sea space. The findings can coordinate the entire research area for management but can also manage according to the different partitions of the affected areas in different regions.

The findings of this work allow us to draw the following conclusions:

(1) The results of the study showed that the intensity of human activities experienced by Xincun Lagoon decreased annually from 2011 to 2015 and the intensity of human activity was greatest at the mouth of the lagoon. Conversely, the intensity of human activities that Li'an Lagoon was subject to is still growing, although intensity was greatest at the Li'an town center.

(2) Generally, remediation measures are proposed based on pressure and state aspects. With regards to decreasing human activity pressure, optimization of aquaculture raft farming and remediation of land-based pollution are major methods proposed in the study. Also, dismantlement of illegal facilities and garbage removal, sediment dredging, bottom culturing and release of shellfish could improve the ecosystem status.

Abstract. Current study focused on two phases; in the first the composition and the amount of extractives were determined. Thus, hexane and acetone:water (95:5, v:v) extracts of *Eucalyptus camaldulensis* and *Liquidamber orientalis* bark were analysed by GC-MS to determine lipophilic and hydrophilic extractive composition of these species. The second phase was to identify anti-bacterial, anti-biofilm and anti-swarming effects of the gathered extractives. Total amount of lipophilic extractives was found 3.90 mg/g in *E. camaldulensis* whereas it was determined as 7.67 mg/g in *L. orientalis* bark. However, total amount of hydrophilic extractives in *E. camaldulensis* bark (55.51 mg/g) had almost 1.5 times more than *L. orientalis* bark (39.19 mg/g). Fatty acids and sugar groups were the dominant groups as lipophilic and hydrophilic, respectively, in both species. Anti-bacterial test was carried out by using three Gram-positive (*Staphylococcus aureus*, *Methicillin Resistant Staphylococcus aureus*, *Bacillus cereus*) and three Gram-negative (*Pseudomonas aeruginosa*, *Escherichia coli* and *Pseudomonas aeruginos*a PA01) strains with agar well diffusion method. In addition, the minimum inhibitory concentrations (MICs) of the extracts were also determined using the micro-dilution method. When hexane and acetone:water (95:5, v:v) extracts of *E. camaldulensis* and the acetone:water (95:5, v:v) extract of *L. orientalis* have anti-bacterial effect on Gram-positive bacteria but they do not have anti-bacterial effect on the tested Gram-negative bacteria. Whereas the hexane extract of *L. orientalis* did not show anti-bacterial activity on any tested strains. The minimum inhibitory concentration of these extracts ranged from 0.52 to 51.5 mg/ml. It was also found that hexane extract of *E. camaldulensis* inhibited biofilm formation and acetone extract of *L. orientalis* and *E. camaldulensis* indicated anti-swarming activity on P. aeruginosa PA01.
Keywords: *Eucalyptus camaldulensis, Liquidamber orientalis, extractives, anti-bacterial activity, quorum sensing*

Introduction

Extractives affect such functions in a tree as texture, odor, taste and color. They compose 5-10% of a tree's chemical substances by weight. In general terms, extractives are lipophilic and hydrophilic substances that are soluble in neutral solvents (Fengel and Wegener, 1989; Sjöström, 1993; Holmbom, 1999). Lipophilic extractives mostly consist of fats, fatty acids, resin acids and sterols and they are chemical substances that are soluble in dichloromethane, ether and some hydrocarbon solvents. Moreover, hydrophilic extractives are substances like carbohydrates, lignans, phenols, stilbens and chalkones that are soluble in such polar solvents as water, alcohol and acetone (Holmbom, 1999).

Although wood and bark of a tree have similar chemical composition, there are big differences regarding the amount of extractives in the bark. The essential chemicals for the plant, like cellulose and hemicelluloses, have lower amount in the bark but the amount of lignin and especially extractives is always higher in the bark than in its wood.

Oriental sweet gum (*Liquidamber orientalis*) is classified in *Hammalidaceae* family in the plant kingdom and it occurs as tree or a bush. It has thick branches and balsam cells in its wood. *L. orientalis* can only be seen in Muğla, Turkey (south Aegean part of Turkey) and can grow up to 15-20 m height (Anşin and Özkan, 1993). The oil, gathering from its stem, is used in the production of soap, perfumery and medicine and also in incenses because of its nice odor. Since most of the studies have been focused on sweetgum oil there are limited knowledge about wood and bark of this species. Istek and Hafizoğlu (2005) investigated main chemical composition and the solubility values of wood and bark of *L. orientalis*.

Eucalypt *(Eucalyptus camaldulensis)* is a fast growing woody taxon in the form of a tall-tree. It usually occurs in coastal areas having warmer weather and it can grow up to 90 m. *E. camaldulensis* has dark-colored heartwood and light yellow sapwood. It has valuable wood that can be evaluated in such industries as mine poles, packaging, pulp and paper. In addition, eucalyptol is produced from the leaves of *E. camaldulensis* and it is used in pharmacy and soap industry. Thus, it is called as "malaria tree" because they dry marshes causing malaria disease in tropical areas (Anşin and Özkan, 1993).

Plant bark is considered as the source of energy by burning it in many industries (Hemingway, 1981). However, in recent years, it is known by the studying of the chemical composition of bark that it is a rich source of chemical substances like lipophilic and other phenolic compounds (Kahkonen et al., 1999; Freire et al., 2002a, b; Pietarinen et al., 2006; Ferreira et al., 2013).

Using plants as a treatment of some illness is common all over the world since ancient times. Besides, plants are also being used for combating bacterial infections. Inappropriate consumption of antibiotics causes the development of resistant bacteria and after a while causes the antibiotics to become inefficient (Chitemerere and Mukanganyama, 2011). All these problems made it necessary to develop new strategies in combating with bacteria. After the discovery of cell to cell communication system in bacteria it has been thought that this is a new way to combat with bacteria and studies have focused on inhibition of this system. This communication known as the quorum sensing (QS), and it is responsible for regulating production of some virulence factors such as elastase, alkaline protease, pyocyanin, phospholipase and exotoxin A, biofilm formation and swarming motility in some bacteria (Lee and Zhang, 2015). *P. aeruginosa* is a major cause of hospital-acquired bacterial infections, especially isolated from patients with cystic fibrosis (Overhage et al., 2008). It is now known that *P. aeruginosa* regulate biofilm formation and swarming motility processes through a QS. Given its importance as a virulence, treatment of bacterial biofilm with antibiotics is more difficult than infections caused by planktonic bacteria (Bjarnsholt et al., 2010; Lee and Zhang, 2015).

For this purposes most researchers focus on plant extracts or essential oils of plants. Therefore, in the present study, it was aimed to determine anti-bacterial properties and anti-quorum sensing effect of bark extractives from *E. camaldulensis* and *L. orientalis* and also the amount and the composition of extractives gathered from different solvents.

Material and method

Material

L. orientalis and *E. camaldulensis* were taken from Köyceğiz, Muğla, Turkey and Tarsus, Mersin, Turkey where the altitude was 100 m and 85 m respectively. Bark samples were supplied from living trees by the aid of sharp knives in April 2017. All samples were stored at -24 °C until analyses. Barks were broken into small pieces, which were freeze-dried and ground by a Wiley mill to 1 mm (Ekman, 1983). To remove volatile compounds, the ground samples were treated with a second drying procedure.

Extraction

Approximately 10 g of ground bark from each sample was successively extracted with n-hexane to get lipophilic extractives and then with acetone:water (95:5, v:v) to obtain hydrophilic extractives by using Soxhlet apparatus. After extraction, aliquots of extractives were removed by using rotary evaporator to 100 ml and gravimetric analyses were carried out (Kilic et al., 2011; Dönmez et al., 2016). For gravimetric analyses, 10 ml of the aliquot was evaporated to dryness, i.e, constant weight, leaving a film of extractives in the solvent container. The containers were weighed before and after extraction to determine the extractive yield. Gravimetric analyzes were performed in 3 replicates. All results, given in mg/g are calculated for freeze-dried samples. The appropriate amount of mixture was evaporated under nitrogen prior to silylation. Hexane and acetone:water (95:5, v:v) extracts were injected to GC-MS for identifying lipophilics and hydrophilics.

Chromatographic analyses

GC-MS analyses were performed using a Shimadzu GC-2010 gas chromatograph equipped with an MS-QP 2010 plus a mass spectrometer (Shimadzu Corporation, Kyoto, Japan). The analyses conditions are as follows: column, Rxi-5Sil MS (30 m × 0.25 mm i.d. × 0.25 μm film thickness; Restek, Bellefonte, PA, USA); temperature program, from 60 °C (1 min) to 280 °C at 2 °C/min; injection temperature, 280 °C; carrier gas, He flow 1 mL/min; injection mode, split (10:1); MS temperature, 280 °C.

Test microorganisms and anti-bacterial activity test

The organisms included in this study were *S. aureus* ATCC 25923 *MRSA* ATCC 43300, *B. cereus* ATCC 11778, *P. aeruginosa* ATCC 27853, *E. coli* 25922, *P. aeruginosa* PA01.

Anti-bacterial activities of tree extracts were carried out by agar well diffusion assay Holder and Boyce (1994). According to assay, 1.5% agar medium as bottom layer and soft agar as an overlay layer was prepared in which 100 μl indicator microorganisms were inoculated (0.5 McFarland turbidity). Then, a hole with a diameter of 6 mm was punched aseptically with a sterile cork borer and 100 μL of the extracts were introduced into the well.

The plates were incubated for 18–24 h at 30/37 °C. Antibacterial activity was determined by the diameter of inhibition zones (mm) around the wells. DMSO was used as a negative control because extraction yields dissolve in it and Gentamicin was used as a positive control. All tests were repeated 3 times.

Minimum inhibitory concentration (MIC)

To determine the minimum inhibitory concentration (MIC) of the plant extracts serial dilution technique using 96-well microliter plates was performed (Andrews, 2001). 100 µl of bark extracts were added to the wells containing 100 µl of the medium and each well was diluted by serial two-fold dilutions. Finally, 10 µl of bacterial culture (0.5 McFarland standard) was added and plates were incubated at 37 °C for 24 h. The MIC was determined at the lowest concentration of the extracts where no visible growth of microorganisms was observed. Dimethyl sulfoxide was used as a control because of bark extracts dissolved in it and Mueller Hinton broth was used as a negative control by adding well without bacteria. Gentamicin was used as a positive control. The experiments were reproduced three times.

Biofilm formation assay

Inhibition effect of extracts on biofilm formation in standard strain *P. aeruginosa* PA01 was evaluated by crystal violet (CV) assay (O'Toole, 2011). For each treatment 3-6 replicate wells were used in a 96-well polystyrene plate. *P. aeruginosa* PA01 and different concentrations of extracts added to the wells and incubated for 48 h. After 48 h of incubation at 36 °C content of each well were dumped out and washed three times with distilled water to remove planktonic cells. Plate let to dry about 15 min. 250 µl 0.1% of crystal violet was added to each well and again left to dry for 15 min. Following staining for 15 min at room temperature all tubes were washed three times with distilled water. 250 µl of 95% ethanol was added each well after 15 min. The optical density of each well was measured at 570 nm by using Epoch Microplate Spectrofotometer. The experiments were reproduced three times and data were expressed as mean ±SD.

Swarming motility assay

For swarming assay prepared medium which contained 8 g/l nutrient broth, 5 g/l bacto agar and 0.5% glucose and 100 µl of bark extracts was added to each 20 ml medium. After poured swarm medium, 5 µl each supernatant of bacteria cultures was inoculated at the centre of the medium and the plates were incubated overnight at 37 °C. The ability to swarm was assessed by the distance of swarming from the central inoculation site (Lee and Zhang, 2015).

Statistical analysis

This study was designed according to Randomized Plot Design. Each treatment had three replications. Data were subjected to analysis of variance ANOVA with JUMP software and the differences among treatments were compared by LSD test.

Results and discussion

L. orientalis and *E. camaldulensis* barks were analysed by GC-MS to determine lipophilics and hydrophilics after extraction with different solvents. The amount of soluble substances in the solvents was calculated gravimetrically and shown in *Table 1*. The extent of solubility in hexane in *L. orientalis* bark (7.67 mg/g) was found two-times higher than *E. camaldulensis* bark (3.90 mg/g). However, the extent of solubility in acetone:water (95:5, v:v) was determined higher in *E. camaldulensis* bark (55.51 mg/g)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_62676279
© 2018, ALÖKI Kft., Budapest, Hungary

than *L. orientalis* bark (39.19 mg/g). Bark gravimetric analyses results is usually more concentrated when the bark is extracted by some polar solvents like acetone (Dönmez et al., 2016). Bark extractives and the amount can be seen in *Table 2*.

Table 1. *Gravimetric amount of extractives from L. orientalis and E. camaldulensis bark (mg/g of dry weight)*

Species	Hexane extracts	Acetone:water extracts
L. orientalis	7.67±0.02	39.19±0.41
E. camaldulensis	3.90±0.10	55.51±0.49

Fatty alcohols, fatty acids and sterols were detected as lipophilic extractives both in *L. orientalis* and in *E. camaldulensis* after extraction with n-hexane and injection to GC-MS. Total identified amount of fatty acids in *L. orientalis* bark was 72.46% and 51.22% in *E. camaldulensis* bark. Total amount of identified phytosterols (39.88%) and fatty alcohols (8.90%) was found higher in *E. camaldulensis* bark compared to *L. orientalis* bark 25.44% and 2.10%, respectively. Alcohol 18:0 was detected as the dominant fatty alcohol both in *L. orientalis* (1.19%) and in *E. camaldulensis* bark (3.14%).

The major fatty acid was Acid 24:0 in both samples. It was determined two-fold higher in *L. orientalis* bark (20.09%) than in *E. camaldulensis* bark (10.28%). Acid 24:0 was also detected in Turkish scots pine bark suberin monomers within the range of 0.52-1.70 mg/g (Dönmez et al., 2012).

Only three sterols were determined from the phytosterol group in both bark samples. While stigmasterol had the highest amount in *L. orientalis* bark (13.03%), stigmastenol was the major component with 27.74% in *E. camaldulensis* bark.

Hydrophilic extractives was determined by the extraction of bark samples with acetone:water (95:5, v:v) and then injected to GC-MS just after n-hexane. Sugar group was seen as the major hydrophilics both in *L. orientalis* and in *E. camaldulensis* bark. Glucose, xylose, arabinose and galactose were determined as dominant monomeric components of some barks (Miranda et al., 2016, 2013; Ruiz-Aquinon et al., 2015). However, the dominant monosaccharides were D-turanose (19.79%), D-glucopyranose (13.37%) and D-fructose (8.30%) in *L. orientalis* bark and D-fructose (22.67%), D-glucopyranose (21.79%) and D-glucitol (20.34%) in *E. camaldulensis* bark.

Total amount of identified phenolics was 21.72% in *L. orientalis* bark and 7.54% in *E. camaldulensis* bark. In the phenolics group, gallic acid (11.04%) and benzoic acid (3.95%) had the highest amount in *L. orientalis* and *E. camaldulensis* bark, respectively.

According to the anti-bacterial test results of the extracts; it was observed that acetone and hexane extracts of *E. camaldulensis* and acetone extract of *L. orientalis* showed anti-bacterial effect on Gram-positive bacteria (*S. aureus*, *MRSA*, *B. cereus*) at different rates whereas no inhibition effect was observed on other Gram-negative bacteria. Unlike these results, it was not observed anti-bacterial effect of hexane extract of *L. orientalis* on both Gram-positive and Gram-negative bacteria. Results obtained from anti-bacterial activity tests can be seen in *Table 3*. Except hexane extract of *L. orientalis* other extracts showed similar inhibition results on the tested bacteria. In acetone extract of *E. camaldulensis*, the highest inhibition zone was found 18.3 mm on MRSA and 17.7 mm, 15.3 mm *B. cereus* and *S. aureus,* respectively. When acetone extract of *E. camaldulensis* with hexane extract were compared similar results were detected. The average MIC value of the plant extracts against *S. aureus* was 12.5 mg/ml to 51.5 mg/ml. All three extracts showed efficient inhibition at the lowest MIC values in *B. cereus* (*Table 4*).

Table 3. *Inhibition zone (mm) of E. camaldulensis and L. orientalis bark extracts (acetone, hexane)*

	E. Cml. **(acetone)**	***E. Cml.*** **(hexane)**	***L. Ori.*** **(acetone)**	***L. Ori.*** **(hexane)**	**Gentamicin**	**DMSO**

Table 4. *MIC value of E. camaldulensis and L. orientalis bark extracts (mg/ml)*

	E. camaldulensis **(acetone)**	***E. camaldulensis*** **(hexane)**	***L. orientalis*** **(acetone)**
S. aureus ATCC 25923	16.7	12.5	51.5
MRSA ATCC 43300	8.35	12.5	51.5
B. cereus ATCC 11778	0.52	0.78	1.61

Inhibition effect of plant extracts on *S. aureus* compared with antibiotic, three different groups were formed (**P < 0.01), hexane and acetone extracts of *E. camaldulensis* (16 mm, 15.3 mm) showed similar effects to antibiotics in the second group. Acetone extract of *L. orientalis* (13.7 mm), however, has been the lowest effective extract for *S. aureus*. In addition to *S. aureus* test results, according to statistical evolution results of MRSA hexane and acetone extracts of *E. camaldulensis* (18.7 mm, 18.3 mm) were significant (**P < 0.01) compared with antibiotic (19.3 mm) (*Fig. 1*).

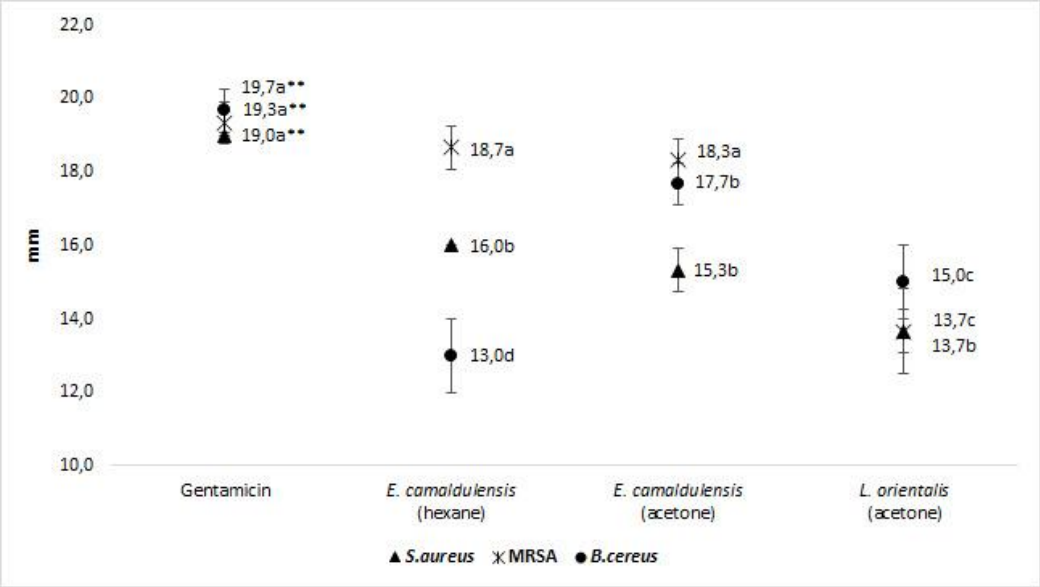

Figure 1. *Antibacterial effects of plant extracts. **Differences between mean values followed by different letters of plant extracts in the same bacteria are statistically significant at P < 0.01. Bars = Sd±*

Anti-biofilm assay results showed that only hexane extract of *E. camaldulensis* had inhibition effect on biofilm formation at 25 mg/ml concentration and 52% inhibition rate on *P. aeruginosa* PA01 (*Fig. 2*). According to statistical analysis of biofilm formation results, acetone extracts of *E. camaldulensis* (1.02) and *L. orientalis* (1.23) showed similar effect by entering the same statistical group as control (1.03) (*Table 5*).

Previous studies showed that some natural compounds from plants had a great potential to inhibit biofilm formation. In a study, gallic and ferulic acids were investigated and the two phenolic acids demonstrated the potential to inhibit swarming

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_62676279
© 2018, ALÖKI Kft., Budapest, Hungary

motility and to prevent biofilm in *P. aeruginosa* (Borges et al., 2012). Our results also showed that acetone extracts of plants include different amount of ferulic and gallic acids.

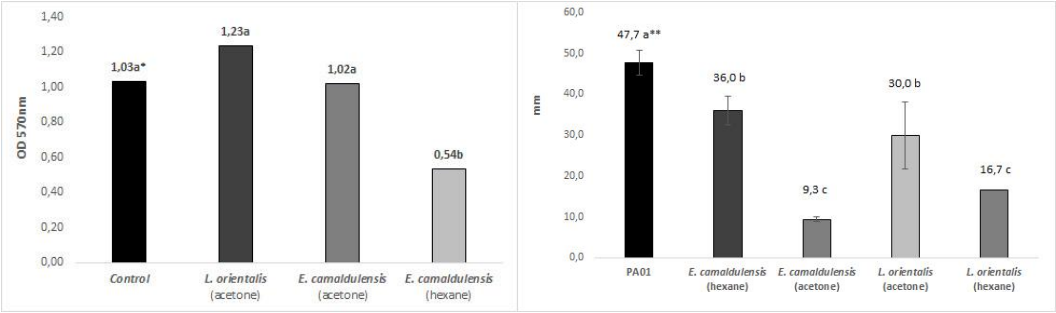

Figure 2. *Anti-biofilm (left) and anti-swarming (right) effect of plant extracts. *Differences between mean values followed by different letters of plant extracts are statistically significant at $p < 0.05$*

Gram-positive bacteria were more sensitive than Gram-negative bacteria to most plant material. It is thought to be due to the lipopolysaccharide layer that the Gram-negative bacteria have. As a result, it might have a role as a barrier to the phytochemical substances that are responsible for anti-bacterial activity (Nazzaro et al., 2013). Results from this study also showed that Gram-positive bacteria were more susceptible to extracts than Gram-negative bacteria. It was also observed that there was not any anti-bacterial activity detected in Gram-negative (*P. aeruginosa*, *E. coli* and *P. aeruginosa* PA01) bacteria in the studied concentration.

QS inhibitory compounds that do not kill or inhibit microbial growth are less likely to impose a selective pressure for the development of resistant bacteria (Uğurlu et al., 2016). In the present study, plant extracts showed no anti-bacterial effect on *P. aeruginosa* PA01. In order to detect anti-biofilm effect of extracts CV assay were done. Anti-biofilm assay results showed that only hexane extract of *E. camaldulensis* had inhibition effect on biofilm formation on *P. aeruginosa* PA01. In a similar study with some Gram-positive and Gram-negative bacteria anti-biofilm effect of bark extract of *E. camaldulensis* were investigated and results showed that there was significant inhibition in biofilm formation on tested bacteria (Sidkey and Omran, 2017). In a study with anti-biofilm activity of eucalypt oil has been evaluated in urinary tract pathogen *Proteus mirabilis* was ascertained (Mathur et al., 2013, 2014). Swarming motility is one of the major virulence factors that is known to play a role in early biofilm development (Uğurlu et al., 2016). As can be seen from *Figure 3* the greatest inhibition of swarming motility was examined by acetone extract of *E. camaldulensis* (81%) and *L. orientalis* (65%).

Figure 3. *Effect of plant extracts on swarming motility (Scale bar = 30 mm)*

For swarming motility assay, the control (PA01; 47.7 mm) received the highest value and the other applications were statistically separated from the control. The lowest swarm diameters of acetone extracts of *E. camaldulensis* (9.3 mm) and hexane extracts of *L. orientalis* (16.7 mm) were included in the third statistical group ($P < 0.01$ **) (*Table 6*). Many studies were reported about inhibition effects of essensial oils of *E. camaldulensis* and *L. orientalis* on swarming motility but this is the first report with bark extracts.

Table 6. *Variance analysis of swarming motility*

Source	DF	Sum of Squares	Mean Square	F Ratio

Mostafa et al. (2014) found the anti-bacterial effects of hexane extract of *E. camaldulensis* against *S. aureus* and *B. cereus* 12 mm and 11 mm zone diameter respectively. There was no inhibition effect on *P. aeruginosa* like in our results.

Although there are some anti-bacterial activity studies with leaf extracts of *L. orientalis*, antibacterial activity of *L. orientalis* bark extracts is out of our knowledge. In a study with leaf extracts of *L. orientalis*, anti-bacterial activity was observed on *S. aureus* with 15.3 mm diameter. Contrary to our work they also detected anti-bacterial activity on Gram-negative *E. coli* and *P. aeruginosa* on leaf extracts (Köse et al., 2016). The differences in results might be the concentration of the extracts or synergistic reactions of the various phytochemicals in different part of plants (Onuh et al., 2017). On the other hand, solvent variation effects diversity of phytochemical compounds via polarity features (Shagal et al., 2012). Most of the anti-microbial active compounds were soluble in polar solvent such as alcohol and water (Parekh et al., 2006; Yazdi et al., 2015). Thus, different results might be revealed in studies. According to our results of bark extracts of *L. orientalis*, the diameter of inhibition zones ranging from 13.7 mm to 15 mm was observed. The highest inhibition activity was found in *B. cereus* with 15 mm and there were other results with the same range (13.7 mm) against *S. aureus* and MRSA.

Conclusions

Hexane and acetone:water (95:5, v:v) extracts of *L. orientalis and E. camaldulensis* bark were analysed by GC-MS to get lipophilic and hydrophilic extractives. It was observed that in the total amount of acetone:water (95:5, v:v) extracts hydrophilics had

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_62676279
© 2018, ALÖKI Kft., Budapest, Hungary

higher value in both species. Fatty acids were the most abundant group as lipophilics in hexane extracts and Acid 24:0 was detected with the highest concentration both in *L. orientalis* (20.09%) and in *E. camaldulensis* bark (10.28%). While D-turanose had the highest value in *L. orientalis* bark (19.79%), β-D-glucopyranose was detected as the major component in *E. camaldulensis* bark (21.79%).

Acetone, hexane extracts of *E. camaldulensis* and acetone extract of *L. orientalis* had anti-bacterial activity against some Gram-positive bacteria. But none of those extracts showed anti-bacterial activity on Gram-negative bacteria. Besides these results, hexane extracts of *E. camaldulensis* bark showed anti-biofilm activity against *P. aeruginosa* PA01 and acetone extract of *E. camaldulensis* and *L. orientalis* showed anti-swarming activity. Antibiotic resistance is a crucial problem in the treatment of infectious diseases, so new strategies must be tried and developed. Thus, *E. camaldulensis*, *L. orientalis* can be good resources to fight against pathogen bacteria and active components of these plants might be tried in further studies. Not only anti-bacterial features but also inhibition effects of bark extracts in QS-regulated virulence are thought to be potential sources to struggle with infectious diseases.

Abstract. As a zero-balance line, lying between snow-covered and snow-free land areas, the snowline reflects the melting and retreating of snow and ice, which also mirrors the basic situation of climate and environment on mountain plateaus and in polar regions where there is a lack of ground meteorological stations. Thus, it is important to accurately extract and assess the distribution characteristics of the snow-line from hydrological, climatological, and geological aspects. This study extracted summer snowline data from the Xinjiang region in China using the snow cover duration ratio (SCDR) method with MODIS daily snow cover products (MOD10A1 and MYD10A1), IMS and Landsat data, and temperature and precipitation observations from 2001–2015. The variation and distribution characteristics of the summer snowline elevation were analyzed comparatively for the Xinjiang region and its different subareas. The results showed that snowline elevation data extracted using the SCDR method passed the accuracy test and therefore, it was considered suitable for the Xinjiang region. During 2001–2015, the average snowline elevation remained at about 3950 m within a 250-m range of fluctuation. However, linear trend analysis revealed an annual increasing trend of average snowline elevation with a tendency rate of 160.38 m/decade. The minimum snowline elevation exhibited a fluctuating upward trend, whereas the maximum snowline elevation showed a slight downward trend. Comparative analysis of snowline elevation in different areas of the Xinjiang region revealed a fluctuating upward trend in the Kunlun, Tianshan, and Altai Mountains. The Altai Mountains showed the most stable variation of snowline elevation, followed by the Kunlun Mountains and then the Tianshan Mountains. Spatially, the distribution of snowline elevation in the Xinjiang region was characterized by a decline from south to north with longitudinal zonation.
Keywords: *Xinjiang, summer snowline, snow cover duration ratio method*

Introduction

Traditionally, snowline elevation has been determined mainly by artificial means (Jiang, 1987; Wang et al., 2003; Hangel and Maurer, 2011; Liu et al., 2015). For example, ground stations for field observations would be established and devices used to perform the measurements. However, such methods are time consuming, costly, and provide only limited numbers of samples (Li et al., 2013). Subsequently, the Hess method was introduced to measure snowline altitude (ELAh) indirectly (Deng et al., 2006; Wang et al., 2010; Nie et al., 2013). Although this method overcame some of the disadvantages of direct measurement, the ELAh measured was primarily confined to large glaciers. Additionally, this method could only acquire static ELAh and it could not

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

rapidly reflect the state of snowline variation. With the development of remote sensing technology, McFadden et al. (2011) identified snowline spatial distribution using Landsat TM and ETM+ satellite images. Furthermore, based on ASTEG–DEM, this research group also extracted the range of ELAh in the area of glacier coverage in the Peruvian Andes. Using LISS III and AWIFS data from the United States, Brahmbhatt et al. (2012) calculated the glacier mass balance and extracted the glacier snowline in the Warwan and Bhut Basins in northern India during 2005–2007. Moreover, Xiao et al. (2010) introduced an analysis of water flow path into the extraction of snowline information based on remote sensing data.

Complex topography makes access difficult to mountainous glacier areas, and therefore, to meet the requirements for macroscopic, comprehensive, and rapid monitoring of snowline variation, remote sensing-based snowline extraction methods remain the focus of future development. Several different types of snowline have been proposed as a consequence of snowline research (Jiang et al., 2004), e.g., the theoretical snowline, local snowline, glacier equilibrium line, permanent snowline, and seasonal snowline. Presently, no research is available in the literature regarding the snowline in the Xinjiang region of China. Recently, the area of snow cover in the Xinjiang region has shown increasing variability with a downward trend (Sa et al., 2013). From the perspective of seasonal variation, a study of summer snowline is most informative regarding snow cover stability and snow water resources. Therefore, in this study of the Xinjiang region, we adopted the term snowline to mean the summer snowline. Using MODIS daily snow cover products (MOD10A1 and MYD10A1) after cloud removal for 2001–2015, we extracted snowline data using the snow cover duration ratio (SCDR) method, and we analyzed the dynamic variation characteristics of snowline elevation.

Materials and methods

Study area

Xinjiang is located in the center of the Eurasian continent (33°86'–48°50'N, 73°18'–96°69'E) (*Fig. 1*). It is part of China's northwest frontier and it covers an area of 1,664,900 km^2, accounting for 1/6 of the total land area of China (Sa et al., 2013). The topography can be described broadly as two basins between three mountain ranges. To the south are the Kunlun Mountains, which extend eastward from Pamirs, bordering the Tarim and Qaidam deserts. They have a warm temperate climate with little precipitation; however, with increasing elevation, the warm temperate climate shifts to alpine desert and the amount of precipitation increases accordingly. To the north are the Altai Mountains, which have a continental climate with warm and rainy summers and cold winters. While there is little snow in the valleys, heavy snowfall occurs in the high mountains. The Tianshan Mountains cross central Xinjiang, dividing the region into two parts. The northern slopes of the Tianshan Mountains have a humid to semiarid climate, with an average annual temperature of 0.9 °C and average annual precipitation of 450–800 mm (Zhang et al., 2015b). The foothills of the southern slopes of the Tianshan Mountains extend southward and connect with the Tarim Basin. Because of the influence of the Tarim Basin desert, the southern slopes have higher temperatures than the northern slopes and they receive little precipitation.

Considering the Xinjiang region as an entity, it is far from the sea and it is surrounded by high mountains. It has a typical temperate continental arid climate, with large variation of temperature, long duration of sunshine hours (average annual

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_62816298
© 2018, ALÖKI Kft., Budapest, Hungary

sunshine duration: 2500–3500 h), and dry air. The average annual precipitation is ~150 mm, but this varies considerably in the different subareas. The average annual surface water resources of the Xinjiang region are 789 × 108 m^3, accounting for only 3% of China's total surface water resources, and in the ranking of water production per unit area in China, Xinjiang is third from bottom (Gao et al., 2010). For a province covering 1/6 of China's total land area, this shortage of water resources is particularly serious (Lu et al., 2007). However, the Xinjiang region has abundant snow cover resources that account for ~1/3 of the total snow cover in China (Wang and Che, 2012). Snow cover water resources provide a lifeline to the arid areas of the Xinjiang region; where there is snow cover on the mountains, there is often an associated oasis development on the piedmont plain. In recent years, the reserves of snow and ice in this region have begun to decrease as temperatures have risen. Furthermore, the snowline elevation has become increasingly unstable, and both the regulation capability and the storage capacity of the solid reservoirs in the mountains have deteriorated (Lu et al., 2007). Therefore, the study of the dynamic variation of snowline in this region is of great significance to the protection and utilization of local water resources and ecological construction.

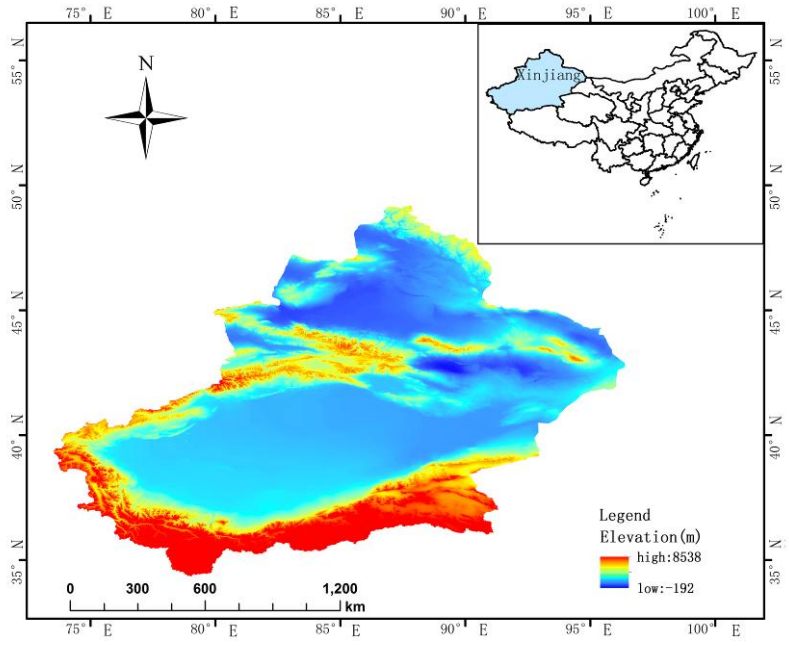

Figure 1. *Location of the study area*

Study data

The data used in this study comprised the following:

(1) MODIS daily snow cover products (MOD10A1 and MYD10A1) covering the Xinjiang region were acquired for 2001–2015 from the NASA Data Center, and 4-km IMS data for 2001–2015 were acquired from the NSIDC website. Cloud removal was accomplished using a combination of temporal and spatial filtering on the MOD10A1 and MYD10A1 data, with the IMS data as reference. Thus, the snowline elevation in the study area was extracted for 2001–2015.

DOI: http://dx.doi.org/10.15666/aeer/1605_62816298
© 2018, ALÖKI Kft., Budapest, Hungary

(2) Cloudless 30-m Landsat data of the Xinjiang region for June–August of 2005, 2010, 2014, and 2015 (downloaded from the official USGS website). These data were used as the "true value" to determine the threshold for snowline extraction when using the SCDR method, and to evaluate the accuracy of the extracted snowline elevation.

(3) SRTM DEM data (derived from the International Scientific Data Services Platform, 90-m resolution). These data were used for extracting snowline elevation within the study area.

Study methods

(1) SCDR method

In this study, we extracted snowline elevation within the study area using the SCDR method. After cloud removal, MODIS daily snow cover products were used to calculate the probability of snow cover occurrence within specific pixels on the study date. Snowline elevation was then extracted at different probabilities and the 30-m Landsat data were used as the "true value" for error analysis. The probability of snow cover occurrence with the minimum error was taken as the threshold for snowline extraction. The extraction of snowlines using this threshold was regarded as the SCDR method (Zhang et al., 2015a).

(2) Statistical methods

1. Statistical methods were used to calculate the daily snow cover area within the study area and to determine the range of the study date.

We used the MOD10A1/MYD10A1 snow cover product data for 2001–2015 to calculate the daily snow cover area for June–August of each studied year. The data of minimum snow cover area in each year was obtained, based on which the date range of the minimum snow cover area over the past 15 years was obtained. This range was determined as the study date. Given the vast area of the Xinjiang region, to be able extract the snowline using the SCDR method with greater accuracy, we divided the study area into three parts for the statistical analysis: the Tianshan Mountains, Altai Mountains, and Kunlun Mountains.

2. Statistical methods were used in two schemes to evaluate the accuracy of the extracted snowline.

The first scheme examined the accuracy difference of planar snow cover area. High-resolution (30 m) Landsat satellite images were used to evaluate the 500-m MOD10A1/MYD10A1 snow cover area image based on the Kappa coefficient (*Eq. 1*). Given the large difference in the spatial resolutions of the two image types, we counted the number of pixels at 500-m resolution in the area extracted by the Landsat satellite snow cover image after the extraction of the snow cover area by visual interpretation. This was performed to keep the pixel size consistent for calculation of the Kappa coefficient:

$$K = (P_o - P_c)/(1 - p_c) \quad \text{(Eq.1)}$$

where Po is the observed consistency rate and Pc is the expected consistency rate. Here, Pc = (a1 × b1 + ao × bo) and Po = s / n, where n is the total number of pixels in the image, a1 and ao represent the number of pixels with snow cover in the remote sensing image representing the actual snow cover conditions on the ground and the number of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_62816298
© 2018, ALÖKI Kft., Budapest, Hungary

remaining pixels, respectively, b1 and bo represent the number of pixels with snow cover in the validation image and the number of remaining pixels, respectively, and s is the number of pixels with equal values in the corresponding raster of the two images.

The second scheme obtained the snowline elevation extracted from the Landsat satellite imagery as the "true value" through visual interpretation. The accuracy of snowlines extracted using the SCDR method was evaluated through calculation of the mean error (Pa), positive and negative errors (Pc and Pb), mean absolute error (Pd), and root mean square error (RMSE) (*Eqs. 2–6*) between the snowline elevation extracted using the SCDR method and the "true value," as well as the correlation between the above two factors (Yu et al., 2009; Zhang et al., 2013).

$$Pa=\frac{1}{n}\sum_{i=1}^{n}(y_i-\hat{y}_i) \quad \text{(Eq.2)}$$

$$Pc=\frac{1}{r}\sum_{k=1}^{r}(y_k-\hat{y}_k)(y_k>\hat{y}_k) \quad \text{(Eq.3)}$$

$$Pb=\frac{1}{m}\sum_{j=1}^{m}(y_j-\hat{y}_j)(y_j<\hat{y}_j) \quad \text{(Eq.4)}$$

$$Pd=\frac{1}{n}\sum_{i=1}^{n}(|y_i-\hat{y}_i|) \quad \text{(Eq.5)}$$

$$RMSE=\sqrt{\frac{\sum_{i=n}^{n}(Z_{ai}-Z_{ei})^2}{n}} \quad \text{(Eq.6)}$$

where y_i, y_j, y_k, and $\hat{y}_i$, $\hat{y}_j$, $\hat{y}_k$ are the true values and their corresponding snowline elevations to be validated, respectively; n, m, and r are the total number of samples, number of samples with a measured value lower than the estimated value, and the number of samples with a measured value higher than the estimated value, respectively; Z_{ai} is the true value of the i-th sample point; Z_{ei} is the estimated value.

(3) Linear trend method

The linear trend method was used to calculate the trend of snowline variation and to establish the linear regression equation (*Eq. 7*) between y_t and time t:

$$y_t = a + bt \quad \text{(Eq.7)}$$

Where a is the regression constant and b is the regression coefficient, i.e., the variation trend; when b is higher (lower) than zero, it indicates an upward (downward) trend. Here, $b \times 10$ (unit: m/decade) is the tendency rate of the snowline (Tang et al., 2012).

Results and discussion

Determination of study dates

Figure 2 shows the dates of minimum snow cover area in the Tianshan, Kunlun, and Altai mountains for each year. To reduce statistical error, we removed the values at two endpoints of anomalies. The results showed that day 206 was the earliest date of minimum snow cover area in the Tianshan Mountains, whereas the corresponding date was day 203 and 216 in the Kunlun and Altai mountains, respectively. The latest date of minimum snow cover area was day 236 in both the Tianshan and Kunlun mountains, whereas it was day 239 in the Altai Mountains. Based on the above, we obtained the study dates for the three major mountain areas of the Xinjiang region: July 25–August 24 (days 206–236) of each year in the Tianshan Mountains (total: 31 days); July 22–August 24 (days 203–236) of each year in the Kunlun Mountains (total: 34 days); and August 4–August 27 (days 216–239) of each year in the Altai Mountains (total: 24 days).

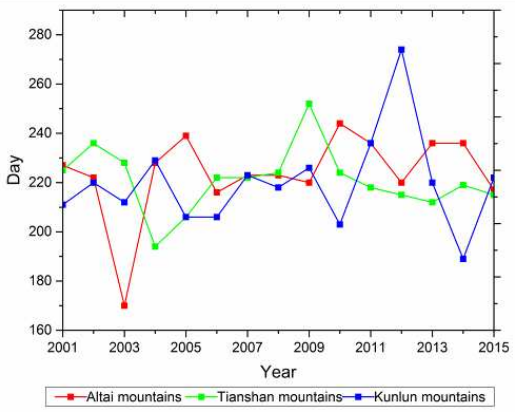

Figure 2. *Dates of minimum snow cover area in three mountain areas of the Xinjiang region for each year*

3.2 Snowline extraction in the Xinjiang region

Threshold determination for the SCDR method

After cloud removal, we overlaid the MOD10A1/MYD10A1 snow cover product data from the Tianshan, Kunlun, and Altai mountains for the study dates of 2005, 2010, and 2014, respectively (*Fig. 3*). Then, we calculated the probability of snow cover occurrence in specific pixels within 31 days (Tianshan Mountains), 34 days (Kunlun Mountains), and 24 days (Altai Mountains). In the Tianshan Mountains, we extracted snowline elevation with 3.2%, 6.4%, 9.6%, and up to 100.0% probability of snow cover occurrence. In the Kunlun Mountains, we extracted snowline elevation with 2.9%, 5.9%, 8.8%, and up to 100.0% probability of snow cover occurrence. In the Altai Mountains, we extracted snowline elevation with 4.2%, 8.3%, 12.5%, and up to 100.0% probability of snow cover occurrence. Then, 30-m Landsat data were used as the "true value" for error analysis. The smaller the difference, the smaller the error, and the probability of snow cover occurrence with the smallest error was determined as the minimum error ratio. Based on the minimum error ratio, we extracted the snowline threshold using the SCDR method when overlaying data for 31, 34, and 24 days in the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

Tianshan, Kunlun, and Altai mountains, respectively. *Figure 4* shows the error curves of different ratios in 2005, 2010, and 2014. The minimum error ratios for the Tianshan Mountains were 83.2%, 70.4%, and 70.4%; for the Kunlun Mountains, they were 67.7%, 79.4%, and 85.3%, and for the Altai Mountains, they were 83.3%, 83.3%, and 87.5%. The average of the minimum error ratios of the three years was obtained as the threshold for the SCDR method when overlaying data for 31, 34, and 24 days in the Tianshan, Kunlun, and Altai mountains, respectively. In the Tianshan Mountains, the average ratio was estimated to be 74.7%, closest to the true ratio of 74.2%, i.e., the lower edge of snow cover that appeared in each pixel for 23 days was taken as the snowline in the Tianshan Mountains. In the Kunlun Mountains, the average ratio was 77.5%, closest to the true ratio of 76.5%, i.e., the lower edge of snow cover that appeared in each pixel for 26 days was taken as the snowline in the Kunlun Mountains. In the Altai Mountains, the average ratio was 84.7%, closest to the true ratio of 83.3%, i.e., the lower edge of snow cover that appeared in each pixel for 20 days was taken as the snowline in the Altai Mountains. In summary, when extracting the snowline elevation in the three mountainous areas using the SCDR method, the threshold values were 74.2%, 76.5%, and 83.3% for the Tianshan Mountains (overlaying data for 31 days), Kunlun Mountains (overlaying data for 34 days), Altai Mountains (overlaying data for 24 days), respectively.

Accuracy evaluation of snowline

(1) Accuracy evaluation of snow cover area

Local areas were selected from the three major mountainous areas in 2015 (*Fig. 5*). The evaluation was accomplished in different areas using the Kappa coefficient, based on the consistency between the snow cover area obtained using the SCDR method and the "true value" of snow cover area based on the MOD10A1/MYD10A1 snow cover classification map. *Table 1* shows that the Kappa coefficients were 0.92, 0.82, and 0.87 for the Tianshan, Kunlun, and Altai mountains, respectively. A study (Klein and Barnett, 2003) has shown that with 0.81 < Kappa < l.00, two images can be considered highly consistent. In summary, relatively high consistency was obtained with the "true value" when extracting the snow cover area, based on the MOD10A1/MYD10A1 daily snow cover image, using the SCDR method with thresholds of 74.2%, 76.5%, and 83.3% for the Tianshan Mountains (overlaying data for 31 days), Kunlun Mountains (overlaying data for 34 days), and Altai Mountains (overlaying data for 24 days), respectively.

(2) Accuracy evaluation of snowline elevation

Local areas were selected from the three major mountain areas of the Xinjiang region in 2015. The accuracy of snowline extracted using the SCDR method was analyzed statistically based on Pa, Pc, Pb, Pd, RMSE, and the correlation with the "true value." As shown in *Table 2,* the value of Pa = –8.15 m for the Kunlun Mountains was the smallest, and the values for the Tianshan and Altai mountains were similar to each other (19.07 and 19.12 m, respectively). The Tianshan Mountains ranked highest for Pc and Pb (93.13 and –85.55 m, respectively); the values for the Kunlun Mountains were 52.41 and –70.38 m, respectively, and those for the Altai Mountains were 71.67 and –53.92 m, respectively. The Kunlun Mountains had the smallest value of Pd (61.81 m), followed by the Altai Mountains (65.88 m) and the Tianshan Mountains (90.63 m). The RMSEs of the Altai and Kunlun mountains were similar to each other (77.01 and 76.32 m, respectively), whereas that of the Tianshan Mountains was relatively large (97.93 m). The above analysis shows that all the errors for the three mountain areas were within the range of 100 m, meeting the accuracy requirement of the study.

© 2018, ALÖKI Kft., Budapest, Hungary

Table 2. *Errors in snowline elevations obtained using the snow cover duration ratio method*

	Mean error (Pa)/m	**Negative error (Pb)/m**	**Positive error (Pc)/m**	**Mean absolute error (Pd)/m**	**Root mean square error (RMSE)/m**
Tianshan Mountains	19.07	-85.55	93.13	90.63	97.93
Kunlun Mountains	-8.15	-70.38	52.41	61.81	76.32
Altai Mountains	19.12	-53.92	71.67	65.88	77.01

Table 3 summarizes the average snowline elevations extracted using the SCDR method and the "true value," together with their correlation coefficients. The average snowline elevations for the Tianshan, Kunlun, and Altai mountains, extracted using the SCDR method, were 4030.12, 5458.15, and 3114.59 m, respectively, whereas the "true value" snowlines were 4046.12, 5449.99, and 3133.71 m, respectively. The correlation between the snowlines extracted using the SCDR method and the "true value" was highest for the Altai Mountains (0.943); the coefficients were 0.843 and 0.887 for Tianshan and Kunlun mountains, respectively. *Table 4* shows that the correlation coefficients of snowline elevations extracted using the SCDR method and the "true value" ranged from 0.8 to 1.0 in the three mountain areas, indicating a relatively high degree of correlation. *Figure 6* shows scatter plots of snowline elevation in the three mountain areas extracted using the SCDR method versus the "true value," which reflects their correlation with the "true value" more directly.

Table 3. *Correlations between snowline elevation extracted using the snow cover duration ratio (SCDR) method and the "true value"*

	Average elevation of snowlines extracted by SCDR/m	**Average elevation of "true-value" snowlines/m**	**Correlation coefficient**
Tianshan Mountains	4030.13	4046.12	0.843
Kunlun Mountains	5458.15	5449.99	0.887
Altai Mountains	3114.59	3133.71	0.943

In summary, the SCDR method achieved high accuracy for snowline extraction in the Tianshan, Kunlun, and Altai mountains with thresholds of 74.2%, 76.5%, and 83.3%, respectively. This method was therefore considered suitable for extracting snowlines in the Xinjiang region.

Table 4. *Degree of correlation for correlation coefficients*

Correlation coefficients	**Degree of correlation**
$0.8 < \|r\| < 1$	High correlation
$0.5 < \|r\| \leq 0.8$	Moderate correlation
$0.3 < \|r\| \leq 0.5$	Low correlation
$0.8 < \|r\| < 0.3$	Extremely low correlation

Dynamic variation characteristics of snowline in Xinjiang

Dynamic variation analysis of snowline elevation in the entire Xinjiang region

Figure 7 shows that the variation of average snowline elevation in the Xinjiang (2001–2005) was within the range of 250 m, while the snowline elevation was maintained at approximately 3950 m. Through linear fitting (*Table 5*), we found that the average snowline elevation increased annually, with a tendency rate of 160.38 m/decade. The lowest average elevation occurred in 2001 (3828.06 m) and the highest occurred in 2015 (4085.00 m). Here, the result of snowline change in the middle of Qilian Mountains and Western Nyainqentanglha are compared with Zhao et al. (2015) and Zhang et al. (2016). Generally, the mean snowline elevation increases. Although the average elevation in Xinjiang, less than that inWestern Nyainqentanglha Range and the Middle of Qilian Mountains, the increase trend in Xinjiang is the fastest. The annually increasing snowline elevation in the Xinjiang region is a consequence of the considerable influence of global warming. A study has shown that global warming poses a profound threat to the ecological environment, and that it is the primary cause of the reductions of permafrost, snow cover area, and glaciers in China. The decrease of ice and the decline in snow cover area lead to the rise of snowline elevation.

Based on linear fitting, we found that the maximum snowline elevation had a weak downward trend, with a tendency rate of 25.14 m/decade. Conversely, the minimum snowline elevation showed a slow upward trend, with a tendency rate of 128.68 m/decade. Compared with the average annual snowline elevation in the Xinjiang region, the minimum and maximum snowline elevations have changed significantly, and the extents of their variations have been larger than the change in average snowline elevation. For different years, the maxima and minima snowline elevations have appeared in different locations within the study area. Compared with the Tibetan Plateau, the minimum snowline elevation is on the rise, but the maximum snowline elevation trend is the opposite. This is because of the vast area of the Xinjiang region and the complex distribution of topography. In addition to climatic factors that have affected the constant variation of minimum and maximum snowline elevations, localized topography, geomorphology, and occurrence of extreme disasters have also had an effect. In some marginal areas of the Xinjiang region with complex topography and geomorphology, even small variations of precipitation and temperature can cause an increase in disastrous weather events because of the impact of aspect, slope, or human factors. For example, were the temperature to increase sharply and precipitation to decrease during summer, the snowline elevation would show correspondingly large variation. This is why the minimum, maximum, and average snowline elevations varied with significant differences.

Table 5. *Linear regression models between snowline elevation and time in different areas*

	Linear regression model
Average snowline elevation in Xinjiang region	y = 16.038t – 28237
Maximum snowline elevation in Xinjiang region	y = –2.5143t + 12221
Minimum snowline elevation in Xinjiang region	y = 12.868t – 23152
Average snowline elevation in Tianshan Mountains	y = 27.563t – 51659
Average snowline elevation in Kunlun Mountains	y = 14.287x – 23612
Average snowline elevation in Altai Mountains	y = 5.5493x – 7999

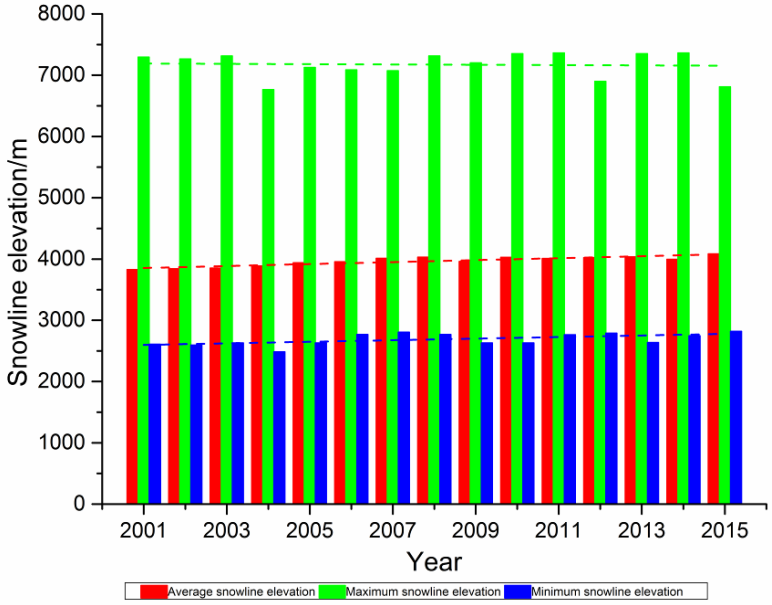

Figure 7. *Dynamic variation of snow elevation in the Xinjiang region (2001–2015)*

Comparative analysis of dynamic variation of snowline elevation in the three mountain areas

To study the dynamic variation of snowline elevation in the different mountain areas of the Xinjiang region, and with consideration of the spatial heterogeneity of the region, we divided the Xinjiang region into the three mountain areas (Kunlun, Tianshan, and Altai mountains) and analyzed their respective snowline elevations comparatively.

Figure 8 depicts fluctuating upward trends of snowline elevation in the Kunlun, Tianshan, and Altai mountains during 2001–2015, consistent with the trend of average snowline elevation across the entire Xinjiang region.

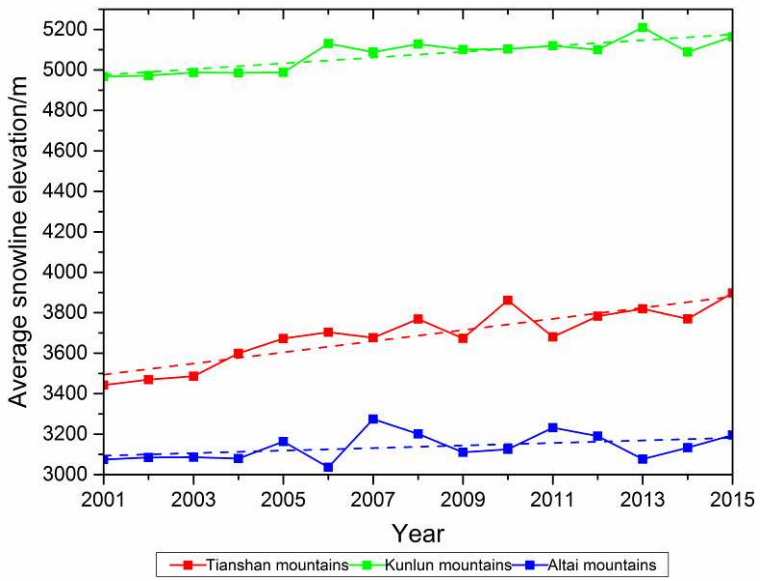

Figure 8. *Dynamic variation of snowline elevation in the three mountain areas of the Xinjiang region (2001-2015)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_62816298
© 2018, ALÖKI Kft., Budapest, Hungary

Figure 9 illustrates the dynamic variation of air temperature and precipitation in the three mountain areas. During 2001–2015, temperature showed an upward trend in all three areas, whereas precipitation showed a downward trend. The temperature rise and decline of precipitation led to the upward trend of snowline elevation in the three mountain areas. *Table 5* shows that the tendency rates and amplitude fluctuations of snowline elevation were 142.87, 275.63, and 55.29 m/decade and 242.81, 454.65, and 200.34 m in the Kunlun Tianshan, and Altai mountains, respectively. The above analysis revealed upward trends of snowline elevation in the three mountain areas of the Xinjiang region during 2001–2015. The Altai Mountains showed the most stable variation of snowline elevation, followed by the Kunlun Mountains, and the Tianshan Mountains.

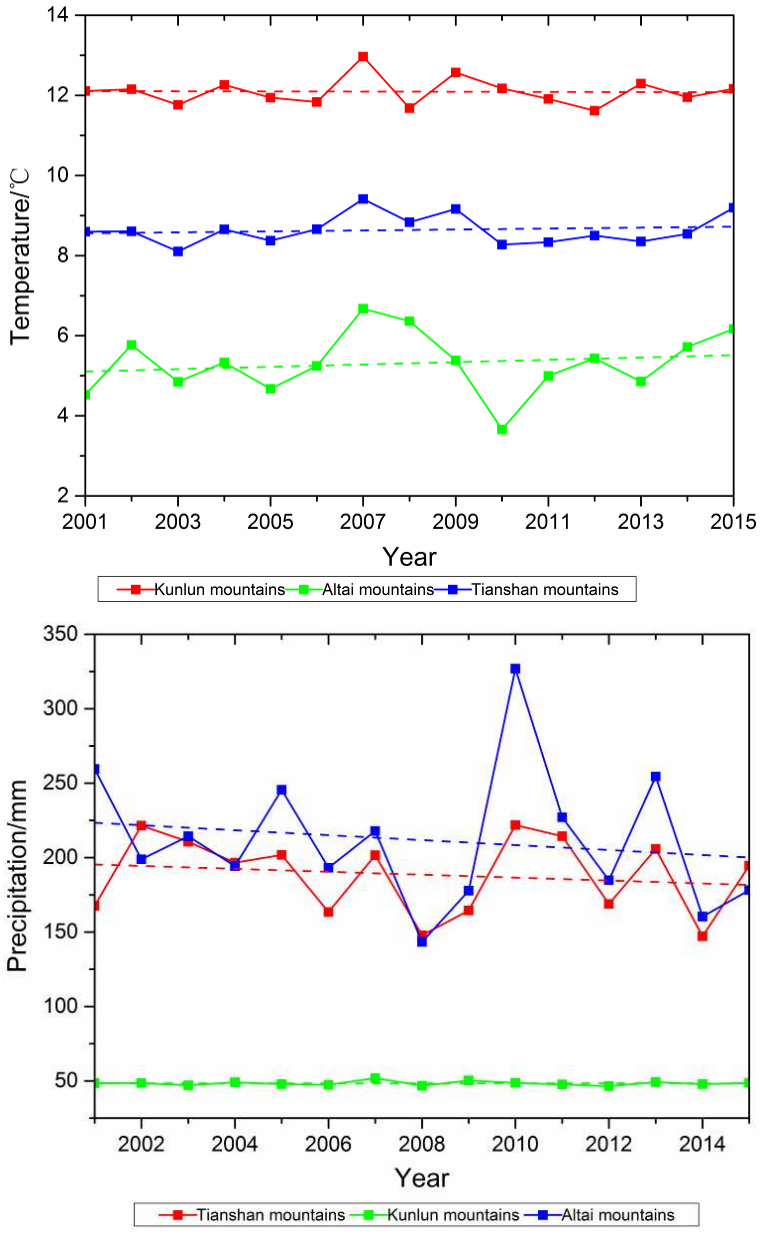

Figure 9. *Variations of temperature (top) and precipitation (bottom) in the three mountain areas of the Xinjiang region (2001–2015)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_62816298
© 2018, ALÖKI Kft., Budapest, Hungary

As shown by the distribution of average snowline elevation in the three mountain areas (2001–2015), the annual snowline elevation of the Kunlun Mountains was highest, followed by the Tianshan Mountains, and the Altai Mountains. This indicates that the snowline elevation decreased from south to north across the Xinjiang region, and that the distribution was characterized by longitudinal zonation. This is mainly because the Indian monsoon weakens as it passes across the Tibetan Plateau (with elevation of 5000 m), and thus, it produces only small amounts of precipitation on the northern slopes of the Kunlun Mountains. Only a strong Pacific monsoon can reach the eastern edge of the Kunlun Mountains during June–August, which can produce some precipitation; however, its impact on the middle section of the Kunlun Mountains is weak. Additionally, the movement of moist air masses from the Atlantic Ocean is prevented by the Pamirs, and thus, they have little effect on the mid-section of the Kunlun Mountains. The southern section of the Tianshan Mountains is relatively sheltered, blocked by high mountain ranges that prevent access by Atlantic water vapour (Gao et al., 2010). Furthermore, this area faces China's largest desert (Taklimakan Desert) and thus, the effect of reduced atmospheric moisture results in decreased precipitation and high temperatures. However, the Ili River Valley is surrounded by mountains on three sides, which trap water vapor from the Atlantic Ocean, resulting in abundant precipitation and low temperatures on the windward slopes in this area. The Altai Mountains are located on the moist westerly windward side, making the area rich in precipitation, particularly solid precipitation in the winter. *Figure 9* shows that the Kunlun Mountains had higher average annual temperature and much lower precipitation than the other two areas during 2001–2015. The highest precipitation and lowest temperature were found in the Altai Mountains every year. The above analysis showed that the snowline elevation decreased from south to north in the Xinjiang region and that the distribution was characterized by longitudinal zonation.

Conclusions

(1) For the SCDR method, the extracted snowline elevations passed the accuracy test and thus, the method was considered suitable for the Xinjiang region.

(2) During 2001–2015, the average snowline elevation remained at about 3950 m within a 250-m range of fluctuation. However, linear trend analysis revealed an annual increasing trend of average snowline elevation in the Xinjiang region, with a tendency rate of 160.38 m/decade. The minimum snowline elevation showed a fluctuating upward trend, while the maximum snowline elevation exhibited a weak downward trend. However, both the minimum and maximum snowline elevations showed larger fluctuations compared with the change of the average snowline elevation.

(3) Comparative analysis of different areas of the Xinjiang region revealed that the snowline elevation showed a fluctuating rising trend in the Kunlun, Tianshan, and Altai mountains during 2001–2015. Of the three areas, the Altai Mountains showed the most stable variation of snowline elevation, followed by the Kunlun Mountains, and the Tianshan Mountains.

(4) According to the distribution of snowline elevation in three mountain areas (2001–2015), the snowline elevation of the Kunlun Mountains in each year was the highest, followed by the Tianshan Mountains and the Altai Mountains. Thus, the snowline elevation has decreased from south to north in the Xinjiang region and its distribution is characterized by longitudinal zonation.

Abstract. This paper adopts the meteorological data from 1951 to 2014 provided by 73 national ordinary stations in Hetao area, China, combines Kendall-tau non-parametric test method and Sen's slope estimation method based on sub-regions divided by fuzzy clustering method and analyses the variation trend of extreme precipitation indexes in the area. The results show that: (1) In the arid and semi-arid sub-region (located in the upper reaches of the Yellow River) and humid and semi-humid sub-region (located in the middle and lower reaches of the Yellow River) in Hetao area, extreme precipitation events have different variation trends, and the spatial distribution of precipitation is unbalanced. (2) Except the precipitation of extreme wet days has significantly increased (R99p is 32.01 mm /10a), other indexes do not increase significantly in the arid and semi-arid sub-region of Hetao area. (3) In the humid and semi-humid sub-region of Hetao area, the variation trends of the other 9 indexes are negative except the indexes consecutive days with rain (CWD) which showed upward trend (0.03d/10a). (4) There is an upward trend of extreme precipitation events in Bayinmaodao, but other regions in Hetao area have not increased.

Introduction

In more than half a century in the past, Scholars all over the world have conducted a lot of research work on extreme climate events in different regions of the world and have achieved research results of different depths. In early 2014, Science published 7 papers in a row to discuss the "the Challenge of Climate Science" and elaborate on some core issues of current climate and hydrology sciences, including the issue of "regional climate and extreme events". The paper believes that an important trend of warming research is to reflect global warming in the research on regional climate and extreme events, but the research needs to be further developed, where also exists great difficulties (Wang et al., 2014). At present, domestic and international researches focus mainly on the observational facts of extreme climate. The assessment report (IPCC-AR4) of the UN Intergovernmental Panel on Climate Change (IPCC) has summed up the observations and research findings of extreme temperature and precipitation events in full length, pointing out that extreme precipitation events are very sensitive to the global climate change, and minor changes in the climate may cause greater changes in

the frequency and intensity of extreme climate (Zhai et al., 2003; Zhou et al., 2010; Wang et al., 2013; Shen et al., 2012).

Scholars all over the world have done a lot of research work on extreme precipitation events on different spatial and temporal scales in different regions, which mainly includes four aspects: determination of representative values of extreme precipitation, characteristics of temporal and spatial distribution and evolution trend of extreme precipitation, factor of influence of extreme precipitation and simulation and prediction of extreme precipitation based on the climate change mode. With regard to the arid area in northwestern China and even the entire country, the research findings are given that the variation of extreme precipitation events in China is extremely complex with obvious regional and local characteristics. The micro-precipitation in the North significantly decreased, the drought continued in North China and the summer monsoon precipitation in the basin of the Yangtze and Huaihe Rivers increased significantly; heavy precipitation decreased significantly in North China, extreme precipitation events showed a significant upward trend in most parts of Northwest China and western part of Northeast China, but that showed a significant downward trend in the eastern part of Northeast China (Wang et al., 2012). the temperature in the northwestern region has shown an overall upward trend in the past 50 years, during which extreme high temperature events have increased and extreme low temperature events decreased; precipitation has shown a slight increase and extreme precipitation events was on the rise (Qi et al., 2015). The precipitation in the Yellow River basin showed a downward trend year by year, while extreme precipitation events in winter showed an upward trend, which mainly centralized in the upper reaches, while the downward trend was mainly seen in the middle and lower reaches, and spatial differences can be found in the Yellow River Basin in terms of precipitation and precipitation variation trend (Zhao et al., 2015). The precipitation in Xinjiang increased, extreme precipitation also showed an upward trend and continuous drying index dropped under the impact of climate warming (Li et al., 2015). The extreme precipitation indexes in the semi-arid region in the north such as maximum precipitation of 5 days, heavy precipitation, precipitation intensity, consecutive wet days, consecutive dry days, heavy rain days and annual total precipitation have shown a downward trend (Wang et al., 2016).

From previous research findings, it can be seen that extreme precipitation events on different scales have different rules or characteristics. The research area in this paper is Hetao area in China, which refers to the “T-shaped” bend of the Yellow River and its surrounding river basins. The whole area is located in the confluence of the Loess Plateau, Ordos Plateau and Inner Mongolia Plateau and the transitional zone of China’s arid, semi-arid and semi-humid regions, where plains, deserts, mountains, platforms, lakes and wetlands are intertwined, topography and landform are complex, terrain changes greatly and the structure of the underlying surface is complex. They have a temperate continental climate with low precipitation, strong evaporation and sensitivity to climate change. At the same time, the area relies on the irrigation of the Yellow River passing through, which is known as the major producing area of grain and cash crops in China and an emerging industrial cluster. It thus can be seen that the economic development in the area requires the sound development of precipitation resources and even extreme precipitation events. If extreme precipitation events occur frequently, it will have an adverse impact on the industrial and agricultural production and urban development in the area. Therefore, it is of both scientific and practical significance to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

study the characteristics and evolution trend of extreme precipitation events in Hetao area.

Predecessors have already conducted some researches on extreme precipitation events in Hetao area. The precipitation within the year in Hetao area was unevenly distributed with about 80% of the precipitation concentrated in the period from June to September, while the precipitation was less in winter. The annual total precipitation in Hetao area has shown an upward trend in the past 50 years, but the trend is not obvious, which is less than 10 mm (Tao et al., 2011). The extreme precipitation threshold in summer in northern Hetao area showed an upward trend from northwest to southeast, and the extreme precipitation events in summer showed a slight upward trend in the past 45 years (Huang et al., 2013). The rainstorm days in Hetao area showed an insignificant downward trend. In addition, the rainstorm is characterized by less rainy day, heavy precipitation, more local rainstorm and less regional rainstorm in terms of distribution (Cai et al., 2014; Zhang et al., 2014). At present, the variation trend and characteristics of extreme precipitation events in Hetao area still need to be further studied to enhance systematic understanding.

Therefore, this paper, based on the daily precipitation data of 73 meteorological stations in Hetao area from 1951 to 2014, uses the extreme precipitation event index recommended by ETCCDMI and the climate change reference period and reference value of 30 years (1981-2010) recently recommended by WMO, and divides the sub-regions for study using fuzzy clustering method (FCM) to conduct an in-depth research on the variation of extreme precipitation events in Hetao area from differential temporal and spatial scales, reveal the variation characteristics and trend and answer the key issue that if the extreme precipitation events tend to increase in the area, hoping to provide a reference for water resource management, ecological vulnerability assessment and hydrogeological hazard warning in the area.

Data and methodology

Data information

When it comes to the research on the variation of extreme precipitation events, this paper usually uses the observed values of precipitation provided by meteorological stations distributed in the research area as data information. This paper adopts the daily precipitation data from 1951 to 2014 of 73 national ordinary stations in Hetao area provided by China Meteorological Data Network (http://data.cma.cn/). Prior to research, the meteorological data selected in this paper has been pretreated, including homogenization inspection; inspection of climate threshold and abnormal value; inspection of station extremum; internal consistency inspection of set value, daily average and daily extremum; temporal and spatial consistency inspection and so on, and the data has been corrected based on the inspection results. In addition, the distribution of meteorological stations is shown in *Figure 1*.

Research method

Fuzzy clustering analysis

Clustering analysis is a multivariate statistical analysis method, which classifies individuals based on their several characteristics, so that individuals of the same category have a higher homogeneity while individuals of different categories have a

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_62996316
© 2018, ALÖKI Kft., Budapest, Hungary

higher heterogeneity. Since the boundaries of individual categories are not always clear and exact, varying degrees of fuzziness is always seen in practical classification problems. When clustering involves fuzzy boundaries between individuals, a fuzzy clustering analysis method is usually used, which is established on fuzzy mathematics. The commonly used fuzzy clustering analysis method is Fuzzy C-Means (FCM for short), which was proposed by Bezkek in 1981. The impact of different number of categories *c* on classification results is highly significant. To evaluate the classification effect under different *c* values in a scientific way, the predecessors have done a lot of research work and defined a number of evaluation indexes to guide the specific classification process. Assuming that different *c* values are determined according to those indexes, the smaller *c* value shall prevail if different *c* values have similar classification effect (Qi et al., 2015).

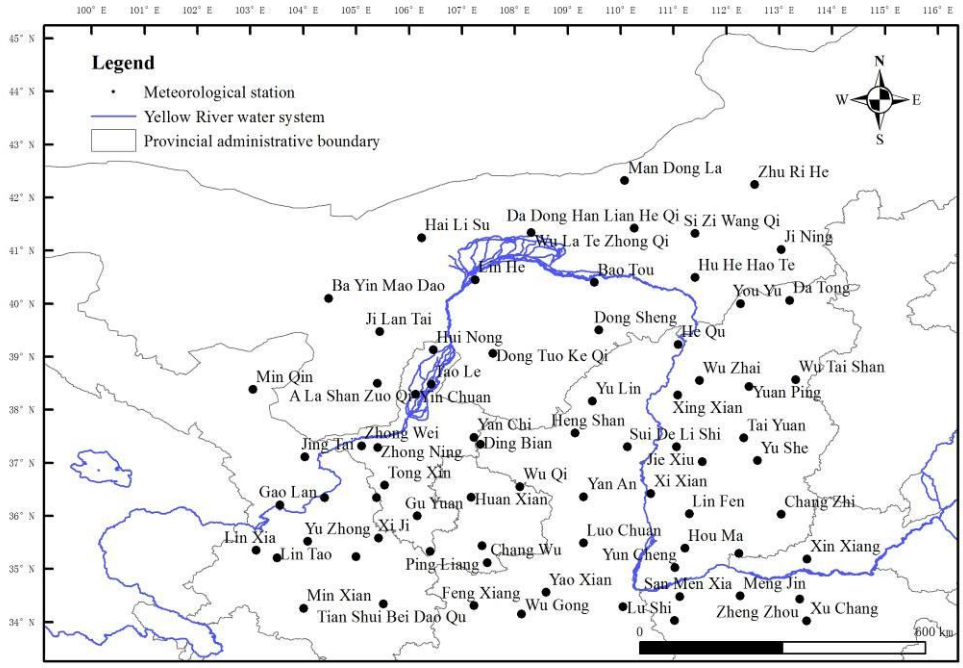

Figure 1. *Diagram of distribution of meteorological stations in Hetao area*

Definition and calculation of extreme precipitation indexes

The extreme precipitation indexes used in the research are "climate change detection and indexes" defined and recommended by CCI, WCRP, CLIVAR and ETCCDMI. These indexes and their calculation methods have been widely used in the world, and the research results also reflect that these indexes in this series are characterized by good regional adaptability, and low noise (Zhao et al., 2015; Li et al., 2012).

There are 29 indexes in this series, including temperature and precipitation. This paper selects 11 indexes of precipitation to analyze the extreme precipitation events in Hetao area, and specific indexes and meanings are shown in *Table 1*. The indexes are calculated using RClimDex1.1 software. In the process of calculation, quality inspection and control is conducted on the said meteorological data including outliers and error

DOI: http://dx.doi.org/10.15666/aeer/1605_62996316
© 2018, ALÖKI Kft., Budapest, Hungary

values. Meanwhile, this paper also adopts the climate change reference period and value of 30 years (1981-2010) recently recommended by WMO (Zhang et al., 2014).

Table 1. *Definitions of extreme precipitation indexes*

S.N.	Abbreviation of index	Index name	Index definition	Index unit
1	CWD	Continuous moisture index (consecutive days with rain)	Maximum stay with daily precipitation greater than or equal to 1 mm	d
2	R10mm	Heavy precipitation days	Total days with annual daily precipitation greater than or equal to 10 mm	d
3	R20mm	Very heavy precipitation days	Total days with annual daily precipitation greater than or equal to 20 mm	d
4	R25mm	Strong precipitation days	Total days with annual daily precipitation greater than or equal to 25 mm	d
5	PRCPTOT	Annual total precipitation	Daily cumulant with precipitation greater than or equal to 1 mm	mm
6	R99p	Precipitation of extremely wet days	Sum of heavy precipitation with the tantile greater than 99%	mm
7	Rx5day	5-day maximum precipitation	Annual/quarterly/monthly/daily maximum precipitation in 5 days in a row	mm
8	SDII	Ordinary daily precipitation intensity (daily precipitation intensity)	Ratio of total precipitation greater than or equal to 1 mm and number of days	mm/d

Analysis method of variation trend of extreme precipitation indexes

Meteorological data belong to time series. For the trend analysis of time series, a linear regression method is usually used, but such method directly calculates the slope based on the actual data value, which is greatly affected by the abnormal value. Sen's slope estimation algorithm has strong anti-noise performance, but it cannot be used to make a significant judgement of sequence trend. The Kendall-tau non-parametric test method does not require the sample to follow a certain distribution, allows the existence of missing values and can achieve significant judgments, but it cannot be used to obtain the slope of the sequence (Zhai et al., 2003). Therefore, Kendall-tau non-parametric test method and Sen's slope estimation method are combined in this paper to analyze the variation trend of extreme precipitation indexes, and since they are subject to no abnormal value, they are more suitable for the time sequence trend analysis in the research of extreme climate changes. In addition, the area weighted average method shall be adopted for zone leveling.

Homogeneity test method for meteorological data

Data quality is the primary condition for drawing the correct conclusion in research and is also one of the decisive conditions. Affected by factors such as the replacement of observation instrument, changes in station position, changes in observation procedures and subjective biases of observers, meteorological data is found to have problems such skewness, lack of observation and outliers, thereby resulting in inhomogeneity of the sequence of meteorological data, which shall be homogenized. In

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_62996316
© 2018, ALÖKI Kft., Budapest, Hungary

this paper, the RHtest method is used to carry out homogenization and correction of the meteorological data sequence in Hetao area. The method was established by Wang et al. from Climate Research Center of Environment Canada to test the entire sequence of meteorological data based on a two-stage linear regression model (Wang et al., 2007; Zhang et al., 2005), whose feasibility and rationality has been widely verified (Zhang et al., 2012; Zhang, 2012).

Results and discussion

FCM-based climate division

Combined with the natural conditions of the geographical location of the research area, latitude and longitude, altitude, average temperature and maximum and minimum temperature of the meteorological stations are regarded as characteristic values to perform clustering analysis on 73 meteorological stations in Hetao area. The number of divisions is preliminarily estimated to be c = 2 or c = 3. By selecting different c values, FCM can obtain corresponding membership matrix. According to the relationship reflected in the matrix, the classification results shall be plotted when c = 2 or c = 3 (see *Fig. 2a, b*). On this basis, the most reasonable number of divisions shall be analyzed. In addition, it can be seen from *Figure 2* that more stations are not classified in Hetao area when c = 3; while the classification shows good results when c = 2.

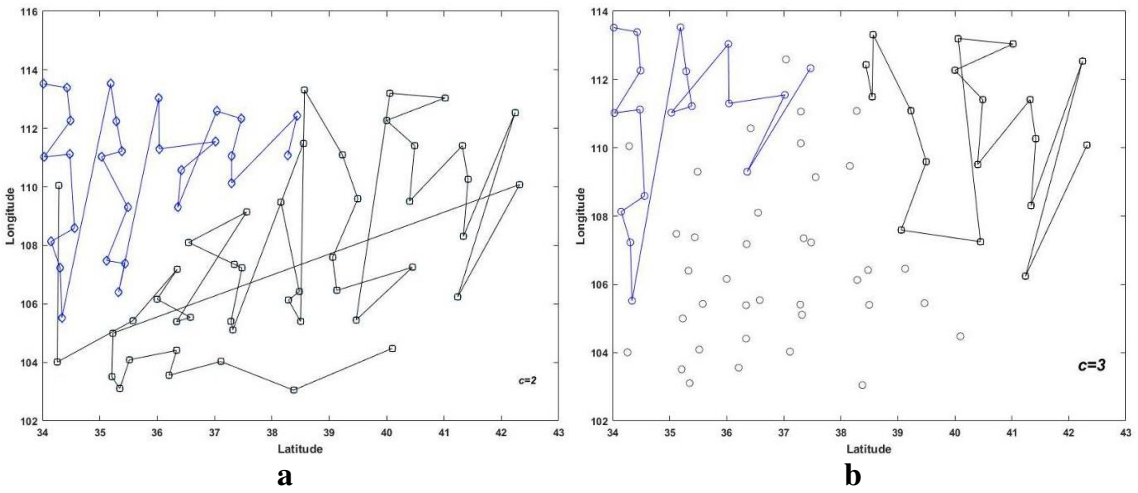

Figure 2. *FCM analysis of meteorological stations in Hetao area: c = 2 (a) and c = 3 (b)*

To more intuitively express the FCM climate divisions in Hetao area, the classification results are represented in a map (see *Fig. 3*). It can be clearly observed that 73 stations are classified into 2 different climate divisions along the line of "Yuanping—Xing County—Suide—Yan'an—Pingliang—Tianshui", and the line is very close to China's 400 mm equivalent precipitation line, which also fully indicates that it is reliable and reasonable to apply the fuzzy clustering algorithm to climate division in this paper. By referring to the significance of the 400 mm equivalent precipitation line, this paper defines 2 different climate divisions in Hetao area obtained by FCM clustering analysis as "arid and semi-arid sub-region" and "humid and semi-humid sub-region", respectively.

Variation characteristics of extreme precipitation indexes in Hetao area

Variation of CWD, R10mm, R20mm and R25mm indexes

There is no station with significant upward trend of CWD; stations with significant downward trend include Linhe, Taiyuan, Wutaishan, Yan'an and Lushi (see *Fig. 4, Table 2*). In addition, the interannual change process of CWD in the entire Hetao area, CWD index have shown an upward trend whether in arid and semi-arid sub-region or humid and semi-humid sub-region (see *Table 2* and *Fig. 5*), but this upward trend is not significant.

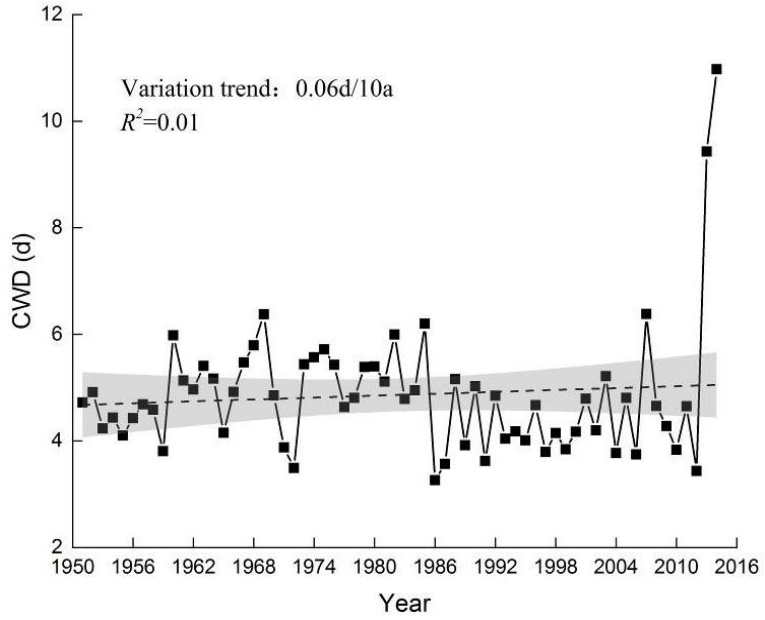

Figure 5. *Interannual variation of CWD index in Hetao area (73 stations involved)*

Stations with significant upward trend of R10mm include Bayinmaodao and Zhongwei; those with significant downward trend include Linhe, Wutaishan and Huashan (see *Fig. 6; Table 2*). Stations with significant upward trend of R20mm include Bayinmaodao and those with significant downward trend include Linhe, Wutaishan and Huashan (see *Fig. 7; Table 2*). There is no station with insignificant upward trend of R25mm; those with significant downward trend include Gaolan, Linhe and Wutaishan (see *Fig. 8; Table 2*).

It is analyzed in this paper that there is a significant upward trend in heavy precipitation days in Bayinmaodao, Inner Mongolia. According to the records and related literature of the local meteorological department, heavy precipitation occurred in the area in 2010, 2013, 2014, 2015 and 2016 (Sun et al., 2013; Song et al., 2015; Ma, 2016; Lv, 2015; Man, 2015; Sun, 2018; Song, 2016). In order to detect whether there is extreme precipitation event at this station, this paper analyses the decades average precipitation and dynamic precipitation averages of Bayinmaodao meteorological station (see *Tables 4* and *5*).

Table 4. *Decades precipitation averages of Bayinmaodao meteorological station*

S.N.	Decades	Average precipitation (mm/year)
1	1957-1960	91.15
2	1961-1970	80.78
3	1971-1980	114.57
4	1981-1990	96.32
5	1991-2000	112.21
6	2001-2010	123.18
7	2011-2014	131.225

Table 5. *Dynamic precipitation averages of Bayinmaodao meteorological station*

S.N.	Periods of time	Average precipitation (mm/30 years)
1	1957-1980（24 years）	95.5
2	1961-1990（30 years）	97.22
3	1971-2000（30 years）	98.99
4	1981-2010（30 years）	107.7
5	1991-2014（24 years）	122.21

Based on statistical evaluation, the upward trend of decades precipitation averages and dynamic precipitation averages passed the 95% confidence level test in Bayinmaodao.

The above four indexes illustrate the extreme precipitation events from the perspective of time duration. Based on comprehensive analysis of the variation trend of the said indexes, this paper believes that the imbalance of precipitation in Hetao area is prominent, there is an extreme trend in Bayinmaodao, but extreme precipitation events in other regions have not increased.

Variation of PRCTOT, R99p, Rx5day and SDII indexes

Stations with significant upward trend of PRCTOT include Hailinsu and Bayinmaodao; those with significant downward trend include Linhe, Wutaishan and Huashan (see *Fig. 12*). There is no station with significant upward trend of R99p, while stations with significant downward trend include Sanmenxia and Gaolan (see *Fig. 13*). Stations with significant upward trend of Rx5day include Bayinmaodao; those with

© 2018, ALÖKI Kft., Budapest, Hungary

significant downward trend include Linhe and Wutaishan (see *Fig. 14*). In addition, stations with significant upward trend of SDII include Bayinmaodao and Luochuan; station with significant downward trend is Linhe (see *Fig. 15*). Based on the comprehensive analysis of the information, it also reinforces the conclusion drawn in the preceding part of this paper that the extreme precipitation events in Bayinmaodao.

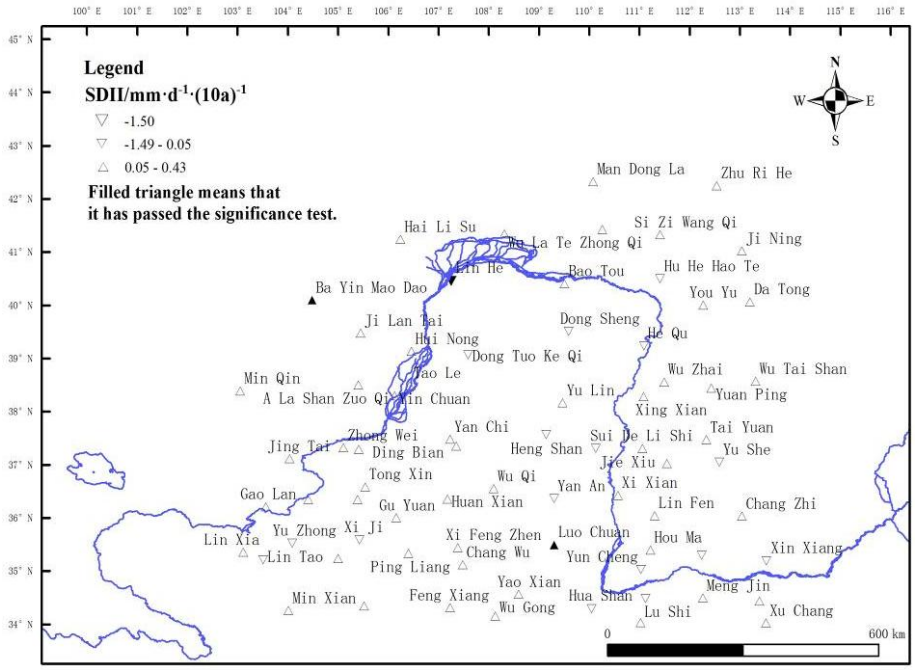

Figure 15. *Space variation of SDII index in Hetao area*

Viewed from interannual variation, the extreme precipitation events in the entire Hetao area have shown an upward trend, but it is not significant (see *Figs. 16, 17, 18, 19* and *Table 6*). However, the variation trend is different on sub-regions scale. The 4 indexes above in arid and semi-arid sub-region are positive, especially the index R99p (32.01 mm/10a) trend is significant; while the 4 indexes above in humid and semi-

Conclusion

It is a focused issue for many scholars to probe into the evolution rule and its reasons of extreme precipitation events. Other studies have shown an increasing trend in extreme precipitation in China. The trend of annual precipitation changes in northwestern China showed a slight upward trend, but extreme precipitation did not increase significantly. Hetao area is located in the transitional zone of arid, semi-arid and semi-humid regions in China and is sensitive to climate change. This paper analyzes 8 extreme precipitation indexes from a temporal-spatial perspective in Hetao area China from 1951 to 2014, and comes to the following conclusions:

(1) Hetao area is located in the transitional zone of arid and semi-arid climate and humid and semi-humid climate, so the variation trend of extreme precipitation events is different in arid and semi-arid sub-region (located in the upper reaches of the Yellow

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_62996316
© 2018, ALÖKI Kft., Budapest, Hungary

River) and humid and semi-humid sub-region (located in the middle and lower reaches of the Yellow River), and precipitation is spatially unbalanced.

(2) Although the R99p index is a significant upward trend, the trend of other indicators is not significant. Except for the Bayinmaodao, the extreme precipitation events in Hetao area has not an obvious trend

(3) In the humid and semi-humid sub-region of Hetao area, only the variation trend of CWD index is positive, the variation trend of other 7 indices are negative. Whether this situation indicates that precipitation is decreasing is yet to be further studied.

Based on the research above, this paper draws the conclusion that the extreme precipitation events in Hetao area has not an obvious trend in the past half a century. In addition, the trend has no spatial consistency due to the trend is quite different in sub-regions. The reasons for this situation is extremely complex, and reasons for such phenomenon still need to be further studied.

Abstract. The present study investigated the causal relationships among interpretive service quality, satisfaction, place attachment and environmentally responsible behavior. 1800 tourists visiting five historic heritage sites in Xi'an, China were surveyed and 1408 valid questionnaires were collected. The validity and reliability of the data were analyzed by using SPSS 22.0 and the structural equation model (SEM) was tested using AMOS 24. The findings of the study showed that interpretive service quality has direct and positive effect on satisfaction and satisfaction directly impacts place attachment and environmentally responsible behavior respectively. In addition, interpretive service quality exerts indirect influence on place attachment and environmentally responsible behavior respectively through satisfaction, indicating the mediating role of satisfaction in the relationship between interpretive service quality and place attachment as well as that in the relationship between interpretive service quality and environmentally responsible behavior. Moreover, the study demonstrated that place attachment influences environmentally responsible behavior directly. In the end, management implications about the improvements in interpretive services at cultural heritage sites are suggested in order to sustain sustainable development of heritage tourism.

Introduction

Xi'an (34°N, 108°E), the capital city of Shaanxi province, China, has a history of around 3100 years and 13 dynasties in Chinese history established their capitals in this city. As a result, it boasts a wealth of historical relics left by past dynasties and enjoys a reputable Natural History Museum in China (Ma, 2007, p. 139). An overwhelming majority of these historical relics have been preserved and developed into tourist attractions. Reflecting the economic, social and cultural development in history, these sites carry the heritage creators' values, aesthetical standards and spiritual needs (Hall and McArthur, 1998). The meaning ascribed to the sites mean more to tourists than what the physical artifacts do to them (Graham, 2007). Unfortunately, many tourists cannot understand the profound meaning carried by such sites (Risk, 1982, p. 195). Heritage tourism management agencies provide interpretive services to help visitors understand values inherent in the heritages to enrich their experiences (Knudson et al., 2003). It is claimed that the enhanced experiences enable tourists to increase

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

knowledge, which results in their behavioral change (Moscardo, 2014). Previous studies examined the influence of interpretation on environmentally responsible behavior (ERB) and found the former could help elicit the latter (Powell and Ham, 2008). Some researchers believed that interpretation also affected tourists' emotional attachments to visited place. Carr (2004) as well as Knudson, Cable and Beck (2003) viewed that emotional attachments to natural and cultural resources were meaningful for tourists to understand the essence of a place**.** Unfortunately, very limited empirical studies explored the relationship between interpretation and emotional attachment.

Past ERB literature indicated place attachment (Ramkissoon et al., 2013; Lee, 2011) and satisfaction (Lee and Moscarbo, 2005) predicted ERB. However, the relationships among satisfaction, place attachment and ERB have not been tested in the field of interpretation. Since interpretation is demonstrated to influence tourists' behaviors, there might be causal relationships among the above 4 variables. Besides, although some researchers held that quality interpretation could enable tourists to exhibit ERB (Powell and Ham, 2008), few quantitative studies have been conducted to examine the outcomes of it. Most of the existing studies were conducted in community-based (Lee et al., 2013b) and natured-based tourism destinations (Kim, 2011; Lee, 2009). Very limited such studies have been conducted at cultural heritage sites. Skibins et al. (2011) argued that it was very necessary to fully study interpretation outcomes if long-term management of tourism resource relied on sustainable use by visitors.

Therefore, the purposes of this study are:

1. To explore the relationship between interpretive service and place attachment.
2. To investigate the causal relationship between interpretive service and ERB.
3. To examine whether interpretive service influences satisfaction.
4. To study whether satisfaction affects place attachment.
5. To explore the relationship between satisfaction and ERB.
6. To test whether place attachment impacts ERB at cultural heritage site.

Selecting 5 heritage sites in Xi'an area as study sites, this empirical study will not only contribute to conceptual models related to interpretation outcomes but will benefit the sustainable development of heritage tourism in Xi'an in the long run.

Literature review

Interpretation service

Interpretive services at heritage sites include personal interpretation given by tour guides and on-site interpreters as well as non-personal interpretive services delivered through various media such as signage, on-site panels, brochures, exhibits, visitor centre etc. (Skibins, 2010). Tourists often depend on interpretation to understand the inherent meaning and value of heritage sites, which helps them experience a worthwhile and enjoyable trip. From the perspective of tourism management, they provide interpretive services to help tourists understand the embodied meaning in heritages resources (Knudson et al., 2003), express their requirements for tourists and inspire them to protect heritage. Obviously, interpretation serves as a communication bridge between tourists and tourism management.

Tilden (2007) defined interpretation as "an educational activity which aims to reveal meanings and relationships through the use of original objects, by firsthand experience, and by illustrative media, rather than simply to communicate factual information". His

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_63176339
© 2018, ALÖKI Kft., Budapest, Hungary

ideas about interpretation had enormous influence on the researchers of later generations. Although researchers after Tilden modified the definition of interpretation (Moscardo, 2014; Poria et al., 2009), the core part of educational function emphasized by Tilden remains. This can be seen from the research focus of some researchers. Munro et al. (2008) and Skibins et al. (2011) found most of studies concerning focused on evaluating knowledge increase of tourists after they experienced interpretive services and these studies also reported knowledge increase (Mace, 2013; Morgan and Hwang, 2014; Powell and Ham, 2008). However, besides educational functions, interpretation has more functions like enhancing tourists' experiences, fostering positive attitudes and behaviors among tourists (Ham and Weiler, 2006), providing them with opportunities to form emotional link to the visited site (Larsen, 2003) etc. Some studies showed that contemporary tourists hoped to gain some emotional experience through interpretation rather than just getting an educational experience (Poria et al., 2009). It is argued that the emotional link between the tourist and the place should be explored to understand and manage historic settings (Poria, 2006). Unfortunately, the affective outcome of interpretation is usually ignored. In addition, effective interpretation was believed to prompt more environmentally responsible behavior among tourists (Ballantyne et al., 2011), which is one of the core goals of interpretation (Ward and Wilkinson, 2006). For instance, the study conducted by Tubb (2003) found that interpretation provided in Dartmoor National Park in the UK encouraged tourists to behave more respectfully towards the local environment. The findings of Powell and Ham (2008) also showed that quality interpretation during the ecotourism experience could help tourists show general environmental behavioral intentions. In short, previous literature showed that interpretation impacted ERB, but such studies mainly used national parks or other nature-based settings.

Tourist satisfaction

In the field of tourism industry, many studies examined the antecedents of tourist satisfaction and its outcomes. According to past literature, the antecedents contributing to overall tourist satisfaction involve leisure service of destination attributes (Bernini et al., 2014), positive destination attributes (Battour et al., 2014; Zabkar et al., 2010), service quality (Song et al., 2010), place attachment (Yuksel et al., 2010). The consequences of satisfaction involved in the past studies mainly include its positive influence on destination loyalty (Yuksel et al., 2010), place attachment (Ramkissoon et al., 2015; Su et al., 2011), behavioral intention (Chen, 2010) and ERB (Davis et al., 2011).

Studies examining the link between interpretive services and satisfaction found the former had direct and positive effect on the latter (Huang et al., 2015; Ham and Weiler, 2007; Lee, 2009). However, these studies mainly focused on personal interpretation and very limited studies examined the impact of both personal and non-personal interpretive services on satisfaction. Although interpretation provided by tour guide is proved to be more effective than non-personal ones (Hughes, 2004), it is still important to study the outcome of non-personal ones since most of the tourists at cultural heritage sites in China depend on them to understand the inherent meaning of visited sites. Besides, past research mainly studied the relationship between interpretive service and satisfaction in nature-based context and that in historic heritage context is usually ignored. What is more, the above studies failed to assess the quality of interpretation, which may affect the accuracy of their research findings.

The findings of previous literature showed inconsistent or opposite results about the relationship between satisfaction and place attachment. Some studies demonstrated that satisfaction affected place attachment (George and George, 2004), while other studies indicated opposite results. (Prayag and Ryan, 2012; Yuksel and Bilim, 2010). Research of the relationship between the two mainly examined satisfaction with service quality (Su et al., 2011), satisfaction with attractiveness of a destination (Hou et al., 2005) and overall level of satisfaction (Petrick et al., 1999). Very limited studies were conducted to study the relationship between interpretive service satisfaction and place attachment and no relative studies have ever been conducted at cultural heritage settings.

Satisfaction was shown to influence customers' behavioral responses in the field of marketing (Baker and Crompton, 2000) and in the field of recreation and tourism satisfaction was viewed as a factor influencing ERB (Lopez-Mosquera and Sanchez, 2011; Powell and Ham, 2008) at national parks or other nature-based settings. For instance, Ramkissoon et al. (2013) surveyed tourists visiting the Dandenong Ranges National Park, Australia to explore the relationships among place attachment, place satisfaction and pro-environmental behavioral intentions and found that visitors' satisfaction with the visited site influenced their on-site behaviors. The existing literature concerning the relationship between the two variables mainly focused on satisfaction with travel experience or with the visited sites at natured-based settings. No study has ever been conducted to examine the relationship between satisfaction with interpretive service quality and ERB at historic heritage sites.

Place attachment

Place attachment is an affective and emotional bond that people develop with a place (Low and Altman, 1992) and the term "place attachment" highlights a positive bond between the two (Trentelman, 2009). Researchers in different fields view it as a multi-dimensional construct including place dependence, place identity, place social bonding (Ramkissoon et al., 2013) and place affect (Hinds and Sparks, 2008). Among these dimensions, the most widely accepted and frequently studied ones are the former two. Place dependence emphasizes functional attachment to a place because the place can provide necessary resources or facilities to meet the individual's specific activity needs (Williams and Roggenbuck, 1989). Place identity reflects the symbolic importance of a place to a person (Williams and Vaske, 2003). In the field of tourism, researchers have studied factors predicting place attachment as well as effects of it. According to past literature, some factors like service quality (Alexandris et al., 2006), attractiveness of a destination (Xu and Zhang, 2016), environmental sensitivity (Cheng and Wu, 2013), activity involvement (Xu and Zhang, 2016), satisfaction with service quality (Su et al., 2011) etc. predict place attachment.

Lee et al. (1997) emphasized that psychological attachment was important in understanding tourist behavior in explaining behavioral phenomena. Several researchers have found that place attachment was a positive predictor of ERB (Halpenny, 2010; Lee, 2011). According to the findings of previous studies, when tourists were highly attached to tourist destinations, they were more likely to exhibit their ERB (Cheng et al., 2013; Ramkissoon et al., 2013). For example, Cheng et al. (2013) examined the causal relationships among place attachment, destination attractiveness and ERB and the study results showed that place attachment was positively associated with stronger ERB.

Past studies mainly focused on place attachment elicited by destination attractiveness (Cheng et al., 2013), environmental sensitivity (Cheng et al., 2013) and satisfaction with service quality of the resort (Su et al., 2011). To date, no research has ever explored whether satisfaction with interpretive service will affect place attachment. In addition, studies of place attachment are extremely limited in interpretation literature (Goldman et al., 2001). For further understanding the nature of human place bonding, it is necessary to study the relationship between place attachment and ERB in the field of interpretation. Research into place attachment is classified into three contexts: personal context, natural environment context and community context (Raymond et al., 2010), but very limited research has been conducted to investigate the relationship between place attachment and ERB in the context of historic heritage site. Evidence shows that sustainability practices in national parks and other natural areas can be improved by fostering place attachment (Halpenny, 2010) and by encouraging ERB among visitors (Ballantyne et al., 2009) and such an inference may also apply to sustainable development of cultural heritage tourism.

Environmentally responsible behavior

Environmentally responsible behavior (ERB) is defined as an intentional action of an individual or group to directly or indirectly benefit the environment (Stern, 2000) and such action contributes to tourism resource protection and conservation (Lee, 2011). Many studies of ERB borrowed the definition given by Sivek and Hungerford (1990) which limits ERB to nature-based settings. In studying ERB at various settings, the attitude-behavior model is frequently employed. According to the theory of reasoned action (Fishbein and Ajzen, 1975) and the theory of planned behavior (Ajzen, 1991), attitude significantly affects an individual's behavior and it is an important predictive variable of behavior (Lee et al., 2013a). According to the theory of reasoned action, the best predictor of behavior is the intention to adopt the behavior (Halpenny, 2005). In empirical studies, it is rather difficult to measure the actual ERB of tourists. Based on the above theory, most studies measured behavioral intentions of visitors instead of their actual behaviors. Smith-Sebasto and D'Costa (1995) classified ERB into six categories including civic action, educational action, financial action, legal action, physical action as well as persuasive action. Compared with measurement scales developed by other scholars for ERB, the construct of ERB developed by Smith-Sebasto (1995) seemed to be more holistic (Lee et al., 2013b) and his categories of environmental action are widely used by tourism scholars to evaluate personal ERB (Ballantyne et al., 2011). ERBs are usually measured from two dimensions: general ERBs and specific ERBs (Lee et al., 2013b).

ERB has been widely studied in the field of tourism. Past research found that factors predicting ERB included place attachment (Lee, 2011; Ramkissoon et al., 2013), environmental attitudes (Schultz et al., 2004), commitment to the natural environment and tourist motivations (Lee, 2011), perceived value, satisfaction and activity involvement (Davis et al., 2011; Ramkissoon et al., 2014), environmental knowledge and environmental sensitivity etc. (Cheng and Wu, 2013). The studies of ERB that involved satisfaction mainly focused on visitors' satisfaction with the global setting at tourism destinations or their travel experience. To date, no study has ever examined whether satisfaction with interpretive service may lead to visitor's adoption of ERB. Some scholars argued that interpretive services helped facilitate tourists' ERB (Ballantyne et al., 2011). Marion and Reid (2007) reviewed the theoretical and empirical

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_63176339
© 2018, ALÖKI Kft., Budapest, Hungary

studies concerning interpretation outcomes in the US and found that most of the interpretation services could effectively modify visitors' behaviors. However, most of the past research of ERB indicated that interpretive services had impacts on ERB mainly as a result of visitors' knowledge increase. Since satisfaction is considered one of the antecedents of ERB, the present study views that satisfaction with interpretive services may impact visitors' ERB. In addition, past studies only studied ERB at nature-based settings and very limited research has ever assessed ERB at historic heritage settings. In addition, the relationship between place attachment and ERB is frequently studied in the field of recreation and tourism, but no study has ever been conducted to evaluate such a relationship in interpretation literature. This research attempts to study whether satisfaction with interpretive service affects tourists' ERB and the relationship between place attachment and ERB in the field of interpretation in historic heritage context in order to enrich the literature of ERB.

Based on the above literature review, the following hypotheses and theoretical model (*Fig. 1*) are proposed:

H_1: Interpretive service quality directly and positively influences place attachment;
H_2: Interpretive service quality directly and positively influences ERB.
H_3: Interpretive services directly and significantly influence tourist satisfaction;
H_4: Satisfaction directly and positively affects place attachment;
H_5: Satisfaction directly influences ERB.
H_6: Place attachment directly and significantly influences ERB

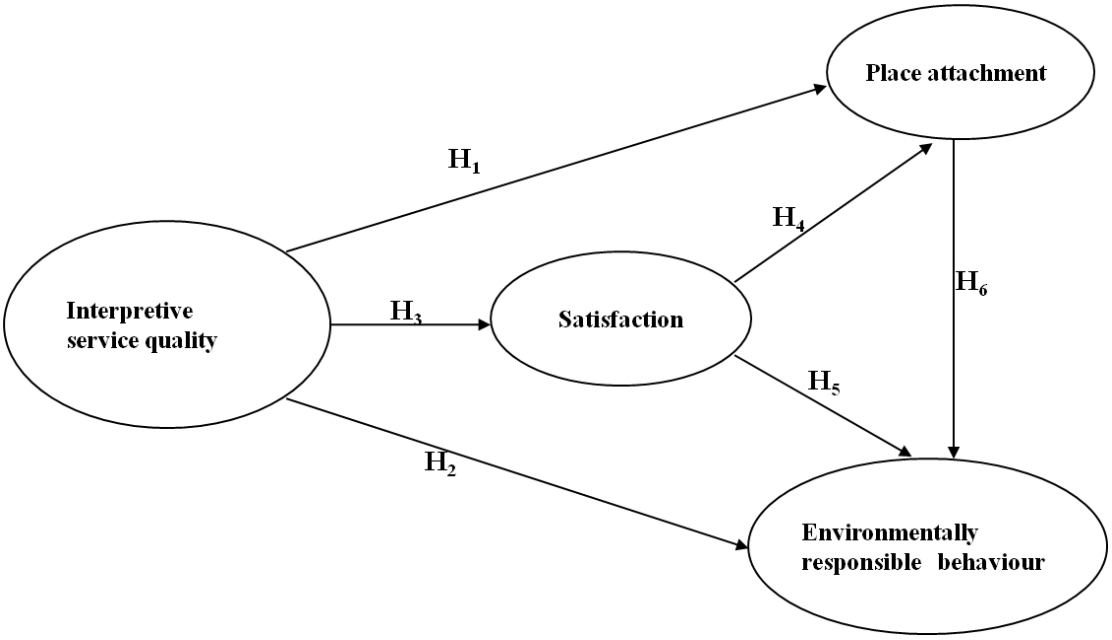

Figure 1. *The theoretical model of heritage site tourists*

Research methods

Study sites

The study sites include the following five historic heritage sites in Xi'an, China (*Fig. 2*). (1) Emperor Qinshihuang's Mausoleum Site Museum is the only cultural historic heritage in Shaanxi province inscribed on the World Heritage List. It is China's

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

largest ancient military museum representing an epitome of the powerful army in the Qin dynasty (221B.C.-207B.C.). (2) Huaqing Palace which characterizes culture of the Tang dynasty (618A.D.-907A.D.) is famous for hot springs, imperial palaces, imperial gardens and historical events in the Tang dynasty. (3) Dayan Pagoda and Tang Paradise are two neighboring historic sites located in Xi'an city. Dayan Pagoda enjoys a history of over 1300 years and is famous for storing Buddhist scriptures. Tang Paradise is a historic site featuring culture of the Tang dynasty. (4) Mausoleum of Yellow Emperor is a holy land to worship the Chinese ancestor—Xuanyuan Emperor and it is claimed No. 1 Mausoleum in China. (5) Honored as royal temple, Famen Temple has a history of 1700 years and is a holy land of Buddhism for storing Sakyamuni's finger bone.

Figure 2. *The map of study location*

Data collection

The questionnaire consists of 3 sections. The first section introduces interpretive services and programs at the heritage sites and one question is designed to investigate the interpretive services used by tourists. The second section consists of 47 items devised to examine tourists' evaluation of interpretive service quality, satisfaction, place attachment and ERB. The third section is the profile of respondents. The pretest of 180 questionnaire surveys was conducted and data analysis was valid and all the items were kept. Based on the suggestions given by some respondents and staff of management agencies, the wording was revised in order to help tourists better understand each item. The final formal questionnaire was established based on the pretest results.

The graduates who were trained how to hand out questionnaires went to the heritage sites to conduct the survey. Convenience sampling was used to survey respondent

© 2018, ALÖKI Kft., Budapest, Hungary

tourists at the exits of the historic sites between May and September 2015. It took about 10 min for each respondent to answer all the questions on the questionnaire. A total of 1800 questionnaires were distributed and 1408 valid ones were collected (*Table 1*).

Table 1. *Survey sample at each heritage site*

Heritage sites	Total surveys	Valid sample	Sampling dates
1. Emperor Qinshihuang's Mausoleum Site Museum	200	154	May 1-3, 2015
2. Huaqing Palace	193	143	June 23-24, 2015
3. Dayan Pagoda and Tang Paradise	1007	841	July 2015 (8 days)
4. Mausoleum of Yellow Emperor	200	139	August 11-12, 2015
5. Famen Temple	200	131	September 19-20, 2015
Total	1800	140	

Measurement of constructs

This study adopted SERVPERF model to assess interpretative service quality including five dimensions like tangibles, empathy, assurance, responsiveness and reliability. 22 items were borrowed and adapted from Cronin and Taylor's (1994) research findings. Satisfaction was evaluated from a holistic perspective and 4 items borrowed and adapted from the research results of Oliver (1980) and Ramkisoon et al. (2013) were used to measure tourists' global satisfaction with interpretive services. The construct of place attachment consisted of two dimensions: place dependence and place identity. 13 items borrowed and adapted from Williams and Roggenbuck's (1989) as well as Morgan's (2009) research findings were used to measure place attachment. Two dimensions were included in ERB. 8 items adapted from Smith-Sebasto and D' Costa's work (1995) were used to measure ERB. All the above-mentioned items were scored on a 7-point Likert scale (7 = strongly agree; 1 = strongly disagree). Demographic variables of the questionnaire included gender, age, marital status, education, city of residence, companion, number of visiting times, visit duration and purposes of visiting the sites.

Results of the study

Respondent profiles

There were more female respondents (54.4%) than male ones (45.6%). 85.6% were between 18 and 50 years old. 50.6% were married and 62.2% received college education. More than half of the respondents (58.7%) came from outside of Shaanxi and 38.9% were locals. Only 1.6% came from Hong Kong, Macao and Taiwan. 76.6% were accompanied by friends or family members and 12.6% were with group tour. Most of the respondents (68.5%) visited the destinations for the first time. It took most of them (76.7%) 2–3 h to visit the sites. The motivation of 58.9% was to seek nostalgic experience and 55.1% went to relax themselves. 41.4% went to broaden their horizon and 36.4% visited the places due to the site reputation. Various interpretive services

were used by the tourists: personal interpretation (51.3%), signage (41.4%), digital interpretation (11.6%), printed materials (12.8%), visitor center (10.4%), films (6.6%), projects participation (7.3%) and websites (7.2%) (*Fig. 3*).

