(Received 23rd Oct 2017; accepted 20th Jun 2018)

Abstract. This study has aimed to diagnose and compare the predominant weed species in cowpea crop in the Amazon region and to evaluate the effectiveness of herbicides applied in pre-emergence. The weed sampling was obtained before planting, the cowpea cultivar was BRS Aracê, by collecting all the plants present within a 0.25 m² hollow frame, randomly thrown 40 times in experimental area to calculate the phytosociological indices. The herbicide efficiency experiment was conducted in a randomized block design with four replications, in time subdivided plot model. Treatments were applied one day after crop planting, their doses (g/ha ai) were: metribuzin (360), sulfentrazone (600), S-metolachlor (1200), pendimethalin (750), oxadiazon (1000), alachlor (2400), metribuzin + pendimethalin (360 + 750), metribuzin + alachlor (360 + 2400), manual weeding and weedy check. The evaluations of weed control were done at 21, 28 and 35 DAP. The most important weed in phytosociology was *Tridax procumbens*. Cultivation of the crop with weeds caused a reduction of more than 66% in crop productivity. The application of the metribuzin herbicide prevented the emergence of all cowpea seedlings while oxadiazon satisfactorily controlled the weeds without affecting the crop yield.
Keywords: *importance value index, chemical control, selectivity, tolerance*

Introduction

Cowpea (*Vigna unguiculata* (L.) Walp) is an annual grain legume (Fabaceae) native to west Africa, and possibly originated in Nigeria (Rachie and Roberts, 1974).

Cowpea is a widely adapted, stress tolerant grain, vegetable, and fodder crop grown on about 7 million ha in warm to hot regions of Africa, Asia, and the Americas (Yadav et al., 2017). Historically, cowpea production is made by small producers using a low technology level (Costa et al., 2017), from the North and Northeast regions of Brazil. The Brazilian average productivity of cowpea is between 300 and 400 kg/ha, considered low when compared to its productive potential (1000 kg/ha) (Mancuso et al., 2016).

The factors contributing to the low productivity of cowpea in Brazil are mainly related to the absence of mechanization and the low investment in the control of weeds and pests (Filgueiras et al., 2009).

Therefore, one of the major problems encountered by producers in the northern region of Brazil is the interference of weeds in the crop, since sowing is done in wide spacing and the initial growth of cowpea is slow (Costa et al., 2017). The problem of weed has been reported more severe during rainy season, as weeds come in 2-3 flushes and growth is very fast, therefore, they compete for light, nutrient and space and are responsible for reduction in crop yield and productivity by up to 70% (Moody,1973).

Type of weeds, weed density, their persistence and crop management practices determine the magnitude of yield loss (Omisore et al., 2016). The identification of weeds at the level of genus and species is a basic task, constituting a fundamental instrument of phytosociological surveys that will be the basis for the knowledge of the main weeds present in a given area. The progress of phytosociological evaluations has been slow and non-isochronous in the different research groups in the country.

The critical period of crop weed competition in cowpea has been identified as 20-30 days after sowing and presence of weeds beyond this period causes severe reduction in yields (Gupta et al., 2016). Hence, weed control needs to be undertaken during initial period of crop growth.

The occurrence of weed flora under any crop production system greatly influenced by range of factors such as history of the planting area, soil seed bank, tillage operations, selection of crops, application of chemical fertilizer, irrigation and agronomic practices etc (Saved et al., 1990). Beside these, the weed control measures (Hass and Streibig, 1982) and environment factors (Schemer and Chilcote, 1969) also significantly influenced the distribution of weed flora. Therefore, it is fundamental to know the phytosociology of weeds that compete with a crop, understanding the plant communities from a floristic and structural point of view and knowing the species present in a specific area (Braun-Blanquet, 1979).

Still widely used by smallholders, manual weeding although proven effective, it is not economically viable on a large scale because of the high labor cost, so integrated weed management is the best approach to minimize weed interference and productivity losses (Kumar and Singh, 2017). The suggestion that integrated weed management can be useful to provide better weed control measures should further be assessed. Omisore et al. (2016) compared different weed control methods in cowpea production and pre-emergence herbicide + hoe weeding at 6 weeks after planting was more effective in controlling weeds and increase grain yield.

Chemical weed control, i.e. use of herbicide proved the most practical, effective and economical means of controlling even unapproachable or in accessible weed or noxious weed (Yadav et al., 2017).

There are no registered herbicides for cowpea in Brazil, which prevents recommendations, however for crops belonging to the same botanical family (Fabaceae) as common bean (*Phaseolus vulgaris* L.) and soybean (*Glycine max* L.) are registered 27 and 55 herbicides, respectively.

Another aspect to be considered in the application of herbicides in this crop is the lack of knowledge about the tolerance of the many varieties to the herbicides (Harrison and Fery, 1993). There is great variability in the tolerance of cowpea genotypes to herbicides such as bentazon, in which more susceptible genotypes were killed, or very affected, with applications of 2000 g ai ha^{-1}, while the most tolerant ones resisted at the dose of 16.000 g ai ha^{-1} (Harrison and Fery, 1993).

Study the selectivity of herbicides to this culture is promising because the chemical control ensure less dependence on labour, efficiency even during the rainy season, effectiveness in controlling weeds in the planting furrow and not affecting the root system of the crops and being efficient in controlling vegetative propagation in the weeds (Costa et al., 2017). Herbicides already available in the Brazilian market, especially those used in common bean and soybean crops, can be effective for the control of weeds in cowpea, without causing injury or yield losses,.

The aim of this study was to get to know the characteristics of the characteristics of weed community of cowpea crop in the Amazon region of northern Brazil and to evaluate the selectivity and efficiency of herbicides applied in pre-emergence in cowpea crop.

Materials and methods

The experiment was conducted in the Agricultural Sciences Center of Federal University of Roraima, Cauamé Campus, municipality of Boa Vista in the State of Roraima, latitude 2°52'15.49" N, longitude 60°42'39.89" W and 85 m of altitude, with annual average precipitation of 1.678 mm (Araújo et al., 2001).

The soil of the experimental area was classified as Yellow Udox Soil and based on interpretation of chemical analysis, the soil was fixed using 1.500 kg/ha of limestone, 50 kg/ha of FTE BR 12, 90 kg/ha of P_2O_5 in the form of simple superphosphate and 60 kg/ha of K_2O in the form of potassium chloride.

Weed collection was performed immediately before planting, by the square inventory standard method. A 0.25 m^2 square was used, which was randomly launched for 40 times in the usable area. All weeds that were contained in the square were collected with root system and aerial part.

The collected species were identified and quantified according to family, genus and species by analysis of the external morphological characteristics of the vegetative and reproductive plant parts, according to literature, by comparison with other species identified and also by consulting experts.

The floristic list with families and species was organized according to the classification system established in the Angiosperm Phylogeny Group III guidelines (APG III, 2009). All scientific names and their authors were confirmed after verification in the International Plant Names Index (IPNI, 2013).

Phytosociological structure was assessed based on parameters such as the relative values of frequency, density and abundance and the importance value for each species according the methodology proposed by Braun-Blanquet (1979) (*Table 1*).

Table 1. *Description of the evaluated characteristics, formulas and evaluation method for the phytosociological survey based on the methodology proposed by Braun-Blanquet (1979)*

Characteristics	Method
Frequency (F)	Number of releases that contain the species/Total number of releases
Density (D)	Total number of individuals per species/Total area collected
Abundance (A)	Total number of individuals per species/Nº of releases that contain the species
Relative frequency (RF)	(Species frequency x 100)/Total frequency of all species
Relative density (RD)	(Species density x 100)/Total density of all species
Relative abundance (RA)	(Species abundance x 100)/Total abundance of all species
Importance value (IV)	RF + RD + RA

The seeds of the BRS Aracê cowpea variety, used in this study, were inoculated with the *Bradyrhizobium* BR 3262 strain recommended for the state of Roraima. The soil management system of the area was no-tillage, with sowing done with a mechanized planter at a spacing of 0.5 m between rows and planting density of 10 seeds per linear meter.

The experiment was designed in randomized blocks with 4 replicates in the time subdivided plot model. The plots consisted of herbicides applied in pre-emergence (*Table 2*) and the subplots consisted of 3 evaluation periods with a 7-day interval between them (21, 28 and 35 days after emergence). Pre-emergent herbicides, registered for the cultivation of soybeans and common bean, were used, in addition to some mixtures, except oxadiazon (registered for some horticultural crops, rice and sugar cane). These herbicides, although presenting different mechanisms of action, presented some degree of selectivity to other varieties of cowpea or to soy or bean crops.

Table 2. *Herbicides used in pre-emergence as a strategy to control weeds in cowpea, their modes of action, crops for which they are registered in Brazil, Boa Vista-RR, 2016*

	Pre-emergent herbicides	**Mode of action**	**Crop (Fabaceae)**	**Dose (g ha^{-1} a.i.)**
T1	Metribuzin	Selective, systemic with contact and residual activity. Inhibits photosynthesis (photosystem II)	Soybeans	360
T2	Sulfentrazone	Cell membrane disruption - PPO inhibitor	Soybeans	600
T3	S-metolachlor	Selective, absorbed through roots and shoots. Inhibition of VLCFA (inhibition of cell division)	Soybeans; Common bean	1200
T4	Pendimethalin	Selective, absorbed by roots and leaves. Inhibition of mitosis and cell division. Microtubule assembly inhibition	Soybeans	750
T5	Oxadiazon	Selective with contact action. Inhibits protoporphyrinogen oxidase, leading to irreversible cell membrane damage	-	1000
T6	Alachlor	Selective, systemic action absorbed by germinating shoots. Inhibition of VLCFA (inhibition of cell division)	Soybeans, Peanuts	2400
T7	Metribuzin +Pendimethalin	Inhibits PSII+ Microtubule assembly	Soybeans	360+750
T8	Metribuzin+ Alachlor	Inhibits PSII+Inhibition of VLCFA	Soybeans	360+2400
T9	Weed-free (manual weeding)	-	-	-
T10	Weedy check	-	-	-

The experimental plot consisted of six rows with 5 m of length, however, it was considered useful area of the plot the two central rows. The two lateral rows in addition to 0.5 of the frontal ends of the plot were considered border. The total area of the experiment was 600 m^2 and the total useful area was 200 m^2.

The herbicides were applied one day after planting and a costal spray, equipped with two TT 110.02 nozzles, spaced 0.5 m, maintained at a pressure of 2 bar, and a syringe volume of 170 L/ha was used.

The evaluation of control efficiency at 21, 28 and 35 days after planting (DAP) was based on a visual scale recommended by the Brazilian Society of Weeds. Percentage notes were assigned from 0 to 100%, where 0 (zero) indicates the absence of control and 100 the total control of weeds.

The results were submitted to the normality test of Shapiro-Wilk, visual control rating data were arc-sine square root transformed prior to analysis. Back-transformed are presented with mean separation based on transformed values. Data were subjected to ANOVA, when the variances were significant, the means were compared by the Tukey test at $p \leq 0.05$, using the software R™ version 2.12.2 and the package ExpDes english (R Core Team, 2017).

Results

This weed community was represented by 29 weed species from 10 different botanical families, 34.5% were monocots and 65.5% were dicots. *Table 3* shows the weed species found in the area and their respective common names and EPPO codes subdivided into botanical families.

Table 3. *Weed species found in the area with their common names and EPPO codes, distributed by botanical families*

Botanic family	Scientific name	Common name	EPPO code[1]
Asteraceae	*Acanthospermum australe* (Loefl.) Kuntze	Paraguayan starbur	ACNAU
	Emilia coccinea (Sims) G. Don	Scarlet tasselflower	EMICO

The botanical families with the highest number of species were Fabaceae, Poaceae and Asteraceae with 7, 6 and 5 species, respectively, representing 62% of the weed species found in the studied area. There is a high number of weed species in the area belonging to the same botanical family of cowpea (Fabaceae).

Table 4 shows the phytosociological parameters (RF, RD, RA and IV) of weed species found in the experimental area. For the values of relative density, there are 5 prominent species: *Tridax procumbens* (21.21%), *Praxelis pauciflora* (13.26%), *Digitaria insularis* and *Digitaria sanguinalis*, (10.23% both) and *Chamaesyce hirta* (9.47%). The other species showed relative density (RD) lower than 5%.

Table 4. *Phytosociological parameters (RF, RD, RA and IV) of weed species found in the experimental area*

Species	RD	RF	RA	IV
Acanthospermum australe	1.89	9.71	2.32	13.92
Alternanthera tenella	4.17	2.18	6.8	13.15
Amaranthus viridis	1.52	2.18	2.47	6.17
Boerhavia diffusa	0.38	0.73	1.86	2.96
Brachiaria decumbens	1.52	2.18	2.47	6.17
Calopogonium mucunoides	0.38	0.73	1.86	2.96
Cenchrus echinatus	2.65	3.64	2.6	8.89
Chamaecrista conferta	0.38	0.73	1.86	2.96
Chamaecrista hispidula	0.38	0.73	1.86	2.96
Chamaesyce hirta	9.47	8.01	4.22	21.7
Chamaesyce hyssopifolia	1.52	1.46	3.71	6.68
Commelina benghalensis	3.03	2.91	3.71	9.65
Cyperus ferax	0.76	1.46	1.86	4.07
Cyperus flavus	0.38	0.73	1.86	2.96
Cyperus rotundus	1.52	0.73	7.42	9.66
Desmodium tortuosum	2.65	4.37	2.16	9.19
Digitaria horizontalis	1.89	2.18	3.09	7.17
Digitaria insularis	10.23	12.38	2.95	25.55
Digitaria sanguinalis	1.14	1.46	2.78	5.38
Emilia coccinea	10.23	6.55	5.57	22.35
Emilia sonchifolia	1.89	1.46	4.64	7.99
Indigofera hisurta	0.38	0.73	1.86	2.96
Ipomoea nil	0.38	0.73	1.86	2.96
Mimosa candolei	0.38	0.73	1.86	2.96
Paspalum dilatatum	2.27	0.73	11.13	14.13
Praxelis clematidea	13.26	12.38	3.82	29.46
Tridax procumbens	21.21	12.38	6.11	39.7
Waltheria indica	2.27	3.64	2.23	8.14
Zornia latifólia	1.89	2.18	3.09	7.17

The species *T. procumbens, P. pauciflora* and *D. insularis* stand out for their high frequency in the study area, as well as *Acanthospermum australe* and *C. hirta*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_53115322
© 2018, ALÖKI Kft., Budapest, Hungary

Paspalum dilatatum showed the highest value of relative abundance (11.13%) followed by *Cyperus rotundus* (7.42%) and *Alternanthera tenella* (6.80%).

From the values of relative density, frequency and abundance the importance value index (IV) was calculated and it is possible to observe in the results the prominence of 5 species, *Tridax procumbens*, *Praxelis pauciflora*, *Digitaria insularis*, *Emilia coccinea* and Chamaesyce hirta, considering the most important with IV of the order of 39.7%, 29.46%, 25.55% 22.35% and 21.70%, respectively. The other species belong to groups that present important value indices ranging from intermediate to low.

Although studies suggest that the best strategy for weed management is the application of pre-emergence herbicides and manual weeding 40 days after planting (Yadav et al., 2015), it was decided to only apply pre-emergence herbicides with the intention of reducing manual labor costs.

Table 5 shows the efficiency of the pre-emergence herbicides applied to control the weed community of cowpea in the Amazon region. There was a significant interaction between the herbicide used and the weed control efficiency at different evaluation times after application

Table 5. *Herbicides efficiency (%) in weed control at 21, 28 and 35 days after planting of cowpea and grain yield (kg/ha)*

Herbicides (H)	**Days after planting (DAP)**			**Yield (kg/ha)[2]**
	21	**28**	**35**	
	Weed control efficiency (%)[1, 2]			
Metribuzin	92.5 Aa	88.7 ABa	91.2 ABa	0.00 D

F(HxDAP)	4.41**			-

[1]Data were arc-sine transformed before analysis; however, back-transformed actual mean values are presented based on the interpretation from the transformed data

[2]Means followed by the same letters, lowercase in the rows and uppercase in columns, do not differ significantly by Tukey's test ($p < 0.05$); **Significant at $p \leq 0.01$ by the F-test

Cowpea grain yield was significantly reduced by weed interference (565.90 kg/ha), evidencing the low competitive capacity of the crop. the treatment without weed control when compared to the treatment maintained under manual weeding, which obtained the highest recorded productivity (1668.93 kg/ha), was responsible for a loss equivalent to 66.09%.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

The herbicides Metribuzin, Sulfendrazone, Oxadiazon and the mixture of Metribuzin with Alachlor showed, until 35 days after sowing the cowpea, weed control efficiency means higher than 75%.

The application of the metribuzin herbicide prevented the emergence of all cowpea seedlings resulting in no grain yield and the mixture of metribuzin with Alachlor or Pendimethalin caused enough crop injury to reduce yields by 66.45% and 76.28%, respectively. These crop yield reductions are superior to the loss caused by weed competition in the treatment without control of the infestation (66.09%). Sulfentrazone reported control results of weed plants (80% at 35 DAP) similar to the herbicide metribuzin, causing severe injury and loss of cowpea productivity compared to weed-free treatment (62.99%).

The herbicide oxadiazon presented a good result in relation to weed control (77.5%), without affecting crop yield.

The herbicides S-metolachlor and Pendimethalin showed good crop yields (1315.52 kg/ha and 1436.92 kg/ha), although not very good weed control efficiency (52.5% for both). The other herbicides tested were statistically placed in intermediate groups regarding weed control efficiency and weedy check plots presented the worst results, being used as a parameter to evaluate herbicides with less efficiency of weed control (Alachlor and the Metribuzin + Pendimethalin mixture) (*Table 5*).

Discussion

The greater infestation of dicots in cowpea compared to monocots was also observed by Batista et al. (2017) and the fact that these weeds belong to the same class of cowpea makes their control, especially the chemical, difficult.

Several authors have highlighted the predominance of Fabaceae, Poaceae and Asteracerae families in the Amazon region, especially in agricultural areas. Marques et al. (2010), while evaluating the floristic composition of weeds in the cowpea culture in the mulch system, verified that the Cyperaceae, Fabaceae, Poaceae, Malvaceae, Asteraceae and Rubiaceae families were the ones presenting the highest number of species and greatest importance. Leal et al. (2006) studying the seed bank in systems of production of agriculture with burning and without burning in the State of Pará, also cited these families as predominant in the area and highlighting their aggressive potential in the Amazon region.

There is a high number of weed species in the area belonging to the same botanical family of cowpea (Fabaceae). Although the relationship between competition between plants and phylogenetic proximity is unimportant in comparison to competitive capacity and functional characteristics of plants, such as height, for example (Cahill et al., 2008), weed species belonging to the same family have botanical characteristics and nutritional requirements similar to those of the crop, which can make them aggressive competitors in the agricultural environment

Tridax procumbens, Praxelis pauciflora, Digitaria insularis, Digitaria sanguinalis and *Chamaesyce hirta* were the species that had higher relative density (RD). According to Swanton et al. (2015), the time of weed emergence relative to the crop is the most important factor in the crop-weed competition, with the density of weed seedlings being the second major variable. There is a relationship between weed density and duration of interference. The length of a critical period for weed control varies with density just as density thresholds vary with time of weed emergence relative to the crop (Dunan et al., 1995).

Frequency (F) is the proportion of sampling units (e.g., quadrat; field) that contains the species. *Tridax procumbens, Praxelis pauciflora, Digitaria insularis, Acanthospermum australe* and *Chamaesyce hirta* stand out for their high relative frequency (RF) in the study area. Recording frequency is fast and nondestructive is less prone to incorrect estimates than density. In situations where appropriate sampling techniques are employed and sampling points are uniformly distributed across the sampled area, frequency can be a good indicator of the spatial distribution of a species within the sampled area (Nkoa et al., 2015)

The species with the greatest abundance (RA) were *Paspalum dilatatum, Cyperus rotundus* and *Alternanthera tenella.* Abundance measures the quantitative significance of a species in its habitat. It describes the species' success in terms of numbers. High relative abundance is related to the appearance of weeds in reeds, and it is fundamental to indicate local actions to control weeds not only in cowpea but also in crops in general (Dias et al., 2007).

The importance value index (IV) was calculated from the values of relative density, frequency and abundance. The IV groups the parameters mentioned above and classifies each species in the weed community according to its ability to cause damage and reduce the productivity of cowpea. The IV groups the parameters mentioned above and classifies each species in the weed community according to its ability to cause damage and reduce the productivity of cowpea (Concenço et al., 2013). *Tridax procumbens, Praxelis pauciflora, Digitaria insularis, Emilia coccinea* and *Chamaesyce hirta* were considered the 5 most important species of the studied area.

In their studies, Kissmann and Groth (1999) also emphasized the importance of the species *T. procumbens*, which, in addition to high relative density and relative frequency, also shows concentration of individuals in specific areas, as shown by the high relative abundance. The IV of this species reveals its competitive potential in relation to the crops. *T. procumbens* is an annual herbaceous species propagated by seeds and should be controlled in the early stages of development or by the use of pre-emergent herbicides. *P. pauciflora* presented the second highest IV, it is an annual herbaceous species and often forms dense populations due to the ease of germination and high potential for spread of seeds which are easily transported by wind.

D. insularis is an annual species and reproduces by seeds and rhizomes. Jakelaitis et al. (2003) emphasize its importance, mainly due to its habit of overgrown growth, which besides competing for area, water and nutrients, can exceed the plants of cowpea in height, harming its development. It is also worth mentioning that its habit of growth facilitates the development of pests and diseases in cowpea. The species *E. coccinea* and *C. hirta* are annual herbaceous plants propagated by seeds and should also be considered important when thinking about weed control to maintain good productivity levels of cowpea.

Due to the short cycle, cowpea becomes extremely susceptible to competition with weeds, especially at the beginning of their development (Lamego et al., 2011). The phytosociological study was done before planting the cowpea to know the local weed community and then defining a weed control strategy.

Although studies suggest that the best strategy for weed management is the application of pre-emergence herbicides and manual weeding 40 days after planting (Yadav et al., 2015), it was decided to only apply pre-emergence herbicides with the intention of reducing manual labor costs.

Cowpea grain yield was significantly reduced by weed interference. In other field experiments, yield reductions reach 90% (Freitas et al., 2009) in the absence of weed control. Untreated weed treatment presented average productivity comparable to treatments that used nonselective herbicides, so interference from competition for essential factors equates to damage caused by the phytotoxicity of the applied products. Pre-emergent herbicides with prolonged residual effect have been used as an effective strategy to control weeds during the critical period of competition with the crop (Monquero et al., 2008).

The herbicide metribuzin is not selective for cowpea and in field experiments the cowpea presented marginal tolerance to the herbicide presenting severe injuries and drastic yield reduction. (Costa et al., 2017). Although promising results for selectivity of cowpea to sulfentrazone (Costa et al., 2017), the use of this herbicide drastically decreased the productivity of the crop in this study, this behavior may be due to the dosage of the sulfentrazone applied or the variety of cowpeas used, since it is known that sulfentrazone can cause phytotoxicity to cowpea in high doses as there is a difference in the effect of the herbicide between the cultivars (Azevedo et al., 2016). For varieties with lower tolerance to sulfentrazone, growers need to ensure the quality of application in relation to soil type and pH, otherwise the herbicide may present phytoxicity.

The herbicide oxadiazon presented a good result in relation to weed control without affecting crop yield. Fontes et al. (2010) obtained similar weed control (82%) in the Amazon region without affecting the BRS Guariba variety using the 600 g ia. ha^{-1} dose. Oxadiazon has as its mechanism of action the inhibition of the enzyme protoporphyrinogen oxidase (PPO) e and when applied in pre-emergence of weeds, phytotoxic actions occur during emergence of seedlings, close to the soil surface in a 0-5 cm depth range. Fontes et al. (2010) obtained similar weed control (82%) in the Amazon region without affecting the BRS Guariba variety using the 600 g ia. ha^{-1} dose. Oxadiazon has as its mechanism of action the inhibition of the enzyme protoporphyrinogen oxidase (PPO) e and when applied in pre-emergence of weeds, phytotoxic actions occur during emergence of seedlings, close to the soil surface in a 0-5 cm depth range (Silva et al., 1999).

Conclusion

Tridax procumbens, *Praxelis pauciflora*, *Digitaria insularis*, *Emilia coccinea* and *Chamaesyce hirta* were the species with the highest index of importance (IV) in the Amazonian cowpea area, difficult to control plants with high reproductive rates, these weeds play aggressive competition with cowpea plants for environmental resources and need to be controlled in the early stages of their development, so the use of pre-emergent herbicides are recommended as a control strategy.

Weed competition severely reduces cowpea productivity. The herbicides metribuzin, sulfentrazone and oxadiazon were satisfactory levels of weed control; however, the use of metribuzin resulted in no yield of the culture, preventing its germination. The sulfentrazon, which is considered selective for cowpea beans, significantly reduced the yield of the crop under the tested conditions and variety. The use of oxadiazon in pre-emergence was an effective strategy for weed control up to 35 DAP without reducing crop yield.

(Received 15th May 2018; accepted 27th Jun 2018)

Abstract. Karakoram mountain range contains the tallest mountain peaks of the world with thousands of glaciers which are microbiologically untapped. This is a pioneer approach of isolation and characterization of fungi from Batura glacier, Karakoram, Pakistan. Total number (CFU/mL or g) was determined at 4 °C and 15 °C to isolate psychrophilic and psychrotrophic fungi, respectively. About 33 different fungi were isolated from sediment (29), ice (2) and water (2) and were identified morphologically and by sequencing of specific internal transcribed spacer region of the species through internal transcribed spacer 1 (ITS1) and internal transcribed spacer 2 (ITS2) primers. Mostly, the fungal isolates belonged to genus *Penicillium*, followed by *Cladosporium*, *Geomyces*, *Cordyceps*, *Mrakia*, *Cadophora*, *Tetracladium*, *Eupenicillium, Trametes*, *Mortierella*, *Scopulariopsis*, *Beauveria, Candida* and *Pseudogymnoascus*. They showed growth at wide temperature range from 4–37 °C, few at 45 °C as well. Most of the isolates were able to grow at pH 1–13. Fungal isolates were able to grow in 2–26% NaCl, with the highest tolerance (26%) by *Mrakia robertii.* All study isolates showed inhibitory activity against *Staphylococcus* sp., and four industrially important enzymes (cellulase, DNase, lipase and phosphatase) were produced by *Mrakia robertii.* The fungal isolates of such cold habitats are potential sources of various industrial and environmental application.
Keywords: *non-polar glaciers, diversity, psychrotrophs, antimicrobial activity, industrial applied enzymes*

Introduction

Psychrophiles are known as cryophile or 'cold-loving' organisms (Margesin et al., 2007) having ability to grow and survive in cold environment. According to Morita (Morita, 1975), psychrophiles grow and survive below 20 °C providing 15 °C as optimum growth temperature. However, the psychrophiles in cold environment are also accompanied by psychrotrophs. The psychrotrophs possess ability to grow below and above 20 °C but their growth optimum has been observed beyond 20 °C (Baross and Morita, 1978; Cavicchioli et al., 2002; Gounot, 1986). Psychrotrophic community have been described as "the survivor's community" by Friedmann (1994) because of their survival strategies and their normal physiological state under low temperature (Morita, 2000).

Psychrophilic and psychrotrophic fungi have widely been studied for their presence in several cold environments as reviewed by Hassan et al. (2016) such as Arctic and Antarctic region (Azmi and Seppelt, 1997; Babjeva and Reshetova, 1998; Selbmann et al., 2005; Vishniac, 2006). Furthermore, different cold environments including permafrost (Broady et al., 1998), cold water (Botha and Wolfaardt, 2000; Dmitriev et al., 1997), ice

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_53235341
© 2018, ALÖKI Kft., Budapest, Hungary

in glacial habitats (Ma et al., 1999), snow and below snow-covered tundra (Schadt, 2000), polar water present in off shore area (Broady et al., 1998) and massive glacial sheets of ice and ice shelves freshwater (Bridge, 2010; Tojo and Newsham, 2012) have been investigated for cold adapted fungi. Limited research data is available on the fungal diversity and characterization in non-polar regions such as Hindukush, Karakoram, and Himalayas (HKKH). A proper investigation was needed for existence of cold adapted and psychrophilic life (microorganisms) in the HKKH glaciers.

The rate of discovery of new antibiotics is very slow as compared to emerging of antibiotic resistant pathogens in the current era. Treatment of several pathogens are now difficult due to dearth of operative antibiotics, e.g. Enterobacteriaceae bacteria producing extended spectrum beta-lactamase (ESBL), *Enterococci* sp. with vancomycin resistant abilities and *Staphylococcus aureus* with methicillin-resistant capabilities. It is important to explore extreme habitats for new antibiotics having diverse and unique characteristics. There is many diverse type of extreme environments however cold habitats could be among important sources for the discovery of novel antibiotics. Therefore, we need to investigate novel antibiotics from extreme and unexplored sites against both multi-drug resistant bacteria and fungi.

Pakistan has one of the world's largest glacier reserves in the Karakoram–Hindu Kush–Himalaya ranges. According to Rahman et al. (2008), the junction of the Karakoram Western Himalayan and Hindu Kush mountain ranges are accompanied by the Northern Areas of Pakistan. Batura glacier considered as the largest glaciers located exterior the polar region. It is present in the north of Passu 7,500 m above sea level. Batura glacier has not been explored yet for the presence of psychrophilic and psychrotrophic fungi. Isolation and characterization of the psychrophilic and psychrotrophic fungal community from samples of glacier (ice sediments and water) taken from Batura glacier was the ambition of the current research.

Materials and methods

Sampling

The length of Batura glacier is 57 km with a termination point of ~3000 m altitude in the valley of Hunza, Pakistan, given in *Figure 1*. Several highlighted peaks of Karakoram (>7000 m in south and >5500 m in the north) surrounded the Batura glacier. Ice, water and sediments samples were taken from Batura glacier (36°30.302N to 074°51.138E) following standard microbiological procedures. Approximately 200–300 g sediments were taken using sterilized gloves and scoops to avoid sample contamination. Nasco Whirl–Pak™ bags (Fisher Scientific) were used to place individual sample (for sediments) and sterilized polyethylene bottles (for ice and water samples). The pH of all samples were 7.0 whereas temperature of glacial sediments and water were 1 °C while glacial ice had –2 °C. All the collected samples were kept at 4 °C until transported to Department of Microbiology Quaid-i-Azam University Islamabad and stored at –20 °C.

Isolation of fungi

For isolation of fungi Sabouraud Dextrose Agar (Sigma – Aldrich) (g/L; 10% mycological peptone 40% dextrose 15% Agar) Potato Dextrose Agar (Sigma – Aldrich) (g/L; 4% potato extract 20% dextrose 15% agar) and Malt Extract Agar (Sigma – Aldrich) (g/L; 30% malt extract 10% mycological peptone 15% Agar) were used as

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_53235341
© 2018, ALÖKI Kft., Budapest, Hungary

growth medium. Incubation temperatures were set at 4 °C and 15 °C. Total viable counts were determined in terms of fungal colony forming units (CFUs/mL or /g) and morphologically distinct colonies were further subcultured to get the pure cultures. Potato Dextrose Agar (PDA) slants were used for preservation of fungal isolates at 4°C and also under mineral oil till further use.

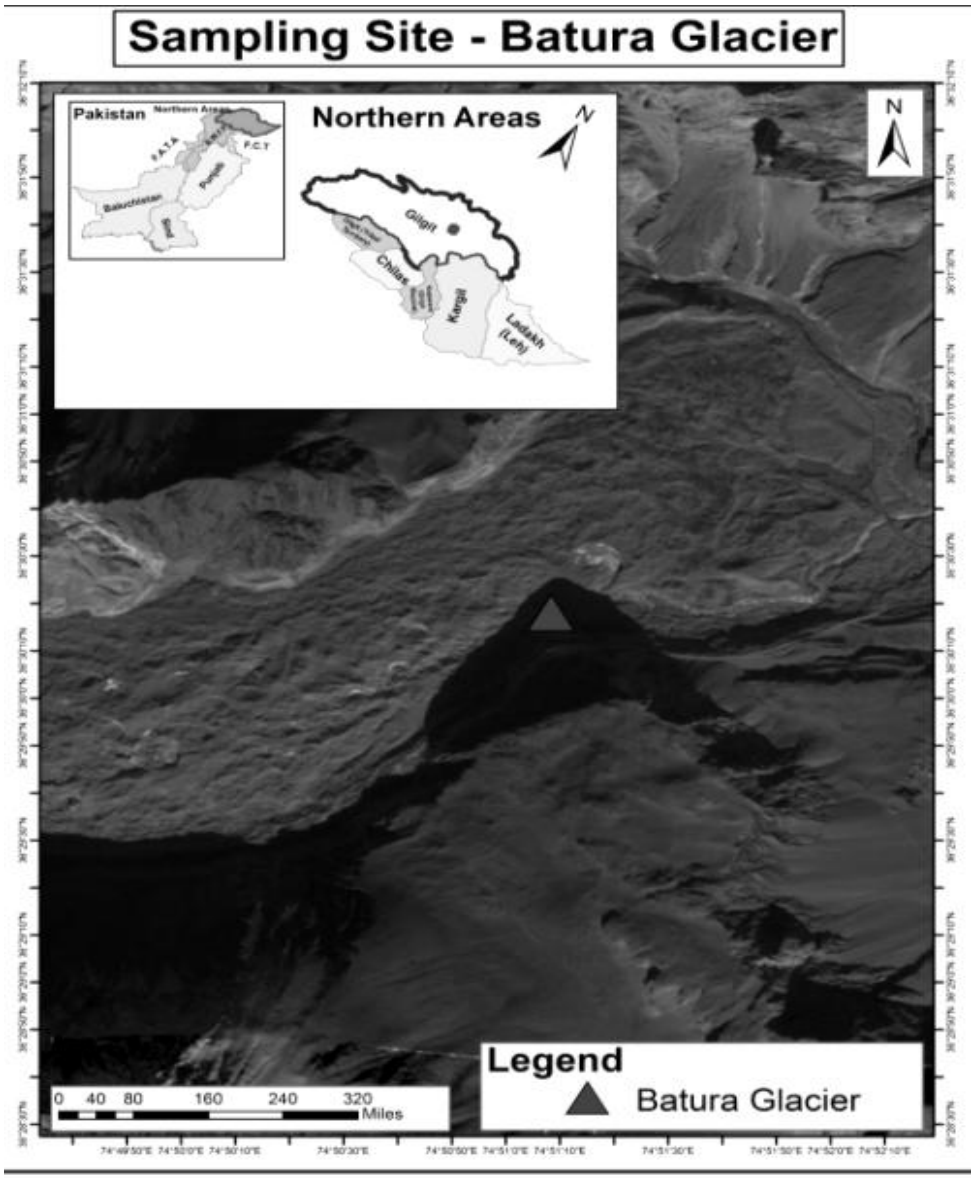

Figure 1. *Location of Batura glacier*

Morphological characterization

Different media such as PDA, Tryptic Soy Agar (Sigma – Aldrich) (g/L; 15% casein peptone 5% soya peptone 5% sodium chloride 15% agar) Sabouraud Dextrose Agar (SDA) and Malt Extract Agar (MEA) was used as growth media for fungal isolates. Color, texture and size (both front and reverse sides) were observed and recorded at 4 C and 15 C. Microscopic examination of fungal isolates was carried out following the protocol of Hassan et al. (2017).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_53235341
© 2018, ALÖKI Kft., Budapest, Hungary

Physiological characterization

All the physiological parameters were measured using SDA, MEA and PDA. Cultures were grown for 10 days. Diverse temperatures from 4 to 50 C (4, 15, 37, 45, and 50 C) were used to determine temperature optima of the fungal isolates. pH tolerance of the fungal isolates was determined by inoculating them separately in a medium adjusted to varying pH values (1, 3, 5, 7, 9, 11 and 13). For determination of halophilic nature of the fungal isolates, SDA complemented with NaCl up to 26% was used. All physiological examinations were carried out at 4 °C and 15°C.

DNA extraction and amplification

Rosa et al. (2009) DNA extraction protocol was used to extract the DNA of all the fungal isolates. The extracted DNA was amplified using internal transcribed spacer 1 (ITS1) – 5.8S – internal transcribed spacer 2 ITS2 region prior to sequencing following the protocol described by Hassan et al. (2016). T100™ Thermal Cycler (Bio Rad) was used for PCR amplification. Agarose gel electrophoresis was used to confirm PCR products *using standard DNA ladder.*

Phylogenetic analysis

Sequencing was done commercially by Macrogen (Macrogen Inc. Seoul Korea) and the sequences obtained were analysed by Chromas Lite, while further evaluation was done using National Center for Biotechnology Information (NCBI) database by comparing with available nucleotide sequences (Thompson et al., 1997). The GenBank sequence database was used to compare the obtained FASTA sequences to data using BLASTn (Altschul et al., 1990; Zhang et al., 2000). Accession no. of all fungal isolates were obtained by depositing sequences to National Centre for Biotechnological Information (NCBI). Tamura–Nei model of Maximum Likelihood method used to infer evolutionary history of fungal isolates (Tamura and Nie, 1993). MEGA6 software following maximum likelihood method has been used to construct phylogenetic tree (Tamura et al., 2013) at the bootstrap value of 1,000.

Evaluation of antimicrobial activity

Antimicrobial activity of isolated fungal isolates was checked against *Staphylococcus aureus* (Multi-drug resistant), *E. coli* (MDR), *Staphylococcus* sp., *Klebsiella pneumoniae* (MDR), vancomycin resistant *Enterococcus* species and fungal isolates *Candida albicans* and *Aspergillus niger* following the protocol described by Hassan et al. (2017).

Screening for extracellular enzyme activity

Extracellular enzyme activity of all fungal isolates was determined on solid media. Ten days old fungal cultures were used as inoculum. Hankin and Anagnostakis (1975) protocol was used to determine amylase, deoxyribonuclease, lipase and protease activities. The phosphatase activity was determined on Pikovskaya's medium (Pikovskaya, 1948). Carboxymethylcellulose (CMC) was used as a substrate for screening cellulolytic activity of all fungal isolates. 0.5% Congo red solution and 1 M NaCl were used to visualize zones of inhibition around fungal colonies formed due to cellulolytic activity. 15 °C were used for all assays of qualitative extracellular enzyme activities.

Results

33 fungal isolates were isolated in this study. The highest CFU/g/mL was observed in sediments ($1.11 \times 10^3$and 7.75×10^2 at 4 and 15 °C, respectively) and given in *Table 1*.

Table 1. *Total viable count (CFU/mL/gm) of fungal isolates at 15 °C and 4 °C*

Temperature (°C)	Samples	No. of colonies/200 µL	CFU/mL/gm
4	Glacier ice	2	1.0×10^1
	Glacier water	3	1.5×10^1
	Glacier sediment	2.2×10^2	1.11×10^3
15	Glacier ice	7	3.5×10^1
	Glacier water	4	2.0×10^1
	Glacier sediment	1.55×10^1	7.75×10^2

Morphology

Colony morphology of all the fungal isolates were different, mostly they were of cottony to powdery textures irregular shapes and sizes and of blue to green in color. The macroscopic and microscopic features of the isolated fungal strains are specified in *Table A1* in the *Appendix*. The hyphae were septate colorless and spores were mostly cylindrical to ovoid in shape.

Molecular characterization

On the basis of DNA sequence of internal transcribed spacer region by (ITS1 – ITS2), all isolated fungal isolates have shown diverse groups of taxonomy. The evolutionary relationships, respective homology and resemblance directory of the isolated fungal strains with narrowly correlated species of fungi as well as their accession no. is summarized in *Table 2* and *Figure 2*.

Physiological characterization

Temperature tolerance of the fungal isolates showed variable results. All were capable to grow between 4 and 37 °C. Two isolates, HB_3 and LB_{13} were capable to grow above 37°C (*Table 3*). However, 4 and 15 °C temperatures were found to be optimum growth temperature values, except for HB_2, HB_7 and HB_{14} in the case of which the optimum growth temperature was 37 °C. The growth pattern of the fungal isolates at varying pH (1, 3, 5, 7, 9, 11 and 13) was very broad. The optimum pH for growth was found to be between 4 and 9. Most of the isolates (79%) grew in acidic range, 7 could not grow at pH 1 while all other isolates showed growth at the lowest pH. All fungal isolates have survived at extreme alkaline pH up to 13. The fungal isolates have tolerated salt concentration between 2 and 26% (33 between 2 and 14% 32 at 16% 24 at 18% 17 at 20% 11 at 22 and 24% and 1 showed growth at 26% salt concentration), given in *Table 3*. Based on such results, the fungal isolates could be categorized as polyextremophiles.

Evaluation of antimicrobial activity

Screening of the fungal isolates for antimicrobial activity showed greater antibacterial than antifungal activities and summarised in *Table 4*. Five fungal isolates exhibited inhibitory activity against *Staphylococcus aureus*, 21 showed such activity against *Staphylococcus* sp., 3 against *Enterococcus* sp., 2 against *E. coli* but none showed antimicrobial activity against *Klebsiella pneumoniae*. The number of fungal isolates that displayed inhibitory activity against *Candida albicans* and *Aspergillus niger* were 10 and 4, respectively.

Screening for extracellular enzyme activity

In this study, maximum number of fungal isolates were found to produce phosphate (13 fungal isolates) followed by lipases (10), cellulases (7), amylases (6), DNases (1) and proteases (1) and summarized in *Table 5*. They were good in lipase production but were very poor in the production of DNase and protease. This research openly revealed that fungal isolates could be a good source of industrially important biocatalysts.

Discussion

The main objective of this research was to isolate and characterize the psychrotrophs and in the current study, a combination of morphological analysis and molecular methods were carried out for the identification of the fungal isolates. Out of 33 fungal isolates, four isolates LB_2 LB_3 LB_{15} and LB_{17} showed a similarity index up to 84, 87, 91 and 95% respectively and their sequences are deposited in database and to determine their taxonomic affiliation further investigations are needed. The fungal isolates were found to belong to mostly genus *Penicillium* (10) followed by *Cladosporium* (7) *Geomyces* (3) *Cordyceps* (1) *Mrakia* (2) *Cadophora* (1) *Tetracladium* (1) *Trametes* (1) *Mortierella* (1) *Scopulariopsis* (1) *Beauveria* (1) *Candida* (1) *Eupenicillium* (1) and *Pseudogymnoascus* (1).

The members of the genus *Geomyces,* are keratinophilic, psychrophilic and psychrotolerant in nature as have been reported by Blehert et al. (2009) and Arenz et al. (2011) from Antarctica and Arctic habitats as well as characterized as halotolerant and moderately cellulolytic. Fell and Stalzell-Tallman (1998) and Margesin et al. (2005) have earlier been documented *Mrakia* species with obligate psychrophilic nature from Antarctica, Alpine and Arctic habitats. Fungal species isolated in the present study that related to *Penicillium*, Candida, *Cladosporium*, *Pseudogymnoascus* and *Cadophora* have previously been reported in Antarctica and Alpine habitats (Burgaud et al., 2010; Dhakar et al., 2014; Duncan et al., 2006; Goncalves et al., 2012; Wang et al., 2015).

Tetracladium species have been found in alpine glaciers and snow-covered soil therefore considered to be cold-adapted (Kuhnert et al., 2012; Robinson et al., 2000). *Mortierella* species have been reported from Antarctic soil and mosses (Bridge and Newsham, 2009). The fungal species *Eupenicillium tularense Beauveria bassiana* and *Scopulariopsis brevicaulis* have not been reported from the low temperature habitats previously these species have been isolated for the first time from non-polar glacier in this study. Although *Trametes* sp. and *Cordyceps* sp. have been found for the first time in non-polar glaciers in this study but as the isolates showed low similarity (87% and 91% respectively) which most probably belong to genera other than *Trametes* and *Cordyceps* because they have homology less than 97% (Goncalves et al., 2012).

Batura glacier is one of the coldest non-polar glacier having very low temperature often below freezing point (–2 °C). In this study fungal isolation from such low temperature habitat indicate the possible role of the spores in their survival. Spores facilitate the existence of both bacteria and fungi in extreme environments as they protect them from UV-radiation and DNA damages (Ma et al., 2000). According to Robinson (2001), fungal persistence may possible due to cold circumvention rather than cold tolerance in Arctic and Antarctic habitats. Vishniac (1996) believed that spores helped more fungi to endure freezing than vulnerable hyphomycete hyphae. Catranis and Starmer (1991) and Ma et al. (2000) have isolated several of fungal isolates up to 140,000 years old from ice cores of Greenland. These studies show that fungal spores are central to survival of fungi in cold environments.

In the current study, the fungal isolates survived and grown at various extreme physiological parameters including temperature, NaCl and pH. Based on such results, fungal isolates grouped as psychrotolerants, halotolerants and thermotolerants as they tolerated broad range of temperature i.e. low and high temperature (from 4 to 45 °C) and the highest NaCl concentration (up to 26%). The isolates are highly diverse in terms of temperature requirement. They showed growth at lower temperature range (4–15 °C) which is a key property of psychrophilic organisms but they also showed growth at

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

higher temperatures. The ability of fungal isolates to grow at low and high temperature and high concentrations of salt possibly indicated mechanisms involved in the protection against such stressful conditions. Production of polyols, lipid/fatty acids and antifreeze proteins, etc. by cold adapted microbes are central mechanisms to overcome stressful conditions (Robinson et al., 2001). In this study the isolate *Mrakia cf. gelida* was capable of surviving at 45 °C and this was the first report of *Mrakia cf. gelida* from the glacier habitat that shown such a thermophilic nature because members of genus *Mrakia* have been reported as of psychrophilic nature (Xin and Zhou, 2007). Maheshwari[46] defined thermophilic fungi as they are able to grow between 20 and 55 °C. Our results are supported by Zucconi et al. (1996), who isolated thermotolerant-mesophilic fungi from Victoria Land Antarctica that was able to grow at 45 °C.

Fungal isolates showed growth on wide range of pH (1–13) which is a remarkable discovery of current research. Generally, acidic environment favors growth of fungi. On the other hand, the isolated fungal strains tolerated diverse salt concentrations (2–26%). Several fungal isolates showed growth at 24% (NaCl), whereas 1 of the fungal isolates could grew at 26% salt concentration as well. According to existing literature, many of the fungal isolates representing different genera isolated from the low temperature environments (*Cladosporium Cordyceps Mrakia Cadophora Tetracladium Trametes, Mortierella, Scopulariopsis, Beauveria, Candida, Eupenicillium* and *Pseudogymnoascus*) were characterized for the first time at such an extreme pH and salt conditions in the present study. However, species of the genera *Penicillium, Geomyces* and a few others (isolated from cold and other habitats) have been observed to grow at both high and low pH as well as the highest salts concentrations (Dhakar et al., 2014; Eliades et al., 2006; Grum-Grzhimaylo et al., 2013; Kochkina et al., 2007).

Secondary metabolites production by fungal isolates most importantly represented by antimicrobial activity have also been investigated in this study. Previously many fungal isolates have been found to produce secondary metabolites with bactericidal and fungicidal activity. In our study, fungal isolates exhibited decent antimicrobial activities against genus *Staphylococcus* as compared to other bacterial fungal genera. Screening of fungi from cold habitats against clinical bacterial isolates and fungal strains has not yet been reported. However, Brunati et al. (2009) screened more than 150 fungi and 165 yeasts (benthic mats of Antarctic lakes) against bacterial and fungal human pathogens from Merck Culture Collection (MB MY) and American Type Culture Collection (ATCC) including *Staphylococcus aureus, Enterococcus faecium, Escherichia coli, Moraxella catarrhalis, Pseudomonas aeruginosa, Candida albicans, Aspergillus fumigatus* and *Cryptococcus neoformans* but they were not found to be multi-drug resistant. A total of 47 (29%) filamentous fungi repressed growth of *Escherichia coli* (10%), *Staphylococcus aureus* (14%) and *Cryptococcus neoformans* (8%) *Candida albicans* (11%).

Based on the previous studies Arctic and Antarctic fungal isolates have been very poorly studied for the enzyme production. Currently, applications of cold adaptive fungi in biotechnological industries are becoming of great interest. Due to the cold adapted nature of various enzymes produced by psychrophilic fungi such as amylases, lipases, cellulases and proteases, their applications are increasing in various industrial fields (Feller and Gerday, 2003; Leary, 2008). In our study fungal isolates showed a broad range of extracellular enzyme production. Generally fungal isolates were reported as good producers of lipases phosphatases and cellulases. In various research studies many of the fungi from cold regions have been found good producers of different extracellular

enzymes cluding amylase, lipase, cellulose, chitinase, polygalacturonase and phosphatase (Fenice et al., 1997; Inglis et al., 2000; Singh et al., 2012, 2014).

Conclusions

Diversity evaluation of psychrotrophic and psychrophilic fungi in Batura glacier was conducted for the first time. Most of the fungal isolates belonging to Ascomycetes followed by Basidiomycetes and Zygomycetes were identified in this study. They were very versatile, capable to survive and grow at different extreme salt concentrations, temperature and pH and were also capable of producing antibiotics and enzymes of industrial importance at low temperatures. In the future, the isolated fungi of this study would be a great source of novel antibiotics and cold active enzymes that need to be properly characterized via both genetic and analytical tools. But utilizing cloning and other genetic manipulation approaches, the polyextremophilic nature of fungal isolates could be a good source of acid, salinity and alkalinity stable enzymes that would contribute greatly to the food, feed, paper and pulp industries, known for their extreme and environmental friendly processes.

APPENDIX

Table A1. *Colony morphology and microscopic characteristics of fungal isolates on SDA*

Isolate	Sample form	Temperature (°C)	Colony morphology		Microscopic characteristics
			Front	Reverse	
LB_1	Sediment	4	Powdery, initially cottony, white with white margins then turned to dim gray	Golden to brown center with dim gray margins	Branched and septate hyphae, smooth-walled to broadly ellipsoidal and scattered conidia, cylindrical phialides and metulae
LB_2	Sediment	4	Mucoid, light goldenrod center with off-white edges	Lemmon chiffon center with off-white margins	Cylindrical to ovoid shaped and scattered spores, no pseudo- hyphae observed
LB_3	Sediment	4	Cottony, initially salmon to white with salmon edges then turned to slate gray to white	Saddle brown center with golden edges	Hyaline, thin-walled and branched hyphae with frequent clamp connections, chlamydospores hyaline, pear to oval shaped.
LB_4	Sediment	4	Velvety, initially dry mucoid to yellow then turned to dark orange with goldenrod margins	Saddle brown center with golden edges	Hyphae septate, branched, Conidiophores simple or sparsely branched and scattered conidiophores

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

LB_5	Sediment	4	Velvety, initially dark olive green with light yellow edges then turned to black to dark green with white surface	Black center with off-white edges	Branched, pale olivaceous brown hyphae, conidia ellipsoidal to limoni-form, smooth-walled or slightly verrucose, olivaceous brown	
LB_6	Sediment	4	Cottony, initially white velvety with off-white margins then turned to dim gray	Golden to brown center with dim gray margins.	Terverticillate to quaterverticillate conidiophores, smooth-walled, globose to suglobose conidia and cylindrical metulae and phialides	
LB_7	Sediment	4	Cottony, initially yellow to green then turned to sea green with dim gray edges	Dark brown center with saddle brown edges	Hyphae hyaline to pale yellow and septate, scattered and erect conidiophores, and branched conidia	
LB_8	Sediment	4	Velvety, initially cottony white then turned to gray with slate gray margins	Dark brown center with light goldenrod margins	Septate and branched hyphae, globose to subglobose shaped conidia, scattered conidiophores	
LB_9	Sediment	4	Cottony, initially velvety with blue to green center, white margin then turned to light gray to dark sea green	Dark orange to brown center with off-white margins	Branched and septate hyphae, conidiophores biverticillate, grey to green and echinulate to globose shaped conidia	
LB_{10}	Sediment	4	Velvety, initially gray to black center with off-white edges then turned to light slate gray	Gray to black center and light yellow edges	Hyaline, smooth and thin-walled conidia, ovoidal to ellipsoidal shaped spores	
LB_{11}	Sediment	4	Cottony, initially slate gray center with white margins then turned to dim gray	Brown center and yellow to off-white margins	Conspicuously roughened and branched conidiophores, septate hyphae, scattered conidia	
LB_{12}	Sediment	4	Velvety, initially white center with off-white margins then turned into light gray	Black to brown center with brown margins	Scattered and branched hyphae, curved, branched and pale greenish conidia	
LB_{13}	Sediment	4	Dry mucoid, initially white center with off-white margins then turned to light goldenrod	Golden center and light goldenrod margins	Spores are globose to ovoid shape, no pseudohyphae was observed	
LB_{14}	Sediment	4	Powdery, initially cottony, white with white margins then turned to dim gray	Golden to brown center with dim gray margins	Cylindrical metulae and phialides, scattered and branched hyphae, scattered conidiophores

LB_{15}	Sediment	4	Velvety, initially white with white edges then turned to light cyan	Saddle brown center with light goldenrod yellow edges	Septate to multiseptate and branched hyphae, colorless and cylindrical to ovoid shape spores	
LB_{16}	Ice	4	Velvety, initially dark olive green gray center with off-white edges then turned to dark green to black	Black center with off-white edges	Septate and branched hyphae, elliptical to cylindrical in shape, pale to dark brown in color	
LB_{17}	Water	4	Velvety, dark olive green with light yellow edges	Black center with light goldenrod yellow edges	Branched hyphae, conidia ellipsoidal to limoni-form, smooth-walled or slightly verrucose, olivaceous brown	
HB_1	Sediment	15	Cottony, initially green to blue then turned to dim gray with white margins	Brown center with golden-rod margins	Septate, branched hyphae, longer and visibly roughened conidiophores producing smooth to finely roughened conidia	
HB_2	Sediment	15	Cottony, initially white to light yellow then converted to gray with whit to off-white edges	Khaki center with pale goldenrod edges	Pseudomycelium and septate hyphae, cylindrical to ovoid shaped and scattered conidia	
HB_3	Sediment	15	Powdery, initially dark sea green then turned to black with pale green edges	Black center with dark orange to golden edges	Branched, septate hyphae, numerous, large and densely packed phialides conidiophore	
HB_4	Sediment	15	Cottony, light yellow to light golden-rod yellow center with white margins	Golden center with light goldenrod margins	Septate and hyaline hyphae, short and globose to ovoid conidiophore, scattered conidia	
HB_5	Sediment	15	Cottony, initially white to gray then turned to brown-black with off-white edges	Off-white to yellow center and light yellow edges	Round to ovoid in shape conidia, septate and branched hyphae, and scattered conidiophores	
HB_6	Sediment	15	Cottony, white to light goldenrod yellow center with white margins	Dark orange to brown center with goldenrod margins	Short distinct branched conidiophores, conidia are 1-celled and either white or yellow	
HB_7	Sediment	15	Cottony, initially green center with white margins then turned to light gray to white	Off-white to yellow center and light yellow edges	Conspicuously roughened and branched conidiophores, septate hyphae, scattered conidia	
HB_8	Sediment	15	Cottony, initially velvety with blue to green center, white margin then turned to light gray to dark sea green	Dark orange to brown center with off-white margins	Conidiophores biverticillate, grey to green and echinulate to globose shaped conidia

HB_9	Sediment	15	Powdery, initially cottony with dark green center and white edges then turned to dim gray	Off-white to yellow center and light yellow edges	Hyphae are septate and hyaline, kidney-shaped to brush-shaped conidiophores on conidia
HB_{10}	Sediment	15	Cottony, initially gray center with white edges then turned to light gray	Off-white to yellow center and light yellow edges	Divergent biverticillate to terverticillate conidiophores, smooth-walled and scattered conidia
HB_{11}	Sediment	15	Cottony, white center with white margins	Golden to yellow center and off-white margins	Sporangiophores subulate, hyaline, smooth, unbranched. Sporangia mainly globose
HB_{12}	Sediment	15	Powdery, initially white center with dark sea green margins then turned into black to brown	Black center with dark olive green margins	Septate and brown hyphae erected and pigmented conidiophores with conidia
HB_{13}	Sediment	15	Cottony, white center with dark salmon margins	Golden to brown center and yellow margins	Short chains or branched conidiophores, obovoidal and scattered conidia
HB_{14}	Sediment	15	Powdery, initially velvety with blue to green center, white margin then turned to gray to green	Light golden-rod center with light golden-rod yellow margin	Septate and branched hyphae, chains of spores (or conidia) from brush-shaped conidiophores
HB_{15}	Ice	15	Velvety, initially dark olive green with light yellow edges then turned to black to green	Black center with light goldenrod yellow edges	Septate, light colored hyphae, erect, pigmented, scattered conidiophores, and conidia
HB_{16}	Water	15	Velvety, dark olive green with light yellow edges	Black center with light golden red yellow edges	Septate and branched hyphae, elliptical to cylindrical in shape conidia, scattered conidiophores

Abstract. In a previous report, grapefruit (*Citrus × paradisi* Macfad.) and tangelo (*Citrus × tangelo* J.W. Ingram & H.E. Moore, 1975) landraces from diversity rich Indo-Gangetic Plain and arid regions of India were characterised using specific SSR markers. Eight grapefruit and two tangelo varieties were compared with germplasm of diverse origin comprising of cultivars, landraces and wild types. Significant differences were observed for different morphological characters studied. The highest phenotypic co-efficient of variance (PCV) and genotypic co-efficient of variance (GCV) were determined for seed weight (104.4 and 103.7, respectively), number of seeds per fruit (102.3 and 101.9, respectively), number of fruits per tree (60.0 and 60.0, respectively) and acidity (40.4 and 38.8, respectively). These mentioned characters were more influenced by environment than other characters. A total of 75 alleles were amplified by 26 polymorphic simple sequence repeat (SSR) loci and the number of alleles ranged from 1 to 4 with an average of 2.88 alleles per locus. The highest number of alleles per locus was four as amplified by CAT01, CS05, CCSM204, CCSM70, CIBE5156, ATC09 and CMS26 followed by three alleles per locus each by CCSM77, CCSM156, CL11, OP29, CMS46, CMS09, CIBE4728, CMS3O and AG14 and the remaining markers amplified two alleles. The highest number of alleles among grapefruit varieties was found in Ray Ruby (75) while the lowest number of alleles was found in Flame (61) while among tangelo varities the highest number of alleles was found in Pearl (64). Average polymorphism (%) of all the polymorphic primer pairs across all the varieties of grapefruit was 69.55 and the highest polymorphism among grapefruit varieties was found in Marsh (82.09) while among tangelo varieties the highest polymorphism was found in Pearl (81.25). The measure of allelic diversity that is PIC value ranged from 0.17 (CS06) to 0.75 (CAT01) with an average value of 0.53.
Keywords: *citrus, germplasm, morphological characterization, molecular markers, polymorphism*

Introduction

Citrus is a sub-tropical fruit that belongs to the family of *Rutaceae.* It is grown commercially throughout India and is known worldwide of its characteristic flavour, attractive evergreen foliage and flower as well as the extraordinary fragrance, which are added aesthetic values (Rabha et al., 2013). In India, it is grown in acreage of 935 thousand hectares with the production of 11515 thousand MT and productivity of 12181 MT/ha respectively (NHB, 2016).

The grapefruit (*Citrus × paradisi* Macfad.) originated from Barbados in the Caribbean islands, is a natural hybrid between pummelo (*Citrus maxima* (Burm.) Merr.) and sweet orange (*C. sinensis* L. Osb). It was first named as *Citrus paradise* Macfad. by James Macfadyen in 1837 (Scora et al., 1982 and Scora, 1988). The tangelo (*Citrus × tangelo* J.W. Ingram & H.E. Moore, 1975) probably originated in southeastern Asia over 3,500 years ago. Tangelo is most likely a result of insect cross pollination of the mandarin orange and the pummelo (pummelo is the ancestor of the grapefruit).

Grapefruit is the fourth most important citrus fruit economically in the world. It is rich in various nutrients, phytochemicals, vitamin C and fiberpectin with pink and red hues that contain the beneficial antioxidants lycopene (Silver et al., 2011). There are many benefits of this fruit worth mentioning: (i) peel and seed extract of grapefruit have antifungal properties (Okunowo et al., 2013), (ii) it helps in lowering cholesterol (Platt, 2000) and also (iii) in animals cell studies, grapefruit powder, limonin and naringenin decrease growth and increase self-destruction of colon, mouth, skin, lung, breast and stomach cancer (Chidambara et al., 2011). Citrus varieties show more diversity in their morphological traits such as size and shape of canopy, color, type, number of seeds, fruit weight, fruit diameter, flower diameter, TSS, acidity etc. Generally in plants, the diversity at the phenotypic level is much larger than at genetic level, as selectively neutral molecular markers are used to evaluate the extent of genetic variation.

For future variety management and conservation purposes this adaptive genetic diversity represents important potential. Recently researchers (Amara et al., 2011; Ahmed et al., 2012; Jianfeng et al., 2012; Uzun and Yesiloglu, 2012), have observed the significant diversity among cultivated genotypes of Citrus genus in respect of physiological, morphological and agronomic traits but very little DNA variation has been detected using DNA-markers. Likewise, in other cases markers were used to determine genetic diversity, characterization and phylogenetic relationships among the Citrus and related genera (Gulsen and Roose, 2001; Shahsavar et al., 2007; Uzun et al., 2009; Marak and Laskar, 2010; Golein et al., 2011). Grapefruits are highly polyembryonic and have low genetic variation due to nucellar and mutation origin (Fang and Roose 1997 and Corazza-Nunes et al., 2002). Substantial genetic variation among citrus species and cultivars is due to frequent bud mutation, interspecific and intergeneric hybridization, apomixes and long history of cultivation. There is an urgent need for diversification of scion citrus cultivars for Punjab citriculture for reducing the high risks associated with the outbreaks of new and more severe diseases and pests. Secondly, there is more variation in characters in citrus than in other fruit crops (Reuther et al., 1967) and citrus is phenotypically the most heterogeneous group (Moore, 2001). In the present study ten varieties of grapefruit and tangelo were studied with the aim (a) to correlate the physico-chemical variation with the genetic diversity (b) to estimate genetic polymorphism and relationships among grapefruit and tangelo varieties based on SSR markers.

Materials and methods

Plant material

In this study we investigate eight grapefruit and two tangelo cultivars (*Table 1*) from the College Orchard, Department of Fruit Science, Punjab Agricultural University, Ludhiana, India in the year 2015-16. Observations were recorded for different morphological characters at different growth and development stages. All the trees received recommended doses of fertilizers and other cultural practices during the course of these investigations.

Morphological evaluation

Morphological evaluation was carried out for two years, i.e. from 2015 to 2016. Fruits were harvested at full maturity, yield and quality parameters data were recorded.

Characterization of grapefruit and tangelo cultivars was conducted on ten genotypes on the basis of IPGRI (International Plant Genetic Resources Institute) citrus descriptors (Anonymous, 1999). Twenty fruits were sampled from each cultivar for quality analysis, and characteristics evaluated including number of seed per fruit, peel thickness, fruit weight, fruit size, juice content, peel content and rag content. Juice was filtered through filter paper, thereafter, juice samples were examined to determine the following parameters; pH, total soluble solids (TSS), titratable acidity (% of citric acid) using N/10 NaOH and phenolphthalein as indicator, using digital refractometer, and ascorbic acid (mg/100 ml of juice) using a dye (2, 6-dichlorophenol indophenol) according to the standard method (Rangana, 1986). Design of experiment was in randomized block with five replications. Data were subject for analysis of variation to one way ANOVA. Statistical analysis was performed using analysis of variance. P values ≤ 0.05 were considered as significant. A cluster analysis was performed using the unwieghted pair group method with arithmetic average (UPGMA) based on simple matching coefficient in NTSYS software. The phenotypic and genotypic coefficients of variation were calculated as per formula described by Burton (1952) and Burton and de Vane (1953). Heritability, in broad sense, was calculated as suggested by Allard (1960) and genetic advance percent of mean was calculated following the method suggested by Johnson et al. (1955).

Table 1. *Citrus paradisi Macf. cultivars and variants used in the study of germplasm characterization*

S. no.	Varieties	Origin
Grapefruit		
1	Flame	Originated in Florida – budwood registration program, winter haven in 1988
2	Foster	Originated as a branch sport of a selection called 'Walters' in Florida, USA in 1907
3	Marsh	Originated as seedling trees on the property of a Mrs. Rushin near Lakeland, Florida, USA (1862)
4	Ray Ruby	Originated in Texas in 1985
5	Red Blush	Originated as sports–lower branches–growing out of 'Thompson' trees in USA in 1929
6	Rio Red	Originated in Texas in 1985
7	Ruby Red	Originated in Texas in 1988
8	Star Ruby	Originated as a lower branch mutation bearing red-blushed fruits, noticed on a 'Foster' tree at San Benito, Texas, USA in 1930
Tangelo		
9	Minneola	Produced at John Carpenter, USDCS, Indio CA in 1961
10	Pearl	Hybrid produced at UCR in 1945

Isolation and purification of genomic DNA

Genomic DNA was extracted from 5 g of well ground tissue using the protocol described by Gusmini et al. (2004). DNA was extracted from young leaves of five randomly selected plants for each variety and then subsequent molecular analysis. Air dried DNA pellets were dissolved in 50 l of 1X TE buffer (Tris-EDTA buffer- 10 mM Tris-HCl, I mM EDTA, pH 8.0. Quantity and quality of DNA was determined by

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_53435358
© 2018, ALÖKI Kft., Budapest, Hungary

Nanodrop 1000 instrument (Thermo Scientific, USA) using 2 l of genomic DNA. Absorbance was recorded at 260/280 nm and readings were taken for both the quantity (ng µ/l) and quality (Absorbance). Only the samples having absorbance value from 1.90-2.00 were taken for DNA analysis. And the samples with absorbent values less are repeated till the desired amount of DNA is achieved.

Selection of primers

The DNA was amplified through polymerase chain reaction (PCR) using 60 SSR primer pairs (synthesized by Integrated DNA Technologies) previously described and used (Ahmad et al., 2003; Barkley et al., 2006; Ollitrault et al., 2010; Soriano et al., 2012; Yaly et al., 2011; Meral et al., 2011) for citrus germplasm characterization. PCR amplification of 20 µl total volume was performed in 2.0 µl of 10X PCR buffer, 2.5 µl of 1 mM dNTPs, 1.25 µl of each of forward and reverse primer (5 µM), 0.25 µl of Taq polymerase (5 units/µl of Promega, USA), 4.0 µl of DNA (15 ng) and distilled de-ionized water using an Eppendorf thermal cycler. The PCR profile consisted of initial denaturation at 94 °C for 3 min and subsequent 35 cycles each with denaturation at 94 °C for 30 s, primer annealing at 48-57 °C for 1 min and primer extension at 72 °C for 1 min. Final extension step was performed at 72 °C for 7 min. Annealing temperature was modified to optimize the reaction conditions for individual primers. PCR products were stored at 4 °C before analysis. PCR-amplified DNA fragments were separated on a 1.5% agarose gel containing 1X TBE (45 mM Tris-borate1 mM EDTA) and 0.5 µg/ml aqueous solution of ethidium bromide. The agarose gel was run at a constant voltage of 100 V for 2–3 h in 0.5 × TBE buffer. Gels were visualized under UV light and photographed using photo documentation system (Alphaimager system). The repeatability of the markers was verified in the whole collection and all null alleles were confirmed by a second amplification.

Data collection and analysis

SSR alleles were scored for the presence (1) and absence (0) of the SSR bands. Polymorphism information content (PIC) for each SSR marker was determined as per the procedure outlined by Senior et al. (1998).

$$PIC = 1 - \Sigma\,(Pij)^2$$

$$i = 1$$

where *Pij* is the frequency of *j*th allele in *i*th primer and summation extends over 'n' patterns.

Genetic similarity coefficients between various genotypes (in pair-wise comparisons) were calculated from the SSR data matrix using dice coefficient and the resulting genetic similarity matrix was analyzed using NTSYS-PC version 2.02 to produce an agglomerative hierarchical classification (Rohlf, 1989) by employing Unweighted Pair Group Method using Arithmetic Averages (UPGMA). For estimating the similarity matrix, null alleles (no SSR allele in a given *citrus* genotype) were treated as missing data to reduce the biased genetic or similarity measures (Warburton and Crossa, 2000).

Genetic diversity (GD) was calculated according to the following formula of Nei (1987):

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_53435358
© 2018, ALÖKI Kft., Budapest, Hungary

$$GD = n\,(1 - p^2)/(n - 1)$$

where (n) is the number of samples and (p) is the frequency of one allele.

Results and discussion

Clustering studies based on morphological diversity

Grapefruit and tangelo varieties consist of four clusters (*Fig. 1*), cluster I consists of only one variety Flame with an average distance of 0.37 cm (*Table 2*) from other varieties. Cluster II consists of two varieties namely Marsh and Red Blush, which are more associated with each other with an average distance of 0.10 cm. While in cluster III there were four varieties namely Foster, Ray Ruby, Star Ruby and Rio Red. Foster have an average distance of 0.13 cm as compared to Rio Red which has 0.24 cm distance from the other varieties. In cluster IV there were three verities Ruby Red, Minneola and Pearl. Minneola and Pearl were closely associated with each other with an average distance of 0.25 cm while Ruby Red have less association with other varieties with an average distance of 1.37 cm from other varieties. Further, the study on inheritance of agronomic traits of citrus reports them to be controlled by multiple genes which can be assessed only through morphological assessment (Liu and Deng, 2007).

Table 2. *Root mean-square distance between grapefruit and tangelo varieties within clusters based on morphological characteristics.*

Number of clusters	Clusters joined		Freq	Norm RMS distance (cm)
9	Ray Ruby	Star Ruby	2	0.0136
8	Marsh	Red Blush	2	0.1072
7	Foster	CL9	3	0.1349
6	CL7	Rio Red	4	0.2447
5	Minneola	Pearl	2	0.2573
4	Flame	CL8	3	0.3715
3	CL4	CL6	7	0.5285
2	Ruby Red	CL5	3	0.7395
1	CL3	CL2	10	1.3799

However, Dorji and Yapwattanaphun (2011) concluded that the groups diverged having similarity coefficient of 0.79 in contrast to 0.41. There is not much variation with respect to qualitative characters of the groups. Golein et al. (2005) reported that the analyzed accessions having high average similarity coefficient (0.91) indicated that all mandarins represented variations of single clones. Likewise, analysis of 43 morphological characters in the 22 cultivars of *C. sinensis* revealed that maximum similarity (0.64) occurred between the cultivars Campbell Valencia and Vanale, both of which are exotic in origin and are most similar in terms of qualitative fruit, leaf and seed characters (Malik et al., 2012). Minimum similarity (0.18) was observed between the

© 2018, ALÖKI Kft., Budapest, Hungary

cultivars Washington navel and Mosambi, which may be attributed to their different centres of origin where they have developed their distinct characters.

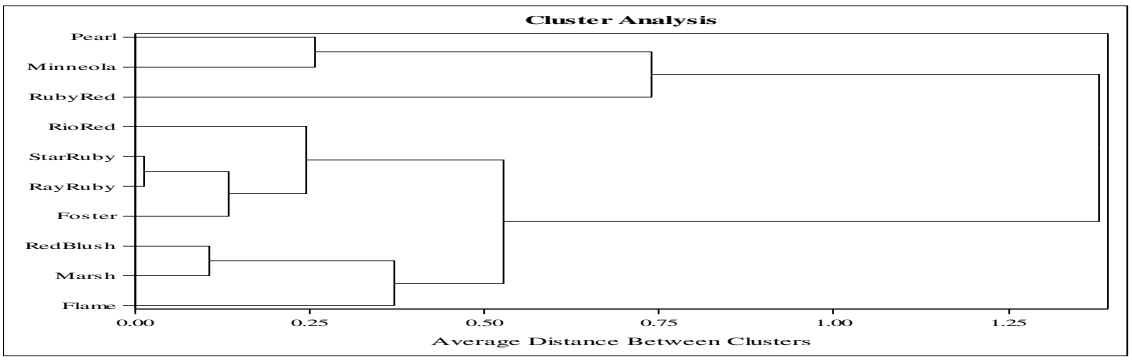

Figure 1. *Dendrogram of grapefruit and tangelo varieties based on morphological characteristics using the UPGMA method*

Variability, heritability and genetic advance in grapefruit and tangelo varieties based on morphological characteristics.

Estimation of genotype for phenotypic variance (PV) and genotypic variance (GV) indicated that variance was recorded maximum for number of fruits per tree, fruit weight, and fruit diameter, number of seeds per fruit and seed weight (*Table 3*). The variation present in population is due to genotypic and environmental effects. It includes both genotypic and environmental condition. The highest phenotypic co-efficient variance (PCV) and genotypic co-efficient variance (GCV) were recorded for seed weight (104.4 and 103.7, respectively), number of seeds per fruit (102.3 and 101.9, respectively), number of fruits per tree (60.0 and 60.0, respectively) and acidity (40.4 and 38.8, respectively). These mentioned characters were much more influenced by the environment than other characters.

In the present investigation of genetic advance coupled with high heritability was observed for seed weight, number of seeds per fruit, number of fruits per tree and acidity. Thus the results indicated that selection would be highly effective for above mentioned characters. Similar finding was made by Baswal et al. (2016), who concluded that the co-efficient of variation (both genotypic and phenotypic) was higher for the characters like density of oil glands/cm^2 (35.1 and 34.8, respectively) followed by albedo thickness (19.5 and 19.4, respectively). GCV associated with high heritability (80% or more) indicated that selection would be effective for the improvement of these characters. Also Roy et al. (2014) concluded that in pummelo germplasm while studying variability, a wide range of variability was observed for almost all variables or characters. The co-efficient of variation was higher (>20) for characters like yield per plant, fruit rind thickness, seed weight and number of fruits per plant.

Burton (1952) observed that if GCV associated with high heritability (80% or more) indicated that selection would be effective for the improvement of these characters but if a character with low heritability (40% or less) selection may be comparatively difficult or virtually impractical due to masking effect of the environment on the genotypic effects. This indicated that selection for density of oil glands, albedo thickness, fruit weight and fruit diameter would be effective. In a similar study, Panse

© 2018, ALÖKI Kft., Budapest, Hungary

(1957) suggested that a high genetic advance coupled with high heritability may be expected if heritability is mainly due to additive genetic effects.

Allele amplification in grapefruit and tangelo varieties

Allele frequency or the frequency at which alleles are found at any locus of interest is used to estimate the frequency of given genetic profile. In grapefruit and tangelo varieties a total of 75 alleles were amplified by 26 polymorphic SSR loci and the number of alleles ranged from 1 to 4 with an average of 2.88 alleles per locus. The highest number of alleles per locus was four as amplified by CAT01, CS05, CCSM204,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_53435358
© 2018, ALÖKI Kft., Budapest, Hungary

CCSM70, CIBE5156, ATC09 and CMS26 followed by three alleles per locus each by CCSM77, CCSM156, CL11, OP29, CMS46, CMS09, CIBE4728, CMS3O and AG14 and the remaining markers amplified two alleles (*Table 4*).

Table 4. *Number of alleles amplified, polymorphism (%), polymorphic information content (PIC) value and genetic diversity of SSR markers in grapefruit and tangelo varieties*

Polymorphic information content and percentage of polymorphism among grapefruit and tangelo varieties based on SSR markers

In Grapefruit and tangelo varieties the percentage of polymorphism of the 26 polymorphic markers ranged from 50 to 100 (*Table 4*). Among these, 6 exhibited 100 percent polymorphism; seven were having 75 %, four having 66.66 % and remaining had 50 %. Average polymorphism (%) of all the polymorphic primer pairs across all the varieties of grapefruit was 69.55. The PIC value which is a measure of allelic diversity

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_53435358
© 2018, ALÖKI Kft., Budapest, Hungary

at a locus ranged from 0.17 (CS06) to 0.75 (CAT01) with an average value of 0.53. Fourteen SSR markers revealed PIC value more than 0.53. Primer CAT01 amplified 4 alleles and had the highest PIC value of 0.75 followed by CSM70 and CIBE5156 in which 3 alleles were amplified and had PIC value of 0.74 (*Table 4*). All the alleles amplified by CAT01 primer pairs on all the varieties of grapefruit were all distinguishable. It has been observed that marker OP29 amplified 3 alleles and had PIC value of 0.38 while GT03 amplified 2 alleles and had PIC value of 0.49. Therefore, there seemed to be no strong correlation between the PIC value and the number of alleles amplified. Across all varieties, a total of 663 alleles (*Table 5*) were amplified by 58 SSR primers with an average of 63.30 alleles for each variety. The average amplified fragments for polymorphic marker was 51.90 whereas for monomorphic, it was 14.40. The maximum number of alleles (75) was detected in Ray Ruby whereas Minneola showed the least number of alleles (52). However, the percent of polymorphic markers was maximum (82.09) in Marsh followed by 81.25 % in Pearl.

Table 5. *Total number of alleles amplified in grapefruit and tangelo varieties using SSR markers*

S. no.	Genotypes	Number of amplified alleles		Total	Polymorphism (%)
		Monomorphic markers	Polymorphic markers		
Grapefruit					
1	Foster	12	48	60	80.00
2	Flame	13	48	61	78.69
3	Marsh	12	55	67	82.09
4	Ray Ruby	15	60	75	80.00
5	Red Blush	20	52	72	72.22
6	Rio Red	16	56	72	77.78
7	Ruby Red	14	60	74	81.08
8	Star Ruby	15	51	66	77.27
Tangelo					
9	Pearl	12	52	64	81.25
10	Minneola	15	37	52	71.15
	Total	**144**	**519**	**663**	**781.53**
	Mean	**14.40**	**51.90**	**66.30**	**78.15**

Likewise, Meral et al. (2011) reported narrow genetic diversity in Satsuma mandarins clones suggesting that the observed morphological polymorphism within the group must be associated with somatic mutations which were not detected by SSR molecular markers. Similarly, Singh et al. (2016) concluded that among 19 different mandarin genotypes that 57 SSR markers amplified, a total of 96 alleles were detected by 39 polymorphic SSR loci and maximum 5 alleles were amplified with an average of 2.46 alleles per primer pair. The CAT01 was the highly informative marker as it revealed maximum number of alleles (5), PIC value (0.75) and genetic diversity (0.79). Across the genotypes, maximum number of alleles (83) was detected in Daisy hybrid and the percentage of polymorphic marker was maximum (80.32) in Nova hybrid. The markers with low number of alleles were able to differentiate the varieties with specific alleles.

Simple Sequence Repeats (SSRs) have proven to be efficient genetic markers for comparative genetic mapping between Citrus species (Luro et al., 2008). Although some SSRs were identified based on EST database in previous studies (Chen et al., 2006) no system analysis of SSRs in citrus has been reported because of incomplete citrus genome. Recently, the Clementine mandarin genome has been sequenced (Gmitter et al., 2012) and the completion of these genome sequences provided an opportunity for us to scan the entire genome for SSR discovery in citrus. In this study, we present our results on the SSR survey for the development of citrus SSR markers.

Genetic diversity

Genetic diversity among grapefruit and tangelo varieties ranged from 0.18 (CS06) to 0.83 (CAT01 and CIBE5156). The average value of genetic diversity across all the primers was 0.58 (*Table 4*). The dendrogram (*Fig. 2*) depicting the genetic relationship classified the genotypes into 3 major clusters (I, II and III). The cluster I contains single variety (Minneola) but cluster II was further sub divided into two sub clusters IIA and IIB with three (Rio Red, Star Ruby and Pearl) and two (Flame and Foster) varieties respectively. While four (Ray Ruby, Marsh, Ruby Red and Red Blush) varieties were clustered in cluster III. The similarity coefficient based on DNA amplification of grapefruit and tangelo varieties using SSR primer was estimated by dice similarity coefficient (*Table 6*). The varieties Ruby Flame and Foster, Ruby Red and Red Blush showed the highest genetic similarity having coefficient of 0.90 and were closely related. However, Rio Red and Pearl showed lowest (0.68) genetic similarity coefficient and these were genetically distinct from each other. Similarly, 19 different mandarin genotypes (Singh et al., 2016) were classified in three clusters, i.e. cluster I, cluster II and cluster III. All the indigenous genotypes (selections) were grouped in cluster -I and it had maximum genetic similarity coefficient. However, the exotic genotypes (hybrids) were grouped in cluster II and cluster III. Clustering was according to the breeding history of genotypes but independent of their geographic origin.

Legend: Marsh, Ray Ruby, Rio Red, Star Ruby, Flame, Red Blush, Ruby Red, Foster, Minneola, and Pearl

The results revealed that the difference in the dendrogram of morphological and molecular data could be due to action of diverse evolutionary forces and environmental attributes. This hypothesis was supported by the findings of Paudyal and Haq (2008) who reported that environmental factors affected up to 40% in pummelo accessions in an un-controlled field survey. The morphological difference in individual accession was supported by the observation of Dorji and Yapwattanaphun (2011a) who reported that phenotypic variation could be attributed to mutations, cross pollination and environmental interactions (*Figs. 3, 4* and *5; Table 7*).

Conclusions

Present study indicated that genetic diversity in grapefruit and tangelo varieties was found to be very low, despite having high morphological variability, which could be elucidated by the fact that much of the phenotypic variation witnessed may be due to

somatic mutations. Genetic diversity among grapefruit and tangelo varieties ranged from 0.18 (CS06) to 0.83 (CAT01 and CIBE5156). Furthermore, based on molecular analysis, varieties Ruby Flame and Foster, Ruby Red and Red Blush showed the highest genetic similarity having coefficient of 0.90 and were closely related. However, Rio Red and Pearl showed the lowest (0.68) genetic similarity coefficient and these were genetically distinct from each other.

Abstract. Interpolation methods are extensively used to map the spatial distribution of water quality parameters. However, the selection of the most appropriate method is a critical issue in environmental studies. The relative performances of deterministic and geostatistical methods in explaining the spatiotemporal variation of water quality parameters/indices in a tank cascade landscape were assessed. Inverse distance weighted (IDW), global polynomial interpolation (GPI), local polynomial interpolation (LPI), radial basis function (RBF), kriging (KR), and empirical Bayesian kriging (EBK) methods were evaluated using root mean square error (RMSE) in a leave-one-out cross-validation. Coefficient of variance, normality, level of autocorrelation, and extreme values near boundaries of the dataset showed a clear relationship with the relative performances of the different interpolation methods. Therefore, a clear understanding of the quality of the dataset is required in order to select the appropriate method to interpolate water quality parameters. EBK performed well for most parameters throughout the study period and is recommended as the best method to interpolate water quality parameters/indices in the Ulagalla cascade and other tank cascade landscapes in Sri Lanka and similar environments.
Keywords: *deterministic interpolation, empirical Bayesian kriging (EBK), geostatistical methods, root mean square error (RMSE), spatial variability*

Introduction

The tank cascade system (TCS) is a unique water storage and supply system used in the intermediate and dry zones of Sri Lanka. The system has been in use since the third century BCE (Madduma Bandara, 1985), mainly for irrigation and domestic water use. The main principle behind the TCS is re-use and recycling of water through a connected series of tanks. Hence, the TCS is defined as a connected series of tanks arranged within a micro- (or meso-) catchment of the dry zone landscape for storing, conveying and utilizing of water from an ephemeral rivulet (Madduma Bandara, 1985). As can be seen

© 2018, ALÖKI Kft., Budapest, Hungary

in *Figure 1,* the major elements of TCS are categorized as meso-catchment, micro-catchment (catchment area of the individual tanks within the cascade), the main valley, side valleys and irrigated paddy lands. It has been recognized as globally important agricultural heritage site by Food and Agriculture Organization of the United Nations (FAO).

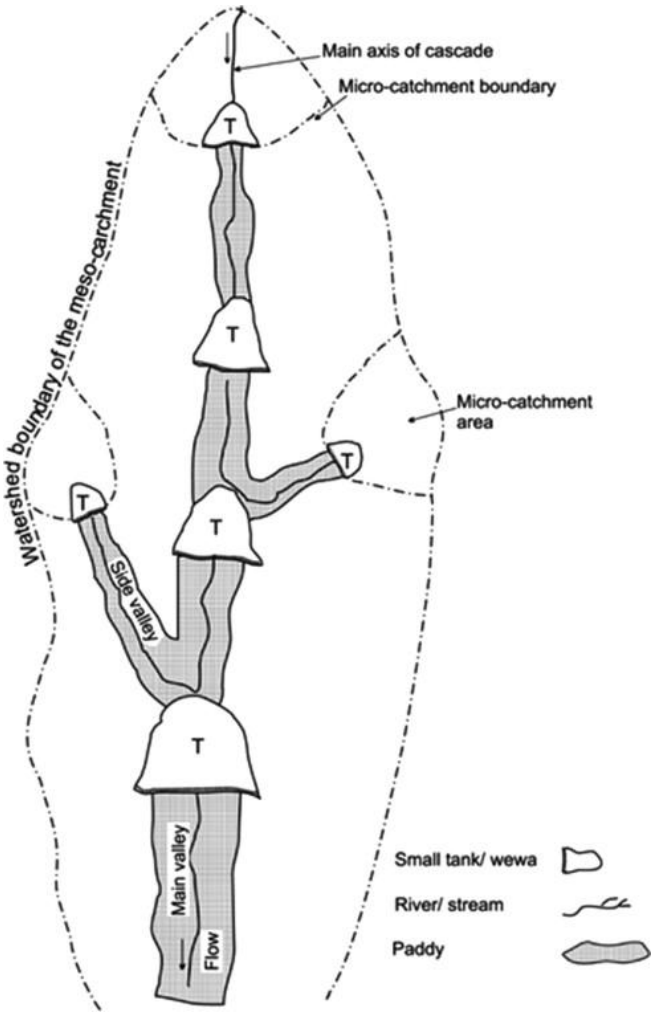

Figure 1. *Schematic representation of tank cascade system in dry zone of Sri Lanka (adapted from Panabokke et al., 2002)*

The dry zone of Sri Lanka receives an annual rainfall less than 1750 mm whereas, annual evaporation ranges from 1700-1900 mm, which implies the water stress condition during dry periods (Panabokke et al., 2002). This area is characterized with short rainy period (from September to January) which receives 80% of the total rainfall and long dry period (from February to October). As this area is dominated with reddish brown earth with low water retention capacity, the water scarcity problem is intensified in this area (Panabokke et al., 2002). This spatial and temporal variation of rainfall has led the ancient farming communities to invent TCS which can act as a sustainable water management system. TCS provides cooler micro-climate which enhances the plant and animal biodiversity while providing habitat for endangered elephants, resident and migrant water birds. Though it is not totally similar to Sri Lankan tank cascade systems,

© 2018, ALÖKI Kft., Budapest, Hungary

comparable environments are in use for paddy irrigation in India (Bitterman et al., 2016; Van Meter et al., 2016; Bebermeier et al., 2017).

As a convenient substitute for insufficient surface water resources in the dry zone of Sri Lanka, groundwater use has dramatically increased during the last three decades, coinciding with changes in agriculture and livelihoods (Jayakody, 2006; Kumari et al., 2013). Moreover, a close relationship between the groundwater and surface water has been identified in tank cascade landscape (Bebermeier et al., 2017). Hence, the sustainability of the tank cascade landscape is endangered along with the overexploitation and quality deterioration of groundwater. Thus, an increasing amount of attention has been given to sustainably managing water resources in tank cascade landscapes, and several monitoring studies of groundwater in this landscape have been conducted (Wijesundara et al., 2012; Gunarathna et al., 2016a, b; Kumari et al., 2016). However, no appropriate continuous monitoring system has been put in place, because continuous monitoring of groundwater over a large area for an extended duration is expensive and labor intensive. Therefore, a suitable method for estimating groundwater availability and quality is needed that requires a minimum number of sampling sites in order to better manage the water resources in tank cascade landscapes.

Spatial interpolation, including deterministic and geostatistical interpolation techniques in ArcGIS, has been used to understand the spatial and temporal variation of natural resources, including groundwater, and related environmental concerns (Chai et al., 2011; Gunaalan et al., 2018). Deterministic interpolation techniques include inverse distance weighted (IDW), radial basis functions (RBFs), global polynomial interpolation (GPI), and local polynomial interpolation (LPI) methods; geostatistical interpolation techniques include kriging/co-kriging (ordinary kriging [OK], simple kriging [SK], universal kriging [UK], etc.), areal interpolation, and empirical Bayesian kriging (EBK). The ArcGIS Geostatistical Analyst extension can fill the gap between geostatistics and GIS analysis and has been used to characterize the spatial variability of variables in detail (Kumar et al., 2007; Uyan and Cay, 2013; Bao et al., 2014).

Interpolation accuracy is sensitive to the precise demarcation of boundaries and areas (Mirzaei and Sakizadeh, 2016; Gunaalan et al., 2018), the effectiveness of predicting parameters of unknown locations using known values, sample size (Stahl et al., 2006), spatial distribution of sampling sites (Güler, 2014), normality of the dataset (Wu et al., 2016), grid size or resolution (Hengl, 2007), and interpolation method (Luo et al., 2008; Xie et al., 2011). Moreover, if the distribution of sampling locations or wells does not appropriately represent the spatial variation of water quality parameters, any biases will be intensified (Heistermann and Kneis, 2011; Wagner et al., 2012). However, different interpolation methods tend to provide similar predictions at low (Mirzaei and Sakizadeh, 2016) and very high sampling densities (Gunnink and Burrough, 1996). In most cases, interpolation methods have been used without proper assessment of their accuracy. Only a few assessments of accuracy have been conducted. Mirzaei and Sakizadeh (2016) evaluated three interpolation methods to estimate a water quality index and found EBK to be the best method. Xie et al. (2011) stated that the best interpolation method to explain the spatial variation of heavy metals in soil varied with the size of the polluted area. Seyedmohammadi et al. (2016) compared five interpolation methods to estimate the spatial variation of electrical conductivity (EC) in groundwater and reported that OK was superior to the others. Based on the relative performance of four interpolation methods to interpolate EC, total dissolved solids (TDS), and pH, EBK was found as the best method (Gunarathna et al., 2016a, b).

To date, no study has evaluated these interpolation methods with an extensive number of parameters covering all contaminant groups (anions, cations, nutrients) and water quality indices along with temporal effects. Because the assessment of spatial and temporal variation of groundwater is essential in sustainable management of water resources, the objective of this study was to describe and predict the relative performance of deterministic (IDW, LPI, GPI, and RBFs) and geostatistical (UK, OK, and EBK) interpolation methods and to select the best interpolation method to explain the spatial and temporal variation of groundwater quality in the Ulagalla cascade, Sri Lanka. Many physicochemical parameters were studied, including anions, cations, nutrients, and other water quality indices, as well as temporal effects. The relationships between characteristics of datasets and those of different interpolation methods were also examined.

Materials and methods

Study area

Ulagalla cascade covers approximately 51 km^2 in the Anuradhapura district of Sri Lanka (8°5'–8°14'N; 80°31'–80°34'E). The economy of this area is based on agriculture, which comprises tank-based paddy cultivation and rainfed or irrigated upland crop cultivation using groundwater. Mean annual rainfall in Anuradhapura is 1255 mm, and there is a distinct dry period from May to September. The monthly average maximum and minimum temperatures in the dry zone range from 25.0 to 37.7 °C and 17.4 to 26.8 °C, respectively. (Gunarathna and Kumari, 2013; Abeysekara and Punyawardena, 2016). A shallow regolith aquifer of the hard rock region is the main aquifer type in the study area. Groundwater potential is comparatively limited because of the low groundwater storage capacity and transmissivity of the underlying crystalline basement (Sirimanne, 1952).

Data collection and data preparation

The total cascade area was divided into 1-km^2 cells, and one agro-well was purposely selected to represent each cell so as to evaluate the quality of groundwater in the study area. Within the existence of agro-wells and the availability of water in the agro-wells throughout the study period, a total of 29 wells were selected (*Fig. 2)*. Three replicates from aforesaid 29 wells were collected monthly from April 2016 to March 2017 to measure the water quality parameters using standard procedures (APHA, 2005). All the chemical analyses were carried out at the laboratory of soil and water sciences, Department of Agricultural Engineering and Soil Science, Faculty of Agriculture, Rajarata University of Sri Lanka. Sodium adsorption ratio (SAR) (Wilcox, 1955) and total hardness (TH) (Todd and Mays, 2005) were calculated from measured data. The following 12 water quality parameters or indices were used: electrical conductivity (EC); pH; concentrations of sodium (Na^+), potassium (K^+), calcium (Ca^{2+}), magnesium (Mg^{2+}), chloride (Cl^-), nitrate (NO_3^--N), phosphate (PO_4^{3-}), and bicarbonate (HCO_3^-); sodium adsorption ratio (SAR); and total hardness (TH).

Attribute data containing information about the physicochemical parameters/indices were joined with geographic coordinates obtained with a handheld global positioning system (GPS) receiver (eXplorist 510, Magellan, USA) of each sampling point (*Table A1* in the *Appendix*). ArcGIS 10.2 (ESRI, California, USA) and R statistical

software (R Foundation for Statistical Computing, Vienna, Austria) (Team R, 2016) were used for the interpolation analysis and statistical analysis, respectively.

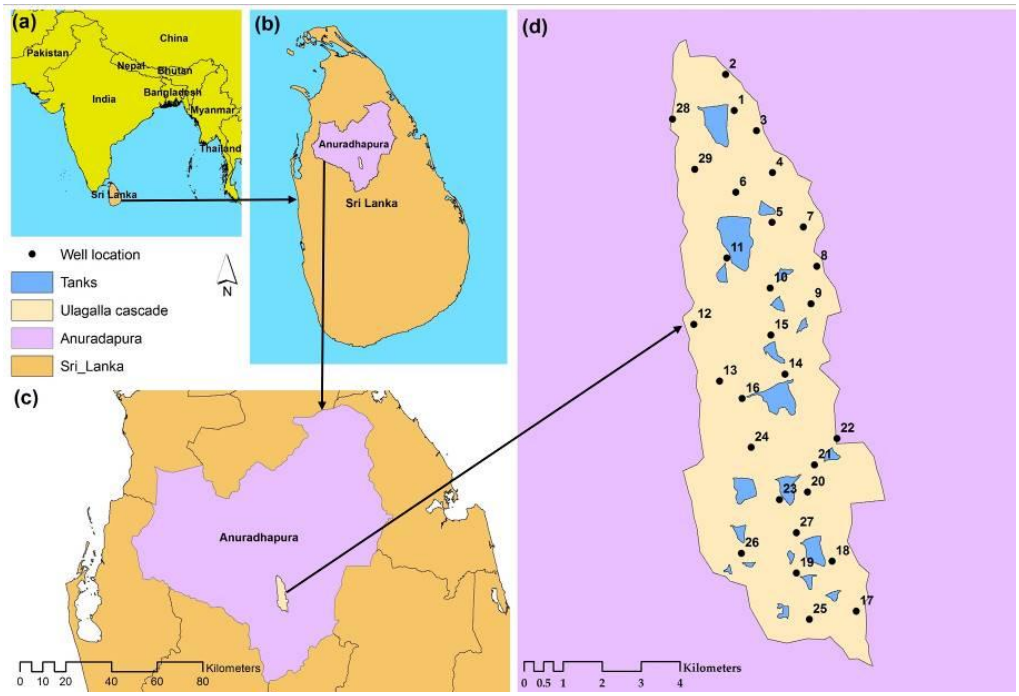

Figure 2. *Location of the study areas: (a) South Asia; (b) Sri Lanka; (c) Anuradhapura district; (d) groundwater sampling locations in Ulagalla cascade*

Interpolation methods

Inverse distance weighted (IDW)

In IDW, the interpolation weights are calculated as a function of the observed sampling point and the prediction point (Gunnink and Burrough, 1996). The accuracy of IDW depends on the number of closest neighboring sampling points (Yao et al., 2013). The values for unknown points are estimated with *Equation 1:*

$$Z(x_0) = \frac{\sum_{i=1}^{n} \frac{x_i}{h_{ij}^{\beta}}}{\sum_{i=1}^{n} \frac{1}{h_{ij}^{\beta}}} \qquad \text{(Eq.1)}$$

where $Z(x_0)$ is the interpolated value, x_i is the i^{th} data value, β is the user-defined exponent for weighting, n is the total number of sampling data values and h_{ij} is the distance between the known point and the unknown point (Seyedmohammadi et al., 2016).

Global polynomial interpolation (GPI)

The GPI method positions a plane between sample points by fitting a polynomial formula to the points. Using a value on the plane that relates to the prediction location,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_53595380
© 2018, ALÖKI Kft., Budapest, Hungary

the unknown point is determined by minimizing the errors (Webster and Oliver, 2008) With the use of low order polynomials GPI creates slowly while describing the physical processes. However, with complex polynomials, it is difficult to ascribe physical meaning to GPI (Johnston et al., 2003).

Local polynomial interpolation (LPI)

Whereas GPI fits one polynomial to the entire surface, LPI fits many polynomials, each within specified overlapping local neighborhoods. Although this method produces smooth surfaces, it is best suited for use only with data that have a narrow range of variation. LPI creates a surface from many different polynomial formulas, each of which is optimized for a specified neighborhood, neighborhood shape, and maximum and minimum number of points. LPI is sensitive to the neighborhood distance, and the sample points in a neighborhood can be weighted by their distance from the prediction location. Because LPI is sensitive to neighborhood distance and a small search neighborhood may create empty areas in the prediction surface, the method shows better results with grid-based sampling data than with random point sampling (Johnston et al., 2003; Hani et al., 2011).

Radial basis functions (RBFs)

RBFs are a form of artificial neural networks with a series of exact interpolation techniques. They use an equation derived from the distance between an interpolated point and the sampling points (Lin and Chen, 2004; Aguilar et al., 2005). The method consists of five deterministic interpolation techniques: thin plate spline, spline with tension, completely regularized spline, multi-quadratic function, and inverse multi-quadratic function. The RBF method is used mainly to create smooth surfaces from a large number of data points. Although RBFs give good results for areas with gently varying surfaces, the method will not provide accurate results if there are any large variations in the surface within a short horizontal distance (Johnston et al., 2003). The most commonly used RBF technique, completely regularized spline was used for this analysis.

Kriging

Kriging is a linear interpolation method that assumes that the parameter to be interpolated can be modeled by random processes with spatial autocorrelation. Hence, kriging techniques are widely used to describe and model spatial patterns and predict values at unmeasured locations. Three types of kriging were evaluated in this study: ordinary kriging, universal kriging and empirical Bayesian kriging.

Ordinary kriging (OK)

OK is the most widely used kriging method. It uses an average of a subset of neighboring points to produce a particular interpolation point. OK can use either semivariograms or covariances to explain the autocorrelation and can use transformations to avoid trends (Johnston et al., 2003), but the semivariance function plays a major role in deriving weights of OK (Johnston et al., 2003). The empirical semivariance function can be used to estimate the parameters of the semivariogram function and the nugget effect as expressed in *Equation 2:*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_53595380
© 2018, ALÖKI Kft., Budapest, Hungary

$$\gamma(h) = \frac{1}{2N(h)} \sum_{i=1}^{N(h)} [Z(x_i) - Z(x_i + h)]^2 \quad \text{(Eq.2)}$$

where γ is the semivariance, $N(h)$ is the number of data pairs within a given class of distance and direction, h is the lag distance, and $Z(x_i)$ and $Z(x_i + h)$ are the sample values at two points separated by the distance interval h (Xie et al., 2011).

Universal kriging (UK)

UK can be used to produce prediction, quantile, probability, or standard error maps. The method is used to estimate the spatial means when the data have a strong trend, and the trend is modeled using simple functions. The use of UK is limited to large surfaces, such as a large country, because it is difficult to follow a trend along the direction of spreading (Kis, 2016).

Empirical bayesian kriging (EBK)

EBK is different from other classical kriging methods because the parameters are automatically optimized using a number of semivariogram models instead of a single semivariogram. The following steps are used in EBK: (1) A semivariogram model is estimated using available data. (2) A new value is simulated for each input data location using the semivariogram model. (3) Based on the simulated data, a new semivariogram model is estimated. Bayes's rule is then used to calculate the weight of the new semivariogram model. By repeating the steps 2 and 3, the semivariogram estimated in step 1 is used to simulate a new set of values at the input locations (Krivoruchko, 2012).

Data preprocessing

Because the Kriging methods require the sample distribution to be normal, Shapiro Wilk test was performed for all 144 datasets (12 water quality parameters/indices × 12 months) to check the goodness-of-fit of the data ($P < 0.05$). The results showed that K^+, Mg^{2+}, NO_3^--N, Cl^- and EC were not normally distributed at any time, and the other parameters and indices were normally distributed only during several months. Hence, datasets that were not normally distributed were log-transformed and thereafter except very few, all the other data sets were normally distributed.

Validation and model evaluation

Cross-validation and validation with an independent dataset are the most common methods used to compare different interpolation methods, whereby the data are divided into a training set and a validation set. The validation set is used to test the model acquired from the training set. Those allowed us to assess the goodness-of-fit of interpolation methods and the appropriateness of the neighborhood (Dashtpagerdi et al., 2013; Gunarathna et al., 2016a, b). Because the number of sampling points was limited, we used leave-one-out cross-validation (Gunarathna et al., 2016a, b) to estimate the spatial variation of water quality parameters/indices in the study area, removing one data point from the known dataset and estimating its value from the other known values. If a model has a standardized mean error close to 0, the RMSE and average standard error are as small as possible as compared with other models, which means the model

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_53595380
© 2018, ALÖKI Kft., Budapest, Hungary

provides the most accurate predictions. Hence, we used RMSE (*Eq. 3*) to compare the models:

$$RMSE = \sqrt{\frac{1}{n}\left(Z_i - \hat{Z}_i\right)^2} \quad \text{(Eq.3)}$$

where $\hat{Z}_i$ is the estimated value, Z_i is the measured value at sampling point i (i = 1,.., n), and n is the total number of observations.

The coefficient of variance (CV), which is the ratio of standard deviation to the mean of each parameter/index, was used to study the relative variability of the dataset. We used the local Moran's Index (MI), one of the most commonly used criteria for spatial autocorrelation of quantitative data (Moran, 1950), to estimate the level of spatial autocorrelation of water quality parameters/indices in the Ulagalla cascade.

Results and discussion

Relative performance of deterministic and geostatistical interpolation methods

The RMSE values of cross-validation for the 12 water quality parameters/indices during 12 consecutive months are summarized in *Tables A2–A13* in the *Appendix*. Note that the RMSE values of the OK and UK interpolation methods were similar to each other for all the parameters/indices, and are considered together as kriging (KR). EBK was superior to all other interpolation methods in estimating spatial variation of K^+, Mg^{2+}, NO_3^--N, and EC in all 12 months (*Tables 1, A4, A6, A7* and *A11*); of Na^+, HCO_3^-, Cl^-, and TH in 11 months (*Tables 1, A3, A9, A10* and *A13*); of SAR in 10 months and of pH and PO_4^{3-} in 7 months (*Tables 1, A2, A12, A8*). EBK was outperformed in only 6 months in the interpolation of Ca^{2+} (*Tables 1* and *A5*). Overall, EBK was the best method for interpolating groundwater quality parameters/indices in 121 out of the 144 incidences.

Based on the number of success incidences obtained from the cross-validation results, the interpolation methods can be sorted, as EBK > LPI > GPI > IDW > KR > RBF (*Table 1*). This ranking supports the findings of Gunarathna et al. (2016a, b) and Mirzaei and Sakizadeh (2016), who also found EBK to be superior to other interpolation methods with the use of a limited number of variables. Even though EBK recorded the lowest RMSE value for most of the parameters/indices that was not the case with Ca^{2+} and PO_4^{3-}, for which several methods had the lowest RMSE during different months (*Table 1*). Hence, we selected Ca^{2+} (*Table 2*) and PO_4^{3-} (*Table 3*) to elucidate differences in the methods.

As inexact interpolators among the selected methods, GPI and LPI showed quite similar results compared to other methods used in the present study and this was supported by Wang et al. (2014). Xiao et al. (2016) also confirmed that GPI is suitable only when the variability of the dataset is relatively small. Although GPI can be used to analyze the surface trend of regionalized variables, it is not accurate when extreme values are present (Mutuna and Kurima, 2012; Wang et al., 2014). LPI is also capable of simulating a narrow range of variability with high accuracy (Xiao et al., 2016). GPI was ranked in the top three methods during 10 months of the study period, and the CV was relatively small in 6 of those 10 months (*Table 2*). Moreover, no extreme values were recorded near the boundaries in those 6 months. In the other 4 months, the variation of the dataset was moderate, and no extreme values were recorded near the boundaries (*Table 2*). According to the summary statistics of phosphate concentration (*Table 3*), the conditions of low variation and no extreme values near boundaries were met in only 3 months, and GPI was ranked among the top three only once.

IDW is widely used in the field of environmental sciences, but it is rarely recommended as the best interpolation method in comparison studies (Li and Heap, 2011). In their review, Li and Heap (2011) reported that IDW is highly sensitive to sample density and data variation (CV). The poor performance of IDW in our study could be attributed to the high spatial data variation and relatively low sample size. In the classification using Ca^{2+} and PO_4^{3-}, IDW was never the best-fit model when the CV was high. Therefore, we do not recommend the use of IDW to interpolate spatial variation of groundwater quality parameters/indices in tank cascade landscapes unless the data show low spatial variation and have a higher sample density with an evenly distributed sampling pattern.

Kriging (KR) is one of the most widely used interpolation methods in the field of environmental sciences, and it has been recommended in comparison studies (Li and Heap, 2011). Basic assumptions of KR are spatially autocorrelated observations (a function of distance between observations) and normally distributed data (Zimmerman et al., 1999). Therefore, KR has a strong ability to predict the overall trend of groundwater contamination when a dataset is autocorrelated (Ahmed, 2002; Nas, 2009; Xie et al., 2011; Mutuna and Kurima, 2012; Zehtabian et al., 2013). As shown in *Table 3,* KR was ranked on first three during 6 months when the data was significantly autocorrelated in 8 months and was in the top three in 5 of those 8 months. This characteristic was also observed in the Ca^{2+} dataset where KR performed well in June when the data were autocorrelated.

Because EBK divides the dataset into subsets and simulates a semivariogram for each subset to reduce the uncertainty relative to that in KR, it provides relatively better interpolation accuracy on small datasets and non-stationary datasets than KR (ESRI, 2015). In *Tables 2* and *3,* EBK was listed in the top three in 21 of 24 incidences. This shows that EBK performs well irrespective of CV, MI, extreme values near boundaries (EVnB), and skewness (SK). However, when the dataset was less variable, showed autocorrelation, and had no EVnB, other interpolation methods performed better than EBK. Hence, we recommend using EBK when data show high variability and no autocorrelation, and extreme values near boundaries and are not normally distributed.

As the quality of the dataset determines the accuracy of different interpolation methods, we assessed the importance of CV, MI, SK, and EVnB (characteristics that show the quality of a dataset) to the success of each method using an attribute evaluation option available in the CORElearn package (Robnik-Sikonja and Savicky, 2017) of R software (*Table 4*). The relative importance of the characteristics can be sorted as EVnB > CV > SK > MI for GPI and EVnB > SK > CV > MI for LPI. These results confirm the sensitivity of GPI and LPI to CV and EVnB. The relative importance for RBF was CV > EVnB > SK > MI, demonstrating that RBF is sensitive to the variability of the dataset and EVnB. The relative failure of RBF in this study can be explained by the high spatial variation of the water quality parameters/indices. The relative importance for IDW was EVnB > CV > MI > SK, confirming its sensitivity to dataset variability and extreme values. The relative importance for KR was EVnB > MI > CV > SK, confirming that KR can be successfully used when the dataset is autocorrelated with low variability while lacking extreme values near boundaries.

Table 4. *Relative importance of attributes on different interpolation methods*

	Relative importance					
Attributes	**GPI**	**LPI**	**RBF**	**IDW**	**KR**	**EBK**
CV	0.013	0.036	0.181	0.274	0.013	0.025
MI	−0.031	0.010	0.010	0.243	0.052	0.009
SK	−0.02	0.081	0.050	0.730	0.001	−0.013
EVnB	0.262	0.093	0.077	0.422	0.218	0.154

CV – coefficient of variance, MI – Moran's Index, SK – Skeweness, EVnB – extreme values near boundary

Distribution pattern of observed and simulated data using EBK method

Figure 3 shows boxplot diagrams of the observed and EBK-predicted values of the 12 parameters/indices. The measured and predicted values of almost all the parameters/indices were right skewed except pH, showing that the majority of the values are clustered below the median and the means are greater than the median (*Table A14*). Further, it can be noted that EBK was unable to properly predict extreme values, but there were no significant differences between observed and predicted values. The final spatial distribution maps of water quality parameters/indices prepared using the EBK interpolation method for the mean values of the 12 parameters/indices are shown in *Figure 4*. It was observed that the concentration of most parameters/indices were comparatively low at the upper part of the cascade and it has increased at the lower part of the cascade due to the accumulation effect.

Conclusions

A clear understanding of spatial and temporal variation in water quality parameters/indices is a key issue in agriculture as well as in environmental studies. At present, many algorithms are used with the aim of selecting the best interpolation method for delineation of the spatial distribution of water quality parameters/indices. We investigated the interpolation accuracy of a variety of methods in a tank cascade landscape.

The EBK method proved superior to deterministic and other geostatistical methods in interpolating groundwater quality parameters (anions, cations, and nutrients) and indices associated with tank cascade landscapes. Kriging interpolation was successful when the dataset was autocorrelated with low variability. IDW had the worst results in estimating the spatial distribution of water quality parameters/indices. Better performance was obtained with the GPI and LPI methods when the dataset was less variable and had no extreme values near boundaries.

Because groundwater monitoring is labor intensive and expensive, it is important to use optimum sampling density and to choose the design in a methodical way. Furthermore, it is advisable to decide on the interpolation method before sampling and then schedule sample density and design accordingly. This study can be used as a guide for such decision making for groundwater monitoring in a tank cascade landscape.

In general, the preparation of composite water quality zonation map for the Ulagalla cascade with the integration of EBK method and water quality indices/parameters can be carried out. Future research can be conducted to find out the optimum number of sampling points to obtain precise estimation of water quality in tank cascade landscape.

(Received 28th May 2018; accepted 31st Jul 2018)

Abstract. Agriculture has become a major user of global freshwater resources. This study measured the consumptive water use of 15 selected crops (cash crops, vegetables, and fruits) in Malaysia. The results indicated that the green water consumption footprint (129.8 m^3/ton -1586.0 m^3/ton) was higher compared to the blue water consumption footprint (21.0 m^3/ton - 931.0 m^3/ton) for all 15 crops in Malaysia. Paddy crop had the highest total water consumption footprint for both off and main seasons with 2265 m^3/ton and 2255 m^3/ton, respectively, due to the cultivation practices under flood conditions. The water consumption footprint depends on the crop yield, implying that the higher the crop yield, the lower the value is. This paper provides a comprehensive review of the assessment of the water consumption footprint of crop production in Southeast Asia from 2007 to 2017 (10 years). The paper also highlights and discusses a feasibility study for the water consumption footprint of crops and future outlooks in Southeast Asia following an LCA-based approach.
Keywords: *water footprint, water scarcity, agriculture water management, sustainability, Malaysia*

Introduction

In line with the increasing world population, increased water use and management issues have become a major global sustainability debate in recent years. A large amount of water is required to satisfy the needs of various sectors. A better understanding of water use and management is necessary to improve water resource stewardship and management at the local, regional, and global levels. The agriculture sector has become a major global freshwater consumer due to the irrigation sector, which consumes about 70% of freshwater around the world (Scanlon et al., 2007; Gordon et al., 2010; WWAP, 2012). Some regions, such as Southeast Asia, have a tropical climate and receive a sufficient amount of rainfall throughout the year, which allows for growing a variety of crops and has made the region a major global agriculture producer. The agriculture sector also makes a significant contribution to economic growth, as there is a high exportation of agricultural products, such as palm oil and rice; however, intensive anthropogenic activities and unforeseen natural events have affected the availability of surface and groundwater. The water footprint (WF) is a sustainability indicator that has been introduced to assess water consumption and the availability for different sectors (e.g., industrial, agricultural, domestic, etc.) and levels (global, national, regional, watershed, etc.). The WF was introduced to assess and quantify the water required for the production of a product and to assess the potential environmental impacts related to water use (Hoekstra, 2017, 2003; Babel et al., 2011; Chapagain and Hoekstra, 2004). WF is categorized into three components (green, blue, and grey)

based on a spatial and temporal water consumption evaluation of the source (Hoekstra et al., 2011; Aldaya et al., 2010).

Development of the water footprint concept

The concept of virtual water and the WF indicator were developed over the last decade. The virtual water concept was first introduced by Allan (1998), who defined it as the volume of freshwater used to produce a product. In other words, virtual water is the volume of water required to produce a product at the consumption level. WF is defined as the volume of water used in the production of a product or service consumed by an individual or group (Hoekstra, 2017). Hoekstra (2003) introduced the concept of WF by developing a framework to analyse the ratio of spatially and temporally explicit water consumption per water availability. The focus of the WF in early studies was quantifying the WF of processes, products, companies, and consumer groups. The WF consists of three components, which are specified geographically and temporally: green, blue, and grey water. The green WF refers to the total rainwater evapotranspiration and water incorporated into harvested crops used in the production of goods or services. The blue WF is defined as the volume of surface and groundwater consumed during the production of a product. The grey WF refers to the volume of freshwater required to dilute pollutants so that the quality of the polluted water complies with ambient water quality standards.

In the 2000s, Hoekstra and Hung (2002), Chapagain and Hoekstra (2003), Hoekstra (2003), Oki et al. (2003), Zimmer and Renault (2003), and De Fraiture et al. (2004) conducted studies to assess virtual water at a global scale. Hoekstra and Hung (2002) and Chapagain and Hoekstra (2004) provided global WF statistics of the agricultural, domestic, and industrial sectors and virtual water flows between nations due to international trade. Early studies of the WF focused on blue and green water consumption, and later, the grey WF was included to assess how much water is needed to dilute the pollutants in a body of water (Chapagain and Hoekstra, 2008). The WF has been further improved in terms of its definition and methodology for the agriculture, industry, and domestic sectors at a global scale by applying high spatial and resolution aspects (Mekonnnen and Hoekstra, 2011). Hoekstra et al. (2011) also developed the Global WF Standard to ensure that a reliable method is applied and a fair comparison can be formed between various WF studies.

ISO 14046 is the standard guideline for reporting WF, and it was launched by the International Standard Organization (ISO) in 2014. The factors that must be considered when applying ISO 14046 include societal, environmental, legal, cultural, and organizational diversity as well as differences in economic conditions (ISO, 2014). The framework consists of four phases: goal and scope definition, WF inventory, analysis, and water impact assessment. WF assessments can be performed either individually or as part of the Life Cycle Assessment (LCA) to identify the hot spots of the process throughout its supply chain; thus, significant environmental impacts from water consumption can be reduced (Sabli et al., 2017). *Figure 1* provides a brief description of the development of the WF assessment concept.

Although several WF studies have been conducted in many developed countries, this approach is still nascent in Southeast Asian countries, especially Malaysia. For the WF of agriculture, few studies have been conducted in Malaysia for cash crops (Harun and Hanafiah, 2017) and palm oil (Aminordin et al., 2014; Vijaya et al.,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_53815403
© 2018, ALÖKI Kft., Budapest, Hungary

2014; Zulkifli et al., 2014; Muhammad et al., 2012). Therefore, the present study aimed to assess the water consumption footprint of selected crops in Malaysia and to provide a comprehensive review of the current state of the water consumption footprint of crops in Southeast Asia from 2007 to 2017 (10 years). Recommendations and potential approaches to the sustainability of water resources in Malaysia are discussed as well.

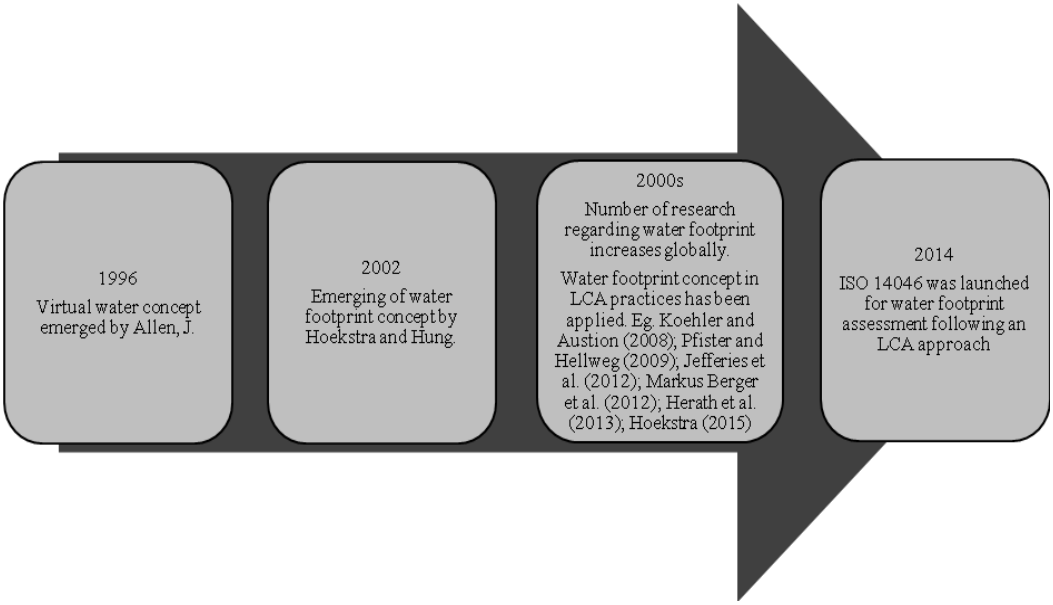

Figure 1. *Development of WF assessment concept*

Assessment of the water consumption footprint of selected crops in Malaysia

Malaysia receives a high amount of rainfall, with an average of 3,000 mm per year, implying a high dependence on rainfall for its water resources (GWP, 2017; WHO, 2011). The area of Malaysia's water supply is around 566 km^2 and includes catchment areas, rivers, lakes, and reservoirs. In Malaysia, the agriculture sector recorded an annual growth rate of 5.6% in 2015 compared to 2010 with a contribution of 8.9% to the Gross Domestic Product (GDP). Palm oil was a major contributor to the GDP of the agriculture sector, followed by other agriculture, livestock, fishery, rubber, and forestry and logging sectors, as shown in *Figure 2*.

According to the World Wildlife Fund (WWF), inefficient agricultural water use is a major issue that must be addressed to ensure the sustainability of water resources, as agriculture consumes about 68% of total water use in Malaysia. The agriculture sector plays an important role in national economic development by securing national food security and also contributes to public incomes, especially for people living in rural areas. Therefore, farmers in Malaysia as well as across the world have taken a step further to strengthen food security, and the government has also allocated billions of Ringgit Malaysia (RM) to maximise Malaysian agriculture production over the past 50 years (Zaim et al., 2013).

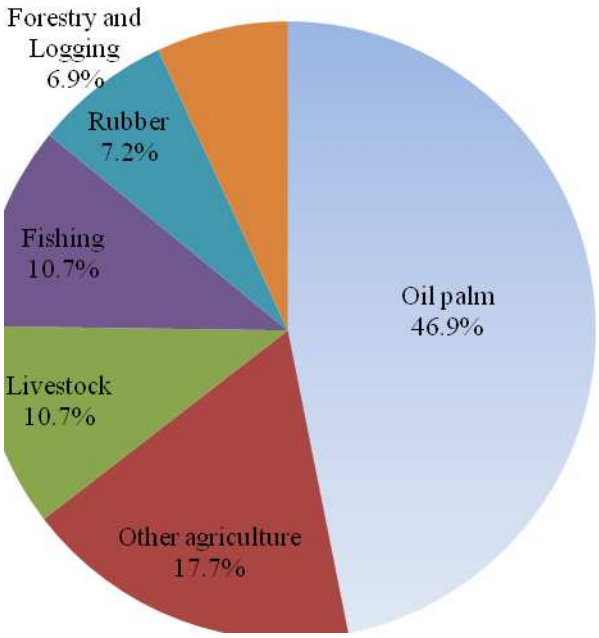

Figure 2. *Malaysia Gross Domestic Products (GDP) 2015 (Department of Statistics Malaysia, 2016)*

Methodological framework

In an agricultural context, the water consumption footprint (WCF) is used to quantify how much water has been consumed to grow a crop, and it is applicable to both annual and perennial crops (Hoekstra, 2011). In the present study, the WCF of three crop categories (cash crops, vegetables, and fruits) in Malaysia was assessed. Fifteen crops from the three crop categories grown in Peninsular Malaysia were selected: cassava, maize, sugarcane, sweet potato, pomelo, mandarin, banana, mango, pineapple, watermelon, cucumber, eggplant, green bean, lettuce, and rice. These 15 crops were chosen based on the high demand and their major contributions to the Malaysian economic sector. The total WCF of the crop cultivation process (WCF_{crop}) was adapted from the general formula of Hoekstra et al. (2011), as shown in *Equation 1.*

$$WCF_{crop} = WCF_{green,crop} + WCF_{blue,crop}\ m^3/ton \quad \text{(Eq.1)}$$

where,

WCF_{crop} = total water consumption footprint
$WCF_{green,crop}$ = green water consumption footprint
$WCF_{blue,crop}$ = blue water consumption footprint

The green water used in the process of the WCF of a crop ($WCF_{green,crop,}$ m^3/ton) was calculated by dividing the green component in the water use of a crop with the crop yield (Y, ton/ha) as shown in *Equation 2*. The blue component ($WCF_{blue,crop}$) was calculated similarly to the green WF and is expressed in m^3/ton.

$$WCF_{crop} = \frac{CWU_{green,crop}}{Y_{crop}} + \frac{CWU_{blue,crop}}{Y_{crop}} \left(\frac{m^3/ha}{ton/ha}\right) \quad \text{(Eq.2)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_53815403
© 2018, ALÖKI Kft., Budapest, Hungary

where,

$CWU_{green,crop}$ = crop water use (green component)
$CWU_{blue,crop}$ = crop water use (blue component)
Y = crop yield

The crop evapotranspiration (ET), which is the combination of the two processes whereby water is lost from the soil surface and from crops by transpiration, was calculated using the following formulae (*Eqs. 3* and *4*) to determine the WCF_{green} and WCF_{blue}:

$$CWU_{green} = 10 \times \sum_{d=1}^{lgp} ET_{green} \ (m^3/ha) \quad \text{(Eq.3)}$$

$$CWU_{blue} = 10 \times \sum_{d=1}^{lgp} ET_{blue} \ (m^3/ha) \quad \text{(Eq.4)}$$

where,

ET_{green} = green water evapotranspiration
ET_{blue} = blue water evapotranspiration

A factor 10 was applied to convert water depths in millimeters into water volumes per land surface in m^3/ha, and lgp is the length of the growing period in days. The Penman-Monteith method by Allen et al. (1998) was used to calculate the evapotranspiration of crops (*Eqs. 5* and *6*). Crops coefficient used in this study was based on the length of crop development stages according to Food Agriculture Organization (FAO).

$$ET_{crop} = K_c \times ET_0 \ (mm/day) \quad \text{(Eq.5)}$$

where,

ET_{crop} = crop evapotranspiration (mm/day)
K_c = crop coefficient
ET_0 = Penman-Monteith crop evapotranspiration (mm/day)

$$ET_o = \frac{0.408\Delta(R_n - G) + \gamma \frac{900}{T+273} u_2 (e_s - e_a)}{\Delta + \gamma(1 + 0.34u_2)} \quad \text{(Eq.6)}$$

where,

ET_o = reference evapotranspiration (mm day^{-1})
Rn = net radiation at the crop surface (MJ m-2 day^{-1})
G = soil heat flux density (MJ m-2 day^{-1})
T = air temperature at 2 m height (°C)
u2 = wind speed at 2 m height (m s^{-1})
es = saturation vapour pressure (kPa)
ea = actual vapour pressure (kPa)
es – ea = saturation vapour pressure deficit (kPa)
D = slope vapour pressure curve (kPa $°C^{-1}$)
G = psychrometric constant (kPa $°C^{-1}$)

A statistical analysis was also used to estimate the rainfall deficit for irrigation water requirements based on long-term rainfall records. This analysis was determined as part of the rainfall, which effectively contributes to cover crop water requirements (CWR). Information from the inventory database was compiled, and all data were used to model the WCF of the selected crop cultivation in Malaysia. Finally, a set of recommendations and suggestions was developed. The conceptual framework of the present study is shown in *Figure 3*.

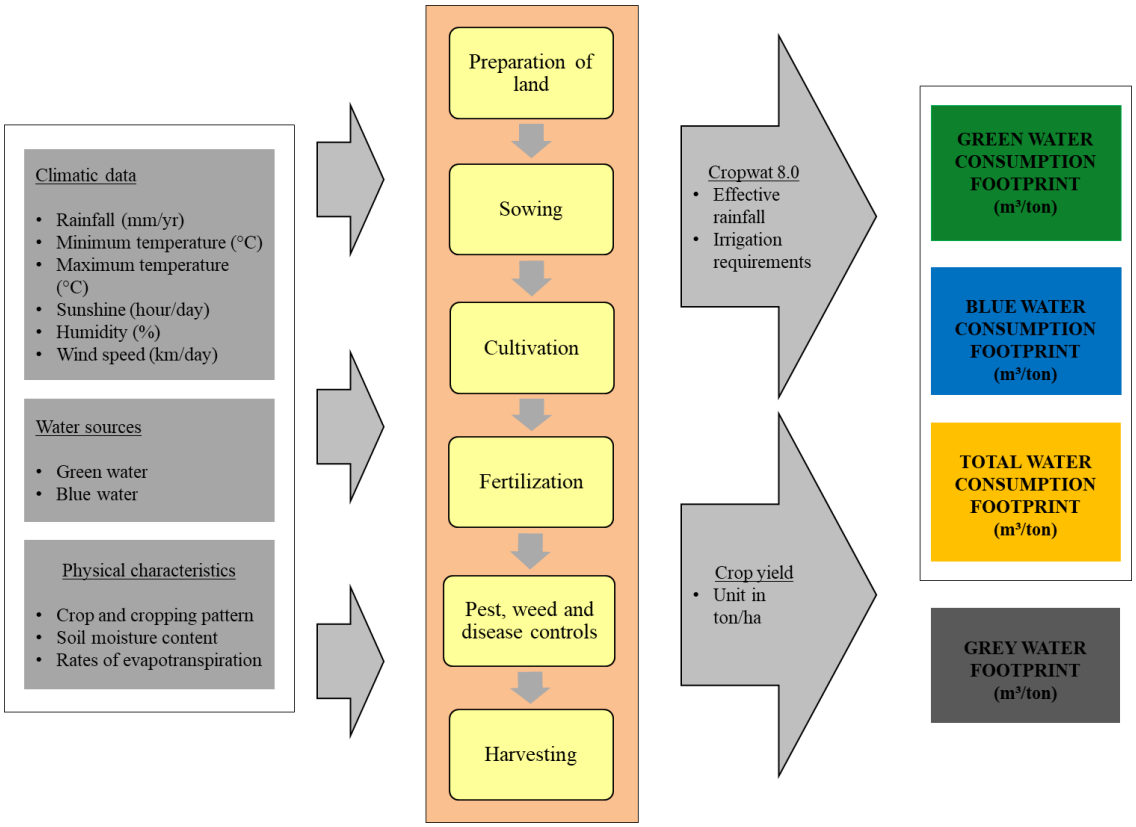

Figure 3. *Conceptual frameworks for WCF study of crop cultivation in Malaysia*

For this research study, data were compiled from various secondary data sources, such as books, publications, reports, government agencies related to the field of studies, including the Department of Irrigation and Drainage (DID), Malaysian Meteorological Department (MMD), Department of Agriculture for Peninsular Malaysia (DOA), Department of Statistics, Malaysian Agricultural Research and Development Institute (MARDI), and National Water Services Commission (SPAN), Malaysian rice cultivation, and Malaysian hydrological information. Foreground data were obtained through a series of site visits by communicating with data providers and administering questionnaires.

Result and discussion

Climatic data

For the WCF analysis, the climatic data provided by Malaysian Meteorological Department (MMD) consisted of minimum and maximum temperature, humidity,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_53815403
© 2018, ALÖKI Kft., Budapest, Hungary

sunshine, rainfall rate, and wind speed for nine years (2005 to 2013), which were used to estimate the water use for crops. Crop water requirements and irrigation requirements were calculated using the CROPWAT 8.0 Model, which is a decision support tool developed by the Land and Water Development Division of FAO. In addition to climatic data, other parameters, such as crop data and soil conditions, were included in the CROPWAT 8.0 model to estimate crop performance under both rain-fed and irrigated conditions.

Peninsular Malaysia experienced a uniform temperature throughout the year and ranged from 24 to 34 °C, while the average temperature over a period of nine years (2005 to 2013) recorded in this study was 28.7 °C. Due to the high evaporation rate, Malaysia's humidity ranged between 80% to 86%, with an average humidity of 82%, which can be considered high with an average of six hours of sunshine per day. In this study, the highest humidity rate was found in November at 85.8%, while the lowest humidity at 78.9% was observed in February. On the other hand, the highest wind speed rates were recorded in January and February at 155.5 and 146.9 km/day, respectively. The lowest wind speed rate of 121.0 km/day was recorded from April to July and September to November. *Figure 4* shows the average temperature, relative humidity, wind speed, and monthly sunshine for Malaysia over the nine-year period.

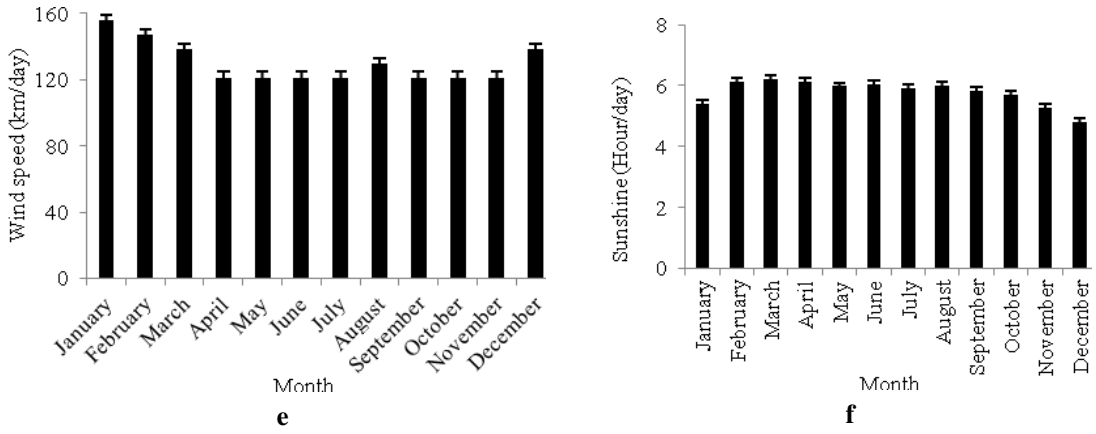

Figure 4. *Average a) rainfall, b) precipitation, c) temperature, d) humidity, e) wind speed, and f) monthly sunshine hours in Peninsular Malaysia over nine years (2005–2013)*

Water consumption footprint of selected crops

The green, blue, and total WCF for each crop along with the average yield from the year 2005 to 2013 are shown in *Figure 5*. The results indicated that perennial trees (banana, mango, and pineapple) require the highest amount of water per ton of crop production because perennial trees require water year-round, unlike annual trees. Variations in the blue and green WCF of crop production were related to the volume of water use, consumption patterns, climate factors, and agricultural management practices (Le Roux et al., 2017; Mekonnen et al., 2011). The evapotranspiration rate, which is mostly determined by climate conditions, is another factor that affects the WCF of crops.

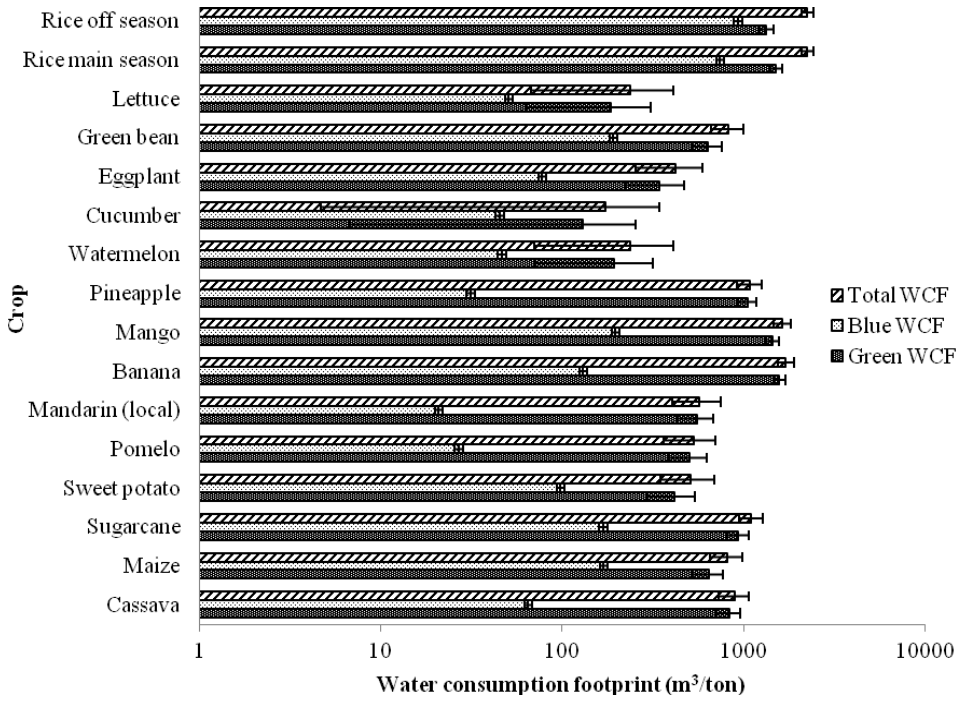

Figure 5. *Average blue, green, and total WCF of 15 crops for nine states in Peninsular Malaysia*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

Green WCF had the highest value compared to blue WCF for all 15 crops in Peninsular Malaysia over the nine-year period. In Malaysia, 80% of irrigation water originates from green water, contributing to a higher green WCF compared to the blue WCF of crop production. In the agricultural sector, the blue water used depends on the crop, crop tolerance to water deficits, irrigation efficiency and green water availability (Lovarelli et al., 2016). If the evapotranspiration rate is higher than the rainfall rate, WCF_{blue} is potentially equal to the difference between evapotranspiration and rainfall (Bochiolla et al., 2013). Crop irrigation systems in Malaysia highly depend on rainwater, especially during the wet season (November to March), and there is a uniform temperature and high humidity throughout the year. It has been shown that the average of the green WCF was higher compared to the blue WCF for nine cultivated crops in Malaysia Ghazali and Hanafiah, 2016). Malaysia usually uses rainfall to meet crop water requirements, and the irrigation supply is only needed when rainfall is not sufficient (Abdul Samad et al., 2017; Ghazali and Hanafiah, 2016). Green water consumption causes less damage to the environment compared to blue water consumption (Falkenmark and Rockström, 2004) because high blue water usage will eventually lead to water scarcity (Gheewala et al., 2014). Terengganu has the highest average of green and total WCF among nine states in Peninsular Malaysia, and the lowest WCF was found for Selangor (*Figure 6*). This is because Terengganu has the lowest yield value compared to all crops included.

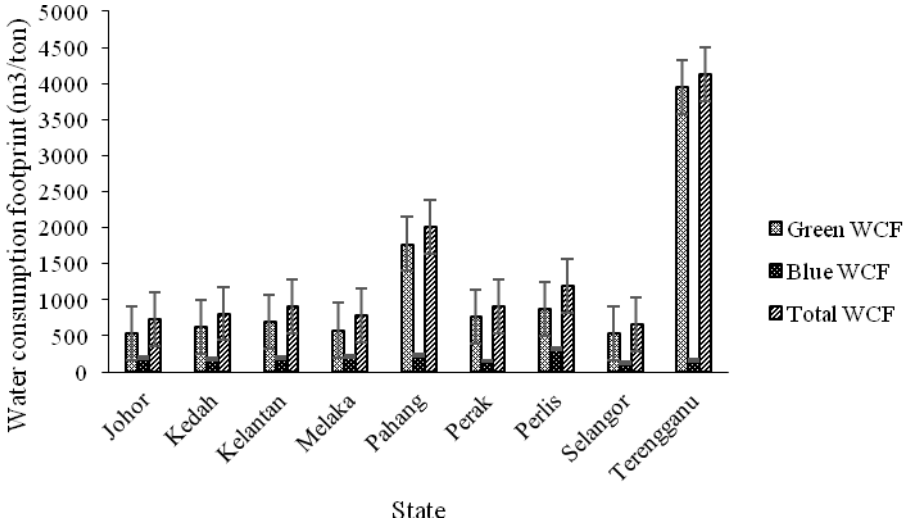

Figure 6. *Average of WCF (nine years) of 15 crops for nine states in Peninsular Malaysia*

The results for total WCF indicate that the cultivation of rice requires the highest amount of irrigation in both seasons compared to other crops, i.e., 2265 m^3/ton and 2255 m^3/ton in the off-seasons and main seasons, respectively, followed by mangoes and green beans. Based on this study, in the off-season, rice has the highest WCF values and contributes 15% of the total WCF of 15 crops in Peninsular Malaysia (*Fig. 7*). Rice requires two or three times more water than any other crop because paddy fields are cultivated under flood conditions (Gheewala et al., 2014; Maclean et al., 2013). Chapagain and Hoekstra (2011) reported that rice is one of the largest water consumers in the world, and large areas are required to irrigate paddy fields. Compared to other

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

selected Southeast Asian countries, Malaysia was ranked 8th for the highest paddy production at 2674.4 tons after Indonesia (recorded the highest paddy production), Vietnam, Thailand, Myanmar, Philippines, Cambodia, and Laos in 2015 (Economic Planning Unit, 2016).

Cucumbers had the lowest WCF (175.07 m^3/ton) compared to other crops due to the higher production yield (19.66 ton/ha). WCF is based on several factors; however, the most important factor is related to crop yield (Gheewala et al., 2014; Bulsink et al., 2010). A higher crop yield results in a lower WCF of crops (Gheewala et al., 2014; Bulsink et al., 2010; Chu et al., 2017). To reduce the WCF, the productivity of the crop per hectare of area must be improved. For instance, improving agriculture practices, such as by using organic fertilizer and regular weed control, can be applied. The results of the total WCF of the present study are similar to the previous study presented by Mekonnen et al. (2014), which reported the average of WCF for crops at the global scale; however, there are some crops that have different WCF values due to regional and climate factors, including climate variability, productivity, and agriculture practices (Gheewala et al., 2014; Mekonnen and Hoekstra, 2014; Bulsink et al., 2010; Hoekstra and Chapagain, 2006).

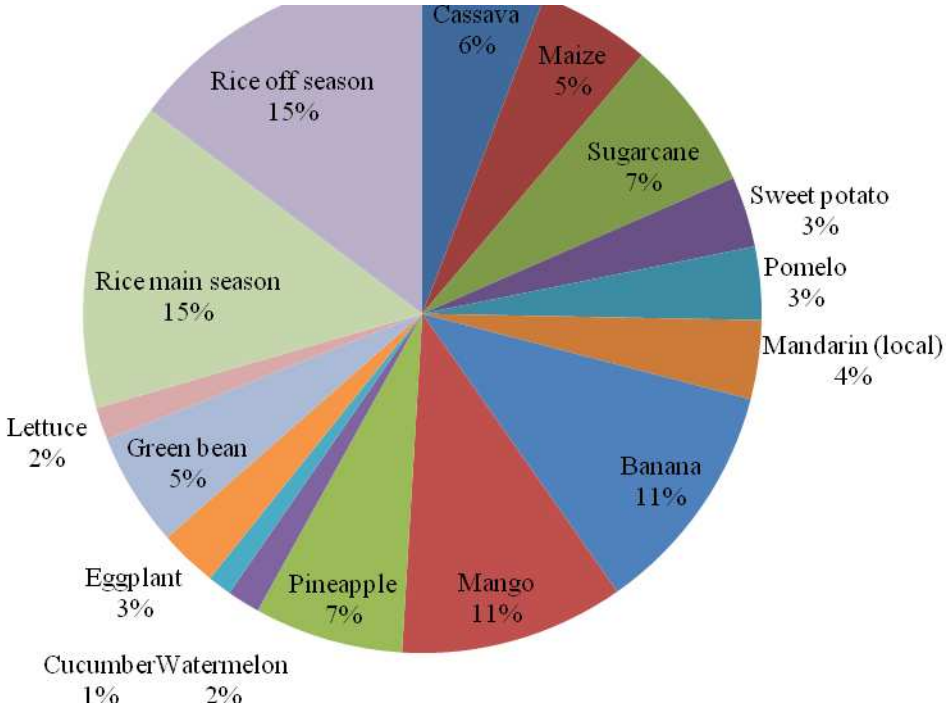

Figure 7. *Percentages of total WCF of 15 crops in Malaysia*

Previous studies of the WCF of crops in Southeast Asia

The next sections of this paper discuss previous studies of the WF of crops conducted in the Southeast Asian region that were published from 2007 to 2017 (10 years). The keywords used to search for published studies included water footprint, blue water, green water, water consumption, water use, water scarcity, agriculture, crop production, and Southeast Asia. Literature from several established databases, such as Scopus and Science Direct, were included. Southeast Asia has a tropical humid climate

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_53815403
© 2018, ALÖKI Kft., Budapest, Hungary

and consists of 11 countries: Brunei, Cambodia, East Timor, Indonesia, Laos, Malaysia, Myanmar, Philippines, Singapore, Thailand, and Vietnam. Agriculture is the primary economic activity in Southeast Asia, and approximately 16% of the land area is planted with crops. Many Southeast Asian countries heavily depend on the export of plantation crops, such as coconut, sugar, rubber, tea, bananas, and abaca, to maintain the balance of trade. Southeast Asian countries are among the largest exporters of commodity crops, such as palm oil and rice. Furthermore, rice is one of the staple foods of Malaysia, Thailand, and Indonesia.

Aim and scope

WF is a new approach used to assess water use in the agricultural sector of Southeast Asia, and few studies have been conducted in this region. *Table 1* provides an overview of studies on the WCF of crops that have been conducted in Southeast Asia. To satisfy the growing demand for food, feed, and biofuel production in the future, information related to water resource availability and crop water requirements is needed for water resource sustainability planning (Gheewala et al., 2014).

Functional unit

The WCF is expressed in terms of water volume per unit of product or as water volume per unit of time (Hoekstra et al., 2011). In an agricultural context, the functional unit frequently used is the volume of water per ton of crop product (m^3/ton); however, m^3/GJ is sometimes used as a functional unit when an analysis of energy crops is conducted. For example, Babel et al. (2011) examined the WCF of the biofuel energy production of palm oil, cassava, and sugarcane.

Component

The WCF considers both the direct and indirect water use of a process or product, which includes water consumption and water pollution throughout the full production cycle. The green, blue, and grey WCF were calculated separately, as they measure different types of water appropriation. The green and blue WCF are quantified to assess water quantity, while the grey WCF focuses on water quality.

Type of crops

Figure 8 shows the type of crops analyzed by the reviewed papers. CROPWAT 8.0 was applied to calculate the water used to cultivate crops. Most reviewed WCF studies assessed the WF of palm oil, followed by sugarcane and cassava, due to the promotion of biofuel in many countries, such as the US, Brazil, China, India, Thailand, and Malaysia. Biofuel use is promoted to reduce fossil fuel consumption, oil imports, and greenhouse gas emissions as well as to decrease the poverty rate of rural communities (Dufey, 2006; De Fraiture et al., 2008).

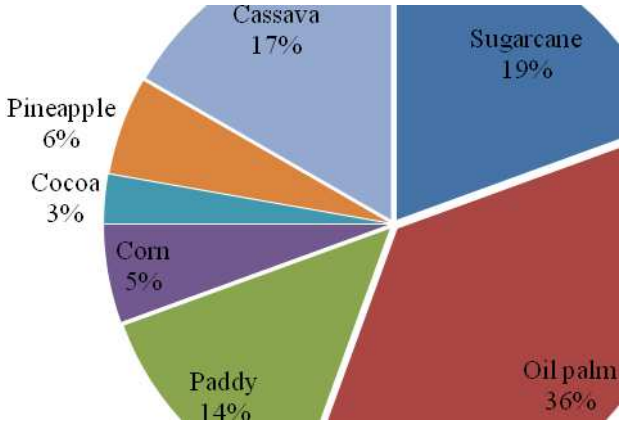

Figure 8. *Type of crops analysed in the reviewed papers*

The government of Thailand has planned to increase the share of renewable energy in the total energy consumption from 0.5% in 2002 to 20.3% by 2022 (Preechajarn and Prasertsri, 2010), many studies on biofuel crops have been carried out in Thailand (e.g., Silalertruksa et al., 2017; Suttayakul et al., 2016; Mungkalasiri et al., 2015; Pongpinyopap et al., 2014; Tiewtoy et al., 2013; Babel et al., 2011; Seewiseng et al., 2012; Gheewala et al., 2014; Namchancharoen et al., 2015; Kongboon and Sampattagul, 2012). In Thailand, biofuel is projected to replace 4928 million liters of fossil fuel annually by the year 2022 (Preechajarn and Prasertsri, 2010). The increase in biofuel crops will lead to land use changes and the replacement of native rainforests and wetlands due to shortages of land for agricultural purposes (Muller et al., 2007). Land use changes affect water resources and the aquatic environment. In addition, the changes can influence evapotranspiration and interception, thus reducing effective rainfall sources and affecting surface runoff and groundwater recharge (Stephan et al., 2001). As biofuel crops are crucial to supporting renewable and sustainable energy, it is necessary to determine which crop is produced in the most water-efficient manner (Babel et al., 2011). Several researchers, such as Gerbens-Leenes et al. (2009), Yang et al. (2009), and Mekonnen and Hoekstra (2011), conducted WCF studies on biofuel production. For instance, Yang et al. (2009) investigated the water requirements of biofuel in China based on the government's biofuel development plans.

Agriculture is a major source of livelihood in Southeast Asia. The Asian Development Bank (ADB) (1999) reported that there are approximately 115 million ha of land that are devoted to the production of rice, maize, palm oil, and natural rubber. Rice is a staple food for about 557 million people in Southeast Asia (Manzanilla et al., 2011); hence, this region is one of the largest producers and exporters of rice at a global scale. An assessment of the WCF of rice was carried out by Chatpanyacharoen et al. (2015) to evaluate water requirements for rice cultivation in the Wang Pha district, Nan Province, Thailand. The WCF of rice in the Nan province was 2258.82 m^3/ton. The green WCF accounted for 1470.33 m^3/ton, and the grey WCF was 788.49 m^3/ton. The results indicated that the value of WCF was within the range of the WCF of rice found by Mekonnen and Hoekstra (2014) (range from 638-2874 m^3/ton). The blue WCF was not assessed because cultivation occurs under rain-fed conditions. The results of the WCF were affected by the maximum evapotranspiration (ET_o) and rice maximum coefficient (K_c). Only two components of WCF (green and grey WCF) were used for

© 2018, ALÖKI Kft., Budapest, Hungary

the study because the green WCF was related to rainfall data, and for grey WCF, the phosphate was selected as the other pollutant (nitrate, ammonia) reduction parallel to the reduction of phosphate concentrations during the cultivation process. Numerous studies have been conducted on the WCF of rice across the globe, including studies by Chapagain and Hoekstra (2011), Bulsink et al. (2010), Aldaya et al. (2010), Yoo et al. (2013), Shresta et al. (2013), Gheewala et al. (2014), Marano and Filippi (2015), and Su et al. (2015). Shresta et al. (2013) estimated the WCF of rice and other crops in different districts, development regions, and physiographic divisions of Nepal. Marano and Filippi (2015) determined the WCF for rice production in two areas in Argentina located in the central-east Entre Rios and Santa Fe regions.

The volumetric WCF indicator does not provide the actual impact of water use directly (Wichelns, 2010); thus, it underestimates the water scarcity or water stress of a specific area. Water scarcity generally varies based on geographical, climate condition, environmental, social, economic, and political factors. The water stress index (WSI) developed by Pfister (2009) is a commonly applied method used to measure water scarcity. The WSI can serve as a characterization factor for freshwater deprivation. The evaluation of the impacts of crop water use in different regions or watersheds using the water stress index and the indication of water deprivation potential was studied by Gheewala et al. (2014) for 10 crops, including rice, maize, soybeans, mung beans, peanuts, cassava, sugarcane, pineapple, and palm oil. The highest amount of water use in irrigation was rice farming, which amounted to 10,489 million m^3/year volume of water used, followed by maize, sugarcane, palm oil, and cassava. In addition, major rice cultivation contributes to the highest water deprivation rate, which is around 1862 million m^3H_2Oeq/year, followed by sugarcane, second rice, and cassava. Crops such as rice, maize, cassava, soybeans, groundnuts, coconut, palm oil, bananas, coffee, and cocoa, which were analyzed by Bulsink et al. (2010), accounted for 86% of total Indonesian water use.

The factors that generally determine the WCF are volume of consumption, consumption patterns, climate, and agricultural practices (Hoekstra and Chapagain, 2008). Several studies have compared the WCF value of crops among provinces. Mungkalasiri et al. (2015) conducted a study to evaluate the WCF of palm oil and fresh fruit bunches (FFB) in two provinces in Thailand (Pathumthani and Chonburi). The results showed that the WCF of palm oil in Chonburi province (1070.65 m^3/ton of FFB) was higher than Pathumthani (678.84 m^3/ton of FFB) due to the lower yield and annual precipitation. The green and blue water WCF mainly depend on climate conditions. Areas with higher precipitation and yield rates have lower WCF values compared to areas with lower precipitation and yield rates (Mungkalasiri et al., 2015). Agricultural practices vary depending on farmers and the technology used and thus influence the yield and WCF values of the crops studied. Bulsink et al. (2010) found that the WCF of the population of Java was low due to high yields, the average consumption rate was just below average, and the evapotranspiration rate was lower compared to other regions.

Water management in Southeast Asia: future outlook following an LCA-based approach

Urbanization and industrialization have grown rapidly in Southeast Asia, thus affecting water resources. Other factors, such as water-related disasters, climate change,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_53815403
© 2018, ALÖKI Kft., Budapest, Hungary

and poor governance, have worsened the water sustainability issue. In acknowledgement of the importance of managing water resources for sustainability, Global Water Partnership (GWP) Southeast Asia was established to develop and influence sustainable water management policies at the national and regional levels (Lautze et al., 2011). The GWP drafted the water vision and framework, which is comprised of at least five countries (Cambodia, Indonesia, Philippines, Thailand, and Vietnam), and has incorporated Integrated Water Resources Management (IWRM). At the regional level, GWP Southeast Asia is working with ASEAN and has contributed to adding water sustainability to the ASEAN agenda through the creation of the ASEAN Working Group on Water Resources Management (AWGWR) (Global Water Partnership, 2017).

Agriculture is a primary sector that contributes to economic growth in Southeast Asian countries; however, it has a significant impact on water consumption. This could lead to water deprivation and scarcity if water resources are not managed properly. As mentioned, considerable efforts have been devoted to improving water management as well as to promoting green and sustainable development. As part of the initiative to sustain water resources, the WCF approach has been adopted in Southeast Asia. As shown by previous studies, Southeast Asian countries have begun to implement WCF in water resource management.

For Malaysia, the country has sufficient water to supply the needs of the agriculture, domestic, industrial, energy production, and environmental sectors; however, water resources must be managed properly to ensure that the resource is sustainable for future generations. The government of Malaysia has put forth various efforts to manage water resources. In the 11th Malaysia Plan (2016-2020), water resources and the agriculture sector were two primary focuses due to the awareness of global climate change (Economic Planning Unit, 2015). The National Water Resources Policy was launched by the Malaysian government in 2012, which provides holistic strategies for water resource management in Malaysia. The policy includes governance collaboration to ensure water security and continued sustainability. In addition, the federal government prioritized the restoration program for water resources by enhancing the IWRM program. Improvements in water quality in some rivers in Malaysia and the water shortage issue in Klang Valley were addressed through this program.

Moreover, a water demand management master plan was established by the Ministry of Energy, Green Technology, and Water (KeTTHA), which provides Malaysia with a better approach to water demand management and a tool to forecast water demands. For the river basin, agencies at the state level (i.e., Lembaga Urus Air Selangor [LUAS], Syarikat Air Kelantan [SAK], Syarikat Air Negeri Sembilan [SAINS], Pengurusan Air Pahang Berhad [PAIP], etc.) that have been established are responsible for effectively managing the river basins due to various legislations related to water management. In addition, communication, public awareness, and education programs for all ages were increased to promote a more efficient and prudent use of water. Awareness campaigns and activities with the cooperation of the relevant non-governmental organizations (NGOs) have also been implemented to promote the efficient use of water and river conservation for local commodities.

The WCF assessment is a nascent approach in Malaysia, especially in the agriculture sector. The actual impact of water use cannot be provided directly through a volumetric WCF indicator because water scarcity issues vary based on geographical, climate condition, environmental, social, economic, and political factors (Gheewala et al.,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_53815403
© 2018, ALÖKI Kft., Budapest, Hungary

2014). Hence, the assessment of WCF is useful to determine the impact of water consumption regarding water deprivation potential. Water deprivation can be calculated by multiplying the blue WCF of crops by the water stress index. Furthermore, the WCF approach following an LCA approach could improve the understanding of water consumption scenarios in crop production. Several WCF studies have been conducted in Southeast Asia following the LCA approach, such as Cheroennet and Suwanmanee (2017), Gheewala et al. (2014) and Silalertruksa et al. (2017). Silalertruksa et al. (2017) determined the impact of greenhouse gases and water use on palm oil cultivation in Thailand. The study combined two methods, including the life cycle greenhouse gas emissions assessment and the water scarcity footprint assessment.

The ISO WF (ISO, 14046) was launched in 2014, and it focuses on water availability and degradation. The LCA and ISO address all input and output in the WF inventory analysis; hence, all environmental effects of water use are also included in the assessment (Pfister et al., 2015; Quinteiro et al., 2015; Núnez et al., 2013; Ridoutt et al., 2010, 2012; Canals et al., 2009). By adopting the WF assessment, relevant input can be applied for the formulation of various types of government policies, such as national or state water policies, river basin policies, local water policies, trade policies, foreign policies, and development cooperation policies (Hoekstra, 2011). ISO 14046 (2014) lists the benefits of WF assessments:

- WF can help in assessing the magnitude of potential environmental impacts related to water.
- Identifying ways to reduce potential water-related impacts of products at various life cycle stages, and of processes and organizations.
- Facilitating water efficiency and optimization of water management at product, process and organizational levels.
- Provide scientifically consistent and reliable information for reporting WF results.

Limitations and uncertainties

During the assessment of the WF, uncertainty is an important factor that must be taken into account, as several variables must be characterized. In most studies, the WF assessment was conducted based on several assumptions and limitations in the data section due to the difficulty in obtaining data from data providers. In addition, it is sometimes impossible to obtain actual data, such as data on water availability, crop water requirements, and crop water use. Another issue is that different irrigation methods, such as surface, sprinkler, and drip irrigation, might contribute to different irrigation efficiencies. Therefore, to limit the uncertainty level of a crop system assessment, the cultivation technique and geographical data should be carefully determined. In the present study, the grey WCF was excluded because the assessment aims to quantify the water quantity instead of the water quality; however, it is important to consider water quality, as shown by several studies conducted in Southeast Asia, because the assessment of green and blue water consumption is more related to water balance than the WF (Loverelli et al., 2016).