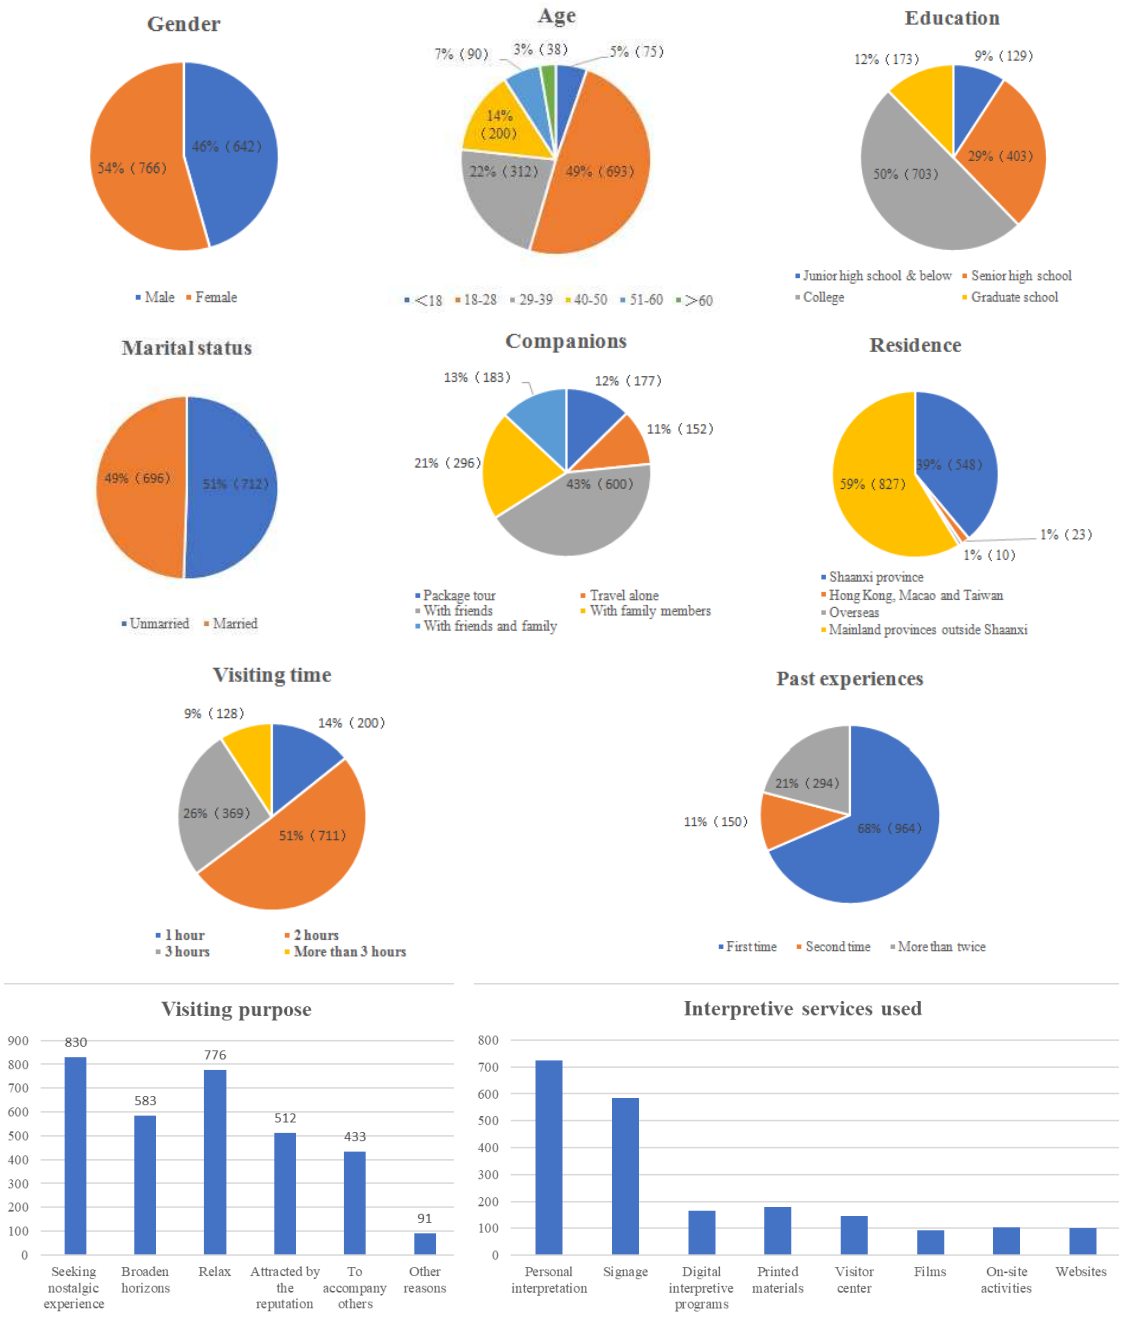

Figure 3. *Demographics of the respondents*

Data analysis

SPSS 22.0 was used to analyze the collected data. The reliability and validity were tested to find whether the instrument had good internal consistency. Principal component analysis and varimax rotation were used for factor analysis and convergent factors extraction and all the items were kept. In the end, the extracted common factors

© 2018, ALÖKI Kft., Budapest, Hungary

as well as the corresponding factor loadings were obtained (*Table 2*). The Cronbach's alpha (between 0.72 and 0.99) exceeded the threshold value of 0.7, indicating a good level of internal of consistency of all the constructs in the study. In addition, factor loadings (between 0.57 and 0.87) of all the variables were significant ($p < 0.001$). Composite reliability (CR) exceeded 0.60, indicating all the constructs in the research had good reliability (*Table 2*).

Table 2. *The results of reliability and validity analysis*

Measured variables and dimensions	Cronbach Alpha	Factor loadings	CR	AVE
Interpretive service quality				
Tangibles	0.77		0.82	0.53
The digital interpretive programs at the heritage site provide effective interpretation	0.74	0.78		
The signage and tour route signs are easily spotted	0.79	0.70		
Tour guide, interpreters and the staff at visitor center are properly dressed	0.75	0.71		
The design, color and character size of the signage are in harmony with the environment	0.75	0.71		
Empathy	0.87		0.87	0.57
The interpretive services meet visitors' needs	0.85	0.71		
The staff at visitor center serve visitors with patience	0.84	0.73		
Interpreters provide appropriate interpretation for visitors	0.84	0.74		
Personal interpretation satisfies visitors	0.85	0.78		
The interpretive programs are rich in variety and sufficient in quantity	0.84	0.82		
Assurance	0.83		0.83	0.55
The interpreter's expertise is trustworthy	0.80	0.72		
The information on signage and printed materials is completely correct	0.80	0.69		
Interpreters and the staff at visitor center serve visitors with courtesy	0.78	0.77		
Interpreters are competent for their job	0.77	0.79		
Responsiveness	0.86		0.86	0.61
Visitors can get information about interpretive services at visitor center	0.85	0.71		
The heritage site provides visitors with the interpretive services that satisfy them	0.82	0.78		
The staff at visitor center are ready to serve visitors	0.81	0.83		
Interpreters can answer visitors' questions precisely	0.82	0.81		
Reliability	0.90		0.90	0.65
The visitor center can provide timely consultative service for visitors	0.89	0.79		
The staff at visitor center value the need of visitors	0.88	0.80		
The interpretive services are reliable	0.88	0.81

Average variance extracted (AVE) was used to assess the validity of the scale. AVE exceeding 0.5 indicates good convergent validity. If the square root of the AVE is greater than the correlation coefficient of other variables, the discriminant validity is good. The result of the data analysis showed that the AVEs of all the dimensions were above 0.5. The square root of the AVE was between 0.73 and 0.82, which was greater than the corresponding correlation coefficient, indicating better convergent validity and discriminant validity (*Table 3*).

Table 3. *Correlation matrix of the latent variables*

Using AMOS 24, the proposed model was tested by utilizing the Structural Equation Modeling (SEM) to measure the causal relationships within the model and the overall fitness of the model. The maximum likelihood estimation was applied to estimate all the parameters. Since a large size of samples may affect Chi-square (x^2) value, several other measurement model fit indices were used to determine whether the model fit was good. Model fit indicators include absolute fit indices and relative indices. Absolute fit indices include x^2/df (1-3), GFI (≥0.9), AGFI (≥0.9), RMR (<0.05), RMSEA (<0.08). The relative fit indices include NFI (≥0.9), RFI (≥0.9), CFI (≥0.9) and IFI (≥0.9).

The testing results of hypothesis 1 and hypothesis 2

The proposed model (Model l) (*Fig. 4*) was created to test whether interpretive service quality positively and significantly impacted on place attachment and ERB respectively. The test on goodness of fit indicated that all the indices were satisfying (RMR = 0.06, RMSEA = 0.08; GFI = 0.94; AGFI = 0.90; NFI = 0.95; RFI = 0.93; CFI = 0.96; IFI = 0.96). GFI, AGFI, NFI, RFI, CFI and IFI were within 0.90 and 1.00. RMSEA was 0.08 and RMA was greater than 0.05, a little bit higher than the threshold value of 0.05, but it still indicated a good model fitness. In short, the above analysis result demonstrated a good model fitness (*Table 4*). According to the calculated path coefficient, interpretive service quality had direct and significant effect on place

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_63176339
© 2018, ALÖKI Kft., Budapest, Hungary

attachment ($\alpha 1 = 0.58$) ($p < 0.001$). It proves that the higher interpretive service quality is, the stronger place attachment will be. Meanwhile, interpretive service affected ERB directly and significantly ($\alpha 2 = 0.45$)($p < 0.001$), which means that higher quality of interpretation elicits stronger intention of exhibiting ERB (*Fig. 4*).

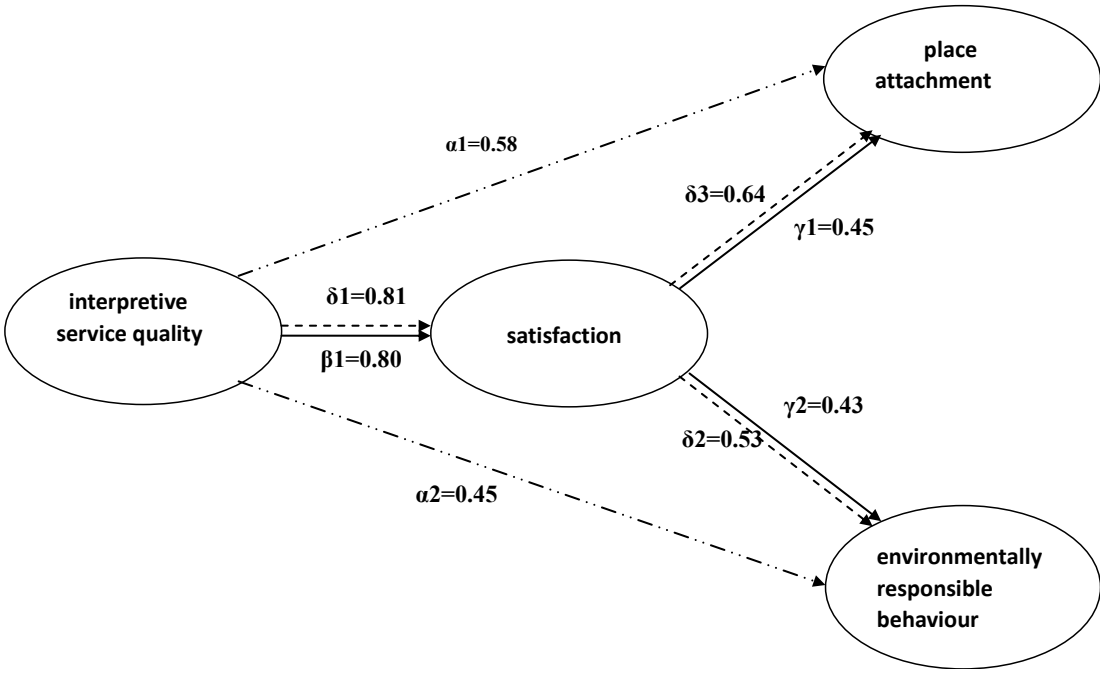

Figure 4. *The model of satisfaction mediating effect*

The testing results of hypothesis H_3, hypothesis H_4 and hypothesis H_5

After confirming the positive direct effect of interpretive service quality on place attachment and ERB, the study further explored whether interpretive service quality impacted on satisfaction and whether satisfaction influenced place attachment and ERB respectively. The authors therefore established a model (Model 2) to test the above-mentioned relationships. The goodness-of-fit indicators were as follows: RMR = 0.04; RMSEA = 0.07; GFI = 0.94; AGFI = 0.90; NFI = 0.95; RFI = 0.93; CFI = 0.96; IFI = 0.96. GFI, AGFI, NFI, RFI, CFI and IFI were between 0.90 and 1.00, while RMSEA (0.07) was a little bit lower than the cut-off point of 0.08 and RMR (0.04) was lower than 0.05. Therefore, the proposed model (Model 2) had a good fitness (*Table 4*). The path analysis results demonstrated that the direct effect of interpretive service quality on satisfaction was significant ($\beta 1 = 0.80$) ($p < 0.001$), indicating that higher quality of interpretation makes tourists feel satisfied with the visited place. Furthermore, satisfaction affected place attachment ($\gamma 1 = 0.45$) ($p < 0.001$) and ERB ($\gamma 2 = 0.43$) ($p < 0.001$) directly and significantly, showing that the more satisfied the tourists are with the destination, the stronger their emotional attachment to it and they are more willing to exhibit pro-environmental behavior. Thus, hypothesis3, hypothesis4 and hypothesis5 are supported (*Fig. 4*). However, after entering satisfaction into the proposed model, the direct effect of interpretive service quality on place attachment and ERB were 0.22 ($p < 0.05$) and 0.12 ($p < 0.05$) respectively. It demonstrated that the direct effect of interpretive service quality on place attachment and ERB were much

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_63176339
© 2018, ALÖKI Kft., Budapest, Hungary

lower after entering the variable of satisfaction, indicating that the effect of interpretive service quality on place attachment and ERB were indirect, with the path coefficients being 0.36 (0.80×0.45) ($p < 0.01$) and 0.34 (0.80×0.43) ($p < 0.01$) respectively.

Based on the above analysis, satisfaction might mediate the relationship between interpretive service quality and place attachment as well as the relationship between interpretive service quality and ERB. Interpretation quality may not have direct causal relationship with place attachment and ERB. In other words, the original causal relationship might be influenced by a mediating variable. Therefore, the real causal relationship between interpretive service quality and place attachment as well as the causal relationship between interpretive service quality and ERB should be further explored.

To further explore the function of satisfaction in depth, the proposed model (Model 3) was created for path analysis. The results of the path analysis demonstrated that the proposed model had good fit indicators: RMR = 0.04; RMSEA = 0.07; GFI = 0.94; AGFI = 0.91; NFI = 0.95; RFI = 0.94; CFI = 0.97; IFI = 0.97. GFI, AGFI, NFI, RFI, CFI and IFI fell within 0.90 and 1.0. RMR was lower than the cut-off point of 0.05 and RMSEA was below the threshold value of 0.08. Such analysis results indicated that the mediating model had good model fitness (*Table 4*). Further path analysis demonstrated that interpretive service influenced satisfaction positively ($\delta 1 = 0.81$)($p < 0.001$), establishing the causal relationship between the two. What is more, satisfaction exerted positive and significant influence on place attachment ($\delta 3 = 0.64$) ($p < 0.001$) and ERB ($\delta 2 = 0.53$) ($p < 0.001$) respectively. It indicates that the more satisfied the tourists are, the stronger their place attachment will be and they are more willing to show ERB. Path analysis also showed that interpretive service quality impacted place attachment 0.52 (0.81×0.64) ($p < 0.01$) and ERB0.43 (0.81×0.53) ($p < 0.01$) indirectly through the mediating role of satisfaction. The results demonstrated that satisfaction had a full mediating effect on the relationship between interpretive service quality and place attachment and the relationship between interpretive service quality and ERB (*Fig. 4*). Such a finding is consistent with the study result about the mediating function of satisfaction between the relationship of service quality and behavioral outcomes by Fullerton and Taylor (2002).

Table 4. *Fit indices for measurement model*

Fit indices	Criteria	Model 1	Model2	Model 3	Model4
Absolute fit indices

The analysis results of hypothesis H_6

To examine the direct effect of place attachment on ERB, the path analysis of place attachment to ERB was added to establish the final structural model (Model 4) for this empirical study. The results showed a good model fitness: RMR = 0.04; RMSEA = 0.07; GFI = 0.94; AGFI = 0.91; NFI = 0.95; RFI = 0.94; CFI = 0.97; IFI = 0.97. GFI, AGFI, NFI, RFI, CFI and IFI ranged from0.90 to1.00. RMR was lower than the benchmark value of 0.05 and RMSEA was below the cut-off point of 0.08. All the figures demonstrated a good model fitness (*Table 4*). The path analysis indicated that place attachment influenced ERB positively and significantly 0.34 ($p < 0.001$). Therefore, stronger place attachment can facilitate stronger ERB. The effect of interpretive service on satisfaction was direct and positive 0.81 ($p < 0.001$), showing that quality interpretation will satisfy the tourists. Path analysis also indicated that satisfaction affected place attachment 0.63 ($p < 0.001$) and ERB 0.29 ($p < 0.001$) directly and significantly. Namely, the more satisfied the tourists with the visited site, the stronger their emotional attachment and ERB will be.

Thus hypothesis 6 is supported. Meanwhile, satisfaction played a role of complete mediation in the relationship between interpretive service quality and place attachment and in the relationship between interpretive quality and ERB. As a result, interpretive service quality had indirect effect on place attachment through satisfaction, with a path coefficient of 0.51 ($p < 0.01$) and interpretive service quality impacted on ERB indirectly and significantly through satisfaction, with a path coefficient of 0.23 ($p < 0.01$) (*Fig. 5*).

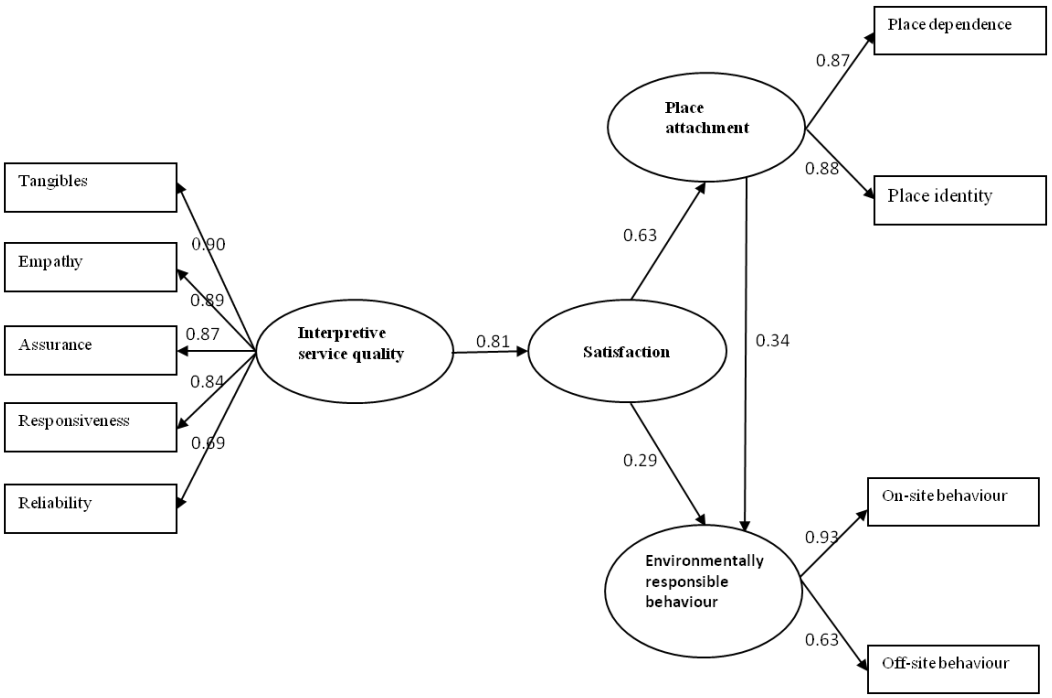

Figure 5. *The structural model*

Discussion

This study investigated the causal relationships among interpretive service quality, satisfaction, place attachment and ERB at five cultural heritage sites in Xi'an. It is the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_63176339
© 2018, ALÖKI Kft., Budapest, Hungary

first time in literature to simultaneously examine the structural relationships among these four variables in the same model. The findings showed that the causal relationship does exist between interpretive service quality and place attachment. Meanwhile, it is found that satisfaction plays a mediating role in the relationship between interpretive service quality and place attachment, which indicates that satisfaction with high quality of interpretive services will help tourists foster place attachment. The more satisfied tourists are with interpretive services, the stronger their place attachment to the visited sites will be. Second, the results also show that satisfaction mediates the relationship between interpretive service quality and ERB. Previous research showed that knowledge gain as a result of experiencing interpretation would elicit ERB among visitors, while this research demonstrates that satisfaction with interpretive service also helps visitors exhibit ERB. Third, the present study indicates that interpretive service affects satisfaction directly and significantly.

The results also demonstrate that tourists' satisfaction positively and significantly influences place attachment. Moreover, the present study shows that satisfaction with interpretive service helps facilitate visitors to demonstrate ERB at heritage sites, which supports the study results found by Moscardo (1996) and Powell and Ham (2008), indicating the importance of high quality of interpretive service at heritage sites. In addition, the young age of the respondents indicates that tourism management departments should strive to provide more vitalized interpretive programs such as well designed signage, movies using modern technology like 5D or 6D, the live programs that young visitors may get involved in to satisfy them. In addition, very few visitors using web sites of the destination to obtain information about the visited sites indicates that tourism management agency should design fantastic web sites with amazing pictures as well as convincing descriptions, which is very informative, attractive and at the same time easy to access, to attract more visitors from outside of Shaanxi province. What is more, larger number of respondents relying on personal interpretation to help them understand the visited heritage sites implies that tour guides should be trained to do their work more efficiently in order to meet the needs of the visitors. Since nearly half of the respondents turn to various signs for getting the information about the destination, well designed and properly located signage are very important to serve the visitors.

Conclusions

Based on the results of this study, the following conclusions can be reached: (1) relationship between interpretive service and place attachment does exist and the former affects the latter indirectly and significantly, with satisfaction playing a mediating role between them. (2) interpretive service influences ERB indirectly and satisfaction plays a mediating role in the relationship between the two. (3) The direct effect of interpretive service on satisfaction is positive. Meanwhile, satisfaction exerts direct influence on place attachment and ERB respectively; (4) place attachment impacts ERB directly.

The findings of this study demonstrate the importance of interpretive service quality in facilitating place attachment and ERB among tourists. High quality of interpretive services is beneficial to satisfying tourists and enriching their travel experience, which leads to their place attachment to the destination. In addition, satisfaction with high quality of interpretive services and place attachment will elicit ERB among tourists and such pro-environmental behavior will contribute to the tourist management as well as

heritage resource management. Ultimately, sustainable use of heritage resources and sustainable development of heritage tourism will be achieved. Therefore, it is very necessary for tourism management agency to improve interpretive service quality.

Limitations

The research limitations are as follows: First, the authors of this study did not analyze how each dimension of interpretive service affected satisfaction respectively. Second, the study did not examine the mediating role of place attachment in the relationship between satisfaction and ERB. Third, the historic sites selected for the study were of higher ranking sites and those of lower ranking were not included. To test the universality of the proposed model, historic sites of different ranking should be investigated. Future research may avoid the above limitations and further explore the outcomes of interpretation in depth.

APPENDIX

VISITOR SURVEY

In this survey we would like to ask you some questions about the place you visited today. Your cooperation will help us make some important management suggestions about the service quality of this place. Your honest, personal opinions are important. It will take you about 10 minutes to complete it. Thanks for your time!

Northwest University

Your evaluations of the interpretive service quality

How would you evaluate the service quality of this place? Please score each item. "1" represents" Strongly Disagree "(SD), "4 " for "Neutral"(N) and "7" for "Strongly Agree" (SA).

Statements	SD			N			SA
1. The digital interpretive programs at the heritage site provide effective interpretation.	1	2	3	4	5	6	7
2. The signage and tour route signs are easily spotted.	1	2	3	4	5	6	7
3. Tour guide, interpreters and the staff at visitor center are properly dressed.	1	2	3	4	5	6	7
4. The design, color and character size of the signage are in harmony with the environment.	1	2	3	4	5	6	7
5. The interpretive services meet visitors' needs.	1	2	3	4	5	6	7
6. The staff at visitor center serve visitors with patience.	1	2	3	4	5	6	7
7. Interpreters provide appropriate interpretation for visitors.	1	2	3	4	5	6	7
8. Personal interpretation satisfies visitors.	1	2	3	4	5	6	7
9. The interpretive programs are rich in variety and sufficient in quantity.	1	2	3	4	5	6	7
10. The interpreter's expertise is trustworthy.	1	2	3	4	5	6	7
11. The information on signage and printed materials is completely correct.	1	2	3	4	5	6	7
12. Interpreters and the staff at visitor center serve visitors with courtesy.	1	2	3	4	5	6	7
13. Interpreters are competent for their job.	1	2	3	4	5	6	7
14. Visitors can get information about interpretive services at visitor center.	1	2	3	4	5	6	7
15. The heritage site provides visitors with the interpretive services that satisfy them.	1	2	3	4	5	6	7
16. The staff at visitor center are ready to serve visitors.	1	2	3	4	5	6	7
17. Interpreters can answer visitors' questions precisely.	1	2	3	4	5	6	7

Your satisfaction with the visited place

How much are you emotionally attached to this tourist attraction? Please score each item by circling the number. "1" represents "Strongly Disagree"(SD), "4 " for "Neutral"(N) and "7" for "Strongly Agree" (SA)

Statements	SD			N			SA
23. I think my decision to use the interpretive services when Visiting the heritage site is correct.	1	2	3	4	5	6	7
24. I'm pleased to use the interpretive services when visiting the heritage site.	1	2	3	4	5	6	7
25. Using interpretive services makes my visit here very pleasant.	1	2	3	4	5	6	7
26. I'm satisfied with the interpretive services here.	1	2	3	4	5	6	7

Your emotional attachment to the visited site

How much are you emotionally attached to this tourist attraction? Please score each item. "1" represents" Strongly Disagree"(SD), "4 " for "Neutral"(N) and "7" for "Strongly Agree" (SA)

Statements	SD			N			SA
27. This is the best choice for historic heritage tourism.	1	2	3	4	5	6	7
28. Visiting this place satisfies me more than other places.	1	2	3	4	5	6	7
29. Other heritage sites cannot replace my visit here.	1	2	3	4	5	6	7
30. No other heritage site is comparative to this place.	1	2	3	4	5	6	7
31. My visit here is more important than visit to other places.	1	2	3	4	5	6	7
32. I always want to come here.	1	2	3	4	5	6	7
33. I like the heritage site very much.	1	2	3	4	5	6	7
34. I think this heritage site fits me well.	1	2	3	4	5	6	7
35. This heritage site is very special to me.	1	2	3	4	5	6	7
36. I'm willing to spend more time visiting the heritage site.	1	2	3	4	5	6	7
37. Visiting this heritage site is of great significance to me.	1	2	3	4	5	6	7
38. I think visiting this place is part of my life.	1	2	3	4	5	6	7
39. I'm proud of the heritage resources at the site.	1	2	3	4	5	6	7

Your behaviors exhibited on and off the visited site

What were or would be your behaviors exhibited on and off the visited site? Please score each item. "1" represents" Strongly Disagree "(SD), "4" for "Neutral"(N) and "7" for "Strongly Agree" (SA)

Statements	SD			N			SA
40. Seeing others damage heritage items and the environment, I'll stop them or report their behaviors to the staff.	1	2	3	4	5	6	7
41. I don't litter at the heritage site.	1	2	3	4	5	6	7
42. I'll protect the heritage resources and the environment here.	1	2	3	4	5	6	7
43. I'll obey the rules of heritage and environment protection.	1	2	3	4	5	6	7
44. I'm willing to learn how to protect the heritage and environment here.	1	2	3	4	5	6	7
45. I'm willing to talk about heritage and environmental protection here with others.	1	2	3	4	5	6	7
46. I'm willing to learn about the heritage and environment protection via Internet, news etc.	1	2	3	4	5	6	7
47. I'm willing to donate money to protect the historic heritage and the environment.	1	2	3	4	5	6	7

Abstract. Blue-crowned laughingthrush (*Garrluax courtoisi*), an endemic species in China, is a critically endangered and sexually monomorphic bird. It is difficult to identify the gender of this species through the observation of its external morphology. To solve this problem, we herein established a *CHD1*-based PCR method for sex-typing of *Garrluax courtoisi*. We first collected blood samples from six Blue-crowned laughingthrush raised in Nanchang Zoo, and then extracted high-quality genomic DNA from blood clots using an optimized phenol/chloroform method. We designed a degenerate primer pair to amplify fragments of the *CHD1* gene, resulting an amplicon of 700 bp for males and an extra PCR product of 600 bp for females. We also performed extensive behavioral observations of these six birds and the obtained data allowed us to deduce the sexes of these birds. The sex-typing results are generally consistent with the behavior-deduced results. This study sheds light on the sex determination of other endangered birds, and also paves a road to further test the reproduction mechanism, taxonomic classification and population relationships of *Garrluax courtoisi*.
Keywords: *blue-crowned laughingthrush, sex identification, CHD1, endangered species*

Introduction

Blue-crowned laughingthrush (*Garrulax courtoisi*, *Fig. 1*) is currently classified as a critically endangered bird by BirdLife International (2017). The only known wild population of approximately 300 birds currently lives in Wuyuan County, Jiangxi Provence, China (He et al., 2017). Its emergence and re-emergence after a long period of disappearance is really a mystery to people. Also its status in taxonomy has changed several times. Thus it is regarded as a legend in birds.

Currently a total of slightly more than 200 birds are kept captive in several zoos located in Asia, Europe, and North America (Liu et al., 2017). We started a captive breeding program for this species in 2010 in the Nanchang Zoo at Nanchang City, Jiangxi Province of China, and joined the Global Species Management Plan (GSMP) (WAZA, n. d.) in 2012. One of the major obstacles we have been facing is the sex-typing of these sexually monomorphic birds, as the birds do not have any external

genitalia. Traditional sexing methods involve physical examination of the cloacae or the use of a laparoscope, both are invasive to such small birds and may cause anaphylaxis or death during the procedures. As sexing is inevitable as a management requirement, we decided to evaluate the feasibility of using a relatively safer molecular sex-typing method.

Figure 1. *The blue-crowned laughingthrush in Nanchang Zoo*

There have been several useful molecular sex-typing protocols established for birds over the past decades (Griffiths et al., 1998; Lessells and Mateman, 1996), among which the amplification of an intron of the *CHD1* gene has been successfully used for a range of avian species (Fridolfsson and Ellegren, 1999, 2000). The *CHD1* gene is located on sex chromosomes and is highly conserved in non-ratite birds. Chromosomes W and Z carry nearly identical exons but different sizes of introns of this gene. The *CHD1*-specific primer pair can be used to generate different amplicons representing *ZW* (female) and *WW* (male) individuals. In this study, we sought to test whether this method can be used for sex-typing of *Garrluax courtoisi*, and discussed its correlation with behavioral characteristics of the birds.

Materials and methods

Animals

Seven *Garrluax courtoisi* birds (numbered 1-7) were kept captives in the Nanchang Zoo, Nanchang City in Jiangxi Provence. Color-coded foot bands were placed to facilitate visual identification of the birds from distance. A total of 40 µl blood was drawn from the brachial vein and dropped into tubes containing 75% ethanol and saved in -20 °C until used for DNA isolation. We were unable to capture bird #5, thus blood sample for this bird was not collected.

Behavioral observations

Extensive behavioral observations of these birds were documented from 2014 to 2016, especially during the breeding seasons. These birds are small in size and move swiftly. It was still quite difficult to trace every individual bird, especially when visibility was low, even though they wore color-coded foot-bands. In order to establish

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

correlations between behavioral characteristics and molecular sexing results, we put our efforts to the following observations: 1) the presence of prelaying behaviors, including preening, elaborate display, or chasing of females; 2) documentation of nesting and egg-laying in varying grouping strategies to identify the reproducing females; and 3) observation of brooding behavior to identify the egg-laying female, and, ideally, the pairing male. It has been known that the breeding bird during the night is predominately the egg-laying female (Reul-Schneider and Schneider, 2006).

Genomic DNA isolation

Genomic DNA was isolated from blood clots using a commercial genomic DNA isolation kit CW2298 (Kang Wei, China), a standard phenol/chloroform method and an optimized phenol/chloroform method by testing different volumes of lysis buffer, concentrations of Proteinase K and digestion time (*Table 1*). DNA concentration and quality were measured using a NanoDrop 2000 spectrophotometer (Thermo Fisher Scientific, USA) and 0.8% agarose gel electrophoresis.

Table 1. *Optimization parameters of DNA extraction*

Lysis buffer (ul)	Digestion time (h)	Proteinase K (ul)
400	2	2
450	4	4
500	6	6
500	8	8
500	10	10
500	15	15

PCR sex-typing

Primers 2550F/2718R (Forward: 5'-GTTACTGATTCGTCTACGAGA-3'; Reverse: 5'-ATTGAAAT GATCCAGTGCTTG-3') were designed based on a conservative intronic region within the *CHD* gene (Fridolfsson and Ellegren, 2000). PCR was conducted in 25 μl reactions containing 40 ng genomic DNA, 2.5 μM 10×buffer, 25 mM MgCl2, 2.5 mM dNTP, 0.2 μM each of primers and 2.5 units Taq polymerase (Tiangen, China). The PCR reaction profile was as follows: 94 °C for 5 min, 29 cycles of 94 °C for 30 s, 65 °C (decreasing 0.5 °C every cycle) for 20 s, 72 °C for 40 s; then followed by 14 cycles of 94 °C for 30 s, 50 °C for 20 s, 72 °C for 40 s; reaction was ended after a final extension of 10 min at 72 °C. Eight μl of the PCR product was loaded to a 2.5% agarose gel (containing ethidium bromide) for electrophoresis. A 50-bp ladder (Tiangen, China) was used to indicate the sizes of the PCR products. DNA bands were visualized under UV light and pictures taken. PCR products were purified from agarose gel using a gel purification kit (Qiagen, Germany) and sent for sequencing using primers 2550F and 2718R (BGI, China).

Results

Behavioral observations indicate the gender of Garrluax courtoisi birds

From 2014 to 2016, eight blue-crowned laughingthrushes including seven birds tested in this study were separated into different groups (*Table 2*). These birds were

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

painstakingly inspected for nest building, egg laying and hatching. Both male and female birds have existed in this flock, as one brood of chicks was hatched each year in 2014 through 2016 (*Table 2*). One extra nest was built, into which no egg was laid, both in year 2014 and year 2016. There had been no obvious courtship displays or aggressiveness observed during the last three mating seasons. However, flocked chasing was frequently seen among blue-crowned laughingthrushes, similar to that seen in Darwin's finches on the Galápagos Islands. It has been believed that chasing of the female by the male promotes sexual synchronization between the two sexes, leading to successful copulation and insemination. Chasing of bird #2, mostly led by bird #6, has been frequently observed during the mating seasons in years 2015 and 2016, although pairing could not be confirmed. Bird #4 also showed chasing activity to a lesser extent in these two mating seasons. In addition, the birds were divided into two groups during the breeding seasons in year 2014 and year 2016, and the broody group included bird #2 in both years (*Table 2*). This suggests that bird #2 was the breeding female in these three years while bird #6 was the dominant male in the same period.

Table 2. *Reproduction record of blue-crowned laughingthrush (Garrluax courtoisi) in Nanchang Zoo from year 2014 through 2016*

Year	Groups	Birds in group	Nests built	Eggs laid	Chicks hatched
2014	A	#2, #5, #8*	Yes	Yes	Yes
	B	#1, #3, #4, #6, #7	Yes	No	No
2015	C	#1~7 (no division)	Yes	Yes	Yes
2016	D	#1, #2, #4, #6,	Yes	Yes	Yes
	E	#3, #5, #7	Yes	No	No

*Bird #8 died for unknown reason at the end of 2014; this bird was male by autopsy

Both male and female blue-crowned laughingthrushes can be broody (Liu et al., 2016), but it is not clear how they cooperate or what specific roles they take. In this study, as the birds are loosely confined in a large wire mesh aviary, it is not clear whether there had been indeed a broody male. Previous captive breeding of this avian species suggests that the females are usually the brooding birds at night [8]. In the breeding season in year 2014, there was an attack by a snake (*Dinodon rufozonatum*) on the hatching nest, and the brooding female bird (bird #2) was thought to be the last to abandon the nest. Birds have weak visions at night, but are sensitive to vibrations of the tree branches and hence the approaching snake. In addition, during the breeding seasons in year 2015 and year 2016, we took daily close-up checks of the hatching nest, and bird #2 was nearly always perching nearby. This further suggests that bird #2 was the only egg-laying female bird in these two years.

An optimized method for isolation of genomic DNA of Garrluax courtoisi birds

In this study, a commercial kit was first used to isolate genomic DNA of *Garrluax courtoisi birds*. However, the isolated DNA was of poor quality as the electrophoresis bands showed uneven brightness and a severe pollution of protein residue (*Fig. 2*). A standard phenol /chloroform method was then explored for DNA isolation, also resulting in poor-quality DNA. To solve this problem, we optimized this phenol /chloroform method by testing three parameters including the volume of lysis buffer, the concentration of Proteinase K and the digestion time. Finally, 500 μl lysis buffer,10 μl

DOI: http://dx.doi.org/10.15666/aeer/1605_63416347
© 2018, ALÖKI Kft., Budapest, Hungary

Proteinase K and a digestion time of 8 hours were used in the extraction protocol, which allowed us to obtain high-quality genomic DNA from each blood clot (*Fig. 2*).

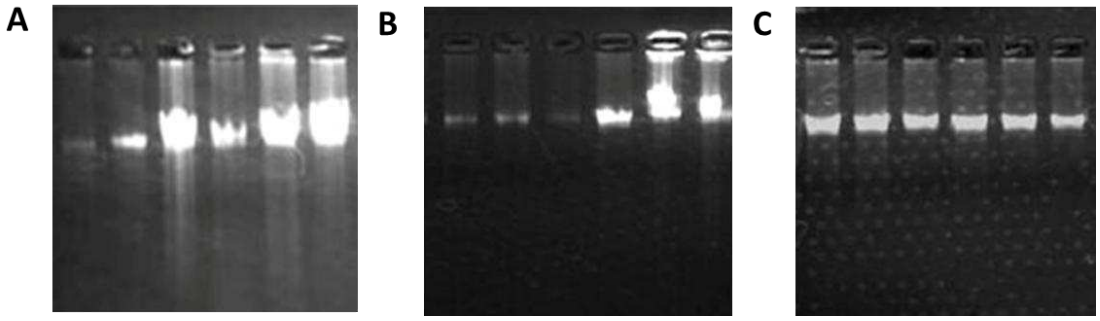

Figure 2. *Electrophoresis patterns of genomic DNA isolated by three approaches. (A) A commercial kit. (B) A routine phenol chloroform method. (C) An optimized phenol chloroform method*

PCR sex typing

The *CHD1*-based PCR generated one or two amplicons representing the two sexes (*Fig. 3*). Sequencing of the two PCR products confirmed that the 700 bp product was from Z chromosome, while the 600 bp product was from the W chromosome. Thus, PCR with primers 2550F/2718R will generate only one band of 700 bp for a male *(ZZ)* blue-crowned laughingthrush, and generate two bands (700 bp and 600 bp) for a female (*ZW*). The two bands can be easily separated in a 2.5% agarose gel, and there was no amplicon other than the two alternative fragments. According to the PCR sex typing results, Birds #2, 3 and 4 are female, and Birds#1, 6 and 7 are males.

Discussion

Blue-crowned laughingthrush is the critically endangered bird and the endemic species in China, it distributed in Simao, Yunnan and Wuyuan, Jiangxi in history. The existing wild blue-crowned laughingthrush is only in Wuyuan, and their population is more than 300. In 1980's and 1990's, blue-crowned laughingthrush were exported to Hong Kong, Europe and North America through wildlife trade. Presently, there are above 200 individuals in zoos or feeding units around the world including Nanchang Zoo. However, as a sexually monomorphic species, it is hard to determine their sex by body, voice or behaviour (Liu et al., 2016).

Bird #2 had demonstrated apparent female behaviors and this is confirmed by PCR sex-typing; on the contrary, bird #6 showed active chasing behavior and is indeed sex-typed by PCR as male. Because there had been more than one nest built during two of the three breeding seasons from year 2014 to 2016, there were likely multiple female birds in the flock. PCR results revealed that birds #2, #3, and #4 were females, while #1, #6 and #7 were males. This represents a 1:1 male/female sex ratio in this small population. Birds #3 and #4 were both captured from the wild in year 2011 without knowledge of their ages or gender. The reasons for the absence of egg-laying from these two female birds could be complex. A sudden environmental change from the wild to the captive status may have affected their breeding behaviors, and the possibility cannot be excluded that they might have been carrying unnoticed diseases that affected reproduction; or they might simply have lost their reproductive ability due to aging. Our study suggests that behavioral characteristics can be used for gender identification with caution, as some of them are weak and sometimes misleading. For example, though bird #4 showed chasing inclination during the two mating seasons in years 2015 and 2016, it was clearly demonstrated by PCR to be a female.

Itoh et al.(2001) have successfully identified the gender of flamingo using two pairs of primers in EE0.6 gene, which was then verified by the CHD1 gene-based method. The unambiguous and easily separable two PCR products from the CHD1 genes on the Z and the W chromosomes make this molecular sexing method a simple and reliable way for sex determination of blue-crowned laughingthrushes, avoiding the risk of severe physical injuries to the bird or death from traditional sex examination methods. It should be noted that DNA isolation from feathers should make this method even safer for the birds (Bello et al., 2001). As successful as in many other avian species, the accuracy of sex-typing brought by this non-invasive method is very helpful for the management of and research on populations of this critically endangered species.

Conclusion

In summary, blue-crowned laughingthrush is a critically endangered avian species. We used CDH1-specific primers for PCR sex-typing of this sexually monomorphic bird, and compared the PCR-typing results with the deduced gender of this bird on the basis of extensive behavioral observations. We believed that the method is reliable and non-invasive to the birds, thus it is an ideal tool for the management and study of this critically endangered species under captivity.

(Received 31st May 2018; accepted 2nd Aug 2018)

Abstract. Comparison analysis was performed for the characteristics of cloud-to-ground (CG) lightning and topography in low latitude plateau of China and showed that CG lightning activity was characterized Gaussian distribution along the variation of elevation centered at approximately 2000 m above sea level and decreased on both sides; it was also linearly inversely correlated with variations in terrain slope. CG lightning activity was showed a typical positive dipole distribution of electric charges in the thunderstorm clouds. The average current intensity of negative CG lightning located in the lower layers was obviously weaker than that of the positive CG lightning located in the upper layers, and decreased initially and subsequently increased as the elevation increased, whereas the positive CG lightning had no significant variation. The CG lightning current intensity increased linearly with terrain slope, and the variation slope of positive CG lightning was smaller than that of negative CG lightning, variation of current intensity with latitude was inversely correlated with the variation of CG lightning densities. The CG lightning activity and variation of current intensity had the same characteristics in specific regions and in zonal and meridional cross-sections, but it was significantly affected by the topography in the low/high regions where elevation was <600 />3500 m.
Keywords: *cloud-to-ground (CG) lightning, elevation, terrain slope, effect of topography*

Introduction

Terrain topography can greatly affect the movement and development of the general circulation of the atmosphere, particularly convergence systems, fronts, and typhoons (Egger et al., 1992; Smith, 1979). Smith (1979) proposed using linear regression to describe the correlation between annual average precipitation and altitude; studies have used linear regression to describe the linear correlation between lightning and precipitation (Ezcurra et al., 2002; Jayaratne and Kuleshov, 2006; Soula and Chauzy, 2001). Without considering the formation mechanisms of lightning, precipitation, and other factors, topography has an obvious influence on precipitation and lightning activity. Topography can directly or indirectly affect the direction of the local prevailing wind, and in appropriate conditions, different elevations and terrain slopes can directly affect updrafts, resulting in strong weather, such as barrier jets and thunderstorms, which are usually accompanied by obvious precipitation and lightning activity. Researchers have also employed numerical model simulations to find that topography has a great influence on lightning activity (Smith, 1979).

Researchers have found that topography can affect the spatial and temporal distributions of lightning. Pinto Jr. et al. (1999) analyzed the spatial distribution of lightning in southern Brazil and found a favorable correlation between topography and lightning activity, and Schulz and Diendorfer (1999) revealed a nonlinear correlation between topography and lightning activity: cloud-to-ground (CG) lightning activity increased linearly as elevation increased, whereas the CG lightning decreased linearly as elevation increased for elevation >1300 m. Wagner et al. (2006) found a favorable correlation between topography, wind direction, and CG lightning flash count in the United States, and Zajac and Rutledge (2001) analyzed the relationships between CG lightning flash density, thunderstorm days, topography, and other meteorological parameters, which showed favorable correlations between the topography, CG lightning flash density, and thunderstorm days in the United States. Bourscheidt (2009) analyzed data on lightning records from 2005 to 2007 in Brazil and found that terrain slope had a highly significant influence on lightning flash distribution. In China, Ma et al. (2004) analyzed 6 years of lightning data recorded using a satellite-equipped optical transient detector (May 1995–March 2000) and lightning imaging sensors (December 1997–March 2003) and obtained the distribution of lightning density in this area with a grid format of 0.5° × 0.5°, which showed significant regional differences in lightning density in mainland China: as with different geographic environments, the high lightning density areas (centers) have different relationships to mesoscale topography. Tong et al. (2008) analyzed the characteristics of lightning activity in Zhejiang Province by using a map of CG lightning density as measured by a lightning coordination system from 2004 to 2007; their study showed a correlation between topography, seasonal climate, and lightning activity. Qie et al. (2003) compared the lightning activity of typical topographies globally using lightning coordination data measured by the lightning detection system on the Tropical Rainfall Measuring Mission satellite, and the results showed significant differences in lightning activities both in lightning flash count and lightning intensity in different topographic regions. Qie et al. (2009) analyzed the electrical characteristics of thunderstorms in different elevations and found that the special-type thunderstorm was positively related to the elevation of the region, in the Chinese Inland Plateau, the height of the charge region neutralized by negative CG flashes ranges from 3 km to 5 km above the ground, corresponding to an ambient temperature between -2 and -15 °C. For the two positive CG flashes, the neutralized charge regions are located at a height of about 5.5 km and the ambient temperature is about -18 °C, indicating the existence of upper positive charge in the thunderstorm. Qie et al. (2013), Wang et al. (2016) analyzed the lightning activity in northeastern China, and the results showed lightning events mainly occurred in regions with a large gradient of CAPE. Comparisons between lightning and non-lightning regions indicated that lightning regions featured more intense ascending motion than non-lightning regions.

Yunnan Province is in the southwestern border region of China, and it has the typical geographic characteristics of a low latitude plateau with the terrain descending from the northwest to the southeast; it has unusually great elevational differences; the maximum elevation difference can be more than 6000 m. Yunnan has frequent CG lightning activity throughout the year, with uneven temporal and spatial distributions (Xie et al., 2013). In the present study, Lightning activity characteristics under complex topography in low latitude plateau was analyzed using 10 years of CG lightning records from 2007 to 2016 and detailed geographic elevation data from Yunnan Province of China.

Data and methods

The CG lightning data were recorded by the Lightning Detection and Coordination Network based on 22 ADTD (ADvanced TOA and Direction) lightning locators and a central data processing station that provided information on each lightning flash, including time, location, intensity, and polarity, with theoretical coordinating accuracy and detection efficiency of approximately 500 m and 95%, respectively. The CG lightning data were not corrected for efficiency.

The topography data comprised a Digital Elevation Model (DEM) measured by the Shuttle Radar Topography Mission (SRTM), with two datasets, SRTM1 and SRTM3, with precisions of 1 arcsecond and 3 arcseconds, respectively. Of these datasets, SRTM3 can cover the globe and is the most widely used topographic dataset. The spatial resolution of the SRTM3 data discussed in this article was 3 s. Its elevation datum was the EGM96 geoid with an accuracy of ±16 m, and the horizontal datum was the WGS84 with a horizontal accuracy of ±20 m. Positive CG lightning whose intensity was less than 20 kA was expelled as cloud-to-cloud lightning (Biagi et al., 2007).

Terrain slope is the degree of inclination compared with the horizontal plane of a point on the ground that can be calculated from the value of the elevation of two adjacent points using DEM data. It is defined as the angle between the tangential plane and the horizontal ground at this point (Monmonier, 1982); the exact calculation formula is

$$slp = \sqrt{\left(\frac{right - left}{res * 2}\right)^2 + \left(\frac{top - bottom}{res * 2}\right)^2}.$$

Within this formula, *top*, *bottom*, *right*, and *left* represent the elevations of the adjacent points, respectively, to the top, bottom, right, and left; *res* represents the distance between two adjacent points, and the units of all these parameters are, m. $tan^{-1}(slp)$ is used in this article to describe the inclination to the horizontal plane as the terrain slope.

The latitude and longitude in the present study ranged from 20.5°N to 29.5°N and from 95.5°E to 106.6°E, and the CG lightning data were integrated into the statistics as a grid with an accuracy of 0.01°, and the average elevation was taken as the elevation value of the grid to analyze the CG lightning activity characteristics.

Results

Topographic variation and lightning density characteristics

Figure 1a is the map of elevation with an accuracy of 0.01° × 0.01°. Yunnan of China is located in the junction region of the southeastern margin of the Tibetan Plateau and the Yunnan–Guizhou Plateau, a region which is mainly mountains and plateaus with low latitude and high elevation. The terrain is highest in the northwest and descends toward the southeast and stretches toward the east, southeast, south, southwest, and west in a fingerlike fashion. In northwestern Yunnan, the terrain is an obvious fold mountain area with sharp rises and drops in elevation because the elevations of the valleys of the Three Parallel Rivers are lower than 1500 m, whereas those of the snow mountains exceed 5000 m; the Kawakarpo Peak of the Meili Snow

Mountain is the highest point in Yunnan Province, ascending to 6740 m. Except for the northwestern part, the terrain of Yunnan Province can be divided into two major regions with the fault area of the Ailao Mountains as the boundary; to the west are the highlands with moderate- and high-elevation mountains as the main terrain. This highland region contains a high concentration of mountains; to the north of the Wuliang Mountain, all the mountaintops are higher than 2500 m, whereas the heights gradually decrease to the south. In the region to the east of the Ailao Mountains, the Honghe Valley and Yuanjiang Valley stretch alongside the Ailao Mountains; the elevation declines rapidly as the valleys stretch southward, and the lowest point is only 76.4 m high. The elevation is relatively high further east and it declines gradually to the southeastern part of Wenshan Autonomous Prefecture. Further north is an area of plateaus and hills whose elevations are relatively high, fluctuating from 1800 to 3000 m; this area stretches northeast to the northern part of Zhaotong City where the elevation declines rapidly. The slope features of terrain in Yunnan Province are also divided by the Ailao Mountains (see *Fig. 1b*); the east is the flattest area in Yunnan, dominated by basins and hills, and corresponding to the mid-altitude regions, mostly with an elevation of 1500–3000 m. To the southwest of the Ailao Mountains is the second region of mild terrain slope. The elevation of this region varies to a greater extent than do theentral and eastern areas of Yunnan, which have elevations between 1000 and 2000 m. The terrain slope of the rest of the region is more complicated and follows the trend of the mountains, and the deviation to the Hengduan Mountains in the northwestern Yunnan is severe. Affected by this topography, the CG lightning density has a typical spatial distribution along the mountains' trends (see *Fig. 1c*).

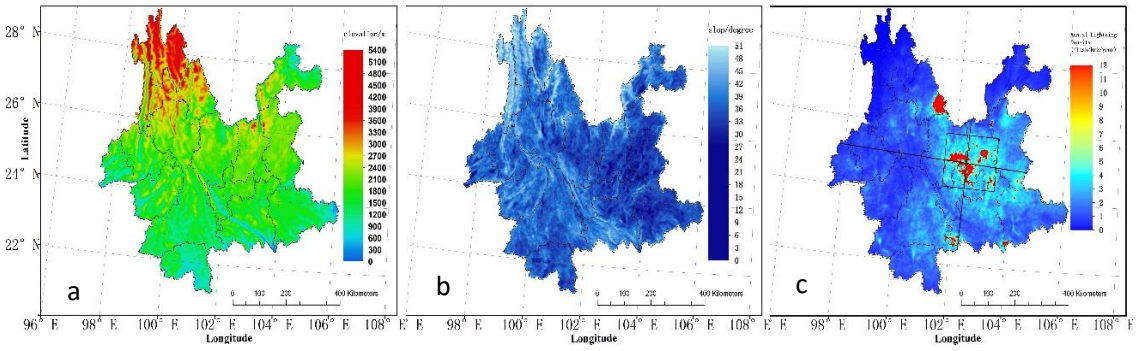

Figure 1. *Map of elevation and annual average CG lightning density distribution of Yunnan Province. a: elevation (m); b: terrain slope (degree); c: CG lightning density (time/year•km^2)*

The area with the highest CG lightning density was in the central region of Yunnan, northeast of the Ailao Mountains, which features relatively flat and unobvious folded topography with elevations of 1800–2500 m. Synoptic analysis showed that this region was mainly affected by cold front shear, convergence shear, and other synoptic systems. The frequent convergence of cold and warm air made this region suitable for forming large-scale strong convective weather systems (Li, 2011; Xu et al., 2011). The second-highest CG lightning density area was in Huaping County, Lijiang City, northwestern Yunnan, which is surrounded by mountains higher than 3100 m to the north, west, and south, whereas the elevation of the high density area is lower than 2000 m. Furthermore, to the east of this area lie the Hengduan Mountains at the Yunnan–Sichuan border, which the plateau trough and southwestern vortex cross when moving southeastward

© 2018, ALÖKI Kft., Budapest, Hungary

into northwestern Yunnan; consequently, an obvious upward stream was formed, thus creating this high CG lightning density area (Li, 2011; Xu et al., 2011). The third-highest CG lightning density area was located in southeastern Pu'er City, which is on the southwestern side of the Ailao Mountains. This area was dominated by warm and humid air flow that could form an upward stream due to the topographic uplift effect. The blockading effect of the Ailao Mountains weakens the effect of cold air in this area; thus, the lightning activity is relatively weak (Li, 2011; Xu et al., 2011). In the valley regions to the western side of the Ailao Mountains and in the low-elevation regions in northeastern and eastern Yunnan (elevation <1000 m, flat topography, and with no mountains higher than 3000 m), the CG lightning activity is relatively weak. The high-elevation regions (elevation >3500 m with obvious folded topography) and northeastern Yunnan, where the effects of warm and humid airstreams are minimal, are nearly zero-zones for CG lightning activity.

Distribution of topographic variation and lightning density

The distribution of CG lightning at different elevations was determined by analyzing the statistics on CG lightning flashes from 2007 to 2016, with 100 m as the elevation increment unit. The result (see *Fig. 2a*) showed that total CG lightning flashes were normally distributed with elevation and mainly appeared in the area between 800 and 3300 m. Within this range of elevation, the area of the corresponding regions accounts for 90.6% of the land area of Yunnan Province, where 96% of the total CG lightning occurred; in particular, in the regions with elevations between 1900 and 2100 m, the number of CG lightning flashes reached 1.56 million.

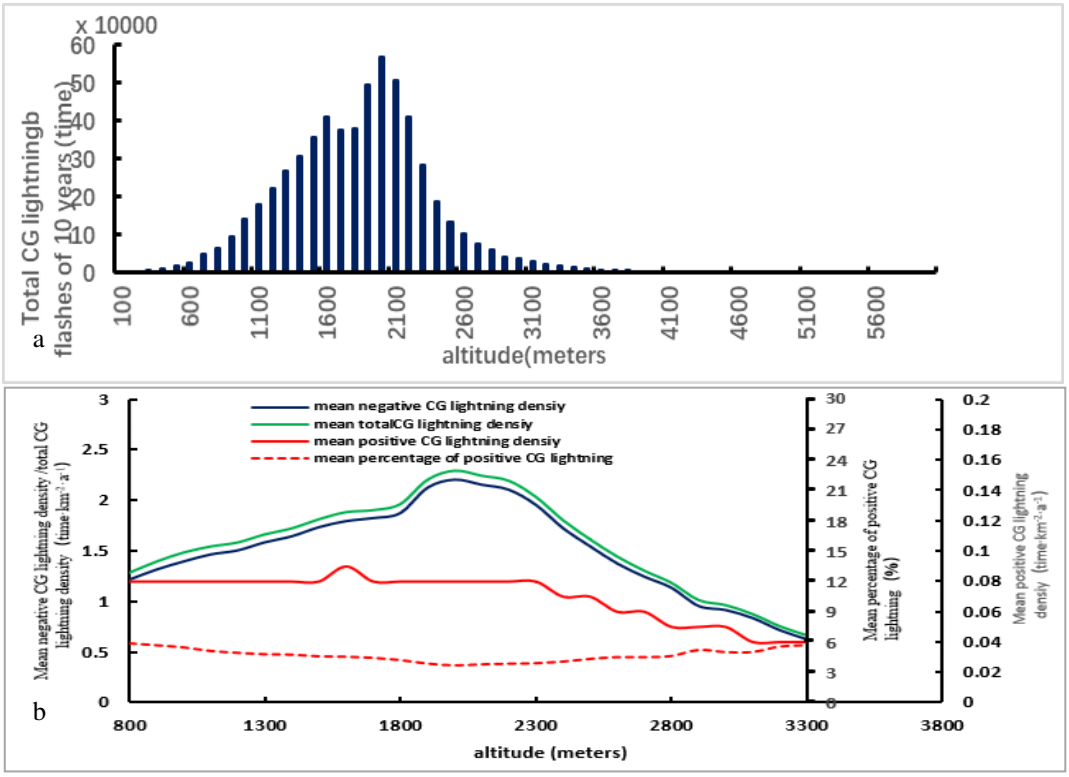

Figure 2. *distribution of elevation variation and total CG lightning counts, average CG lightning density and the proportion of positive CG lightning (a: variation of total CG lightning counts; b: variation of CG lightning density and proportion of positive CG lightning)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

The regions with elevation <800 m account for 3.7% of the land area of Yunnan Province, and only 3% of the CG lightning flashes were recorded in these regions, whereas regions with elevation >3300 m account for 5.7% of the land area, and only 1% of the CG lightning flashes were recorded in these regions. Therefore, the CG lightning activity in regions <800 m or >3300 m was unrepresentative; thus, only the effect of elevation within the range of 800 to 3300 m on CG lightning activity was analyzed (see *Fig. 2b*). The average total CG lightning density and average negative CG lightning density corresponded to the trend of elevation, which exhibited unimodal variation with the peak in the 1900–2000-m range where the average total CG lightning density peaked at 2.29 events·km^{-2}·a^{-1} and the average negative CG lightning density peaked at 2.2 events·km^{-2}·a^{-1}, whereas the average positive CG lightning density was stable at 0.08–2.2 events·km^{-2}·a^{-1} from 800 to 2000 m. As the elevation increased, the average total/negative CG lightning density decreased linearly, the average positive CG lightning density fluctuated between 0.06 and 0.08 events·km^{-2}·a^{-1}, and the average total/negative (positive) CG lightning densities exhibited fluctuating reduction when elevation >2300 m. Land area increased linearly as elevation increased when elevation <1600 m, fluctuated at approximately 1800 m, and peaked between 1900 and 2000 m. This phase corresponded to the peak value of average negative/total CG lightning densities, and the average positive CG lightning density was stable in this area, exhibiting frequent CG lightning activity at the elevation band of 1900–2000 m, where the convergence of cold and warm air frequently occurs.

As can be seen from the variation characteristics of positive CG lightning and elevation, the average percentage of positive CG lightning was only approximately 5%, there was bipolar structural characteristics of thunderstorms in Yunnan Province because the center of negative charge is close to the ground and the center of positive charge is located at high layers. Positive CG lightning exhibited slow fluctuating reductions as the elevation increased from 800 to 2000 m, and the proportion of them was at a minimum of 3.69% at approximately 2000 m, which corresponded to the peak value of negative CG lightning activity. This indicated that the negative charge of the thunderstorm cloud was abnormally active in the area of cold and warm air interaction. In the range of 2000–3300 m above sea level, the proportion of positive CG lightning flashes fluctuating increased as the elevation increased, indicating a significant difference between the excitation conditions of positive/negative CG lightning flashes in the high- and low-altitude regions and the excitation conditions in the mid-altitude (1900–2000 m) regions where negative CG lightning flashes were concentrated.

Distribution of terrain slope and CG lightning density

The terrain slope has a promoting effect on airflow uplift and convection. Statistics on average CG lightning density for each slope section of 1° were analyzed (see *Fig. 3*), and the results showed that CG lightning activity increased rapidly and decreased linearly after peaking as the terrain slope increased, and the total CG lightning count significantly decreased when the tendency declined as the terrain slope continued to steepen more than 20°. CG lightning was mainly concentrated in the slope sections between 0° and 30°, where 98.6% of the total CG lightning occurred; these sections contained 97.7% of the total land area of Yunnan Province, particularly the sections between 0° and 5° where CG lightning was most active and where the 10-year total count reached 2.75 million, approximately 46% of the total CG lightning count. These sections contained approximately 37% of the total land area. Only 3% of total CG

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_63496367
© 2018, ALÖKI Kft., Budapest, Hungary

lightning occurred within the slope sections steeper than 30°, which constituted only 1.3% of the total land area, indicating that within the range of 1 km^2, regions with terrain slope >30° were few and the CG lightning in these regions was too infrequent to be further analyzed. Thus, the analysis of the effects of terrain slope on CG lightning density and the proportion of the positive lightning in *Figure 3b* consisted only of the sections less than 30°.

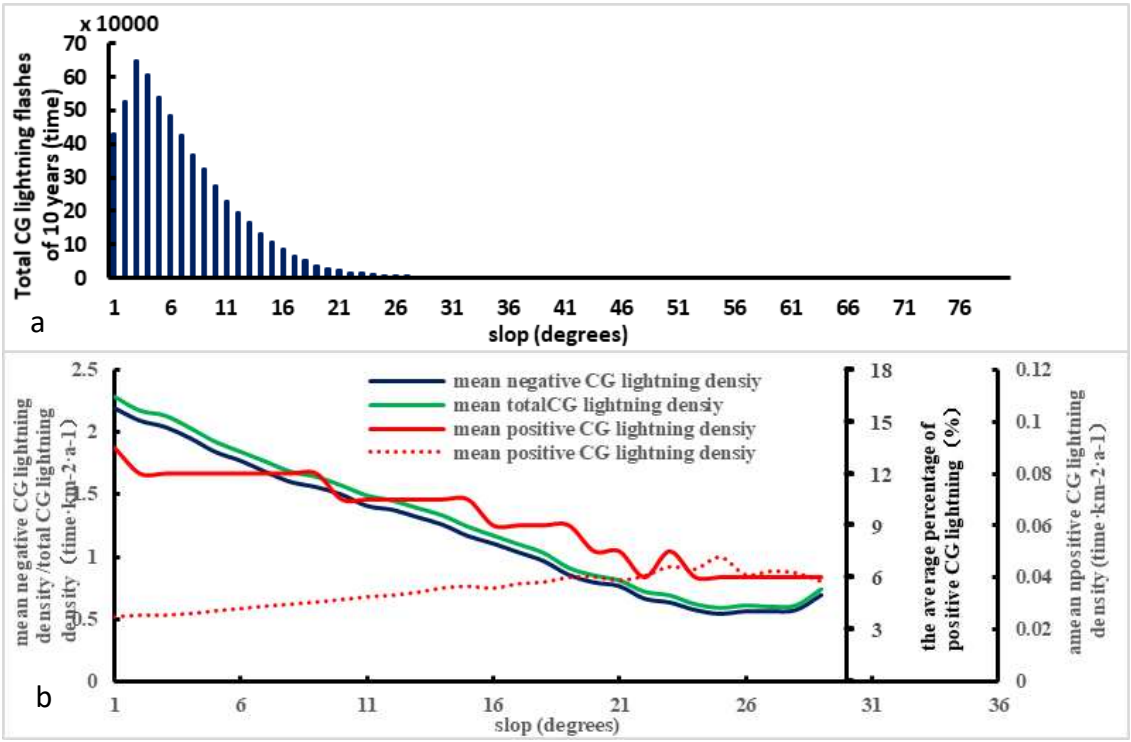

Figure 3. *Variations in total CG lightning counts, average CG lightning densities, and the proportion of positive CG lightning over terrain slope of 2007–(2016). a: Variation of total CG lightning counts over terrain slope; b: variations of average CG lightning densities and the proportion of positive CG lightning over terrain slope*

The average total/negative CG lightning density peaked (2.28 events·km^{-2}·a^{-1} and 0.57 events·km^{-2}·a^{-1}) at a slope of 1° and declined linearly as slope steepened and reached a minimum (0.6 events·km^{-2}·a^{-1} and 0.57 events·km^{-2}·a^{-1}) at a slope of 27°. As the terrain slope steepened, the average total/negative CG lightning density increased again. These findings, as well as the topographic characteristics of Yunnan Province, indicated that 90% of the land was undulating plateau with many south-northward mountains and that the synoptic systems of the strong convection in Yunnan come mainly from the east to the west and create thunderstorms because of the uplift airflow affected by the terrain slope, causing an increase in CG lightning activity in regions of slope >27°. Overall, the average positive CG lightning density declined in the performance of the staircase-like trend as the slope increased. At a slope of 1°, the average positive CG lightning peaked (0.9 events·km^{-2}·a^{-1}) and subsequently dropped at 10°, 16°, and 20°, and after a slight increase at a slope of approximately 23°, it remained at approximately 0.04 events·km^{-2}·a^{-1}. The downward trend in CG lightning density indicated the smaller decline for positive CG lightning density and an obvious positive correlation between the

© 2018, ALÖKI Kft., Budapest, Hungary

proportion of positive CG lightning and the terrain slope. Furthermore, a comparison between elevation and terrain slope in Yunnan Province indicated that regions with slope >27° and elevation >3000 m corresponded favorably. The uplift airflow caused by the windward slope of the mountains accelerated convection development, and this, combined with the rate of precipitation, reduced negative charges in the lower part of the cloud during the falling process (Biagi, 2007). This resulted in precipitation current formation, thereby reducing the frequency of low-level negative CG lightning and indirectly resulting in an increase in positive CG lightning in regions of high elevation and terrain slope.

Variation in CG lightning densities and terrain slope at different elevations

Bourscheidt's (2009) research on the variation in CG lightning density as terrain slope changed in Brazil was limited to elevations <1000 m, with the result that the CG lightning density increased linearly with increases in terrain slope, which was contrary to the conclusion reached in this paper. To further analyze the relationship between CG lightning density and terrain slope at different elevations, elevation was divided into four bands: 0–1500 m, 1500–2300 m, 2300–4000 m and >4000 m, and the variations in the CG lightning density with terrain slope were analyzed for the four bands (see *Fig. 4*).

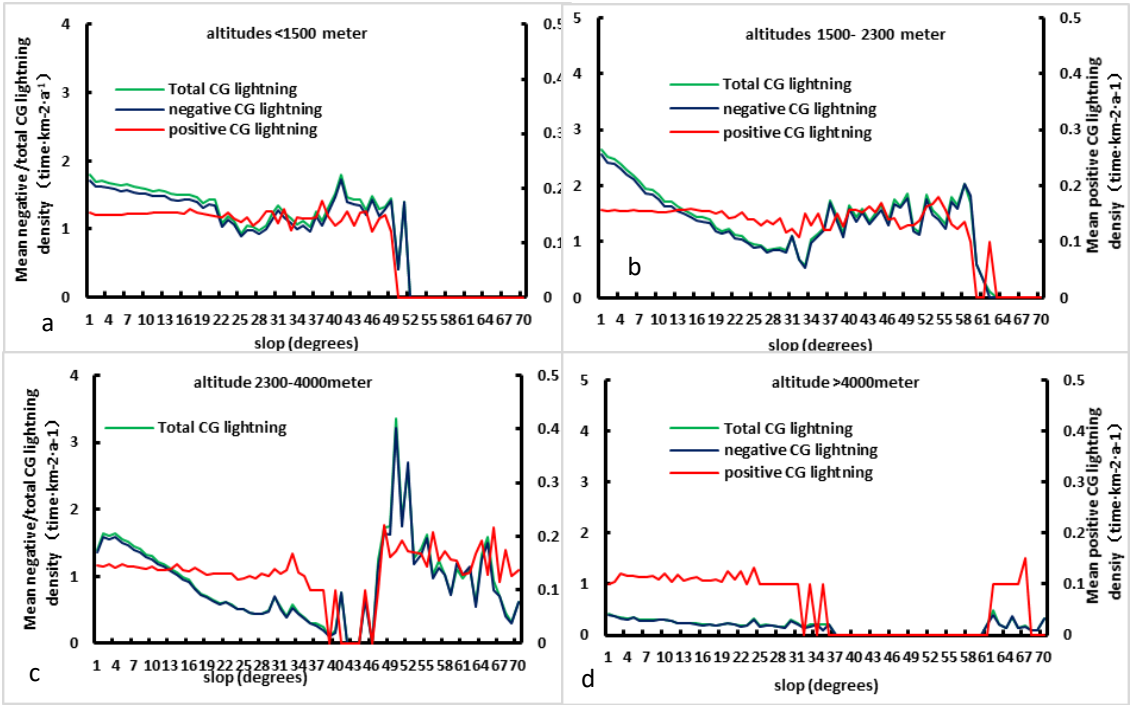

Figure 4. *Variations in average total/negative and positive CG lightning densities over terrain slope at different elevations. a: <1500 m; b: 1500-2300 m; c: 2300-4000 m; c: >4000 m*

In the <1500 m band, the average total/negative CG lightning densities decreased linearly as the terrain slope increased from 0°–25° and peaked at 1.79/1.7 events·km^{-2}·a^{-1} at a slope of 1°. It subsequently reached a minimum of 0.93/0.9 events·km^{-2}·a^{-1} at a slope of 25°. Subsequently, as the terrain slope steepened, the average total/negative CG

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_63496367
© 2018, ALÖKI Kft., Budapest, Hungary

lightning densities also increased, fluctuating between slopes of 25° and 50°; within this range, the average total/negative CG lightning densities exceeded 1 events·km^{-2}·a^{-1} and exhibited many peaks, with terrain slope having a strengthened uplift effect on airflow. Subsequently, the average total/negative CG lightning densities dropped rapidly for slopes of >52°. The trend of average positive CG lightning density was consistent with the trend of average total/negative CG lightning densities because average positive CG lightning decreased slowly and linearly as terrain slope increased in flat (slopes <25°) regions and fluctuated between 25°–50°. Additionally, CG lightning activities tended to decrease for slopes >45°. Within the 1500–2300 m band, which constitutes the largest proportion of land area (total 58% of land area and 49% of land area), the tendency of average CG lightning was consistent with the lower elevation band. The average total/negative CG lightning densities peaked (3.64/0.9 events·km^{-2}·a^{-1}, 2.55/0.9 events·km^{-2}·a^{-1}) where the terrain slope was 1° and reached a minimum (0.57/0.9 events·km^{-2}·a^{-1}, 0.52/0.9 events·km^{-2}·a^{-1}) where the terrain slope was 33°. Additionally, they fluctuated between the terrain slope range of 34°–59° and tended to decrease when terrain slope >60°. The average positive CG lightning density was consistent with the trend of total/negative CG lightning density, except for fluctuation in flat terrain (0°–30°), where the positive CG lightning density remained approximately 0.15 events·km^{-2}·a^{-1}. The topographic distribution in the 2300–4000 m elevation band exhibited two-stage differentiation, and the variation in the average CG lightning density showed consistent characteristics of a linear decrease for slopes of 1°–20°. The variation in the average CG lightning density land area (where terrain slope ranged from 20° to 36°) decreased rapidly, but the lightning activity remained stable, resulting in peaks in the average CG lightning density. No land had a slope in the range from 37° to 45°, and regions with terrain slope >45° comprised just 1% of the land area and total CG lightning count. Additionally, the small sample size resulted in larger average total/negative and positive CG lightning densities, indicating that greater terrain slope was favorable for updraft uplift and formation of local lightning activity and convection. The CG lightning density was less than 0.4 where the elevation >4000 m, and topography and lightning activity also exhibited two-stage differentiation.

The CG lightning activity and elevation in Yunnan Province were normally distributed but inversely correlated with the slope. Within all the elevation bands, when slopes were less steep, the CG lightning activity was relatively dense as long as the terrain slope remained smaller than 30°. In regions with elevation <2300 m and slope of 30°–59°, a small peak occurred due to the topographic uplift effect of airflow, and almost no CG lightning activity was recorded in the mountain regions where slope >60°. Regions whose elevation >2300 m comprised gentle basins and high mountains, causing a blank zone of CG lightning activity between the terrain slope range of 40°–55°. Scattered CG lightning activity occurred in greater terrain slopes, further indicating the importance of topography on CG lightning activity in Yunnan Province.

Latitude and lightning density distribution

Studies have determined that the total lightning density gradually decreases from low latitudes to high latitudes, and the proportion of CG lightning within the total lightning also decreases gradually from low latitudes to high latitudes (Chen, 2003). At a given elevation, the convective clouds in low latitudes are more active, resulting in higher CG lightning densities than in the high latitudes. *Figure 5a* shows the distribution of average CG lightning density by latitude with a resolution of 0.01° for Yunnan Province

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_63496367
© 2018, ALÖKI Kft., Budapest, Hungary

from 2007 to 2016, showing that the average total/negative CG lightning densities tended to increase first and subsequently decrease with multiple peaks as latitude increased. The first peak appeared at 22.8°N, and the average total/negative CG lightning density was 1.72/1.66 events·km^{-2}·a^{-1}. The two regions with CG lightning densities larger than 12 events·km^{-2}·a^{-1} within this latitude band were located to the west of the Ailao Mountains and to the east of Honghe Valley where the elevation rises from the west to the east. Subsequently, the average total/negative CG lightning density dropped rapidly within the mountainous region of the Ailao Mountains and the lower regions where elevation <1800 m. The second peak in average total/negative CG lightning density appeared between 24°N–25.2°N with density sustained at 1.6–1.8 events·km^{-2}·a^{-1}; these regions corresponded to the convergence area of cold and warm air to the east of the Ailao Mountains, where the low 0 °C layer, sufficient moisture, and strong uplift airflow caused a high negative lightning density. The third peak in average total/negative CG lightning densities appeared at approximately 26.5°N, located near the Hengduan Mountains by the Yunnan–Sichuan boundary, which was also one pathway for the intruding cold air. Subsequently, the average total/negative CG lightning density dropped rapidly as the latitude increased. Compared with the average total/negative CG lightning density, the average positive CG lightning density was approximately one order of magnitude less, and the trend of variation almost corresponded to the average total/negative CG lightning except that the third peak was obviously southward. To further analyze the relationship between the CG lightning densities and latitude of the dense CG lightning area (1900–2100 m), the variation in CG lightning density by latitude in this elevation band is shown in *Figure 5b*.

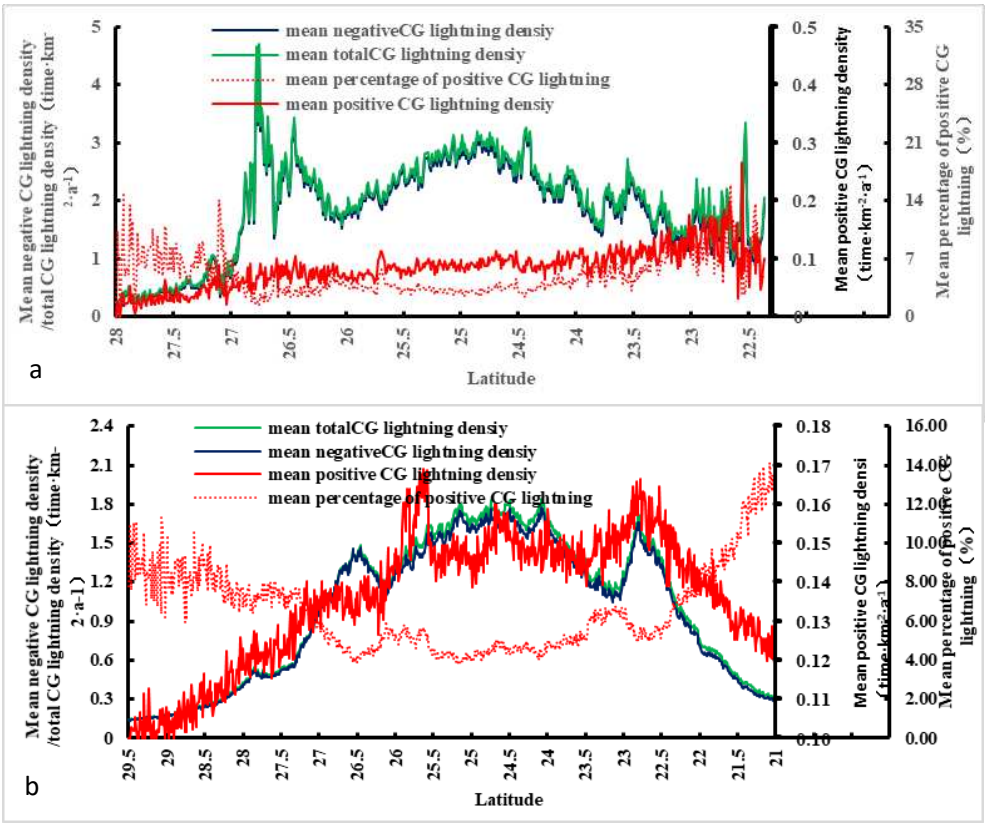

Figure 5. *Variations in CG lightning densities and proportion of positive CG lightning over latitude in Yunnan Province. a: Entire province; b: Elevations between 1900 and 2100 m*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_63496367
© 2018, ALÖKI Kft., Budapest, Hungary

South of 26.7°N, the average total/negative CG lightning density tended to increase with latitude, albeit with fluctuations, and three peaks were observed, essentially as already described, with the maximum density, 4.65 events·km^{-2}·a^{-1}, appearing at 26.7°N. The average positive CG lightning density decreased with latitude with fluctuations. The variation in the proportion of positive CG lightning for latitudes between 1900–2100 m of elevation was consistent with the variation of the entire province.

Topographic variation and the current intensity of CG lightning

To determine the differences in CG lightning activity in the complex topography in Yunnan Province, the average intensity of positive/negative CG lightning of different elevations, terrain slope, and latitude were analyzed and are described as follows.

Distribution of terrain and the current intensity of CG lightning

Because the CG lightning activities in Yunnan mainly occurred between 800 and 3300 m above sea level, analysis on the effect of elevation on CG lightning intensity was limited in this range. *Figure 6a* shows that the average current intensity of positive CG lightning was significantly greater than that of negative CG lightning. The average current intensity of positive CG lightning fluctuated within the range of 60–63 kA as the elevation increased except for the abrupt increase at 1000 m above sea level. The current intensity of negative CG lightning initially decreased and subsequently increased with elevation and was negatively correlated with the variation in negative CG lightning density by elevation, with the minimum value (33.3 kA) appearing between 1900 and 2000 m where the peak value of negative CG lightning density appeared. The CG lightning activity in Yunnan Province was dominated by negative CG lightning, and the distribution of electrical charges in the thunderstorm cloud was negative–positive from the lower to the upper layers. The typical plateau topography facilitated rapid accumulation of the energy of low-layer negative electric charge and rapid formation of the CG lightning channel, causing the discharge process to occur when current intensity was still weak. This finding is basically consistent with Li (2011), who concluded that the variation in the current intensity of negative CG lightning and elevation tended to be stable at approximately 40 kA. In regions whose elevation >2000 m, as the elevation increased, the average current intensity of negative CG lightning increased slowly and linearly. CG lightning activity in high-elevation regions mainly occurred from local convection caused by solar radiation. As the elevation increased, water vapor content continuously decreased, and the energy required for accumulating electric charge in the cloud to form the CG lightning channel was high relative to that of the low-elevation regions, resulting in the linear increase of current intensity with elevation in high-elevation regions. In lower regions with elevation <1000 m, compared with the special topography in Yunnan Province, descending motion dominated the airflow. Because of the higher elevation differences between the troposphere and ground level, thunderstorms could release their energy after fully maturing, causing the relatively strong current intensity of negative CG lightning in low-elevation regions.

Distribution of terrain slope and the current intensity of CG lightning

The topography of Yunnan Province has five major characteristics: plateau waviness, mountains speckled with valleys, staircase-like decreases, fault basins, and rivers and lakes dividing the region. Relatively large fluctuations in terrain slope are present in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_63496367
© 2018, ALÖKI Kft., Budapest, Hungary

regions with different elevations, and *Figure 6b* shows the variation in the average current intensity of CG lightning over terrain slope.

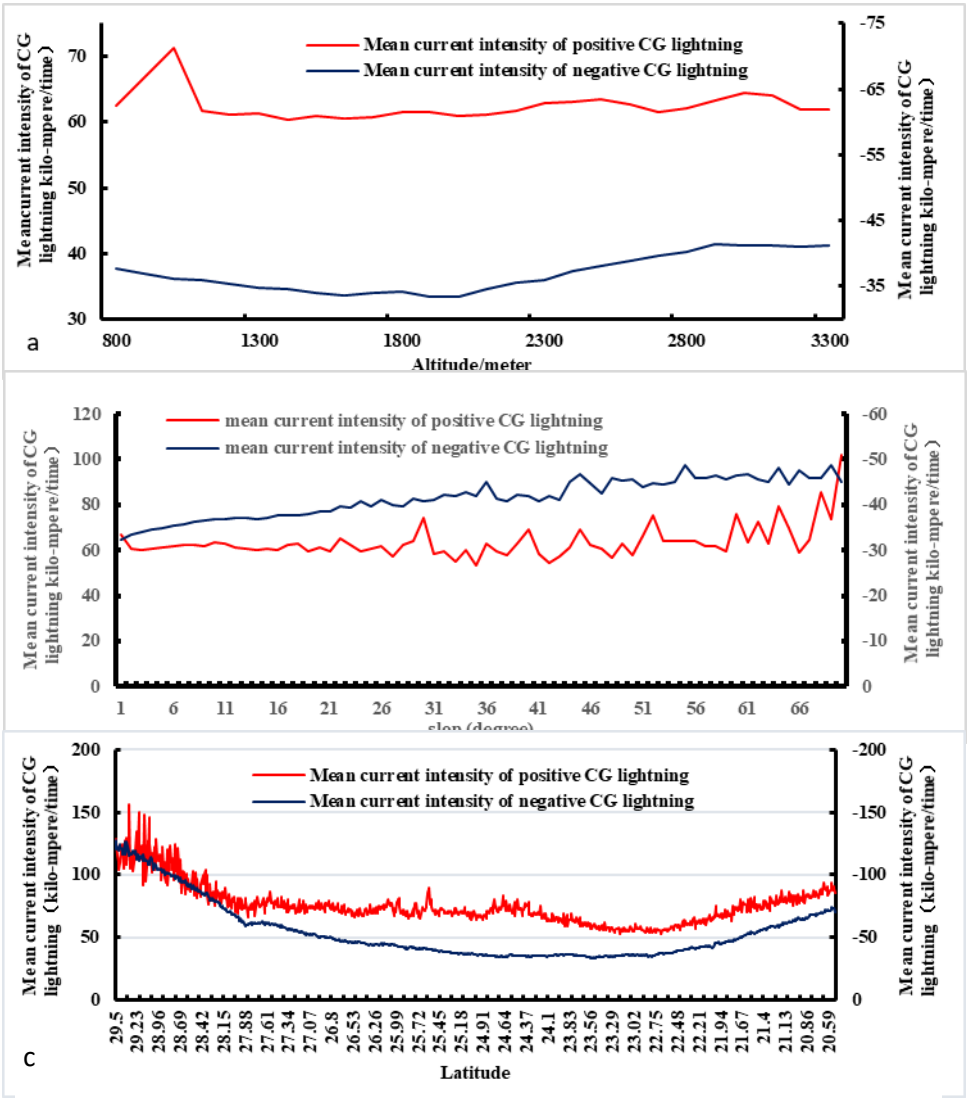

Figure 6. *Variation in average current intensity of CG lightning with elevation and terrain slope from 2017–2016. a: variation in average current intensity of negative/positive CG lightning with elevation; b: variation in average current intensity of negative/positive CG lightning with terrain slope; c: variation in average current intensity of negative/positive CG lightning with latitude*

The average current intensity of negative CG lightning increased linearly with terrain slope, and in the basins and smooth regions with terrain slope <20°, the average current intensity of negative CG lightning was <40 kA. However, the average current intensity of negative CG lightning in regions with terrain slope >20° exhibited fluctuating increases, further indicating the dipolar characteristics of the electric charge distribution of thunderstorms of Yunnan Province, which means that the lower layers were mostly negatively charged, and as the terrain slope increased, the water vapor carried in the ascending airflow gradually decreased. Furthermore, negative electric charge

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_63496367
© 2018, ALÖKI Kft., Budapest, Hungary

accumulation increased the energy of CG lightning discharge, resulting in the linear increase of current intensity of negative CG lightning in regions with steep terrain slope. Additionally, the larger mountains in Yunnan Province are mostly distributed in the high-elevation regions. Generally, the current intensity of positive CG lightning was 20 kA stronger than that of the negative CG lightning, whereas the linear variation slope of average current intensity was less than that of negative CG lightning, indicating an obvious stronger energy requirement for positive lightning discharge in the upper troposphere. In areas of flat terrain with slopes of <30°, the average current intensity of positive CG lightning fluctuated slightly between 60 and 63 kA. Although the average current intensity of positive CG lightning fluctuated between 53 and 75 kA in regions where the terrain slope was between 30° and 60°, which was related to the drastic change in elevation in these regions. The average current intensity of positive CG lightning in regions with terrain slope >60° increased significantly. Both the current intensities of positive and negative CG lightning showed a significant linear positive change with variation in terrain slope. Where slopes are steeper, more energy is required to generate CG lightning, resulting in more infrequent CG lightning but with stronger current intensity on steep slopes. The current intensity of positive CG lightning was larger than that of negative CG lightning but the variable slope was smaller. The center of negative electric charge was located in the lower layer of the thunderstorm cloud, and negative CG lightning was more easily affected by topography.

Distribution of latitude and the current intensity of CG lightning

The distribution of electric charge in cumulonimbus cloud was as follows: the lower layer between 0 and -20 °C was the negative charge accumulation area, and the higher layer between -20 and -50 °C was the positive accumulation area. For a given amount of electric charge, a pilot stroke with a small distance to the ground could reach the ground to form a CG lightning bolt easily; the energy requirement was small, and the chance of CG lightning formation was small if the distance to the ground was large and the energy required for CG lightning discharge was relatively large. The current intensity of positive CG lightning in Yunnan Province was significantly larger than that of the negative CG lightning because the number of return stroke of positive CG lightning was significantly less than that of the negative CG lightning. The current intensity decreases rapidly due to multiple discharges caused by multiple flashbacks (Xie, 2013). The average current intensity of positive/negative CG lightning initially decreased and subsequently increased as latitude increased. In the low latitude regions south of 23°N, the average current intensity of positive CG lightning decreased from 85 kA to 55 kA as latitude increased. Regions between 23°N and 27°N in Yunnan are areas of frequent intense convection, which significantly increased the development of positively charged particles in the cloud and caused the average current intensity of positive CG lightning to increase with fluctuations. The regions north of 27.8°N in Yunnan Province include the snow mountains in the northwest with elevations >3000 m and the river valleys with elevations <1000 m, where the terrain slope was steeper and the amount of CG lightning was lower; thus, the current intensity of CG lightning increased linearly with latitude. The variation in average current intensity of negative CG lightning with latitude fluctuated less. In the low latitude regions, the 0 °C level height was relatively high, and the average current intensity was stronger. Additionally, within the range 23°N–27°N, the convergence of the cold and warm air caused severe convection, reducing the 0 °C level height; therefore, the average current intensity weakened obviously to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_63496367
© 2018, ALÖKI Kft., Budapest, Hungary

approximately -35 kA, and the negative CG lightning current intensity increased linearly to 100 kA where latitude >27°N.

The current intensity of CG lightning in Yunnan Province was obviously affected by the combination of topography, terrain slope, and latitude. South of 23°N, the topography was mainly basins, river valleys, and hills with steep terrain slope, low elevation, and high 0 °C level height; thus, the current intensity of CG lightning was relatively strong. Regions between 23°N and 27°N were mainly basins and hills with less steep terrain slope and elevation of approximately 1900–2100 m; because of the decrease in 0 °C level height caused by more active cold air, the current intensity of CG lightning was relatively weak. North of 27°N were the snowy mountains with high elevation and steep terrain slope and river valleys with low elevation and steep terrain slope where forming convection currents was more difficult; therefore, the current intensity of CG lightning was obviously stronger.

Relationship between CG lightning activity and topography in the central Yunnan region

Previous analysis revealed that CG lightning activity was highly concentrated in basins and placid hills whose elevation was between 1500 and 2300 m with terrain slope <30°. Of these areas, the central Yunnan region was the most active for CG lightning activity. In this study, CG lightning data on more than 20,000 grids with a definition of 0.01° × 0.01° ranging within 101.6°N–103.6°E and 24.5°N–25.5°N were chosen and analyzed.

Figure 7a shows the variation in CG lightning density over elevation in central Yunnan and reveals that within the elevation range of 1100–2700 m, the average CG lightning density was positively linearly correlated with elevation ($R = 0.65$) because as elevation increased, the CG lightning density increased.

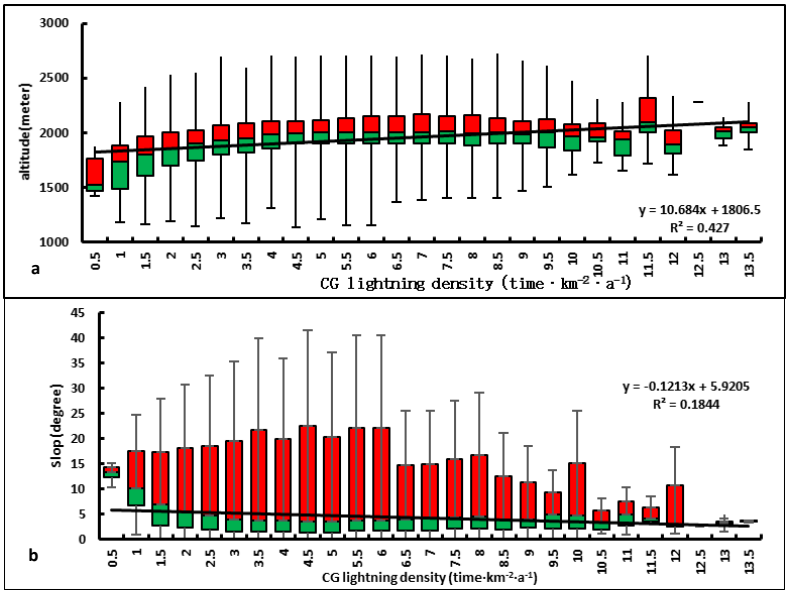

Figure 7. *Correlation between CG lightning densities with elevation and terrain slope in grid of 0.01°× 0.01° and using 0.5 time·km^{-2}·a^{-1} as intervals in central Yunnan. The variation range of CG lightning densities was 0.5-13.5 time·km^{-2}·a^{-1}; a: the correlation parameter of average CG lightning densities and elevation was 0.65; b: the correlation parameter of CG lightning densities and terrain slope was 0.43*

Furthermore, areas with a lower CG lightning density were mainly concentrated within the elevation range of 1400–1800 m, whereas areas with a higher CG lightning density were mainly concentrated within the elevation range of 1800–2000 m. However, the CG lightning density was inversely correlated with the change in the terrain slope (R = *0.43*). CG lightning activity with a density <6 events·km^{-2}·a^{-1} was vastly spread between terrain with slope ranging 3°–24°, whereas CG lightning activity with density >10 events·km^{-2}·a^{-1} was mainly distributed over the terrain with slope ranging 2°–12°.

The variation characteristics of current intensity of CG lightning over elevation in this region were generally the same as the variation characteristics of the entire province (see *Fig. 7b*); the current intensity of negative CG lightning was weaker, and the positive current intensity was approximately twice the negative current intensity. Additionally, as the elevation increased, the current intensity increased slowly. The variation in current intensity of CG lightning over terrain slope in this region was relatively complicated because the average negative current intensity initially increased and subsequently decreased, whereas the current intensity of positive CG lightning stabilized at 53–56 kA with terrain slope <20° and fluctuated violently with terrain slope >20° (*Fig. 8*).

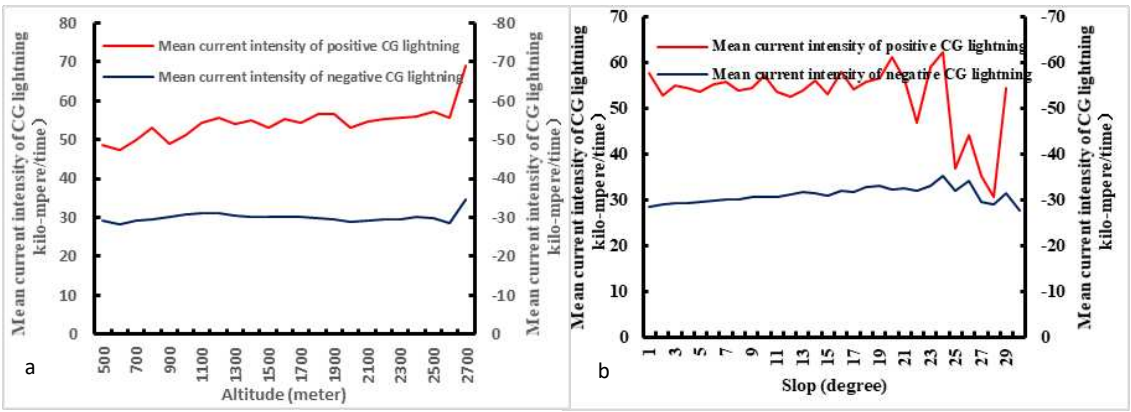

Figure 8. *Correlations between average current intensity of CG lightning, elevation, and terrain slope in 0.01°× 0.01° intervals in the central Yunnan region. a: Variation in current intensity with elevation; b: Variation in current intensity with terrain slope*

Relationship between CG lightning activity and topography in specific regions

CG lightning data, topography, and terrain slope of fixed zonal and meridional cross-sections along the central Yunnan region where CG lightning activity was dense were selected for further analysis. The east-west cross-section of 25.2°N was chosen for analysis of the synoptic systems and CG lightning activity, whereas the influence of the greater elevation and slope difference was analyzed using the north-south cross-section of 102.5°E. In *Figure 9a,* from east to west in the zonal cross-section, the elevation remained stable at approximately 2000 m and the CG lightning density in 101.6°E–103.6°E exhibited clear peaks, indicating that the main synoptic systems and the CG lightning densities exhibited a positive correlation within this longitude range. The CG lightning densities and terrain slope of the corresponding area exhibited a significant inverse correlation (see *Fig. 9c*) as the CG lightning densities increased and the terrain slope decreased, and vice versa. From the south to the north in the meridional cross-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_63496367
© 2018, ALÖKI Kft., Budapest, Hungary

section, the elevation fluctuated and increased from 23.4°N–25.5°N (see *Fig. 9b*) and exhibited a positive correlation with the corresponding CG lightning densities; however, the terrain slope initially increased and subsequently decreased within this area (see *Fig. 9d*) and was inversely correlated with the CG lightning densities. In summary, the CG lightning activity in Yunnan had a favorable correlation with the topography and terrain slope, particularly in the area between 101.6°E–103.6°E and 24°N–25.5°N because the CG lightning densities were correlated with elevation and inversely correlated with terrain slope. Furthermore, the effect of the large-scale strong convective synoptic systems was most significant in this same area.

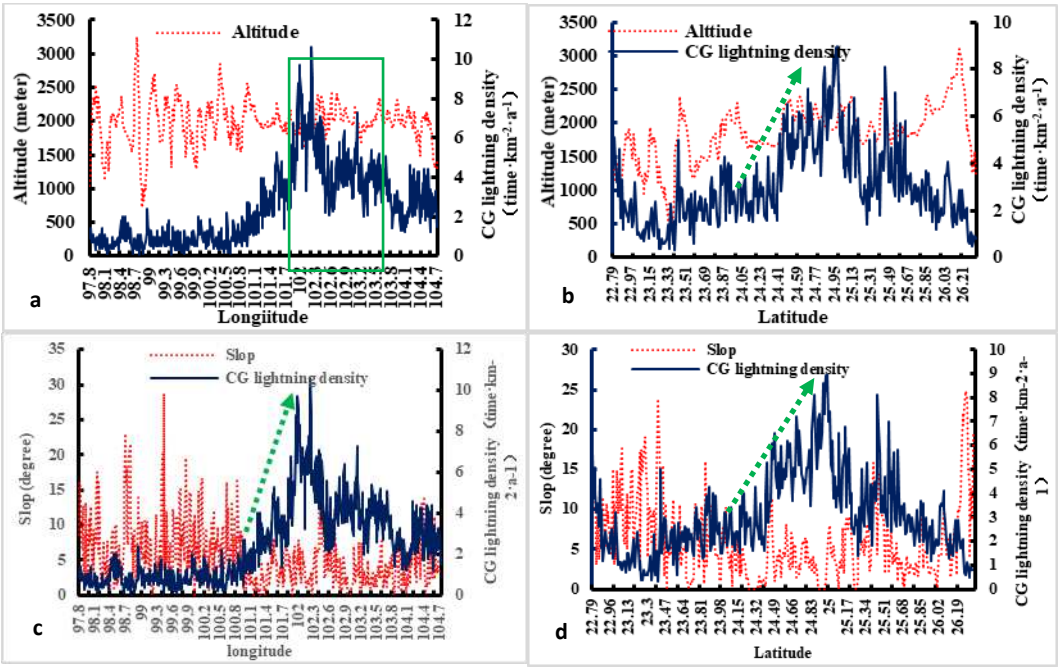

Figure 9. *Relationship between CG lightning densities and elevation and terrain slope along the zonal cross-section of 25.2°N and the meridional cross-section of 102.5°E. a: CG lightning densities and elevation in cross-section of 25.2°N; b: CG lightning densities and elevation in cross-section of 102.5°E; c: CG lightning densities and terrain slope in cross-section of 25.2°N; d: CG lightning densities and terrain slope in cross-section of 102.5°E*

Hourly variation characteristics of CG lightning activity at different elevations

Figure 10 shows the diurnal variation in the average CG lightning frequency in Yunnan from 2007 to 2016 with 100-m increments of elevation to further elucidate the contributions of the topography. The dense area of CG lightning is an elliptical shape 600–3500 m above sea level, indicating that as the elevation increases, the effect of the large-scale convection systems decreases. Low-elevation areas dominated by topography (<600 m) were night thunderstorm hotspots and generally occurred between 21:00 and dawn on the subsequent day. Affected by the topography, terrain slope, and elevation, the main forming and enhancement period of large-scale strong convective systems in Yunnan Province was between afternoon and midnight, which corresponded to the period of enhancement of convection caused by solar radiation (Xu et al., 2011; Zhang et al., 2013). The double influence of topography and large-scale strong convection system aggravated the CG lightning activity, resulting in the consistent

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

large-amplitude variation characteristics of CG lightning in Yunnan Province at 600–3500 m above sea level, and in low (high) elevation areas where elevation was lower than 600 m (higher than 3500 m), the effect of topography on CG lightning activity was more significant.

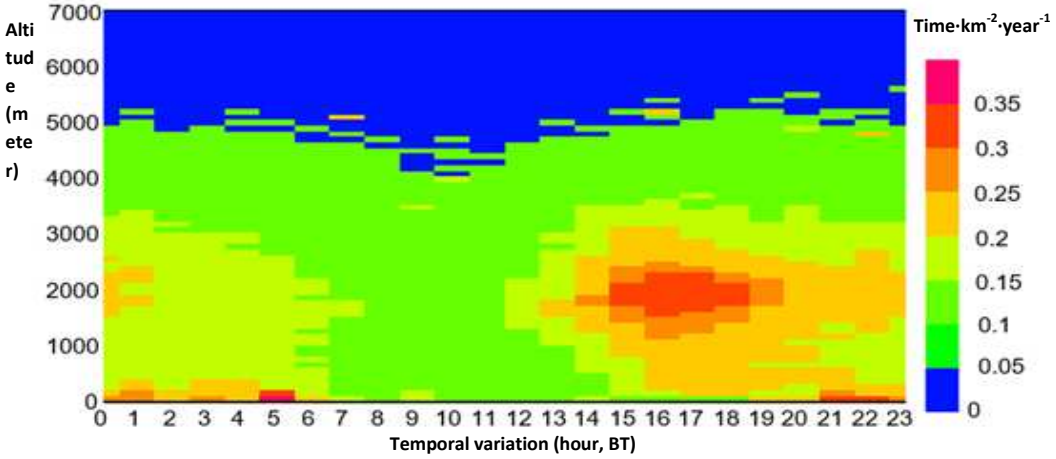

Figure 10. *Diurnal variation of the average CG lightning frequency (with elevation range from 0–7000 m and using 100 m as intervals)*

Discussion and conclusion

CG lightning activity was normally distributed along the variation in elevation, which centered on 2000 m above sea level and decreased on both sides and which exhibited linear inverse correlation characteristics between terrain slopes because when the terrain slope is less steep, the CG lightning activity is relatively dense. Regions of elevation <2300 m were generally basins, river valleys, or hills, and their corresponding CG lightning densities were approximately twice as high as those in regions whose elevation >2300 m. Within these regions, the uplift effect in areas with terrain slope from 30° to 59° could cause smaller peaks of CG lightning activity, and no significant CG lightning activity was observed in areas with terrain slope >60°. However, in regions where elevation >2300 m, the topography was mainly basins and large mountains. Furthermore, a blank zone was observed in areas with terrain slope 40°–50°, and only sporadic CG lightning activity was observed on the windward side of mountain areas with terrain slope >60°, indicating the substantial influence of topography on CG lightning activity. Furthermore, the results showed that the CG lightning activity in Yunnan Province initially increased and subsequently decreased with the increase of latitude, indicating that the influence of topography and large-scale synoptic systems was larger than the influence of variations in solar radiation along latitude.

The electric charge distribution in thunderstorms in Yunnan exhibited a typical positive dipole characteristic, and the average current intensity of positive CG lightning was significantly greater than that of negative CG lightning. Furthermore, the positive charge was located in the upper layers of the thunderstorm cloud; thus, the average current intensity fluctuated stably within a small range, 60–63 kA, as the elevation varied and the current intensity of negative CG lightning initially decreased and subsequently increased with the change in elevation and was inversely correlated with

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

CG lightning densities. The current intensity of CG lightning increased linearly with the increase of terrain slope, and the slope of variation of positive CG lightning was less than that of negative CG lightning, indicating that the effect of topography on the current intensity of negative CG lightning was more significant than that of the positive CG lightning in lower layers. The variation in intensity of CG lightning with latitude was inversely correlated with the variation in CG lightning density. South of 23°N, the current intensity was strongly affected by solar radiation and the relatively high 0 °C level height and greatly affected by the uplift effect of the large mountains. The current intensity was relatively strong north of 27°N. Within 23°N–27°N, affected by the impact of the large-scale synoptic systems and the low 0 °C level height, the current intensity was relatively weak.

The present study on the relationship between CG lightning activity and topography in central Yunnan, which is greatly influenced by large-scale synoptic systems, found a favorable positive correlation between the CG lightning density and elevation in the range 1100–2700 m; it was inversely correlated with the variation in terrain slope steeper than 40°. The variation in current intensity was essentially the same as reported in previous studies.

Analysis of CG lightning activity and topography in zonal and meridional cross-sections revealed that the CG lightning activity was positively correlated with elevation less than 2500 m, but was inversely correlated with terrain slope less than <15°.

Abstract. Various anaerobic environments exist in the Earth's ecosystem, which can produce a great deal of organic matter each year. In anaerobic habitats, bacterial sulfate reduction may occur due to the action of sulfate-reducing bacteria. As a result, hydrogen sulfide (H_2S) is formed. This paper focuses on sulfate-reducing bacteria and the revision of the activity characteristics of these bacteria in the reducing environment. It discusses the metabolic process of sulfate-reducing bacteria using sulphate and organo-sulfur compounds as sulfur source, the mechanism of bacterial sulfate reduction and H_2S formation mechanism. There are two main ways of H_2S formation in sulfate-reducing bacteria, the production of metabolic sulphate and the metabolic organo-sulfur compounds (mainly cysteine). The paper, combined with the activity characteristics of sulfate-reducing bacteria and the pathway of metabolic formation of H_2S, also discusses the circulation of sulfur in the environmental system of the Earth due to the action of sulfate-reducing bacteria, concerning the redox zone division in submarine sedimentary strata and landfills, the biogas formation phase of sulfate-reducing bacteria metabolism in sedimentary formations, and the bacterial sulfate reduction action in salt lakes (seawater) systems. Moreover, the production of hydrogen sulfide and the formation model of dolomite are both presented here. The findings support that sulfate-reducing bacteria are the most important biological source of H_2S production. The study of the physiological characteristics of sulfate-reducing bacteria and the formation mechanism of H_2S due to bacterial sulfate reduction can provide useful reference for the exploration of the laws of sulfur geochemical cycle and the rules of the ecological environment, which is essential for the protection of the natural environment and the restoration of polluted ecosystems, and can also provide a useful reference for the control of aerobic microorganisms.
Keywords: *microorganism, hydrogen sulfide (H_2S), bacterial sulfate reduction, formation mechanism*

Introduction

Hydrogen sulfide is mostly the product of the decomposition of organic matter under the microorganisms' action, the action of bacterial sulfate reduction (BSR), or the chemical process byproducts (Deng, 2017). The sulfate-reducing bacteria absorbs sulfate without the participation of oxygen, obtains energy from the oxidation of organic compound and discharges H_2S produced by the reduction of sulfate, which metabolic process is defined as bacterial sulfate reduction (Machel, 2001; Orr, 1974). The gaseous pollutant of H_2S mainly comes from man-made pollution and natural pollution. Man-made pollution mainly includes exploitation of petroleum, coal-bed methane, shale gas

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

etc, mining and non-ferrous metal smelting, low-temperature coking of coal, extraction of sulfur-containing substances, rubber, leather, dyes and other industrial production. Natural pollution often exists in many anaerobic environments in the Earth's ecosystems, such as underground pipeline, rice fields, industrial effluent, mud, swamps, lake bottom sediments, oil and gas wells, hot springs, landfills, and farm excretion, deposits and other venues (Martins et al., 2009).

The hazards of H_2S are mainly manifested in the following two aspects:

(1) Hazards to health. H_2S, a polar molecule, is highly toxic and flammable. It is colorless, smelly and prone to explosion. A small amount of H_2S in high concentration inhaled can be fatal to a person in a short time (Wei et al., 2014; Deng et al., 2018). And H_2S in low concentration affects the eye, respiratory and central nervous system badly. The physiological effects of H_2S concentration and contact time on human body are shown in *Figure 1* (Wei et al., 2014).

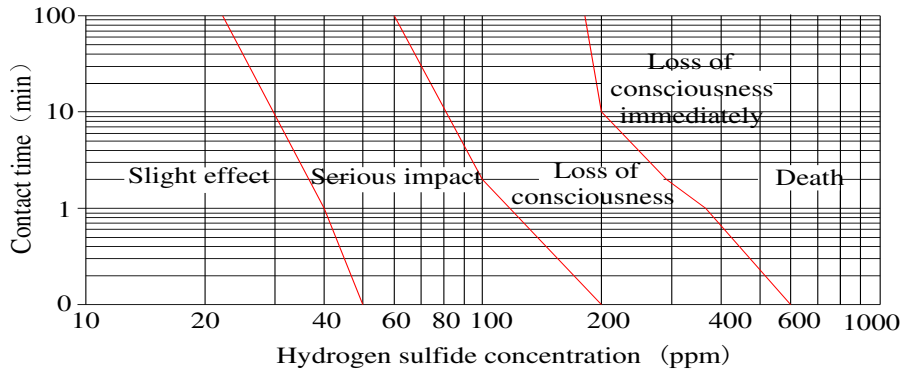

Figure 1. *Physiological influence to human of H_2S*

(2) Pollution to the environment. In the combustion process or in the atmosphere, H_2S will be quickly oxidized to sulfur dioxide, which will increase the concentration of SO_2 in the atmosphere to damage the plants and animals. Furthermore, it is also the main reason for the formation of acid rain (smog). Sulfate-reducing bacteria (SRB) is considered to be one of the main causes of corrosion of industrial equipment (Wei et al., 2014). H_2S in the water and air has a strong corrosion effect on concrete, electrical equipment, pipe networks, metals and plastics. When the H_2S content in the water exceeds 0.5 to 1.0 mg/L, it will cause great harm to the aquaculture (Ren et al., 2009).

H_2S is estimated to account for 100 million tons into the atmosphere per year in the world, of which about 3 million tons are produced annually by humans. The majority of the remaining H_2S produce naturally, mainly derived from the metabolic activities of producing H_2S sulfate-reducing bacteria. Therefore, SRB is the most important biological source for H_2S production. Therefore, the study on the physiological characteristics of SRB and the formation mechanism of H_2S under BSR can provide reference for revealing the laws of sulfur geochemical cycling and ecological environment.

Activity characteristics of SRB

The group SRB is heterotrophic and mixed that can utilise sulfates, sulfites, thiosulfates, sulfur, or other oxidized sulfides as electron acceptors to catabolize organic

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

materials and form H_2S (Gibson, 1990; Xiao et al., 2011). 18 genera and more than 40 species of SRB have been studied respectively. The names and characteristics of some genera are shown in *Table 1* (Ren et al., 2009; Liao, 2004). The common 9 genera mainly involve Desulfovibrio which does not produce spores and Desulfotomaculum which produce spores. The former is generally medium or low temperature, and it is likely to die when the temperature exceeds 43 °C. The latter is generally medium temperature or high temperature (Luptakova et al., 2005).

Table 1. *Characteristics of SRB*

Name	Features	Exercisability	Growth T (°C)
Desulfovibrio	No spores, curved rods	+	25-40
Desulfomicrobium	Rod-shaped, no spores	+/-	25-40
Desulfobollus	curved	+/-	
Desulfotomaculum	Straight or curved rod	+	25-40, 40-65
Desulfobacter	Round, rod-shaped, without spores	+/-	20-23
Desulfococcus	Spheroidal, no spores	-/+	28-35
Desulfosarcina	Stacking, without spores	+/-	33
Desulfoarculus	curved	+/-	
Desulfomonile	Rod-shaped, spheroidal	-	37
Desulfobulbus	Oval, shape of Lemon, No spores	-/+	25-40
Desulfacinum	Spheroidal or oval type		
Thermodesul fobocterium	Small shape, arc, rod		65-70
Desulfobacula	Oval		
Desul fonema	Screw shape, no spores	slide	28-32
Desulfobacterium	Round, rod-shaped	+/-	20-35

The group SRB is heterotrophic and mixed, and it survives in facultative anaerobic environment. The suitable grow temperature is between -5 and 75 °C. Some strains can grow below -5 °C, and some with spore species can withstand high temperatures of 80 °C. The optimum growth temperature for most mesophilic SRB is 28 ~ 38 °C, and some can grow in the condition of 45 °C (Larry, 1995). The surviving pH value of SRB is 4 to 9.5. Most SRBs are neutrophils. The most suitable pH is 6.5 ~ 7.8 (Vallero et al., 2005). SRB can survive in salinity greater than 1 g/L water. The best growth salinity is 100 g/L, and the upper limit reaches to 240 g/L. Some SRBs are halophilic, and they can be detected in some high-salt (such as salt lakes, the Dead Sea) ecosystems. Most of the halophilic bacteria isolated in the laboratory are mild halophilic bacteria (suitable salinity ranged from 1 to 4%), and rarely isolated moderately halophilic bacteria (Zhao et al., 1995). The growth of SRB is generally lower than -150 mV in Eh (Barton et al., 1995). Fe^{2+} is the active component of various enzymes in SRB cells. Decreasing the concentration of Fe^{2+} ions can reduce the growth rate of SRB.

The carbon sources used by different strains of SRB are different. The carbon source not only increases the amount of bioenergy required, but also acts as an electron donor to reduction and dissimilation sulfates. The most common source is the use of C_3, C_4 fatty acids. In addition, the sources as some volatile fatty acids and easily fermented substances are also applied. Stephenson et al. (Stephensonl et al., 1931) presented that

© 2018, ALÖKI Kft., Budapest, Hungary

hydrogenases contained in SRBs and (Jannasch, 1988) illustrated that 33 out of 39 SRBs can absorb hydrogen at 28 °C.

Formation mechanism of H_2S by SRB

SRB can produce H_2S by assimilation of sulfates, or degradation of sulfur-containing organics (mainly cysteine). The former has a small yield and is quickly assimilated into organic sulfur compounds. The latter, with a larger yield, is the main formation of H_2S (Luhachack et al., 2014).

The metabolic mechanism of sulfate as a sulfur source

The metabolic process of SRB with sulfate as sulfur source can be divided into three stages. Decomposition, electron transfer, and oxidation, as shown in *Figure 2* (Xu et al., 2009).

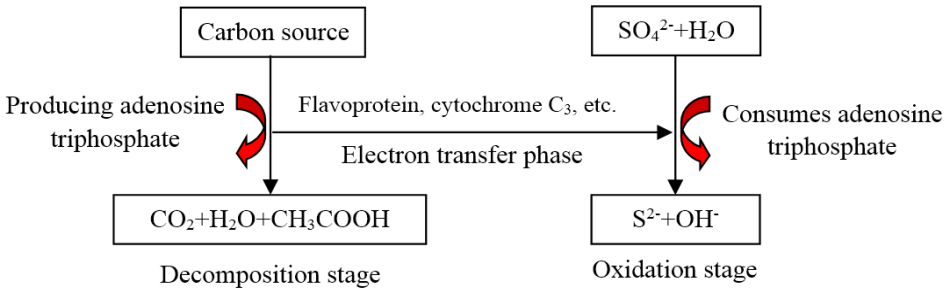

Figure 2. *The metabolic process of SRB with sulfate as a sulfur source*

(1) Decomposition stage. Sulfates are highly thermostable. Under anaerobic conditions, the sulfate ion (SO_4^{2-}) first accumulates out of cell and then enters the cell of SRB, while organics produce adenosine triphosphate (ATP) and energetic electrons through substrate level phosphorlation. Thereafter, SO_4^{2-} is activated by ATP sulfurylase to produce pyrophosphoric acid (PPi) and adenosine-5'-phosphosulfate (APS), PPi quickly decomposed into inorganic phosphate (Pi) (Zhao et al., 1997), stepwise reaction formulas are shown *Equation 1* and *2*, and total reaction formula is shown in *Equation 3*.

$$SO_4^{2-} + ATP + 2H^+ \xrightarrow{\text{ATP sulfurylase}} APS + PPi \quad \text{(Eq.1)}$$

$$PPi + H_2O \xrightarrow{\text{Pyrophosphatase}} 2Pi \quad \text{(Eq.2)}$$

$$SO_4^{2-} + ATP + 2H^+ + H_2O \rightarrow APS + 2Pi \quad \text{(Eq.3)}$$

(2) Electron transfer stage. In the previous stage, the energetic electrons released by energy are transferred step by step through SRB-specific electron transport chains (such as flavoprotein, cytochrome C_3, etc.). Affected by APS reductase, APS is continuously decomposed to sulfite and adenosine monophosphate (AMP). Sulfite is dehydrated into pyrosulfite ($S_2O_5^{2-}$). $S_2O_5^{2-}$ is extremely unstable and then would be converted to the intermediate dithionite ($S_2O_4^{2-}$). Afterwards, $S_2O_4^{2-}$ is rapidly reducted to trithionate

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_63696383
© 2018, ALÖKI Kft., Budapest, Hungary

($S_3O_6^{2-}$), and $S_3O_6^{2-}$ is broken down to thiosulfate ($S_2O_3^{2-}$) and sulphite (SO_3^{2-}). The reaction formula is shown in *Equations 4–6,* and the electron transfer is shown in *Figure 3* (Bradley et al., 2011).

$$\text{E-FAD} + \text{Electronic carrier (RED)} \leftrightarrow \text{Electronic carrier (OX)} + \text{E-FADH}_2 \quad \text{(Eq.4)}$$

$$\text{E-FADH}_2 + \text{APS} \leftrightarrow \text{E-FADH}_2(SO_3^{2-}) + \text{AMP} \quad \text{(Eq.5)}$$

$$\text{E-ADH}_2(SO_3) \leftrightarrow \text{E-FAD} + SO_3^{2-} \quad \text{(Eq.6)}$$

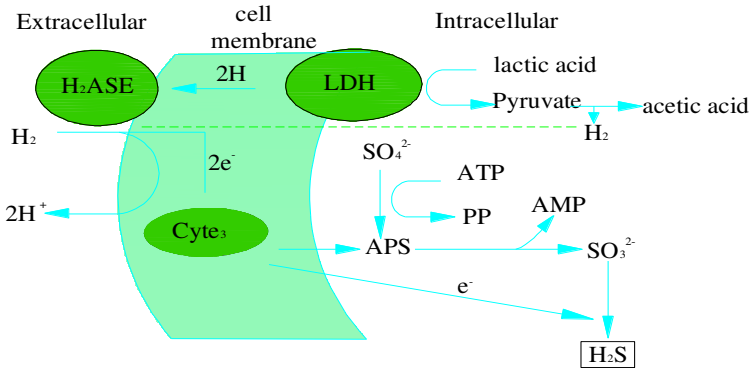

Figure 3. *Electron transfer process of SRB. ATP - adenosine triphosphate; PP - Polypyrrole; APS - adenosine-5'-phosphosulfate; AMP - adenosine monophosphate; LDH-lactate dehydrogenase*

(3) Oxidation stage. The electrons are transferred to the oxidized sulfur elements ($S_2O_3^{2-}$, SO_4^{2-}, SO_3^{2-}), which consume a lot of ATP. From SO_4^{2-} to S^{2-}, there are 8 electron transfers. ATP thiokinase catalyzes the adsorption of SO_4^{2-} to ATP phosphatase, which in turn forms APS. The sulfated portion of APS is directly reduced to sulfite and releases AMP. The initial product of sulfate reduction is sulfite. Once the sulfite is formed, the reaction process shown in *Figure 4* can be proceed (Bradley et al., 2011), finally producing H_2S, H_2S and the reaction formula is shown in *Equation 7*.

$$SO_4^{2-} + 8e^- + 10H^+ \rightarrow H_2S\uparrow + 4H_2O \quad \text{(Eq.7)}$$

The followings may be the reaction pathway from SO_3^{2-} to H_2S formation (Cai et al., 2009). (1) 3 consecutive two-electron transfer, forming $S_3O_6^{2-}$ and thiosulfate ($SO_3^{2-} \rightarrow S_3O_6^{2-} \rightarrow S_2O_3^{2-} \rightarrow S^{2-} \rightarrow H_2S$). (2) SO_3^{2-} directly lose 6 electrons, the above-mentioned intermediate product is not formed and is referred to as coordinated 6-electron reaction, namely $SO_3^{2-} + 6e^- + 8H^+ \rightarrow H_2S + 3H_2O$. (3) In the continuous two-electron transfer process, the reverse reaction may also occur. The reaction formula is shown in *Equation 8*.

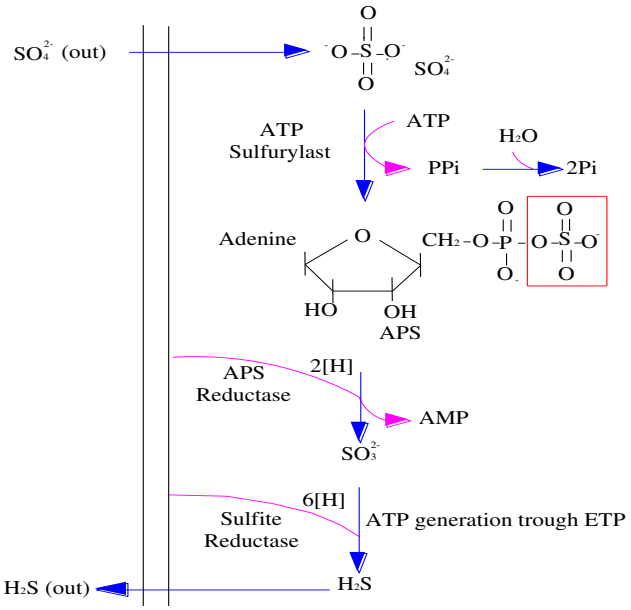

Figure 4. *Diagram of dissimilatory sulfate reduction. ATP - adenosine triphosphate; PPi - pyrophosphoric acid; Pi - inorganic phosphate; APS - adenosine-5'-phosphosulfate; AMP - adenosine monophosphate; ETP - electron transport particles*

SRB utilizes lactate as an electron donor and SO_4^{2-} as an electron acceptor for BSR action. There are three enzymes involved in the sulfite reduction process during the reduction of SO_3^{2-} to S^{2-}, namely $S_3O_6^{2-}$ forming enzyme, $S_3O_6^{2-}$ reductase or thiosulfate-forming enzyme and thiosulfate reductase. In BSR, SRB produces and accumulates large amounts of S^{2-} or HS^- in the cells. When the concentration of S^{2-} or HS^- in the cell reaches to a certain value, it will be released into the solution through the cell membrane, increasing the concentration of S^{2-} in the surroundings, which leads to the change in the redox potential of the environment and the concentration of related ions (Ren et al., 2009; Pérez et al., 2001). SRB metabolic H_2S formation process is shown in *Figure 5* (Peck et al., 1982).

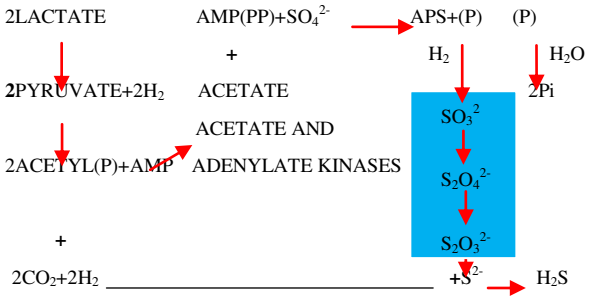

Figure 5. *Flowchart of SRB metabolism forming H_2S. Pi - inorganic phosphate; APS - adenosine-5'-phosphosulfate; P - Phosphorum*

The carbon of dibenzothiophene (DBT) as metabolic material is reacted with SRB to decompose the aromatic ring structure and form a sulfur-containing compound. The Kodama pathway is shown in *Figure 6* (Kodama et al., 2008).

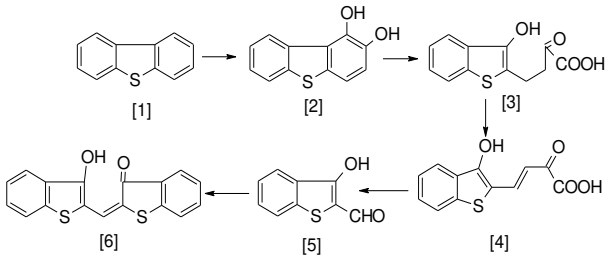

Figure 6. *Kodama pathway of metabolic mechanism of SRB use the carbon*

The metabolic mechanism of organo-sulfur compounds as a sulfur source

SRB is degraded by sulfur-containing organic substances (such as sulfur amino acids, cysteine, cysteine, sulfanilic acid, methionine, sulfonate, glutathione, etc.) as sulfur sources to produce H_2S. The degradation process differs depending on the types of SRB. Usually some SRBs will completely degrade some polymer-containing organic compounds to produce H_2S. Some will only degrade them into relatively low-molecular-weight sulfur-containing organic compounds such as mercaptans, and then other species. The SRB degrades it to the end product such as H_2S (Ren et al., 2001). The sulphur-containing organic degradation reaction can be summarized as shown in *Equation 9.*

$$\begin{array}{l} \text{R-SCH}_2\text{CHCOOH} \rightarrow \text{H}_2\text{S}\uparrow + \text{NH}_3\uparrow + \text{R-CH}_2\text{COOH} \\ \quad\quad | \\ \quad\quad \text{NH}_2 \end{array} \qquad \text{(Eq.9)}$$

The 4S pathway of sulfur metabolism (sulphoxide/sulphone/sulponate/sulphate) (Isbister et al., 1998). For different strains, the 4S pathway is not exactly the same, all of which have a common role in the C-S bond. For example, Rhodococcus sp. strain IGTS8 bacteria are considered to have two desulfurization pathways (Ma et al., 2000), as shown in *Figure 7.*

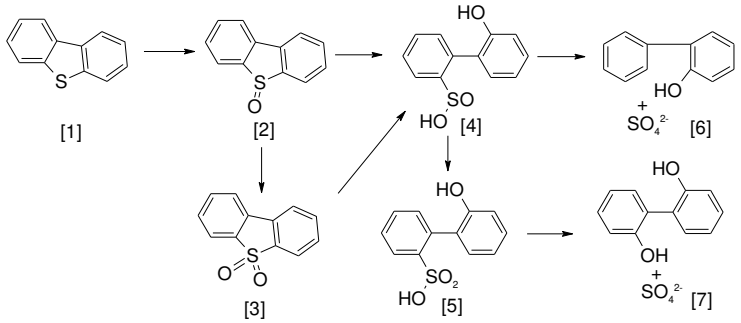

Figure 7. *The 4S pathway of Rhodococcus sp. strain IGTS8 bacterium*

The sulfur in DBT will generate SO_4^{2-}, SO_3^{2-} and 2, 2'- 2- Dihydroxybiphenyl or 2-hydroxybiphenyl and sulphur containing compounds after 4 steps.

Metabolic pathway of SRB

The sulfur cycle is an important geochemical cycle in the Earth's environmental system, and SRB plays an indispensable role in this system. The basic process can be described as the following (Rasch et al., 2000): when the onshore volcanic eruptions, sulfur in the earth's crust and magma is released into the atmosphere in the form of H_2S, sulfate and SO_2. Some of the sulfur emitted from the volcanic eruption of the submarine is dissolved in sea water and some of it is released into the atmosphere by gaseous sulfides. Sulfur in the atmosphere circulates through sulfuric acid or sulphate aerosols into the biosphere, pedosphere and hydrospheres. These sulphur compounds are then passively absorbed and assimilated by plants and animals. The absorbed sulfur forms the body of plants and animals. Animal and plant residues are decomposed by microorganisms, and sulfur becomes H_2S escaped into the atmosphere or deposited into peat. The reduction of sulphate in water is accomplished by reverse sulfidation of various sulfate-reducing bacteria. In the absence of oxygen, sulfates are produced into H_2S as hydrogen acceptors. Sulfate, H_2S and sulfur is mineralized under the common action of aqueous medium and organic matter to generate organic sulfide or inorganic sulfide. The sulfur cycle in global ecosystem is shown in *Figure 8* (Deng et al., 2013).

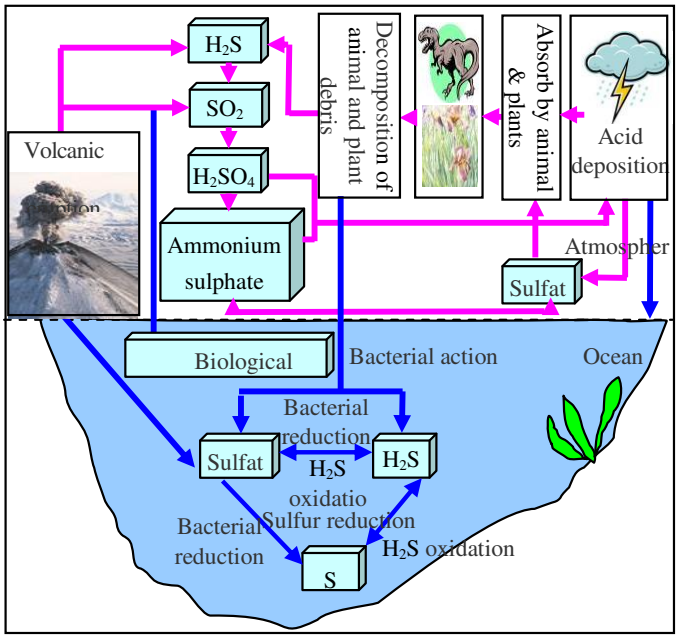

Figure 8. *Sulfur cycle in the Earth's environmental systems*

It has been known that due to the action of microorganisms, there are obvious redox zone from the top down of shallow sediment layers in the seabed, which can be divided into oxidation zone, weak oxidation zone, reduction zone and methanogenic zone in turn. The SRB is mainly distributed in the reduction zone in *Figure 9,* where it plays a dominant role and produces H_2S (Berner, 1981; Froelich et al., 1979).

There are also four sequential redox zones in the sulfate reduction zone, iron reduction zone, nitrate reduction zone and oxidation zone in landfill leachate sites, as shown in *Figure 10* (Zhou et al., 2008). The biocenosis structure in each zone has obvious bacterial species properties. Accordingly, sulfate-reducing bacteria, iron-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

reducing bacteria (IRB) and denitrifying bacteria (NRB) are the dominant bacterial groups. The distribution of redox zone and microbial flora indicates that there is a certain overlap between the redox zones, where the sulfate reduction zone is the main zone where malodorous gas (H_2S) is generated.

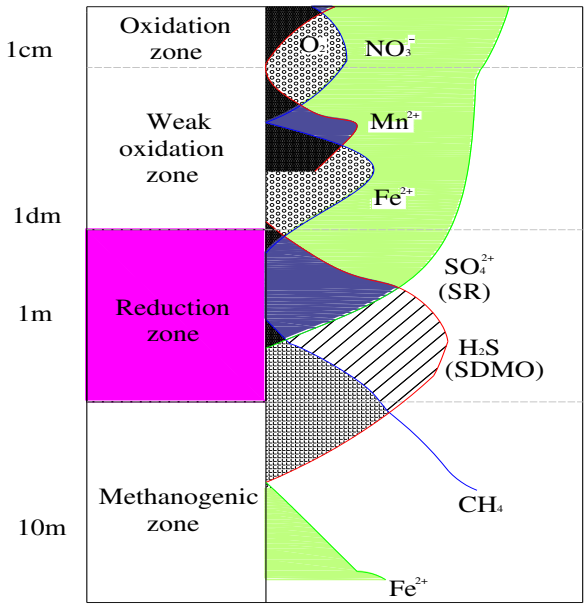

Figure 9. *SRB and redox zone division in submarine deposits*

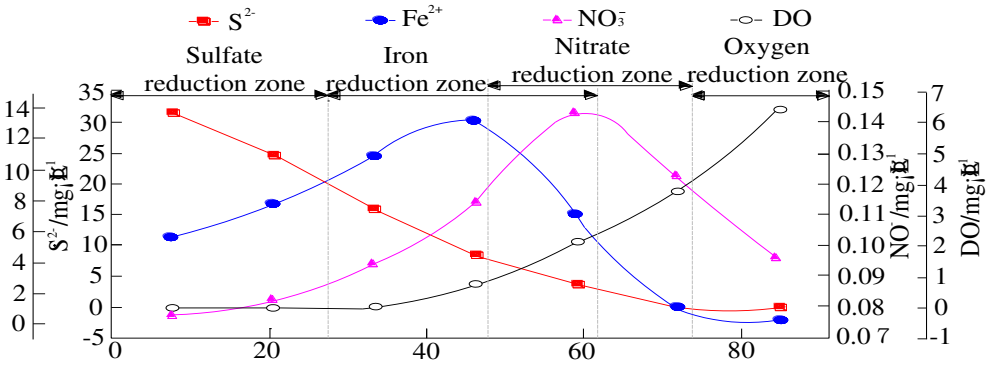

Figure 10. *Distribution of redox zones in landfills*

Organic sulfur compounds are produced mainly in humification stage. H_2S, CH_3SH, and (CH_3) S, S^0, or polysulfide compounds generated by the bacteria dissociation are oxidized to sulfates in an oxygen-rich environment. When the interface between the aqueous medium and the sediment exists in anoxic environment and the sulphate solubility reaches a certain value, SRB is metabolized by SO_4^{2-} as a sulphur source, and BSR works after decomposition, electron transfer and oxidation. The metabolic activity of SRB reduces the solubility of SO_4^{2-} and releases H_2S, HS^-, or S^0. HS^- or S^0 can react with organic matter to form organic sulfur, which can also react with iron ions to form pyrite. If the active iron ion is absent in the system and the SO_4^{2-} content is relatively

sufficient, a large amount of secondary organic sulfur compounds may be produced under suitable conditions, which is shown in *Figure 11* (Dai et al., 1996).

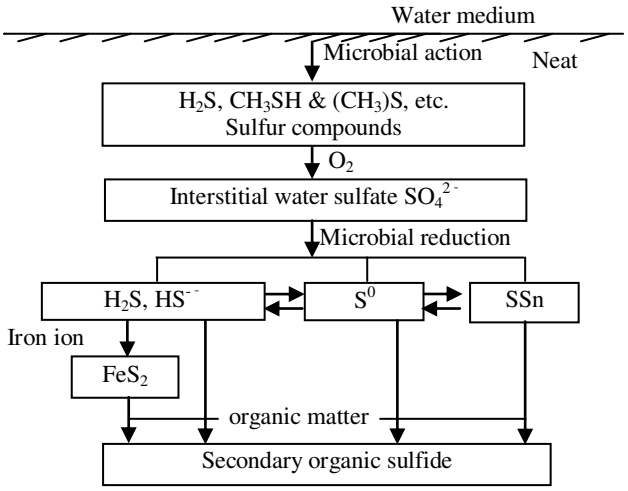

Figure 11. *The evolution of organic sulfur*

In sedimentary formations, due to the interaction between sedimentary factors and ecological factors, three different biological systems are formed, each of which is dominated by different microbial populations, namely the Aerobic microbial zones, sulfate reduction zones and organisms Methane generation zone. In the sulfate reduction zone, H_2S may be generated as shown in *Figure 12* (Lin et al., 2015).

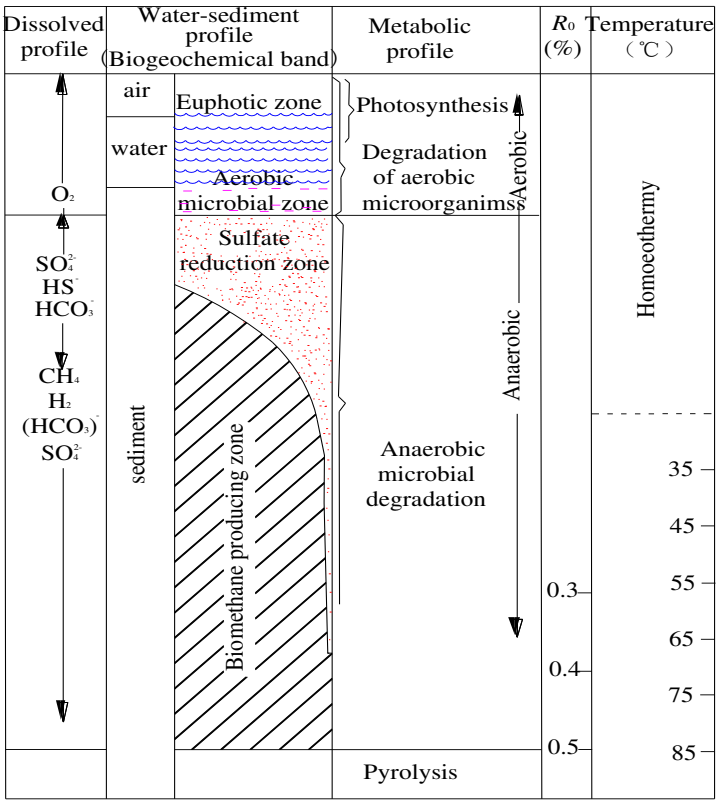

Figure 12. *Schematic diagram of biogenic gas phase in sedimentary strata*

(1) In a reducing environment, anaerobic sulfate-reducing bacteria reduce the sulfate in the water to form H_2S (*Eq. 10*).

$$SO_4^{2-}+2C+H_2O \xrightarrow{BSR} {}_2S\uparrow+4HCO_3^- \quad \text{(Eq.10)}$$

(2) In the oxygen-enriched oxidizing environment, biosulfur and sulfuric acid are formed under the action of sulfur oxidizing bacteria (*Eq. 11*).

$$2H_2S+O_2\rightarrow 2H_2O+2S,\ 2S+3O_2+2H_2O\rightarrow 2H_2SO_4 \quad \text{(Eq.11)}$$

(3) If the solution contains Fe^{2+}, native pyrite framboids and microbial dolomite will be appeared. The principle is that Fe^{2+} reacts with H_2S to produce pyrite (*Eq. 12*).

$$Fe^{2+} + S^{2-} \rightarrow FeS\downarrow \quad \text{(Eq.12)}$$

SRB has become an active participant in the early diagenesis process (Brüchert et al., 2001; Krause et al., 2012). Krause et al. found that in anoxic, low-temperature (21 °C) modern seawater (normal salinity and Mg^{2+}/Ca^{2+} values), BSR action occurs under the action of SRB, which can lead to the formation of H_2S and precipitation of dolomite. Its formation model is shown in *Figure 13*. The possible reaction formulas are shown in *Equations 13* and *14* (Glud et al., 1998).

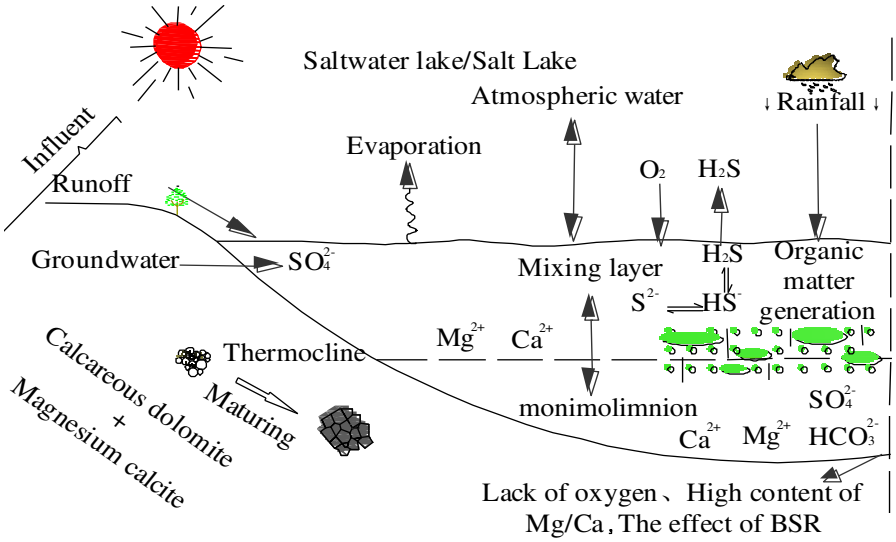

Figure 13. *Microbial mechanism model of primary dolomite in lake system*

$$2CH_2O + SO_4^{2-} \xrightarrow{SRB} S\uparrow + 2HCO_3^- \quad \text{(Eq.13)}$$

$$2HCO^{3-} + Mg^{2+} + Ca^{2+} \rightarrow CaMg(CO_3)_2 + 2H^+ \quad \text{(Eq.14)}$$

In the formation of dolomite and H_2S under the action of BSR in the salt lake (seawater) system, the SRB metabolic activity and intracellular reaction processes can be described as shown in *Figure 14* and *Equations 15–18* (Corzo et al., 2005).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_63696383
© 2018, ALÖKI Kft., Budapest, Hungary

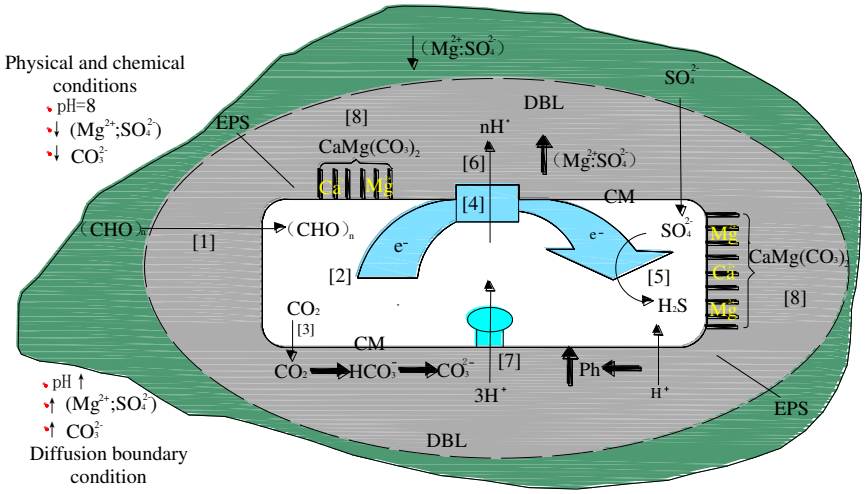

Figure 14. *SRB metabolic activity and intracellular reaction process. DBL - diffusion boundary layer; EPS - cell membrane and outer polymer matrix; CM - cell membranes*

$$2CH_2O + 2H_2O \rightarrow 2CO_2 + 4H_2 \quad \text{(Eq.15)}$$

$$CO_2 + H_2O \rightarrow HCO_3^- + H^+,\ HCO_3^- \rightarrow CO_3^{2-} + H^+ \quad \text{(Eq.16)}$$

$$SO_4^{2-} + 8e^- + 10H^+ \rightarrow H_2S + 4H_2O\ \text{(BSR)} \quad \text{(Eq.17)}$$

$$2CO_3^{2-} + Mg^{2+} + Ca^{2+} \rightarrow CaMg(CO_3)_2 \quad \text{(Eq.18)}$$

In the process of degrading organic matter, SRB in solution can reduce the SO_4^{2-} solubility, increase the concentration of Mg^{2+}/SO_4^{2-}, pH value, HCO_3^- concentration and dolomite saturation, and generate H_2S, which will produce a micro-environment conducive to the precipitation of dolomite. SRB cells, which are in the dark green area, are surrounded by the effective diffusion boundary layer (DBL) in the colour of the dark gray. The low-molecular-weight organic compounds in surroundings enter the cells [1], which are oxidized to CO_2 [2, e.g. (*Eq. 16*)] and released to DBL [3, e.g. (*Eq. 16*)]. The ions formed by the oxidation of organic matter pass through cell-electron-transporting cell membranes (CM) [4] to SO_4^{2-} and undergo a reduction to generate H_2S [5, e.g. (*Eq. 17*)]. The electron flow (H^+) migrates to the DBL[6] through the anaerobic respiratory chain, forming an electrochemical gradient across the cell membrane and stimulating H^+ entry via ATP synthetase. Hence, under fully constrained stoichiometry ($3H^+$. ATP), the H+ ion flux in these cells is coupled to ATP synthase [7]. Since these processes cause the cells to be negatively charged, Ca^{2+} and Mg^{2+} are adsorbed to the cell membrane and outer polymer matrix [8, e.g. *(Eq. 18)*] (Lith et al., 2010, 2003). Therefore, near the cell membrane and DBL, H_2S is formed and dolomite is produced and precipitated [8, e.g. (*Eq. 18*)].

Conclusion

In anaerobic (reduced) habitats, sulfate-reducing bacteria have a unique sulfate-reducing activity. The physiological characteristics and mechanism of H_2S formation not only provide a basis for revealing the biogeochemical cycle of sulfur elements,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

which is conducive to the protection of the natural environment and the restoration of polluted ecosystems, and also provide a useful reference for the control of aerobic microorganisms.

The metabolic reduction process of SRB, using sulfate and sulfur-containing organic material as sulfur source, is not only related to sulfate-reducing bacteria, but also closely related to non-sulfate-reducing microorganisms. A large number of sulfur sources metabolized by SRB are converted into soluble intermediate organic products that can be used by non-SRBs in the metabolic system.

In the earth system, there are many places of metabolism of sulfate-reducing bacteria. And under the metabolism of SRB, BSR may occur to form H_2S. The metabolites in various places are closely related to their micro-environment.

It finds that SRB is the most important biological source for H_2S production. The study on the formation mechanism of H_2S under BSR can provide meaningful reference for the disclosure of the geochemical cycle law of sulfur and the rules of the ecological environment, and supply with a helpful reference for the control of aerobic microorganisms.

(Received 31st May 2018; accepted 2nd Aug 2018)

Abstract. Very few studies are concerned with the medium and long-term soil nutrients of plantations, which often have inconsistent research results. This paper studied the characteristics of the surface soil nutrient changes in two types of plantations with different stand age: 30 years and 60 years. They are needle-leaved plantations (*Pinus thunbergii* plantation and *Pinus densiflora* plantation) and broad-leaved plantations (*Quercus variabilis* plantation). Research results showed: 1) When the stand age is 30 years, the content of organic matters and the nitrogen of the surface soil was presented as follows: *Pinus thunbergii* plantation>*Quercus variabilis* plantation>*Pinus densiflora* plantation, and the content of organic carbon, available phosphate and rapidly available potassium of the surface soil was presented as follows: *Quercus variabilis* plantation>*Pinus thunbergii* plantation>*Pinus densiflora* plantation. Significant differences were found in the content of active organic carbon in the surface soil. 2) When the stand age is 60 years, the content of organic matters, the total nitrogen and rapidly available potassium in the surface soil was presented as follows: *Pinus densiflora* plantation>*Quercus variabilis* plantation> *Pinus thunbergii* plantation and significant differences were found in the content of organic matters and total nitrogen of the surface soil. The content of active organic carbon in the surface soil was ranked as follows: *Pinus thunbergii* plantation>*Pinus densiflora* plantation>*Quercus variabilis* plantation. 3) Among the plantations with 60-year stand age, the content of five nutrients all increased in the surface soil of the *Pinus densiflora* plantation, namely, organic matters, active organic carbon, total nitrogen, available phosphorus and rapidly available potassium. The content of organic matters, total nitrogen and available phosphorus significantly increased in the surface soil, but no significant differences were found in the surface soil nutrient content of *Quercus variabilis* plantation and *Pinus thunbergii* plantation.
Keywords: *plantation, soil nutrient, organic matter, active organic carbon, total nitrogen, available phosphorus, available potassium*

Introduction

At the Asia-Pacific Regional Conference on Forest Restoration on March 26, 2018, Peng Y. D., deputy director of the State Forestry Administration, pointed out that as of 2017, China's plantation forest area was 693,300 km^2, ranking first in the world. Forest plantation is a major measure to recover the degraded ecosystem and conserve the ecosystem service functions (Togonidze and Akhalkatsi, 2015; Wei et al., 2017; Yin et al., 2018). In the forest ecosystem, the vegetation of plantations influences a lot of ecological processes above and below the ground, and plays a crucial role in maintaining the stability and diversification of the forest ecological system (Nilsson and Wardle, 2005). In the ecological restoration of the forest, the changes of soil nutrients have been a focus of the modern ecological research. Soil, an important component of

the forest ecosystem, provides necessary nutrients for the growth and propagation of plants as well as serves as carriers to the multiple ecological processes in the ecosystem (Trumbore and Czimczik, 2008). The status of forest soil nutrients is influenced by factors like climate, soil types and vegetation types together (Roy et al., 2010; Schmidt et al., 2015; Hedwall et al., 2015). Soil nutrients are important quantitative indexes of soil fertility, and they are crucial to the species composition and structural changes of vegetation. Moreover, they directly influence the productivity level of the ecosystem (Xu et al., 2008; Schmidt et al., 2015). The forest succession and the compound afforestation pattern obviously influence the soil fertility (Rutigliano et al., 2004; Hedwall et al., 2015). Vegetation influences the characteristics and development of the soil because the changes accompanying the vegetation succession, plant litters and root exudates directly influence the quantity of the input soil nutrients (Jia et al., 2005). Different development stages of plantations are throughout the whole life cycle of the forest growth. Therefore, it is of great ecological significance to understand the soil fertility of different development stages and the fertilizer requirement characteristics of forests in the plantation management. It could provide the scientific basis for the operation and management of the local plantations and evaluate the ecological consequences of the introduced exotic tree species.

The existing experimental research shows that broad-leaved species could immobilize more nutrients than coniferous species in the restoration of the forest the stand age of which is less than 30 years (Laganière et al., 2010; Li et al., 2012; Nave et al., 2013). However, the research ignores the changes of the soil nutrient storage in the restoration of the forest the stand age of which is over 30 years (Wang et al., 2016). Coniferous species are more difficult to resolve than broad-leaved species. Theoretically, the former is higher than the latter in the quantity of the immobilized soil nutrients (Vesterdal et al., 2008; Wang et al., 2016). These research inconsistencies reflect that: the soil nutrient data of the medium and long term plantations (trees whose stand age is over 30 years) are required for the research, especially those plantations with over 50 years of stand age because of their scarcity and preciousness (Bai et al., 2008; Gao et al., 2013).

Mount Meng is located in the low hilly areas of the central-south Shandong Province of China, and it is one of the two major ecological reserves in Shandong. Meanwhile, it is also a typical representative of the rocky mountain areas in northern China as well as one of the earliest areas to develop plantations in China. Typical plantations are *Pinus thunbergii* (black pine) plantation, *Pinus densiflora* (red pine) plantation and *Quercus variabilis* (cork oak) plantation (Gao et al., 2009, 2011, 2013). According to different forest types, studies relevant to surface soil nutrients and their dynamics are conducted, which helps to understand the surface soil nutrient supply of the forest ecosystem. This study will explore the soil surface nutrient changes of needle plantations (*Pinus thunbergii* plantation and *Pinus densiflora* plantation) and broad-leaf plantations (*Quercus variabilis* plantation) in terms of the stand age: 30 years and 60 years. The presupposed scientific hypotheses of the study are as follows: 1) Litters of coniferous species are more difficult to resolve than those of broad-leaf species. If the stand age of plantations are the same, more surface soil nutrients should be accumulated, namely, needle plantations are higher than broad-leaf plantations in the content of soil surface nutrients when their stand age are both 60 years. 2) The content of soil surface nutrients of plantations increases progressively along with the time, namely, the 60-year plantations have more soil surface nutrients than the 30-year plantations.

Materials and methods

Research sample plot

The research was conducted in typical areas of Mount Meng. Located in the warm temperate zone of the southeastern hilly areas in Shandong Province, Mount Meng covers an area of 1,125 square kilometers, and its soil is the brown forest soil. The research selected *Pinus thunbergii* plantation, *Pinus densiflora* plantation and *Quercus variabilis* plantation with two types of stand age—30a and 60a as research plots by investigating the community structure of wild plants and interviewing the technicians of the forest station in order to carry out the soil sampling. Forest in this area has been damaged by man-made for a long time. In 1949, only about 25 km^2 of forest was left, the forest coverage rate was less than 2%, and there were less than 300 plant species. The government has successively established 7 forest farms in Tashan, Wanshou Palace, Tianma, Mingguang Temple, Datun, Hailuo Temple and Tianbao Mountain to restore and reconstruct Mengshan vegetation from the 1950s to the 1980s.

Research methods

The sample plots were selected as follows: 12 sample plots of *Pinus thunbergii* plantation (6 sample plots with 30 years of stand age and 6 sample plots with 60 years of stand age), 12 sample plots of *Pinus densiflora* plantation (6 sample plots with 30 years of stand age and 6 sample plots with 60 years of stand age), and 16 sample plots of *Quercus variabilis* plantation (8 sample plots with 30 years of stand age and 8 sample plots with 60 years of stand age). The sampling area coordinates were 35°10'~36°00'N, 117°35'~118°20' E. The plot spacing is more than 1 km. There was no garbage in the plot, and the roots of the plant were dried when the soil sample was treated.

1 quadrat of 20 m × 30 m was selected in each sample plot, and the five-point sampling method was used to drill 5 repeated soil samples. The diameter of the earth boring auger was 3.5 cm and the sampling depth was 10 cm (Wang et al., 2017). Then, the repeated soil samples were mixed into one soil sample and taken to the lab. Sampling was conducted in August, 2016, and the lab was responsible for the assay determination of organic matters, active organic carbon, total nitrogen, available phosphorus and rapidly available potassium of the soil samples. According to the LY/T1237-1999 standard for the organic matters of forest soil, the external heating method of potassium dichromate was used for measuring the organic matters of soil, and the potassium permanganate oxidation method was adopted for measuring the content of active organic matters. According to the LY/T 1228-2015 standard of nitrogen measurement for the forest soil, the Kjeldahl nitrogen method was used to measure the content of total nitrogen. According to the LY/T 1232-2015 standard of phosphorous measurement for the forest soil, the colorimetric method was used for measuring the phosphorous content. According to the LY/T 1234-2015 standard of potassium measurement for the forest soil, the atomic absorption spectrophotometer was used for the rapidly available potassium measurement.

Statistical analysis

The single factor statistical method was used to analyze the soil nutrient differences of the forest type, and T test was applied to measure the soil nutrient differences of the

plantations with different stand age. SPSS 17.0 and Excel 2003 were used for the data analysis and table introduction.

Results and analysis

Organic matters of surface soil

In plantations with the same stand age but different forest types, the organic matter content was as follows: 1) when the stand age of plantations is 30 years, *Pinus thunbergii* plantations (33.03 ± 8.86 g·kg^{-1})>*Quercus variabilis* plantation (28.78 ± 5.33 g·kg^{-1})>*Pinus densiflora* plantation (24.40 ± 11.26 g·kg^{-1}). 2) when the stand age of plantations is 60 years, *Pinus densiflora* plantation (64.02 ± 11.06 g·kg^{-1})>*Quercus variabilis* plantation (46.6 ± 11.48 g·kg^{-1})>*Pinus thunbergii* plantations (29.20 ± 4.95 g·kg^{-1}). And *Pinus densiflora* plantation was significantly higher than the other two types of plantations in terms of the organic matter content (*Fig. 1A*).

In plantations with the same forest type but different stand age, the organic matter content of the surface soil was as follows: three plantations with 60 years of stand age had more organic matters than those with 30 years of stand age, where the *Pinus densiflora* plantation with 60 years of stand age is significantly higher than that with 30 years of stand age in terms of the organic matter content (*Fig. 1A*).

Active organic carbon of surface soil

In plantations with the same stand age but different forest types, the content of active organic carbon of surface soil was as follows: 1) when the stand age of plantations is 30 years, *Quercus variabilis* plantation (22.80 ± 1.87 g·kg^{-1})>*Pinus thunbergii* plantation (14.21 ± 2.22 g·kg^{-1})>*Pinus densiflora* plantation (12.06 ± 3.66 g·kg^{-1}), where *Quercus variabilis* plantation was significantly higher than the other two types of plantations in terms of the content of active organic carbon. 2) When the stand age of plantations is 60 years, *Pinus thunbergii* plantation (20.39 ± 0.34 g·kg^{-1})>*Quercus variabilis* plantation (20.30 ± 0.41 g·kg^{-1})>*Pinus densiflora* plantation (19.87 ± 0.34 g·kg^{-1}) (*Fig. 1B*).

In plantations with the same forest type but different stand age, the content of active organic carbon of surface soil was as follows: 1) the group of *Pinus thunbergii* plantation and *Pinus densiflora* plantation with 60 years of stand age were higher than the group with 30 years of stand age, while the *Quercus variabilis* plantation group with 60 years of stand age was lower than the group with 30 years of stand age in terms of the active organic carbon content (*Fig. 1B*).

Total nitrogen of surface soil

In plantations with the same stand age but different forest types, the content of total nitrogen of surface soil was as follows: 1) When the stand age of plantations is 30 years, *Pinus thunbergii* plantation (1.54 ± 0.44 g·kg^{-1})>*Quercus variabilis* plantation (1.43 ± 0.37 g·kg^{-1})>*Pinus densiflora* plantation (1.14 ± 0.32 g·kg^{-1}). 2) When the stand age of plantations is 30 years, *Pinus densiflora* plantation (2.56 ± 0.50 g·kg^{-1})>*Quercus variabilis* plantation (1.65 ± 0.34 g·kg^{-1})>*Pinus thunbergii* plantation (1.22 ± 0.23 g·kg^{-1}), where *Pinus densiflora* plantation was significantly higher than the other two types of plantations in terms of the total nitrogen content of surface soil (*Fig. 1C*).

In plantations with the same forest type but different stand age, the total nitrogen content of surface soil was as follows: the *Pinus densiflora* plantation group with 60 years of stand age was significantly higher than the group with 30 years of stand age in terms of the total nitrogen content, but the *Pinus thunbergii* plantation group with 60 years of stand age was lower than the group with 30 years of stand age. Contrarily, the *Quercus variabilis* plantation group with 60 years of stand age was higher than the group with 30 years of stand age in terms of the total nitrogen content of surface soil.

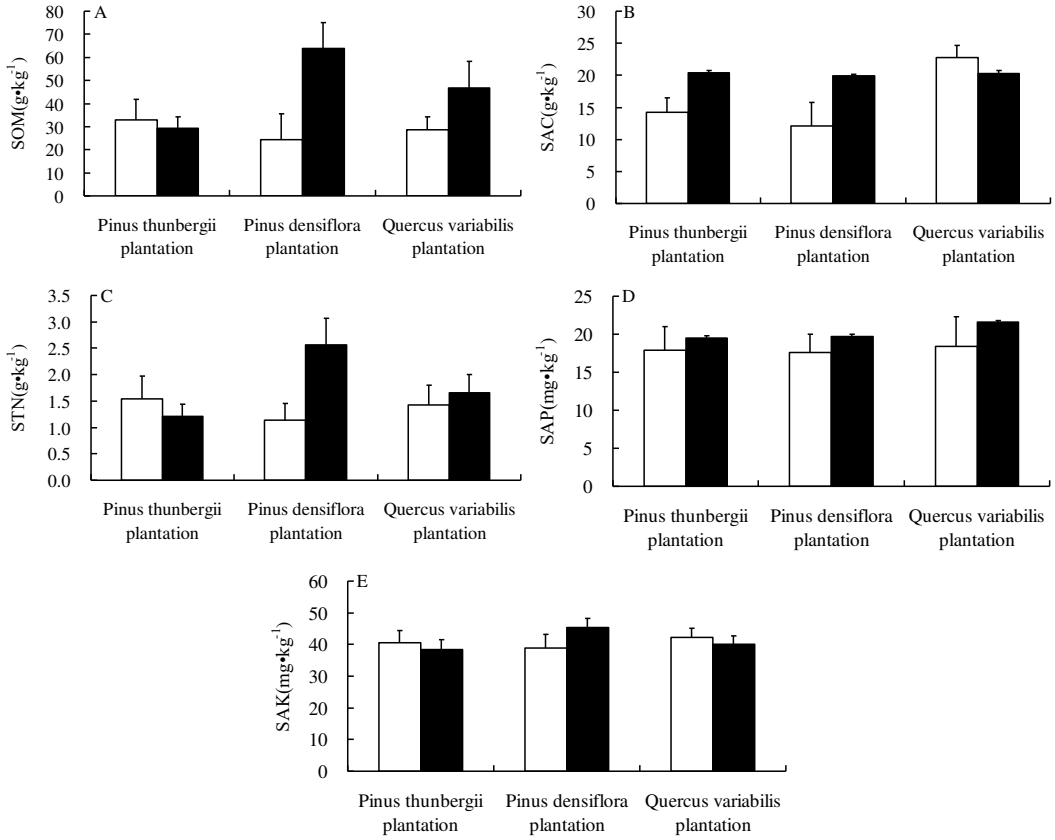

Figure 1. *Content difference of soil organic matter (SAM, A), soil active organic carbon (SAC, B), soil total nitrogen (STN, C), soil available phosphorus (SAP, D) and soil available potassium (SAK, E) of Pinus thunbergii plantation, Pinus densiflora plantation and Quercus variabilis plantation in 30 years of age and 60 years of age in Mount Meng (average + standard error). □ 30 years of age; ■ 60 years of age*

Available phosphorus of surface soil

In plantations with the same stand age but different forest types, the available phosphorus content of surface soil was as follows: 1) When the stand age of plantation is 30 years, *Quercus variabilis* plantation (18.43 ± 3.85 mg·kg^{-1})>*Pinus thunbergii* plantation (17.85 ± 3.15 mg·kg^{-1})>*Pinus densiflora* plantation (17.64 ± 2.38 mg·kg^{-1}). 2) When the stand age of plantation is 60 years, *Quercus variabilis* plantation (21.65 ± 0.18 mg·kg^{-1})>*Pinus densiflora* plantation (19.74 ± 0.21 mg·kg^{-1})>*Pinus thunbergii* plantation (19.55 ± 0.26 mg·kg^{-1}) (*Fig. 1D*).

In plantations with the same forest type but different stand age, the available phosphorus content of surface soil was as follows: 1) The three types of plantations with 60 years of stand age were higher than those with 30 years of stand age in terms of the available phosphorus content of surface soil, where the *Pinus densiflora* plantation group with 60 years of stand age had significantly more available phosphorus than the group with 30 years of stand age (*Fig. 1D*).

Rapidly available potassium of surface soil

In plantations with the same stand age but different forest types, the rapidly available potassium content of surface soil was as follows: 1) When the stand age of plantation is 30 years, *Quercus variabilis* plantation (42.20 ± 2.86 $mg \cdot kg^{-1}$)>*Pinus thunbergii* plantation (40.53 ± 3.93 $mg \cdot kg^{-1}$)>*Pinus densiflora* plantation (45.37 ± 2.77 $mg \cdot kg^{-1}$). 2) When the stand age of plantation is 60 years, *Pinus densiflora* plantation (45.37 ± 2.77 $mg \cdot kg^{-1}$)>*Quercus variabilis* plantation (40.09 ± 2.64 $mg \cdot kg^{-1}$)>*Pinus thunbergii* plantation (38.43 ± 3.15 $mg \cdot kg^{-1}$) (*Fig. 1E*).

In plantations with the same forest type but different stand age, the rapidly available potassium content of surface soil was as follows: 1) in terms of the rapidly available potassium content, the *Pinus densiflora* plantation group with 60 years of stand age was higher than the group with 30 years of stand age, while the other two types of plantations with 60 years of stand age were lower than those with 30 years of stand age (*Fig. 1E*).

Principal component analysis of soil nutrients

The accumulative variance contribution rates of the first and second principal components respectively reached 81.05% and 80.81% in Mount Meng's plantations with 30 years and 60 years of stand age as shown in *Tables 1* and *2,* which revealed the majority of information. In Mount Meng's plantations with 30 years and 60 years of stand age, the first principal component was closely relevant to organic matters, total nitrogen, available phosphorus and rapidly available potassium, with the accumulative variance contribution rates being 59.85% and 59.05% as shown in *Table 1* and *Figure 2A*. In Mount Meng's plantations with 30 years and 60 years of stand age, the second principal component was closely relevant to the active organic carbon of the soil with the accumulative variance contribution rates being 21.20% and 21.76% as shown in *Table 2* and *Figure 2B*.

Table 1. *Soil nutrients of 30a plantation in principal component analysis in Mount Meng, China*

	SAM	**SAC**	**STN**	**SAP**	**SAK**
Main component 1	0.95	–0.11	0.91	0.88	0.70
Main component 2	0.05	0.98	–0.09	0.28	–0.15

The total explanatory power of two principal components was 81.05%, where principal component 1 and principal component 2 were 59.85% and 21.20%, respectively

SAM: soil organic matter; SAC: soil active organic carbon; STN: soil total nitrogen; SAP: soil available phosphorus; SAK: soil available potassium

Discussion

The differences of the surface soil nutrients in the forest are largely influenced by the types of vegetation. They are mainly reflected like this: plant litters and root exudates keep supplementing the surface soil nutrients and energy substances (Hedwall et al., 2015; Jia et al., 2005). Litter is an important structure and functional unit of material circulation and energy flow in the forest ecosystem (Jia et al., 2016). As the folia of needle-leaved trees have more lignin content (Wang et al., 2009) and relatively less leaf area than broad-leaved trees (Wang et al., 2004; Guo et al., 2006), the litter decomposition rate gets limited, thus influencing the nutrient return rate of litters. Some research shows that: when the stand age is the same, the soil of broad-leaved threes has more nitrogen than that of needle-leaved trees. It is thought that a large quantity of deciduous input and quicker litter decomposition rates could be used to explain why broadleaved trees are higher than needle leaved trees in terms of the topsoil fertility in the broadleaved deciduous forest (Jiang and Xu, 2006; Laganière et al., 2010). We suggest that for plantations with similar environmental backgrounds, *Pinus densiflora* are more suitable than *Pinus thunbergii* and *Quercus variabilis* in terms of maintaining soil nutrients when selecting tool species.

Conclusion

The research found that: when the stand age is 60 years, the content of organic matters, total nitrogen and rapidly available potassium was presented in a descending order: *Pinus densiflora* plantation>*Quercus variabilis* plantation>*Pinus thunbergii* plantation, and the content of active organic carbon was as follows: *Quercus variabilis* plantation>*Pinus densiflora* plantation>*Pinus thunbergii* plantation. The content of available phosphorus was as follows: *Quercus variabilis* plantation>*Pinus densiflora* plantation>*Pinus thunbergii* plantation. The research result relevant to *Pinus densiflora* plantation and *Quercus variabilis* plantation supported the first research hypothesis.

When the stand age of *Pinus densiflora* plantation changes from 30 years to 60 years, the content of surface soil nutrients all increased, including organic matters, active organic carbon, total nitrogen, available phosphorus and rapidly available potassium, where the content of organic matters, active organic carbon, total nitrogen, available phosphorus significantly increased. The research result relevant to *Pinus densiflora* plantation basically supported the second research hypothesis.

Abstract. Under the impact of climate change, extreme events occur frequently and the speed of alternation of drought and flood gets faster. Based on the daily rainfall data of 42 meteorological stations for the years 1963-2013, Haihe River basin in China was divided into four sub-regions (region A, region B, region C, region D) by means of cluster analysis of the meteorological stations using the self-organizing map (SOM) neural network method. The drought index of the number of consecutive days without rainfall was used to identify the drought magnitudes and the first rainfall intensity and the maximum daily rainfall after a drought period was analyzed with the Pearson-III frequency curve, then the relationship between rainfall intensity and different drought magnitudes was observed. The results indicated that: (1) Annual rainfall reduced significantly and the drought number increased in the Haihe River basin, meanwhile the occurrence frequency of different drought level showed an overall increasing trend. This region was dominated by light drought, with the probability as 76%, while the probability of moderate drought was about 20%. The spatial difference was significant. The occurrence frequencies of moderate drought and severe drought were higher in region A. The frequency of extraordinary drought was the most in region B as 0.35%. (2) As the drought level increased, the probability of the first effective rainfall reaching heavy rain decreased in region A, region B and region C, while the probability increased in region D. With the increase of the drought number, rainfall frequency decreased and rainfall intensity enhanced obviously.
Keywords: *frequency analysis, evolution characteristics, drought, rainfall, climatic change, Haihe River basin, semi-arid area*

Introduction

Under the impact of climate change, the occurrence frequency and strength of extreme climate events, such as heavy rain, flood and drought has shown an increasing trend as a result of atmospheric circulation anomaly (Burke et al., 2001). Meanwhile, extreme drought and flood events have occurred frequently and widely in the Haihe River basin in China in recent years (Yan et al., 2013). These disasters can create the huge economic loss and the society affects, creating a new challenge for disaster risk management. Rain is a key factor in the occurrence of droughts and floods, as the

© 2018, ALÖKI Kft., Budapest, Hungary

variation of rainfall intensity determines the intensity and range of droughts and floods (Zavareh, 1997). With the speeding alternating drought and flood (Feng et al., 2012), there is an intensive and concentrated rainfall after a long duration of drought (Yan et al., 2013; Feng, 2014). The change of rainfall intensity after drought is the most important for water resources management.

A large number of scholars have studied the temporal and spatial evolution characteristic and driving mechanism of drought events and higher rainfall, such as the drought evaluation method based on the long series of observational rainfall data (Cancelliere et al., 2007; Łabędzki, 2010; Palmer, 1965) and hydrological frequency analysis method based on Pearson-III frequency curve (Narasimhan and Srinivasan, 2005) used to scale the drought severity. Based on the components of water cycle, drought is characterized by meteorological drought, soil moisture drought, hydrological drought, socio-economic drought and ecological drought (Tallaksen, 2009; Huijgevoort, 2012). As such a complex phenomenon, it requires multiple climatological and hydrological parameters to calculate (Mishra and Singh, 2010). Moreover, due to the arid conditions and low precipitation patterns, Haihe River basin is susceptible to drought in crop growing season. Therefore, this paper used consecutive rain-less days as the standard to identify the start and end day of drought released by the Ministry of Water Resources of the People's Republic of China. In a wide range of frequency analysis method, the Pearson-III frequency curve is the most used curve, which is widely applied in hydrological frequency analysis in China. Most studies focused on the analysis of the spatial-temporal distribution of floods and droughts, while little analysis regarding the rainfall intensity change patterns following the drought exists. Thus, this article selected the daily rainfall data of 42 representative meteorological sites in Haihe River from 1963 to 2013, and the basin was divided into four sub-regions by SOM neural network method. The drought index of continuous rain-less day was used to determine the drought degree. The first effective daily rainfall and the maximum daily rainfall following the drought were analyzed with the Pearson-III frequency curve, and then the relationship between rainfall and drought magnitudes was shown.

Materials and methods

Description of the study area

The Haihe River basin includes Beijing, Tianjin, Hebei, Shanxi, Shandong, Henan, Inner Mongolia, Liaoning provinces and is located within the geographic coordinates of 112°-120°E and 35°-43°N. The total area of the basin is 318,000 km^2, including the mountainous area of 189,000 km^2 and the plain area of 129,000 km^2. This basin belongs to the temperate zone and semi-humid continental climate. Annual rainfall is 536 mm and it shows a negative trend. It suffers from drought risk frequently in China. Annual rain is mainly concentrated in the summer monsoon season and average monthly rainfall between June and August accounts for 50-75% of annual rainfall. In particular, heavy rain mostly occurs in July and August, leading to flood as one of the most water logging areas. The flood frequency between 1970 and 1994 is more than 45 times in the basin. The frequent drought and flood disasters are attributed to uneven seasonal distribution of rainfall and its inter-annual variability, which directly affects the sustainable development and property safety.

In this paper, the rainfall data for 42 meteorological stations with continuous observation series in and around the Haihe River basin for the years 1963 to 2013

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_63956407
© 2018, ALÖKI Kft., Budapest, Hungary

provided by China National Climate Center were selected to analyze the drought and higher rainfall. The numbers of consecutive days without rainfall for both inter-annual and inter-decadal periods were determined.

Clustering methods of SOM and division

Due to the geographical position of the meteorological stations, the altitude and rainy features differ throughout the basin. Thus, meteorological stations within the basin with similar features require the clustering analysis. In this paper, the longitude and latitude of each meteorological station, as well as their respective altitudes and annual mean rainfall were selected for the cluster analysis by the SOM (self-organizing map) neural network algorithm.

A homogeneous area refers to the rainy characteristics of various meteorological sites in the area that are similar and their spatial distribution is even (Gwo-Fong and Lu-Hsien, 2006). The result of regional frequency analysis is representative and credible if the stations in the region belong to a homogeneous area. Using rainfall data for meteorological stations in the homogenous area is more accurate than using rainfall data at single station to analyze regional frequency. Therefore, the SOM neural network algorithm was selected to process the rainy data of 42 meteorological sites and Haihe River basin was divided according to the clustering results.

This article selected the longitude (m), latitude (m), the average annual rainfall (mm), 5-9 monthly rainfall (mm) as eight variables on behalf of regional rainy characteristics, and carried on the normalized processing. Training steps directly influence the performance of the SOM neural network clustering. The greater the training steps are, the more precise classifications are. This article carried on the classification of 42 meteorological sites in the basin and the basin was divided into four regions based on the cluster result with training steps as 2. The results of spatial classification were shown in *Table 1* and the locations of these stations were shown in *Figure 1*.

Drought magnitude standards

Less rain or no rain for a long time lead to drought and no effective continuous rainfall days are used to characterize the drought magnitude in crop growing season. Consecutive rainless days refer to the number of consecutive days without rainfall. Based on the standard of the classification for drought severity released by the Ministry of Water Resources of the People's Republic of China, the drought evaluation criteria are shown in *Table 2* as follows: If consecutive rain-less days last for 15 to 30 days, it belongs to the light drought; If consecutive rain-less days last for 31 to 50 days in a row, it belongs to the moderate drought; If consecutive rain-less days last for 51 to 75 days, it belongs to severe drought; If consecutive rain-less days exceed 75 days, it belongs to the extraordinary drought.

Pearson-III frequency curve

Pearson-III frequency distribution model has been widely applied in the field of hydrology and meteorology. This distribution is the third of 13 types of distribution curves which is put forward by the British biologist Pearson. Pearson-III frequency curve is asymmetric unmoral and skew normal distribution curve which one end is limited and the other end is unlimited. It refers to gamma distribution and the probability density function is as follows (*Eq. 1*):

$$f(x)=\frac{\beta^{\alpha}}{\Gamma(\alpha)}(x-b)^{\alpha-1}e^{-\beta(x-b)}(b\le x<\infty) \quad \text{(Eq.1)}$$

Where $\Gamma(\alpha)$ is gamma function, $\Gamma(\alpha)=\int_0^{\infty}x^{\alpha-1}e^{-x}dx;\alpha,\beta>0$. Three original parameters *α, β, b* can be converted appropriately, and can be shown as three statistical parameters $\bar{x}$, C_v, C_s (*Eqs. 2, 3* and *4*):

$$\alpha=\frac{4}{C_s^2} \quad \text{(Eq.2)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_63956407
© 2018, ALÖKI Kft., Budapest, Hungary

$$\beta = \frac{2}{\bar{x} C_V C_S} \quad \text{(Eq.3)}$$

$$b = \bar{x}(1 - \frac{2C_v}{C_S}) \quad \text{(Eq.4)}$$

where C_v is dispersion coefficient; C_S is deviation factor; $\bar{x}$ is the average. The three statistical parameters can be determined primarily by the moment's method. Moment method is used to calculate the three statistical parameters of the formula which is as follows (*Eqs. 5, 6* and *7*):

$$\bar{x} = 1/n \sum x_i \quad \text{(Eq.5)}$$

$$C_V = \sqrt{\frac{\sum (k_i - 1)^2}{n-1}} \quad \text{(Eq.6)}$$

$$C_s = \frac{\sum (k_i - 1)^3}{(n-3) C_v^3} \quad \text{(Eq.7)}$$

Adding these undetermined parameters into the equations of Pearson-III type curve, the equation is written as (*Eq. 8*):

$$y = f(\bar{x}, C_v, C_s, x) \quad \text{(Eq.8)}$$

The division of rainy intensity

According to the national 24-h rainfall standard, rainfall is divided into light rain, moderate rain, heavy rain, rainstorm, heavy rainstorm and extraordinary rainstorm. If total rainfall during 24 h is less than 10.0 mm, it is light rain; if between 10.0 and 24.9 mm, it is moderate rain; if between 25.0 and 49.9 mm, it is heavy rain; if between 50.0 and 99.9 mm, it is rainstorm; if between 100.0 and 249.0 mm, it is heavy rainstorm; if more than 250.0 mm, it is extraordinary rainstorm. Considering water availability, light rain and heavy rainstorm are not effectively used for crops and sometimes cause natural disasters. Thus, in the paper, only effective rainfall (including moderate rain, heavy rain, rainstorm) was use to analyze its relationship between drought.

Results and discussion

The analysis of drought in the Haihe River basin

Time evolution characteristic of droughts

According to no effective rainy days in a row, the sum of the drought frequency in different regions in the Haihe River basin was calculated. The results indicated that drought frequency showed an increasing trend in the Haihe River basin from 1963 to 2013. The total drought frequency increased at a rate of 2.23% per year in 18 meteorological stations of region A, the total drought frequency increased at a rate of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_63956407
© 2018, ALÖKI Kft., Budapest, Hungary

about 7.8% per year in 12 meteorological stations, 8.9% per year in 9 meteorological stations, 2.5% per year in 3 meteorological stations, respectively in region B, region C and region D. Drought frequency increased notably in region A, while it increased more slowly in region D. Region A was the economic society center of the basin, and the increase of no-rainfall day seriously affected the crop growth and the social and economic development.

Space evolution characteristic of droughts

According to no effective rainy days, the drought frequency in four areas under different drought degree was calculated between 1963 and 2013 as shown in *Table 3*. It could be seen that region A, region B, region C and region D were all given priority to light drought which accounted for about 75% of the total number of drought, the second was moderate drought, and the probability of extraordinary drought occurred least. The probability of moderate drought and severe drought in region A was higher than that of region B, C and D, and the probability of extraordinary drought was the largest in region B with 0.35%.

Table 3. *The proportion of different drought numbers of regional total numbers during 1963 to 2013*

Drought degree	Region A		Region B		Region C		Region D	
	Frequency	Proportion (%)	Frequency	Proportion (%)	Frequency	Proportion (%)	Frequency	Proportion (%)
Light drought	2468	74.70%	1748	76.23%	1277	78.15%	464	76.07%
Moderate drought	692	20.94%	452	19.71%	300	18.36%	125	20.49%
Severe drought	133	4.03%	85	3.71%	55	3.37%	21	3.44%
Extraordinary drought	11	0.33%	8	0.35%	2	0.12%	0	0

The analysis of rainfall frequency after drought in Haihe River basin

The frequency of multi-yearly mean effective rainfall

Only effective rainfall is available for crops. Thus, the paper used the Pearson-III curve to only analyze the frequency of multi-yearly mean effective rainfall in each subarea of the Haihe River basin, and the probability of the moderate rain to heavy rain was calculated but probably sum of rainfall percentage within a region was less than 100%. According to Pearson-III frequency curve, the probability of the multi-yearly mean effective rainfall was different and the results were illustrated in *Table 4*.

Table 4. *The frequency of multi-yearly mean effective rainfall in different areas*

Subarea	Moderate rain (%)	Heavy rain (%)	Rainstorm (%)	Heavy rainstorm (%)
Region A	9.65	2.24	0.2	0
Region B	12.57	3.78	0.54	0.02
Region C	15.3	5.54	1.1	0.06
Region D	13.99	4.82	0.88	0.04

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_63956407
© 2018, ALÖKI Kft., Budapest, Hungary

The probability of moderate rain, heavy rain, rainstorm and heavy rainstorm was 9.65%, 2.24%, 0.2% and 0 for region A, 12.57%, 3.78%, 0.54% and 0.02% for region B, 15.3%, 5.54%, 1.1% and 0.06 for region C, 13.99%, 4.82%, 0.88% and 0.04% for region D, respectively.

The frequency of the first effective rainfall after different drought degrees

This paper used consecutive rain-less days as drought standard and the first effective rainfall after drought period to represent the rainfall intensity at the end of the drought. The crop growing season in Haihe River basin was from May to September and in the periods the droughts and floods occurred frequently, causing disasters for the most important cash crop of summer corn growing. Thus, the first effective rainfall after different drought degrees during the growing season of crops was calculated. For further analysis, Pearson-III was used to analyze the frequency of the first effective rainfall after drought with different magnitudes in each subarea.

This paper only took region A as an example to analyze the first effective rain frequency after different drought degrees. *Figure 2* listed the Pearson-III curve after different droughts for region A. The results were as follows: The probability of moderate rain, heavy rain, rainstorm and heavy rainstorm after light drought were 39.02%, 9.65%, 1.26% and 0.33%, respectively shown in *Figure 2a*. From the Pearson-III curve for moderate drought in *Figure 2b,* it illustrated that the respective probabilities of moderate rain, heavy rain, rainstorm and heavy rainstorm were 40.85%, 8.28%, 0.7% and 0.13%. As shown in *Figure 2c* of the Pearson-III curve for severe drought, the respective probabilities of moderate rain, heavy rain, rainstorm and heavy rainstorm were 38.06%, 9.28%, 1.17% and 0.3%. From the Pearson-III curve of extraordinary drought in *Figure 2d,* the respective probabilities of moderate rain, heavy rain, rainstorm and heavy rainstorm were 50.25%, 7.97%, 0.12% and 0.

The rainfall frequencies after drought with different magnitudes in the other subareas for the years 1963-2013 were shown in *Table 3*. We presented the frequency of first effective rainfall after a drought period in sub-areas in *Table 5*. The effective rainfall did not include light rain (total rainfall during 24 h is less than 10.0 mm) and extraordinary rainstorm (total rainfall during 24 h is more than 250.0 mm), which could not been used and managed effectively for crops in growing seasons. Thus, the sum of frequency in different clusters was less than 100% within one region in case of all drought degrees.

From *Table 3* it was concluded that in region A, for the light and moderate drought, the occurrence frequency of moderate rain increased, then reduced and finally increased. The probability of moderate rain was the maximum after extraordinary drought at 50.25%, while the frequency for heavy rain first reduced, then increased and finally reduced, and the frequency for heavy rain was the least after extraordinary drought. In region B, for the light and moderate drought, the frequency for moderate rain decreased continuously, while the probability of rainfall after drought was higher than region A. In region C, for the the light and moderate drought, the occurrence frequency for moderate rain increased, while for the extraordinary drought, the occurrence frequency for moderate rain increased obviously. In region D, for the light and moderate drought, occurrence frequency of moderate rain increased significantly and the occurrence frequency for heavy rain first reduced, then increased and finally reduced. The probability of flood disaster of the first effective rainfall after severe drought was the most in region D.

In summary, from the analysis of the probability of the first effective rainfall after the different degrees of drought, it was concluded that with the increase in drought magnitude, the probability of extraordinary rainstorm, in the Haihe River basin became lower in region A, region B and region C, however, the probability of extraordinary rainstorm increased in region D. With the increase in drought magnitude, the probability of different degrees of rainfall in different areas showed different trends. In region A, for the light and moderate drought, the occurrence frequency for moderate rain first reduced, then increased and finally reduced. In contrary, for region B, it showed a continuously decreasing trend. In region C and D, for the light drought and moderate drought, the occurrence frequency for moderate rain first reduced and then increased.

Compared with the probability of multi-yearly mean effective rainfall, it presented that the probabilities of moderate rain, heavy rain, rainstorm, heavy rainstorm were 9.65%, 2.24%, 0.2% and 0, respectively in region A. However, the respective probabilities of moderate rain, heavy rain, rainstorm, heavy rainstorm of the first effective rainy after light drought were 39.02%, 9.65%, 1.26% and 0.33%, the respective probabilities of moderate rain, heavy rain, rainstorm, heavy rainstorm of the first effective rainfall after moderate drought were 40.85%, 8.28%, 0.7% and 0.13%, those of the first effective rainfall after severe drought were 38.06%, 9.28%, 1.17% and 0.3% and after extraordinary drought were 50.25%, 7.97%, 0.12% and 0. The probability of the first effective rainy after drought was relatively higher than that of multi-yearly mean effective rainfall in region B, region C and region D. The results showed that the probability of heavy rain for the first effective rainfall after drought was strongly higher and it was easy to suffer flood disaster after droughts.

The frequency of maximum daily rainfall after different drought degrees

Pearson-III curve was used to analyze the frequency of the maximum daily rainfall after droughts with different magnitudes in each subarea of the Haihe River basin. The results of the frequency of maximum daily rainfall after droughts in region A were presented in *Figure 3*. Based on the Pearson-III curve of light drought, the probability of moderate rain was 62.47%, that of heavy rain was 23.96%, that of rainstorm was 5.19% and that of heavy rainstorm was 1.83%, respectively. For the moderate drought, the respective probabilities of moderate rain, heavy rain, rainstorm and heavy rainstorm reached 58.2%, 23.73%, 6.48% and 2.76%. For the Pearson-III curve of severe drought, the respective probabilities of moderate rain, heavy rain, rainstorm and heavy rainstorm were 72.02%, 35.61%, 10.17% and 4.17%. Moreover, for the Pearson-III curve of extraordinary drought, the respective probabilities of moderate rain, heavy rain, rainstorm and heavy rainstorm were 81.75%, 60.46%, 23.64% and 8.81%, respectively.

The rainfall frequencies after drought with different magnitudes in the other subareas for the years 1963-2013 were listed in *Table 6*. In this table, it was concluded that in region A, for the light drought and moderate drought, the occurrence frequency for moderate rain first reduced then increased and the frequency for rainstorm increased continuously. In region B, for the light drought, moderate drought and severe drought, the occurrence frequency for moderate rain decreased continuously. On the contrary, the occurrence frequency for rainstorm increased obviously after moderate drought. With the increase of drought degree, the occurrence frequency for heavy rain increased significantly. In region C, for the light drought magnitude, the occurrence frequency for heavy rain decreased continuously. With the increase of drought degree, the occurrence frequency for moderate rain increased significantly. Region D showed the same trend as region C.

Generally, from the analysis of the probability of the maximum daily rainfall after different droughts, it was concluded that with the increase in drought magnitude, the probability of heavy rainstorm after drought increased. However, with the increase in drought magnitude, the probability of different degrees of rainfall in different areas showed different characteristics. The whole trend showed that for the light and moderate drought magnitude, the occurrence frequency for moderate rain first reduced and then increased in the four subareas for region A, region B, region C and region D generally. The probability of rainfall after moderate drought was lower than other degree of drought in region A, region C and region D, while the probability of rainfall after severe drought was notably lower than other degree of drought in region B.

Compared with the probability of multi-yearly mean effective rainfall in *Table 2,* the results indicated that the respective probabilities of moderate rain, heavy rain, rainstorm, heavy rainstorm were 9.65%, 2.24%, 0.2% and 0 in region A for the multi-yearly average. However, the respective probabilities of moderate rain, heavy rain, rainstorm, heavy rainstorm of the maximum daily rainfall after light drought could reach up to 62.47%, 23.96%, 5.19% and 1.83%, those after moderate drought 58.2%, 23.73%, 6.48% and 2.76%, those after severe drought 72.02%, 35.61%, 10.17% and 4.17% and those after extraordinary drought 81.75%, 60.46%, 23.64% and 8.81%, respectively, in *Table 4*. Furthermore, in the same way, the probability of the maximum daily rainfall after drought was significantly higher than multi-yearly mean effective rainfall in region B, region C and region D. The results showed that the probability of heavy rain for the maximum daily rainfall after drought was higher and the region there was more vulnerable to suffer flood disaster after drought.

Conclusions

In recent years, extreme climatic events such as alternating droughts and floods, sharp transitions between droughts and floods, and floods following extreme droughts, have been a research hotspot. This paper analyzed the relationship between drought and rainfall intensity through the rainfall frequency after different drought magnitudes based on the daily rainfall data from 42 stations for the years 1963-2013 in the Haihe River basin in northern China. The conclusions were as follows:

(1) Annual rainfall showed a dramatical reduction trend in the Haihe River basin and drought frequency increased. The result was consistent with the finding that the mean values of daily precipitation declined, and its fluctuation became weak with years by Sang (2014). Drought numbers for region A increased the most at a rate of about 0.223 times per year. The region was dominated by light drought. The probability of light drought and moderate drought were 76% and 20%, while that of extraordinary drought was the least.

(2) With the increase in drought magnitude, the probability of extraordinary rainstorm of the first effective rainfall became lower in region A, region B and region C, however, the probability of extraordinary rainstorm increased in region D. And with the increase of drought degree, the probability of extraordinary rainstorm of the maximum rainfall in A, B, C, D four regions increased significantly. Compared with the probability of multi-yearly mean effective rainfall, the probability of heavy rain to heavy rainstorm of the first effective rainfall was 4 to 5 times than the multi-yearly mean effective rainfall and the probability of heavy rain to heavy rainstorm of the maximum rainfall was 9 to 10 times than the multi-yearly mean effective rainfall.

Based on the frequency levels of different rainfall after different droughts in the region, we evaluated that more rainfall happened after higher drought and a dry-wet alternation happened frequently. With the increase of the drought numbers, rainfall frequency decreased and the rainfall intensity enhanced obviously. This result was consistent with the findings of Zhang (2014) that the frequency of extreme precipitation was decreasing, but the intensity of extreme precipitation was increasing in the Huang-Huai-Hai River basin, and moreover, the probability distribution functions of simple daily intensity index and consecutive dry days were positively shifted while the rest of the indices were negatively shifted. Because the flood in the basin was primarily caused by the intensive heavy rainstorm, the Haihe River basin was in higher frequency of simultaneous flood and drought disasters and more vulnerable to the impact of climatic change.

(Received 31st May 2018; accepted 13th Sep 2018)

Abstract. Two-year-old seedlings of *Pinus* species typical in North China (*Pinus thunbergii*, *Pinus tabuliformis* and *Pinus koraiensis*) were selected as the research object. The water extracted from the litter of *P. thunbergii*, *P. tabuliformis* and *P. koraiensis* were used to test the changes of photosynthetic pigment Chl. a, Chl. b and allelochemicals. The results were as follows: aqueous extract of *P. thunbergii* needle litter had significantly low inhibition on *P. thunbergii* while strongly inhibited *P. tabuliformis* and *P. koraiensis*. It also showed a markedly low inhibition on *P. thunbergii*, a moderate inhibition on *P. tabuliformis*, and a greatly strong inhibition on *P. koraiensis*. Obviously strong inhibition on *P. thunbergii*, *P. tabuliformis* and *P. koraiensis* were observed as well. Our study showed that pine needle water leaching solutions, such as *P. tabuliformis*, *P. thunbergii* and *P. koraiensis*, significantly inhibit their Chl. a and Chl. b, and will be a norm, which provides a new explanation for the decline in the coniferous forests of northern China.
Keywords: *Pinus thunbergii, Pinus tabuliformis, Pinus koraiensis, allelopathy, Chl. a, Chl. b*

Introduction

Allelopathy refers to the process that those chemical substances produced by plants, which can have beneficial or detrimental effects on the growth of the plants themselves or other plants around, are released into the environment through leaching, volatilization, stubble degradation and root excretion, (Peng and Shao, 2001; Kong et al., 2002; Zhou et al., 2004). Studies on allelopathy have dramatically increased since the 1970s and have undergone rapid development since the 1990s. In recent years, the research has become a hot topic in the fields of botany, ecology, agronomy and soil science (Albuquerque et al., 2011; Cheng and Cheng, 2015). At present, allelochemicals mean basically secondary metabolites. The most common allelochemicals are organic acids, phenols and terpenoids (Yan et al., 2000; Chen et al., 2015).

Allelopathy exists widely in nature and significantly affects forest community succession, vegetation restoration and forestry production (Li et al., 2010; Albuquerque et al., 2011; Cheng and Cheng, 2015). Conifers are important timber and afforestation species in China. In recent years, many coniferous plantations have faced such problems as productivity decline, soil degradation and natural regeneration obstacles. The traditional view is that this phenomenon is caused by rotation, inappropriate harvesting

© 2018, ALÖKI Kft., Budapest, Hungary

methods, harvesting residues, tillage and land preparation (Chen et al., 2003; Wang et al., 2007). However, in recent years, convincing evidence has showed that allelopathy may be the key factor affecting the natural regeneration of coniferous forests. Allelochemicals can be transported to the ground through pine needles and litters (Kimura et al., 2015), which will limit the growth of seedlings and herbaceous plants (Kil and Yang, 1983; Kato-Noguchi et al., 2011) and will impede the regeneration of the stands (Pan et al., 2009; Wang et al., 2007). Researches on the allelopathy of the main afforestation species in northern China can provide important theoretical and practical guidance for the management and survival of regional man-made forests.

The type and dose of allelochemicals released by plants to the environment are decided by combined effects, namely the plant itself and environmental factors. Environmental stress can increase the release of allelochemicals (Albuquerque et al., 2011). Therefore, both the environment and the plant itself must be taken into consideration in the study of allelopathy. *P. thunbergii*, *P. tabuliformis* and *P. koraiensis* are the main afforestation species in northern China (Wei et al., 2017; Yin et al., 2018). At present, only few studies focus on the allelopathic effects of *P. thunbergii* tissue and understory extracts on Brassica rapa pekinensis (Zhang et al., 2012), litter leaf and soil extract on seed germination and seedling growth of *P. koraiensis* (Chen et al., 2016), Allelopathic effects on the growth and photosynthesis of *P. tabuliformis* seedlings (Jia et al., 2003), the autotoxicity of *P. tabuliformis* (Li et al., 2010), the allelopathic effect of *P. tabuliformis* soil in the Loess Plateau (Zhu et al., 2014), and the allelopathic effect of *P. tabuliformis* root in Hilly Loess Plateau (Wang et al., 2015), etc. There is no study focusing on the interaction between *P. thunbergii*, *P. tabuliformis* and *P. koraiensis*. In this research, 2-year-old seedlings of *P. thunbergii*, *P. tabuliformis* and *P. koraiensis* were selected for the pot experiment to study the effects of water and aqueous solution of *P. thunbergii* pine needles, *P. tabuliformis* pine needles and *P. koraiensis* pine needles. Changes of Chl. a, Ch. b, allelochemicals, also total triterpenes in seedlings were examined after 30 days.

Materials and methods

Testing materials

The pine needle litter of *P. thunbergii* and *P. tabuliformis* was collected from Tianmeng area of Mountain Meng, China. All target trees grew in a natural environment, with a height of about 10 m, and a diameter of about 15 cm. The pine needle litter of *P. koraiensis* was purchased from Hunchun seedling breeding base in Jilin, China. *P. thunbergii* and *P. tabuliformis* seedlings were purchased from the seedling breeding base of Junan County in Linyi city, China, the seedlings were about 0.5 m in height and 1.5 cm in diameter. *P. koraiensis* seedlings were purchased from Hunchun seedling breeding base in Jilin, China, the seedlings were about 0.5 m in height and 1.5 cm in diameter. The pot experiment was conducted at the science exploration laboratory base in Linyi, China.

Testing method

1) Five 600 m^2 *P. thunbergii* and *P. tabuliformis* sample plots were set up, and a 1 m^2 litter box was placed in each plot; 2) From January 2017 to July 2017, pine needles in the collection boxes of *P. thunbergii* and *P. tabuliformis* were packaged and transferred to the laboratory and summarized for natural drying; 3) From July 25 to August 25, 2017, pine needle litters of *P. thunbergii*, *P. tabuliformis* and *P. koraiensis* were soaked; 4) From July

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_64096417
© 2018, ALÖKI Kft., Budapest, Hungary

20 to August 25, 2017, *P. thunbergii*, *P. tabuliformis* and *P. koraiensis* seedlings were potted; 5) From August 25 to September 25, 2017, the seedlings of *P. thunbergii*, *P. tabuliformis* and *P. koraiensis* were inoculated in pots. Four treatments (clean water control group, *P. thunbergii* needle water leaching solution treatment group, *P. tabuliformis* needle water leaching solution treatment group and *P. koraiensis* needle water leaching solution treatment group) were set for each of the three young pine trees. Five plants were cultivated in parallel. 100 mL water or pine needles water leachate was added to the young pine trees every 5 days for 6 times, a total volume of 600 mL was used; 5) On September 25, all pine needles were sampled and sealed in bags for inspection.

Determination method

Determination of Chl. a and Chl. b content

0.1 g pine needles were weighed, cut and placed into the mortar. More than 15 mL absolute ethanol was added to the mortar until the total volume of the liquid was 25 mL. These solutions were stored in the dark for 24 h and then were filtered. The pigment's optical density was measured by a spectrophotometer 721 at a wavelength of 665 nm and 649 nm, and the content Chl. a and Chl. b were calculated.

Determination of total triterpene content

After extraction and centrifugation of the pine needles the sample solution was filtered through a 0.3 μm membrane filter. The residue was separated on a C_{18} column by high performance liquid chromatography. The mobile phase was $(NH_4)_2HPO_4$-H_3PO_4 buffer solution (pH = 2.7). For detection a UV detector at 210 nm was used. External standard method was performed for the determination of total triterpene content. The test was completed in the Environment Laboratory of Scistd Testing Qingdao Branch, China.

Data processing

Excel 2003 and SPSS 17.0 Chinese version were used for processing, and one-way analysis of variance was performed.

Results

Effects of 4 kinds of treatment on the Chl. a content in 3 kinds of seedlings

Groups of *P. thunbergii* seedlings for Chl. a content test: clean water control group> *P. thunbergii* needle water leaching solution treatment group> *P. tabuliformis* needle water leaching solution treatment group> *P. koraiensis* needle water leaching solution treatment group. *P. thunbergii* needle water leaching solution treatment group, *P. tabuliformis* needle water leaching solution treatment group and *P. koraiensis* needle water leaching solution treatment group showed significantly lower results than clean water control group ($P < 0.01$, $P < 0.01$, $P < 0.01$), and *P. koraiensis* needle water leaching solution treatment group showed significantly lower results than *P. thunbergii* needle water leaching solution treatment group and *P. tabuliformis* needle water leaching solution treatment group ($P < 0.01$, $P < 0.01$) (Fig. 1A).

needle water leaching solution treatment group and *P. thunbergii* needle water leaching solution treatment group had no significant difference (Fig. 1C). *P. koraiensis* needle water leaching solution, *P. tabuliformis* needle water leaching solution and *P. thunbergii* needle water leaching solution had a significant allelopathic effect on *P. tabuliformis* seedlings.

Groups of *P. koraiensis* seedlings for total triterpene content test: *P. koraiensis* needle water leaching solution treatment group> *P. thunbergii* needle water leaching solution treatment group> *P. tabuliformis* needle water leaching solution treatment group>clean water control group. *P. koraiensis* needle water leaching solution treatment group and *P. thunbergii* needle water leaching solution treatment group showed significantly higher results than clean water control group ($P < 0.05$, $P < 0.05$), while *P. tabuliformis* needle water leaching solution treatment group and clean water control group had no significant difference (Fig. 1C). *P. koraiensis* needle water leaching solution and *P. thunbergii* needle water leaching solution had a significant allelopathic effect on *P. koraiensis* seedlings.

Relevance of Chl. a, Chl. b and total triterpene

Analysis indicated significant positive linear correlation between Chl. a and Chl. b in 3 kinds of seedlings, such as *P. tabuliformis*, *P. thunbergii* and *P. koraiensis* ($y = 0.3976 x - 0.1056$, $R^2 = 0.9435$, $P < 0.01$, $n = 58$) (Fig. 2A). Relevance of Chl. a and total triterpene is significant in 3 kinds of seedlings ($y = -0.1303 x^3 + 0.4627 x^2 - 0.4896 x + 0.3312$, $R^2 = 0.37$, $P < 0.01$, $n = 58$) (Fig. 2B). Relevance of Chl. b and total triterpene is significant in 3 kinds of seedlings ($y = -0.3161 x^3 + 1.1339 x^2 - 1.2147 x + 1.0971$, $R^2 = 0.3815$, $P < 0.01$, $n = 58$) (Fig. 2C).

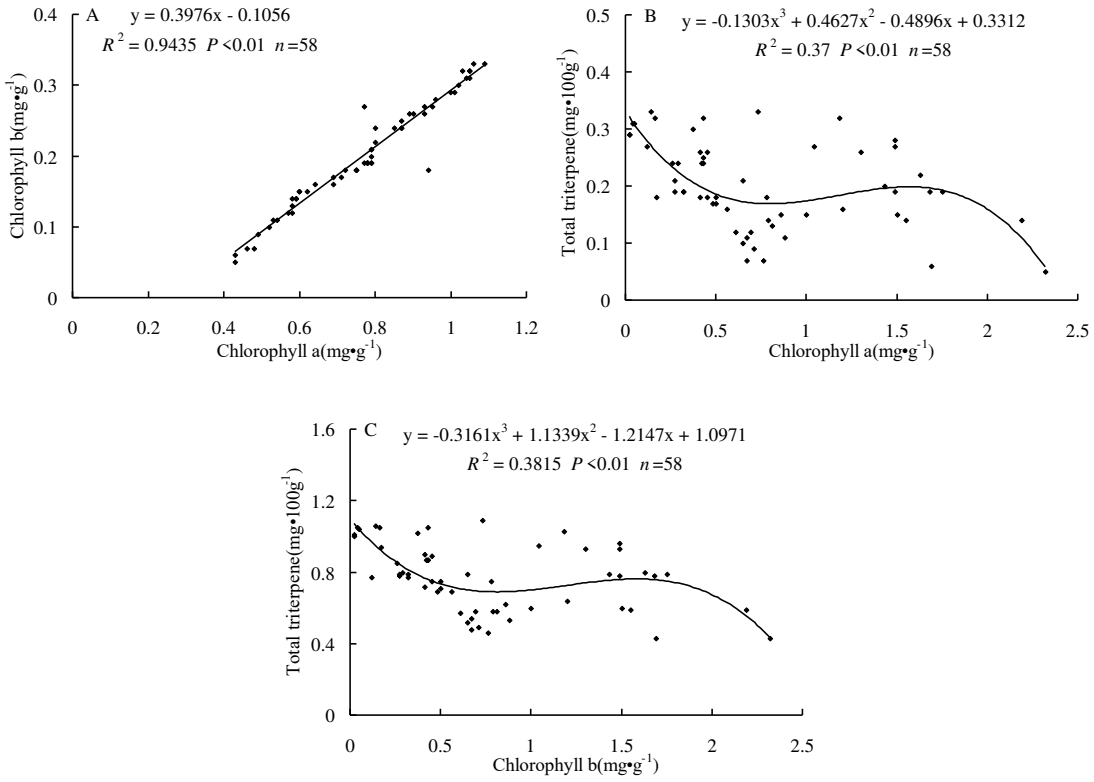

Figure 2. *Relevance of Chl. a, Chl. b and total triterpene in 3 kinds of seedlings (A, B, C)*

Discussion

In recent years, it has been found that allelochemicals can inhibit the absorption and transport of amino acids, and can interfere with the protein synthesis (Li et al., 2010), inhibit or damage the synthesis of photosynthetic pigments and accelerate the decomposition of photosynthetic pigments (Poonpaiboonpipat et al., 2013). It also affects the shape and structure of plant cells, and change the transport of nutrients and nutrient accumulation efficiency (Singh et al., 2009; Sunar et al., 2013; Grana et al., 2013), eventually causing a strong change in plant cells and growth of plants. The soil leaching liquor in *P. koraiensis* plantation had suppressive effects on the 7 measured indices, such as germination percentage, germination potential, hypocotyl and radicle length, seedling height, root length and dry mass (Chen et al., 2016). The leaf litter, semi-decomposed litter and surface soil infiltration solution of *P. tabulaeformis* significantly inhibited the growth, chlorophyll content (especially Chl. a content) and net photosynthetic rate of *P. tabulaeformis* seedlings (Jia et al., 2003). Japanese red pine (*P. koraiensis*) produces resin acids, such as abscisic acid-β-d-glucopyranosyl ester (Kato-Noguchi et al., 2011), 9α,13β-epidioxyabeit-8(14)en-18-oic acid and abscisic acid-β-Dglucopyranosyl ester (Kimura et al., 2015), 15-hydroxy-7-oxodehydroabietate and 7-oxodehydroabietic acid (Kato-Noguchi et al., 2017), which are transported to the surface soil through fallen leaves, inhibiting the growth of roots and shoots of other plants, resulting in sparse understory vegetation. The cedar (*Cedrus deodara*) leaves volatiles have a strong allelopathic effect, and its main components are terpenoids (Li et al., 2015). Their leaf water leaching liquid affects root length, shoot length and chlorophyll content, and reduce seed germination and plant dry weight (Talukdar and Talukdar, 2012; Uddin and Robinson, 2017). Allelochemicals reduce plant absorption and increase the availability of soil nutrients (Aslam et al., 2017; Mohammadkhani and Servati, 2018). Our study showed that pine needle water leaching solutions, such as *P. tabuliformis*, *P. thunbergii* and *P. koraiensis*, significantly inhibit their Chl. a and Chl. b, and will be a norm, which provides a new explanation for the decline in the coniferous forests of northern China. We propose to carry on research in this direction, such as dividing the concentration of the pine needle litter water extract, separating and identifying more new allelochemicals, thus revealing the plant physiological and biochemical reactions and countermeasures of the three major *Pinus* species in northern China.

Conclusions

P. thunbergii needle water leaching solution treatment significantly reduced chl. a and chl. b contents in *P. thunbergii* seedlings. It greatly reduced the total triterpene content in *P. tabuliformis* seedlings while enhanced the total triterpene content in *P. tabuliformis.* In addition, it significantly reduced the total triterpene content in *P. koraiensis* seedlings while enhanced the total triterpene content in *P. koraiensis* seedlings.

P. tabuliformis needle water leaching solution treatment significantly reduced Chl. a and Chl. b contents in *P. thunbergii* seedlings and Chl. a and Chl. b contents in *P. tabuliformis* seedlings as well. However, it strengthened the total triterpene content in *P. tabuliformis* seedlings, with the decrease of Chl. a and Chl. b contents in *P. koraiensis* seedlings.

Although *P. koraiensis* needle water leaching solution treatment significantly reduced Chl. a and Chl. b contents in *P. thunbergii* seedlings, it dramatically increased total triterpene content in *P. thunbergii* seedlings. And it also caused the total triterpene content in *P. tabuliformis* seedlings to decrease and the total triterpene content in *P. tabuliformis* seedlings to increase. Moreover, it decreased the total triterpene content in *P. koraiensis* seedlings while it increased the total triterpene content in *P. koraiensis* seedlings.

Comprehensive assessment showed that *P. thunbergii* needle litter water leaching solution had a significantly low inhibition on *P. thunbergii* while a significantly strong inhibition on *P. tabuliformis* and *P. koraiensis*. It also showed a significantly low inhibition on *P. thunbergii*, a moderate inhibition on *P. tabuliformis* and a significantly strong inhibition on *P. koraiensis*. *P. koraiensis* needle litter water leaching solution had a significantly strong inhibition on *P. thunbergii*, *P. tabuliformis* and *P. koraiensis*.

Abstract. Polycyclic aromatic hydrocarbons (PAHs) are hydrocarbons composed of two or more benzene rings, and they are widely found in nature. The degradation of PAHs remains in a dynamic equilibrium, which has suffered from the increasing PAHs emissions under the continuous development of society. Therefore, the environmental pollution is getting increasingly serious. Many scholars have conducted researches on the degradation of PAHs. In this paper, the origin and properties of PAHs are introduced. Besides, the physical, chemical and biological methods for the degradation of PAHs were reviewed. Among them the biodegradation of PAHs has been especially analyzed. Meanwhile, the advantages and disadvantages of each method were described through comparison.
Keywords: *PAHs, remove, physical methods, chemical methods, biological methods, characteristics*

Introduction

Polycyclic aromatic hydrocarbons (PAHs) are organic compounds that consist of either at least two condensed benzene rings or pentad molecules that are arranged in various chemical configurations. PAHs are categorized as low molecular weight (LMW) and high molecular weight (HMW) PAHs based on molecular structure. The structures of LMW PAHs include two-rings structure and three-rings structure while those of HMW PAHs include at least four rings. The aqueous solubility of PAHs decreases almost linearly with the increase in molecular mass (Mahler et al., 2012).

PAHs feature high melting points, high boiling points, and the low aqueous solubility, which gradually decreases with the increase of molecular weight. At the same time, the high fat solubility enables PAHs to dissolve in organic solvents easily. PAHs are widely available as they can be released into the environment by nature or by human activities. Bio-combustion, such as the combustion of forest and grassland, is the main source of PAHs. In addition, the emission of PAHs is also caused by the combustion of gasoline and coal, as well as the combustion of industrial waste (Liu et al., 2008; Tiwari et al., 2013). Moreover, in urban areas, street dust and sewage contain not only PAHs but also heavy metals such as lead and copper. In areas abounded with coal mines, the formation of PAHs caused by incomplete combustion of bituminous coal leads to soil and air pollution (Brown and Peake, 2006; Sprovieri et al., 2007). When the PAHs are released into the air, it can be deposited in the soil or water. Road traffic emissions are related not only to vehicles exhaust but also to problems concerning tire, brake wear and re-suspended dust. Traffic re-suspended particles contain road dust accumulated from vehicle track-out from construction sites, water or

© 2018, ALÖKI Kft., Budapest, Hungary

wind erosion from nearby areas, tire and brake wear, oil leaks and spills, street repair materials and atmospheric deposition (Ravindra and Grieken, 2008). When humans eat plants that have been irrigated by the water, PAHs are transmitted to human through the food chain, and therefore harm humans. The toxicity of PAH compounds was noticed by many researchers. Researchers found that only a low concentration of PAHs could cause tissue mutations or cancer (Ruge et al., 2015). The U.S. Environmental Protection Agency has included 16 of them in the list of priority pollutants (naphthalene, acenaphtalene, acenaphtene, fluorene, phenanthrene, anthracene, fluoranthene, pyrene, benzo (*a*) anthracene, chrysene, benzo (*b*) fluoranthene, benzo (*k*) fluoranthene, benzo (*a*) pyrene, indeno (1,2,3-*cd*) pyrene, dibenzo (*a*,*h*) anthracene, benzo (*g*,*h*,*i*) perylene) (Llobet et al., 2006).

The degradation of PAHs in nature is in a dynamic equilibrium. With the current industrial development, more and more PAHs are released, which has serious adverse effect on the environment and human health (Debajyoti et al., 2016). Therefore, more and more researchers pay their attention to PAHs and their degradation methods, including physical, chemical, biological methods and other methods (Cerniglia, 1992; Kalmykova and Moona, 2014). In this paper, the methods for the degradation of PAHs are reviewed and their advantages and disadvantages are summarized in turn.

Physical methods

Most PAHs are colorless or pale-yellow crystals, There are also some PAHs which are dark crystals. Besides, they feature high melting points and boiling points, while their vapor pressure is very small. In addition, they are mostly insoluble in water but soluble in benzene aromatic solvents, and slightly soluble in other organic with high adsorption affinity for solid media (Lamichhane et al., 2016). Therefore, the use of suitable adsorption and extraction materials can effectively degrade the PAHs in water, soil and sludge. Due to these properties, many researchers use adsorption, extraction and other physical methods to remove PAHs (Belo et al., 2017; Li et al., 2017).

Sorption

Sorption is one of the widely used methods of PAHs degradation, as PAHs possess low aqueous solubility and great sorptive ability for solid media. When the fluid is contacted with the porous solid, at least one type of component of the fluid accumulate on the solid surface. This process is called adsorption, which includes absorption, adsorption and ion exchange (Khattri and Singh, 2009; Lamichhane et al., 2016; Yuan et al., 2011). Several kinds of adsorbent media such as activated carbon, biochar and modified clay minerals have been largely used to remove PAHs from aqueous solution and to immobilise PAHs in the contaminated soils (Luna et al., 2016).

According to the functions of different kinds of adsorbent and adsorbed substance, there two types of adsorption: physical adsorption and chemical adsorption. In general, physical adsorption is a reversible process, while chemical adsorption is irreversible. Compared to other methods, adsorption is regarded as a good method to remove PAHs for its simple design, low cost and no secondary pollution. Therefore, choosing suitable adsorbent can solve the problems concerning the pollution of PAHs in water, soil and sludge (Yuan et al., 2010).

The choice of adsorbent material plays an important role in the degradation of PAHs. Pyrene, benzo (b) fluoranthene, benzo (k) fluoranthene, benzo (a) anthracene, indene

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_64196440
© 2018, ALÖKI Kft., Budapest, Hungary

(1,2,3) pyrene, dibenzo (a, h) anthracene, benzene (g, h, i) perylene were studied by adsorption experiments. It was found that activated carbon was an excellent adsorbent and could effectively remove PAHs (Lamichhane et al., 2016). Some scholars applied activated carbon to the absorption of PAHs pollutants in soil and sludge, and the removal rate reached 95%. However, they did not take into account the fact that the metal ions in the sludge has effect on the adsorbent, which need to be noticed in actual operations (Oleszczuk et al., 2012). In fixed-bed column experiments, activated carbon is uesd by Luna et al. to carry out continuous adsorption and desorption experiments on PAHs in heavy naphthenic oil. It was found that the PAHs content in samples decreased from 8% to 3% (Luna et al., 2016).

Biochar is a kind of solid product produced by the pyrolysis of biomass in an anaerobic environment. Because of its porous structure and high surface area, bio-carbon is conducive to the removal of PAHs in water and soil. The biochar can be produced by the pyrolysis of the coniferous, corn stover, peanut shell, wheat residue that occurs under the hypoxia condition and at the temperature ranging from 500 to 600 °C (Yongwoon et al., 2013). Black carbon, a kind of bio-carbon, does not function solely in the adsorption degradation of PAHs and other organic pollutants, but completes the process together with soil constituents. Rhodes et al. added black carbon to the soil, resulting in a significant reduction in the content of phenanthrene, which may be caused by the decrease in the concentration of aqueous solution containing phenanthrene owing to the adsorption of black carbon (Rhodes et al., 2008). Oleszczuk et al. added the biochar prepared at 600 °C to sludge containing napthalene, phenanthrene, anthracene, fluoranthene, pyrene, benzo (a) anthracene, chrysene, benzo (b) fluoranthene, benzo (k) fluoranthene, benzo (a) pyrene, indeno (1,2,3cd) pyrene, benzo (g, h, i) perylene and so on, and the dosage of biochar ranged from 0.5% to 10%. It was found that biochar could reduce 57% of the PAHs in sludge (Oleszczuk et al., 2012). There are scholars who use charcoal in adsorption experiments on the pyrene and phenanthrene in the water, and the results show that the conversion rate of PAHs is more than 60% (Yuan et al., 2010). The above studies show that the biochar has a good adsorption effect on most PAHs. It is worth mentioning that the biochar has better PAH adsorption effect on the PAHs with five- or six-ringed structures, than on those with two- to four-ringed structures. Besides, only few types of PAHs can achieve good adsorption effect, and biochar needs a very high temperature to convert from peanut shell and other materials. Maybe the more lowering conversion temperature is a key element to the future research direction for the researchers.

Magnetic nanomaterial is a kind of magnet containing hematite core and silica mesoporous material (Ríos and Zougagh, 2016). They can be used as adsorbent to remove PAHs. Yuxiong Huang et al. used this kind of material to adsorb acenaphthene in industrial wastewater. The results show that in 30 min, the capture rate of acenaphthene reached 85% and the adsorption capacity reached 1060 mg/kg. It was proved that the removal rate of magnetic nanometal ions is very high. Besides, the adsorption capacity of magnetic nanomaterial increases with the increasing pH and magnetic nanomaterial has excellent regeneration performance (Huang et al., 2016).

In addition to the abovementioned materials, grapheme oxide, electro spun nanofibers; laccase carrying electric fiber membrane can also be used for the adsorption of PAHs in the degradation (Feng et al., 2013; Niu et al., 2013). Through a large number of experiments, researchers have demonstrated that these materials can effectively adsorb and degrade PAHs. Moreover, in recent years, a combination of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_64196440
© 2018, ALÖKI Kft., Budapest, Hungary

adsorbent materials and enzymes can not only achieve the physical adsorption, but also completely degrade the PAHs. Of course, there are many factors that affect the adsorption, such as temperature, pH value, humidity and so on. The removal rate of PAHs may vary under different conditions. Zhang et al. used black carbon to study the adsorption of pyrene in the soil. It was found that the adsorption capacity of pyrene was stronger when the soil moisture was higher, especially when the pyrene concentration was low. The adsorption of pyrene varies with different soil organic compounds. Compared with the black soil, the paddy soil has much higher polarity, therefore the adsorption capacity of black carbon to pyrene decreased more obviously (Zhang et al., 2013). By using plant residues to remove the PAHs in water, Xi et al. found that the higher the polarity of the aqueous solution, the more detrimental to the removal of PAHs. They removed the polar components by acid hydrolysis and the results show that the adsorption rate of phenanthrene increased by 6 to 18 times, and the adsorption rate of naphthalene, acenaphthene and pyrene increased by 6 to 8 times. It was also found that deodorized pine has the best adsorption capacity due to its lowest polarity (Zeledón-Toruño et al., 2007). Hiller et al. experimentally investigated the effect of temperature on the adsorption of naphthalene, phenanthrene and pyrene. When the temperature ranges from 4 to 27 °C, with the increase of temperature, the adsorption rate of naphthalene decreased by 27.3%, and the adsorption rate of phenanthrene decreased by 17% while the adsorption rate of pyrene decreased by 27.4% (Hiller et al., 2008). It can be concluded that with the increase of temperature, the adsorption rate of PAHs decreased gradually. Some scholars prepared activated carbon by using orange peels and then conducted an adsorption test. They found that orange peel activated carbon can effectively remove the phenanthrene in the water (Chen et al., 2011). At the same time, they also investigated the factors affecting the adsorption. It was found than the adsorption rate of phenanthrene increased with the increase of the absorbent dose. When the absorbent dose was 18 mg, the phenanthrene was completely absorbed, therefore this adsorption dose was also found to be the best value. The experiments on the adsorption of phenanthrene at different pH values showed that the adsorption rate of the adsorbent decreased with the increasing pH value. Of course, some scholars pointed out that the pH value has little effect on the adsorption of some PAHs., Zeledon et al. (2007) used weathered lignite as an adsorbent to remove PAHs (fluorene, pyrene, benzo (k) fluoranthene, benzo (a) pyrene and benzo (g, h, i) perylene) in water. There was no significant difference in the adsorption rate of other contaminants at different pH levels except for that of fluorene, which is higher when pH value is small. When the pH value was 2, the adsorption rate of fluorene was 86%. As the pH value increased to 6, the adsorption rate of fluorene dropped to 63%. Therefore, we drew a conclusion that the results vary due to different conditions, which have different effects on different adsorbent materials. No matter what kind of material, we need to find the best conditions to achieve the best results.

Extraction

Extraction is also a commonly used method for treating PAHs in water and soil. The extraction agents include acetone, methanol, n-hexane and dimethyl ether (Lambropoulou, 2010; Noordkamp et al., 1997; Szulejko et al., 2014). Some scholars have demonstrated that these extractants can extract PAHs successfully. However, these solvents may cause re-contamination for the environment. Thus, more and more

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_64196440
© 2018, ALÖKI Kft., Budapest, Hungary

researchers are looking for other solvents or comprehensive methods to improve the extraction process and extraction rate.

Song et al. (2012) were studied the removal of phenanthrene in soil by combining ultrasound with soil cleaning. It was also found that increasing the ultrasonic time and the concentration of phenanthrene can be of great help to the removal of phenanthrene. According to the results, the removal rate of phenanthrene reached to 69.5% after 20 min of sonication. The investigation provides a viable method for the modification of highly contaminated soils. Sliva et al. used non-in situ extraction techniques to treat hydrocarbons contaminated soils. The contaminated soils was treated by a ethanol-acetone-water ternary miscible systems, and a kinetic equilibrium was achieved after 10 min. The extraction rate of the compound reached 85% and it increased by 8% with the increase of solid-liquid ratio from 1: 2 to 1: 8 (Silva et al., 2005).

More and more scholars use vegetable oils as extractants in the extraction of PAHs, because they are naturally non-toxic, cheap and feasible to be used for biodegradation. Lau et al. (2014) found that peanut oil is an excellent extractant to remove PAHs. They used peanut oil whose concentration ranges from 2.5% to 20% to extract the anthracene from garden soil, and the extraction rate reached higher than 90%. At the same time, through experiment, they found that the optimum pH was 6-7. In addition, the extraction rate of PAHs increased from 51.5% to 81.4% when the temperature rose from 20 to 60 °C, which indicated that when peanut oil is the extractant, the extraction rate of PAHs increased with the increase of temperature. Some scholars used sunflower oil to extract PAHs so as to repair the soil (Gong et al., 2005). The results show that sunflower oil has excellent ability to remove PAHs, especially for soil with a high concentration of PAHs, and the removal rate was close to 100%. Different vegetable oils have different If the vegetable oils that used for extraction are different, the extraction rates of the same PAH as different as well. Lau et al. extracted the fluoranthene and phenanthrene with palm kernel oil and soybean oil. It was demonstrated that using palm kernel oil for extracting PAHs can achieve a higher extraction rate compared with using soybean oil. Besides, with these two vegetable oils being used as extractant, the extraction rates of PAHs was lower when gravel was highly polluted, compared with that of PAHs when gravel was low-polluted (Lau et al., 2014). The investigation also indicated that the difference of temperature affects the extraction rates of fluoranthene and phenanthrene. Especially at a high temperature, the extraction rate of fluoranthene is higher than that of phenanthrene. When the soybean oil was utilized to extract, PAHs, the extraction rate of fluoranthene was 0.7% and 4.75% higher than that of the phenanthrene at the temperature of 30 °C and 70 °C respectively. When the palm kernel oil was used as extractant, the extraction rate of anthracene was 3.35% and 1.35% higher than that of fluoranthene at the temperature of 30 °C and 70 °C respectively (Von et al., 2012). Sanchez-Trujillo et al. studied the biodegradation of PAHs contaminated soils by using cyclodextrin as an extractant (Sáncheztrujillo et al., 2013). It is proved that cyclodextrin has a good degradation effect on PAHs. They studied the PAHs composed of three benzene rings (anthracene, phenanthrene, fluorene, acenaphthene, etc.) with chemically modified cyclodextrin, $Ca(NO_3)_2$ electrolyte solution and natural cyclodextrin utilized as extractants. It was found that the chemically modified cyclodextrin achieved the highest extraction rate of PAHs, about 10% higher than those achieved by the other two extractants.