In Southeast Asia countries, technology constraints could lead to high water consumption even if water use efficiency and water management are applied. According to Mekonnen and Hoekstra (2015) and Pfister and Bayer (2014), considerations of the available technology and practices (i.e., crop residue management, optimized nutrient

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_53815403
© 2018, ALÖKI Kft., Budapest, Hungary

management, and effective rainfall enhancement) could be useful in WF evaluations. Nevertheless, these aspects do not represent actual farming contexts. Regional conditions and technologies in different countries have significant effects on water management in the agricultural sector. Policies on more sustainable agricultural techniques must be endorsed to help reduce stress on the water use system. In addition, a more environmentally friendly system must be introduced to farmers to improve environmental quality (i.e., reducing fossil fuel dependence, mitigating soil erosion, improving soil quality, optimizing water use), economy (i.e., reducing operating costs) and public health safety (i.e., avoiding hazardous pesticides and fertilizers, producing more nutritious crops, producing food that safe for communities).

Conclusion

Based on this study's results, the green WCF had the highest value compared to the blue WCF for all 15 crops in Peninsular Malaysia for an average of nine years. The results for total WCF indicated that the cultivation of rice requires the highest amount of irrigation in both seasons compared to other crops, i.e., 2265 m^3/ton in the off-season and 2255 m^3/ton in the main season, followed by mangoes and green beans. Cucumbers had the lowest WCF compared to other (175.07 m^3/ton) crops due to higher production (19.66 ton/ha). The value of the WCF depends on the crop yield, and a higher crop yield results in a lower WCF of crops (Gheewala et al., 2014; Bulsink et al., 2010; Chu et al., 2017).

In conclusion, some improvements can still be achieved in WCF calculations and are required to make this indicator more valid in a crop production context. The WCF can be used to compare the water use efficiency of each product, particularly during a water shortage period, so that policies can be developed to determine which plant to promote in consideration of the net profit of a product, market requirements, labour requirements, etc. The findings of this study could be used as a guideline and can provide useful information for both stakeholders and policymakers for better water management practices, particularly in Malaysia.

Abstract. The experiment was designed to study allelopathic effect of *Rhazya stricta* Decne. against selected weeds of wheat crop by using aqueous, hexane and methanolic extracts on filter paper and soil. The germination percentage, radicle length and plumule length were observed. The results revealed that *R. stricta* methanolic extract showed the highest degree of seed germination percentage inhibition of *C. album*, *P. minor* and *R. dentatus* with 47%, 43% and 42%, respectively in soil, and minimum germination for *C. album* (53%). The same extract caused significant radical length reduction of *R. dentatus* and *A. fatua* measuring 51% and 50%, respectively. The highest degree of inhibition in plumule length was measured for *A. fatua* and *R. dentatus* with 55% and 34%, respectively by *R. stricta* methanolic extract. Based on the results, it can be concluded that *R. stricta* showed good allelopathic activity that may be used in future herbicide screening program to launch in the market.
Keywords: *allelopathic effect, seed germination, radicle length, plumule length, Phalaris minor, Avena fatua, Chenopodium album, Euphorbia helioscopia, Triticum aestivum*

Introduction

Weeds are regarded as a major problem in agricultural productivity of various crops globally. For controlling weeds, synthetic chemicals (weedicides) are used which possess negative effect on human health and cause environmental pollution (Dallali et al., 2017) that augments to develop alternate weed management strategies (Thi et al., 2008). Allelopathy offers an important strategy for biological weed management (Arora et al., 2015) by production and release of chemical substances from leaves, flowers, seeds, stems or roots of plants which ultimately affect growth and development of other plants (Delcour et al., 2015). The most auspicious scheme to replace synthetic herbicides is to use environmental friendly natural chemical plant products. The synthesis of biochemical based on natural plant products and management of the allelopathy towards improvement

of crop productivity are the major areas that has gained attention of allelopathy research (Chon et al., 2005). The phytotoxic potential of these biologically active substances is widely searched by using highly advanced procedures for chemical identification (Dayan et al., 2000).

Rhazya stricta Decne., is an evergreen medicinal shrub of the family Apocynaceae distributed abundantly across Western and South Asia (Sabir et al., 2016). In Pakistan, it is commonly reported from Salt Range as well as periphery of District Khushab, Punjab, Pakistan (Qureshi et al., 2011). This plant has various ethno-medicinal values which may be attributed due to the presence of various phytochemicals in the plant. *R. stricta* invades and has deteriorated rangelands and have harmful effects on the growth and development of various plants by causing reduced seed germination (Ebid, 2016). Several alkaloids, glycosides, triterpenes, tannins and volatile compounds are present in the leaves of *R. stricta* (Khan et al., 2011). It has been reported to develop an ecological hazard such as autotoxicity to other plants due to presence of allelopathic potential (Alqarawi et al., 2018). So, it was assumed that due to presence of some chemicals *R. stricta* could be employed in biological weed management strategies. The aim of the present study was to explore the possible allelopathic potential of different leaf extracts of *R. stricta* on seed germination and seedling growth of selected weed species.

Materials and methods

Collection and processing of R. stricta

This research was carried out at Plant Physiology Laboratory, Department of Botany, Pir Mehr Ali Shah Arid Agriculture University, Rawalpindi (PMAS-AAUR), Pakistan. The mature leaves of *R. stricta* were collected from district Bahawalpur (73°15′12″ E longitude and 29°59′55″ N latitude, 159 m above sea level), Punjab, Pakistan and washed for several times under running tap water to remove dust following the methodology of Manimegalai et al. (2012) and Omar and Almaghrabi (2008). The same were dried in blotting paper for 4 weeks under shade at room temperature (20-25 °C). These were crushed using heavy duty blender (waring Lab.) to make fine powder (500 g), passed through mesh of 2 mm size and kept in air tight plastic zip lock bags separately at 4 °C (Anwar et al., 2013).

Procurement and surface sterilization of test species seeds

Seeds of monocotyledonous (*Phalaris minor, Avena fatua*) and dicotyledonous weeds (*Chenopodium album, Euphorbia helioscopia* and *Rumex dentatus*) were collected since all these are sensitive to herbicide (Shahid et al., 2006). These weeds are reported to be the most densely populated weeds of wheat crop (Qureshi et al., 2009). Wheat seeds were procured from the Barani Agricultural Research Institute (BARI), Chakwal (72.7211° E longitude and 32.9309° N latitude). Seeds were surface sterilized with 2% (w/v) solution of Sodium hypochlorite (NaOCl) for 5-8 min. After disinfection, these seeds were washed several times with distilled water (Biljana and Kragujevac, 2015; Anwar et al., 2016).

Studied parameters

Three growth parameters were used for screening allelopathic potential (Anwar et al., 2017 a, b) as follows:

(a) Germination percentage

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_54055421
© 2018, ALÖKI Kft., Budapest, Hungary

(b) Radical length (cm)
(c) Plumule length (cm)

Aqueous extract preparation

An aliquot (10 g) of dried leaf powder of *R. stricta* was soaked in 100 ml distilled water in a flask and agitated at room temperature (20-25 °C) for 24 h on an orbital shaker (160 rpm). The extract was strained through muslin cloth and finally filtered through Whatman filter paper No. 1. Aqueous extract was obtained as filtrate of the mixture and final volume was attuned to 100 ml giving 10% water extract. This stock solution was then diluted with distilled water to prepare the different concentration of the extract i.e. T_1 (100%), T_2 (75%), T_3 (50%) after Sahu and Devkota (2013). Distilled water (0%) was used as control and indicated as T_4. The extract was stored at 4 °C in pre-disinfected flasks. To evade adulteration and forthcoming chemical modifications, the extracts were ensured to be used within 3-4 days (Anwar et al., 2017 a, b).

Hexane extract preparation

An aliquot (300 g) of dried leaf powder of *R. stricta* was mixed with hexane (2 L) repeated three times for 6 h on shaker. This extract was filtered, concentrated and dried over a rotary evaporator in pre-weighed flask. The obtained residue was 6.14 g. The stock solution was then diluted with hexane to prepare three concentrations i.e. T_1 (100%), T_2 (75%), T_3 (50%) and T_4 (0% control). These stored at 4 °C in pre-sterilized flasks (Sahu and Devkota, 2013).

Methanolic extract preparation

The defatted marc (after hexane extraction), was again placed on shaker with methanol (2 L) repeated three time for 6 h on shaker. This extract was filtered, concentrated, and dried over a rotary evaporator in pre-weighed flask. The obtained residue was 25.29 g. The stock solution was than diluted with methanol to prepare three concentrations i.e. T_1 (100%), T_2 (75%), T_3 (50%) and T_4 (0% control). These stored at 4 °C in pre-sterilized flasks (Sahu and Devkota, 2013).

Bioassay techniques

An aliquot (15 ml) of *R. stricta* extract was added to 25 g soil per Petri dish and 5 ml extract was added to filter paper in per Petri dish; while distilled water, hexane and methanol used as control in aqueous, hexane and methanolic extracts, respectively. Ten seeds of selected test species were sown in per Petri dish. Each treatment was replicated for five times. The Petri dishes were wrapped with squash tape, enclosed with Aluminium foil and incubated in the growth chamber (NTS Model MI-25S) at room temperature (20-25 °C) for 15 days. The data on germination percentage, radical length (cm) and plumule length (cm) were recorded and calculated of each test species by comparing with control (Khan et al., 2008).

Statistical analysis

A completely randomized design (CRD) was used for the experiment. The statistical analysis was done by using STATISTIX 9 and means were separated by using Fisher's protected LSD test (Nekonam et al., 2014).

Results

Allelopathic potential of R. Stricta aqueous extract

Germination percentage

The results revealed that *R. stricta* aqueous extract significantly inhibited germination of *C. album* (35%), followed by *R. dentatus* (32%) and *P. minor* (31%) on filter paper (*Table 1*); whereas, no significant effect on germination percentage was recorded for *T. aestivum*, *A. fatua* and *E. helioscopia*. On the soil, *R. stricta* aqueous extract also significantly inhibited seed germination of *R. dentatus* (50%), followed by *C. album* (45%) and *P. minor* (47%) compared to control (*Tables 1* and *2*). In the case of filter paper and soil, minimum germination percentage was noted for *R. dentatus* (50%) and *C. album* (55%), respectively. It has been noted that maximum germination percentage reduction of the *C. album*, *R. dentatus* and *P. minor* was accomplished at 100% concentration revealing concentration dependent (*Fig. 1a*).

Radical length

The data revealed that the highest radical length inhibition activity was exhibited by *R. dentatus* (44%) and *A. fatua* (40%) in *R. stricta* aqueous extract on filter paper.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_54055421

Likewise, extract on soil caused significant radical length reduction of *R. dentatus* (48%) followed by *A. fatua (*45%) as compared to control. The data suggested that radical length of *C. album*, *P. minor, E. helioscopia* and *T. aestivum* remained unaffected. The results also illustrated that minimum radical length was noted for *A. fatua* (56%) and *R. dentatus* (52%) on filter paper and soil, respectively. The final data concluded that maximum radical length (97%) was noted for *C. album*, *P. minor, E. helioscopia* and *T. aestivum* (*Tables 3* and *4*). The results revealed that allelopathic inhibitory effect was concentration dependent for *R. dentatus* and *A. fatua* (*Fig. 1b*).

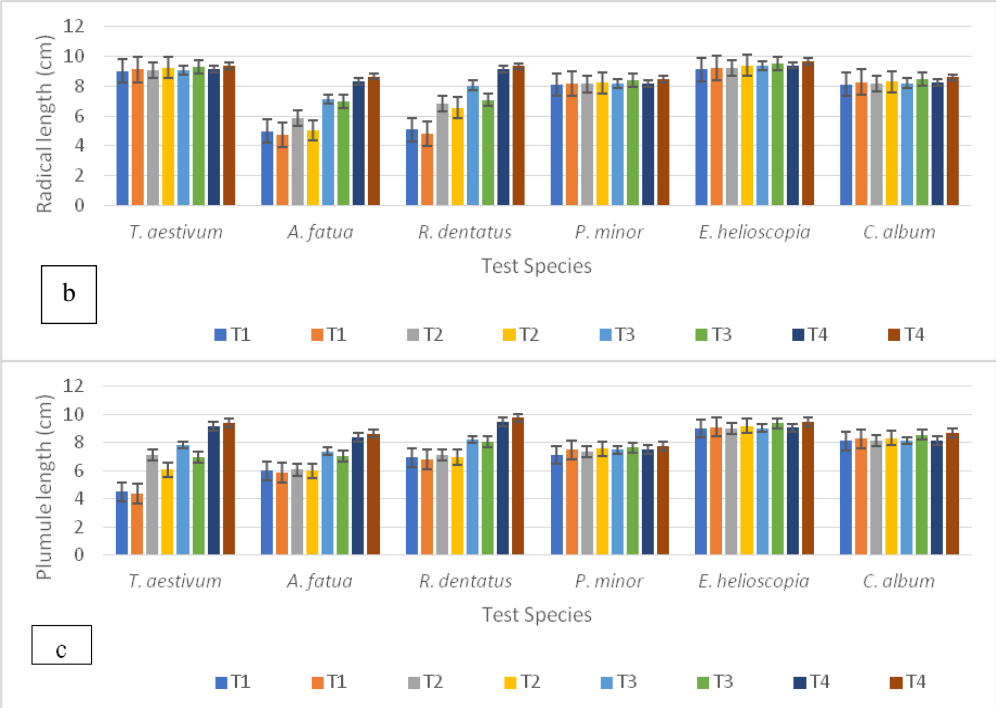

Figure 1. *Allelopathic potential of R. stricta aqueous extract against test species on filter paper (FP) and soil (S) on: (a) germination percentage (b) radical length (c) plumule length*

Plumule length

The experimental results of the current study indicated that aqueous extract of *R. stricta* significantly inhibited the plumule length of *T. aestivum* (51%), *A. fatua* (28%) and *R. dentatus* (27%) as compared to control, on filter paper. Interestingly, there was no significant effect on plumule elongation of *P. minor*, *E. helioscopia* and *C. album*. The statistical study recommended that *R. stricta* aqueous extract significantly inhibited plumule length of *T. aestivum* (53%), *A. fatua* (32%) and *R. dentatus* (30%) in soil. The statistical data concluded that minimum plumule length was noted for *T. aestivum* i.e. 49% and 47% on filter paper and soil, respectively (*Tables 5* and *6*). The statistical figures also proposed that maximum plumule length (96%) was noted for *P. minor*, *E. helioscopia* and *C. album* (*Fig. 1c*).

Allelopathic potential of R. stricta hexane extract

Germination percentage

There was significant reduction of germination of *C. album* (42%), *R. dentatus* (45%) and *P. minor* (41%) as compared to control on filter paper, whereas, no significant effect was observed on the germination of *T. aestivum*, *A. fatua* and *E. helioscopia* showing resistance to the allelopathic effect. Similarly, the highest seed germination inhibition was noted for *C. album* (51%), *P. minor* (50%) and *R. dentatus* (51%) by incorporation of *R. stricta* hexane extract into soil. It was experiential that the maximum (97%) germination noted for *T. aestivum*, *A. fatua* and *E. helioscopia*. In the present study, minimum germination was noted for *R. dentatus* (65%) and *C. album* (49%) on filter paper and soil, respectively (*Tables 7* and *8*). The statistics also recommended that allelopathic inhibitory effect was concentration dependent for *C. album*, *P. minor* and *R. dentatus* with concentration increase, suppression potential was gradually enhanced (*Fig. 2a*).

Radical length

The statistical data concluded that the highest radical length inhibition activity was exhibited by *R. dentatus* (44%) and *A. fatua* (40%) in *R. stricta* hexane extract on filter paper. Similarly, hexane extract on soil caused significant reduction in radical length of *R. dentatus* (51%) and *A. fatua* (50%) compared to control, while *T. aestivum*, *P. minor, E. helioscopia* and *C. album* remained unaffected. The results also illustrated minimum radical length for *R. dentatus* i.e. 46% and 49% on filter paper and soil, respectively (*Tables 9* and *10*). The maximum radical length (96%) was noted for *T. aestivum*, *P. minor, E. helioscopia* and *C. album* (*Fig. 2b*).

Allelopathic potential of R. stricta methanolic extract

Germination percentage

The methanolic extract of *R. stricta* significantly inhibited germination of *P. minor* (49%), *R. dentatus* (48%) and *C. album* (47%) on filter paper, whereas, no significant effect was noted on the germination of *T. aestivum*, *A. fatua* and *E. helioscopia* showing resistance against extract. Similarly, the same extract significantly suppressed seed germination of *C. album* and *R. dentatus* (51% each), followed by *P. minor* (50%) on soil. It was noted that maximum (95%) germination was observed for *T. aestivum*, *A. fatua* and *E. helioscopia*. Besides, minimum germination was noted for *P. minor* i.e. 51% and *R. dentatus* (49%) on filter paper and soil, respectively (*Tables 13* and *14*). The results revealed that germination reduction of the *C. album*, *P. minor* and *R. dentatus* was concentration dependent (*Fig. 3a*).

Plumule length

Analysis of the data revealed that *R. stricta* methanolic extract significantly suppressed the plumule length of *T. aestivum* (55%), *A. fatua* (33%) and *R. dentatus* (28%) as compared control on filter paper. Interestingly, there was no significant effect on plumule elongation of *P. minor, E. helioscopia* and *C. album*. Likewise, *R. stricta* methanolic extract significantly inhibited plumule length of *T. aestivum* (58%), *A. fatua* (35%) and *R. dentatus* (34%) in soil. The statistical data concluded that minimum plumule length was noted for *T. aestivum* i.e. 45% and 42% on filter paper and soil, respectively (*Tables 17* and *18*). The statistical figures also proposed that maximum plumule length (96%) was noted for *P. minor, E. helioscopia* and *C. album* (*Fig. 3c*).

Discussion

This study was aimed at investigating allelopathic potential of *R. stricta* by using various solvent (i.e. aqueous, methanolic, hexane) leaf extracts against selected noxious weeds of wheat crop. The germination percentage, radicle length and plumule length were observed. The results revealed that all plant extracts showed significant allelopathic activity, however, the same was varied from species to species as well as solvents. Overall, methanolic extract showed the highest degree of seed germination

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

percentage inhibition, radical and plumule length for *C. album*, *P. minor* and *R. dentatus*.

The results revealed that *R. stricta* aqueous extract significantly inhibited germination percentage of *C. album, R. dentatus* and *P. minor* (*Tables 1* and *2*). The results revealed that germination percentage reduction of the *C. album*, *R. dentatus* and *P. minor* was concentration dependent (*Fig. 1a*). As far as radical length is concerned, the aqueous extract had significantly affected radical length for *R. dentatus* and *A. fatua* (*Tables 3* and *4*). The results revealed that allelopathic inhibitory effect was concentration dependent for *R. dentatus* and *A. fatua* (*Fig. 1b*). The current study indicated that aqueous extract of *R. stricta* significantly inhibited the plumule length of *A. fatua* and *R. dentatus* as compared to control, on filter paper as well as on soil (*Tables 5* and *6*). The results agree with that of Khan et al. (2011) who reported germination inhibition of *Zea mays* by stem aqueous extracts of *R. stricta*, while plumule and radical growth was significantly decreased by aqueous leave extract. Like the present investigation, the later study also revealed that the inhibitory effects were directly proportional to the extract concentration. In another study, leaf extracts of *R. stricta* significantly inhibited germination percentage and decreased plumule and radical length of seedlings of *Vicia faba, Hordeum vulgare* and *Triticum aestivum* (Ebid, 2016). Aqueous extracts from the leaves of *R. stricta* significantly reduced germination and growth of *Salsola villosa* by hampering functioning of the membrane and photosynthetic capacity due to reduced synthesis of chlorophyll pigments (Alqarawi et al., 2018).

R. stricta leaf aqueous extract owed to some toxic factors of the extract. Noteworthy, there was variation among the test treatments of different concentrations of *R. stricta* extract and control. There was significant morphological variation in the radical and plumule elongation of the tested weeds that may be attributed due to the presence of various allelochemicals in plant extract. Allelopathic interaction more effectively inhibited growth on soil in contrast to filter paper (Hegazy and Fadl-Allah, 1995; El-Khatib, 2000). These findings agreed with those of Migahid and El-khazan (2002), who studied the allelopathic effect of *Zygophyllum* aqueous extract on sesame and corn.

This study exhibited the allelopathic activity of various solvents on the germination and growth parameters of selected weeds. Overall, the activity of *R. stricta* extracts was found concentration dependent. Wardle et al. (1992) reported a concentration dependent inhibition of radical, plumule growth and seed germination for some weeds by *R. stricta* extract. Besides, Alam (1990) and Bora et al. (1999) also observed concentration dependent inhibition of plumule length by *R. stricta* extract. Another study revealed that there was significant reduction in germination, radical and plumule length of *Z. mays* by *R. stricta* extract (Zackrisson and Nilsson, 1992). El-khawas and Shehata (2005) stated that the inhibitory effect of allelochemicals on seed growth due to changes in enzyme activities that affect the transport of storage substances.

Our results revealed that *R. stricta* methanolic leaf extract imposed significant inhibitory effects on the germination and growth parameters of all the tests weeds. The findings of current study confirmed the earlier findings on cowpea and rice plumule, radicle length and germination that were significantly checked with increasing concentration of *R. stricta* methanolic leaf extract (Jadhar and Gayanar, 1992). Moreover, seed germination and seedling growth of different crops and weed had been significantly checked by inhibitory potential of *R. stricta* extracts (Lisanework and Michelson, 1993; Khan et al., 2008).

Suppressive effect on plumule length and seed germination was also described by Tefera (2002) and Siddiqui et al. (2009). These findings were in accordance to previous studies who stated that *R. stricta* leaf extract reduced growth of weeds species (Maciel et al., 2003; Kaul and Bansal, 2002). Germination response of various field crops varies in the presence of *R. stricta* leaf extract that confirms our observation of the differences in germination response of tested species. Several studies demonstrated the allelopathic potential of *Parthenium hysterophorus* (Tawaha and Turk, 2003), *Brassica nigra* (Singh et al., 2003) and *Raphanus raphanistrum* (Batish et al., 2002).

The leaf extracts were more toxic and more allelopathic in nature owing to relatively higher inhibitory potential in contrast to other plant parts (Hussain and Gadoon, 1981; Norsworthy, 2003). Similar allelopathic effects were reported from other plants (Inderjit and Duke, 2003; Hussain et al., 2011).

Conclusion

This study was aimed at evaluation of allelopathic potential of *R. stricta* against some noxious weeds of wheat crop by using aqueous, hexane and methanolic extracts on filter paper and soil. The results revealed that methanolic extract highly reduced seed germination percentage of *C. album*, *P. minor* and *R. dentatus*. The same extract caused significant radical and plumule length reduction of *R. dentatus* and *A. fatua*. Based on the results, it can be concluded that *R. stricta* showed good allelopathic activity that may be used in future herbicide screening program prior to launch in the market.

(Received 9th Jun 2018; accepted 1st Aug 2018)

Abstract. Cognition of the bioclimatic conditions in any place can be the first step in conducting many environmental studies. This study was performed with the aim of determining the thermal stress of Iran. For this purpose, the daily data of the climatic variables in 288 synoptic stations were prepared from the Iran Meteorological Organization during the period 1981-2010. First, the bioclimatic conditions in each of the stations were calculated based on UTCI (Universal Thermal Climate Index) and PET (Physiologically Equivalent Temperature) indices. Then, using the thermal stress of 288 synoptic stations, the bioclimatic conditions throughout Iran were interpolated using a Simple Kriging method. The results of this study showed that the bioclimatic conditions are immensely varied spatially and temporally, such that in specific times all bioclimatic conditions can be seen in Iran. Also, during the year, each place can experience different bioclimatic conditions. Based on UTCI, extreme cold and extreme heat stress are the only bioclimatic conditions that do not exist during the year. However, based on PET, all bioclimatic conditions exist during the year. Also July and January, respectively, are the hottest and coldest months of the year. Based on UTCI in April, October and November, more than 70% of Iran has comfortable conditions, whereas PET showed that in March and October 24.6 and 23.7% experienced comfortable conditions respectively. It seems that the obtained results of PET index have high efficiency in relationship with UTCI index to show Iran's bioclimatic conditions.
Keywords: *applied climatology, bioclimatic conditions, climatic comfort, human heat balance, extreme climatic conditions*

Introduction

Climate and weather conditions are the most important components of the environment. Atmospheric conditions can have an effect on some activities and even create restrictions in our lives. Identification and understanding the weather conditions in any place is inevitable and necessary. It is clear that there is no place in the world experiencing favourable conditions and thermal comfort throughout the year. Nowadays, there has been much interest in the study of differentiation of bioclimatic conditions in outdoor spaces (Nikolopoulou, 2004; Geletič et al., 2018). Most of the research performed in different countries has been focusing on aspects such as the relations between thermal comfort, microclimate, behavior and use of place and spatial variation (Nikolopoulou and Lykoudis, 2006 and 2007; Thorsson et al., 2007; Kántor et al., 2012a, b). Such research is often carried out because of climate change and increased occurrence of heat stress in the earth's surface (Frich et al., 2002; Givoni et al., 2003; Matzarakis et al., 2013). An important use of bioclimatic studies is energy management and architecture. In many parts of Iran, architecture is designed to harmonize with the climate (Pourvahidi and Ozdeniz, 2013). In general, for

© 2018, ALÖKI Kft., Budapest, Hungary

comprehensive and sustainable development, environmental studies, especially bioclimatic studies are very important. In the past years, many indices on different aims and goals were developed to assess the suitability of climate for tourism activities and thermal stress issues including adaptation factors (Morgan et al., 2000; Maddison, 2001; Lise and Tol, 2002; Potchter et al., 2018). The recognition of human bioclimatic comfort in geographical areas is important for the planning of tourism (Matzarakis, 2006; Kovács et al., 2017). It could also help in the planning of building and housing, architectural patterns and the use of natural attractions of ecotourism in environmental planning (Ramazani Gourbi, 2010; Milošević et al., 2016).

The evaluation of bioclimatic conditions and atmospheric variables in each place can be used to choose the best time and place to travel, requirements that are important for tourism purposes (Caliskan et al., 2012). For example, research by Shakoor (2011) showed that in the Yazd province, the best season for tourists activities is autumn and the most ideal bioclimatic conditions with the emphasis on tourists health is seen in the Anar region (south west of Yazd province). Evaluation of the role of climate on tourism in the northwest of Iran, using the PET (Physiologically Equivalent Temperature) index showed that the months of June, July and August are in the comfortable category representing the most suitable months for tourism and tourist activities (Farajzadeh and Matzarakis, 2009). In another study using the Predicted Mean Vote (PMV) index the highest level of climatic comfort for Tabriz is in August, July and September, while the lowest value of climatic comfort is in November, December, January, February and March (Ghavidel Rahimi and Ahmadi, 2013). In another study, Eslami and Tirandaz (2011) showed up in their study that there are suitable conditions during the days, from May to November and during the night, from June to September in the Gilan province. There are several indicators to check the bioclimatic conditions. According to research by Cendrowska (2013) UTCI (Universal Thermal Climate Index) compared to the PET index is more efficient in assessing the bioclimatic conditions of urban areas for tourism and recreational purposes. In addition, climatic conditions can affect the health and welfare of humans. For example cold or very hot weather types, especially in young people and children can aggravate respiratory diseases (Lecha Estela, 1998). Several studies on bioclimatic conditions in different regions have been carried out.

Most studies that have been done in this field in Europe and the United States have been centered on human health (Scott et al., 2004; Ruuhela et al., 2017; Basarin et al., 2018). For example, the role of the climate on mortality rates in US cities was studied by Kalkstein (2008). The Dadbakhsh et al. (2017) study was conducted to evaluate the relation between respiratory-related mortality and temperature in Shiraz, Iran. Heat stress in Greece stuadied by Matzarakis and Mayer (1997). In Austria, has been studied heat-related mortality in Vienna (Matzarakis et al., 2011). A similar study was conducted by Nastos and Matzarakis (2008) on Athens. Such studies in Japan, to assess the environmental effects and in particular the effect of weather conditions on human activities and behaviors have also been done (Ichinose et al., 2008; Matzarakis, 2008). Studies in this discipline have progressed in China, similarly to popular studies in Europe, although the climatological background and acclimation potential of the peoples of China are partially similar to those of Japan.

Temperature and humidity are the important determinants of the bioclimatic conditions in any place. In addition to these two variables, wind speed, cloudiness and vapor pressure have an important role in our sense of climatic conditions. Though, each person is affected by a series of climatic variables simultaneously, their perception,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_54235445
© 2018, ALÖKI Kft., Budapest, Hungary

feeling and response to these factors, however, due to physiological characteristics and coverage, are different (Lin et al., 2011). The review of a number of recent studies has shown that identification of bioclimatic regions has become an attractive issue worthy of investigation. These studies were focusing on tourism activities, diseases and health (Matzarakis, 2006). In this study, bioclimatic zones of Iran were identified by UTCI and PET indices. These indices are the best indicators used to assess the bioclimatic conditions in all climatic regions (Richards and Havenith, 2007; Bröde et al., 2009; Matzarakis et al., 1999).

The main purpose of current research is study of the bioclimatic conditions of Iran using PET and UTCI indexes. In fact, the obtained results of research can be the foundation of other research including planning of building and housing, architectural patterns, ecotourism, health, and so on. It is pinpointed that the two mentioned indexes rarely have been performed to show the bioclimatic conditions of Iran based on monthly scale in previously. Therefore, the characteristics and scope of each area based on bioclimatic regions were evaluated and final results of both indices were compared.

Materials and methods

In this study, the bioclimatic conditions in 288 synoptic stations of Iran based on the PET and UTCI indices were evaluated. However, these stations studied, did not have the statistical period equal. For example, Tehran, Isfahan, Tabriz, Mashhad and some old stations had a statistical period of more than 30 years, while in some other stations; the length of the survey period was less than 10 years.

Therefore, due to the inequality of the length of the study period, their long-term average daily was used. If the station has daily 10-year data, the long- term daily average of that station is calculated based on 10 years. For stations with more or less data, the same calculations have been done. In fact, in this study have been used long-term average daily data and maps provide with this data.

Atmospheric variables including average temperature, wind speed, relative humidity, cloudiness, and water vapor pressure were used. A database of meteorological variables mentioned was created for each station on a daily basis. After calculating the bioclimatic conditions of each station on daily, the long-term average daily thermal stress was calculated. Then, using interpolation techniques, bioclimatic conditions in Iran was estimated. The PET and UTCI indices were calculated by RayMan and BioKlima software respectively. Both indices can be calculated by several meteorological variables manually. But manual calculations are often difficult and very complex. Therefore, in most bioclimatic indices related software are often used in these cases (Mohammadi and Karimi, 2017). In this research, the homogeneity of the data was done using a Kolmogorov-Smirnov test .The data used were normal distribution, so their homogeneity was confirmed. The data used was obtained from the Meteorological Organization of Iran (*Fig. 1*).

Usually studies carried out in the field of bioclimatic conditions are in two different groups; bioclimatic conditions in outdoor and indoor spaces. Theoretically, the same indicators that the study of thermal stress indoors (climate discussion of architecture) are used, can also be used in open spaces of thermal stress. But the indices used for any geographic environment should be precisely identified. In fact, in evaluating thermal stress in outdoor spaces, many climate variables are not in the control of the researcher. So to solve this problem, the UTCI and PET, with the aim of a better assessment of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_54235445
© 2018, ALÖKI Kft., Budapest, Hungary

thermal stress for the outdoors, were presented. In this study, to investigate thermal conditions of Iran, two indices (UTCI and PET) as the biometeorological indices based on the human heat budget are applied (Cendrowska, 2013). In fact, UTCI offers a better portrayal of biothermal conditions for human beings compared to other indices Temperature Effective (TE), Wet Bulb Globe Temperature (WBGT), Heat Stress Index (HIS), Wind Chill Temperature (WCT), Physiological Subjective Temperature (PST) and Physiological Strain (PhS) (Blażejczyk et al., 2012). Many variables are used to calculate and estimate this index. In addition to climatic variables, some personal variables such as metabolic rate and thermal resistance of clothes, was chosen. Another benefit of using PET and UTCI indices is their calculating units (°C). Calculation in degrees Celsius creates a better understanding of these indices by experts in the fields of energy management, health and environmental planing (Lin and Matzarakis, 2008). To calculate the UTCI index, variables of air temperature (°C), relative humidity (%), vapor pressure (hPa), wind speed (m/s) and the sun altitude (degree), during the period 1981-2010, were used. Therefore, a database of these variables for each of the stations was prepared to a dimension of 365 * 5. In this database, 5 is the number of variables and 365 is also the number of days of the year. For each station, bioclimatic conditions of Iran were calculated individually. Although UTCI index can be calculated by complex equations, in this study Bioklima 2.6 software was used to assess of thermal stresses. Different values of the UTCI have been classified according to thermal stress (*Table 1*). All steps for calculating the UTCI index were also performed for the PET index. The PET Index is one of the best indicators that based on the human energy balance equation (Matzarakis et al., 1999; Gulyas and Matzarakis, 2007; Charalampopoulos et al., 2013). The results of this index can be displayed as bioclimatic maps. The PET index is appropriate to evaluate the bioclimatic conditions in different geographical regions (Gulyas, 2005; Matzarakis et al., 2013). In this research, air temperature (°C), relative humidity (%), average wind speed (m/s), and cloudiness (Octas) were used to calculate PET values for Iran.

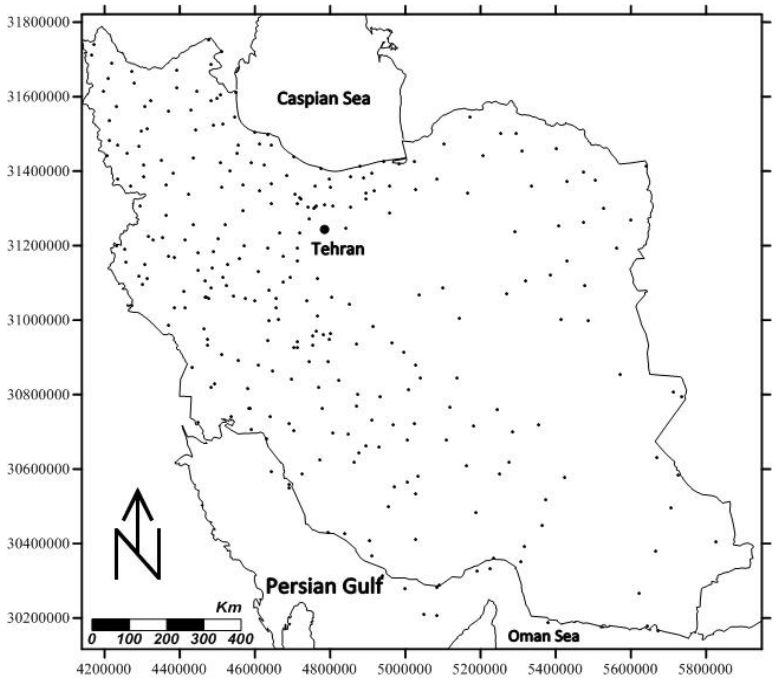

Figure 1. *The geographic distribution of 288 synoptic stations in Iran*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

Table 1. *Ranges UTCI and of PET indices for different grades of thermal stress and thermal perception by human beings (Ketterer and Matzarakis, 2012)*

Thermal stress based on UTCI index (°C)		**Thermal perception based on PET index (°C)**	
Extreme heat stress	above +46	Very hot	below 4
Very strong heat stress	+38 to +46	Hot	4 to 8
Strong heat stress	+32 to +38	Warm	8 to 13
Moderate heat stress	+26 to +32	Slightly warm	13 to 18
No thermal stress	+9 to +26	Comfortable	18 to 23
Slight cold stress	+9 to 0	Slightly cool	23 to 29
Moderate cold stress	0 to -13	Cool	29 to 35
Strong cold stress	-13 to -27	Cold	35 to 41
Very strong cold stress	-27 to -40	Very cold	above 41
Extreme cold stress	below -40	-	-

Due to the complexity of the calculations, in this study, PET and UTCI indices were calculated using RayMan 1.2 and BioKlima 2.6 software respectively.

The PET index is calculated as follows in several stages:

- In the first step body temperature must be calculated with MEMI (Munich Energy balance Model for Individuals) model based on meteorological parameters.
- In the second step the calculated values of mean skin temperature and core temperature imported into the MEMI model and energy balance equation for air temperature based on T_a (with v = 0.1 m/s, VP = 12 hPa and $T_{mrt} = T_a$) dissolved. Eventually air temperature obtained is equivalent to the PET.

The UTCI is defined as the air temperature (t) of the reference condition causing the same physiological response as the actual condition. Thus, UTCI is the air temperature which would produce under reference conditions the same thermal strain as in the actual thermal environment. Therefore, with the help of the mathematical relation, the UTCI can be calculated:

$$UTCI = CalcUTCI\ (temp, wind, mrt, hum)$$

Where temp: air temperature (°C); wind: wind speed (m/s); mrt: mean radiant temperature (°C); hum: humidity ratio (%).

By calculating the bioclimatic conditions of all stations, two databases from output UTCI and PET indices with dimensions of 288 * 365 were prepared. In this database, 365 and 288, respectively, are the numbers of days of the year and stations. One purpose of this research was the mapping of Iran's bioclimatic conditions. To draw these maps from the estimated heat stress, data of 288 of Iran's synoptic stations based on PET and UTCI were used. In fact, using thermal stress to calculate these stations, interpolation was performed. In the atmospheric and geographical field of numerical analysis, interpolation is a method of constructing new data points within the range of a discrete set of known data points. In some cases it may be the average value of a parameter to be estimated over an area. This average, by the Simple Kriging method

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_54235445
© 2018, ALÖKI Kft., Budapest, Hungary

will be calculated on different parts of that region and from their average the results will be achieved. Therefore, in this study, the Simple Kriging method was used to estimate Iran's bioclimatic conditions. In Simple Kriging, all input points are used to calculate each output pixel value. The output of a Simple Kriging method is a raster map. For each pixel in the output map, a value is calculated by an interpolation on input point values. Finally, based on this database, bioclimatic conditions in Iran were estimated. Thus, for each day throughout the country, a bioclimatic map was prepared. In addition to using monthly averages of bioclimatic conditions, bioclimatic maps were drawn.

Results

Annual and seasonal differentiation of bioclimatic conditions

Based on the UTCI index, Iran's bioclimatic conditions during the year showed, on average, a comfort bioclimatic condition prevailing in 45% of Iran. In total, 31.7% of Iran has gone towards a warming condition over the year (the moderate heat stress, strong and very strong heat stress). On the other hand, cold bioclimatic conditions (slight cold stress, moderate cold stress, strong cold stress and very strong cold stress) in 21.3% of Iran have been seen. It should be noted, according to UTCI, strong and very strong heat stress condition, did not prevail in any part of Iran over the year. Each of the bioclimatic conditions during different months of the year, have shown a different situation. So, strong cold stress and strong heat stress conditions have not been seen, at any time, in Iran. Other bioclimatic conditions, such as very strong cold stress, has been record in Iran, for both January (0.9%) and February (0.2%). Also a very strong heat stress condition has been determined in Iran, for June (6.5%), July (10.7%) and August (6.8%). PET analysis on Iran's bioclimatic conditions during the year showed that, on average, a comfort bioclimatic condition has been experienced in 11.9% of Iran. In total, 55.6% of Iran has experienced warming conditions over the year (slightly warm, warm, hot and very hot). On the other hand, 32.5% of Iran has experienced cold conditions (low cold stress, cold stress, strong and very strong cold stress). It should be noted, according to this index, very cold and hot bioclimatic conditions, 3.5 and 15.1%, respectively, are in the lowest and highest parts of Iran. In general, according to *Table 2,* we can say that each of the bioclimatic conditions during the year have shown a different situation. For example, comfortable and slightly warm conditions were seen throughout the year in Iran. Other bioclimatic conditions, like very cold, have been reported in Iran, during winter and autumn. Also a very hot condition has been experienced in Iran during spring and summer. Other conditions and affected zones in different seasons can be seen in *Table 2* and *Figure 2*.

In general, in the annual assessment of PET and UTCI indices from Iran, significant differences were observed in thermal stress. Comparing Iran's annual differentiation of bioclimatic conditions based on mentioned indices, suggests that the PET index has a more reasonable estimate of Iran's thermal comfort compared to the UTCI index. Because Iran was located in the world's desert belt and also identified as an arid and semi-arid region, the thermal comfort does not dominate climatic conditions. Hence PET's assessment of Iran's thermal comfort is closer to the climatic reality. The difference in the quality of assessment of these indices can also be seen clearly in monthly maps.

Monthly differentiation of bioclimatic conditions

January

Studying the bioclimatic conditions of Iran by UTCI showed that extreme heat stress, strong and very strong heat stress, moderate heat stress and strong cold stress conditions in January, have not been experienced in Iran. In 27.4% of Iran's territory, any thermal stress has not been seen. In this month, southern and southwestern regions of Iran, as well as scattered parts of the Caspian Sea coasts do not have heat stress. In January, slight cold stress in large parts of Iran (37.8% of Iran) was dominant. In addition, moderate cold stress, strong cold stress and very strong cold stress, with 25.6, 8.3 and 0.9%, respectively, covered a considerable part of Iran in northern latitudes and higher elevations. In January, by reducing the height and latitude, Iran's bioclimatic conditions have changed to climatic comfort. Based on the PET index, Iran does not have warm, hot and very hot bioclimatic conditions in January. In this month, cold conditions are dominant from the south to the northwest and northeast of Iran. However, the northwest of Iran, Kurdistan and Hamadan provinces are coldest places in Iran. Of course, on along the northwest to the southeast of Iran to the center of Kerman province, also Alborz Mountains and some parts of northeast and north of Iran, cold conditions has been experienced. On the other hand, slight warmth is experienced only in some parts of Hormozgan, Sistan and Baluchistan provinces. Generally, in this month, cool, cold and very cold conditions, 32.3, 20.3 and 18.2%, respectively, covered most parts of the country. Also, 10% of Iran was located in differentiation of bioclimatic conditions (*Fig. 3*).

February

Bioclimatic conditions of Iran in February revealed a very similar thermal stress to that of January. In this month, extreme heat stress, very strong heat stress, strong heat stress and moderate heat stress was not observed in Iran. In addition, extreme cold stress in any part of Iran cannot be seen. In this month, bioclimatic conditions with no thermal stress, compared to January, have shown a significant increase. The scope of areas without any thermal stress has increases from 27.4% in January to 33.2% in February. Slight cold stress in large parts of Iran (37.7%) has not been experienced. In this month, the extent of areas under moderate cold stress, strong cold stress and very strong cold stress has been reduced. In February, very hot and hot conditions cannot be seen in Iran. Compared to January, the extent of the areas that had experienced cold conditions has reduced. As well as the extent of areas with differentiation of bioclimatic conditions, slightly warm and warm conditions increased. From the southwest to the southeast of Iran, thermal comfort and slightly warm conditions are prevalent. In this month, in the highlands, as well as high latitude, there are cold conditions. In February such as in January, the northwest experienced colder conditions than other regions of Iran. Cool, cold and slightly cool conditions were experienced in 27.5, 24.4 and 16.5% of Iran, respectively (*Fig. 3*).

March

In March, extreme cold stress and very strong cold stress in the territory of Iran had not been seen. Compared to the months of January and February, cold stress in March is dominant in smaller parts of Iran. Therefore, it can be said that in March the beginning

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_54235445
© 2018, ALÖKI Kft., Budapest, Hungary

of heat stress become evident in Iran, meaning that in March, the comfort conditions, compared to January and February, have been experienced in more parts of Iran. In fact, thermal comfort in March is the most abundant bioclimatic conditions of Iran. These conditions prevailed in 66.2% of the territory of Iran. By reducing the height and latitude, cold stress conditions in Iran has declined. Also start of heat stress can be seen in the Persian Gulf and Southeast of Iran. There is an obvious difference among Iran's bioclimatic conditions in March compared to January and February. In March, the heat stress conditions in large parts of this country have developed. In other words, in this month, Iran was beginning to get out of the cold climatic conditions (slightly cool to very cold). There are cold and very cold conditions in less than 8% of Iran. In contrast, slightly cool, comfortable and cool conditions, have been experienced, in 25.5, 24.6 and 20.8% respectively, of Iran. In this month, more than 20% of Iran's climatic conditions tend to be warm. For example, areas that are in high latitudes and with greater height have experienced relatively colder bioclimatic conditions (*Fig. 3*).

© 2018, ALÖKI Kft., Budapest, Hungary

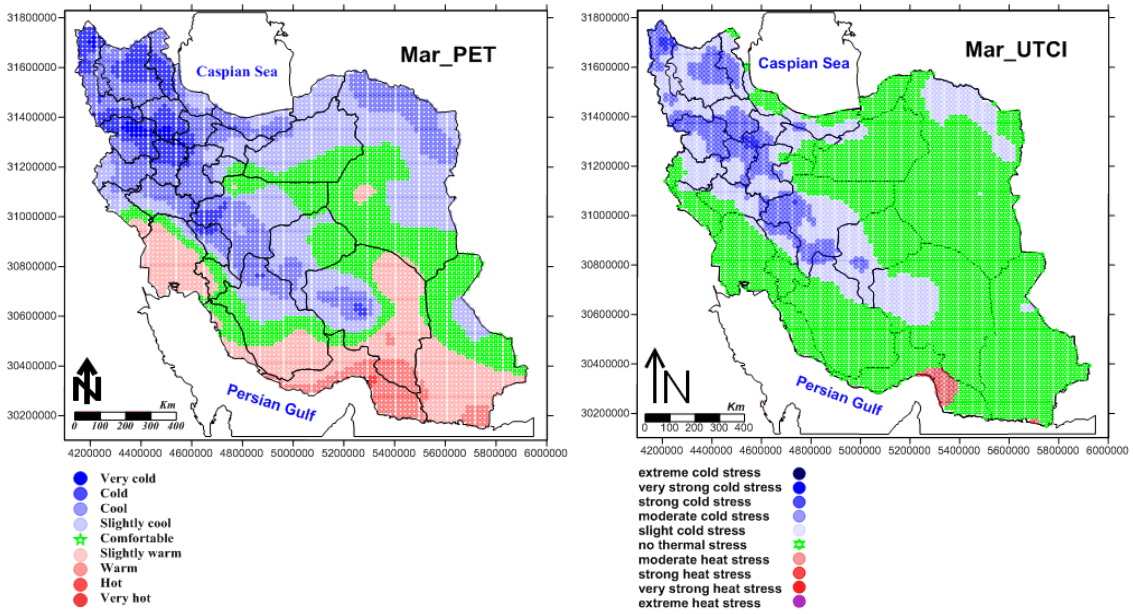

Figure 3. *Iran's bioclimatic conditions in January, February and March*

April

In April, bioclimatic conditions of extreme cold stress, very strong cold stress, strong cold stress, extreme heat stress, very strong heat stress and strong heat stress has not been seen in Iran. No thermal stress conditions in April, compared to the previous months (winter), in the wider parts have expanded. In this month, more than 76% of Iran has experienced no thermal stress conditions. The important point in this month is an increase in the range of moderate heat stress conditions that Iran has experienced. Within 15.5% of Iran, there was moderate heat stress. The belt of the south, southeast, parts of the southwest of Iran as well as parts of Kerman province are in the territories of moderate heat stress. In this month, scattered parts of the Kurdistan province and also along the Zagros Mountains have cold stress. In April, Iran's bioclimatic conditions have changed compared to winter, especially in the months of January and February. In this month, severe bioclimatic conditions (very cold and very hot) are not experienced in Iran. In general, slightly cool, cool, cold conditions ruled about 20% of Iran's territory. Unlike March, in this month, the extent of the regions with climatic comfort is reduced. Warm conditions also extended in large areas of Iran. In this month slightly warm, warm and comfort to the respectively 28.8, 23.1 and 21% in the major part of Iran have been seen. Southern of Iran being the warmest in this month and the northwest of Iran to the Alborz and Zagros Mountains being the coolest parts of the country (*Fig. 4*).

May

Bioclimatic conditions prevailing in May show a significant increase in heat stress. In this month, only a small part in the northwest of Azerbaijan is experiencing slight cold stress. From the beginning of the year (from January to May) cold stress with different intensities is seen in a small region of Iran. The important point in this month is the reduction in areas affected by thermal comfort. From January to April, the extent

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_54235445
© 2018, ALÖKI Kft., Budapest, Hungary

of comfort conditions showed an increasing trend. This condition in Iran has shown a significant reduction (dropping from 76.6% in April to 54.6% in May). By contrast, moderate heat stress and strong heat stress were observed in 29.7 and 15.3% of Iran's territory. Therefore the warming trend of Iran in this month suddenly increased. In this month, in reduced elevation and latitude, heat stress has increased. In fact, large parts of central Iran and also Iran's southern tapes have experienced this situation. Iran's bioclimatic conditions in May, is very similar to April. In May, bioclimatic conditions of very cold, cold and cool have almost left Iran. Moreover, only 2.4% has experienced slightly cool conditions. Comfort condition in less than 15% (highlands and higher latitudes) has prevailed. Also for the first time, about 10% of Iran is in hot conditions. Hot, warm, and slightly warm conditions have covered Iran, 28.3, 23.4 and 22.1%, respectively. In this month, only scattered parts of the northwest of Iran have slightly cool conditions (*Fig. 4*).

© 2018, ALÖKI Kft., Budapest, Hungary

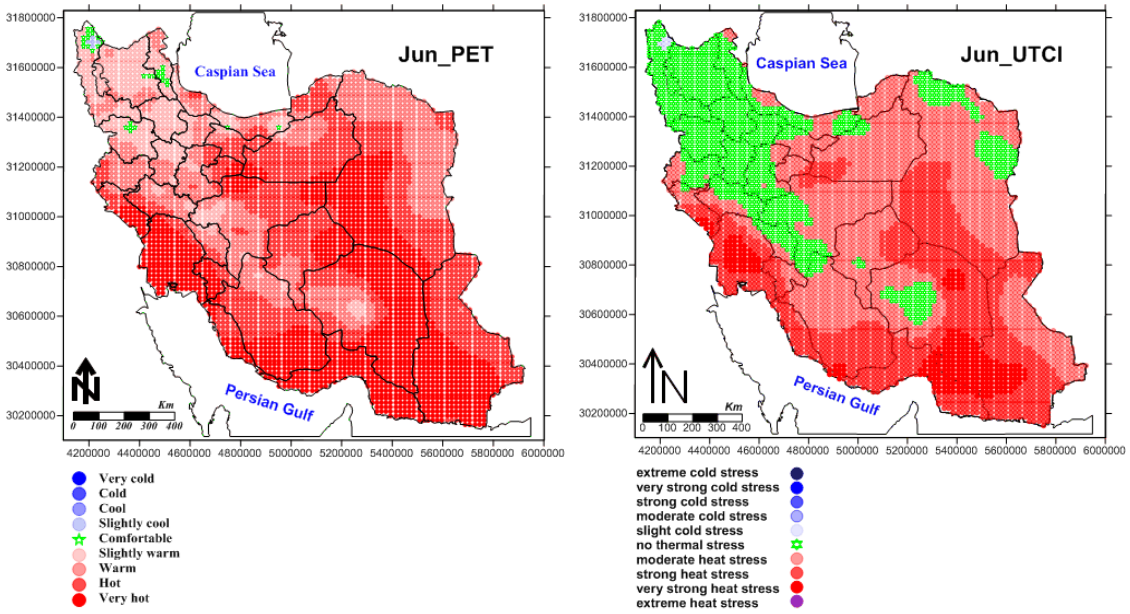

Figure 4. *Iran's bioclimatic conditions in April, May and June*

June

In June, almost all cold stress bioclimatic conditions in Iran have vanished based on the UTCI index. In only 0.1% of Iran slightly cold stress conditions prevailed. From the northwest of Iran to the south of Isfahan province, scattered areas in the northeast of Iran and the middle of Kerman province comfort conditions prevail. These areas include about 24.9% of Iran. Other parts of Iran are under the influence of moderate heat stress (39.8%); strong heat stress (28.7%) and very strong heat stress (6.5%), respectively. Generally, in June, the severe heat stress can be seen. Heat stress in the lower latitude and longitude, as well as Iran's low-lying areas, is more than other regions. Based on the PET, very cold, cold, cool conditions have not been seen in Iran. However, there is a slightly cool condition in about 0.1% and thermal comfort in about 0.6% of a small part of the northwest of Iran. Thus, in more than 99% of Iran, warm conditions with different intensities have been reported. It should be noted that in the highlands and of course the higher latitude there is less intense heat. In this month, very hot, hot, and warm conditions are seen in 34.4, 30.6 and 23.5%, respectively, of Iran (*Fig. 4*).

July

Iran's bioclimatic condition in July is similar to June. In July, almost no cold stress is seen in Iran. Less than 0.1% of the Iranian region has experienced slight cold stress conditions. However, there is a significant difference in July compared to June. Thermal stress in this month has declined to 7.8%. Only in small parts of Iran, no thermal stress can be seen. In this month, more elevated areas and areas with higher latitude have experienced thermal comfort conditions. Reduced thermal stress and the lack of cold stress condition in this month, expanding heat stress condition with varying severity, have been confirmed. Overall, more than 90% of the region has experienced heat stress conditions with different intensities. The current bioclimatic conditions of this month, is a strong heat stress condition (42.2% of Iran). Bioclimatic conditions of moderate heat

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_54235445
© 2018, ALÖKI Kft., Budapest, Hungary

stress with 38.3% and very strong heat stress with 10.7% prevailed in large parts of the country. The PET index showed that in July, no part of Iran experienced slightly cool, cool, cold and very cold conditions. In this month, the thermal comfort condition was experienced in only in 0.2% of Iran (a small part of the northwest of the country). Therefore, 99.8% of Iran's territory experienced warm conditions. Large parts of the country (45.1, 33.3 and 18.9%) were in very hot, hot, and warm conditions, respectively. Heat intensity in the higher places (Alborz and Zagros mountains) and the northwest is less than other parts of Iran (*Fig. 5*).

August

No significant changes can be seen in the bioclimatic conditions of Iran in August compared to July and June. In August, only 0.1% is under the influence of slight cold stress. Cold stress with more intensity like Jun and July cannot be seen in any part of Iran. In August, comfort conditions, compared to previous months, increased slightly. In this month, 13% of Iran, including parts of the northwest and northeast of the country, west of Isfahan province and central Kerman, experienced no thermal stress conditions. Increasing climatic comfort conditions (no thermal stress condition), on the one hand, and a reduction in the range of areas that have experienced very strong heat stress and strong heat stress on the other hand, indicates the relative cool air in Iran. In this month, very strong heat stress conditions are limited to 6.8%. Also the strong heat stress conditions decreased to 35.1%. In this month, the thermal stress condition reduction in the highlands and northern latitudes is remarkable. Based on the PET index, Iran's bioclimatic conditions in August are very similar to July. In this month 99.8% of Iran is experiencing hot conditions (with different intensities). In total, only 0.2% of Iran is in thermal stress and slightly cool conditions. In this month, cool, cold and very cold conditions in the scope of Iran cannot be seen. However, a significant difference is in the extent of very hot bioclimatic conditions between July and August. The extent of the hot condition in August (39.3%) is lower than in July (45.1%) in Iran. However, hot and warm conditions in August compared to July have increased significantly (*Fig. 5*).

September

Bioclimatic conditions in September showed that in many parts of Iran, the severity of heat stress is reduced. Contrary to June, July and August, very strong heat stress conditions in the territory of Iran have been eliminated. In addition, strong heat stress and moderate heat stress in comparison with the months before 16.5 and 37.6%, respectively, has decreased. Among the bioclimatic conditions, no thermal stress conditions were experienced in 45.8% of the territory of Iran. An increase in the range of areas that have no thermal stress conditions on the one hand, and a reduction in the severity of heat stress on the other hand, represent a new stage entering Iran's bioclimatic conditions. In this month highlands (including the Zagros mountain range, Alborz and northeast of Iran) and also northern latitudes of Iran have bioclimatic comfort conditions (no thermal stress). In the lowlands and lower latitude, strong heat stress can be seen. Based on the PET index, the intensity of heat over Iran has reduced in September. In addition, comfort condition has expanded to 1.8%. Along the Zagros and Alborz mountains, and generally highlands, heat with intensity is further reduced (*Fig. 5*).

October

With the onset of autumn in October, significant changes in Iran's bioclimatic conditions have occurred. In this month, limited parts of Iran are under slight cold stress (0.7%) and moderate cold stress (less than 0.1%). The province of west Azarbaijan and Kurdistan, Zanjan and Hamedan experienced such conditions. The most important bioclimatic characteristics of this month, is the lack of heat stress conditions in 79.1% of the country. Most parts of Iran compared to other months are in the range of climatic comfort. Cold stress conditions in the narrow strip of the southwest to the southeast can be seen. Moderate heat stress and strong heat stress was reported only in 18 and 2.1% of Iran. The increasing extent of no thermal stress on the one hand and reduced thermal stress on the other hand, are indicative of the start of the cold period. Based on PET, slightly cool and cold conditions can be seen in less than 0.10 of Iran. However, in October, cold and very cold conditions have not yet begun. Heat conditions in this month to the lower latitude and low-lying areas have receded. In fact, the highlands with high-latitude have moved towards cold conditions. In this month, slightly warm, comfortable and warm conditions were seen in 30.6, 23.7 and 22.3% of Iran, respectively. Very hot conditions are in less than 5.0% of Iran. Therefore, October, can be called a transitional month moving towards cold conditions (*Fig. 6*).

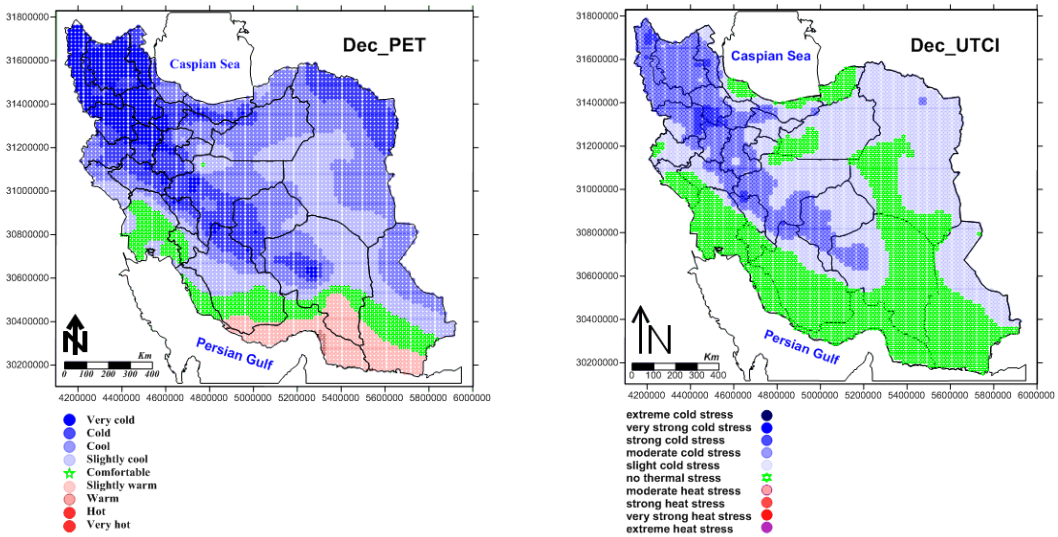

Figure 6. *Iran's bioclimatic conditions in October, November and December*

November

In November, only 3.3% of the territory of Iran (including southern Iran) has reported heat stress conditions. In fact, with the exception of the southern coast, heat stress conditions with different intensities are not seen in Iran. In parts of the Khorasan province and from the northwest of Iran to Kerman province, slight cold stress and moderate cold stress dominates the region. What is obvious is that compared to October, conditions of heat stress and no thermal stress conditions have shown a significant decrease. Moreover, significant increase, especially in slight cold stress condition (23.5%) and moderate cold stress (1.9%) can be observed. Based on the PET index, the bioclimatic condition in November shows a major difference with October. In this month, very hot and hot conditions have left Iran and on the other hand very cold and cold conditions are reported only in about 5% of the region. Overall, in about 20% of Iran, slightly warm and warm conditions can be seen. Compared to October, in November, there is a slight increase in the expansion of thermal comfort (24%). In this month 29, 24 and 22% of Iran respectively, is surrounded by slightly cool, comfort and cool conditions. Also thermal stress to the low latitudes and low-lying areas has been displaced (*Fig. 6*).

December

The Cooling trend in Iran that began in September has become more intense in December. In December, in no part of this country have heat stresses been experienced. In addition, thermal stress conditions of 71.3% in November decreased to 39% in December. In this month, no thermal stress conditions are experienced in low-lying areas and low latitudes especially in coastal areas as well as parts of the Caspian Sea. Overall, more than 60% of Iran has experienced cold stress with different intensities. Highlands and higher latitudes have more severe cold stress conditions. Temperature reduction in December continues based on the PET index. In this month, only 0.2% is in hot conditions and 7.9% of Iran was in slightly warm conditions. Therefore, any effect of hot and very hot conditions cannot be seen in Iran. On the other hand, very cold and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_54235445
© 2018, ALÖKI Kft., Budapest, Hungary

cold conditions have shown a significant increase in December compared to April to November. In fact December, after the months of January and February, is the coldest month in Iran. In addition, significant reductions in thermal stress can be seen in this month. In this month, thermal stress can be seen in about 10% of Iran. Cold severity to the northwest of Iran and highlands is more. However, in some parts of the south coast, slightly warm conditions can still be experienced (*Fig. 6*).

Discussion

Iran is one of the largest countries that located in Middle East. Iran has an area of 1,648,195 square kilometres. It lies between latitudes 24° to 40° N, and longitudes 44° to 64° E. Iran consists of the Iranian Plateau and it is one of the world's most mountainous countries, its landscape dominated also by rugged mountain ranges. Therefore, Iran's climate is very diverse ranging from arid and semi-arid, to subtropical along the Caspian coast and the northern forests. This study was performed with the aim of determining the thermal stress and bioclimatic conditions of Iran. Most of the researches in terms of bioclimatic conditions in Iran have been done within the cities and/or provinces. However, in the estimation of bioclimatic conditions of Iran, the different indices are used. Comparison of this research to other researches that have been conducted in different parts of the country shows there are slight differences in the estimation of bioclimatic conditions. Without a doubt, such differences may be caused by the type and volume of data and the different methods used. However, analysis of bioclimatic conditions in Iran is the most important feature of this research. The impact of bioclimatic conditions on thermal comfort in different areas of the world has been carried out recently, indicating the impact of urban bioclimatic on human morbidity (Schwartz et al., 2004; Nastos and Matzarakis, 2006), tourism potential and decision making (Didaskalou and Nastos, 2003; Hamilton and Lau, 2003), urban planning (Nikolopoulou and Lykoudis, 2006; Thorsson et al., 2007), and mortality (Analitis et al., 2008; Almeida et al., 2010). In general, the result of this research is almost in alignment with the work of Ramazani Gourbi (2010). Looking at the map of bioclimatic Iran, it can be said that in the eastern and western parts of the Gilan province, comfort conditions can be seen throughout the year. However, the eastern parts of this province have more thermal comfort. The results of this study have some differences to the research that Shakoor (2011) conducted on on Yazd. Shakoor believes that in the months of October, November and January, favourable climatic conditions exist in Yazd. The findings of this study are no in alignment with the findings of Ghavidel Rahimi and Ahmadi (2013). The results of this study are however in line with the studies of Tavoosi and Sabzi (2013) and Mohammadi (2014). However, there are the slight differences between findings of this study and other researches, a part or parts of Iran have studied. In these regions, temperatures rarely fall below freezing and the area remains humid for the rest of the year. To the west, settlements in the Zagros basin experience lower temperatures, severe winters with below zero average daily temperatures and heavy snowfall. The eastern and central parts of Iran are arid, with less than 250 mm of precipitation, and have occasional deserts. Average summer temperatures rarely exceed 38 °C. The coastal plains of southern Iran have mild winters, and very humid, sultry and hot summers with annual precipitation of less than 350 mm. Generally the results of this study showed that Iran's bioclimatic conditions are very diverse during the year.

According to UTCI, all bioclimatic conditions (except extreme cold and extreme heat stress conditions) in a limited time and a small territory of Iran were at least experienced. In contrast to some areas experiencing cold condition in winter (with different intensities), some areas of Iran show a thermal comfort conditions which highlights the climatic diversity of the country as well as high tourism potential throughout the year. These regions are mostly located in south latitudes and Iran's lowland areas which display the lowest thermal stress conditions. In spring, cold stress and comfort conditions is reduced. However in this season, especially, thermal stress condition is prevalent in considerable parts of Iran, but heat stress conditions with different intensities is expanding. At the beginning of the summer the regions that have experienced thermal stress conditions have decreased. The results of this research reveal that heat stress with different intensities has been experienced in more than half of Iran. In late summer, heat stress in Iran will gradually decline. In the autumn, with the increasing cold stress and reducing heat stress, we can see the cooling process in Iran. The other results of this study showed that moderate cold stress and thermal stress conditions can be seen all year round. In fact, the existence and expansion of thermal comfort and generally bioclimatic conditions with different intensities at any time of year (in large or small parts of Iran), shows Iran's bioclimatic ability. The occurrence of simultaneous bioclimatic conditions also reflects the fact that Iran is a country of four seasons. This means, when many parts of Iran (northwest, west and northeast) are experiencing strong cold stress conditions in December, January and February, other parts of the country are experiencing comfort and moderate heat stress conditions. Such a contradiction in the bioclimatic conditions event is even in some provinces of the country. For example, very diverse bioclimatic conditions have been experienced in the months of June and July in the Isfahan province. Kerman province has this climate variety in August, September and December. Comparisons of the results of PET and UTCI indices showed that in some months of the year (such as January and February) there is very little difference between the estimated bioclimatic conditions in Iran. However, in March, April, May, September, October and November, there are considerable differences in bioclimatic conditions estimated by these indices.

Compared with previous studies of thermal stresses in other parts of Iran, the advantage of the method employed in this research is that the PET index is more understandable for people who (tourists) can assess the outdoor thermal condition based on their experience in an indoor environment (Farajzadeh et al., 2015; Roshan et al., 2018). About half the country is covered with mountains and moreover due to the vastness of Iran, it has various and different climates. Iran's climatic diversity in terms of spatial and temporal scale is visible. According to studies that published in Farsi, Iran is divided into several climatic regions. The south of Iran has very humid hot weather. Winters are very pleasant. Iranians travel to the south of Iran in winters; especially Kish and Gheshm islands have the best weather in winters. Therefore, the temperature difference in different parts of Iran can reach up 40 to 50 degrees in winter. Considering such explanations, we can say it seems that the PET index compared to the UTCI index showed a great ability in estimating Iran's bioclimatic conditions. In fact, the PET Index shows Iran's climatic diversity better than the UTCI index. Bioclimatic maps that are presented in this study can provide a good platform for doing a lot of planning, energy management, human activities such as tourism and even other environmental studies. Furthermore, the results of this study are important for government agencies to offer detailed tourism climate information to improve the success of the tourism industry.

Conclusion

The evaluation of the bioclimatic conditions for Iran was carried out based on the analysis of the UTCI and PET indices. The results of this study showed that at the spatial and temporal scales Iran has different bioclimatic conditions. The results of this research have several applications in the fields of tourism, agriculture, medical, and architecture, etc. In general, bioclimatic maps in this research have a useful uses for decision makers on various levels, including health, tourism and regional planning. The results of this study suggest that the bioclimatic conditions of Iran during the year are very diversity. However, warm and very warm bioclimatic conditions in most cases have been experienced in the southern parts of Iran and areas with lower altitude. These regions are affected by heat stress in spring and summer seasons. Analysis of the bioclimatic conditions is subject of applied investigation among various scientists such as urban planners, climatologists, architects, and biologists. According to the studies mentioned in discussion section can be said that there are several research recommendations in the field of bioclimatic conditions in Iran. To better understand the bioclimatic conditions of Iran, the trend analysis of the Iran's bioclimatic conditions has been suggested. Also, the relationship between bioclimatic conditions and the rate of hospital admissions for cardiovascular disease in Iran can be the other topic for future research.

Abstract. In this study, land surface energy balance in the oasis-desert ecotone of the northern piedmont of the East Tianshan Mountains, Xinjiang, China was calculated using meteorological data from a Bowen ratio system, in conjunction with modified Bowen ratio method. The daily variation in land surface energy balance was then investigated, along with energy partitioning under different weather conditions. The four weather conditions including sunny day, overcast day, rainy day and average condition. Finally, based on the analysis of relationship between land surface energy and land surface temperature, prediction models for land surface temperature were constructed and validated. The results show that the *splendens* grassland soil has a cache energy function. Latent heat (*LE*) plays a dominant role in the energy budget of the oasis-desert zone for all weather conditions, which is inconsistent with some previous studies on other arid areas. The average value of *LE/Rn* (59%) of this zone is between those of the desert and of the oasis due to the transitional thermal-hydrologic property of the land surfaces and the local circulation. The variations of energy partitioning during the daytime are the same among the different weather conditions, while these curves fluctuate continuously at night, especially before sunrise and after sunset. Except for *H*, the correlations between each energy component and the surface temperature for different conditions are ordered as follows: clear days > average values> overcast days > rainy days. The same rule is also found in the response intensities (regression coefficients) of the land surface temperature to energy change. The established and validated models for land surface temperature suggest that the soil surface layer temperature is mainly influenced by dry heat energy factors (*Rn*, *G*, and *H*) because of not in the summer monsoon zone and coarser soil particle, rather than the hygrothermal energy factor (*LE*).
Keywords: *Bowen ratio, latent heat, sensible heat, energy budget, temperature, Xinjiang*

Introduction

Land surface processes describe the exchange of matter and energy between the earth surface and the atmosphere, which closely connect the atmosphere, hydrosphere, biosphere, and pedosphere (Mathew et al., 2018; Pal and Ziaul, 2017; Xystrakis et al., 2017; Yaşar Korkanç, 2018). The atmosphere-land energy exchange dominated by land surface energy balance significantly impacts the formation and evolution of regional environments and global climate change. Thus, land surface energy balance is the main topic of research on land surface processes. This energy balance directly influences the changes in land surface (soil) temperature. On the other hand, land surface temperature also exert significant effect on energy exchange at the land-atmosphere interface (Burakowski et al., 2018; Wang et al., 2018). Hence, several

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_54475465
© 2018, ALÖKI Kft., Budapest, Hungary

large-scale field experiments on land surface processes consider land surface energy and temperature to be major observational items, such as EFEDA (Osann Jochum et al., 2006), NOPEX (Halldin et al., 1998), BOREAS (Sellers et al., 1995), and EBEX-2000 (Oncley et al., 2007). Significant progress has been made in understanding the land surface energy balance and temperature for different land surfaces/ecosystems, including studies on plateaus (Luo et al., 2018; Zhang et al., 2014), mountains (Gualtieri, 2018; Wagner et al., 2014), deserts (Urqueta et al., 2018), and forests (Gage and Cooper, 2017). Moreover, many studies have found a problem with the unclosure of the energy balance, i.e., the available energy is found to be larger than the sum of the turbulent fluxes of sensible and latent heat measured in these land surfaces (Foken, 2008). This energy unclosure is mainly attributed to the energy storage in the upper soil layer and the heterogeneity of the land surface (Foken et al., 2006). Thus, these two reasons must be considered and corrected through studying the land surface processes, especially in the ecotone where vertical sensible heat advection may generate due to the heterogeneous land surface (Zhang et al., 2012a).

The oasis-desert ecotone that lies between the oases and deserts is an ecologically fragile zone (Tiyip et al., 2005), where characteristics of land surface energy balance strongly affect regional atmospheric circulation and surface temperature. In addition, there are some significant differences in the response of land surface energy balance with surface temperatures to different weather conditions. However, very few studies have focused on these aspects concerning oasis-desert ecotones thus far. Hence, investigating the land surface energy balance and its relationship with land surface temperature in this area can contribute to the research on regional surface energy balance and improve the regional weather and global climate model. It will also provide references for the optimal regulation of water resources in this region. The objectives of this study are: (1) to compare the characteristics of surface energy balance under different weather conditions; (2) to compare the patterns of surface energy partitioning with those of other nine land surfaces in the arid zone of Northwest China; and (3) to quantify the relationship between land surface temperature and energy component.

Materials and methods

Study area

The trial was conducted on the *Achnatherum splendens* grassland near the Wanmuchun forest-farm, Qitai County, Xinjiang Province, China. The area is 2 km southeast of the Gurbantunggut Desert in the northern piedmont of the East Tianshan Mountains. It represents a typical oasis-desert ecotone in northwest China (*Fig. 1*). The geographic location of the study site is 44°11′19″ N, 89°25′32″ E, and the altitude is 693 m above sea level. The climate of the region is temperate continental and arid climate with an annual mean precipitation of only 150 mm, whereas annual potential evaporation reaches above 2100 mm. The average annual temperature is approximately 5 °C, with 2933.6 annual sunshine hours.

The area of experimental zone is approximately 2100 ha (3000 m × 7000 m). It is mainly covered with *A. splendens*, a perennial, densely tufted Gramineae, accompanied by sparse *Sophora alopecuroides* and *Salsola collina Pall*. The total coverage is roughly 30%. The soil is sandy loam, and the groundwater depth range from 3 to 5 m.

Bowen ratio/energy balance method and its modification

The Bowen ratio/energy balance (BREB) method (Bowen, 1926) has been widely used to measure land surface energy. This method can provide accurate, continuous measurement of micrometeorological elements and energy balance components over an extensive surface area (Dugas and Mayeux Jr, 1991). The core concept of BREB method is to divide the available energy into turbulent sensible heat and latent heat fluxes by using the Bowen ratio (Uddin et al., 2013).

The energy balance of land surface, neglecting small amount of photosynthetic energy storage, can be expressed as:

$$Rn = LE + H + G \quad \text{(Eq.1)}$$

where Rn is the net radiation (W/m^2), LE the latent heat of evapotranspiration (W/m^2), H the sensible heat flux (W/m^2), and G the soil heat flux (W/m^2). Rn and G are obtained from the observation. Except in extremely unstable or stable atmospheric situation, The Bowen ration (β) is defined as the ratio of sensible heat flux to the latent heat (H/LE) (Bowen, 1926). Therefore, *Equation 1* can be rewritten as (*Eq. 2*):

$$LE = (Rn - G) / (1 + \beta) \quad \text{(Eq.2)}$$

The Bowen ratio (β) can be calculated as

$$\beta = H / LE = \rho c_p K_H \Delta t / \rho c_p K_V \Delta e = \gamma (\Delta t / \Delta e) \quad \text{(Eq.3)}$$

where ρ is air density, c_p the specific heat of air at a constant pressure (cal·g^{-1}·K^{-1}). K_H and K_V are the turbulent transfer coefficients for heat and vapour, respectively. γ is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_54475465
© 2018, ALÖKI Kft., Budapest, Hungary

psychrometric constant, Δt and Δe the differences in the air temperature (°C) and water vapor pressure (hPa) between the two heights, respectively. In *Equation 3,* K_H is assumed to be equal to K_V for neutral to moderately unstable atmospheric condition over smooth terrain (Spittlehouse and Black, 1980). And this assumption is usually valid except in extremely unstable or stable atmospheric condition (Dugas and Mayeux Jr, 1991). For instance, K_H is greater than K_V for stable conditions.

Many previous studies assumed the G to be the direct measured value of soil heat flux transducer at 0.05 m below the soil surface, but in reality G also includes the heat stored in the 0 to 0.05 m layer computed from measurement of the change in temperature of the layer with time and the heat capacity of the layer. Thus its computation should be modified as (*Eq. 4*):

$$G = G_{0.05} + C_S \frac{\partial T}{\partial t} \Delta Z \quad \text{(Eq.4)}$$

where $G_{0.05}$ denotes heat flux obtained from heat flux transducer at 0.05 m below the soil surface (W/m^2), C_S the specific heat of dry soil (J·kg^{-1}·°C^{-1}), $\frac{\partial T}{\partial t}$ is the rate of change in soil temperature over time, and ΔZ the depth of the soil layer measured, i.e., 0.05 m.

Additionally, with respect to the flat and homogeneous surface, vertical sensible heat advection can be not taken into account due to its almost no occurrence. However, since there are some differences in surface thermodynamic properties between the oasis and the desert surface, sensible heat can be advected vertically to some extent in the inhomogeneous surfaces of ecotones, thereby generating vertical sensible heat advection (H_{vad}) (Zhang et al., 2012a, b). Thus, here the sensible heat (H) comprises not only the turbulent sensible heat (H_0) but also comprises the vertical sensible heat advection (H_{vad}) (*Eq. 5*):

$$H = H_0 + H_{vad} \quad \text{(Eq.5)}$$

where H_0 and H_{vad} can be calculated as follows (*Eqs. 6* and *7*):

$$H_0 = \beta LE \quad \text{(Eq.6)}$$

$$H_{vad} = -\rho c_p z_r w_r \frac{\Delta T}{\Delta Z} \quad \text{(Eq.7)}$$

where ρ is air density; c_p is the specific heat capacity of air at a constant pressure (cal·g^{-1}·K^{-1}); w_r is the vertical wind speed of height Z_r; and $\Delta T / \Delta Z$ is the vertical gradient of temperature.

Experimental design

The Bowen ration system (Delta-T Devices Ltd., UK), similar to that used in (Peacock and Hess, 2004; Todd et al., 2000), was set up on the center of the experimental zone. Its main observed elements included net radiation, air temperature, air humidity, wind speed, soil temperature, soil moisture, the soil heat flux, and precipitation. Net radiation was measured at 0.5 m above the maximum height of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

splendens canopy by a net radiometer. Sensors of air temperature and air humidity were installed in two layers, that is, 0.5 m and 2.5 m above the height of the canopy. Sensors of soil temperature and moisture were arranged in eight layers, that is, 0.05, 0.1, 0.15, 0.2, 0.4, 0.6, 0.8, and 1 m underground. The soil heat flux was measured with soil heat flux plate at 0.05 m below the soil surface. More details on each sensor are listed in *Table 1,* including sensitivity and estimation of errors. The diagrams of measurement configurations Bowen ratio system is seen in *Figure 2*. All observed data were automatically recorded at 30-min intervals by a data collector and then exported by a computer. Measurements were taken from 22 July to 3 September 2010. The distance between the site of instrument setup and the boundary of the experimental zone varied from 1510 m to 3534 m, which meets the fetch requirement that the ratio of fetch (upwind distance of uniform conditions) to the height of the instrument above the surface needs to be greater 100 (Wiernga, 1993).