Chemistry methods

In summary, the two physical methods of adsorption and extraction have significant effects on the removal of PAHs. However, there is no chemical change in these physical processes. These materials simply transfer PAHs from water or soil, and the PAHs cannot be completely removed. Therefore, chemical methods have been used to degrade PAHs.

Physical adsorption and extraction have a significant effect on the degradation of PAHs, but these physical processes are time-consuming and inefficient. Therefore, many researchers have paid their attention to chemical methods. At present, the most important approaches to the PAHs degradation are oxidation and photocatalysis (Rubio-Clemente et al., 2014).

Oxidation

It is well known that potassium permanganate is highly oxidizing, therefore some researchers used it to deal with PAHs contaminated soil. Brown et al. utilized potassium permanganate to deal with potassium the benzo (a) pyrene, chrysene, fluoranthene, phenanthrene, and pyrene in the soil. After 30 min, the content of benzo (a) pyrene, pyrene, phenanthrene and anthracene were decreased 72.1%, 64.2%, 56.2% and 53.8%, respectively. Under the same conditions, fluoranthene and chrysene were reduced by at least 13.4% and 7.8%, respectively. According to the investigation, the order of the oxidation degradation rates of potassium permanganate for these six kinds of PAHs can be listed as: benzo (a) pyrene> pyrene> phenanthrene> anthracene> fluoranthene> chrysene (Brown et al., 2003). The results show that the effect of potassium permanganate on the degradation of low molecular weight PAHs is obvious. However, the adverse effects of potassium permanganate on aquatic plant are severe.

Ozone has a strong oxidizing power and it is mostly used in the degradation of PAHs. However, many researchers found that the shortcomings of ozone will be revealed if ozone is used alone. Many studies show that the degradation efficiency of the combination of ozone and certain reagents is better than that of ozone (Bouzid et al., 2017; Ji et al., 2018).

Bernal-Martinez et al. used ozone to conduct anaerobic digestion experiments on 12 kinds of PAHs such as anthracene, phenanthrene and pyrene, so as to study the efficiency of ozone degradation of PAHs in sludge (Bernalmartinez et al., 2007). They conducted three comparative experiments. In the first experiment, oxidant was not added to the samples. On the contrary, the oxidant was the only thing that had been added to the samples of the second experiment. Moreover, samples of the third experiment contained not only oxidant but also tetrabutyl phenol. Under the same experimental conditions, the comparison of the three experiments showed that the oxidant had the most obvious degradation effect on PAHs. The other two groups of sample also showed the degradation of PAHs, but the effect was not obvious. At the same time, the amount of added oxidant is also critical factor. Through anaerobic digestion experiments, they found that the optimum ozone dose is of 0.11 g per gram of sludge.

Oxidative degradation of PAHs has proven to be an effective means by many researchers, but some scholars have suggested that relying on ozone oxidation alone is less efficient. Brown also proposed to use ultraviolet radiation or the addition of other oxidants such as hydrogen peroxide to improve ozone oxidation rate (Brown et al.,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_64196440
© 2018, ALÖKI Kft., Budapest, Hungary

2003). Beltran et al. improved the ozonation of fluorene, phenanthrene and acenaphthene by UV radiation and the addition of hydrogen peroxide. Experiments show that the use of ultraviolet radiation and the addition of hydrogen peroxide do not always play a role in the degradation of PAHs. These method can only improved the efficiency of fluorene degradation and phenanthrene degradation, and there is almost no effect on acenaphthene (Beltrán et al., 1996).

With a method combining UV radiation and ozone, Ledakowicz et al. (2014) also conducted degradation experiments on benzo (a) pyrene, chrysene and fluorene in water. The mechanism of this process is listed as follows (*Eqs. 1–7*):

$$O_3 + h\nu \longrightarrow O_2 + O(1D) \quad \text{(Eq.1)}$$

$$O(1D) + H_2O \longrightarrow H_2O_2 \quad \text{(Eq.2)}$$

$$H_2O_2 + h\nu \longrightarrow 2\ {\bullet}OH \quad \text{(Eq.3)}$$

$$H_2O_2 \rightarrow HO_2^- + H^+ \quad \text{(Eq.4)}$$

$$O_3 + OH^- \longrightarrow HO_2^- + O_2 \quad \text{(Eq.5)}$$

$$O_3 + HO_2^- \longrightarrow HO_2{\bullet} + O_3{\bullet}^- \quad \text{(Eq.6)}$$

$$PAH + O_3 + h\nu + {\bullet}OH \longrightarrow products \quad \text{(Eq.7)}$$

Among them, • OH, HO^{2-}, O_3 • achieved a major oxidation. The results show that the degradation rate of benzo (a) pyrene reached 85% with ultraviolet radiation and ozone, and the degradation rate of chrysene and that of fluorene reached 90%. As for the method that using ozone alone, the degradation rates of benzo (a) pyrene, chrysene and fluorene were 10%, 70% and 50%, respectively. As for the method that using UV radiation alone, the degradation rates of benzo (a) pyrene, chrysene and fluorene were 80%, 40% and 55%, respectively. Because of the hydrogen ions emerging in the reaction process, the pH value has a certain effect on the oxidation process, and this effect needs to be further investigated. In contrast, combining UV radiation with ozone is more effective for the degradation of PAHs. Eberius et al. studied the aromatic core structures by using the mass-spectra. They found that the final product of pyrene is benzene with the possible functional groups such as carboxyl (Eberius et al., 1997). Fenton (Fe_2 + / H_2O_2) has been widely used in the treatment of organic pollutants (Pérez et al., 2002). The reaction of divalent iron ions in Fenton and hydrogen peroxide generates oxidative hydroxyl radicals and lead to the formation of ferric ions (*Eq. 8*). The main oxidative component of the Fenton reagent is hydroxyl radicals.

$$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + OH^- + OH \quad \text{(Eq.8)}$$

Homem et al. demonstrated the feasibility of removing benzo (a) pyrene (BaP) in water with Fenton reagent (Homem et al., 2014). They also researched the effect of temperature, pH value, divalent iron ion concentration and the concentration of hydrogen peroxide on the removal efficiency of BaP. As the temperature increased from 30 to 70 °C, the removal rate of BaP increased from 90 to 100%. But pH value has little

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_64196440
© 2018, ALÖKI Kft., Budapest, Hungary

effect on the removal rate of BaP. The effect of divalent iron ion concentration is similar to that of temperature, as the removal rate of BaP increased with the increase of divalent iron ion concentration. The increase in the concentration of hydrogen peroxide will improve the removal rate, but an excessive concentration will contrarily reduce the removal rate. Homem proved that Fenton had a good effect on the removal of PAHs. With an initial concentration of 50 mg L^{-1}, 90% removal was achieved, while with the concentration of 150 mg L^{-1}, only 80% BaP was eliminated. Therefore, it can be concluded that advanced oxidation technology is more helpful to PAHs degradation than conventional oxidation technology.

Photocatalytic

Photocatalysis is also an important way to remove organic matter such as PAHs and other pollutants. Photocatalytic materials consist of titanium dioxide, zinc oxide, silicon dioxide and so on. Among them, titanium dioxide is extensively applied because of its high degree of oxidability and stability (Jiang et al., 2018, 2017; Woo et al., 2009).

Veréb et al. used UV lamps as light sources to perform degradation experiments on phenanthrene in water. Titanium dioxide absorbs the energy produced by ultraviolet light so as to produce electrons. Besides, the reaction of positive charge and water produces hydroxyl radicals and hydrogen ions, while the negative charge reacts with oxygen and hydrogen ions to form a peroxy radical (Veréb et al., 2012). Hydroxy radicals and peroxygen have strong oxidizing properties, which play an important role in photocatalytic degradation of phenanthrene. The results show that titanium dioxide photocatalytic materials were the most effective for the removal of phenanthrene. Besides, the final oxidation product of phenanthrene is carbon dioxide and so on (Wen et al., 2002).

Different experimental conditions may have an effect on photocatalytic efficiency. Lair et al. (2008) used titanium dioxide as the photocatalytic material for naphthalene degradation experiments. At the same time, they studied the impact of the photoelectron flux, temperature, pH value and inorganic ions on the photocatalytic efficiency. When the received photoelectron flux rises from 0 to 10^{16} photons per second, the degradation rate also increases. When this range is exceeded, the amount of photoelectron flux has no effect on the degradation rate. When the temperature increases from 10 to 4 °C, since the photoactivation is independent of the thermal activation, the temperature has no effect on the photocatalytic rate. Under the strong acid or strong alkaline conditions, the degradation rate will be reduced. The study also pointed out that carbonates and carbonates will inhibit photocatalysis.

Similar to titanium dioxide, zinc oxide is also a kind of semiconductor material., Currently, in the field of photocatalysis, titanium dioxide materials are widely the most widely used materials, while people have little knowledge of Zinc Oxide materials. Zinc oxide is a kind of wide band gap semiconductor material with a 3.37 eV, and its exciton binding energy at room temperature is 60 eV (Ramasamy et al., 2013). In the degradation of PAHs, using oxidation alone and using photocatalysis alone can improve the efficiency. Therefore, combining these two methods may have a better effect. It has been experimentally demonstrated by Vela et al. that zinc oxide and titanium dioxide have excellent effects on removing PAHs in water. They applied a method concerning the combined use of ZnO and $Na_2S_2O_8$ to the degradation of PAHs in groundwater. After comparison, it was found that compared to utilizing photocatalytic method alone, the use of the combined method improved the total organic carbon reduction by 21%

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_64196440
© 2018, ALÖKI Kft., Budapest, Hungary

(Vela et al., 2012). The combination of photocatalysis and oxidation seems to have a better effect.

From the above results, it is not difficult to conclude that the chemical method has a significant improvement in the degradation rate of PAHs compared to physical methods. However, when use photocatalysis alone or use ozone alone, the efficiency of PAHs degradation is lower than that of adding other oxidants together. Moreover, it is necessary to pay attention to the secondary pollution caused by intermediate products.

Biodegradation

In recent years, with the improvement of environmental awareness, the concern of many researchers has gradually shifted from physical and chemical degradation methods to biodegradable methods. Because of no secondary pollution, low cost and simple operation and so on, biodegradation methods are considered as the best ways to deal with PAHs. Fungi, bacteria, and plants have good abilities to degrade PAHs (Haritash and Kaushik, 2009; Kronenberg et al.; 2017; Nzila, 2018).

Plant

Plants belong to autotrophic organisms that features using light and carbon dioxide for photosynthesis. Because the roots of plants can absorb some toxic compounds, plants function as natural cleaning systems. Therefore, for the purpose of repairing PAHs contaminated soils plants can be applied to the degradation of PAHs (Alagić et al., 2015; Chen et al., 2011). Alagić et al. demonstrated that plant has the ability to degrade BaP, which is mainly due to a series of biotransformation of the enzyme system in plant roots (Alagić et al., 2016). Chen et al. labeled pyrene with ^{14}C, and evaluated the degradation abilities of tall fescue (Festuca arundinacea) and switchgrass (Panicum virgatum L.) (Yenchih Chen et al., 2003). After 190 days, 37.7% and 30.4% of pyrene were mineralized in the soil where tall fescue (*Festuca arundinacea*) was planted and where switchgrass (Panicum virgatum L.) was planted, respectively. Only 4.3% of the pyrene in the soil without the two plants was mineralized. At the end of the experiment, the residual quantity of pyrene in the two kinds of soil was only 7.6 and 8.7%, respectively. Somtrakoon et al. studied the degradation of anthracene and fluorene that affected by sweet corn, cucumber, and winged bean. They transplanted these three plants to the soil that contained containing 138.9 mg/kg of anthracene and 95.9 mg/kg of fluorene (Somtrakoon et al., 2014). After 15 to 30 days, the plant elongation, plant weight, chlorophyll content, and PAHs content in soil and plant tissue were determined. The results show that winged bean achieved the best degradation rate of anthracene and fluorene, which were degraded by 92.2% and 75.8%, respectively. Besides, 91.2% and 95.9% of the anthracene and fluorene degraded in the soil mixed with corn and four ribbean. Corn and cucumber grown in soil After 15 days, 14% of fluorene remained in the corn-planted, and 17.3% of fluorene remained in the cucumber-planted soil. The degradation of fluoranthene, pyrene, and a mixture of fluoranthene and pyrene affected by Scenedesmus platydiscus, Scenedesmus quadricauda, Chlorella vulgaris, and Selenastrum capricornutum has been studied by scholars. In the experiment, the concentrations of fluoranthene, pyrene, and a mixture of fluoranthene and pyrene were all 1 mg/L. The results show that Selenastrum capricornutum achieved the highest conversion efficiency, and the removal rate of PAHs reached 78% in 7 days. However,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_64196440
© 2018, ALÖKI Kft., Budapest, Hungary

among these four kinds of algae, vulgaris achieved the lowest efficiency of, the removal rate was only 48% (Lei et al., 2007).

Bacteria

Bacteria are microorganisms that are critical to the degradation of organic pollutants. It is well known that many bacteria can accelerate the degradation of PAHs with a very high efficiency (Kuppusamy et al., 2016; Mohanrasu et al., 2018). Bacteria can produce dioxygenase, which enable bacteria to facilitate PAHs degradation through the enzyme catalysis. Subsequently, the oxygen is added to the benzene ring, and the formation of the C-O bond is achieved. Moreover, after hydrogenation and dehydration, the benzene ring is eliminated, and the degradation is completed (Cerniglia, 1992). Xia et al. found that *Pseudomonas aeruginosa WJ6* can produce surface active agents, fermudamycin and lichen proteins. It was concluded that *Pseudomonas sp. WJ6* excels in facilitating the degradation of PAHs. During the 20-day period, the fluorene, naphthalene and phenanthrene in the culture dish were decreased significantly by 39.45%, 23.14% and 21.93%, respectively. The degradation rate of pyrene affected by *Pseudomonas sp. WJ6* to was only 19.50% for two-ring PAHs and three-ring- PAHs (Xia et al., 2014). Romero et al. isolated yeast strains from contaminated rivers and studied their ability to facilitating the degradation of tricyclic PAHs. Phenanthrene is the only carbon source, while red yeast and Pseudomonas aeruginosa are the main microbes. The researchers added different amounts of phenanthrene to the mineral medium containing ethanol. At a temperature of 3 °C, the samples were irradiated with ultraviolet light for 40 min so that the ethanol volatilized subsequently. They found that the medium phenanthrene underwent an almost complete degradation after one-month incubation period (Romero et al., 1998). Some scholars conducted the same experiments, and they drew the conclusion that the culture of the phenanthrene is not completely degraded and the degradation rate was only about 60%, which is different from Romero's finding. Rahman et al. studied the ability of immobilized bacteria to degrade hydrocarbons (Rahman et al., 2006). Rahman et al. planted hydrocarbon-degrading bacterial strains in alginate and are cultured in contaminated artificial seawater. After 30 days, it was found that the pollutants contaminated by petroleum hydrocarbons were removed effectively. Evidently, the immobilized bacteria in the alginate could be used to degrade the hydrocarbons effectively. As PAHs are hydrocarbons, it can be concluded that immobilized bacteria can be of great help to the degradation of PAHs. For the degradation of PAHs, Rehmann et al. proposed a method concerning the use of the mycobacterium strain *KR2*. Using *Mycobacterium strain KR2*, they investigated the degradation ability of pyrene-contaminated soils. Pyrene was the sole carbon source, and the *mycobacterial strain KR2* was the only strain (Rehmann et al., 1998). The experiment was carried out at a temperature of 20 °C. After 8 days of incubation, the degradation rate of pyrene reached 60%. The degradation products of pyrene are cis-4,5-pyrene diethylene glycol, 4,5-phenylene dicarboxylic acid, 1-hydroxy-2-naphthoic acid, 2-carboxybenzaldehyde, phthalic acid and the original Catechins, etc., and these products are easy to remove. It can be concluded that the use of mycobacteria is also effective to degrade PAHs.

Dean-Ross et al. used the *mycobacterial strain* to determine the ability of bacteria through the mineralization of PAHs (Dean-Ross et al., 2002). The mineralization rate of pyrene was 0.044 mg/L, and the mineralization rate of anthracene was 0.470 ug/L. At the same time, they also found a degradation method of fluoranthene. Among the two

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_64196440
© 2018, ALÖKI Kft., Budapest, Hungary

strains, the metabolism of fluoranthene occurred on the fused ring of fluoranthene molecules. The degradation products of fluorinated anthracene mineralized by *mycobacteria* were 9-fluorenone-1- carboxylic acid, and the degradation product of fluoranthene mineralized by *Rhodococcus* is α-(carboxymethylene) fluorene-1-carboxylic acid. Muangchinda et al. studied the degradation of PAHs in river sediments of the Chao Phraya River Basin (Muangchinda et al., 2017). They isolated two *actinomycetes* in the river sediments: *Arthrobacter* and *Rhodococcus*. These two bacteria showed a high degradation activity in the culture medium. The concentration of fluorene, phenanthrene and pyrene in the medium was initially 300 mg/kg, and the concentration of acenaphthene was 600 mg/kg. After 70 days of incubation, fluorene and phenanthrene were all degraded and the degradation rates of pyrene and acenaphthene reached 50%. It was proved that *Agrobacterium* and *Rhodococcus sp.* play important roles in the degradation of PAHs with high concentration. Jin et al. selected two strains (*JB1* and *JB2*) from the contaminated wetland sediments and fixed them on the cinder, which means the bacterial cells is immobilized (Jin et al., 2017a). The degradation rate of benzo (a) pyrene reached 71.9% after 40 days in the medium, while the degradation rate of free cells was only 47.7%. The reason is that the cinder has a large specific surface area and pore size, which is conducive to the aerobic degradation of strains. It also indicates that the carrier material plays an important role in the degradation of PAHs. Tetracyclic pyrene has a low biological activity and a strong biological resistance. *Strain F14* was constructed by protoplast fusion of *Sphingomonas GY2B* and *Pseudomonas sp. GP3A*. Lu et al. studied the degradation of pyrene with F14 (Lu et al., 2014). When the concentration of pyrene was 15 mg/L, the degradation rate of pyrene was 40.4% in F14 medium, while only 9.8% of the pyrene in the GP3A was degraded. When the concentration of pyrene was 50 mg/L, the degradation rates of pyrene was 37.1% and 22.3%, respectively. Experiments showed that the F14 strain constructed by protoplast fusion has better ability to degrade than the original strain. While GY2B is inefficient to degrade pyrene. They also found that when several kinds PAHs were mixed together, the degradation velocity and degradation rate has improved. When naphthalene and phenanthrene were simultaneously added to the medium, 42% of the pyrene degraded in 120 h. After 240 h, 79% of the pyrene degraded. Contaminated soil, sludge and water generally contain metal ions, which are likely to affect the degradation of PAHs. Chen et al. studied the role of copper ions in the degradation of PAHs by the utilization of bacteria (Chen et al., 2013). The degradation of BaP was studied by using BaP as the carbon source and using matrix of coexisting maltose and copper ion. The initial BaP concentration was 1 mg L^{-1}, subsequentlly, after 3 days at a temperature of 30 °C and natural pH, 45% of BaP was degraded. When the temperature rose to 35 °C, the degradation rate was 48% after two days. The different contents of copper ions also affect the degradation of BaP. When the concentration of copper ions is 2 mg L^{-1}, the degradation rate of BaP can be improved slightly. When the concentration of copper ions is 100 mg L^{-1}, only 5% of BaP is degraded and the removal rate of copper ions is 70%. Because a portion of the copper ions converted to copper hydroxide precipitation, which inhibited the activity of bacteria, therefore the degradation rate of BaP decreased. Doping some sucrose as a carbon source can make *Maltobacter* function better, which facilitates PAHs degradation. Some plants contain bacteria, and they are called endophytic plants. When the soil is contaminated by PAHs, these bacteria can improve soil quality. For example, *Aims Endophytic* bacteria that are widely found in plants. Sun et al. extracted

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_64196440
© 2018, ALÖKI Kft., Budapest, Hungary

Staphylococcus BJ06 from plants, and the concentration of pyrene in the medium was 50 mg/L (Sun et al., 2014). After 15 days, 56% of the pyrene was degraded in the medium. Ryegrass and bamboo shoots are endophytic plants from which BJ06 can be extracted. It is found that the content of pyrene in the ryegrass-planted soil and bamboo shoots-planted soil is 31.01% and 44.22% lower than that planting non - endemic plants. Evidently, *Staphylococcus BJ06* can remove the PAHs in the soil effectively, which is an efficient way to reduce PAHs from the beginning of the food chain. Some scholars have found *Leclercia adecarboxylata PS4040*, which is isolated from oil and contaminated soil. When pyrene is used as a carbon source and affected by *Leclercia adecarboxylata PS4040*, 61.5% of the pyrene in the culture medium was degraded after 20 days of observation. After 5 days, the metabolites of pyrene were 1-hydroxypyrene. Besides, through high performance liquid chromatography and magnetic resonance, it was found that the 1-hydroxypyrene could also be used as a carbon source and can produce acid or aldehyde by being further mineralized by *Leclercia adecarboxylata PS4040* (Sarma et al., 2010).

Fungi

At present, it is found that several kinds of fungi help to maintain the sustainable degradation of PAHs contaminants. In recent years, the study of fungal degradation of PAHs has been further improved (Cutright, 1995; Shi et al., 2018; Szczepaniak et al., 2015). *Aspergillussp, Trichocladium canadense* and *Fusarium oxysporum* are widely used to degrade low-molecular-weight PAHs, while *Verticillium sp.,* and *Areremonium sp.* are used to degrade high-molecular-weight PAHs (Silva et al., 2009). Fungi can produce enzymes, which facilitates the degradation of PAHs. Kristanti et al. found that enzymes are a key factor in the degradation of polycyclic aromatic hydrocarbons affected by fungi (Kristanti and Hadibarata, 2015). They used *Pestalotiopsis sp. W15* to carry out a degradation experiments on fluorene. *Pestalotiopsis sp. W15* could produce laccase. After 23 days of experiment, fluorene was completely degraded and the degradation products were salicylic acid and indanone. In order to facilitate the production of laccase, Tween 80 and Brij35 were added to the culture medium. The results show that the addition of Tween 80 could facilitate the production of laccase. When, Waszak et al. studied BaP degradation by using the mixtures of several kinds of bacterial and fungal to achieve the degradation of pollutants. The mixtures contained *Pseudomonas aeruginosa*, *Candida albicans, Aspergillus flavus, and Fusarium sp.* (Waszak et al., 2015). With BaP as carbon source and its concentration of 16 μL/g, the degradation rate of BaP was about 65.51% after 42 days of incubation in an oven at a temperature of 35 °C. Hadibarata et al. used white-rot fungus *Armillaria sp. F022* in the study of fluoranthene (Hadibarata and Kristanti, 2014). The genus Armillaria is produced in the process of degradation of ligninolytic enzymes, namely laccase and 1,2-dioxygenase. These two enzymes play key roles in the degradation process. In the experiment, different concentrations of *Armillaria sp. F022* were added to culture medium. After 30 days of incubation, when F022 concentration is 10 mg/L, the fluoranthene was completely degraded. The degradation rate decreased with the increase of F022 concentration. When the concentration of F022 was 20 mg/L and 30 mg/L, the degradation rate of fluoranthene was 79.2% and 61.6%, respectively.

Zhang et al. investigated the degradation rates of different PAHs affected by the same kind of fungus under the same conditions (Zhang et al., 2015). They studied the metabolic transformation of anthracene and pyrene affected by *Pangnoporus*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_64196440
© 2018, ALÖKI Kft., Budapest, Hungary

sanguineus H1. Under the vivo conditions, the degradation rate of anthracene reached 67.5% and the degradation rate of pyrene was 31.1%. When the tert-butyl ether was added to the samples, it enhanced the activity of laccase. Therefore, the degradation rate of anthracene increased to 73.1% while the degradation rate of pyrene declined, accurately, only 5.3%. In the in vitro conditions, 59.9% of the anthracene was degraded in the extracellular fluid. Subsequently, after adding 2, 2' -azabis (3-ethylbenzothiazoline-6-sulfonate) to the anthracene sample, the degradation rate increased to 92%, but pyrene cannot degrade in the extracellular fluid. It can be concluded that the ability of *Pangnoporus sanguineus H1* to facilitate the degradation of anthracene is better than that to facilitate the degradation of pyrene. There was no laccase in the extracellular fluid, which demonstrates that laccase is critical to the degradation of PAHs. This study has fully demonstrated that fungi can produce laccase and degrade PAHs due to the oxidative catalytic ability of laccase, and therefore provides a good basis for researchers to study the degradation of PAHs utilizing laccase. Garonet et al. studied the degradation of maltosyl-cyclodextrin-modified fluorine (Garon et al., 2004). They screened 47 strains from the fungus to find the most effective strains to be used in the process of biological proliferation, and they finally selected *Trichoderma* spore bacteria. With the presence of *Trichoderma sp.*, more than 90% of the fluorene was degraded after 288 h. However, it takes 576 h for fluorene degradation rate to reach 90% without the fungal proliferation process. Hilton et al. isolated 146 filamentous fungal strain in the separation of contaminants from the Amazon region and named them from S1 to S146 (Souza et al., 2016). The results show that only *Megasporoporia sp. S47* and *Sordariales S69* showed the highest activity of laccase and manganese peroxidase during BaP degradation. Besides, *Megasporoporia sp. S47* achieved the best results, and it enabled the degradation rate of BaP to reach 54%. While the other strains reached only about 23%. The fungal strain *Aspergillus BAP14* was isolated from coastal sediments by Wu et al. and it was used in the degradation of BaP (Wu et al., 2009). In the experiment, the initial concentration of BaP was 10 mg /L. After 3 days of incubation, 30% of BaP was degraded. After 9 days, BaP was degraded by 60%. When sugar and other carbon compounds are added to the culture medium, especially lactose and naphthalene, the degradation rate increases significantly. The changes in pH value in the culture medium has little effect on the degradation rate. *Monascus* is a kind of white rot fungus, which can be easily isolated from the rotting woods. Hadibarata et al., investigated the degradation of naphthalene by *Monascus* and tested the metabolites (Hadibarata et al., 2013). *Monascus* and naphthalene was added to the culture medium for 14 days, and naphthalene was the only carbon source. Subsequently, naphthalene metabolites were tested by the use of ultraviolet, thin layer chromatography and gas chromatography-mass spectrometry, and the metabolites included 1,4-naphthoquinone, benzoic acid and catechol. At the same time they also detected enzyme, which plays an important role in the degradation, including manganese peroxidase, lignin peroxidase, laccase, 1,2-dioxygenase and 2,3-dioxygenase. Oil spill is also a source of PAHs that pollutes the oceans. Michel et al., extracted eight fungi from the oceans to study their influence on the degradation of PAHs (Passarini et al., 2011b). In the experiment, pyrene and benzo (a) pyrene were carbon sources. With the use of *Aspergillus sclerotiorum CBMAI 849*, the degradation rate of pyrene was up to 99.7% after eight days. After a 16-day use of *Aspergillus sclerotiorum CBMAI 849*, the optimum degradation rate of benzo (a) pyrene was achieved, and the degradation rate was 76.6%. The degradation rate of benzo (a) pyrene

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_64196440
© 2018, ALÖKI Kft., Budapest, Hungary

achieved by *Mucor racemosus CBMAI 847* was more than 50%. The metabolites of pyrene and BaP being dealt with these fungi are pyrenyl sulfate and benzo (a) pyrenyl sulfate, respectively. This study provides an effective remedy for the PAHs pollution of marine. Arun et al., found that *Pseudomonas sp.* is the most potent fungus that degrades pyrene, and the degradation rate of pyrene is 42% (Arun et al., 2008). In the subsequent experiment, they added C. versicolor and P. ostreatus active agents to the culture medium. The results show that the degradation rate of pyrene reached 93.7%, which indicated that the surfactant was important for improving the ability of fungi to facilitate PAHs degration. The degradation rate is not only related to surfactant, but also related to the role of enzymes. The degradation of pyrene was positively correlated with the potential of lignin peroxidase (Lip), manganese peroxidase (MnP) and laccase, but it was not related to the activity of the enzyme. Da et al. screened *Cyclothyrium sp.*, which has a positive impact on the degradation of pyrene. In medium mixed with PAHs, *Cyclothyrium sp.* also exhibited good ability to improve degradation efficiency. Da selected four kinds of fungi, including *Cyclothyrium sp.; Penicillium simplicissimum; Psilocybe sp.* and *a sterile mycelium*, the degradation rate and metabolites of pyrene in culture medium were studied by applying HPLC and UV. In the culture medium, 48% pyrene was converted to trans-4,5-dihydrogenated diol, pyrene-1,6-quinone, pyrene-1,8-quinone and 1-hydroxypyrene. After 192 h of incubation, influenced by Cyclothyrium sp., the degradation rates of phenanthrene, pyrene, anthracene and benzo (a) pyrene are 70%, 74%, 59% and 38%, respectively(Da et al. 2004).

In recent years, many non-white rot fungi strains have been observed to be highly resistant to adverse environment. Many non-white rot fungi have been proved to have the ability to degrade PAHs (Marcourrea and Aranda, 2015; Veignie et al., 2004). *Fusarium sp.'s* (Strain E033) excellent ability to degrade BaP has been demonstrated by Chulalaksananukul et al. (2006). According to the investigation, the initial concentration of BaP in the medium was 100 mg/L, and 65% to 70% of the BaP was degraded after 30 days of culture at a temperature of 32 °C. In addition, there were two degradation products: dihydroxybenzo (a) pyrene and benzo (a) pyrene quinone. Increasing air and carbohydrates can improve degradation efficiency of PAHs. Anaisell et al., isolated nine natural non-lignin-decomposing fungal strains in crude oil-contaminated soils, including *Fusarium, Neurospora, Aspergillus, Scedosporium, Penicillium, Neosartorya* and *Talaromyces* (Reyes-César et al., 2014). Researchers selected *Aspergillusterreus, Talaromyces spectabilis*, and *Fusarium sp.* to conduct an experiment on the degradation of naphthalene and pyrene, and the concentration of mixed PAHs was 2,000 mg/kg. After 14 days, about 21% of the PAH mixture was degraded.

In summary, there are two mechanisms for fungi to impact on the degradation of PAHs, one is the lignin degrading enzyme system, and the other is the single oxygenase degradation system. Lignin degrading enzymes are lignin peroxidase, manganese peroxidase and laccase. These enzymes can convert PAHs into quinone, and subsequently achieve the PAHs degradation with the help of hydrogenation and dehydration (Ryu et al., 2003). As for monooxygenase degradation system, the initial process is adding oxygen to benzene ring to achieve the formation of epoxy compounds based on the catalysis of *cytochrome P-450*. Then phenol derivatives are generated and combined and rearranged with sulfate, glucose, xylose and glucuronic acid, so as to obtained degradation intermediates with high water solubility and low toxicity (Haritash and Kaushik, 2009; Shoun et al., 1989). No matter which mechanism is used, the

© 2018, ALÖKI Kft., Budapest, Hungary

purpose is to achieve the best results by ensuring the best external conditions to maintain the activity of the enzyme.

In general, biodegradation process is environmentally friendly and is able to remove PAHs completely. More and more scholars are paying attention to it and are working to improve the degradation rate. In addition, the vital role of enzymes can help us better study the biodegradation process of PAHs.

Each method has a significant effect on the degradation of PAHs, but each method has its own characteristics. As shown in *Table 1*, the advantages and disadvantages of each method are compared, and the average degradation rates that each method can achieve are summarized.

Table 1. *The characteristics of different methods*

Methods		Advantages	Shortages	Possible efficiency
Physical	Sorption Extraction	The material is easy to obtain. It is cost-effective and environmental friendly. The resource can be reused, which has obvious effects on the degradation of PAHs.	Although PAHs can be transferred, they cannot be completely decomposed. The temperature required to prepare materials such as biochar is too high.	60%
Chemical	Oxidation Photocatalytic	The degradation rate is extremely high and the time taken for degradation is short.	The intermediate produced by degradation is likely to cause secondary pollution.	85%
Biological	Plants Bacteria Fungi	It is environmentally friendly and it can degrade PAHs rather than transfer them. Intermediates do not cause secondary pollution.	The degradation rate is lower than the chemical method and the cycle is too long.	65%

Conclusion

Concerning the PAHs pollution, more and more scholars are committed to finding the most effective way to degrade PAHs. Currently, physical, chemical and biological methods have been used to control it. Physical degradation is related to the utilization of activated carbon, bio-carbon, mesoporous silicon and other materials. These materials all feature high specific surface area which is conducive to adsorb polycyclic aromatic hydrocarbon. An appropriate selection of extraction agent is critical to the extraction of PAHs in sludge or water, and external environmental factors such as temperature, pH value, etc. will influence the extraction efficiency. Compared with physical methods and biodegradation, chemical methods excel in the removal of PAHs. Photocatalysis and oxidation have been proved to facilitate high degradation efficiency. Among the chemical methods, the advanced oxidation technology is the most effective. Its mechanism is about generating lively oxygen which can destroy toxic organic compounds. There is an oxidation reaction between •OH and PAHs till carbon dioxide and water are generated. In advanced oxidation, active oxygen production requires external conditions such as ultraviolet light, divalent iron ions, ultrasound, etc. Scientific studies show that the external environment has an obvious influence on the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_64196440
© 2018, ALÖKI Kft., Budapest, Hungary

oxidation degradation efficiency. For instance, the higher the temperature is, the higher oxidation efficiency will be. Certainly, the combination of photocatalytic and advanced oxidation techniques can also greatly improve the degradation efficiency with the utilization of synergistic effects. The bioremediation efficiency of PAHs depends on the number, type and chemical structure of the microorganisms. The degradation efficiency of various PAHs affected by bacteria or fungi isolated from diverse environments also varies. At present, in PAHs bioremediation, white rot fungi is used the most widely, which can produce a series of enzyme lignin peroxidase, manganese peroxidase and laccase. These enzymes play crucial roles in the PAHs repair and degradation by converting PAHs into simple and less harmful compounds. Mostly, the degradation of PAHs impacted by bacteria and plants is also dependent on their own enzymes.

Physical, chemical and biological methods have their own advantages and disadvantages. The physical method is a good way for PAHs degradation owing to its simplicity, availability and low cost. However, it cannot completely solve the problem by moving PAH pollutants from one place to another. Chemical method can achieve a high degradation rate of PAHs, especially the advanced oxidation technology. But chemical materials may cause secondary pollution to the environment. Biological method is the most environmentally friendly way and it can completely remove PAHs, but it takes at least 15 to 20 days to remove the PAHs. At the same time, the external environment greatly impacts the enzyme activity, and there are many destabilizing factors in the environment.

To sum up, among the three types of methods, the best method is biological method. As for biological methods, the plants, bacteria and fungi are used to produce enzymes to degrade PAHs. Therefore, protecting the activity of enzymes is the key to improve the degradation rate. Storing enzymes in a certain environment can protect their activity and reduce the harm from the outside world. In recent years, metal organic frameworks (MOFs) have been developed rapidly and used in many fields. This kind of material is porous and has large surface area and other characteristics. Therefore, it functions as a kind of adsorption material for the adsorption of polycyclic aromatic hydrocarbon molecules. Combining MOFs and enzyme molecules can fix the enzyme molecule on the material and give full play to its catalysis. The reverse micelle system can provide a suitable place for enzymes, and effectively prevent the destruction of enzymes from external factors. Therefore, it is necessary to explore more effective ways that combine the advantages of physical, chemical and biological methods.

(Received 9th Jun 2018; accepted 14th Aug 2018)

Abstract. Today, advances in technology help humans to overcome emissions to some extent. Environmental researchers have attempted in recent years to find low-cost and effective approaches to pollutants control. It is important to consider the economic sphere in the approaches of dealing with pollution, as it has merits that should not be ignored, because of the existence of inefficient and expensive rules. To control air pollution, effective and long-term strategies should be identified and implemented. Among the components of air pollution control systems, pollution remediation equipment is of high importance. The present study aimed to assess air filtration systems, with emphasis on hybrid and new technologies, economic evaluation and prioritization of particle control technologies using a cost-benefit analysis method. According to the results, the research Cost-benefit analysis of particles control technologies based on research aspect had different weights. Wet ESP, Nano fiber beds, and ESP Bag Filter respectively were identified as the most appropriate particulates control techniques.
Keywords: *particle filtration, priority, equipment, new technology, air pollution*

Introduction

Industrial and technological developments and increasing energy consumption have led to renewable sources pollution (Zhang et al., 2015; Zeng et al., 2017). Given operating costs of different methods of pollution control and lack of return on investment have become air pollution control into an unprofitable economic burden (Robert and Erson, 1983; Moridi et al., 2017; Yarahmadi et al., 2010). To control air pollution, effective and long-term strategies should be identified and implemented (Vlachokostas et al., 2011; Yarahmadi et al., 2010; Lei, 2005; Vanoye and Mendoza, 2014; Chen et al., 2018). However, most decision-makers are not able to properly assess and reduce the costs of environmental degradation and the expenditure necessary to comply with the standard rules of air pollution reduction. For this reason, in many cases managers have had to use methods that are either expensive and unaffordable, or inexpensive but unreliable. Engineering Economics is a specialized field in economics that uses analysis methods to estimate costs (Zhao et al., 2016) and determine the value of industrial projects. This field has many roles, including the evaluation of industrial project usefulness, estimating values, and evaluating them in terms of technical and engineering issues (Salehi and Tavakkoli-Moghaddam, 2008). General methods used to particles are settling chamber, cyclone, bag house, scrubber, ESP and extra. The final composition is applying control measures and using technical equipment based on economic aspects (Boardman et al., 2017; Jin et al., 2018; Min et al., 2017). The absence of relevant studies can lead to health, safety, economic, energy, environmental (HSE_3) and social losses; this research was the first to prioritize and select the most

appropriate particles control hybrid and new technologies based on cost benefit analysis. Effective and affordable control measures are an optimal solution for administrative-managerial considerations (Murty et al., 2006; Nath and Cholakov, 2009; Yarahmadi and Sadoughi, 2012; Spiegel and Maystre, 1998). Previous studies indicate that, the high initial and operative costs of common filtration methods and lack of return on investment have turned air pollution control into an unprofitable economic burden. Based on these concern policy makers have hence made numerous efforts to develop cost-effective methods and optimized techniques to manage air pollution based on all economic, environmental, and social considerations. Therefore, selection of air pollution new technologies have been proposed to prioritize and chosen by seeking an option which provides maximum benefit based on all mention criteria (Moridi et al., 2017).

These also include the cost of raw materials, design costs, consulting costs, personnel costs and maintenance costs. A study entitled cost analysis framework project was published; it used cost-benefit analysis as a practical tool for evaluating different types of projects. This study aimed to analyze costs and benefits, assess money value, and offer the highest quality of results in order to optimize the use of valuable resources (Qld, 2011). The most common method for assessing the beneficial effects of environmental policies is cost-benefit analysis (CBA) (Voorhees et al., 2001; Gao et al., 2016; Bollen et al., 2009; Huang et al., 2017; Sen, 2000).

Robert et al. (1983) considered the economic sphere in the approaches of dealing with pollution to have merits that should not be ignored, as inefficient and expensive rules exist (Robert and Erson, 1983). Studies show that in most cases, the most cost-effective pollution control program is the cheapest one (Yarahmadi et al., 2012). The aim of research is assessment of new technologies with economic, environmental, social consideration for particulate control technologies using a cost-benefit method.

Methods

The cost-benefit analysis (CBA) method is often used as an efficient tool for estimating environmental costs and benefits. This method is used in decision-making relating to development projects as well as the evaluation of policies (Voorhees et al., 2001; Quah, 2007).

This method, which uses the simple cost-benefit approach tool (SCBAT), selects the best option in regard to economic-executive considerations that help project managers in managerial decision-making. This method was used for optimized air filtration technologies selection with the cost-benefit aspects include of Financial, Personnel, Service and maintenance, Environmental-social, Production and HSE risks for the first. Using this method in our study, the procedure is as follow (Cellini and Kee, 2010):

1. A list of innovative technologies in the field of particles control was collected.
2. Experts assessed the initial survey list. Determination the aspects of cost-benefits associated for key selected technologies were done by expert panel groups (brainstorm).
3. Criteria for the costs and benefits and their elements associated with each option of the investigated technologies in *Table 1* were identified (Treasury, 2006; Campbell and Brown, 2003).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_64416451
© 2018, ALÖKI Kft., Budapest, Hungary

4. According to the method, the criteria of cost benefit were scored through linguistic variables (scores: 1–3 Scale Rating: Low = 1, Moderate = 2, High = 3).
5. The benefit-to-cost ratings ratio and the ranking by the outcome of technology from benefit-cost standards were determined (Svensson, 2016).
6. If the resulting number is greater than one, it means there is more profit than cost and high priority will be given. If the number is one, the benefit is equal to the cost, and priority will be given with caution. If the benefit ratio is less than the cost and the obtained value is smaller than one, the action will be in completion. Cost-benefit in this case does not have any benefit, and this option will not be given priority.
7. Setting priorities based on larger concessions will be a top consideration.

According to the method, a list of hybrid and new control equipment for particle air pollutants was given to the experts to be indexed**.** In this study, an expert panel of six technicians with high experience in the fields of air pollution, environmental sciences, occupational health and industrial safety was used. The present study expert panel of was selected of four company in Iran with the ability of design, manufacture, install, and maintenance. The criteria of each cost-benefit exercise and their constituent elements associated with each option were scored by experts and specialists from design and manufacturing companies. Then, the benefit-to-cost ratio was calculated and ranked.

Table 1. *Aspects of costs and benefits associated with each action*

The cost-benefit aspects	More description
Financial	Investment - required equipments to build and launch
Personnel	Training - internships - internal, external period - absence from work
Service and maintenance	Operating period - services - operational energy - maintenance and service
Environmental-social	Release of toxic substances - waste management - the rule of law - efficiency
Customer orientation	Investment - new products - the need of new information
Production	Development - efficiency - replacing equipment and entrance fees
HSE risks	Personnel's safety - fires - the damage to the production network

Results

Initial and selected list of particulate control technologies were shown in *Table 2*. Information collected in the *Tables 3–7* for rating particle-filtering technologies after the preliminary analysis:

Table 2. *Initial and selected final particulate air pollution control*

Initial list			Key selected technologies by expert panel
Bag house	Wet ESP	Fabric filters	ULPA Filter
Settling chamber	Nano fibers bed	HEPA Filter	Wet ESP
ULPA filter	Scrubber	Wet cyclone	Nano fibers bed
Cyclone	ESP bag filter	Multicyclone	ESP Bag filter

Discussion

ULPA filter technology

The results in *Table 3* show more costs in the financial, personnel, customer service, and production areas. Possible changes to the original design, heat-resistant compounds, maintenance and service, blocked pores and vulnerability to high temperatures, and recycling are the costs of using this technology. High efficiency, information localization, least risk of fire and explosion, and the re-use of filters after cleaning are the benefits of using this technology. The results of previous research study showed that the filtration efficiency of ULPA filter is over 99.999% with a particle diameter of 0.12–0.17-μm Along with significant costs in maintenance and operations (Liu et al., 2017).

Wet ESP technology

According to the results *Table 4,* the financial, personnel, environmental, social, and customer benefits are a result of lower operating costs, short-term training, low power consumption, high temperature tolerance, and high filtration efficiency stemming from the use of this technology. The simultaneous collection of gas and particle is also an advantage of using this technology. The costs of this technology include those incurred in changes to the original design, the need for more physical space, maintenance and servicing, and corrosion caused by the generated sludge. According to the results, the obtained benefits of this technology outweigh the costs. Brandley (2005) announced that ESPs are a common means of reducing PM emissions from boilers, kilns and engines. Collection efficiencies was various, depending on the size and quality of the ESP, but in some cases have reached to upwards of 99% levels. The economic impact was found to be $5,430/tpy (Brandley, 2005).

Wet ESP technology provides with many features and benefits including low operating and maintenance costs, ultra low particulate emissions, compatibility with wet flue gas desulfurization (wet FGD) technology, and an optimized system design for sorbent injection technologies. For manufacturers with existing air pollution control equipment, wet ESP upgrades draw praise from customers who are eliminating carryover and costly maintenance. Improvements to water treatment, gas flow distribution and mist elimination enhance performance, reduce operating costs and protect downstream equipment (http://www.babcock.com/technology/pollution-control/particulate).

ESP bag filter technology

According to the results in *Table 5* the benefits of this technology include the removal of environmental emissions and social benefits resulting from the simultaneous

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_64416451
© 2018, ALÖKI Kft., Budapest, Hungary

control of ESP Bag filter and neutral chargeable particles, as well as high profits from pre-filtering bags. The technology however has high financial and design costs, as well as investment-related costs such as the need for supply source, ES pages, and the need for lightning protection systems. Research and education, especially for service and maintenance, have been allocated a big budget. Localization and the reuse of filters after cleaning are the advantages of using this technology. The combination of electrostatic precipitator (ESP) with bag filter technologies, which can filter smaller particles but fail to work effectively on larger particles, were selected as the proper alternative (closeness coefficient = 0.867) (Moridi et al., 2017).

Nano fibers beds technology

Results in *Table 6* show that the removal of particles (10 microns and smaller) in nano-technology fibers platform leads to social consequences and damage control, and is therefore beneficial. Recycling is however costly with this technology. Removal of organic and non-organic radicals, simultaneous extraction of particles and gases, odor elimination, low power operation, and access to raw materials and polymer composites are the advantages of using this technology. On the basis of the results captured in *Table 7* and T-test (one-sample-test) with a significance level of 5%, one can relatively have a realistic judgment in estimating the approximate financial, human, environmental costs.

Bennett (2016) announced that nanofiber coatings Plus filter cartridges are another development from Freudenberg. According to Freudenberg, high initial efficiency can be guaranteed because, unlike conventional filters, these filters do not need pre-coating with dust. The corrugated filter medium ensures constant low resistance, reducing power and compressed air consumption, potentially extending the product lifetime. Nanofiber coated filter cartridges are straight for-ward to handle and require minimal maintenance (Bennett, 2016).

Conclusion

In this study, the problem of choosing the effectively technical and economic for particulate control technologies, were addressed based on the cost benefit analysis method, which is a reliable scientific method for decision-makers. The methodology developed in this work in term of weighting the seven aspects of cost and benefits (financial, personnel, service and maintenance, environmental-social, customer orientation, production, HSE risks) for selected effectively technical and economic particulate control technologies. Furthermore, decision-makers could use the results obtained via this method to better assess their performance in particulate control. The use of hybrid technologies, including Wet-ESP, has been a top priority for research, but it is feasible to use emission sources with limitations that require extensive research.

(Received 11th Jun 2018; accepted 2nd Aug 2018)

Abstract. The aim of this study was to investigate the effects of irrigation levels (irrigation after 70, 110 and 150 mm of pan evaporation), phosphorus fertilizer levels (non-application of phosphorus fertilizer and application of 25 and 50% of recommended doses) and different species of Mycorrhiza (non-application of mycorrhiza, application of *Glomus intraradices*, *Glomus mossae*, *Glomus hoei* and co-application of the three species) on growth, essential oil production and physiological characteristics of medicinal plant, purple coneflower, in two crop years of 2015 and 2016. The study was performed in the form of split-split plot based on random block design. In most of the studied traits, decrease in water content for irrigation after 70 to 110 mm had no significant effect on vegetative traits and essential oil yield of purple coneflower. In irrigation after 150 mm of pan evaporation, despite a significant reduction of 44% in vegetative traits such as plant yield, the use of a number of fertilizer treatments, such as 50% of phosphorus application, combined with the application of mycorrhizal species and *G. hoei* species without phosphorus fertilizer, completely prevented the depressant effect of dehydration. In most of the traits, including wet and biological function per unit area, percentage of colonization, relative water content and aperture length, application of phosphorous fertilizer alone in full irrigation conditions (irrigation after 70 mm of pan evaporation), moderate dehydration (irrigation after 110 mm of pan evaporation) and severe dehydration (irrigation after 150 mm of pan evaporation), had no effect. The combined application of phosphorus and mycorrhiza fertilizer in irrigation after 70 and 150 mm of pan evaporation had no effect on the traits; however, at irrigation after 110 mm of pan evaporation, most of the treatment of combined application of phosphorus fertilizer and mycorrhiza increased significantly, especially in vegetative traits. Therefore, increase in the growth characteristics of purple coneflower at irrigation after 110 mm of pan evaporation with most fertilizer treatments did not affect these traits. The highest and lowest essential oil yields were obtained as 27.4 and 25.5 g in *G. intraradices* treatment with irrigation after 150 mm of pan evaporation and non-application of fertilizer with irrigation after 70 mm of pan evaporation. Considering the economic importance of the essential oil of purple coneflower, planting of this plant even in severe dehydration with the application of mycorrhiza may appear possible without reducing the essential oil yield, even though growth is negatively affected by dehydration.
Keywords: *bio fertilizer, chemical fertilizer, drought, essential oil, physiological characteristic*

Introduction

The purple coneflower (*Echinacea purpurea* L.), is an herbaceous and perennial plant. The active ingredients in the root and vegetative body of the various species of purple coneflower have anti-fungal, antibacterial and anti-viral properties. Medications

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

for prevention and also treating cold and respiratory illnesses are prepared from this plant (Chevallier, 1996). Chemical fertilizers increase the growth and production of active ingredients in medicinal and crop plants. However, the excessive use of these fertilizers without soil degradation, combined with severe crop agronomic practices and adverse management, leads to instability in agriculture and serious threats to the health of underground resources, the destruction of microorganisms and insects, soil degradation and soil organic matter reduction (Pajooheshgar et al., 2015). Phosphorus is the essential food ingredient of plants which plays an important role in maximizing production in crops. The efficiency of phosphorus application in crops is between 10 and 30% (Arshad et al., 2016). Reduction of inorganic phosphorus uptake is an appropriate strategy for reducing production cost. The application of mycorrhizal fungi is one of the suitable methods for reducing the amount of phosphorus consumed. The hypha massive fungi network effectively increases the absorption rate of the roots, allowing the plant to have more access to phosphorus. Phosphate ions are released into the heifers more rapidly than the roots, because they have a high tendency to absorb phosphorus in the hyphas and reduce threshold concentrations for absorption into the hyphas (Elbon and Valen, 2014). The results of several studies reveal the importance of mycorrhiza in helping plants with drought stress. One of the reasons for increasing resistance to stress is that, root colonization with mycorrhizal fungi in different plant species results in increased adsorption and proline production in drought stress conditions (Rapparini et al., 2013). Studies have shown that the effects of mycorrhizal fungi vary depending on the species of fungus. Das (2015) examined the type of mycorrhizal fungus in 12 herbal medicines and observed that, the type and intensity of fungal coexistence varied in different plants. Robinson et al. (2014) examined the effect of mycorrhiza on physiological growth and response of sesame. The application of mycorrhizal fungus enhanced the number of leaves, number of roots, the length of the aerial organ, the root biomass and chemical parameters. Total chlorophyll, chlorophyll a, chlorophyll b and carotenoids also increased with the use of mycorrhizal fungi. Mohseni et al. (2015) investigated the effect of inoculation with mycorrhizal fungi on cumin, and showed that the application of mycorrhizal fungus increased the number of branches, shoot dry weight, root length, root fresh weight, root volume, root diameter, root dry weight, root length density and root surface. Considering the importance of less water consumption and increasing plant tolerance to it and the role of mycorrhiza in these conditions on one hand, and reduction of the use of phosphorus fertilizer in line with sustainable agricultural goals on the other hand, the aim of this study was to investigate the effects of mycorrhiza species on the reduction of phosphorus in low irrigation conditions and response of some of physiological traits and yield and yield components of essence in Purple Coneflower (*Echinacea purpurea* L.) to these factors.

Materials and methods

In order to evaluate the effect of different species of mycorrhiza at different levels of phosphorus fertilizer application on some morpho-physiological traits of purple coneflower in dehydration conditions, an experiment was performed at Agricultural Station of Islamic Azad University, Tabriz, Iran during two crop years of 2015 and 2016. This area is located 5 km from Tabriz, at longitude 46° and 17’ E, latitude 38° and 5’ N, and 1360 m above sea level. Based on the cluster classification of Dumontron, the region has a semi-arid cold climate. The average annual temperature is 10 °C, the average annual temperature is 16 °C and the mean annual temperature is 2.2 °C. The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_64536468
© 2018, ALÖKI Kft., Budapest, Hungary

average annual precipitation in this area is 271.3 mm (Khalilvand and Yarnia, 2016). The soil pH of the region is in the weak alkaline range (*Table 1*).

Table 1. *The results of physical and chemical analysis of the test site soil*

Organic carbon percent	Organic matter percent	Sand	Silt	Clay	Conductivity (ds/m)	pH	P (ppm)	K (ppm)	Potassium solution (mg/l)
1.7	2.9	76	13	11	1.56	7.53	25.7	7.7	45

The experiment was carried out as split-split plot in a completely randomized block design with three replications in two crop years of 2014 and 2015. The test factors include:

Different levels of dehydration as the main factor in three levels: Irrigation after 70 mm of evaporation from class A pan (control), irrigation after 110 mm of evaporation from class A pan (medium stress) and irrigation after 150 mm of evaporation from class A pan (severe stress). Phosphorus at three levels as a sub-factor: Non use of phosphorus, 25% and 50% recommended**.** The application rate of phosphorous fertilizer for treatment of 0 and 50% of the recommended dose was 25 and 50 kg of phosphorus fertilizer per hectare, respectively. Different species of mycorrhiza in five levels as sub-factor including: Non-use (control), Rhizophagus intraradices species (*G. intraradices*), Funneliformis mosseae (*G. mossae*), *G. hoci* species, and mixture of the three species.

For the test, land acquisition operations were performed in March 2014, with appropriate climatic conditions. After leveling the land, dimensions of 1.5 × 2 m was applied on the plot. Each plot has three rows of irrigated crops and a stack of 45 cm in east-west direction. The spacing of the subplots was one-to-one plot, the main plots were 1.5 m and the distance between the two blocks was 2 m. In early spring, after preparation of the land, different levels of phosphorus were applied based on the planting plan in the experimental plots. After the purple coneflower straws were prepared in mid-May, they were transported to the main land during the second to third leaf stages. Before planting, different strains of mycorrhiza (prepared from the Institute of Water and Soil) were based on the experimental map and 9 g were added to each straw. In the case of each mixed strain, 3 g were added to the planting site, and then transplantation was carried out. The straws were planted 30 cm apart from each other and in hot water stacks. Irrigation was done immediately after seedling. Irrigation was done every three to one day for the nesting. To combat weed, manual weeding was done at the required time. To supply nitrogen, 200 kg/ha of urea was applied in two steps: half of the recommended amount was applied after nesting, and the other half was applied at the 8-10 leaf stage and before application of the aqueous treatments. After the first flowers emerged, dehydration stress was applied on the basis of irrigation after evaporation from class A pan. Each irrigation was done after 70 ± 5, 110 ± 5 and 150 ± 5 mm of evaporation from class A pan. The daily evaporation rate of the pan, after reaching the desired amount for each treatment (70, 110 and 150 mm), indicated irrigation time.

The amount of irrigated water was calculated for each treatment based on the total water requirement, and by random sampling from three different parts of each plot and determining the percentage of soil water content; the amount was calculated at about

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_64536468
© 2018, ALÖKI Kft., Budapest, Hungary

24 h before irrigation. To measure vegetative traits, 5 samples from each plot were harvested. To determine the vegetation factor, *Equation 1* was used:

$$ET_c = K_c \times ET_{0;} \text{ and } ET_0 = K_{pan} \times E_p \quad \text{(Eq.1)}$$

where, ETC and ETO are the plant and reference evapotranspirations, Kpan and Ep are the pan coefficient, respectively (Allen et al., 1998; Fazeli Rostampour et al., 2013).

Total volumes of irrigation water applied in the control treatment (Irrigation after 70 mm of evaporation) were 4885.7 and 5026.4 m^3 in 2015 and 2016, respectively. The volume of water used in other treatments (irrigation after 110 and 150 mm of evaporation) were 3574.6, 3685.4, 2169.8 and 2344.1 m^3, respectively; so the lowest volume of water used in the irrigation after 150 mm of evaporation in 2015.

Relative water content (RWC) was obtained after determining fresh weight (FW), saturation weight (TW) and dry weight (DW) of the 10 end leaves of the plant using the following formula (*Eq.2;* Levitt, 1980):

$$RWC = \left(\frac{FW - DW}{TW - DW}\right) * 100 \quad \text{(Eq.2)}$$

To determine the biological yield, the specimens were kept in ventilated condition under shade conditions at room temperature for one month (25 °C) and after that, they were weighted with a weighing scale of 0.01 g and their average in grams was used in the study. Fresh weight of total organs of shoot (stem, leaf and flower) known shoot fresh weight. Flower shoots together with dried leaves in shade conditions were powdered using the mill and the essential oil was extracted by water distillation with Clevenger. A sample of 25 g of herbal powder was selected and it was put inside a balloon together with 5.00 ml of distilled water. It was then heated by a Clevenger device for three hours. The yellow-colored essence was collected and the dehydration rate and essential oil percentage were determined using sodium water-free sodium sulfate and diethyl ether. The essential oil yield was obtained by multiplying dry matter yield by essential oil percentage.

The Arnon method (1949) was used to determine the amount of chlorophyll a, b and total chlorophyll, and carotenoids content in mg per grams of fresh leaf weight (*Eq. 3*). For this purpose, 0.5 g of fresh leaves was washed with 5 ml of acetone 80% (*W/V*). After 15 min of centrifugation at 1000 rpm per minute and 4 °C, it reached 10 ml. The absorbance of the extract was read by spectrophotometer at 663, 645, 510 and 480 nm wavelengths and the following relationships were used to measure the parameters. In these relationships, C is chlorophyll, A is the wavelength, V is the volume of solution, and W is the leaf sample weight.

$$\begin{aligned} C_a &= 12.7\ (A_{663}) - 2.69\ (A_{645}) \times V/P50\%M0W \\ C_b &= 22.9\ (A_{645}) - 2.69\ (A_{663}) \times V/P50\%M0W \\ C_T &= 20.2\ (A_{645}) + 8.02\ (A_{663}) \times V/P50\%M0W \\ \text{Carotenoid} &= 7.6\ (A_{480}) - 14.9\ (A_{510}) \times V/P50\%M0W \end{aligned} \quad \text{(Eq.3)}$$

For assessment of the stability of cytoplasmic membrane, ion leakage measurement method was employed using a conductivity meter.

Statistical data analysis was performed based on statistical model of split-split plot test using SAS 9.1 software and the mean of the treatments was compared by Duncan's multi-range test method at 5% level. Diagrams were obtained with Excel software.

Results and discussion

The effects of experimental factors and compounds on the traits evaluated are presented in *Table 2*.

Number of flowering branches

In this study, interaction between the levels of irrigation and phosphorus fertilizers and interaction between levels of phosphorus fertilizer and mycorrhizal fertilizer treatment with regards to the number of flowering branches were significant (*Table 2*). Under irrigation conditions, change in irrigation water after 70 to 150 mm of pan evaporation had no significant effect on the number of flowering branches in the purple coneflower. Nevertheless, consumption of 25% of the recommended dose of phosphorus fertilizer with irrigation after 150 mm pan evaporation, the number of flowering branches as compared to irrigation after 70 mm pan evaporation was higher by 31.4%; this reaction appears to be due to an incremental effect of 25% of recommended dose of phosphorus fertilizer. In this study, number of flowering branches increased in consumption of 25 and 50% of the recommended dose of phosphorus with reduced water irrigation after 70 and 150 mm of pan evaporation (*Fig. 1*). Research has shown that dehydration reduces the number of branches produced; one of the main reasons is decrease in the amount and activity of the hormone, cytokine (DaCosta and Huang, 2007). The cytokine hormone plays an important role in the formation of side stems (Miyawaki et al., 2004). According to Evers et al. (2011), the branching depends on the presence of assimilates. While dryness reduces assimilate content in the plant (Ash et al., 2001), phosphorus that plays an important role in photosynthesis, production of photosynthetic materials and their transfer to various parts of plants, reduces the effects of dryness reduction (Khan et al., 2013; Hammond and White, 2008). Kotoky et al. (2015) also observed that application of phosphorus fertilizer significantly increases the number of branches produced in *Aristolochia indica* plant.

In this study, among the fertilizer treatment combinations, the highest number of flowering branches with 7.3% was obtained in the treatment of 25% recommended phosphorus dose combined with the mixture of all mycorrhiza species; the lowest was 4.1 which was associated with *G. hoei* application without phosphorus fertilizer application. In the present study, with 25% of recommended phosphorus fertilizer dose, the application of mycorrhiza fertilizer, and also in mixture, a significant increase of 48.9% in the number of purple coneflower branches was observed (*Table 3*). The most important role of mycorrhizal fungi is in increasing phosphorus absorption (Yadav and Aggarwal, 2015). Application of mycorrhiza increases phosphorus effect on plant branching by increasing plant access to phosphorus. Increasing phosphorus absorption via the use of fungi can increase the number of side flowering branches by increasing the production of assimilates. On the other hand, these microorganisms play an important role in the morphology of plants by releasing growth stimulants such as auxin and cytokine (Salvucci et al., 2010).

Table 3. *Comparison of the mean of studied traits under the influence of phosphorous fertilizer levels and mycorrhizal fungi species*

Means with different letters in each column have significant difference at 5% probability level.

Leaf area index

In this study, the highest leaf area index (3.5) was related to non-use of phosphorus fertilizer with irrigation after 70 mm of pan evaporation, and the lowest (3.1) was associated with non-use of phosphorus chemical fertilizer and irrigation after 150 of the pan evaporation. Dehydration at levels of 25 and 50% of recommended phosphorus fertilizer dose did not have a significant effect on leaf area index of purple coneflower leaves. In the case of non-application of phosphorus fertilizer, water reduction with irrigation after 70 to 150 mm of pan evaporation reduced the leaf area index to 11.4% (*Fig. 2*). According to the results of this study, application of phosphorus prevented the reduction of leaf areas in low-irrigation conditions. The positive effect of phosphorus fertilizer application on the increase of plant tolerance to dehydration in terms of leaf growth has been also reported by Jamali (2013) in *Coriandrum sativum* herb. Phosphorus

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

is an essential nutrient for leaf growth, which plays an important role in the production of new leaves and increase of the area of each leaf in plants (Fletcher et al., 2004; Trindade et al., 2010). Anatomical studies have revealed that, using phosphorus fertilizer increases the length of leaf cells which increases leaf growth (Esmail et al., 2014).

In the present study, the maximum leaf area index was 3.5% for 50% of recommended dose of phosphorus fertilizer with *G. mossae*, and the lowest was associated with the application of 25% of recommended dose of phosphorus fertilizer without mycorrhiza application. At phosphorus fertilizer level of 25% and non-application of phosphorus fertilizer, none of the mycorrhizal treatments had a significant effect on leaf area index of purple coneflower. Nevertheless, in application of 50% of recommended phosphorus fertilizer dose, the application of *G. mossae* increased the leaf area index of purple coneflower by 7.8% (*Table 3*). The positive effect of mycorrhiza on the growth of plant leaves has been also reported by other researchers. In a study conducted on *Coriaria nepalensis*, Bargali and Bargali (2009) observed that, the application of mycorrhiza causes a 17% increase in the leaf area of *C. nepalensis*. In the present study, differences were observed between the studied species of mycorrhiza in terms of effectiveness on leaf area index. Kumar et al. (2009) in a study, evaluated the effects of two types of mycorrhizal fungi on *Salvia officinalis* growth and there was a significant difference between the species of mycorrhizal fungi in terms of leaf area. Thus, one of the species increased leaf area of *S. officinalis* by 45%, and *G. mossae* increased the leaf area of peppermint by 85%.

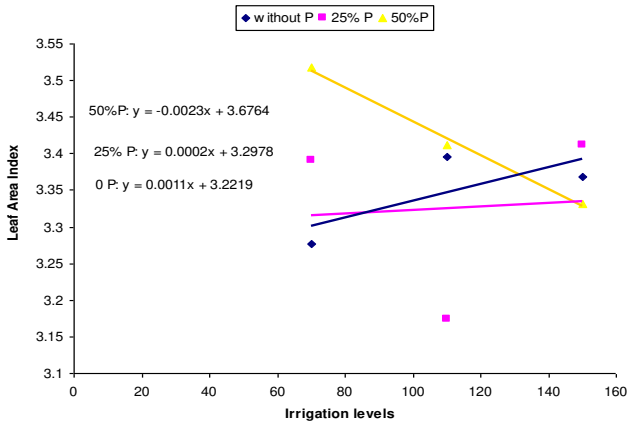

Figure 2. *Effect of phosphorous on leaf area index under irrigation levels*

Essential oil yield and percentage

In this study, the highest percentage of essential oil was related 25% of recommended dose of phosphorus fertilizer and *G. hoei*, and the lowest value was associated with 50% of recommended dose of phosphorus fertilizer alone. In this study, in the case of non-application of mycorrhiza, 50% of the recommended dose decreased the percentage of purple coneflower essential oil by 8.3%; however, with the use of mycorrhiza, no reduction was found in the percentage of essential oil due to the application of phosphorous fertilizer (*Fig. 3*). Similar results have been obtained by Hosseini Valiki et al. (2015) for Rosemary plant and Le et al. (2013) for *Salvia miltiorrhiza*. Lo et al. (2013) stated that probably, under conditions of increased phosphorus fertilizer levels, growth and early metabolism of the plant were more

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_64536468
© 2018, ALÖKI Kft., Budapest, Hungary

affected by phosphorus fertilization and consequently, the production of essential oils in medicinal herbs reduced.

The highest and lowest essential oil yield per unit area was 27.4 and 25.5 g in *G. intraradices* treatments with irrigation after 150 mm of pan evaporation and non-application of the fertilizer after 70 mm of pan evaporation. In this study, an increase of 7.9% was observed in essential oil yield per square meter in only non-application of mycorrhiza with reduced water irrigation after 70 and 150 mm of pan evaporation (*Fig. 3*). In addition, among the fertilizer treatments, *G. mossae* fertilizer treatment alone, 50% recommended phosphorus fertilizer alone and 50% of recommended dose of phosphorus fertilizer with *G. intraradices* significantly increased the essential oil yield; however, other fertilizer compounds did not have a significant effect on the yield of essential oil. Therefore, the effect of application of fertilizer on essential oil yield depends on mycorrhiza species and phosphorus level. Habibzadeh (2015) reported that the degree of coexistence of different mycorrhiza species with plants is different at different levels of phosphorus fertilizer; this is due to structural and secretion changes of the roots at different levels of chemical phosphorus fertilization. In the present study, high levels of phosphorus fertilizer with application of mycorrhiza species alone reduced essential oil content. At high levels of phosphorus fertilizer application, the amount of carbohydrate secretion from plant roots decreased and the thickness of the epidermis layer of the root increased which reduced the coexistence of fungi with plants (Habibzadeh, 2015).

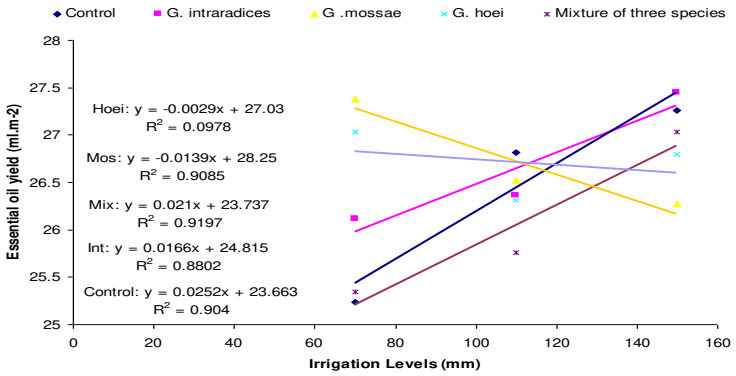

Figure 3. *Effect of mycorhiza on essential oil yield under irrigation levels*

Percentage of colonization

The highest percentage of root colonization of 58.6% was observed in the treatment of *G. intraradices* alone and with irrigation after 110 mm of pan evaporation and the lowest (21.33%) in the application of 25% of recommended dose of phosphorus fertilizer with *G. hoei* was obtained for irrigation after 150 mm of pan evaporation. According to the results obtained from this study, dehydration had a significant effect on the percentage of root colonization in *G. mossae* treatment alone. In the application of *G. mossae* alone, by decreasing irrigation water, 32.5% of root colonization was reduced (*Table 3*). At irrigation level after 150 mm of evaporation, fertilizer treatment had no significant effect on the root colonization percentage. At irrigation level after 110 mm of pan evaporation of some fertilizer treatments, a significant increase was observed in percentage of root colonization. At irrigation level after evaporation of 110 mm from the evaporation pan, application of *G. intraradices* and *G. mossae*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_64536468
© 2018, ALÖKI Kft., Budapest, Hungary

treatments alone and 25% of recommended dose of phosphorus fertilizer in addition to *G. hoei*, increased this trait by 93.4, 87.9 and 74.2%, respectively. According to the results, the *G. intraradices* species can be considered as a superior species in the establishment of coexistence with purple coneflower.

Biological yield and shoot fresh weight

In this study, the highest wet and biological yields were obtained as 303.6 and 235 g in 50% of recommended dose of phosphorus fertilizer with *G. mossae* and irrigation after 70 mm of pan evaporation. The lowest wet and biological yields were observed as 108 and 65.4 g, respectively, in treatments with 50% of recommended dose of phosphorus fertilizer together with *G. hoei* and 50% of recommended dose of phosphorus fertilizer with a mixture of mycorrhizal fertilizers at irrigation after 150 mm of pan evaporation. From the results, irrigation water reduction had negative effect on wet and biological yields per square meter. With decrease in irrigation water from after 70 to 150 mm of pan evaporation, the highest reduction of 62.4% was achieved in the application of 25% of recommended dose of phosphorus fertilizer alone. Nevertheless, in the fertilizer mixture of *G. intraradices*, *G. hoei* and a mixture of fertilizers alone and 25% of recommended dose of phosphorus fertilizer with *G. intraradices*, dehydration did not affect the wet and biological yields (*Table 4*). Research has shown that by decreasing irrigation water, the accumulation of dry matter and the rate of water absorption reduces (Nazarli and Zardashti, 2010). The absorption of water and food in the plant is dependent on the activity of the roots, and in the case of dehydration, root growth and absorption activity of the roots will be reduced (Boomsma and Wyn, 2008). On the other hand, decrease in dry weight due to dehydration can be as a result of reduced assimilate production and the capacity to absorb assimilates for growth (Yardanova and Popova, 2007).

Table 4. *Comparison of the mean of studied traits under the influence of irrigation levels, phosphorus fertilizer levels and mycorrhizal fungal species*

Means with different letters in each column have significant difference at 5% probability level.

In this study, application of fertilizers, especially in dehydration, has a moderate effect on resistance to dehydration in plants. In irrigation after 110 mm of pan evaporation, most fertilizer combinations cause a significant increase in wet and biological yields. The most desirable fertilizer compounds with irrigation after 110 mm of pan evaporation in terms of wet and biological yields, were 25% of recommended dose of phosphorus fertilizer alone, 25% of recommended dose of phosphorus fertilizer combined with *G. mossae*, 50% recommended phosphorus fertilizer dose with *G. intraradices* and 50% of recommended dose of phosphorus with *G. hoei*. Various studies have shown that phosphorus fertilizers can play an important role in increase in the resistance of plants to dehydration (Mirabello et al., 2013). On the other hand, mycorrhizal fertilizers can increase the water access of plants by increasing the absorption rate of the roots and reducing the impact of dehydration on plants (Sharma et al., 2015). It seems that in environmental conditions, moderate dehydration enhances the efficiency of phosphorous and mycorrhizal fertilizers in the growth of purple coneflower. The application of phosphorous fertilizer in moderate dehydration conditions increased biological yield of purple coneflower, which is probably due to reduced plant access to phosphorus in dehydrated conditions. Studies have shown that by reducing irrigation water, plant access to soil phosphorus decreases linearly; therefore, increase in the amount of phosphorus available in the soil through fertilization can play an effective role in increasing plant growth in dehydration conditions (Mirabello et al., 2013). Mycorrhizal fertilizers have also shown little impact in full irrigation conditions in different studies, while more effectiveness of this group of microorganisms has been obtained in dehydration conditions (Krishnakumar et al., 2013). This is because in dehydration conditions, the role of mycorrhizae becomes more pronounced by restricting plant access to growth resources such as fertilizers and water (Krishnakumar et al., 2013). In dehydrated conditions, mycorrhizae increase the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_64536468
© 2018, ALÖKI Kft., Budapest, Hungary

absorption level and the amount of water absorbed by the plant (Sharma et al., 2015). However, researchers believe that in severe dehydration, the growth and activity of mycorrhizal can be reduced (Krishnakumar et al., 2013) and thus, these fertilizers cannot have a positive effect on plants in severe dehydration. In a study, Khalili et al. (2014) examined the effects of different levels of phosphorus fertilizer on *Lepidium sativum* herb. Based on the results of that study, application of phosphorous fertilizer increased the wet yield of peppermint significantly. However, in this study, there was a difference in the effectiveness of different species of mycorrhizal fungi in plant growth. Hedayati Mahdi Abadi et al. (2015) examined the effect of *G. mossae* and *G. intraradices* species on Caraway plant and observed that *G. intraradices* species did not have a significant effect on Caraway biomass, but *G. mossae* caused a significant increase in the biomass.

Photosynthetic pigments

The highest leaf carotenoid content of 6.6 mg per gram of shoot fresh weight was obtained with the treatment of 25% of recommended dose of phosphorus fertilizer combined with *G. intraradices* in irrigation after 110 mm of pan evaporation and the lowest values of 3.4 and 3.2 mg per gram were obtained in two treatment combination of 25% recommended phosphorus fertilizer. The dose was combined with a mixture of mycorrhizal fertilizers and 50% of recommended dose of phosphorus fertilizer combined with *G. mossae* with irrigation after 70 mm of pan evaporation. At irrigation after 70 mm of pan evaporation, fertilizer treatment including 25% of recommended dose of phosphorus fertilizer alone, 50% of recommended dose of phosphorus fertilizer alone and 50% of recommended dose of phosphorus fertilizer combined with *G. intraradices* increased leaf carotenoid content by 77.3, 70.1 and 78.3%, respectively (*Table 4*). Chlorophyll content decreased under the influence of dehydration. At 25% of the recommended phosphorus fertilizer dose, by decreasing irrigation water from 70 to 150 mm pan evaporation, a decrease of 8.2% was observed in chlorophyll a content. In this study, a non significant increase was observed in chlorophyll content in only 25% of the recommended phosphorus fertilizer dose with reduced water irrigation after 70 to 150 mm of pan evaporation (*Fig. 4*). Dehydration reduces chlorophyll content by reducing the amount of chlorophyll produced and increasing its degradation (Rapparini et al., 2013). Chlorophyll a and carotenoid content were not affected by mycorrhiza but chlorophyll b content was only affected by mycorrhiza which decreased it. Robinson et al. (2014) showed that the application of mycorrhiza increases the chlorophyll b content in sesame.

Plasma membrane stability

In this study, in all the combinations of phosphorus fertilizer and mycorrhiza species, dehydration had no significant effect on plasma membrane stability and only in non-application of fertilizer, did reduction in irrigation water after 70 to 150 mm of evaporation caused a decrease of 33.7% in plasma membrane stability. In this study, in irrigation after 70 mm of pan evaporation, a number of combinations of phosphorus fertilizer and mycorrhiza had a significant effect on the stability of the plasma membrane. At this irrigation level, the treatments of *G. mossae* and *G. hoei* application alone, 25% of recommended dose of phosphorus fertilizer with *G. hoei*, 25% of recommended dose of phosphorus fertilizer with a mixture of fertilizers, 50% of recommended dose of phosphorus fertilizer alone and 50% of recommended dose of phosphorus fertilizer with *G. intraradices* increased the plasma membrane stability by 29.2, 41.7, 41.6, 30.6 and 28.7%, respectively (*Table 4*).

Stoma properties and relative water content

According to the ANOVA results, traits of interactions between irrigation levels, phosphorous fertilizer levels and mycorrhiza species had a significant effect on aperture length and width (*Table 2*). In this study, the maximum aperture length of 8 μm in the treatment combination was observed for 25% of recommended dose of phosphorus fertilizer with *G. intraradices* and irrigation after 150 mm of pan evaporation. The minimum (4.8 μm) was associated with the application of 25% of recommended dose of phosphorus fertilizer with *G. intraradices* and irrigation after 70 mm of pan evaporation. In addition, the maximum aperture width of 5.6 μm was observed in the mixture of mycorrhizal fertilizers alone with irrigation after 70 mm of pan evaporation and the lowest (2.3 μm) was associated with the treatment of 50% recommended phosphorus fertilizer with a mixture of mycorrhizal fertilizers and irrigation after 150 mm of pan evaporation. In this study, a significant increase of 65% for the aperture length was observed only at 25% of recommended dose of phosphorus fertilizer with *G. intraradices* and reduced irrigation water at irrigation after 70 to 150 mm of pan evaporation. Moreover, except for the application of mixture of fertilizers alone or with 50% of recommended dose of phosphorus fertilizer, there was no significant difference between the irrigation levels in terms of aperture width in the fertilizer treatments. In the mixture of fertilizers alone, reducing irrigation water after 70 to 110 mm of pan evaporation decreased the aperture width by 2.4%. In the treatment of a mixture of fertilizers with 50% of the recommended dose of phosphorus fertilizer in irrigation treatment after 150 mm of pan evaporation, the aperture width was 50% lower than the case of irrigation after 110 mm of pan evaporation (*Table 4*). Thus, in this plant, in the presence of mycorrhiza and conditions of dehydration, the aperture length increases and their width decreases, this will lead to higher carbon dioxide input and a decrease in transpiration.

In this study, except for *G. intraradice*s application alone, relative water content was not affected by irrigation levels in the fertilizer treatments. In the application of *G. intraradices* alone, by reducing irrigation after 70 and 150 mm of pan evaporation, a decrease of 39.2% in relative water content was observed (*Table 3*).

Conclusion

The results of this experiment prove that the application of mycorrhiza prevented a significant change in plant production due to dehydration by increasing leaf area and the production of flowering shoots, even under the conditions of less phosphorus fertilizer application. Changes in physiological traits, especially, the plasma membrane stability and aperture movements with the application of mycorrhiza, led to an increase in plant cellular power in the continuation of metabolic reactions and the production of essential oils also increased with mycorrhizal application even under extreme stress conditions. Reduction to at least, 50% of phosphorus consumption without significantly reducing the production of purple coneflower in terms of mycorrhiza application is more important in sustainable agriculture, even in the case of dehydration.

(Received 13th Jun 2018; accepted 2nd Aug 2018)

Abstract. The objective of this study was the evaluation of the Ceres-Rice model under different density and water management options in Semi-Mediterranean climate condition. An experiment was conducted in a randomized complete block design (RCBD) with three replications in north of Iran during cropping seasons of 2014 and 2015. There were 5 levels of irrigation treatments in this research including: I_1: Flood irrigation, I_2: Saturation, I_3: Irrigation with 8 days alternative before anthesis, I_4: Irrigation with 8 days alternative after anthesis, I_5: Irrigation with 8 days alternative whole growth season) and there were three plant spacing including: $D_1 = 15 \times 15$, $D_2 = 20 \times 20$, $D_3 = 25 \times 25$cm. Evaluation simulated and measured grain yield, total crop biomass, and crop biomass by adjusted coefficient of correlation and by absolute and normalized root mean square errors (RMSE). Grain yield of D_2 was predicted the most accurate than other density treatments (RMSE = 439 and RMSEn = 11%). Biomass of D_2 was predicted the most accurate than other density treatments (RMSE = 873 and RMSEn = 9%). Observed and predicted planting densities by rice showed good agreement in both calibration and evaluation steps. The Ceres-Rice model can be applied to research purposes (irrigation and planting densities) under northern Iranian conditions.
Keywords: *Semi-Mediterranean, Ceres-Rice, Irrigation, Crop Model, Water Productivity*

Introduction

Rice is a main food for majority of the world's population, raised on about 146.5 million ha of the agricultural fields of the world. So it is necessary to optimize usage of available resources due to shortage of water resources in rice fields (Thakur et al., 2014; Gill et al., 2014; Murumkar et al., 2014). Water necessity is more for this plant than other grains and the amount of it is affected by the rice cultivar, stage of growth, length of growth stage, plant density and even method of cultivation and weather conditions. Iran is an area with an annual rainfall of 240 mm and 0.57 million ha paddy field. Most rainfalls occur out of rice growth stages. Water allocation is not sufficient for low efficient irrigation in Iran, and surface water storage will be increased by construction of dams (Amiri et al., 2011).

Agricultural water productivity directly affects crop production; therefore, various water saving techniques and managements have been developed for rice producers to minimize water use and maintain optimum yield (Pascual, 2016). For instance, observed yield and simulated water balance, the calculated average WP_{ET} was significantly lower than the average WP_T: 37%. The average WP_I, WP_{ET}, WP_T and WP_{ETQ} were 1.01, 0.89, 1.41 and 0.65 kgm^{-3} (Amiri and Rezaei, 2013).

Severe drought stress at mid-tillering delayed flowering, and caused substantial yield losses by large percentage of unfilled grains (Davatgar et al., 2009). This finding has been confirmed by Pirdashti et al. (2009) who pointed out that water shortage in the vegetative growth stage extended the number of days for flowering in different rice cultivars. It has been documented that dry matter is more affected under vegetative stage stress whereas severe effects on sink size (spikelet fertility, 1000 grain weight and seed yield) under reproductive stage stress would be resulted (Guan et al., 2010).

Roderick et al. (2011) concluded in a research that alternate wet and drying irrigation deficit method has reduced about 38% of irrigation water usage, with the same yields and farmers profits.

High densities of rice cultivation reduce plant yield and yield components (Chamara et al., 2016). Some researchers have reported increased yield per unit area as a result of increasing density per unit area (Clerget et al., 2016). Other researchers have also reported declined yield and biomass per unit area due to increasing density (Awan et al., 2014). In addition, high densities are recommended to suppress weeds and increase yield in rice (Chauhan et al., 2011).

In order to detect the effect of planting density on the water productivity of rice product, an experiment was conducted in a split plot design with three plant-distance (20 × 20, 15 × 15, 20 × 10 cm) as a sub plots and four different irrigation regimes (permanent flooding treatment as a control group and 100%, 75% and 50% evaporation from the pan) as the main factors. The best yield in irrigation was reported for 75% evaporation from the pan and the plant-density of (20 × 20 cm) (Amiri et al., 2011).

In recent years, there has been an increasing amount of literature on simulation and modeling application on rice production (Amiri et al., 2014; Vijayalaxmi et al., 2016)

Until now, the most conducted researches have been about the method of irrigation management based on fixed round of irrigation from the first to the end of growing season. Fewer researches have been conducted about the method of irrigation management regarding cultivation density. At present, information required for the rice production improvement with suitable management practices is a need of hour. The generation of new data through agronomic research methods is insufficient and time consuming to meet these needs. So crop simulation models are considered as potentially useful tools in agricultural decision making. The major objectives of this study were to investigate: (i) Modeling response of Hashemi rice variety to change in planting densities and irrigation managements (ii) Calibrate and validate the DSSAT v 4.5. model based on experimental data; (iii) To explore on-farm strategies which result in higher economic gains and water productivity.

Materials and methods

Experimental design, crop establishment, and crop management

The experiment was conducted as split plot based on randomized complete block design with three replications on rice Hashemi cultivar during growing season of 2014 and 2015 in Koosal-Lahijan region located in north of Iran. The height of the site is 3 m from the sea level and it is located at 14”3’37° of north latitude and14”1’50° of east length. Irrigation treatments were at five levels: full irrigation = I_1 saturated = I_2 irrigation with 8 days alternative until anthesis = I_3, irrigation with 8 days alternative after anthesis = I_4, irrigation with 8 days alternative during the whole period of growth = I_5 and density was at 3 levels: 15 × 15 = D_1, 20 × 20 = D_2, 25 × 25 = D_3 cm

(444000, 250000, 160000 plants per hectare, respectively). Each experimental plot was 9.2 m long and 3 m wide. After transplanting the markers to the main land, the plots were kept for 10 days in permanent flooding until the markers were settled. After that, irrigation management was applied in the plots based on the program. I_1 was often flooding and I_2 was often saturated. I_3 was irrigated every 8 days before anthesis and then was flooded. The treatments I_4 was irrigated every two to three days before anthesis and then irrigated every 8 days. I_5 was completely irrigated every 8 days. It should be noted that the management of irrigation with frequency of 8 days (Amiri and Rezaei, 2013) was performed based on the alternation according to the growth of rice, using optimal water management in drought stress condition and in order to cope with damages caused by water stress on Hashemi cultivar.

According to the *Table 1,* soil of the experiment site is suitable for rice. *Table 2* also shows crop information and *Figures 1* and *2* shows the meteorological characteristics of the site. The first 20 days were irrigated by flooding. Urea, potassium and phosphate fertilizers were each used at baseline of 60 $kg.ha^{-1}$. 60 kg urea fertilizer was also consumed one month after the baseline stage. Graining was carried out at the end of April in the treasury environment and transplantation of the treatments was done at the end of May. After handling and harvesting, the clusters were placed in an oven for drying for 72 h at 70 °C.

Ceres-Rice description

Ceres-Rice model was selected as a tool for simulating growth and yield of rice under different environment and management strategies. The Ceres-Rice model simulates rice crop growth and development from either planting or transplanting to physiological maturity and is based on the physiological processes that describe the response of rice to local soil and weather conditions. Potential growth is mainly dependent upon photosynthetically active radiation (PAR), light interception and the light conversion efficiency, while actual growth is a constraint of crop management, soil and weather interactions.

The input data required to run the DSSAT models include daily weather data, i.e. maximum and minimum temperature, rainfall, and solar radiation; soil characterization data, genetic coefficients and crop management information, such as date of planting, age of seedlings, row and plant spacing, rates and dates and amount of fertilizer and irrigation applied. Input data files of Ceres-Rice model are as per IBSNAT standard input/output formats and file structure described in DSSAT v 4.5 (Hoogenboom et al., 2003).

Model inputs

The DSSAT models require the minimum data set for model operation. They encompass data on the site where the model is to be operated, on the daily weather data, on the soil properties, and on the all aspects management of the crop growth. Important crop management factors include planting date, planting depth, row spacing and direction, plant population, fertilization, irrigation, inoculation, residue applications, tillage, and harvest date.

Calibration of Ceres-Rice model

The calibration of the Ceres-Rice model was based on data from measured data of grain yield, total biomass in 2014-2015 field experiment. The genetic coefficients of the rice cv. Hashemi that affect the occurrence of phonological stages in the Ceres-Rice models were derived using the GLUE Estimator of DSSAT v 4.6. This program estimates the coefficients for a genotype by iteratively running the crop model with an approximate value of the coefficients concerned.

One would expect to have, for good model performance, values of RMSE as close as possible to 0. A model produces experimental data perfectly when α is close to 1, β is close to 0, R^2 is close to 1, RMSEa is similar to the SD of measured values, and RMSEn is similar to the coefficient of variation (CV) of measured values.

Model evaluation

Summary measures used in the present study were the mean of measured and simulated values, the standard deviations (SD) of the observations and simulations, the slope α, intercept β, and coefficient of determination (R^2) of the linear regression line between simulated and measured values. The different measures were based on the analysis of residual errors, that is, the difference between simulated and measured values. We computed the absolute and normalized root mean square errors (RMSE and RMSEn, respectively). Also, based on the measured data and relationship data and statistical estimation of the model were done through the root mean square error (RMSE), normalized root mean square error (RMSEn), relative error of the model (ME). When the RMSE and RMSEn values are closer to zero, it indicates that the prediction has been done better by relations (*Eqs. 1–3*).

$$RMSE = \sqrt{\frac{\sum_{i=1}^{n}(P_i - O_i)^2}{n}} \quad \text{(Eq.1)}$$

$$RMSE_n = 100\ (\sum_{i=1}^{n}(P_i - O_i)^2 / n)^{0.5}) \Big/ \overline{O} \quad \text{(Eq.2)}$$

$$RMSE = 100\ (\frac{P_i - O_i}{O_i}) \quad \text{(Eq.3)}$$

In the first two relations (*Eq. 1* and *2*), S_i and O_i are respectively the values of relative and observed performance equations. $\overline{O}$ is the mean of observed values and n is the number of observations (Amiri et al., 2011).

Water balance components

The water balance of lowland rice model includes (*Eq. 4*):

$$dW = I + R + C - E - T - S - Q - D \quad \text{(Eq.4)}$$

where dW is the change in stored water, I is irrigation supply, R is rainfall, C is capillary rise, E is evaporation, T is transpiration, S is seepage, Q is percolation, and D is surface drainage/runoff (all units are mm) (Bouman et al., 2001).

Water productivity

WP indices express the profit derived from the consumption of water and can be used for assessing the impact of on-farm strategies under water scarce situations. They provide a proper vision of where and when water could be conserved. The following equations (*Eqs. 5–9*) were used to calculate the water productivity components (Singh et al., 2006).

$$WP_T = \frac{Y_g}{T} \quad \text{(Eq.5)}$$

$$WP_{ET} = \frac{Y_g}{E+T} \quad \text{(Eq.6)}$$

$$WP_I = \frac{Y_g}{I} \quad \text{(Eq.7)}$$

$$WP_{I+R} = \frac{Y_g}{I+R} \quad \text{(Eq.8)}$$

$$WP_{ETQ} = \frac{Y_g}{E+T+Q} \quad \text{(Eq.9)}$$

where Yg (Kg) is the crop grain yield, T (mm) is the actual transpiration, E (mm) is the actual soil evaporation, I (mm) is irrigation, R (mm) is rainfall and Q (mm) is the percolation. WP_I (kg/m^3), WP_{I+R} (kg/m^3), WP_{ET} (kg/m^3), WP_T (kg/m^3) and WP_{ETQ} (kg/m^3) are expressed in crop grain yield (Yg) per unit amount of I, I+R, ET, T and ETQ respectively.

Results and discussion

Model calibration

The calibrated genetic coefficients (cv. Hashemi) as derived by Gencalc for Ceres-Rice are given in *Table 3*.

Table 4 shows the goodness-of-fit parameters for grain yield and aboveground biomass at harvest of the whole data set. The model simulated aboveground biomass

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_64696482
© 2018, ALÖKI Kft., Budapest, Hungary

and Grain yield quite well, with the absolute and normalized RMSE values greater than the error in the measured value (*Table 4*). For biomass, the slope was close to 1, and the intercept ß was high, indicating general overestimation of simulated values. Almost the same pattern was observed for grain yield. The model simulated grain yield and biomass generally good. The slope in validation was a little bit greater than that of calibration while the intercept ß was less than that of calibration. The relatively high R^2 reflects the low spread of the data. The error value in validation step has decreased, which is a reason to accept the results of the model. Also, the mean square error should be less than the standard deviation of the actual values that the results of the evaluation of Ceres-Rice model accuracy in irrigation management and different crop distances indicate that.

Table 3. *Genetic coefficients of the rice cv. Hashemi as derived by GENCALC of DSSAT model*

Genetic parameters	Description	Coefficient for Hashemi
P1	Time period (expressed as growing degree days (GDD) in °C above a base temperature of 9 °C from seedling emergence during which the rice plant is not responsive to changes in photoperiod	320.0
P20	Critical photoperiod or the longest day length (in h) at which the development occurs at a maximum rate	5.0
P2R	Extent to which phasic development leading to panicle initiation is delayed (expressed as GDD in °C) for each hour increase in photoperiod above P20	13.5
P5	Time period in GDD °C) from beginning of grain filling (3 to 4 days after flowering) to physiological maturity with a base temperature of 9 °C	240.0
G1	Potential spikelet number coefficient as estimated from the number of spikelets per g of main culm dry weight (less lead blades and sheaths plus spikes) at anthesis	55.2
G2	Single grain weight (g) under ideal growing conditions, i.e., nonlimiting light, water, and nutrients and absence of pests and diseases	0.0200
G3	Tillering coefficient (scaler value) relative to IR64 cultivar under ideal conditions	1.00
G4	Temperature tolerance coefficient. Usually 1.0 for varieties grown in normal environments	1.00

Model evaluation

Grain yield the graphical comparison between simulated and measured grain yield is presented in *Figure 3*. The Ceres-Rice model simulated grain yield in 2015 quite well. Grain yield of D_2 was predicted the most accurate than other density treatments ($R^2 = 0.85$).

The graphical performance of the Ceres-Rice model in simulating total crop biomass at harvest is presented in *Figure 4*. Similar to the simulation results of the grain yield, the best performance of the model in simulating total crop biomass was obtained in

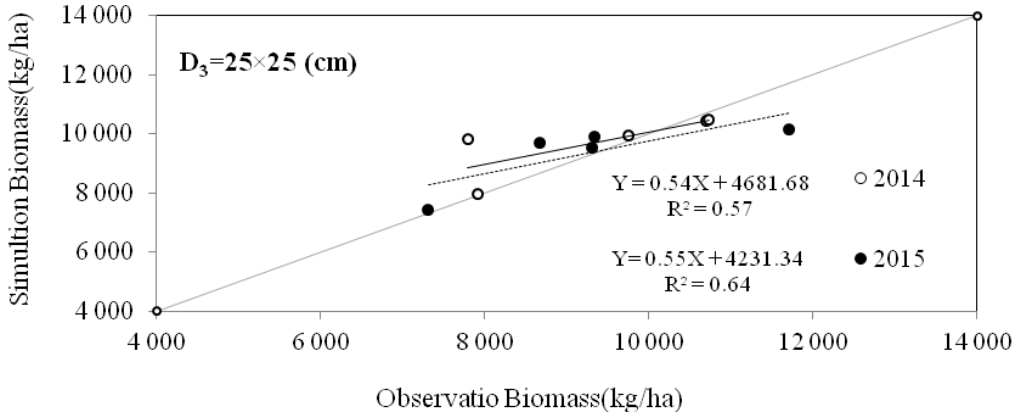

Figure 4. *Evaluation of Ceres-Rice model for final above ground biomass under different density and water management*

The use of Ceres-Rice model in different years to simulate rice yield in irrigation management and different densities is shown in *Figure 5*. The ability of the Ceres-Rice model to simulate the total biomass of rice in different years under irrigation management and different densities is shown in *Figure 6.* In the second year, the plant was exposed to warmer days and the rice plant was subjected to more severe drought stress, which caused the plant to close its stomata more than the first year, and the yield and total biomass decreased compared to the first year.

Water balance components

An examination of simulated components of water balance under different density and water management reveals interesting facts (*Fig. 7*).

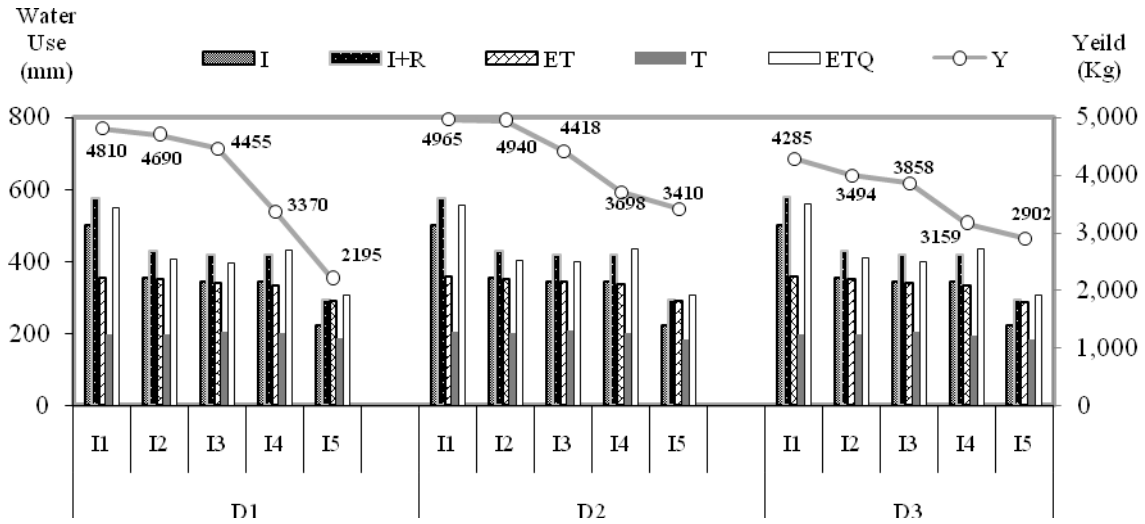

Figure 7. *Water productivity values at different irrigation and crop distance treatments*

The seasonal evaporation varied from 103 to 159 mm and showed a significant reduction with a decrease in plant spacing and applied water amount. The results of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_64696482
© 2018, ALÖKI Kft., Budapest, Hungary

model showed that the amount of evaporation (E) is 36-44% of evapotranspiration (ET). The variability of physiological function of rice plant in irrigation management and different intervals of cultivation and changing environmental conditions leads to different transpirational requirements and consequently the amount of transpiration (T) in the plant. Changing the irrigation method from floodwaters to non-floodwaters results in increased transpiration (T). Investigation of transpiration amount in irrigation management and planting distance showed that transpiration values varied in the range of 187-217 mm; the highest transpiration (T) was observed in I_3: Irrigation with 8 days alternative before anthesis for irrigation and crop distance $D_2 = 20 \times 20$ cm was observed at 209 mm. Estimation of depth of penetration (ETQ) in irrigation and planting intervals showed that depth of penetration (ETQ) varies in the range of 534-295 mm; the results of deep penetration in the study period showed that the maximum amount of water loss Through deep penetration (ETQ) was observed in flood management. Amounts of rainfall from transplanting to harvest stage were 38 mm for 2014 and 169 mm for 2015. The amount of irrigation water applied varied between 221 mm to 502 mm. As the spacing increased, the depth of penetration (ETQ) increased. Irrigation with 8 days alternative before anthesis with only 4% reduction in yield (Y) compared to the usual method of flooding reduced water consumption and savings of 16% in irrigation water + precipitation (I + R).

Water productivity components

The water productivity for rice was analyzed using the Ceres-Ricesimulation model. We calculated the water productivity rates using the simulated water balance components of T and ET by Ceres-Rice and the actual (observed) grain yield (*Table 5*).

Table 5 shows the WP values at different irrigation and crop distance treatments in the experiment. Water productivity values for irrigation management and different densities are shown in *Table 5*. Water productivity is based on the amount of mechanism secretion in the plant and depends on the type of plant. As a result, WP_T for a rice plant is a measurable variable that depends on eco-hydrological conditions. The results of this study indicate that the WP_T value varies between 1.6 and 2.46 kg/cm^3. Water productivity is discussed based on the amount of evapotranspiration on soil and plant matter and shading, depending on the type of soil and climate and plant. The inevitable water shortage due to evaporation from the surface water and saturated soil (E) leads to a reduction in water productivity from WP_T to WP_{ET}; on average, WP_{ET} is 41% lower than WP_T. By changing the irrigation management from flood to non-waterlogging, water productivity (WP_I) increases, so that the lowest water productivity (WP_I) in flood treatment is I_1 = 0.92 kg/m^3 and The highest water productivity (WP_I) was observed in saturated treatment of I_2 = 1.27 kg/m^3. The average amount of water-based components of irrigation, evapotranspiration, transpiration and total evapotranspiration and deep penetration (WP_I, WP_{I+R}, WP_{ET}, WP_T and WP_{ETQ}) were 1.13, 0.94, 16.1, 1.97 and 0.49 kg/m^3 respectively. In general, I_3D_3 treatment has reduced water consumption while maintaining optimum performance and water productivity. Continuously surface water flooded method result in high soil evaporation in Hashemi rice planting. Reducing water allocation from continuous flooded methods to soil saturation or alternative irrigation methods will slightly decrease the rice yields but will substantially increase the water productivity (Amiri and Rezaei, 2013).

Conclusion

The results from this study showed that the Ceres-Rice model generally predicted biomass and grain yield, fairly satisfactorily across a range of data sets covering varying levels of water- and density management during 2 years. Results showed that predicted grain yields agreed well with observed yields (RMSEa = 382 and RMSEn = 10%). Also total biomass also were simulated well (RMSEa = 975 and RMSEn = 10%). High evaporation rate at initial stages of crop growth due to traditional irrigation method, has decreased WP_{ET} by 41% compared to WP_T. The results showed that I_3: Irrigation with 8 days alternative before anthesis and D_2 = 20 × 20 cm plant density is the optimum irrigation method and crop density management. The Ceres-Rice model is calibrated and validated using field experimental data, and can be used to predict the experimental results of irrigation and different densities conditions in northern Iran, thus helping to identify target domains and irrigation and density management recommendations for farmers.

Abstract. Manor parks established on oak-hornbeam habitat (*Tilio-Carpinetum*) are very characteristic elements of agricultural landscapes in Poland. In light of the loss of old growth oak-hornbeam forests because of deforestations, these habitats have the potential to become refuges. Thus, the aim of the study was to determine the influence of surroundings landscape structure on the development of the plant species composition on the herb layer in selected manor parks in the southern part of Poland. The study was conducted in 60 manor parks located in southern Poland characterized by differences in land use of the surroundings. Manor parks located close to forest were characterized by higher numbers of forest plant species in the herb layer. Both the percentage share of the *Tilio-Carpinetum* species and the percentage share of ancient forest species were increased in parks adjacent to forests. However, forest size seems to be of minor importance. Indicator plant species for manor parks adjacent to villages as well as indicator species for parks nearby forests could be identified. The results of the study are important for landscape planners and landscape ecologists in order to formulate directions of shaping and management of rural landscapes including manor parks.
Keywords: *Forest species, Ancient species, Tilio-Carpinetum, Landscape ecology, Poland*

Introduction

The impact of anthropogenic and natural factors is important for shaping the species composition of the forest herbaceous layer (Verheyen et al., 2003; Hale et al., 2006; Verheyen et al., 2012; Hofmeister et al., 2013). The diversity of the forest herb layer constitutes the largest fraction of the total plant diversity in deciduous forests (Gilliam, 2007; Alberdi et al., 2010). The distribution of forest species in human-dominated forests and agroforests varies as a function of the species traits that are vulnerable to disturbance and fragmentation (Carreneo-Rocabado et al., 2012). Characteristics of a habitat patch and its surrounding matrix and the degree of fragmentation are important determinants of plant species composition (Honnay et al., 2005; Moxham and Turner,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

2011; Aggemyr and Cousins, 2012; Amici et al., 2015, Ojoyi et al., 2015; Pao and Upadhaya, 2017). Therefore, the floristic diversity and forest plant species composition of isolated patches is limited (Ewers and Didham, 2006; Tscharntke et al., 2012), based on the relative importance of the landscape and habitat factors.

Herbaceous plants are very dynamic so they are suitable indicators of changes of habitats in short time (Alberdi et al., 2010; Del Vecchio et al., 2016). Among them, a special role can be attached to ancient forest plant species. Ancient forest plant species are plants that are characteristic of ancient woodlands (older than 200 years) and old woodlands (200-100 years old) according to Wulf (2003). The list of ancient forests indicator species for Central and Western Europe was proposed by Hermy et al. (1999). Then, for Polish conditions it was complemented by Dzwonko and Loster (2001). In this context the role of the forest islands in the agricultural landscape was determined as the places of forest flora refuges (Wojcik, 1991; Dzwonko and Loster, 1992; Dzwonko and Gawroński, 1994; Braun and Koch, 2016). Ancient plants are proper indicators of long term continuity of the habitat (Hermy et al., 1999; Nordén and Appelqvist, 2001; Verheyen et al., 2003; Kolb and Diekmann, 2004; Stefanska-Krzaczek et al., 2016; Lalechère et al., 2017; Webb and Goodenough, 2018). The degree of naturalness of forests is one of the attributes for the assessment of the ecological stability of forests (Macků, 2012).

Many of the vascular species that grow in these forests have slow dispersal mechanisms and/or rely heavily upon the forest structure for survival (Webb and Goodenough, 2018). Secondary forests located close to an ancient forest are often distinguished by a high abundance of "ancient forest species" (Brunet and von Oheimb, 1998; Hermy and Verheyen, 2007), despite colonization by "ancient forest species" (Hermy et al., 1999) demands a lot of time (e.g. Dupouey et al., 2002). Mixed-oak–hornbeam forests are one of the potentially dominant forest vegetations in Eastern Europe (Matuszkiewicz et al., 2013). Mixed forests provide with habitat for a rich biodiversity and their decline in abundance has endangered a large number of species (Berg et al., 1994). The herbaceous understory plays a key role during restoration of the biodiversity of forest plantations (Gilliam, 2007). Agricultural landscape fragmentation in central Europe has resulted in decreased species richness in the forest herbaceous layer (Honnay et al., 1999; Mortelliti et al., 2010). Deforestation and forest management have resulted in a negligible share of the oak–hornbeam forests in the total forest area in Poland (Matuszkiewicz et al., 2013). Manor parks are an essential part of the Polish countryside. Most of the manor parks were established on oak-hornbeam habitat (*Tilio-Carpinetum*), and they were abandoned and uncultivated after World War II (Fornal-Pieniak and Wysocki, 2009b). In light of the loss of old growth oak-hornbeam forests because of deforestations, manor park habitats have the potential to become refuges (Glendell and Vaughan, 2002; Jonsell, 2012; Liira et al., 2012). Forest plants of oak-hornbeam forest (*Tilio-Carpinetum*) are very important for keeping the biodiversity of rural landscapes.

Therefore, it is important to analyze the impact of the surroundings forest landscape structure on the flora of the manor parks. However, studies dealing with the effects of the surroundings landscape structure on the development of the composition of plant species in herbaceous layer in manor parks in Poland are rare (Lirra et al., 2008; Fornal-Pieniak and Wysocki, 2009a).

The aim of the study was to determine the influence of surroundings landscape structure on the development of the species composition of the herbaceous layer in four

types of manor parks differing with respect to their surrounding in the Sandomierska Basin Region in Poland. It was tested, (1) whether the neighborhood of a forest influences the species composition and frequency of forest species in the herbaceous layer of manor parks, and (2) if there are existing characteristic / diagnostic species for different types of manor parks depending on the surroundings landscape structures. Since many forest species are sensitive to habitat fragmentation (Brunet et al., 2011), a special focus was set on forest plants from *Tilio-Carpinetum* as well as ancient forest plants.

Materials and Methods

Study area and field methods

The study was carried out in the area of the Sandomierz Basin (*Fig. 1*). 166 manor parks of the landscape style registered as historical monuments are located in this area. According to geobotanical division (Lencerewicz and Kondracki, 1959) the Sandomierz Basin belongs to the South Uplands area with a surface of about 14.5 thousand km^2. It is situated between the Carpathian foothills, Miechów Upland, Sandomierz Upland and Roztocze and is a foreground of Carpathians (Starkel, 1999). Potential vegetation is represented by a mosaic of diverse habitats in the area of the Sandomierz Basin. The largest area of the Sadomierska Basin is occupied by forests represented by: *Quercoroboris Pinetum*, *Serratulo-Pinetum*, *Tilio-Carpinetum*, *Lecobryo-Pinetum*, *Cladonio-Pinetum* and *Molinio-Pinetum*. Along watercourses especially the Vistula, San and Wisłoka habitats are lowland riverine riparian elm-ash forests (*Ficario-Ulmetum minoris*).

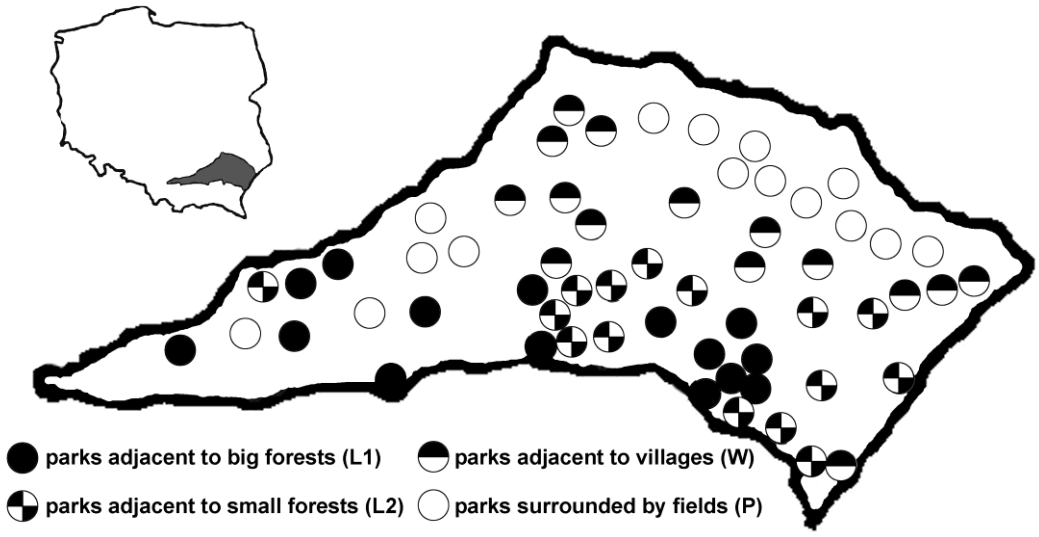

Figure 1. *Location of the Sandomierz Basin area in Poland and location of the manor parks in the area*

The manor parks were subjected to the following evaluation criteria: the same type of habitat, size of afforestrated areas, and landscape structures in the surrounding (size of the forests, fields, villages). Based on these criteria, 60 manor parks located in the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

Sandomierz Basin with 3 to 5 ha of afforestrated areas were selected for the study (*Fig. 1*). All these manor parks were established on oak-hornbeam habitat. Based on their specific localization the study objects were divided into four types of manor parks: 15 parks adjacent to big forests (L1), 15 parks adjacent to small forests (L2), 15 parks surrounded by fields (P), and 15 parks adjacent to villages (W). The surrounding forests were growing on the same oak-hornbeam habitats as the manor parks. As big forests (L1) those with a size of 15 to 20 ha were defined and small forests (L2) had a size range from 2 to 4 ha. The studied parks surrounded by fields were located in a distance of at least 2 km from the nearest villages.

In the herbaceous layer of each manor park 10 phytosociological records using the Braun-Blanquet method (1951) were carried out during the spring and summer time in the years 2016-2017. Syntaxonomic division was made according to Matuszkiewicz (2008) and plant species were named according to Mirek et. al. (1995). Existing plant species were grouped according to naturalness of vegetation (Keddy, 2016). The degree of naturalness is often assessed by the similarity of a biocoenosis to the presumed natural state before it was affected by man (Reif and Walentowski, 2008). We distinguished according to Matuszkiewicz (2008) between plants of natural (forest plants), seminatural (meadows, pasture plants), and synantropical (segetal and ruderal plants) vegetation as well as companion species.

Statistical methods

In order to determine the influence of the surroundings on the species composition in the manor parks, it was first compared the share of the distinguished species groups based on the criteria of naturalness of vegetation (Keddy, 2016) between the four types of parks. It was calculated the percentage of species of the relevant groups on the whole species number for each plot (phytosociological record). The resulting values were averaged for each park type.

Next, it was studied a more detailed impact on the forest species in order to determine the degree of long term continuity of the habitat. For that purpose the influence of the park's neighborhood on two parameters was analyzed: the percentage share of *Tilio-Carpinetum* class species and the percentage share of ancient forest species on the whole number of species in the individual phytosociological records. The average share of both parameters and the significance of their differences for parks and park types was studied by two identical analyses, using a Generalized Linear Model with two categorical factors in a nested design. The main factor was park surrounding type (four types) and the nested factor was park (60 parks, 15 for each type). Each single record was a repetition (10 per each park). Because share of species (dependent variable) is a typical ratio variable (varying between 0 and 1) the beta distribution was chosen as model distribution and as a link function identity was selected (Song and Tan, 2000). Based on the adopted model, it is possible to assess not only the differences in the average share of forest species depending on the character of the park's neighborhood, but also to determine the magnitude of this difference to the variability between individual parks (of the same type). The statistical analyses were carried out using STATISTICA v. 10.5.

In order to detect characteristic / diagnostic species whose presence or absence depends on the forms of land use in the surrounding of the parks, the Classification And Regression Trees (CART) method was used (Breiman et al., 1984). As dependent variable park type was chosen. This is a categorical (qualitative) variable, determining a

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_64836497
© 2018, ALÖKI Kft., Budapest, Hungary

classification algorithm of CART. As independent variable the abundances of each species denominated in Braun-Blanquet scale were used. Single phytosociological records were used as repetitions, without considering their origin from a specific park, but considering their origin from a given group of parks.

Since the abundances were encoded as categorical variables, it was possible to evaluate the quality of the analysis. Splits consistent with an abundance gradient, i.e. lower values for one side compared to the other one, should be interpreted as real effect, whereas those with mixed low and high values for both sides should be interpreted as errors. Additionally, it was analyzed the secondary splits (near optimal variables) in order to detect all diagnostic species. Finally, it was checked the allocation of the records to the end nodes of the CART tree in order to discover any regularities. It especially focused on records causing inhomogeneities in the end nodes.

The CART analysis were carried out using R 3.4.1 (R Development Core Team, 2013) with *rpart* and *rpart.plot* libraries.

Results

In the herb layer of parks adjacent to the forest (L1 and L2 types) the forest species (natural vegetation) distinctly dominated, constituting approximately 85% of all species supplemented with associated companion species (*Fig. 2*). Other species representing seminatural and synantropical vegetation occurred only occasionally. In parks neighboring with villages or surrounded only by crop fields, an increase share of species which are no indicators of long term continuity of the habitat was noticeable, i.e. species representing synantropical and seminatural vegetation, which represented 20% and 10% of the species composition in village-adjacent parks (W) and 21% and 9% of the species composition in field-adjacent parks (P) respectively.

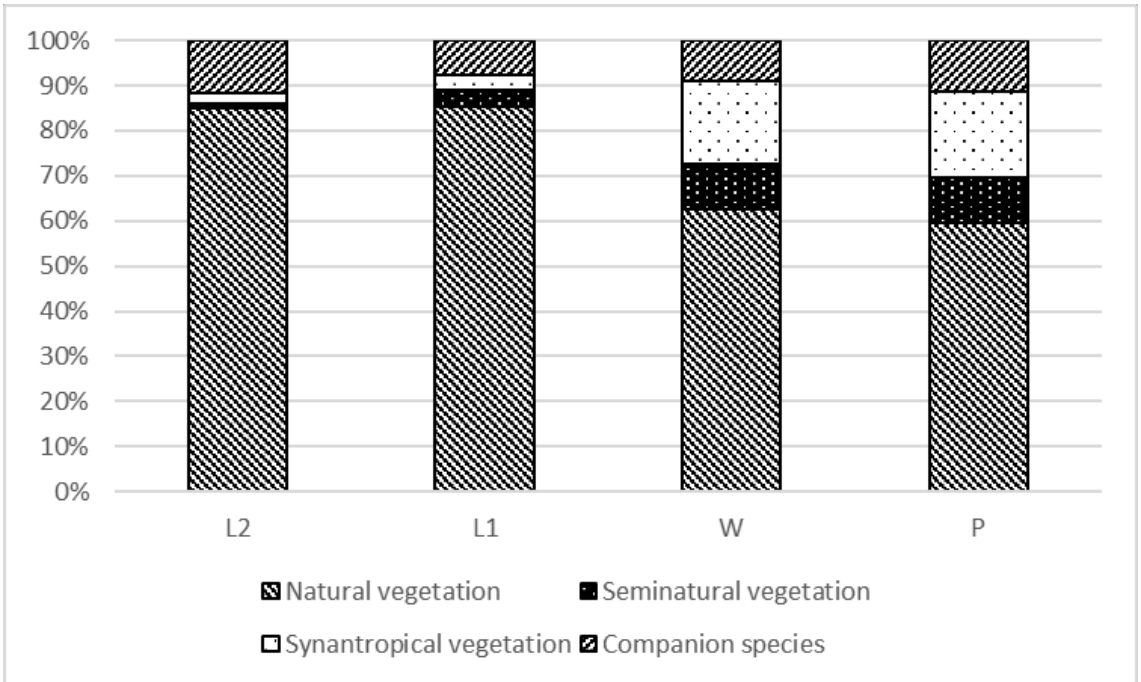

Figure 2. *Mean percentage share of species belonging to different types of naturalness of vegetation for the four types of manor parks (L1, L2, W, P)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_64836497
© 2018, ALÖKI Kft., Budapest, Hungary

The mean share of *Tilio-Carpinetum* species differed significantly ($p<0.001$) by type of park neighborhood (*Fig. 3*, *Table 1*). In forest-adjacent parks it reached 78% (L1) and 75% (L2) but in village-adjacent parks only 50% and in field-adjacent parks 47%. The mean share of *Tilio-Carpinetum* species for single parks varied ($p<0.001$). However, for both types of forest-adjacent parks it fluctuated between 60% and 90 % and for parks of type W and P between 40% and 60%.

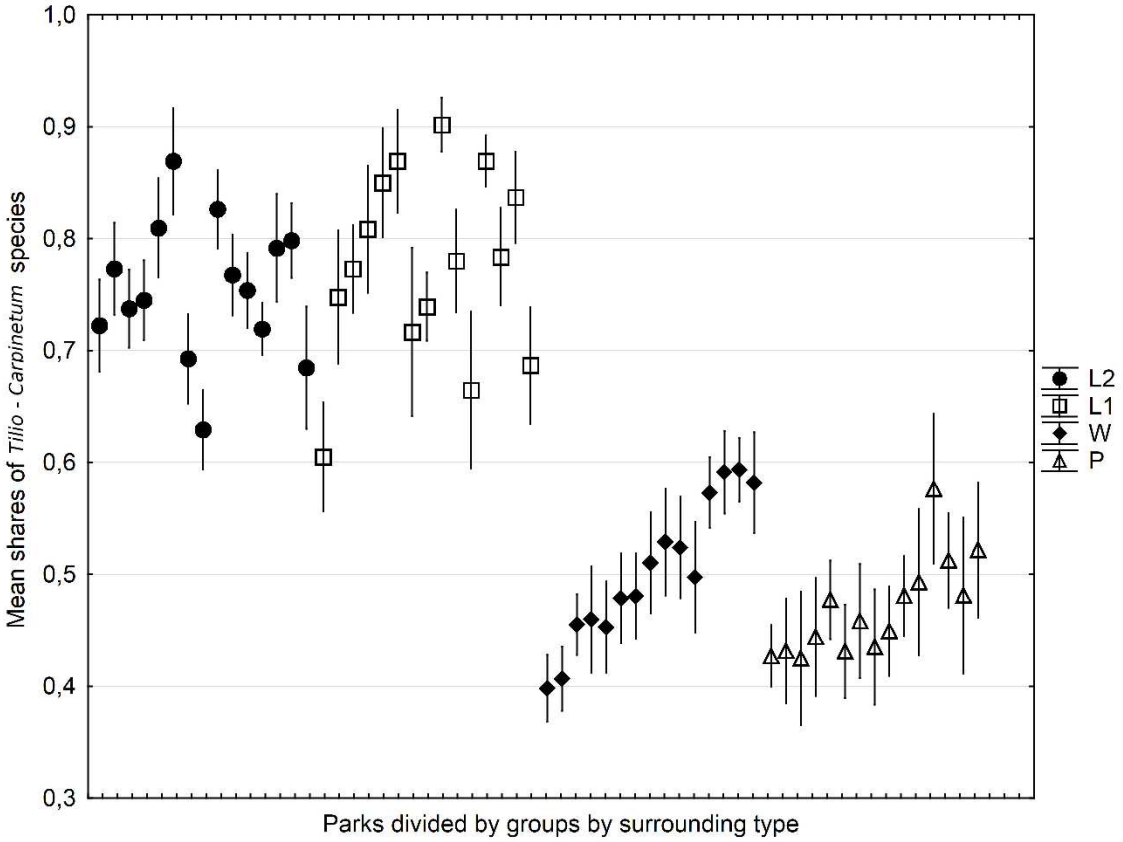

Figure 3. *Mean percentage shares of Tilio-Carpinetum species per record in parks apportioned to type of surroundings (L2, L1, W, P). Bars show 95% confidence intervals*

Table 1. *GLM results of the effects of surrounding type and park on mean shares of Tilio-Carpinetum species per record*

Factor	SS	df	MS	F	p
Intercept	234.9391	1	234.9391	58509.41	0.00
Surrounding type	11.8540	3	3.9513	984.05	0.00
Park	2.3582	56	0.0421	10.49	0.00
Error	2.1683	540	0.0040	-	-

The share of ancient forest species showed a pattern similar to the shares of the *Tilio-Carpinetum* species (*Fig. 4*, *Table 2*). It was also significantly ($p<0.001$) higher for forest-adjacent parks (63% for L1 and 70% for L2) than others (38% for W and P). Similarly, we were able to observe a clear border between the average shares in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_64836497
© 2018, ALÖKI Kft., Budapest, Hungary

individual parks. On all forest-adjacent parks it was above 42% and in the other below 42%. The mean share of species for single parks varied too ($p<0.001$).

Two of the first splits of the CART analysis (*Fig. 5*) divided most of the records into more or less homogenous groups. An almost homogenous group containing 93 (out of 150) records from parks adjacent to villages (type W) with a small infusion of other types was extracted by the first node. The division criterion was the presence of *Oxalis fontana* (common yellow woodsorrel). The near optimal variables were the presence of *Geranium sylvaticum* (wood cranesbill), *Convolvulus arvensis* (field bindweed), and *Chelidonium majus* (greater celendine) and the absence of *Melica nutans* (mountain melick). The power of the alternative variables was not distinctly lower than that of the main variable. The second node was split on two descendants. The left (node 4) contained most of records from parks adjacent to forests (type L1 and L2), and the right (node 5) encompassed almost all records from parks surrounded only by agricultural land (type P). The left node (node 4) was distinguished by the presence of *Melica nutans*. The alternative criteria were the absence of *Geranium sylvaticum*, *Allium ursinum* (buckrams), *Chelidonium majus* and *Lysimachia nummularia* (moneywort). Practically, after the two first splits we obtained three groupings of nodes that correctly classified most of the records, but nodes 4 and 5 were not homogenous. The further splits represented purging efforts. Twenty-five type W parks were separated from node 4 based on the presence of *Convolvulus arvensis*, a higher abundance of *Urtica dioica* (common nettle) (more than 1 on the Braun-Blanquet scale) and a lower abundance of *Lathyrus vernus* (spring vetchling) as criteria.

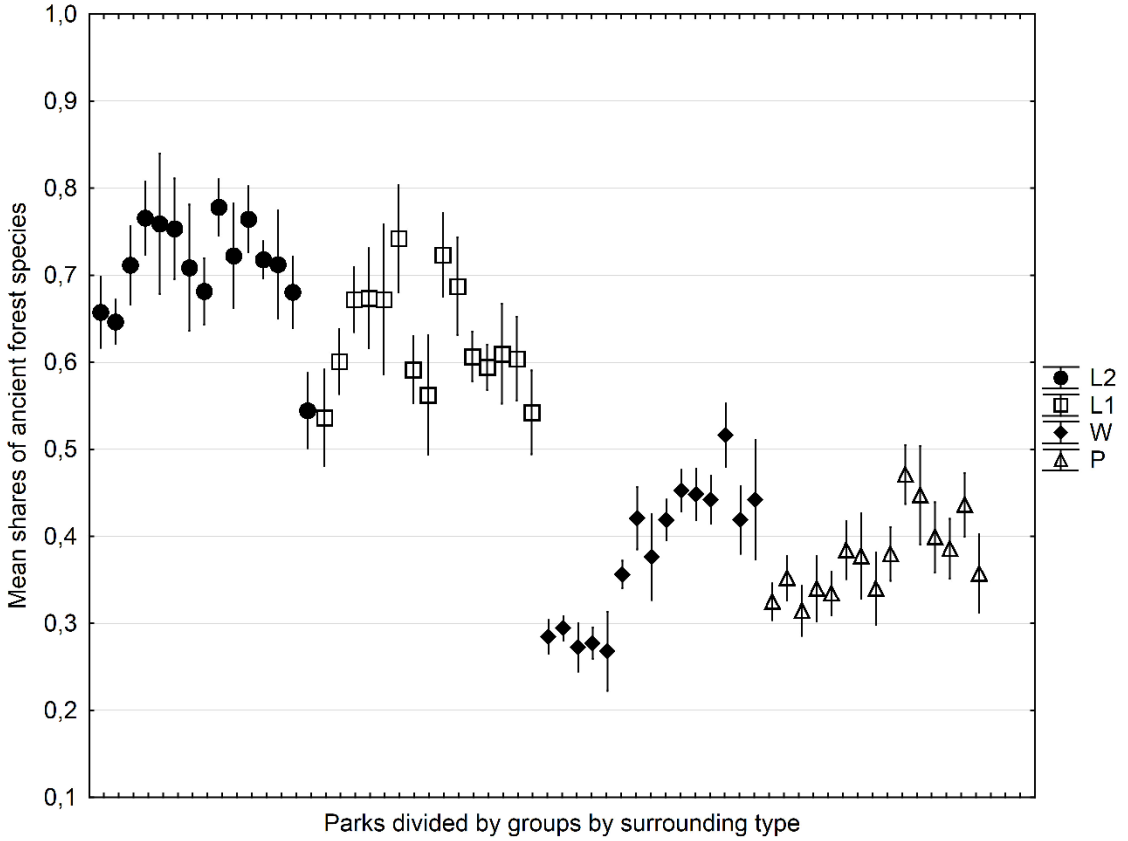

Figure 4. *Mean shares of ancient forest species per record in parks apportioned to type of surroundings. Bars show 95% confidence intervals*

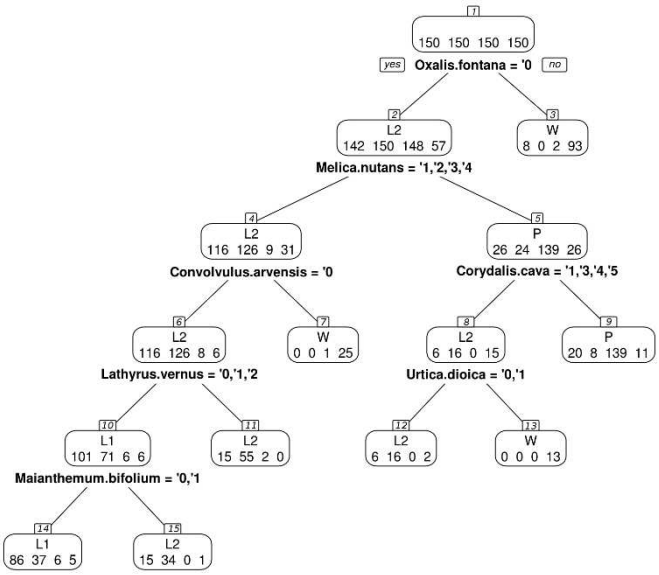

Figure 5. *CART tree. The little squares above the nodes contain the node numbers. The type of extracted records and the quantities of records of each type, from left: L1, L2 P and W, are plotted in the node. Under the nodes are the names of the species that provide the criterion for division and the respective abundances denominated in Braun-Blanquet scale for the left descendant node*

The CART analysis treated all records separately, but after the analysis, we checked the association between individual parks. We looked for patterns between records of type L1 and L2 from nodes 3 and 5 and between records of type P and W from node 4. Moreover, it was checked the association of records of type L1 and L2 with nodes 11, 14 and 15. In most cases, misclassification concerned single records from different parks, which could be considered as elements of statistical noise. Only two forest parks (L1, numbers 22 and 23) showed some distinctness. Most of the records were classified with W (in node 3) and P (in node 5) types.

Discussion

The study confirmed that the surroundings landscape structure influences the species composition and frequency of forest species in the herbaceous layer of manor parks (research question 1). Both the percentage share of *Tilio-Carpinetum* species and the percentage share of ancient forest species were increased in parks adjacent to forests. However, forest size seems to be of minor importance. Some species could be identified as characteristics for some of the studied park types (research question 2).

The results are in agreement with other studies, which show that different management and human activities modify the species composition (Jamoneau et al., 2011), also in manor parks. Studies have shown that rural areas surrounding the parks, such as fields and built-up areas, have an impact on the appearance of non-forest plant species. Changes in habitat conditions have a strong impact on the occurrence of many ruderal plant species (Gawenda-Kempczyńska et al., 2017). An increased number of grasses and synantropical plants was observed in manor parks located nearby fields and village. According to Dzwonko and Gawroński (1994) and Bossuyt (2001) forest patches are very important for forests and ancient plants colonization. Forests patches have also positive effects with respect to natural regeneration of the herbaceous layer (Hill and Curran, 2003). Authors like LaPaix and Freedman (2010) and Liira et al. (2012) argue that forest stands, as well as the studied parks adjacent to the forests, can be suitable habitats for some forest species.

Large patches may be more important for maintaining the stability of populations (Ewers and Didham, 2006; Økland et al., 2003; Honnay et al., 2005; Naaf and Kolk, 2015). According to Erikson (1996) many plants species characteristic for the herb layer of old forests have the ability to adapt to the new fragmented small and isolated forests in the agricultural landscape. However, the minimum size of forest islands in order to retain optimum conditions for forest species is an open question. Vestal and Heermans (1945) mention that the forest patches of an area of 1.6 ha and over retain forest plant species, but according to Levenson (1981) the critical value is 2.3 ha. Oostermeijer et al. (2003), stated that the reduction of the forest surface by fragmentation leads to reduction of the population of forest species. In addition, the size of the forest is obligatorily more important for plants that can grow only in forest communities (Kolb and Diekmann, 2004; Brunet et al. 2011). Higher species richness of plants was observed in bigger forest patches than in small ones (MacArthur and Wilson, 1967; Forman and Godron, 1986; Connor and McCoy, 1979, 2001; Saunders et al., 1991; Hill and Curran, 2001, 2003; Graae and Oakland, 2004). Some of the studied manor parks in the Sandomierz Basin area are adjacent to big forests, which might allow for a higher chance of the migration of forest plants into the parks. However, in this study we did not detect a clear influence of the size of the neighboring forests.

Size and management of the respective manor park is also of importance. A higher frequency and diversity of oak-hornbeam species in forests was observed in manor parks with a minimum area of 5 hectares (Fornal-Pieniak and Ollik, 2013). Studies by Fornal-Pieniak and Wysocki (2009a,b) on the vegetation of manor parks (2003-2007 and 2011-2012) allowed to confirm that mowing and the size of the forested timberland have an influence on the formation of the species composition of parks' undergrowth. In our study we observed a higher number of forest plants and ancient plants in manor parks, which were adjacent to forests. However, we analyzed only manor parks with afforestrated parts up to 5 ha. We can suppose that bigger afforestrated parts of manor parks could keep higher numbers of ancient and forest plant species. Yet, this is only an hypothesis which has to be verified by future research.

Another important factor affecting the number of forest species in the forest patches is their distance from forests with the same type of forest community (Dzwonko and Loster, 1988; Baker et al., 2013; Naaf and Kolk, 2015). Forest ecosystem fragmentation and habitat loss change spatial landscape features; consequently, fragmented and isolated habitats may vary more in terms of species composition than more connected habitats. The existence of forests adjacent to our studied manor parks facilitate the

colonization of forests plants in these objects. In the agricultural landscape many forest species can survive only due to the presence of small residues of formerly large forest complexes, because they are quite vulnerable to anthropogenic pressure caused by humans (Wójcik, 1991; Anderson et al., 2007). Many of the vascular species that grow in these forests have slow dispersal mechanisms and/or rely heavily upon the forest structure for survival. Protection of these forest settings is essential for keeping biodiversity of rural environments (Webb and Goodenough, 2018).

Forest communities have a vertical structure which determines ecological conditions specific to each type of forest for plant species in the herbaceous layer. The CART analysis detected *Oxalis fontana* as the indicator plant species in parks adjacent to villages, where it was observed as a component of human activities or in their immediate surroundings. Alien species are indicators in a given area whose presence is due to human pressure, regardless of whether these activities are intentional or unintentional (Pysek et al., 2004). *Oxalis fontana* is an alien species which is classified as an agriophyte. Agriophytes are neophytes that penetrate natural habitats (Zając at el., 1998). According to Dajdak and Wuczyński (2008), Rzymowska and Skrajna (2015) and Kolářová et al. (2017) *Oxalis fontana* was found more frequently in cultivated fields (segetal habitats). In our study, *Oxalis fontana* occurred in manor parks adjacent to villages but also in two parks adjacent to forest (L1 numbers 22 and 23). However, these two parks were located near to small forests (approximately 3 ha) with high anthropogenic pressure. As source of the anthropogenic pressure the respective village located behind the forest, as seen from the park, may be assumed. Many footpaths were discovered, which were caused by local people crossing the forest when walking to the village. Therefore, *Oxalis fontana* was very common in two types of manor parks (W, P). According to Chmura (2004) and Kolářová et al. (2017) *Oxalis fontana* mostly occurs close to roads, footpaths and forest margins. Other indicators of anthropogenic pressure in our study were *Geranium sylvaticum*, *Convolvulus arvensis*, *Chelidonium majus* and *Lysimachia nummularia*.

Parks which are adjacent to forests were characterized by a higher share of forest and ancient plant species than the other manor parks. The CART method identified *Melica nutans* as indicator species for manor parks adjacent to forests (L1, L2). According to Zielewicz and Kozłowski (2011) the stand structure constitutes important ecological factors, especially the amount of light reaching to the bottom of the forest determines the changing participation of grass species. Grass species need large amounts of solar energy for initiation of their development. At the beginning of spring a higher proportion of coverage with grasses was observed, followed by a decrease with increasing density of tree canopies. Such conditions allow the occurrence of *Melica nutans* in the forests (Slezák et al., 2011). In our study we did not analyze the light factor and density of tree canopies in the manor parks, but it can be assumed that proper ecological conditions allowed the growing of Melica nutans in their herbaceous layer. Another species associated with forest in our study was *Lathyrus vernus*. Distinguishing the species composition of parks adjacent to larger (L1) and smaller (L2) forest was impossible. The splits after node 6 (group of most of L1 and L2 records) reflected the character of the park habitat (humidity or fertility) rather than the type of surroundings. Thus, it can be assumed that some species (e.g. *Melica nutans*) require natural forests in the surroundings and do not survive in isolated manor parks.

The results indicated that manor parks are important as “forest islands” in the agriculture landscape, because they contain ancient and forest plant species typical for

Tilio-Carpinetum habitats. Because of their values, manor parks should be considered as important refuges in the ecological structure of the Sandomierz Basin. To formulate directions of shaping and management of rural landscapes including manor parks is a challenging task for landscape planners and landscape ecologists. In this context it is also recommended to monitor the impact of land-use practices, which are of particular importance with regard to biodiversity hotspots (Braun and Koch, 2016; Alphan, 2017) as *Tilio-Carpinetum* forests and manor parks.

Conclusions

Manor parks constitute a suitable habitat for survival of many forest species characteristic for oak-hornbeam forests and therefore are important ecological islands in the rural landscape. The surrounding of the parks decides to a large extent about the herb layer composition. Isolated parks are settled by a distinct lower number of forest species and numerous synantropical species. Some species (*Melica nutans*) cannot survive in isolated parks and occur only in those close to natural forest. However, forest size seems to be of minor importance. The results of the study are important for landscape planners and landscape ecologists in order to formulate directions of shaping and management of rural landscapes including manor parks.

(Received 15th Jun 2018; accepted 7th Aug 2018)

Abstract. Biogas is a renewable energy source that is generated by the decomposition of organic waste in anaerobic process. The theoretical biogas potential is defined as the possible amount of gas production from biomass. This potential can be evaluated using various calculation methods each of which considers different parameters. The objective of this study was therefore to compare the potential of biogas energy generation from the livestock waste produced from the animal husbandry in Iran using different calculation methods. Using 4 methods of calculation indicated that the amount of 11.82, 5.25, 16.05 and 2.1 million ton of animal waste could be produced in Iran in 2016 with a biogas generation potential of 886.57, 173.36, 745.37 and 565.85 million m^3, energy equivalent of 5.14, 1, 4.32 and 3.28 thousand GWh and electricity generation of 1.59, 0.31, 1.34 and 1.02 thousand GWh. These amounts of electricity generation could provide 2.03%, 1.71%, 0.39% and 1.3% of the electrical energy consumed in household sector in 2016 in Iran, respectively. Furthermore the methane yield potential from the livestock manure with considering the different types of substrate (lipid, lignin, dry matter and cellulose) was evaluated. The highest methane yield was obtained from biochemical methane potential (BMP) value based on lipid and lignin content at 5.27E + 10 NL CH_4 $digester^{-1}$ day^{-1}. The results showed that livestock waste is a low-cost and extensive source of renewable energy in Iran that can be used optimally for biogas energy and electricity generation. Also the treatment of huge amount of livestock manure in anaerobic digestion is helpful for reducing its polluting effects on the environment.
Keywords: *renewable energy, biogas, anaerobic digestion, organic waste, manure livestock*

Introduction

Global demand for energy is increasing rapidly, because of population growth and technological advancements. Use of renewable energy sources is essential due to the limitation of fossil fuel sources and negative environmental effects (International Energy Agency, 2015; United Nations Environment Programme, 2014; Achinas and Euverink, 2016; Abdeshahian et al., 2016; Santos et al., 2018; Chandekar and Debnath, 2018). Biogas is one of the important renewable energy sources which is produced through decomposing organic waste under anaerobic conditions by microorganisms (Travnicek et al., 2018; Scarlat et al., 2018a; Angelidaki et al., 2018). Biogas is mainly composed of CH_4 (60%) and CO_2 (35–40%) (Ilaboya et al., 2010; Sahota et al., 2018). Organic materials such as animal, human and plant wastes are biodegradable and can be converted into biogas (Zareei, 2018; Cu et al., 2015; Ozer, 2017; Yazan et al., 2018). Manure waste obtained from livestock industries are the largest and cheapest source for biogas production in anaerobic process (Comparetti et al., 2012; Ch'ng et al., 2014; Plume et al., 2012; Than, 2005; Cu et al., 2012; Yildirim et al., 2017; Mohammadi Maghanaki et al., 2013). Manure livestock is a type of organic waste which will be

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

hazardous to environment if it is not managed suitably. Livestock manure contains residues of some harmful substances such as growth hormones, antibiotics and heavy metals. So, disposal of them contaminates air, soil and water sources and prevalence of the human diseases (Abdeshahian et al., 2016; Pessuto et al., 2016). Anaerobic treatment of manure has the beneficial outcomes of reducing environmental pollution through proper waste management, reduction of unpleasant odors and microbial pathogens with a sustainable production of energy source as biogas (Wyman and Goodman, 1993; Mata-alvarez, 2000; Gebrezgabher et al., 2010; Holm-Nielsen et al., 2009; Wang et al., 2018; Samun et al., 2017; Neshat et al., 2017). Also it can be used for the production of a rich fertilizer which is favorable for the improvement of agricultural lands (De-Vries, 2012; Meyer et al., 2018; Eze and Agbo, 2010).

Considering the importance of animal waste as the enormous raw substances for energy production, many studies have been carried out on assessing the potential of biogas production from livestock waste. For instance, the potential of biogas production from livestock waste was studied in Turkey. The results showed that the amount of 2177.55 million m^3 of biogas can be produced annually in Turkey (Onurbas-Avcioglu and Turker, 2012). Similar studies have also been performed in Finland, Sweden and Denmark to estimate the potential of energy production from livestock waste as evaluated in Turkey. These studies showed that the potential of biogas production is 332.97, 352.09 and 402.1 million m^3 yr^{-1} in mentioned countries, respectively (Abdeshahian et al., 2016; Luostarinen, 2013).

In recent years, the animal husbandry is drastically grown in Iran (Hamzeh et al., 2011; Government of Islamic Republic of Iran and Food and Agriculture Organization, 2012; Tehran Chamber of Commerce, Industries, Mines and Agriculture, 2016; Beldman et al., 2017). Number of industrial cattle farms in Iran based on capacity from 1990-2016 is shown in *Figure 1*.

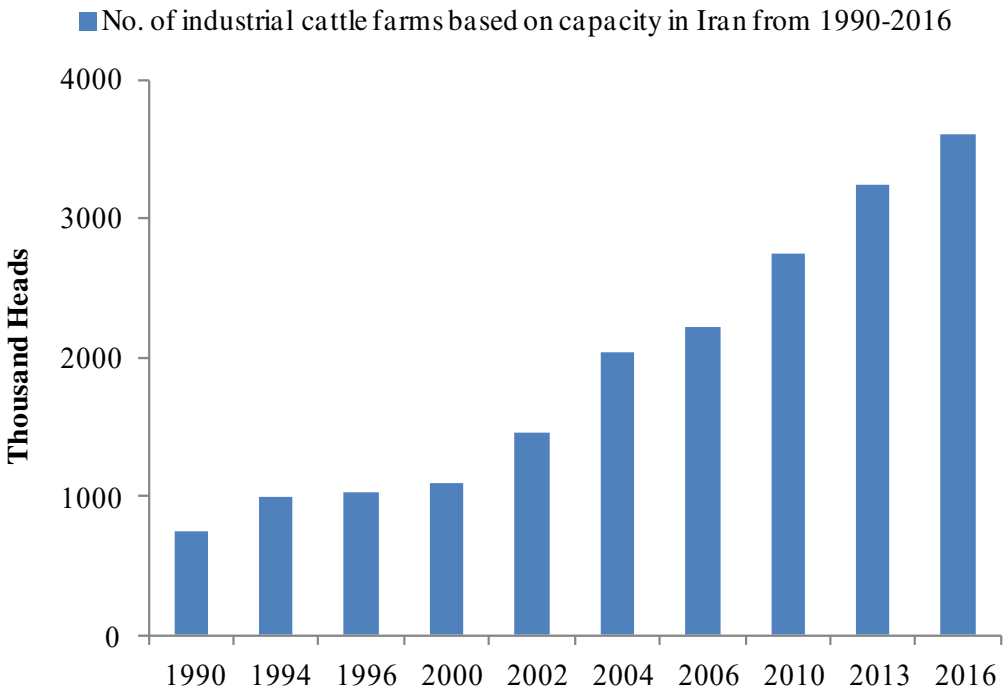

Figure 1. *The increasing capacity of industrial cattle farms in Iran from 1990-2016 (Tehran Chamber of Commerce, Industries, Mines and Agriculture, 2016)*

As can be seen, industrial cattle farms capacity in Iran has revealed an increasing trend from 1990-2016. The increase population of the livestock has caused an elevated production of livestock waste, resulting in the difficulty with the disposal of a large amount of manure. Unsafe disposal of livestock waste and its accumulation in environment has caused unfavorable conditions due to creating a favorable environment for growth and spread of microbes, in addition to intolerable odor and insects (Zareei, 2018), but could instead be used as a tremendous source for generating biogas energy. A wide variety of calculations exist to evaluate the potential of biogas generation from livestock waste, each of them considers different parameters such as pH, temperature, type, concentration and composition of raw materials and the time remaining in digester (Costa et al., 2016; Abdeshahian et al., 2016; Boysan et al., 2015; Cu et al., 2015; Burg et al., 2018; Zareei, 2018).

A wide variety of calculations exist to evaluate the potential of biogas generation from livestock waste. Some studies provide information about the factors that affect the biogas production such as pH, temperature, type, concentration and composition of raw materials and the time remaining in digester (Costa et al., 2016; Abdeshahian et al., 2016; Boysan et al., 2015; Cu et al., 2015; Burg et al., 2018; Zareei, 2018). But variation of quantity of biogas generated from different evaluation methods has rarely been studied in a distinct study. The current study aims to compare the potential of biogas energy generation from the livestock waste produced from the animal husbandry in Iran using different calculation methods.

Materials and methods

Livestock population in Iran

In order to calculate the potential of biogas generation from the livestock manure, initial data was collected from the Statistical Centre of Iran (SCI) (Statistical Centre of Iran, 2017). According to the data reported by SCI, in 2016, Iran had a total of 26061 industrial cattle farms with a capacity of 3619696 heads. In this year 18547 cattle farms were active and the rest were inactive. The total number of cattle was 1439391 heads in Iran in 2016. *Table 1* shows the number of specified groups of cattle population in each province of Iran.

Livestock manure production

Livestock waste is composed of the organic matter that can be treated as the potential raw substance for the production of bioenergy (Afazeli et al., 2014; Mathias, 2014). The amount of livestock manure can vary based on the type of animal, feeding methods, animal body size, the type of breeding and keeping time at day or night (Onurbas-Avcioglu and Turker, 2012; Omrani, 1996). Abdeshahian et al., (2016) categorized cattle into the large ruminants and calculated the amount of livestock manure based on the live body weight. The amount of the manure was calculated based on the 9% of body weight for large ruminants. The average live body weight accounted 250 kg for the large ruminants. Accordingly, the average amount of the manure was calculated based on 22.5 kg/day for the large ruminants. This is while that Boysan et al. (2015) calculated the amount of livestock manure production based on 10 kg/day for one cattle. On the other hand, Plume et al. (2012) calculated the manure output from livestock in a year using *Equation 1*.

$$M = \sum_{n=1}^{i} N_i * M_i \qquad \text{(Eq.1)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_64996523
© 2018, ALÖKI Kft., Budapest, Hungary

where:
M- Livestock manure produced in region (t),
n- Number of specified groups of livestock population in region,
N_i- Average number of livestock present year-round within i^{th} group of livestock,
m_i- Manure produced per one head in a year in the i^{th} group of livestock (t).

Furthermore Zareei (2018) denoted that the livestock manure production can be calculated using parameters including livestock weight and the ratio of the annual manure generation to livestock weight as shown in *Table 2*.

Table 2. *Coefficient for calculation of manure production from livestock (Zareei, 2018)*

Material type	Livestock weight	The ratio of the annual livestock manure to livestock weight
Cow manure	500-620	2.6

The average weight of livestock was estimated according to the dominant races of the area. As stated in *Table 2,* livestock weight was considered in the range of 500 to 620. The total amount of livestock waste can be calculated by multiplying the waste mass by the population number (Zareei, 2018).

The potential of biogas production from the livestock manure

The biogas produced from the livestock waste is affected by the different factors such as feeding regime, animal type, body weight, the proportion of total solids and the waste availability (United Nations Environment Programme, 2014; Than, 2005). Abdeshahian et al. (2016) considered the total solids of the waste as an important factor for the production of biogas from the livestock waste. They considered the total solids value of livestock manure as 25% for the large ruminants with the quantity of estimated biogas produced per kilogram of the total solids as 0.6 (0.6 m3/kg TS). Also they have pointed that the collection of the manure cannot always be carried out efficiently for the production of biogas and the availability of the manure is varied. Hence, for the calculating of biogas production from the livestock manure the availability coefficient was considered as 50% for large ruminants (Onurbas-Avcioglu and Turker, 2012; Afazeli et al., 2014). By taking into account the mentioned assumptions, the theoretical potential of biogas production from the livestock manure and the potential of electricity generation from the biogas was calculated as shown in *Equations 2* and *3* (Abdeshahian et al., 2016).

$$TPB = M * TS * AC * EB_{TS} \quad \text{(Eq.2)}$$

where:
TPB- Theoretical potential of biogas (m^3 yr^{-1}),
M- Total amount of the manure produced for each region (kg yr^{-1}),
TS- Ratio of the total solids of the animal manure,
AC- Availability coefficient,
EBTS- Quantity of estimated biogas produced per kilogram of the total solids (m^3 kg^{-1} TS).

$$e_{biogas} = E_{biogas} * n \quad \text{(Eq.3)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_64996523
© 2018, ALÖKI Kft., Budapest, Hungary

where:
e_{biogas}- Quantity of generated electricity (kWh yr^{-1}),
E_{biogas}- Unconverted raw energy in the biogas (kWh yr^{-1}),
n- Overall efficiency of the conversion of biogas to electricity (%). The amount of *n* is varied depending on the power generation plants. The *n* value is considered 35-42% and 25% in the power plants with large turbine system and small generators, respectively (Hosseini and Wahid, 2014; Benito et al., 2015). In this study, the *n* value was assumed as 30%based on Iran power plants characterization (Iran Energy Ministry, 2017).

The quantity of E_{biogas} is calculated using *Equation 4* (Abdeshahian, 2016).

$$E_{biogas} = Energycontent_{biogas} * m_{biogas} \quad \text{(Eq.4)}$$

where:
Energy $content_{biogas}$- Calorific value of biogas (kWh m^{-3}). The quantity of the Energy $content_{biogas}$ is assumed as 6 kWh m^{-3} by considering the biogas calorific value as 21.5 MJ per m^3 biogas (1 kWh = 3.6 MJ) (Hosseini and Wahid, 2014; Garcia, 2014).
m_{biogas}- Amount of biogas produced per year (m^3 yr^{-1}).

On the other hand, Boysan et al. (2015) calculated the potential of biogas production from livestock manure based on 0.33 m^3/cattle with considering assumptions including fermenter temperature as 37 °C, 20% mass in manure and waiting time as 30 days. It is while that in the study conducted by Zareei (2018) the biogas production potential per kilogram of cow manure was considered as 0.28-0.28 m^3. Furthermore, Plume et al. (2012) proposed *Equation 5* for calculating the potential of biogas production from livestock manure.

$$V_B = \sum_{n}^{i} N_i * m_i * K_{DMi} * K_{OMi} * v_{Bi} \quad \text{(Eq.5)}$$

where:
V_B- Biogas volume, potentially obtainable from manure biomass in region in a year (m^3),
K_{DMi}- Dry matter content in manure produced by i^{th} group of animals in region,
K_{Omi}- Organic matter content in dry matter of manure produced by i^{th} group of animals in region,
v_{Bi}- Specific biogas output from manure organic matter for i^{th} group of animals in region (m^3 t^{-1}).

The energy of biogas obtainable from manure biomass in region then was calculated according to *Equation 6* (Plume et al., 2012).

$$E_B = \sum_{n=1}^{i} N_i * m_i * K_{DMi} * K_{OMi} * v_{Bi} * e_{Bi} \quad \text{(Eq.6)}$$

where:
E_B- Energy potential obtainable from biogas produced from manure (kWh),
e_{Bi}- Specific heat energy content of biogas obtained from manure produced by i^{th} group of animals (kWh m^{-3}).

Calculation of methane (CH_4) content of biogas

The biogas obtained from the anaerobic digestion process of livestock manure is composed of 50-70% of methane (Omar et al., 2009; Nasir et al., 2012; Ounnar et al., 2012; Nasir et al., 2013). The methane yield can be calculated based on the original Hashimoto equation (*Eq. 7* below) (Chen and Hashimoto, 1978; Hashimoto et al., 1981).

$$\gamma = \frac{\beta_0 * S_0}{HRT}\left(1 - \frac{K}{HRT * \mu m - 1 + K}\right) \quad \text{(Eq.7)}$$

where:
γ- Methane yield (NL CH_4 digester^{-1} day^{-1}),
β_o- Biochemical methane production (BMP) value of specific substrate (NL CH_4 kg VS^{-1}),
S_o- VS concentration (g kg^{-1}),
HRT- Hydraulic retention time (days),
K- Kinetic constant (K = 0.6 + 0.0206.EXP[0.051.S_0],
μm- Maximum specific growth rate (day^{-1}). μm = 0.013 T – 0.129, for temperature (T) between 20 and 60 °C.

Rennuit and Sommer (2013) extended the Hashimoto equation to calculate the methane yield for a biogas digester. The extended equation takes into account the difference in lowland and highland temperature regimes. It is assumed that the mean monthly air temperature represents the mean monthly digester temperature (Perrigault et al., 2012). Hence, the methane yield for a biogas digester for an air temperature between 15 to 30 °C and 20 to 60 °C is calculated based on *Equations 8* and *9,* respectively (Rennuit and Sommer, 2013).

$$\gamma_{winter}(HRT, \mu m, TD) = \beta_0 * \left[1 - \frac{K}{\mu m(TD) * \left(HRT + \frac{1}{\mu m(TD)}\right) - 1 + K}\right] \quad \text{(Eq.8)}$$

$$\gamma_{summer}(HRT, \mu m, TD) = \beta_0 * \left[1 - \frac{K}{\mu m(TD) * HRT - 1 + K}\right] \quad \text{(Eq.9)}$$

where:
μm(Td)- maximum specific growth rate of the microorganisms at the digester temperature in the temperature interval from 10 to 30 °C (μm[Td] = 0.0039 $e^{0.1188 \cdot (Td)}$ (day^{-1}) and (Td) is the digester temperature which is set to be equal to the average monthly air temperature (°C) represented by region.

In line with this, Cu et al. (2015) suggested that the BMP value (β_0 in the Hashimoto equation) from different types of substrate can be predicted based on their chemical composition. Biogas production is related to the chemical composition of the substrate. Low concentrations of organic matter such as lipids and protein will lead to a low biogas production. However, the high concentration of organic matter in substrates will have a negative effect on biogas production, causing foaming and inhibition if not co-fermented with biomasses low in protein and lipids (Cu et al., 2015; Kougias et al.,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_64996523
© 2018, ALÖKI Kft., Budapest, Hungary

2013). There is a clear relationship between lipid content of the biomass and biochemical methane potential. Lipid content is the most important factor for biochemical methane potential compared to other components. However, in a biogas technology every component in the substrates affects biogas production. It was found that lipid, lignin, protein, and cellulose contents were the main chemical components of substrates contributing to the variation in the BMP (Cu et al., 2015). Equations to predict BMP are shown in *Table 3*.

Table 3. *Equations to predict BMP for livestock manure (Cu et al., 2015)*

Variables	Equations for BMP
Lipid	57.9+35×lipid
Lipid, lignin	186+30.6×lipid–5.13×lignin
Lipid, lignin, dry matter	167+30.1×lipid–5.43×lignin+1.15×dry matter
Lipid, lignin, cellulose	201+31.5×lipid–3.85×lignin–1.88×cellulose

Results and discussion

Calculation of livestock manure production in Iran

The amount of livestock manure production was calculated for all provinces of Iran based on Abdeshahian, Boysan and Zareei methods. The results are shown in *Table 4*.

Manure production by livestock in different groups based on Plume et al. (2012) is presented in *Table 5*.

Table 5. *Manure production by livestock in different groups based on Plume et al. (2012)*

Group characteristics	Manure production per head t yr^{-1})
Dairy cows	$0.0024Y_D+0.447$
Heifers	8
Calves	2.6
Cattle	12

Average values of manure production per one head in a year for all groups of livestock, except dairy cows, are given in *Table 5*. Average manure production per one dairy cow is dependent on cow's milk yield and calculates help by regression *Equation 10* (Plume et al., 2012).

$$m_1 = 0.0024 * Y_d + 0.447 \quad \text{(Eq.10)}$$

where:
m_1- Average manure production per dairy cow in region in a year (t yr^{-1}),
Y_d- Average milk yield per dairy cow in region in a year (kg yr^{-1}).

Aiming to improve accuracy of manure resources evaluation, all the animals was divided in 4 groups (dairy cows, heifers, calves and cattle) according to its manure production capability per one head. The number of livestock within specified groups in each province of Iran in 2016 is presented in *Table 6*.

Calculation of methane (CH_4) content of biogas from manure livestock in Iran

The chemical composition of the livestock manure which is required to calculate the biochemical methane potential based on Cu et al. (2015) including dry matter, volatile solid, protein, lipid, cellulose and lignin are shown in *Table 13*.

Table 13. *Chemical composition of livestock manure based on Cu et al. (2015)*

Substrates	Animal manure group
Dry matter	10.94
Volatile solid[1]	73.01
Protein[1]	7.55
Lipid[1]	3.63
Cellulose[1]	17.59
Lignin[1]	10.41

[1]% in dry matter

The BMP value based on chemical composition of the substrate was calculated according to chemical composition of the livestock manure (*Table 13*) and equations to predict BMP (*Table 3*) and is presented in *Table 14*.

Table 14. *The estimated values of BMP based on chemical composition of the substrate*

Variables	BMP
Lipid	184.95
Lipid, lignin	243.67
Lipid, lignin, dry matter	232.31
Lipid, lignin, cellulose	242.34

The potential of livestock manure production, biogas, electricity and energy obtainable from livestock manure and methane yield of biogas were calculated for all provinces in Iran in order to compare the results between provinces and determine which of them has the least and most potential. The amount of livestock manure production in different provinces in Iran based on Abdeshahian, Boysan and Zareei methods (*Table 4*), shows that the higher amount of the manure was produced in Tehran while the lowest amount of the manure is related to Hormozgan and it is because of this

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_64996523
© 2018, ALÖKI Kft., Budapest, Hungary

that Tehran and Hormozgan have the highest and the lowest number of livestock, respectively, compared to that other provinces of Iran. On the other hand, the amount of livestock manure based on Plume method (*Table 7*) shows that the higher amount of the manure was produced in Isfahan. This is due to considering the different manure production for each group of livestock (dairy cows, heifers, calves and cattle) in this method. The lowest amount of manure production still belongs to Hormozgan.

Figure 2 shows the potential of livestock manure production in Iran according to 4 different methods. It is shown that the higher amount of the manure was produced in Plume method with the annual manure production of 16.05 million ton followed by Abdeshahian, Boysan and Zareei methods with a manure production of 11.82, 5.25 and 2.1 tons, respectively. As can be seen, the amount of livestock manure produced using Zareei method was much less compared to that from Plume, Abdeshahian and Boysan methods. This is due to the fact that the lowest coefficient of manure production was considered in this method (the ratio of the annual livestock manure to livestock weight = 2.6).

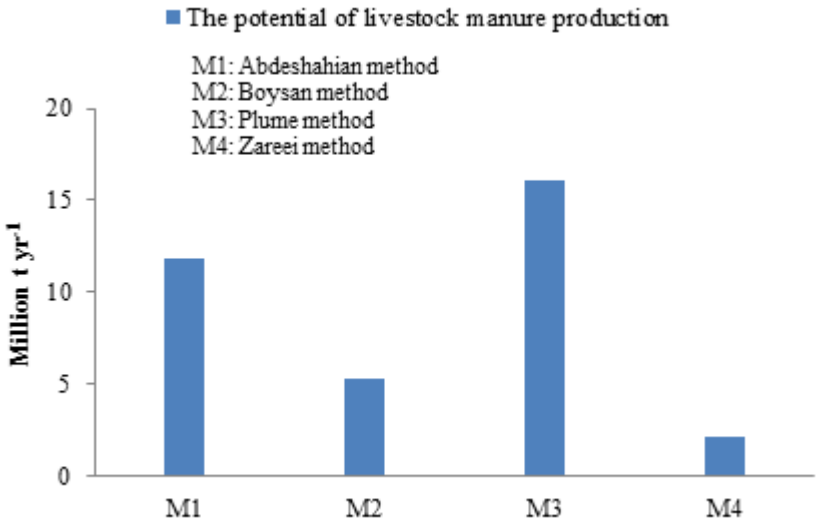

Figure 2. *Comparison the estimated values of the manure production potential in Iran using 4 different calculation methods*

The comparison of the biogas production potential in different provinces of Iran (*Tables 8* and *10*) revealed that Tehran had the highest potential of biogas evolution based on Abdeshahian, Zareei and Boysan methods, while Isfahan had the highest potential of biogas evolution based on Plume method. Hormozgan had the lowest amount of biogas production potential in each method.

The biogas production potential from the livestock manure based on 4 mentioned methods is shown in *Figure 3*. It is found that the highest potential of biogas from the manure is obtained from Abdeshahian method with the biogas production potential of 886.57 million m^3 yr^{-1}, followed by Plume, Zareei and Boysan methods with a biogas generation potential of 745.37, 565.85 and 173.36 million m^3 yr^{-1}, respectively.

This study showed that the cattle manure can be considered as the good source for the generation of biogas in an AD process. Similar observations were reported by other studies. For instance, it has been reported that Vietnam has the potential of generation

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_64996523
© 2018, ALÖKI Kft., Budapest, Hungary

of 16878 TJ y^{-1} biogas in 2014 from the cattle manure (Roubik et al., 2017). The study on the Nigeria biogas potential has revealed that Nigeria biogas potential from livestock manure represents a minimum of 1.62×109 m^3 of biogas per annum (Adeoti et al., 2014).

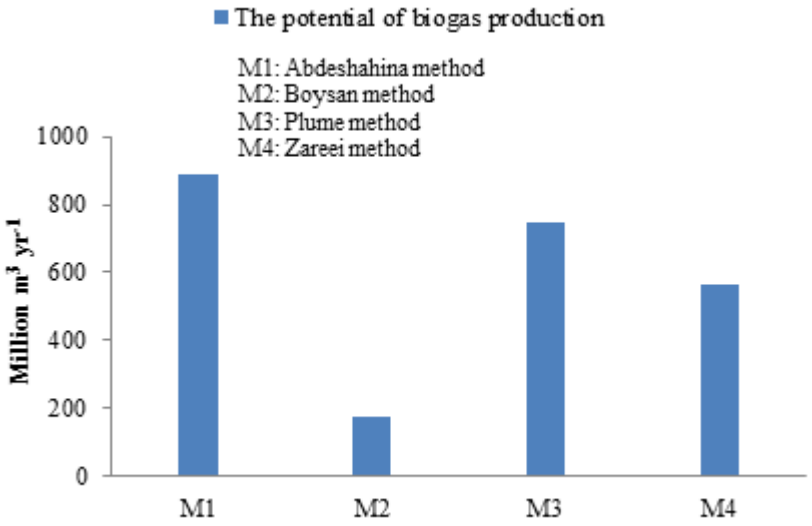

Figure 3. *Comparison the estimated values of the biogas production potential in Iran using 4 different calculation methods*

Figure 4 depicts the energy and electricity potential from livestock manure in Iran based on 4 calculation methods. As can be seen, the biogas produced from the livestock manure based on Abdeshahian, Boysan, Plume and Zareei methods was potentially able to provide the heat energy with the value of 5.14, 1, 4.32 and 3.28 thousand GWh yr^{-1}, respectively. The results shown in *Figure 4* also indicated that the total amount of electricity generation estimated in Iran based on Abdeshahian, Boysan, Plume and Zareei methods was 1.59, 0.31, 1.34 and 1.02 thousand GWh yr^{-1}, respectively. These estimated values could provide the 0.67%, 0.56%, 0.13% and 0.42% of the total electrical energy consumed in Iran in 2016 with the total electricity consumption of 237.4 billion kWh (Iran Energy Ministry, 2017). It should be noted that the electricity consumption with the value of 237.4 billion kWh was related to household, public, agricultural, industrial and other uses of the electrical energy consumed. The share of electrical energy consumption in household sector in Iran in 2016 was mainly for lightning, electrical household appliances and cooling systems with amount of 33% of the total electricity consumption. Hence, the electricity generation from livestock manure based on Abdeshahian, Plume, Boysan and Zareei methods could provide the 2.03%, 1.71%, 0.39% and 1.3% of the total electrical energy consumed in household sector in Iran in 2016, respectively, with the total electricity consumption of 78378 million kWh.

In this regard, the investigation on the potential of electricity generation from livestock manure in Malaysia showed that the total amount of electricity generation was 6.85E + 09 kWh yr^{-1} (Abdeshahian et al., 2016). Also the study on the potential for electricity generation from biogas in South Africa showed that the potential of electricity production from cattle manure was 2098553 MWh (Laks, 2017).

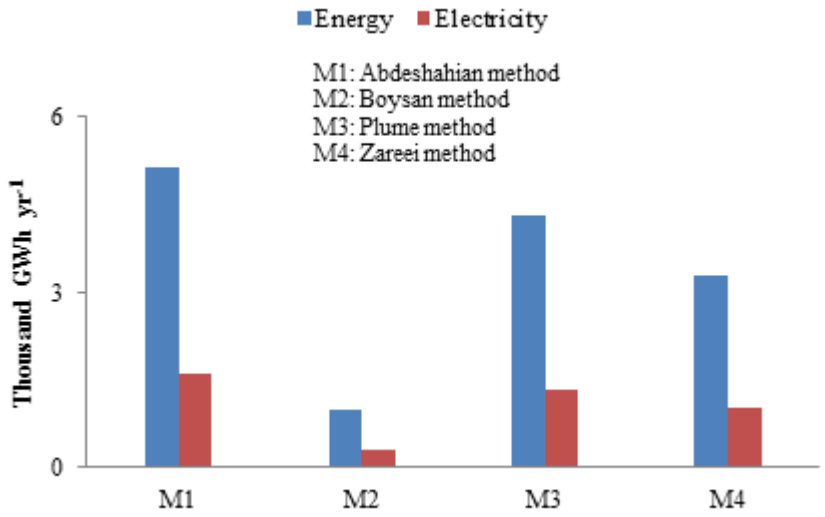

Figure 4. *Comparison the estimated values of the energy and electricity potential from livestock manure in Iran using 4 different calculation methods*

The methane production potential from the livestock manure in Iran with considering the different types of substrate (lipid, lignin, dry matter and cellulose) is shown in *Figure 5.* As can be observed, the highest potential of methane yield is related to the BMP value of lipid and lignin content at 5.27E + 10 NL CH_4 digester^{-1} day^{-1} followed by BMP value of lipid, lignin and cellulose, BMP value of lipid, lignin and dry matter and BPM value of lipid, at, respectively, 5.25E + 10, 5.03E + 10 and 4.01E + 10 NL CH_4 digester^{-1} day^{-1}.

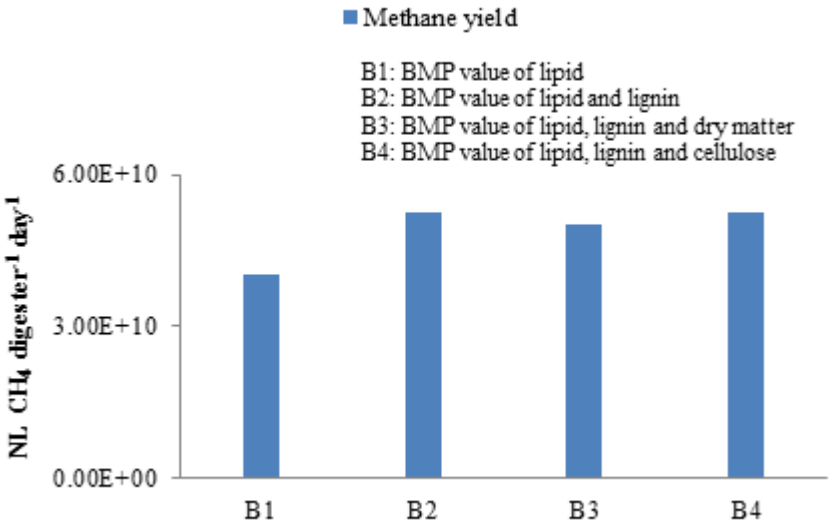

Figure 5. *Comparison the estimated values of the methane production potential from livestock manure in Iran considering the BMP value of specific substrate*

Study fulfilled by Scarlat et al. (2018b) revealed that the potential of methane production from livestock manure in Belgium, Germany, Ireland, Spain and France is 556, 2907, 893, 2298, 3952 million m^3, respectively. These results reflect the lower methane potential in mentioned countries than Iran. This discrepancy could be related to the variation in the biotransformation rate of manure into methane and different amount of the livestock waste produced.

Conclusion

Present study focuses on the evaluation of the different methods for estimating biogas production potential from livestock manure in Iran. Biogas generation from animal wastes has rarely been assessed based on their chemical structure and the findings of this research reveal the significance of manure chemical properties to be considered or the estimation of biogas production in husbandry industry. As a result of the calculations made, the manure production was estimated as 11.82, 5.25, 16.05 and 2.1 million ton yr^{-1} based on Abdeshahin, Boysan, Plume and Zareei methods with a biogas generation potential of 886.57, 173.36, 745.37 and 565.85 million m^3 yr^{-1}, energy equivalent of 5.14, 1, 4.32 and 3.28 thousand GWh yr^{-1}, and electricity generation potential of 1.59, 0.31, 1.34 and 1.02 thousand GWh yr^{-1}, respectively. The electrical energy values could provide the 2.03%, 1.71%, 0.39% and 1.3% of the total electrical energy consumed in household sector in Iran in 2016, respectively. Furthermore the methane yield potential from the livestock manure with considering the different types of substrate (lipid, lignin, dry matter and cellulose) was evaluated. The highest methane yield was obtained from BMP value based on lipid and lignin content at 5.27E + 10 NL CH_4 $digester^{-1}$ day^{-1}. This study shows that the treatment of the livestock manure by the anaerobic digestion process is helpful for producing the huge amounts of renewable energy as biogas. In addition, anaerobic digestion of livestock waste reduces their deleterious impacts on the environment and the treated organic matters could be used for the improvement of crops growth in the agriculture land. For future studies it is recommended to develop new applicable models based on chemical composition of animal wastes to further reveal the contribution of animal waste composition in generation of biochar and precisely estimate biogas production potential from such wastes.

Abstract. In this paper we studied a bio-system which could be applied to the treatment of high concentration organic wastewater and aimed at increasing its efficiency by laboratory scale wastewater treatment reactors. The reactors were divided into control reactor, reactor one (Adding Pellet bacteria and pumice) and reactor two (Adding Pellet and pumice). The reactors had two patterns of long aeration, and intermittent aeration which could be divided into four stages. The COD, NH_3-N, NO_3-N, Total Nitrogen (TN), Total Phosphorus (TP) were measured. The experimental results showed that the removal abilities of COD, NH_3-N, NO_3-N, TN and TP of reactor one and two were better than those of the control reactor in two modes. Above all, the reactor one and two increased the removal efficiency of high concentration organic wastewater. The reactor two achieved the best removal efficiency of high concentration organic wastewater. The best effect was reached when the operating condition was 1 h 20 min/1 h 20 min (Aeration / Stopping aeration), and the average removal rates were enhanced by 3%, 21%, 54%, 21%, 25% respectively.
Keywords: *pellet, pumice, reactor, intermittent aeration, water quality analysis*

Introduction

China is a country with serious water shortage, and the per capita water consumption is very low, accounting for only 1/4 of the world's per capita level (Chen et al., 2002):. In addition, serious problems such as serious waste and serious pollution in China's water resources still exist. For a long time, water pollution had been the most prominent problem in the national environmental safety (Zhang, 2014). According to the national environmental statistics bulletin, the total amount of wastewater discharge in 2015 was 735.3 million tons, including 199.5 tons of industrial wastewater and 535.2 million tons of urban sewage discharge. It can be seen that industrial wastewater accounts for about 27% of the national wastewater discharge, and industrial wastewater was mainly organic wastewater with high concentration. Additionally, the slaughterhouse wastewater and livestock wastewater have been high concentration organic wastewater and therefore the treatment of high concentration organic wastewater was very significant in the process of sewage treatment.

High concentration organic wastewater generally refers to the wastewater whose COD was more than 2000 mg/L (Wang and Liao, 2011), which was mainly discharged from papermaking, leather, food and slaughterhouse. As the high concentration, organic wastewater contains a large number of organic compounds such as carbohydrates, fat, protein, cellulose and many organic pollutants which were extremely difficult to decompose and contained high levels of toxicity, it would cause serious water environmental pollution (Chen et al., 2008), even endangering human health if they were not treated properly and discharged directly. It has been one of the most difficult

© 2018, ALÖKI Kft., Budapest, Hungary

problems in the field of environmental protection research in China and abroad because it caused wide range and high degree of pollution (Huang et al., 2004).

Currently, there have been mainly three kinds of technologies commonly used for high concentration organic wastewater treatment, which were chemical treatment, physicochemical treatment and biological treatment. At present, the two which commonly used chemical treatment technologies were Incineration (Bie et al., 2000) and Catalytic wet oxidation (Sun et al., 1999; Du et al., 1997a, b) respectively. The two widely used physical extraction technologies included complexation extraction (Yang and Dai, 1997; Rousseau, 1987) and Pulsed extraction (He et al., 2002; Zhu et al., 2001). Biological treatment technology mainly uses the decomposition of microbes, which means that the microorganism decomposes the polluted material in the wastewater as its own nutrition and energy, and finally realizes sewage purification (Zhao et al., 2003). In recent years, biological treatment technology has played an extremely important role in the treatment of high concentration organic wastewater, because it accorded with the idea of sustainable development (Ren, 2000). At present, the activated sludge process has become the main treatment technology of various organic wastewaters (Li and Yang, 2002; Lu et al., 2001). Complete Mixing Activated Sludge Process was one of the most common wastewater treatment processes in an aerobic activated sludge process. It has many advantages. First of all, it can resist a high sludge load. Secondly, the automatic reflux of sludge can be realized. Thirdly, it is easy to manage and the delayed aeration can be reached by prolonging the age of sludge. Last but not least, the primary sedimentation tank can be saved (Wang and Sun, 1995). However, when to use the activated sludge process, especially the traditional activated sludge process to treat high concentration organic wastewater, the phenomenon that the water quality of the effluent was poor such as the high content of N and P will always happen. The Sequencing Batch Reactor Activated Sludge Process (SBR) was developed later and it greatly made up the deficiency of the activated sludge process. Therefore, it was widely used in the treatment of high concentration organic wastewater (Ganigué et al., 2012; Liu et al., 2015; Jena et al., 2016). The technology of SBR has expressed many strengths. First of all, the most prominent feature of SBR is the realization of intermittent aeration. Secondly, the precipitation performance of SBR is great and the push flow state is ideal. Thirdly, it can efficiently remove organic matter, there is no need to increase the performance to involve more reactors (Wu, 2017). Additionally, it can also provide anaerobic, anoxic and aerobic living environment for microorganism and this kind of environment was beneficial to improve the treatment efficiency of refractory wastewater including the removal of N and P. Finally, due to the large gradient of substrate concentration in the SBR system and the alternating between aerobic and anoxic (or anaerobic); the breeding of filamentous bacteria can be inhibited effectively, and the sludge bulking was controlled (Liu and Meng, 2008).

In addition to these traditional biological processes, there are also some derived processes such as the Reactor-Bio-System (RBS). RBS system was a relatively advanced high concentration organic wastewater treatment technology developed in Japan (Jiang et al., 2008; Zhai, 2014). RBS technology imitates nature and achieves the artificial induction and screening of microorganisms in the soil in the soil reaction by adding many small particles filled with humic precursors and some silica, for which the soil reaction can provide a large number of soil dominant bacteria and highly active nutrients for the whole sewage treatment system and then enhance the efficiency of sewage treatment. Therefore, RBS technology was also named “natural purification.”

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_65256547
© 2018, ALÖKI Kft., Budapest, Hungary

RBS technology uses the biochemical effect of highly active facultative soil bacteria to purify sewage, and it embodies many advantages when compared with the traditional activated sludge process. It has six major advantages (Jiang et al., 2008). Firstly, it can be directly used to treat high concentration organic wastewater and the influent does not need to be diluted. Secondly, it can ensure SS concentration in the sewage treatment system. Thirdly, it has a high efficiency. Fourthly, it performs well in removing N and P. Fifthly, it has a good sludge characteristic. Lastly, it can effectively inhibit odor. The COD in the sewage discharged from the original field of Anshan's Tianyi pig farm was 2000 mg/L, and the BOD_5 reached 500 mg/L. The sewage was one kind of high concentration organic wastewater, and it would cause serious pollution to the receiving water. Tianyi pig farm introduced RBS technology from Japan to discharge sewage and formally put it into using in June 2001. The operation results showed that after the application of this technology, the concentrations of COD and BOD_5 in the sewage were obviously reduced, and the water quality of the effluent reached the standard of sewage discharge (Zhao, 2002). Above all, the application of RBS in Tianyi pig farm achieved good results.

This experiment applied laboratory scale wastewater biological treatment reactor to the treatment of high concentration organic wastewater with a bio-system, which was used with pellet and pumice.

Materials and methods

Materials

Pellet and Pellet (bacteria) for bio-system were columnar materials made in the laboratory. Pumice was purchased from the Tianhe pumice factory in Songjiang River town of Fusong county.

Production method of Pellet: Mix peat soil (pH 5.47) 40 g, bentonite 20 g, calcium alginate 0.6 g and cement 15 g in a beaker, then spray a certain amount of distilled water into the beaker. The cultivation (*Bacillus* CGMCC13429: CICC23692: CICC20666 = 1: 1: 1) for production pellet （bacteria） was sprayed in distilled water ($\geq 10^8$ cfu/ml).

Production of artificial wastewater

The artificial wastewater was made from glucose, NH_4Cl, KNO_3, urea, KH_2PO_4 and deionized water. The concentration range of COD was 2000 ~ 3000 mg/L; NH_3-N was 30 ~ 70 mg/L; NO_3-N was 10 ~ 15 mg/L; TN was 100 ~ 140 mg/L; TP was 30 ~ 40 mg/L. 1 ml trace element solution was added to 25 L artificial wastewater in order to provide microelement for microorganism.

Trace element solution (Li et al., 2007): MoO_3 1.0 mg, $ZnSO_4 \cdot 7H_2O$ 7.0 mg, $CuSO_4 \cdot 5H_2O$ 0.5 mg, H_3BO_3 1.0 mg, $MnSO_4 \cdot 5H_2O$ 1.0 mg, $CoCl_2 \cdot 6H_2O$ 1.0 mg, $NiSO_4 \cdot 7H_2O$ 1.0 mg, 1 L deionized water.

Experimental reactor

The laboratory scale bioreactor was made of organic glass (*Figure 1*). It consisted of three parts including aeration tank, sedimentation tank and reaction tank (consist of the bio-system with pellet and pumice). The effective volumes of the aeration tank, the sedimentation tank and the reaction tank were 48 L, 11 L, 15 L respectively. Water

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

distribution bucket was used to fill the artificial wastewater with a total volume of 25 L. The mechanical agitator was used to mix. The peristaltic pump was used to control influent and sludge reflux and the air lift pump was used to control sludge return. The electromagnetic air pump was used to offer aeration for aeration tank and reaction tank. The quantity of influent, sludge return was 8 L/d, 3 L/d and the overall HRT of reactor was 6 days.

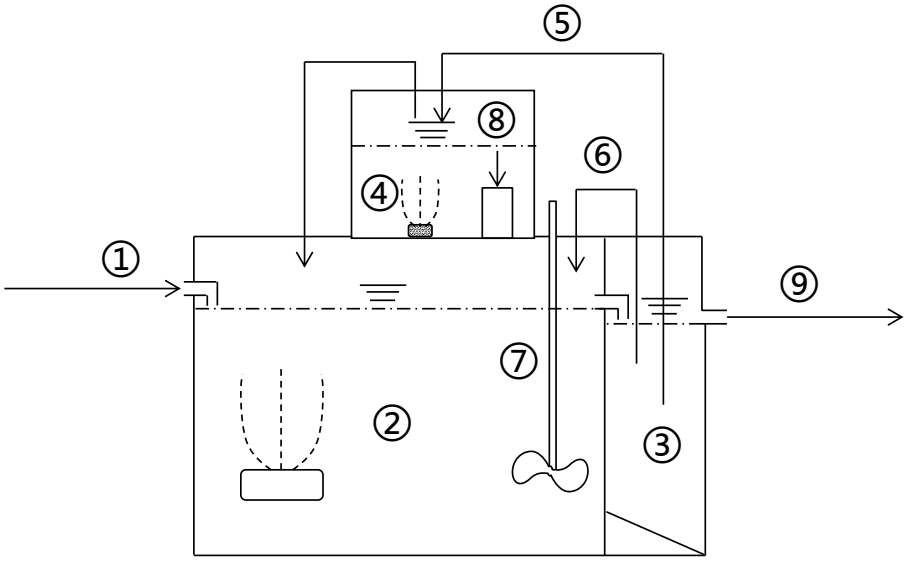

Figure 1. *Laboratory scale wastewater treatment reactor. ① influent, ② aeration tank, ③ sedimentation tank, ④ reaction tank, ⑤ sludge reflux, ⑥ sludge return, ⑦ mechanical agitator, ⑧ pellet + pumice, ⑨ effluent*

There were three reactors, which were controlled reactor, reactor one and reactor two. Six Pellet bacteria (about 363.72 g) and 727.44 g pumice were added to the reaction tank of reactor one and six Pellet (about 363.72 g), and 727.44 g pumice were added to the reaction tank of reactor two. The reaction tank of three reactors continued to be aerated. The reactor operation included two modes, which were long-term aeration and intermittent aeration. The intermittent aeration was divided into four stages, which were 1 h/1 h (the first stage), 1 h 20 min/1 h (the second stage), 1 h 20 min/1 h 20 min (the third stage), 1 h/1 h min (the fourth stage).

Water quality analysis

The researchers were analyzed the amount of COD, NH_3-N and NO_3-N with APHA Standard Method (Gilcreas, 1998). The GB (GB 11901, 1989) was used to the analysis of SS. The pretreatment of TN and TP analysis was carried out by digestion with persulfate (Qualls, 1989) and the subsequent treatment followed the APHA Standard Method.

SiO_2 determination

In the long-term aeration of 120 days, the concentration of SiO_2 was measured from the aeration tank and the reaction tank. SiO_2 was determined by citric acid extraction and silicon molybdenum blue colorimetric method (Bao, 2000).

Results and discussion

COD analysis

Figure 2 shows that the influent COD concentration was from 2000 to 3000 mg/L. For the control reactor, the effluent COD remained stable after running 113 days. The concentration range was stable from 189 mg/L to 237 mg/L and the average concentration was 208 mg/L. *Figure 3* shows that the average COD removal rate was from 91% to 94%, and the average removal rate reached 93%. For the reactor one, the effluent COD remains stable after running 99 days. The concentration is stable from 91 mg/L to 117 mg/L and the average concentration is 101 mg/L. The removal rate of COD is from 96% to 98% and the average removal rate reached 97%. For the reactor two, the effluent COD remains stable after 106 days. and the concentration was stable from 91 mg/L to 128 mg/L and the average concentration was 110 mg/L. The removal rate of COD was from 95% to 98% and the average removal rate reached 96%. The effluent COD of the reactors one and two was less than 150 mg/L. After the reactor operation was stable, the COD concentrations of the reactor one and two were lower than those of the control reactor and the reactor one was the lowest. It was shown that the removal effect for COD of reactor one was better than reactor two and both of them were better than the control reactor under the long-term aeration condition, which could be attributed with the creation of the bio-system which was similar to RBS in the reaction tanks of reactor one and two.

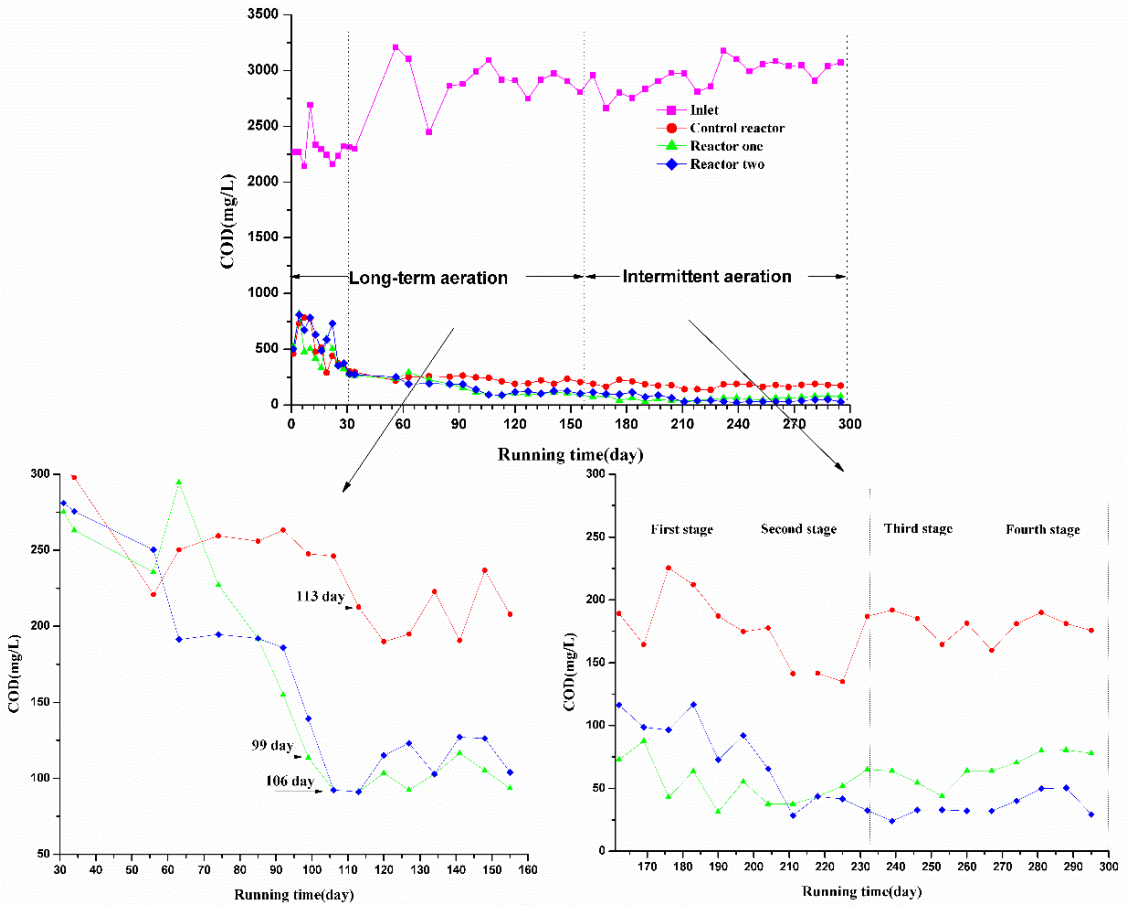

Figure 2. *Changes of COD concentration in the influent and effluent*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

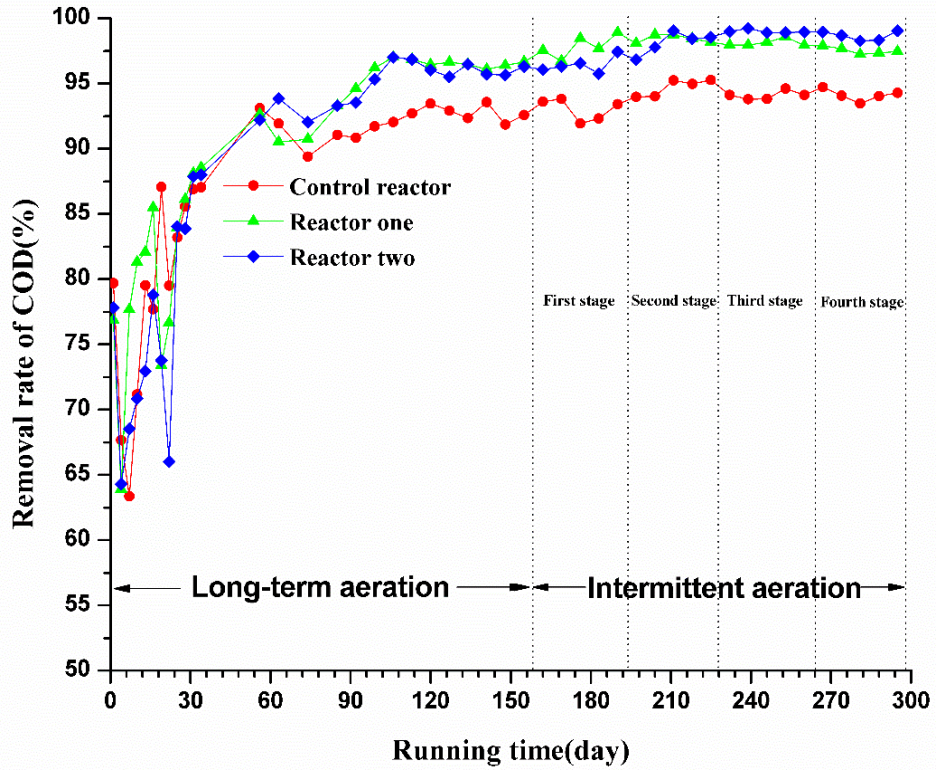

Figure 3. *Changes of COD removal rate*

During the four stages of intermittent aeration, the effluent COD concentration ranges as shown in *Table 1*. The average concentrations of four stages were 195.58 mg/L, 154.05 mg/L, 181.91 mg/L, 177.57 mg/L in control reactor. The average concentrations of four stages were 59.62 mg/L, 43.47 mg/L, 58.25 mg/L, 74.60 mg/L in reactor one. The average concentrations of four stages were 100.18 mg/L, 47.00 mg/L, 30.80 mg/L, 40.37 mg/L in reactor two. Therefore, the lowest effluent COD concentration of control reactor appeared in the second stage. The removal rate of COD was from 92% to 96% and the average removal rate was 95%. The lowest effluent COD concentration of reactor one appeared in the second stage. The removal rate of COD was from 98% to 99% and the average removal rate was 98%. The lowest effluent COD concentration of reactor two appeared in the third stage. The removal rate of COD was from 98% to 100% and the average removal rate was 99%. Therefore, for the removal of COD, the most suitable aeration conditions for control reactor, reactor one, reactor two were 1 h 20 min/1 h, 1 h 20 min/1 h, 1 h 20 min/1 h 20 min. During the four stages of intermittent aeration, the effluent COD of reactors one and two was less than 150 mg/L.

Table 1. *Effluent COD concentration ranges*

Stage	Control	Reactor one	Reactor two
1	164.38 ~ 225.50 mg/L	31.17 ~ 87.67 mg/L	72.73 ~ 116.56 mg/L
2	135.06 ~ 177.78 mg/L	37.43 ~ 55.17 mg/L	28.24 ~ 91.95 mg/L
3	164.38 ~ 192.00 mg/L	43.84 ~ 64.97 mg/L	24.00 ~ 32.88 mg/L
4	160.00 ~ 190.00 mg/L	64.00 ~ 80.50 mg/L	29.27 ~ 50.31 mg/L

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_65256547
© 2018, ALÖKI Kft., Budapest, Hungary

Figure 4 shows that the COD concentrations in the aeration tank were stable after a long period of aeration of three reactors. The concentration of COD in the aeration tank of control reactor was reduced from 2000 ~ 3000 mg/L to 1000 mg/L while that of reactor one and reactor two was reduced to 800 mg/L. After the intermittent aeration mode was converted to intermittent aeration, the COD concentrations in the aeration tank reduced. In the third stage of intermittent aeration, the COD concentrations in the aeration tank of three reactors were minimum and those of control reactor, reactor one, reactor two were 493.15 mg/L, 482.19 mg/L, 405.48 mg/L. It was indicated that the aeration tank played an important role in the removal of COD in the long-term aeration stage and the intermittent aeration stage. Since the operating modes of three reactors were changed from long-term aeration to intermittent aeration, the COD removal efficiency has been increased.

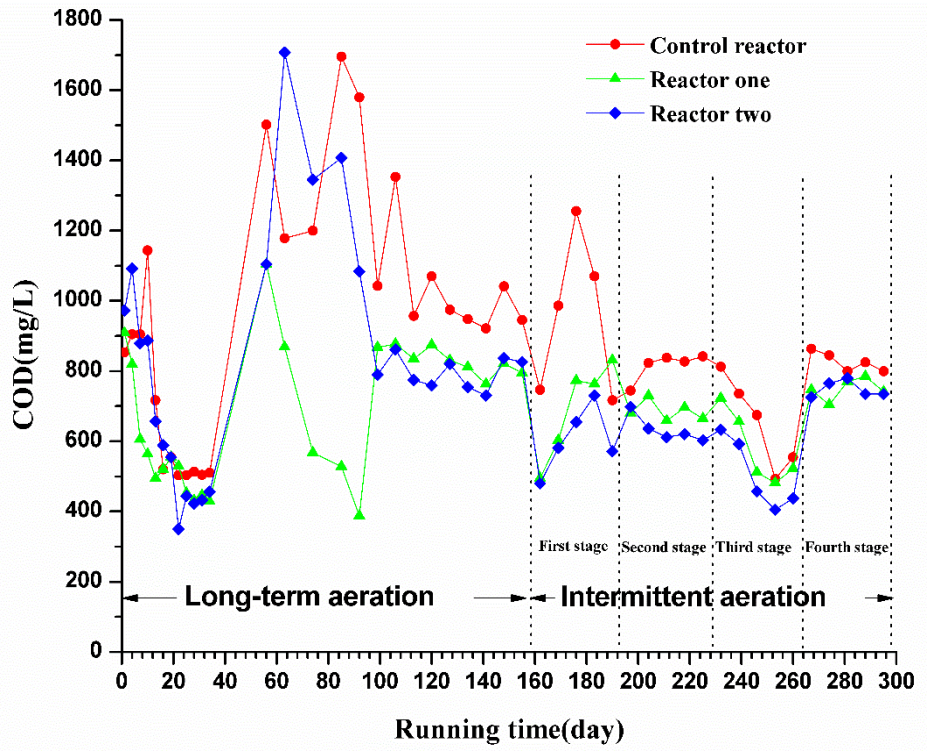

Figure 4. *Changes of COD concentration in the aeration tank*

NH_3-N analysis

Figure 5 shows that the influent NH_3-N concentration was from 35 to 70 mg/L. For the control reactor, the effluent NH_3-N remained stable after running 120 days. The concentration was stable from 26 mg/L to 32 mg/L and the average concentration was 30 mg/L. *Figure 6* shows that the average removal rate of NH_3-N was from 10% to 24% and the average removal rate reached 16%. For the reactor one, the effluent NH_3-N remained stable after running 120 days. The concentration was stable from 22 mg/L to 27 mg/L and the average concentration was 24 mg/L. The removal rate of NH_3-N was from 25% to 40% and the average removal rate reached 33%. For the reactor two, the effluent NH_3-N remains stable after 120 days. The concentration was stable from 19 mg/L to 26 mg/L and the average concentration was 22 mg/L. The removal rate of NH_3-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

N was from 29% to 46% and the average removal rate reached 38%. The effluent NH_3-N of the reactor one and two were less than 25 mg/L. When the reactor operation was stable, the NH_3-N concentrations of the reactor one and two were lower than those of the control reactor and the reactor two was the lowest. It was shown that the removal effect for NH_3-N of reactor two was better than that of reactor one and both of them were better than that of the control reactor under the long-term aeration condition, which could be attributed to the creation of the bio-system which was similar to RBS in the reaction tanks of reactor one and two.

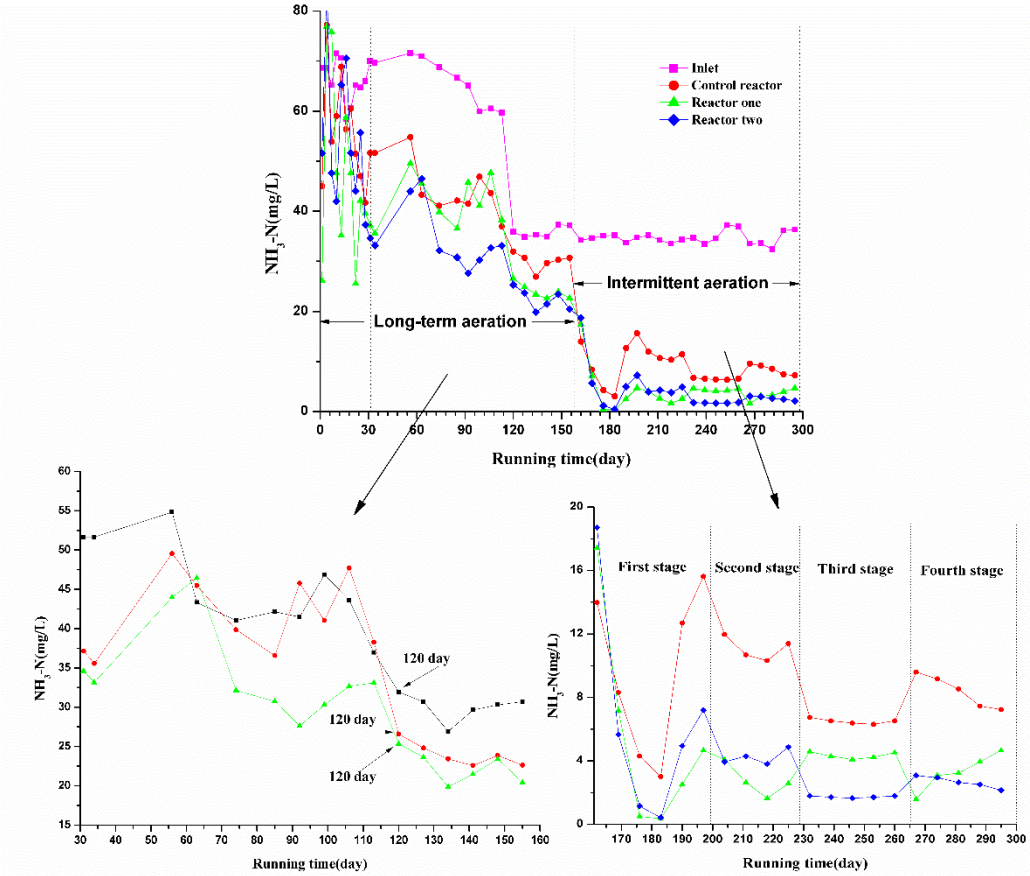

Figure 5. *Changes of NH_3-N concentration in the influent and effluent*

During the four stages of intermittent aeration, the effluent NH_3-N concentration ranges as shown in *Table 2*. The average concentrations of four stages were 8.46 mg/L, 12.00 mg/L, 6.49 mg/L, 8.4 mg/L in control reactor. The average concentrations of four stages were 5.59 mg/L, 3.13 mg/L, 4.34 mg/L, 3.30 mg/L in reactor one. The average concentration of four stages were 6.18 mg/L, 4.82 mg/L, 1.73 mg/L, 2.67 mg/L in reactor two. Therefore, the lowest effluent NH_3-N concentration of control reactor appeared in the third stage. The removal rate of NH_3-N was from 71% to 81% and the average removal rate was 75%. The lowest effluent NH_3-N concentration of reactor one appeared in the second stage. The removal rate of NH_3-N was from 82% to 96% and the average removal rate was 90%. The lowest effluent NH_3-N concentration of reactor two appeared in the third stage. The removal rate of NH_3-N was from 90% to 95% and the average removal rate was 92%. Therefore, for the removal of NH_3-N, the most suitable

aeration conditions for control reactor, reactor one, reactor two were 1 h 20 min/1 h 20 min, 1 h 20 min/1 h, 1 h 20 min/1 h 20 min. During the four stages of intermittent aeration, the effluent NH_3-N of reactor one and two was less than 25 mg/L.

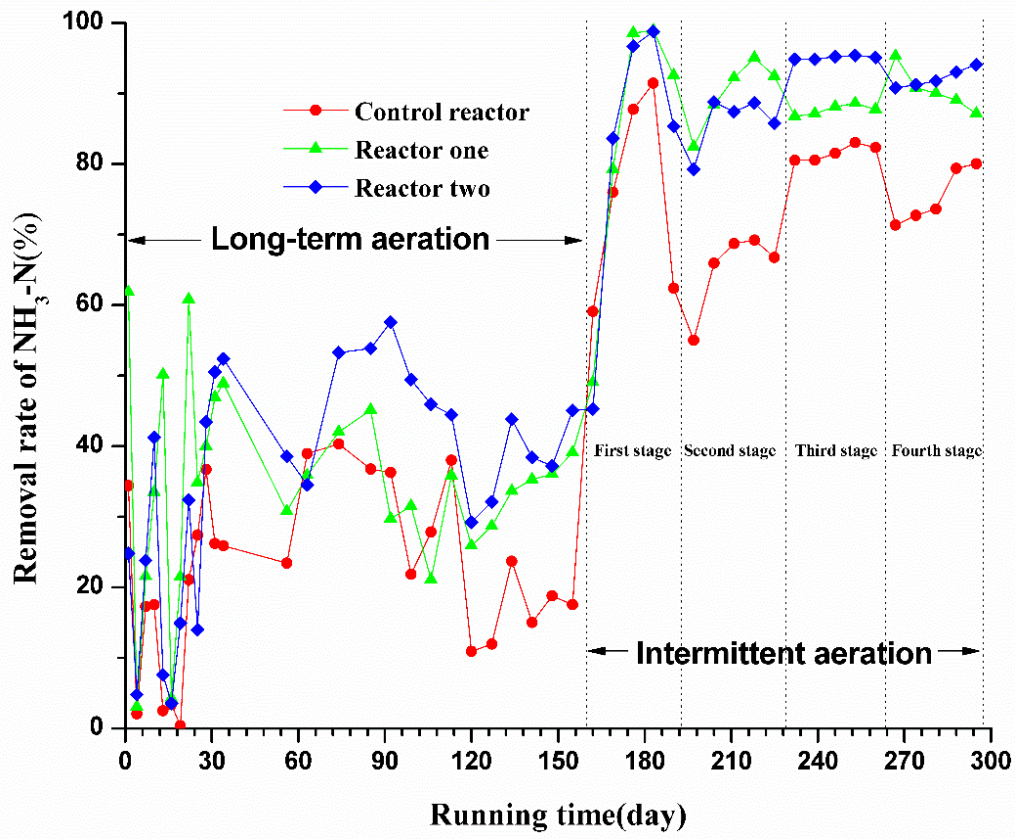

Figure 6. *Changes of NH_3-N removal rate*

Table 2. *Effluent NH_3-N concentration ranges*

Stage	Control	Reactor one	Reactor two
1	3.01 ~ 13.98 mg/L	0.36 ~ 17.42 mg/L	0.43 ~ 18.71 mg/L
2	10.32 ~ 15.63 mg/L	1.65 ~ 6.09 mg/L	3.80 ~ 7.20 mg/L
3	6.31 ~ 6.74 mg/L	4.09 ~ 4.58 mg/L	1.65 ~ 1.79 mg/L
4	7.24 ~ 9.60 mg/L	1.58 ~ 4.66 mg/L	2.15 ~ 3.08 mg/L

Figure 7 shows that the NH_3-N concentrations in the aeration tank were stable after a long period of aeration of three reactors. The concentration of NH_3-N in the aeration tank of control reactor was reduced from 30 ~ 70 mg/L to 28 mg/L while that of reactor one and reactor two was reduced to 22 mg/L and 21 mg/L. After the intermittent aeration mode was converted to intermittent aeration, the NH_3-N concentrations in the aeration tank of three reactors were reduced. In the third stage of intermittent aeration, the NH_3-N concentrations in the aeration tank of three reactors were minimum and that of control reactor, reactor one, reactor two were 2.29 mg/L, 0.22 mg/L, 0.57 mg/L. It was indicated that the aeration tank played an important role in the removal of NH_3-N in

the long-term aeration stage and the intermittent aeration stage. Since the operating modes of three reactors were changed from long-term aeration to intermittent aeration, the COD removal efficiency increased.

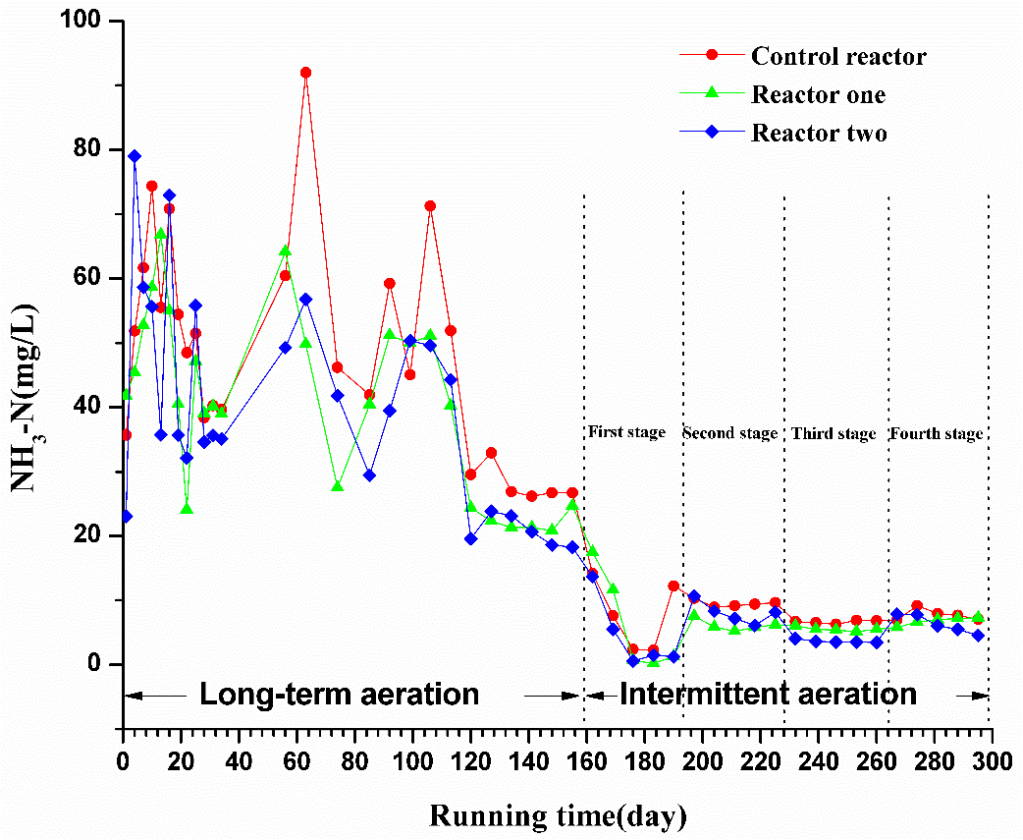

Figure 7. *Changes of NH_3-N concentration in the aeration tank*

NO_3-N analysis

Figure 8 shows that the influent NO_3-N concentration was from 10 to 15 mg/L. For the control reactor, the effluent NO_3-N remained stable after running 120 days. The concentration was stable from 8 mg/L to 13 mg/L and the average concentration was 11 mg/L. *Figure 9* shows that the average removal rate of NO_3-N was lower than 24% and the average removal rate reached 13%. For the reactor one, the effluent NO_3-N remains stable after running 106 days. The concentration was stable from 7 mg/L to 11 mg/L and the average concentration reached 8 mg/L. The removal rate of NO_3-N was from 10% to 41% and the average removal rate reached 30%. For the reactor two, the effluent NO_3-N remains stable after running 99 days, and the concentration was stable from 7 mg/L to 9 mg/L and the average concentration was 8 mg/L. The removal rate of NO_3-N was from 7% to 40% and the average removal rate reached 30%. When the reactor operation was stable, the NO_3-N concentrations of the reactor one and two were lower than that of the control reactor. It was shown that the removal effect of reactor one and reactor two on NO_3-N was better than the control reactor under the long-term aeration condition, which could be attributed to the creation of the bio-system which was similar to RBS in the reaction tanks of reactor one and two.

During the four stages of intermittent aeration, the effluent NO_3-N concentration ranges as shown in *Table 3*. The average concentrations of four stages were 6.19 mg/L, 6.54 mg/L, 5.41 mg/L, 5.01 mg/L in control reactor. The average concentrations of four stages were 1.99 mg/L, 0.66 mg/L, 2.47 mg/L, 2.20 mg/L in reactor one. The average concentrations of four stages were 0.39 mg/L, 0.39 mg/L, 0.83 mg/L, 0.30 mg/L in reactor two. Evidently, among the effluent NO_3-N concentrations of the four stages, the lowest was one of the last stage. The removal rate of NO_3-N was from 47% to 63%, and the average removal rate was 55%. The lowest effluent NO_3-N concentration of reactor one was the one of the second stage. The removal rate of NO_3-N was from 92% to 96%, and the average removal rate was 94%. The lowest effluent NO_3-N concentration of reactor two was the one of the fourth stage. The removal rate of NO_3-N was from 90% to 95%, and the average removal rate was 93%. Obviously, for the removal of NO_3-N, the most suitable aeration conditions for control reactor, reactor one, reactor two were 1 h/1 h 20 min, 1 h 20 min/1 h, 1 h/1 h 20 min.

Figure 10 shows that the NO_3-N concentrations of three reactors in the aeration tank were stable after a long period of aeration while the concentration of NO_3-N was higher than the influent. After the intermittent aeration mode was converted to intermittent aeration, the NO_3-N concentrations in aeration tank has reduced. In the fourth stage of intermittent aeration, the NO_3-N concentrations in the aeration tank of the three reactors were minimum and those of control reactor, reactor one, reactor two were 7.19 mg/L, 0.45 mg/L, 0.34 mg/L. It was indicated that the aeration tank played an important role in the removal of NO_3-N in the long-term aeration stage and the intermittent aeration stage. Since the operating modes of three reactors were changed from long-term aeration to intermittent aeration, the COD removal efficiency increased.

TN analysis

Figure 11 shows that the influent TN concentration was from 10 to 15 mg/L. For the control reactor, the effluent TN remained stable after running 113 days. The concentration was stable from 60 mg/L to 64 mg/L and the average concentration was 62 mg/L.

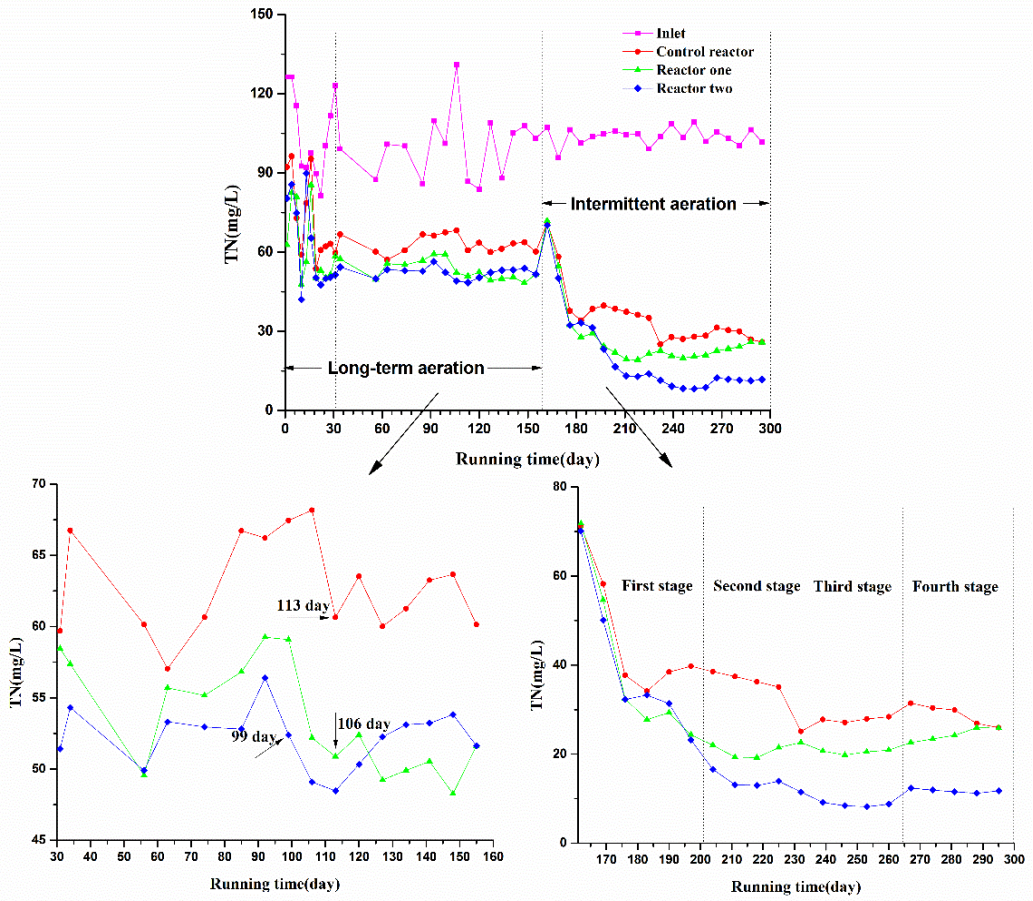

Figure 11. *Changes of TN concentration in the influent and effluent*

Figure 12 shows that the average removal rate of TN was from 39% to 54% and the average removal rate reached 43%. For the reactor one, the effluent TN remained stable after running 106 days. The concentration was stable from 48 mg/L to 53 mg/L and the average concentration was 50 mg/L. The removal rate of TN was from 49% to 62% and the average removal rate reached 54%. For the reactor two, the effluent TN remains

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_65256547
© 2018, ALÖKI Kft., Budapest, Hungary

stable after running 99 days. The concentration was stable from 48 mg/L to 54 mg/L and the average concentration was 51 mg/L. The removal rate of TN was from 48% to 64% and the average removal rate reached 54%. When the reactor operation was stable, the TN concentrations of the reactor one and two were lower than those of the control reactor and the reactor one was the lowest. It was shown that the removal effect for TN of reactor one was better than reactor two and both of them were better than the control reactor under the long-term aeration condition, which could be attributed to the creation of the bio-system which was similar to RBS in the reaction tanks of reactor one and two.

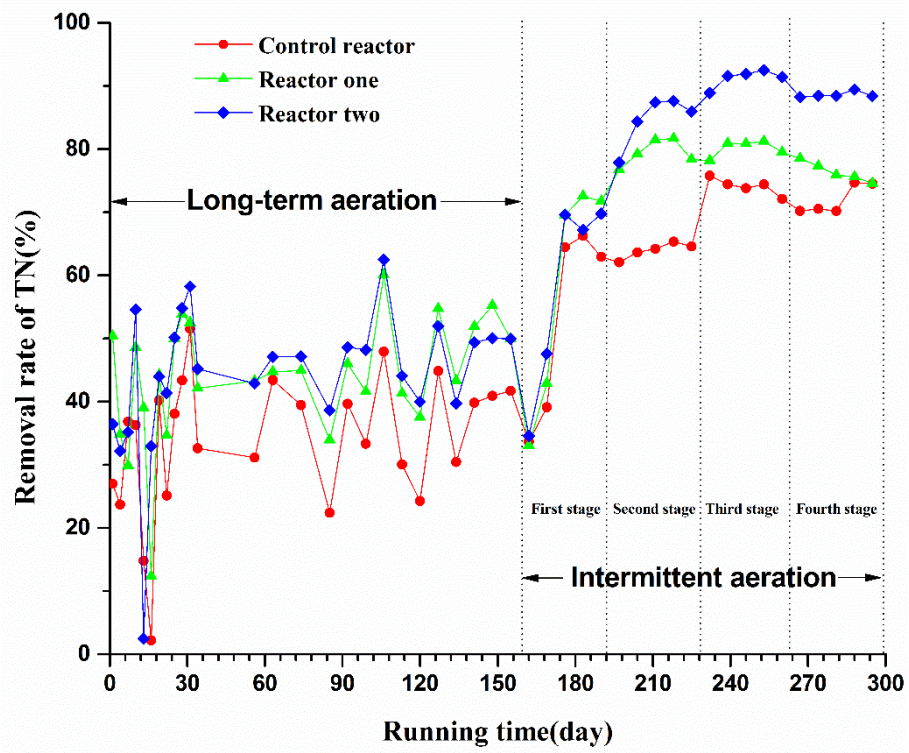

Figure 12. *Changes of TN removal rate*

During the four stages of intermittent aeration, the effluent TN concentration ranges as shown in *Table 4*. The average concentrations of four stages were 47.94 mg/L, 37.39 mg/L, 27.25 mg/L, 28.90 mg/L in control reactor. The average concentrations of four stages were 43.16 mg/L, 20.90 mg/L, 21.26 mg/L, 24.39 mg/L in reactor one. The average concentration of four stages are 43.42 mg/L, 15.94 mg/L, 9.18 mg/L, 11.76 mg/L in reactor two. It can be observed that the lowest effluent TN concentration of control reactor was the one of the third stage. The removal rate of TN was from 70% to 75% and the average removal rate was 72%. The lowest effluent TN concentration of reactor was the one of the second stage. The removal rate of TN was from 76% to 82% and the average removal rate was 80%. The lowest effluent TN concentration of reactor two was the one of the fourth stage. The removal rate of TN was from 88% to 90% and the average removal rate was 89%. Therefore, for the removal of TN, the most suitable aeration conditions for control reactor, reactor one and reactor two were 1 h 20 min/1 h 20 min, 1 h 20 min/1 h, 1 h 20 min/1 h 20 min.

Table 4. *Effluent TN concentration ranges*

Stage	Control	Reactor one	Reactor two
1	34.14 ~ 74.16 mg/L	27.78 ~ 71.78 mg/L	31.35 ~ 70.13 mg/L
2	35.06 ~ 39.74 mg/L	19.18 ~ 24.34 mg/L	12.93 ~ 23.17 mg/L
3	25.09 ~ 28.39 mg/L	19.80 ~ 22.62 mg/L	8.18 ~ 11.48 mg/L
4	25.92 ~ 31.42 mg/L	22.62 ~ 25.92 mg/L	11.21 ~ 12.38 mg/L

Figure 13 shows that the TN concentrations of three reactors in the aeration tank were stable after a long period of aeration. The TN concentration of control reactor was higher than the influent concentration while that of reactor one and reactor two reduced to 97 mg/L and 95 mg/L. After the intermittent aeration mode was converted to intermittent aeration, the TN concentrations in the aeration tank have reduced. In the first stage of intermittent aeration, the TN concentration in the aeration tank of control reactor was minimum and that of control reactor was 54.04 mg/L. In the first stage of intermittent aeration, the TN concentration in the aeration tank of reactor one was minimum and that of reactor one was 45.38 mg/L. In the third stage of intermittent aeration, the TN concentration in aeration tank of reactor two was minimum and that of reactor two was 34.1 mg/L. It was indicated that the aeration tank played an important role in the removal of TN in the long-term aeration stage and the intermittent aeration stage. Since the operating modes of three reactors were changed from long-term aeration to intermittent aeration, the COD removal efficiency increased.

TP analysis

Figure 14 shows that the influent TP concentration was from 30 to 40 mg/L. For the control reactor, the effluent TP remained stable after running 120 days. The concentration was stable from 25 mg/L to 29 mg/L and the average concentration was 27 mg/L. *Figure 15* shows that the average removal rate of TP was from 8% to 18% and the average removal rate reached 12%. For the reactor one, the effluent TP remained stable after running 113 days. The concentration was stable from 20 mg/L to 24 mg/L and the average concentration was 22 mg/L. The removal rate of TP was from 22% to 33% and the average removal rate reached 28%. For the reactor two, the effluent TP remains stable after running 113 days. The concentration was stable from 20 mg/L to 24 mg/L and the average concentration was 21 mg/L. The removal rate of TP was from 26% to 34% and the average removal rate reached 30%. After the reactor operation was stable, the TP concentrations of the reactor one and two were lower than those of the control reactor, and the reactor two was the lowest. It was shown that the removal effect on TP of reactor two was better than reactor one and both of them were better than the control reactor under the long-term aeration condition, which could be attributed to the creation of the bio-system which was similar to RBS in the reaction tanks of reactor one and two.