In addition, in order to analyze the effect of different land surfaces types on energy partitioning, we collected observation data of nine other stations with different surfaces types in the same arid zone of Northwest China, which were mainly obtained from previous published papers (*Fig. 3*). These stations are classified into three groups, namely, Desert/Gobi, Oasis-desert ecotone, and Oasis. *Table 2* lists their geographic information, land surfaces types, and climatic backgrounds.

Examining relationship between land surface energy and temperatures

In order to investigate the relationship between soil temperature and surface energy accurately, a Pearson correlation coefficient (Pearson, 1895) and linear regression (Weisberg, 1985) method were used to quantify the relationship between land surface energy and temperatures. More detailed information about the methods can be found in Pearson (1895) and Weisberg (1985)

Results and discussion

Daily variation in land surface energy

In order to analyze the effects of different weather conditions on the land surface energy, 14 typical clear days (total cloud cover < 1 okta), 5 overcast days (total cloud cover > 7 okta), and 2 rainy days (1.2 mm/h, 3–7 okta) are derived from the observation period as sample data. Then, the daily variation in land surface energy at half-hour scales for different weather conditions are shown in *Figures 2–5*. These curves are generated according to the average of the sample data with similar weather conditions.

Clear days

On clear days, all of the surface energy components (*Rn*, *LE*, *H*, and *G*) display a single peak with a clear day-night difference (*Figure 4*). Although the general pattern of *LE* change is the same as that of *Rn* change, its daily maximum is half an hour later than that of *Rn*. *LE* become negative after sunset because of the water vapor exchange

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_54475465
© 2018, ALÖKI Kft., Budapest, Hungary

between soil and atmosphere over a desert surface near an oasis in the summer. After midnight, it shifted to a low positive, thus implying that slight evapotranspiration still occur. *H* is positive in the daytime and negative at night, which suggests that the *H* flux moves from the land surface to the atmosphere in the daytime, while it moves from atmosphere to land surface at night. The range of the daily variation in *G* is only approximately 80 W/m^2, and its daily maximum is more than two hours later than that of *Rn*. When the value of *G* is greater than 0 in the daytime, the soil absorbed heat as a heat sink. By contrast, the soil releases heat as a heat source when the value of *G* is less than 0 at night.

The total daily values on clear day of *Rn*, *LE*, *H*, and *G* are 13.53×10^6, 9.41×10^6, 3.91×10^6, and 0.27×10^6 J/m^2, respectively. This finding indicates that *LE*, rather than *H*, is dominant in terms of surface energy budget (accounting for 70% of *Rn*) on clear days. This is significantly different from the other arid regions in northwest China under the same weather condition. For instances, the value of *LE* is lower than that of *H* in Zhangye oasis-desert ecotone (Zhang et al., 2007) and Dunhuang oasis-gobi ecotone (Wang et al., 2005) over the same period (*Table 3*). This result can be attributed to the fact that the vegetation coverage index of the Zhangye oasis-desert ecotone is only 37% of that of the current study area. Furthermore, the Dunhuang oasis-gobi ecotone is mainly covered with *Alhagi sparsifolia*, where PAI (plant area index, which is the sum of the leaf area index and the woody area index) and annual precipitation is low. Thus, *LE* induced by plant transpiration is lower in the Zhangye and Dunhuang ecotone than that in the current study area. Likewise, *H* is dominant in the Dunhuang Desert (Zhang and Cao, 2003), Taklimakan Desert (Wang et al., 2014), and Dingxin Gobi (Wang et al., 2008) because of sparse vegetation and bare soil (*Table 2*). Although *LE* is dominant in the non-irrigated farmland of Dingxi Oasis (Yang et al., 2004), its proportion is smaller than that of the current study area. This is because farmland is converted into bare land, after reaping wheat in mid-August. These comparisons showed that different vegetation cover conditions significantly affect the surface energy partitioning.

-- in the body of table indicates that the observation data is not available

Overcast days

On overcast days, energy curves affected by fluctuating cloudiness are divided into multiple peaks and troughs (*Figure 5*). The highest peaks of *Rn*, *LE*, and *H* are lowered to 46%, 40%, and 45% of the corresponding values on sunny days, respectively. With the exception of the period from 12:00 to 13:30, the value of *G* is less than 0 throughout the day, thus indicating that soil mainly releases heat into the atmosphere as a heat source to compensate for the insufficient *Rn* on overcast days.

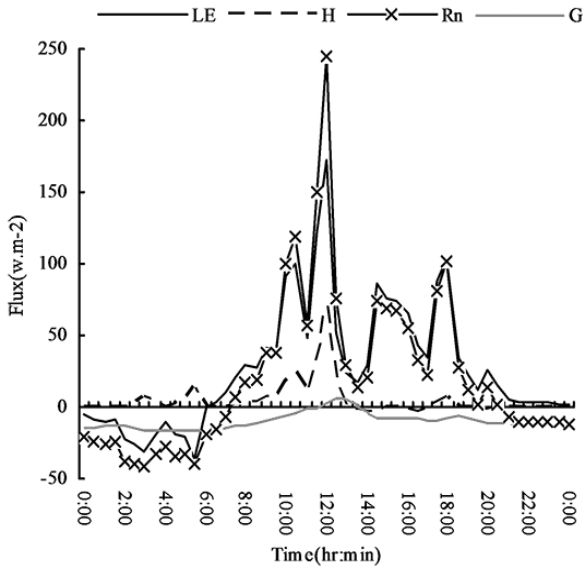

Figure 5. *Daily variations in surface energy balance on overcast days in splendens grassland. LE is the latent heat of evapotranspiration, H the sensible heat flux, Rn the net radiation, and G the soil heat flux*

The total daily values on overcast day of *LE*, *H*, and *G* are 2.32×10^6, 0.38×10^6, and -0.92×10^6 J/m^2. These values account for 130.80%, 21.37%, and −52.16% of *Rn*, respectively. The reason why *LE*/*Rn* > 1 and *G*/*Rn* < 0 is that the soil continually releases heat to the atmosphere to replenish the inadequate energy for evaporation.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_54475465
© 2018, ALÖKI Kft., Budapest, Hungary

Therefore, the value of *LE* which also includes the additional heat derived from soil, is higher than *Rn*. This phenomenon is specific for the *splendens* grassland and not the Dunhuang Desert, Taklimakan Desert, Dingxin Gobi, and Dingxi Oasis (*Table 3*). That may be explained by the differences in the soil property and vegetation cover among them. Although the value of *Rn* decreased, the large heat storage capacity of *splendens* grassland soil can provide sufficient energy for evapotranspiration on overcast days. As a result, $LE > Rn$ and $G < 0$. This finding demonstrates that *splendens* grassland soil stores heat on clear days, and then releases it on overcast days, that is, it has a cache energy function.

Rainy days

On rainy days, moderate amounts of rain fell early in the morning and stopped at noon. The weather then turned fine. As a result of precipitation, the time-point of each energy balance component begins to increase rapidly is more than four hours later than that on sunny days (*Figure 6*). This lag contributes to the "lagged peak" of each energy curve. The maxima of *Rn* and *H* are 117% and 214% of those generated during sunny days, respectively. This result shows that the few clouds and low air turbidity might enhance the energy exchange between atmosphere and land when the sun shines again once the rain ceases. The peak value of *LE* is similar to that on sunny days. This finding implies that grassland evapotranspiration rate remains high due to the increased available water and increased *Rn* on rainy days. *G* remains negative during rainfall, that is, the soil releases heat to the atmosphere. Once the rain stopped, *G* reaches the minimum value, i.e., the soil releases more energy to the atmosphere and promotes the appearance of the *LE* peak.

The total daily values of *LE*, *H*, and *G* on rainy day are 6.35×10^6, 3.49×10^6, and -6.35×10^5 J/m^2, respectively. These values are responsible for 68.96%, 37.94%, and −6.90% of *Rn*, respectively. This finding indicates that *LE* is dominant in rainy days. That is consistent with the results of Dingxin Gobi and Dunhuang Desert, where *LE* is also dominant because of rainfall.

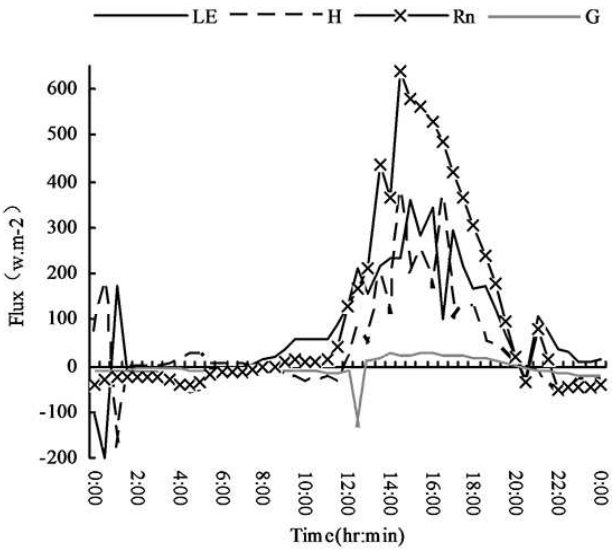

Figure 6. *Daily variations in surface energy balance on rainy days in splendens grassland. LE is the latent heat of evapotranspiration, H the sensible heat flux, Rn the net radiation, and G the soil heat flux*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_54475465

Average

The average values of each energy components (calculated from the average of all observed data during the observation period) decrease compared to those of clear days. Nonetheless, the general trends of the daily variation curves are consistent with those observed on clear days (*Figure 7*). The average value of *LE/Rn* (59%) is significantly higher than that observed in the Linze Desert (Zheng et al., 2000), Dunhuang Desert, Taklimakan Desert, and Dingxin Gobi over the same period. However, this value is lower than that obtained in the irrigated farmland of the Hexi Corridor Oasis (Zheng et al., 2000; *Table 4*). As a result of the dry climate and sparse vegetation, the reduced capability of holding and retaining water leads to the severe scarcity of water for evapotranspiration in the first four ecosystems. Nevertheless, in the irrigated farmland of the Hexi Corridor Oasis, the high water content of the soil and vegetation due to the high vegetation coverage and artificial irrigation induces vigorous evapotranspiration. Therefore, *LE* plays a predominant role in the energy exchange, whose proportion is 9.2% larger than that observed in the current study area. The current study area's transition property in the energy partitioning might be attributed to the thermal-hydrologic property between deserts and oases and the local circulation. The differences in the thermal property between the oasis and the desert cause the local circulation. Then the horizontal advection caused by local circulation transfers the hot and dry air from the desert to the oasis-desert ecotone. Consequently, the temperature gradient decreases and the humidity gradient increases that leads to a reduction in *H* and increase in *LE* so that *LE* become predominant in the surface energy budget of ecotone. Moreover, the value of *LE*/*Rn* is slightly higher than that of the Ejina oasis-desert ecotone (Si et al., 2010) because the annual precipitation in the Ejina oasis-desert is only one quarter of that in the current study area. This suggests that surface energy balance is not entirely controlled by vegetation cover, and climatic conditions may be also important.

Daily variation in energy partitioning

Figure 8 shows the daily variations in energy partitioning for different weather conditions. The general pattern in the daytime variation of energy partitioning is similar among the four different weather conditions. The available surface energy is primarily transformed into *LE*, as indicated in the order *LE/Rn* > *H/Rn* > *G/Rn*. However, before midnight (20:30–24:00), *LE/Rn* > *G/Rn* > *H/Rn* is observed for clear days and the average condition, thus suggesting that a certain amount of evapotranspiration still occur (*Fig. 8a* and *d*). By contrast, *H/Rn* is highest on overcast and rainy days at the same time (*Fig. 8b* and *c*). After midnight (24:00–8:00 the next day), *G* is dominant in the energy balance for all different weather conditions except rainy days. It implies that the soil becomes the main heat source of the soil–plant–atmosphere continuum (SPAC) system in the grassland after midnight.

In the daytime, the curves of *G/Rn*, *H/Rn*, and *LE/Rn* have not significant change for each weather condition (*Fig. 8*). However, at night, these curves fluctuated continuously. At sunrise and sunset, with the conversion of the heat source between the atmosphere and the soil (from soil to atmosphere or from atmosphere to soil), the changes in the direction of energy transport and energy intensity trigger the severe oscillation of curves, thus resulting in large peaks or troughs. The range of fluctuation in *LE/Rn* is the widest among all of the curves at sunrise. The result might be because following night condensation, much dew available for evapotranspiration is generated on the soil surface and the vegetation surface at sunrise. Although the value of *Rn* changes from negative to a relatively low positive, this value is far lower than that of *G* (whose direction is negative). Thus, at this point, the value of *LE* is almost equal to the sum of *Rn* and *G.* As a result, *LE/Rn* is greater than 1 (on rainy days, this value is close to 10), thereby mutating *LE/Rn* significantly. It also explains why the trend of change in the curve of *LE/Rn* is opposite to that of *G/Rn* in the peak. The time-points at which all of the curves change substantially in the mornings and evenings of overcast days are half an hour later and half an hour earlier, respectively, than those under the average condition because of the decreased solar radiation and reduced sunshine hours. On sunny days, the time-points are half an hour earlier and four hours later than those under the average condition because of the strong radiation and long sunshine hours. On rainy

© 2018, ALÖKI Kft., Budapest, Hungary

days, the time-points at which all energy curves deviate to the right are one and a half hours later than that under the average condition.

Relationship between land surface energy and surface temperature

Correlations between land surface energy and soil temperature at different depths

In order to investigate the relationship between soil temperature and surface energy accurately, this study stratified soil into four layers measuring, namely, 5, 10, 15, and 20 cm. Since surface energy exchange mainly occurs during the daytime, only the results during daytime (8:00–18:00) over the observation period are analyzed here (*Table 5*). Moreover, their significance level is also tested.

The correlation between each energy component and soil temperature decreases gradually and is increasingly negatively correlated, with increasing soil depth (*Table 5*). This finding is due to the gradual delay in the peak time of soil temperature with the increase in depth, which enhanced the non-synchronism between the soil temperature and land surface energy. At 20 cm, the trend of soil temperature is opposite to that of land surface energy; therefore, the correlation between both is predominantly negative. Among the layers, the soil temperature at 5 cm displays the best correlation with energy components. For instance, the coefficient between the soil temperature at 5 cm and *G* is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_54475465
© 2018, ALÖKI Kft., Budapest, Hungary

0.61, 5.81, 1.72, and 0.54 times larger than those at 10, 15, and 20 cm on average, respectively. This result is ascribed to the fact that the energy exchange firstly begins in the topsoil which is the critical plane of the SPAC system. Therefore, only the relationship between the soil temperature at 5 cm and energy components is analyzed as presented in the following section.

Table 5. *Correlation coefficients between the energy components and soil temperature. ** represents $p < 0.01$, denoting the correlation between the two corresponding variables is statistically highly significant*

	Rn	***G***	***LE***	***H***
$T_{soil\text{-}5cm}$	0.4234**	0.8754**	0.2328**	0.2804**
$T_{soil\text{-}10cm}$	0.0556**	0.5426**	−0.0145	−0.0337
$T_{soil\text{-}15cm}$	−0.2289**	0.1286**	−0.1733**	−0.2675**
$T_{soil\text{-}20cm}$	−0.3653**	−0.3215**	−0.1955**	−0.3667**
$T_{soil\text{-}average}$	0.1410**	0.5695**	0.0707**	0.0241**

The correlations between each energy component (*Rn*, *LE*, *H*, and *G*) and soil temperature are all significant; however, that of *G* and soil temperature is the best. The correlations of *Rn* and *H* with soil temperature are intermediate, while the correlation of *LE* with soil temperature is the least significant (*Table 5*). This finding is mainly resulted from the fact that *G* has the most direct effect on the change in soil temperature compared to other energy components, because it represents the amount of heat passing in and out of the soil. For instance, when the value of *G* is positive and high, the heat flow transferred continuously from the land surface to soil layers, thus accumulating soil energy and increasing soil temperature. However, *Rn*, *LE*, and *H* exerted their indirect effects on the soil temperature by means of *G*. These results demonstrate that soil temperature is more sensitive to *G* than to other energy components.

Relationship between land surface energy and soil temperature under different weather conditions

G is most closely related to soil temperature under sunny conditions, followed by its correlations under overcast and rainy conditions (*Table 6*). On overcast days, the negative correlation between the amount of clouds and soil temperature on overcast days weakens the relationship between *G* and soil temperature. In addition, *Rn* and air temperature decrease on overcast days because of clouds. Thus, *G* lessens and soil temperature changes very slowly. Finally, the correlation coefficient (R^2) between *G* and soil temperature is only 81% of what it is on sunny days (*Table 6b*). On rainy days, a significant cooling effect of precipitation on soil temperature contributes to a negative correlation between precipitation and soil temperature. It interferes with the synchronism of *G* and soil temperature. Thus, the coefficient on rainy days is equivalent to only 50% of that on sunny days (*Table 6c*). Since there are less overcast and rainy days during the observation period, the value of the coefficient under the average condition is similar to that on sunny days (approximately 0.61) (*Table 6d*). The response sensitivity (linear regression coefficient) of soil temperature to change in *G* indicates that the values observed during sunny days are equivalent to those generated under the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_54475465
© 2018, ALÖKI Kft., Budapest, Hungary

average condition, followed by those observed on overcast days. Those observed on rainy days are the lowest.

Similar to *G*, the linear correlations between *Rn*, *LE*, and soil temperature among different conditions are ordered as follows: sunny days > average condition > overcast days > rainy days. On sunny days, the soil temperature change substantially because of the increased *Rn* and *LE*. Therefore, soil temperature is mostly close to *Rn* and *LE on sunny day* compared to that under other weather condition. On overcast and rainy days, the correlations observed are weakened because of the the interference of clouds and precipitation on these energy components.

The linear correlations between *H* and soil temperature under different conditions are arranged as follows: average condition > rainy days > sunny days > overcast days. The response sensitivity (linear regression coefficients) of soil temperature to change in *H* demonstrates that average condition > sunny days > rainy days > overcast days.

Surface temperature model

As overcast and rainy days are rare in the observation period, the observed half-hour scale data of thirteen sunny days, four overcast days, and two rainy days derived from

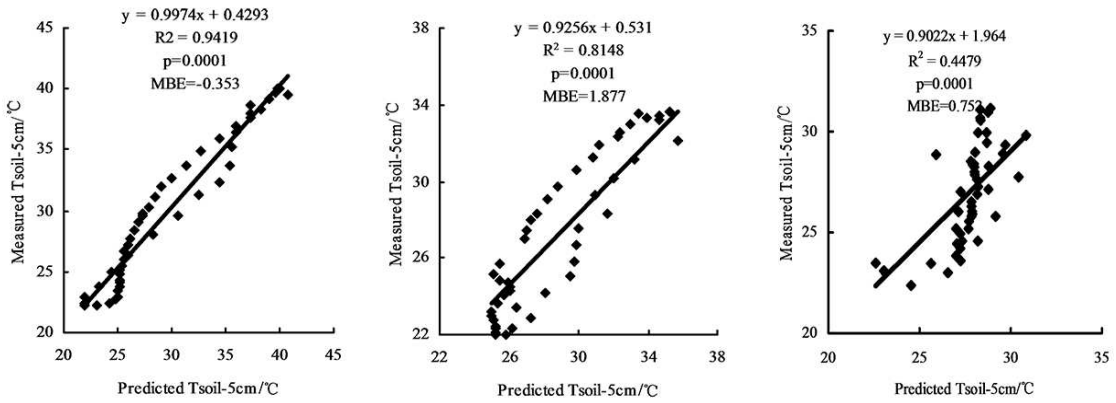
http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_54475465
© 2018, ALÖKI Kft., Budapest, Hungary

sample data are used to establish the land surface temperature model using the stepwise multiple linear regression (*Table 7*). In these empirical statistical models, soil temperature is chosen as a dependent variable, where each energy components as independent variables (the amount of clouds and rainfall may be included in overcast and rainy days, respectively). Then, the remaining sample data for different weather conditions are applied to validate the models.

Table 7. *Soil temperature models for different weather conditions*

	Equation for multiple linear stepwise regression	**R^2**	**p**	**F**
Sunny days	$T_{soil\text{-}5cm} = 3.085 \times 10^{-1}G - 2.547 \times 10^{-2}Rn + 2.004 \times 10^{-3}H + 30.427$	0.8093	0.0000	895.19
Overcast days	$T_{soil\text{-}5cm} = 2.469 \times 10^{-1}G - 1.662 \times 10^{-2}Rn + 28.726$	0.6623	0.0000	141.23
Rainy days	$T_{soil\text{-}5cm} = 3.576 \times 10^{-2}G - 3.794 \times 10^{-3}Rn + 1.034 \times 10^{-2}H + 28.203$	0.2112	0.0002	8.39
Average	$T_{soil\text{-}5cm} = 3.444 \times 10^{-1}G - 3.755 \times 10^{2}Rn + 1.8470 \times 10^{-2}H + 30.455$	0.9471	0.0000	268.77

The established models for different weather conditions are all highly significant ($p < 0.01$). However, the models for sunny days ($R^2 = 0.8093$) and for the average condition ($R^2 = 0.9471$) performed best, followed by those for overcast ($R^2 = 0.6623$) and rainy days ($R^2 = 0.2112$) (*Table 7*). For validation, all simulation results agree with the measured values ($p < 0.01$, slope ≈1, the mean bias error MBE is little) (*Fig. 9*). Nonetheless, the sunny model displays a superior R^2 value and slope, followed by the overcast and rainy models. These results might be because the sample size for constructing models is different among different weather conditions.



a. sunny day b. overcast day c. rainy day

Figure 9. *Comparisons of simulated versus observed (half-hour) land surface temperatures for model validation*

LE is excluded in the established models using stepwise multiple linear regression method. This result shows that surface layer soil temperature is mainly affected by dry heat energy factors (*Rn*, *G*, and *H*) than to *LE* under various weather conditions (*Table 7*). It might be attributed to the fact that the oasis-desert ecotone in Northwest China is outside the East Asian summer monsoon zone. Thus, there is only minimal

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

amount of water available for evapotranspiration in the surface layer soil. Furthermore, the precipitation primarily infiltrates into the deeper soil because of coarser soil particle (sandy loam). Consequently, the strong evapotranspiration power does not directly impact the surface layer temperature, but can affect deeper layer temperature. The result is in contrast to that observed in Northeast China and Loess Plateau (Zhang et al., 2012b), where the soil temperature is sensitive to both dry heat energy factors (*Rn*, *G*, and *H*) and *LE* due to monsoon precipitation and loamy or clay soil.

Conclusions

Unlike the *LE* reported in most previous studies in the Desert/Gobi, the *LE* in the current study area is dominant in the energy exchange for all weather conditions. The average value of *LE*/*Rn* (59%) over the observation period is between that of desert and oasis. These results might be explained by the transitional thermal-hydrologic property and the local circulation. The comparisons of energy partitioning among the ten selected station in the Northwest China, show that the general pattern in energy partitioning is significantly affected by the vegetation coverage, as well as climatic condition.

At sunrise and sunset, the conversion of the heat source between the atmosphere and the soil contributes to large peaks or troughs in the energy fluxes curves. At sunrise, the fluctuation amplitude of *LE/Rn* is the greatest among all of the curves. As a result of different radiation intensities and sunshine hours, there is a difference in the time-point at which energy fluxes begins to change violently in mornings and evenings among the four different weather conditions.

The correlations between each energy component and soil temperature imply that they are all highly significant for all weather conditions. However, they are ordered as follows: $G > Rn > H > LE$. The correlations of *G*, *Rn*, *LE*, and soil temperature under different weather conditions can be ranked as follows: sunny days > average value > overcast days > rainy days. Moreover, the response sensitivity (regression coefficients) of soil temperature to change in each energy component indicates that the average and sunny conditions are equal, followed by the overcast and rainy conditions.

The prediction models for land surface temperature without *LE* under different weather conditions imply that soil surface layer temperature is mainly affected by dry heat energy factors (*Rn*, *G*, and *H*) and less sensitive to the hygrothermal energy factor (*LE*) in the oasis-desert ecotone. It is difficult for us to make an in-depth, detailed analysis on the mechanism of land surface process in the oasis-desert ecotone due to the limited temporal coverage. Thus, it's necessary to accumulate longer time series of observational data for refining our findings.

(Received 6th Jul 2018; accepted 14th Aug 2018)

Abstract. SQUAMOSA promoter binding proteins (SBPs) are considered as being a major family of plant-specific transcription factors which plays an important role in flower improvement process. To discover SBP genes in common bean [*Phaseolus vulgaris* (L.)] genome, in silico analysis methods were carried out in this study. Twenty-three members of Pvul-SBP gene family were identified from common bean genome. A phylogenetic tree drawn using SPB proteins of *Phaseolus vulgaris*, *Arabidopsis thaliana* and *Glycine max* was separated into three main groups (A, B, and C). The C group was clustered into nine subclades. The chromosome locations of *Pvul-SBP* genes showed that *Pvul-SBP-1*/*Pvul-SBP-6*, *Pvul-SBP-2*/*Pvul-SBP-16*, *Pvul-SBP-5*/*Pvul-SBP-14* and *Pvul-SBP-9*/*Pvul-SBP-15* gene couples were segmentally-duplicated. Also, orthologue genes were defined using SBP proteins of *Arabidopsis thaliana* and *Glycine max*. The expression levels of *Pvul-SBP* genes in different plant tissues such as roots, leaf and floral organs showed some of *Pvul-SBP* genes were up or down regulated in certain tissue types. The results of this research would provide the estimation of the evolutionary relationships between *SBP* genes in various plants such as *P. vulgaris*, *G. max* and *A. thaliana*.
Keywords: *gene expression, orthologue relationship, phylogeny, synteny*

Introduction

Identification and characterization of transcription factor (TF) families in plants has been turned into one of the most important topics for plant scientists in recent years due to their importance in regulation networks of plant growing processes (Buyuk et al., 2016; Inal et al., 2017; Ilhan et al., 2018). There have been many well-conducted studies for characterization of several plant-specific TFs in many plant species. However, there is no information about some of them including SBP (SQUAMOSA promoter binding protein family) in certain plant species (Wang et al., 2015).

SBPs are considered as being a major family of plant-specific transcription factors which plays an important role in flower improvement processes (Pan et al., 2017). SBP domain, a highly-conserved DNA-binding domain, has specific properties for each member of this TF family. Even though this domain is known to be a zinc-binding domain, structures within this domain are not similar to those ones in other zinc-binding domains and thus has been declared as representing a novel type of zinc binding motif (Wang et al., 2015).

Recent studies which were aimed at defining the roles of SBP family of transcription factors showed divergent roles of them in plant developmental processes (Zhang et al., 2016).

Among sixteen identified *SBP* genes in *Arabidopsis* genome, many of them have been revealed to play role in embryogenesis (Unte et al., 2003), development of shoots and leaves (Schwarz et al., 2008), flowering process (Gandikota et al., 2007), transition

between vegetative and generative phases (Jung et al., 2012) and plant hormone signaling (Zhang et al., 2007)

Genome-wide characterization and expression studies of SBP genes have been conducted in a number of plant species including *Betula pendula*, *Chlamydomonas*, *Oryza sativa*, *Zea mays*, *Populus trichocarpa*, *L. esculentum*, *Malus* × *domestica* Borkh., *Salvia miltiorrhiza*, *Gossypium hirsutum*, *Arachis hypogaea* L., petunia, *Capsicum annuum* L., *Chrysanthemum morifolium*, *Phyllostachys edulis*, *Solanum tuberosum*, *Ziziphus jujuba* and (Lannenpaa et al., 2004; Kropat et al., 2005; Xie et al., 2006; Chuck et al., 2010; Lu et al., 2011; Salinas et al., 2012; Li et al., 2013; Zhang et al., 2014, 2015, 2016; Li et al., 2016; Preston et al., 2016; Song et al., 2016; Pan et al., 2017; Kavas et al., 2017; Shao et al., 2017).

The common bean [Phaseolus vulgaris (L.)] is a self-pollinated legume species. It has a small genome size of 588 Mbp and a diploid genome ($2n = 2x = 22$) (Arumuganthan and Earle, 1991). It is one of the earliest plant species cultivated. As a result of its nitrogen fixation ability, it enriches the nitrogen content of soil. It has an important role in human nutrition, especially in developing countries, due to its high protein content (Broughton et al., 2003). It has been possible to analyze and characterize the SBP gene family with the publication of the whole genome sequence of common bean by Schmutz in 2014 (Schmutz et al., 2014). However, the SPB proteins in *Phaseolus vulgaris* L. have not been identified and characterized yet. To fill this gap in the literature and due to importance of this gene family in plant developmental processes, this study aimed at describing and characterizing SBP proteins in *Phaseolus vulgaris* L. Accordingly, 23 Phvul-SBP members were identified and comprehensive analysis of the sequence phylogeny, genomic organization, exon-intron architecture variation, conserved protein motifs, gene duplication events, and expression analysis were performed.

Materials and methods

Identification of SBP genes in P. vulgaris genome

Phaseolus vulgaris of SBP protein sequences were retrieved from Phytozome database v12.1 (www.phytozome.net) using keyword searching with Pfam Accession Number (PF03110) obtained from Pfam Database (http://pfam.xfam.org). BLASTP and BLASTX searches (National Center for Biotechnology Information [NCBI]: http://www.ncbi.nlm.nih.gov) was used to confirm Pvul-SBP proteins. Non-redundant sequences were obtained using decrease redundancy tool (http://web.expasy.org/decrease_redundancy/). SBP domains in non-redundant sequences were checked by HMMER (http://www.ebi.ac.uk). The solid and chemical traits of SBP proteins in *Phaseolus vulgaris*, such as the theoretical isoelectric point (pI), the number of amino acids, and the molecular weight (Da), were identified using the ProtParam tool (http://web.expasy.org/protparam/).

Phylogenetic analysis, physical location, conserved motifs of phvul-SBP genes, gene structure and gene duplication events

Chromosomal locations and CDS sizes (bp) were identified by using Phytozome database v12.1. The *Pvul-SBP* genes were mapped with MapChart (Voorrips, 2002).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_54675480
© 2018, ALÖKI Kft., Budapest, Hungary

Multiple sequence alignment of Pvul-SBP proteins was conducted with ClustalW. Phylogenetic analysis was performed using MEGA v7 (Tamura et al., 2013) and Neighbor-joining (NJ) algorithm with 1000 replicated-bootstrap value.

The conserved motifs in Pvul-SBP protein sequences were identified using the MEME (Multiple Expectation Maximization for Motif Elucidation) online tool (Bailey et al., 2006). The limits for maximum number of motifs and minimum/maximum width were adjusted as 20 and 2, 50, respectively. Motif sites were among 2 and 300. Site distribution was set as any number of repetitions. The described conserved motifs were examined in InterProscan with default adjusting (Quevillon et al., 2005).

Online Gene Structure Display Server program tool (GSDS) was used (Guo et al., 2007) to predict the exon/intron organization of the *Pvul-SBP* genes. Genomic DNA sequences and coding sequences of Pvul-SBP genes were utilized.

Segmental duplicate gene pairs were examined on the Plant Genome Duplication Database server (PGDD) (Lee et al., 2013), with a display range of 100 kb. The nonsynonymous rates (Ka), synonymous rates (Ks) and developmental constraints (Ka/Ks) with the duplicated pairs of Pvul-SPLs were evaluated using the CODEML program in PAML (Yang, 2007). The roughly date of the duplication events was determined using $T = Ks / 2\lambda \times 10^{-6}$ Mya (million years ago), in terms of the synonymous substitution rates (λ) in common bean of 8.46×10^{-9} (Schmutz et al., 2014).

Synteny analysis

P. vulgaris and *A. thaliana*, *P. vulgaris* and *G. max* of orthologue *SBP* genes were identified with PGDD (Lee et al., 2013). Then, the protein sequences of orthologue genes were retrieved from Phytozome v12.1. The retreived synteny map was created using iTAK - Plant Transcription factor & Protein Kinase Identifier and Classifier (Zheng et al., 2016).

Gene expression analysis in silico

The expression levels of Pvul-SBP genes examined in special tissue libraries of plants at different stages of growth, including root_10 (10 days after planting), nodules, root_19 (19 days after planting), young pods, stem_10 (10 days after planting), stem_19 (19 days after planting), green mature buds, leaves, young triloliates, flower buds and flowers were retrieved from Phytozome Database v12.1 (http://phytozome.jgi.doe.gov/pz/portal.html#!info?alias=Org_Pvulgaris). FPKM (expected number of fragments per kilobase of transcript sequence per millions base pairs sequenced) units were used for the expression levels *in silico*. FPKM values were log2 transformed and the heatmap was produced with the algorithm CIMMiner (http://discover.nci.nih.gov/cimminer).

Results and discussion

Identification of SBP gene family in common bean

Sequences of SBP proteins in the *P. vulgaris* genome were downloaded from Phytozome database v12.1 (www.phytozome.net) using keyword searching with Pfam Accession Number (PF03110) retrieved from Pfam Database. Subsequently, SBP domains were analyzed by searching HMMER and Pfam databases in candidate Phvul-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

SBP proteins and the redundant sequences were discarded after the confirmation. A total of 23 candidate *Phvul-SBP* genes in *Phaseolus vulgaris* genome was discovered and some descriptive information was given in *Table 1* which involves the information about chromosomal location, the coding sequences (CDS, lengths), amino acid (length), molecular weight and number of isoelectric point (pI). As shown in *Table 1* and *Figure 1,* all of the non-redundant *Phvul-SBP* genes were distributed on 10 chromosomes of P. vulgaris. While the lowest number of *Phvul-SBP* genes was obtained on chromosome 11 (one *Phvul-SBP* gene), the highest number of Phvul-SBPs was found on chromosome 3 (4 *Phvul-SBP* genes) (*Fig. 1*). The CDS of the *Phvul-SBP* genes extended from 378 (*Phvul-SBP-4*) to 3210 (*Phvul-SBP-9*). The length of Phvul-SBP proteins extended from 125 (Phvul-SBP-4) to 1039 (Phvul-SBP-9) amino acids (aa). pIs of Phvul-SBP proteins were among 5.8 (Phvul-SBP-15) and 9.46 (Phvul-SBP-12) ranging from acidic to alkaline, and the molecular weight of Phvul-SBPs were between 14756.09 Da (Phvul-SBP-14) and 114838.01 Da (Phvul-SBP-9) (*Table 1*). *SBP* gene family which is essential to plants was detected and classified in various species such as *Arabidopsis* (Rhoades et al., 2002), rice (Xie et al., 2006), tomato (Salinas et al., 2012), *Citrus* (Shalom et al., 2015), *Gossypium raimondii* (Ali et al., 2017), wheat (Wang et al., 2015), maize (Mao et al., 2016) and grape (Hou et al., 2013).

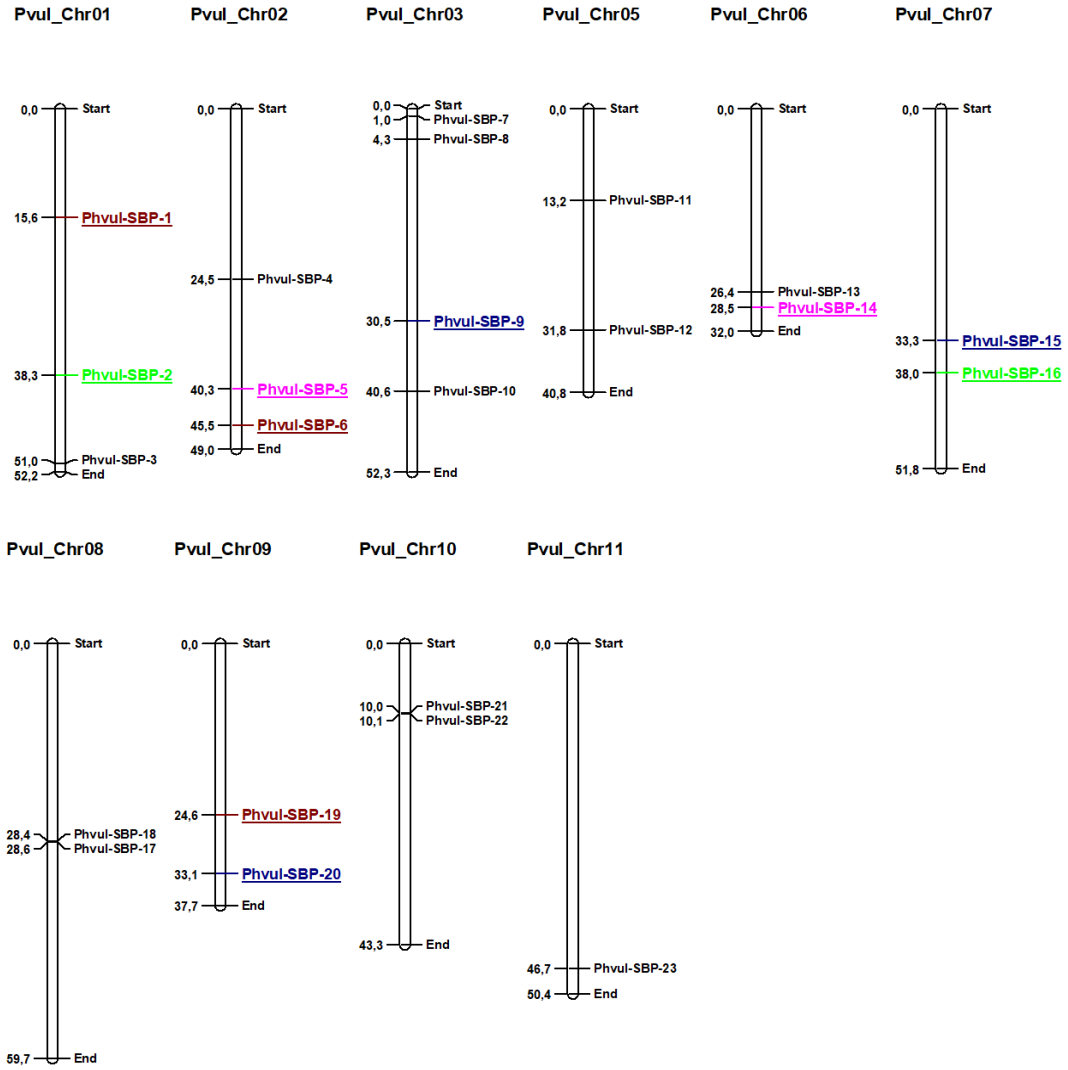

Figure 1. *Distribution of Phvul-SBP genes on common bean chromosomes. Similar colors present segmentally – duplicated genes*

Several paralogous gene pairs are originated from gene duplication events (Cannon et al., 2004). Furthermore, organisms adapt to different environments via gene duplication events throughout processes of development and growth (Bowers et al., 2003; Gu et al., 2003). Plant genomic structure, which can occur by independent events involving in segmental or tandem duplications, is one of most important characteristics of gene duplication (Flagel and Wendel, 2009). Based on significance of gene duplications on evolution of gene families in plants, the gene duplication events of putative *Phvul-SBP* genes in common bean genome have been examined. After the duplication analysis, six segmentally-duplicated gene couples (*Phvul-SBP-1*/*Phvul-SBP-19*, *Phvul-SBP-2*/*Phvul-SBP-16*, *Phvul-SBP-5*/*Phvul-SBP-14*, *Phvul-SBP-6*/*Phvul-SBP-19*, *Phvul-SBP-9*/*Phvul-SBP-15* and *Phvul-SBP-9*/*Phvul-SBP-20*) among the identified 23 *Phvul-SBP* genes in common bean (*Table 2*) were detected. According to the gene duplication analysis, none of the gene couples have been found to include tandem repeats.

The Ka/Ks ratio has been become a popular parameter for genome-wide identification researches of gene families in recent years. This ratio gives a worthwhile information about the selective evolutionary pressures that are acting on that gene (Yang and Swanson, 2002; Kryazhimskiy and Plotkin, 2008). According to Juretic et al. (2005), a Ka/Ks larger than 1 reflects the positive selection during the evolution of the gene sequence. Additionally, a Ka/Ks lower than 1 indicates duplications have undergone purifying selection and a Ka/Ks = 1 means neutral selection in duplication events. As displayed in *Table 2,* the divergence time of segmentally duplicated Phvul-SBP gene pairs extended from 32.77 to 101.61 million years (MYA). Except for one, all of the duplicated Phvul-SBP gene pairs showed Ka/Ks ratio lower than 1 which reflects the occurrence of purifying selection after the duplication events. The Ka/Ks ratio (=1) of Phvul-SBP-1/Phvul-SBP-19 indicated the predominance of neutral selection during duplication events of this gene pair (*Table 2*).

Table 2. *The Ka/Ks ratios and identified divergence times for the segmentally duplicated Phvul-SBP proteins*

Paralogous gene pairs		Ka	Ks	Ka/Ks	Duplication date (MYA)
Phvul-SBP-1	Phvul-SBP-19	0	0	1	-

Phvul-SBP-6	Phvul-SBP-19	0.2174	0.7511	0.2834	44.39
Phvul-SBP-9	Phvul-SBP-15	0.3989	1.7193	0.1484	101.61
	Phvul-SBP-20	0.1836	0.5544	0.2868	32.77

Phylogenetic analysis, gene structure and conserved motifs of Phvul-SBPs

To discover the relationships between Phvul-SBP proteins, a phylogenetic tree of SBP domain proteins in *Phaseolus vulgaris*, *Arabidopsis* and *Glycine max* was structured using amino acid sequences with contributed bootstrap values (1000 replicates; *Fig. 2*) via neighbour joining method. Phvul-SBP proteins were clustered into twelve groups, A - C9 (*Fig. 2*). Similar coding and exon-intron sequences were observed in most of the Phvul-SBP genes which were found in the same subgroup in phylogenetic tree.

To investigate conserved motifs in Phvul-SBP proteins, MEME (v5.0.1) was used. MEME software finds the most statistically significant (low E-value) motifs based on its log likelihood ratio, its width and number of occurrences, the background letter frequencies and the size of the training set. Motifs with E-values larger than 0.01 (1e-2) are possibly just statistical artifacts, and not real motifs (Bailey et al., 2009).

A total of 20 conserved motifs were described (*Fig. 3* and *Table 3*). The lengths of identified motifs were between 8 and 50 amino acids. A total of Phvul-SBP proteins consist of Motif 1 which is one of the two motifs which have SBP domain among all motifs. A similar result was found in Ali et al. (2017).

Twenty-three common bean SBP gene structures were investigated and the estimated number of exons among the 23 *Phvul-SBP* genes extended from two to 10 (*Fig. 4*). As seen in *Figure 4,* these genes were also clustered into twelve groups in terms of the gene structure analysis in line with the phylogenetic tree of Phvul-SBP proteins shown in *Figure 2*. Deep examinations of the segmentally duplicated gene pairs, which have

same exon–intron structures and similar motifs, would contribute to a comprehension of the different roles they play in development and growth. In a recent research, it has been reported that the gene pairs, which have similar motif sequences and orders could show similar functions in moso bamboo (Pan et al., 2017). These gene pairs could be originated from an ancestor in evolutionary process.

Comparative and synteny events among SBP genes of P. vulgaris, Arabidopsis thaliana and Glycine max

To calculate evolutionary relationship of the *SBP* gene family in *P. vulgaris*, *Arabidopsis* and *Glycine max*, the synteny events among SBP protein sequences of these plants are shown in *Figure 5*.

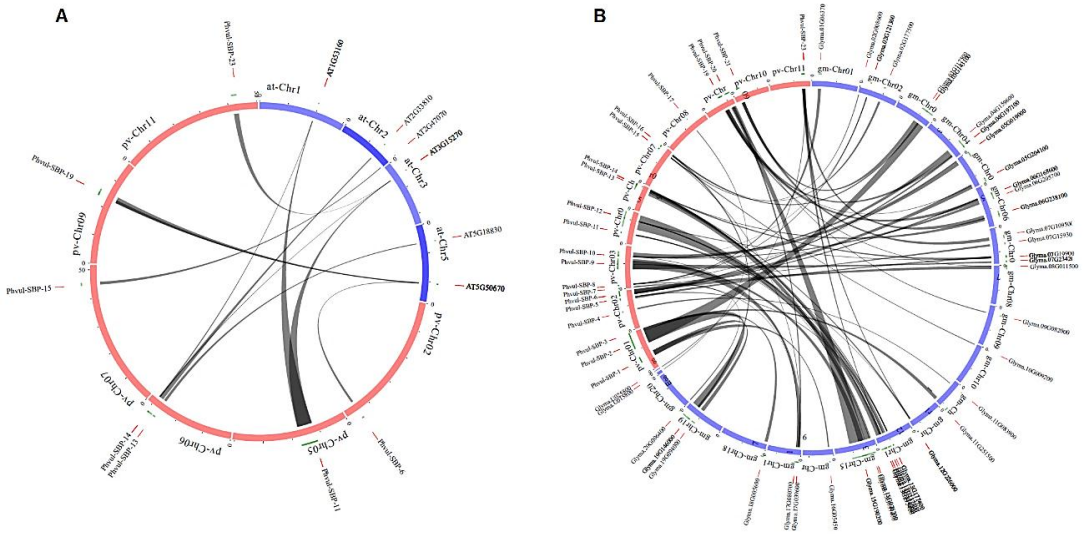

Figure 5. *Genome wide synteny analysis of SBP genes.* ***A.*** *Comparative map between P. vulgaris and A. thaliana.* ***B.*** *Comparative map between P. vulgaris and G. max*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_54675480
© 2018, ALÖKI Kft., Budapest, Hungary

This synteny analysis was established on SBP proteins of 6 *Arabidopsis* and 40 *Glycine max*. Since *P. vulgaris* and *G. max* were closely related genomes (Schmutz et al., 2014), *SPB* genes of these plants showed high similarity. However, 22 *Pvul-SBP* genes were matched to 40 *G. max SBP* genes distributed on all chromosomes of *G. max*. In a recent study, it was reported that some *Arabidopsis SBP* genes were syntenic to those of diploid cotton genes and these genes showed an evolutionary relationship (Ali et al., 2017). In another study, the synteny analysis between apple and *Arabidopsis* demonstrated that 11 apple and *Arabidopsis* genes were located in the duplicated genomic regions. In the same study, it was notified that duplications such as segmental, tandem and genomic duplications have important roles in evolutionary processes (Li et al., 2013).

Expression profiles of Phvul-SBPs in different tissues

In this research, a common mRNA analysis of *Phvul-SBP* genes were performed via publicly available expression data in Phytozome v12.1 online plant genomics resource (https://phytozome.jgi.doe.gov). The heatmap shows the expression variance between identified 21 *Phvul-SBP* genes in different plant tissues (*Fig. 6*).

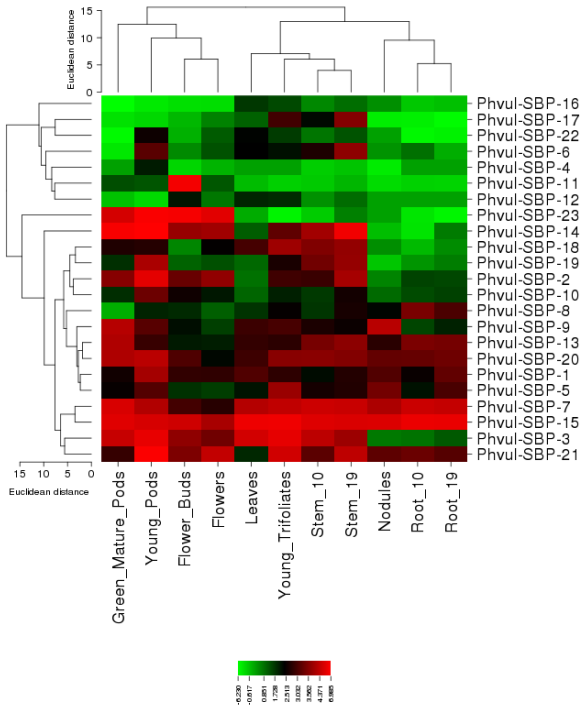

Figure 6. *Hierarchical clustering of expression profiles of Phvul-SBP genes in 11 different tissues of common bean. Heat map was drawn with CIMminer online tool*

As seen in the *Figure 6,* the *Phvul-SBP-16*, *-17*, *-22*, *-6*, *-4*, *-11* and *-12* genes revealed relatively low expression levels in almost all tissues including green mature pods, young pods, flower buds, flowers, leaves, young trifoliates, stem_10, stem_19, nodules, root_10 and root_19. The rest of the *Phvul-SBP* genes exhibited relatively high mRNA levels in most of the developmental stages of common bean. *Phvul-SBP-14*, *-15* and *-23* were the genes which exhibited the highest expression levels at least in one of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_54675480
© 2018, ALÖKI Kft., Budapest, Hungary

certain tissue types among all genes. Additionally, some of the genes were only up- or down-regulated in certain tissue types. For instance, *Phvul-SBP-1*, *-3*, *-5*, *-7*, *-8*, *-9*, *-13*, *-15*, *-20* and *-21* were highly expressed in root tissues. *Phvul-SBP-1*, *-2*, *-3*, *-5*, *-7*, *-8*, *-9*, *-10*, *-13*, *-14*, *-15*, *-18*, *-19*, *-20* and *-21* were highly expressed in stem tissues. *Phvul-SBP-1*, *-2*, *-3*, *-5*, *-7*, *-8*, *-9*, *-10*, *-13*, *-14*, *-15*, *-18*, *-19*, *-20*, *-21* and *-23* were highly expressed in floral organs. The other *Pvul-SBP* genes were low expressed in these tissues of *P. vulgaris*. Similar results were obtained in grapevine genome (Wang et al., 2010). *SBP* genes in this genome were up or down regulated in various tissues such as root, leaf, flower and fruit. *SBP* genes in *P. vulgaris* were suggested to express in different tissues.

Conclusion

In this study, genome sequences, identification, conserved motifs of 23 *Pvul-SBP* genes were identified in *P. vulgaris* genome. The Pvul-SBPs were divided into twelve classes and 23 *Pvul-SBP* genes were distributed across 10 chromosomes with different densities. Also, expression levels of 23 *Pvul-SBP* genes in different plant tissues such as roots, leaf and floral organs were determined using *in silico* analysis. To the best of our knowledge, this is the first report of a genome wide analysis of the common bean SBP gene family. This study would provide beneficial information for understanding the classification and functions of the *SBP* genes in common bean.

Abstract. Proper management of watersheds is one of the most important methods for using water and soil resources. In the last few decades, accurate and timely estimates of the quantitative and qualitative runoff status are one of the major concerns of large-scale management. The aims of this research are a simulation of monthly runoff, sensitivity analysis, optimization of sensitive parameters, investigation of the effect of land use change over the last four decades on the quantity and quality of the Maroon River (southwest of Iran) at the exit point of the Maroon Watershed (Idnak) in Iran using the SWAT model. For this purpose, the semi-distributed SWAT model and the SUFI2 program were used in the SWAT CUP software package for sensitivity analysis, calibration, validation and uncertainty analysis. In this research, the map of land use change and soil mapping and vegetation cover in the Maroon watershed were first identified over the course of the four decades between 1970 and 2010, using TM and ETM satellite measurements in Landsat. Observations of the Idnak Hydrometer Station were used as the base station during 1970 to 2010 over a period of four decades. Comparison of the effects of land use management options on various components of the hydrological cycle as well as different runoff rates show that if the pessimistic scenario occurs, and with the continuation of the destructive trend in land use to the retreat, values of runoff will increase and there will be more permeability and the drainage will go down to deeper aquifers.
Keywords: *watershed, SUFI 2, management, Iran*

Introduction

The proper management of watersheds is one of the most important methods for optimal use of water and soil resources. For this purpose, comprehensive information of different methods of management and executive is needed. In our country, more catchments, especially mountainous watersheds lack sufficient numbers of measurement stations which will cause any development planning and management schemes to fail. To tackle this issue, practitioners and researchers in water and irrigation management have offered solutions such as empirical formulae and mathematical models. So far, no optimal solutions have been provided. It is believed that simulation of hydrological phenomena of basins could be the optimal solution (Rostamian et al., 2010). During the past few decades, correct and timely estimates of the quantity and quality of runoff are one of the concerns of senior management. Watershed management, water resources management, especially management of reservoir exploitation and water supply network are faced with challenges. Generally, to understand and predict the processes of generation and transmission to the output stream basin is one of the most fundamental discussions in

hydrology (Salmani, 2011). Rainfall-runoff simulations are one of the key issues considered in hydrologic sciences and environmental management. In recent years, the need for water is growing rapidly. There is an increasing demand for water resources to integrate, sustain and manage basins as well as the proper understanding of water balance in basins (Anwar, 2010). Therefore, hydrologic models have been developed to simulate rainfall-runoff, river flow analysis and to better understand the factors affecting the hydrological cycle in watersheds (Alavinia et al., 2010). These basin hydrological models are vital tools to better understand different hydrological processes, to optimize management strategies and evaluate the impact of land use changes in different time periods (Spruill et al., 2000). In these models, studying the processes of rainfall - runoff is difficult and there are uncertainties due to the influence of various parameters. These models are accurate in predicting the hydrological response of basins and can be improved with localization of optimal parameter values (Karlinger et al., 1988). The purpose of the model is to find, and as a representational image, to simply represent the facts and phenomena. The mathematical model describes the behavior of a system mathematically. These models have many applications, especially in the natural sciences and engineering systems (Mirabzadeh et al., 2005). Due to the temporal and spatial variations in the water cycle factors affecting natural watershed, identifying all components through analysis or theory of the water cycle is often impossible and time consuming. Hydrological models have been developed to overcome this problem and have been used in watersheds around the world. Since the results of some of these models matched the actual values, there has been an increase in using these models in watershed studies. With access to distributed spatial information, distributive hydraulic models are increasingly used to simulate the various hydrological processes in order to identify and manage natural and human activities that affect the watershed systems (Zhang et al., 2008). SWAT is a model in catchment basin scale that is provided by Jeff Arnold. The SWAT model is a multi-purpose simulation model for watershed management. This model is developed using several other models to estimate and predict the impact of different land management practices on water levels, sediment and chemical-agricultural watersheds within complex and large data without soil, land use and conditions management in the long run. This model has been used successfully to simulate the runoff, sediment and nutrient loads to many basins throughout North America, Asia and Europe (Duan, 2009). The review of the Omani studies showed that to predict the effects of changes in land use and conservation activities on the amount of suspended sediment Gharehsou basin with an area of 5739 km^2 using SWAT2000, this model can be used as an effective tool to review basin hydrological components used in response to corresponding changes in land use (Omani et al., 2007). In basins of West Africa using SWAT model caused changes of conditions in changing areas of forest, grassland and shrub land in relation to agricultural land or natural hydrology in urban areas resulting in areas becoming watershed transformations and resulting in an increase in the volume of surface runoff, groundwater resources and water-based power reduction as well as changes in the amount and intensity of river erosion and sedimentation (Liu, 2009). Wang et al. showed by modeling the effect of different land use options in a basin in China that it is evident that land use has different effects on the amount of runoff and underground water basin and converts forest land to pasture land within the basin leading to an increase in annual runoff and reduction in permeability of the soil and groundwater due to reduced transpiration reduction in basin (Willems, 2009). Palamuleni (2011) examined time changes in land cover and land use and its effects on river flow regime Prshayr during the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_54815502
© 2018, ALÖKI Kft., Budapest, Hungary

two time periods (1989 and 2002). The SWAT model (Phomcha et al., 2011) showed that the result of converting forest land to pasture, farmland and residential areas are effective on the rate of runoff and concentration time (t_c). Salmani (2011) simulated the effects of changes in land use on runoff in the Qazzaqli catchment in Golestan province using the SWAT model and showed that this model can be used as an effective tool in the study of the hydrological basin Qazzaqli catchment in components used in response to changes in land use (Salmani, 2011). Land use changes in a basin could significantly impact the hydrological cycle and water resources in the basin, therefore effects of land use changes on watershed hydrology are a guideline to determine appropriate strategies for sustainable development of water resources within a watershed. Natural earth ecosystem exploitation along with changes in land cover and land use especially in ecosystem environmental conditions affect hydrological responses to such as floods, erosion and sedimentation. Land use and land cover is one of the main factors in water resources management, erosion, and sedimentation basin. This complexity is not easy to study and analyze. Considering the importance of the subject and to aid in improved management of water resources, this study will utilize the Maroon Basin model and will be provided with SWAT as semi-distributed hydrological model. Accordingly, weather, soil, topography, observational discharge outlet of the basin, changes in land use and types of vegetation factors affecting the quantity and quality of water resources at the basin scale will also be investigated.

The studied area

Maroon basin is located in the southern and south-western domains of Central Zagros 50° 05' East longitude and North latitude are 30° 39' and 31° 21', respectively. The study area is supervised by the Regional Water Company in Kohgiloyeh and Boerahmad Province. The area of this range is 3801 km^2. The maximum height of this area is 3403.4 m and the minimum is 397 m. The highlands area is 3703.8 km^2 and the plain area is 196.9 km^2. The average height in highlands is 1689.22 m and in plains it is 984.32 m (Water Resources Management Co of Iran, 2009). The climate of the affected area is of low latitude with elevation changes, and is adjacent to the Persian Gulf in the southern areas. The geology of Maroon basin consists of outcrops of sandstone, conglomerate and alternation of colored marl and silty limestone. The type of precipitation at higher elevations is in the form of rain and in the form of snow at lower altitudes. Average annual precipitation in this basin is 150 mm in the coastal plains, and 900 mm in elevations. *Figure 1* shows the location of the studied area that is characterized by 7 sub-basins with numbers 1-7.

Materials and methods

The SWAT model is a continuous and semi-distributed physical model that is used to simulate complex hydrological processes in watersheds with respect to changes in soil, land use and weather conditions for long periods of time. This model requires comprehensive information, including topographic maps, digital elevation model (DEM), land use, utilized soil properties, management information, meteorological data and other watershed characteristics to simulate watershed hydrological process. The topography defined by a digital elevation model (DEM) represents the height of each point in each region with specific spatial resolution that is displayed by a cellular network. DEM map of the area with 1: 50000 scale is provided by the Forest

Rangelands and Watershed Organization. Geographical coordinates were then entered into the model. In this study, the DEM map is used to specify the basin and sub-basins surface drainage pattern analysis. Sub-basin parameters such as length and width of the channel slope are extracted from the DEM map. Maroon watershed DEM map is shown in *Figure 2*.

Digital River network with SHAPE file format was introduced to the model as shown in *Figure 3*. The database of drainage network is added to the DEM map to determine the state of the river network. Map drainage network is used to draw more precise drainage pattern details in the event that the DEM basin used is not able to specify this pattern.

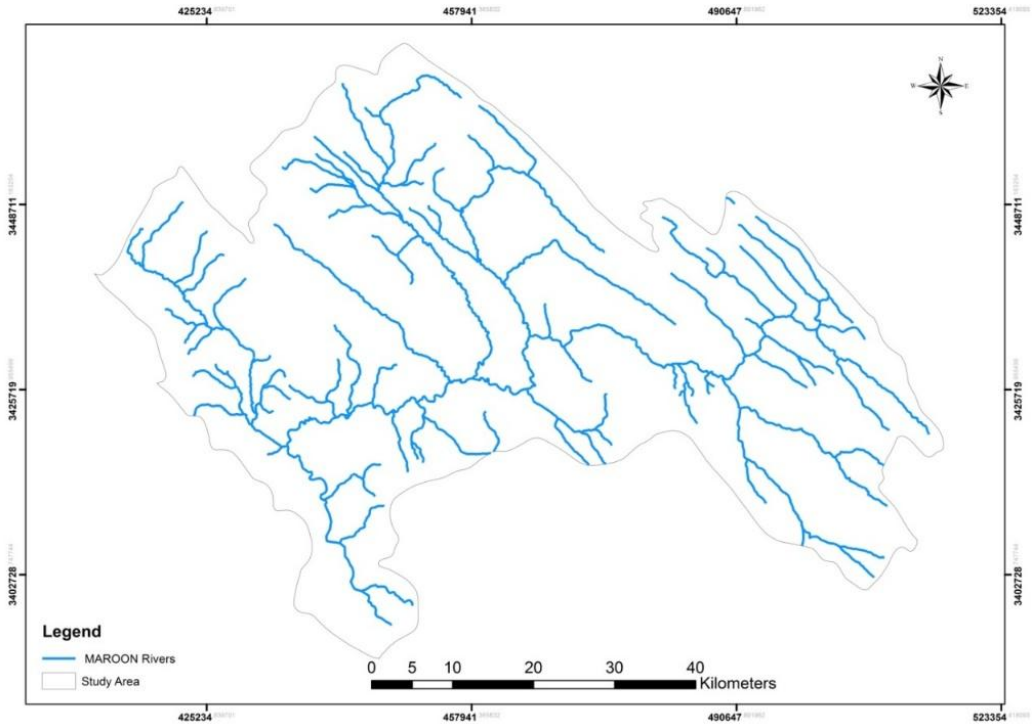

Figure 3. *Network River Maroon Basin*

One of the requirements for each hydrological basin simulation is the map of land use and vegetation. In the simulations with the SWAT model, the land use map is one of the essential items. Land use is one of the most important factors that affect the amount of runoff, evapotranspiration and surface erosion in the basin. Land cover information is important for many activities including land use planning and land management. Nowadays, satellite images and remote sensing techniques have been widely used in land use mapping to provide updated data, high capability analysis, variety of forms, digitization and processing in all sectors, including agriculture, natural resources and land use mapping as base maps. In the current study aimed at extracting Maroon watershed land use, initially, the images of land sat satellite for 1980-1990 and 2000-2010 were prepared. Then, topographic map digitization and mosaic, slope maps, aspect and elevation from sea map were prepared to identify the area in GIS software. Subsequently, correcting and processing operations on satellite images using 30 ground control points were done using Geomatica software. Furthermore, the supervised classification map of the area was produced by combining bands 3, 4, 5, and the final map was obtained after applying the filter operation. Type of land use with a four-digit code can be identified by the model. Land use map of the study area was classified again by the SWAT model as shown in *Figures 4, 5, 6* and 7. Land use changes per hectare during four decades clearly shown in *Table 1*.

Soil texture map of the study area

Soil data is the most basic information required for this model. The SWAT requires various physico-chemical properties of the soil, such as soil texture, available moisture content in the soil, hydraulic conductivity, bulk density, organic carbon content and model of different soil layers to simulate the characteristics of the basin. The map of the re-categorized soil map of the Maroon watershed land use and the map of vegetation during four decades from 1980 to 2010 were prepared using satellite images shown in *Figure 8*. Considering that 100 years of time is required to change the texture of the soil and the timeframe for this research is 40 years the soil texture map is identical in four decades and the model of 2010 is used in the model.

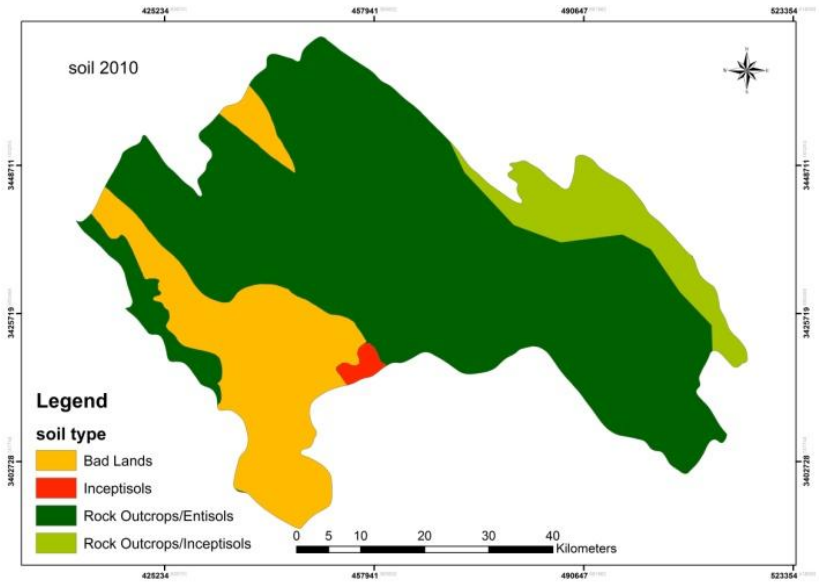

Figure 8. *The soil maps of the study area during 2010*

Meteorological and hydrological data

Climate as the source of input energy, determines the humidity of basins and controls water balance as well as determines the relative importance of different components of the hydrological cycle. The SWAT model requires information on basic daily climate variable rainfall, maximum and minimum temperature, solar radiation, relative humidity and wind speed for simulating the conditions of the basin. This information may be read as an input file, observational values or be created by the SWAT model by using monthly average values summarized in the weather generator input file (userwgn.dbf).

Hydrological data are required for sensitivity analysis, calibration, and validation analysis of hydrological models uncertainty. Hydrological data used in this study consist of monthly and daily discharge values at Idnak stations located at the basin output. This data was collected from Khuzestan Province Regional Water Organization. Idnak gauging stations are used as base stations for the runoff changes. This data is converted into the format required for the model. The simulation is done automatically. Then, upon parameter optimization, the simulated value is closer into the observed data. *Figure 9* shows the position and number of meteorological and hydrometric stations in the studied area.

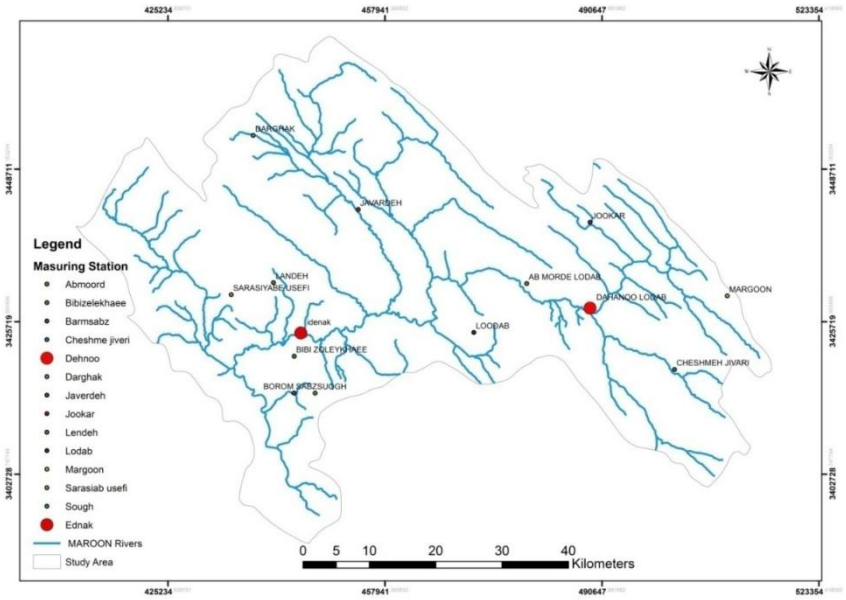

Figure 9. *Position of meteorological stations in the studied area*

Running the SWAT 2012 model

In this study, a semi-distributed SWAT model 2012 with a GIS extension was used for analysis and simulation. Basically, the SWAT model database is designed for the conditions of the United States of America. So to use this model in other areas the input information should be modified including data related to soil (usersoil.dbf), land (landuse.dbf), weather generator stations (userwgn.dbf) as well as management information. Data related to GIS development of the SWAT model is identified with unique functions to determine the Basin Hydrological Response Unit (HRU). The model used the data digital elevation model data to automatically divide each area based on current conditions and then accumulated the data into several sub-basins. In general, there are 25 sub-basins in the Maroon watershed with 21 sub-basin located at the outlet. Also the number 5 sub-basin with an area of 27.5 km^2 is the smallest sub-basin. The sub-basin number 2 with an area of 278.36 km^2 is the largest sub-basin. The hydrological response units are integrated lands that are located within the sub-basin and in the areas where land use, soil, slope and management is homogeneous and monolithic. To determine the HRU map, the gradient map was used. Different tilt classes were obtained based on the characteristics of the study area and aimed at the DEM map. According to a wide range of sub-basins in the studied area, using several

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

slopes to a common dip for all sub-basins is a priority. The slope classes are different in each area depending on the characteristics of the topography of the area. In various studies done in this area, there is no single classification for slope classes. Thus, the user selects the slope classes based on topography. Generally, in the study area 4 gradient classes (0-2, 2-10, 10-20, and > 20%) were introduced to the model.

The sensitivity analysis of the model

Sensitivity analysis is the study of quantitative and qualitative changes based on input variables for Output Models. In other words, in this analysis, the effective variables ordered in the model is based on their role in the amount of general error. Maroon watershed, in terms of hydrological basin is very complex. Also sensitivity analysis was performed using the indicators t-stat and p-value SUF12 program in the bundle SWA CUP. Generally, higher absolute value of t-stat represents the most sensitive parameter. The closer the p-value is to zero, the more sensitive the parameter is. It should be mentioned that in this study, the parameter range has been set at default values for the Maroon watershed model.

The calibration model

After identifying the most critical parameters affecting the flow rate, calibration was performed to describe the optimal values. Calibration is the modification of input parameters, so that it is the best fit for the observed data. Inverse modeling in recent years is used as a suitable method in many branches of Earth Sciences and environmental studies. Maybe it is because direct measurement is time-consuming, expensive and often faced with limitations while measuring a few output parameters makes it easier for some of the input parameters (Rostamian, 2009). The calibration process may be performed in the form of trial and error methods (manually) and automatic (using computer programs). Automatic calibration is more optimal compared to manual methods and its implementation is easier (Liu, 2009). In this study, automatic calibration methods were used to identify the optimal values of model parameters. This process was done by changing the parameters specified in the input file and by using the qualitative evaluation model (Himesh, 2000). The calibration process was conducted both on a monthly and daily basis and based on the Maroon basin flow. At first, the model was simulated for a suitable period (the period of warming-up) and based on the initial values obtained for a given period which was implemented in the model. In total, 27 parameters were selected based on various studies conducted in this area that upon sensitivity analysis and identification decreased to 13 parameters, which were the most effective parameters. Reducing the number of parameters during sensitivity analysis caused reductions in the implementation time and increased accuracy by reducing the uncertainty of the model. So, after knowing the most sensitive parameter, the model was run using critical parameters affecting the discharge.

Validation of the model

When calibration is performed to check the accuracy of the calibrated model for use in estimation and subsequent management activities, the independent model using observed data was implemented (1970 and 1971 in the first decade, 1980 and 1981 in the second decade, 1990 and 1991 in the third decade, 2000 and 2001 in the fourth decade) without changing the parameters of the calibration. The model validation will

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_54815502
© 2018, ALÖKI Kft., Budapest, Hungary

be done to ensure that the calibration model on the output of all variables and conditions that affect calibration, correctly evaluates models of the relevant periods. Here, the same validation method and calibration process was done using the software package SWAT CUP and SUFI2program.

Model performance evaluation

To evaluate the performance of the model to simulate hydrological processes, it can be compared and simulated using different statistical models with observational data (Green, 2006). It is very difficult to only investigate one statistical method for the model's performance, therefore to evaluate the efficiency of the model; several statistical methods were used simultaneously. Williams used the correlation coefficient (R2) plus the efficiency factor Nash - Sutcliffe (ENS) proposed as a way to assess and analyze the data simulated (Willems et al., 2009). In this study, the SWAT model is used for evaluating performance.

Results and discussion

The first model was run by using input data and relevant default data. *Figures 10-17* show the output in the initial run based on monthly time period. As shown in these figures, the simulated basin in the initial run is very weak. In order to check the quality of simulation in the initial run, the Nash-Sutcliffe (E_{NS}) coefficients of correlation between observed and simulated values were used.

Sensitivity analysis

After the initial run off, sensitivity analysis was carried out on the output model of the basin. In sensitivity analysis, the effect of various parameters on model output based on objective function (in this study, Nash was considered as the objective function) were clearly identified. For the sensitivity analysis and to determine the relative importance of each model parameter, the SWAT, SWAT CUP and LH-OAT methods were used in addition to the SUF12 program during calibration. Sensitivity analysis in the LH-OAT method presented is based on 27 selected parameters. Also, the identification of sensitive parameters on a monthly basis was conducted using SUF12 programs on 27 parameters as shown in *Table 2*.

The results of the sensitivity analysis carried out using the LH-OAT method on the 27 parameters indicated that GWQMN, RCHRG-DP, CN2 SMFMN ESCO flow are the most sensitive parameters on a monthly basis. The most sensitive parameters affecting the discharge area of Maroon on a monthly basis using the SUF12 program software are SWAT CUP SOL-K, CN2 ESCO, SMFMN, RCHRG-DP, REVAPMN, GWQMN, SLSUBBSN ALPHA-BNK, excluding the most critical parameters affecting the discharge of Maroon River. In general, due to the different regional and climatic conditions, sensitive and effective parameters are different for the studied region on a daily and monthly basis (Sangjun, 2007). As seen in all methods and based on the daily and monthly activities, CN2 is the most sensitive parameter. The CN2 Parameter (number of CSC curve for the average moisture conditions (II) and the slope 5%) is a function of the soil permeability, land use and former humidity conditions. The value of this parameter is different for the various soil types, land use and for each sub-basin. Generally, increasing the amount of CN2 increases runoff volume. The high sensitivity of this parameter indicates the important role of land use in the amount of runoff from the basin. Also, most of the region is mountainous, which increases the amount of runoff by reducing the amount of permeability. In this case, In this case more runoff is outside of catchment area. CH-N2 (Manning roughness coefficient of Main River) is an effective parameter on the routing of stream flow and is used to calculate the concentration of the watershed. High sensitivity of CH-K2 (effective hydraulic conductivity river bed) in this region indicates the presence of lateral branches in the area to form intermittent or seasonal activities that impact the flow of the main river

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

(Beven, 2001). This basin has rigid seasonal streams and numerous rivers, especially in semi-arid areas that in the case of rain and flooding, has considerable impact on the outflow at Idnak gauging stations. SOLK (saturated hydraulic conductivity of soil layers) is scaled to facilitate movement of water in soil layers that represent a balance between water flow and hydraulic gradient. Other important parameters on the HRU level include SUBBAN (average length of the slope of the land in each HRU) that may have the same value for each HRU as well as the ESCO parameter (evaporation from soil coefficient offsetting) which is an important parameter influencing the hydrological cycle surface. Generally, decline in this parameter increases surface runoff base flow and vice versa. ESCO reduction causes the transmission of more water from the lower layers to the upper layers of the soil and consequently the amount of surface runoff and base flow will increase. Effective parameters on groundwater are effective on surface water. These parameters show that the river flow is mainly controlled by groundwater flow. GWQMN (minimum shallow water table depth required for the reverse flow) is relevant to current production base. Considering the depth of the water in the aquifer level, groundwater flow occurs when the water level in the aquifer level is equal to or greater than GWQMN. This parameter has an impact on base flows and affects the flow of the river (Reungsang et al., 2005). RCHRG-DP (recharge percentage deep aquifer from shallow or confine aquifer) represents the percentage drop of water from the root zone that feeds the deep aquifers. The high sensitivity of this parameter in the studied area entails the probability of water transfer from the shallow aquifer to the deep aquifer and may create problems in water balance and consequently for the region (Sanjay, 2010). REVAPMN (minimum depth of water table levels in shallow aquifers to climb through the capillary or recharge deep aquifer) is representative of the water movement to the unsaturated zone and deep aquifers. ALPHA-BMK (alpha factor for storing base flow the sidebar) represents the side which is affected on the main channel or sub-basin within the range.

Model calibration

After the initial run the SWAT CUP software package and SUF12 programs were implemented for calibration and uncertainty analysis to determine variable Maroon River discharge areas in the basin outlet. According to various studies conducted in this field, about 27 parameters are effective and important for calibration. Varying ranges of parameters were set according to their default model and based on hydrometric station of Idnak. Each parameter was entered in the model within the limits of permitted changes, and implemented in order to optimize the output of the simulation model. Then, sensitivity analysis reduced the number of parameters. A total of 13 known parameters from the 27 selected primary parameters were more effective and were entered in the final stage of the model. Calibration was performed on a monthly basis during various stages for various parameters. Finally, the optimal values of parameters were determined to simulate the monthly watershed runoff. *Table 3* shows optimal values of parameters that affect the rainfall-runoff (amount or percentage changes) upon simulation and calibration of the parameters after the 2000 runoff model. Also *Figures 18-25* show calibration results based on a monthly time period using the SUF12 program and also the correlation coefficient between observed and simulated runoff model.

Validation of the model

In this research, Idnak hydrometric station was an aid and supplement for computational parameters required for the SWAT model during calibration and validation. In accordance to studies conducted by Omani et al., two-thirds of the available data for calibration and one-third was used for validation. Statistical and graphical simulation results indicate acceptable water flow for the period of calibration results at this stage. For validation of the model, optimized parameters were used in the calibration stage from the SWAT CUP software package and the SUFi2 program.

Model evaluation

To evaluate the performance of the SWAT model in the simulation of monthly discharge at Idnak hydrometric station, indicators were presented during calibration and validation based on the criteria for evaluating the accuracy of the simulation. Numerous researchers have recommended using several methods for parameter optimization and uncertainty analysis instead of one particular method (Abbaspour et al., 2004), (Abbaspour et al., 2007). This is the reason that for this study, the SUFi2 program was used in the form of an extension in the SWAT model bundle within the SWAT CUP software package. The usefulness of model was examined by coefficients such as p-factor, r-factor, R2, ENS, bR2, MSE and RMSE in the watershed outlet (*Table 4)*. In this study, the Nash-Sutcliffe efficiency was used as an objective function for the model calibration and verification. P-factor index in watershed Maroon is from 0.72 to 0.92 for the monthly period variable. The greater the index, the more effective the simulation is. The value of this parameter in these areas is low which indicates great uncertainty in forecasts. One of the reasons for low p-factor is that the current value is greater than the values predicted by the model base. The results for the observed data are located outside the 95% prediction uncertainty ranges. Lack of information about the uptake and upstream water use is a reason for the incompetency of the base flow prediction model. Therefore, in order to reduce uncertainty in models, there is a need to use comprehensive data on water management in the studied area. R-factor is the average

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

thickness of the band 95 PPU which is divided by the standard deviation measured data. The less the value of this index, the less the simulation is done with greater precision so that the optimal value is zero. This index regarding Maroon basin is a variable for monthly periods showed values of 0.93 to 90.2 during the calibration. Relatively small values of p-factor and r-factor in this basin on a monthly basis indicate good calibration and runoff in the basin and there is lower prediction uncertainty. The value of R2 (R2 coefficient multiplied by the coefficient of linear regression) using the SUFI2 program for calibration for the monthly period is 0.75. The value of this coefficient for the validation period is 0.82 on a monthly basis. The Mean Square Error (MSE) is scaled to consider the random mean difference between simulation and observations. MSE and RMSE Square represent the value of these parameters which can be varied from zero to infinity and the optimal value is zero. In addition, these factors along with E_{NS} and R_2 coefficients were used to determine suitability. The optimal value of R_2 is one. Although, there is no specific rule as reported by (Santi et al., 2001) that 0.5 is not acceptable for hydrological models. According to *Table 5,* the index in the SUFI2 program at calibration period is 0.84 and for validation period 0.82 on a monthly basis. In general, according to the simulation results, the accuracy of the model for the basin hydrological process simulation was relatively good. Finally, this model can be used for future analyses of basins and sub-basins and to check the different components of the hydrological cycle.