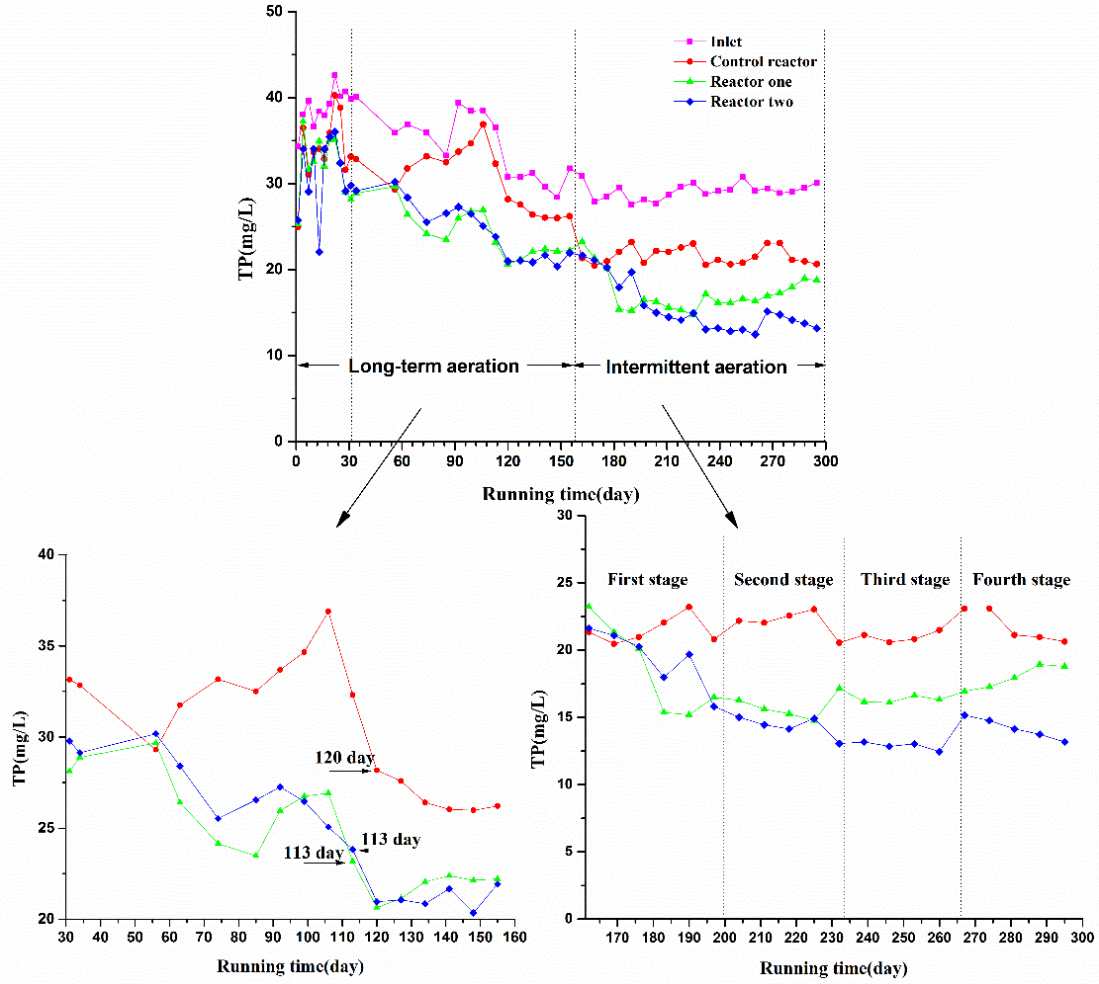

Figure 14. *Changes of TP concentration in the influent and effluent*

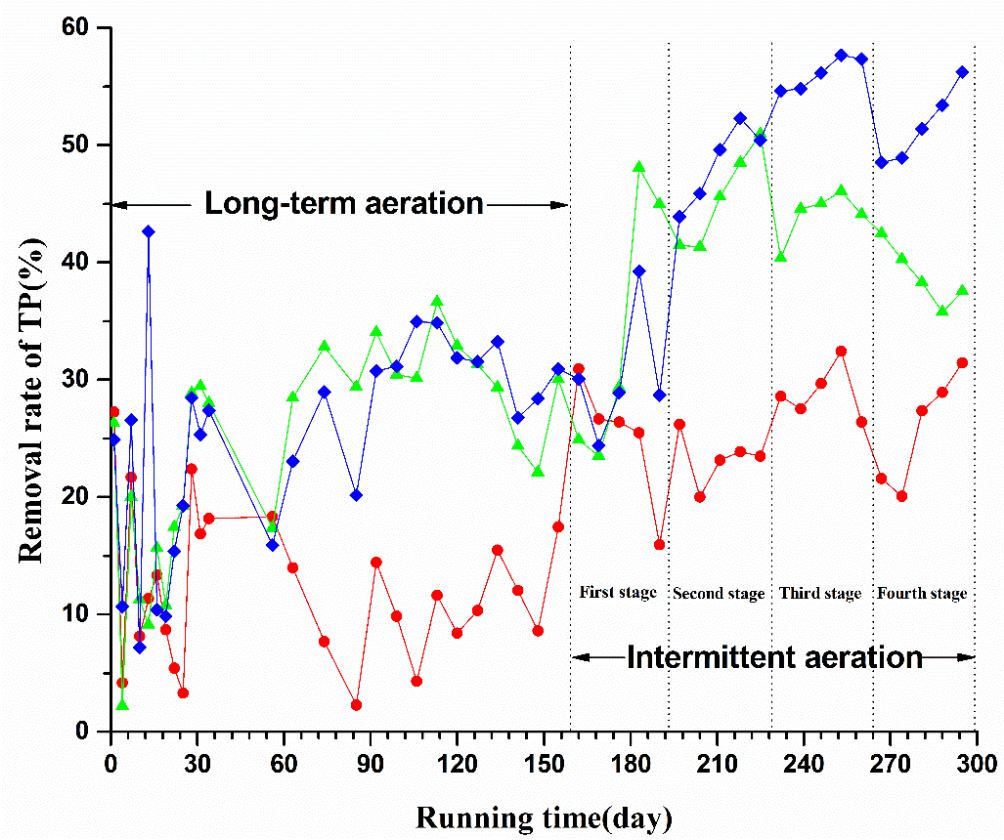

Figure 15. *Changes of TP removal rate*

During the four stages of intermittent aeration, the effluent TP concentration ranges as shown in *Table 5*. The average concentrations of four stages were 21.60 mg/L, 22.12 mg/L, 20.91 mg/L, 21.78 mg/L in control reactor. The average concentrations of four stages were 19.04 mg/L, 15.67 mg/L, 16.46 mg/L, 17.97 mg/L in reactor one. The average concentrations of four stages were 20.12 mg/L, 14.86 mg/L, 12.91 mg/L, 14.19 mg/L in reactor two. Therefore, the lowest effluent TP concentration of control reactor was the one of the third stage. The removal rate of TP was from 20% to 32% and the average removal rate was 26%. The lowest effluent TP concentration of reactor one was the one of the second stage. The removal rate of TP was from 41% to 51% and the average removal rate was 46%. The lowest effluent TP concentration of reactor two was one of the fourth stage. The removal rate of TP was from 48% to 57% and the average removal rate was 52%. It can be concluded that for the removal of TP, the most suitable aeration conditions for control reactor, reactor one, reactor two were 1 h 20 min/1 h 20 min, 1 h 20 min/1 h, 1 h 20 min/1 h 20 min.

Table 5. *Effluent TP concentration ranges*

Stage	Control	Reactor one	Reactor two
1	20.46 ~ 23.19 mg/L	15.18 ~ 23.22 mg/L	17.96 ~ 21.62 mg/L
2	20.80 ~ 23.03 mg/L	14.76 ~ 16.49 mg/L	14.13 ~ 15.81 mg/L
3	20.54 ~ 21.48 mg/L	16.10 ~ 17.15 mg/L	12.45 ~ 13.16 mg/L
4	20.62 ~ 23.09 mg/L	16.94 ~ 18.94 mg/L	13.16 ~ 15.15 mg/L

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_65256547
© 2018, ALÖKI Kft., Budapest, Hungary

Figure 16 shows that the TP concentrations of three reactors in the aeration tank appeared stable after a long period of aeration of three reactors. The concentration of TP in the aeration tank of control reactor reduced from 30 ~ 40 mg/L to 29 mg/L while that of reactor one and reactor two reduced to 26 mg/L and 27 mg/L. After the intermittent aeration mode was converted to intermittent aeration, the TP concentration in the aeration tank reduced. In the third stage of intermittent aeration, the TP concentrations in the aeration tank of three reactors were minimum and those of control reactor, reactor one, reactor two were 24.53 mg/L, 20.33 mg/L, 12.00 mg/L. It was indicated that the aeration tank played an important role in the removal of TP of the long-term aeration stage and the intermittent aeration stage. Since the operating modes of three reactors were changed from long-term aeration to intermittent aeration, the COD removal efficiency increased.

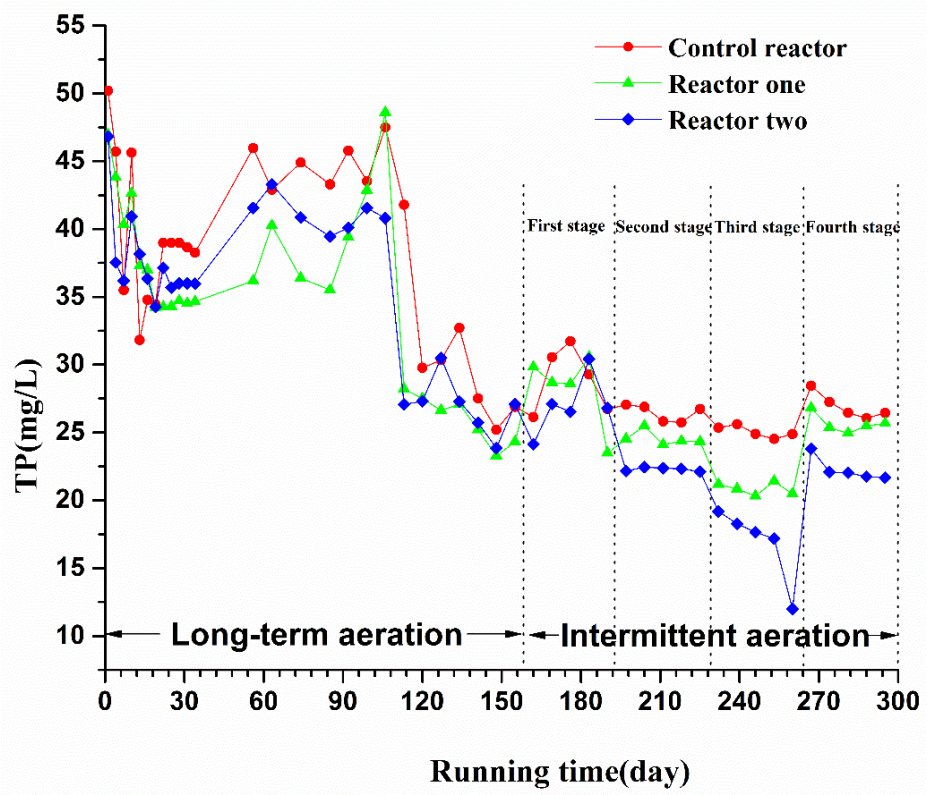

Figure 16. *Changes of TP concentration in the aeration tank*

Above all, after 120 days of long-term aeration, three reactors became a stable state. The removal of COD, NH_3-N, NO_3-N, TN, TP of reactor one and two were better than those of control reactor, especially the removal of COD. In terms of the removal of COD, the capacity of reactor one was better than reactor two. In terms of the removal of NH_3-N, NO_3-N, TN, TP, the capacities of reactor one and two were basically alike. In the intermittent aeration mode, the most optimum aeration condition for reactor one was 1 h 20 min/1 h; reactor two was 1 h 20 min/1 h 20 min. Under the optimum conditions of three reactors, reactor two achieved the highest removal efficiency of COD, NH_3-N, NO_3-N, TN, TP, which were better those of reactor one, and both of them were better than that of control reactor.

SS analysis

Figure 17 shows that for the reactor one, the concentration of SS in the aeration tank reached the maximum of 2084 mg/L in the second stage of intermittent aeration. In this stage, the highest removal efficiency of COD, NH_3-N, NO_3-N, TN, TP was achieved. For the reactor two, the concentration of SS in the aeration tank reached the maximum of 1946 mg/L in the third stage. The highest removal efficiency of COD, NH_3-N, TN, TP was achieved in this stage.

As shown in *Figure 17*, the control always showed a steady trend from the beginning to the fourth stage, while the reactor one and reactor two showed an upward trend and tended to be gentle in the third to fourth stages. In the operating, the SS concentration reached a maximum in the second stage, at which stage the highest removal efficiency of COD, NH_3-N, NO_3-N, TN, TP were achieved. In the long-term aeration mode, the SS concentration from large to small was the control reactor, reactor two, reactor one, and the three reactors had significant differences ($P < 0.05$); in the first phase and the second phase the concentration of reactor one were significantly higher than those of the control and reactor two ($P < 0.05$). In the third stage, the SS concentration of the reactor two was the highest, and there was significant difference between the two reactors and the control and reactor one ($P < 0.05$); The fourth stage was basically the same as the third stage. The reactor two had the highest concentration, the reactor one was the second, and the control was the lowest.

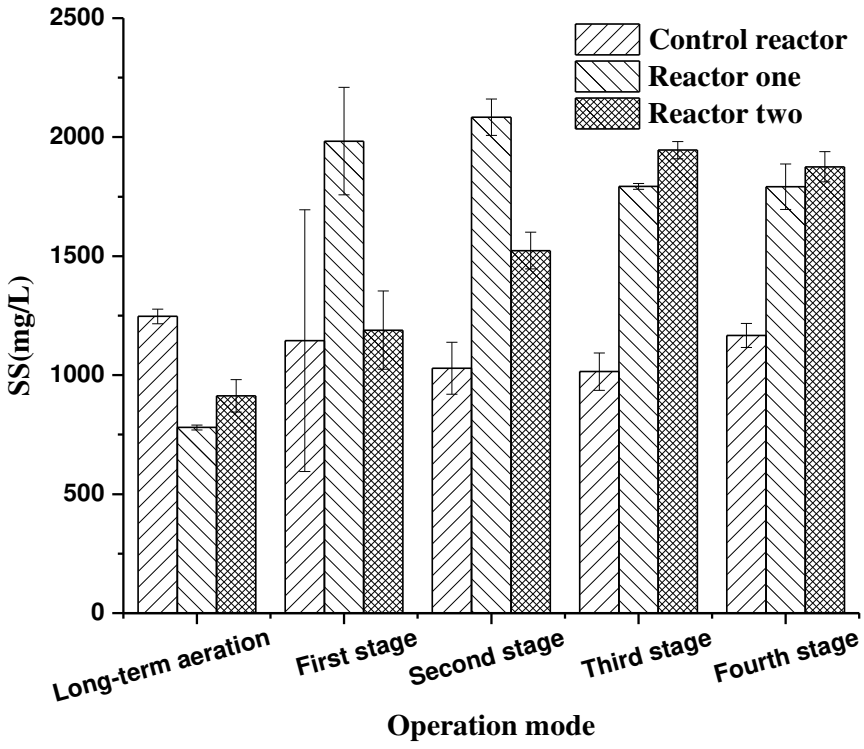

Figure 17. *Changes of SS concentration in the aeration tank*

SiO_2 analysis

Figure 18 shows that the concentrations of SiO_2 in reactor one's and reactor two's aeration tanks and reaction tanks were higher than those of control reactor. The reactor

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_65256547
© 2018, ALÖKI Kft., Budapest, Hungary

one achieved the highest SiO_2 concentrations in its aeration tank and reaction tank, which were 0.218 mg/L and 0.310 mg/L. It shows that silicates in reactor one and two were decomposed into SiO_2. However, the SiO_2 concentration in reactor one was the highest, which indicated that three kinds of silicate bacteria inoculated in Pellet (bacteria) played roles in the process of silicate decomposition.

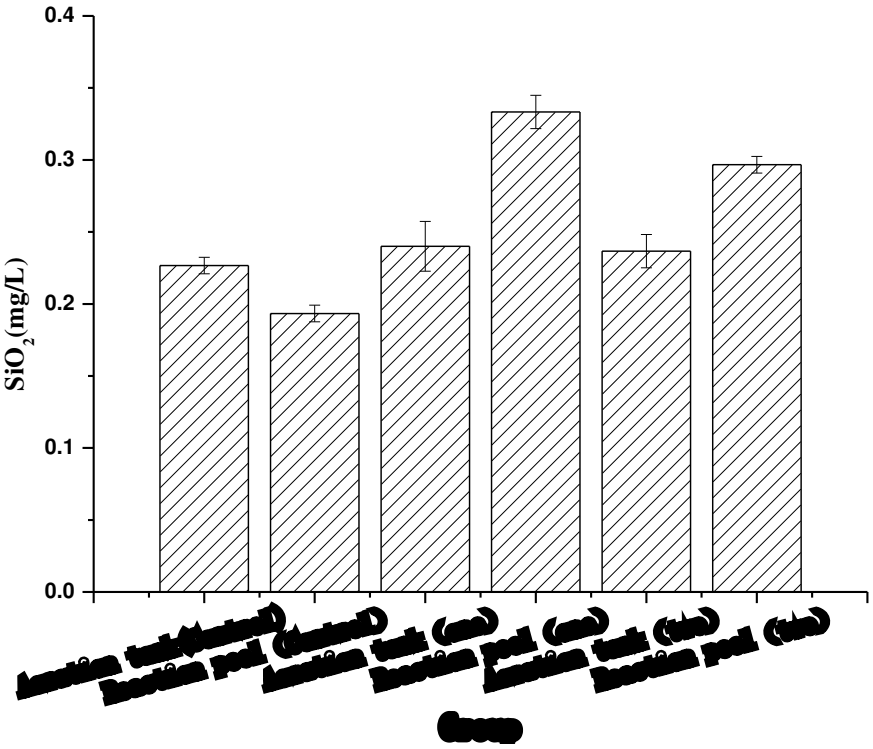

Figure 18. *SiO_2 concentration in the aeration tank and reactor in the 120th day*

For the operation of three reactors, the removal efficiencies of reactor one and two on COD, NH_3-N, NO_3-N, TN, TP were better than those of control reactor under long aeration and intermittent aeration, which indicated that the removal efficiency of the high concentration organic wastewater is enhanced. Pellet (bacteria), Pellet and pumice have been aerated in the reaction tank of reactor one and reactor two for a long time. The main component of Pellet was peat soil and the content of organic matter in the peat soil was 70 ~ 80%. The peat soil contains a large amount of water and incompletely decomposed plant residues, humus and a part of mineral matter and therefore there are a lot of humic precursors in Pellet. *Figure 18* shows that the SiO_2 concentrations in the reactor one and reactor two were higher than that of control reactor and thus the humic precursor and SiO_2 existed in the reaction tank of reactor one and reactor two, which satisfies the condition of the soil bacteria culture system (Jiang et al., 2008) in the RBS system. The reaction tank of reactor one and two created a good environment for inducing, domesticating and screening the soil bacteria. Therefore, a large number of dominant soil bacteria are found throughout the whole reactor. In addition, *Figure 18* shows that a decomposition process happens in the reaction tank of reactor one or reactor two. Silicate bacteria can decompose and oxidize the soil aluminosilicate minerals and release the elements such as K, Al, Si and some other

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_65256547
© 2018, ALÖKI Kft., Budapest, Hungary

elements (Zhang, 2000), which were the constant or trace elements for the growth of microbes. In this way, the reaction tanks of reactor one and two were provided a large amount of soil dominant bacteria and nutrients for the whole wastewater treatment system, so that the removal efficiency of the wastewater was enhanced.

He Wenyuan (He, 2008) has studied the effect of pumice in the process of bioactive water. The results of his study showed that the pumice had a large specific surface area and a lot of pores. It offers microorganism a place to live and can absorb organic compounds at the same time. It could release minerals, which can stimulate the growth of microbes. Therefore, it was possible because the minerals released from pumice in reactor one and two stimulate the growth of microbes which the treatment effects of reactor one and two were enhanced.

The removal capacity of three reactors for COD, NH_3-N, NO_3-N, TN, TP was improved after the operation mode was transferred from long-time aeration to intermittent aeration, especially removal capacity of NH_3-N. Therefore, the intermittent aeration is better than long-term aeration for three reactors. In the process of intermittent aeration, the maximum SS concentration of reactor one appears in the second stage of intermittent aeration, which corresponds to the best removal capacity of COD, NH_3-N, NO_3-N, TN, TP in this stage. The maximum SS concentration of reactor two appears in the third stage, which corresponds to the best removal capacity of COD, NH_3-N, TN, TP in this stage.

After 120 days' long-term aeration, three reactors were reached the stable state. The effluents of COD, NH_3-N, NO_3-N, TN, TP concentrations in reactor one and two had little difference, especially the TN concentration and TP concentration, indicating that three kinds of silicate bacteria inoculated in the reactor pellet were less effective than the system itself in the removals of COD, NH_3-N, NO_3-N, TN, TP, but played a role in the process of silicate decomposition.

Conclusions

By analyzing the water quality of COD, TN and TP, compared with DW, BW and BW (bacteria), two bioactive waters increased the removal rates of COD, TN and TP. And the main function of bioactive water was its own, including the structure of biologically active water. Bioactive water increased the decomposition of silicates and releases mineral elements that stimulate microbial activity. In the process of production of bioactive water, the structure of water molecules' changes, that is, the number of water molecules of the water clusters was reduced; the solubility of salt was increased, and the metabolic activity of microorganisms was enhanced. The bioactive water itself (including its own structure) enhanced the activity of the microorganisms, thereby enhancing the removal ability of the high-concentration organic wastewater.

Laboratory scale wastewater treatment reactor one and reactor two enhanced the removal efficiency of high concentration organic wastewater. The reactor had realized its own optimization after the operating mode transfers from long-time aeration to intermittent aeration. The most suitable aeration condition for reactor one was 1 h 20 min/1 h while the most suitable aeration condition for reactor two was 1 h 20 min/1 h 20 min. According to our comprehensive analysis, reactor two achieved the best removal efficiency for high concentration organic wastewater. The optimum intermittent aeration condition of reactor two was 1 h 20 min/1 h 20 min and the average removal rates of COD, NH_3-N, NO_3-N, TN, TP were increased by 3%, 21%,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

54%, 21% and 25% at this stage. The results show that bio-system was able to improve the treatment efficiency of high concentration organic wastewater and played an important role in the treatment reactor.

(Received 22nd Jun 2018; accepted 14th Aug 2018)

Abstract. This study was aimed to highlight the significance of medicinal plants, used for the treatment of diabetes from Azad Jammu and Kashmir, Pakistan. A total of 340 informants including 171 males and 169 females were interviewed through questionnaire. For reliability of medicinal knowledge, relative frequency of citation (RFC) and family importance value (FIV) were calculated. Novelty of the work was found out with the help of Jaccard index (JI). RFC and FIV were further analysed by multivariate cluster analysis. A total of 42 plant species belonging to 41 genera and 30 families were recorded during the survey. Leaves were the most commonly used plant part and decoction was the most recommended remedy preparation method. *Momodica charantia, Berberis lycium, Syzygium cumini* and *Oxalis corniculata* were the most cited species with relative frequency of citation 0.81, 0.72, 0.59 and 0.55 respectively. The highest consensus between informants and indigenous uses of family was shown by Lamiaceae with 97.44 FIV followed by Fabaceae (87.05) and Myrtaceae (85.88). Novelty index showed that *Berberis lycium*, *Beta vulgaris, Coriandrum sativum* and *Oxalis corniculata* were the newly documented species against diabetes. The results of present study could play vital role in conservation of traditional knowledge of study area.
Keywords: *medicinal knowledge, cluster analysis, traditional knowledge, Jaccard index, Berberis lycium*

Introduction

Diabetes is a major public health problem currently affecting 284.6 million people worldwide and according to the latest International Diabetes Federation estimates it is expected to affect 438.4 million adults by 2030 becoming one of the world's main disabler and killer (IDF, 2010). It disturbs the function of heart, eyes, kidneys and overall body. It is a major health problem that results in reduced life quality and increased illness (Wei et al., 2010). Diabetes is usually managed by diet, exercise, oral hypoglycemic agents and insulin (Ayodhya et al., 2013).

In addition to modern allopathic treatments, plants have also been used for the treatment of diabetes throughout the world in traditional systems of medicines (Donga et al., 2015). Many plants have the potential to lower the blood glucose level and to manage diabetes mellitus like *Morinda citrifolia* (Goodman and Ghafoor, 1992), *Musa sapientum* (Jain et al., 1998)), *Allium cepa* (Mossa, 1999), *Brassica juncea* (Yokozawa, 2003), *Herichrysum odoratissimum*, *Herichrysum petiolare*, *Hypoxis hemerocallidea* and *Hypoxis colchicifolia* (Masika and Afoloayan, 2003). The rural inhabitants of Azad Jammu and Kashmir are mostly depend on traditional medicines and traditional health

DOI: http://dx.doi.org/10.15666/aeer/1605_65496566
© 2018, ALÖKI Kft., Budapest, Hungary

practitioners as the primary source of health care. There are several reports of ethnobotanical surveys in Azad Jammu and Kashmir (Ajaib et al., 2015; Ajaib and Khan, 2014; Mahmood et al., 2011) concerning use of medicinal plants for the management and treatment of diseases including diabetes mellitus. However, in Azad Jammu and Kashmir, the traditional medicinal plants that are used for the treatment of diabetes are not studied in great detail.

Pakistan is ranked 7th in the world for the diabetes prevalence. A recent diabetes prevalence survey has revealed staggering 16.98 percent prevalence of diabetes as 35.3 million people among the adult population are found diabetic in Pakistan. If awareness programs and proper treatment are not adopted, Pakistan may have double of diabetic patients by 2040 (WHO, 2016). Such high prevalence of diabetes calls for continued efforts to improve public awareness regarding the disease. Keeping in view the current scenario of diabetes, the present study was designed to document plant knowledge used exclusively for the treatment of diabetes in rural areas of Azad Jammu and Kashmir, Pakistan.

Materials and methods

Study area

The Himalaya, the emporium of biodiversity, have been variously divided into Western Himalaya, Central Himalaya and Eastern Himalaya. Azad Kashmir (34.22°N 73.28°E) is located in foothills of Western Himalaya with an area of 13,269 km^2 which is divided into two distinct geographical zones. North and East are mostly hilly and mountainous while South and West are valleys and plains (*Fig. 1*). Due to extensive topographical variations, the area supports a variety of plant species (Afshan et al., 2011). In Himalaya, about 70% of flora have medicinal value and rural population largely depends on these plants for medicines (Shaheen et al., 2012). These plants based on traditional medicine system, continue to play an essential role in health care, with about 80% of the world's inhabitants relying mainly on traditional medicines for their primary health care (Franz, 1985). Till date, 6000 species are identified from different parts of Pakistan and Azad Kashmir, and off these, more than 400 species are only dwelling only in Azad Kashmir region with high medicinal values (Shinwari and Shinwari, 2010). In remote areas about 60% of the local population is engaged in collection and processing of different medicinal herbs (Qamar et al., 2010).

Field study

A wide-ranging survey in rural and remote areas was carried out during 2013-15. Information was gathered using open and close ended questioners. A sum of 340 informants including 171 males and 169 females were interviewed after initial survey and many group discussions with the native people. Selection criteria of choosing informants were based on the individual's expertise in the collection and utilization of medicinal plants for diabetes. Prior Informed Consent was obtained from informants involved in interviews and plant collection walks. Ethical approval was not required for this study as research participants were only interviewed on knowledge of plant species used for medicinal purposes. Participants were not subjected to any treatment, were not part of any clinical trials, and no information is presented here that could identify individual participants. Plant samples were collected, pressed with the help of plant

© 2018, ALÖKI Kft., Budapest, Hungary

presser and dried at room temperature. Completely dried plant specimens were mounted on the herbarium sheets. For long term preservation and to avoid fungal attack, each mounted sample was treated with 1% $HgCl_2$ preservative. Plants were identified by the plant taxonomist at The Department of Botany and further clarification was done through herbaria comparison and available taxonomic literature. The International Plant Name Index (IPNI), Scopus, Web of Science and Google Scholar, Catalog of vascular plants of West Pakistan and Kashmir (Ali and Nasir, 1970-2002) were also consulted to obtain correct botanical names. Plant specimens with voucher number were deposited in Herbarium of University of the Poonch Rawalakot.

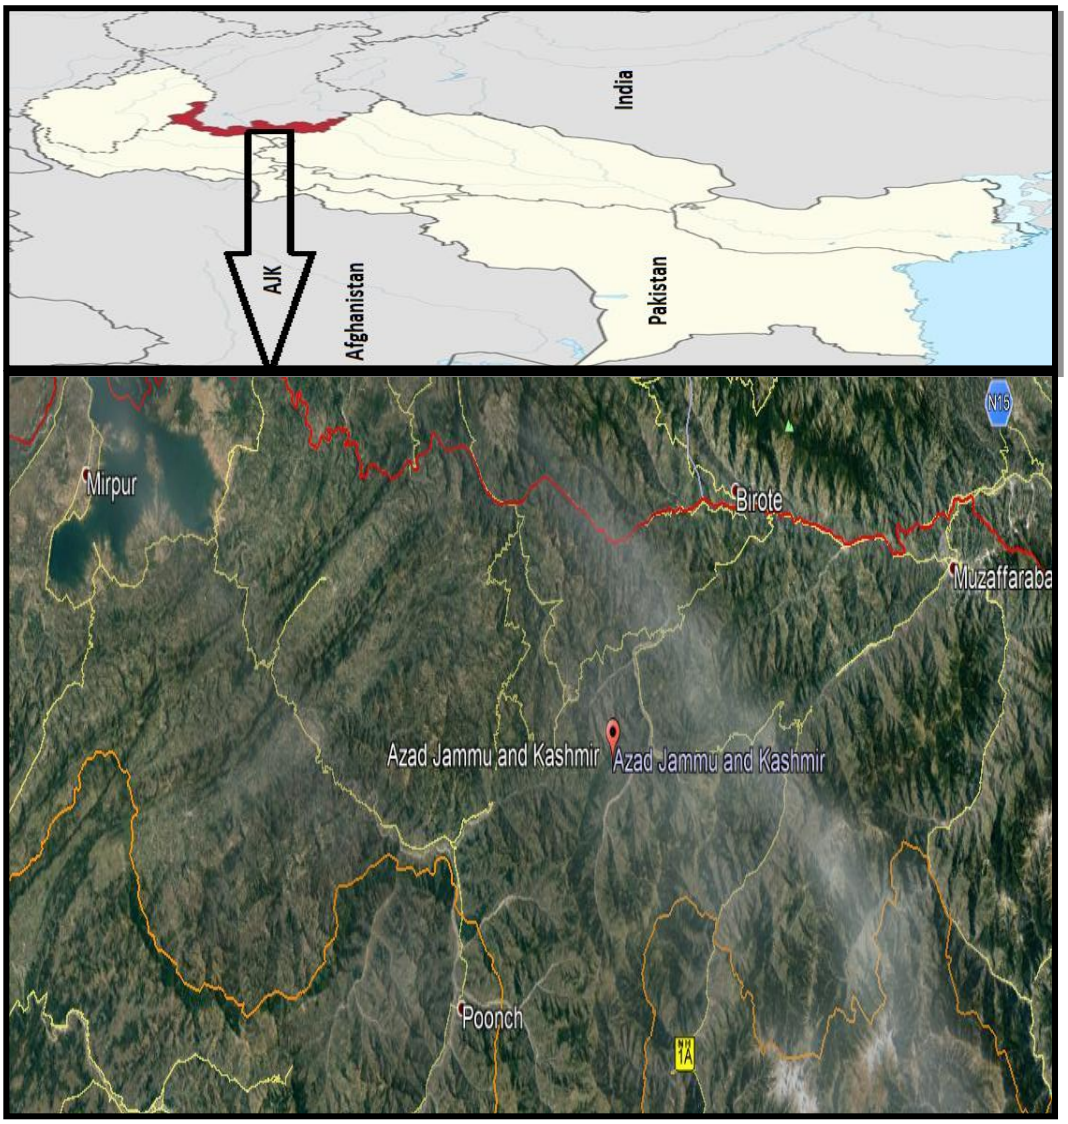

Figure 1. *Map of the study area (AJK)*

Data collection

Data was collected from people of different age groups belonging to different professions (formers, shopkeepers, teachers, herbal practitioners, wood sellers, students etc.) by using semi structured questionnaire (see *Appendix*), developed by using the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_65496566
© 2018, ALÖKI Kft., Budapest, Hungary

method of Edwards et al. (2005). The collected data comprised of local names of the plants, the parts of plant, recipe and usage method, quantity of dose and duration of treatment.

Relative frequency of citation

The frequency of citation was calculated to assess the incidence of one particular plant species used for the treatment of diabetes in relation to the overall citations for all plants. The relative frequency of citation for a plant species was calculated as *Equation 1* (Tardio and Pardo-de-Santayana, 2008).

$$RFC = \frac{FC}{N} \quad (0 < RFC < 1) \qquad \text{(Eq.1)}$$

Where FC is the number of informants who mentioned the use of plant and N is the total number of informants.

Family importance value

The consensus between informants and indigenous use of family was evaluated by formula in *Equation 2* (Molares and Ladio, 2009)

$$FIV = FC_{Family} / N \times 100 \qquad \text{(Eq.2)}$$

Where FC = Number of informants mentioned indigenous use of family for particular disease and N= total number of informants mentioning all family for particular disease.

Jaccard index

JI was used to find the resemblance in indigenous data among various ethnic groups and geographical areas by comparing present study with published works from the neighboring areas as in *Equation 3* (Gonza et al., 2008).

$$JI = \frac{c \times 100}{(a+b) - c} \qquad \text{(Eq. 3)}$$

where a is the species present in our area only, b is the species present in neighboring area only and c is the species found in both areas.

Data analysis

Measuring the importance of plants and vegetation to people is a central concern in quantitative ethnobotany. Quantitative indices help to obtain quality information on medicinal plant usage which in turn contributes conservation of natural resources. Furthermore, such indices helped to establish consensus on which species are effective to cure diabetes, as well as the species' relative importance and enabled us to understand the extent of the potential utilization of each species. In this study, data ethnobotanical data was tested using quantitative indices namely: RFC, FIV, and JI. Multivariate cluster analysis was done on RFC and FIV.

Results

Demographic profile

The present study was conducted in rural areas of Azad Jammu and Kashmir, Pakistan. A total of 340 informants have been interviewed (*Table 1*). The demographic profile of the area showed that there were 51% male and 49% female respondents. All the informants were classified into 3 age groups viz. Below 30 years (20%), 30 to 50 years (27%) and above 50 years (56%). It was observed that indigenous knowledge was more confined to older people.

Table 1. *Demographic data of the informants*

Variable	Categories	Total	%
Gender	Male	175	51
	Female	165	49
Age groups	Below 30	69	20
	30-50	91	27
	Above 50	190	56

Documentation of plants

The ethnobotanical data showed that inhabitants of Azad Jammu and Kashmir use 42 plant species belonging to 41 genera and 30 families for the treatment of diabetes. Most of them were angiosperms while gymnosperms and pteridophytes are represented by only one species each. All the recorded plant species are arranged in alphabetical order with their families, voucher specimen, local name, part used and recipes (*Table 2*).

Family participation

It was found that most dominant families with respect to species number were Fabaceae and Lamiaceae with 4 species each followed by Apiaceae, Chenopodiaceae, Ranunculaceae, Rosaceae and Solanaceae with 2 species each (*Fig. 2*). All other families were represented with one species. The dominance of the families is corresponded to the fact that these are well known among the people and easy to access.

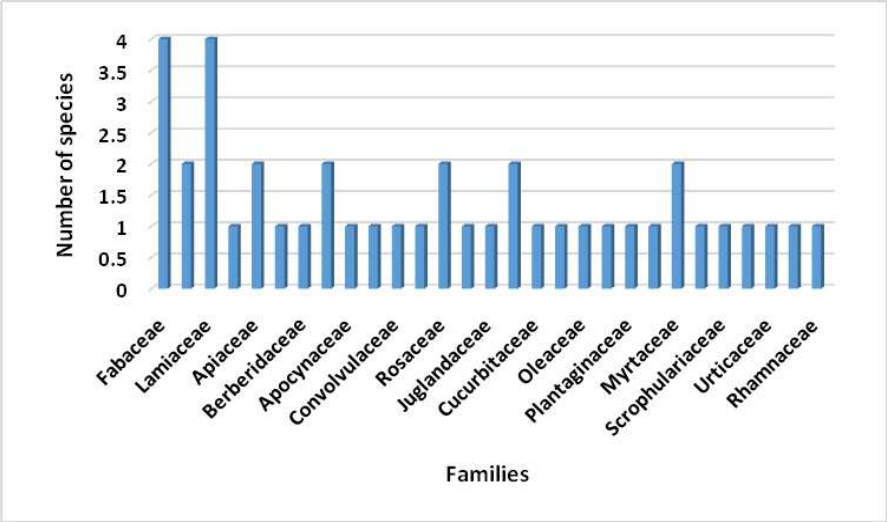

Figure 2. *Number of species per family*

Parts used and methods of administration

Most frequently used plant parts were the leaves (28%) and fruits (16%) followed by whole plant (13%), seeds (12%), roots (10%), bark (7%), flowers (4%) and aerial parts (3%) as shown in *Figure 3*. Herbal medicines were prepared by using different preparation methods, i.e. decoction, powder, juice, extract and vegetable (*Fig. 4*). Most frequent used method was decoction (48%) followed by extract (21%), juice and vegetable (11% each) and powder (9%) as presented in *Figure 4*.

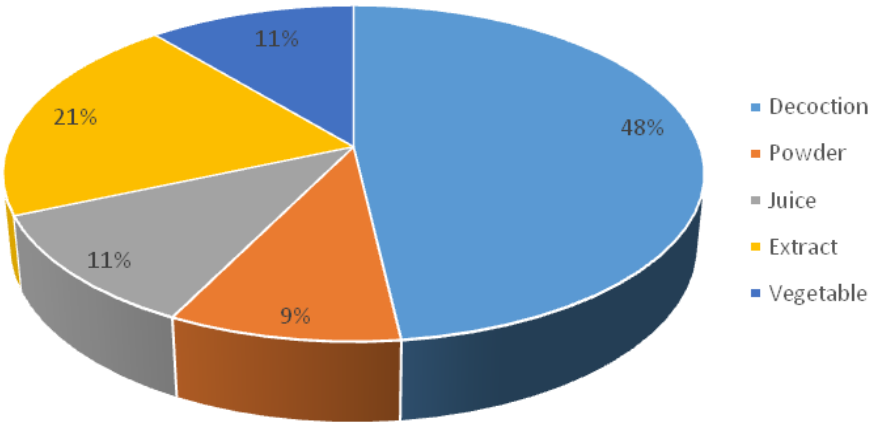

Figure 4. *Methods of herbal drug preparation*

Relative frequency of citation

Most common plants used to treat diabetes as mention by informants were determined by calculating RFC. The RFC values were shown in *Table 2,* which ranged from 0.09 to 0.95. The highest RFC was found for *Berberis lycium* (0.95) followed by *Momordica charantia* (0.91) and *Beta vulgaris* (0.80).

Family importance value

The results of FIV are shown in *Table 3*. The highest consensus between informants and indigenous uses of family was shown by Lamiaceae with 97.44 FIV followed by Fabaceae (87.05), Myrtaceae (85.88), Cucurbitaceae (81.47), Berberidaceae (75.58) and Apiaceae (71.17).

Jaccard index

It was used to compare the indigenous knowledge use to treat diabetes among different communities as the ethnobotanical knowledge greatly vary among the communities because of different origins, geography, culture and social behavior. This comparison of knowledge may result in discovery of many new drugs (Leonti, 2011). The present study was compared with 9 other studies from Pakistan, India, Bangladesh, Iran (*Table 4*). The maximum degree of parallel index was found with studies by Bahmani et al., (Bahmoni et al., 2014) from Uramia, Northwest Iran, Ahmad et al. (2009) Attock Pakistan and Kumari et al. (2011) Uttarakhand, India.

Table 4. *Jaccard index comparing present study with previous studies*

Area	Study year	Number of recorded plant species	Total species common in both area	Species enlisted only in aligned areas	Species enlisted only in study area	JI	Citation
Attock, Pakistan	2009	37	5	32	37	7.81	Ahmad et al., 2009
Tamil Nadu, India	2017	65	5	60	37	5.43	Aadhan and Anand, 2017

Novelty and future impact

The novelty index was determined by comparing present study with previous studies conducted in Pakistan, India, Bangladesh and Iran as shown in *Table 3*. In Azad Jammu and Kashmir, no previous study was found on anti-diabetes uses of medicinal plants. In Pakistan only few studies were found. There was very little resemblance with previous studies in uses of plants to treat diabetes. Some of the newly documented medicinal plants used to treat diabetes were *Berberis lycium*, *Beta vulgaris, Coriandrum sativum, Oxalis corniculata, Phaseulus vulgaris, Psidium guajava, Zizpiphus mauritiana, Mentha arvensis, Hedra helix, Bauhinia variegata, Taraxacum officinale and Zanthoxylum alatum.*

Multivariate cluster analysis

Based upon RFC values, multivariate cluster analysis results reveal significant relationship among plant species. There were two main clusters (*Fig. 5*).

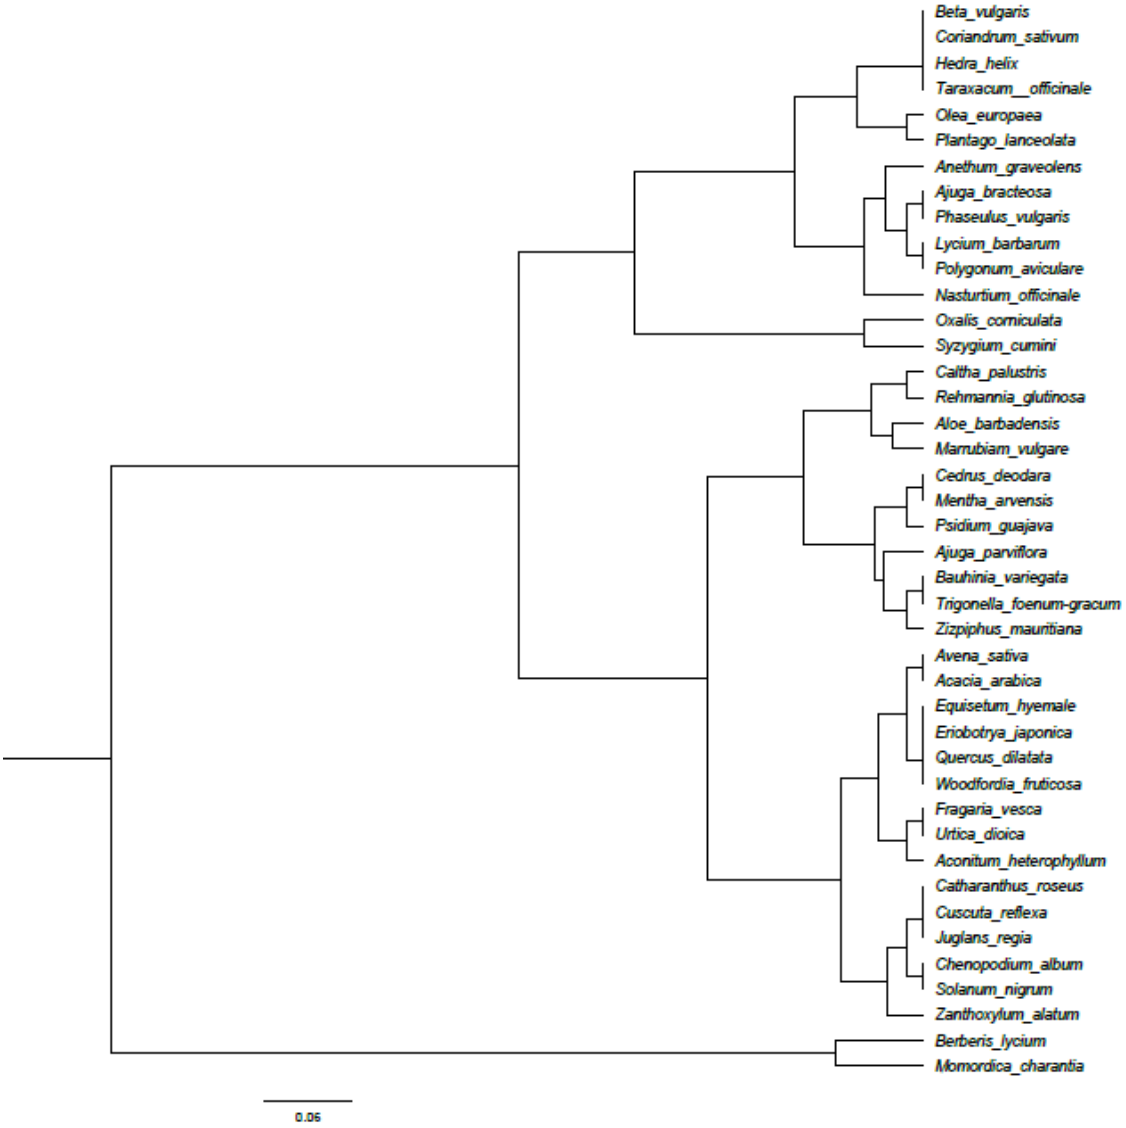

Figure 5. *Cluster analysis based on RIF values of plants*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_65496566
© 2018, ALÖKI Kft., Budapest, Hungary

Cluster one comprised of *Berberis lycium* and *momordica charantia*. Both species showed close relationship based upon RFC. Cluster two received 41 species, it was the largest group. Cluster two was further divided into 4 sub clades. *Beta vulgaris*, *Coriandrum sativum*, *Hedra helix* and *Taraxacum officinale* showed closed RFC values. *Olea europea* and *Plantago lanceolata* were sister species, showing close association. *Anethum graveolens* and *Nasturtium officinale* showed weak association with rest of the species in the clade, i.e. *Ajuga bracteosa*, *Lycium barbarum* and *Polygonum aviculare*. *Oxalis corniculata* and *S. cumini* were closely associated based on RFC values. *C. palustris* was closely related to *R. glutinosa*. *F. vesca*, *A. dioca* and *A. hydrophyllum* were closely related species. In the next cluster, *C. reflexa*, *J. regia*, *C. album* and *S. nigrum* were more closely related plant species. In the cluster, *B. variegata* was more closely related *T. foenum-gracum* and *Z. mauritiana* than *A. parviflora*. Whereas *C. deodara* was more closely related to *M. arvensis* than *S. guajava*.

Multivariate cluster analysis, on the basis of FIV, suggested a close relationship among the families. It is divided into two main clusters (*Fig. 6*). Cluster 1 showed the association of Rosaceae, Equitaceae, Lythraceae and Poaceae. Cluster 2 is further divided into 3 sub clusters. Brassicaceae was most closely related to Polygonaceae. Chenopodiaceae was closed to Urticaceae than Oxalidaceae. Apiaceae and Berberidaceae were more close to each other on the basis of FIV.

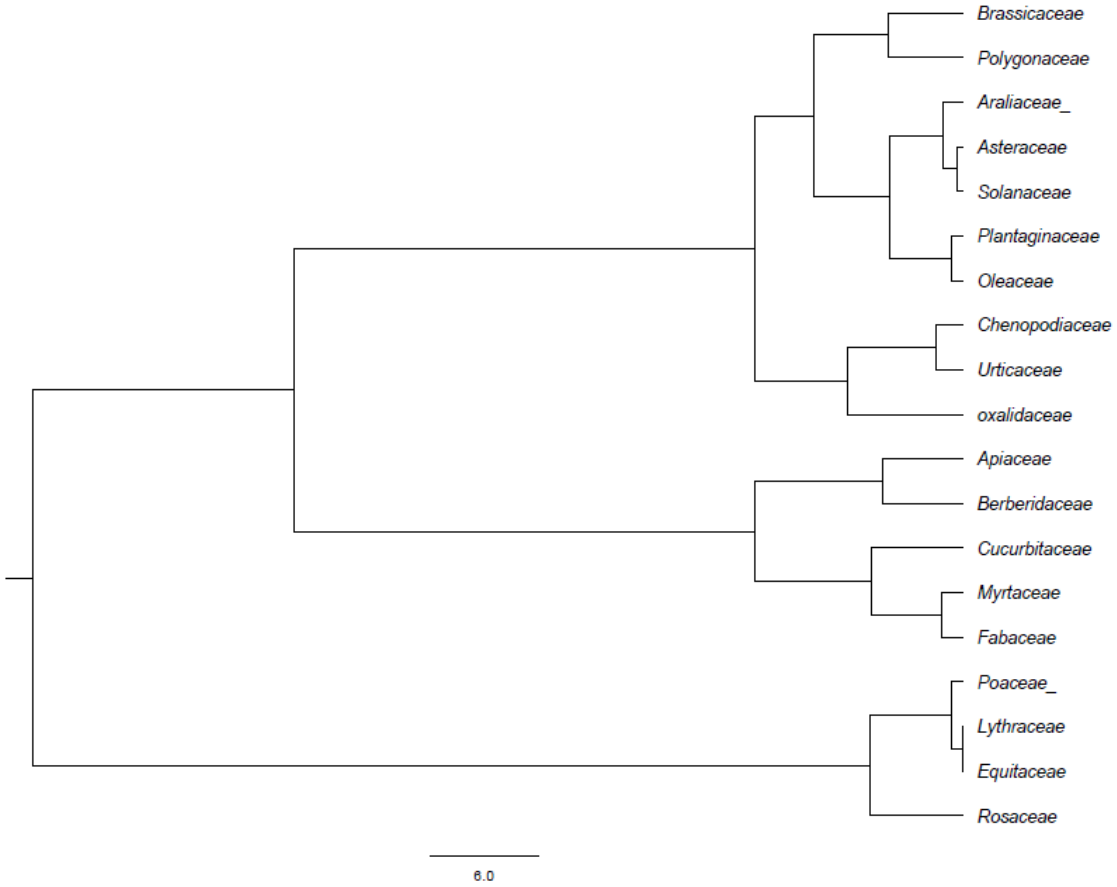

Figure 6. *Cluster analysis of families based on FIV*

Discussion

The present investigation was confined in rural areas of Azad Jammu and Kashmir, Pakistan. The objective was to document the medicinal flora of the area traditionally used for the treatment of diabetes and to explore the constituents of these medicinal plants. To collect the ethnobotanical information, 340 informants were interviewed. There had been tendency of increasing ethnobotanical knowledge with the age of informants. The ethnobotanical data showed that 42 plant species belonging to 41 genera and 30 families were used for the treatment of Diabetes. The reason is that older people are more familiar with the use of medicinal plants and are involving in ethnomedicinal practicing and traditional knowledge. However younger people have less interest in older traditional knowledge regarding the use of plants for treatment of diseases. Previous studies also show that elder people have more ethnomedicinal knowledge (Kpodar et al., 2015; Abouri et al., 2012).

Fabaceae and Lamiaceae were the dominant families in the study area with 4 species each followed by Apiaceae, Chenopodiaceae, Ranunculaceae, Rosaceae and Solanaceae with 2 species each. The dominance of the families is corresponded to the fact that these are well known among the people and easy to access. Furthermore, locals have more knowledge about these families and used these plants for generations to generations. Frequent use of these families also suggests that important secondary metabolites are present in the member of these families. In previous study, it was found that members of Fabaceae and Lamiaceae are used for the treatment of diabetes (Aadhan and Anand, 2017).

Most frequent used plant parts were the leaves, followed by fruits, whole plant, seeds, roots, bark, flowers and aerial parts Leaves are mostly used parts because of the fact that leaves are the main photosynthetic organs and they are the part of the plants which is most easily reachable and accessible throughout the year (Fezon et al., 2008). Leaves are also valuable in phytotherapy because they contain more effortlessly extractable phyto-compounds, crude drugs and several additional mixtures (Bano et al., 2014a, b). Moreover, leaves are easy to collect and process and their collection does not harm the plant considerably in contrast to collection of bark, roots and whole plant (Telefo et al., 2011; Zheng and Xing, 2009). Leaves are most frequent plant parts used as ethnopharmacology as reported in previous studies (Amjad et al., 2017; Khan et al., 2015).

Most frequent used method was decoction followed by extract, juice, vegetable and powder. In ethnobotanical practices, the major forms of herbal drug preparation are the decoction (mixing plant part with water, tea or soup (Amjad et al., 2017). The other reason of the use of decoction is that it is prepared by heating which may hasten the biological reactions resultant in the increased accessibility of many bioactive compounds (Han et al., 2007; Zhang et al., 2005).

The RFC values were from 0.09 to 0.95. The highest RFC was found for *Berberis lycium* and *Momordica charantia* reflected that these species were very famous and familiar among the local inhabitants of the study area and these species could be further investigated for their pharmacological and phytochemical properties (Mukherjee and Wahile, 2006). Number of studies suggests that *Momordica charantia* has higher potential as antidiabetic (Chaturvedi, 2012; Nama et al., 2011; Shibib et al., 1993; Ali et al., 1993).

Jaccard index results showed ethnobotanical knowledge varied greatly among the communities because of different origins, geography, culture and social behavior. This

© 2018, ALÖKI Kft., Budapest, Hungary

comparison of knowledge may result in discovery of many new drugs (Leonti, 2011). The maximum degree of parallel index was found with studies by Bahmani et al. (2014) from Uramia, Northwest Iran, Ahmad et al. (2009) Attock Pakistan and Kumari et al. (2011) Uttarakhand, India. The highest similarity index corresponds to same type of vegetation and geographical conditions or same ethnic values. Most common species were the *Momordica charantia*, *Trigonella foenum-gracum* and *Syzygium cumini*. These species are found in almost all compared areas, which demonstrate their importance for the treatment of diabetes. The lowest JI was found for the study of Yadav et al. (2012) from Madhya Pradesh, India. This difference is might be due to geographical barriers and different type of vegetation and habitat (Leonti, 2011). Strong positive correlation between UV and RFC showed that increase in number of informants also increases the knowledge of the uses of species (Ishtiaq et al., 2007; Ahmed et al., 2017). This suggested that this study is a significant contribution towards the documentation of plants used for the treatment of diabetes.

Conclusions

This ethnobotanical study documented the ethnophytotherapeutic management of diabetes mellitus and support of traditional healers in Azad Jammu and Kashmir. The indigenous population still relies to a great extent on traditional healers and medicinal plants to meet their healthcare needs because of the perceived effectiveness, presumed safety with minimal side effects and affordability. In conclusion, this article presented a list of anti-diabetic plants used in the treatment of diabetes mellitus. Medicinal plants are good alternative to synthetic drugs due to biocompatibility, cost effective and less or no side effects. Further studies are needed to be carried out to explore the exact mechanism of these medicinal plants' antidiabetic activity. The documented plants should also be further screening for their phyctochemical constituents, pharmacognostic characters and biochemical assays for their sustainable and effective uses.

Acknowledgements. This study was not funded by any organization. We thank local inhabitants of the study area for their hospitality and cooperation.

APPENDIX

Questionnaire for collecting ethnomedicinal data during Ethnobotanical Study

Questionnaire:

Informants' consent for the participation in the study:

I..... (name of informant) hereby give my full consent and conscious to participate in this study and declare that to the best of my knowledge the information that I have provided are true, accurate and complete.

Date..... (Signature/Thumb impression of Informant)

Informants' details:

Name.....
Gender.....
Age.....
Occupation.....
Education.....
Location/Residence.....

Data about medicinal plant and its use:

Plant (Local name).....
Habit (Tree/Herb/Shrub/Climber/…...)
Plant part used.....
Cultivated/Wild.....
If cultivated, cultivated for…….....
If wild, availability in natural resources (easy/difficulty/very difficult)
Conservation needs.....
Conservation efforts made by Government and local residents……..…
Method of collection and storage…….....
Name of disease(s) treated…….....
Method of crude drug preparation.....
Mode of administration.....
Dosage.....
Other uses (if any)…….....…….....

Remarks:

Plant identified as …… (Botanical name and family)

Information provided by informants will be used for research purposes only

Abstract. Currently, the threats of mountain disasters are continuously increasing due to the highly vulnerable feedback mechanism of mountain ecosystems, and the construction land use type is most strongly affected by human activities. This study uses multiple index coupling models to evaluate the suitability of construction land. The evaluation uses mountain disaster risk, topographic and geomorphic environments, hydrogeological environments, human activity factors and socio-economic factors as the suitability standards. We use geographic information system (GIS) technology to improve the evaluation model and establish a suitability map of construction land for Baoxing County, Sichuan province, China. This study indicates that the mountain disaster risk is the core factor of the suitability zoning of construction land in Baoxing County, wherein, the development suitability of construction land in the central sectors is relatively high while the mountain disaster risk is relatively high due to the high socio-economic value of the disaster-bearing areas in the central sectors. The development suitability of construction land near the fracture zones and the natural reserves is relatively low.
Keywords: *construction land, suitability assessment, mountain disasters, vulnerability, risk assessment*

Introduction

Mountainous areas account for approximately 25% of the global land area, and the feedback mechanisms in mountain ecosystems are highly vulnerable; therefore, disasters occur frequently (Peng et al., 2016). The characteristics of the limited, easily destroyed and unrestored land resources are obvious, and these characteristics restrict the development, economic value and social benefit of construction land in mountainous areas. At the same time, the international disasters reduction strategy has gradually shifted the "hard" measures of a project to "soft" land planning measures, and land planning limits the development of land in areas where there are disaster potentials (Leroi et al., 2005). All countries and regions throughout the world have combined construction land suitability planning in mountainous areas with research on mountain disasters and have taken the corresponding measures to contribute to the sustainable development of mountainous areas (Hemingway and Gunawan, 2018). For example, the United Nations issued the "Hyogo framework for action 2005-2015: building the resilience of nations and communities to disasters." (ISDR, 2005). Italy has combined hazard risk assessments with land use planning and has applied this theory to actual urban construction. The Advisory Committee, the Planning Association and the United

States Geological Survey released the "Landslide disasters and Planning: Incorporating Geological disasters Planning into the Planning Process," which notes that land use planning should be focused on reducing the risks of disasters (Lovell, 2010). A series of urban land use plans and natural disaster risk evaluations have become an essential component in the sustainable development of mountainous areas in China. Mountain disaster risk is the most prominent factor in mountain cities and towns, as discussed in., "The National Comprehensive Disaster Prevention and Mitigation Plan (Year 2016-2020)" and "Outline of National Territorial Planning (Year 2016-2030)," for example (The State Council of China, 2017).

In China, mountainous areas cover 6.66 million km^2, accounting for 69.4% of the territorial areas of China, and the population in mountainous areas is more than 1/3 of the total population (Chen et al., 2010). The mountainous areas are vulnerable to landslides, collapses, mudslides and other mountain disasters, which seriously threaten the safety of lives, property and engineering construction and limit the utilization of land resources and economic development. Therefore, the original resource-rich mountainous areas in China have become the "topographic uplift areas and the economic valley areas" (Cui, 2014).

With the rapid development of urbanization, tremendous changes have taken place in China's mountain towns in terms of construction spatial patterns, population structure and living standards (Liu et al., 2016). Mountain disasters pose a serious threat to people's lives and property (Zhang et al., 2009; Deuskar et al., 2015). Construction land is different from other land types as it is relatively irreversible, and once a piece of land is converted into construction land, it is difficult to restore that land to other land use types. Construction land development that is affected by the mountainous environment and disasters induces and intensifies mountain disasters (Wang, 2012). Additionally, the disaster risk is increasing due to the high economic value of various disaster-bearing areas in the central sections of the mountain towns, which seriously restricts the development suitability of construction land. However, disaster risks are often ignored during construction in mountain towns in China, and scientific evaluations are often not conducted (Jiao et al., 2017). These high-intensity land use development and engineering construction activities may lead to a decline in the environmental carrying capacity and exacerbate the problem of larger population and less land. Many scholars and the Chinese government are aware of the need to correctly understand the correlations among mountainous environment, mountain disasters and construction land development. Moreover, the degree of stress related to mountain disasters needs to be measured, and a suitability evaluation of construction land development needs to be conducted, which would fundamentally guarantee the sustainable utilization of land resources in mountainous areas.

The frameworks of the suitability evaluation for construction land at home and abroad mainly include: 1) Pressure-Status-Response (P-S-R) proposed by Organization for Economic Co-operation and Development (OECD). It mainly illustrates the interrelationship among human activities, social development and ecological environment (Ying et al., 2009; Guo et al., 2003). The advantage of P-S-R framework system is that it can be used for reference to evaluate the suitability of construction land in mountainous areas with fragile natural environment and frequent mountain disasters. However, there is no inevitable logical correlation between the driving force indicator and the state indicator, so it is difficult to quantify the specific indicator, and regional promotion and application are also relatively difficult. 2) Goal-Estimate-Consequence

(G-E-C) from "The Outline of Land Evaluation" and "The Outline of Sustainable Land Management Evaluation". The goals, types and methods of land use need to be identified first, and on this basis, the judgment results are analyzed (FAO, 1993). The advantage of G-E-C is that the indicators are easily quantified, and the empirical significance is greater. The disadvantage is that the location and social factors of land use are not taken into account, and the economic value and benefit efficiency of land use cannot be fully reflected. As a result, the tracking monitoring and efficiency of economic, environmental and social benefits cannot be comprehensively analyzed and compared, and the optimal layout of land use cannot be determined. 3) Nature-Economy-Society (N-E-S), which is to resolve the land use system to natural, economic and social subsystems under the premise of the comprehensive research on the land use system. This multi-subsystem method can measure the integrity of the system and realize the dimensionality reduction of complex systems (Wang and Bao, 2011). The N-E-S framework focuses on the research on other subsystems, rarely discussing the driving mechanism among the ancillary systems. The advantage of this framework is that it can comprehensively and systematically form the unified evaluation of construction land use in the three-dimensional view of nature, economy and society, but there are difficulties in the typicality and regional promotion of some factors in the evaluation system.

Construction land suitability research and evaluation in mountainous areas has mainly focused on the suitability of land for specific uses and the ecological suitability of the land use type. For example, urban construction land has been classified to determine the quality of the land that is suitable for construction at different levels and the areas that are suitable for construction land. The existing soil information system has been utilized to interpret satellite remote sensing images and obtain digital elevation model (DEM) data and map data. An ArcGIS spatial database that includes soil erosion risk data in high-risk areas, land use types, use strength and other land parcel information has been established to combine these layers with the relevant socio-economic information (Akinci et al., 2013). The superposition slope, flood inundation line, public facilities and other factors have been comprehensively considered to analyze and identify suitable construction land parcels and provide basic data for land use suitability evaluations in mountainous areas (Montanarella and Nègre, 2001; Rusdi et al., 2015).

Statistical and econometric model analysis methods have been used in previous research, and there is an obvious shortage of spatial information processing during simple modeling and quantification. For instance, multifactor comprehensive evaluation models, Markov models, neighborhood algorithms, generalized regression neural network (GRNN) models and fuzzy comprehensive evaluation methods have been used to conduct suitability evaluations of on construction land (Zhou, 2010; Liu et al., 2014; Wei et al., 2014; Qiu et al., 2017).

The advancement of computer-aided superposition mapping methods has resulted in the wide use of technical methods to evaluate construction land suitability in mountainous areas based on ArcGIS. Domestic and foreign researchers have used ArcGIS technology to further the processing of previous econometric models (Nan, 2009; Ambarwulan et al., 2016). Integrated superposition analysis methods, multi-indicator decision models, artificial intelligence methods, and mixed data models for vector and raster analysis have been widely used to conduct comprehensive suitability

© 2018, ALÖKI Kft., Budapest, Hungary

judgments for construction land in mountainous areas (Gimblett and Ball, 1994; Malczewski, 2006; Chandio, 2014; Promper et al., 2014).

From the perspective of stress related to mountain disasters, this study combines the unique hazard risks of mountainous areas with the development of construction land suitability based on the actual needs of social and economic development regulations. Baoxing County is a typical mountainous county in Southwest China and is used as an example in this study. After Baoxing County experienced the "5 • 12 Wenchuan Earthquake (Ms 8.0)" in 2008 and the "4 • 20 Lushan Earthquake (Ms 7.0)" in 2013, the number of disaster sites drastically increased, and the hidden dangers of construction land have become more serious (Wu et al., 2016). This study builds multiple coupling models and introduces the risk factors of mountain disasters to evaluates the suitability of construction land in mountain towns. It makes the evaluation results more accurate and reasonable. For the research methods, the weight of other indicators is assessed weight in the suitability evaluation of construction land in mountainous areas in addition to mountain disaster risk factors. The hypermatrix method of the analytic network process (ANP) is adopted so that the correlations among all factors can be fully considered. This study is different from previous research that evaluated the conditions while considering only the relative independence of each factor.

Study area and data sources

Study area

Baoxing County (102°28 - 103°02′E, 30°09′ - 30°56′N) is located in Sichuan province of China, on the western edge of the Sichuan Basin and north of Ya'an City. Baoxing County borders Wenchuan County and Xiaojin County to the north, Tianquan County to the south, Kangding County to the west and Lushan County in the east. The transportation is mainly based on highways, and provincial highway No. 210 runs throughout the territory. The county is 61 km wide from east to west and 81 km long from south to north, and the jurisdiction area is approximately 3114 km^2 (*Fig. 1*).

Data sources

Statistics used in this study is originated from field investigations of Land use of Baoxing county, Sichuan province China in 2016-2017 of institute of Mountain Hazards and Environment, Chinese Academy of Sciences & Ministry of Water Conservancy. The main types of mountain disasters in the county are collapses, landslides and mudslides. At present, there are a total of 337 disaster sites, including 153 landslides, 144 collapses and 40 mudslides. The density of dangerous areas is 8.49 m^2/km^2, and the hazard volume density is 105.4110^4 m^3/km^2. The threatened population is 15,750, accounting for 26.71% of the total population in the county. The total area of construction land in the county is 2,456.67 hm^2. The urban and rural land for industry and mining, land for highways and water and land for water conservation facilities (including reservoir water and hydraulic construction land) constitute areas of 1714.66 hm^2, 219.88 hm^2 and 522.12 hm^2, respectively, accounting for 69.80%, 8.95% and 21.25% of the total construction land area in the county, respectively.

The latest DEM (1:50000 data), administrative division maps, present land use map, river system map, fracture structure map, traffic roadmaps, and population and related socio-economic data were obtained in accordance with the mountain disasters tracking

survey and construction land development in Baoxing County from research groups between 2014 and 2016. The data originate from the Statistical Bureau, Meteorological Bureau, Land Bureau, archives, geological environment monitoring stations and other relevant government departments of Baoxing County.

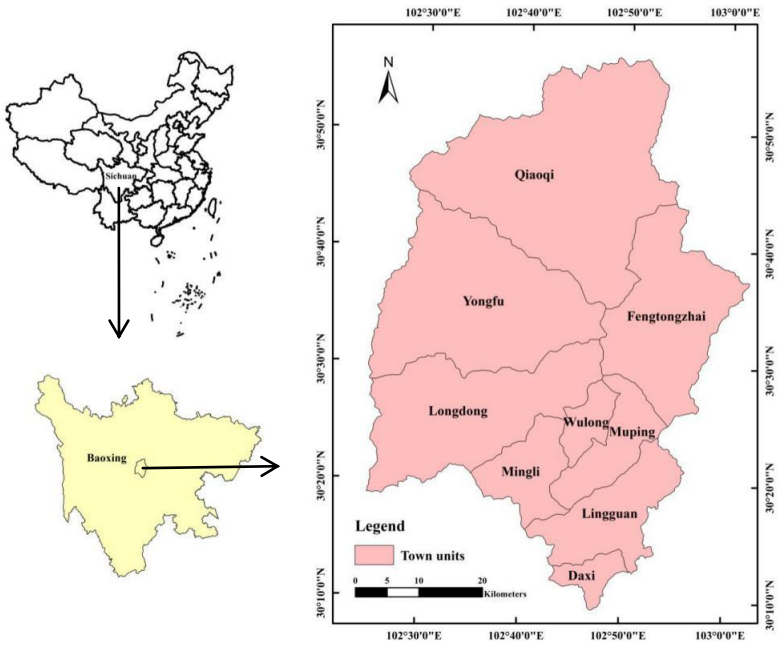

Figure 1. *Title of the given figure, graph or image included in the document*

To facilitate the matching of the vector and raster data, this study first utilized ArcGIS to process the evaluation units of the study area into a square 25 m × 25 m grid. Administrative units were then utilized to perform the regional calculations and evaluate the results of the previous grid unit and obtain the data for each grid unit in each administrative unit. The grid format is convenient for the subsequent comprehensive comparison and analysis. The grid unit is more precise than the land use patches, land types and soil units that have been used previously. Moreover, the land use evaluation attributes are more homogeneous in a grid unit, which improves the accuracy of the evaluation results. The grid unit format is consistent with that of ArcGIS raster data, and the use of computer processing is relatively simple. Additionally, the research results are conducive to the ultimate implementation by the relevant departments of the Chinese government.

Model methods

Mountain disaster risk evaluation models

The analysis of mountain disasters risks, the degree of mountain disasters influence and the degree of vulnerability of hazard-bearing areas are comprehensively studied based on the analysis of mountain disaster risks. To balance the process of the differences in the influencing degree, this study mainly determined the models for hazard risk evaluations in the study area according to the hazard degree and the degree of mountain disaster vulnerability.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_65676587

The degree of mountain disasters is closely related to the density of disasters in an environment, and the relative surface structure and tectonic environment indicators were selected. The number, area and volume of 337 disaster sites in Baoxing County were used to determine the contribution rate of each indicator to the development of mountain disasters (Change, 2007). The weight of each indicator and the mutual weight between various indicators were obtained to establish the formula for the degree of mountain disasters, which can be presented as follows (*Eq. 1*):

$$H_j = w_i w_{ij} X_i \quad \text{(Eq.1)}$$

where H_j refers to the degree of mountain disasters; w_i indicates the self-weight; w_{ij} indicates the mutual weight; and X_i denotes the independent variable of the indicator.

The degree of mountain disaster vulnerability is correlated with the possibility for hazard damage and the difficulty level of repairing the damage to the hazard-bearing areas in the county (UNDP, 2004; ADRC,2005; Cardona, 2005; Smith, 2013). The relevant indicators are selected according to the actual situation, and the indicator weight can be represented as a multiplicative summation of the individual and mutual weight of each indicator and the indicator weight value to establish the formula for the degree of mountain disaster vulnerability, which can be determined using *Equation 2:*

$$V_S = \sum_{t=1}^{n} W_z W_h y \quad \text{(Eq.2)}$$

where V_S represents the degree of mountain disasters vulnerability; W_z indicates the individual weight; W_h means the mutual weight; and y refers to the independent variable of the indicator.

Based on *Equations 1* and *2,* the formula for the comprehensive degree of mountain disaster risk (R_I) is obtained as follows (*Eq. 3*):

$$R_I = H_j \cdot V_S = w_i w_{ij} X_i \cdot \sum_{t=1}^{n} W_z W_h y \quad \text{(Eq.3)}$$

Models to evaluate the suitability of construction land development under the stress of mountain disasters

The present land use patterns and the layout of construction land in the study area were taken into account, and the prohibited development areas (areas with slopes greater than 25°, areas within 100 m of fracture zones and core-protected areas) were excluded. The important factors that affect the suitability of construction land in mountainous areas were analyzed, and an evaluation indicator system was established. The weights of the ANP evaluation indicators were obtained by using Super Decisions software, and the comprehensive scores of various indicators were calculated on the grid unit. The ANP uses the hypermatrix method to quantify the degree of influence between indicators and can more objectively and effectively express the complex practical problems than the analytic hierarchy process (AHP). Many decision-making problems cannot be simply expressed as hierarchical structures, and the various levels of elements are interactional and interdependent. The formula to model the suitability of construction land development can be expressed as follows (*Eq. 4*):

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_65676587
© 2018, ALÖKI Kft., Budapest, Hungary

$$L_s = \sum_{i=1}^{n} Z_{j,i}(f, w) \quad \text{(Eq.4)}$$

where, L_S indicates the total score; j refers to the j^{th} evaluation unit; i denotes the i^{th} indicator; n represents the number of indicators; f means the score of the indicator; and w stands for the weight of the indicator. When the calculated value of L_S is high, it indicates that the level of the suitability of construction land will be higher.

Based on *Equations 3* and *4,* the calculation formula for the suitability of construction land under the stress of mountain disasters is determined as follows (*Eq. 5*):

$$O_H = K_i \cdot R_I \cdot L_s \quad \text{(Eq.5)}$$

where, O_H refers to the suitability of construction land under the disaster stress; R_I denotes the comprehensive risk degree of mountain disasters; L_S indicates the suitability of construction land under the non-disaster stress; and K_i means the coefficient of variation, with a value range of 0~1. The value of K_i, the coefficient of variation, is mainly based on the different types of the present situation of construction land in the study area.

Analysis of mountain disaster risk and design of evaluation indicators

Analysis of hazard classification of mountain disasters

The degree of mountain disasters is closely related to various factors of the hazard-prone environment, including surface structure and hydrological structure conditions. Based on the evaluation methods and factor selection used in previous studies, this study focuses on selecting indicators that play a leading role in the degree of mountain disasters in Baoxing County and are convenient for the collection of spatial data. The surface structure factors can be extracted directly from the digital elevation data of the 1:50000 DEM for Baoxing County using ArcGIS software. These factors include the relative height difference, slope, slope aspect and slope shape. The influence on the development of mountain disasters becomes more significant as the relative height increases. It is easier for disaster sites to develop as the steepness of the slope increases. The slope aspect has a remarkable influence on mountain disasters. The south slope typically has the highest solar radiation, and the north slope has the lowest. The light, temperature, precipitation, wind speed and soil vegetation all differ between the windward and leeward slopes. A concave slope is a mature stage that is more stable and has fewer developed disaster sites. A convex slope is in a period of intense evolution, and there are more developed disaster sites. The number of disaster sites on a straight slope is between that of a convex slope and a concave slope. The tectonic environmental factors are extracted using the Proximity Analysis tools in ArcGIS. The distance from rivers and the distance from fracture zones are determined using a buffer analysis. Rivers have a significant influence on the formation and development of disaster sites, and the instability of the geological conditions and the susceptibility of the area is to developing disaster sites increase for areas closer to a fracture zone.

The spatial analyst function in ArcGIS was used to import the classification layers of various indicators, and the Raster calculator was adopted to superimpose the hazard

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_65676587
© 2018, ALÖKI Kft., Budapest, Hungary

degree indicators to obtain the value of the comprehensive mountain disaster risk for each evaluation unit according to the previously described formula. The continuous hazard degree partition was divided into equal intervals and reclassified. Identical cells were merged, and the degree partition of mountain disasters was conducted. A higher degree of mountain disasters is associated with the higher contribution of each indicator to the occurrence of mountain disasters.

As seen from *Table 1* and *Figure 2,* the area of the region in Baoxing County with the lowest degree of mountain disasters (the low-hazard region) is 55,000 km^2, accounting for 17.65% of the total county area.

Table 1. *The distribution of mountainous disasters hazard classification*

Type/level	Area		Disaster spots		
	Number/hm^2	Percentage/%	Number	Percentage/%	Density/hm^2
Low-hazard region	55,000	17.65	55	16.32	0.10
Medium-hazard region	155,400	49.87	193	57.27	0.12
High-hazard region	101,189	32.48	89	26.41	0.09

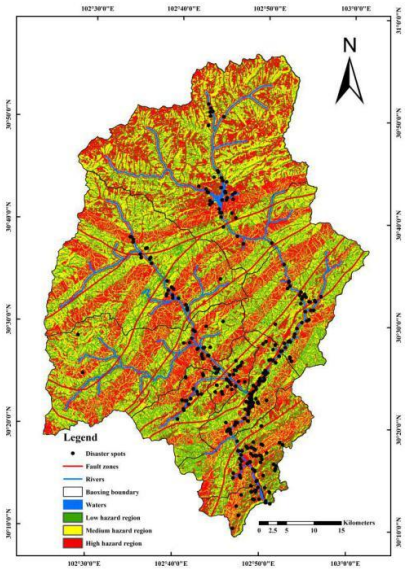

Figure 2. *The distribution map of mountain disasters hazard in Baoxing*

Within this region, 55 disaster sites, which account for 16.32% of the total disaster sites, are distributed in Fengtongzhai Township and Mingli Township, and the density is 0.10/hm^2. The area of the region with a medium degree of mountain disasters (the medium-hazard region) is 155,400 km^2, accounting for 49.87% of the total county area. Within this region, 193 disaster sites that account for 57.27% of the total number of disaster sites, are located in Muping Town, Lingguan Town, Longdong Town and Yongfu Township, and the density is 0.12/hm^2. The area of the region with a high degree of mountain disasters (the high-hazard region) is 101,189 km^2, accounting for 32.48% of the total county area. Within this region, 89 disaster sites that account for 26.41% of the total number of disaster sites are distributed along rivers and near fracture

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_65676587
© 2018, ALÖKI Kft., Budapest, Hungary

zones in Qiaoqi Tibetan Township, Wulong Township and Daxi Township, with the density of 0.09/hm^2.

Analysis of mountainous disasters vulnerability classification

The degree of mountain disaster vulnerability is affected by socio-economic conditions and the conditions of hazard-affected areas. The socio-economic conditions include the spatial distribution of the population, land resources, water resources, transport facilities, large enterprises and other factors. The conditions of hazard-affected areas contain the type, quantity, and value of hazard-affected areas. In socio-economically developed regions, there is a dense population, intensive urbanization, highly concentrated industrial activities, numerous dense hazard-affected areas with high economic value, and the probability of damage from a wide range of mountain disasters is great, leading to the corresponding increase in casualties and economic losses. In view of this, this study selects six indicators for analysis, namely, population density, gross domestic product (GDP) density, fixed asset density, threatened property density, road density and land resource abundance for analysis.

The spatial analyst function in ArcGIS was used to import the classification layers of various indicators. According to the above formula, the Raster calculator was adopted to superimpose the vulnerability indicators to obtain the degree of hazard vulnerability value for each evaluation unit. The raster was reclassified. Identical cells were merged, and the vulnerability degree partition of mountain disasters was conducted. A higher vulnerability degree value indicates a higher degree of mountain disasters vulnerability. The study area is divided into three regions according to the degree of vulnerability, namely, the high-vulnerability region, the medium-vulnerability region, and the low-vulnerability region.

As seen from *Table 2* and *Figure 3,* the degree of vulnerability is higher where the density of disaster sites is greater. In Baoxing County, the area of the low-vulnerability region accounts for 83.22% of the total county area.

Table 2. *The distribution of mountain disasters vulnerability region degree level disaster spots*

Type/vulnerability degree level	Area		Disaster spots		
	Number/hm^2	Percentage/%	Number	Percentage /%	Density/hm^2
Low-vulnerability region	259289	83.22	141	41.84	0.05
Medium-vulnerability region	40000	12.84	149	44.21	0.37
High-vulnerability region	12300	3.95	47	13.95	0.38

Within this region, 141 disaster sites account for 41.84% of the total disaster sites in the county, and these sites are mainly distributed in Qiaoqi Tibetan Township, Yongfu Township, Fengtongzhai Township and Mingli Township, with the density of 0.05/hm^2. The area of the medium-vulnerability region accounts for 12.84% of the total county area. Within this region, 149 disaster sites, 44.21% of the total disaster sites in the county, are located in Muping Town and Lingguan Town, and the density is 0.37/hm^2. The area of the high-vulnerability region accounts for 3.95% of the total county area. Within this region, 47 disaster sites, accounting for 13.95% of the total in the county, are in Wulong Township and Daxi Township, and the density is 0.38/hm^2.

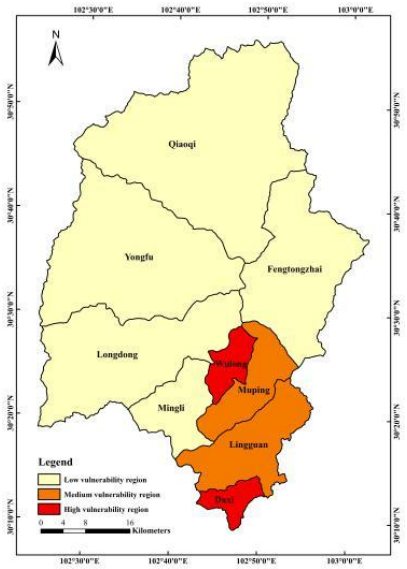

Figure 3. *The distribution map of mountain disasters in Baoxing*

Interpretation of the comprehensive risk degree partition of mountain disasters

Based on the above mentioned results of the hazard degree and partitions of hazard vulnerability degree, the value of the comprehensive degree of mountain disasters risk of each evaluation unit is calculated in accordance with the formula. ArcGIS is used to reclassify the raster. Identical cells are merged, and the comprehensive degree partition of mountain disasters risks is obtained.

As shown in *Table 3* and *Figure 4,* the low-risk region in Baoxing County is located in Fengtongzhai Township and Mingli Township, covering an area of 55,000 hm^2, which accounts for 17.65% of the total county area. The medium-risk region is distributed in Yongfu Township and Longdong Town, covering an area of 115,400 hm^2, which accounts for 37.04% of the total county area. The high-risk region is located in Qiaoqi Tibetan Township, Wulong Township, Muping Town, Lingguan Town and Daxi Township and is mainly on the periphery of the buffered areas of rivers and fracture zones. The high-risk region covers an area of 141,189 hm^2, accounting for 45.31% of the total county area. In general, there are more disaster sites in the areas near fracture zones and rivers, but there are fewer hazard-affected areas in these regions. However, in the peripheral regions, there are more hazard-affected areas and the economic value is higher. Therefore, the potential losses are greater, and the risks are higher in the peripheral regions.

Table 3. *Mountain disasters comprehensive risk degree partition results*

Type/risk degree level	Area		disaster spots		
	Number/hm^2	Percentage /%	Number	Percentage /%	Density/hm^2
Low-risk region	55000	17.65	55	16.32	0.10
Medium-risk region	115400	37.04	44	13.06	0.04
High-risk region	141189	45.31	238	70.62	0.17

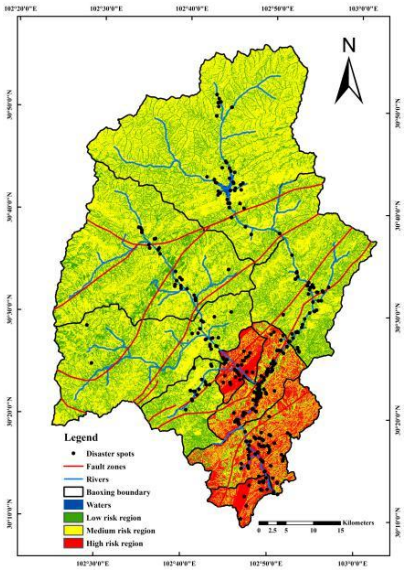

Figure 4. *The distribution map of mountain disasters risk in Baoxing*

Design of evaluation indicators for construction land development suitability

The surface structure factors

Baoxing County is a typical mountainous county, and the layout of its construction land, which is mainly segmented by mountains, rivers and gullies, is scattered. This layout is not conducive to construction land sustainability or infrastructure construction. Areas with slopes greater than 25° are directly classified as prohibited construction areas by the relevant land regulations in China, So the score is 0. Altitude, slope aspect and relief amplitude also play key roles in the stability and safety of buildings, the difficulty of construction and the costs of construction, and these factors directly restrict the layout of land use, the choices of roads and the spatial distribution patterns of buildings.

As can be seen from *Table 4,* we classify and assign values based on the proportion of the number of disaster sites in the developing mountains. The slope is within the 0-5° range, and the proportion of developed mountain disaster points accounts for 3.56% of the total, and within the 5-8° range, 5.90%, 8-15°, 7.67%; 15-25°, 25.82%, greater than 25°, 56.97%, it can be seen that the smaller the slope, the less likely the development disaster point, so the higher the score, the higher the suitability of the construction land. Less than 800 m above altitude, the proportion of mountain disaster sites is 14.24%, 800-1200 m, 15.13%, 1200-1600 m, 19.58%, 800-1600 m, 16.32%, greater than 2000 m, 34.72%. The higher the altitude, the greater the probability of developing disaster points, the lower the score, and the lower the suitability of the construction land. Similarly, the greater the topography fluctuation, the greater the relative height difference, the less suitable for construction. From the slope aspect of view, the proportion of mountain disaster sites developed on the southern slope is 5.93%. The Northern slope is 9.50%, the Northwest slope is 10.09%, the Eastern slope is 10.68%, the Southwest slope is 13.06%, the Northwest slope is 13.06%, the southeast slope is 18.69%, the Western slope is 18.99%. The more disaster points developed up each slope, the lower the score, the less suitable it is to build.

Hydrogeological factors

Due to the constant movements of geological structures in mountainous areas and the long-term effects of river water erosion, the complex hydrogeological environment greatly hinders the development of construction land. The drainage conditions have an important influence on the development of construction land and the construction of a project, and good drainage conditions can reduce construction costs. The cumulative amount of running water was used to measure the displacement of land in the study area, and the drainage conditions were considered to be worse if the cumulative amount of running water was large.

As shown in *Table 5,* the rock formations in mountainous areas are complex, and generally speaking, areas that are farther away from fault zones are more suitable for

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

construction due to the higher stability and safety. In terms of the number of disaster sites, the proportion of mountain disaster sites is 33.23% within 500 m of the fault zone. The 500-1000 m range is 24.63%, 1000-2000 m is 13.35%, 2000-4000 m is 17.51%, greater than 4000 m is 11.28%. It can be seen that the farther the distance from the fault zone, the higher the construction score, the more suitable construction.

The fluvial action of rivers has a significant effect on the formation of landform types, and the distance from rivers is directly related to the guarantee for water supply in urban construction. The water supply conditions for construction land near rivers are better, which increases the suitability. In addition, the distance from water (lakes, reservoirs, etc.) can reflect the degree of water pollution, especially the pollution from

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

domestic waste and industrial wastewater. Among them, the water conditions within 500 m are the best, so the score is 5. According to field survey studies, for each additional 500 m, the water level is reduced by one level, and when the water conditions after the distance is greater than 2,000 m do not have a significant impact, so, We divide each classification according to such a rule.

The water area in this study refer to the planar distributed areas except for rivers, lakes and reservoirs. Residential areas, factories and other related public production and living facilities should be located far away from the safe distance range of waters to reduce the influence of water pollution sources. The ecology of the water area is fragile, and the closer it is to the water area, the less suitable it is for construction. Therefore, we follow the distance from far to near, and the score is from high to low.

Human activity factors

Human activities have a remarkable impact on the development of construction land in mountainous areas (Bucała, 2014; Chen et al., 2016). In this study, the current land use conditions were selected as an indicator, which can reflect the land use types. As shown in *Table 6,* industrial and mining lands and Waterworks construction land have large number of construction projects, so the suitability for construction land is higher, that is why we scored highest in our classification. The suitability of dry land and other land is lower than the land mentioned above, but it is higher than forest land, grassland, etc., so the score is second. Moreover, forest land and grassland are highly vulnerable ecologically, and the development and construction costs are high there, so the suitability is lower. Paddy fields and water area (lakes, reservoirs, etc.) can hardly be used for construction. The distance from the built-up areas is also selected as an indicator. Here, built-up areas refer to the tracts where construction has been completed throughout the county, and these areas are the economic growth point, with strong agglomeration and radiation effects. In general, areas closer to built-up areas are more suitable for construction land development due to lower construction costs. The distance from the roads is selected as another indicator that can reflect the accessibility of the regional roads, and the conditions of these roads affect the cost of construction and the development of urban construction land. The suitability of construction land will be higher when the distances between roads are shorter. Finally, the core areas and the periphery of protected areas were selected as indicators. Protected areas have high ecological sensitivity and are banned as construction areas, whereas the areas outside the core-protected areas are more suitable for construction.

Analysis of the assessment of construction land evaluation results

Analysis of evaluation indicator weight

An evaluation indicator system was established using ANP, and the weight of each indicator was calculated using Super Decisions software based on the evaluation indicator selection described above (*Table 7*).

Table 7. *Evaluation indicator weight for construction land development suitability*

Evaluation indicator	Weight	Evaluation indicator	Weight
Slope	0.1547	Distance from the rivers	0.0881
Altitude	0.1404	Distance from the waters (reservoirs)	0.0610
Relief amplitude	0.0468	The present situation of land use	0.2074
Slope aspect	0.0213	Distance from the built-up areas	0.0397
Drainage condition	0.0662	Distance from the roads	0.1110
Distance from the fracture zones	0.0475	Protected areas	0.0159

The Raster calculator function from the spatial analyst tools for ArcGIS10.1 software was used to calculate various evaluation indicators according to the formula, and obtain

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

the suitability partition of construction land development in Baoxing County. The construction land suitability level was divided into four categories based on natural breaks classification, and then the regional mean value was used to calculate the spatial distribution of construction land suitability in various townships and towns of the county.

Analysis of evaluation construction land suitability level results

Based on the above results of the mountain disaster risk partitioning and the evaluation indicator weight for construction land development suitability, the coupling model formula was used with the Raster calculator function from the in spatial analyst tools for in ArcGIS. To visually show the analysis results, the spatial analyst reclassification was used to classify the suitability levels into 4 categories according to natural breaks classification. We then determined the construction land suitability levels under the stress of mountain disasters (*Table 8*).

Table 8. *Construction land suitability level results under the stress of mountain disasters*

Suitability degree level	Number of grid cells	Area (hm^2)	Percentage (%)
High-suitability region	451	28.318	0.009
Medium-suitability region	6516	409.136	0.131
Low-suitability region	52028	3266.806	1.048
Unsuitability region	4903453	307884.741	98.811

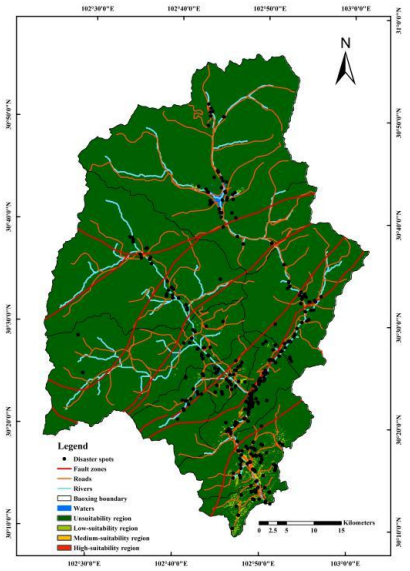

Figure 5. *Construction land suitability degree level in Baoxing*

As shown in *Table 6* and *Figure 5,* the high-suitability region is the smallest area of the four land types and covers an area of 28.318 hm^2, which accounts for 0.009% of the total county area. The high-suitability region is mainly located southwest of Baoxing County, mostly in Wulong Township, Muping Town, Lingguan Town and Daxi Township. The highway mileage in this region is 286.7 km, and the traffic conditions

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_65676587
© 2018, ALÖKI Kft., Budapest, Hungary

and the hazard emergency rescue and response conditions are good. For example, in this region, there are 7 hospitals and health centers, 107 practicing (assistant) physicians and 197 medical beds, which account for 58.33%, 75.89% and 79.76% of the county's total for each of these services, respectively. Most areas of the regions are built-up areas with good infrastructure. There are 16 villages with broadband networks, 26 villages with cable TV, 27 villages with tap water and 20 villages with centralized waste disposal, accounting for 72.73%, 50.00%, 49.09% and 52.63% of the county's total for each of these services, respectively. In addition, the region has high economic value for construction land, and high suitability for construction land development. Nevertheless, these conditions are also associated with higher economic density, land value and construction costs. Moreover, if a disaster occurs, there will be substantial losses will be caused, and the hazard risks will be high.

The medium-suitability region covers an area of 409.136 hm^2, which accounts for 0.131% of the total county area, and the region is located mainly on the periphery of the high-suitability land. Most parts of this region are cultivated land and rural residential areas, with better land drainage conditions, longer highways, better traffic accessibility conditions, higher population densities and higher per capita GDP. In general, compared with the high-suitability region, the conditions of this region are worse, and it is closer to built-up areas.

The low-suitability region covers an area of 3266.806 hm^2, which accounts for 1.048% of the total county area. Generally, the conditions here are worse than those of the medium-suitability region. Specifically, its hazard rescue and response capabilities are weaker, and there are only 3 hospitals, 11 practicing (assistant) physicians and 25 medical beds, which account for 25.00%, 7.80% and 10.12% of the county's total for each of these services, respectively.

Located on the periphery of the low-suitability land, the region that is unsuitable for construction land development covers an area of 307884.741 hm^2, which accounts for 98.811% of the total county area. It covers the largest area in the county, mainly because the Fengtongzhai Nature Reserve, a giant panda protection base is sited there. In addition, the region has a better natural ecological environment, higher vegetation coverage and is far away from the town center, suggesting that there is less interference by human production and living activities. Moreover, this region is regarded as a nature conservation area and development is prohibited there.

Conclusions and discussion

Conclusions

Based on the results indicate that the disaster spots have a significant impact on the suitability of construction land and are directly related to the future development and construction of land resources. At the same time, the built-up areas are smaller than those in the suitable land in Baoxing County, meaning potential for future construction land development in the county. With the continuous improvement of technology, the construction of hazard prevention and mitigation project and the further reduction of hazard stress degrees, more land will likely be available for construction. We also find that the mountain disaster risk is the core factor for the suitability evaluation of the urban construction land in mountainous areas. And the central areas of the mountain towns are the high-risk and high-suitability areas for the development of construction land.

Discussion

In view of the above evaluation results, this study proposes construction land development paths in Baoxing County, which mainly include the following aspects:

There is a need to establish a planning system that combines construction land with mountain disasters, and the planning and design must comply with the relevant laws and regulations to ensure the standardized development of construction land. All projects under construction in the county must strictly conduct an mountain disasters risk evaluation, especially during the planning and site selection for town relocation and major projects.

Hazard monitoring and construction should be carried out simultaneously in the high-risk high-suitability construction regions. In the county, the high-suitability construction region is also the high-risk region. There are good regional land use conditions, complete public infrastructure, high value-added land use benefits, good traffic accessibility and high vulnerability and high risks of mountain disasters. It is necessary to conduct real-time monitoring and provide early warning for schools, hospitals, industrial and mining enterprises, scenic spots, special land and other hazard-bearing bodies with weak hazard resistance abilities in the region. Moreover, targeted measures must be taken, especially for industrial and mining land, which has a serious hidden danger of mountain disasters and poses a threat to the safety of residents during production, life and travel. It is necessary to combine the regional industrial bases, consider the land function orientation and develop corresponding supporting facilities, so as to improve value and transfer the benefits of construction land assets and achieve better development of the high-risk high-suitability region.

Construction land in rural residential areas should be integrated into the medium-suitability construction region. In this region, new rural construction will be achieved mainly by integrating construction land in rural residential areas. It is necessary to dismantle and merge villages, renovate hollow villages and construct center villages according to local conditions and improve the utilization efficiency of rural homesteads. There is a small amount of urban industrial and mining land in this region, so it is necessary to rely on the county to integrate regional space, promote the division of labor and cooperation between the villages and towns and realize the complementary advantages. In this way, the comprehensive carrying capacity of the county can be improved to fully enhance the overall land use efficiency.

The low-suitability construction region is mainly remote and poverty-stricken areas, which are dominated by agricultural land and bare land. It has a large proportion of idle land, and low per capita net income of farmers. Most of its population belongs to the left-behind elderly, left-behind children and the disabled, and these result in the high vulnerability of this region. Therefore, there is a need to ease the burden on farmers, reduce the prices of agricultural chemical fertilizers and other production materials, develop and utilize the idle land resources and implement precise poverty alleviation measures. Sustainable land use can also be promoted by arranging the idle land and changing the land use patterns. For instance, idle old factories can be converted into a breeding base for farmers, and old rural homesteads can be changed into new housing land.

A protected land network system should be constructed in the unsuitable construction area. The core area of the protected land in this region is habitat for the giant panda. The construction of the protected land network has restricted the sustainable livelihoods of the surrounding farmers to a certain extent. Due to their sole reliance on the fiscal

© 2018, ALÖKI Kft., Budapest, Hungary

transfer payments and ecological compensation from the government, the transformation of the livelihoods of farmers will be faced with challenges.

As a result, when the Chinese government establishes and manages a protected land network, the connection between resource management and the needs of community residents should be considered, and corresponding supportive strategies should be implemented. For instance, the characteristic industry of Baoxing County and a labor export strategy, as well as an ecotourism strategy, can bring a more diversified selection of livelihood strategies for local farmers.

Abstract. Respondents (n = 180) from Mutale municipality, Limpopo Province, South Africa, were interviewed so as to assess the factors affecting the use of medicinal herbs in treatment of livestock diseases. A significantly greater proportion of males (79.8%) than females (52.7%) preferred a combination of treatment methods ($P < 0.05$). A significantly greater proportion of females (36.8%) than males (10.6%) preferred using medicinal herbs only ($P < 0.05$). There was no significant difference in the proportions of males and females using conventional drugs only ($P > 0.05$). Overall, a significantly greater proportion of respondents between 20-40years old (83.1%) preferred to use a combination of treatment methods ($P < 0.05$). A significantly greater proportion of the unschooled respondents (46.6%) preferred to use medicinal herbs only ($P < 0.05$). A significantly greater proportion of the tertiary-schooled respondents (50%), however, preferred to use conventional drugs only ($P < 0.05$). Parts from Cassia abbreviata and Cissus quadrangularis were the preferred oral treatments for retained placenta, Pterocarpus angolensis and Combretum collinum were the preferred oral treatments for constipation in cattle. Cissus quadrangularis, Dichrostachys cinerea and Ximenia americana were preferred for topical treatment of wounds, Synadenium cupulare for arthritis, Ziziphus mucronata for mastitis, Maytanus eduncularis for fractures and Gossypium herbaceum for blindness in cattle, sheep and goats.
Keywords: *herbal, ethno-veterinary, practices, Cassia abbreviata, South Africa*

Introduction

Mutale is a rural Municipality in the Vhembe District of the Limpopo Province of South Africa. The municipality, like other places in Limpopo Province, is affected by climate change and receives minimal rainfall. Its poor human population depends mostly on livestock production. Viability of livestock production in Mutale is under threat of diseases which appear to be on the increase, in recent times, due to climate change. However, farmers cannot afford to buy modern drugs for treatment of livestock diseases. To keep their animals alive and healthy, farmers have resorted to the time-honoured approach of using plant remedies (ethno-veterinary or ethno-botanical) to treat the diseases affecting their animals.

The demographics of the farmers using ethno-veterinary medicine, their reasons for doing so, the species of plants used, the parts of plants used, and the specific diseases so treated, though documented elsewhere in South Africa and other developing countries, have, hitherto, not been documented in Mutale Municipality. The objective of this study was to document the demographics of farmers using plant and conventional drugs and the species of plants thus used in the treatment of common animal diseases in Mutale

Municipality. The overarching aim of this study was to highlight the use of locally available natural resources (plant remedies) by resource constrained rural farmers as a sustainable way of combating climate change.

Literature review

Food security and opportunity for gainful employment has been a challenge with increasing population pressure the world over and is continually threatened by the effects of global warming. It is estimated that demand for animal products will be doubled by 2050. There is an urgent need for innovative sustainable production that also improves livelihood and food security (Notenbaert et al., 2017). Such production initiatives must harness knowledge from the informal sector that possibly helps protect the environment (Munda et al., 2016). Livestock production is one such solution to global food shortage contributing up to 80% of agricultural GDP in developing countries, including those in Africa. In addition, 600 million rural poor people rely on livestock for their livelihoods. Moreover, livestock and derived products act as a buffer against climatic unpredictability, greatly contributing to food security especially in periods of scarce agricultural resources. Livestock diseases and poor management practices are a major threat to sustainable livelihoods of resource-poor rural communities (Marandure et al., 2016). The livestock sector in Mutale local municipality sustains the livelihoods of the majority of inhabitants who are mainly small-scale livestock producers. In this area, the main vegetation type is the *Mopane* woodland, a type of savanna woodland ecosystem dominated by the tree *Colophospermum mopane* (also called *mopane* in local languages) (Makhado et al., 2012, 2014). Due to dry climate and poor soil conditions, land cultivation is difficult and livestock production is the only viable option to farmers and is thus their main and often sole means of survival and source of income. However, successful livestock production has been challenged by changing rural contexts such as limited or lack of grazing land (Doumbia et al., 2012), lack of medications (Usha et al., 2016), increased costs (Ritter et al., 2012) and drug resistance (Raot et al., 2016). In light of the foregoing, resource-limited farmers resort to using locally available resources to control livestock diseases, ectoparasites and other related vectors (Mutibvu et al., 2012).

Over the years, rural farmers have used indigenous methods as an alternative solution for coping with disease constraints in both humans and animals (Ahmad et al., 2016; Paindla et al., 2013). These methods of treatment of animals using indigenous knowledge are broadly referred to as ethno-veterinary medicine (EVM) (Shen et al., 2010; Bartha et al., 2015; Usha et al., 2016; Caudell et al., 2017). The pharmacopeia usually used includes animal products, plant products as well as minerals for treating animals (Bartha et al., 2015; Raikwar and Maurya, 2015). According to Ahmad et al. (2016), the role of EVM in livestock production is beyond dispute. The knowledge is owned communally, under the custody of older members of the population depending on the community, ethnicity, sex, age and caste and is passed down through generations by oral tradition (Ahmad et al., 2016). It is clear from literature that EVM is usually practiced alongside or as an alternative to allopathic (modern western style) veterinary medicine (Shen et al., 2010; Claudell et al., 2017). It has been observed that, in nature, animals consume certain plants in order to derive treatment of various ailments afflicting them (Huffman, 2016). Raikwar and Maurya (2015) pointed out that availability and accessibility of such products at little or no cost are the major selling points for EVM to poor rural communities. In addition, EVM has gained popularity in recent times, in the face of an increasing demand for

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

organically raised meat traceable to farms of origin; and the rise of a modern-day consumer willing to pay a higher premium for meat arising from organic farms that strictly adhere to animal welfare guidelines (Lans et al., 2012; Adedeji et al., 2013; Mayer et al., 2014).

There has been an interesting explosion of publications in the last decade from various sub regions of the world including North America (Lans et al., 2012), Australia (Vogl et al., 2016), China (Shen et al., 2010), Europe (Mayer, 2014; Bartha et al., 2015) the Indian subcontinent (Vijayagiri et al., 2012; Mamidala, 2013; Raikwar and Maurya, 2015; Ahmad et al., 2016; Usha et al., 2016) and Africa (McGaw and Eloff, 2008; Marandure, 2016; Caudell et al., 2017; Teklehaymanot, 2017) on EVM. Literature from India outnumbers that arising from any other part of the world, an indication of the strength of the link between India's tribal communities and nature (Paindla et al., 2009). The World Health Organization estimates that nearly 80% of the world's poor depend on EVM (Raikwar and Maurya, 2015). However, it is disappointing to note that, of the recent publications, only a few demonstrate the efficacy of EVM (Luseba et al., 2007; Ndhlala et al., 2009; Adamu et al., 2014; Sserunkuma et al., 2017). The majority of recent publications are EVM surveys documenting which diseases are treated by which plants (McGaw and Eloff, 2008; Shen et al., 2010; Lans et al., 2012; Vijayagiri et al., 2012; Mamidala, 2013; Mayer, 2014; Bartha et al., 2015; Raikwar and Maurya, 2015; Ahmad, et al., 2016; Marandure, 2016; Usha et al., 2016; Vogl et al., 2016; Caudell et al., 2017; Teklehaymanot, 2017) Studies in Africa and elsewhere indicated inadequate veterinary services and lack of low cost alternative technologies as impediments in overcoming livestock diseases (Getachew et al., 2015; Raikwar and Maurya, 2015; Shamim et al., 2015). There is a need to look for environment-friendly technologies in support of livestock welfare and health. Evidence gathered from previous research indicated that there is a scope for the use of EVM within the Southern African Sub region (Gabanakgosi et al., 2012; Maroyi, 2012; Chinsembu et al., 2014; Marandure, 2016) and particularly in South Africa (Luseba and Van der Merwe; 2006; McGaw et al., 2007; Moyo et al., 2009; Ndhlala et al., 2009; Maphosa, 2010; Moyo et al., 2013; Chauke et al., 2015; Tyasi and Nkohla, 2015). Documentation of ethno-veterinary practices is critically urgent so that the knowledge can be preserved, plants conserved and sustainably managed for the control of livestock diseases (Vijayagiri et al., 2012).

Some recent studies have shown that people living in the Venda area still hold a valuable knowledge on food and medicinal plants and that some of these plants can act as crucial factors in livelihood strategies of indigenous communities. *Mopane* woodlands are also believed to host a high diversity of plants with potential ethno-veterinary applications (Luseba and van der Merwe, 2006; Luseba and Tshisikhawe, 2013; Chinsembu et al., 2014). However, to date no systematic information has been gathered on plants locally used in maintaining livestock health and welfare in Mutale municipality. The aim of this study was to record and analyze traditional ethnobotanical knowledge concerning EVM and fodder plants in some communities living in *Mopane* woodlands surrounding the municipality of Mutale.

Materials and methods

The study was conducted in selected villages of Mutale local municipality, Vhembe district, Limpopo Province of the Republic of South Africa, over a period of three months (January-March 2014). Mutale local municipality is situated far north of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

Limpopo Province largely inhabited by the Venda speaking people. The coordinates of the study area are 22° 35' 0" S, 30° 40' 0" E (*Fig. 1*). The geographical outlook of the area is dominated by the Soutpansberg Mountains and sandy soils. The natural vegetation around the study area was identified as the savannah biome of the Mopane units (*Colophospermum mopane*) and central bushveld (Mucina and Rutherford, 2006). The area receives about 681 mm of rain per year with high rainfall of about 137 mm in summer and about 2 mm of rain experienced in winter (S. A. Explorer, 2014). The average midday temperature in the study area ranges from 29.2 °C in summer to 22.1°C in winter. Small scale livestock production compliments crop production to provide food security and income for the households of the Mutale local municipality. Participation by the respondents in this study was voluntary and under no circumstances were the authors handling or applying any medication to animals during data collection of this study.

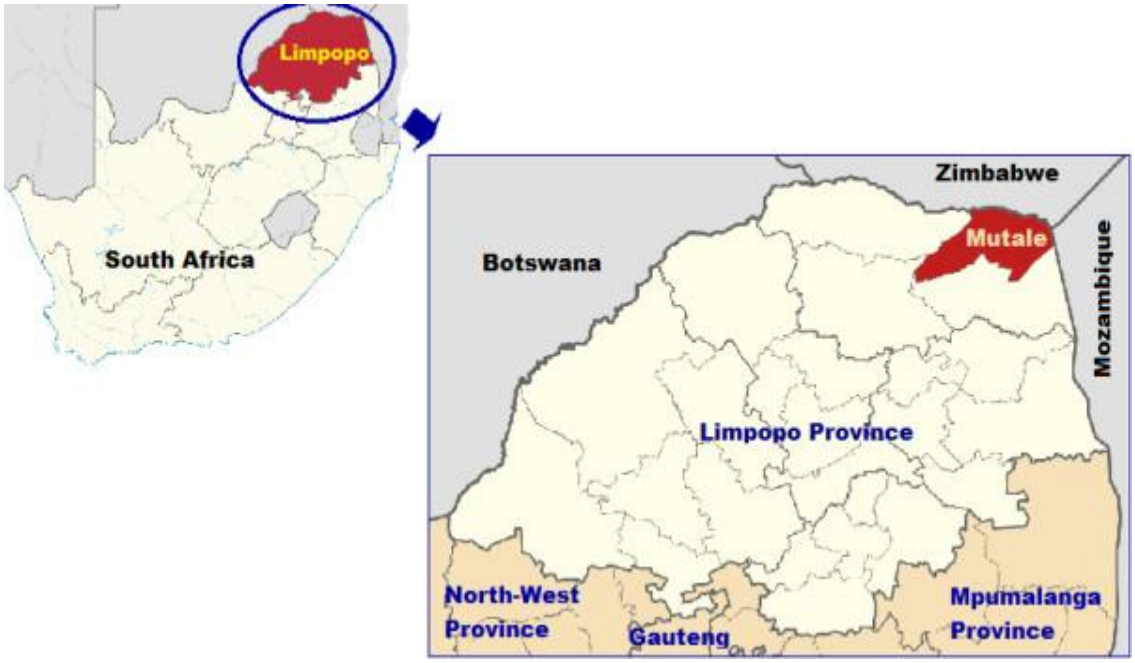

Figure 1. *Map of Mutale local municipality, Vhembe District, South Africa*

One hundred and eighty farmers (104 males and 76 females) were purposely selected and interviewed on their knowledge of livestock diseases and plants used for treatment of identified animal diseases. A structured questionnaire was used to gather information on the demographic characteristics (gender, age and level of education) of the respondents, livestock species kept and ability to identify common livestock diseases based on presenting symptoms. Additionally, the questionnaire captured data on the respondent's knowledge of the history of medicinal plants found in the study area. A majority of the respondents were not keen on stating their exact age thus leading to age being divided into three categories for this study; youth (less than 20 years old), medium aged (between 20 and 40 years old) and seniors (above 40 years of age). Identified plants were collected from their location during field trips within the study area and were further subjected to scientific identification at the University of Limpopo Larry Leach herbarium. Plant parts used, methods of preparation and the conditions for

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

which the plants were used were recorded. For the interest of this study, a bark was referred to as the outermost layers of the stem in woody plants while layers covering the roots and branches were referred to as root bark and branches respectively. The data of this study was captured in Microsoft Excel 2013 and statistically analysed using the Statistical Package for Social Sciences (SPSS Inc. 2012). The Z test for comparison of proportions was also used to ascertain statistical significance and $p < 0.05$ was considered significant.

Results

The demographic distribution of the respondents is presented in *Table 1*. The majority of the respondents (57.8%) were males. Almost half of the respondents (49.4%) were in the >40year old age category and the least (17.8%) were in the <20year old category.

Table 1. *Proportional distribution of respondents according to category*

Category	Number of respondents	Proportion (%)
Gender		
Male	104	57.8
Female	76	42.2
Age		
<20years old	32	17.8
20-40years old	59	32.8
>40years old	89	49.4
Education		
None	60	33.3
Primary	29	16.1
Secondary	63	35.0
Tertiary	28	15.6
Main livestock reared		
Cattle	89	49.4
Poultry	52	28.9
Goats	34	18.9
Sheep	5	2.8
Method of animal treatment		
Conventional drugs only	18	10.0
Medicinal herbs only	39	21.7
Combination	123	68.3
Conditions frequently encountered		
Retained placenta	115	63.9
Mastitis	103	57.2
Wounds	97	53.9
Unthriftiness	84	46.7
Fractures	48	26.7
Arthritis	27	15.0
Constipation	19	10.6
Blindness	6	3.3
Overall	180	100

A third of the respondents had no education and yet another third had secondary level education. Of the remaining third, almost equal proportions of respondents had primary (16.1%) and tertiary (15.6%) education. Most of the respondents reared cattle (49.4%)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

followed by poultry (28.9%) and goats (18.9%) whilst very few respondents (2.8%) reared sheep. The majority of the respondents (68.3%) preferred to use a combination of conventional drugs and the least proportion preferred conventional drugs only (10%). The proportion of respondents that preferred medicinal herbs only (21.7%) was significantly smaller than those using a combination and significantly greater than those using conventional drugs only ($P < 0.05$). The conditions that respondents most frequently encountered in livestock were retained placenta (63.9%) followed by mastitis (57.2%), wounds (53.9%), unthriftiness (46.7%), fractures (26.7%), arthritis (15%), constipation (10.6%) and blindness (3.3%).

Gender

Statistical analysis of the results in *Table 2* using the Z test for comparison of proportions showed that the proportion of males using a combination of treatment methods (79.8%) was significantly greater than that of the females (52.7%) ($P < 0.05$). The proportion of females using medicinal herbs (36.8%) only was significantly greater than that of the males (10.6%) ($P < 0.05$). There was no significant difference in the proportions of males and females using conventional drugs only ($P > 0.05$).

Table 2. *Proportional preference of treatment method according to gender, age and educational level*

Category	Conventional drugs only (%)	Medicinal herbs only (%)	Combination (%)	Total (%)

*The structure of the South Africa education system. Kindergarten is known as 'grade 0' in South Africa, and primary schools are generally divided into junior preparatory schools (grades 0-3) and senior preparatory schools (grades 4-7) before children attend high school (otherwise known as college) from grades 8-12.
https://www.google.com.na/search?q=primary+and+secondary+school+in+south+africa&rlz=1C1CHZL_enNA719NA719&oq=Primary+and+secondary+school+in+South&aqs=chrome.1.69i57j33l5.21755j1j7&sourceid=chrome&ie=UTF-8

Age

Table 2 also showed that a significantly greater proportion of respondents in the 20-40-year-old category (83.1%) preferred to use a combination of treatment methods than in the <20 years old (50%) and the >40 years old category (65.1%) ($P < 0.05$). There was no significant difference between the preferred use of a combination of treatment methods between the <20years old and the >40years old categories ($P > 0.05$). A

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_65896605
© 2018, ALÖKI Kft., Budapest, Hungary

significantly greater proportion of respondents in the >40years old category (32.6%) preferred to use medicinal herbs only ($P < 0.05$). There was no significant difference in the preference of medicinal herbs between the <20 years old and the 20-40 years old categories ($P > 0.05$). A significantly greater proportion of respondents in the <20 years old category (37.5%) preferred to use conventional drugs only ($P < 0.05$). A significantly greater proportion of respondents in the >40years old category (32.6%) preferred to use medicinal herbs only ($P < 0.05$).