Table 4. *The statistical coefficients evaluation of the accuracy of the model to simulate the monthly runoff during calibration and validation*

SUF12		The statistical indices
Validation	**Calibration**	
0.92	0.79	P_factor
2.91	1.51	R_factor
0.86	0.85	R^2
0.82	0.86	E_{NS}
0.829	0.654	bR^2
82.07	58.88	MSE
9.05	7.6	RMSE

Conclusion

One of the specific applications to examine different components of the hydrological cycle is to utilize the SWAT model based on different scenarios. The results of this study states that SUF12 program and the basic monthly runoff curve number are the most sensitive parameters. On the other hand, there is a direct relationship between this parameter and land use. Parameter CN2 (primary SCS Curve Number for average moisture conditions (II) and the slope 5%) is a function of the soil permeability, land use and previous humidity conditions. The value of this parameter for different soil types and land use is different for each sub-basin. In general, increasing the amount of CN2 increases the volume of runoff water and reduces power losses, waterborne rivers and underground water resources, soil erosion and sediment changes (Setegn et al., 2010). The high sensitivity of this parameter indicates the important role of land use in these areas in the amount of runoff from the basin. A comparison of the effect of land

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_54815502
© 2018, ALÖKI Kft., Budapest, Hungary

use management options on different hydrological cycle components show different amounts of runoff over the past four decades. A pessimistic scenario occurs with the continuing damage to the state in land use regression and various increases of runoff amounts which decrease permeability and gullies to the shallow and deep aquifers, stream sub cortical and results in actual evapotranspiration. *Figure 26* shows a comparison of the flow surface runoff, base flow and susceptibility of model to CN.

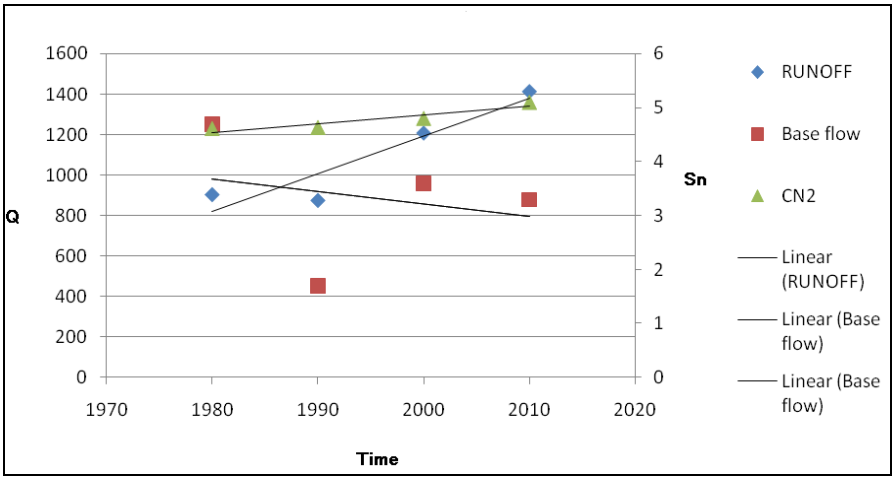

***Figure 26**. Comparison of the flow surface runoff, base flow and susceptibility of model to CN*

As evident in each scenario, by changing land use, changes in runoff peak values should entail a positive trend for reducing the negative trend for an increase in peak flow and peak values. This is due to change in the type of vegetation, and the result is a change in the runoff curve number. In this case, by reducing the permeability, greater quantities of rainfall run off the surface. Thus, the hydrological response basin in a state of regression and degradation is more severe than in the user regenerative mode; Hence, the need to maintain the current state of the basin and improving land use is one of the basic strategies for managing surface runoff.

Abstract. Some herb plants can be adapted to green roof systems when provided with better growing conditions such as irrigation. The aim of this study was to determine the effects of different amounts of water retentive, hydrophilic polymers used in green roof substrate mixtures, on the growth of *Agastache rugosa*. Coir dust and perlite were mixed at a ratio of 80 to 20% (coir dust to perlite, v/v) (termed C_4P_1), 50 to 50% (C_1P_1) or 20 to 80% (C_1P_4) at a substrate depth of 20 cm. Hydrophilic polymer was added to the substrate mixtures at 0 (polymer: medium (w/v), dry weight basis) (control), 0.25, 0.5, 1.0 or 2.0 $kg \cdot m^{-3}$. Our study indicated that *Agastache rugosa* can withstand extended dry conditions experienced in green roofs. Substrates C_4P_1 and C_1P_1 with high coir dust matter are not suitable for *Agastache rugosa* because of the low growth and poor ornamental quality observed in these plants, especially during the summer rainy season. For the determination of difference in growth, flower development and overwintering of *Agastache rugosa* among the different substrate conditions, Duncan's multiple range test was conducted. It was found that the addition of 1.0 $kg \cdot m^{-3}$ hydrophilic polymer to C_1P_4 significantly increased the number of inflorescences and resulted in good growth and ornamental quality during both drought and rainy seasons. Moreover, higher overwintering rate was associated with lower coir dust and hydrophilic polymer content. These results indicated that addition of 1.0 $kg \cdot m^{-3}$ hydrophilic polymer to C_1P_4 was optimal for the growth of *Agastache rugosa* in green roofs under dry and rainy seasons.
Keywords: *rooftop, hydrogel, native herb, water content, urban agriculture*

Introduction

Green roof is an environmentally friendly way to reduce urban heat island, noise and air pollution. At the same time, it can improve storm water management with delayed runoff, water quality, building's microclimate as well as aesthetic value and habitats for wildlife (Santamouris, 2014). Because of their numerous environment benefits, and more green, and open-air amenities without additional land acquisition cost, green roofs has become popular in many cities around the world. However, environmental conditions on the rooftops are often extreme compared to those on the ground, such as high temperature, strong wind, and long-term drought. Extensive green roof with light and thin layer of substrate demonstrate water deficit conditions (Dunnett and Nolan, 2004). The composition and characteristics of green roofs depend on many factors.

With the tremendous upsurge of interest in increasing the diversity of plant species in green roof systems, the edible plants were used extensively in recent year (Butler et al., 2012). It is also important to choose an appropriate substrate in which plants demonstrate drought-tolerant growth and can withstand the harsh rooftop environment.

Agastache rugosa is a perennial herb native to Korea, China and Japan that can grow to a height of 100-150 cm with quadrangular stems, displaying mauve or purple - blue flowers between June and September (Schafer, 2011). *Agastache rugose* thrives in warm and humid weather. It does grow best in full sun and well-drained sandy loam rich in organic matter, but also tolerate under somewhat poor soil and dry conditions. It can survive winter temperatures of at least -10 °C without protection. It can propagate by seeds in the spring and autumn, as well as with rooted cutting (Yamani et al., 2014). The flowers attract various species of butterflies and are also known as a valuable source of nectar for honeybees and native bees. It is also used in traditional Chinese medicine to treat cholera, vomiting, fever, headaches, colds, vomiting, nausea, and stomach problems, as well as in other eastern Asia countries (Choi and Seo, 2007).

Hydrophilic polymers (hydrogel), able to hold water several hundred times their weight, are widely used to improve the moisture of soil in the field of agriculture, horticulture and forestry (Baran et al., 2015). Since the 2000's, studies have been conducted on the application of hydrophilic polymers in green roofs, along with the development of high interest in green roofs. Hydrophilic polymers are used in green roof substrates to enhance the water holding capacity and improve the growth of plants. Young et al. (2017) revealed that coarser particle size substrates amended with 1% (v/v) dry hydrophilic polymer can significantly improve the drought tolerance of green roof plants， such as *Festuca ovina* and *Linaria vulgaris*. The growth of *Salvia officinalis* in 8 cm deep substrate mixed with hydrophilic polymer at a rate of 0.6% was the best under drought stress (Savi et al., 2014). Farrell et al. (2013) examined the impact of hydrophilic polymer addition to two green roof substrates, scoria-based and crushed terracotta roof-tile based, on the growth of winter wheat (*Triticum aestivum* L.) and white lupin (*Lupinus albus* L.). The results suggest that hydrogel addition can improve the plant available water, but had no effect on increasing wilting time. Olszewski et al. (2010) reported that the use of hydrophilic polymers increased the total porosity and container capacity of the substrate. The study also showed that hydrophilic polymer addition improved the initial plant growth of *Sedum floriferum* and *Sedum spurium*. Oschmann et al. (2007) conducted a three-year experiment with extensive green roof systems using crushed expanded slate substrates with 12 species of wild plants. The results revealed that use of hydrophilic polymers can enhance the water holding capacity and plant available water of substrates. In addition, the plants in substrates showed the best growth, especially at a concentration of 3 $g \cdot L^{-1}$, which resulted in the best coverage and regeneration. Meanwhile, our previous study found that the use of hydrophilic polymers in peat moss-based substrates significantly increased the substrate water content, but adversely affected plant growth, flowering and the visual quality of the drought-tolerant plant *Aster koraiensis* under no irrigation conditions (Xu et al., 2014). The response to hydrophilic polymers will thus depend upon the specific plant species and environmental conditions in the area. The objectives of this study were to determine the effect of different levels of water-retentive, hydrophilic polymer in three types of substrates on the growth, flower development and overwintering of *Agastache rugosa* in green roofs during the dry as well as rainy season.

Material and methods

Substrate preparation

A total of 45 square containers ((50 cm (L) × 50 cm (W) × 25 cm (H)) were installed on the flat rooftop of the Complex Practice Building in Konkuk University, Chungju, Chungcheongbuk-do, South Korea located at latitude 35°49' N and longitude 127°08' E (*Fig. 1*). Monthly precipitation was about 88.2, 110.6, 277.7, 122.7, and 153.8 mm in June, July, August, September, and October, respectively, with very little precipitation in May and November. Diurnal maximum air temperature was 35.3 °C, 31.7 °C, 34.4 °C, 34.4 °C, 31.0 °C, 27.2 °C, and 17.5 °C in May, June, July, August, September, October, and November, respectively. Minimum air temperature was 4.6 °C, 15.1 °C, 17.0 °C, 17.4 °C, 9.5 °C, 1.6 °C, and -4.5 °C, respectively.

Figure 1. *Experimental blocks on flat rooftop of the Complex Practice Building in Konkuk University, Chungju, Chungcheongbuk-do, South Korea*

From top to bottom, each container was filled with the following four layers: vegetation, growing medium, geotextile filter, and plastic drainage. A geotextile filter with good air permeability and water permeability was used to filter the substrate and separate it from the drainage layer. Plastic drainage was used to support the three layers above, to cut off roots, increase insulation, and retain excess water (Papafotiou et al., 2013). Based on the growth habits of *Agastache rugosa* and previous studies on green roof substrates, experimental substrates were formulated consisting of 80, 20, or 50% (by volume) coir and 20, 80, or 50% (by volume) perlite. Hydrophilic polymer (K-SAM, Kolon Chemical Co., Ltd., Korea) was incorporated into the substrates at concentrations of 0 (referred as control), 0.25, 0.5, 1.0, or 2.0 $kg \cdot m^{-3}$ (polymer: medium (w/v), dry weight basis) with three replicates per treatment. Organic fertilizers were

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

added to the substrates at 5% total volume to ensure that the same quantity was applied in each substrate which depth was 20 cm.

Plant material

Seedlings of *Agastache rugosa* were obtained from a commercial nursery, grown on 10 cm-diameter pots. Three seedlings of *Agastache rugosa* with consistent heights of 20 cm were transplanted into green roof containers on the 14th of May 2014. The initial height of the transplants differed by <1 cm. All plants were watered every 2 days in the first week followed by no watering when they were considered well established.

Measurement of volumetric water content of the substrate and plant growth

The volumetric water content in the top 10 cm of the substrates were monitored using a portable soil humidity tester (DM-5, Takemura®, Japan), respectively, at four locations selected randomly. Three replications were performed at 5 p.m. every week during the experimental period. Meteorological data were recorded every 30 min using an automatic weather station (Sensus, Casella Group Ltd., UK).

The growth parameters observed were plant height, leaf number of all the plants (n = 9) in June (dry season) and August (rainy season), respectively. Plant height (H) above the stem base, widest width at the widest vegetative point of the plant passing through the center (W1), and widest width perpendicular to W1 (W2) were measured. The data for the height and width were used to calculate the growth index (GI) ([W1 + W2]/2 + H)/2, commonly used as an indicator of plant size (Hammond et al., 2007). The relative appearance of the plant was evaluated based on its visual quality. The visual quality evaluations were divided into five grades, with grade 1 standing for severely stressed and completely dried out, grade 2 for stressed with less than 50% of the leaves retaining green pigmentation, grade 3 for mildly stressed with 50% of the leaves retaining green pigmentation, grade 4 for minor stress with over 50% of the leaves appearing to be healthy, and grade 5 for unstressed with all leaves appearing healthy (Nagase and Dunnett, 2010).

Leaf color was measured using a Chroma meter (CR-400, Konica Minolta Group, Japan) with L*, a*, and b* mode. The L* values ranged from black (L* = 0) to white (L* = 100). The a* values ranged from red (a* = 100) to green (a* = -100). The b* values ranged from yellow (b* = 100) to blue (b* = -100). Chroma C* was calculated as $(a^*2 + b^*2)^{1/2}$ measures for color saturation or intensity. Hue angle h was calculated as $\tan^{-1}$ (b* / a*). When a* was less than 0 and b* was greater than 0, h was 180 + $\tan^{-1}$ (b* / a*). The value of h is a 360° color wheel, with 0°, 90°, 180°, and 270° representing red-purple, yellow, bluish-green, and blue, respectively (Wang and Camp, 2000). The leaves measured were the third from the top to the bottom of the plant. The Leaf color, chlorophyll contents of leaves and number of inflorescences were measured in August when plants were at peak flower time.

The chlorophyll meter (SPAD-502) is a simple tool used to measure the relative chlorophyll content or greenness, thus is an efficient indicator of stress in plants (Netto et al., 2005). The chlorophyll contents were measured for 9 leaves per container using a SPAD-502 meter (Minolta Camera Co., LTd, Osaka, Japan).

All the herb plants in green roofs overwinter with no protection. Overwintering survival rates and self-sown seeding number for all plants were recorded in May and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

June 2015 by measuring the number of sprouts aboveground from the roots and growing seedlings from seeds, respectively.

Experiment design and statistical analysis

This experiment was a completely randomized design with two factor, substrate design and hydrophilic polymer rate. There were three replicates for each treatment and each replicate consisted of three plants. Data were subjected to analysis of variance (ANOVA) with SAS 9.1 software package (SAS version 9.1, SAS Institute, Cary, NC). Significant mean separation was indicated by Duncan's multiple range test. Statistical significance was considered when the p value was less than 0.05.

Results

Volumetric water content of substrate

Under C_4P_1 treatment, the average volumetric water content was 52.7, 60.3, 61.3, 66.5, or 85.3% with 0 (control), 0.25, 0.5, 1.0, or 2.0 $kg \cdot m^{-3}$ of hydrophilic polymer, respectively. Under C_1P_4 treatment, it was 14.0, 14.1, 14.4, 17.8, or 25.3%, respectively, and 48.9, 50.4, 53.4, 58.5, or 82.6% under C_1P_1 treatment (*Fig. 2*). The moisture contents of substrate C_4P_1 and C_1P_1 under the control treatment were almost 3.8- and 3.5- fold higher than that of substrate C_1P_4, respectively. There was a significant ($p < 0.001$) interactive effect of the substrate and the hydrophilic polymer content on the volumetric water content. The temperatures of the substrates were significantly affected by treatment with hydrophilic polymer during the study (data not shown). The temperature of the substrate dropped significantly ($p < 0.001$) as the hydrophilic polymer content in the substrate was increased.

Plant growth

As shown in *Table 1,* the growth index of *Agastache rugosa* was not significantly different among the three substrates when measured in June. However, the leaf number ($p = 0.009$) and visual rating ($p = 0.028$) were significantly greater in substrate C_1P_4 than in substrate C_4P_1 in August. In addition, the growth index ($p < 0.001$), leaf number ($p < 0.001$) and visual rating ($p < 0.001$) of *Agastache rugosa* were significantly greater in substrate C_1P_4 than those in other two substrates when they were measured.

Flower development

The purple-blue flowers of *Agastache rugosa* started to bloom from mid-July to mid-October, with a flowering period extending more than 90 days. The peak blooming period was from mid-August to early September. The total number of inflorescences per *Agastache rugosa* plant was significantly ($p = 0.002$) higher in C_1P_4 than in the other substrates (*Fig. 3*). Incorporation of 1.0 $kg \cdot m^{-3}$ hydrophilic polymer significantly increased the total number of inflorescences per *Agastache rugosa* plant in C_1P_4, which was more than 2- fold higher than those in either the control or other hydrophilic polymer treatments. However, there was no significant difference in the total number of inflorescences per plant between the control and hydrophilic polymer treatment in C_4P_1 and C_1P_1.

As shown in *Table 2,* there was an interactive effect between the substrate and the hydrophilic polymer on lightness (L*) (interaction $p = 0.010$), values of a* (interaction $p = 0.003$), b* (interaction $p = 0.009$), Chroma (C*) (interaction $p = 0.007$) and hue angle (h) (interaction $p = 0.040$) in August when plants were at the peak flowering stage. Lower values of L* and a* as well as higher hue angles were recorded in the leaves of plants in C_1P_4, confirming the darker green color of the foliage compared to C_4P_1 and C_1P_1. The leaves in C_4P_1 had a less vivid green color than those in C_1P_4 and C_1P_1. Treatment with 1.0 $kg \cdot m^{-3}$ hydrophilic polymer greatly increased the value of L* (brighter), b* (more yellow) and Chroma (more vivid), but decreased the value of a* (more green) in substrate C_4P_1. In C_1P_1, hydrophilic polymer amendment increased the value of L* (brighter), b* (more yellow), and C* (more vivid), but decreased a* values (more green) and h values (greener). The SPAD value for all treatments in C_1P_4 was better than for other substrates. Moreover, the leaf performances were the highest under C_1P_4 treatment when measured in August, with large leaf sizes and green healthy leaves (*Fig. 4*).

substrate C_1P_4, the addition of hydrophilic polymer decreased the overwintering rate, especially at rate of 2.0 kg·m^{-3}. However, hydrophilic polymer increased self-sown seedling number of *Agastache rugosa* in substrate C_1P_4, especially at the rate of 1.0 and 2.0 kg·m^{-3} compared to other hydrophilic polymer treatments or control. While in substrate C_4P_1 and C_1P_1, self-sown seedling number decreased by hydrophilic polymer treatment.

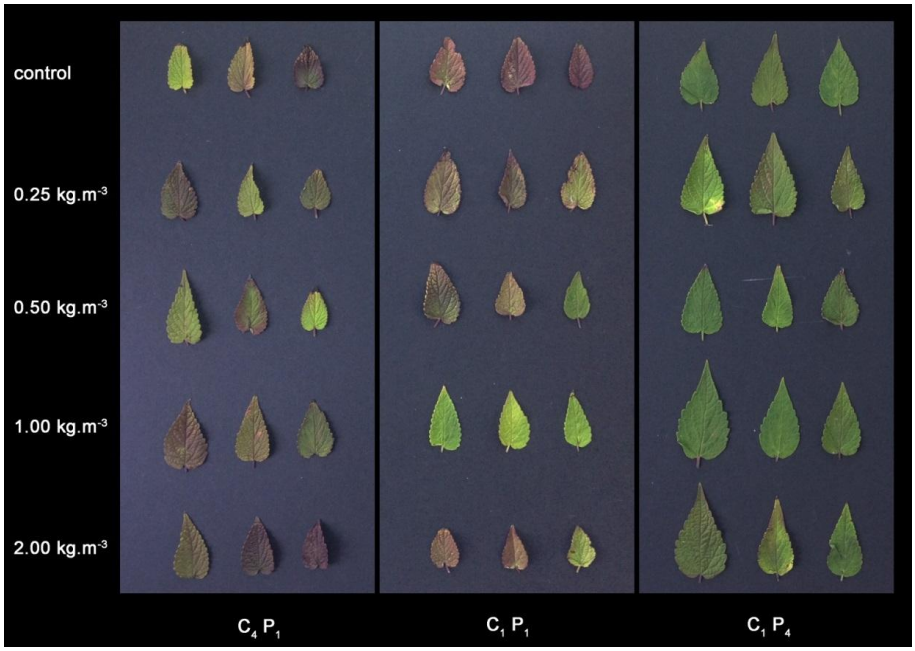

Figure 4. *Leaf performance for Agastache rugosa in the three different green roof substrates (C_4P_1: coir 80%, perlite 20%; C_1P_1: coir50%, perlite 50%; C_1P_4: coir 20%, perlite 80% (% by vol.)) containing different amounts of hydrophilic polymer: 0 (Control), 0.25, 0.5, 1.0, and 2.0 kg·m^{-3} (polymer: medium (w/v), dry weight basis) in August at peak blooming time*

Discussion

Our results revealed that more water was retained in the substrates when hydrophilic polymers were added compared to the control substrate. However, the amounts of additional volumetric water content in the three substrates depended on the compositions of the substrate. Hydrophilic polymer at 2.0 $kg \cdot m^{-3}$ significantly increased the average volumetric water content to values 1.62-, 1.81-, and 1.69- fold greater than that with no hydrophilic polymer in substrates C_4P_1, C_1P_4, and C_1P_1, respectively. In agreement with our study results, many studies have demonstrated that water retention in soil was increased with the addition of hydrophilic polymers, particularly in coarse-textured sandy soil (Dorraji et al., 2010). As the hydrophilic polymer content in the substrate increased, the substrate water content also increased, resulting in decreased temperature in the substrate (Nardini et al., 2012). The difference in volumetric water content between substrates with and without hydrophilic polymers decreased over time, especially in the coarse-textured substrate C_1P_4 starting from August. The difference also decreased with hydrophilic polymer concentrations less than 2.0 $kg \cdot m^{-3}$ in other substrate treatments. This reduction might be due to the loss of hydrophilic polymer effectiveness with time (Geesing and Schmidhalter, 2004). According to Han et al. (2013), the capacity of absorbing and desorbing water decreased with time and outside water condition. However, Jobin et al. (2004) found that there was no difference in available water and air-filled porosity in three substrates containing hydrophilic polymer after 9 weeks. Bai et al. (2010) studied the soil moisture of sandy soils mixed with four types of super-absorbent polymers under alternating dry and wet conditions. They found that the water retention capacity of the polymer decreased sharply when soil moisture was lower than a critical threshold. In addition, the water holding capacity of hydrophilic polymers could be affected by the extreme environmental conditions on the rooftop such as intensive solar radiation, high temperature, water deficits, freeze-thaw cycles caused by season change, and wetting-drying cycle due to weather change (Andry et al., 2009). In the present study, high temperature and frequent rainfall during the summer rainy season in August might have resulted in frequent wetting and drying of the substrates, leading to the loss of hydrophilic polymer effectiveness. This was associated with coarse-textured substrates, such as C_1P_4, that have a lower holding capacity, even with 2.0 $kg \cdot m^{-3}$ hydrophilic polymer.

Our study revealed that the C_4P_1 and C_1P_1 substrates, which have high coir dust content, are not ideal for *Agastache rugosa* in green roofs, either under drought stress or frequent rainfall. In our study, the moisture contents of substrate C_4P_1 and C_1P_1 under the control treatment were almost 3.8- and 3.5- fold higher than that of substrate C_1P_4, respectively. Although high coir dust content can increase the water content of substrates remarkably, it had no significant effect on plant growth for *Agastache rugosa* in June with little rainfall. Conversely, decreased leaf number and visual rate were observed in C_4P_1 with high coir dust content. In this study, the high coir dust content significantly decreased the number of inflorescences and ornamental quality in the peak flower period. Because of the high water-holding capacity, high organic content substrates are commonly used as container media, but are not recommended in green roofs in many studies (Cho et al., 2006). Beattie and Berghage (2004) suggested that substrates composed of 80-100% mineral matter and 0-20% organic matter suited for green roofs. Dunnett and Kingsburry (2004) also stated that low proportions of organic matter should be used, at between 10% and 20% of the total volume. The result is also consistent with the study findings that the substrate containing 10% organic matter was

optimal for *Allium schoenoprasum*, *Limonium latifolium*, *Melica ciliate* and *Nepeta* × *faassenii* because of stable growth under dry and wet conditions in green roofs (Nagase and Dunnett, 2011). Bates et al. (2015) conducted a six-year experiment which showed that the substrate with low organic matter content was suitable for brown (biodiversity) roofs. In our study, the peak flower time for *Agastache rugosa* was the summer rainy season with high temperatures and frequent rainfall, which might have resulted in frequent wetting and drying of the substrates in the green roof. Increased coir dust content could result in lush growth that may suffer damage under drought stress or frequent rainfall, resulting in frequent drying and wetting. Rowe et al. (2006) found that high organic matter in substrates may result in shrinkage because of decomposition. They may also increase poor growth of *Agastache rugosa* in the substrates C_4P_1 and C_1P_1, with worse flowering and reddish purple leaves in August. In our study, the results showed that hydrophilic polymer addition had no significant effect on the growth of *Agastache rugosa* in June, during which plants were exposed to less rainfall, though the hydrophilic polymer significantly increased the water content of the substrates. The results indicated that *Agastache rugosa* has high drought tolerance that can withstand extended dry conditions on green roofs. Although mineral-based substrates are recommended in green roofs, water scarcity is typically the main problem because of extreme environmental conditions, even in the rainy season. The flowering is the most sensitive phase to water stress (Álvarez et al., 2013) and the effect of water deficits on flowering has been suggested in many studies. Koshita and Takahara (2004) found that water stress reduced the number of flowers produced by *Citrus unshiu* during flower-bud induction periods. Caser et al. (2017) showed that severe water stress significantly decreased flower number and delayed the flowering period of *Primula vulgaris* 'Heidy'. The importance of water stress was also examined by Razmjoo et al. (2008), who found that the number of flowers produced by *Matricaria chamomile* decreased with long interval irrigation. Similar effects of water stress on flower production have also been observed in crops. Passioura (2006) observed that water deficit greatly affected crop productivity, especially when it occurred at the flowering stage. The number of flowers and yield of *Solanum melongena* L. was markedly decreased when water regimes were adopted (Lovelli et al., 2007). In our study, hydrophilic polymer addition at a concentration of 1.0 $kg \cdot m^{-3}$ increased the water content in substrate C_1P_4, thereby improving the substrate condition and significantly increasing the number of flowers produced by *Agastache rugosa*.

The *Agastache rugosa* in substrate C_1P_4 had high rate of overwintering success with over 70%, except in 2.0 $kg \cdot m^{-3}$ hydrophilic polymer treatment. Higher overwintering rate was associated with lower coir dust and hydrophilic polymer content. The low temperature injures the growth of plant roots, and cold weather freezes the surface soil sometimes, inflicting damage on shallow roots such as those planted in green roofs. Another type of winter root injury is caused by frost heaving, which is the result of the formation of ice lenses in the soil caused by a segregation of the soil water. Ice lenses are growing from below and pushed upward, which cause the plants to move upwards in the soil, sometimes pushing them out of the soil altogether. This can break many of the fine roots (Cleavitt et al., 2008). Injury or death usually follows if roots are broken or the shoots and exposed roots become dried out. Frost heaving is most likely to occur in fine-textured soils with high water content (Tarnocai and Bockheim, 2017). The higher coir dust and hydrophilic polymer content resulted in higher water content in substrates, thus leading to the low rate of overwintering.

The result also confirmed that the self-sown seedling number was affected by the composition of substrate, hydrophilic polymer rate. The germination of seed associated with moisture content, suitable temperature, and adequate supply of oxygen (Finch-Savage and Leubner-Metzger, 2006). However, long-term high moisture maintenance may result in seeds of some species rotting. As to *Agastache rugosa,* there was more number of seed starting seedlings under the C_1P_4 treatment by the perlite based (perlite) substrate, compared to coir dust based substrate.

Conclusions

Our results indicated that higher moisture was retained in substrates with hydrophilic polymers compared to that in the control substrate. We found that *Agastache rugosa* had a high drought tolerance capable of withstanding extended dry conditions in green roofs. The C_4P_1 substrate, which has high coir dust content, is not recommended for *Agastache rugosa* because of its low growth and poor ornamental quality, especially in the rainy season. Addition of 1.0 $kg \cdot m^{-3}$ hydrophilic polymer to substrate C_1P_4 increased the inflorescences number and resulted in good growth and ornamental quality both under drought and rainy seasons. Higher overwintering rate was associated with lower coir dust and hydrophilic polymer content. A greater number of seeds started seedling in substrate C_1P_4, especially at rates of 1.0 and 2.0 $kg \cdot m^{-3}$. These results indicated that the addition of 1.0 $kg \cdot m^{-3}$ hydrophilic polymer to substrate C_1P_4 is optimal for *Agastache rugosa* in green roofs. Further research studies are needed to determine the physical and chemical properties of substrates with different amounts of hydrophilic polymers. In addition, a follow up study on the effects of hydrophilic polymers on overwintering and the growth of *Agastache rugosa* in the second year would be useful.

Abstract. The effect of different long-term (2001-2016) tillage practices on soil nitrogen forms in different soil layers were studied to provide a scientific basis for evaluating soil fertility and establishing rational fertilization measures. Soil contents of total nitrogen (TN), particulate organic nitrogen (PON), microbial biomass nitrogen (MBN), water soluble organic nitrogen (WSON), NO3-N content, NH4-N content ammonium nitrogen and organic acid nitrogen component contents were measured under no-tillage (NT) and mould plow (MP) treatments based on a long-term (16 year) conservation tillage experiment in Northeast China. The results showed that no-tillage increased soil total nitrogen, active nitrogen, inorganic nitrogen and organic nitrogen content, which varied with soil depth. Compared with MP, NT significantly ($p < 0.05$) increased total nitrogen and active nitrogen content in the surface soil (0-30 cm); TN, PON, MBN and WSON increased significantly ($p < 0.05$) by 28.32%, 23.07%, 15.13% and 25.21% in 0-5 cm and by 10.17%, 19.4%, 15.97%, and 31.33% in 5-10 cm, respectively. For soil inorganic nitrogen, the content of ammonium nitrate at 0-5 cm and at 5-10 cm under NT was significantly ($p < 0.05$) higher than that of MP by 28.1% and 32.13%, respectively, and the content of ammonium nitrogen in soil at 0-5 cm was significantly ($p < 0.05$) higher, by 12.86%, than that of MP. No-tillage significantly increased the content of total hydrolysable nitrogen, hydrolysable ammonia nitrogen, hydrolysable amino acid nitrogen and hydrolysable unidentified nitrogen in the 0-10 cm soil layer, but no significant effect was found on the content of hydrolysable amino sugar nitrogen. Soil nitrogen content was closely related to tillage practices. These results suggest that no-tillage was beneficial in augmenting soil nitrogen supply capacity by increasing soil total nitrogen, active nitrogen, inorganic nitrogen and organic nitrogen content.

Introduction

Soil nitrogen (N) is one of the necessary nutrients for plant growth and development, as well as a major nutrient limiting factor for crop yield (Gao et al., 2008; Karra et al., 2018; Lenssen et al., 2007; Sainju et al., 2009). Soil organic and inorganicnitrogen are the main forms of the nitrogen pool. Soil organic nitrogen content of approximately 70%-90% in surface soil could not only maintain soil nitrogen fertility (Xu et al., 2003), but also has an important function for soil nitrogen supply capacity (Ju et al., 2004). Soil inorganic nitrogen pools with ammonium and nitrate, is the most effective nitrogen pool type for crop absorption (Mkhabela et al., 2008). Approximately 50% of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

accumulated nitrogen in crops comes from soil, especially for the black soil of Northeast China where more than 70% of the plant's accumulated nitrogen comes from the soil (Fuzzi, 1996; Ballb et al., 1999). Therefore, soil N mineralization from organic to inorganic N is the key process for crop absorbing and utilizing N.

Tillage practices have a great impact on soil N availability and nitrogen reserves. Intensive agricultural systems may deplete soil N pools by removal of the above ground portion of the plants, which may result in negative nutrient balance depleting soil fertility. Conservation tillage with returned straw could improve the soil aggregate structure, maintain soil moisture, reduce water runoff and evaporation, increase water infiltration, stabilize soil temperature changes, promote the reproduction of beneficial microorganisms and regulate nutrient metabolism, thus affecting the mineralization and transportation of soil N and plant absorption and utilization (Patra et al., 1993; Ram et al., 2003; Barajas-Guzmán et al., 2006). Therefore, it is critical to understand the dynamic and cycling of the soil N pools and their fractions under different agriculture management styles. Previous studies have shown that compared with traditional tillage, conservation tillage changed the soil microenvironment, thus affecting the mineralization and content of soil N, such as no-tillage significantly increasing the total N content in the 0-5 cm soil layer (Lou et al., 2012; Varvel et al., 2011; Sainju et al., 2009; Dikgwatlhe et al., 2014). However, the soil total N pool changes slowly responding to the management practice changes because of its large size, inherent spatial variability, and small fraction available to plants. Therefore, more attempts have been made to labile fractions as plant-available N (Wander, 2004; Haynes, 2005), which is the most active component of soil organic N. Particulate organic nitrogen (PON), microbial nitrogen (MBN) and water-soluble organic nitrogen (WEON) are the important active N pools, which play an essential role in the process of soil N cycle (Jones et al., 2004). No-tillage (NT) may temporarily increase N immobilization leading to reduced plant-available N, while long-term NT can also increase soil labile N pool to improve the availability of N to crops in the upper soil layers (Sun et al., 2015; Sainju et al., 2013).

The mollisol area in Northeast China is the main grain-producing area in the country. With the increment of reclamation years and predatory production, fertility degradation of the mollisol has become more and more prominent. It is now considered urgent to change the traditional farming methods and carry out conservation tillage as an effective means of preservation. Several previous studies have focused mainly on soil total nitrogen content change under conservation tillage, but focused less on soil active nitrogen, inorganic nitrogen and organic nitrogen components. Thus, in the current study, soil organic nitrogen contents between conservation tillage and conventional tillage were analyzed based on a long-term conservation experiment started in 2001. This involved analysis of soil nitrogen and organic nitrogen components under protective tillage and conventional tillage conditions, with a view to evaluating soil fertility, formulating reasonable fertilization measures and providing a scientific basis for sustainable development of agriculture.

Material and methods

Study site

The study was conducted on Dehui Experimental Station (44°12'N, 125°33'E) of the Northeast Institute of Geography and Agroecology, Chinese Academy of Sciences, in

Dehui County, Jilin Province, China. The climate is described as a temperate continental monsoon; based on data from the past 30 years, the annual mean air temperature is 4.4 °C, and the annual mean precipitation is 520.3 mm, with more than 70% of the rain occurring in June, July, and August. The winter (November–April) is long and cold. The soil is a clay loam (Typic Hapludoll) unusually covered with snow in winter. More details about the soil can be found in *Table 1* (Chen et al., 2018). Conventional management practices were used on the land to grow a monoculture of maize for more than 20 years before the establishment of this tillage experiment.

Experimental design

The present study was conducted using monoculture maize in a long-term (2001-2016) tillage field experiment. The tillage and rotation treatment are as follows. The tillage treatments consisted of no-tillage (NT), mould plow (MP) tillage and ridge tillage (RT), with two crop rotations (continuous maize (*Zea mays L.*), and maize-soybean (*Glycine max L.*). All the treatments were arranged in a randomized complete block design with four replicates at the whole plot level, and each plot was 5.2 m × 20 m. The NT treatment had no soil disturbance except for planting, usually in early May. The RT treatment included ridging in June and less than one-third row width smashing of maize stalks/roots in fall. The MP treatment included one approximately 15 cm in depth moldboard plowing after maize harvest, generally in early October, and one 7.5 to 10 cm in depth disking during the spring, as well as field cultivation (ridging in June). Herbicides were applied before and after seeding for all the tillage treatments to control weeds. Starter fertilizer (100 kg·ha^{-1} N, 45.5 kg·ha^{-1} P and 78 kg·ha^{-1} K) and an additional 50 kg·ha^{-1} N at the V-6 stage were applied for maize. Starter fertilizers (40 kg·ha^{-1} N, 60 kg·ha^{-1} P and 80 kg·ha^{-1} K) were applied concurrently at the time of planting for soybean. The crop residues were returned onto the soil surface after harvest under NT and RT treatments with the exception of the plots under MP.

Table 1. *Selected soil physical and chemical properties in 2001 prior to the tillage experiment (Chen et al., 2018)*

Depth (cm)	pH	Clay (%) (<2 µm)	Silt (%) (2-20 µm)	Sand (%) (20-200 µm)	Bulk density (g/cm^3)	Soil organic carbon (g/kg)	Total soil nitrogen (g/kg)
0-5	6.48	36.03	24.00	39.97	1.24	16.48	1.42
5-10	6.45	35.83	23.78	40.39	1.38	16.29	1.39
10-20	6.51	35.68	24.35	39.98	1.36	16.08	1.37
20-30	7.03	36.56	25.00	38.72	1.38	14.22	1.16

Soil sampling and measurements

Soil samples (7 replicates per plot) were collected at depths of 0-5 cm, 5-10 cm, 10-20 cm and 20-30 cm with S-type sampling on 23 April, 2017. The collected samples were divided into two parts, one was stored at 4 °C as a fresh sample for determination of microbial biomass nitrogen (MBN) and water-soluble organic nitrogen (WSON), and the other was air-dried for soil total nitrogen (TN), organic nitrogen components, etc. Soil total nitrogen was determined by an elemental analyzer (Flash EA1112, Thermo Finnigan, Italy). Particle organic nitrogen (PON) was extracted first and then analyzed

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

by elemental analysis (Cambardella et al., 1992). Soil water-soluble organic nitrogen was determined by the TOC-VCPH automatic analyzer (Model TOC-VCPH, Shimadzu, Tokyo, Japan) (Gigliotti et al., 2002). Soil microbial nitrogen (MBN) was determined by a modified CHCL3 fumigation-extraction method (Vance et al., 1987), and the extractions were analyzed by the automatic TOC-VCPH analyzer. Soil organic nitrogen components were determined according to Bremner's method (Bremner, 1965). Soil inorganic nitrogen was determined by a fully automatic continuous flow analyzer (SKALAR SAN + +, The Netherlands).

Data analysis

Statistical analyses were carried out using SPSS (Version 11.5, SPSS Inc., Chicago, IL, USA). Treatment means were compared using the least significant difference (LSD) and a significance level of $P < 0.05$.

Results

Total nitrogen content

Compared with MP, NT significantly ($p < 0.05$) increased the total nitrogen content by 28.32% and 10.17%, in the 0-5 cm and 5-10 cm soil depth intervals, respectively (*Fig. 1*). While the total nitrogen content of the 10-20 cm and 20-30 cm layers under NT treatment was slightly lower than that of MP, the difference was not significant. Under both NT and MP, soil total N decreased with increased soil depth.

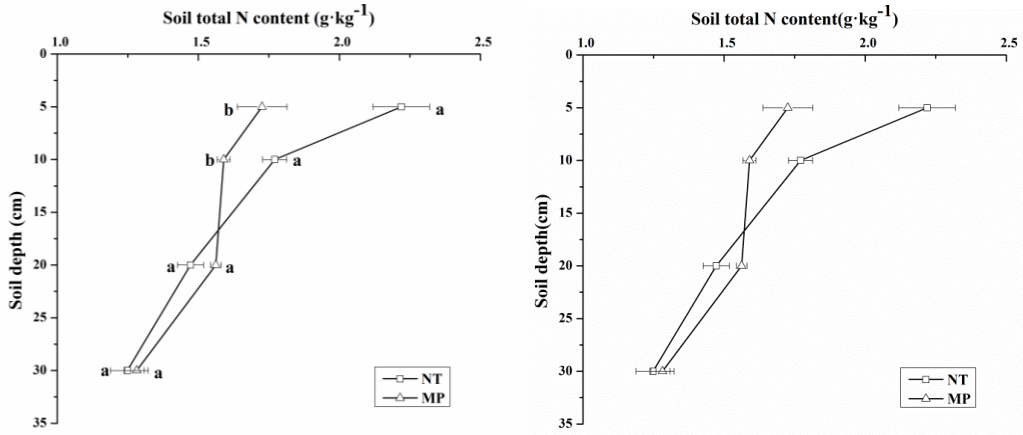

Figure 1. *Soil total nitrogen at different soil depths under different tillage practices ($P < 0.05$). (NT: no tillage; MP: mould plow. Different letter indicates significant difference of soil total N content between different tillage practices at the same depth)*

Active nitrogen

NT significantly ($p < 0.05$) increased soil active nitrogen in the 0-5 cm and 5-10 cm soil layers more than MP (*Fig. 2*). Particulate organic nitrogen increased by 23.07% and 19.4%, microbial biomass N increased by 15.13% and 15.97%, and soil soluble organic nitrogen increased by 25.21% and 31.33% in the 0-5 cm and 5-10 cm soil layers, respectively (*Fig. 2*). No significant differences were found between NT and MP for

The NH_4^-N content in the 0-5 cm soil layer under MP was 12.86% significantly ($p < 0.05$) higher than that of NT, the NH_4^-N content under MP in the 5-10 cm soil layer was also higher than NT although the difference was not significant. There was no significant difference between NT and MP for NO_3-N and NH4-N in the 10-30 cm soil layer. With the increment of soil depth, the content of nitrate nitrogen and ammonium nitrogen decreased.

Soil organic nitrogen components

NT significantly ($p < 0.05$) increased total hydrolysable nitrogen content, hydrolysable ammonia nitrogen content, and hydrolysable amino acid nitrogen in topsoil (0-5 and 5-10 cm) more than MP (*Table 2*). Compared with MP, total hydrolysable nitrogen content increased by 22.03%, and 9.67%, hydrolysable ammonia nitrogen increased by 22.24% and 19.67%, and hydrolysable amino acid nitrogen increased by 21.48% and 22.95% in the 0-5 cm and 5-10 cm soil layers, respectively (*Table 2*). No significant difference was observed in the 10-30 cm soil layers for the hydrolysable nitrogen. Tillage practices had no significant effect on the content of hydrolysable amino sugar nitrogen. The content of hydrolysable amino sugar nitrogen in the 10-30 cm soil layer was slightly lower than MP, but the difference was not significant. The hydrolysable unidentified nitrogen content in the 0-5 cm soil layer of the NT treatment was 30.87% significantly ($p < 0.05$) higher than that in MP, while the differences between the two nitrogen types for NT and MP in the 5-30 cm depth interval were not significant. The differences of all types of nitrogen between NT and MP in the 10-30 cm soil layer were not significant.

Table 2. *Soil organic nitrogen components under different tillage practices*

Soil depth (cm)		0-5	5-10	10-20	20-30
Total hydrolysable nitrogen	NT	1438.76a	1249.49a	957.18a	812.79a
	MP	1121.87b	1038.37b	1015.78a	839.70a

Same letter means no significant difference under different layers and tillage practices for a single soil nitrogen property. NT: no tillage; MP: mould plow

Discussion

Effect of tillage on soil total nitrogen content

After 16 years of conversion from traditional farming to conservation tillage, the TN content in the 0-10 cm surface layer increased under no-till practices. Our results were consistent with other research, such as that no-tillage had shown that total nitrogen at 0-5 cm and 0-30 cm layers was higher than that for other tillage (Power et al., 1998;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_55175528
© 2018, ALÖKI Kft., Budapest, Hungary

Purakayastha et al., 2009). As a result of the NT straw surface coverage, soil disturbance decreased, leading to a reduction of total nitrogen mineralization and eventually an increase in total nitrogen (Franzluebbers et al., 1999). No-tillage straw also increased the soil C/N ratio by adding organic matter to the soil, thus enhancing the solid holding capacity of nitrogen (Kushwaha et al. al., 2000; Hemwong et al., 2008; Zavalloni et al., 2011). The total nitrogen content both in NT and MP decreased with increases in soil depth. This was due to the accumulation of organic matter in the surface NT soil. In the 10-30 cm soil layer, total nitrogen content under MP treatment was higher than NT (*Fig. 1*). For this phenomenon, underground biomass may play an important role. In traditional farming, the stubble was turned into the deeper layer of soil. However, in NT, the root system showed a high density in the soil surface and a low density in the deep soil (Qin et al., 2006). Therefore, different subsurface biomass in NT and MP may cause the difference of total nitrogen in various soil layers between treatments. The results of the present study are consistent with other findings; no-tillage straw returning to the soil led to accumulation of soil nitrogen on the soil surface (Torbert et al., 1995; Thomas et al., 2005).

Effect of tillage on soil active nitrogen

Soil particulate organic nitrogen (PON) was considered as a stable part of soil organic nitrogen, as it could be converted into inorganic nitrogen, which could then be used to supply nitrogen sources for plant growth and crop yield, and maintain soil nitrogen balance (Rosell et al., 2000). PON was sensitive to farmland management practices such as soil disturbance and crop straw inputs; therefore, it responded quickly to management practice changes (Cambardella et al., 1992). These results showed that conservation tillage mainly increased the PON content in the 0-5 cm and 5-10 cm soil layers, which is consistent with other related studies (Fabrizzi et al., 2003; Bessam et al., 2003; Malhi et al., 2006; Sainju et al., 2012). There are three reasons for this. First, no-till straw returning could provide a good environment for soil aggregate formation, and a large amount of PON could be physically protected in soil aggregates. Second, cultivation such as autumn plowing could disturb the soil and destroy soil aggregates, thus accelerating PON mineralization (Wander, 2004). Third, the location of crop straw returning may affect the distribution of PON. In the NT treatment, the straw covered the soil surface. However, in the MP treatment, straws were buried in the soil stubble in more close contact with the soil. The variable distribution of straw returning to the field could explain that the PON content in NT treatment was significantly higher than MP in the 0-10 cm soil layer. To summarize, the results showed that no-tillage straw returned to the soil helps increase soil PON content.

Soil microbial biomass nitrogen was the source and reservoir of nitrogen nutrients and an important biological indicator of soil quality (Shukla et al., 2017). In the present study, conservation tillage significantly increases soil microbial biomass nitrogen. This may be due to the higher total nitrogen content in conservation tillage soils, which provided a higher material basis for MBN formation. The positive impact of NT on soil microbial communities could also be attributed to the reduction of soil disturbance, which led to the reduction of fungal mycelium damage, the conservation of microbial habitat, the improvement of soil moisture conditions and the reduction of extreme temperature conditions (Rhoton, 2000). In short, NT increased soil microbial and physic-chemical conditions, improved microbial habitat, disturbed soil less, and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

provided relatively high levels of organic nitrogen, ultimately resulting in an increase in surface microbial biomass nitrogen.

Soil soluble organic nitrogen played an important role in the farmland nitrogen circulation system (Kranabetter et al., 2007). In this study, no-tillage straw surface coverage resulted in an increase in soil soluble organic nitrogen in the 0-10 cm soil layer. The disturbance of mould plow tillage soils improved the aeration of the soil and destroyed the soil aggregates, thus accelerating the mineralization of PON. Therefore, the soil soluble organic nitrogen tended to decrease, resulting in the decrease in the surface layer content. Meanwhile, no-tillage straw covering the surface could improve soil moisture and boost nitrogen fixation.

Effect of tillage on soil inorganic nitrogen

Soil inorganic nitrogen played an important role in the forms of nitrate nitrogen and ammonium nitrogen in the soil nitrogen cycle, and was the main form of crop absorption and utilization, although only a minor portion of the total nitrogen (Nguyen et al., 2017). Halvorson found that the NO_3-N content in mould plow tillage in the northern plains of the United States was higher than that of no-tillage systems (Halvorson et al., 2000). In this study NO_3-N content in 0-10 cm soil under NT layer was significantly higher than that of MP, which is not consistent with this finding. which may be related to different crop types, tillage years, soil types and planting systems. Our results showed that no-tillage with straw returned to the soil would increase the number and continuity of macropores in the topsoil and may cause a large amount of NO_3-N to be stored in the surface soil (Li et al., 2007). At the same time, no-tillage could effectively store soil moisture and reduce NO_3-N leaching to the lower soil. In addition, the straw covered the surface of no-tillage soil, which increased soil nitrogen fixation, thereby reducing the loss of NO_3-N. In contrast, conventional farming led to large disturbances of surface soil with high porosity with NO_3-N tending to move downwards. Sainju et al. (2013) found that the NH_4-N content in MP was higher than in NT, which is consistent with our findings. Under dry land conditions, Li et al. (2007) found that no-tillage increased the quantity of earthworms in farmland and the number and continuity of macropores in the soil, thus improving soil aeration. In well-aerated soil, NH_4-N was more easily transferred into NO_3-N, resulting in soil NH_4-N content decreasing under no-tillage.

Effect of tillage on soil organic activated nitrogen components

Soil organic nitrogen is the source of mineral nitrogen for crops, and as the main form of soil nitrogen, it plays a key role in the stability of farmland ecosystems (Schulten et al., 1997). In this study, no-tillage significantly affected the total hydrolysable nitrogen, hydrolysable ammonia nitrogen and hydrolysable amino acid nitrogen in the 0-10 cm soil layer, and hydrolysable unidentified nitrogen in the 0-5 cm soil layer. The reason may be that no-tillage increased the total nitrogen content of soil, and the increase in total nitrogen would inevitably lead to the increase in soil hydrolysable ammonia nitrogen (Follett et al., 1989). Hydrolysable ammonia nitrogen was composed of inorganic exchangeable ammonium and part of the fixed ammonium composition, the mineralization of two ammonium after soil disturbance accelerated under conventional farming, and the absorption and utilization of crops to ammonia, led to the average content of hydrolysable ammonia nitrogen decreasing obviously; hence,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_55175528
© 2018, ALÖKI Kft., Budapest, Hungary

hydrolysable ammonia nitrogen in the 0-10 cm layer of mould plow tillage was significantly lower than no-tillage (Jiang, 2005). The addition of organic material under no-tillage increased the soil organic matter content, which was continuously converted into humus under the action of microorganisms. Soil amino acids nitrogen and other compounds of N were fixed into humic acid during the humification (Porter et al., 1964). Under acidic conditions, the amino acid nitrogen released, which made the higher hydrolysable amino acid nitrogen content of the 0-10 cm soil layer than that of conventional tillage. Hydrolysable unidentified nitrogen is a difficult component to mineralization in soil organic nitrogen pools of acidolysis, and the mineralization rate of unknown nitrogen of acidolysis is very small, so it is easy to accumulate in soil (Stevenson, 1982). The increase in total nitrogen in the surface layer under no-tillage also leads to the increase in hydrolysable unidentified nitrogen. Tillage practices have no significant effect on hydrolysable amino sugar nitrogen. Since hydrolysable amino sugar nitrogen is mainly derived from residues of microbial cell walls, and hydrolysable amino sugar nitrogen reflects the accumulation of dead microorganisms rather than live microorganisms. Therefore, hydrolysable amino sugar nitrogen is a very small percentage of soil total nitrogen, and it is less affected by tillage practices (Stevenson, 1982). Liu's preliminary studies conducted in the same site reported that the soil organic nitrogen mineralization plays an important role in the nitrogen nutrition of crops. The total soil nitrogen mineralization rate in no-tillage has a significant stratification phenomenon. The contribution of no-till active organic nitrogen to total mineralization rate (75-89%) was significantly greater than that of conventional tillage (31-45%), indicating that tillage practices will affect the source of soil organic nitrogen mineralization. The degree of humification, humic acid content, and aromaticity of organic matter in long-term no-tillage mollisol were significantly lower than that of mould plow tillage, so the mineralization of active organic nitrogen pool contributed more to the total primary mineralization rate. This means that much more organic nitrogen in no-till agecan be converted into inorganic nitrogen and absorbed by plants (Liu et al., 2017).

Conclusion

The results of this study showed that the effects of conservation tillage on the soil nitrogen pool occurred in the surface layer by significantly increasing the contents of total nitrogen, particulate nitrogen, microbial biomass nitrogen, water-soluble organic nitrogen, nitrate nitrogen and acidolysis of organic nitrogen components. In sum, no-tillage was suitable to increase the accumulation of nitrogen in dry farming areas, which would provide a theoretical basis for optimizing mollisol management and sustainable development of agriculture with rational fertilizing in Northeast China.

(Received 6th Jun 2018; accepted 14th Aug 2018)

Abstract. High temperature stress is a major environmental stress factor for all photosynthetic organisms. Some lichen species could have the ability of tolerance against global warming. In the present study, we investigated the effects of high temperature on GABA metabolism in two different lichen species *Evernia prunastri* and *Usnea* sp.. *Evernia* and *Usnea* sp. were collected from unpolluted locations in Bilecik, TURKEY. *Evernia* and *Usnea* sp. were kept at 45 °C for 0, 24 and 48 h. We analyzed GABA content, glutamate dehydrogenase (GDH) and glutamate decarboxylase (GAD) activities and also chlorophyll and MDA contents in the thalli of the lichens. The chlorophyll degradation and lipid peroxidation data indicated that *E. prunastri* thalli showed tolerance to high temperature while *Usnea* sp. thalli were found to be sensitive under these conditions. GABA content was enhanced by high temperature stress in *E. prutastri* thalli, while GAD and GDH activities were decreased. According to our results, we can suggest that GABA accumulation in lichen thalli could occur via different metabolic pathways.
Keywords: *Evernia, GABA, glutamate decarboxylase, glutamate dehydogenase, high temperature, Usnea*

Abbreviations: GABA: gamma-amino butyric acid; GAD: glutamate decarboxylase; GDH: glutamate dehydrogenase; MDA: malondialdehyde

Introduction

Global warming is one of the most serious problems for all organisms, populations, and ecological communities (Walther et al., 2002; Liu et al., 2003; Pisani et al., 2007). Climatic changes can negatively influence photosynthetic organisms; disrupt cellular homeostasis, and alter their morphology, biochemical structure, and physiology (Karl et al., 2007; Bita and Greats, 2013). High temperature stress can cause membrane damages, inhibit protein and carbohydrate metabolisms via inactivation of the enzymes in mitochondria and chloroplasts (Bita and Greats, 2013).

Gamma-amino butyric acid (GABA) plays different roles in plant metabolism including carbon–nitrogen metabolism, energy balance, signaling and development. It is found in a wide range of organisms including plants, algae and lichens (Bouché and Fromm, 2004;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_55295538
© 2018, ALÖKI Kft., Budapest, Hungary

Yolcu et al., 2013). GABA probably plays a dual role as both a signaling molecule and a metabolite (Fait et al., 2008). GABA is mainly synthesized in metabolic pathway known as GABA shunt. It plays a major role in primary C/N metabolism. GABA shunt includes three main enzymes; cytosolic enzyme glutamate decarboxylase (GAD; EC 4.1.1.15), the mitochondrial enzymes GABA transaminase (GABA-T; EC 2.6.1.19), and succinic semialdehyde dehydrogenase (SSADH; EC 1.2.1.16). Enhancement in GABA content under various stress conditions such as drought, chilling, salt, heavy metal stresses was reported by several researchers (Bor et al., 2009; Al-Quraan et al., 2013; Wang et al., 2016). Previous studies demonstrated that GABA shunt pathway plays an important role in the alleviation of oxidative stress caused by high temperature stress (Cao et al., 2013; Nayyar et al., 2014).

Lichens are poikilohydric organisms and highly adapted to osmotic dehydration (Hájek et al., 2006). Most of the species have ability of tolerance against global warming and can live in the range of 35-46 °C and survive even at 70 °C (Pisani et al., 2007; Dyakov et al., 2015), although some air-dried lichen species are being sensitive to high temperature stress (Van Herk et al., 2002). Similarly, in higher plants, high temperature could have an effect on the growth and physiological process of the lichens (Pissani et al., 2007). Previously studies demonstrated that increasing temperature caused to a reduction in chlorophyll content and directly or indirectly altered the synthesis of lichen substances (Bjerke et al., 2003). In the literature, there are very limited studies on the heat tolerance or stress, and physiological mechanisms of high temperature tolerance are not fully known in lichens. Moreover, the role of GABA metabolic pathway under high temperature conditions is not clearly elucidated yet. In the present study, our aim was to determine the role of GABA shunt under high temperature conditions. To find out the answers of these questions, we showed that the alteration of GABA accumulation, and activities of GAD and GDH enzymes in different lichen species; *E. prunastri* and *Usnea* sp. under high temperature.

Materials and methods

Materials

The lichen species, *E. prunastri* and *Usnea* sp. were collected from unpolluted locations from Bilecik Center Forest, Turkey (N 40° 11.526', E 029° 57.962') at February 2017. 90 individual samples were transferred to the laboratory in the plastic bags, cleaned from impurities, and washed three times for 5 s with distilled water to remove dust from the surface. All lichen species were transferred to petri dishes and incubated in a growth chamber under 100 µmol m^{-2} s^{-1} light intensity and 16:8 light/dark cycle at 23 ± 2 °C and humidity was %38 for 48 h (Hall et al., 2002). Lichens were sprayed with distilled water once a day according to Calatayud et al. (1997). After laboratory adaptation, experimental conditions were designed. Lichen thalli was used as a control after the incubation for 48 h in normal growth conditions (as seen in *Table 1;* 0 h data).

For temperature experiments, 30 individual thalli of *E. prunastri* and *Usnea* sp. in petri dishes were kept for 0, 24 and 48 h in an incubator 100 µmol m^{-2} s^{-1} light intensity and 16:8 light/dark cycle at 45 ± 2 °C and likewise watered once a day. Heat stress temperature was chosen according to Pissani et al (2007) studies. The data presented in this study are the averages of three independent experiments.

Chlorophyll content analysis

Chlorophyll analysis was determined using the method described by Wellburn (1994). Approximately 20 mg of thalli were extracted in the dark for 1 h at 65 °C in 3.0 mL of dimethyl sulfoxide (DMSO) in the presence of polyvinylpolyrrolidone to minimise chlorophyll degradation. The absorbances of the extracts were measured using a UV-visible spectrophotometer (Perkin Elmer). For the chlorophyll analysis, measurements were taken at the wavelengths 665.1 and 649.1 nm.

Lipid peroxidation

Formation of malondialdehyde (MDA) was evaluated as an indicator of lipid peroxidation. The determination of MDA was performed by the thiobarbituric acid reactive substances method (Heath and Packer, 1968). The absorbance differences between 532 and 600 nm was used to calculate MDA formation as a by-product of lipid peroxidation.

GABA analysis

GABA content was detected by HPLC (Agilent 1200) according to Bor et al. (2009). 0.1 g of lichen samples (*E. prunastri* and *Usnea* sp. were homogenized in 5 mL solution of water:chloroform:methanol (3:5:12 v/v/v), and centrifuged at 4 °C for 10 min. The supernatant was dried. The dried samples were dissolved in water, Borax buffer (pH 8.0) and 2-hydroxynaphthaldehyde (0.3% in methanol) and heated at 80 °C for 30 min. The samples were separated by reversed-phase column Supelco LC18 (250 × 4.6 mm^2, 5 µm) at 330 nm with a mobile phase of methanol:water (62:38 v/v). The injection volume was 5 µL. GABA content was calculated according to the peak areas of GABA standarts.

GAD and GDH enzyme analysis

GDH activity was measured according to Akihiro et al. (2008) and Yolcu et al. (2013). The extracts were mixed with the assay mixture containing 50 mM $(NH_4)_2SO_4$, 13 mM α-ketoglutarate, 0.25 mM NADPH and 1 mM $CaCl_2$ in 100 mM Tris-HCl buffer (pH 8.0). GDH activity was measured according to the absorbance differences at 340 nm and expressed as micromoles per minute per gram fresh weight (FW).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_55295538
© 2018, ALÖKI Kft., Budapest, Hungary

GAD activity was assayed according to Bartyzel et al. (2003) and Yolcu et al. (2013). 100 µL of sample was mixed with reaction mixture containing 3 mM L-glutamate, 20 µM pyridoxal phosphate and 50 mM potassium phosphate (pH 5.8) and incubated at 30 °C for 1 h for the decarboxylation process. HCl (0.5 M) was added to the mixture to stop the reaction. The samples were derivatized with 0.35% (w/v) ninhydrin solution. GAD activity was determined spectrophotometrically by comparing with the standard GABA values, and calculated as micromoles per minute per gram.

Statistics

Statistical analysis was performed with one-way analysis of variance (ANOVA) and Student's t-test followed by *posthoc* Tukey test as appropriate (SPSS for Windows version 11.0). The critical values for statistical significance was $p < 0.05$ and 0.01.

Results

Malondialdehyde (MDA) is often used as an indicator of oxidative damage at the cellular level. *Figure 1* shows the MDA content of thalli after exposure to high temperature for 0, 24 and 48 h. In *E. prunastri* thallus, MDA content was not significantly changed at 24 h, but the MDA content significantly increased ($p < 0.001$) at 48 h under high temperature (*Fig. 1*). In *Usnea* sp. thallus, the MDA content significantly increased at 24 h and 48 h.

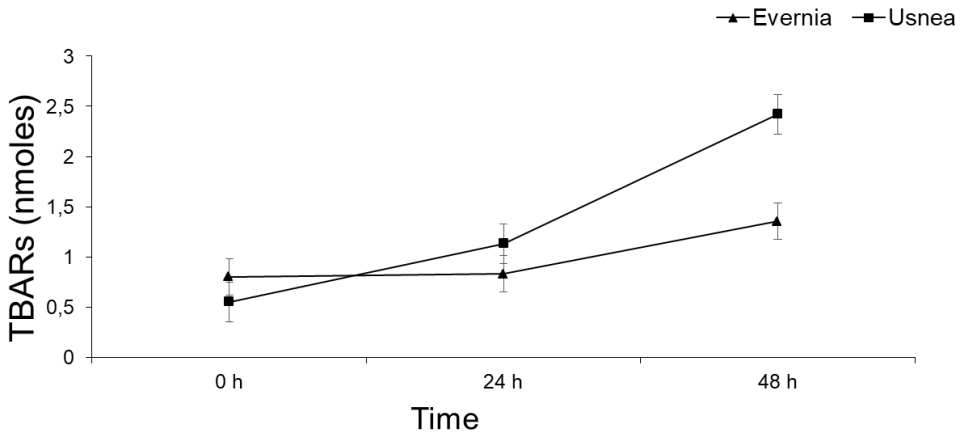

Figure 1. *Lipid peroxidation of different two lichen species under heat stress (45 °C) for 0 h, 24 h and 48 h*

The results of this study showed that the chlorophyll *a* content was significantly ($p < 0.001$) altered by high temperature treatment at 24 h and 48 h between lichen species. In *E. prunastri* thalli, however the chlorophyll *a* content gradually decreased at 24 and 48 h, chlorophyll *b* content was not significantly changed at 24 h (*Table 1*). The chlorophyll *a/b* ratio in the thallus of *E. prunastri* showed differences under 24 and 48 h exposures. In *Usnea* sp. The chlorophyll a content was significantly decreased at 24 and 48 h when compared to the control groups ($p < 0.001$) (0 h, as seen in *Table 1*). The content of chlorophyll *b* increased significantly under 48 h high temperature exposure. The chlorophyll *a/b* ratio decreased significantly after 24 h and 48 h exposures in *Usnea* sp. (*Table 1*).

As shown in *Figure 2,* GABA was enhanced under heat especially by time exposures. The highest increase was determined in *E. prunastri* under 48 h heat treatment. The lowest increase was detected in *Usnea* sp. However, we did not find any significant increase in the GABA content under 24 h treatment in *Usnea* sp.

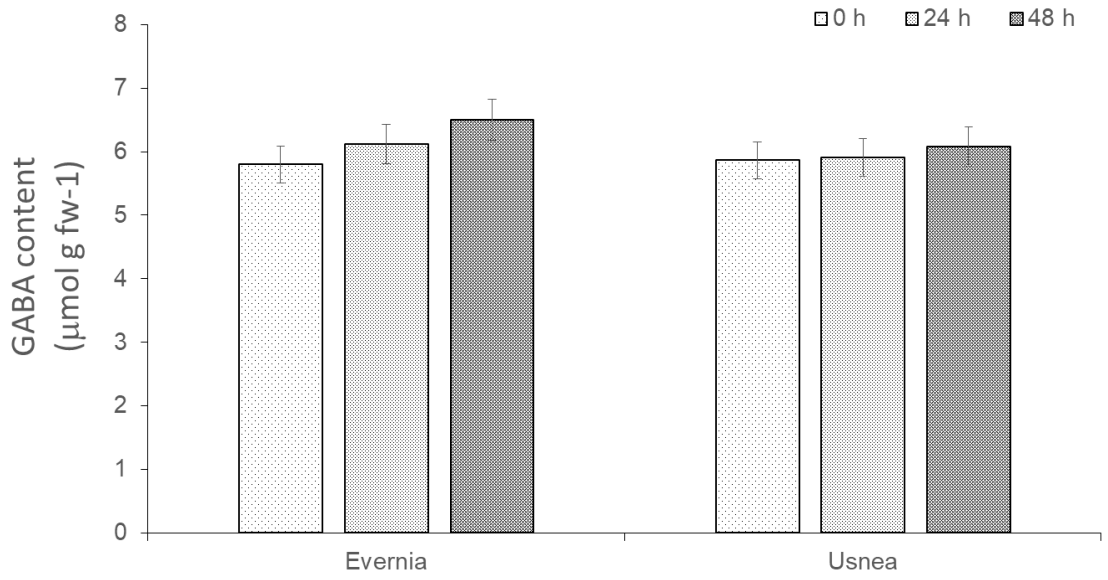

Figure 2. *GABA content of different two lichen species under heat stress (45 °C) for 0 h, 24 h and 48 h*

GAD activity was significantly decreased by heat treatments in *E. prunastri* when compared to the control group (*Fig. 3*). However, it was significantly increased by 24 h heat treatment in *Usnea* sp. as compared to the control group ($p < 0.05$). 48 h heat treatment did cause a decline in GAD activity in all of the species.

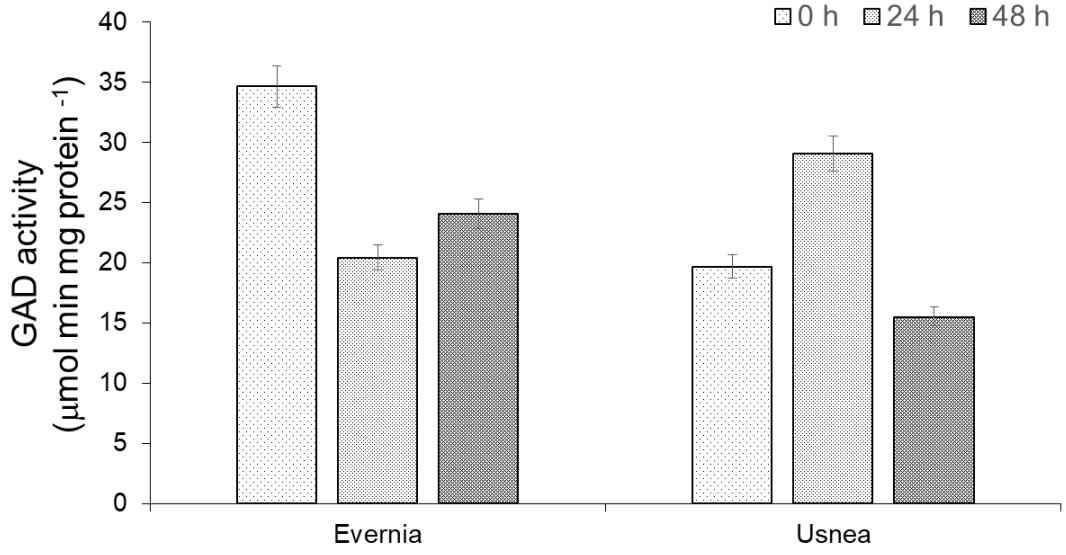

Figure 3. *GAD enzyme activities of different two lichen species under heat stress (45 °C) for 0 h, 24 h and 48 h*

GDH activity was not significantly changed in both lichen species as compared to their control groups. However, GDH activity was increased under 24 h heat treatment in *E. prunastri* when compared to the control group (*Fig. 4*). In addition, GDH activity was significantly increased when compared to 48 h heat teratment in the thalli of *Usnea* sp ($p < 0.05$).

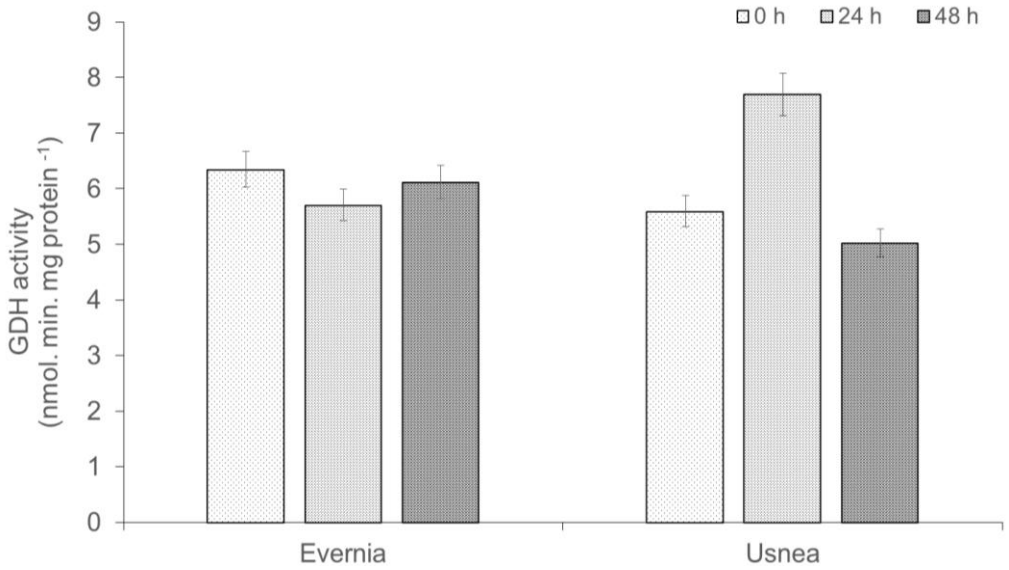

Figure 4. *GDH enzyme activities of different two lichen species under heat stress (45 °C) for 0 h, 24 h and 48 h*

Discussion

High temperature can induce oxidative stress via ROS production and lead can cause loss of cellular homeostasis in the photosynthetic organisms (Liu et al., 2003; Almeselmani et al., 2006). Oxidative stress also causes destruction of cell membranes via lipid peroxidation (Almeselmani et al., 2006). Malondialdehyde, MDA, is produced naturally as a result of lipid peroxidation and is often used as an indicator of oxidative damage at the cellular level (Mittler, 2002). Previous studies reported that high membrane damage occurs at higher temperatures and this could cause to the loss of structural organization of the membranes (Liu et al., 2003; Almeselmani et al., 2009; Hafmann, 2012). In our study, lipid peroxidation rate increased in *Usnea* sp., while MDA content did not significantly change in *E. prunastri* thalli at 24 h (*Fig. 1*). Our results indicate that thallus of *E. prunastri* could be more tolerant to heat stress.

Chlorophyll content is an important indicator for the photosynthetic process. It is also very sensitive to stress-initiated oxidative stress such as photo-oxidation (Chettri et al., 1998). Chlorophyll *b* is formed from chlorophyll *a* by the oxidation of the methyl group on the ring II to the aldehyde group (Chettri et al., 1998), and the ratio of chlorophyll *a/b* is more sensitive to the modification than chlorophyll *a+b*. In green plants, the antenna size is determined by the amount of light-harvesting chlorophyll *a/b* protein complex that is associated with the PSII (Takana and Takana, 2006). Conversion of chlorophyll *b* to chlorophyll *a* is the first step in chlorophyll degradation, as well as influencing chlorophyll a / b ratio (Chettri et al., 1998; Takana and Takana, 2006). Therefore, chlorophyll degradation is frequently used to identify the physiological

© 2018, ALÖKI Kft., Budapest, Hungary

conditions of the lichens (Chettri et al., 1998; Bačkor and Zetiková, 2003). Many lichen species could have tolerance to climate change and high temperature (Pisani et al., 2007). Pisani et al. (2007) showed that the content of photosynthetic pigments was not significantly changed at 40 °C for 24 h in *E. prunastri*. Similarly, in our study, chlorophyll degradation was not decreased in the range of 4-2 in *E. prunastri* thalli under high temperature stress (*Table 1*). However, the chl *a/b* ratio significantly decreased in the thalli of *Usnea sp.* during 24 and 48 h. Exposure of *Usnea* sp. to the temperature of 45 °C had significantly negative effect on the content of photosynthetic pigments (*Table 1*). Our results indicated that *E. prunastri* has more tolerance capacity than *Usnea* sp. under high temperature stress.

GABA biosynthesis is enhanced via various stress conditions (Bor et al., 2009; Al-Quraan et al., 2011; Paradisone et al., 2015), and GABA pathway could regulate the adaptation mechanisms (Al-Quraan and Al-Share, 2016). GABA is synthesized from glutamate by the activity of cytosolic GAD (Bouche et al., 2003). In higher plants, many researchers have suggested that GAD activity played a dominant role in the accumulation of GABA (Cao et al., 2012). Yolcu et al. (2013) also reported that GAD activity is highly correlated with high GABA levels. GDH is an enzyme found in the mitochondria that catalyzes the deamination of glutamate which is then converted to GABA by the action of GAD (Andersson and Rager, 2003; Forde and Lea, 2007). In higher plants, GABA accumulation can have a role in the tolerance under many environmental stress conditions (Nayyar et al., 2014). Previous studies also demonstrated that rapid accumulation of GABA in response to heat-stress (Bouche et al., 2004; Nayyar et al., 2014). In the present study, high GABA accumulation could decrease lipid peroxidation at 48 h with increasing lipid peroxidation rate at 48 h exposure in *E. prunastri* thalli (*Figs. 1* and *2*). Therefore, we can suggest that GABA could be a signal for high temperature tolerance.

Among lichens, Jager and Weigel (1978) reported that GABA is one of the predominant amino acids in the lichen *P. furfuracea*. Yolcu et al. (2013) also found that lowest GDH activity showed in *P. furfuracea* thalli as compared to higher plant species. In *Usnea* sp. under 24 h heat treatment, we can suggest that GABA could be synthesized by the activity of GAD via GABA pathway. However; under 48 h heat treatment GAD activity did not increase when compared to control group while GABA contents were enhanced under the same conditions (*Fig. 3*). In *E. prunastri* thalli, GDH and GAD enzymes activities did not show any relation with GABA accumulation under high temperature stress (*Figs. 3* and *4*). Numerous publications in higher plants link GABA metabolism with polyamine biosynthesis pathways, however there is not any information in lichens. GABA can also be synthesized via polyamine pathway by polyamine degradation or reduction (Moschou et al., 2008; Yolcu et al., 2013). Moreover, Wang et al. (2016) showed that the elevated chilling tolerance in NO-treated banana fruit may be attributed to enhanced accumulation of polyamines and GABA.

Conclusion

According to our results, we can suggest that GABA could be mainly synthesized via GAD activity during normal conditions in *Evernia* and *Usnea*, but in stress conditions, GABA can be synthesized via polyamine accumulation. However, further studies should be done to identify the effects of polyamine pathway on GABA metabolism in lichens both under normal and stress conditions.

(Received 13th Jun 2018; accepted 1st Aug 2018)

Abstract. *P. syluestriformis* is an endemic plant in Changbai Mountain area of China. Some sample plots were set up in natural distribution communities of *P. syluestriformis*. Based on the survey data of the plots, the spatial distribution pattern of *P. syluestriformis* population was studied by the aggregation index. The niche breadth of Levins, Hurlbert and the Pianka niche overlap methods were used to analyze the niche characteristics of *P. syluestriformis* population in different communities. The results showed that in the pure forest of *P. syluestriformis* at about 700 m above sea level, *P. syluestriformis* population was in an aggregate distribution state, and in the scattered community of *P. syluestriformis*, *P. syluestriformis* population was randomly distributed in different forest stands under natural conditions, *P. syluestriformis* population had obvious advantages in each resource location. The maximum niche breadth of Levins was 5.3094. In the aspect of niche overlap index, there was a large niche overlap between the population of *P. syluestriformis* and *U. japonica*, which had obvious sharing advantages. Followed by *L. olgensis*, *A. tegmentosum*, *Q. mongolica*, *A. nephrolepis*. *P. syluestriformis* population and the above-mentioned associated species had the same or similar requirements for the same resource, and competition would occur when the resources were insufficient. The succession dynamics of *P. syluestriformis* populations were mainly characterized by narrow geographical distribution and narrow habitat, few populations, no individual seedlings and saplings, and lack of self-renewal ability, so they belonged to the recession-type populations.
Keywords: *P. syluestriformis, aggregation degree, niche overlap, niche breadth*

Introduction

The niche is the smallest unit of species distribution. Since Grinnell J proposed niche conception in 1917. The study of niche theory has been one of the research hotspots in the field of world ecology (Grinnell, 1917). Niche theory is widely used in species relations, biodiversity, community structure and function, community succession dynamics, intraspecific and interspecific competition studies.

To analyze the status and relationship of target species in communities, Chinese and foreign scholars used multiple niche breadth and niche overlap formulas to measure the niche characteristics of main populations of different communities. Seen from the existing results, the plant communities that developed on different types of landforms in different regions have different manifestations of their population niche characteristics (Chang et al., 2015; Chen et al., 2010). Among them, Chinese scholars have made relatively successful attempts to study the niche of plant populations in Changbai Mountain, China (Chen et al., 2009; Ye et al., 2011). The research on the population niche characteristics of rare and endangered plants is of great significance for further exploring the utilization of space resources and the interrelationships between other

© 2018, ALÖKI Kft., Budapest, Hungary

endangered plants and other populations, and revealing the mechanism of endangered plants.

P. syluestriformis, is an evergreen tree of *Pinus* L. and a rare and endangered tree species in Changbai Mountain area of China. The natural population is relatively narrow and is located at N 42°06' - 42°32', E 128°07' - 128°21', scattered on the northern slope of Changbai Mountain, China (Jin et al., 2015).

Due to population increase, economic development and environmental destruction, the distribution area of natural population of *P. syluestriformis* have gradually narrowed and it has reached the edge of extinction. At present, the number of existing plants of *P. syluestriformis* is less than 110000 (Wang, 2007).

Since the 1980s, some Chinese scholars began to pay attention to the special species of *P. syluestriformis*. Aiming at the ecological characteristics, the growth pattern, the introduction and afforestation techniques, the biomass, diversity of interspecific seed traits in population, and so on (Lu et al., 2004; Cheng et al., 2013; Zou et al., 1995), and research cases on the niche characteristics of the rare population of *P. syluestriformis* have not been reported so far. Therefore, in this paper, the field survey data of community of *P. syluestriformis* population distribution as the data source were used to quantitatively measure the niche characteristics of the dominants to reveal the function and status of *P. syluestriformis* population in the community and analyze the interrelation between various groups. It will provide scientific support for judging the stability of *P. syluestriformis* population and theoretical basis for revealing its endangered mechanism.

Material and methods

Regional survey of research

The research area is located in the Changbai Mountain Nature Reserve in Jilin, China. The zonal climate belongs to the continental mountain climate with monsoon influence. Winter is cold and dry; summer is warm and humid. The precipitation is mostly concentrated in July-August, with an average annual temperature of 4.4 °C, extreme minimum temperature of -40 °C, the extreme maximum temperature of 37.5 °C, annual precipitation of 600-1340 mm, relative humidity of more than 70%, and the frost-free period of 90-100 days. The soil in the distribution area of *P. syluestriformis* is mostly formed dark brown soil on volcanic ash. The soil layer is thin, the pH is 4.2-4.9, the content of humus is low, and the water holding capacity is poor.

The plant in the area belongs to floristic plant of Changbai Mountain. The upper part of the natural distribution area of *P. syluestriformis* is mixed with coniferous forest, and the lower part is interlaced with coniferous and broad-leaved mixed forest belt, forming a unique mixed forest and a small piece of pure forest of *P. syluestriformis*.

Sampling method

In 2015, one sample plots of 30m × 30m were set up in the pure forest of *P. syluestriformis*, two sample plots of 30m × 30m were set up in the scattered forest of *P. syluestriformis* in Changbai Mountain Nature Reserve. The species, crown width, coverage and diameter at breast height (DBH) of woody plants with DBH ≥ 1.3 cm were investigated and recorded in detail. The sample area was summarized in *Table 1*. The distribution map of *P. syluestriformis* is shown in *Figure 1*.

Data processing

Population distribution pattern measurement method

There are many mathematical models for determining the types of distribution patterns of biological populations. In practical applications, each model has its adaptive application effect and the method is simple and effective. This paper combines with five kinds of aggregation index, such as the diffusion coefficient (C), aggregation index (I), average congestion (M^*), convergence index (M^*/x) and M index (C_A). The distribution pattern is determined by means of t test of mean variance and F test of deviation degree of random distribution, and the population aggregation is determined by negative binomial parameters (K) (Wang, 2012; Guo, 2004).

Niche breadth (Hurlbert, 1978; Li et al., 2003)

$$Bi = \frac{1}{r\sum_{j=1}^{r} P_{ij}^2} \quad \text{(Eq.1)}$$

Equation 1 of Levins (1968) is quantitatively calculated, γ is the number of resource bits, P_{ij} is the proportion of the species is using the j-th resource for all resources and is the population number; the niche breadth range is [1/γ, 1].

$$B_a = \frac{1}{\sum_{j=1}^{n} \frac{p_j^2}{a_j}} \quad \text{(Eq.2)}$$

Equation 2 stands for Hurlbert niche breadth index. P_j is the proportion of the species i that uses the j-th resource to the total resource bit used by the species, a_j is the number of items available in resources j($\Sigma a_j = 1.0$), B_a is the standardized Hurlbert niche breadth index.

Niche overlap (Hurlbert, 1978)

$$O_{ik} = \sum_{j=1}^{r} P_{ij}P_{kj} \Big/ \sqrt{\left(\sum_{j=1}^{r} P_{ij}\right)^2 \left(\sum_{j=1}^{r} P_{kj}\right)^2} \quad \text{(Eq.3)}$$

Pianka (1973) overlap index was used for analysis. In *Equation 3,* O_{ik} value is between 0 and 1.

Age class division of P. syluestriformis

For the classification of age class of *P. syluestriformis*, this paper takes 30 years as an age class, altogether divides into 8 age classes, which are I grade, II grade, III grade, IV grade, V grade, VI grade, VII grade, VIII grade. Those over 240 years old are classified as VIII grade.

Data statistical analysis

The original data is input into Excel table, and the data format can be read by R software according to the need of analysis. The spatial distribution pattern is analyzed, using the Riplely correlation function in the Spatstat library of R software.

Results

Spatial distribution pattern of P. syluestriformis population

According to the survey sample data, the indexes mentioned above of aggregation were measured by distribution (*Table 2*). It could be seen from the results in the table that the maximum diffusion coefficient of P2 sample plot was 2.243, which was greater than 1, and the diffusion coefficient of other sample plots was less than 1. After comparing t and $t0.05(36\text{-}1)$, both reached significant level of difference. According to the analysis of sample plots, the pure forest community of *P. syluestriformis* presented a clustered distribution. While in the scattered forests, the distribution state showed random and scattered in various forest communities. The M^*/x index was greater than 1 in P2 sample plots, the indexes in the other samples were all less than 1. To more accurately reflect the spatial pattern of a natural population of *P. syluestriformis* in different habitats, the regression analysis of 6 plots M^*/x of scattered forests was carried out. The regression equation was as follows: $M^* = -0.05161 + 0.43806x$ $R = 0.6927$. In the regression relationship, the α value was -0.05161, which was approximately 0, indicating that the basic component of the distribution was a single individual. The space β used to explain the basic component, the β value was 0.43806, and the value β was < 1, which was a uniform distribution. Using the statistical method of Taylor's power law, the regression equation was: $lgS^2 = -0.16858 + 0.88407lgx$ $R = 0.9959$, further confirmed that the populations of *P. syluestriformis* were scattered in the communities in the scattered state.

Table 2. *Spatial distribution and aggregation index of P. syluestriformis population*

Sample number	$\bar{x}$	S^2	Diffusion coefficient C	I index	Average congestion M^*	M^*/x index	C_A index	Distribution pattern

C: cluster distribution, *R:* random

The spatial distribution pattern of a natural population of *P. syluestriformis* was analyzed by using C, M^*, C_A index. The results showed in *Table 3* that in pure forest there was no individual of *P. syluestriformis* in addition to VIII age-class, and there were distributions at all other levels, of which III and IV age-classes were clustered, and other age-classes were random. It also showed that the population had a certain diffusivity from young to mature individuals, and C, C_A had the same result of judgment. In pure forest community, the spatial distribution pattern of *P. syluestriformis* population changed from young to mature, which was a general trend from random type to clustered type and then to random type.

C: cluster distribution, *R:* random, *N:* lack of this type

However, aggregation index of *P. syluestriformis* population of the scattered community below 1000 m above sea level showed that only one individual of I age-class was present in the investigated community, the individuals of II-III age-classes were missing, and the individuals of IV-VIII age-classes were randomly distributed.

Aggregation index of *P. syluestriformis* population of the scattered community above 1000 m above sea level showed that there were no individuals of I-V age-classes in the community, and only individuals of VI-VIII age-classes had the spatial distribution pattern of random distribution.

Analysis of niche breadth measurement results

Niche breadth is an indirect measurement of the scale and population dynamics of the population's ability to use environmental resources. The niche breadth depends on the quantitative expression of species' position and role in the community, which can better explain the environmental adaptability and resource utilization ability of the population during the succession process. The greater the niche breadth of the population, the stronger its ability to adapt to the environment, the fuller the utilization of various resources, and the more dominant position it often plays in the community. To overcome the impossibility of comparing the niche of different communities and within the same community, levins index and Hurlbert index were used to study the niche breadths of major populations. Comprehensive analysis of survey plots, niche

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_55395549
© 2018, ALÖKI Kft., Budapest, Hungary

breadths were calculated of 12 species with relatively high important value and wide distribution range by using *Equations 1* and *2*.

It could be seen in *Table 4* that the order of the levins niche breadth index was P. syluestriformis > A. nephrolepis>L. olgensis>B. platyphylla>T. amurensis>U. japonica >A. tegmentosum>Q. mongolica>P. jezoensis> A. mono>S. pohuashanensis>P. koraiensis. The maximum of Levins niche breadth of P. syluestriformis population was 5.3094, indicating that P. syluestriformis had obvious superiority in each resource location. As one of the community species, it was distributed in 8 resource locations. The second was A. nephrolepis, and the Levins niche breadth was 4.1782, and it also occupied a wide range of niches. It was distributed in all six resource locations except for pure forests. B. platyphylla and T. amurensis had wide niche amplitude and wide distribution, the Levins niche breadth was 3.3196 and 3.1864, respectively. L. olgensis and P. koraiensis were the main associated tree species in the arbor layer of scattered communities, and the Levins niche breadth was 3.4050 and 2.3611, respectively.

Table 4. *Niche breadth of main species in arbor layer of P. syluestriformis community*

Species number	*Pi*1	*Pi*2	*Pi*3	*Pi*4	*Pi*5	*Pi*6	*Pi*7	*Pi*8	*Bi*	*Ba*

L. olgensis	0.000	0.000	0.339	0.290	0.000	0.299	0.072	0.000	3.4050	0.8513
B. platyphylla	0.049	0.004	0.383	0.054	0.000	0.035	0.370	0.104	3.3196	0.4742
A. mono	0.001	0.000	0.208	0.000	0.000	0.103	0.580	0.108	2.4885	0.4977
P. koraiensis	0.000	0.000	0.011	0.034	0.572	0.021	0.302	0.059	2.3611	0.3935
A. nephrolepis	0.000	0.000	0.001	0.355	0.090	0.141	0.205	0.209	4.1782	0.6964
S. pohuashanensis	0.000	0.000	0.026	0.061	0.000	0.061	0.270	0.583	2.3638	0.4728
A. tegmentosum	0.029	0.000	0.107	0.126	0.000	0.555	0.184	0.000	2.7089	0.5418

Taking full account of the fact that the resource status was highly variable under actual circumstances, the Hurlbert niche breadth value was calculated. The index took into account the magnitude of each resource's state. The analysis data showed that the Hurlbert niche breadth was the largest due to *U. japonica,* it had a larger important value in the *P. syluestriformis* pure forest, its utilization of resources and space in forest was similar to that of *P. syluestriformis*. The Hurlbert niche breadth of other species were basically the same as the Levins niche breadth, which reflected the status and the distribution range of major arbor populations determined the niche breadth.

Analysis of niche overlap measurement results

Niche overlap is the similarity between two species in relation to ecological factors. Niche overlap occurs when two species use the same resource or share one resource (food, nutrients, space, etc.). Niche overlaps make connections between species, and the niche overlap value can explain the competition or coexistence between species.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

Calculation of niche overlap index by *Equation 3,* as shown in *Table 5,* the maximum niche overlap occurred between *A. mono* and *B. platyphyll*, followed by *A. Nephrolepis* and *T. amurensis*, indicating that there may be higher niche overlap among species with narrow niche breadth. There was a large niche overlap between *P. syluestriformis* and *U. japonica* population, with an overlap index of 0.704, followed by *L. olgensis*, *A. tegmentosum*, *Q. mongolica*, *L. olgensis* and *A. nephrolepis*, with niche overlap indices of 0.395, 0.392, 0.369, 0.368 and 0.367, respectively.

In the communities of natural *P. syluestriformis* population, the degree of niche overlap of various populations was great, the relationship between species was complex, the trend of resource sharing was obvious, and the utilization of resources by species was similar. The niche overlap of populations with large importance value and wide niche breadth was greater than that of other populations. On the contrary, the niche overlap of populations with small importance value and narrow niche breadth was smaller than that of other populations.

Discussion

The niche breadth of the populations in each community depends on the adaptability of the species to the environment, the intensity of interspecific competition, and the distribution of environmental factors (Chen et al., 2014).

This research found that the niche breadth of *P. syluestriformis* was large in the community, indicating that the species had strong adaptability to the environment. Wei Zhiqin and others thought that rare and endangered plants were mostly inhibited in the community, and the niche was very narrow (Wei et al., 2004). The conclusion of this study is contrary to it. The reason may be that, on the one hand, it is possible that the purpose of the study is to use *P. syluestriformis* as the target tree. When selecting the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_55395549
© 2018, ALÖKI Kft., Budapest, Hungary

plots, the gathering community of *P. syluestriformis* was artificially selected as the survey site, but this did not affect the community structure and its status in the community. On the one hand, it may be because *P. syluestriformis* itself had a special habitat requirement, and the population had a widening niche breadth to obtain sufficient resources (Zhang, 2011).

This research reflects that the view is consistent with Liu Wei's research on the niche of main plant species of the Spruce-fir forests in Changbai Mountain, that is, the greater niche breadth, the greater overlap (Liu and Cao, 2011). However, due to the individual niche breadth, the species' biological and ecological characteristics are unnecessarily the same, and the niche overlap between them is unnecessarily high. It is considered that the decrease in the degree of overlap reflects the differentiation of inter-species resource utilization (Du et al., 2015). Therefore, for species pairs with large niche overlap in the community, it is considered that there are two possibilities: one is that there is a competitive relationship while sharing resources among the species, and the other is that the resources are similarly used while promoting the relationship between the species (Xu et al., 2014). Vannette proposed the niche construction hypothesis, which held the view that if the niche of species was divided into three parts: niche overlap between species, the environmental impact niche and the requirement niche of environmental resources, the prediction of community construction based on niche would be more accurate (Vannette and Fukami, 2014).

Field investigations showed that there were fewer young seedlings of *P. syluestriformis* under the forest, indicating that the habitat of *P. syluestriformis* was higher than the interaction between the species. This paper only explored the resource utilization status between *P. syluestriformis* and the current community dominant species from the perspective of community science. The resource utilization ability of *P. syluestriformis* under different growth conditions was not compared, and further research would be needed. Besides, the distribution of two communities of *P. syluestriformis* could be regarded as the key protection habitat, and the difference of population dynamics caused by the difference of their habitats needed to be further explored.

Conclusions

The research showed that populations with similar habitat requirements could form a good symbiotic relationship under the condition of sufficient resources, which supported the theory that niche overlap and competition were not related. There were relatively few individuals in each resource location of *P. syluestriformis*, and most of them were older, occupying the absolute superiority in the height niche of the arbor layer, and occupying the upper layer of the forest canopy and occupying the absolute dominant position in the community.Therefore, this advantage of *P. syluestriformis* was temporary, and the succession dynamics of *P. syluestriformis* populations were mainly characterized by narrow geographical distribution and narrow habitat, few populations, no individual seedlings and saplings, and lack of self-renewal ability, so they belonged to the recession-type populations. After a certain period of succession, it would probably be replaced by other arbor species, which had many saplings, and had relatively large niche overlap with its *P. syluestriformis,* such as *P. koraiensis, A. nephrolepis,* and so on.

DOI: http://dx.doi.org/10.15666/aeer/1605_55395549
© 2018, ALÖKI Kft., Budapest, Hungary

The reason for the rarity of *P. syluestriformis* was mainly caused by the combination of internal and external factors. The internal factors were the defects of ecological and biological characteristics of *P. syluestriformis*. The ecological adaptability of *P. syluestriformis* was relatively narrow and the distribution area was limited; the seed regeneration was difficult, and the ability of self-regeneration was extremely lacking; the resources for the growth of seedlings and saplings were limited. External factors included historical overuse and habitat destruction, and natural communities were largely absent. Therefore, the community resources of Changbai Mountain area were very rare. The protection of wild populations and their habitats of *P. syluestriformis* was the most effective protection measure. With establishment of a different forest for further implementation of *P. syluestriformis* by local conservation and artificial cultivation, the artificial cultivated individuals were transplanted into their original habitats. In this way, they could be naturalized into the natural environment, could develop normally and produce future generations, and consequently expand the size of natural populations.

THE IMPORTANT ROLE OF AMINOETHOXYVINYLGLYCINE (AVG) PRE-HARVEST APPLICATION IN FRUIT HARVEST TIME, FRUIT QUALITY AND MINERAL ELEMENT CONTENTS OF 'AKÇA' (*PYRUS COMMUNIS* L.)

ÇETINBAŞ, M.

Fruit Research Institute, Egirdir, Isparta, Turkey
(e-mail: melikecetinbas@gmail.com; phone:+90-246-313-2420; fax:+90-246-313-2425)

(Received 19th Jun 2018; accepted 7th Aug 2018)

Abstract. 'Akça' pear is one of the most grown early varieties in Turkey. Although it is of high quality, it forms smaller fruits than other early varieties. In order to investigate the role of aminoethoxyvinylglycine (AVG) application in the harvest time, fruit yield and quality of 'Akça' pears, this study was carried out for 2 years in 2012 and 2013 in an orchard located in Isparta-Egirdir (Turkey) Fruit Research Institute. ReTain plant growth regulator was used for AVG. ReTain containing 15% AVG was applied to the 'Akça' pear fruits and leaves. Four concentrations of AVG (0, 100, 125, 150 ppm) and three application times [30, 21, 7 days before commercial harvest (DBH)] were evaluated using the field system. Harvest time, fruit yield, fruit size, fruit weight, fruit flesh firmness, titratable acidity (TA), soluble solid contents (SSC), fruit color, ethylene production and respiration rate, and nutritional status of fruits were determined at the harvest time. In addition, the effect of AVG applications on some leaf properties (macro-micro element content, leaf area and chlorophyll) was determined. As a result, 30 and 21 DBH AVG applications delayed the harvest time for 3 days. AVG applications reduced both ethylene production and respiration rate. All AVG applications dramatically increased fruit size (2-16%) and fruit weight (7-57%) as well as fruit flesh firmness (1-55%) of the 'Akça' pear. Given all these results, it is considered that 21 DBH AVG applications at 100 ppm will be suitable for the 'Akça' pear in terms of harvest time and fruit and leaf quality parameters.

Introduction

The amount of pears produced in the world is 25.798.644 tons and, with a production amount of 462.336 tons, pear takes the 5th place in Turkey (FAOSTAT, 2018). However, it falls behind other European countries in terms of both yield per decare and exportation. One of the biggest reasons for this is that products with sufficient quality cannot be obtained due to problems related to cultivation techniques. There are many studies conducted in the world for the purpose of increasing fruit quality, and most of them are on plant growth regulators. The most frequently used natural plant growth regulator in the world is the ethylene group (23%), followed by the auxin group and gibberellins (17%), respectively. Cytokinin and Dormin are not yet widely used in the world (Barut, 1995). In recent years, AVG (aminoethoxyvinylglycine), an ethylene blocker, has been used to increase pre-harvest fruit fall and fruit quality. AVG is commercially sold worldwide as ReTain® plant growth regulator. ReTain contains 15% AVG and is a human and environmentally friendly, organic commercial product (Rath and Prentice, 2004) registered in 2001 for use in apples, peaches and nectarine fruits in Australia. Preharvest application of AVG 1–4 weeks prior to harvest inhibits biosynthesis of ethylene and influences abscission, ripening and senescence and reduces quality loss after harvest in many crops (Martinez-Romero et al., 2007; Lurie, 2008; Pech et al., 2012; Kuçuker et al., 2015b; Pasa, et al., 2017). Jobling et al. (2003) found

that AVG treated plums allowed a delay in harvested timing, and resulted in retaining higher firmness and SSC in comparison with untreated fruit, suggesting that accumulation of soluble solids can take place when fruits are on trees for longer. Dussi et al. (2002) applied 14 DBH 125 and 180 ppm AVG to 'Williams' pears. In this study, AVG had no effect on pre-harvest fall, but both fruit size and fruit hardness increased. It was reported that 21, 14 and 7 DBH 125 ppm AVG applied to 'Abbe Fetel' pear delayed the harvest for 5 to 15 days (Andreotti et al., 2004). The pear variety 'Akça' is desired by producers and consumers for being an early comer and its quality characteristics. The fruit size of this variety is slightly smaller than other early comers, meaning a decrease in its market price and a disadvantage for producers. The purpose of this study is to determine the appropriate dose and application time of AVG as well as the effectiveness of AVG applications to improve the fruit quality of the 'Akça' pear.

Material and methods

Plant-chemical materials and experiment design

The plant material of the study was the 12-year-old Akça/Quince A trees in the pear orchard of Egirdir Fruit Research Institute Directorate Isparta, Turkey) Cultural practices such as irrigation, fertilization, plant protection and pruning were carried out regularly during the trial. Thinning was not performed for the fruits. In our study, ReTain (15% AVG) plant growth regulator (Valent BioScience Corporation) was used as the chemical material, and AVG doses were calculated based on the active substance. Four doses of AVG – namely, 0 (control), 100, 125 and 150 ppm – were used. These doses were applied to all fruits and leaves of the 'Akça' pear 30, 21, 7 days before harvest (DHB) for two years. All spray solutions contained 0.2% 'Tween 20' as surfactant. Control trees were sprayed with water + surfactant. A knapsack sprayer was used to apply AVG onto fruits and leaves at the rate of 8 L per tree (*Fig. 1*). The experiment was set up according to the design pattern of 4 repetitive random blocks, and each repetition consisted of 1 tree.

Figure 1. *'Akça' pear and application*

Determination of the effect of applications on harvest time

Determination of harvest time; observation of the fruit size, greenish-yellow coloration of the fruit ground color, hardness of the fruit flesh, and formation of the fruit top color. Harvest was carried out according to these harvest criteria and harvest time

© 2018, ALÖKI Kft., Budapest, Hungary

scales (Ozelkok and Kaynaş, 1995), and the effect of AVG applications on harvest time was determined.

The effect of applications on yield and some fruit quality properties

Of the trees from each application, yield (kg tree^{-1}) per tree and yield (kg cm^{-2}) per trunk section area were determined. Average values were calculated by measuring the width (mm) and length (mm) of the fruit with the help of a calliper. The average fruit weight (g) of the fruit was calculated by weighing. Flesh firmness measurements were determined as Newton (N) with Lloyd Instruments LF Plus (Ametek, U.K.) texturing equipment. Using a CR-300 Minolta (Japan) color meter and taking measurements from both cheek areas of the fruits, fruit color was determined by CIE L*, a*, b*, C* and Hu°. SSC (with digital refractometer, %) and TA (titration method, %) were determined.

The effect of applications on ethylene production and respiratory rate in fruits

As reported by Dilmaçunal (2009), pears weighing approximately 1 kg were put into jars and kept at 20 ± 1 °C for 24 h to determine ethylene production (μL kg^{-1} h) and respiratory rate (μL kg^{-1} h). Ethylene production and respiratory rate were determined by using gas chromatography.

The effect of applications on fruit and leaf mineral element contents

N (nitrogen) analysis in fruit and leaf

In the plant sample burned with a salicylic-sulfuric acid mixture of 2.5%, ammonia formation was obtained in the base environment of the kjeldahl distillation unit. The ammonia formed was then kept in boric acid and titrated with 0.1 N sulfuric acid. It was calculated as shown in the formula below (Ryan et al., 2001) (*Eq. 1*).

$$N\% = \frac{(T-B) \times N \times 1.4}{S} \quad \text{(Eq.1)}$$

T: Amount of sulfuric acid consumed for plant sample titration
B: Amount of sulfuric acid consumed for stratum corneum (witness) titration
N: Normality of sulfuric acid
S: Amount of plant sample used in the analysis
1.4: Coefficient

P (phosphorus), K (potassium), Ca (calcium), Mg (magnesium), Cu (copper), Fe (iron), Mn (manganese), Zn (zinc), B (boron) analysis in fruit and leaf

Since a considerable amount of boron is lost during wet combustion, dry combustion was performed. Reading was made by ICP (Inductively Coupled Plasma Atomic Emission Spectophometer) (Ryan et al., 2001). The following steps were taken as part of dry combustion: 0.5 g ground plant material was put into porcelain crucibles, which were then placed into the muffle furnace. Furnace temperature was gradually increased to 550 °C. After reaching 550 °C, combustion continued for 6 h. Following combustion, 5 ml 2 N HCl was added into the cooled porcelain crucibles and the samples were dissolved and stirred with a plastic stick. After 15-20 min, pure water was added until

DOI: http://dx.doi.org/10.15666/aeer/1605_55515569
© 2018, ALÖKI Kft., Budapest, Hungary

reaching 50 ml and thoroughly stirred. 30 min later, it was filtered using a filter paper, and the extract obtained was read by ICP.

The effect of application on leaf area (LA) and total chlorophyll (spad value)

Total chlorophyll was measured using a portable chlorophyll meter on July 15 (first year) – July 10 (second year) (Minolta SPAD-502, Osaka, Japan). Designed and manufactured based on the principles of Inada (1963), this chlorophyll meter measures the amount of chlorophyll in leaves indirectly. It measures the red and infrared regions in the leaf structure (at 659 nm and 940 nm wavelengths, respectively) to determine the relative chlorophyll density. 15 leaf samples were taken in total from four sides of the trees in all applications, and the surface area of one side of each leaf was calculated as a cm^2 by a digital planimeter (Koizumi KP-90 N) (Kucukyumuk et al., 2015).

Statistical analysis of results

Variance analysis was performed with the obtained data, and differences between the treatments were tested by Duncan's multiple range test at $P < 0.05$ using SSPS (V. 18; Statiscal software, SPSS. Inc., USA) software program. The experiment was based as a completely randomized blocking pattern as four replications and was assigned as one tree for each replication, and was assigned to one tree at each replication with each plot having 20 pear fruits.

Results

Fruit harvest time and yield

The harvest was made 2 times a year for both years, and it was seen that the applications affected harvest dates. In the 1st and 2nd years, the control group and the fruits with 7 DBH AVG ripened at the same time, while the fruits with 30 and 21 DBH AVG ripened later. After reaching maturity for the first harvest, the control and the fruits with 7 DBH AVG were harvested on July 14 in the first year and on July 6 in the second year. On the other hand, other fruits with 30 and 21 DBH AVG were harvested on July 18 in the first year and on July 9 in the second year. It was determined that AVG applications (except for 7 DBH) delayed the harvest maturity of Akça pear for up to 3-4 days. AVG applications did not have any statistically significant effect on yield per tree or yield per trunk section in both years (*Table 1*).

[1]Days before harvest (DBH)

Fruit quality

As a result of the variance analysis performed in both application years, the time x dose interactions were found statistically significant ($p < 0.05$) in terms of fruit width (*Table 2*). In both years, the AVG applications increased fruit width. The applications with the highest fruit width in the first and second years were 21 DBH 100 ppm AVG (48.32 mm) and 30 DBH 100 ppm AVG (49.54 mm), respectively (*Table* 2). The effect of AVG applications on fruit length was statistically significant ($p < 0.05$) only in the first year as time x dose interaction (*Table* 2). Just like in fruit width, the applications with the highest fruit length were 21 DBH 100 ppm AVG (1st year). On the other hand, the lowest fruit length was observed in the control fruits with 7 DBH AVG application (1st year) (*Table 2*). Fruit weight increased with the applications in both years, and the time x dose interaction was found to be statistically significant in the analysis of variance ($p < 0.05$). The heaviest fruits were obtained from 30 and 21 DBH 100 ppm AVG applications. The least heavy fruits were again obtained from the controls (*Table 2*).

[1]Days before harvest (DBH)
*Each column, values followed by the same letter are not significantly different at $p < 0.05$ level according to Duncan's multiple range test

The time x dose interaction of AVG applications was statistically significant ($p < 0.05$) in terms of fruit flesh firmness in both years. In both years, fruit flesh firmness increased with the applications, and the fruit flesh firmness of the applications of 21 DBH was higher than others. 21 DBH 100 ppm AVG in the first year and 30 DBH 150 ppm AVG in the second year gave the hardest fruits (*Table 3*).

[1]Days before harvest (DBH)
*Each column, values followed by the same letter are not significantly different at $p < 0.05$ level according to Duncan's multiple range test

In the first year, the applications increased the amount of SSC, and the time x dose interaction was found to be significant ($p < 0.05$) as a result of the variance analysis. In the second year, however, the applications were statistically insignificant. In the first year, the highest SSC (13.47%) was found in 7 DBH 125 ppm AVG *(Table 3*). The time x dose interaction was statistically significant ($p < 0.05$) in terms of TA in both years, and the highest TA was obtained from 21 DBH 100 ppm AVG (*Table 3*).

In the first year, the effect of AVG applications on fruit color values (L*, a*, b*, C*, h°) was statistically significant ($p < 0.05$) in time x dose interactions (*Table 4*).

[1]Days before harvest (DBH)
*Each column, values followed by the same letter are not significantly different at $p < 0.05$ level according to Duncan's multiple range test

The values of L*, which indicates brightness, decreased with the AVG applications. The lowest L* was obtained from 21 DBH 100 ppm AVG (67.96). The values of a*, which indicates redness, also decreased with the applications, and the lowest value was obtained from 21 DBH 100 ppm AVG, which also gave the value of b* indicating yellowness. On the other hand, the highest value of b* was obtained from 7 DBH 100 ppm AVG. As in b* values, the highest C* value was produced by 7 DBH 100 ppm AVG. The hue values of AVG-applied fruits were higher than those of the control fruits, and the highest h° value was produced by 21 DBH 100 ppm AVG (*Table 4*). In the second year of the project, the time x dose interactions of L*, a*, h° values were found to be statistically significant ($p < 0.05$). L* and a* values decreased with the AVG applications, and the lowest L* (67.78) and a* (22.58) values were observed in 21 DBH 150 ppm AVG. It was found that the h° values of the AVG applications were higher than the control fruits, and the highest h° value was obtained from 21 DBH 125 ppm AVG (*Table 5*).

*Each column, values followed by the same letter are not significantly different at $p < 0.05$ level according to Duncan's multiple range test

Ethylene production and respiration rate

In the first year, ethylene production could not be determined. In terms of respiration rate, the time x dose interaction was found statistically significant ($p < 0.05$). In the second year, however, the effect of the applications on both ethylene production and respiration rate was found to be statistically significant ($p < 0.05$) in terms of time x dose interaction (*Table 6*). All AVG applications slowed both ethylene production (μL kg^{-1} h) and respiratory rate (μL kg^{-1} h) in the fruit. The lowest ethylene production was 0.15 μL kg^{-1} h and the lowest respiration rate was 12.32 μL kg^{-1} h obtained from 21 DBH 150 ppm AVG (*Table 6*).

Fruit and leave mineral element contents determination

The effect of AVG applications on the nitrogen contents of fruits was found to be statistically significant ($p < 0.05$) in both years as time x dose interaction. In both years, nitrogen contents increased with 30 and 21 DBH AVG applications but decreased with 7 DBH AVG applications. The highest and lowest nitrogen contents were obtained from 30 DBH 150 ppm AVG and from 7 DBH 125 ppm AVG, respectively (*Table 7*).

[1]Days before harvest (DBH)
*Each column, values followed by the same letter are not significantly different at $p < 0.05$ level according to Duncan's multiple range test

In the variance analysis made for calcium content, only the time x dose interaction of the applications in the second year was found statistically significant ($p < 0.05$). In general, calcium content increased with the applications. In terms of magnesium content, however, no statistically significant difference was observed in both years (*Table 7*). In terms of phosphorus and potassium, there was no statistically significant difference in phosphorus content in both years, while the difference between dose averages was statistically significant ($p < 0.05$) in potassium content and the dose of 150 ppm had the highest amount of potassium (*Table 8*).

[1]Days before harvest (DBH)
*Each column, values followed by the same letter are not significantly different at $p < 0.05$ level according to Duncan's multiple range test

In both years, the effect of AVG applications on iron content was statistically significant ($p < 0.05$) as time x dose interaction. However, manganese and boron contents were not found to be statistically significant (*Table 9*). The effect of AVG applications on copper and zinc contents is given in *Table 8*. In zinc content, the time x dose interaction was statistically significant ($p < 0.05$) only in the first year of AVG applications. The application with the highest iron content was 30 DBH 150 ppm AVG in both years. On the other hand, the lowest iron content was observed in the control fruits with 7 DBH AVG (*Table 9*).

Table 9. *The effect of AVG treatments on iron, manganese, boron in the 'Akça' pear fruit, 2012 and 2013*

The leaves with the highest calcium content (2.42 ppm) were obtained from 21 DBH 100 ppm AVG in the first year and from 30 DBH 125 ppm AVG in the second year (*Table 10*). In terms of magnesium contents, the amount of magnesium decreased with the applications in the second year in general; it increased only in 30 DBH 125 ppm AVG (*Table 10*). With respect to the effect of AVG applications on phosphorus and potassium contents, the time x dose interaction for phosphorus and the difference between doses for potassium were found statistically significant ($p < 0.05$) (*Table 11*). *Table 11* shows the effect of AVG applications on the copper and zinc contents of the Akça leaves. It was seen that the applications increased the copper content. The effect of AVG applications was statistically significant on the iron and boron contents of leaves as well. As time x dose interaction, iron content in both years and boron content only in the second year were found statistically significant ($p < 0.05$) (*Table 12*). Iron content had the highest value in 30 DBH 125 ppm AVG in the first year and in 7 DBH 100 ppm AVG in the second year. For boron, however, it was 7 DBH 100 ppm AVG with a value of 36.72 ppm (*Table 12*).

[1]Days before harvest (DBH)
*Each column, values followed by the same letter are not significantly different at $p < 0.05$ level according to Duncan's multiple range test

The effect of applications on leaf area (cm^2) and chlorophyll value (spad value) in the leaves of 'Akça' variety

The effect of AVG applications on the leaf area of 'Akça' variety was statistically significant ($p < 0.05$) as time x dose interaction only in the first year. Leaf area expanded with the applications, and the largest leaf area was observed in 21 DBH 125 ppm AVG (*Table 13*). Their effect on the chlorophyll value of the leaves of 'Akça' variety was found statistically significant ($p < 0.05$) as time x dose interaction in both years. The amount of chlorophyll increased in general with the applications. The highest spad value was obtained from 30 DBH 125 ppm AVG and 21 and 7 DBH 100 ppm AVG (*Table 13*).

Discussion

It was determined that 30 DBH and 21 DBH AVG applications (all doses) delayed the harvest maturity of Akça pear for up to 3-4 days. It was well documented that AVG inhibits ethylene biosynthesis, thus retards fruit ripening (Amarante et al., 2002; Schupp and Greene, 2004; Petri et al., 2006; Kang et al., 2007). Similar results were also observed in this study. Clayton et al. (2000) reported that ReTain applied 14 and 7 days before harvest delayed the harvest for up to 4-10 days in the Bartlett pear. The increase in fruit weight with the AVG applications also led to an increase in fruit yield. As reported by Romani et al. (1983), since AVG allows for late ripening, fruit continues to grow, leading to an increase in size and yield. Delayed harvest provides flexibility in fruit processing-packing, storage and marketing planning. Pasa et al. (2017) stated that fruit set, number of fruit per tree and yield were significantly improved by AVG sprayed one week after full bloom with doses ranging from 40 to 100 mg L^{-1} for 'Santa

Maria', while for 'Abate Fetel' the most responsive dose was 100 mg L^{-1}. Fruit quality attributes and fruit size were not affected by treatments. Dussi et al. (2002) applied 14 DBH 125 and 180 ppm AVG to Williams pears**.** In this study, AVG did not have any effect on pre-harvest fall, but an increase in size and hardness was detected. Pre-harvest AVG applications to Williams pear caused a delay in fruit ripening and increased fruit size (Romani et al., 1983). In our study, compared to the control fruits, the AVG applications increased fruit width by about 2-16% and fruit weight by 7-57%.

In the study performed by Clayton et al. (2000) on Bartlett pear, it is reported that AVG increased fruit firmness compared to the control group and maintained both their shelf life and storage as well as their firmness more than controls. The 'Akça' pear is in demand in both domestic and international markets because it is an early comer summer variety. Therefore, shelf life shortens during transport. Higher fruit firmness means a longer shelf life. For this reason, in line with the data obtained by this study, an increase in fruit firmness is considered to reduce quality losses during transport. According to our findings, L* values expressing brightness decreased with the AVG applications. a* values indicating redness were lower in the AVG applications, which is parallel with AVG's retardant effect on ripening and thus coloring.

All AVG applications slowed both ethylene production (μL kg^{-1} h) and respiratory rate (μL kg^{-1} h) in the fruit. Similar to our findings, Clayton et al. (2000) and Butar and Çetinbaş (2017) reported that AVG reduced both ethylene amount and respiration rate and that the application doses had the same effect in Williams pear. In the AVG studies conducted on other varieties, it was reported that ethylene production and respiration rate slowed down (Amarante et al., 2002; Schuup and Greene, 2004; Petri et al., 2006; Kang et al., 2007; Ozturk et al., 2012; Yıldız et al., 2012).

When applied externally, plant growth regulators, which are synthesized naturally in the plant, may have different physiological effects depending on application period and concentration (Salisbury and Ross, 1985). In our study, different application periods and doses of AVG plant growth regulator affected fruits' mineral element contents differently even in different years. Butar and Çetinbaş (2017) stated that a change in AVG application time and dose led to different mineral element contents in 'Williams' pear fruits. In a study conducted on the 'Akça' pear, the contents of N, P, K, Ca, Mg, Zn, Fe, Mn and Cu in the fruit were found to be 3.37, 0.73, 8.25, 0.65, 8.25, 6.63, 4.08, 3.01 mg kg^{-1}, respectively (Kuçuker et al., 2015a). Partly similar results were obtained in our study. AVG applications affect mineral element contents in different ways in leaves as in fruits. It is reported that pear contains 1.134-1.682% nitrogen, 0.46-1.08% potassium, 1.81-3.1% calcium, 0.28-0.55% magnesium, 0.078-0.22% phosphorus, 51.5-197.5 mg kg^{-1} iron, 4.85-8.0 mg kg^{-1} copper, 16-57.5 mg kg^{-1} zinc, and 20-99.5 mg kg^{-1} manganese (Gunen et al., 2003). In our study, these elements were found to exist in the above-given ranges. AVG plant growth regulator is thought to have both increasing and decreasing effects on the mineral element contents in the fruits and leaves of 'Akça' pear. However, decreases did not negatively affect fruit or leaf quality in our study.

Since ethylene hormone causes chlorophyll decomposition in plants (Taiz and Zieger, 2008; Karaçalı, 2009), in an environment where ethylene hormone is suppressed, chlorophyll decomposition is either delayed or slowed down. Accordingly, in our opinion, the AVG applications in our study led to an increase in both leaf area and chlorophyll amount because delayed ethylene production enabled the leaves to nourish and photosynthesize more and have a larger area, and delayed chlorophyll decomposition gave rise to a higher chlorophyll amount.

Conclusion

Taking all results into account, it was concluded in present study that AVG was definitely effective in increasing the quality of 'Akça' pears. The treatments applied in a dose of 100 ppm 21 days before the anticipated harvest time had more effective results in 'Akça' pear in terms of harvest time and fruit quality. Furthermore, since plant nutrients (macro and micro) and plant growth regulator are in interaction with each other, more detailed studies are necessary on this subject.

(Received 25th Jun 2018; accepted 7th Aug 2018)

Abstract. The objective of the present work was to determine the effect of various biostimulants on sand lucerne yielding and content of chlorophyll, proteins, and simple sugars against the background of nitrogen fertilisation regime. A field experiment was arranged as a randomized subblock design (split-plot) with three replicates at the Siedlce Experimental Unit of the University of Natural Sciences and Humanities in Poland in the second decade of August 2013). The following factors were examined: type of biostimulant: Algex, Tytanit, Asahi SL and a control (no biostimulant addition); nitrogen application rate: 0 (control) and 30 kg ha^{-1}. Statistical analysis demonstrated that the biostimulants applied significantly increased plant biomass yields but the effect was more beneficial in plots to where no nitrogen had been applied. Chlorophyll content in lucerne leaves and monosaccharide content were significantly higher following an application of all the biostimulants. Their effect on the sand lucerne content of protein compounds varied. An application of Tytanit and Algex contributed to an increase in protein compounds in test plants but, for Algex, the differences were statistically insignificant. By contrast, an application of Asahi SL was followed by a significant decline in the concentration of protein compounds in lucerne plants. Significantly higher average dry matter yields, a higher average chlorophyll content and a higher average concentration of protein compounds were noted in plots fertilised with nitrogen compared with non-fertilised units. However, nitrogen fertilisation regime significantly reduced the sand lucerne content of simple sugars.
Keywords: *chlorophyll, protein compounds, monosaccharides, Algex, Tytanit, Asahi SL*

Introduction

At present, a challenge for scientists is to look for new technological solutions which would beneficially affect the growth, development, yielding and chemical composition of plants, coupled with limiting e.g. natural environment pollution, and production of healthy food. Recently, products which stimulate metabolic processes in plants, even if they are grown under unfavourable conditions, have been appearing, including biostimulants or growth stimulants (Kocira et al., 2016) of mineral or organic origin (alga and seaweed extracts, phytohormones, micro- and macroelements such as titanium). Biostimulants are products which contain biologically active substances which, by influencing metabolism, contribute to an increase in yields. As it is frequently accompanied by an improvement in yield quality (Kocira et al., 2015; Godlewska and Ciepiela, 2017), the products supplement an application of plant protection preparations and mineral fertilisation. When rationally used, they may be one of the main factors which positively affect the environment and soil productivity (Murawska et al., 2017). According to many authors, an application of biostimulants significantly contributes to an increase in yield, nutrient content, e.g. protein (Szabo et al., 2011), sugars (Godlewska and Ciepiela, 2016), and chlorophyll. It is well known that the effect of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

biostimulants depends on many factors, including crop plant species (Sultana et al., 2005). There are few reports in scientific literature on the effect of biostimulants in herbage legume cultivation, which prompted the authors to undertake research in this field.

The objective of the present work was to determine the effect of various biostimulants on sand lucerne yielding and content of chlorophyll, proteins, and simple sugars against the background of nitrogen fertilisation regime. Protein compounds and monosaccharides are basic components in an assessment of nutritional value of roughages. Chlorophyll content in lucerne leaves is indicative of photosynthesis which has a direct influence on plant growth and development.

Materials and methods

A field experiment was arranged as a randomised sub-block design (split-plot) with three replicates at the Siedlce Experimental Unit of the University of Natural Sciences and Humanities in Poland (52.169° N, 22.280° E) in mid-August 2013. The plot area was 10 m^2 (2.5 m × 4.0 m). According to the Polish soil classification system (Systematics of Polish Soils, 2011), the soil used in the experiment was Hortic Anthrosol (WRB), developed from loamy sand. Based on the analysis performed at the Regional Chemical Station in Wesoła, it was found that the soil was of neutral reaction (pH in 1n KCL = 6.8), with a high humus content (3.78%), available phosphorus content ($H_2PO_4^-$ − 170 mg·kg^{-1}) and magnesium content (Mg^{2+} − 84 mg·kg^{-1}), and average total nitrogen (N – 1.3 g·kg^{-1}) and available potassium (K^+ − 114 mg·kg^{-1}) contents. The following factors were examined:

- Type of biostimulant: Algex, Tytanit, Asahi SL and a control (no biostimulant addition)
- Nitrogen application rate: 0 (control) and 30 kg·ha^{-1}

Algex is an extract of the sea alga *Ascophyllum nodosum* which contains vitamins, amino acids, phytohormones (auxins, cytokinins, gibberellins), polysaccharides, betaine as well as macro- and microelements such as N − 8%, P − 3.6%, K − 7%, B − 0.036%, Zn − 0.025%, Cu − 0.009%, Fe − 0.016%, Mn − 0.036% and Mo − 0.0036%. Algex is manufactured by Rosier, Moustier, Belgium.

Tytanit is produced by INTERMAG Ltd., Olkusz, Poland. Tytanit contains 8.5 g Ti per 1 dm^3 (0.8% m/m) in the form of Ti-ascorbate.

Asahi SL is produced by Arysta Life Science Ltd., Warsaw, Poland. The product contains the following phenolic compounds: sodium p-nitrophenolate − 0.3%, sodium o-nitrophenolate − 0.2% and sodium 5-nitroguaiacolate − 0.1%.

The sowing rate of *Medicago x varia* T. Martyn cv. Marshal was calculated based on the standards drawn up by IMUZ (the Institute for Land Reclamation and Grassland Farming) (Jankowski et al., 2005). Standard cultivation methods were applied in the experiment and, additionally, plants were fertilised with different biostimulants.

The lucerne sowing rate was 23 kg·ha^{-1}. In 2013, when seeds were sown, neither biostimulants or nitrogen fertiliser was applied. In October 2013 only one cut was performed at the plant height of 10 cm. Over the study period (2014-2016), the cutting regime consisted of three harvests per year. Ammonium nitrate was applied three times per year. The total nitrogen amount was split into three equal rates which were applied before each cutting. P and K fertilisation was applied to all the plots. Phosphorus was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_55715581
© 2018, ALÖKI Kft., Budapest, Hungary

applied once as triple superphosphate at the rate of 40 kg·ha^{-1} P_2O_5 in the spring. The amount of potassium (160 kg·ha^{-1} K_2O) was split into three equal rates and applied prior to each cutting as 60% potash salt. The biostimulants was sprayed as an aqueous solution. The spraying was performed before each cutting: the first application was three weeks before the first cutting, the second one two weeks after the first harvest and the last one three weeks after the second harvest. Biostimulant rates following each cut were applied as recommended by the manufacturer, that is thinned with water to obtain the volume of 400 dm^3: Algex − 6 dm^3·ha^{-1}, Tytanit − 0.4 dm^3·ha^{-1}, Asahi SL − 0.6 dm^3·ha^{-1}.

Leaf chlorophyll was determined using a Minolta Chlorophyll Meter SPAD-502. It measures the light absorption by leaves at the wavelength of 650 and 940 nm. The quotients of light absorption at the two wavelengths are unitless and are called SPAD values. They reflect the leaf greenness index which corresponds to the total chlorophyll content (Machul, 2005; Pacewicz and Gregorczyk, 2009). Measurements were taken in each plot on 10 randomly selected sand lucerne leaves (top leaves) the day before harvest.

During harvest of each cut, green matter from each plot (whole area, that is 10 m^2) was weighed to determine the yield, and 0.5 kg green matter samples of lucerne were taken to determine the drying-up coefficient, and to carry out chemical analyses. The samples were left to dry in a ventilated room. Airy dry matter was weighed (to determine dry matter yield per plot) and was then shredded and ground. The obtained material was subjected to chemical analysis to determine dry matter (by determining moisture content), protein compounds, and monosaccharides. The method of determination was near-infrared spectroscopy (NIRS) using a NIRFlex N-500 spectrometer and ready-to-use INGOT calibration applications.

Statistical analysis was conducted by means of the program STATISTICA StatSoft, Inc. (2011). STATISTICA (data analysis software system), version 10 (www.statsoft.com) was used. Significance of differences between means was checked using the Tukey test at the significance level of $\alpha \leq 0.05$.

Meteorological conditions during the study period were changeable and precipitation was very unevenly distributed (*Table 1*). The mean air temperature in the 2015 growing season was by 2 degrees lower than the mean across 2006-2016 whereas precipitation sum in 2016 was by 24 mm higher than the value for the preceding decade. July 2016 was of particular interest as the precipitation sum was twice as high as the mean across 2006-2016 and amounted to 25.6% of the precipitation sum for the whole growing season. By contract, unusual precipitation shortages occurred in September 2014, April and July 2015, and May and September 2016.

Results and discussion

An analysis of average results for three study years demonstrated significant variation in sand lucerne yields regardless of the experimental factors (*Table 2*).

Table 2. *Dry matter yield of Medicago x varia T. Martyn (t ha^{-1}) (sum of three cuts)*

Year	Dose of N kg ha^{-1}	Biostimulant				Mean

Different lower-case letters within the same line indicate significant differences. Different uppercase letters indicate that the values in the column for individual factors (Dose N and Years) and their interaction differ significantly

Significantly the lowest biomass yields were obtained in the first study year, them being the highest in the second year. Precipitation amount is an important factor which determines yield levels. Thus, it can be inferred that such low yields in the first study year may have been due to relatively the lowest precipitation amounts (*Table 1*). An application of biostimulants, regardless of the study years and nitrogen fertilisation regime, increased plant yields (by 15.6%, on average). The effect of biostimulants in the individual study years and in combination with nitrogen rates was equivocal. In non-fertilised plots, the biostimulants Algex and Tytanit contributed to a significant increase in lucerne yields in each study year compared with yields harvested from plots not treated with the biostimulants. Such an effect for Asahi SL was observed in the first study year only. A significant rise in yields obtained from plots fertilised with nitrogen

© 2018, ALÖKI Kft., Budapest, Hungary

was observed following an application of Asahi SL (in the first and third study year) and Tytanit (in the third year). Also Tan et al. (2011), Kováčik et al. (2018) and Whitted-Haag et al. (2014) obtained significant plant yield increases following an application of Tytanit. In each study year, the biostimulant Algex increased lucerne yields in plots fertilised with nitrogen but the differences were insignificant, which is in disagreement with results obtained by other researchers. Many authors have reported a significant effect of an application of sea alga extract on plant yields (Kumar and Sahoo, 2011; Sabir et al., 2014; Nerrisa et al., 2016). However, one should bear in mind that the effect of natural biostimulants is to a great extent determined by crop plant species and cultivar (Sultana et al., 2005; Godlewska and Ciepiela, 2016). Regardless of the remaining factors, nitrogen fertilisation regime significantly influenced yields produced by the test plant.

Dry matter yield (t ha^{-1}) harvested with individual cuts as affected by nitrogen fertilisation regime and type of biostimulant is presented in *Table 3*.

Table 3. *Dry matter yield of Medicago x varia T. Martyn (t ha^{-1}) (average of three years)*

Different lower-case letters within the same line indicate significant differences. Different uppercase letters indicate that the values in the column for individual factors (Dose N and Cut) and their interaction differ significantly

Regardless of the experimental factors, the lowest lucerne yields were harvested in the first cut, them being the highest for the second cut (mean across years), which should be linked with the meteorological conditions (*Table 1*). Irrespective of the biostimulants, nitrogen regime increased yields harvested in each cut. The effect of the biostimulants on lucerne yields was favourable but the differences were not always significant. Regardless of the N fertiliser factor, in the first and second cut, the biomass of plants in plots treated with biostimulants was significantly higher compared with control yields. In individual cuts, the effect of biostimulants as influenced by nitrogen regime was equivocal. In units without nitrogen application, a significant increase in yield was observed for the first cut following an application of Algex and Tytanit, for the second

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

cut following spraying with all the biostimulants, and for the third cut after Asahi SL had been applied. Significantly higher yields harvested in plots fertilised with nitrogen were recorded for the second and third cut only after spraying with Asahi SL compared with control yields.

The nitrogen status of plants, important in terms of the effectiveness of crop plant production and yield quality, can be determined by means of an application of a test which measures the chlorophyll content in leaves (Rostami et al., 2008). Chlorophyll content in the leaves of sand lucerne harvested in individual cuts and study years as affected by nitrogen fertilisation and biostimulant application is presented in *Table 4*. Data analysis revealed that nitrogen regime increased SPAD in lucerne leaves by 7.66%, the differences being significant. In their study, Szulc et al. (2012) found similar relationships. The effect of biostimulants examined in the experiment reported here was unidirectional. Regardless of the nitrogen regime, cuts and study years, each biostimulant significantly increased chlorophyll content in test plants (by 6.70%, on average). The obtained results correspond to data presented by other authors. Murawska et al. (2017) applied Asahi SL, a sea alga extract and Tytanit, and observed a clear increase in chlorophyll content in winter wheat leaves. Also, El-Miniawy et al. (2014) demonstrated in their work a banaficial effect of a sea alga extract on SPAD in strawberry leaves. Research by other workers revealed that an application of Tytanit increased chlorophyll content in the leaves of timothy (Radkowski, 2013), winter wheat and winter oilseed rape (Kováčik etal., 2014).

Table 4. *The effect of the biostimulants on content of chlorophyll in leaves of Medicago x varia T. Martyn (value of SPAD) by nitrogen fertilization, cut and study year*

© 2018, ALÖKI Kft., Budapest, Hungary

lucerne leaves was observed to increase in individual study years. Similar relationships were reported in the works by Olszewska (2008) and Ciepiela et al. (2013). Soil moisture may be one of the factors affecting chlorophyll content in plants. Thus, the highest chlorophyll content in the second cut plants may have been due to a large amount of precipitation accompanied by high 24-hour air temperatures during the period of growth of these plants.

The sand lucerne content of protein compounds in dry matter averaged 176.3 g·kg^{-1} DM (*Table 5*) and was affected by all the experimental factors. Regardless of biostimulant application and nitrogen regime, significantly the lowest level of protein compounds was recorded for the second cut lucerne, it being the highest for the third cut plants. When study years are taken into consideration, the lowest concentration of protein compounds was determined in the second cut plants, it being the highest in the third cut.

Table 5. *The effect of the biostimulants on content of protein compounds in Medicago x varia T. Martyn by nitrogen fertilization, cut and study year (g kg^{-1} DM)*

Tested trait		Biostimulant				Mean
		Without biostimulant (control)	Algex	Tytanit	Asahi SL

Different letters within the same line indicate significant differences. Values in column for individual factors indicated with different, capital letters differ significantly

The effect of biostimulants varied considerably. The most beneficial effect of Titanit was observed on protein compound content in sand lucerne. The biostimulant significantly increased (by 6.55%, on average) this content compared with control plants. The results correspond to findings reported by Murawska et al. (2017) who observed an increase in the winter wheat grain content of protein after spraying with Tytanit. An application of Algex contributed to an increase in protein compounds compared with their concentration in control plants (by 3.76%, on average) but the differences were statistically insignificant. However, a significant effect of sea alga extracts has been reported in many works (Matysiak et al., 2012; Ciepiela and Godlewska, 2014). It may follow from the fact that components in sea alga extracts (auxins, cytokinins, gibberellic acid and amino acids) increase plant physiological activity including protein synthesis (Szabo et al., 2011).

The biostimulant Asahi SL applied in the experiment contributed to a decline in protein compound content (by 4.28%, on average) in sand lucerne plants harvested in each cut (mean across years) compared with control plants. Significant differences

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_55715581
© 2018, ALÖKI Kft., Budapest, Hungary

between values reflecting the decline in the content of this component were recorded for plants harvested in the third cut only.

Regardless of biostimulant application, cuts and study years, nitrogen fertilisation regime significantly increased the concentration of protein compounds in lucerne (by 12.8%, on average) compared with the content in lucerne harvested in plots where no nitrogen had been applied.

Monosaccharide content (*Table 6*) was significantly the highest in the dry matter of the first cut sand lucerne (mean across years) compared with plants in the second and third cut. This was due to the fact that these compounds were used in large amounts during increased plant respiration under the conditions characterised by high temperatures (the second and third cut) when sugars are utilised. The findings correspond to results of the study reported by Ciepiela and Godlewska (2014). Moreover, statistical analysis confirmed significantly the highest concentration of simple sugars in plants harvested in the third study year compared with the first and second study year.

Table 6. *The effect of the biostimulants on content of monosaccharides in Medicago x varia T. Martyn by nitrogen fertilization, cut and study year (g kg^{-1} DM)*

Tested trait		Biostimulant				Mean
		Without biostimulant (control)	Algex	Tytanit	Asahi SL	
Dose of N kg ha^{-1}	0	51.9 a	58.3 b	62.4 bc	55.0 ab	56.9 A

Different letters within the same line indicate significant differences. Values in column for individual factors indicated with different, capital letters differ significantly

Biostimulants tested in this study significantly increased monosaccharide content in lucerne compared with control plants (by 10.6%, on average), regardless of nitrogen application regime, cuts and study years. An application of Algex and Tytanit to plots which were and were not fertilised with nitrogen contributed to a significant increase in the lucerne content of monosaccharides. A beneficial effect of sea alga extracts on the concentration of simple sugars in plants has been confirmed in research by other authors (Roussos et al., 2009; Pacholczak et al., 2012; Godlewska and Ciepiela, 2013; El-Miniawy et al., 2014). However, there is no data available for sand lucerne. The biostimulant Asahi SL increased monosaccharide content in plants, too, but the differences were insignificant. Contrasting findings were reported by Cwalina-Ambroziak and Amarowicz (2012) who applied Asahi SL and found a decline in sugar content in tomato and red pepper fruit.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_55715581
© 2018, ALÖKI Kft., Budapest, Hungary

Regardless of biostimulants, nitrogen fertilisation regime significantly reduced monosaccharide content in lucerne dry matter, which corresponds to research results reported by Godlewska and Ciepiela (2013).

Conclusions

Statistical analysis demonstrated that the biostimulants applied significantly increased plant biomass yields but the effect was more beneficial in plots to where no nitrogen had been applied. Chlorophyll content in lucerne leaves and monosaccharide content were significantly higher following an application of all the biostimulants. Their effect on the sand lucerne content of protein compounds varied. An application of Tytanit and Algex contributed to an increase in protein compounds in test plants but, for Algex, the differences were statistically insignificant. By contrast, an application of Asahi SL was followed by a significant decline in the concentration of protein compounds in lucerne plants. Significantly higher average dry matter yields, a higher average chlorophyll content and a higher average concentration of protein compounds were noted in plots fertilised with nitrogen compared with non-fertilised units. However, nitrogen fertilisation regime significantly reduced the sand lucerne content of simple sugars.

Abstract. Many epidemiological studies, whether in vivo or in vitro in human or mammals indicate that particulate matters emitted by diesel vehicles have impacts on health. While the effects of daily particulate matter exposure have been well reviewed, the physiological evidence of mice blood alteration associated with the exposure to the diesel exhaust particles has not been investigated well. In this study, we examined the association between the exposure to ultrafine particles contained in the diesel exhaust emission and mice erythrocyte deformation. Ultrafine particles (diameter: 0.02 μm to 0.10 μm) were filtered from three different diesel engine cars. There were 50 male mice used as the experimental animals. The mice were exposed to the ultrafine particles in the different concentration for eight consecutive days. The total concentration of ultrafine particles was measured using a P-Trak Ultrafine Particle Counter (TSI, Model 8525). The mice were sacrificed after the eight-day exposures. The blood samples were observed using a Binocular BX-51 Computer Microscope to examine the level of erythrocyte deformation. The results showed that the increasing amount of the ultrafine particle concentrations caused the increasing extent of the erythrocytes deformation level significantly.
Keywords: *particulate matter, ultrafine particle, diesel vehicle, mice erythrocyte, deformation level*

Introduction

Diesel engines are widely used as a rapid mass transportation mode. The increasing amount of diesel engines is correlated with the exhaust emission. One of the problems with the diesel engine use is the exhaust particles. Diesel exhaust particles are the particles that generated from a diesel engine and become the major constituents of the ambient air pollutant. They consist of ultrafine particles or $PM_{0.1}$ (particulate matter with an aerodynamic diameter ≤ 0.1 μm) (Waly et al., 2013), PM_1 (particulate matter with an aerodynamic diameter ≤ 1 μm) (Xu et al., 2013, Wierzbicka et al., 2014), and $PM_{2.5}$ (particulate matter with an aerodynamic diameter < 2.5 μm) (Hemmingsen et al., 2009). Considering toxicity level, ultrafine particles, as the smallest particulate matter has become a prevalent problem in the whole world regarding both quality and quantity.

There is a well-established correlation between exposure to ultrafine particles emission and health and environment. Inhalation of ultrafine particles increases the risk of adverse health effects associated with the endothelial progenitor cells (Jantzen et al., 2016), abnormal sedimentation, hemagglutination, dose-dependent hemolysis in erythrocytes (Li et al., 2008), increasing of oxidative stress in human embryonic kidney cells (Wang et al., 2009), and a potential risk for atherosclerotic vascular disease (Stewart et al., 2010). Especially the impacts of ultrafine particles in the blood, the erythrocyte deformation or the morphological changes may relate to the abnormal function of blood. Any alteration due to erythrocytes deformation become a marker of iron deficiency anemia and thalassemia (Zhang et al., 2012). Similarly, a previous study

© 2018, ALÖKI Kft., Budapest, Hungary

showed that the erythrocyte deformation was related to the sickle cell disease (Charrin et al., 2016). Our previous studies confirmed the correlation between the exposure to particulate matters from motorcycle exhaust emission and the cell deformations in mice model, in red blood cells (Wardoyo et al., 2017) and kidney cells (Wardoyo et al., 2018). However, there are no published novel data reporting the trends of ultrafine particles concentration from diesel exhaust emission and erythrocyte cell alteration, which are determined useful for investigating a deeper impact of particulate matters emission in the road traffic. Furthermore, the degree to which ultrafine particles from heavy vehicles mean a risk in the organ is a scientific scope that has not previously been tested by direct exposure in human and experimental animals. Although there have been numerous researchers that investigated this case, the sharp mechanisms and effects of the ultrafine particles in the erythrocytes are poorly understood. In this study, exposure to the ultrafine particles focused on the diesel exhaust emission (as a heavy-duty motor vehicle) was chosen due to the negative impact possibilities in health, i.e., in mice erythrocytes. This study is also needed to develop a biomarker for assessing a better understanding of the effect of the ultrafine particles for an acute exposure in the blood.

Materials and Methods

Ultrafine Particles

Three diesel engine cars (D1, D2, and D3) were preferred as the motor samples chosen based on the availability around the University of Brawijaya Malang, Indonesia. The diesel exhaust emission was filtered using a particulate filtering system that consists of an N95 particulate respirator (3M, Model 8210) and a sucking pump (constant debit: 33.05 cm^3/s; flow rate: 2.03 m/s) as described in our previous study (Wardoyo et al., 2018). The filtered ultrafine particles (diameter: 0.02 μm to 0.10 μm) were injected into the exposure chambers in three different injection times (20 - 60 seconds) in order to generate the varied ultrafine particle concentrations of C1 (20 seconds), C2 (40 seconds), and C3 (60 seconds). The concentrations of the ultrafine particles were measured using a P-Trak Ultrafine Particle Counter (TSI, model 8525) (*Fig. 1*) (Wardoyo et al., 2007). The different injection times were used to generate different concentrations of ultrafine particles.

Experimental Animals and Treatments

The study included 50 male Wistar mice (12 weeks old, body weight: 21 - 23 g). All mice were treated humanely, provided with water and foods *ad libitum*, and kept under controlled light (12:12 dark-light cycle) and room temperature (27.4 - 28.1^{o}C). An acclimatization period of three days was allowed for the mice before any exposure treatment. All animal treatment procedures were approved by the Animal Care and Use Committee of Brawijaya University Malang, Indonesia (Ethical Clearance number: 541-KEP-UB).

After the acclimation, the mice were randomly divided into a control group (C0) - the group of unexposed mice (n = 5) - and the exposure groups (C1, C2, and C3, n = 5 per car sample per group). The mice from C1 groups were exposed to the ultrafine particles with the car sample D1, D2, and D3 with the injection time of 20 seconds. The mice from C2 and C3 groups were exposed to the ultrafine particles with the car sample D1, D2, and D3 with the injection times of 40 and 60 seconds, respectively. The exposures were conducted for 100 seconds on eight consecutive days (100 seconds per day). Our previous research gave us information that the mice collapsed more than eight days after the exposure. After the last day of the exposure, all mice were sacrificed using a cervical vertebra dislocation method in order to take the blood drop samples. The blood was collected in tubes, and the smears were made on object glasses and fixed with methanol solutions (70%). When they came dried (±5 minutes), they were colored using Giemsa-buffer pro-Giemsa solution (1:3) as long as 15 minutes. The samples were washed in running tap water. Any section showing abnormal morphology caused by the drying procedure was discarded.

Deformation Calculation

Digital images of the blood samples were taken with a 400x magnification of areas can reliably be judged from an overall evaluation of the slide. Five different investigators scored random fields of view using a Binocular BX-51 Computer Microscope (Wang et al., 2017, Cannizzaro et al., 2009). The deformation level (DL) of the mice erythrocytes was calculated using equation (1) (Wardoyo et al., 2017). The total of deformed and normal erythrocytes were averaged from those ten fields of view for each animal and then averaged from 5 animals.

$$DL = \frac{\sum deformed\ erythrocytes}{\sum erythrocytes} x\ 100\% \qquad \text{(Eq.1)}$$

Statistical Analysis

Values are expressed as the means ± SD (standard deviation). The differences between two groups (C0 and an exposure group) were evaluated using a Student's *t*-test. We compared the results obtained in the control group and the D1 group, the control group and the D2 group, and the control group and the D3 group. The association between the exposure to the ultrafine particles and the erythrocyte deformation level was interpreted by a linear regression analysis using Microsoft Excel 2016. $R^2 > 0.85$ was considered as significantly correlated, and $p < 0.05$ was considered to show statistical significance (Eeftens et al., 2015).

Results

Ultrafine Particles Concentration

The concentrations of ultrafine particles mice were exposed to for eight consecutive days are presented in *Table 1*. Based on the measurement results, a longer time needed to inject the exhaust emission to the exposure chamber generates a higher ultrafine particle concentration. Compared to C1, the concentrations of C2 and C3 are higher, in which the highest concentration is found in C3. On the other hand, the lowest ultrafine particle concentration is found in C1.

Table 1. *Ultrafine particles concentration mice were exposed to(mean ± SD)*

Ultrafine Particle Concentrations	Ultrafine Particles Concentration (x10^7 particles/ cm^3)		
	D1	D2	D3
C1	3.65 ± 0.04	2.26 ± 0.02	1.03 ± 0.10
C2	4.87 ± 0.26	2.87 ± 0.16	1.10 ± 0.07
C3	5.46 ± 0.35	3.28 ± 0.08	1.22 ± 0.01

Deformation Level

The digital images used to observe histological changes (deformation) in the mice erythrocytes are shown in *Fig. 2*. The erythrocytes in those examples are obtained from the control and the exposure groups. The control group is used to observe the native deformation of the healthy mice (normal mice, without exposure). According to *Fig. 2*, there are significant differences in the deformation level between the control mice and the exposed mice. The normal erythrocytes are interpreted as the red circles, and the abnormal ones are shown by the black circles. A normal erythrocyte has a biconcave shape. The abnormal erythrocytes are obtained as (1) teardrop-shaped, (2) helmet-shaped cells, (3) sickle-shaped cells, (4) ovalocytes, (5) saddle-shaped, and (6) stomatocytes (Zhang et al., 2009). *Table 2* below interprets the calculated deformation levels of the mice erythrocytes.

Table 2. *Deformation levels from the control and exposure groups ($p < 0.05$ between two groups: the control group and an exposure group)*

Ultrafine Particle Concentration	Deformation Levels (%)		
	D1	D2	D3
Control	12 ± 1	12 ± 1	12 ± 1
C1	32 ± 1	31 ± 1	25 ± 2
C2	33 ± 3	32 ± 1	26 ± 1
C3	35 ± 2	33 ± 3	29 ± 1

Figure 2 shows that the exposure of ultrafine particles with the concentration of C1 induces a significant increase in the deformed erythrocytes compared to the control group. It has been observed that the exposure to ultrafine particles with the

© 2018, ALÖKI Kft., Budapest, Hungary

concentration of C1 induced 110 ± 5, 119 ± 3, and 93 ± 9 deformed erythrocytes in D1, D2, and D3 car samples, respectively. In the group of C2, the exposed ultrafine particles significantly decrease the number of normal erythrocytes compared to the control group (245 ± 7 cells). The deformed erythrocytes in the group of C2 for the car sample D1, D2, and D3 are 103 ± 11 cells, 111 ± 6 cells, and 99 ± 5 cells, respectively. Similarly, a significant difference is also found in the other exposure group among the C3 and the control groups. The erythrocyte deformation in the group of C3 for the car sample D1, D2, and D3 involved 107 ± 5 cells, 135 ± 16 cells, and 81 ± 5 cells, respectively.

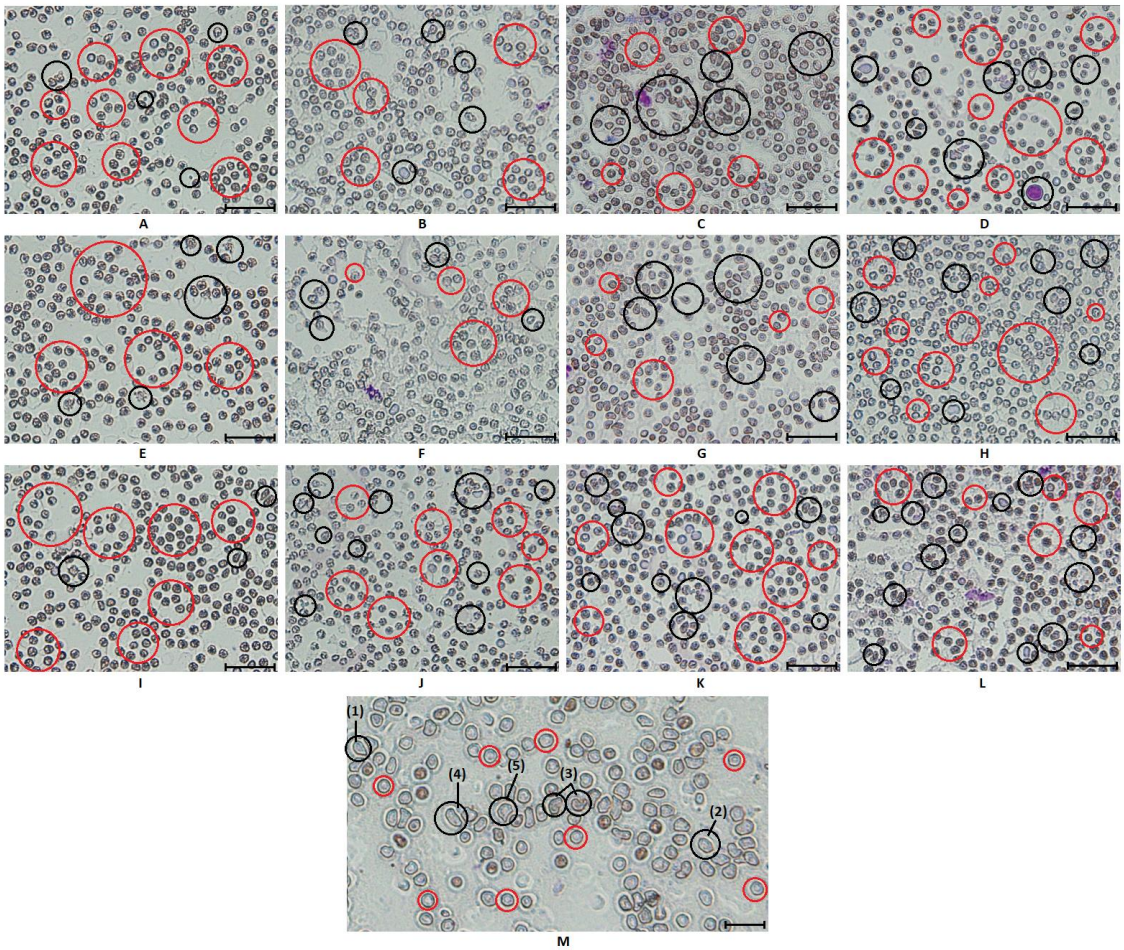

Figure 2. *Digital images from the control group (A; E; and I) and the treatment groups, with 400x of magnification (scale bar: 30 µm): B-D = C1 groups; F-H = C2 groups; and J-L = C3 groups. The normal and deformed erythrocytes (M), scale bar: 20 µm*

Ultrafine Particle Concentration vs Deformation Level

For a better understanding, *Fig. 3* depicts the correlation between the exposure to the ultrafine particles and the deformation levels of the mice erythrocytes (D1-D3). In order to investigate the influence of the exposure to ultrafine particles, the deformation levels of the mice erythrocytes were alleviated by the deformation level obtained in the control group. The correlation between the ultrafine particle concentration and the erythrocyte deformation was interpreted in a linear regression. In the car sample of D1, the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_55835593
© 2018, ALÖKI Kft., Budapest, Hungary

increasing amount of the ultrafine particle concentrations increase the level of erythrocytes deformation (R^2 = 0.86). Interestingly, the similar trend is found in the different car samples D2 (R^2 = 0.99) and D3 (R^2 = 0.98). The increased concentrations of ultrafine particles in the diesel exhaust emission cause more deformation on the erythrocytes. Based on *Fig. 3*, it is confirmed that a higher dose of ultrafine particles enhanced the deformation levels compared to the control group (see *Table 2*). The figure above shows that the concentration of the ultrafine particles contained in the car exhaust emission had direct influences on the mice erythrocytes deformability (R^2 > 0.85). All graphs indicate a high correlation, since the values of each R^2 approach 1.

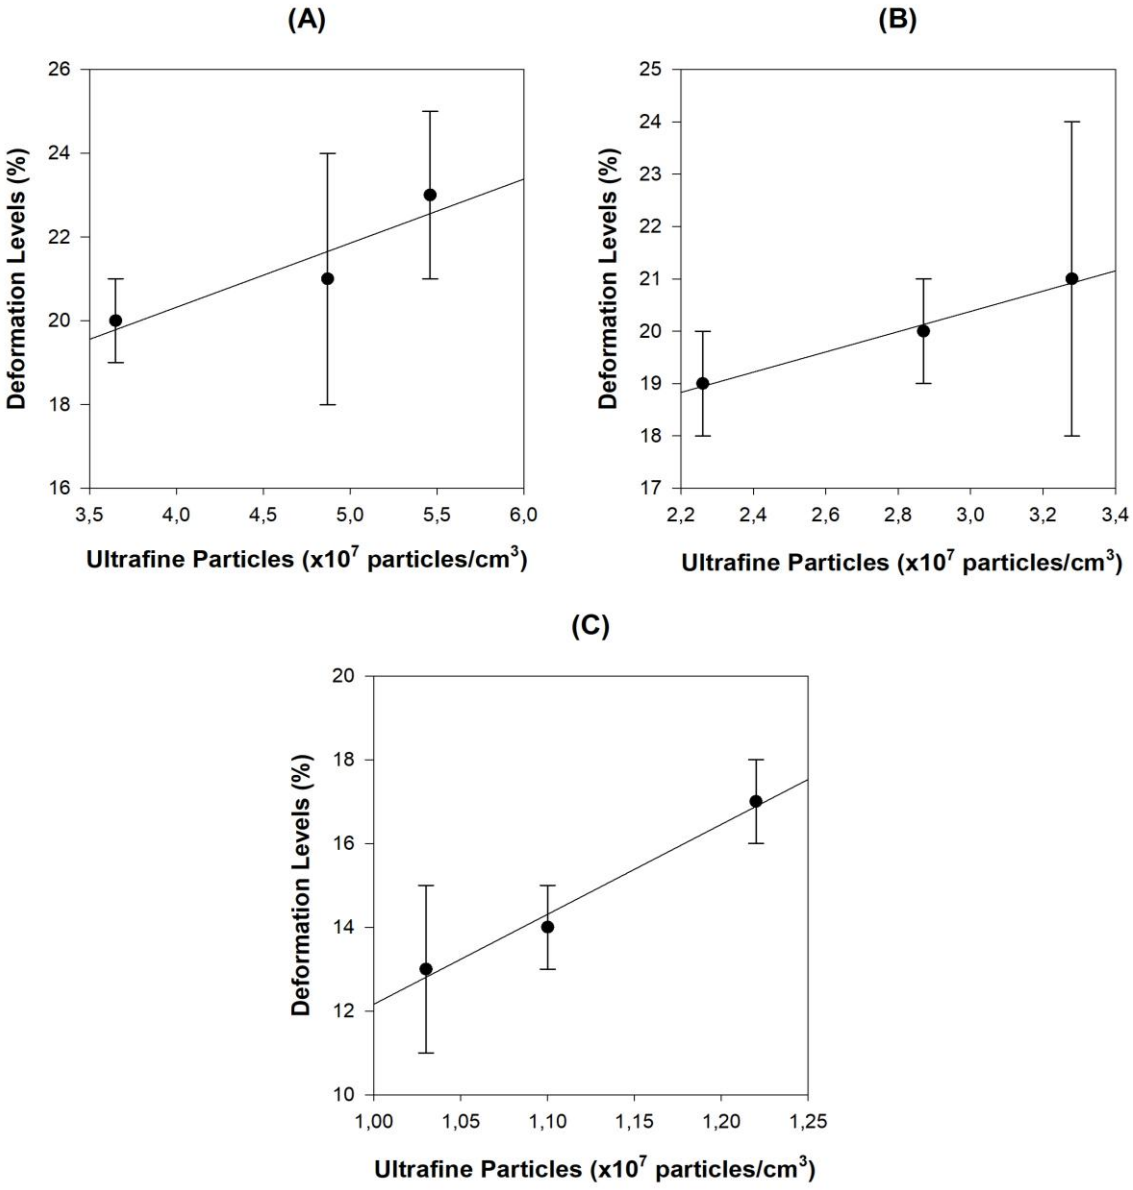

Figure 3. *The correlations between the concentration of ultrafine particles in the car exhaust smoke and the mice erythrocytes deformation: A). D1; B). D2; and C). D3*

Discussion

The present study of the erythrocyte deformability is of great importance in hemorheology. This study reveals a novel association between exposure to ultrafine particles contained in the exhaust emission emitted by diesel engine cars and mice erythrocytes deformation. The deformation was indicated by the alteration in the erythrocyte shape that might be related to the erythrocyte function in the body system. As we know, a normal erythrocyte needs flexibility in transporting gases in the body. A biconcave shape of a normal erythrocyte is related to its work in squeezing through capillaries. It is necessary to investigate the erythrocytes morphological changes (deformation). The existence of erythrocyte deformation or the morphological changes may relate to the abnormal function of blood. For example, a previous study showed that the erythrocyte deformation was related to the sickle cell disease (Charrin et al., 2016). Similarly, any alteration due to erythrocytes deformation becomes a marker of iron deficiency anemia and thalassemia (Zhang et al., 2012), as well as the sickle cell disease (Charrin et al., 2016).