Educational level

Table 2 also showed that greater proportions of both primary (79.3%) and secondary-schooled respondents (90.5%) significantly preferred to use a combination of medicinal herbs and conventional drugs for treatment of their livestock ($P < 0.05$). There was, however, no significant difference in the proportions of these two groups ($P > 0.05$). A significantly greater proportion of the unschooled respondents (46.6%) preferred to use medicinal herbs only ($P < 0.05$). There was no significant difference in the proportions of primary (17.3%), secondary (6.3%) and tertiary-schooled respondents (7.1%) that preferred only medicinal herbs as a method of treatment ($P > 0.05$). A significantly greater proportion of the tertiary-schooled respondents (50%) preferred to use conventional drugs only ($P < 0.05$). There was no significant difference in the proportions of primary (3.4%), secondary (3.2%) and unschooled respondents (1.7%) that preferred only conventional drugs as a method of treatment ($P > 0.05$).

As shown in *Table 3* below, *C. abbreviata* (stem bark) and *C. quadrangularis* (branch infusion) were the preferred oral treatments for retained placenta in cattle by the respondents. *P. angolensis* (stem bark) and *C. collinum* (stem bark) were the preferred oral treatments for constipation in cattle by the respondents. *A. crytopoda* (leaf infusion) was the only preferred oral treatment of unthriftness in poultry. The rest of the plants were used topically for treatment of wounds in cattle, sheep and goats (*C. quadrangularis, D. cinerea* and *X. Americana*), arthritis (*S. cupulare*), mastitis (*Z. mucronata*), fractures (*M. eduncularis*) and blindness (*G. herbaceum*) in cattle, sheep and goats.

Discussion

This study has shed some light on the dynamics of use of EVM in Mutale municipality of Vhembe district of South Africa. The study showed that EVM is used more by the older (more than 40 years old) members of the community (49%) than by younger generation (*Table 1*). These results are in agreement with several previous workers who reported that knowledge of medicinal plants use is mostly limited to older people in the communities (Shen et al., 2010; Bartha et al., 2015; Nyahangare et al., 2015; Ahmad et al., 2016; Usha et al., 2016). According to Bartha et al. (2015), the older members of the population have a tendency to choose EVM over allopathic veterinary medicine. This scenario where the aged population is the custodian of EVM and vanguard of its use presents a real risk of permanent loss of this treasure of knowledge that has been gathered over generations. Ahmad et al. (2016) contends that vesting the EVM in older members of the community is vulnerable to and may be undermined by mortality. Consequently, urgent documentation of EVM in rural communities such as Mutale is required so as to conserve such knowledge before this biocultural heritage disappears altogether.

Table 3. *Plants and plant parts used by respondents for treatment of livestock conditions*

Botanical name	English/local name	Indications	Preparation used	Route of administration
Caesalpiniaceae Cassia abbreviate	Long pod cassia Muboma	Retained placenta in cattle	Stem bark infusion	Oral
Vitaceae Cissus quadrangularis	Devil's backbone Malongakanya	Retained placenta in cattle Wounds in cattle	Branch infusion Branch infusion	Oral Topical
Asphodelaceae Aloe cryptopoda	Dr Kirk's aloe Tshikhopha	Unthriftiness in poultry	Leaf infusion	Oral
Fabaceae Pterocarpus angolensis	Bloodwoood/wild teak Mutondo	Constipation in cattle	Stem bark infusion	Oral
Euphorbiaceae Synadenium cupulare	Dead-man's tree Muswoswo	Arthritis in cattle, sheep and goats	Resin	Topical
Combretaceae Combretum collinum	Bicoloured bushwillow Muvuvha	Constipation in cattle	Stem Bark	Oral
Olacaceae Ximenia americana	Tallow wood/Sour plum Muthanzwa	Wounds in cattle sheep and goats	Root bark powder	Topical
Celastraceae Maytenus eduncularis	Silkybarks Mukwatukwatu	Fractures in cattle	Root bark paste	Topical
Mimosaceae Dichrostachys cinerea	Sicklebush/ Kalahari Christmas tree Murenzhe	Wounds in sheep and goats	Fried fruit powder	Topical
Rhamnaceae Ziziphus mucronata	Buffalo thorn tree Mutshetshete	Mastitis in cattle	Leaf paste	Topical
Malvaceae Gossypium herbaceum	Levant cotton Muluvha	Blindness in cattle, sheep and goats	Seed powder	Topical

According to our results, more males (57.8%) than females (42.2%) responded to our questionnaire. The majority of them reared cattle compared to other livestock species (*Table 1*). In spite of there being more male that female respondents, the results show that EVM is made use of mainly by females (*Table 2*) in the more than 40-year age group (*Table 3*). These findings are similar to those reported by Mwale and Masika (2009) in the Eastern Cape and Luseba and Van der Merwe (2006) in Limpopo Province of South Africa. Elsewhere in Ethiopia, Teklehaymanot (2017) reported that more males than females were involved in EVM. Similarly, Taliq et al. (2014) reported that, in the Kohat region of Pakistan, women and younger generations were not

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_65896605
© 2018, ALÖKI Kft., Budapest, Hungary

involved in the use of EVM. Taliq et al. (2014) reported that men had better knowledge regarding ethno veterinary practices as compared to women. The reason advanced for this observation was that men are mostly favoured in shift of knowledge while women in the majority of the cultures are relegated to family care. The noticeable gender bias observed in our study suggests limited involvement of men in cattle production and herd health in the Mutale local municipality.

The study also shows that EMV is embraced more by the members of the society with no education (46.6%) or with primary education (17.3%) (*Table 4*). This scenario is not sustainable, and the literate section of the society must begin to embrace and document the use of such practices. The fact that the majority (78.3%) of the farmers use EVM in one way or another (conventional and allopathic veterinary medicine 68.3% and EVM alone 10%) is encouraging. This means that only 21% of the farmers in Mutale municipality have not yet adopted the use of EVM. Use of a combination of EVM and allopathic medicine is not unique to South Africa and has been reported elsewhere (Claudell et al., 2017). However, it is not clear from our results if the trend towards adoption of EVM is increasing or decreasing. Given that in South Africa, as in other African countries, many veterinarians and decision makers have not critically examined and incorporated the potential of EVM into primary animal healthcare, the future of EVM appears to be bleak. The fact that EVM has not yet been incorporated into technical and undergraduate veterinary training curricula does not bode well for the future of this practise either. Empirical evidence suggests that many in positions of veterinary authority tend to ignore or ridicule EVM paints a gloomy picture on the adoption of EVM in South Africa. There is need for the documentation, validation and incorporation of EVM in primary animal healthcare in South Africa to the benefit of future generations. Enhancement of this approach is most likely to spur research and development of EVM and undoubtedly enable it to make immense strides in the development of the livestock industry.

Rural farmers rely economically on small scale livestock production which may be complemented by seasonal crop production. Particularly in tropical areas, animal husbandry plays a key role in rural economies as a source of cash income and employment (Herrero et al., 2013). In rural communities where livestock theft is a challenge, farmers keep their livestock in the kraals at night and provide them access to grazing during daylight hours, thus, keeping themselves updated on their livestock's health status. When abnormal health conditions are identified, farmers with little or no access to the modern veterinary services resort to indigenous methods of treating identified diseases. Results of the present study complement the previous findings that wild fodder plants and traditional EVM practices based on medicinal plants can help local communities to cope with environmental and socioeconomic disturbances within livestock systems. As pointed out by several studies (Gómez-Baggethum et al., 2012), transmission of this biocultural heritage is at the base of human adaptive strategies and can play a critical role in minimizing the impact of disturbances on livelihood of local communities, especially those living in highly unpredictable systems like *Mopane* woodlands. On the other hand, these biological resources could be expected to play an increasingly critical role in securing feed and health for livestock in the near future. Furthermore, results from the present study supported the view that initiatives to conserve indigenous knowledge is paramount as loss of this vital knowledge system affects rural communities (Dwebaa and Mearns, 2011). Recognizing problems at community level is an essential step for supporting any interventional activities

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_65896605
© 2018, ALÖKI Kft., Budapest, Hungary

(Ravikumar et al., 2016). Local communities need to be in forefront towards knowledge creation, distribution and sharing system (Lwoga et al., 2010). Creative expressions of informal society can provide solutions and accessibility to appropriate technology (Kumar et al., 2013).

Previous research results revealed several plants that can be used reliably and safely to treat livestock. Legal registration of these botanical products is usually not required for their promotion. This approach offers sustainable strategies directed towards developing sound and appropriate animal health care systems suitable and relevant to rural communities in improving livestock performance and production and, hence, livelihood (Stevenson et al., 2010). The current study identified nine livestock conditions which were treated by 11 plants belonging to 10 families. Among the livestock conditions reported mastitis, retained placenta and wounds were frequently mentioned to occur in cattle. These livestock conditions were similar to the ones reported elsewhere in literature and treated by the use of medicinal plants (Dilshad et al., 2010; Gebrezgabiher et al., 2013; Luseba and Tshisikhawe, 2013). Retained placenta was found to be most common in domestic animals and two plant families were used against this condition (*Table 1*). This contradicts with Taliq et al. (2014) who reported gastrointestinal infections to be most common in domestic animals. Similar to previous studies, farmers in Mutale municipality reported that they were able to define diseases using clinical signs. However, the use of clinical signs only for diagnosis of diseases is not effective as it reduces the accuracy of the diagnosis thereby resulting in incorrect dosages and reduced effectiveness of herbal remedies.

Although livestock conditions in this study are similar to the ones reported previously, different medicinal plants, methods of preparation and to a certain extent administering methods were used. Lack of knowledge or prior experience with alternative therapies can influence willingness of farmers to use plants in treatment of ailments (Richert et al., 2013). Furthermore, different production systems influence decision by farmers to implement disease control strategies (Jemberu et al., 2015). Fabaceae family was only mentioned for the treatment of constipation in cattle. This observation is different from that of Appidi et al. (2008) who in an ethno veterinary survey reported Fabaceae family as the most commonly used plant by livestock farmers. Luseba and Tshisikhawe (2013) reported the use of *Bolusanthus speciosus* (Fabaceae) as a remedy for retained placenta when orally supplied in cattle after crushing and immersing the roots in water for 12 h. In this study when retained placenta was identified two plants (*Cassia abbreviata* and *Cissus quadrangularis*) from two different families (Caesalpiniaceae and Vitaceae) were used respectively. The bark of *Cassia abbreviata* when crushed and infused in water for more than 30 minutes (or less if shaking is done to facilitate quicker extraction of the chemicals) was reportedly used for treatment of retained placenta in the current study. The solution was reported to be administered orally until the complete discharge of placental membranes (*Table 2*). The difference among studies might be related to the differences in the dominant vegetation of the areas or might be associated with traditional beliefs of different cultures in traditional use of specific plants. Plants from the Asteraceae family were reportedly popular among traditional healers in Pakistan for the preparation of traditional medicines used in treatment of different livestock and human ailments (Khan et al., 2014; Akhtar et al., 2013). The fleshy branches of *Cissus quadrangularis* were crushed and infused in water; the solution was then used to clean the wound area. These results are in line with the findings of Gebrezgabiher et al. (2013) who reported that wound

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

treatment was done by topical application of the medication. Previous studies reported that *Cissus quadrangularis* exhibits strong antioxidant and free radical scavenging ability due to the presence of β-carotene (Mallik and Shymala Devi, 2005).

A high tannin-containing plant species *Ziziphus mucronata* was frequently mentioned by the respondents for treating mastitis in cattle. These results are in agreement with the findings of Dilshad et al. (2010) who reported the use of tannin containing plants for treating mastitis in dairy cows. *Combcv xbretum collium* was used in ruminants as a remedy to relieve constipation. According to Edwards et al. (1995), leaves and bark of *Combretum collium* are widely used in local medicine to treat various intestinal disorders including diarrhea, colic and jaundice. Interestingly, in the present study the bark of the same plant species was reportedly used for treating constipation. *Pterocarpus angolensis*, well known for its high tannin content, was also mentioned with respect to constipation (Luseba et al., 2007). Tannins occur naturally in plants and have been reported to have a wide range of medicinal uses due to their anti-inflammatory, anti-fungal, mucoprotectant, antioxidant, enzyme inhibition and anti-bacterial properties (McGaw et al., 2007). Swollen joints were reportedly treated by topical application of the latex-like sap from the branches of *Synadenium cupulare*. The roots of this plant have been reported to possess medicinal properties (Chauke et al., 2015). Respondents reported the use of *Aloe* species for treating poultry conditions. The findings are similar to those from previous studies where *Aloe* species were commonly used for treating poultry diseases including Newcastle disease (Mwale et al., 2005; Adedeji et al., 2013). Patterns in the ethnographic literature indicate that widespread, common *Aloe* species in Southern Africa are more likely to be popular, multi-use ethno medicines than rare species with narrow ranges (Glen and Hardy, 2006). Aerial parts of the plants were frequently reportedly used instead of beneath ground parts (*Table 5*). These results are in line with those of Ul Hassan et al. (2014); Luseba and Tshisikhawe (2013) who reported the frequent use of aerial plant parts containing medicinal properties in a plant instead of parts beneath the ground.

The present results are in agreement with other studies where roots were also used in ethno veterinary practices (Cheikhyoussef et al., 2011). However, the use of roots in preparation of herbal remedies is not advisable, as this results in loss of plants from their natural habitats. In the present study, leaves were only mentioned for the family Rhamnaceae (*Table 3*) in contradiction with previous findings which reported a more frequent use of leaves followed by whole plant (Tariq et al., 2014; Gebrezgabiher et al., 2013; Maphosa and Masika, 2010; Setlalekgomo and Setlalekgomo, 2013; Bhatt, 2013). The use of leaves in preparation of herbal remedies is considered a sustainable type of harvesting as it reduces loss of plants from the natural habitats. Farmers in Mutale municipality ought to use aerial plant parts such as leaves rather than the whole plant or roots to prevent plants from becoming extinct (Maroyi, 2012). Furthermore, leaves are the main site of the photosynthetic apparatus and are involved in a variety of physiological processes of plants and produce numerous secondary metabolites that could be a possible reason for their effectiveness and efficacy against different livestock diseases (Bhatt, 2013).

In the current study, few plants possessed medicinal properties in their fruits. Hassan et al. (2013) reported the use of a whole plant for medicinal purposes. In our study there was no case where respondents cited the use of a whole plant for medicinal purposes. This is a good indication since the use of whole plants could lead to a very destructive type of harvesting especially for rare and slow-growing plants from a conservation point

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_65896605
© 2018, ALÖKI Kft., Budapest, Hungary

of view (Tariq et al., 2014). Furthermore, a majority of the medicinal plants cited in this study were not cultivated by the respondents. However, one farmer reported to have planted a shrub (*Synadenium cupulare*) specifically for medicinal purposes. A study conducted in Pakistan by Dilshad et al. (2010), reported the use of cultivated plants (*Oryza sativa* and *Triticum aestivum*) for treating mastitis in dairy cows. A majority of the Mutale farmers interviewed collected the medicinal herbs from their natural habitats. This is a good indication since it is advisable to use wild plants that grow under stress conditions and competition, as they possess secondary metabolites which improve their medicinal properties (Schippmann et al., 2003). In addition, banana roots (*Musa paradisiacal*) were reported to treat internal parasites (worms) in animals when crushed and administered orally after infusion in water. Most plant parts were crushed and infused in water to influence easier extraction of the chemicals within. The methods of application used by local farmers in the current study did not differ from the methods reported by Sindhu et al. (2010) among Pakistan local farmers. Crushing of plant parts and mixing with water were common when medication was administered orally. This is in agreement with Maphosa and Masika (2010) and (Djoueche et al., 2011). Deeba (2009) indicated that powdering or boiling is the most common method of drugs extraction. These findings are in line with a study conducted in the Malakand valley of Pakistan (Ul Hassan et al., 2014). The difference in application methods are in agreement with the findings of McCorkle and Mathias-Mundy (1992) who reported that the mode of preparation of the medication depends on active ingredient to be extracted, and the method of administration.

Oral and topical routes were the only mentioned routes of administration in the present study. This agrees with the findings from previous studies (Tariq et al., 2014). Similar to what was reported in other studies, the ethno veterinary practices of livestock farmers in Mutale municipality are not extensively documented and are mostly passed orally from elders (Farooq et al., 2009). It is important to document ethno-veterinary knowledge so that it will not be lost and to increase the use of common plants.

Conclusion

The present study revealed that EVM is an important part of the livelihood of local farmers residing in the Mutale local municipality. The concept of EVM is highly appreciated and embraced mostly by old farmers who indicated to have acquired the knowledge from their elders' earlier. At present the transfer of this valuable knowledge to younger generations is a challenge considering the substantial development and education system limited to modernized drugs. EVM should not be neglected since it is the only hope for resource limited livestock farmers. However, further studies are still needed to educate farmers on sustainable utilization of indigenous natural resources and evaluation of the chemical composition of medicinal plants reported in this study. Gaining knowledge on the chemical composition of medicinal plants may be beneficial in drug development. It is expected that the situation regarding the use of plants to treat livestock in Mutale Municipality has most probably remained the same or, better still, improved.

Acknowledgements. The authors wish to express their gratitude to the livestock farmers of Mutale local municipality for their cooperation and University of Limpopo's Department of Agricultural Economics and Animal Production for allowing us to carry out this study.

Abstract. Unregulated land use/cover change (LUCC) has imposed significant local, regional and global impacts on livelihood and environment, particularly in sub-Saharan Africa. Previous studies well documented the extent and drivers of such spectacular LUCC in East Africa. However, data on regional/local impacts particularly that combine its socioeconomic and environmental effects are very scanty currently. Hence, this study is aimed to assess the socio-environmental impacts of LUCC in more dynamic and fragile landscapes of the Ethiopian Central Rift Valley lakes region. We used a combination of data from Remote Sensing, GIS-based processing, household survey and meteorological stations to quantify and analyze LUCC impacts. Results indicated that a rapid LUCC has occurred in the region over the last three decades which imposed a number of socioeconomic and environment-related impacts. Based on the percentage of respondent farmers, climate change (95%), soil productivity decline (94%), land degradation (92%), shortage of wood (91%), shortage of grazing land (89%), soil erosion (88%), loss of biodiversity (81%) and lake water retreat (74%), are the principal impacts of LUCC perceived. Such perceived impacts of LUCC are in line with the observed results obtained from comprehensive measured data analysis. Future land use policies need to consider management options that work on reducing anthropogenic-induced pressures on the environment and encouraging livelihood diversification in order to minimize the adverse socio-environmental impacts of spectacular LUCC in the region.
Keywords: *anthropogenic, climate change, household, land degradation, perception*

Introduction

Anthropogenic activities have altered the planet Earth at unprecedented rates, magnitude and spatial scales since the beginning of human life on Earth (Turner et al., 1994) which made land change science to emerge as one fundamental component of global environmental change and sustainability research (Turner et al., 2007). These changes are complex in nature in space and time (Lambin et al., 2003). For instance, the changes could be land modification, subtle alterations in the attributes of a land cover or land conversion, the complete replacement of one cover type by another (e.g., forest

© 2018, ALÖKI Kft., Budapest, Hungary

land to cropland) (Lambin et al., 2003); or it could be land restoration, human intervention in the form of land cover maintenance and restoration (e.g. degraded land rehabilitation by area closure) (Wortley et al., 2013). Depending on the speed of change, other scientists also consider land changes as gradual or abrupt changes (Geist et al., 2006). Depending on the nature of these changes, the impact they imposed and the subsequent driver for the changes also varies in space and time.

Unregulated land use/cover change (LUCC) has multiple socio-environmental impacts that can significantly affect key aspects of Earth System functioning as well as human life on Earth (Chhabra et al., 2006). For instance, LUCC directly impacts biodiversity loss worldwide (Haines-Young, 2009; Carpio et al., 2016); it affects the carbon balance of terrestrial environments (Houghton and Goodale, 2004; Maharjan and Joshi, 2013); and is the primary source of land and land resources degradation (Meshesha et al., 2012; Matano et al., 2015). By altering ecosystem services (Polasky et al., 2011; Yirsaw et al., 2016), LUCC also affects the ability of biological systems to support human needs and hence affects livelihood systems (Mutoko et al., 2014). Furthermore, LUCC affects spatial landscape pattern and configuration (Pang et al., 2013; Wan et al., 2015). Such impacts of LUCC are more noticeable in developing countries where the livelihood of the majority of the population is directly dependent on natural resources and hence the environment is highly vulnerable to such changes (Lambin and Meyfroidt, 2011).

The other principal impact of anthropogenic-induced LUCC that has been well recognized in recent decades, and also given emphasis in this study, is its effect on local and regional climate change (Dirmeyer et al., 2010; Mutiibwa et al., 2014; Fan et al., 2015) as well as on global warming (Vitousek, 1994; Brovkin et al., 2004). It is known that LUCC affects climate mainly through an accumulation of greenhouse gases (GHG) (Houghton et al., 2012) which is partly originated from intensive agriculture and deforestation (Maharjan and Joshi, 2013). Studies show that LUCC also affects land surface temperature and surface moisture (Jiang et al., 2015; Pal and Ziaul, 2017), carbon balance of terrestrial ecosystems (Houghton and Goodale, 2004), and precipitation and evapotranspiration rates and hence the sustainability of hydrological and climatological systems (Liu et al., 2008). This indicates that in addition to natural factors, LUCC also plays a significant role in world climate change in general.

Natural variability and human activities are the main causes of climate change (Maharjan and Joshi, 2013). However, the contribution of human activities (e.g. LUCC) to climate change has increased from time to time. The increase in atmospheric concentration of GHGs is the major factor contributing to climate change caused by the human activities. For instance, according to Maharjan and Joshi (2013), energy sector, agriculture, land use change and forestry, and industrial process contribute to 68%, 15%, 13% and 4% of global GHG emission respectively. This indicates next to energy sector emission, the carbon emission from the agricultural sector and land use change (e.g., deforestation and forest degradation) (Pacheco-Angulo et al., 2017) is about 28%. Under increased deforestation, not only the amount of GHGs added to the atmosphere increase, but also the capacity of the remaining forest to serve as a sink to such gases is decreasing.

Although LUCC impacts were recognized globally, the degrees of such impacts are markedly different in various time, landscapes and regions. Hence, in sub-Saharan Africa, particularly East Africa, where both LUCC and climate change are the major environmental and livelihood concerns in recent decades (Lambin and Ehrlich, 1997;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_66076632
© 2018, ALÖKI Kft., Budapest, Hungary

Houghton and Hackler, 2006), detail analysis of the socio-environmental impacts of LUCC has a paramount importance in contributing to future policy and management strategies. This is particularly true for the Central Rift Valley (CRV) lakes region of Ethiopia where a tremendous LUCC has occurred over the last three decades (Temesgen et al., 2013; Ariti et al., 2015). In Ethiopia, previous studies documented the extent and drivers of LUCC in different parts of the country (Tsegaye et al., 2010; Kindu et al., 2015; Bekele et al., 2018a; Temesgen et al., 2018). However, the studies on impacts of LUCC, particularly that combine socioeconomic and environmental effects, by comparing farmers' perceived results with the observed result from measured data analysis is very scarce currently. In this study, it is assumed that the perceived impact of LUCC by farmers is in line with the observed results from measured data analysis.

Hence, this study is intended to examine the socio-environmental impacts of LUCC by integrating Remote Sensing, GIS, socioeconomic and climatic datasets, using the fragile and most dynamic landscapes of the Ethiopian CRV lakes region as an ideal case study site. Such a combined study of socioeconomic, ecological and environmental impacts of LUCC helps to reduce the adverse effects and to devise appropriate policy intervention that works on the root drivers of spectacular LUCC.

Materials and methods

The study area

The Central Rift Valley Lakes Region is located about 170 km south of the capital city, Addis Ababa, Ethiopia which is specifically found in the limits of 38°20'-38°50' east longitude and 7°20'-8°00'north latitude (*Fig. 1*). It is situated in the current administrative regions of Oromia and Southern Nations, Nationalities and Peoples Region, and covers approximately an area of 13,401 km^2. The area is topographically characterized by a depression zone with steep marginal faults along its edges and bounded by eastern and western highlands. The geological and geomorphologic features of the region are the results of Cenozoic volcano-tectonic and sedimentation processes (Ayenew, 2007; Macgregor, 2015). The Ethiopian CRV is part of the Great East African Rift Valley, that originates from Aden Junction (Arabian Plate) in the Middle East and continues in the direction of south-west, traversing longitudinally eastern African countries such as Djibouti, Eritrea, Ethiopia, Kenya, Uganda and Tanzania, and reaches to Mozambique (Hengsdijk and Jansen, 2006; Ayenew, 2007).

The climate of the CRV varies markedly with altitude and season (Jansen et al., 2007). It is humid to sub-humid in the highland portion and semiarid in the rift floor which is characterized by warm and wet summer, and dry, cold and windy winter. The study area receives a bimodal rainfall distribution pattern. The small rainy season (Belg) occurs between February and May (FMAM), which is followed by the main rainy season (Kirmet) that occurs from June to September (JJAS). Based on long-term data from four meteorological stations in CRV namely: Arsi Negele, Bulbula, Meki and Ziway, the mean rainfall is 252 and 386 mm for Belg and Kirmet season respectively, and the overall mean annual rainfall is about 740 mm. The coefficient of variation for rainfall is higher for Belg season (31%) than for Kirmet season (22%). On the other hand, the minimum temperature of the study area ranges from its lower mean value (11.5 °C) for winter season (October to January) to its higher mean value (14.2 °C) for Kirmet season, while the maximum temperature ranges from its lower mean value

© 2018, ALÖKI Kft., Budapest, Hungary

(25.9 °C) for summer season to its higher mean value (28.5 °C) for Belg season. Rainfall in CRV is generally highly erratic which is one of the main constraints to rain-fed agriculture in the region (Jansen et al., 2007).

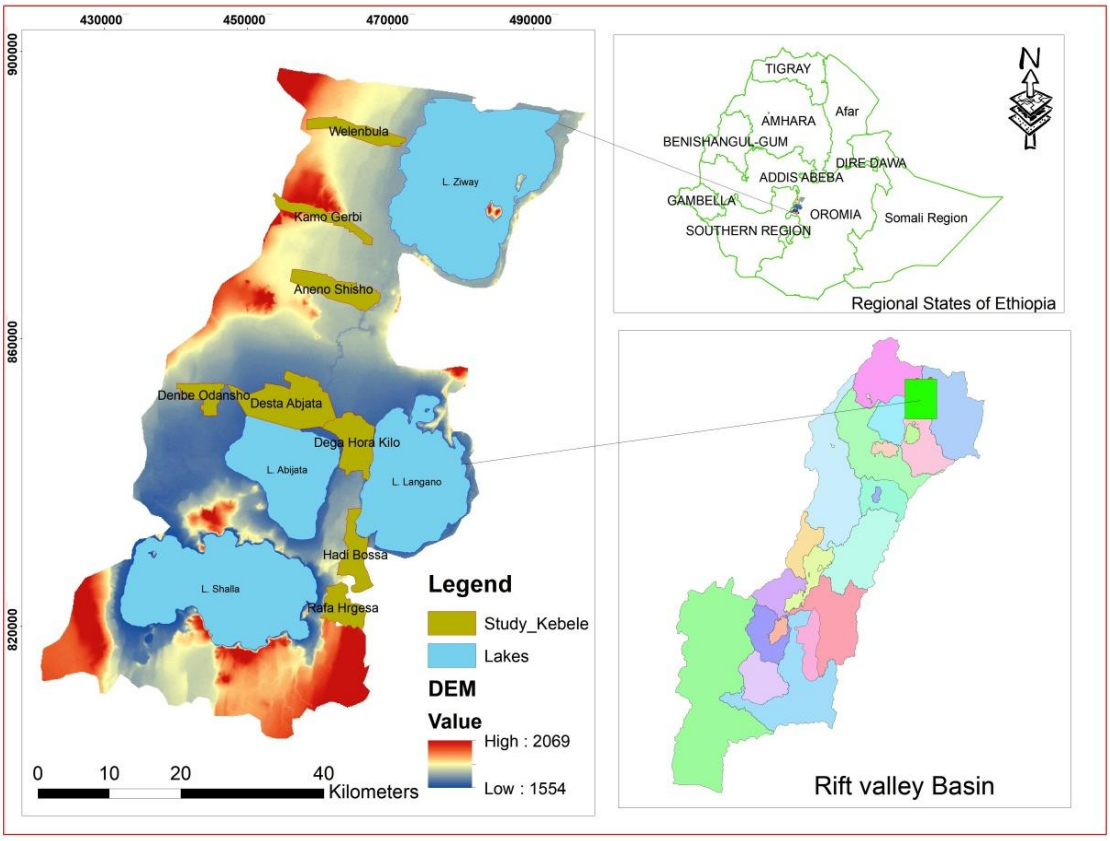

Figure 1. *Location map of the study landscape with agroclimatic areas*

The major land use/cover (LUC) types include agricultural land, dense and open acacia woodlands, water body, bush/shrubland, grazing land, swampy/marshy land and bare land (Bekele et al., 2018a). Acacia woodland is the dominant vegetation type in the region. The Rift Valley Lakes Basin is known for its huge water resource potential in the country which consists of four sub-basins namely: Ziway-Shalla, Awassa, Abaya-Chamo and Chew Bahir basins (*Table 1*). Shalla is the deepest lake (266 m) while Abaya is the largest (1160 km^2) in terms of size in the basin. The study site, Ziway-Shalla sub-basin, encompasses four major interconnected lakes on its rift floor namely: Ziway, Langano, Abijata and Shalla (*Table 1* and *Fig. 1*). These lakes together form one closed basin and a unique hydrological habitat in the region. Lake Abijata receives water from Lake Ziway via Bulbula River and from Lake Langano via Horakalo River. Lake Abijata and Shalla are terminal lakes (i.e. no outflow from such lakes) and hence known for their salty water.

The environment and the natural resources of the study area are currently under enormous pressure due to increased population pressure, agricultural investment expansion, urban expansion, mismanagement of land resources, and natural factors like recurrent drought (Jansen et al., 2007). Studies show that the woodland vegetation of the region has been declined in the expense of agricultural land expansion and continual deforestation over the last half century (Garedew et al., 2009; Biazin and Sterk, 2013;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

Temesgen et al., 2013; Ariti et al., 2015). The lakes and their feeding rivers are intensively used for domestic water use, irrigation, soda ash extraction, fishery, and recreation, while the lakes and their surrounding wetlands supported a wide variety of endemic birds (Hengsdijk and Jansen, 2006; Ayenew and Legesse, 2007). As a result of such anthropogenic pressures, land degradation became a serious threat to natural resources, environment, and livelihood in CRV area in recent decades (Ayenew and Legesse, 2007; Meshesha et al., 2012).

Table 1. *Major lakes of Rift Valley Lakes Basin. (Data from JICA, 2012)*

Sub-basin	Lake	Altitude (m.a.s.l)	Surface area (km^2)	Maximum depth (m)	Average depth (m)	Volume (km^3)

	Chamo	1235	551	13	6	3.3
Chew Bahir	Chew Bahir	nd	nd	nd	nd	nd

nd = no data

The population in CRV has shown an accelerated growth over the last three decades with an average growth rate of about 3%, and average family size of 7. For example, the total population for three districts in CRV, namely Dugda, Adami Tulu-Jido Kombolcha and Arsi Negele, has grown from 383 608 in 1994 to 546 444 in 2007, and 659 177 in 2016 (CSA, 1994, 2007), which indicates a sharp increase in population growth in the region. About 85% of the population of the study area is still living in a rural area (CSA, 2007), and unpublished reports indicate that rural-urban migration in search of employment has increased both at the local and national level in recent years.

Subsistence farming, the smallholder mixed rain-fed production system (*Table 2*), is the main economic activity for the vast majority (85%) of the population in the region (Scholten, 2007; Melka et al., 2015). One of the developments reported in the past decades is the introduction and rapid expansion of irrigated agriculture into the region. Smallholder farming irrigation schemes, large-scale private and state domestic farms and foreign investment, particularly in horticulture and floriculture, have been established during the last decades (Hengsdijk and Jansen, 2006). Due to these major agricultural developments, high competition for available water resource becomes a major threat to lake ecosystems in the region (Hengsdijk and Jansen, 2006). In the agro-pastoral areas and areas with no access to irrigation, food insecurity is a major problem and a significant portion of the rural population is still relying on relief assistance from government and external agencies (Bekele et al., 2018a). This is evident from the low household yearly income generated from farming (*Table 2*). As confirmed by farmers and experts during discussion, one of the main causes of poverty in the CRV among others is the low level of agricultural productivity as a result of erratic rainfall and recurrent drought occurrence over the recent decades.

Data used and sources

The data required for this study was generated through both primary and secondary sources. 1986, 2000 and 2016 LUCC area statistics data was partly adopted from previous work of Bekele et al. (2018a). Primary data on household characteristics, socioeconomic background, historical LUCC extent, drivers and its impacts were gathered by an in-situ formal household survey (see *Appendix*), focus group discussion, field observations, and informal discussion with key informants, and experts working at the study site. A questionnaire with semi-structured type was designed to assess rural farmers' perception of LUC dynamics and its impacts. The survey questions covered a wide range of issues regarding socioeconomic characteristics of households, perception on LUCC extent and drivers, its livelihood and environmental impacts, and adaptation strategies to cope up with such changes. The first fieldwork was conducted in April to June 2017 and the second in September to October 2017. Important secondary socioeconomic and biophysical data was obtained from concerned governmental organizations like: Rift Valley Lakes Basin Authority, Kebele (Village) Administrative Offices (the lowest administrative unit in Ethiopia), and Woreda (District) Agricultural Offices. In addition, population data were obtained from the Central Statistical Agency (CSA, 1994, 2007). The long-term rainfall (1981-2016) and temperature (1988-2017) data for selected sites in CRV namely: Arsi Negele, Bulbula, Meki, and Ziway were taken from the National Meteorological Agency (NMA).

Household survey and sampling

The household survey was conducted in two consecutive districts found in CRV lakes region namely: Adami Tulu-Jido Kombolcha and Arsi Negele Districts which were selected based on agroecology and vulnerability to drought and LUCC in recent decades. From these Districts, representative Villages were purposively selected based on access to market and infrastructure (e.g., road), drought vulnerability (e.g., relief aid dependency in last ten years) and experience in using adaptation measures like small-scale irrigation to cope up with LUCC and drought impacts. Such basic socioeconomic and biophysical background information of the sample Villages were gathered with the help of experts who have been worked in the Districts for a long time. Accordingly, five Villages from Adami Tulu-Jido Kombolcha District namely: Welenbula, Kamo Gerbi,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_66076632
© 2018, ALÖKI Kft., Budapest, Hungary

Aneno Shisho, Desta Abjata and Deneba Odansho, and three Villages from Arsi Negele District namely: Dega Hora kilo, Hadi Bossa and Rafa Hargesa, were selected for household interview and focus group discussion (*Fig. 1*). The households interviewed were selected randomly from each Village considering age, sex, wealth status, and literacy. The list of the households was obtained from each Village Administration Office. A total of 297 households were interviewed with an average of 37 households from each Village. In addition, at least one focus group discussion (five to ten people per group) and an interview with one key informant (elder), age at least 60, were conducted in each Village. A checklist of questions of interest was used to guide the group discussion which availed information that could not be picked up by using structured questionnaires. Additional discussion was also made with Development Agents (medium level experts assisting farmers in adoption of modern agricultural practices), at Village level and experts working at District level.

Data analysis

A combination of techniques, including Remote Sensing, GIS-based data processing and descriptive statistics were employed for data analysis. The LUC classification was done by employing a supervised maximum likelihood algorithm classification approach (Booth and Oldfield, 1989; Hogland et al., 2013; Richards, 2013) for the reference years of 1986, 2000 and 2016 using Landsat5 Thematic Mapper (TM), Landsat7 Enhanced Thematic Mapper Plus (ETM^{+}) and Landsat8 Operational Land Imager (OLI) imageries respectively with an overall accuracies of at least 90% for each year. Accordingly, the LUC of the study area was classified in to agricultural land, dense and scattered acacia woodlands, grass/grazing land, bush/shrub land, water body, marsh/swampy area and bare land (Bekele et al., 2018a).

Data on socioeconomic characteristics of households and their perceived responses on impacts of LUCC and climate data on rainfall and temperature were coded, summarized and analyzed using descriptive statistics. Data collected through group discussions, key informants interview and field observation was analyzed qualitatively and used in the elaboration of discussion part.

Mean, standard deviation, a coefficient of variations and standardized rainfall anomalies were employed to evaluate inter-annual rainfall fluctuations and temperature variations. The standard deviation for temperature and rainfall variability was calculated using the formula in *Equation 1*. The coefficient of variation (*Eq. 2*) is used as a statistical descriptor of rainfall and temperature variability and calculated as the ratio of the standard deviation to the mean in a given period. Standardized anomalies of rainfall of the crop growing season were calculated using the formula given in *Equation 3* and used to assess the frequency of droughts as in Agnew and Chappell (1999) and Bewket and Conway (2007).

$$SD = \sqrt{\left[\sum_{i=1}^{n} \frac{(x_i - X)^2}{n}\right]} \quad \text{(Eq.1)}$$

$$CV = \frac{SD}{X} * 100 \quad \text{(Eq.2)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_66076632
© 2018, ALÖKI Kft., Budapest, Hungary

$$SRA = \frac{P_t - P_m}{SD} \quad \text{(Eq.3)}$$

where, SD = standard deviation, CV = coefficient of variation, x_i = individual temperature/rainfall observation, X = mean rainfall/temperature, n = number of years considered, SRA = standardized rainfall anomaly, P_t = annual rainfall in year t, P_m = long term mean annual rainfall over a period of observation (1981-2016).

Results

Major land use/cover changes

The spatiotemporal trend of LUCC in the study area for 1986, 2000 and 2016 is shown in *Figure 2* for each LUC class.

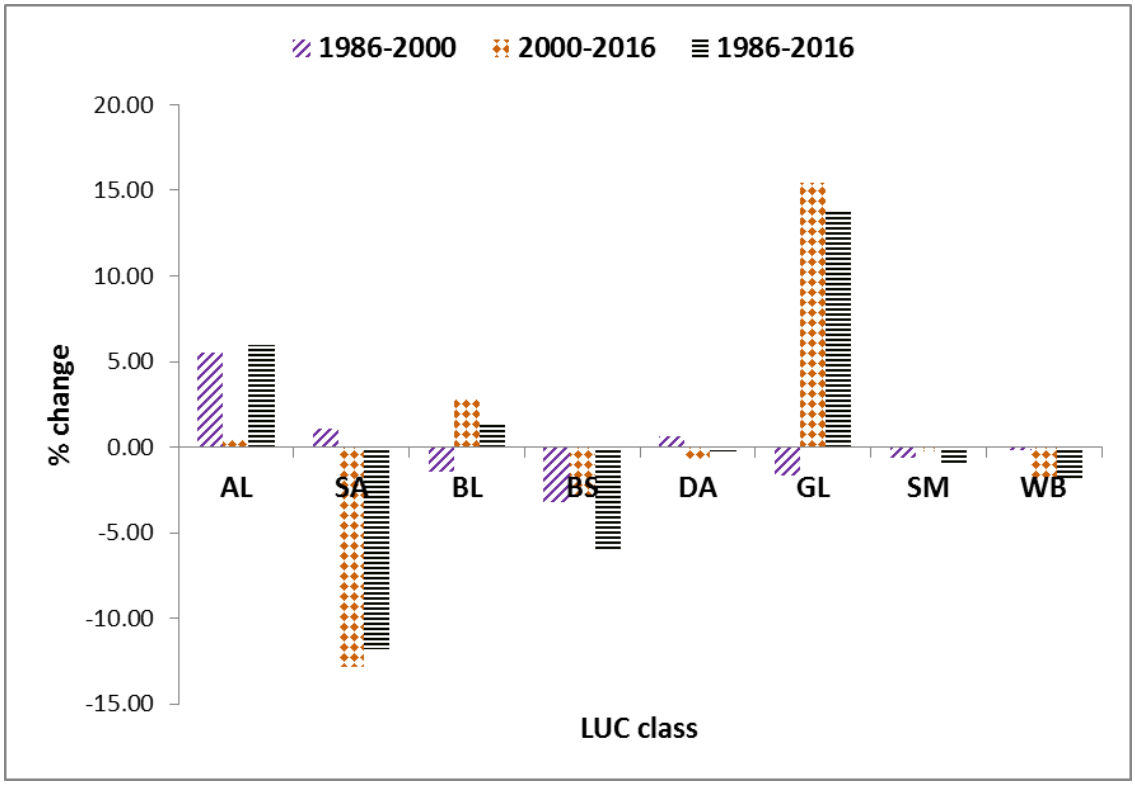

Figure 2. *LUCC (%) in CRV lakes region, adopted partly from Bekele et al. (2018a). AL = Agricultural land, SA = Scattered acacia woodland, BL = Bare land, BS = Bush/shrubland, DA = Dense acacia woodland, GL = Grass/grazing land, SM = Swampy/marshy land, WB = Water body*

Our result indicated that a tremendous LUCC has occurred in CRV lakes region over the last three decades. For instance, during the first phase of the study period (1986-2000), agricultural land and dense acacia woodland have increased by 39% and 23%, whereas bare land and bush/shrub land have declined by 39% and 27%, respectively. On the other hand, during the second phase of the study period (2000-2016), grazing land and bare land have increased by 164% and 121%, while scattered acacia woodland,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_66076632
© 2018, ALÖKI Kft., Budapest, Hungary

bush/shrubland and dense acacia woodland have declined by 54%, 32% and 27%, respectively. This implies bush/shrubland has declined throughout both study periods. Waterbody and its associated swampy/marshy lands also declined during both study periods. Agricultural land on the other side had increased with a substantial rate until 2000, after which it showed only slight increment. During the overall study period (1986-2016), grass/grazing land, agricultural land and bare land have increased by 124%, 42% and 34%, whereas scattered acacia woodland, bush/shrubland and swampy/marshy land have declined by 52%, 50% and 31%, in that order.

Socio-environmental impacts of land use/cover changes

Climate change and food insecurity

Results show that LUCC has imposed a number of significant socio-environmental impacts in CRV lakes region of Ethiopia during the last three decades. This was confirmed by a number of impacts perceived by rural farmers of the study area and observed evidences from field survey (*Fig. 3*). About 95% of respondent farmers mentioned climate change, particularly rainfall variability and frequent drought, as the main impact of LUCC in the region. They accused LUCC, particularly the rapid decline in vegetation coverage, as a main reason for erratic and shortage of rainfall, and an increased diurnal temperature in recent years in the study area. According to open discussion witness by focus groups, key informants, and experts, this change in climate, in turn, has directly affected the rain-fed agriculture and contributed to high food insecurity problem in the region in recent decades.

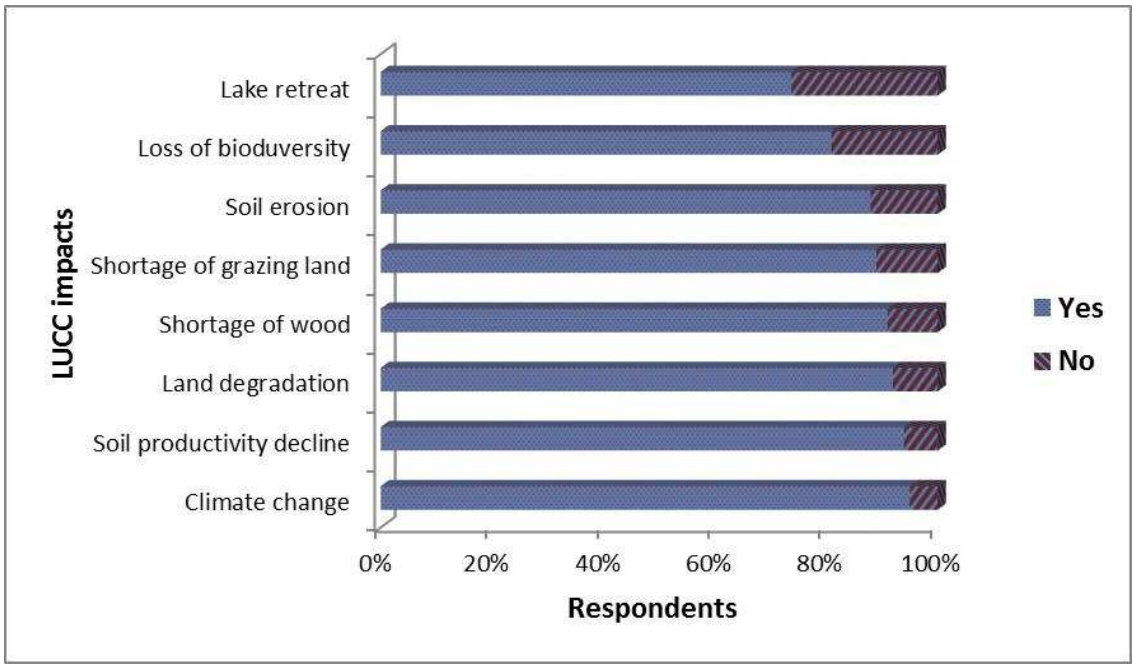

Figure 3. *Impacts of LUCC as perceived by rural households (%) in CRV lakes region of Ethiopia (N = 297)*

Table 3 summarizes rainfall and temperature statistics while *Figure 4* shows the standardized rainfall anomaly of the study area. In line with household perceived

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_66076632
© 2018, ALÖKI Kft., Budapest, Hungary

results, the standardized rainfall anomaly of the growing season showed high inter-annual and inter-seasonal variability and a general decreasing trend (*Fig. 4*) for both Belg (CV = 31%, mean = 252 mm±78) and Kirmet (CV = 22%, mean = 386 mm ± 86) (*Table 3*). Of the 36 years of observation, 20 years (56%) for Belg season and 18 years (50%) for Kirmet season had negative anomalies, implying dry years, which is a risk for rain-fed agricultural production in the region. The coefficient of variation of rainfall is higher during the Belg season (31%) than during Kirmet season (22%). However, average minimum and maximum temperatures did not show significant inter-annual and inter-seasonal variation over the last three decades, though the trend line in *Figure 5* indicates that it is generally hotter in recent years than in earlier years, and it is evident that an increased temperature, in turn, will increase evapotranspiration rate. The mean minimum temperature ranged from 11.5 °C for winter season to to 14.2 °C for Kirmet season, while the mean maximum temperature ranged from 25.9 °C for Kirmet season to 28.5 °C for Belg season. In general, the temperature has shown considerable variability during the last 30 years.

Table 3. *Mean, standard deviation and coefficient of variation (%) for long-term rainfall (1981-2016) and temperature (1988-2017) at CRV lakes region. (Data from NMA)*

Land degradation

Soil productivity decline, land degradation, and soil erosion are other major impacts of LUCC perceived by 94%, 92% and 88% of respondent farmers respectively (*Fig. 3*). Development Agents and District agricultural experts also confirmed that severe soil erosion and subsequent decline in agricultural productivity are mainly attributed to rapid LUCC in the study area over the last three decades. As observed during the field survey, indicators of land degradation (*Fig. 6*), specifically serious gulley erosion, expansion of bare lands, and decline/drying of streams, rivers, and lakes are among the high threats to the environment and rural livelihood in CRV lakes region. It is common to see severe gulley erosion like the one in *Figure 6a*, in cultivated lands, along a roadside, and in grazing lands. In addition to water erosion, wind erosion is also a common phenomenon observed in CRV area during the dry season. Extensive bare lands are mainly found along the shore of Lake Abijata (*Fig. 6d*) due to its fast retreat and water loss in recent decades. The Bulbula River was already dried due to decline in the level of Lake Ziway (its source), high water consumption for irrigation, drought and catchment degradation in general (*Fig. 6c*).

Shortage of wood and grazing land

Other major important impacts of LUCC mentioned by more than 89% of respondents were a shortage of wood and grazing land (*Fig. 3*). During the discussion,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_66076632
© 2018, ALÖKI Kft., Budapest, Hungary

focus groups pointed that due to firewood shortage and lack of access to electricity and alternative energy sources, currently they were forced to use either crop residues or cow dung, or buy firewood with expensive price from nearby markets, which had been otherwise accessed from nearby woodlands/forests three decades ago. In addition, respondent households mentioned that due to a shortage of cropland and productivity decline from time to time, they were forced to change part of their previous grazing land to croplands, which contributed to a shortage of grazing land. Hence, coupled with recurrent drought, shortage of grass/grazing land has made cattle rearing the most difficult rural livelihood option, and hence most farmers have been forced to limit the number of their cattle holding in recent decades.

Figure 6. *Indicators of land degradation in CRV lakes region of Ethiopia: (**a**) active gulley head; (**b**) bare and eroded land; (**c**) drying of Bulbula River which flow from Lake Ziway to Lake Abijata; and (**d**) retreat of Lake Abijata. (Photo by B. Bekele)*

Water resources degradation and biodiversity loss

Last but very important impacts of LUCC perceived by about 81% and 74% of interviewees respectively were the loss of biodiversity and lake water retreat (*Fig. 3*). Drying of rivers and streams specifically of Bulbula River (*Fig. 6c*) and lake water loss, particularly of Lake Abijata (*Fig. 6d*) and Lake Ziway, was strongly emphasized by survey participants (individual households, key informants, focus groups and experts) during the discussion. Key informants (elders) confirmed that Lake Abijata now lost at least one-fourth of the area coverage it has 20 years ago.

In agreement with perceived results, the observed trend (*Table 4a*) and projected trend (*Table 4b*) indicate high water resources degradation in CRV lakes region. During 34 years period, Lake Abijata lost about 51% of its area in 1973 (*Table 4*a). The rate of loss is faster in recent years than in earlier years. For example, as shown in *Table 4a,*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_66076632
© 2018, ALÖKI Kft., Budapest, Hungary

during 1999-2006, eight years alone, Lake Abijata lost about 42% of its area in 1999. The projected change (*Table 4b*) also shows that Lake Abijata will continue to lose about 17% of its area and 1.28 m of its level until 2034 followed by Lake Ziway, which will be expected to lose 10.7% area and 0.57 m level. Such high degradation on lakes, in turn, is a major threat to biodiversity loss particularly bird and fish species inhabiting these lakes.

Table 4. *Observed changes in size of Lake Abijata (1973-2006) (**a**) and long term projected change in level and area of four CRV lakes (2005-2034) (**b**). (Data from Jansen et al., 2007 and Raventós Vilalta, 2010)*

(a) Lake Abijata observed change		**(b) Projected change**

Discussion

In their previous studies, the authors reported the systematic and random LUCC transitions (Bekele et al., 2018a) and its principal drivers (Bekele et al., 2018b submitted) in CRV lakes region of Ethiopia. The results of these studies show that a rapid LUCC has occurred in CRV lakes region of Ethiopia in recent three decades and these changes are driven by population growth, fuelwood extraction, agricultural land expansion, charcoal making, recurrent drought and overgrazing. This unregulated change in LUC has imposed a number of socioeconomic and environmental related impacts, according to farmers' perception, experts' opinion and authors' field observation. The impacts are highly interrelated and hence further aggravate each other. These include climate change and subsequent food insecurity, land degradation, shortage of wood and grazing land, degradation of water resources and loss of biodiversity.

Climate change, particularly rainfall variability (late onset, early set-off, accidental flood, frequent drought) as confirmed by respondents and analysis of meteorological dataset, is a major problem in CRV lakes region in recent years, which is also consistent with previous studies (Biazin and Sterk, 2013; Kassie et al., 2013). This unpredictable and erratic rainfall, in turn, increased the vulnerability of rain-fed agriculture to climate change (Gizachew and Shimelis, 2014) which resulted in food insecurity and relief aid dependency of thousands of farmers in the region. Frequent drought is the main challenge to food security in East African countries in recent decades (Pricope et al., 2013; Masih et al., 2014). For instance, historical records showed that Ethiopia has experienced a repeated dry-spells hit over the last half century (Jury, 2010; Fazzini et al., 2015). One causative factor of this variability in rainfall in Ethiopia among others is believed to be the rapid change in LUC of the country, particularly massive deforestation (Gurmessa, 2015). This agrees with our starting assumption that LUCC is one potential contributor that increases climate change vulnerability in the country. It is known that LUCC has local and regional climate change effects especially through the accumulation of GHGs (Pielke, 2005; Houghton et al., 2012). In addition to increasing

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_66076632
© 2018, ALÖKI Kft., Budapest, Hungary

the atmospheric concentration of GHGs and therefore influencing global climate, LUCC, particularly deforestation could also affect the regional or local climate by altering the water and energy budget at the Earth's surface via changing albedo, Bowen ratio and surface moisture (Hagos et al., 2014; Ahmed et al., 2016). Studies also show that LUCC affects land surface temperature and surface moisture (Jiang et al., 2015; Pal and Ziaul, 2017), carbon balance of terrestrial environments (Houghton and Goodale, 2004), and precipitation and evapotranspiration rates and hence influencing the hydrological and climatological systems (Liu et al., 2008).

Land degradation in CRV lakes region, particularly decrease in soil productivity, severe soil erosion, expansion of bare lands and abandon lands are consequences directly linked to unregulated LUCC (e.g. deforestation) and mismanagement of land, for example, overgrazing in the region. It is known that expansion of bare lands further exposes the soil to water and wind erosion, and soil erosion, in turn, is the primary cause for deterioration in soil fertility, and productivity decline (Lal, 2001). Previous studies also reported severe land degradation and subsequent soil productivity decline in CRV region (Meshesha et al., 2012; Adimassu et al., 2013) and in other parts of Ethiopia (Taddese, 2001; Teketay, 2001; Zeleke and Hurni, 2001; Amsalu et al., 2007) which are directly or indirectly related to the rapid LUCC in the country. Studies show that LUCC, particularly extensive vegetation removal and mismanagement of croplands could accelerate soil erosion (Teketay, 2001; Nunes et al., 2011). For instance, keeping other factors constant, soil erosion is expected to be more severe on bare lands and croplands, than on forest lands (Nunes et al., 2011). Some unpublished government reports claim for an increased productivity per hectare of land in recent years in Ethiopia; but as confirmed by farmers and experts during discussion, this could be possible only for good rainy years and at the expense of high inputs (fertilizer, pesticide, herbicide, and labour) which is unaffordable by poor farming households due to high price inflation of such inputs in the country in recent years.

High shortage of wood and wood products is another critical problem faced in Ethiopia following massive deforestation in the country in general and the study site in particular. The wood shortage crisis is evident from the high price of wood products on the local market currently. The demand on wood and wood products, on the other hand, is highly increased in Ethiopia from time to time following population growth, as wood is the basic material required for construction, house furniture, energy supply, and an alternative source of income in the country (Gurmessa, 2015). The demand for wood for firewood is further exacerbated by lack of access to primary energy sources, like rare rural electrification in Ethiopia currently. On the other hand, the domestic supply base for wood products is already in its critical stage in Ethiopia in recent years. This is because the natural forest resource of the country was already lost as a result of rapid deforestation over the last half century (Teketay, 2001; Guta, 2014), whereas efforts made to fill the gap with the expansion of plantation forest is too low to supply the demand and is constrained by several management problems (Lemenih and Kassa, 2014). Such wood shortage crisis is also evident from common usage of crop residues and cow dung as firewood in both urban and rural areas of the country (Guta, 2014) which also further contribute to soil fertility and productivity decline.

The CRV lakes region is known for its huge water resource in the country; because with the exception of Lake Tana, all principal Ethiopian lakes are found within the catchment of Rift Valley Lakes Basin. These lakes are interconnected to each other and together form a closed sub-basin. However, currently there exists a high competing

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_66076632
© 2018, ALÖKI Kft., Budapest, Hungary

claim for land and water resources by different stakeholders in this basin, and managing these different claims to achieve sustainable development remained the most challenging and an issue of environmental and economic debate currently (Jansen et al., 2007). In CRV, land, and water resources are highly interrelated and hence any change in LUC directly affects the water and its habitats. Anthropogenic-induced activities, for example, rapid LUCC and natural processes like climate change in the region imposed a number of critical impacts on lake water resources, their associated wetlands and biodiversity (Seyoum et al., 2015). For instance, the rapid retreat of lakes' volume (e.g., Lake Abijata and Lake Ziway), drying/decline of streams and rivers (e.g., Bulbula River), and water pollution due to chemical-intensified farming (e.g., Laka Ziway) are indicators of severe lakes' degradation in the region. With current rate of retreat studies projected that Lake Abijata will totally dry within the coming 50 years (Jansen et al., 2007; Temesgen et al., 2013; Seyoum et al., 2015), and unless urgent measures are taken, Lake Ziway will be the second to share a similar fate in the coming near future. For example, the drying of Bulbula River, which discharges water from Lake Ziway to Lake Abijata, is a signal of warning for a significant decline in the level of Lake Ziway currently. The average level of Lake Ziway has decreased by approximately 0.5 m since 2002 which is equivalent to a loss of about 200 million m^3 of water (Jansen et al., 2007). High water abstraction for irrigation, climate change, rapid LUCC and land degradation are the major factors for such severe consequences on CRV lakes (Legesse and Ayenew, 2006; Getnet et al., 2014). For instance, the irrigated land has increased from almost zero ha in 1973 to about 10 000 ha in 2006 (Jansen et al., 2007), and an estimated 285 Mm^3 yr^{-1} of water was abstracted for irrigation in 2009 alone (Getnet et al., 2014). Most of these irrigation development activities are situated in the downstream catchments of Lake Zway, which makes it the most vulnerable lake to such pressures. In addition, though the CRV lakes are endowed for tourism potential and they are being home for different migratory species of birds and fish, this biodiversity is currently highly threatened and became extremely vulnerable by such high human-induced pressures on the habitats of these lakes (Jansen et al., 2007).

Conclusions

Based on the results obtained from comprehensive analysis, we can conclude that there has been a rapid and tremendous LUC dynamics occurred in CRV lakes region of Ethiopia. This change, in turn, has imposed adverse socioeconomic and environmental impacts during the study period. Climate change, soil productivity decline, land degradation, shortage of wood and grazing land, soil erosion, loss of biodiversity and lake retreat were the principal impacts of LUCC claimed by respondent farmers in decreasing order of percentage of respondents. The perceived impacts are in line with the results obtained from physical data analysis and eyewitness from in-situ field verification.

Previous studies in CRV and elsewhere mainly focused on spatiotemporal analysis of the extent and drivers of LUCC with little emphasis to its prolonged impacts. Apart from these studies, this study tried to integrate Remote Sensing, GIS, climatic data and socioeconomic survey to investigate LUC dynamics for the last three decades and its wider livelihood as well as environmental impacts in the CRV lakes region of Ethiopia. In addition, this study also tried to compare observed impacts of LUCC with that of farmers' perceived results which will hope to increase the scientific knowledge of the

DOI: http://dx.doi.org/10.15666/aeer/1605_66076632
© 2018, ALÖKI Kft., Budapest, Hungary

study area. It is also believed that the result of this study will serve as one of the information inputs to be used in formulating future policies and management plans for a rapidly changing CRV lakes region. However, this study might have limitations and hence further studies are important. For example, for a better understanding of climate change trends, it needs further research that addresses detail analysis on the extent of meteorological drought and how these could be affected by LUCC by incorporating data from wider meteorological stations in CRV lakes region. In addition, it is better to investigate the LUCC effect on environment and ecosystem functioning, for example, its effect on ecosystem services and human-wellbeing. Furthermore, it is important to assess the adaptation strategies and the constraints of farmers to overcome the impact of LUCC.

The study result implicated that LUCC has still continued in developing countries like East Africa, where the majority of the economy is directly dependent on natural resources. These rapid and extensive LUC dynamics is mainly driven by human-induced pressures and climate change vulnerability, which has imposed significant socioeconomic and environmental impacts at the local, national and regional level. The natural resources of the study area are currently under enormous pressure, and hence the adverse impacts of LUCC observed for this study calls for urgent measures that work on the drivers, particularly population growth and options that help strengthen the adaptation capacity of farmers to cope up with climate change. High land degradation in the region needs integrated and sustainable environmental conservation activities by all stakeholders. The high demand for wood products, especially for firewood, needs strong action on plantation forest establishment and expansion of rural electrification, and improving access to alternative energy sources and efficient energy utilization technologies. Lake water and associated aquatic ecosystems degradation require immediate practice on integrated water resource management and formulation of policies that govern sustainable and efficient water use for irrigation. In general, future land use policies at local, national and regional level needs to address such rapid LUCC and the principal drivers, in order to reduce the adverse impacts and maintain the fragile ecosystems of the CRV lakes region while diversifying alternative livelihood options to feed the ever-growing population of the region.

Acknowledgements. The authors are indebted to thank the National Natural Sciences Foundation of China (Fund No. 41571176), International Cooperation and Cultivation Project of Nanjing Agricultural University (Fund No. 2018-AF-22), and The 111 Project (Fund No. B17024) by State Administration of Foreign Experts Affairs and Ministry of Education of China for financial support and encouragement in conducting this study. We are grateful to thank the Chinese Government Scholarship Council (CSC) for giving the first author a chance to pursue his Ph.D. study in China. Special thanks also go to all the staff members of Agricultural Office of the Dugda, Adami Tulu-Jido Kombolcha and Arsi Negele Districts who helped during field data collection and all the rural farmers of the three Districts who took part during the field survey. We are also pleased to acknowledge the anonymous reviewers for their helpful comments and opinions on the earlier draft of this manuscript.

APPENDIX

Household survey questionnaire

Name of respondent (Household Head): _____ PA Name: _____

Woreda (District) Name: _____ Date of interview: _____

Name and signature of enumerator: _____

I. Household characteristics

1. Wealth category of a household: a) Poor [] b) Medium [] c) Relatively better-off []
2. Household head sex, age, marital status, family size, education level and occupation

Name	Sex	Age	Marital Status	No. of family members	Level of education	Occupation	
						Primary	Secondary

3. Years of experience as a farmer: a) 5-10 [] b) 11- 15 [] c) 16-20 [] d) 21-25 []
   e) 26-30 [] f) 31-35 [] g) 36- 40 []
4. Main livelihood activity you engaged in:
   - before certain years:

   a) Mixed farming [] b) Pastoralist [] c) Agro-pastoralist [] d) Off-farm income []
   e) Others (specify) _____
   - Currently:

   a) Mixed farming [] b) Pastoralist [] c) Agro-pastoralist [] d) Off-farm income []
   e) Others (specify) _____

II. Land tenure and land holding size

5. Means of land acquisition (tenure): a) Distribution [] b) Inheritance []
   c) Gift [] d) Share cropping [] e) Renting []
6. No of plots of land you own? a) One [] b) Two [] c) Three [] d) Four []
   e) Five or more []
7. The total size of all your land in 'Timad'/hectares: _____
8. Your land holding is currently: a) Certified [] b) Not certified []

III. Income sources

9. Main source of household subsistence income and cash: a) Farm (crops consumed & sold, livestock consumed and sold, and others, specify) _____ b) Non-farm (petty trading: sale of fire wood, charcoal, bole soil, sand, vegetable, grain and others, labor outside the local area, remittance, fishing, private or government job e.g. teaching, health service) [] c) Others (Specify) _____

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_66076632
© 2018, ALÖKI Kft., Budapest, Hungary

10. If your main source of income is non-farm activities, does it enable you to buy all your household basic necessities? a) Yes [] b) No []
    Specify the amount of non-farm income you get per year (Birr)._____
11. Your farm income: a) during 'good' year (Birr/Quintal): _____ b) during 'moderate' year (Birr/Quintal): _____ c) during 'bad' year (Birr/Quintal): _____
12. Do you have saving in 'good' year?: a) Yes [specify amount] _____ b) No []
13. Your household major expenditures: a) Purchase of grain [] b) Buy food ingredients (salt, food oil, etc.) [] c) Buy seeds (local/improved) [] d) Buy fertilizer []
    e) School fees [] f) Government tax [] g) Social affairs ('edir', 'serg', etc.) []
    h) Others (specify) _____

IV. Energy sources

14. Main sources of fuel for cooking & heating: a) Firewood [] b) Charcoal []
    c) Crop residues [] d) Kerosene [] e) Animal dung [] f) Others (specify) []
15. The main source of your fire wood: a) Own farm [] b) Others' farm []
    c) Communal woodland [] d) Market [] e) Others (specify) _____

V. Crop production

16. Area of your crop land during the last 30 years:
    a) Decrease [] b) Increase [] c) No change []
17. Crop yield per hectare of your major crops during specified periods (quintal):

	Crop Type							
Yield/hectare	Maize	'Teff'	Wheat	Sorghum	Potato			
20 years before								
10 years before								
5 years before								
Currently								

18. If crop yield per hectare of your land decreased from time to time, in your opinion, mention major causes of this yield reduction. a) Erratic rainfall [] b) Improved seed scarcity and high price []
    c) Unaffordable price of fertilizer [] d) Shortage of plowing oxen []
    e) Soil degradation (erosion, low fertility) [] f) Prevalence of pests, diseases and weeds []
    g) Lack of credit [] h) Others (specify) _____

VI. Livestock production

19. In case you own livestock, what is your major source of fodder for your animals?
    a) Grazing land b) Crop residues [] c) Forest reserve areas []
    d) Market [] e) Others (specify) _____
20. Did you observed any reduction or disappearance of palatable herbs, grass and trees in the grazing areas during last ten years? a) Yes[] b) No []
21. In which season/s of the year you face more shortage of livestock feed and how do you overcome this problem? _____

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_66076632
© 2018, ALÖKI Kft., Budapest, Hungary

22. The types and number of livestock you own:

a) Cattle (Cows, Oxen, Heifer, Bulls, calves) [] b) Goat [] c) Sheep []

d) Chicken [] e) Donkey [] f) Horse [] g) Mule []

23. What is the trend of the livestock you own in terms of their number and type over the past 30 years?

a) Decreasing [] b) Increasing [] c) No change []

24. If decreasing, what are the major reasons, in the order of importance?

a) Lack of fodder [] b) Shortage of grazing land [] c) Disease prevalence and lack of veterinary services [] d) Drought & shortage of water [] e) Others (specify) _____

VII. Land use/cover change (LUCC) perception

25. Did you observed any LUCC over the last three decades? a) Yes [] b) No []

26. How do you see the trend of LUCC over the last 30 years?

No	LUC type	Change observed		
		Increase	Decrease	No change
1	Dense wood land (forest)			
2	Scattered wood land			
4	Grazing land			
5	Cultivated land			
6	Water bodies			
7	Bare land			
8	Settlement areas			

27. What do you think are the major causes/drivers for LUCC in the last three decades?

a) Population pressure [] b) Agricultural expansion [] c) Over grazing []

d) Fuel wood extraction [] e) Charcoal making [] f) Settlement [] g) Drought (climate change) []

h) Agricultural investment [] i) Livelihood change [] j) Government policy & institutional changes []

k) Social unrest [] l) Market & infrastructure access m) Others (specify) _____

28. What major impacts of LUCC you observed on your livelihood/environment?

a) Soil fertility/productivity decline [] b) Soil erosion [] c) Land degradation []

d) Lake retreat [] e) Climate change/drought [] f) Loss of biodiversity []

g) Shortage of wood [] h) Shortage of grazing land [] i) Others (specify) _____

VIII. Climate change perception

29. Did you observed any climate change over the last three decades? a) Yes [] b) No [].

If your answer to question 29 is 'Yes', answer questions 30-43.

30. Trend of rainfall amount during main rainy season (Kirmet) over the last one decade:

a) Decreased [] b) Increased [] c) No change []

31. Trend of rainfall amount during small rainy season (Belg) over the last one decade:

a) Decreased [] b) Increased [] c) No change []

32. Trend of rainfall of Kirmet season over the last one decade:

a) Coming late [] b) Coming early [] c) Early set-off [] d) Frequent dry spells []

e) Increased intensity in few period [] f) More erratic [] g) No change observed []

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_66076632
© 2018, ALÖKI Kft., Budapest, Hungary

33. Trend of rainfall of Belg season over the last one decade:
    a) Coming late [] b) Coming early [] c) no rain in some years [] d) Normal []
34. Temperature trend over the last one decade:
    a) Increased [] b) Decreased [] c) No change []
35. Have you observed any drought occurrence over the last three decades?
    a) Yes [] b) No []. If yes, how frequent does it occurred? a) Once 2-5 years []
    b) Once 5-10 years [] c) Once 10 years []
36. The most disastrous drought you ever observed occurred in the year/s: _____
37. Have you observed any flood occurrence over the last three decades? a) Yes [] b) No []
    If yes, how frequent it has occurred? a) Every year [] b) Every two year []
38. The most disastrous flood you ever observed occurred in the year/s: _____
39. What do you think is the causes for climate change?
    a) Deforestation [] b) Overgrazing [] c) Agricultural expansion []
    d) Urbanization [] e) Industrial wastes [] f) Others (specify) _____
40. What are the major impacts of climate change on your livelihood and environment?
    a) Total crop failure [] b) Yield decrease [] c) Pest and disease prevalence[]
    d) Decrease in streams and lakes volume [] e) Flood and soil erosion []
    f) LUCC [] g) Others (specify) _____
41. Which adaptation measures did you take to cope up with climate change? Answer by (Yes/No)
    a) Planting trees [] b) Soil and water conservation [] c) Changing crop/animal variety []
    d) Changing planting date [] e) Changing crop type [] f) Using irrigation [] g) Crop diversification [] h) Off-farm employment [] i) Destocking livestock [] j) Asking for disaster relief [] k) Seasonal migration [] l) Storing livestock feed for dry periods []
    m) Others (specify) _____ n) Doing nothing []
42. What are the barriers that hinder you from using adaptation measures?
    a) Lack of early warning/information [] b) Lack of access to irrigation []
    c) Shortage of labor [] d) Lack of resources (money, input) []
    e) Lack of external support [] f) Shortage of land [] g) Others (specify) _____
43. Which of the following livelihood/ land use type you prefer to better cope up with climate change in the future?
    a) Mixed farming b) Agro pastoralist C) Pastoralist

IX. Perception on environmental degradation and conservation

44. Have you ever experienced soil degradation incidence on your farm? a) Yes[] b) No[]
45. If you answered "Yes", mention the indicators. a) Decreased crop productivity[]
    b) Loss of topsoil [] c) Other (specify) _____
46. Soil fertility status of your land currently: a) Poor[] b) Moderate[] c) Relatively fertile[]
47. Traditional land rehabilitation measures used for mitigating soil fertility problems:
    a) Addition of compost [] b) Crop rotation [] c) Fallowing [] d) Ploughing once []
    e) Repeated tillage [] f) Others (specify) _____

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_66076632
© 2018, ALÖKI Kft., Budapest, Hungary

48. The major causes of forest decline in your area?
    a) Expansion of cropland [] b) Illegal cutting of wood [] c) Over-grazing []
    d) Government weak forest law enforcement [] e) Others (specify) _____
49. What type of aquatic habitats (rivers, wetlands, lakes) degradation problem you observed?
    a) Drying/decreasing of water volume [] b) Pollution []
    c) Excessive water withdraws for irrigation [] d) Introduction of invasive species []
    e) Others specify _____

X. Market and infrastructural access, and institutional support

50. Distance to the nearest market center (Km): _____ and distance to the nearest main road (Km): ____
51. Transport type used to sell your produce: a) Public transport [] b) Donkey back []
    c) Donkey cart [] d) Others (specify) _____
52. Do you have any access to the following supports? (Answer by saying Yes/No)
    a) Credit [] b) Inputs (seed, fertilizer) [] c) Training [] d) Extension on field support []
    e) Farmer-to-farmer skill exchange [] f) Weather broadcast [] g) One-to-five social network []
    h) Infrastructures (Tele, road, health center, water supply etc.).

Open-ended questions for key informants, focus groups and local experts

1. How you observed the LUC type and change:
    - Before the 'Derg' regime (before 1974)
    - During 'Derg' regime (1974-1990)
    - During the current government (since 1991 to the present)

---

2. What do you think are the major causes of LUCC?

---

3. What impacts does LUCC brought on people's livelihood and environment of the area?

---

4. How you observed the trend of climate variability (temperature, rainfall) and extremes (drought, flood, disease prevalence etc.) occurrence during the last three decades?

---

5. What do you think are the major causes of climate change in the area?

---

6. What impacts does climate change brought on peoples livelihood and environment?

---

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_66076632
© 2018, ALÖKI Kft., Budapest, Hungary

7. What impacts does climate change brought on peoples livelihood and environment?

---

8. What measures you and other farmers took to cope up with the impacts of climate change?

---

9. What are the barriers to climate change adaptation in the area?

---

10. What are the extent, cause and impact of aquatic habitats (rivers, lakes, wetlands) degradation you observed in this area?

---

11. What measures you expect from the government and community to safeguard degraded aquatic habitats?

Thank you for your cooperation!

THE CONTENT OF IRON AND MANGANESE IN POTATO TUBERS TREATED WITH BIOSTIMULATORS AND THEIR NUTRITIONAL VALUE

MYSTKOWSKA, I.

State School of Higher Education, Biała Podlaska
Sidorska 95/97, 21-500 Biała Podlaska, Poland
(e-mail: imystkowska@op.pl)

(Received 30th Jun 2018; accepted 6th Sep 2018)

Abstract. The aim of the study was to evaluate the content and nutritional value of iron and manganese in edible potato tubers. Field experiments were carried out in 2015-2017 with the use of biostimulators on the individual farm in Międzyrzec Podlaski, Poland. The experiment was based on the random split-plot method. The influence of two factors was examined. The first row factor included three varieties of edible potato: Honorata, Jelly, Tajfun, and the second row – five methods of using biostimulators: Kelpak SL, Titanit, GreenOk, BrunatneBio Złoto Cytokininy, potato plants sprayed with distilled water were the control object. Potato plants were treated three times with biostimulators (at the beginning of flowering, at full flowering and after plant flowering). The high amount of rainfall in 2017 contributed to the increase of iron and manganese content in potato tubers. Plant tubers treated with the BrunatneBio Złoto Cytokiny preparation were characterized by the highest content of iron and manganese in comparison to plants from the control object. Titanite reduced the content of manganese and iron in tubers. The content of micronutrients in tubers was significantly differentiated by the genotype of the variety. The highest Mn concentration was found in the Jelly tubers, Fe in the Honorata variety. The average content of manganese was 4.4 $mg \cdot kg^{-1}$, and iron 43.5 $mg \cdot kg^{-1}$, which covers the demands in 1.7 and 5.5% per day, respectively.
Keywords: *edible potato, minerals, nutritional value, bioregulators*

Introduction

Nutritionists encourage an increase in the consumption of potato (*Solanum tuberosum* L.) tubers due to low caloric value and high nutritional and dietary values. The calories cooked potato (50-90 kcal per 100 g) slightly exceeds the energy value of apples (54 kcal per 100 g) or milk (62 kcal per 100 g), it is also three times smaller than wheat bread's (275 kcal per 100 g) and seven times smaller than chcolate's (540 kcal per 100 g) (Kunachowicz et al., 2010). This plant also provides a number of valuable nutrients, such as: carbohydrates, proteins, vitamins (C, B_1, B_2, PP, B_6), minerals (K, Mg, Fe, Cu, Mn, J), dietary fibre (Lutaladio and Castaidi, 2009).

The nutritional value of potato tubers, in addition to protein, carbohydrates and vitamins, is also determined by the content of minerals that after digestion and absorption into the blood are used by the body as a building block or a factor regulating life processes (Żechałko-Czajkowska, 1992; Spiak, 2000; LAW ON food and Nutrition Safety, 2009). Potato tubers contain 1-1.2% of minerals. Minerals are those components which remain in the form of ash after burning. In order for the human body to function properly, it must receive all necessary nutrients from outside, including minerals. Microelements control enzymatic processes, the largest amount (73-79%) comes from manure (Kaniuczak et al., 2009). In modern agriculture, more and more attention is paid not only to the amount of harvested crop, but also to its quality. According to Czuba (2000), the content of micronutrients in the crop yields is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_66336641
© 2018, ALÖKI Kft., Budapest, Hungary

an important agrotechnical issue, as well as an important quality feature assessed according to consumption and feed criteria. For this purpose, in addition to pesticides, a number of preparations are used as plant development regulators or biostimulators (Maciejewski et al., 2007). Biostimulators control mineral metabolism, increase the plant's resistance to stressful environmental conditions (Sawicka and Mikos-Bielak, 2002; Wierzbowska et al., 2015; Papenfus et al., 2013; Panda el al., 2012), as well as increase resistance to attacks of diseases and pests (Grzyś, 2012). Several authors have demonstrated the effect of acid pH < 5.5 on increasing the availability of manganese and iron in it (Prośba-Białczyk and Mydlarski, 2000; Rogóż, 2009). Iron participates in the process of photosynthesis and nucleic acid metabolism, stimulates the formation of chlorophyll, participates in the reduction of nitrates and the binding of free nitrogen, and regulates oxidation-reduction reactions. Manganese is involved in oxidation-reduction processes, photosynthesis, decarboxylation and binding of free nitrogen (Kabata-Pendias and Pendias, 1993; Zarzecka, 2004). The aim of the article is to examine the effect of biostimulators on the content of manganese and iron in potato tubers and to assess the nutritional value of the selected minerals.

Materials and methods

The experimental site

Potato tubers from a field experiment carried out in 2015–2017 in an individual farm in Międzyrzec Podlaski, Poland were the material for testing. The experiment was established in triplicate using the random split-plot method, on the soil included in the very good rye complex, class IVA. In individual years of research, soils differed in the content of organic matter and absorbable macro-elements. In 2015 and 2016, the soil was characterized by slightly acidic reaction, and in the last year of research, alkaline. The content of organic matter ranged from 15.0 to 18.7 g/kg. The content of absorbable phosphorus (P) was from high to very high, potassium (K) from medium to very high, and magnesium (Mg) was high. The first factor was three moderately early varieties of edible potato: Honorata, Jelly and Tajfun, and the second one, four types of biostimulators used in three dates (beginning of flowering, fully flowering and after flowering of plants):

1. Control object – without the use of biostimulators spraying with distilled water
2. Biostimulator Kelpak®SL (active substance – *Ecklonia maxima* algae extract) containing plant hormones: auxin – 11 mg/l and cytokinin – 0.031 mg·l, at a dose of 0.20 $L \cdot ha^{-1}$
3. Biostimulator Tytanit® (active substance – titanium) at a dose of 0.20 $L \cdot ha^{-1}$,
4. Biostimulator GreenOk® (active substance – humus substances 20 g/l) at a dose of 0.20 $L \cdot ha^{-1}$
5. Biostimulator BrunatneBio Złoto (active substances – plant hormones: auxin – 0.06 mg·l and cytokinin – 12 mg·l,) at a dose of 0.20 $L \cdot ha^{-1}$

The forecrop for potato in particular years of research was winter wheat. After harvesting the forecrop, a team of post-harvest crops was made. In autumn, each year preceding planting, natural fertilization in the form of manure in the amount of 25.0 $t \cdot ha^{-1}$ and mineral fertilization with phosphorus-potassium in the amount of P – 44.0 (100 $P_2O_5 \cdot 0.44$) kg/ha (lubofos for potatoes 7%) and K – 124.5 (150 $K_2O \cdot 0.83$)

© 2018, ALÖKI Kft., Budapest, Hungary

$kg \cdot ha^{-1}$ (lubofos for potatoes 25%) was applied. These fertilizers were plowed pre-season plowing. Nitrogen fertilizers were sown in the spring in an amount of N 100 kg/ha (nitro-chalk 27%) and mixed with the soil using a cultivator. Potatoes were planted manually under the marker at a spacing of 67.5 × 37 cm, in the third decade of April (2015, 2016, 2017). Each plot consisted of five ridges. Cultivation and care treatments were carried out in accordance with the requirements of correct agrotechnics and methodological assumptions of the experiment. Prior to harvest, random samples of tubers were collected from each plot and used for chemical analysis and assessment of consumption-related characteristics of the tubers.

Chemical analysis methods

Weight of about 0.2–0.3 g of sample was transferred to the PTFE vessel and HNO_3 and HCL was added, 3:1 respectively. The vessels were placed in the rotor and loaded to the microwave. The following digestion program has been used:

Step 1 – 10' at 350 W

Step 2 – 35' at 650 W

Step 3 – cooling and ventilation

Mineralized samples were transferred to the 50 ml flasks through filtering paper and diluted with ultra-pure water.

Samples were examined with SpectroBlue ICP OES spectrometer at the Regional Research Center for Environment, Agricultural and Innovative Technologies, Pope John II State School of Higher Education in Biała Podlaska. Analytical curves were built by diluting Bernd Kraft Der Standard Spectro Genesis ICAL Solutions and VHG SM68-1-500 Element Multi Standard 1 in 5% HNO_3. Operating parameters for ICP OES instrument: coolant flow: 12 l/min; auxiliary flow: 0.90 l/min; nebulizer flow: 0.78 l/min; pump speed: 30 Rpm; number of measurements: 3.

Meteorological conditions

The weather conditions in the potato growing years were shown by precipitation sums and average air temperatures in *Table 1*.

Table 1. *Weather conditions during of potato vegetation*

Years	Months						April-September
	April	May	June	July	August	September	
Air temperature (°C)							
2015	8.2	12.3	16.5	18.7	21.0	14.5	15.2
2016	9.1	15.1	18.4	19.1	18.0	14.9	15.8
2017	6.9	13.9	17.8	16.9	18.4	13.9	14.6
Multiyear mean 1996-2010	8.0	13.5	17.0	19.7	18.5	13.5	15.0

The growing season of 2015 proved to be an average air temperature of 15.2 °C, 0.2 °C higher than the long-term average and precipitation at 295.1 mm. The highest average air temperature was recorded in 2016 and amounted to 15.8 °C, it was higher than the long-term average by 0.8 °C, while this year was characterized by the lowest amount of precipitation – 200.9 mm, lower by 134.5 mm from the long-term sum. The highest number of rainfall was recorded in the growing season of 2017 – 325.4 mm and the lowest average air temperature -14.6 °C (*Table 1*).

Statistical analysis

Results of the study were analysed by ANOVA. Significance of sources of variation was checked with the Fisher-Snedecor test and the significance of differences between means was tested using the multiple comparison Tukey's test at the significance level of P = 0.05. Statistical calculations were performed in Excel using the authors' own algorithm based on the split-plot mathematical model.

Results and discussion

The average iron content in tubers was 43.5 $mg \cdot kg^{-1}$ d.m., ranging from 41.5 to 46.4 $mg \cdot kg^{-1}$ (*Table 2*). The research shows that the genetic factor had a significant effect on the iron content in potato tubers. The variety that contained the most of this ingredient was the Honorata variety, followed by Tajfun and Jelly. The influence of varietal properties on iron content is emphasized by Leszczyński and Lisińska (1986), Mikos-Bielak and Sawicka (1992), Gąsior (1996), as well as Sawicka (1996). Among the biostimulators used in the experiment, only the BrunatneBio Złoto biostimulator significantly increased the iron content in the tubers of the tested varieties. The factor that also significantly modified the content of the analysed component were the hydrothermal conditions prevailing during the years of research. High content of iron was found in tubers harvested in 2017 in which the sum of rainfall was 124 and 30 mm than in 2016 and 2015, respectively (*Table 1*). The problems of biostimulators on mineral content in potato tubers were investigated by Wierzbowska et al. (2015). When analysing the effect of Asahi SL, Bio-Algeen S90 and Kelpak SL biostimulators, the authors showed that the iron content in tubers was significantly modified only by the Kelpak SL biostimulator. The opposite direction of changes in iron content was observed by the authors in relation to the Bio-Algeen S90 biostimulator. In the light of the presented research, it should be stated that the iron content in tubers depends on the type of biostimulator and the mechanism of its impact on plants and on hydrothermal conditions. The large amount of rainfall caused that the potato tubers accumulated twice as much iron as in the remaining years. Lombardo et al. (2014) and Griffiths et al. (2012) found that the "mineral profile" can be influenced by the cultivation system. Lipiński et al. (2006) in their research proved that higher soil pH and higher humus content causes iron reduction. Iron affects the proper functioning of the circulatory system, participates in the synthesis of haemoglobin and in the oxidation and delivery of oxygen to tissues (Błoniarz et al., 2005). It is part of cytochrome oxidase, peroxidase and catalase enzymes (Jędrzejczak, 2004). The iron content in potato tubers treated with biostimulators was on average 43.5 $mg \cdot kg^{-1}$ d.m., and the daily norm of this element is 8 mg according to the recommendations of the Academy of Food Science and Nutrition in the USA (Wierzbicka, 2012). Consumption of 100 grams of potatoes covers the daily demand

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_66336641
© 2018, ALÖKI Kft., Budapest, Hungary

for iron in approx. 5.5% of the daily requirement (*Table 3*). The established iron content in potato tubers corresponds to the research of: Prośba-Białczyk and Mydlarski (2000), Rogóż and Trąbczyńska (2009), Sawicka and Mikos-Bielak (2008), Różyło and Pałys (2006), Wierzbicka (2012), Wierzbicka and Trawczyński (2011) and Wierzbowska et al. (2015), who fund iron content in potato tubers from 26.9 $mg \cdot kg^{-1}$ - 91.85 $mg \cdot kg^{-1}$ d.m., while Kabata-Pendias and Pendias (1993) considered 21-58 $mg \cdot kg^{-1}$ of dry matter as the optimal content, while Ostrowska et al. (1991) estimate that the content of this element in potato is 93-188 $mg \cdot kg^{-1}$ of dry matter. The correct ratio of iron to manganese in feeds is assumed to be 2.5:1 (Rogóż, 2009). If it is larger, manganese deficiency is likely (Wierzbicka, 2012; Wierzbowska et al., 2015). In the tests carried out, the ratio was 10:1, which indicates a deficiency of manganese. The content of manganese in tubers treated with biostimulators was on average 4.4 $mg \cdot kg^{-1}$ d.m., which with demand of 1.8-2.3 (Wierzbicka, 2012) per 100 g of tubers realizes the demand for this component in the range of about 1.7% (*Table 3*). The studies carried out show that varietal features were the dominant factor that influenced the formation of manganese content in potato tubers (*Table 4*). The variety that contained the most of this ingredient was the Jelly variety. The observed interaction between the varieties and the years proves the individual reaction of the varieties to the weather conditions in the research years. The highest average manganese content was obtained in the Jelly and Tajfun varieties in 2017 (with the highest rainfall total). Tubers originating from objects treated with biostimulators in relation to the control object were characterized by a significantly higher content of manganese. The content of manganese in tubers was significantly modified by the BrunatneBio Złoto biostimulator. The applied biostimulator reacted to the atmospheric conditions in the years of research as indicated by the object x years interaction. The BrunatneBio Złoto biostimulator caused a significant increase in manganese content in 2017, which turned out to be wet and cold. The level of manganese content in potato tubers in the conducted experiment coincides with that given by other authors – 3.6-15 $mg \cdot kg^{-1}$ of dry mass (Kabata-Pendias and Pendias 1993; Sawicka, 1996; Sykut et al., 1998). In the studies by Mikos-Bielak (1999), the upper limit of the range was exceeded twice, and in Kucharzewski et al. (2002) almost ten times. The Mn concentration of approx. 500 $mg \cdot kg^{-1}$ of dry mass is toxic for most plants (Kucharzewski and Dębowski, 2001). It should be emphasized that Fe and Mn accumulate mainly in the outer layer of the potato tuber, so their excess can be removed by peeling (Mikos-Bielak, 1999). In the research conducted by Wierzbicka and Trawczyński (2011), the average contents of micro-elemenys in the tubers of organic potatoes were equal to: Fe-46.9; Mn-7.3 $mg \cdot kg^{-1}$ d.m. The spatial distribution of minerals in potato tubers is not even (Subramanian et al., 2011; Petryk and Bedla, 2010; Srek et al., 2012). According to Zarzecka (2004), some herbicides cause an increase in manganese in potato tubers. Kaniuczak et al. (2009) found in their research that liming reduces the content of manganese, and mineral fertilization increases the content of Mn in potato tubers. Manganese performs important functions in the plant. It takes part in the process of photosynthesis, the transformation of nitrogen compounds in the plant and in the biosynthesis of vitamin C (Jędrzejczak, 2004). It influences the uptake of phosphorus and iron from the soil. Manganese deficiency in potato delays plant development. In humans, it is responsible for the absorption of vitamins, the formation of connective tissue and bones, metabolism of carbohydrates, lipids and normal brain function (Wierzbicka, 2012).

Conclusions

The content of iron and manganese in potato tubers was significantly differentiated by the genotype of the variety. The highest concentration of Mn was found in the Jelly variety tubers, and of iron in the Honorata variety tubers. Tubers of plants treated with the BrunatneBio Złoto Cytokiny preparation were characterized by the highest content of iron and manganese. Weather conditions, particularly the high amount of rainfall in 2017, contributed to the increase of iron and manganese in potato tubers.

Abstract. Urbanization is only a carrier of human activities, and it does not directly affect carbon emissions. Based on the essential relationship of carbon emissions and urbanization, and summarizing the shortcomings of the present research methods, this paper first classifies the degree of urbanization in China by using the multi-index cluster analysis method based on panel data, and then analyzes the influence factors of carbon emissions by the STIRPAT model for different urbanization levels. The results show that the elasticity of factors affecting carbon emissions is quite different under different urbanization levels. The conclusion is that the policy of reducing emissions should be different for different levels of urbanization. Differentiated emission reduction policies are necessary for a vast China.
Keywords: *classification of urbanization, factors of carbon emission, STIRPAT model, entropy weight, multi-index cluster analysis*

Introduction

At present, the greenhouse effect has seriously affected the global climate and has become a serious obstacle in the process of human social development, and carbon dioxide is the most important component of greenhouse gases, and its contribution to the greenhouse effect is more than 60%. It can be seen that the excessive emission of carbon dioxide is the main reason for the greenhouse effect.

Scholars have started a lot of work around the causes of excessive carbon dioxide emissions. They have analyzed the possible factors, including economic growth, income level, industrial structure and so on, and the degree of urbanization is also regarded as an important factor. However, in most of the research work, "urbanization" is regarded as an explanatory variable into the model, which is a one-sided approach. In essence, the extent of carbon emissions depends on changes in human activities. Urbanization is a carrier of changes in human activities, affecting human activities, but it does not directly affect carbon emissions.

Based on the essential relationship between carbon emission and urbanization and the shortcomings of current research methods, the degree of urbanization in China is classified by using the multi-index cluster analysis method based on panel data. The influence factors of carbon emissions are analyzed through the STIRPAT model, and it is found that under different levels of urbanization, the influence of various factors on carbon emissions is quite different. The conclusion is that for provinces and cities with different urbanization levels, the emission reduction policy should be different, and for a vast China, differentiated emission reduction policies are very necessary.

Basic conception

First of all, the scientific connotation of "urbanization" should be clarified. Cities and towns are only one of the geographic carriers of human activities where people form unique production mode, consumption mode and social mode. In a narrow sense, urbanization is a process of increasing urban population. However, urbanization in a broad sense is a trend of gradual change from a traditional rural society dominated by agriculture to a modern urban society dominated by industry and service industries. It includes the changes in the occupation of the population, the transformation of the industrial structure, and the changes in land and geographical space (Lu, 2007). Urbanization is not only a simple migration of rural population to towns, but also a change in social structure (Poumanyvong and Kaneko, 2010). This is a dynamic process, manifested in the transformation of people in the geographical space of towns and villages. Therefore, using only the proportion of urban population does not fully describe the degree of urbanization.

The level and speed of urbanization are affected and restricted by the socio-economic environment and the natural environment. As Knox and McCarthy (2011) pointed out, "Urbanization is the interaction of a variety of factors, including economic, demographic, political, cultural, technological, environmental, and social, and it is also influenced by two kinds of contingency factors, such as geographical location and historical reasons."(Paraschiv, 2012). Therefore, in different countries and regions, the level and speed of urbanization show great differences.

Urbanization also plays an important role in ecological and social activities, making the natural environment and social environment change. These effects are positive and reverse. On the one hand, urbanization has brought about the increase of urban population, aggravated social and economic activities, resulting in greater demand for energy. At the same time, congested traffic brings congestion on the road. These two factors will cause serious air pollution and waste discharge. On the other hand, urbanization has produced an "agglomeration effect", which has concentrated the scope of social and economic activities and increased public transport at the same time. This can effectively reduce carbon emissions from commutes. Towns and cities are often centers of technological innovation, new technologies and new industries. The birth of these products can often increase production efficiency and reduce unit energy consumption, which can also effectively reduce carbon emissions.

Literature review

There is a correlation between urbanization and carbon emissions, which has become the consensus of researchers and policy makers. A large amount of research work has focused on the impact of urbanization on carbon emissions. If the impact of urbanization is neglected in the prediction of CO_2 emissions and the formulation of energy and environmental policies, the model's forecast results and the effect of the implementation of policies will be seriously affected, and even result in a deviation in the direction of work (Sadorsky, 2014).

The ecological modernization theory founded by Joseph Huber and Martin Jänicke in Germany in the early 1980s pointed out that the ecological environment is inevitably affected by socio-economic activities, and that can be transformed from negative to positive in the process of economic development and social system transformation. Specifically, excessive carbon emissions are unavoidable in the primary and secondary

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_66436654
© 2018, ALÖKI Kft., Budapest, Hungary

stages of development. However, with the further advancement of modernization, the improvement of social environmental awareness, the innovation and application of environmental protection technologies, the scientific nature of urban planning and the adjustment of industrial structure, these factors will all contribute to the reduction of carbon emissions. Sun et al. (2013) studied the total carbon emissions of 76 countries and regions from 1980 to 2007, examined the relationship between the dynamic evolution of urbanization and carbon emissions, and verified the rationality of ecological modernization theory.

The theory of urban environmental change has put forward the opposite view, which is established on the base of a series of researches (Bartone et al., 1994; Lee, 1994; McGranahan et al., 1996; Pugh, 1996; Satterthwaite, 1997). McGranahan (2000) summed up these research results and developed this theory (Marcotullio and Lee, 2003). From the perspective of urban development, these scholars point out that the environmental problems faced by cities are different at each stages of development. Only in the middle and later stages of urban development can carbon emissions become one of the main problems of urban environment.

The problem of urban density was originally concerned by architecture and urban planning. When economists are involved in this field, how urban density affects environmental changes and energy consumption has become an interesting and practical topic, which has evolved a compact city theory. Most scholars supported the idea that compacting cities can bring environmental benefits. They believe that compact cities can bring about the scale effects of urban public facilities such as public transportation, public education and water supply. At the same time, compact cities can also reduce the use of private cars, shorten travel distances, and reduce losses in the power supply, thereby reducing energy consumption and CO_2 emissions. However, some other critics pointed out that compact cities are more likely to cause new problems such as traffic jams and urban heat island effects, resulting in increased CO_2 emissions (Gaigné et al., 2012).

Although the impact of urbanization on carbon emissions has become an important research area for urban economics, in most research work, the level of urbanization is simply measured by the proportion of urban population, and directly enters the model as an explanatory variable (Shahbaz et al., 2016; Yang et al., 2018), which does not accurately portray the true relationship between urbanization and carbon emissions. First, urbanization embodies a comprehensive process of change, and it is not enough to measure only the proportion of urban population. Secondly, using the urbanization level as an explanatory variable directly into the analysis model does not meet the true relationship between the two. The impact of urbanization on carbon emissions plays a role through human activities, and urbanization itself does not have a direct impact on environmental change.

The lack of research has attracted the attention of a few researchers who have put forward new ideas for research. Chikaraishi pointed out in the 2015 study that the relationship between urbanization and environmental change can be described by two relationships: indirect effect and moderating effect. He expressed the two effects by functions as follows: $y = f(\beta, x(z))$ and $y = f(\beta(z), x)$, where y indicates environmental change, x indicates human activity, z indicates urbanization degree, and β indicates the influence of human activities on environmental changes. In the two functions, the former indicates that the explanatory variables (human activities) are influenced by the degree of urbanization, and the latter indicates that the degree of

© 2018, ALÖKI Kft., Budapest, Hungary

urbanization affects the elastic coefficient of human activity - environmental change. And the above three modern urban environmental theories have realized that the impact of urbanization on the environment may have both positive or reverse effects, which means that when the mathematical model determines that urbanization does not have a significant impact on environmental changes in statistical sense, it is in fact possible that the positive and negative effects of urbanization on environmental change are comparable.

Research on carbon emission according to urbanization distiguish based on STIRPAT model

As mentioned earlier, urbanization does not directly affect carbon emissions. People's social and economic activities are the direct cause of carbon emissions. In the process of urbanization, as people's agglomeration activities increase, their social and economic pattern also change, which in turn has a further impact on carbon emissions. Furthermore, in areas with different levels of urbanization, people's socio-economic pattern is naturally very different, and there is a huge difference in the level of carbon emissions among regions.

China has a vast territory with significant difference in social and economic development level among different regions. In order to make a scientific research on the influence factors and the impact of carbon emissions all over the country, a carbon emission difference analysis model based on the urbanization level is established in this paper.

STIRPAT model and its extension

STIRPAT (Stochastic Impacts by Regression on Population, Affluence, and Technology) model is a random model developed from the IPAT equation and has become the most classic model for conducting environmental impact assessments. A large amount of research work is based on it whose function expression is $I_i = aP_i^b A_i^c T_i^d e_i$ (Dietz and Rosa, 1997), where, I, P, A and T respectively denote environmental impact, population, wealth and technological level. The subscript i represents each observation object. The parameter a is regarded as a constant. b, c and d determine the influence of three factors, population, wealth and technology, on the environment, respectively. The residual item e represents the social structure, system and culture that can affect the environment, and other factors that can affect human activities. In explaining the model, technology includes not only the technology itself, but also the social structure, the system, the culture, and all the other factors that can affect human activities. In practical research, STIRPAT models usually appear in logarithmic form for parameter estimation and hypothesis testing.

Based on the STIRPAT model, a series of extensions and modifications on the model can be made. First, the STIRPAT model can add other relevant factors as explanatory variables into the model, among which population structure, urbanization level and industrial structure level are the most frequently introduced variables. Maruotti (2011) and York et al. (2003) considered the variable "proportion of people between 15-65 years old" in the model. Maruotti (2011), York et al. (2003), Zhang (2013), Sadorsky (2014), Poumanyvong and Kaneko (2010), Wang et al. (2016) took into account the influencing factor of urbanization level. Second, the dummy variable can be added to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_66436654
© 2018, ALÖKI Kft., Budapest, Hungary

the STIRPAT model. The parameters of the dummy variable in the model do not indicate the effect on the environmental change. The "year dummy variable" and "country dummy variable" are two common dummy variables with which the researchers distinguish the impact elasticity of carbon emissions in different years or different countries (Poumanyvong and Kaneko, 2010; Zhang et al., 2013). York et al. (2003) introduced the dummy variable "Whether the subject is in the tropics" to assess the impact of tropical regions on environmental changes. Third, the quadratic term and multiple items can also be added to the model to build nonlinear relationships between variables, which can sometimes make the model more realistic. For instance, Dietz and Rosa (1997) added a quadratic item to the population in an attempt to prove that the environmental changes and population changes are nonlinear, while York et al. (2003) added the quadratic form of per capita GDP.

Classification of urbanization level

China has a vast area and great differences in regional development. Therefore, it is necessary to classify and discriminate the urbanization status.

Population urbanization and land urbanization are two aspects of the process of urbanization. In measuring the level of urbanization, the two factors of population urbanization and land urbanization level have been comprehensively considered in this paper. Regarding the urbanization level of the population, this paper adopts the indicator of "the ratio of urban population to total population" in accordance with international practice. The research work on the level of land urbanization should include the integration of land urbanization of city and established towns. According to the stipulations of the *Regulations for the Statistical Division of Urban and Rural Areas* and the *National New Urbanization Plan (2014-2020)*, the township is an important part of the scope of urbanization. At present, a large number of research work limit the scope of the inspection targets to urban areas, for example, Bai Xianchun used the land index of urban area when adjusting land factors for urbanization level (Bai, 2004) and other scholars use the area of urban built-up areas to conduct research on land factors (*Table 1*). In this paper, the urban and the designated town built-up area are summed up to obtain the urban built-up area, which is used to describe the level of land urbanization. The specific formula is as *Equation 1:*

$$\text{Land urbanization level} = \frac{\text{urban built} - \text{up area} + \text{designated town built} - \text{up area}}{\text{land survey area}} \quad \text{(Eq.1)}$$

Table 1. *Composition and data sources of urbanization classified index*

Urbanization rate	Urban built-up area	Designated town built-up area	Land survey area
%	sq.km	sq.km	Ten thousand hectares
China Statistical Yearbook	China Statistical Yearbook	Statistical yearbook of urban and rural construction in China	China Statistical Yearbook

In this paper, lessons are drawn from the multi-index cluster analysis method of panel data based on entropy weight algorithm designed by Zheng Dachuan in 2016 to classify the level of urbanization. The specific steps are as follows:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_66436654
© 2018, ALÖKI Kft., Budapest, Hungary

- Measurement of entropy weight of index (*Table 2*). In this paper, the most commonly used discrete degree statistics namely the standard deviation coefficient $CV_{nk} = \sigma_{nk} / \mu_{nk}$ is used to get the entropy weight result.

Table 2. *Entropy weight of each urbanization index*

Index *k*	Level of population urbanization	Level of land urbanization
Entropy weight α_k	0.6113	0.3887

- The Euclidean distance is used to calculate the individual distance of each index D_k separately.
- The full distance of individual is calculated as:

$$D = \sum_{k=1}^{K} \alpha_k D_k \quad \text{(Eq.2)}$$

- Based on *Equation 2,* the type distance measurement is carried out by the sum of squares of deviations (Ward method), and the type of the sample is divided.

According to the results of hierarchical cluster analysis, the level of urbanization in the whole country can be divided into four categories:

- Category I: Beijing, Tianjin, Shanghai
- Category II: Liaoning, Guangdong, Jiangsu, Zhejiang
- Category III: Shanxi, Ningxia, Shaanxi, Jilin, Hubei, Hainan, Shandong, Inner Mongolia, Heilongjiang, Fujian, Chongqing, Hebei, Hunan, Jiangxi, Anhui, Qinghai, Henan, Guangxi, Sichuan and Xinjiang
- Category IV: Guizhou, Yunnan, Gansu

Variable and data selection

Carbon emission accounting

The carbon dioxide emission level is measured according to the terminal consumption of primary energy on the regional energy balance. In this paper, the total CO_2 emissions from the 16 main energy sources are used as the accounting results of carbon emissions (*Table 3*).

Table 3. *The CO_2 emission coefficient of 16 energy sources (Ren, 2014)*

Energy source	Raw coal	Cleaned coal	Other coal washing	Coal briquette	Coke	Coke gas	Blast furnace gas	Other gases
Carbon dioxide emission coefficient (kg-CO_2/kg or kg-CO_2/m^3)	1.9003	2.2829	0.7247	1.7622	2.8604	0.8469	0.1636	0.7091

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

Energy source	Crude oil	Gasoline	Kerosene	Diesel	Fuel oil	Liquefied petroleum gas	Refinery dry gas	Natural gas
Carbon dioxide emission coefficient (kg-CO_2/kg or kg-CO_2/m^3)	3.0202	2.9251	3.0179	3.0959	3.1705	3.1013	3.0119	2.1622

Population

In the current research work, the indicators of population variables are usually expressed in terms of total population (Othman and Jafari, 2016; Yang et al., 2018). Some researchers have joined the total number of working age population. This paper holds that population density is an important factor affecting urban carbon emissions, and a higher population density will affect the degree of urban traffic congestion and have a negative impact on carbon emissions. On the other hand, high population density can promote efficient planning of the urban system and bring convenience to people's travel activities. Therefore, in this study, for the population influencing factors described, in addition to the total population, the population density index was specifically added[1].

Treasure

For the factor on wealth in STIRPAT model, almost all research work is described by GDP capita (Dietz and Rosa, 1997; Poumanyvong and Kaneko, 2010; Rozanov et al., 1990), so does this paper. In order to eliminate the interference of inflation, the description of wealth in this paper especially adopts the actual GDP after deducting the price effect according to the GDP index.

Technology

Energy intensity = total energy consumption / GDP, which represents the amount of energy consumed per unit of GDP produced. The greater the value, the lower the technical level. The greater the value of energy intensity, the greater the amount of energy consumed per unit of GDP, which indicates that GDP production is more dependent on energy consumption rather than technological progress; on the contrary, it means that the higher the technological level of wealth creation, the less energy consumption can provide more output.

Analysis of the factors of carbon emissions

The principle of estimation of panel data model is included two categories: fixed effect and random effect among which the random effect RE model is the individual effect model: $y_{it} = x'_{it}\beta + (\alpha_i + \epsilon_{it})$. For a given i, the mixed error term$\mu_i = \alpha_i + \epsilon_{it}$ is related to different t, that is, $\mathrm{Cov}(u_{it}, u_{is}) = \delta_\alpha^2/(\delta_\alpha^2 + \delta_\varepsilon^2)$, for all s≠t.

[1] Population density = total population / total area, usually taking the unit of "person/km^2". In model building, we perform natural logarithm transformation on all variables to reduce the influence of heteroscedasticity. However, the population density of Qinghai Province is less than 1 in all years and cannot be converted logarithmically. Therefore, in the research process of this paper, the unit of population density is taken as "person/10 km^2".

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_66436654
© 2018, ALÖKI Kft., Budapest, Hungary

For regional economic analysis, it should be considered that there is a random effect for a certain region in a continuous period. That is to say, there is correlation between error items at different time points. This development correlation is determined by the inertia of regional social and economic development and the invariance of basic development conditions. Therefore, even if the Hausman test refuses the original hypothesis of the RE model in statistical sense, we still use the random effect model to classify the regional carbon emissions.

Based on the results of the classification of urbanization level in the whole country, the panel data analysis of four categories of provinces was conducted based on random effects in this paper. At the same time, in order to illustrate the necessity of categorical analysis, the national data are specifically estimated by a non-classified random effects model. It is easy to see from *Table 4* whether classifying the level of urbanization has a great influence on the estimation result of the model.

Table 4. *Comparison of estimation results based on random effects model*

	Nationwide	**Category I**	**Category II**	**Category III**	**Category IV**
Ln (total population)	-0.1735	-0.9151	-0.5975	-0.2696	-0.2092
Ln (population density)	0.0038	0.2690	0.1324	0.1157	0.1067
Ln (actual GDP)	1.1556	1.3660	1.5469	1.1394	0.8654
Ln (energy intensity)	1.2528	1.6169	1.8601	1.1691	0.84224

When estimating over the entire country, the total population and the total carbon emissions are inversely related. When the total population increases by one percentage point, CO_2 emissions fall by 0.17%. The population density elasticity of carbon emissions is almost zero, only 0.003%. The GDP elasticity and energy intensity elasticity of carbon emissions are positive, indicating that changes in GDP and energy intensity all over the country will bring about the same direction of CO_2 change.

According to different levels of urbanization, the elasticity of each variable of CO_2 and the estimation of the entire country are the same under different levels of urbanization, which indicates that there is no difference in the basic direction of urbanization between different levels of urbanization. However, in terms of elasticity, there is a great difference according to the level of urbanization.

Under the background of rapid urbanization, people's awareness of the impact of carbon emissions is growing. With the increase of population, the emission of CO_2 is decreasing, while with the improvement of urbanization level, the population elasticity of carbon emissions is increasing progressively. As the first category, the three largest cities of Beijing, Tianjin and Shanghai have the largest population elasticity of carbon emissions, and when the population increases by 1%, CO_2 emissions also drops by nearly 1%. In the third and fourth category provinces with lower urbanization level, the population elasticity of CO_2 is 0.26% and 0.21% respectively. China has become the world's second largest economy today. In China, the level of urbanization has also been greatly improved. At the same time, people's awareness of environmental protection has also been improved. The higher the level of urbanization, the deeper people's understanding of the hazards of carbon emissions, they are also more motivated to take measures to strictly control the impact of population increase on CO2 emissions. However, this does not prove the same conclusion under all conditions. In poor

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_66436654
© 2018, ALÖKI Kft., Budapest, Hungary

countries or regions, people's awareness of environmental protection is low, but the increase in population is likely to lead to an increase in carbon emissions.

The impact of population density on carbon emissions shows a positive effect at all levels of urbanization. That is, regardless of the level of urbanization, the total carbon emissions will increase correspondingly with the increase in population density, and the degree of increase will decrease with the urbanization level. In the first category of cities with the highest level of urbanization, if the population density increases by one percentage point, CO_2 emissions increase by 0.26%; with urbanization levels gradually decreasing, the population density elasticity of CO_2 is 0.13%, 0.11% and 0.106% in order, indicating urban congestion caused by urbanization is a positive factor affecting CO_2 emissions. Regardless of the level of urbanization, the road traffic planning and population distribution planning at this stage can not effectively reduce CO_2 emissions.

With the continuous growth of the regional economy, the resulting economic activities, such as production, sales, transportation and service, have also increased, resulting in the increase of CO_2 emissions, which is also verified in the model's estimation results. In particular, the growth of CO_2 emissions from economic growth is more obvious in areas with relatively fast economic development, such as regions in the first and second categories. In this paper, the carbon emissions of real GDP is carried out. In these two types of regions, the real GDP elasticity of CO_2 is 1.36% and 1.54%, respectively, exceeding 1.13% and 0.86% of the third and fourth categories, which shows that in the more economically developed regions, the high-emission secondary industry is still driving economic growth at the current stage; at the same time, higher economic levels have led to a significant increase in people's economic activity, which has led to more emissions. In the regions of the third and fourth categories, the primary industry still accounts for a large proportion, and people's economic activities are not as good as those in developed regions. Therefore, the GDP elasticity of CO_2 emissions is rather small.

Energy intensity reflects the level of energy consumption needed to create a unit of GDP, and its value reflects the production technology capabilities of a region: the higher the numerical value, the lower the technology level; conversely, it represents a higher level of technology. When estimating the energy intensity elasticity of CO_2 emissions, we found that in the economically developed regions, the elastic index value is relatively large, while in the regions where the economic development level is relatively low, the elasticity level is even smaller, which means that in the economically developed regions, because the secondary industry and the tertiary industry are the pillar industries, when the level of production technology is increased and the energy intensity value is reduced, the CO_2 emissions in the region will be significantly reduced, while in regions with relatively backward economies, the proportion of primary industries is still relatively large, so the reduction in CO_2 emissions brought about by the increase in production technology levels is relatively limited.