Our findings suggest that the cell alteration by exposure to ultrafine particles is confined to the erythrocyte deformation. In this study, unexposed mice (control group) had healthier erythrocytes with normal biconcave cells, and on the contrary, the exposed mice showed a positive correlation with the abnormal erythrocytes ($p < 0.05$) (*Fig. 3*). In addition to the cell alteration, the deformation of the mice erythrocytes can be linked to the cell physical alteration (Yoon and You, 2016) and the existence of eryptosis, suicidal death erythrocytes (Mischitelli et al., 2016). Consistent with this assessment, we found that deformation level, as well as the deformed erythrocytes, were significantly increased in the mice exposed to the ultrafine particles. The deformation effects of the exposure to ultrafine particles are in accordance with a previous study (Wardoyo et al., 2017), confirming that exposure to ultrafine particles contained in the motorcycle exhaust emission induces erythrocytes deformation, such as sickle-shaped cells, teardrop-shaped cells, and helmet-shaped cells, which then increase the level of erythrocyte deformation.

This study corroborates previous findings obtained from mice exposed to acute ultrafine particles contained in the motorcycle exhaust emission (ten consecutive days), implicating the deformation effects in the mice tubular epithelial cells (Wardoyo et al., 2018) and erythrocytes (Wardoyo et al., 2017). Consistent with this result, erythrocytes are highly deformable and may also exhibit reduced deformability and stronger aggregation in many pathological situations, such as sickle cell anemia (Popel and Johnson, 2005). Eryptosis itself can be triggered by any kind of erythrocyte injury, including oxidative stress due to reactive oxygen species (Mischitelli et al., 2016). This deformation effect is likely to be due to the continuous exposure of diesel exhaust particles which alter the lipid bilayer. This suggests that an important role may exist between exposure to diesel exhaust particles and erythrocyte deformation, oxidative stress, and chronic inflammation. Interestingly, there is a significant correlation between erythrocyte deformability and oxidative stress and chronic inflammation markers (Gyawali et al., 2015). This probably may develop due to the erythrocyte responses in countering the effects of oxidative stress and chronic inflammation. Oxidation of membrane lipids and proteins may alter the erythrocytes (Richards et al., 1998).

The oxidative stress and chronic inflammation can be related to the production of reactive oxygen species (Jantzen et al., 2016). The generation of reactive oxygen species due to the exposure to ultrafine particles might be related to the cytotoxic effect

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_55835593
© 2018, ALÖKI Kft., Budapest, Hungary

on endothelial cells (Mo et al., 2012). Reactive oxygen species can be related to the translocation of particles. When particles transport through the bloodstream or lymphatic system to vital organs, they can cross the lung-blood barrier and translocate into the blood circulation, unite to erythrocytes, and disturb the cation transport on the membrane causing erythrocytes deformation (Li et al., 2008, Delfino et al., 2005). This deformation can be linked to the decreasing amount of mice antioxidant (becoming the free radicals generators) (Kampa and Castanas, 2008). However, the effect of deposited particulate matters in altering the mice erythrocytes was found in some abnormal forms of erythrocytes. Diesel exhaust particles exposures indeed had a significant role in generating the inflammatory and genotoxic effects (Hougaard et al., 2008). The form of a normal erythrocyte in the two-dimensional model is a biconcave capsule, and its radius is ± 3.91 μm (Zhang et al., 2009). However, this form may change due to the existence of particles, as explained above. In addition, the most erythrocytes found in our research are in a normal form. This state becomes the evidence that not all erythrocytes can be influenced by the particles. We consider that the membrane rigidity prevents large deformation and large cell contact area, resulting in a less dense erythrocytes cores (Zhang et al., 2009). Moreover, the deformations were influenced by some factors, such as neo-Hookean elastic (Bagchi et al., 2005) and the local tangential and the normal directions of the membrane (Zhang et al., 2009). The above analysis conveyed that the possible interactions occurred between exposure to diesel exhaust particles and erythrocyte deformability.

Motor vehicle emission may consist of polycyclic aromatic hydrocarbons (Lai et al., 2013) and volatile organic compounds (Ge et al., 2018). Similarly, previous studies measured the substances of particulate matters emitted by motor vehicles, including polycyclic aromatic hydrocarbons and volatile organic compounds (Pham et al., 2013, Yan et al., 2015, Wierzbicka et al., 2014). Epidemiologic studies have investigated the toxic impacts related to the exposure to polycyclic aromatic hydrocarbons and volatile organic compounds. Polycyclic aromatic hydrocarbon substances, such as anthracene, phenanthrene, fluoranthene, benzo(a)pyrene, pyrene, and naphthalene, and many other forms are well-known to be the carcinogens for human health (Tongo et al., 2017, Sarigiannis et al., 2015, Bortey-Sam et al., 2017, Louis et al., 2016, Pham et al., 2013). On the other hand, volatile organic compounds also become hazardous chemicals and toxic to human health due to the carcinogenic and mutagenic characteristics (Kumar et al., 2018).

Conclusion

In conclusion, diesel exhaust ultrafine particles significantly affect the mice erythrocyte deformation. The dose concentration of diesel exhaust ultrafine particles have an influence on the erythrocyte deformation level. The more diesel ultrafine particles mice were exposed to the more damage to the erythrocytes was observed. The correlation between the ultrafine particle exposure and the erythrocyte deformation was obtained proportionally with the $R^2 > 0.85$.

Abstract. The female to male flower ratio of *Jatropha nigroviensrugosus*, a new cultivar, is higher than that of the common *J. curcas*. However, the sex determination mechanism of *J. curcas* remains elusive. In the present study, gene expression analysis of inflorescence buds, female and male flowers, and new leaf buds of *J. nigroviensrugosus* was performed, using second-generation sequencing. The results demonstrated that high expression of genes related to sucrose phosphate synthase, soluble starch synthase (EC:2.4.1.21) and granule-bound starch synthase promoted the formation and development of male flowers, and the genes CUP-SHAPED COTYLEDON 2 (*CUC2)* and *CUC3*, played pivotal roles in regulating the formation and development of female flowers. The initial development of female flower primordia required cytokinins (CTK) induction, while late developmental stages only required a low concentration of CTK. The characteristic genes for floral organ development were conservatively expressed in the four tested parts. In this investigation, we not only provide genetic information regarding the differential developmental processes between female and male flowers, but also deepen our understanding of *J. nigroviensrugosus*.
Keywords: *Jatropha, new cultivar, differential expressed gene, transcription factor*

Introduction

Jatropha curcas L., a plant of the *Jatropha* genus in the *Euphorbiaceae* family, is an important energy-bearing tree which is extensively distributed worldwide. *J. curcas* has a high, untapped potential to contribute towards sustainable production of food and bioenergy, rehabilitation of degraded land, and reduction of atmospheric carbon dioxide, its potential oil productivity is 1.9 t/ha, beginning the fourth year after planting (Montes et al., 2016; Dias et al., 2012). However, the low seed yield of has been a stumbling block in realizing its full potential as an ideal bioenergy crop, the small number of female flowers and a low female to male flower ratio (ranges from1:20 to 1:108) are the main factors limiting its seed yield (Gangwar et al., 2018; Ashoke et al., 2005). Breeders are mainly concerned with shortening the young growth cycle of *J. curcas*; increasing the ratio of female to male flowers; increasing oil content, seed weight, seed volume and other traits. Seed weight had positive correlation with seed length, breadth, thickness and oil content (Kaushik et al., 2007). The shortening of the breeding cycle and the increasing the number of female flowers contribute to the number of seeds, and the traits such as seed size, density and volume are important indicators affecting yield. Changing the offspring traits through interspecific hybridization in *J. curcas*, or through the method of discovery, identification, promotion and application of high-yield new varieties is a necessary way to genetic improvement.

J. nigroviensrugosus CV Yang, a new variant of *J. curcas* discovered in 2005, its main features are the downward cotyledons and true leaves, bulged leaf tissues (wrinkled leaves). It has a larger number of female flowers and a higher female to male flower ratio, which means a higher seed yield, the experimental plots for many years of afforestation showed that the dry seed yield per hectare of five-year-old stands in *J. nigroviensrugosus* reached 3196.8 kg/ha, which was 6 times higher than *J. curcas* (349.5~559.5 kg/ha); the oil content of the seeds in *J. nigroviensrugosus* was 40~42%, which was higher than *J. curcas* (30 ～ 40%) (Yang et al., 2012, 2013, 2015). Comparison of the $\delta^{13}C$ values and various photosynthetic indices between *J. nigroviensrugosus* and *J. curcas*, with respect to different flowering stages, demonstrated that during the leaf bud stage, *J. nigroviensrugosus* transported a large amount of nutrients to the leaf buds for their differentiation to flower buds. Therefore, flower differentiation is likely determined during the transformation from leaf to flower buds, and the flowering numbers may be determined during the inflorescence stage (He et al., 2016).

Flower formation has continuously been a focus in Plant developmental biology. Studies regarding sex expression and floral morphology are essential for deep understanding of breeding and for the determination of the reproductive potential of plant genotypes (De Lourdes Adriano-Anaya et al., 2016). The transcriptome describes all RNA transcribed by a certain tissue or cell at a certain developmental stage or in a specific physiological state, reflecting the overall expression pattern and regulation of genes. The female or male favorable analysis of floral development in both monoecious and dioecious plants by transcriptome profiling or microarray analysis may help to better understand flower development and the gender regulatory network (Mao et al., 2017; Gao et al., 2013; Rocheta et al., 2014). Hence, we performed high-throughput RNA sequencing (RNA-Seq) and differential analysis on the inflorescence buds, leaf buds, and male and female flowers of *J. nigroviensrugosus*. The present study shed light on the molecular basis of sex determination of *J. nigroviensrugosus* and elucidated the expression patterns of flowering-related genes prior to and following inflorescence and leaf bud differentiation, providing directions for the study of the flowering mechanism of *J. nigroviensrugosus*.

Materials and methods

Materials

The tested plants were collected from Qiaoma Experimental Foreast, Ceheng County, Guizhou Province, China. The place is a typical dry-hot valley climate which is situated 830 m above sea level, with an annual average temperature 19.2 °C, rainfall 1340.7 mm, sunshine duration 1514 h and annual frost-free period is 305 days. It is known as the “natural greenhouse”. The soil is yellow sandy loam developed from sand shales, slightly acidic.. Three 8-year-old *J. nigroviensrugosu* (JCw) plants were selected for the present investigation. The following four tissues were collected from each of the three plants: inflorescence buds at the terminal vegetative shoots (JCw_p) (early-forming adaxial bulges with a diameter <0.3 cm); slightly red new leaf buds at the branch tips (JCw_l); female flowers not yet open (JCw_f) (slightly visible white ovules showing after vertical cut); and male flowers not yet open (JCw_m) (slightly visible yellow anthers showing after vertical cut). Immediately after sample collection, wrap it

in foil paper and put it into liquid nitrogen. Bring it back to the laboratory and transpose it in a -80 °C ultra-low temperature freezer.

RNA extraction and transcriptome sequencing

Total RNA was extracted from the above-mentioned tissue samples, using TRIzol (Invitrogen, USA). After passing the quality examination, the RNA samples were sent to Shanghai Meiji Biological Cooperation for sequencing from both ends with an Illumina Hiseq sequencing platform.

Sequencing

Following completion of the sequencing, the raw data were quality controlled and compared with the genome of *J. curcas* (https://www.ncbi.nlm.nih.gov/genome/915). The read counts were transformed into FPKM (expected number of fragments per kilobase of transcript sequence per million base pairs sequenced) values for gene expression analysis. The thresholds of $|\log_2 (\text{fold change})| \geq 1$ and q-value < 0.05 were used to determine the differential expressed genes (DEGs) in the resulting reads. The related DEGs were subjected to Gene Ontology (GO, http://www.geneontology.org/) functional enrichment and Kyoto Encyclopedia of Genes and Genomes (KEGG, http://www.genome.jp/kegg/) pathway enrichment.

Results

Transcriptome sequencing and alignment

FastQC (https://www.bioinformatics.babraham.ac.uk/projects/fastqc/) was used to perform quality control on the raw data, demonstrating a Q20 above 97%, a Q30 above 93%, and an average QC content of 43.5%. HISAT2 (https://ccb.jhu.edu/software/hisat2/index.shtml) was used to align the sequenced transcriptome data of *J. nigroviensrugosus* with the genome of *J. curcas* (https://www.ncbi.nlm.nih.gov/genome/915), demonstrating alignment rates higher than 96% (*Table 1*).

Form 40.30 to 53.41 million sequences were aligned to unique positions in the genome, the alignment rates is ranging from 77.22 to 78.33%, form 18.99 to 20.04% sequences is aligning to multiple positions in the genome. These indicating overall matched *J. nigroviensrugosus* sequences with the *J. curcas* genome. Consequently, the sequences may be analyzed as reference-based transcriptome. The small differences between the sequences indicate that the data were highly qualified to reveal differences in inflorescences prior to and subsequent to leaf bud differentiation.

PCA and gene expression analyses

The gene expression of four samples of *J. nigroviensrugosus*, based on the quantitative results of FPKM, was subjected to principal component analysis (PCA), using R (https://www.r-project.org/) which is an open source software. The results denote that the tip inflorescence buds (JCw_p) were closely related to the new leaf buds (JCw_l), with a PC1 value on the X axis of 44.4% and a PC2 value on the Y axis of 31.5%. Three-dimensional (3D) visualization shows significantly clustered samples with no outliers, suggesting good biological repeatability (*Fig. 1a*). According to the DEG screening thresholds, statistical analysis of all pairs of *J. nigroviensrugosus* samples, there were 2995 DEGs between JCw_m and JCw_f, with 1733 upregulated and 862 downregulated genes in JCw_m; 4238 DEGs between JCw_p and JCw_f, with 2138 upregulated and 2100 downregulated genes in JCw_p; 6153 DEGs between in JCw_p and JCw_m, with 3226 upregulated and 2927 downregulated genes in JCw_p. There were 74 genes specifically expressed in JCw_f or JCw_m (*Fig. 1b*).

Functional enrichment of female and male flowers of J. nigroviensrugosus

GO functional enrichment analysis was conducted on the DEGs between male and female flowers. With respect to the biological process, genes related to carbohydrate metabolism, including glucose, sucrose, polysaccharides and starch, were significantly enriched. With respect to the cell components, genes associated with inner and outer membranes, extracellular regions, transcription factor complexes and the cell skeleton were significantly enriched. In molecular function, genes coupled to glucosidase, hydrolase and oxidoreductase were significantly enriched. Pathway enrichment analysis of DEGs between male and female flowers (*Fig. 2a*) displays significantly enriched metabolic pathways such as starch and sucrose (ko00500), and pentose and glucuronic acid interconversion (ko00040). Moreover, there were significant differences in the plant hormone signal transduction pathway (ko04075), with a total of 16 hormone synthesis-related genes upregulated in female flowers and 18 upregulated in male

flowers. The abscisic acid (ABR) synthesis-related genes SnRK2 (gene 20150) and ABF (gene 13255 and gene 14512) were significantly upregulated in male flowers. The cytokinin (CTK) synthesis-related gene A-ARR (gene 13354) was significantly upregulated in female flowers, and B-ARR (gene 20147) was significantly upregulated in male flowers.

DEGs analysis between inflorescence and leaf buds, and female and male flowers

Between inflorescence buds and male flowers, the starch and sucrose metabolic pathway (ko00500) was significantly enriched (*Fig. 2b*). In male flowers, the expression of 84 genes related to fructokinase (EC: 2.7.1.4) (gene 5753, gene 8905, and gene 17326), starch synthase (EC: 2.4.1.21) (gene 4801), granule-bound starch synthase (EC: 2.4.1.242) (gene 13471) and sucrose-phosphate synthase (EC: 2.4.1.14) (gene 7836, gene 12091, and gene 14471) were significantly upregulated, and 21 were downregulated. However, there was no significant enrichment of the starch and sucrose metabolic pathway between inflorescence buds and female flowers. The pathway enrichment of the DEGs between inflorescence buds and female flowers reveals enriched metabolic processes such as ribosomes, plant hormone signaling and DNA replication (*Fig. 2c*). With respect to the phytohormone signaling pathway, the ethylene synthesis-related gene ERF1/2 (gene 18694) was upregulated in female flowers. The pathway enrichment of the DEGs between inflorescence and leaf buds displayed enriched metabolic processes such as ribosomes, photosynthesis, photosynthesis-antenna proteins, and plant hormone signaling (*Fig. 2d*). With respect to the photosynthetic pathway, with the exception of gamma (gene 7618) being upregulated in inflorescence buds, the remaining 48 DEGs involved in photosynthesis and 15 DEGs associated with photosynthesis-antenna proteins were all upregulated in leaf buds.

Changes in MADS-box gene expression

Download the *J. curcas* proteinome data (http://www.ncbi.nlm.nih.gov/genome/915) (Sato et al., 2010) and the MADS-box Hidden Markov Model (HMM) model file (PF00319, http://pfam.sanger), using the HMM file as a seed, run HMM search in the *J. curcas* proteinome database (e-value < 1e-20). Construct a *J. curcas*-specific HMM model based on the screening results, then perform HMM search again (e-value < 0.01), non-repetitive MADS-box related protein ID are extracted and the corresponding gene ID sequence and length information are extracted according to genomic annotation file. Search through the Pfam database, NCBI conserved domain database (https://www.ncbi.nlm.nih.gov/Structure/cdd/wrpsb.cgi) and SMART (http://smart.embl-heidelberg.de/) to confirm that all predicted genes contain the MADS-box domain. The MADS-box gene family is divided into two main lineages, type-I and type-II, that origi- nated from a duplication of ancestor genes during the divergence of plants and animals, the major difference between type-I and type-II genes is that type-II genes possess the K-box domain (Alvarez-Buylla et al., 2000; Theißen et al., 1996). Contained the K-box domain was identified as the type-II MADS-box gene, the otherwise is identified as the type-I MADS-box gene. Heatmap clustering and multiple annotations are performed using the circlize package (Gu et al., 2014). Two

types of MADS-box-related genes were subjected to hierarchical cluster analysis and visualized as four clusters according to the number of tissue samples (*Fig. 3*). The results show that for *J. nigroviensrugosus*, the MADS-box-related genes could be divided into two expression patterns (clustered by sample), one expressed in female and male flowers, and the other in inflorescence and leaf buds. In addition, the gene highly expressed in all samples is the type-II MADS-box gene.

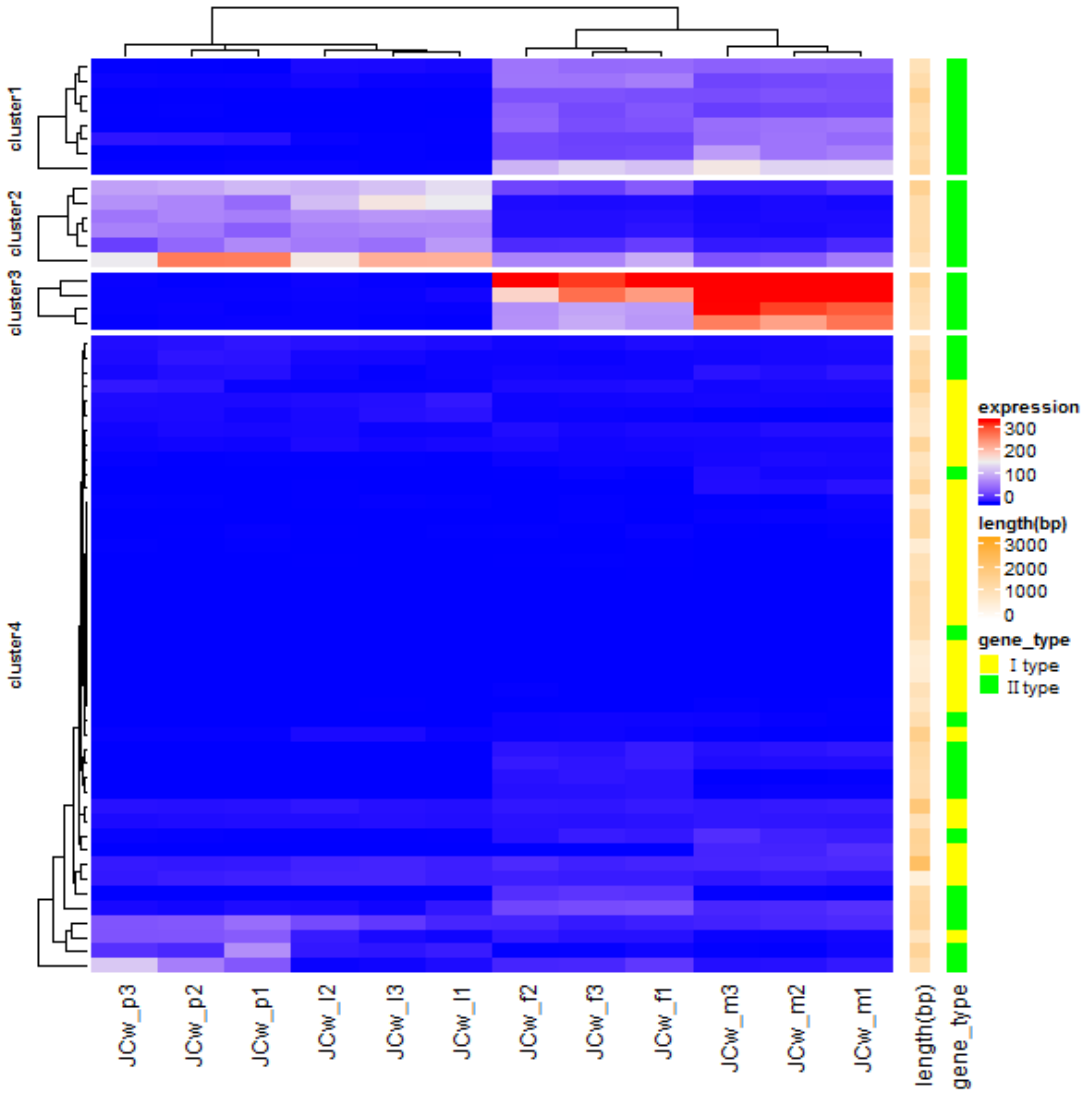

Figure 3. *MADS-box gene expression profile of the four parts of J. nigroviensrugosus*

Discussion

The low yield and low oil content of *J. curcas* seeds are the biggest problems encountered in the current planting of *J. curcas* trees; therefore, the identification of the most favorable genotypes is extremely important (Junqueira et al., 2016). As a new species, *J. nigroviensrugosus* has a higher female to male ratio and a higher seed yield than common *J. curcas.* Several papers have investigated flower induction of *J. curcas* in China and abroad, for instance, histological analysis of the differentiation of male and female flowers at different developmental stages (Xu et al., 2016), transcriptome

differences between pure female and bisexual inflorescences (Chen et al., 2017), and gene responses subsequent to hormone induction (Ghosh et al., 2010; Pan et al., 2016). However, there is a lack of information regarding the flowering mechanism of *J. nigroviensrugosus*, and whether the relevant measures applied to the common *J. curcas* can be applied to *J. nigroviensrugosus*. Studies of *J. nigroviensrugosus* prior to and subsequent to inflorescence differentiation are beneficial for expanding knowledge of the sex determination mechanism of this energy-rich plant.

A plant undergoes a major physiological change during the transition from vegetative growth to reproductive development, and this transition is a result of responses to various endogenous and exogenous signals (Srikanth and Schmid, 2011). The expression of a specific gene, including the tissue specificity and the difference in transcriptional level, may influence the sex determination of a flower (Ramos et al., 2017). The differentially-expressed genes in the comparison group of female and male flowers may be involved in the regulation of gender differentiation. During this period, carbohydrates may act as mobile signals to regulate flower morphogenesis (Turnbull, 2011; Corbesier et al., 2006). Sugar catabolism enzymes may increase the assimilation ability of the shoots, thereby accelerating shoot growth and increasing primordium numbers (Ito et al., 2002). Low concentrations of sucrose may promote flowering, whereas high concentrations may delay flowering (Ohto et al., 2001). Sucrose-mediated signaling is integrated into the photoperiod pathway, located downstream of the CONSTANS (CO) gene and upstream of the FLOWERING LOCUS T (FT) gene (Seo et al., 2011). Sucrose-phosphate synthase (SPS) (EC: 2.4.1.14) is considered to be a key enzyme in the control of sucrose synthesis (Sawitri et al., 2018). With respect to inflorescence buds and male flowers, the SPS-related genes (gene 7836, gene 12091 and gene 14471) were upregulated in male flowers. In addition, polygalacturonase (PG) was involved in the development of pollen (Ogawa et al., 2009), whichwas significantly upregulated in male flowers. The distribution of sugars and starch is known to be related to flower transformation. Studies conducted on various angiosperm species have shown a correlation between flower abortion and starch content (Reale et al., 2009). Starch is composed of linear and branched glucose (Glc) polymers (Zeeman et al., 2010). The soluble starch synthase (EC: 2.4.1.21) is primarily related to amylopectin catalysis, while granule-bound starch synthase (EC: 2.4.1.242) is primarily associated with the production of amylose, both of which were found to be highly expressed in the male flowers of *J. nigroviensrugosus*. This data indicates that high expression of sucrose and starch synthesis-related genes plays an important role in the development of male flowers in *J. nigroviensrugosus*.

Plant hormones play essential roles in gender determination (Aryal and Ming, 2014). Auxin plays a dominant role in floral organ initiation and organogenesis (Chandler, 2011), and CTK triggers the initiation of female flower primordium (Hui et al., 2017). Application of exogenous cytokinin (6-benzyladenine, BA) on inflorescence buds can significantly increase the number of female flowers, BA treatment may delay floral organ formation by inhibiting the transcription of the A, B and E classes of floral organ-identity genes, which allowing extra time for the plant to produce more primordia in inflorescence meristems (Chen et al., 2014). Type-B Arabidopsis response regulators (ARRs) are positive regulators of the CTX response (Mason et al., 2005), and type-A ARRs are thought to work as negative regulators of CTX to inhibit the activity of type-B ARRs (To and Kieber, 2008; To et al., 2004). B-ARR (gene 8030 and gene 17670) was significantly upregulated in inflorescence buds compared with leaf buds.

Comparing the male and female flowers, A-ARR (gene 13354) was significantly upregulated in female flowers, whereas B-ARR (gene 20147) was significantly upregulated in male flowers. These data suggest that the initial development of *J. nigroviensrugosus* female flower primordia requires the induction of CTK, but the late developmental stage only needs a low concentration of CTK. As a gaseous plant hormone, ethylene regulates the flowering time of plants through interactions with other plant hormones (Iqbal et al., 2017). In J. *curcas*, treatment with a low concentration of ethephon (25 ppm) is thought to increase the number of female flowers (Makwana and Robin, 2013), and increasing the ethephon concentration has been shown to decrease the number of male and female flowers per inflorescence as well as the total flower number (Costa et al., 2016). Compared with inflorescence buds and male flowers, the expression of ERF1/2 (gene 18694) was significantly increased in female flowers of *J. nigroviensrugosus*, highlighting the importance of ethylene in the regulation of female flower formation and development. In the ABA signaling pathway, the SnRK2 signal plays a crucial role in the sex determination of ferns and regulates the sex ratio of male to hermaphrodite in the reproductive cycle (McAdam et al., 2016). However, there is no related report regarding the impact of SnRK2 on the female to male flower ratio of angiosperms, especially *J. curcas*.

The differential expression of transcription factors (TFs), also known as trans-acting factors, play an essential role in the control of organ development (Latchman, 1997). Six signaling pathways have been identified to regulate the flowering of A. thaliana: photoperiod, vernalization, autonomous, gibberellin (GA), temperature-sensitive, and age-dependent control (Fornara et al., 2010). These signaling pathways are both independent and connected, and converge the flowering signals to several key integrators such as FT, TWIN SISTER OF FT (TSF) and SUPPRESSOR OF OVEREXPRESSION OF CONSTANS 1 (SOC1), activating the expression of meristem-specific genes such as LEAFY (LFY), APETALA1 (AP1) and FRUITFULL (FUL), eventually initiating plant flowering (Cho et al., 2017). Among these, the expression of SOC1 was high in leaf and inflorescence buds, but low in male and female flowers. Conversely, FT was highly expressed in male and female floral organs. The zinc finger transcription factor CONSTANS contains a B-box domain (Gangappa et al., 2014), which plays a central role in photoperiod sensing (Lee et al., 2017). The expression of CONSTANS-LIKE 7 (gene 24482) and CONSTANS-LIKE 3 (gene 12833) were upregulated in both male and female flowers, with respect to inflorescence buds.

NAC genes encode plant-specific transcription factors that are closely related to vegetative reproduction, and embryo and flower development (Olsen et al., 2005). CUP-SHAPED COTYLEDON 1 (CUC1), CUC2 and CUC3 have been shown to regulate organ segregation and meristem formation (Vroemen et al., 2003). In addition to controlling shoot meristem activity, CUC1 and CUC2 also play key roles in female organ development (Kamiuchi et al., 2014). Genetic interaction analyses using single, double and triple mutants of cuc1-1D, cuc2-1D (a CUC2 mutant similar to cuc1-1D), and hws-1, demonstrate that HWS (HAWAIIAN SKIRT), CUC1 and CUC2 act together to control floral organ number (González-Carranza et al., 2017). It is believed that CUC2 is associated with female flower opening of *J. curcas* (Gangwar et al., 2016). Through comparison of female and male flowers of *J. nigroviensrugosus*, we found nine NAC-related genes upregulated in female flowers (including homologous genes of CUC2 and CUC3), and 12 NAC-related genes upregulated in male flowers (including

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_55955610
© 2018, ALÖKI Kft., Budapest, Hungary

NAC2 and NAC29). These data indicate that CUC2 and CUC3 make a contribution in the formation and development of *J. nigroviensrugosus* female flowers.

The MADS-box TFs are the primary components of the current well-known ABCDE model which are closely related to the origin and evolution of plant reproductive organs (Smaczniak et al., 2012; Theissen et al., 2000). The MADS-box TFs play a pivotal role in floristic differentiation (Theissen and Melzer, 2007). Ming et al. (2011) showed that the structural determinants of floral organs are randomly distributed in autosomes, therefore only the spatiotemporal patterns are expressed between sexes, but the expression are not sex-specific. With respect to the DEGs selected in the comparison group of female and male flowers in *J. nigroviensrugosus*, seven genes including ANR1, AGL14 and AGL7 were upregulated in female flowers, while 11 genes including AGL11, AGL62 and AGL20/SOC1 were upregulated in male flowers. The B- and C-class genes, the characteristic genes of flower organ development (Pařenicová et al., 2003), and the dependent SEP1, SEP2 and SEP3 genes, were all similarly expressed in both female and male floral organs of *J. nigroviensrugosus*, and the expression was not sex-specific. The MADS-box-related genes from the four different tissues of *J. nigroviensrugosus* were primarily divided into two expression patterns (*Fig. 3*). Cluster 3-related genes were expressed only in male and female flowers, while cluster 2-related genes were expressed in inflorescences and leaf buds, with a certain degree of conservativity. Two MADS-box-related genes in cluster 3 were only highly expressed in male flowers, spatiotemporally. In addition, the gene highly expressed in all samples belongs to the type-II MADS-box gene. Several cluster 4-related genes, including AGL62 and AGL80, were not expressed in any of the four tissues, suggestive of involvement in early endosperm development (Kang et al., 2008; Portereiko et al., 2006) and regulation of certain physiological activities.

Conclusion

As a new cultivar, transcriptome sequencing of inflorescence and leaf bud differentiation in *J. nigroviensrugosus* was beneficial to analyze the nutrient supply relationship and hormonal regulation of different plant parts. Genes related to sucrose phosphate synthase, soluble starch synthase and granule-bound starch synthase were highly expressed in male flowers of *J. nigroviensrugosus*, suggestive of an important role in the formation and development of male flowers. Initial development of female flower primordia required the induction of CTK, while late stage development only required a low concentration of CTK in coordination with other hormones. CUC2 and CUC3 were very important in the formation and development of female flowers of *J. nigroviensrugosus*. As the most important transcription factors, MADS-box-related genes were conserved throughout different parts of *J. nigroviensrugosus*. Moreover, a number of DEGs were screened during the differentiation of male and female flowers, this study provided an important basis for further research regarding the differentiation of flowers and the molecular mechanism of high-yield *J. nigroviensrugosus* breeding.

(Received 21st Feb 2018; accepted 2nd Aug 2018)

Abstract. A study was conducted to explore the plant biodiversity and vegetation structure of Biha Valley, District Swat, Pakistan. On the basis of the physiognomy of the vegetation the study area was divided into 19 stands. Line transect (50 m) method was used to sample the phytosociological attributes of the study area. PCORD software (version 5) was used to recognize communities by two-way indicator species analysis (TWINSPAN) and CANOCO software (version 5) for ordination analysis was done for detrended correspondence analysis (DCA) and canonical correspondence analysis (CCA) to find variation directories of different plant species. Different life-form classes and leaf size spectra were recorded according to the Raunkiaer classification. The floristic composition of the area consists of 203 plant species belonging to 154 genera and 70 families. The biological spectrum of the area indicated that Therophytes was dominant with 46.60% among the life-classes, followed by Hemicryptophytes having 15.53%. Leaf spectra of study area revealed that Microphylls was dominant (41.26%) followed by Nanophylls (32.04%). Seven plant communities were recognized by TWINSPAN classification, which showed that species diversity decreased with altitude. Moreover, the result indicates the importance of soil organic matter in top soil layers for plant species distribution. The increases in soil nutrients (OM, P, N, and K), improvement in site conditions (community cover, depth of litter, depth of humus, soil water content) and decrease in soil bulk density indicated the natural habitat restoration following abandonment.
Keywords: *multivariate analysis, similarity index, vegetation structure, biological spectrum, Pakistan*

Introduction

Vegetation can be defined as the group of plants growing together in a particular locality. It can also be defined as a unit which retains their structure and physiognomic characteristics to permit their distinction from other units (Khan et al., 2012). Plants are

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

common feature of the natural sceneries and grow in all environments. Though, each species being dispersed according to its own unique tolerance of a multitude of factors that consist its environment no species occur all over the world. Species with certain environmental tolerances develop into recognizable plant formations with distinctive floristic and structural characteristics. At a comprehensive scale these signify the major biomes of the world (Archibold, 1995). Vegetation of an area can either be characterized by its component species or by the functional combination and physical qualities that differentiate the physical appearance of vegetation. It is an essential variation that is illustrated by the different methods available for describing vegetation (Goldsmith et al., 1986; Kent and Coker, 1992). Floristic diversity and its biological spectra rely on topography and elevation. Plant-life characters like life form, leaf size spectra, and phenological traits mirror the conditions of the existing ecological and natural surroundings (Rahman et al., 2018).

Phytosociology is the study of the characteristics, classification, relationships and distribution of plant communities and attempts to describe the species diversity in plant communities (Haq et al., 2015a). It displays a high association between vegetation and environmental conditions, enabling us to discover, the complicated relations of ecosystem parts by studying resources and environment (Asri, 1994). Plants of similar nature and ecological needs (niche) are associated with each other, creating plant ecological groups (Braun-Blanquet, 1983). Plant communities include one or more ecological groups (Khademi, 2009). Phytosociology is a branch of plant ecology that explains the association of plant species in communities (Ewald, 2003). Plants type and characteristics of soil are so related that they cannot be isolated from of each other. Phytosociology is the quantitative study of vegetation and its prime purpose is to describe the vegetation its pattern and classify it in a meaningful method. It shows species diversity which determines the dispersal of individuals among the species in a specific habitat (Haq et al., 2015b). A number of quantitative, qualitative and synthetic characteristics of plant communities e.g. density, dominance, richness, floristic composition, structure, physical appearance, development and exchange multilateral relations of plants to one another and to the environmental factors and the classification of communities are examined by phytosociology.

To date, the Biha Valley (Swat) has not been studied using recently developed analytical methods for vegetation characterization. The current study was therefore carried out to document the floristic diversity of the area, to recognize the major plant communities of the site and to identify the key environmental variables influencing vegetation structure, species composition and species diversity in the research area.

Materials and methods

Study area

The study site (Biha Valley) is located in the northwestern part of District Swat in the Hindu Raj series of Hindukush Mountains (*Fig. 1*). The Valley is one of the Union councils of Tehsil Matta that comprises 22991 ha. It is situated in the North West corner of District Swat. It lies between 35° 60 and 35° 20 North latitude and 72° 30 to 72° 40 East longitude (Adnan, 2003). The valley is surrounded by Usherai Dara (Dir) from West, Dir Kohistan on the North, Shawar valley from the South West and Mandal dag, Charma and Sulatan valley from the Eastern North. Pushtoni, Nalkot, Biha, Fazal banda, Chatikal, Dughalgay and Swatai are the important villages situated in this area.

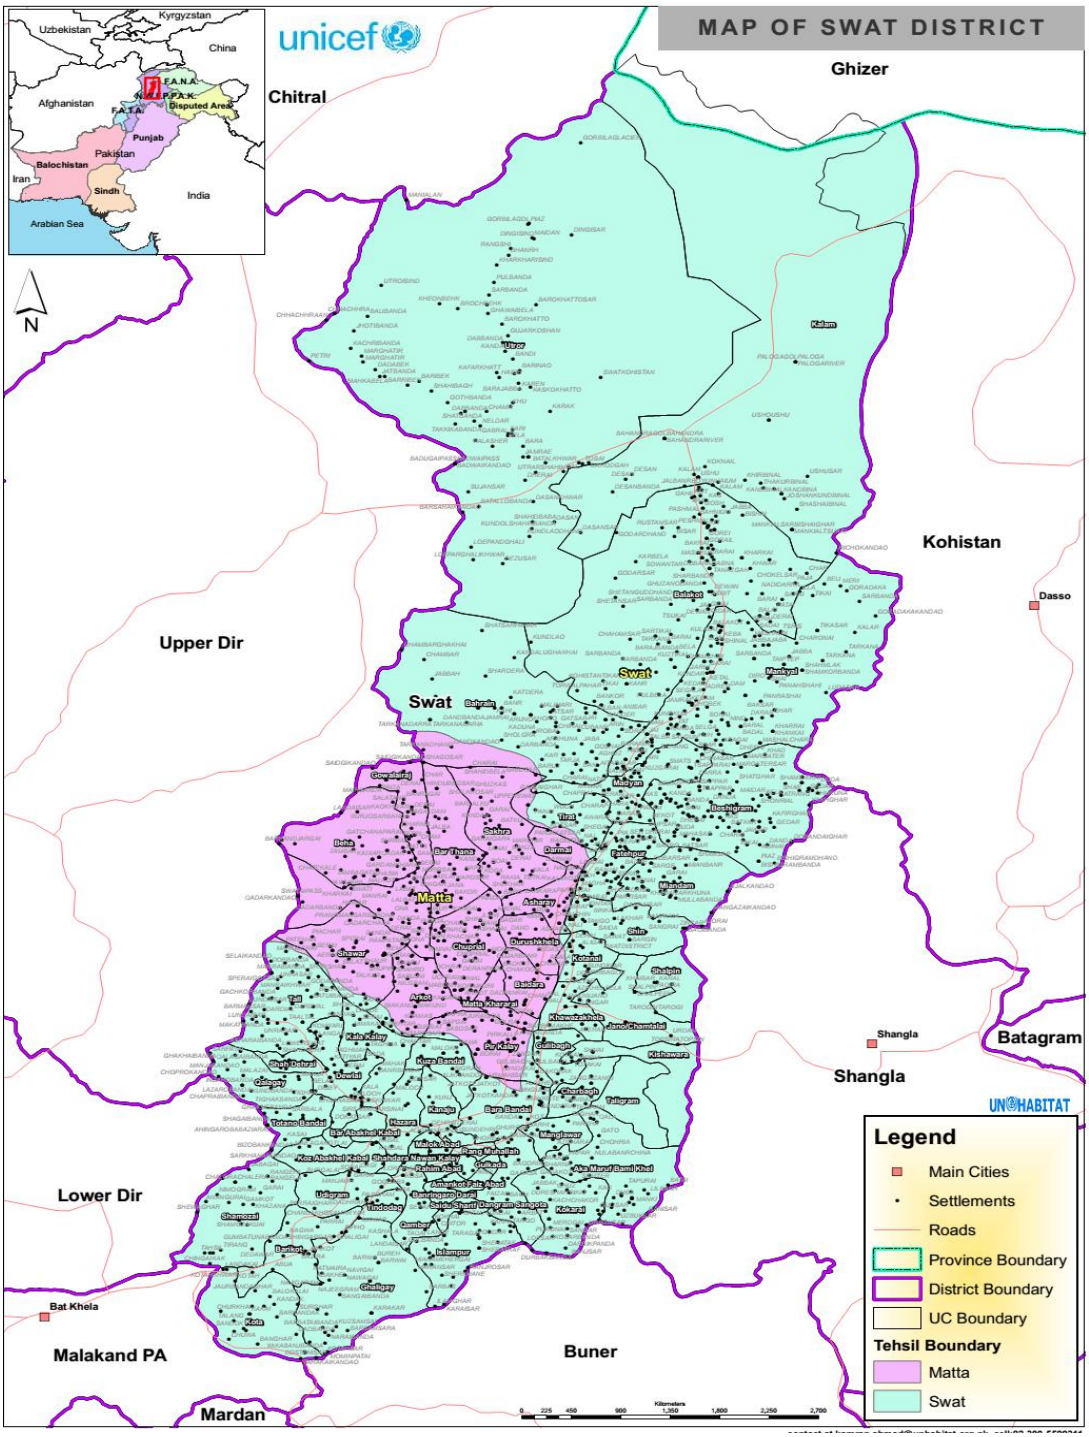

Figure 1. *Map of the study area*

Natural vegetation

The site has diverse vegetation setup and cool climatic condition in summer due to high elevation that varies from 1600 to 4100 m from sea level. Phyto-geographically, the study area lies in Sino-Japanese region (Ahmad and Sirajuddin, 1996). Vegetation of the area consists of moist temperate forests (Champion et al., 1965) extending to sub

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

alpine and alpine types. The mountains along the valley are densely forested. The project area has unique flora as it occupies nexus of the three great mountains i.e. Landaysar, Brajosar and Datkor soki. Nature has been very generous to the region in its endowments of very tall invincible peaks, enormous glaciers, majestic streams, and the meadows of high altitude plateaus. Due to its geographical location within the monsoon belt, farmers of the lower parts of the area cultivate orchards, cereals as well as cash crops. In upper parts of the valley forests and alpine pastures prevail widely. Accordingly, the valley gives home to vast diversity of useful plants i.e. edible, medicinal and aromatic plants are common. Various products like honey, morels, and handicrafts are also obtained by the local people from the valley. Doghalgo khvar Chatikal and Swatai are the main streams which meet with each other in Biha Valley.

Regarding the altitude, climate, soil and topography, vegetation of Biha valley can be classified into the following broad categories:

1. *Olive–White Oak Zone:* These forests are located at lower altitudinal ranges from 1400 to 1700 m above sea level.
2. *Blue Pine Zone:* These forests can be observed between 1700 and 2700 m and represent the major part of vegetation in the valley. This type of vegetation is located in Derai sargay, Pakani, Yag bila and Cyakas etc.
3. *Fir Spruce Zone:* Fir spruce forests can be observed above 2700 m upto an elevation of 2900 m at Kotago, Kadyar, Kamali chari, Dolo, Jargogo and Jaby.
4. *Tree Line Iron Oak Forest:* These forests are usually located between 2900 and 3400 m at Goryal, Sangwano kandaow, Mero kandaow and Dat kor. However, in some areas these forests occur from 2750 m where they are usually mixed with fir and spruce at the lower boundary. These forests change to pure iron oak forest as the elevation increases.
5. *Alpine and Sub-Alpine Zone:* This type of vegetation can be observed above 3200 m and is present in Kandaw sar, Mero kandaow, Landay sar, Brajo sar, and Sangwano kandaow.

Climate

Climatically, the area comes under typical sub-tropical dry temperate zone. The sub-tropical, semi-arid climate of Saidu Sharif is comparable to that in the lower parts of the valley while the upper parts of the valley have a climate of temperate type up to 2500 m height and above 2500 m there is subalpine and alpine zone. Winter is hard and summer precipitation remains high at higher altitudes as compared to lower parts of the valley (Weiers, 1995). Monsoon winds (from subtropical regions of the Arabian Sea) bring summer rainfall while westerlies are responsible for winter rain and snowfall in the valley. Due to considerable precipitations in both seasons the upper regions of the Biha valley are comparatively much humid than the lower areas. June and July are the hottest months and December, January and February are the coldest months of the year. Relative humidity is also an important atmospheric factor governing the distribution of plants and vegetation (Hussain and Ilahi, 1991). The value of relative humidity is higher in the months of July, August and September. There are usually two rainy seasons per year: One lasts from January to April (winter rainfall and the other one occurs in July/August (summer rainfall). Snowfall frequently occurs from November to March. Coldest months of the year are December, January and February in which the valley remains permanently under snow cover. The lower snow line in winter in Doghalgay Valley is 1800 to 4000 m. Beside rainfall and snowfall hailing, that damage the crops

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_56115631
© 2018, ALÖKI Kft., Budapest, Hungary

and orchards badly, is also common during May and June (summer) and September and October (autumn) (Khan, 1991). Relative humidity is also an important atmospheric factor governing the distribution of plants and vegetation (Hussain and Ilahi, 1991). The value of relative humidity is higher in the months of July, August and September.

Rock types and soil

The area is characterized by very complicated geological structures and rocks. Quartz and mica, with minor iron garnet or graphite etc are its major components. The rocks are usually dark grey with a micaceous shine on the surface. The main soil materials are silty clay loam and in moderately deep silt loam (Shangla-rockland complex), which is closely related to the parent rock. The area has different parent rocks therefore wide variety of soil types can be found in the area.

Field investigations

The entire study area was surveyed to identify the different stands of vegetation on the basis of the physiognomy of the vegetation. The Geological Positioning System (GPS) coordinates including altitude, longitude and latitude were taken from each stand by using GPS. Line transect method by using 50 m transect was used to sample the phytosociological attributes of the study area (Kent and Coker, 1992). Density, cover, frequency, relative density, relative cover and relative frequency for each species was calculated following Daubenmire (1959) and Hussain (1989). Phenology of the species was documented by visiting the study area in different intervals during 2012-2013. Different life-form classes and leaf size spectra were recorded according to the Raunkiaer classification.

Community homogeneity

Similarity Index determines the interspecific association between the species of plant communities**.** The index of similarity was calculated after Sorenson (1948) by using the following formula (*Eq. 1*):

$$SI = 2C \ / \ A+B \times 100 \qquad \text{(Eq.1)}$$

where, C = the least importance value of common species, A = importance value of community A, B = importance value of community B.

Dissimilarity Index is the reverse sequence of similarity index. It was calculated by using the following formula (*Eq. 2*):

$$ID = 100 - Is \qquad \text{(Eq.2)}$$

where, Is = Index of similarity and S = Sorenson Index.

Soil analyses

For soil analysis, the soil will be dugout, the surface soil up to 10 cm depth was removed and about 500 g of soil from each sample was collected, mixed well individually before the use and analyzed in the soil laboratory at ARI (Agriculture research institute) Mingora, Swat, Pakistan. Then samples were air dried at 20 to 25 °C,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_56115631
© 2018, ALÖKI Kft., Budapest, Hungary

and passed through a 2 mm sieve and analyzed for different physiochemical characteristics. Soil pH and texture were measured with the help of dynamic digital pH meter and hydrometer respectively (McLean, 1982; Koehler et al., 1984; Rahman et al., 2015, 2017). Nitrogen through Macro-Kjeldahl method (Paul and Berry, 1921), Phosphorus and Potassium were analyzed through ammonium bicarbonate-diethylene triamine penta acetic acid (AB-DTPA) method (Soltanpour and Woekman, 1979). While, soil organic matters were determined by following Nelson et al. (1996).

Data analyses

The data were statistically analyzed to find out the relationship between plant species composition and different physiographic and edaphic attributes. PCORD software (version 5) was used to recognize communities by two-way indicator species analysis (TWINSPAN) and CANOCO software (version 5) for ordination analysis was done for detrended correspondence analysis (DCA) and canonical correspondence analysis (CCA) to find variation directories of different plant species (Ter Braak, 1986, 1994).

Results

Floristic composition

The study area consists of 203 plant species belonging to 70 different families and 154 genera. The biggest family was Asteraceae consisting of 19 species, while the other major families were Rosaceae comprising of 16 species.

Flowering stage

During field observations in the research area two flowering seasons were recorded. The first flowering seasons were observed from May to August, in which total 174 species (85.35%) were observed in flowering and in peak flowering period. The species included herbs (71.41%), shrubs (11.83%), trees (10.65%), ferns (2.37%) with prominent sori (reproductive phase) and climbers were present with 1.78%. While in the second spell (September to October) only 29 plant species with 14.65% were observed in flowering stage in which 62.07% were herbs, 13.79% shrubs, 10.34% trees and 6.90% grasses and ferns each. The flowering stage of the plants starts to decline from 15 October in the Alpine areas and continues from the middle of November in the lower sub-tropical regions. The remaining 80% of the plants were in either fruiting stage or dormant condition and remain dormant till April (*Table 1*). The distribution of flowering species showed significant variations with altitude. Plants living at high elevations especially in alpine and sub-alpine areas were found in blooming condition from July to August while plants at lower altitude were found in blooming condition from May to July.

Table 1. *Flowering seasons of plant species recorded in the Biha Valley*

Season	Herbs		Shrubs		Trees		Grasses		Ferns		Climber		Total	
May-Aug	122	71.4%	20	11.8%	18	10.6%	5	2.3%	6	2.9%	3	1.8%	174	85.3%
Sep-Oct	17	62.1%	4	13.8%	3	10.3%	3	6.9%	2	6.9%	0	0	29	14.6%

© 2018, ALÖKI Kft., Budapest, Hungary

Fruiting stage

The main fruiting period of the study area was recorded from September onward, 185 plant species (91.41%) were observed in fruiting stage while from May to August the poorest fruiting period was recorded during which only 18 plants species (8.59%) were observed (*Table 2*).

Table 2. *Fruiting seasons of plant species recorded in the Biha Valley*

Season	Herbs		Shrubs		Trees		Grasses		Ferns		Climbers		Total	
May-Aug	16	88.2%	1	5.9%	1	5.9%	0		0		0		18	8.6%
Sep onward	123	67.4%	23	12.7%	20	11.1%	8	3.3%	8	3.8%	3	1.7%	185	91.4%

Phytosociology

TWINSPAN classification

The phytosociological data of 19 stands having 203 species were analyzed by TWINSPAN Classification. In this classification a total of seven plant communities were recognized in the study area (*Fig. 2*). These communities are described below.

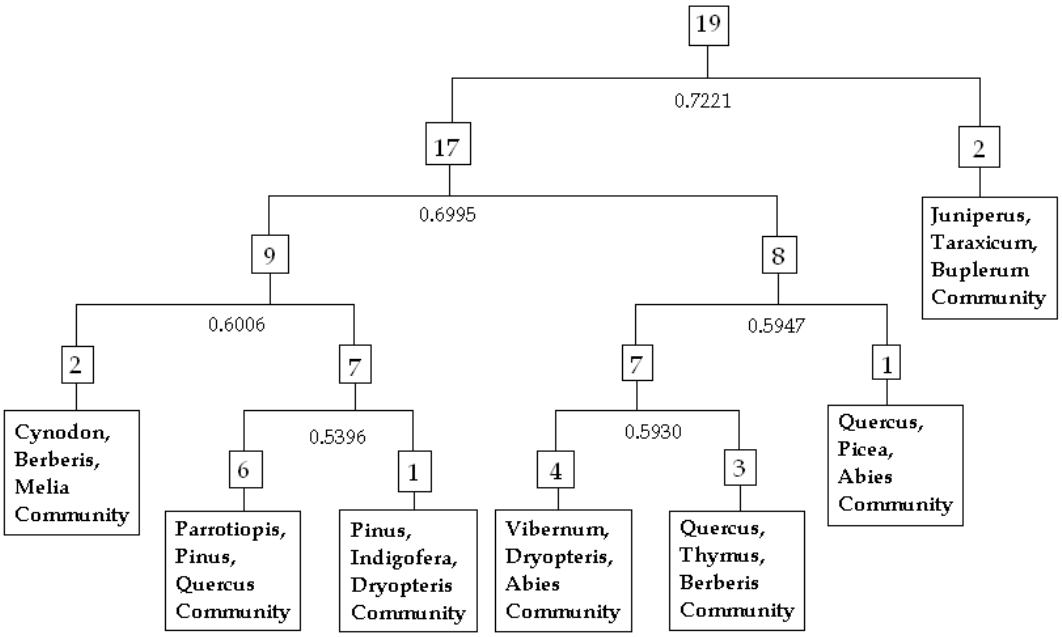

Figure 2. *TWINSPAN classification of plant communities of the Biha Valley*

The Cynodon-Berberis-Melia (CBM) community

This community was recorded at Nalkot sarbira and Nalkot shigartan from longitude (E = 072° 18.127' to 072° 18.127') and latitude (N = 35° 03.516' to35° 04.080') from north-east to south exposure with 15° to 30° slope at 5174-5445 ft elevation. The community consists of 70 plant species including 43 herb species, 12 species of shrubs and trees each, 2 grass species and 1 fern species. The dominant species in this

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

community was *Cynodon dactylon* with 32.97 IVI the co-dominant species were *Berberis lyceum* with 13.83 IVI and *Melia azadarach* with 12.92 IVI. In the community, 135.07 IVI contributed by herbs, 68.06 by trees, 61.96 by shrubs, 36.28 by grasses and 0.95 by ferns (*Table 3*). Therophytes was the dominant life form in the community (40%) followed by Nanophanerophytes (17.14%). Microphylls was the dominant leaf spectra in the community (52.86%) followed by Nanophylls (24.29%). This community existed in loamy sand soil with basic nature (pH = 7.2 to 7.6). The organic matter in the soil was 2.90 to 4.28%, nitrogen was 0.14 to 0.21%. Phosphorous was 6.67 to 7.86 mg/kg, potassium was 132 to 138 mg/kg and electric conductivity was 0.03 to 0.09.

The Parrotiopsis-Pinus-Quercus (PPQ) community

From 5606 to 7503 ft altitude, *Parrotiopsis, Pinus and Quercus* community was found in More Khwar, Koza Pakani, Bara Pakani, Sarma Pakanai, Pakani Shaheed and Wale Drab locality. The longitude of the community varies from E = 072° 17.397' to 072° 16.852' and latitude N = 35° 02.675' to 35° 03.456' on S/E, N/W, N/E, E and N exposures with 28° to 40° slope degree. The community comprised of 98 plant species out of which 58 species were herbs, 19 species were shrubs, 11 species were trees, 5 species were ferns, 3 species were climbers and 2 species were grasses. In this

© 2018, ALÖKI Kft., Budapest, Hungary

community *Parrotiopsis jacquemontiana* was the dominant species with 17.33 IVI while the co-dominant species were *Pinus wallichiana* 16.47 and *Quercus incana* with 16.43 IVI. In the community the herbs contributed a total of 112.58 IVI, 82.88 by shrubs, 44 by trees, 22.29 by ferns, 3.49 by climbers and 3.31 by grasses (*Table 3*). The dominant life form class in the community was Therophytes (44.44%) followed by Nanophanerophytes (17.17). The dominant leaf spectrum in the community was Microphylls (45.45%). The loamy sand soil of this community had basic nature (pH = 6.8 to 7.8) in comparison with other communities. The organic matter in the soil was noted 0.69 to 4.14% and nitrogen was 0.03 to 0.21%. The total amount of phosphorous found in the soil was 5.75 to 14.11 mg/kg, potassium was 112 to 162 mg/kg and electric conductivity was 0.02 to 0.08.

The Pinus-Indigofera Dryopteris (PID) community

At 7078 ft elevation, *Pinus-Indigofera-Dryopteris* was observed in Yag bila/Chatikal E = 072° 13.501'. N = 35° 05.626' on the southwest facing with 20° slope. The community consists of 31 plant species out of which 22 species were herbs 4 species were shrubs, 2 species were ferns and trees each, and 1 species was grass. The dominant species in this community was *Pinus wallichiana* with IVI 37.38 while the associated species were *Indigofera heterantha* (36.34) and *Dryopteris blonfordii* with 34.0 IVI. In this community 170.37 IVI contributed by herbs, 52.65 by shrubs, 42.64 by trees, 39.90 by ferns and 8.41 by grasses (*Table 3*). The dominant life form class in this community was Hemicryptophytes (35.71%) followed by Therophytes (32.14%). Based on the leaf spectra the community is categorized in Microphylls (39.29%). The soil chemistry of the community was loamy sand and had a pH of 7. The organic matter in the soil was the lowest as compared to other communities (1.04%) while nitrogen was 0.05%, phosphorous was the highest in the soil (19.57 mg/kg). Potassium was 158 mg/kg and electric conductivity was 0.03 of the soil.

The Vibernum-Dryopteris-Abies (VDA) community

Vibernum grandiflorum, Dryopteris blonfordii and Abies pindrow community was recorded from 7557 to 8850 ft elevation in Jarogo jai, Jarogo khwargai, Jarogo banda and Goryal jai 072° 13.224' to 072° 12.207' E and 35°.05.776' to 35° 06.240' N on the south-east and north-east facing slope with 22° to 33°. The community consists of 39 plant species out of which 26 species were herbs, 7 species were trees, 4 species were ferns and 2 species were shrubs. The highest IVI in community was of *Viburnum grandiflorum* with 39.13 while the associated species were *Dryopteris blonfordii* 29.43 and *Abies pindrow* with 29.38 IVI. In this community a total of 126.37 IVI was contributed by herbs 87.92 by trees 47.87 by ferns and 39.86 by shrubs (*Table 3*). In this community the Therophytes was the dominant life form (41.03%), followed by Hemicryptophytes (25.64%). On the basis of leaf spectra, the community is characterized by Microphylls (30.77%), Nanophylls (25.64%), Mesophylls (20.51%), Leptophylls (15.38%) and Megaphyll (7.69%). The physico-chemical analysis showed that the community was established in pure loamy to loamy sand soil with pH highly acidic slightly neutral 6 to 7.2. Organic contents in the soil were observed (1.73 to 4.83%) the highest in comparison with other communities and nitrogen was 0.09 to 0.17%. Phosphorous was measured 6.14 to 13.12 mg/kg, potassium was 112 to 164 mg/kg and electric conductivity was 0.01 to 0.14.

The Quercus-Thymus-Berberis (QTB) community

At 9450 to 10513 ft altitude, Goryal 1, Goryal 2 and Kandaow locality 072° 11.899' to 072° 11.608' N and 35° 06.284' to 35° 06.567' E on northeast and southeast exposures with 24° to 49° slopes, the community *Quercus semicarpifolia, Thymus linearis* and *Berberis jaeschkeana* was recorded. The community contains 41 plant species out of which 31 species were herbs, 6 species were shrubs, 3 species were trees and 1 species was fern. In this community *Quercus semicarpifolia* was the dominant species with 41.83 IVI while the co-dominant species were *Thymus linearis* 19.52 and *Berberis jaeschkeana* with 19.14 IVI. In the community the herbs contributed a total of 191.2 IVI, trees 68.33, shrubs 43.93, and ferns 2.68 (*Table 3*). The dominant life form in the community was Therophytes (43.90%) followed by Hemicryptophytes (19.51%). The dominant leaf spectrum in the community was Microphylls (43.90%), Nanophylls (29.27%), Leptophylls (12.20%), Mesophylls (9.76%) and Megaphyll (4.88%). The soil chemistry of the community was loamy sand with highly acidic nature to neutral of 5.8 to 7 pH. The organic content in the soil was observed 2.42 to 4.14%, whereas the nitrogen was 0.12 to 0.21%. The amount of phosphorous was measured high as compared to other communities (6.14 to 19.67 mg/kg), potassium was 138 to 160 mg/kg and electric conductivity was observed 0.02 to 0.12.

The Quercus-Picea-Abies (QPA) community

At an altitude of 10345 ft, *Quercus semicarpifolia*, *Picea smithiana and Abies pindrow community* was recorded in Mero kandaow locality E = 072 ° 14.678', N = 35° 08.546' on south facing slope with 31°. The community comprised of 21 plant species out of which 13 species were herbs, 3 species were trees and 1 species was a shrub. In this community *Quercus semicarpifolia* was the dominant species with 57.97 IVI while the co-dominant species were *Picea smithiana* 28.66 and *Abies pindrow* with 26.52 IVI. In the community the herbs contributed a total of 159.14 IVI, trees 113.15 and shrubs 18.13 (*Table 3*). The dominant life form in the community was Therophytes (47.62%) followed by Hemicryptophytes (19.05%). The dominant leaf spectrum in the community was Microphylls (47.62%). The physiochemical analysis of the soil showed that this community was present in loamy sand soil with a highly basic character (pH = 8) in comparison with other communities. The organic matter in the soil was noted 2.42% and nitrogen was 0.12%. The total amount of phosphorous found in the soil was 7.33 mg/kg, potassium was 156 mg/kg and electric conductivity was 0.01.

The Juniperus-Taraxacum-Bupleurum (JTB)

The community was observed at Landay sar and Sali kandaow of Dughalgo side at longitude E = 072° 15.842' to 072° 15.586' and latitude N = 35° 08.224' to 35° 08.292' of the area on southeast and northeast exposures with 20° to 27° slope at 11225 to 11760 ft elevation. The community comprised of 28 plant species having 22 species of herbs 3 species of grasses 2 species of shrubs and 1 species of ferns. In this community, *Juniperus communis* has the highest importance value index 45.07 followed by the co-dominant species *Taraxacum officinale* and *Bupleurum longicaule* having 34.2 and 18.91 importance value index respectively. A total of 212.09 importance value index was contributed by herbs 60.12 by shrubs, 23.58 by grasses and 4.2 by ferns (*Table 3*). The major life form in the community observed was Therophytes (50%) followed by Chamaephytes (25%). The highest leaf spectra observed in the community was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

Nanophyll (32.14%), followed by Microphyll (28.57%). Physico-chemical analysis showed that the soil of the area was pure loamy to loamy sand with acidic nature of 5.8 to 6 pH. The organic matter noted was 2.76 to 4.83% and nitrogen was 0.14 to 0.24% in the soil of the community while phosphorous was 6.93 to 8.38 mg/kg and potassium was the highest as compared to other communities 144 to 186 mg/kg. The electric conductivity (EC) of the community was also high in comparison with other communities 0.52 to 0.67.

Index of similarity (IS)

The highest index of similarity (50.63%) was recorded between *Vibernum grandiflorum, Dryopteris blonfordii, Abies pindrow,* and Quercus semicarpifolia, *Thymus linearis* and *Berberis jasckeana* communities followed by (48.57%) between *Pinus wallichiana, Indigofera heterantha, Dryopteris blonfordii* and *Vibernum garndiflorum, Dryopteris blonfordii Abies pidrow* communities (36.68%) between *Cynodon dactylon, Berberis lycium, Melia azadarch* and *Parrotiopsis jacquemontiana, Pinus wallichiana, Quercus incana* communities. Intermediate similarity was recorded (27.77%) between *Pinus wallichiana, Indigofera heterentha, Dryopteris blonfordii* and *Quercus semicarpifolia, Thymus linearis* and *Berberis jasckeana* communities (27.53%) between *Parrotiopsis jacquemontiana, Pinus wallichiana, Quercus incana* and *Vibernum garndiflorum, Dryopteris blonfordii Abies pidrow* communities (26.15%), *Parrotiopsis jacquemontiana, Pinus wallichiana, Quercus incana* and *Pinus wallichiana, Indigofera heterantha, Dryopteris blonfordii.* The highest index of similarities ranges from 26.15% to 50.63% between communities due to same conditions of soil such as soil texture, organic matter and pH and physiographic factors such as slope angle, slope exposure and less difference in altitude. The least similarity index (2.02%) was noted between *Cynodon dactylon, Berberis lycium*, *Melia azadarch* and *Juniperus communis, Taraxacum officinale*, *Bupleurm longicaule* communities. Remaining communities also showed less than 20% similarity due to variation in altitude (5350 to 12000 ft), soil condition, organic matter, pH and phosphorus percentage (*Table 4*).

Index of dissimilarity (ID)

According to Muller-Dumbois and Ellenberg (1974), plant communities having less than 65% similarity were considered as dissimilar. All the plant communities of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_56115631
© 2018, ALÖKI Kft., Budapest, Hungary

investigated area showed less than 65% similarity hence considered as different communities. The highest dissimilarity (97.96%) was recorded between *Juniperus communis, Taraxacum officinale*, *Bupleurm longicaule* and *Cynodon dactylon, Berberis lycium, Melia azadarch* communities (97.02%), between *Juniperus communis, Taraxacum officinale*, *Bupleurm longicaule* and *Vibernum garndiflorum, Dryopteris blonfordii Abies pidrow* communities (96.86%), between *Juniperus communis, Taraxacum officnale*, *Bupleurm longicaule* and *Parrotiopsis jacquemontiana, Pinus wallichiana, Quercus incana* communities (96.62%), *Juniperus communis, Taraxacum officnale*, *Bupleurm longicaule* and *Pinus wallichiana, Indigofera heterentha, Dryopteris blonfordii* while the lowest dissimilarity (49.37%) was observed between *Quercus semicarpifolia, Thymus linearis* and *Berberis jasckeana* and *Vibernum grandiflorum, Dryopteris blonfordii, Abies pindrow* communities (51.43%), between *Vibernum garndiflorum*, *Dryopteris blonfordii Abies pidrow* and *Pinus wallichiana, Indigofera heterentha, Dryopteris blonfordii* and *Vibernum garndiflorum.* All the other communities have greater than 60% dissimilarity (*Table 4*).

Ordination

Ordination of species

All species of the 19 stands and 7 communities were analyzed through Detrended Correspondence Analysis DCA which showed that the species of *Cynodon dactylon* and *Melia azadarch, Oenothera rosea* and *Dactylis glumerata, Diospyros lotus* and *Celtis caucasica, Spirea canescens* and *Trifolium repens, Quercus dilatata* and *Berberis lycium, Pinus wallichiana* and *Indigofera heterentha*, *Achyranthes aspera* and *Quercus incana*, *Abies pindrow* and *Rumex dentatus*, *Anemone obtusiloba* and *Viola canescens, Bupleurum longicaule* and *Rumex nephalensis*, *Epilobium hirsutum* and *Juniperus communis* have positive correlation with each other. While the species of *Juglans regia* and *Quercus semicarpifolia, Beberis lycium* and *Juniperus communis, Diospyros lotus* and *Piecea smithiana, Rubus fruticosus* and *Barberis jaeschkena* have negative correlation with each other and *Bistorta amplexicaulis* was found an isolated species as no correlated species was found with it (*Fig. 3*).

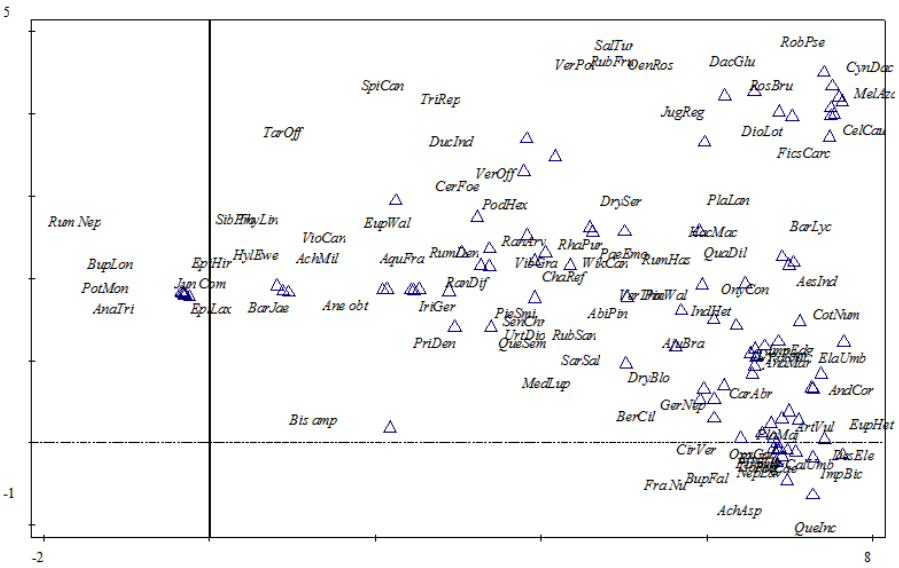

Figure 3. *DCA ordination of species*

Ordination of stands

The ordination of all stand of the study area given Detrended Correspondence Analysis DCA (*Fig. 4*). The DCA of stand indicated that both stands 1 and 2 correlated with each other, stand 3, 12, 13, 14, 15 and 16 correlated as well, 5, 6, 7 and 8 correlated too, 9, 10 and 11 also correlated, 17 and 19 correlated as well with each other in environmental variables and similar vegetation while stand 4 and stand 18 have no correlation with any stand therefore, these are considered as individual communities.

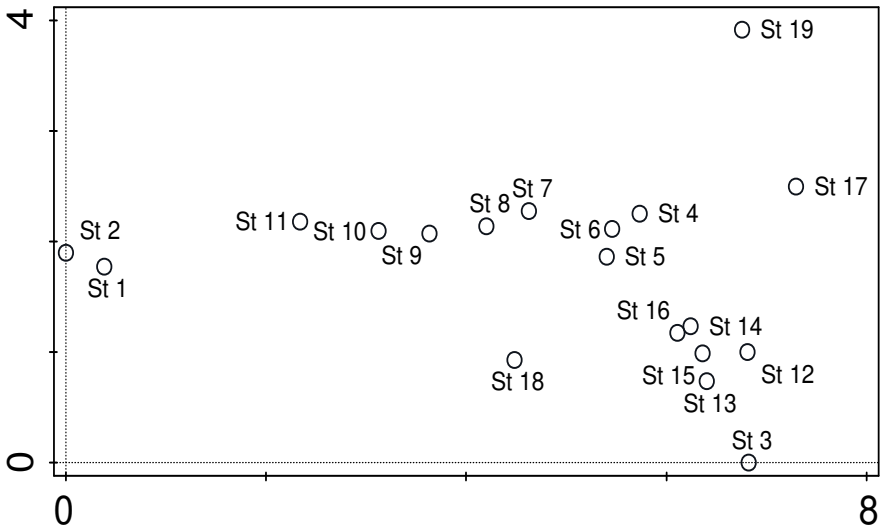

Figure 4. *DCA ordination of stands*

Ordination of species with environmental variables

The correlation between vegetation and environmental variables was indicated in the ordination diagram produced through Canonical Correspondence Analysis (CCA). In which the direction and length of the arrow indicated the environmental variables and the triangle shaped clusters indicated the vegetation while length of the arrow shows the strength of variable between the variable at each axis representing the degree of correlation between them, the variables on the same axis show positive correlation while the variables on the opposite axes indicated negative correlation. As shown in (*Fig. 5*) that *Abies pindrow, Verbena officinalis* and *Rumex dentatus* were highly correlated with slope steepness while these species were less correlated with electric conductivity, silt, soil fertility, pH, latitude and soil classes. *Viburnum grandiflorum, Trifolium repens, Duchesnea indica, Primula denticulate, Sibbaldia procumbens, Viola canescens, Anemone obtusiloba,* were highly correlated with phosphorous and less correlated with silt, latitude, electric conductivity, pH, and classes. *Barberis jaeschkena*, *Taraxacum officinale* and *Hylotelephium ewersii* were highly correlated with potassium and less correlated with classes, pH, latitude, silt, and electric conductivity. Similarly, *Trachydium roylei*, *Bupleurum longicaule*, *Genetiana olivieri*, *Eritrichuim canum, Anaphalis triplenervis, Bergenia stracheyi, Cerastium pusillum, Circea cordata* and *Potentella Monenthes* have close association with electric conductivity and nitrogen and less relationship with slope angle, slope facing, phosphorous and potassium. *Chenopodium album, Calamintha umbrosa, Elscholtzia fruticosa, Baberis lyceum, Andrachne cordifolia* and *Desmodium elegans* were closely associated with latitude and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

less associated with slope steepness, altitude, longitude, slope exposure, clay, soil fertility, potassium and phosphorous. *Carpesium abrotonoide, Artemisia vulgaris* and *Elaeagnus umbellate* were highly associated with pH and less correlated with altitude, longitude clay, slope exposure and slope steepness. No species was found closely associated with altitude and longitude however the density of species decreases with the increase in altitude.

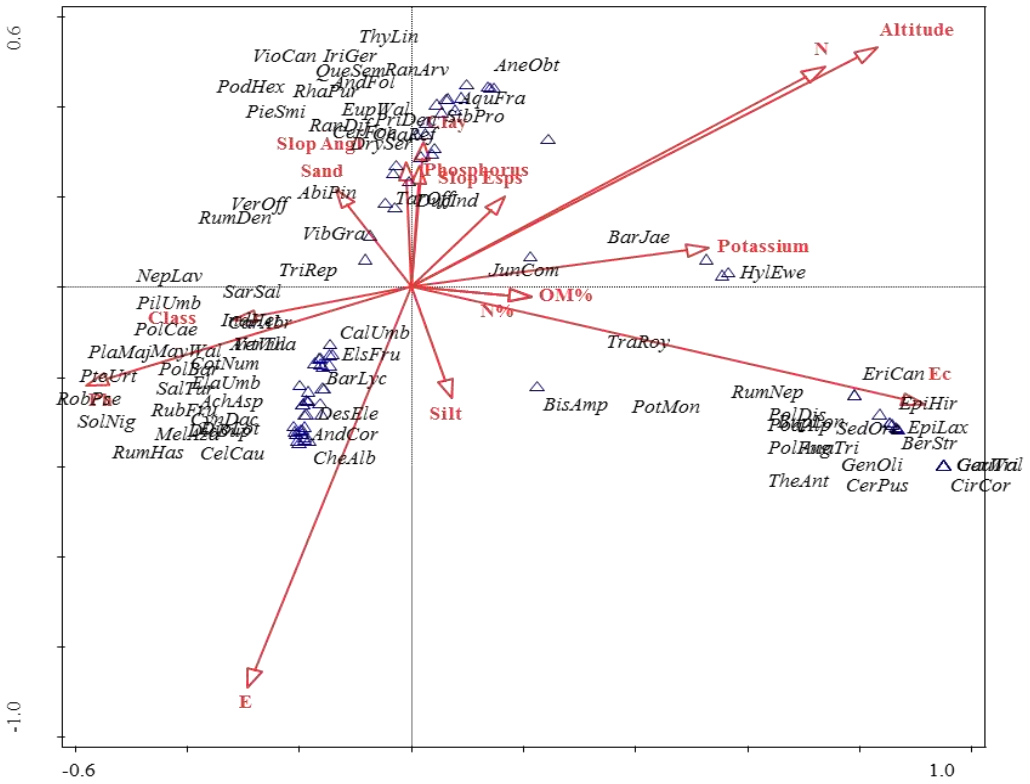

Figure 5. *CCA ordination of species with environmental variables*

Ordination of communities with environmental variables

CCA ordination was used to find the correlation of environmental variables and plant communities of the study area (*Fig. 6*). The maximum strength was recorded for the environmental variables like altitude, electric conductivity and nitrogen. The minimum environmental variable strength was recorded for Organic matter. The stands of *Cyanodon, Berberis, Melia* community and *Parrotiopsis, Pinus, Quercus* community positively correlated with Latitude and pH. *Pinus, Indigofera, Dryopteris* community positively correlated with sand. *Vibernum, Dryopteris, Abies* community positively correlated with sand, slope angle, clay and phosphorous. *Quercus, Thymus, Berberis* community were positively correlated with slope aspect, clay and phosphorous. *Quercus, Picea, Abies* community positively correlated with slope angle and clay. The stands of *Juniperus, Taraxacum, Bupleurum* community positively correlated with electrical conductivity. In constrained CCA ordination the total variation was 5.859, explanatory variables account for 84.5%. The CCA ordinations of different axis are given in *Table 5*.

Discussion

In the present study a sum of 203 plants species of 70 families were recorded in which the leading families were Asteraceae, Rosaceae and Lamiaceae; therefore, the area was considered rich floristically. Our results are in accordance with previous reports of many researchers of the country. Ijaz (2016) and Khattak et al. (2015) mentioned Asteraceae while Rahman et al. (2016a, b) cited Lamiaceae as the leading families from their study areas. During the present study the ratio of flowering was found different at different time of the year. A very few herbaceous and shrubby plants initiated vegetative growth at the end of April. Early May is the blooming time for few plant species. Plant species such as *Juglans regia*, *Melia azaadarch, Morus alba, Rosa moschata, Rubus fruticosus, Caltha alba* and *Lactuca dissecta* were active during this period. May to August is the favorable season for the flowering for the majority of shrubby, trees and herbaceous species. July and August were the peak flowering months after that flowering stage starts declining. Similarly, Zhanghe et al. (1999) also described that peak of flowering happened during May in various parts of China.

The study of characteristics, classification, relationships and distribution of plant communities is known as phytosociology (Dastagir et al., 1999). From elevation of 5174 ft to 12760 ft 7 different plant communities were established from 19 stands with

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

203 plant species in the study area by using TWINSPAN classification. Seasonal fluctuations and sampling time change the structure of the community which is the consequence of the environmental conditions, habitat and existing vegetation types. Champion et al. (1965) and Bano et al. (2018) recognized different communities of plants from various areas and reported that it was due to the degradation of environmental and anthropogenic factors therefore the current investigation also signify that the major vegetation units were degraded by different environmental variables and man-made factors. Kumar (1996) found the relation between species distribution and soil physical factors like soil moisture and texture and El-Ghani (1998) reported a close relationship between soil chemistry (pH), calcium and organic carbon and composition of plant species. Organic matter content as a pivotal soil fertility factor can affect phytodiversity (Zhang et al., 2010). Our results indicate the importance of soil organic matter in top soil layers for plant species distribution. The increases in soil nutrients (OM, P, N, and K), improvement in site conditions (community cover, depth of litter, depth of humus, soil water content) and decrease in soil bulk density indicated the natural habitat restoration following abandonment.