Conclusions

How to reduce carbon emissions is an important issue in China at the present stage. In the process of in-depth analysis of the factors affecting carbon emissions, it is necessary to classify and study according to the level of urbanization. The discrepancy of urbanization level will inevitably lead to differences in the elasticity of carbon emission factors. Sometimes, the difference is huge. Through the empirical research in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_66436654
© 2018, ALÖKI Kft., Budapest, Hungary

this paper, we can see that there are different policy focuses on measures to reduce total carbon emissions for different levels of urbanization.

For the first and second categories of regions with high level of urbanization, they have something in common in policy-making. First of all, restricting population entry does not bring about a reduction in CO_2 emissions. At the same time, because of the congestion in the core aggregation areas of the population, the increase in population density and the increase in economic activity will all increase CO_2 emissions. Therefore, reasonable and scientific urban development planning and population distribution planning are particularly important. Secondly, the industrial restructuring of these two categories of regions has achieved certain results, but the second industry is still the backbone of their development, so it is necessary to continue to optimize and adjust the industrial structure for the emission reduction work in these two regions. The role of technological progress in reducing CO_2 emissions is quite obvious in these two regions. Therefore, encouraging and supporting the application and innovation of these two regions in technology emission reduction is the key area that the two categories of regional governments should attach importance to.

For the third and fourth categories of regions with relatively low level of urbanization, the conclusion is obvious. First, we see that the population elasticity of carbon emissions is also negative, but its absolute value is obviously smaller than the first two categories, which shows that the urban expansion of the two regions is lower because of the weak economic development, and the capacity of the cities to accommodate the new population is lower than that of the first and the second categories. Therefore, accelerating the healthy development of urban social economy is very necessary for these two categories of regions, otherwise, in the near future, the increase in population may lead to the increase in CO_2 emissions. However, in terms of the population density elasticity of CO_2, these two regions are advantageous because the increase in CO_2 emissions caused by the increase in population density is relatively limited. However, it is still necessary to do a good job in urban planning. Second, the impact of GDP growth on CO_2 emissions in these two regions is also relatively small, which seems to be inconsistent with our usual concept. As a matter of fact, the first industry accounts for a relatively large proportion in the industrial structure of these two categories of regions, so the impact of GDP growth on CO_2 emissions is relatively limited. Moreover, due to income level restrictions, the economic activity of these two categories of regions will be weaker than those of the first and second categories of regions, and will result in less emissions. Similarly, in these two categories of areas, the improvement of technological progress has relatively limited impact on reducing CO_2 emissions. Therefore, for these two regions, it is necessary to pay attention to improving the elasticity of technological progress in carbon emissions while optimizing the industrial structure.

In this paper, an analysis model for carbon emissions based on the level of urbanization is established. Based on the level of urbanization, the carbon emission factors and their impact elasticity under different levels of urbanization are scientifically studied in depth. The results of the study proved that “one size fits all” policy development is unable to adapt to different provinces and cities where actual conditions are not the same. This method can also be applied to other countries or regions or worldwide carbon emission studies. Different levels of urbanization will produce different conclusions. But they all prove a conclusion that it is only feasible to formulate

targeted emission reduction policies based on the actual urbanization level of each province and city and the various factors that affect carbon emissions.

(Received 1st Jul 2018; accepted 13th Sep 2018)

Abstract. Changes in the trend of the total natural light illumination value in Chongqing, China was studied based on solar irradiance data of Chongqing from 1961 to 2010. The overall and inter-annual change trends of annual and monthly total natural light illuminance values were analyzed by Mann-Kendall method, meanwhile the luminous efficacy model was integrated in the analysis of data. The result showed that the basic trend in the change of total illuminance value is due to the reduction of natural light intensity. The change in trend was very obvious, and the alteration occurred in 1974. Monthly total illuminance values in Chongqing had no changed trend in May, in September, in November, a very obvious decreasing trend occurred in January, in July, in August and in December, an obvious trend occurred in February, in April and in October, and a not obvious one in March. At the same time, the annual variation of the total monthly illuminance of natural light fluctuates little in January, in February, in October, in November, and in December, and fluctuates widely in March, in April, in May, in June, in July, in August, and in September. The lowest monthly total illuminance values were observed in January and December, and the highest monthly illuminance values were observed in July and in August. The total natural light illuminance has the highest value in summer, and the lowest value in winter, and a moderate value in spring and in autumn.
Keywords: *solar radiation, luminous efficacy, natural light illuminance, Mann–Kendall method*

Introduction

With shortages of energy resources, it is of great significance to make full use of natural light and pursue ecological and sustainable development. Daylighting climate data are the basis for the application of natural light in buildings; illuminance data are one of the core contents of daylighting climate data. China has obtained illuminance data in a study from 14 cities through two consecutive years of observation of natural light (1983 to 1984) in typical Chinese daylighting climate regions (Wu, 1987a). China was divided into five daylighting climate zones according to natural light distribution and designed daylighting design standards (Wu, 1987a). The International Daylighting Measurement Program (IDMP) was implemented in 1991 to acquire daylighting climate observation data from some cities (including Beijing and Chongqing in China) throughout the world (He et al., 2012). After that, the relevant daylighting climate observation work is basically in a state of stagnation.

As the visible part of solar irradiance, natural light has a close relationship with solar irradiance. Data on solar irradiance are abundant owing to the regular observation project of the meteorological department. Therefore, natural illuminance data can be obtained through solar irradiance. However, luminous efficacy is the key factor in obtaining

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_66556665
© 2018, ALÖKI Kft., Budapest, Hungary

illuminance data from solar irradiance. Luminous efficacy is the ratio of natural illuminance to solar irradiance. Several authors have suggested models to derive the luminous efficacy for different sky condition. Littlefair model, Perez model (Perez et al., 1990), Olseth & Skartveit model, Chung model and Munerer & Kinghorn model (Muneer and Gul, 1998). The starting points and the model structures of these model calculations are different, and the accuracy of different models in different countries and regions is also different (Luo et al., 2011; Wang et al., 2011). Wu (1987a) proposed a monthly and annual luminous efficacy calculation model by combining China's daylighting climate observation data to meet the requirements of daylighting chimate zones and daylighting design. Solar irradiance values throughout the world have changed greatly in recent years as a result of the changing global climate (Zhang et al., 2011), worsening atmospheric pollution (Streets et al., 2008; Wand et al., 2012), and rapid urbanization process (Alpert et al., 2005). Consequently, natural illuminance has also changed (Shen et al., 2008). However, only very few relevant reports examine the changing characteristics and trends of natural illuminance. Since the total illuminance values of natural light varies greatly from year to year, missing values and outliers may occur, the accuracy of ordinary linear regression methods will be affected. The non-parametric test method (Mann–Kendall test method; Kendall, 1975) can reveal the trend of the time series well. It does not require the sample to follow a certain distribution, nor is it subject to a few abnormal values, and does not require statistical analysis. It is suitable for non-normally distributed data and it has been widely used in meteorological research (McBean and Motiee, 2008; Hamed, 2009; Shen, 2010), but it has not applied to analyze the changing natural light illuminance so far. For this reason, in this paper, the Mann–Kendall test method and statistical methods are used to analyze the variation trend of natural light illumination in Chongqing, China.

Chongqing is located in western China, lacking natural light resources, and the use of natural light is particularly important. Therefore, it is necessary to study the natural illuminance of Chongqing to obtain the natural light trend in Chongqing over the years, and then accurately assess the natural light environment in Chongqing. It will provide basic data for the use of natural light, and guide the design and application of natural light.

Data and methods

Although Chongqing has accumulated some annual light climate observation data, more long-term and large-scale light climate observation data are required to understand the changes in Chongqing's daylighting climate. Therefore, it is necessary to use rich irradiance data to obtain illuminance data.

Luminous efficacy model

Irradiance data can be obtained from meteorological observatories, so luminous efficacy K is the key factor in obtaining data on outdoor natural illuminance value. As far as we know (Wu, 1987a; Wang et al., 2011), there are many luminous efficacy models at present. Different models have different model parameters, and their accuracy varies from region to region. How to choose a conversion model suitable for Chongqing is the key to accurately obtain the natural illuminance value. The monthly and annual luminous efficacy model proposed by Wu et al. (1987a) has a relatively high accuracy. Its relevant parameters can be obtained from meteorological observation data suitable for determining daylighting climate characteristics. Therefore, we choose this model as the luminous

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_66556665
© 2018, ALÖKI Kft., Budapest, Hungary

efficacy model. This model was utilized in the present study to obtain natural illuminance values in China. The model considers four factors as parameters. These factors are geographic latitude, altitude, vapor pressure, and sunshine duration. A quaternary simple linear regression equation (*Eq. 1*) was established in this study by integrating annual K values:

$$K_{Gi} = B_i + C_i N + D_i H + E_i \mathrm{e} + F_i S \quad \text{(Eq.1)}$$

In the equation, i is year or month; K_G is the value of annual or monthly luminous efficacy (lx/w·m^{-2}); N is geographic latitude (°); H is altitude (m); e is annual or monthly vapor pressure (hPa); S is monthly for the whole year or monthly average sunshine duration (h); B_i, C_i, D_i, E_i, F_i are equation regression coefficients. The regression coefficients of the equations for the whole year and each month in *Equation 1* can be found in the *Table 1* (Wu, 1987a).

Data sources

Radiation data, geographic latitude, altitude, vapor pressure, and sunshine hours were obtained from the China National Meteorological Information Center. The data of the center was handed by the "Monthly Meteorological Record Monthly Data Report" published by climate data processing departments of Chinese provinces, municipalities and autonomous regions. All data has undergone rigorous quality control and inspection, and the data quality is guaranteed.

There are two meteorological observation stations in Chongqing city, one of which is Chongqing Station and the other is Shapingba station. The two stations are only 10 km apart, and the different in meteorological conditions is extremely small, so the geographical influence can be ignored. The data of Chongqing station are from 1958 to 1986, and the data of Shapingba station are from 1987 to present. In this paper, the solar radiation annual value, monthly value, sunshine hours, geographical latitude, altitude and average absolute humidity in Chongqing from 1961 to 2012 are come from the two meteorological observation stations and selected as the basic data for the study. All data were quality controlled using quality control methods, including climate limit value or

allowance value check, internal consistency check, time continuity check and time series consistency check.

Conversion of annual total illuminance data

The annual or monthly luminous efficacy value of Chongqing under different climate conditions (K_{Gi}) can be obtained with *Equation 1*. Combined with the annual or monthly total irradiance value （E_e） in the region, annual or monthly total illuminance data （E_v） in this region can be calculated with *Equation 2*. The distribution of total illuminance values in Chongqing is shown in *Figures 1* and *4*.

$$E_v = K_{Gi} E_e \quad \text{(Eq.2)}$$

Research methods

Mann–Kendal trend analysis

We suppose that time series (x_1, x_2, …, x_n) has no trend. Statistics S is calculated through the following calculation method (*Eq. 3*).

$$S = \sum_{k=1}^{n-1} \sum_{j=k+1}^{n} \mathrm{sgn}(x_j - x_k) \quad \text{(Eq.3)}$$

where S has a normal distribution, a mean value of 0, and variance of $\mathrm{var}(S) = \frac{n(n-1)(2n+5)}{18}$. The standard calculation method for normal statistics is provided below (*Eq. 4*):

$$Z = \begin{cases} \frac{S-1}{\sqrt{\mathrm{var}(S)}} & S > 0 \\ 0 & S = 0 \\ \frac{S+1}{\sqrt{\mathrm{var}(S)}} & S < 0 \end{cases} \quad \text{(Eq.4)}$$

For a given confidence level α in the bilateral trend test, we suppose that the null hypothesis is unacceptable if $|Z| \geq Z_{1-\alpha/2}$. The time series data exhibit an obvious increasing or decreasing trend at a confidence level of α.

Based on the trend test, Sen's method is insignificantly affected by missing data errors or outliers. Using Sen slope calculate *Q'*, if *Q'* is a positive number, indicating that the data has a growing trend; if *Q'* is a negative number, indicating that the data has a downward trend. We can obtain the slope estimate *Q'* by using *Equation 5:*

$$Q' = \mathrm{median}\left(\frac{x_i - x_j}{i - j}\right) \quad \forall j < i \quad \text{(Eq.5)}$$

where $1 < j < i < n$; median represents the median function.

Mann–Kendall mutation test

We suppose that time series (x_1, x_2, …, x_n) exists. One order series, m_i (Kendall, 1975), is constructed to represent the sample accumulative number of $x_i > x_j$ $(1 < j < i)$. d_k is defined as (*Eq. 6*)

$$d_k = \sum_{i=1}^{k} m_i \quad 2 \le k \le n \tag{Eq.6}$$

The mean value and variance of d_k can be approximately expressed as (*Eqs. 7* and *8*)

$$E(d_k) = \frac{k(k-1)}{4} \tag{Eq.7}$$

$$\mathrm{var}(d_k) = \frac{n(n-1)(2n+5)}{72} \quad 2 \le k \le n \tag{Eq.8}$$

Under the hypothesis that the time series is random and independent, the statistics is defined as (*Eq. 9*)

$$\mathrm{UF}_k = \frac{d_k - E(d_k)}{\mathrm{var}(d_k)} \quad k = 1, 2, ..., n \tag{Eq.9}$$

Given the significance level of α, $|\mathrm{UF}_k| > \mathrm{UF}_{\alpha/2}$ means that the series has an obvious change trend. Tine series x_i is arranged in a reverse order and calculated it with *Equation 7* while ensuring that (*Eq. 10*)

$$\begin{cases} \mathrm{UB}_k = -\mathrm{UF}_k \\ k = n + 1 - k \end{cases} \tag{Eq.10}$$

By analyzing statistical series UF_k and UB_k, the change trend of series x_i can be further analyzed and the mutation time and region can be determined. $UFk > 0$ indicates that the series tends to increase; $UF_k < 0$ indicates that the series tends to decrease. When the series exceed the credibility line, then they exhibit an obvious increasing or decreasing trend. If an intersection point exists between the curves of UF_k and UB_k and falls between the credibility lines, the corresponding time of the intersection point is the starting moment of mutation.

Results

Change trend analysis of annual total illuminance

Based on the series of annual total illuminance values in Chongqing from 1961 to 2010, the statistical values Z obtained through Mann–Kendall trend test method was -3.96. A positive Z value represents an increasing trend, whereas a negative Z value represents a decreasing trend. Absolute Z values equal to or greater than 2.56 indicate that the values passed significance tests with confidence coefficients of 99%. This shows that

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_66556665
© 2018, ALÖKI Kft., Budapest, Hungary

the change trend of the annual total illuminance in Chongqing is decreasing, and the change trend is very obvious. Therefore, the natural annual total illuminance value in Chongqing should be corrected by combining the change trend of the data.

According to the slope (Q') value obtained from the Mann–Kendall trend test (Sen Slope) (*Fig. 1*), the natural annual total illuminance of Chongqing dropped by 2.4×10^8 lx/10a. According to the slope Q' value, compared with the standard value of the natural annual total illuminance in the mid-1980s, the natural annual total illuminance decreases by about 10%. Using the original daylighting illuminance standard value to design will bring greater errors. Therefore, the annual total illuminance standard value of Chongqing should be revised to adapt to the current natural lighting design requirements under current climate conditions in Chongqing.

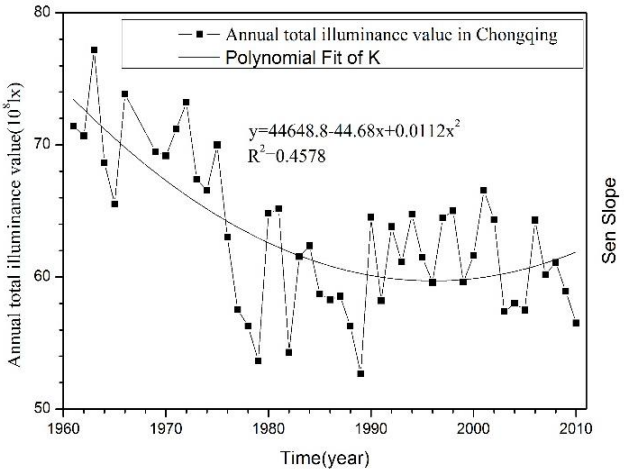

Figure 1. *Changes of annual total illuminance value in Chongqing between 1961 and 2010*

Mutation analysis of annual total illuminance

The annual total illuminance mutation map (shown in *Fig. 2*) of Chongqing was drawn through Mann–Kendall mutation test method. From *Figure 2* we can see that the curves of UF_k and UB_k intersect in 1974, and the intersection point exists between and falls between the credibility lines, the corresponding time of the intersection point is the starting moment of mutation, so the Mutation occurred in 1974. Relevant research findings are also found in other cities in China (He et al., 2013). From *Figure 2* we also find the forward sequence curve (UF_k) is almost below 0. It indicates that the series tends to decrease. The forward sequence curve (UF_k) showed a rapid downward trend after 1974, and passed the 1.96 confidence level critical value. It shows that the decreasing trend became more obvious. After that, the absolute value of statistics in 1979 exceeded 3, and even reached 4.65 in 1989. It shows that the annual total illuminance value of natural light in Chongqing has a very significant downward trend in recent years.

The monthly illuminance distribution and change trend of Chongqing

Total illuminance distribution for each month

Equation 1 is used to calculate the K_{Gi} values for each month of Chongqing from 1961 to 2012, and the monthly illuminance values of each year can be calculated according to *Equation 2*. *Table 2* shows the average value of the total natural light intensity for each

(a) Monthly total illuminance **(b) Monthly sunshine duration**

Figure 3. *Average monthly total illuminance and monthly sunshine duration of natural light between 1961 and 2012*

From *Figure 3* we can see the change trend of the monthly total illuminance in Chongqing is similar to that of the corresponding monthly sunshine duration. The low values of the monthly total illuminance and sunshine duration are observed in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_66556665
© 2018, ALÖKI Kft., Budapest, Hungary

December and in January. The high values are observed in July and in August. In addition, monthly total illuminance and monthly sunshine duration in summer is the largest; the minimum is in winter; and the middle is in spring and autumn. The total monthly illuminance and sunshine duration in spring are greater than those in autumn. The lowest value of total illumination in December was less than 1/5 of the highest value of total illumination in August, and the average number of sunshine duration in December was even less than 1/7 of the average number of duration of sunshine in August. This also shows that the monthly total illuminance in Chongqing varies with the seasons, with uneven distribution of total natural illuminance in each month. natural light is sufficient in Summer and scarce in winter.

Based on the above analysis, in accordance with the existing daylight design standards, daylighting can fully meet the needs of indoor illuminance, and may lead to the introduction of excessive natural light in summer, so we should pay attention to the orientation of the building windows and shade. In winter, the outdoor natural illumination is low, and due to the impact of climate change, the actual natural illuminance value is often lower than the standard value, which will lead to insufficient indoor illuminance, which will affect the use of building and cause energy waste. Therefore, the window area should be appropriately enlarged, or increase structural measures to increase the amount of natural light introduced into the room to meet the daylight needs.

The change trend of monthly total illuminance

The statistical values *Z*, Sen slope value *Q'*, of monthly total illuminance were obtained through Mann–Kendall trend test method based on the series of monthly total illuminance values in Chongqing (*Table 3*).

Table 3. *Monthly total illumination Mann–Kendall trend test statistics in Chongqing*

Month	**1**	**2**	**3**	**4**	**5**	**6**	**7**	**8**	**9**	**10**	**11**	**12**
Z	-3.07	-1.77	-1.446	-1.738	0.405	-2.19	-2.87	-2.57	0.698	-1.79	-0.731	-3.25
Q'	-0.011	-0.012	-0.012	-0.017	0.006	-0.024	-0.038	-0.033	0.009	-0.015	-0.004	-0.015

A positive *Z* value represents an increasing trend, whereas a negative *Z* value represents a decreasing trend. Absolute Z values equal to or greater than 1.64, 1.96, and 2.56 indicate that the values passed significance tests with confidence coefficients of 90%, 95% and 99%, respectively. *Table 3* shows that in January, in July, in August and in December passed the significance test with a confidence coefficient of 99%, indicating that the change trends in these months are very obvious. In February, in April and in October passed the significance test with a confidence coefficient of 95%, indicating that the change trend in these months is obvious. In March passed the significance test with a confidence coefficient of 90%, indicating that the change trend in the month is not obvious. In May, in September and in November failed to pass the significance test with a confidence coefficient of 90%, which means that no change trend exists.

Slope value Q' represents monthly total illuminance change. A positive Q' value denotes an increasing trend, whereas a negative Q' value denotes a decreasing trend.

DOI: http://dx.doi.org/10.15666/aeer/1605_66556665
© 2018, ALÖKI Kft., Budapest, Hungary

Table 3 and *Figure 4* show that only the monthly total illuminance changes exhibit positive values in May and in September, The other months exhibit a decreasing trend. The monthly total illuminance have large change in July and in August, the change values are -0.38 × 10^8 lx/10a and -3.3 × 10^8 lx/10a. The monthly total illuminance have Minimum change in May and in November, the change values are 0.06 × 10^8 lx/10a and -0.04 × 10^8 lx/10a. The variation trend of monthly total illuminance values in most months in Chongqing is consistent with the variation in annual total illuminance values, that is, the overall trend shows a downward trend. In January, in February, in October, in November, and in December in Chongqing, there are many overcast days, and the sunshine duration are low, therefore, the monthly total illuminance values in these months are stable. But in March, in April, in May, in June, in July, in August and in September, the climate change was relatively large, and the sunshine duration changed greatly. As a result, the monthly total illuminance values in these months were drastically changed.

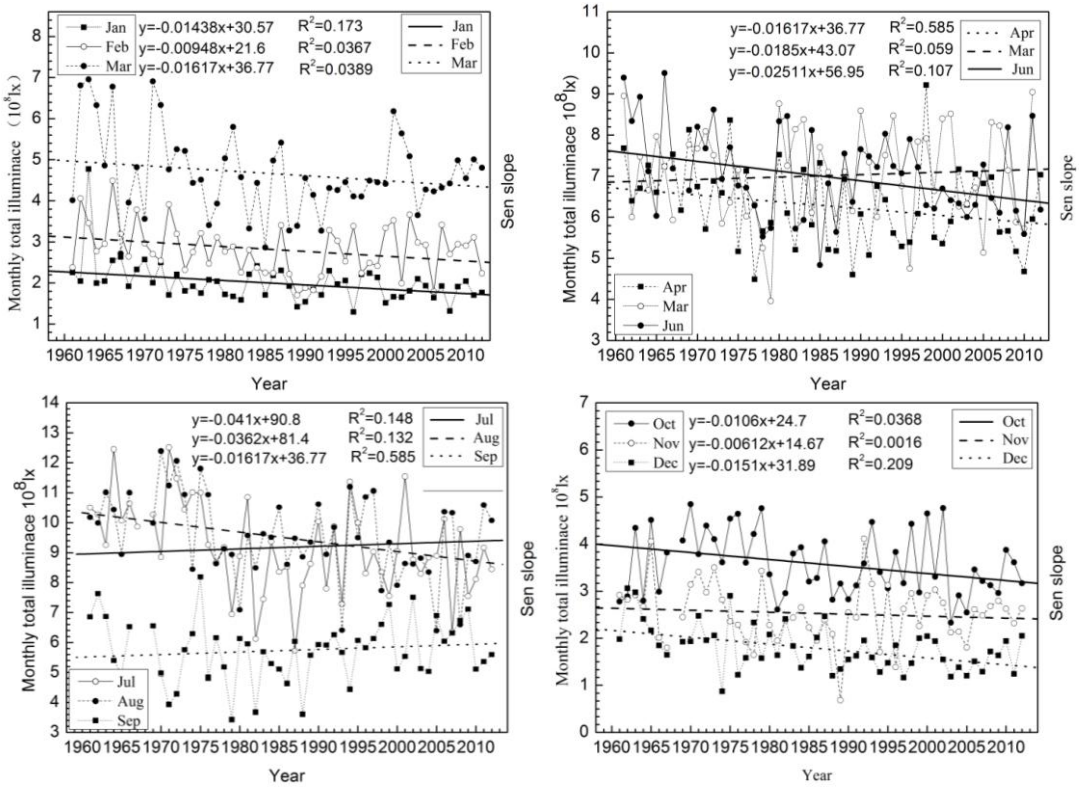

Figure 4. *Variation trend of monthly total illuminance value in Chongqing between 1961 and 2012*

Discussion

Natural light is the visible part of solar radiation; thus, the effects of solar radiation corresponding to meteorological factors also affect natural illumination changes. Solar radiation that reach the ground is influenced by clouds, atmosphere (including basic atmospheric composition, aerosols, and water vapor), and changes in solar radiation. We discuss the influencing factors of natural light illuminance in the following subsections.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_66556665
© 2018, ALÖKI Kft., Budapest, Hungary

Cloud

Clouds have a significant impact on natural lighting climates. Clouds affect not only the natural light reaching the ground but also the sky luminance distribution. In general, changes in the cloud cover will lead to a decrease or increase in natural light.

Aerosol

Aerosol is another important and complex influencing factor of natural light. Aerosol not only reflects, scatters, or absorbs sunlight but also produces indirect effects by changing the microphysical nature of clouds. The effects of aerosols on sunlight vary. An increase in aerosol content increases atmospheric optical thickness, thus correspondingly reducing the natural illumination that reaches the surface.

Water vapor

Water vapor absorbs sunlight. Research indicates that the global average of columnar water vapor content is 25 mm. For every 1% increase in solar radiation, water vapor content increases from 3 mm to 6 mm (Ramanathan and Vogelmann, 1997). Water vapor changes will have insignificant effects on natural illumination.

Atmospheric molecular scattering and absorption

Atmospheric gas molecules also scatter and absorb sunlight. However, human activity has changed atmospheric gas composition in recent decades (such as CO_2). Given that gas composition has low levels of ingredients in the atmosphere, the effect of atmospheric gas on natural illumination can be neglected.

Solar activity

Solar activity changes are mainly observed by satellite. To date, four independent space-based instruments directly observe total solar irradiance (Fröhlich, 2004). Solar radiation is typically an 11-year cycle and the amount of change is usually small and not more than 1% (Hamed, 2009). Therefore, the effect of solar activity can be ignored.

Conclusion

- Using solar radiation data to obtain natural illuminance data can greatly enrich daylighting climate data.
- The trend of total illuminance value of natural light in Chongqing is very obvious, with a drop of 2.4×10^8 lx/10a, and the mutation occurred in 1974. Therefore, the design standard of daylighting in Chongqing should be revised to meet the needs of daylighting demand.
- Monthly total illuminance values in Chongqing have no change trend in May, in September, in November, very obvious decreasing trend in January, in July, in August and in December, obviously in February, in April and in October, and not obvious in March.
- The annual variation of the total monthly illuminance of natural light fluctuates little in January, in February, in October, in November, and in December, and fluctuates widely in March, in April, in May, in June, in July, in August, and in September.

Abstract. Urban expansion and land use/land cover change (LULCC), driven primarily by human activities, have significant influences on the environment; in addition, the two factors, together with climate change, have an impact on urban vegetation. This study explored spatiotemporal dynamics of net primary productivity (NPP) and calculated relative contributions of driving factors from 2001 to 2013 in Guangzhou City, China. The effects of climate variables, urban expansion, and subsequent LULCC on interannual NPP variability were analyzed and compared. Results showed that NPP fluctuated and generally declined in Guangzhou over the 13-year study period, especially significant in inner suburbs (southern, eastern, and northern regions ($p < 0.05$), due to increasingly intensive human activities. LULCC, especially the reduction of cropland due to urban sprawl, resulted in significant NPP losses and positive relative impact index (RII) values, which indicated that LULCC played a negative role in NPP accumulation. More than 67.2% of NPP variability was controlled by LULCC in the whole area under study and mean RII values in all regions were higher than 50%, indicating that the influence of LULCC on NPP variability was greater than that of climate change. Particularly noteworthy is the fact that local climate change had a greater influence on NPP in forested areas (e.g. in the northeastern region), but it should not be ignored that RII kept increasing annually in this region and therefore more efforts paid in conservation were required. In conclusion, urban expansion and LULCC across the whole study area are resulted from human activities, and this, rather than climate change, was the primary driving force for the regional reduction in NPP.

Keywords: *net primary productivity, urban expansion, climate change, land use/land cover change (LULCC), human activities*

Introduction

Net primary productivity (NPP), the amount of photosynthetically fixed carbon available to the first heterotrophic level in an ecosystem (Field et al., 1998), is a key component of energy and matter transformation in terrestrial ecosystems. NPP plays an important role in global change and carbon balance as a key regulator of ecological processes, and is often used to quantify ecosystem service values. A decline in vegetation productivity is the primary manifestation of vegetation degradation, and NPP is an important indicator of productivity. In recent years, many studies of NPP have conducted long-term monitoring of vegetation dynamics in terrestrial ecosystems on both local and global scales, and results showed that vegetated ecosystems are susceptible to the effects of climate conditions and human activities, or the combined effects of them (Fu et al., 2013; Zhang et al., 2016; Wu and Wu, 2018; Chao et al., 2018; Fang et al., 2017).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_66676690
© 2018, ALÖKI Kft., Budapest, Hungary

Climate change influences NPP variability by altering levels of photosynthesis, respiration, and the decomposition of organic carbon in the soil (Gong et al., 2012; Pei et al., 2013b, 2015; Wang et al., 2013). According to the study by Nemani et al. (2003), the increase in global NPP from 1982 to 1999 was partly due to global climate change, and this trend was observed in China over the same period (Piao et al., 2005). NPP variability is highly sensitive to climate change, but the mechanisms involved are complicated (Liang et al., 2014; Ahlström et al., 2012; Gu et al., 2017). Human-induced change, especially urbanization, is another important influencing factor of NPP variability with complex mechanisms (Buyantuyev and Wu, 2012; Zhang et al., 2015; Peng et al., 2016). Growing evidence has shown that urban expansion has a great influence on regional ecosystems due to increased levels of greenhouse gas in the atmosphere, the destruction of the ozone layer, biodiversity loss due to deforestation (Verburg et al., 2002), and the reduction in landscape-level photosynthetic activity (Imhoff et al., 2000). In addition, urban expansion, together with land use/land cover (LULC) change, has dramatically influenced hydrological systems, biogeochemical cycles, and climate (Grimm et al., 2008). This has led to alterations in the distribution, structure, and material cycling of terrestrial ecosystems, ultimately affecting carbon storage and flux (Imhoff et al., 2000; Piao et al., 2009; Hutyra et al., 2011). Urbanization often causes reductions in NPP due to land cover transformation and carbon fixing potential drops greatly when the land converts from cultivated land or forests to developed land, or when a region transforms from a suburban area into an urban area (Zhao et al., 2012; Jiang and Wu, 2015; Chen et al., 2017). Therefore, climate change and human activities are two of the most important driving forces of NPP variability. With aggravating global climate change and increasing human activities, quantifying the effects of different driving factors on vegetation dynamics has become a critical issue for mitigation and management planning. To date, some studies have attempted to quantify relative contributions of climate change or human-induced LULCC to NPP within specific regions (Yan et al., 2016; Xu et al., 2011; Zhang et al., 2016). However, such studies are often lack a spatial quantitative component relating to climate change and LULCC, and they do not take the spatial differences in the impacts of these different driving forces on NPP into account.

Guangzhou City is ideal for the study of climate change and human-induced impacts on NPP because it has hot and humid subtropical monsoon climate that favors year-round vegetation growth. The city has experienced dramatic urbanization and LULCC, which have converted large patches of croplands and woodlands into built-up areas within a matter of a decade or even a few years. Guangzhou's urban development strategy of "southern expansion, northern optimization, eastern advance, western union" in its 11th Five-year Plan will continue to accelerate urban sprawl, which may lead to multiple ecological problems. Some studies have noted that climate variables and human activities have led to a significant change in vegetation productivity in urban areas over a short period, with clear spatial heterogeneity. Accordingly, the study of NPP variability and the driving mechanisms in Guangzhou can be regarded as a representative case for southern China. This paper attempts to achieve the following goals: (1) to examine the spatiotemporal variability in NPP across five regions during 2001-2013; (2) to analyze the effects of climate variables, urban expansion, and subsequent LULCC on NPP; and (3) to reveal the relative contribution of driving forces on NPP accumulation and describe the spatial heterogeneity.

Material and methods

Study area

Guangzhou City (112°57'E~114°3'E and 22°26'N~23°56'N) is an important political, economic, educational, scientific, and technological center within Guangdong Province and South China (*Fig. 1*). It is located in the north end of the Pearl River Delta region and adjoins the extension of the Nanling Mountains in the north and the South China Sea in the south, with a total land area of 7,434.4 km^2. The topography of Guangzhou consists of hilly areas and plains, with elevation decreasing from northeast to the southwest. It has a subtropical, marine monsoon climate with an annual average temperature of 22 °C and annual precipitation of 1,982.7 mm. Guangzhou has experienced dramatic urbanization due to China's reform and opening up policies. In recent decades, Guangzhou's economy has developed fast, which supports a population of over 12.9 million. Its regional Gross Domestic Product (GDP) has grown from $268.48 billion in 2001 to $1,542.01 billion in 2013 (http://www.gzstats.gov.cn/). According to urban planning (Urban Master Development Plan of Guangzhou (2001-2010); the 10th Five-year Plan (2001-2005) and the 11th Five-year Plan (2006-2010)), the development of Guangzhou was predominantly in five regions, namely the central part, the south, the east, the north, and the northeast (*Fig. 1*). The central region mainly includes old districts with overwhelming urbanization and significant economic development. The southern, eastern, and northern regions are inner suburbs with rapid urban development. The northeastern region is composed of outer suburbs which are mainly dominated by forests and agricultural land, with relatively slower urban development.

Data collection and pre-processing

In this study, Terra MODIS data over the study area from 2001 to 2013 were selected for the NPP simulation. Data included 16-day NDVI composites (MOD13Q1) at a spatial resolution of 250 m, monthly land surface temperature (LST) (MOD11C3) at a spatial resolution of 0.05° (5.55 km), and monthly evapotranspiration (ET) and potential evapotranspiration (PET) (MOD16A2) at a spatial resolution of 1 km. All MODIS datasets were downloaded from the National Aeronautics and Space Administration's (NASA) Earth Observation System. The monthly NDVI data were produced from the MODIS 16-day products by using the maximum value composites (MVC) method, which eliminated disturbances from clouds, the atmosphere, and altitude angle, and minimized non-vegetation effects (Tucker et al., 1994). Other MODIS data were aggregated to grid cells at a resolution of 250 m from their original Sinusoidal Projection using the MODIS Reprojection Tool (MRT) to get the same spatial resolution and projected coordinate system as the MODIS-NDVI data. All MODIS data were checked using quality flags from the companion Quality Assurance (QA) images. The MODIS LST products (MOD11C3) were used to estimate air temperature (T_{air}) for the CASA model. Other studies have used this method to estimate T_{air} from MODIS LST data, and confirmed that LST is highly correlated with T_{air} (Vancutsem et al., 2010; Fu et al., 2011; Benali et al., 2012). In this study, T_{air} was estimated using LST data based on cross validation across years (Fu et al., 2011). The results showed that the best model had r^2 values ranging from 0.82 to 0.90 and RMSE values ranging from 1.64 to 2.17 °C, for 2001-2013.

The climate data included monthly mean air temperature, total precipitation, and total solar radiation data derived from 13 meteorological stations in and around Guangzhou. These three weather variables were used to analyze the correlation with NPP and simulate NPP_p. and the percentage of sunlight was derived in order to calculate the total solar radiation for simulating NPPp and NPP. These climate data were then interpolated into raster format at 250 m spatial resolution by using the universal Kriging method to match the MODIS NDVI data. All meteorological data were downloaded from the Chinese National Metrological Information Center/China Meteorological Administration (NMIC/CMA).

Finally, a time series of Landsat images were used to extract land cover over the study areas. Data sources included Landsat Thematic Mapper (TM; bands 1-5 and 7) images acquired on November 2005, December 2006, January 2009, October 2011; Enhanced Thematic Mapper (ETM+; bands 1-5 and 7) images acquired on November 2001 and January 2003; and Operational Land Imager (OLI; bands 2-7) images acquired on December 2013. These images were rectified to the Universal Transverse Mercator (UTM) projection and World Geodetic System 1984 (WGS84) datum. After Line-of-Sight Atmospheric Analysis of Spectral Hypercube (FLAASH) and image mosaicking, the 2001 image was selected as the base image for automatic registration of other images with Root Mean Square Errors (RMSE) of less than 0.5 pixels. Subsequently, the images were masked using the boundary of the Guangzhou Metropolitan area. A maximum likelihood supervised classification approach was used to classify the Landsat images and they were combined with the actual land cover in Guangzhou and the International Geosphere-Biosphere Program (IGBP) schemes. Finally, land cover maps from seven years were classified into 12 categories (*Table 1*). The overall accuracy of the classification results was higher than 82.5%.

Table 1. *Land use/land cover classification scheme*

LULC types	Description	ε_{max}
EBF	Lands dominated by broadleaf trees with a canopy cover great than 60% and height exceeding 2-m. Almost all trees remain green all year	0.985
ENF	Lands dominated by needleleaf trees with a canopy cover great than 60% and height exceeding 2-m. Almost all trees remain green all year	0.389
MF	Lands with evergreen broadleaf and needleleaf forest	0.475
DBF	Lands dominated by broadleaf trees with a canopy cover great than 60% and height exceeding 2-m. Consists of seasonal broadleaf tree communities with an annual cycle of leaf-on and leaf-off periods	0.692
GL	Lands with herbaceous, tree and shrub cover is less than 10%	0.542
SL	Lands with woody vegetation less than 2-m tall and mainly shrub and lands with herbaceous types of cover, shrub cover is greater than 60%	0.429
WG	Lands with herbaceous and with tree canopy between 10 and 30%	0.542
CL	Lands covered with temporary crops followed by harvest and a bare soil period	0.542
CL&NVM	Lands with a mosaic of croplands, forest, shrub-land, and grasslands in which no one component comprises more than 60% of the landscape	0.542
WB	Oceans, seas, lakes, reservoirs, rivers and dike-pond	0.296
U&BL	Land covered by buildings and other man-made structures	0.196
UL	Exposed soil, sand, rocks, landfill sites, areas of active excavation	0.217

EBF: evergreen broadleaf forests; ENF: evergreen needleleaf forests; MF: mixed forests; DBF: deciduous broadleaf forests; GL: grasslands; SL: shrub lands; WG: woody grasslands; CL: croplands; CL&NVM: cropland/nature vegetation mosaics; U&BL: urban and built-up lands; UL: unused lands; WB: water bodies

NPP estimation

NPP was assessed by using the Carnegie-Ames-Stanford Approach (CASA) model, a parameter-based model based on light use efficiency (Potter et al., 1993). The CASA model can be calculated as the product of the amount of photosynthetic active radiation absorbed (APAR) ($MJ \cdot m^{-2}$) and the actual light use efficiency (ε) ($g\ C \cdot MJ \cdot m^{-1}$) factor. NPP can be expressed as (*Eq. 1*):

$$NPP(x,t) = APAR \times \varepsilon \quad \text{(Eq.1)}$$

where NPP (x, t) ($g\ C \cdot m^{-2}$) is the net primary productivity for grid cell x in month t. The actual light use efficiency (ε) is affected by temperature and water, and can be calculated by using *Equation 2:*

$$\varepsilon(x,t) = T_1(x,t) \times T_2(x,t) \times W(x,t) \times \varepsilon_{max} \quad \text{(Eq.2)}$$

where $T_1(x, t)$ and $T_2(x, t)$ are temperature stress coefficients; $W(x, t)$ is a moisture stress coefficient; and ε_{max} represents the maximum light use efficiency that needs to be simulated for different vegetation types. ε_{max} differs greatly in different situations and is mainly affected by temperature, water availability, soil type, etc. (Prince, 1991). In this paper, the ε_{max} values for different land cover types were adopted from Zhu et al. (2006) who computed ε_{max} according to the principle of minimal error based on simulated NPP and measured ground NPP.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_66676690
© 2018, ALÖKI Kft., Budapest, Hungary

APAR is the product of *PAR* and the fraction of photosynthetically active radiation (*FPAR*) (Wang et al., 2009), and *PAR* depends on the solar surface radiation (*SOL*) ($MJ \cdot m^{-2}$). Thus, NPP at location *x* and time *t* becomes (*Eq. 3*):

$$NPP(x,t) = FPAR \times SOL \times 0.5 \times T_1(x,t) \times T_2(x,t) \times W(x,t) \times \varepsilon_{max} \quad \text{(Eq.3)}$$

FPAR is defined as a linear function of *NDVI* and the simple ratio (*SR*) (*Eq. 4*):

$$FPAR(x,t) = \alpha FPAR_{NDVI} + (1-\alpha) FPAR_{SR} \quad FPAR \in [0.001, 0.95] \quad \text{(Eq.4)}$$

where α is set to 0.5; $FPAR_{\mathrm{NDVI}}$ and $FPAR_{\mathrm{SR}}$ are FPAR estimated by the *NDVI-FPAR* model (*Eq. 5*) and the *SR-FPAR* model (*Eq. 6*):

$$FPAR(x,t) = \frac{(NDVI(x,t) - NDVI_{i,min}) \times (FPAR_{max} - FPAR_{min})}{(NDVI_{i,max} - NDVI_{i,min})} + FPAR_{\mathrm{min}} \quad \text{(Eq.5)}$$

$$FPAR(x,t) = \frac{(SR(x,t) - SR_{i,min}) \times (FPAR_{max} - FPAR_{min})}{(SR_{i,max} - SR_{i,min})} + FPAR_{\mathrm{min}} \quad \text{(Eq.6)}$$

where $NDVI_{i,\ max}$ and $NDVI_{i,\ min}$ values correspond to 95% and 5% of the *NDVI* population respectively, and *i*; $SR_{i,\ max}$ and $SR_{i,\ min}$ correspond to $NDVI_{i,max}$ and $NDVI_{i,\ min}$ respectively. The relationship between *NDVI* and *SR* can therefore be expressed as (*Eq. 7*):

$$SR(x,t) = \left[\frac{1 + NDVI(x,t)}{1 - NDVI(x,t)}\right] \quad \text{(Eq.7)}$$

SOL is the total solar radiation over time period ($MJ \cdot m^{-2}$), can be calculated based on the percentage of sunshine, namely (*Eq. 8–12*):

$$SOL = \left[a + b \times \frac{n}{N}\right] \times R_a \quad \text{(Eq.8)}$$

$$R_a = S_0 \times \frac{24}{\pi} \times d \times (W_0 \times sin\varphi \times sin\delta + cos\varphi \times cos\delta \times sinW_0) \quad \text{(Eq.9)}$$

$$d = 1/[1 + 0.033 \times cos\ (2\pi \times J/365)] \quad \text{(Eq.10)}$$

$$\delta = 0.409 \times sin\ (2\pi \times J/365 - 1.39) \quad \text{(Eq.11)}$$

$$W_0 = arcos\,(-tan\varphi \times tan\delta) \quad \text{(Eq.12)}$$

where R_a is the vertical incidence of solar radiation from the upper atmosphere; *n/N* is the percentage of sunshine; *a* and *b* are set to 0.191 and 0.758, respectively, according to Hou et al. (1993); S_0 is a solar constant (0.082 $MJ \cdot m^{-2} \cdot min^{-1}$); *d* is a correction factor for the relative distance between Earth and the Sun; δ is solar declination (unit: radians);

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_66676690
© 2018, ALÖKI Kft., Budapest, Hungary

W_0 is the hour angle between sunrise and sunset (unit: radian); φ is geographic latitude (unit: radians), and is set to 0.540; and J is the number of days in a year.

Additionally, $T_1(x, t)$, $T_2(x, t)$ and $W(x, t)$ are the temperature and moisture stress coefficients, and can be calculated as (*Eq. 13–15*):

$$T_1(x,t) = 0.8 + 0.02 \times T_{opt} - 0.0005 \times (T_{opt})^2 \quad \text{(Eq.13)}$$

$$T_2(x,t) = 1.184/[1 + e^{0.2*(T_{opt}-10-T(x))}]/[1 + e^{0.3*(-T_{opt}-10+T(x))}] \quad \text{(Eq.14)}$$

$$W(x,t) = 0.5 + 0.5 \times ET(x,t)/PET(x,t) \quad \text{(Eq.15)}$$

where T_{opt} is the temperature at which *NDVI* reaches its maximum for the whole year, and T_2 falls to half its value at T_{opt} at temperatures 10 °C or 13 °C below T_{opt}. The moisture stress coefficient (W) reflects the influence of the effective water condition of plants and can be used for light utilization. It is determined by regional actual evapotranspiration (*ET*) (mm) and potential evapotranspiration (*PET*) (mm), derived from the MOD16A2 products.

Mann-Kendall trend analysis and Theil–Sen median slope estimator

In the present study, both spatial and temporal NPP change trends were analyzed using a robust non-parametric Mann-Kendall (M-K) method, which is widely applied to long-time series trend analysis of non-normal data (Prince, 1991; Wang et al., 2001, 2015b). It has been reported that the M-K test statistic Z is approximately normally distributed with the sample size $n \geq 8$ (Neeti and Eastman, 2011). A positive or a negative of Z value indicates an increasing or a decreasing trend, which is monotonic (Neeti and Eastman, 2011). The M-K test statistic S is calculated as (*Eq. 16;* Kendall, 1975):

$$S = \sum_{i=1}^{n-1} \sum_{j=i+1}^{n} sgn(x_j - x_i) \quad \text{(Eq.16)}$$

where n is the number of data points; x_i and x_j are the data values in time series i and j ($j > i$), respectively; and $sgn(x_j - x_i)$ is the sine function expressed as (*Eq. 17*):

$$sgn(x_j - x_i) = \begin{cases} 1, if\ x_j - x_i > 0 \\ 0, if\ x_j - x_i = 0 \\ -1, if\ x_j - x_i < 0 \end{cases} \quad \text{(Eq.17)}$$

The variance is computed as (*Eq. 18*):

$$Var(S) = \frac{n(n-1)(2n+5) - \sum_{i=1}^{m} t_i(t_i-1)(2t_i+5)}{18} \quad \text{(Eq.18)}$$

where n is the number of data points, m is the number of tied groups, and t_i denotes the number of ties with extent i. A tied group is a set of sample data that share the same value. In cases where the sample size n > 8, the standard normal test statistic Z_S is calculated (*Eq. 19*) using *Equation 18:*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_66676690
© 2018, ALÖKI Kft., Budapest, Hungary

$$Z = \begin{cases} \frac{S-1}{\sqrt{Var(S)}}, & if\ S > 0 \\ 0, & if\ S = 0 \\ \frac{S+1}{\sqrt{Var(S)}}, & if\ S < 0 \end{cases} \quad \text{(Eq.19)}$$

In this study, the Z score thresholds used for testing significance over time were 1.96 for the 5% significant level ($\propto = 0.05$), and 2.576 for the 1% significant level ($\propto = 0.01$), which provided both the significance and direction of the trend.

The Theil–Sen median slope estimator for estimating the slope of the trend in a sample with N pairs of data, which is appropriate for assessing the rate of change in a short or noisy time series (Wang et al., 2015a), can be calculated as (*Eq. 20*):

$$\beta_i = Median\left(\frac{x_j - x_k}{j-k}\right) \quad for\ i = 1, \ldots, N \quad \text{(Eq.20)}$$

where x_j and x_k are the data values at times j and k ($j > k$), respectively.

All analyses were conducted using ENVI 5.1 (Exelis Visual Information Solutions, Boulder, CO, USA), ARCGIS 10.2 (ESRI, Redlands, CA, USA), and MATLAB R2014a (The Mathworks, Inc., Natick, MA, USA).

Impacts assessment of LULCC on NPP

Based on the relative impact index (RII) from Wu et al. (2018), we applied RII to assess the impact of LULCC driven by human activities on NPP. RII was calculated based on NPP_{lulcc} and NPP_p, namely (*Eq. 21*):

$$RII = \frac{NPP_{lulcc}}{NPP_p} \times 100\% = \frac{NPP_p - NPP_{lulcc}}{NPP_p} \times 100\% \quad \text{(Eq.21)}$$

where NPP_{lulcc} is the NPP variability that is due to LULCC driven by human activities, and NPP_p is the NPP of potential vegetation. If $RII > 0$, it implies that there is a negative impact of LULCC on NPP and vegetation activity, and if $RII < 0$, it implies that there is either a limited human impact or more effective vegetation protection and management. When $|RII| > 50\%$, it indicates that LULCC is the primary driver of NPP change. For more details about *RII* and the calculation of NPP_p see Wu et al. (2018).

Relative contributions of climate and LULCC on NPP

The correlation between climatic variables (temperature, precipitation and solar radiation) and annual NPP can be expressed as (*Eq. 22*):

$$R_{xy} = \frac{\sum_{i=1}^{n}[(x_i - \bar{x})(y_i - \bar{y})]}{\sqrt{\sum_{i=1}^{n}(x_i - \bar{x})^2 \times \sum_{i=1}^{n}(y_i - \bar{y})^2}} \quad \text{(Eq.22)}$$

where R_{xy} is the correlation coefficients between x and y, x_i and y_i is the value of NPP and climatic variables in the ith year respectively; $\bar{x}$ and $\bar{y}$ is the mean value of NPP and climatic variables from 2001 to 2013.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_66676690
© 2018, ALÖKI Kft., Budapest, Hungary

The method of Wu et al. (2014) was employed to compare the comprehensive impact of climate change and LULCC on NPP on a spatial scale, using the variation slope of NPP in different situations to quantify and compare the comprehensive impacts. Assuming that the slope of NPP was K_1 and K_2 in the situation of constant climate and constant LULCC respectively, the slope of actual NPP was K, so the impact of climate change and LULCC on NPP can be expressed as $\Delta Cli.NPP = K\text{-}K_1$ and $\Delta LULCC.NPP = K\text{-}K_2$ respectively. The impact of other factors on NPP was $\Delta Inter.NPP = (K_1 + K_2)\text{-}K$. Therefore, the contributions of climate change, LULCC and other factors on NPP change can be described by *Equations 23–25:*

$$Contr_{cli} = \frac{|\Delta Cli.NPP|}{|\Delta LULCC.NPP| + |\Delta Cli.NPP| + |\Delta Inter.NPP|} \times 100\% \quad \text{(Eq.23)}$$

$$Contr_{LULCC} = \frac{|\Delta LULCC.NPP|}{|\Delta LULCC.NPP| + |\Delta Cli.NPP| + |\Delta Inter.NPP|} \times 100\% \quad \text{(Eq.24)}$$

$$Contr_{inter} = 100 - Contr_{cli} - Contr_{LULCC} \quad \text{(Eq.25)}$$

The sum of the contributions of climate change, LULCC and other factors on NPP change is equal to 1. The contributions of the three impact factors can be mapped individually at the pixel scale, and the synthesized impact image can be derived from the three images using a Maxwell Triangle.

Results

NPP model validation

There was little field data on NPP available for validating the CASA model outputs. We compared our simulated average annual NPP values over the period from 2001 to 2013 with MOD17A3 NPP values and other domestic simulation results. As shown in *Figure 2,* there was a strong agreement between our simulated NPP results and MOD17A3 NPP values with a correlation coefficient of 0.860 and a mean relative error of 24.88% across the 118 random sample points. The NPP values from our simulation results were clearly different from those of other studies (*Table 2*), which may have been due to differences in the study range, stand age and density, hydrothermal conditions, vegetation coverage, input data sources, parameter values for the CASA model, and so on.

Spatial-temporal dynamics of NPP

The estimated mean NPP had an overall decreasing trend from 2001 to 2013 in Guangzhou (from 807.45 gC m^{-2} in 2001 to 719.84 gC m^{-2} in 2013). From a geographical perspective, the average mean NPP decreased markedly from the northeast to the south and had clear geographic heterogeneity (*Fig. 3a*).

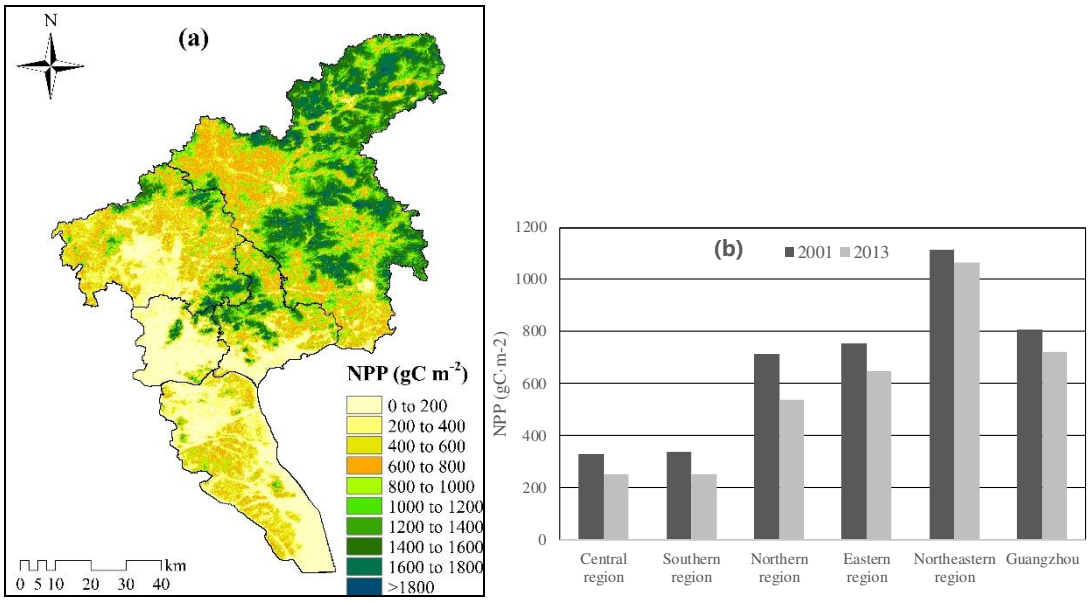

Figure 3. *Spatial pattern of mean NPP during 2001-2013 (a) and NPP variability between 2001 and 2013 in Guangzhou (b)*

For individual grid cells, the annual mean NPP values ranged from 7 gC m^{-2} yr^{-1} in the central region to more than 1189 gC m^{-2} yr^{-1} in the northeastern region. For different

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_66676690
© 2018, ALÖKI Kft., Budapest, Hungary

land cover types, the highest NPP values (greater than 850 gC m^{-2}) were found in forests, which are mainly located in the northeast and the important conservation areas within Guangzhou city. Low NPP values (less than 250 gC m^{-2}) were found in the areas dominated by urban land cover with little green space, implying that NPP was closely related to NDVI and the light use efficiency (ε) of the land cover type. *Fig. 3b* details the changed in NPP from 2001 to 2013 in Guangzhou city and the five regions. Average NPP values across Guangzhou and the five regions between 2001 and 2013 varied significantly and declined sharply by 2013. Estimated NPP values in the northern region decreased the most (175.47 gC m^{-2}), followed by the eastern and southern regions (108.26 gC m^{-2} and 86.52 gC m^{-2} respectively). Values in the northern region also decreased, and the lowest value was 46.90 gC m^{-2}. The pattern overall showed that the order of dynamic changes in annual NPP ranked from high to low was inner suburbs, inner city, and outer suburbs.

To further assess the temporal changes and regional disparity in NPP under changing land cover, land types in Guangzhou city and the five regions were analyzed for 2001, 2005, 2009, and 2013. The results showed that the mean NPP of land cover classes in those regions varied significantly (*Fig. 4*). The lowest NPP values for all land cover types were found in the central region, while land cover in the northeastern region contained more NPP with more than 3,000 gC m^{-2} in all year. The average NPP for all land cover types decreased across the whole study area and all regions, with the most significant decreases occurring in the northern region with a remarkable decline of -183.78 gC m^{-2} between 2001 and 2013, followed by the southern and eastern regions with respective losses of -72.73 gC m^{-2} and -64.95 gC m^{-2}, respectively.

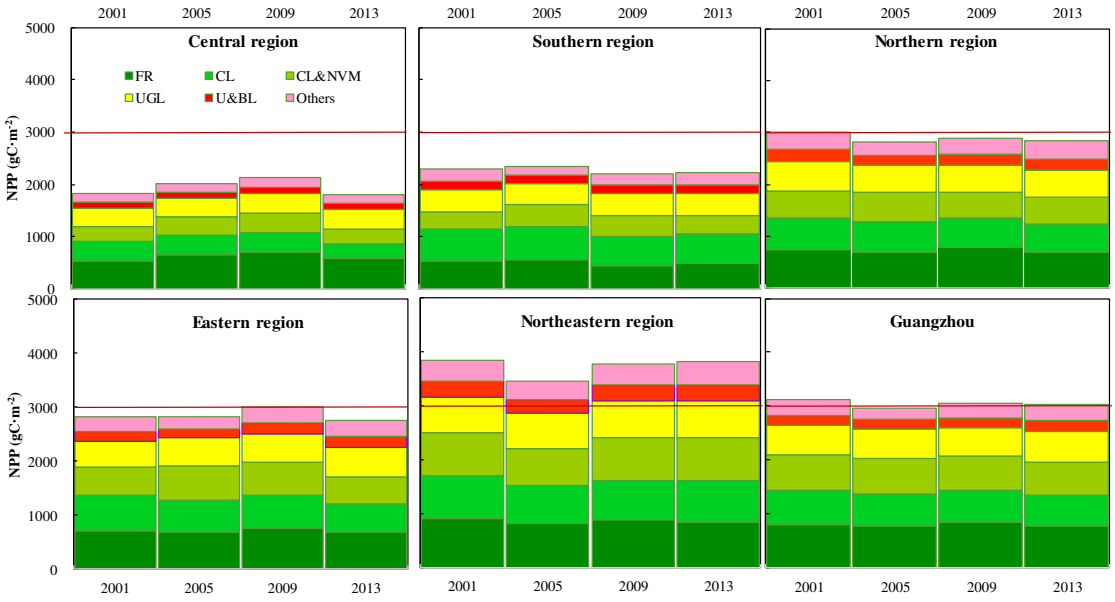

Figure 4. *Changes in the mean NPP across Guangzhou City and its five regions. (FR: forest; CL: croplands; CL&NVM: cropland/nature vegetation mosaics; UGL: urban green lands: mainly includes grasslands: shrub lands and woody lands; U&BL: urban and built-up lands; Others: include water bodies and unused lands)*

Spatial NPP trends and tests for significance across Guangzhou and the five regions were analyzed at the pixel level (*Fig. 5a-b*). Results showed that NPP decreased in all

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_66676690
© 2018, ALÖKI Kft., Budapest, Hungary

regions over the duration of the study (*slope* < 0). About 70.2% of all NPP pixels had a decreasing trend with an average slope of -10.94, and this was especially noticeable in the central part of the northern region and most areas of the southern region. Pixels with a significant decreasing trend ($p < 0.05$) accounted for 19.34% of the total pixels, and only 3.44% of pixels had a significantly increasing trend ($p < 0.05$). Significant negative trends ($p < 0.05$) were mainly observed in the northeastern region (7.75%) and in portions of the northern region (5.34%). Of all pixels with significant positive trends ($p < 0.05$), about 61.01% were concentrated in the forested lands of northeastern region due to relatively less human interference and policy protection measures (e.g., Land Use Master Plan of Guangzhou, 1997-2010); however, the increasing number of pixels with a declining trend in this region cannot be ignored. Moreover, in the five regions where human modifications of land cover occurred the most, the proportion of areas with significant NPP decreases was much higher than the area of increase.

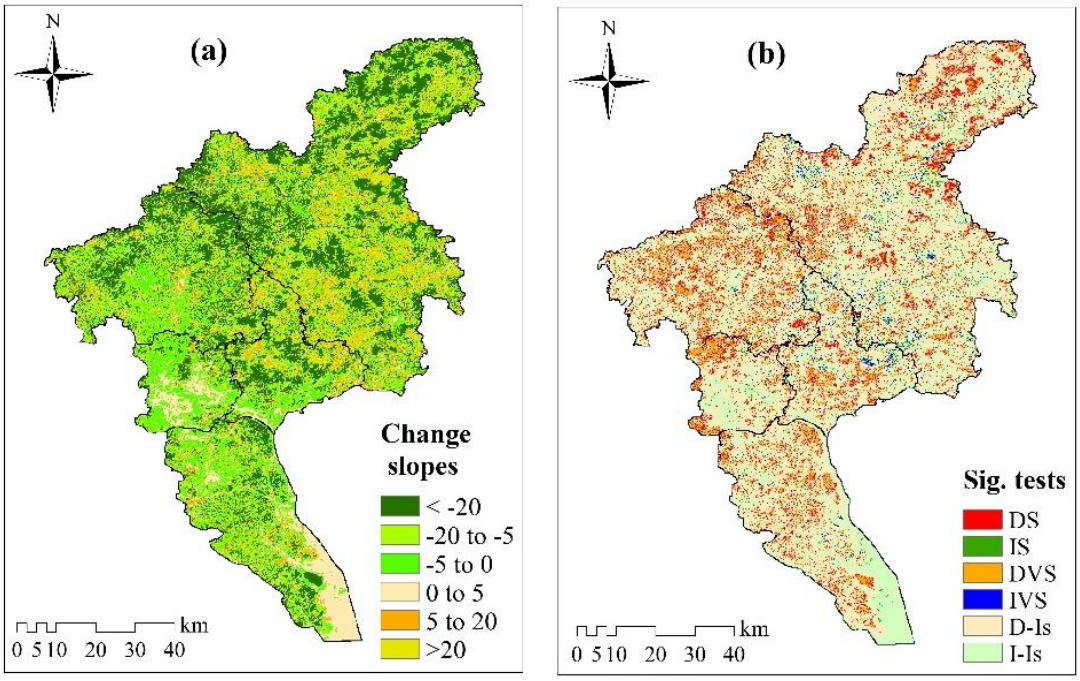

Figure 5. *Change trends (a) and significance tests for NPP (b) from 2001 to 2013. (DS: decreased significantly; IS: increased significantly; DVS: decreased very significantly; IVS: increased very significantly; D-Is: decreased insignificantly; I-Is: increased insignificantly)*

The influence of climate variability on NPP

Correlation analysis was performed between each climate factor (annual mean temperature (TEM), total precipitation (PRE), and total solar radiation (SOL)) and annual mean NPP across Guangzhou City and the five regions from 2001-2013 (*Table 3*). At the 13-year time scale, temperature and solar radiation tended to have positive impacts on NPP over the entire region, while precipitation had a negative relationship that was especially significant in the eastern and northeastern regions. The results indicated that rising temperatures and increasing solar radiation were associated with NPP increases, and solar radiation had a greater effect on NPP than temperature did.

Table 3. *Correlation coefficients between climate variables and NPP*

Correlation	Central region	Southern region	Northern region	Eastern region	Northeastern region	Guang zhou
R_{NPP-T}	0.530	0.394	0.512	0.351	0.444	0.476
R_{NPP-P}	-0.301	-0.217	-0.166	-0.582*	-0.645*	-0.572*
$R_{NPP-SOL}$	0.654*	0.440	0.644*	0.661*	0.779**	0.304

R_{NPP-T}, R_{NPP-P} and $R_{NPP-SOL}$ are the correlations between NPP and temperature, precipitation and solar radiation, respectively

For further analyzed the influence of each climatic factor (TEM, PRE, SOL) on NPP dynamics, the proportion of areas whose NPP variability was influenced by climate variables were calculated, and those percentages are shown in *Figure 6*. Across the whole study area, the area proportion dominated by solar radiation variation was the largest, being 37.9%, followed by temperature. For the five regions, solar radiation was the most dominant; particularly, the figures in the northern and northeastern regions reached 42.3% and 40.3%, respectively, while the figures in the areas dominated by precipitation were always smaller (less than 30%). These results suggested that the variability in solar radiation in the study area had the greatest influence on NPP, followed by temperature. Furthermore, changes in solar radiation and temperature strongly affected NPP in most areas of Guangzhou, while precipitation was a limiting factor for NPP accumulation due to the regional rainy and humid climate characteristics.

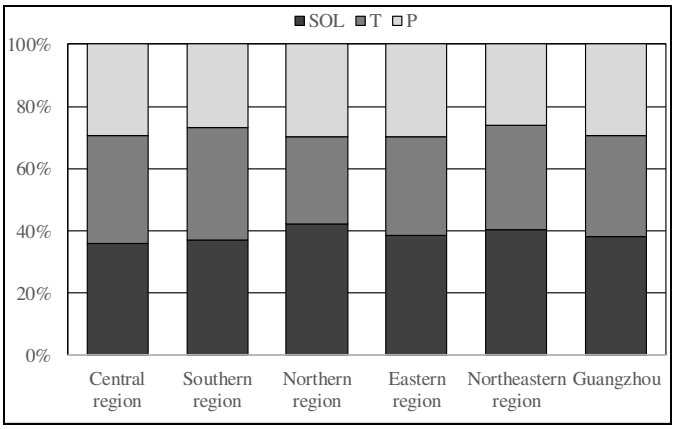

Figure 6. *Pixels percentages dominated by climate variables*

The response of NPP to LULCC

Since 1978, Guangzhou has experienced rapid urbanization and industrialization. A trend of sustained and accelerating development has taken place from 2001 to 2013 (Wu et al., 2016), and there was considerable change in land use types during this period. For example, urban and built-up areas increased by 979.72 km^2 at an annual rate of 8.13%. This was especially pronounced in the southern and eastern regions, where urban land increased by more than 20.0% as cropland decreased significantly in both (*Table 4*). In addition, there was a significant conversion from cropland, forest, and cropland/natural vegetation patches to impervious surface. In most cases, this resulted in significant losses of NPP.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_66676690
© 2018, ALÖKI Kft., Budapest, Hungary

Results showed that about 0.59 Tg C of NPP was lost due to the transformation from vegetated to non-vegetated areas between 2001 and 2013, and 85.1% of that was due to the conversion to urban land. In the five regions, the most significant losses in total NPP due to the conversion from other land cover types to urban land occurred in the northeastern region (a 42.5% loss), followed by the eastern region (18.6%) and northern region (17.9%). The greatest NPP losses due to conversion to other land cover types, especially urban land, occurred in cropland. This process reduced the carbon sequestration capacity of Guangzhou City. To further illustrate the impacts of urban expansion and cropland reduction on NPP loss, NPP changes in the urban and built-up coverage in 2013 and in the cropland coverage in 2001 during 2001-2013 were analyzed and compared (*Fig. 7*). Results showed that within the coverage of urban and built-up of 2013, urban and built-up areas had increased by 1,133.82 km^2 from 2001 to 2013, resulting a significant NPP loss of 0.55 Tg C of NPP with a decreased rate of 15.73 $gC\ m^{-2}yr^{-1}$ due to the conversion from vegetation to built-up areas over the 13-year period, especially from cropland to construction lands. Based on the cropland coverage of 2001, cropland declined sharply by 746.75 km^2 from 2001 to 2013, and about 320.93 km^2 was swallowed up by urban expansion, this directly led to the decline of the carbon fixation capacity of vegetation. During the 13-year period, NPP decreased significantly with a loss of 0.40 Tg C, and about 0.19 Tg C loss was mainly ascribed to the conversion from cropland to impervious surface. The above analysis showed that in both coverages, NPP decreased very significantly from 2001 to 2013 due to gradually reducing vegetation coverage and increasing built-up lands caused by anthropogenic influence.

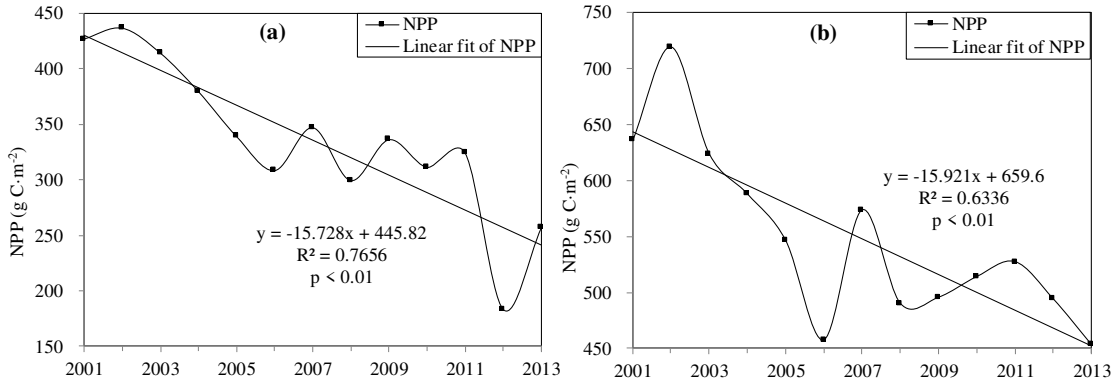

Figure 7. *NPP changes from 2001 to 2013 based on the range of urban and built-up lands in 2013 (a) and cropland in 2001 (b)*

Table 4. *Change in three indices in the five regions from 2001 to 2013*

Region / Indices	Central region	Southern region	Northern region	Eastern region	Northeastern region
ΔU&BL (%)	19.84	20.73	15.85	22.16	6.48
ΔCL (%)	-9.81	-14.36	-6.51	-12.23	-4.90
ΔRII (%)	4.62	6.52	9.19	7.27	5.98

ΔU&BL and ΔCL is the proportion of urban area and cropland change respectively; ΔRII is the difference in RII between 2013 and the 13-year average

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_66676690
© 2018, ALÖKI Kft., Budapest, Hungary

The impacts of LULCC on NPP were further investigated by examining the RII over the whole study area and the five regions from 2001 to 2013. Results showed that more than 91.0% of pixels in whole area had positive RII values and the mean RII value was greater than 50% across all regions, indicating LULCC driven by human activity had a negative influence on NPP and was the primary cause for NPP losses. Moreover, there was a clear increasing trend in RII across the five regions over the 13 years (*Table 4*) that was especially significant in the northern region followed by the eastern and southern regions, which suggested that intense human development radiated outward from the central urban areas to the urban fringe, where the inner suburbs were the first to be affected.

Comparison of the effects of LULC and climate change on NPP

In this study, we measured the relative contributions and synthesized the spatial impacts of climate and LULCC on NPP (*Fig. 8a*). The results showed that there were significant differences between the major factors controlling NPP at the pixel level. Over 13 years in the study area, 67.2% of all pixels had NPP variability that was dominated by LULCC due to increased human activities (*Fig. 8b*).

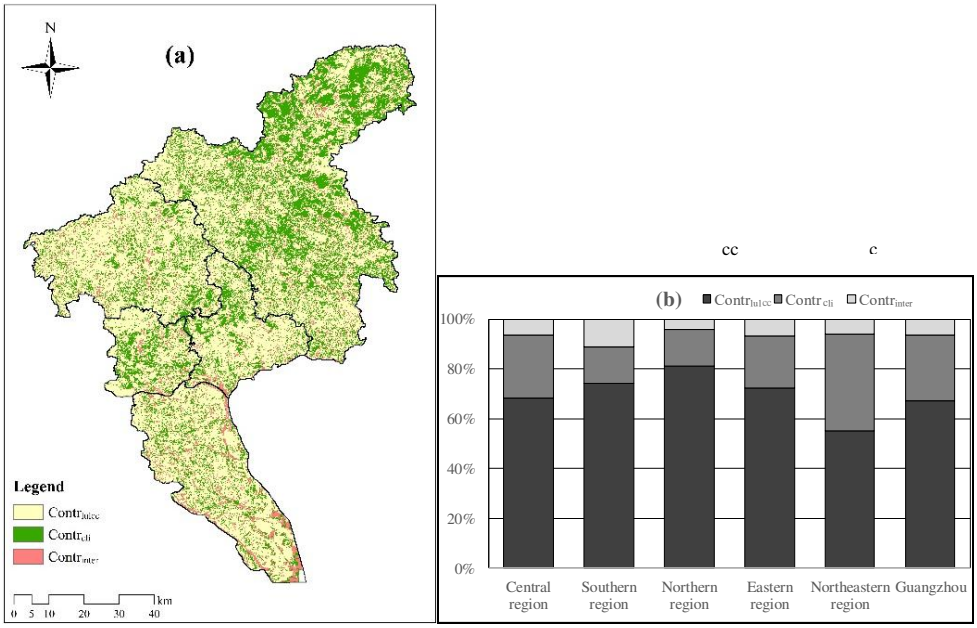

Figure 8. *Spatial distribution (a) and percentages (b) of the relative contributions of climate change, land cover change, and their interaction on NPP. ($Contr_{lulcc}$: contributions of LULCC; $Contr_{cli}$: contributions of climate change; $Contr_{inter}$: contributions of the interaction effects)*

These were mainly distributed in the northern, eastern, and southern regions, indicating that LULCC had a negative influence on NPP. On the other hand, 26.6% of pixels with NPP variability were more sensitive to climate change and mainly concentrated in the northeastern region dominated by forested lands. Only 6.2% of the total pixels were controlled by the interaction of climate and LULCC, and they were mainly concentrated in central region and some areas of southern region. Moreover, the proportion of pixels whose NPP changes were controlled by LULCC was higher than 50.0% across all regions, indicating that LULCC dominated by human activities and had a greater

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_66676690
© 2018, ALÖKI Kft., Budapest, Hungary

influence on NPP variability than climate change, especially in the inner suburbs (about 76.66% of pixels with NPP variability were controlled by LULCC). Overall, results showed that the influence of urban expansion and LULCC on NPP was much greater than the influence of climate, and LULCC was the main cause of reduced NPP in most of the areas under study.

Discussion

Uncertainties in NPP estimates

Compared with MODIS NPP, we found that our simulated NPP values for all land cover types were higher than MOD17A3, which may be because the fact that MODIS NPP is derived at the global scale with diverse climate and vegetation conditions and at a relatively coarse spatial resolution (1 km). The NPP estimates in this study were also very different from previous research studies of NPP change during China's urbanization (*Table 2*), which may be due to the fact that Guangzhou is a southern city with a warmer climate, higher vegetation coverage, and better hydrothermal conditions than that of other cities and the whole country.

In addition, there could be large uncertainties in this NPP estimation due to input data, parameters, model structure, and the applicability of the model (Wu and Wu, 2018). Some parameters (e.g., ε_{max} and *FPAR*) in the CASA model may not be appropriate across all areas of China and the process parameters should be optimized (Wang et al., 2013; Gong et al., 2012; Zhang et al., 2009). Furthermore, there was a large disparity in the spatial resolution of meteorological data and MODIS products in this study, which may have caused bias in NPP estimation. Although we reduced these errors by resampling, further adjustment and higher resolution data may be needed. Additionally, ground NPP data-based site observations of biomass within the study would have been better for validation than MODIS NPP. Overall, there were still some uncertainties in the NPP estimates due to the factors mentioned above, and in future studies, optimization of model parameters and more multisource data validation will be needed to enhance the accuracy of NPP estimation.

Correlation between climate variability and NPP

Climate variables are important factors affecting vegetation conditions, for example, temperature, precipitation and solar radiation can affect the vegetation distribution and NPP dynamics of various biomes at regional, and even local, scales (Dekker et al., 2007; Hu et al., 2009; Zhu et al., 2007a). In this study, the effects of these three climate variables on NPP variability were different, however, negative correlations with NPP and precipitation, and positive correlations with NPP and temperature and solar radiation occurred in all regions (*Table 3*), indicating that precipitation was unfavorable for vegetation growth, while temperature and solar radiation benefited NPP accumulation. This was consistent with Fu et al.'s (2013) study on Guangzhou where an increase in precipitation caused a decrease in temperature and radiation, which reduced the solar radiation exposure and for photosynthesis for photosynthesis in plants and may have decreased the soil organic matter content (Mohamed et al., 2004; Eisfelder et al., 2014; Zhang et al., 2016), resulting in less absorption of photosynthetically active radiation and the accumulation of vegetation biomass (Piao et al., 2003).

Solar radiation serves as an important energy source for plant photosynthesis, and we found it had a better regression coefficient with NPP than temperature and precipitation across all regions (*Table 3*). This implied that the NPP distribution and production are closely related to climatic variables and always dominated by a single climatic factor (Zhao and Running, 2010; Wu et al., 2014), and in most areas of Guangzhou City, the response of interannual NPP variability to solar radiation was the main controlling factor (*Fig. 6*). The results also have been verified by other studies (Zhang et al., 2014; Liang et al., 2014). Moreover, according to Zhu et al. (2007a), solar radiation had a larger influence on vegetation NPP in the South China compared with temperature and precipitation. Although other environmental factors may also affect NPP variability to some extent, such as soil texture (Pan et al., 1996), topography (Gao et al., 2013), drought (Pei et al., 2013a), CO_2 concentration (Mu et al., 2008), and so on, their effects on NPP were less climatic factors on carbon storage of vegetation (Sui et al., 2013; Gao et al., 2013).

NPP dynamics and associated urbanization and LULCC

Urbanization and subsequent LULC driven by human activities are important factors affecting vegetation dynamics, particularly in highly urbanized areas that are characterized by extremely fragile ecosystems (Wu and Wu, 2018; Zhang et al., 2014; Liu et al., 2018). In this study, NPP exhibited spatial heterogeneity across the whole area under study and decreased in the five regions from 2001 to 2013. Similarity, previous studies found that vegetation was degraded at different levels in Guangzhou in recent decades (Fu et al., 2013; Hu et al., 2009; Wu and Wu, 2018). In our study, a significant reduction in NPP was concentrated in the inner suburbs (southern, eastern, and northern regions; *Fig. 5*), this was mostly because that the amount of urban sprawl increased gradually from center to the periphery from 2001 to 2013 (Wu et al., 2016), and urbanization "hot spots" have moved from the center to the suburbs, resulting in a substantial reduction in vegetation areas and vegetation carbon fixation. Following intense urban development, ecological degradation slows and new urban ecosystems develop (Peng et al., 2016), which always leads to large losses in NPP. Moreover, the significant increase in RII in the inner suburbs implied that vegetation productivity in these areas was still subjected to disturbance by human activities. Most studies have demonstrated that the urban fringe is gradually emerging as the most human-disturbed area and this phenomenon has been observed in most urban areas during urbanization (Xu et al., 2007; Wu et al., 2014; Wu and Wu, 2018). Conversely, increased NPP and smaller RII values were widely distributed in the outer suburbs (northeastern region), which are dominated by mountains and hills with higher elevations, and low population density combined with conservation efforts that have effectively reduced the impacts of humans on vegetation activity. This phenomenon has also been confirmed by other studies (Peng et al., 2016; Hu et al., 2009).

Prior research has verified that different urbanization stages, finance aggregation, and population growth may also be important factors affecting NPP variability (Peng et al., 2016; Lu et al., 2010). Substantial environmental change occurs under increased demand by city dwellers for green space and corresponding ecosystem services. Thus, maintaining green spaces and adaptive urban planning could have benefits for the urban ecosystem and a favorable impact on vegetation productivity. However, it should be noted that growing human activity and urban sprawl are still a serious threat to vegetation NPP accumulation, and more plausible adaptation strategies should be

employed to cope with the conflict between urban development and ecosystem carbon balance.

Dominant driving forces of NPP variability

Over the 13-year study period, temperature and solar radiation were generally favorable for vegetation growth, whereas human activities had a negative impact. As shown by the absolute values of the contributions made by climate and LULCC, the influence of LULCC on interannual NPP variability in most parts of the area under study was always greater than climate. Notably, negative impacts of LULCC on NPP were most significant in the inner suburbs due to the conversion from vegetated to non-vegetated land, especially from cropland to new urban areas. This finding was in agreement with several studies (Pei et al., 2013b; Fu et al., 2013; Wu et al., 2014; Yang et al., 2015; Liu et al., 2018). A considerable proportion NPP change was undeniably dominated by climate factors in some croplands and wooded areas (e.g. the northeastern region; *Fig. 8*), where LULCC actually caused an increase in NPP. This was closely related to regional land cover types, population and economic conditions, terrain, conservation policies, and so on. In addition to the roles of regional population, economic conditions, and terrain, the effects of protection policies must be acknowledged. For example, the Land Use Master Plan of Guangzhou (1997-2010) effectively prevented excessive losses of agricultural land in this region. The Urban Master Development Strategic Plan of Guangzhou (2010-2020) defined Conghua and Zengcheng (the two districts are mainly in northeastern region) as eco-agricultural and eco-tourism zones, which further promoted the protection of agricultural and forested lands in the northeastern region and contributed to forest carbon accumulation. This limited the NPP reduction caused by climate change.

RII is an effective index for evaluating the effects of LULCC alone, independent of climate change, on NPP. In this study, we used RII to further assess the effects of climate change and LULCC on NPP. The fit curve of frequency by pixels of RII indicated that RII values were mostly positive (*Fig. 9*) in five regions, ranging from 50-90%, indicating that human activity had a negative effect on vegetation productivity and NPP.

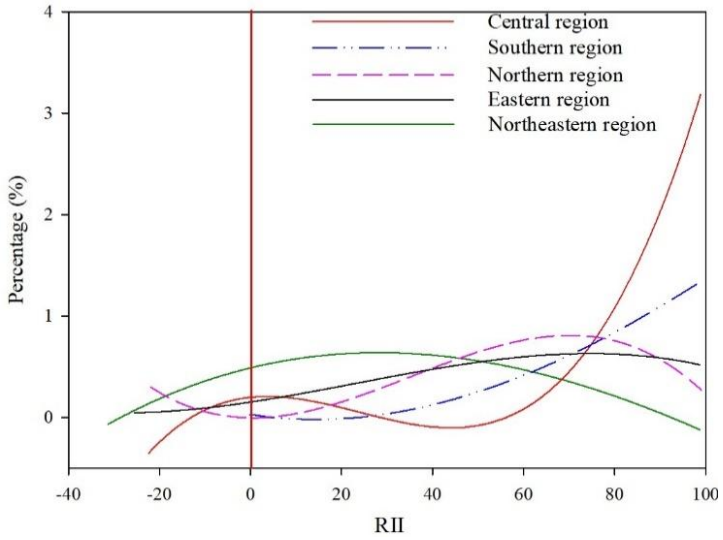

Figure 9. *Fit curve of frequency by pixels of RII in five regions*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

In addition, mean RII values were greater than 50% in all regions and about 77.3% of those pixels were concentrated in the inner suburbs, suggesting that NPP variability was most affected by human activities. These findings were consistent with our results based on the method of Wu et al. (2014). Especially, about 17.12% pixels in RII were less than 0 in northeastern region, which was benefited by the protection policies of agriculture and forested lands. Nonetheless, it is worth noting that the increase in RII over the five regions (*Table 4*) meant that human impacts on NPP through LULCC also increased, and vegetation productivity was affected by human disturbance, especially in inner suburbs. Although the creation and protection of urban green spaces, forests, and wetlands contributed to the increase in NPP, the effects of some protection projects were less than satisfactory. The effectiveness of restoration projects and urban and industrial land use plans should be adjusted to balance environmental conservation and economic development, and more plausible adaptation strategies should be applied to cope with climate change.

Conclusions

NPP is one of the most significant factors characterizing ecosystem structure and function, and can be used to describe the spatiotemporal pattern of urban carbon storage and its driving mechanisms. The current study estimated NPP change in Guangzhou and its five regions from 2001 to 2013 and examined the effects of driving forces on NPP variability in a spatially explicit way. Nonlinear NPP trends indicated that NPP decreased across the study area and most significantly in the inner suburbs (southern, eastern, and northern regions) due to rapid urbanization and human interference, while a slight increase of NPP was concentrated in the western part of the northeastern region. Solar radiation and temperature strongly influenced NPP increases, while precipitation was a limiting factor. NPP reductions were correlated with urban sprawl combined with land conversions from vegetated areas to impervious surface, especially cropland to built-up land. More than 91.0% of pixels had positive RII values, implying that LULCC played a negative role in NPP accumulation.

Comparatively, there were significant differences in the effects of climate change and LULCC on NPP. More than 67.2% of pixels exhibited NPP trends that were dominated by LULCC, and absolute average RII values further confirmed that LULCC had a greater impact than climate change on NPP. The interacting effects of climate change and LULCC led to slight NPP variability. In the northeastern region, about 38.1% of pixel NPP trends were dominated by climate change, but it cannot be ignored that the influence of human activities on vegetation productivity is still increasing and prolonged efforts will be needed to protect and expand environmental resources in this region. The above results revealed that LULCC due to urban expansion, rather than climate variability, was the main cause for regional NPP reductions in Guangzhou.

NPP variability can also be an indicator of urban development intensity and will provide further insights into terrestrial carbon change resulting from urbanization. In particular, the obvious spatial heterogeneity in the effects of LULCC and climate change on NPP change can provide valuable decision support information for ecological conservation and management in this region. Moreover, it is noteworthy that with the increase in impervious surface and decrease in vegetation cover resulting from human activities, the urban heat island effect will likely be intensified and the decline of cultivated land and forest will threaten food security and ecosystem function. Future

work should aim to improve data resolution and delve further into the mechanisms coupling land use change, climate change and the carbon cycle for a long time. And further work is also needed to identify the mechanisms of cropland NPP and food security to urban expansion.

(Received 2nd Jul 2018; accepted 13th Sep 2018)

Abstract. The present study shows the economic effects of climate alteration on grain (maize, wheat, and rice) production in Iran using a Ricardian method. The model was estimated using the longitudinal data on grain yields and climate variables from 1983-2014. The marginal effects of climate changes on productivity of crops were estimated by applying Panel Corrected Standard Error (PCSE) models. Empirical results showed a considerable hill-shaped correlation between wheat yield and spring and fall rainfalls and temperatures. The joint effect of the spring and fall rainfall and temperature for wheat was significantly negative. For maize, the outcomes showed a considerable hill-shaped correlation between crop productivity and spring precipitation. Moreover, there was a meaningful interaction term between winter rainfall and temperature at 1%. Our results for maize yield were not as robust as those for wheat. For rice, winter temperature had a considerable U-shaped relationship with rice yield, while summer precipitation and temperature had a considerable hill-shaped relationship with yield. The annual marginal impacts of rainfall and temperature for all the crops were positive. The outcomes showed that in Iran, the sensitivity of cereal production to enhance in precipitation levels would be less compared to the increase in temperature.
Keywords: *climate change, grain yield, panel regression, ricardian method*

Introduction

One of the global concern is climate change due to its impending threats to sustainable economic development. The effects of climate variations are more severe on agriculture compared to other economic activities (Stern, 2006; Mendelsohn et al., 2006; Rosenzweig and Iglesias, 1994; Adams et al., 1998; Cline, 2007; Nelson et al., 2009; Kurukulasuriya and Ajwad, 2007; De Salvo et al., 2013). The effects are probably too strong for developing nations, because of their strong dependency on agriculture and absence of economic resources for reducing and adapting to climate alteration (Mendelsohn et al., 2006; Stern, 2006; Nelson et al., 2009). Studies suggests that climate variation will considerably impact the agriculture sector of developing nations, leading to serious consequences in food safety and production. It would also have adverse effects on enormous population along with more effects on poor farmers with small farms.

Review of literature

Many researchers have measured the effects of climate variables on crop yield via simulation models for example CERES-rice, CERES-maize, and EPIC models (Phillips et al., 1996; Rosenzweig et al., 2002; Tan and Shibasaki, 2003) or regression models

(Mendelsohn et al., 1994; Chang, 2002; Haim et al., 2008). Previous studies have generally employed two major approaches to assess the effect of climate on agriculture: the approach of production function (agronomic model or crop modeling) (Mearns et al., 1997), and the Ricardian approach (Mendelsohn et al., 1994). Employing controlled experiments, the first approach simulates data on crop yields and climate variables in a laboratory. With a precise control and randomized usage of environmental circumstances, this method can anticipate the climatic influences on agriculture yields. However, it does not consider farmers' attitudes towards climate change adaptation. This leads to overestimation of negative effects and underestimation of positive impacts (Adams et al., 1990, 1999; Haim et al., 2008; Mendelsohn et al., 1994). On the contrary, the Ricardian model estimates the association among values of land and agro-climatic variables through cross-sectional information (Kumar and Parikh, 1998; Mendelsohn et al., 1994). The major power of the Ricardian model is that it considers farmers' adaptations which influence land values as measured by farm earnings or net revenue. The model has been used in different countries, namely the USA (Mendelsohn and Dinar, 2003; Mendelsohn et al., 1994), England and Wales (Maddison, 2000); Kenya (Mariara and Karanja, 2007), Taiwan (Chang, 2002), South Africa (Gbetibouo and Hassan, 2005), Cameroon (Moula, 2009), China (Wang et al., 2009), and India and Brazil (Sanghi and Mendelsohn, 2008). Nevertheless, the approach, in its main form, may not be used for most developing countries since there are no influential land markets and reasonable land expenses in these countries.

Although the research about climate outcomes on Iranian agriculture is restricted, it is rising. In coming sections, we review the studies conducted on the influence of climate variation on agricultural crop productivity in developing nations generally, continued by reviewing of studies in Iran.

Liangzhi et al. (2005) studied climate effect on Chinese wheat yields using crop specific cross-section and time series data over 1979-2000 for main wheat generating provinces in China along with climate data like solar radiation, rainfall, and temperature during this period. They observed that 1% enhance in the heat in the germination season of wheat reduced wheat yields by almost 0.3%. They also report that rising temperatures over the two decades prior to their research accounted for a 2.4% reduction in wheat productivities in China while a major growth in wheat yields (i.e., 75%) is induced by increasing application of physical inputs.

Guiteras (2009) estimated the influence of climate variation on Indian agriculture with the feasible generalized least squares (FGLS) approximation method. His results offer that climate variation is probable to impose considerable costs on the Indian economy unless producers can quickly distinguish and adjust with temperature rises. The study also declared that such a quick adaptation might be fewer probable in a developing country, where availability of capital and information for adjustment is limited.

Ayinde et al. (2010) studied climate variation and agricultural crops in Nigeria using time series data. They used descriptive statistics and a Granger causality test analysis as analytical tools. According to their results, the temperature remains relatively constant and has no effect on agricultural output. However, using the Granger causality approach in their research revealed that alterations in precipitation positively affected agricultural crops in Nigeria.

Lee et al. (2012) evaluated the climate variation effects on agricultural crops in Asia over 1998-2007. They applied agricultural crop model and estimated a country-level

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_66916707
© 2018, ALÖKI Kft., Budapest, Hungary

constant impact panel model for agricultural crops by seasonal climate and other input variables. Their outcomes showed that greater temperatures and higher precipitation in summer increased agricultural crops while a decrease in temperatures was dangerous in South and Southeast of Asia. Moreover, they reported that a general enhance in annual temperature decreased agricultural crops in Asia. They stated that adapting to climate alteration through development new varieties with more tolerance to greater temperatures was essential. Moreover, they suggested increasing investments in agricultural productivity and expansion of appropriate adaptation programs or strategies.

Kumar and Sharma (2013) analyzed the climate alteration effects on agriculture sector productivity, the production value, and food safety in India according to secondary information over 1980-2009. They performed a regression analysis with the Cobb-Douglas production type model. They revealed that climate variations had harmful effects on lots of the food and non-food grain products in quantity and production value terms. The reported negative influences of climate alteration on the agricultural crops and food grains value shows food security risks to marginal farming households. Moreover, the research reported an econometric estimating of the state-wise food security measure, revealing the harmful impacts of climatic variations on food safety.

Vaseghi and Esmaeili (2008a) studied the outcomes of climate alteration on agriculture in Iran, using chronological combined series of climate data over 1984-2004 and Ricardian model in 17 provinces and reported that climatic alterations had a considerable and nonlinear impact on net income per hectare of wheat. Moreover, they illustrated that the rise in temperature and fall in precipitation in the following 100 years would cause the decrease in yields per hectare by 41%.

Elsewhere, Vaseghi and Esmaeili (2008b) applied the Ricardian scheme to measure the economic outcomes of climate alteration on maize production in 11 Iranian provinces for 1990 to 2004. They reported that climatic variables had considerable nonlinear effects on net income of maize. In addition, they demonstrated that the increase in temperature and fall in precipitation during the future 100 years would cause a 29% decrease in the maize yield (584 thousand Rials per hectare).

Sabzevary et al. (2012) examined the impacts of climatic variables on dry farming and irrigated wheat yields in selected stations of Hamadan Province, Iran. The investigation was performed by bivariate linear regression technique and the impact of all factors on wheat productivity was compared utilizing explanatory and correlative coefficients. Overall, the dry farming wheat yields index sensitivity to agroclimatic and atmospheric parameters was greater than irrigated wheat.

Pahrizkari et al. (2014) evaluated the climate alteration effect and consuming agricultural inputs (seeds, fertilizers, poisons, machinery) on the irrigated wheat yield over 2001-2013 in Shahrood watershed of Iran. The outcomes showed that increasing temperature over the generation season negatively affected the yield of wheat so that through enhancing the temperature, the yield of this crop has declined by 0.683%. Also, they showed a considerable relation between the yield of wheat and inputs consumption.

Agriculture sector of Iran, despite its decreasing share in countrywide income, counts for almost 18% of national GDP, 85% of the food supply, above 20% of employment, 25% of non-oil products, and 90% of feedstock utilized in agro-industry (NCCOI, 2014). Therefore, incomes of a main group of people depend on agriculture that are in danger because of considerable negative influences of climate alteration on agriculture.

The objective of this study is, thus, to assess the impacts of climate alteration on the yields of major grain crops (wheat, maize, and rice) of Iran using panel data. In this regard, a Richardian model is employed.

Materials and methods

Wheat growing regions in Iran are divided into four main climates in terms of weather conditions and cultivars: hot and humid, hot and arid, temperate, and cold climate. Irrespective of the growth habits of the cultivars (winter, spring, and intermediate), wheat in Iran is generally grown in autumn. In hot and humid climate, its sowing date is mid-November to mid-December and it is harvested in late-May. In hot and arid climate, it is sown in mid-December and harvested in mid-April. Temperate climate itself is sub-divided into northern and southern regions due to its stretch. In the northern regions, it is sown in late-October to late-November and in the southern regions, it is sown from November 6 until December 6. The harvest time is late-May to late-June. Wheat in cold climate is sown in late-December to mid-October and it is harvested in late-May to early-July.

Maize is a crop of tropics and subtropics and unlike other grains, it requires high temperatures and solar heat from sowing until harvest. In Iran, maize can be grown in most regions (hot, temperate, and cold). It may be sown in spring or summer depending on the regional climate and sowing type. Maize is mainly planted as a second crop after harvesting wheat. The sowing date of maize as the first crop varies from June 10 to June 20, and its sowing date as the second crop is July 11 in temperate regions. In hot regions, summer maize is sown from mid-July to early-August and spring maize is sown from late-February until mid-March. In cold regions, maize is planted in early-May. In all regions, maize is harvested about 4 months later.

Forty percent of total rice production in Iran is accounted for by Mazandaran province. The first crop starts in late-March in all provinces and it is finally harvested in late-July to mid-August. In recent years, farmers in some cities in the north of Iran prepare their farms for the second crop of rice immediately after harvesting the first crop. The second crop is harvested in October-November.

The data

Longitudinal data regarding three major grain yields and climate variables (i.e., rainfall and temperature) from chosen provinces in Iran were applied for estimating the model. The number of provinces selected for all crops was 5 for rice, 15 for wheat, and 9 for maize. The bases of including these provinces in the study have been the ‘major grain-producing provinces’ and accessibility of data for a minimum period of 30 years from1983 to 2014. Data on crop productivity measured in kilograms per hectare (kg/ha) were prepared from the Agricultural Jihad Ministry. Province-level climate information for monthly average temperature and monthly total precipitation were gathered from the Iran Meteorological Organization (IRIMO). Then, the monthly data were applied to group the climate factors into seasonal averages for rainfall and temperature for three crops. Crop productivities are usually reported for the production year, which is resembling to the financial year. So, the years were merged for the simplicity of analysis. Thus, for example, rice yield data in 1982-83 were considered as the yield for the year 1983. Accordingly, climate factors were in accordance with the yield data. Although yields depend on numerous factors, only climate variables (i.e., rain and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_66916707
© 2018, ALÖKI Kft., Budapest, Hungary

temperature) were noticed in this research. Other factor inputs such as fertilizer, seed, and herbicides could have been involved but these were not existent on a crop-by-crop basis. Data related to the crop productivity and climate variables utilized in the present research are displayed in *Table 1*. According to the descriptive statistics of the model for a 30-year period, the average yield of wheat, maize and rice in Iran are 2920, 5175 and 3826 kg ha^{-1}. In wheat-producing provinces, mean temperature is 14, 27, 16 and 4 °C and mean precipitation is 118, 7, 60 and 122 mm in spring, summer, autumn, and winter, respectively. In the case of maize producing provinces, the mean temperature in these seasons is 17, 29, 18 and 6 °C and the mean precipitation is 100, 2, 54 and 130 mm, respectively. These are 18, 29, 20 and 9 °C and 121, 52, 230 and 235 mm for rice-producing provinces, respectively.

Methodology

The Ricardian log-linear model applied in current research is an empirical method proposed by Mendelsohn et al. (1994) for measuring the economic effect of climate variation on grain production in Iran. The technique was called after Ricardo due to his innovative results that the land value would reveal its net productivity at a situation under perfect competition. This method that predicts the impacts of climate and other factors on land values and farm incomes, has been generally utilized in various researches (Mendelsohn et al., 1994 and 1999; Sanghi and Mendelsohn, 1999; Gbetibouo and Hassan, 2005; Kurukulasuriya and Ajwad, 2007; Mendelsohn and Reinsborough, 2007).

The approximated variations in productivity resulted by alterations in ecological factors are accumulated with the total national effect (Olsen et al., 2000) or combined with an economic scheme for simulating the yield variations welfare effects under diverse climate variation scenarios (Kumar and Parikh, 1998; Chang, 2002). This model provides the probability of accounting the direct influence of climate alteration on crop productivities and the indirect replacement between diverse inputs contain introducing several activities, and other possible adaptations to climate alterations by direct measurement of farm costs or incomes (Deressa and Hassan, 2009). Applying Ricardian method, net incomes were regressed on climate parameters for identifying the effects of climate in explanation of net incomes.

The Ricardian method includes determining a net productivity function of the subsequent form (*Eq. 1*):

$$\pi = \sum P_i Q_i(X, C, Z) - \sum P_x X \qquad \text{(Eq.1)}$$

where π is the net income per hectare, P_i is the price of crop i, Q_i is output of crop i, X represents a purchased inputs vector (excluding land), C represents a climate factors vector, Z represents a vector for other control factors related with the farm including seeds and economic factors like market accessibility, and P_x represents an input prices vector. The producer is expected to select X for maximizing net incomes considering the features of the farm and prices.

Resolving *Equation 1* causes a decreased type model (*Eq. 2*) in which net income is a function of all the exogenous factors P_i, P_x, Z, and C:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_66916707
© 2018, ALÖKI Kft., Budapest, Hungary

$$\pi = R\,(P_i, P_x, C, Z) \qquad \text{(Eq.2)}$$

The empirical model applied in current research was a log-linear description of the Ricardian methodology (*Eq. 3*):

$$ln\pi = \beta_0 + \beta_1 T + \beta_2 T^2 + \beta_3 P + \beta_4 P^2 + \beta_5 T \times P + \varepsilon \qquad \text{(Eq.3)}$$

where T and P represent vectors for seasonal temperatures and rainfalls, and ε represents an error expression. The square and interaction expressions related to climatic factors are showed in the model to see if there is any nonlinearity in the impacts of mentioned parameters on the crop yield. In the log-linear functional model, the linear coefficients offer approximations for the proportional alteration in π for a change in the climate parameter and the quadratic terms related to rainfall and temperature reveals the nonlinear shape related to the response function between climate and net incomes (*Eq. 3*). When the net income function has a U shape, the quadratic term has a positive value, while in the case of having negative value for the quadratic term, the function has a hill shape. According to agronomic study and earlier cross-sectional analyses, a hill shape for correlation with temperature is expected for the farm value. Since there is a specific temperature at which a specific crop has its optimal growth over the seasons, products frequently show a hill-shaped relation with the yearly temperature. However, the correlation of seasonal climate factors is more complicated and may contain a mix of negative and positive coefficients over seasons. The predicted marginal effect of only one climate factor on net income of the farm assessed at the mean of factor is (*Eq. 4*):

$$(\partial\pi/\partial C_j) = (\alpha_{1j} + 2\beta_{2j} \times \mathrm{C}) \times \pi \qquad \text{(Eq.4)}$$

The alteration in yearly welfare, ΔW, causing by a climate variation from C_0 to C_1 can be calculated as following (*Eq. 5*):

$$\Delta W = \pi(C_1) - \pi(C_0) \qquad \text{(Eq.5)}$$

where π is the expected net income under the coming climate situation, C_1 represents the forecasted level for climate factors (rainfall or temperature), C_0 shows the normal mean temperature under the present climate situation, and ΔW represents the difference between the forecasted value of net income per hectare under the upcoming climate situation and the existing climate situation. Farm-level net-revenues, which reveal the modifications done by farmers for the normal climate conditions, can be employed to evaluate the climate response function. However, no such information is accessible for Iran. Hence, this study uses annual yield in the approximation of climate response function and other descriptive variables are taken in the similar ways. Similar to state level constant impact determined by Kumar (2009) while analyzing Indian agriculture and country-level fixed effects specified by Deschenes and Greenstone (2007) while analysing of US agriculture, we specified a district level constant-effect panel regression in the existing research. The Hausman specification test also confirms for the same. If there is AR cross-sectional dependence along with heteroscedasticity, FGLS with fixed effects was recognized to be an appropriate method of estimation.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_66916707
© 2018, ALÖKI Kft., Budapest, Hungary

However, one of the disadvantages of FGLS estimation is that it generates excessively optimistic standard error estimates. Furthermore, the estimates are only feasible if N < T, suggesting that there are less number of observations comparing to the number of time period, which is not the case for the three crops. In this regard, Beck and Katz (1995) propose using Panel Corrected Standard Errors (PCSE) models with Monte Carlo analysis. These models work well and yield correct estimates of sampling variability even in the existence of complicated panel error structures. Following Beck and Katz (1995), this study employs the PCSE model for measuring the impacts of climate variation on the yield of major cereal crops in Iran.

Table 1. *Summary statistics of yields and climate variables applied in the Ricardian model. (Source: Research findings)*

	Variables	Unit	N	Mean	Std. dev.	Min.	Max.

Results

The independent factors utilized in the scheme are linear, quadratic, and interaction terms between precipitation and temperature. Cross-sectional dependency is detected using Pesaran test. The Wooldridge autocorrelation test signs for the autocorrelation and Wald test signs for the heteroscedasticity. The panel unit root test presents that the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

factors we used are unit root free variables. To overcome the autocorrelation, cross-sectional dependency, and heteroscedasticity problem, we estimated two econometric models: Feasible Generalized Least Squares (FGLS) and Prais-Winsten models with Panel Corrected Standard Errors (PCSE).

Tables 2, 3, and *4* present the outcomes of panel regression with district constant impacts for wheat, maize, and rice crop productivity, respectively. We compared the obtained PCSE and FGLS and, as expected, detected that the standard errors of FGLS are lower comparing to those of PCSE for nearly all estimates. This evidence, compatible with the findings of Beck and Katz (1995), shows that FGLS underestimates the standard errors. Therefore, we study only the PCSE estimates in discussing results and making inferences.

Impacts of climate factors on wheat yield

Table 2 presents the panel regressions for wheat yield. We discuss the PCSE regression estimates for explaining the influence of climate factors on wheat yield. The R^2 value is 0.89, which demonstrates that the climate variables in the model explain more than two-thirds of alterations in the crop yield. The PCSE regression results specify that the variables of temperature and precipitation in spring, autumn, and winter influenced wheat yield positively, but only the variables of temperature in autumn and winter and precipitation in spring were statistically significant. Further, the variables of the squared temperature of spring and autumn and squared precipitation of spring were negative and statistically significant; this means that the increase in these variables is related to the increase in wheat yield up to a threshold beyond which crop yield is negatively influenced. According to Thapa-Parajuli and Devkota (2016), assuming that all other conditions are constant, the increase in temperature resulted in the increase in wheat yield up to a certain threshold in Nepal. Since wheat in Nepal is sown in cold season, the increase in temperature of this season enhances the yield. The same trend is observed for precipitation. This result is supported by Attri and Rathore's (2003) study in India. Also, interaction between fall and spring climate are usually negative and considerable whereas summer and winter climate interaction impacts are positive but insignificant. Accordingly, the joint effect related to temperature and precipitation for the fall and spring damages the wheat yield significantly. It can be clarified that increasing temperature and precipitation of both fall and spring would cause the significant negative joint climatic impact in wheat yield in Iran. Thus, it can be asserted that the climate variation although initially promotes producing wheat in Iran, this trend terminates following a determined threshold level.

Impacts of climate factors on maize yield

The PCSE outcomes indicate that the increase in temperature and precipitation in spring, summer, and autumn, which are the growing seasons of grain maize in Iran, affects the yield of this crop positively, but only the variables of temperature and precipitation of spring are statistically significant. Also, the yield of maize is negatively and significantly influenced by the squared precipitation of spring and is positively and significantly influenced by the squared precipitation of autumn. So, we can say that the precipitation of spring improves the yield of maize up to a specific threshold and then it affects its yield adversely. Further, the winter precipitation shows a considerable undesirable effect on maize yield. The decrease in crop productivity per hectare with increasing winter precipitation specifies that the available level of rainfall is enough for planting. The interaction term between winter rainfall and temperature is significant at 1%, suggesting that the winter rainfall impact on yield is affected by the degree of temperature and vice versa. We found that our results related to maize yield are not as robust as the findings related to wheat (*Table 3*).

Impacts of climate factors on rice yield

The yield of rice was positively and significantly influenced by the temperature and precipitation of summer, whereas it was negatively and significantly affected by the squared temperature and precipitation of this season. So, it can be said that the increase in these variables entails the enhancement of the crop yield up to a specific threshold, beyond which it starts to be lost. Saravanakumar (2015) indicated that precipitation had

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

an inverse U-shaped relationship with rice yield. This implies that more precipitation can improve its yield up to a certain threshold, but further precipitation would influence it negatively. This sort of the quadratic relationship between precipitation and yield has been reported by Chen and Chang (2005) in Taiwan and by Auffhammer et al. (2012) and Gupta et al. (2012) in India. Saravanakumar (2015) reported an inverse U-shaped relationship between temperature and rice yield, too. These findings are in agreement with studies on the effect of higher temperature on rice crop during its vegetative phase (Morita et al., 2004). It has been documented that the increase in temperature over a critical threshold can result in the loss of rice yield (Dash and Hunt, 2007; Geethalakshmi et al., 2011). The temperature of winter had, also, a significant U-shaped relationship with crop yield (*Table 4*).

To prevent the complicated analysis and explanation of climate factors because of quadratic and interaction terms, the computed marginal effects and elasticities of climate factors are shown in *Tables 5* and *6*, respectively.

Marginal effect analysis

Table 5 presents the marginal effects of seasonal climate factors on cereal grain yields, which were assessed at the average. The magnitudes of the marginal effects show that at current levels of rainfall, enhancing temperature over the summer, fall, and winter seasons boost wheat yield. The marginal increase in spring temperature, however, reduce wheat yield. In addition, a rise in rainfall over the spring, summer, and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

winter seasons causes a positive marginal effect while a rise in rainfall during fall season causes a negative marginal impact on the wheat yield. Also, outcomes indicate that at present levels of rainfall, a rise in summer and spring temperatures would increase maize yield, while the same increase in fall and winter seasons would decrease the yield. Moreover, analyzing season precipitations for maize shows that spring rainfall causes a positive marginal effect but that of other seasons have a negative marginal effect.

Finally, marginal impacts for rice show that rising temperature in spring season has a significantly harmful effect on rice productivity. However, increasing temperatures of summer, fall, and winter has beneficial effects on rice yield. Also, increasing summer and fall precipitation increases rice yield. The annual marginal impacts of temperature and rainfall for each crop are positive.

Table 5. *Marginal effects of climate factors on grain yield*

***, ** and * indicate significance at 1%, 5%, and 10% levels, respectively

Table 6 represents the elasticities of climate factors in the model. The regression coefficients and average values of climate factors were applied for computing elasticities of seasonal temperature and precipitation. The outcomes demonstrate that a 1% rise in temperature over the summer, fall, and winter will enhance yield by 0.027, 0.021, and 0.01%, respectively, while the rise in temperature by 1% during the spring reduces yield by 0.033%. Also, when the spring, summer, and winter precipitations are increased by 1%, wheat yield increases by 0.00063, 0.0013, and 0.000009%, respectively. However, rising rainfall over the fall season decreases yield by 0.00013%. Elasticities of annual climate factors offer that higher temperature and more precipitation increase wheat yield by 0.024% and 0.0018%, respectively.

In the case of maize, the results are different but the impacts of annual climate factors are similar. A 1% rise in temperature over the spring and summer increases yield by 0.139 and 0.157% but the same increase in fall and winter temperatures decrease

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_66916707
© 2018, ALÖKI Kft., Budapest, Hungary

yield by 0.0046 and 0.024%, respectively. Besides, a 1% increase in rainfall during the spring increases yield by 0.0023%. However, rainfall increase over the summer, fall, and winter reduces the maize yield.

Finally, the magnitudes of the elasticities show that a 1% rise in temperature over the summer, fall, and winter seasons would enhance rice productivity by 0.068, 0.087, and 0.01%, respectively. However, the rise in temperature by a 1% during the spring would reduce yield by 0.1%. The sum of elasticities is 0.065 showing that warming up of weather is beneficial for the rice yield. If annual average temperature rises by a 1%, rice yield enhances by 0.065%. Also, outcomes indicate that a 1% rise in rainfall over summer and fall seasons would increase rice yield by 0.0061 and 0.0017%, while the same increase in spring and winter seasons would decrease rice yield by 0.0057 and 0.0035%, respectively. The aggregate effect, i.e., the sum of all seasons, was found to decline the yield by 0.0013%.

As observed, the rainfall impact on product yield is unimportant comparing to the temperature effect. This difference could be because of the application of irrigation to cultivate the crops.

Discussion

The present research was conducted based on the Ricardian method to investigate the climate alteration impact on cereal production in Iran with emphasizing on wheat, maize, and rice crops. The outcomes based upon Prais-Winsten models with panels corrected standard errors (PCSEs) estimation offer that climatic change influences cereal production significantly; however, the impact varies across the crops. The marginal effect analysis revealed that a marginal temperature rise over the summer, winter, and fall seasons boost wheat yield, while a marginal temperature rise over the