DCA and Cluster analysis are very useful in plant communities and classification of species and other than this to give structure to plant life. Soil pH, texture and density of trees are the major causes of vegetation pattern (Saima et al., 2009).

The ranges of altitude have an important effect on qualitative and quantitative characteristics of trees (Fallah Chay and Marvie, 2005). The mean of temperature, evaporation and transpiration are reducing with increasing altitude range, while the humidity will be increasing. Some species of plants do not prefer the high altitudes because of short growth period and low temperatures. The presence of severe winds in highlands also confines the growth of plant. At lower altitude (5445 ft) of the study area *Cynodon-Berberis-Melia* community exists while the *Parrotiopsis-Pinus-Quercus* was present at 5606 to 7503 ft elevation; similarly, at high elevation of 10000 to 12000 ft the *Quercus-Thymus-Berberis* community and *Juniperus-Taraxacum-Bupleurum* community was recorded. Agreed findings were reported by Bano et al. (2018). They recorded the presence of *Berberis* community at 2485–2937 m. Similarly, *Thymus* and *Artemisia* community is reported by Aleyha and Shokuii (2003) at 2350–2500 m elevation in Semnan. Karimi (1997) documented the *Thymus* and *Agropyron* community in Anzali-Khalkhal area at 1400 to1800 m altitude. The elevation in the area showed positive correlation with the number of species. Our findings are in line with Dasti and Malik (1998) who indicated that altitude is an environmental variable which affects the density and association of plants. Our results reveal that soil characteristics such as electric conductivity, pH, clay and fertility have great effect on community distribution and plants species association.

The results revealed that slope exposure was one of the most important variable influencing the plant distribution. South and north facing slopes have completely unlike vegetation covers. South facing slopes have high temperature and low humidity because of severe solar radiation in comparison with north facing slopes. In contrast, north facing slopes have low temperature and has high humidity because of low radiation. As the community of *Juniperus -Taraxacum* and *Bupleurum* exists on northeast facing slopes and at lesser altitude such a situation is resulted from the deficit of radiation and temperature. *Vibernum-Dryopteris* and *Abies* community was recorded also in north facing slopes. While on south facing slope *Cynodon-Berberis* and *Melia* community was recorded at lower altitude and *Quercus-Picea and Abies*

community was observed at high elevation. According to Nazarian (2003), the Salix community was present in north-northeast facing slopes, and the thorny assemblages on south, southwest, southeast, north, northwest and northeast facing slopes in Central Alborz. In our investigation direction of east and west slope were only found effective on growth of diameter and north exposure was found effective on species richness, canopy cover and species association (*Fig. 7*). The analysis of site exposure is commonly used for the determination of qualitative and quantitative indices (Corney et al., 2006; Ajbilou et al., 2006).

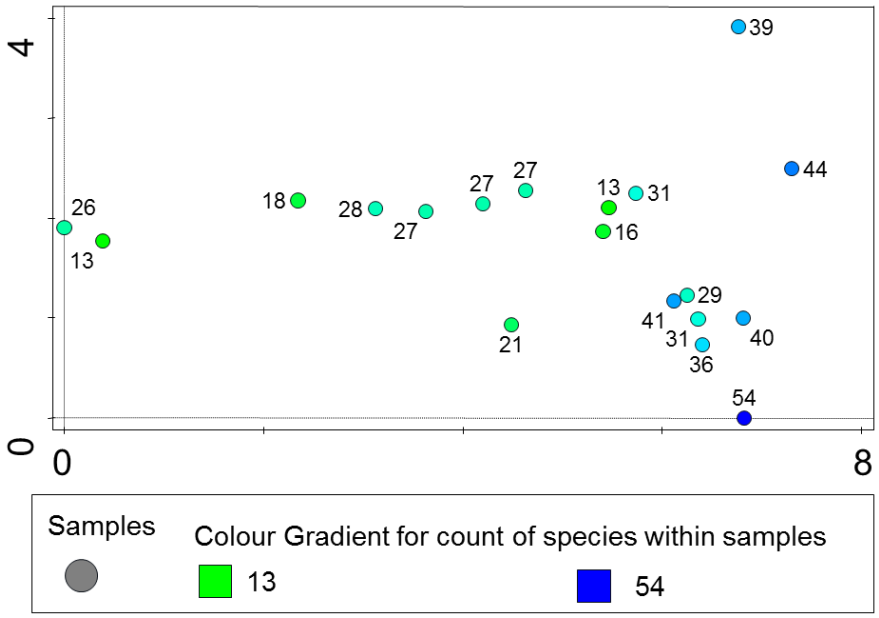

Figure 7. *DCA ordination showing the taxonomic richness of species*

Slope angle or steepness influences the cover of vegetation on different kinds of slopes. In the studied area, *Cyanodon* as a grass, *Pinus* community as a tree and *Juniperus* as a shrub accumulation are present on moderate slopes, but *Parrotiopsis, Vibernum* as a shrub *Quercus* and *Quercus* as tree communities are stretched on sharp slopes. Khageaddin in (2000) described the existence of *Amygdalus haussknechtii* on high slopes of more than 100% in Kolah ghazi National Park.

The distribution and composition of plant communities in the studied area seems to be controlled by different environmental variables together with climate, topography, soil and biotic pressure. These variables go through variations of various points due to relations with each other and may possibly result in micro-gradients (Hanson and Churchill, 1965). The soil characteristics also influence the distribution of plant on smaller scale (Bakkenes et al., 2002). Landscape also plays significant role in physical features of vegetation. It influences the plant life by changing other variables of environment. Diverse aspects, slopes and altitudes support various plant communities in Biha Valley. Similar findings were recorded by Ahmed et al. (2009) during their research work on *Olea ferruginea* forests of lower Dir.

Conclusion

The present investigated area has rich phytodiversity containing 203 plant species including 137 herbs, 25 shrubs, 21 trees, 8 grasses, 8 ferns and 3 species of climbers. Most of the local inhabitants are depending upon the biodiversity of the area. The local people use plant resources for various purposes including medicinal, for fodder, fruits, vegetables, fuel wood etc. The dominance of Therophytes and Microphylls type of biological spectrum shows that the area has sub-tropical and moist temperate type of climate. The ecological characters of plants such as density, frequency and abundance were completely influenced by the natural as well as biotic pressures mainly at the sites of the investigation area. The highest values of density and frequency were observed in the rainy season and the minimum values in the cold season. Plants have revealed relatively higher frequency and density, consequently higher degree on distribution and numerical strength of species in summer season on account of most sustainable climatic conditions. It seems in such natural communities, that constancy appears to depend on the balance between the stability and variability of the environment. The diversity of plant species decreases with altitude in the site. Soil electric conductivity, pH, slope angle, slope exposure were found to be the highest environmental variables influencing the distribution of species and communities in the area.

It can be concluded that seasons have great effect on characteristics of soil and species diversity. It was observed that species diversity increases during spring and summer season which decreased later as autumn and winter come close which resulted in decline in the diversity due to dry environmental conditions, slow growth rate and other climatic factors. Difference in numerical parameters like, species richness and species diversity is correlated with variations in soil factors, slope aspect elevation, and micro-climatic conditions in different sites of the area.

Further it is concluded that the site faces the pressure from the local inhabitants in the form of overgrazing and deforestation, which have reduced regeneration of woody plants. Overgrazing, human population explosion, uprooting of medicinal plants by the local laypeople and other informal factors are responsible for habitat loss, soil erosion and proper functioning of ecosystems. There is dire need to conserve the biodiversity of the area in order to provide the resources and resource alternatives for the people's survival in the future.

It could be recommended that rare plant species in the specific micro-habitat can further be studied for conservation management purposes and future ethnobotanical projects must be initiated.

Author's Contributions. AZ conducted the fieldwork, collected data, plant species and conducted the herbarium work, SMK helped in the field work. AM identified the plants specimens. IUR drafted the manuscript. ZI and IUR analyzed the data, FI and MAK helped in organizing the data. ZI supervised the work. IUR and NA critically reviewed the manuscript, EFA, AAA, AH and AA helped in discussion. NA and IUR revised the manuscript, MS, YA and ESC helped in the revision. All the authors have read and approved the final manuscript.

Acknowledgements. The authors would like to extend their sincere appreciation to the Deanship of Scientific Research at King Saud University, Saudi Arabia for its funding to the Research Group number (RG-1435-014).

Abstract. Genetic diversity and relationships among 100 genotypes of *Rhynchosia minima* collected from four districts of Malakand Division was assessed using 16 morphological characteristics and total seed protein profile. Based on qualitative characteristics, inter-district trait similarity index among genotypes of Swat-Dir Lower and Swat-Buner was 100%, while for Dir Lower-Buner, Dir Lower-Dir Upper, and Buner-Dir Upper, it was 85.71%, 28.57%, and 42.85%, respectively. Total seed protein profile resulted in 8 reproducible bands/loci, where inter-district locus contribution to the genetic disagreement was 75%. Among the 8 loci, B-6 and B-7 were monomorphic and could be *R. minima* specific, whereas loci B-1, B-4, B-5 and B-8 were observed only in genotypes collected from Buner. All but locus B-1 were present in genotypes of Dir Upper; locus B-8 was missing in genotypes from Dir Lower; loci B-1 and B-4 were absent in genotypes collected from Swat. Two-way cluster analysis resolved genotypes of District Buner and Dir Upper into discrete clusters, highlighting the role of habitat-specific adaptation. Genotypes of Dir Lower and Swat formed mosaic cluster, indicating to the transfer of genes and/or their coevolutionary descent. To the best of our understanding, this is the first ever report addressing genetic variability in *R. minima*.
Keywords: *genetic variability, climate change, SDS-PAGE, two-way cluster analysis, Rynchosia*

Introduction

Grain legumes are important dietary constituents for both humans and livestock and are ranked third in global importance after cereals and oilseeds (Ilyas et al., 2009; Naim-Feil et al., 2017). With the estimated rise in human population, food security is generally uncertain and warrants the need for safeguarding the biodiversity provided by nature and arable land for specific adaptation to stresses as well as ecosystem resilience under changing climatic conditions (Jacobsen et al., 2013; McCouch et al., 2013; Ali et al., 2016). Under these circumstances, demands for grain legume consumption will increase, and biotic and abiotic constraints will push the limits of legume production

further (Ilyas et al., 2009). Nevertheless, the role of tropical grain legumes is critically important for areas where protein intake from animal sources is low. Population growth and limited land and water resources for agriculture are the major concerns that have gained considerable recent attention (Takeda and Matsuoka, 2008; McCouch et al., 2013). Although there have been consistent increases in crop productivity, these efforts are no longer meet the demands of future populations (Heslop-Harrison and Schwarzacher, 2012). Therefore, exploiting and tapping the wealth of wild and cultivated genetic resources provided by nature and currently warehoused in our seed repositories are vital (Tenskley and McCouch, 1997; Mujeeb-Kazi et al., 2017). However, in spite of all efforts, the world currently faces a greater demand on agricultural output than at any time in history (Tanksley and McCouch, 1997; Naim-Feil et al., 2017).

Indeed, plant breeders have been largely successful in developing high-yielding crop varieties; demands for greater yield potential were previously approached with genetic improvements coupled with increased farming inputs and addition to arable land (Helsop-Harrison and Schwarzacher, 2011). More recently, as the arable land surface has begun to shrink due to population growth, freshwater resources are becoming scarce, and agricultural inputs are associated with increased pollution; thus, major benefits will most likely result from genetic improvement of crops (Lobell et al., 2008; McCouch et al., 2013). However, the last several decades of intense plant breeding and selection are regarded as the most important force that has narrowed the genetic variability of crop species after their domestication some 10,000 years ago (Lu et al., 2009; Schwarzacher et al., 2011; Ali et al., 2012). Today, humanity depends on less than a dozen flowering plant species for 80% of all caloric intake (McCouch et al., 2013). Without sufficient adaptation measures in place, this will not be sufficient to support the feeding demands of 2050 in the face of climate change, habitat fragmentation, and limited water and land resources (Lobell et al., 2008; Mujeeb-Kazi et al., 2017).

Rhynchosia minima (L.) DC., a herbaceous, vining, perennial weed of the family Fabaceae, is found on all five continents (Lopez, 2012). The plant has considerable plasticity and can colonize disturbed areas as well as gaps within natural communities (Shaukat and Burhan, 2000). The plant has tremendous potential to be used in forage, pharmaceutical and other agricultural products, and more importantly, there are no known major threats to this species (Lopez, 2012); however, the plant has negligible uses worldwide, including in Pakistan. Traditionally, *R. minima* is applied to alleviate boils, colds, respiratory infections, diarrhea, dysentery and joint pains, and has been used as an abortifacient and an ecbolic and for general healing. It is also used as a food (in sweets), and its seeds are used as repellents and have antimicrobial potential. Furthermore, a number of important compounds that could fight cancer and may reduce carcinogenesis have been isolated from the seeds (Morris, 2008; Gweru et al., 2009; Jia et al., 2015).

A wide genetic base is critical to adaptation and will determine the future severity of climate change impacts. Genetic bottlenecks jeopardize the potential of crop species for sustainable agriculture and render them vulnerable to stresses (Ali et al., 2012, 2016; McCouch et al., 2013; Mujeeb-Kazi et al., 2017). With the continuous developments in DNA-based technologies and computational tools, more objective measurements of genetic diversity at the genomic level could be made, and important loci could be precisely mapped.

However, not all of these tools are currently available to plant breeders in developing countries, which house large food-insecure human populations. Plant breeders still rely on traditional approaches to screen entries for a clearly defined character recognizable in the phenotype. Once a line with the desired characteristic is pinpointed, it is crossed with an elite cultivar in order to introduce the genes from the exotic donor into the cultivated type (Tanksley and McCouch, 1997; Mujeeb-Kazi et al., 2017).

Proteins are end products of gene expression, and measuring the diversity of the total seed proteins using the SDS-PAGE method is robust, inexpensive and important in practice to crops such as grain legumes (Nisar et al., 2009, 2016; Zahoor et al., 2015). Furthermore, seed storage protein markers have been successfully used to resolve taxonomic relationships and to identify potential lines in both wild and cultivated crop species (Lioi et al., 1999; Ghafoor et al., 2002; Nisar et al., 2007, 2009; Hameed et al., 2009; Win et al., 20011; Wadood et al., 2016). Overall, a combination of morphology with measurements of SDS-PAGE diversity of the total seed proteins has been largely successful, and the genetic diversity of seed storage proteins has been studied in many plant species of agronomic and commercial importance.

Our understanding of the potential of wild plant species and their objective diversity is still limited and needs enhancement (Payne, 1987; Rogl et al., 1996; Ali et al., 2016; Masood et al., 2017). To date, wild plants have received little attention, and thus, the main objective of the current study was to measure intraspecific genetic variation within the population of *R. minima* naturalized in different geographical regions. The present study was designed to study genetic relationships among natural populations of *R. minima* collected from four districts at random for morphological and seed storage protein evaluation. To the best of our understanding, the present study is the first documented report from Pakistan on the genetic diversity of *R. minima*.

Materials and methods

Climatic conditions of Malakand division

Malakand division in general is a hilly area located within the Northern Pakistan covering an area of nearly 29,872 Km^2 and having a range of climatic conditions (*Fig. 1*). Moving along the foothills of the Hindu Kush, Himalayas and Karakoram ranges, the climate of Malakand division changes from humid subtropical at the foothills to the typical arid climate characteristic of the plains of South Asia (Muhammad et al., 2016). District Swat stretches from 35.2227° North to 72.4258° East longitude and the climatic conditions varies from dry to moist temperate. The climate is influenced by various factors including latitude, altitude, the Indian Ocean Summer, Monsoon and the Western cyclonic currents, coming from the Mediterranean Sea, in the winter. Dir lower is located in the Dry temperate zone (34.9161° N, 71.8097° E; 4411 ft above sea level), Dir upper is a moist temperate region (35.3356° N, 72.0468° E; 3174 ft above sea level) while, District Buner having areas of both Dry and moist temperate regions (34.3943° N, 72.6151° E; 4049 ft above sea level).

Plant materials

Field trips were arranged during 2016–2017, and 100 genotypes of *R. minima* growing in the wild were collected from four districts of Malakand Division, Pakistan (i.e., 25 genotypes from each of District Swat, Dir lower, Buner and Dir upper) and are

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

listed in *Table A1* in the *Appendix*. Plants were identified, the genotypes were labeled [first letter(s) corresponding to District, followed by species abbreviated name and accession number], and voucher specimens were submitted to the Herbarium at Hazara University Mansehra, Pakistan. These genotypes were assessed for estimation of inter- and intra-district variation and genetic diversity of morphological traits and total seed storage protein profile.

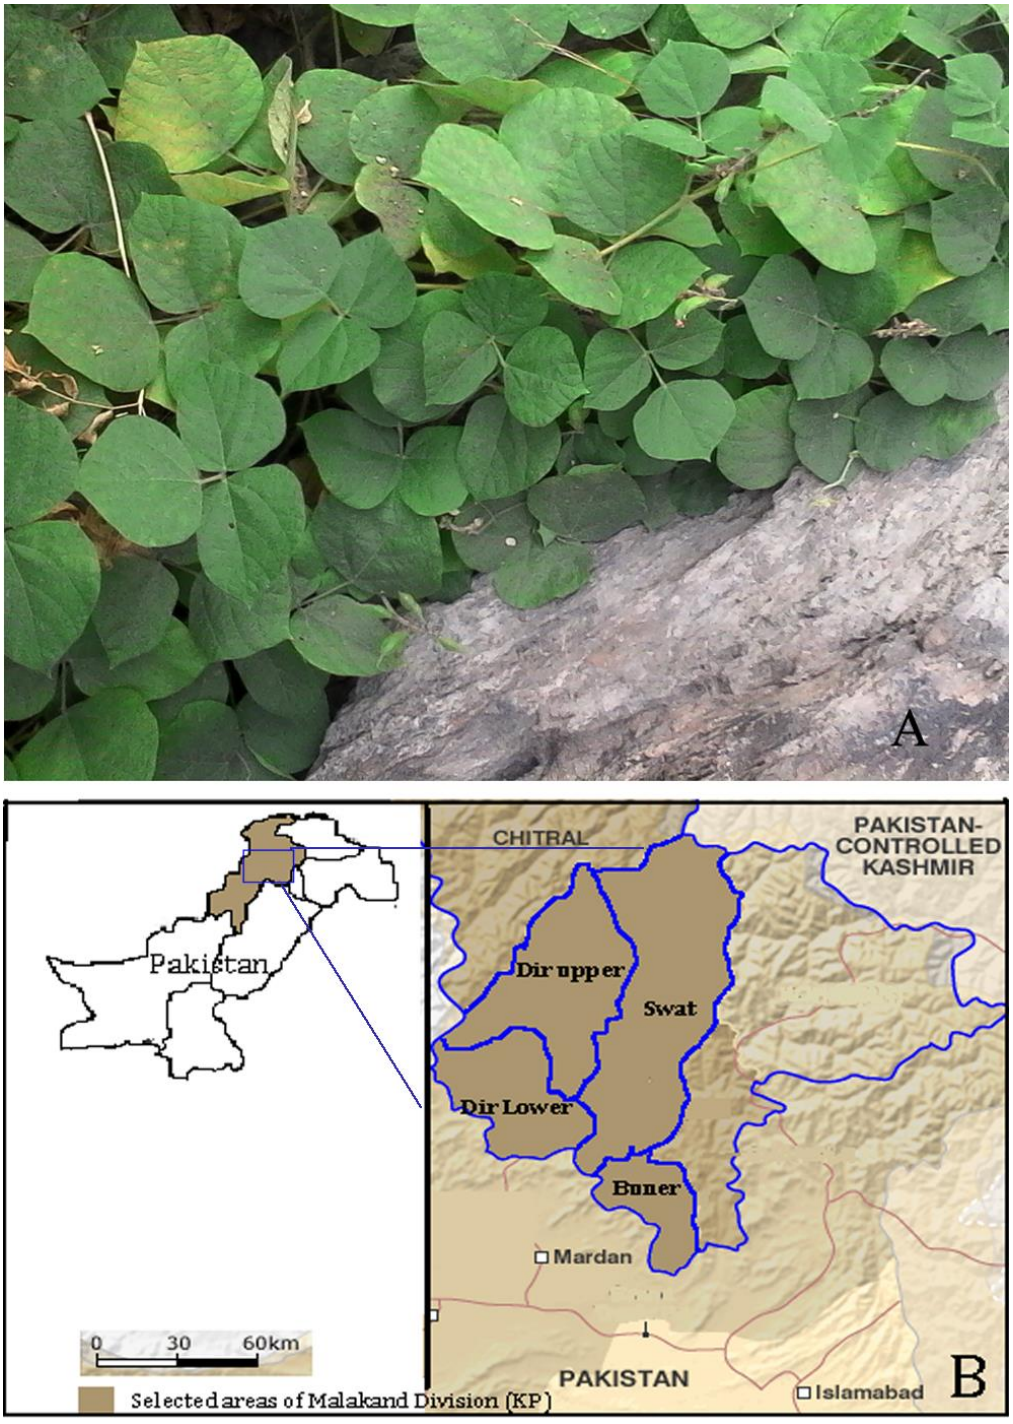

Figure 1. *Rhynchosia minima plants growing on a rocky substrate (A) and map of the study area (B)*

Morphological characterization

Morphological characterization was registered on site and all randomly selected 25 mature genotypes were accounted (*Fig. 1*). A total of 16 morphological traits, including qualitative and quantitative traits, were scored. Qualitative traits were scored visually and encompassed leaf upper surface color (Luc), leaf lower surface color (Llc), inflorescence color (Ic), seed color (Sc), seed shape (Ss), hilum color (Hc) and testa texture (Tt). Quantitative traits were measured with the help of Vernier calipers or the centimeter scale and encompassed petiole length (PL), leaf length (LL), leaf width (LW), inflorescence length (IL), seed length (SL), seed weight (SW), seed thickness (ST), no. of pods per plant (PP) and 100 seed weight (SWT).

Protein profiling

For a total seed storage protein profile, sodium dodecyl polyacrylamide gel electrophoresis (SDS-PAGE) was performed following the method described by Laemmli (1970) and modified by Zahoor et al. (2015). A single seed of each genotype was crushed into a fine flour, and then 400 µl of protein extraction buffer (0.5 M Tris-HCl, 0.2% SDS, 5 M urea, 1% β-mercaptoethanol pH 8.0) was added to 0.01 g of the fine seed powder in an Eppendorf tube and homogenized with a vortex. The mixture was kept for 20 min at room temperature (RT) for protein extraction. Bromophenol blue (BPB) was added to the sample buffer for observing protein sample movement. Samples were centrifuged at 13,000 rpm for 14 min at RT and the supernatant was transferred to a clean 1.5 ml Eppendorf tube and run on a 12% polyacrylamide gel (composition of resolution gel: 3.0 M Tris-HCl pH 9.0, 0.4% SDS and stacking gel 0.4 M Tris-HCl pH 7.0, 0.4% SDS) at 100 V for 2 hrs. The gel was stained with Coomassie brilliant blue for 20 min and destained (5% methanol, 20% acetic acid) until the background color disappeared.

Data analysis

Morphological and SDS-PAGE data were assembled in an MS Excel sheet. Two-way cluster analysis was based on binary data in PC-ORD software (Lepsˇ and Sˇmilauer, 2003). Genetic similarity estimates (F) were designed following Nei and Li (1979), and CANOCO software was used for specific loci/band enrichment in *R. minima* and to find the influence/relationship of the morphological traits and geographical origin on the total seed protein diversity in *R. minima*.

Results and discussion

Morphological diversity in R. minima genotypes

For morphological diversity, both the qualitative and quantitative characteristics were assessed, revealing substantial variability among genotypes for most traits: plants collected from different districts harbored higher variability than genotypes from within the same district. Descriptive statistics of the morphological parameters are summarized in *Table 1*. The CV% was calculated for petiole length, leaf length, leaf width, stipule length, inflorescence length, seed length, seed width and seed thickness, No. of pods per plant, 100 seed weight.

Petiole length in genotypes collected from district Swat was 13.2637%, for district Dir lower was 10.789, for district Buner was 5.112 and for district Dir Upper was 8.585. Significant variation was found for the leaf length among the genotypes of four districts; the highest value was observed for genotypes collected from district Buner (8.554) followed by district Dir Upper (8.661%) and Dir lower (5.518%) while, lowest value was recorded for the genotypes collected from Swat (5.3461%). For leaf width in genotypes collected from Swat was (16.582%), Dir lower (40.836%), for district Buner (38.191%) whereas for district Dir Upper was 54.401%. Furthermore highest variation was observed for seed length and seed width. Number of pods/plant varied for genotypes collected from Swat, Dir lower, Buner and Dir Upper was 27.324%, 11.961%, 28.976% and 54.801% respectively (*Table 1*).

Based on qualitative characteristics, the inter-district trait similarity index among genotypes of Swat-Dir Lower and Swat-Buner was 100%, while for Swat- Dir Upper, Dir Lower-Buner, Dir Lower-Dir Upper, and Buner-Dir Upper, it was 28. 571, 85.71%, 28.57%, and 42.85%, respectively (*Table 2*). Similarly, based on quantitative traits inter-district traits similarity index among genotypes of Swat-Dir Lower, Swat-Dir Upper, Swat-Buner, Dir lower-Buner and Dir upper-Swat was 22.2%; while for Dir Lower-Dir upper was 11.1%; Buner-Dir upper was 33.333% and that of Buner-Dir Upper was 42.85%. Furthermore, the Pearson correlation coefficient revealed a significant positive as well as a negative association ($p = 0.05$ and 0.01) among the studied traits of *R. minima* (*Tables 3* and *4*). Several traits revealed strong interrelationships within phenotype categories, particularly leaf traits with yield contributing traits and a few traits correlating with other categories, such as inherently linked growth and phenology-related traits (*Tables 2* and *3*). Furthermore, quantitative data set of 100 genotypes was used for cluster analysis. The dendrogram resolved all the 100 genotypes of *R. minima* into four discrete clusters (groups), each representing the geographical origin of collection and highlighting the determining role of geography rather than variation within the traits themselves (*Fig. 2*).

SDS-PAGE analysis

For exploration of genetic polymorphisms, modern tools can provide better understanding of species relationships and heterogeneity. Furthermore, morphometric, biochemical and molecular marker approaches have been used for examining genetic diversity and for inferring the intra- and interspecies relationships in plants (Tomooka et

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_56335651
© 2018, ALÖKI Kft., Budapest, Hungary

al., 2002). Moreover, isozymes (Jaaska and Jaaska, 1990), low-molecular-weight carbohydrates (Yasui et al., 1985), RFLPs (Fatokun et al., 1993), and nuclear as well as chloroplast DNA, (Vaillancourt and Weeden, 1993), RAPDs (Kaga et al., 1996), SSRs, EST-SSRs (Ali et al., 2016) and AFLPs (Tomooka et al., 2002), among others, have been used to study crop species.

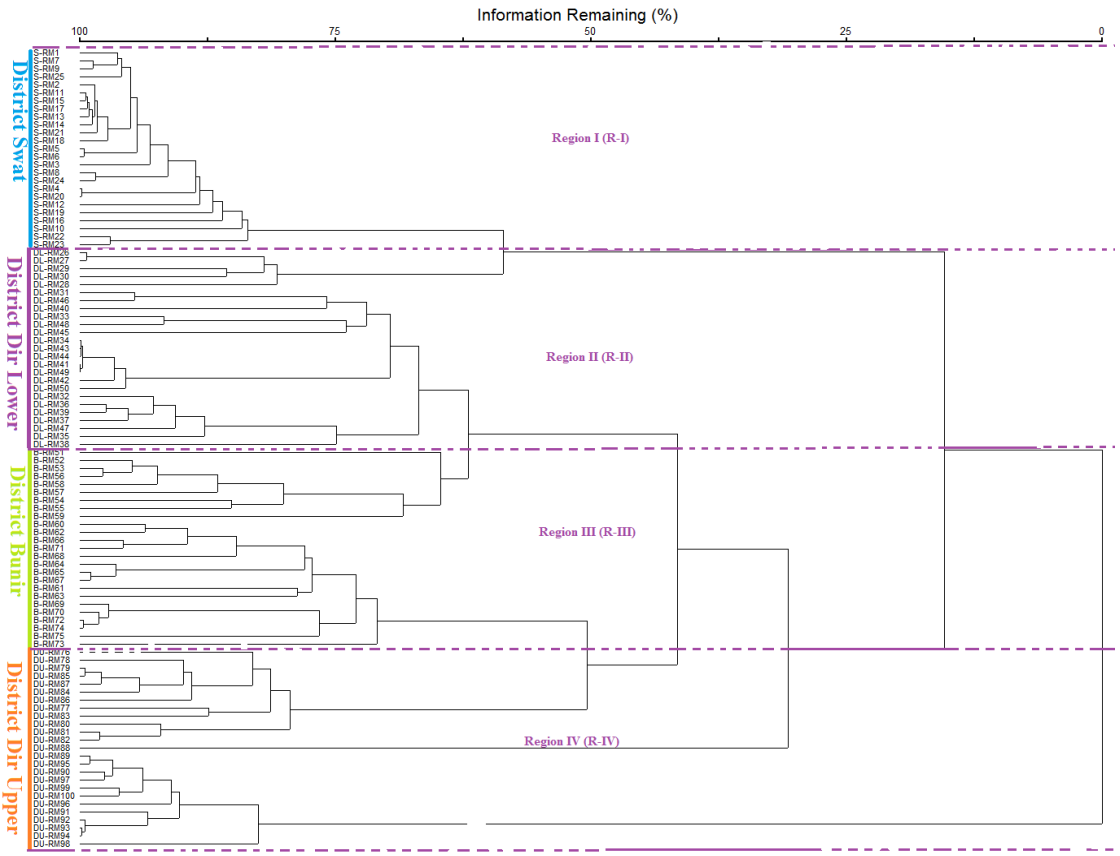

Figure 2. *Intra-species relationship identified through morphological characteristics in different genotypes of R. minima collected from four districts of Malakand Division, Pakistan. RM indicates R. minima, S = Swat, DL = Dir lower, B = Buner and DU = Dir upper*

Eight reproducible bands of ~10–180 kDa were observed in the *R. minima*; a representative PAGE is shown (*Fig. 3*). The binary data of these loci were used to estimate relationships among all genotypes with cluster analysis, and all *R. minima* were divided into six clusters (*Fig. 4*). In cluster-1 (also referred to as Region I, R-I), genotypes collected from District Buner were resolved as having 25% genetic diversity, whereas genotypes of R-II consisted of samples collected from District Dir Upper with 24.07% genetic diversity among genotypes. Genotypes in R-III belonged to District Dir lower with 29.37% genetic variation among genotypes, and R-IV genotypes collected from District Swat had 50% diversity. Similarly, genotypes in R-V and R-VI consisted of genotypes of *R. minima* collected from Dir lower (5 genotypes) and Swat (13 genotypes with 48.07% genetic diversity).

SDS-PAGE has shown promise in understanding the genetic relationships in angiosperms at the generic as well as at the species levels and is reliable for assessing polymorphisms in crops (Payne, 1987; Ghafoor et al., 2002; Nisar et al., 2009; Win et

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_56335651
© 2018, ALÖKI Kft., Budapest, Hungary

al., 2011; Zahoor et al., 2015). The results for the mean square values and response of protein loci/band enrichment within genotypes showed significant variations as indicated (*Fig. 5*). Variability in color and size indicates variation, and the species-specific loci B-6 and B-7 revealed maximum enrichment (present in 100% genotypes), followed by B-8 (72%), B-5 (69%), B-4 (65%), B-3 (63%) and B-2 (50). Furthermore, loci B-2 and B-3 were negatively associated with B-1, B-4 and B-5, while B-8, B-6 and B7 have a neutral association because these bands are evenly distributed among the *R. minima* genotypes collected from these four geographical areas (*Fig. 5*). The overall inter-district locus contribution towards the genetic disagreement was 75%, whereas within the district, it varied from 0.00 to 75%. Among the 8 loci, B-6 and B-7 were monomorphic, present in all genotypes and are likely to be species specific. In contrast, loci B-1, B-4, B-5 and B-8 were observed in genotypes collected from Buner, whereas these genotypes were missing loci B-2 and B-3 and genotypes collected from Dir Upper had all loci except B-1. *R. minima* genotypes collected from Dir Lower and Swat had a mixed protein profile, i.e., showing higher diversity and intermixing within the genotypes. This indicates frequent gene flow within these genotypes and their potential to withstand extreme environmental events (*Fig. 4* and *Table 5*). Details of all of these loci and whether they are monomorphic or polymorphic have been determined and are given in *Table 5*. There was a high inter-district locus contribution towards genetic disagreements among *R. minima* genotypes; SDS-PAGE could be a consistent procedure for documentation of these genotypes, while intra-district locus contributions towards genetic disagreement in genotypes of *R. minima* collected from Swat (S-RM) and Dir lower (DL-RM) were high (100%) compared to those from Buner (B-RM) at 85.71% and from Dir upper (DU-RM) at 28.57% (*Table 2*).

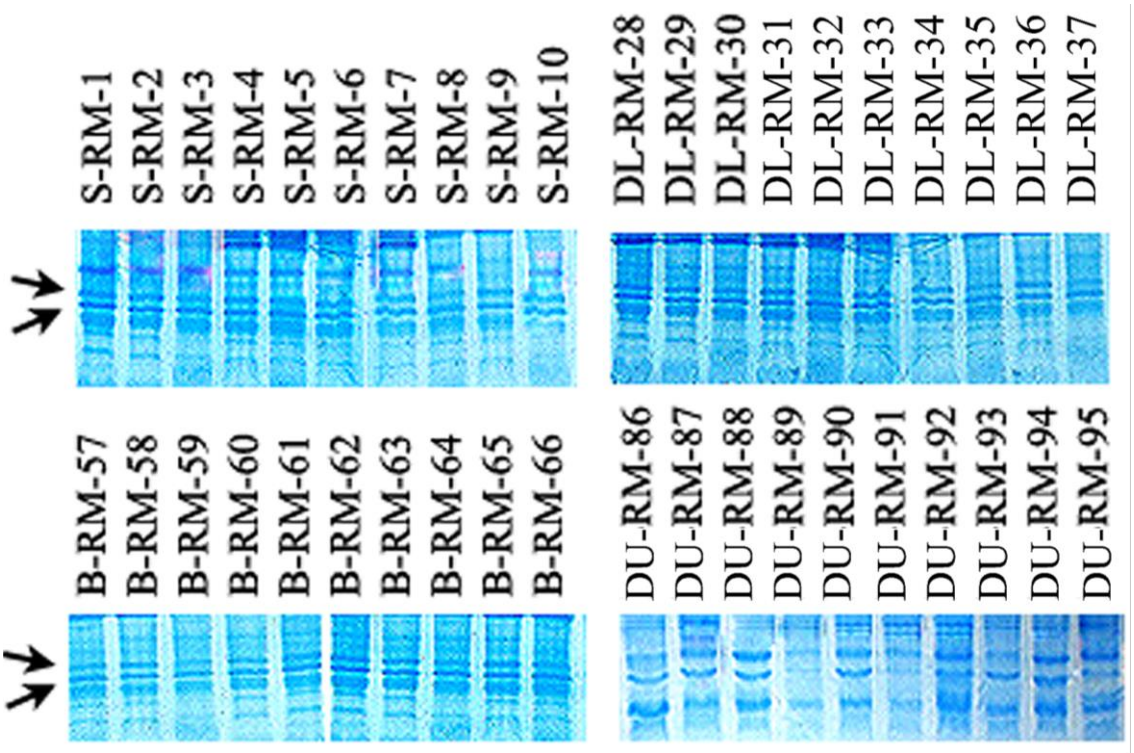

Figure 3. *Representative polyacrylamide gel (12%) electrophoresis showing diversity in total seeds storage proteins among different genotypes of R. minima. Arrow indicates the species-specific loci (B6, B7). S = Swat, DL = Dir lower, B = Buner, DU = Dir upper, RM = R. minima*

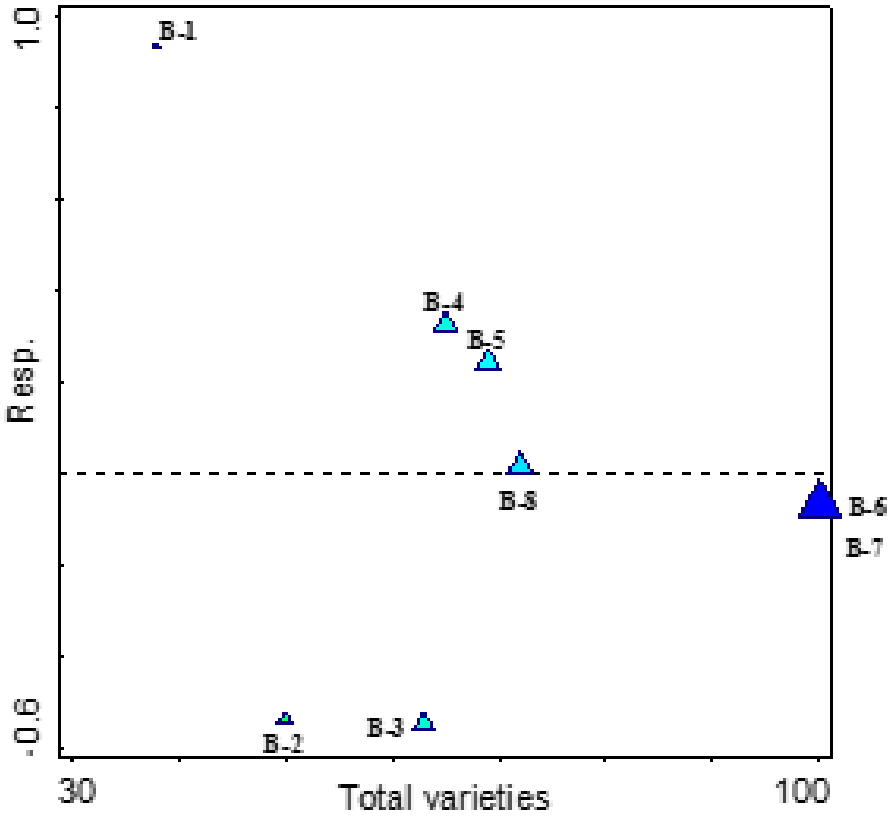

Figure 5. *Different colours showing the R. minima genotype (X-axis) enrichment on the basis of particular loci/band categories*

These four Districts are located adjacent to one another, but altogether, they cover an area of approximately 12,484 km^2, and each District is characterized by distinct environmental conditions and vegetation types. Nonetheless, the wide ecological amplitude and genomic plasticity of *R. minima* allow it to invade new areas and gaps within established plant communities (Shaukat and Burhan, 2000; Jia et al., 2015). This highlights the potential of finding useful genes for adaptation and climatic resilience as well as introgression of genes for improving productivity and resistance in leguminous crops via intergeneric crosses. We have no evidence whether such intergeneric crosses are likely to be successful, but wide crosses (interspecific and intergeneric) have been reported to be tremendously successful in cereals (Ali et al., 2012; Masood et al., 2016; Mujeeb-Kazi et al., 2017). There are numerous reports where not only cultivated plants but also their distant wild relatives have been hybridized successfully, and the size of the alien chromatin associated with linkage drag has then been reduced while still retaining the useful trait (Schwarzacher et al., 2011; Ali et al., 2016; Patokar et al., 2016; Mujeeb-Kazi et al., 2017).

To the best of our knowledge, this is the first study addressing diversity in *R. minima*, although we have no idea whether the seed storage proteins were overlapping as reported in other legumes. Therefore, no attempt was made to assign the recorded polypeptides into respective classes, i.e., legumin and vicilin (Mirali et al., 2007). Instead, for fine resolution, the dendrogram was divided into six regions, and genotypes collected from District Dir lower and Swat segregated with one another, while genotypes from District Dir upper and Buner assorted into discrete clades/groups

(*Fig. 4*). *R. minima* enrichment on the basis of specific seed protein bands indicated that B-6 and B-7 were species specific and present in all genotypes (*Fig. 5*). The presence of common loci (B-6 and B-7) among these genotypes suggests their close genetic similarity and common ancestry. These loci encoded proteins that have been fixed in different genotypes of *Rhynchosia* over evolutionary time. These findings are in agreement with those of Azeez and Morakinyo (2004), who associated the presence of common protein bands in *Lycopersicum* and *Trichosanthes* species with their common evolutionary origin.

with the data of morphological as well as total seed protein diversity. Area of collection (origin) played a marked role in the grouping of *R. minima* genotypes as well as a positive/negative association with a particular set of morphological traits and seed protein profile (*Fig. 6*). Furthermore, comparison of the two cluster dendrograms were in general agreement with one another, indicating the stability of the morphological traits and the potential of *R. minima* to adapt to various climatic and soil conditions (compare *Figs. 2* and *4*). The DCA plot revealed important information regarding the distribution of genotypes with morphological traits and total seed protein profile. Here, the role of geographical origin again was overwhelming and leaf-related traits as well as protein loci B-1 had a strong and positive impact (*Fig. 6*). It will be extremely interesting to study specific genes in *R. minima* that allow adaptation to new habitats and to compare them to those that have previously played an important role in plant domestication under human influence (Baudoin and Marechal, 1985; Chen et al., 2006).

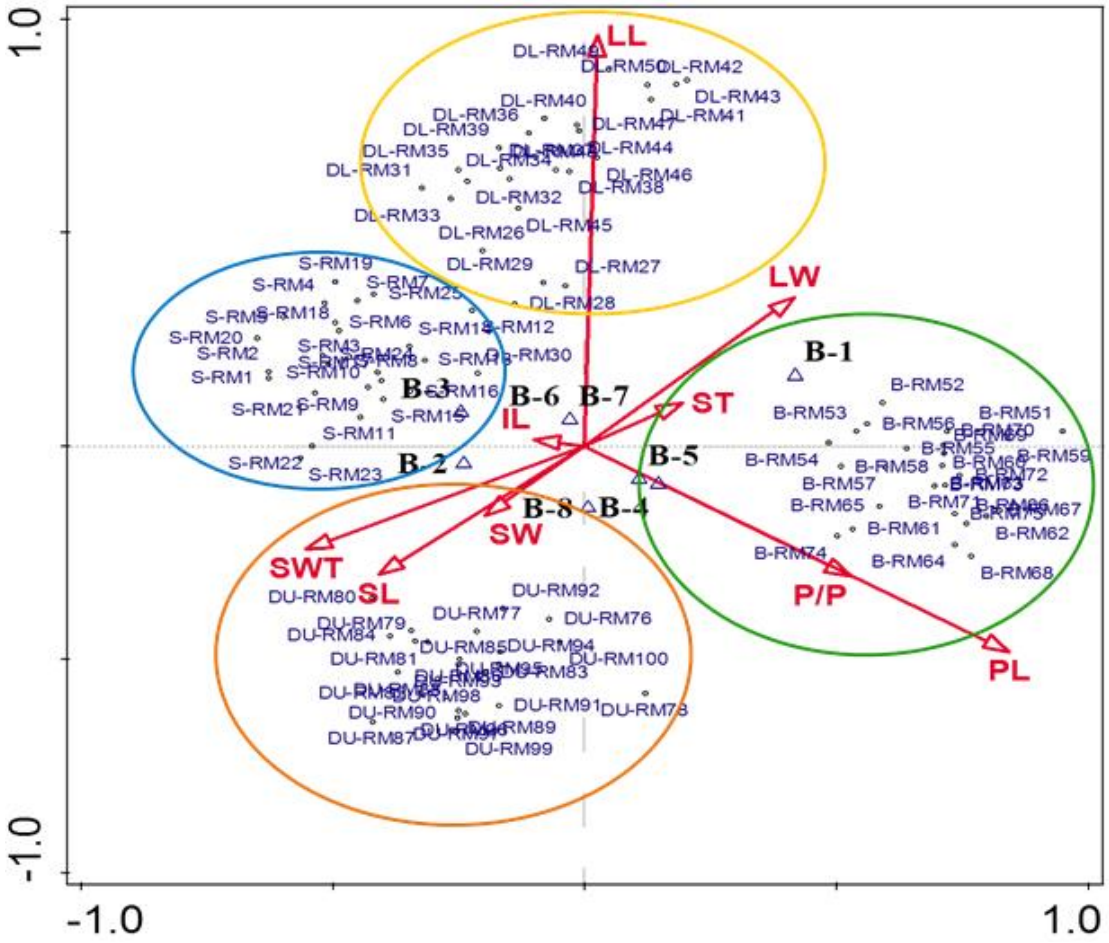

Figure 6. *Detrended correspondence analysis (DCA) diagram showing the distribution of R. minima genotypes and their association/relatedness based on morphological traits and total seed protein profile*

All together, humanity depend on a fraction of the genetic diversity residing in fewer than a dozen of the approximately 300,000 species of angiosperms for 80% of their caloric intake (McCouch et al., 2013). This is not enough to support our food system in

the future, and unlike conventional breeding that relies on crossing the best with the best, more predictable breeding outcomes are possible with linkages of genes with specific traits. Wild relatives of crops have tremendous genetic potential that can be released by searching for superior genes. In the past, where the increased crop productivity was based on improved agricultural practices and other changes, future gains will rely on improved genetics (Heslop-Harrison and Schwarzacher, 2012).

Conclusion

A total of 16 important morphological traits as well as SDS-PAGE of the total seed protein profile were assessed, and the data revealed the existence of ample diversity. Further, cluster analysis based on seed storage protein analyses demonstrated that the 100 genotypes of *R. minima* collected from four districts had close similarities to each other. The SDS-PAGE electrophoresis results also demonstrated that seed protein profiling provides a powerful tool for genotype discrimination based on geographic differences. Furthermore, the results indicate that high variability exists in *R. minima* and that the differences observed among populations were associated with both genetics and geography. Grain legumes are ranked third after cereals and oilseed crops due to their importance for both humans and livestock (Ilyas et al., 2009; Naim-Feil et al., 2017), and therefore, improvements in leguminous crops are of paramount significance. In the future, where adaptation to stresses is likely to address the severity of climate change impacts as well as worldwide food security concerns (Lobell et al., 2008), minor modifications such as changes in sowing dates are helpful to mitigate negative impacts, but long term benefits will be linked to genetic improvements (Heslop-Harrison and Schwarzacher, 2012). Wild crop relatives offer rich sources of genes for resistance to both biotic and abiotic stresses and therefore could improve agriculture (Vavilov, 1940). Nevertheless, *R. minima*, a distant relatives of crop legumes, has so far undergone only limited utilization in foraging as well as for pharmaceutical purposes (Gundidza et al., 2009; Jia et al., 2015), yet it demands attention for the isolation of important phytochemicals and provides an opportunity for widening the genetic base of important legumes.

(Received 25th May 2018; accepted 17th Jul 2018)

Abstract: Shells were used to produce biomass materials through calcining due to their excellent mechanical properties. In this paper, the mussel shells were calcined by the vacuum tube furnace and muffle furnace at 600 °C, 700 °C and 800 °C respectively, and that prepared under optimum conditions was activated by K_2CO_3 in the hydrothermal method. The pore structure and morphology of the sample were characterized by specific surface area analyser (BET) and scanning electron microscopy (SEM). Then the *Chlorella sp.* was immobilized by mussel shell powder and chitosan, which was co-cultured for 60 days. The results showed that calcined shells at 700 °C in a vacuum tube furnace have an optimal specific surface area, up to 4.107 m^2/g. K_2CO_3 hydrothermal modification method could effectively enlarge the pores of shell powder, from 4.107 nm up to 16.557 nm. The shell powder modified by chitosan had positive charges, which could attract the microalgae with negative charges, could live for up to 60 days. This article aims to use waste shells to immobilize microalgae, which is not only of great importance to the protection of the environment but also provides a novel way to immobilize microalgae.
Keywords: *Chlorella sp., immobilization, nanoporous mussel shell materials, microstructural characterization, recovery growth rate*

Introduction

Biomass has been assigned numerous roles to human beings from ancient times because of its massive and recyclable nature, however, with the rapid expansion of man-made materials, like alloy, plastic fibre, and so on, a great number of natural materials have been neglected and abandoned. Most of the non-renewable and non-biodegradable synthetic materials were used and subsequently became wastes, resulting in seriously environmental "white pollution" at present (Wang et al., 2017). Therefore, high-value utilization of biomass resources has been paid more and more attention to researchers

because of their renewability and biodegradability (Wang et al., 2016). Shells are often used to prepare porous materials by calcination as carrier-loaded functional ions due to its main component is 95% $CaCO_3$ and a small amount of organic matter (Currey et al., 1977; Okumura and Gennes, 2001; Currie et al., 2007). The previous study was performed a shell-based catalyst by the impregnation process using potassium hydroxide to extract economical biodiesel fuel synthesis from castor oil (Nurdin et al., 2015). The current use of seashells is limited to feed additives (J. et al., 2013), adsorbents (Paradelo et al., 2016), cement reinforcing phase (Martinez-Garcia et al., 2016), antimicrobials (Li et al., 2016), and carriers for functional materials (Edralin et al., 2017) at present.

Chlorella sp. is a kind of unicellular green microalgae that around 40% of global photosynthesis is performed by microalgae (Myers, 1980). From the 1960s, Oswald et al. first found the chlorella in the oxidized pond had an excellent removal effect on nitrogen and phosphorus in the water (Oswald et al., 1957). However, due to its small size of single cells, the presence of free-living microalgae in treated effluents remains a problem (Chevalier and Noüe, 1985), so researchers focused on the use of immobilized microalgae (Jiménez-Pérez et al., 2004). Immobilization techniques can be primarily divided into two groups: “passive” and “active” immobilization (Moreno-Garrido, 2008). Because the microalgae tends to adhere and naturally grow on the surface of natural organisms, the “passive” immobilization mostly uses it as a carrier (Robinson et al., 1986), but this process is easily reversed. Therefore, the “active” immobilization method, such as chemical attachment (Moreira et al., 2006), flocculant agents (Seki and Suzuki, 2002), and gel entrapment (Solé and Matamoros, 2016), are most widely used. Alginate gel, a gel entrapment type, has been most widely used because the immobilized cells do not undergo extreme physicochemical changes during the immobilization process (Smidsrød and Skja˚K-Br˛K, 1990).

Most frequent current uses of chlorella sp. are the metabolite production cultured, improvement of culture collections handling, obtaining of energy, nutrients, removement of metal or organic pollutant from aquatic media, measurement of toxicity and co-immobilization system production for different purposes (Abdel-Raouf et al., 2012). The use of immobilized algal cells in water purification processes has been reported previously (Bruun, 2013) as microalgae form part of the organisms fixed in percolating filters of wastewater treatment plants. At present, the immobilization technology of microalgae mostly uses natural polymer materials as carriers, such as agar(Kandilian et al., 2017), alginate (Smidsrød and Skja˚K-Br˛K, 1990) and so on. The advantage of these materials is that they have good biocompatibility, but the immobilization power is not strong, as a result, the microalgae is easy to fall off. In addition, the polymeric polymer material as a carrier to immobilized microalgae has the disadvantages of low biocompatibility and toxicity to microalgae cells (Timofeeva and Kleshcheva, 2011). There are few reports on the use of porous biomass materials as carriers to immobilize microalgae.

In this paper, mussel shell was calcined, activated and modified by chitosan, used to be as a carrier, to immobilize microalgae. Because modified shell has positive charges, it could attract the microalgae with negative charges, and achieve microalgae immobilization with a strong immobilization power. At the same time, Chitosan has the dual functions of electric neutral flocculation and adsorption flocculation, which is not only can provide nutrients for the growth of microalgae, but also non-toxic and harmless. This material will has broad prospects in the field of water quality control.

Materials and methods

Materials

Mussel shell was provided by a food processing factory (Zhejiang province, China). *Chlorella sorokiniana* was obtained from the laboratory of Marine Biological Chemical Laboratory, Zhejiang Ocean University. BG-11 medium ($NaNO_3$, 1.5 g; K_2HPO_4, 0.04 g; $MgSO_4.7H_2O$, 0.075 g; $CaCl_2.7H_2O$, 0.036 g; Na_2CO_3, 0.02 g; H_3BO_4, 2.86 g; $MnCl_2.4H_2O$, 1.81 g; $ZnSO_4$, 0.222 g; Na_2MoO_4, 0.39 g; $CuSO_4.5H_2O$, 0.079 g; $Co(NO_3)_2.6H_2O$, 49.4 g; Citric acid, 0.006 g; ferric citrate, 0.006 g; ampicillin, 50 μg/mL; distilled water, 1000 mL; agar, 20 g; trace element solution A5, 1 mL). All chemical reagents were analytical grade. All solutions were prepared by using deionized water.

Microalgae cultivation

Chlorella sp. was cultured in the BG-11 medium. The culture broth and the container were sterilized in an autoclave (1.2 kg/cm^2). Under sterile conditions, the algae seeds were evenly inoculated on the medium (300 mL), transferred to a conical flask (500 mL) and placed at 25 (± 1) °C with a sterile breathable film sealing with the bottle mouth; then the whole bottle was illuminated under a LED growth lamp with a red to blue ratio of 5:1 for 24 h, shaken three times a day at regular time.

Shell calcining

The cleaned shells were immersed in 1% HCl for 24 h and calcined at 600 °C, 700 °C and 800 °C for 2 h by using vacuum tube furnace (SKGL-1200-II, SIOMM, Shanghai) and muffle furnace (SX2-5-12, TAISITE, Tianjin), and sieved to < 100 μm (average particle size: 75 μm) mesh particle size by micro-nano-pulverizer (MKCA6-2J, Masuko, Japan; *Table 1*).

Table 1. *Experimental design*

Temperature	Muffle furnace	Vacuum tube furnace	Modified by K_2CO_3
600 °C	MM600 °C	MT600 °C	MMM600 °C
700 °C	MM700 °C	MT700 °C	MTM700 °C
800 °C	MM800 °C	MT800 °C	MTM800 °C

Activation of shell powder

0.5 g shell powder and 30 mL, 1% K_2CO_3 were dissolved to 50 mL tube, sonicated for 30 min by using an ultrasonic cleaning machine (G-040S, Geneng Cleaning Equipment Co., Ltd., Shenzhen, China, 600 w) and the sample was dissolved. The mixture was placed into a Teflon reactor at 160 °C for 24 h. After filtering, precipitation was washed to neutrality and dried at 60 °C for 8 h.

Modification by chitosan

Chitosan, a linear polymer with high specific surface area, has the dual functions of electric neutral flocculation and adsorption flocculation, non-toxic and harmless,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_56535664
© 2018, ALÖKI Kft., Budapest, Hungary

which is not only can provide nutrients for the growth of microalgae, but also conducive to the immobilization of microalgae.

100 mg chitosan and 10 mL HCl (1%) were dissolved in 100 mL deionized water. The chitosan mixed with activated shell powder with a mass ratio of 1:2, stirring for 1 h and vacuum drying at 80 °C for 24 h. The sample was marked as CS-M (*Fig. 1*).

Preparation of immobilized microalgae

100 mL *Chlorella sp.*, growing in logarithmic phase, 20 mL, 2% tea extract solution, 0.5 g CS-M, stirring for 30 min, standing in layers, removing as much supernatant as possible, adding 0.2 g Sodium alginate, 2 mL, 3% glycerol, stirring for 30 min, standing for 2 h, centrifugal separation, storage of the precipitate in sterile, sealed, dark conditions, storage temperature were 25 °C, 4 °C, -24 °C, respectively. 0.1 g CS-M and 1 mL steamed water, diluted 20 times, injected on slides, covered with coverslips. Optical microscopy (OM) was used to observe the combined situation of microalgae and shell powder under the ratio of 10 ×10 (ECLIPSE Ti, Nikon, Japan).

Determination of chlorophyll-a (chl.a) content in immobilized microalgae

5 mL algae were centrifuged at 5500 r/min for 15 min, collecting the precipitate, adding 5 mL, 80% acetone solution, extracting the chlorophyll-a in darkness at 4 °C for 24 h until the chl.a and acetone were fully mixed, centrifuge at 6000 r/min for 15 min. Finally, measuring the absorbance (OD) of supernatant by using UV-vis (UV-2600, SHIMADZU, Japan) at 663 nm and 645 nm wavelength respectively, with the reference solution of 80% acetone. All tests are repeated three times.

Reference calculation formula of chl.a concentration (Gao and Sun, 2000) is as follows:

$$\text{Concentration of chl. a (mg/L)} = 12.71 \times OD_{663} - 2.59 \times OD_{645}$$

OD_{645}, OD_{663}: OD of the extract at 645 nm and 663 nm wavelengths, respectively.

Test methods of microalgae cell density

Take algae fluid, which cultivated in the BG-11 medium for 24 h, 48 h, 72 h, 96 h, 120 h, and 162 h. The absorbance (OD_{680}) of the algae was measured at a wavelength of 680 nm. After fixing with Rochelle's solution, the *microalgae* was diluted and counted its number using a hemocytometer (Shanghai refinement Biochemical Instrument Co., Ltd., Shanghai, China). Repeat three times and take the average. Establish a standard curve of OD_{680} and the number of *microalgae* cells.

Characterization

The specific surface area and porosity tester (BET) was used to analyze the specific surface area, and pore size distribution of shell powder under 77 k with N_2 is the analysis gas (Quadrasorb SI, Quantachrome, USA). The surface morphology of the sample was observed by using JSM-7800F ultra-high resolution thermal field emission scanning electron microscope (JEOL, Japan).

Statistical analysis

Statistical analysis was performed using Origin 8.5 (Origin Corp., USA). All the experiments were performed independently at least three times.

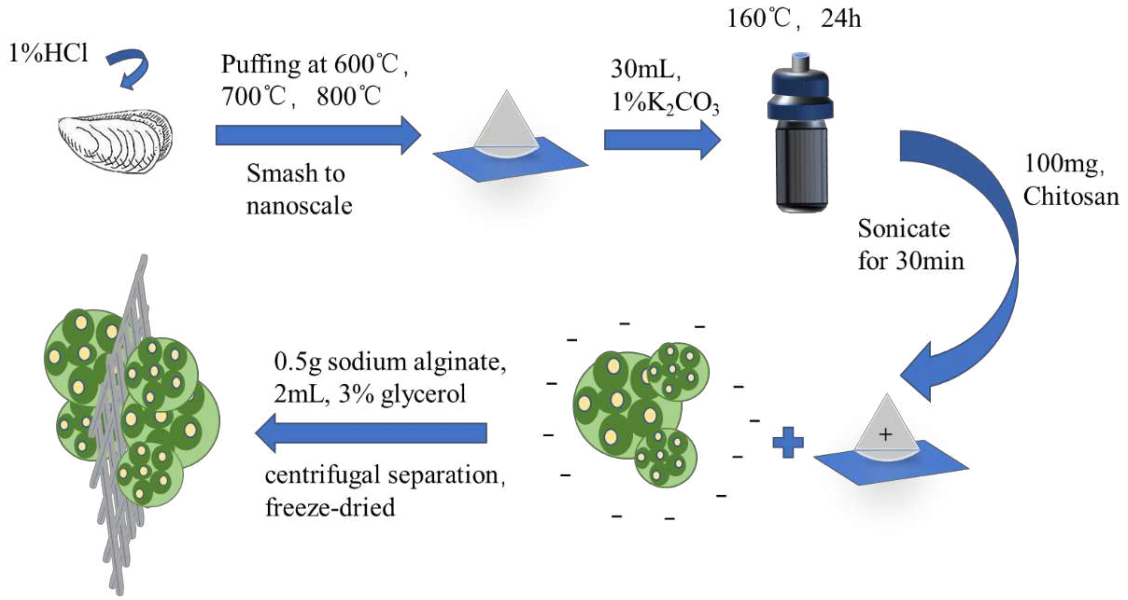

Figure 1. *The schematic illustration of Chlorella sp. immobilized by nano mussel-shell powder and chitosan*

Results and discussion

BET characterization

The curves of adsorption isotherms and pore diameter distribution of MM (mussel powder calcined by muffle furnace) and MT (mussel calcined by tube furnace) under 600 °C (a), 700 °C (b) and800 °C (c) are as shown in *Figure 2*. The isothermal adsorption curves of MM and MT at 600 °C and 700 °C are similar, and all type III (Sing, 1985). The lateral interaction between the adsorbed molecules is greater than the interaction between the adsorbent surface and the adsorbate. Adsorption takes place in multiple layers, and the amount of adsorption increases with enhancement of pressure. While the specific surface area of MM is generally superior to MT under 600 °C, 1.308 m^2/g vs 0.435 m^2/g the average pore diameter of MT is about 5 nm, while that of MM is about 2 nm. The average pore diameters of MM and MT at 800 °C are not significantly different. The reason may be that the organic matter in shell powder has been completely decomposed since 700 °C. Adsorption isotherms of MM at 800 °C has a hysteresis loop, which belongs to type H_1, indicating that the pore distribution of the material is relatively narrow, the particle is spherical and its size is uniform. In general, the organic matter of shell powder will completely break down at 700 °C. According to the average pore size of each material, it can be proved that the shell powder will form a well-distributed, less porous mesoporous material after high-temperature calcination. The puffing effect of the tube furnace is slightly better than that of the muffle furnace (*Tables 2* and *3*).

whose calcined condition is 600 °C, 700 °C, 800 °C. All the adsorption isotherms of MTM are type IV (Sing, 1985), similar to type III at first, but at higher pressures, the adsorption increase rapidly with the hole is condensed in capillary. However, the hysteresis loops appeared on the adsorption isotherms of MMM, regardless of temperature, which belongs to type H_1. Comparing the surface area and average pore size of shell powder before and after modifying with K_2CO_3, we found that the average pore diameter of the shell powder, which calcined in the tube furnace, is greatly improved. The average pore size of shell powder increased from 3.406 nm to 15.176 nm at 600 °C, 4.107 nm to 16.557 nm at 700 °C, and 3.177 nm to 7.804 nm at 800 °C. But with the decrease of pore numbers, the specific surface area has reduced. The calcined shell powder in the muffle furnace does not have much difference before and after modification. We chose MTM (700 °C) as the best sample (*Tables 4* and *5*).

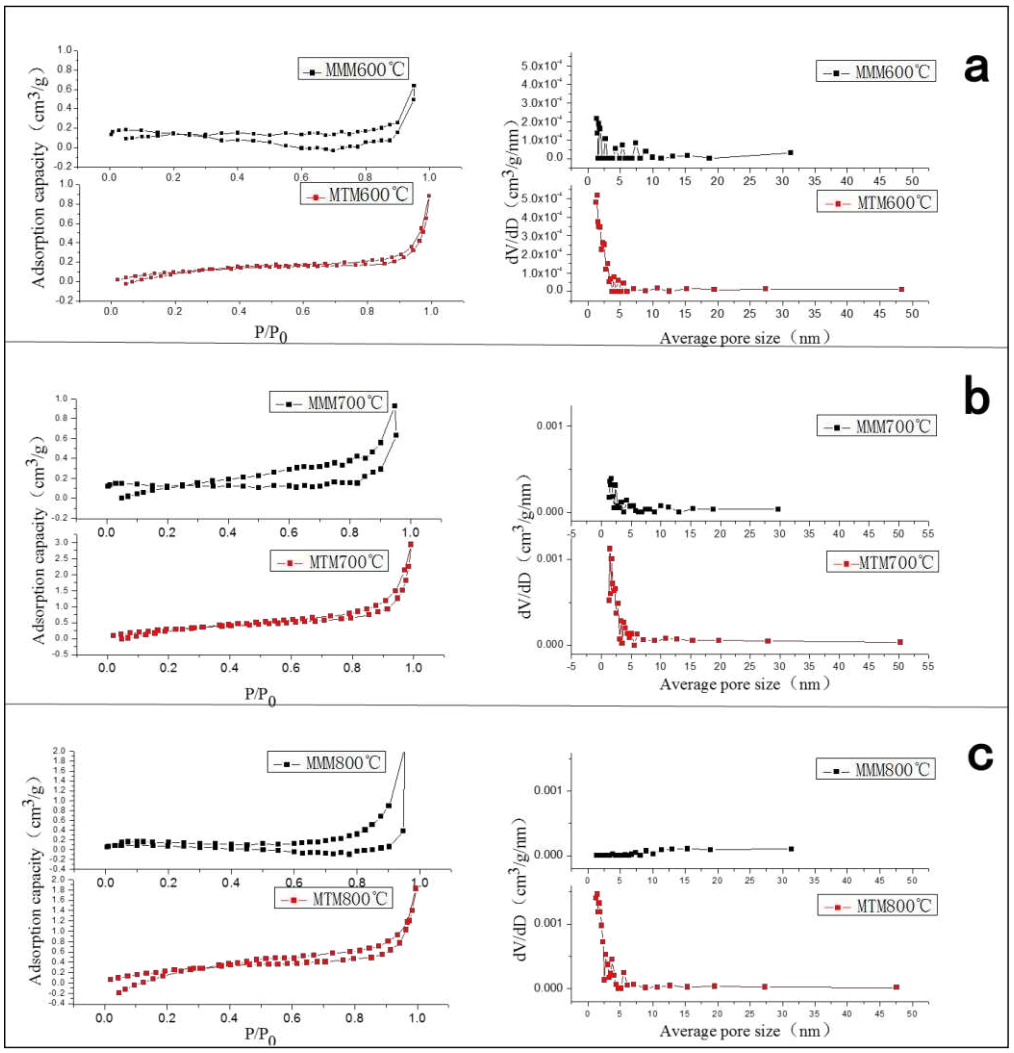

Figure 3. *Adsorption isotherms and pore diameter distribution curves of MMM (MM modified by K_2CO_3) and MTM (MT modified by K_2CO_3) under different expansion temperatures (600 °C, a; 700 °C, b; 800 °C, c)*

There are few reports on the use of biomass materials as carriers to immobilize microalgae. Shell powder, a excellent porous material, immobilizes microalgae by

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_56535664

means of charge attraction and physical adsorption, has strong immobilization power and can provide certain nutrients to microalgae and prolong its life.

Table 4. *The specific surface area and average pore size of MMM*

Temperature (°C)	600	700	800
Specific surface area（m^2/g）	2.894	5.4272	0.888

Table 5. *The specific surface area and average pore size of MTM*

Temperature (°C)	600	700	800
Specific surface area（m^2/g）	0.336	0.364	0.123
Average pore size（nm）	15.176	16.557	7.804

SEM characterization

Two SEM photographs of M (Mussel calcined at 700 °C in a vacuum environment), MTM as shown in *Figure 4,* the texture of M is loose, and there are several pores on the surface, with the pore diameter is about 0.5 μm, which determines the excellent adsorption performance of shell powder. The size of pores in MTM is increased, compared with M, which is 1 μm, because 1% potassium carbonate and water vapor have the good pore-forming ability, enhancing adsorption and sustained release capabilities of shell powder.

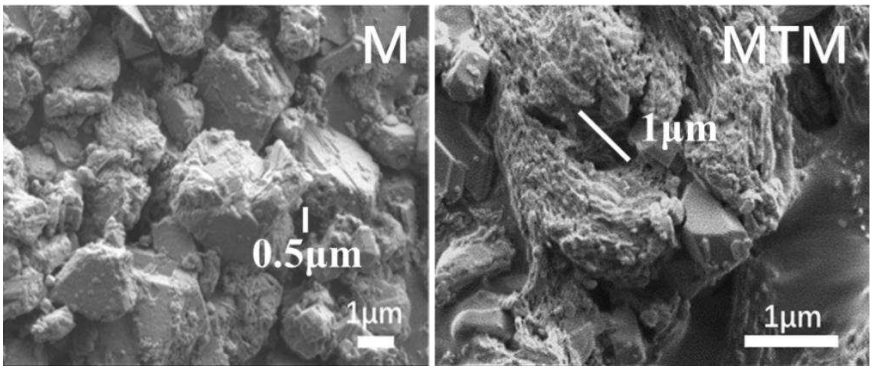

Figure 4. *SEM images of M and MTM*

OM characterization

Photomicrographs of immobilized microalgae under a bio-optical microscope are shown in *Figure 5*. It can be seen that the diameter of shell powder is about 200 μm, and the chlorella sp. cells are about 10 μm with a partial shell powder stacked. A large number of Chlorella sp. cells accumulate around the shell powder, indicating that modification of the shell by CS increased the "fixed" effect of the shell on the microalgae. It is beneficial to the dispersion of microalgae during the use of the immobilized microalgae. Sodium alginate also has a certain reinforcement and moisturizing effect.

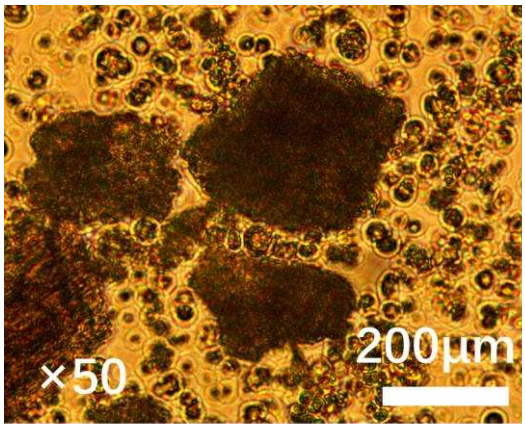

Figure 5. *OM images of immobilized microalgae*

The growth of immobilized microalgae

Growth curve of *microalgae* was determined in *Figure 7a,* during the preservation process, the chl.a content of all samples in the first 20 days changed slowly, however, after 20th day, decreased linearly. Loss rate of chl.a in immobilized microalgae after 60 days are respectively 59.04%, 50.22%, 42.77%, with the content of chl.a are respectively 3.41778 mg/L, 4.72185 mg/L, 5.31715 mg/L, which preserved in 25 °C, 4 °C and -24 °C. The changes of chl.a content in immobilized microalgae at 4 °C and -24 °C are similar. However, it can be observed that there was a greatly decrease from 30th to 40th days at 25 °C, from 6.88823 mg/L to 4.26672 mg/L, which is the best growth temperature of *microalgae*, with a highest activity, but it can only perform respiration and cannot synthesize chl.a due to the dark environment. The nutrients provided by shell powder are limited. Over time, *microalgae* lacks nutrient intake, resulting in the death of a large number of *microalgae* and the loss rate of chl.a increased rapidly. The loss rate of chl.a was the lowest after 60 days, which kept at 24 °C, 42.77%, probably because of the low activity of chlorella sp. at low temperature. In general, microalgae can survive 60 days in immobilized *microalgae,* which is rarely founded in recent research (*Fig. 6* and *Table 6*).

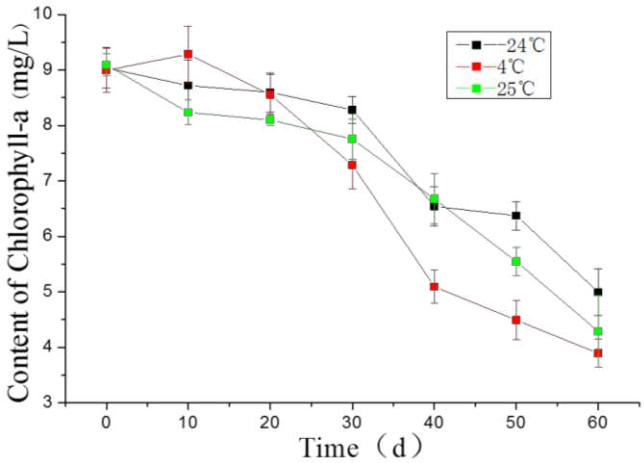

Figure 6. *The curve of microalgae growth within 60 days under different storage conditions (-24 °C, 4 °C, 25 °C)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

Table 6. *The loss rate of chl.a (%) during 60 days in immobilized microalgae*

Storage conditions (°C)	25	4	-24
Loss rate of chlorophyll-a (%)	59.04	50.22	42.77

Regrowth of immobilized microalgae

Regrowth curve of *microalgae* was determined in *Figure 7b,* the reactivation rate of *microalgae* in the immobilized microalgae at 4 °C is the fastest and the highest, with the cells number is up to 3.41769 × 10^6 cell/mL and the recovery rate is 26% (*Table 7*). The curves of *Chlorella sp.* cells number in immobilized microalgae are similar at 4 °C and -24 °C, which have a rapid recovery period of microalgae from the 15th day to19th day, and reaching the stable at the 9th day. However, the overall growth rate is slow at 25 °C. The reason may be the ultimate mortality of *Chlorella sp.* is high in the preservation process of immobilized microalgae, at 25 °C. Generally, the resuscitation curve of microalgae in immobilized microalgae was consistent with the Logistic growth curve.

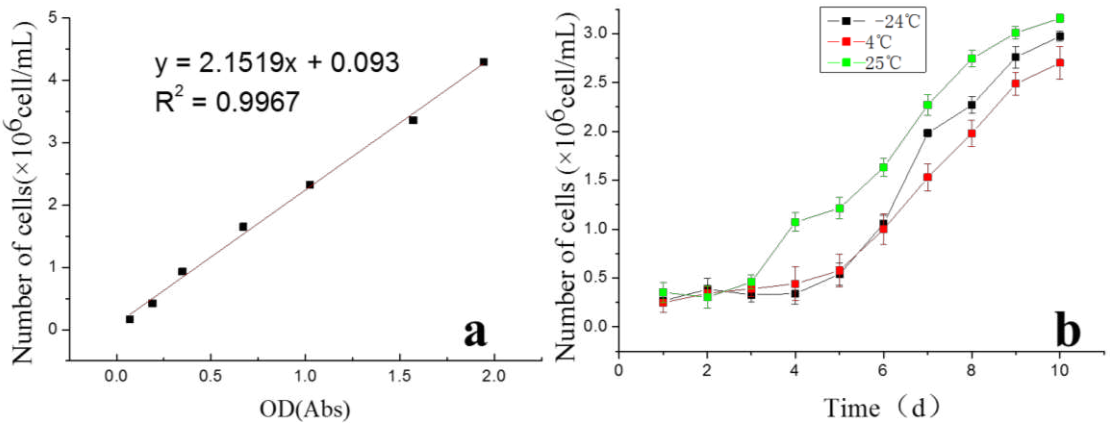

Figure 7. a. *The stand curve of microalgae cells numbers.* ***b.*** *The regrowth curve of microalgae within 10 days under different storage conditions (-24 °C, 4 °C, 25 °C)*

Table 7. *Recovery growth rate of microalgae (%) during 60 days*

Conclusion

In summary, it was found that the shell powder calcined at 700 °C in a vacuum tube furnace and hydrothermal modification with K_2CO_3 has the optimum pore structure with an average pore size of 16.557 nm. The OM picture of CSM clearly shows that the *Chlorella sp.* is fixed with chitosan-modified shell powder, whose surface is positive. This structure can extend the shelf life of *Chlorella sp.* to 60 days and the best sample of the resurrection rate is 26%, the number of cells is 3.41769 × 10^6 cell/mL, reviving at 4 °C. With the rapid development of industrialization, this material has bright prospects. This is a new technology for immobilizing microalgae that can be used in water

(Received 25th May 2018; accepted 31st Jul 2018)

Abstract. Efficient electrochemical ammonia oxidation system was studied with an objective to enhance the selectivity of ammonia to nitrogen gas and to remove the by-products in an undivided electrochemical cell, in which various cathodes (Ti, Cu/Zn, Fe) and Ti/IrO_2-Pt anode were assembled. In the present study, anodic oxidation of ammonia and cathodic reduction of by-products were achieved, especially with Cu/Zn cathode. The ammonia-N decreased from 100.0 mg/L to 0.0 mg/L in the presence of 1.0 g/L NaCl after 120 min electrolysis at the current density of 30.0 mA/cm^2 with Cu/Zn cathode and Ti/IrO_2 anode. No nitrite was detected in the treated solutions. The concentration of chloramine was 0.24 mg/l. About 97.34% of initial TN was transformed into nitrogen gas in Cu/Zn system, indicating that Cu/Zn cathode has better performance than Ti and Fe cathode. The results indicated that Cu/Zn cathode exhibited a little higher reduction ability, possibly attributed by the higher electrocatalytic activity of brass containing Zn (35-41 wt%) which significantly influenced the kinetics of current density. As ammonia could be completely removed by the simultaneous oxidation and reduction in this study, it is suitable for deep treatment of ammonia polluted water.

Keywords: *water pollution, electrocatalysis, ammonia nitrogen, dimensionally stable anode, electrocatalytic activity*

Introduction

Ammonia contamination in water bodies is a widespread environmental problem. Usually, two main categories of treatment processes, physicochemical and biological treatment methods, were employed for ammonia removal from domestic and industrial wastewaters, including ion exchange, air stripping, breakpoint chlorination, and biological process and so on (Rahmani et al., 2004; Du and Liu, 2005; Wang and Liu, 2006). As electrochemical oxidation of ammonia has high treatment efficiency, minimized sludge production, small area occupied and relatively low investment cost, many researchers have focused on it in decades.

The electrochemical method is widely used to remove ammonia from ammonia-containing underground water or industrial wastewater, which contains low concentrations of organic matter and cannot be effectively treated by biological method. In the last decades, researchers have tried to improve electrochemical denitrification by different ways, such as using different electrodes, designing different electrochemical

© 2018, ALÖKI Kft., Budapest, Hungary

cells, addition of different supporting electrolytes and employing different power supply, etc.

In the past years, various electrodes such as Pt, Ru, Ir, Ti, graphite, Ni, Lead dioxide, dimension stable anode (DSA), boron-doped diamond (BDD) and bimetallic or multi-metallic electrodes have been used in electrochemical oxidation (Feng, 2003; Vitse et al., 2005; Chen et al., 2007; De et al., 2009). It was shown that ammonia is effectively removed from solution while active chlorine was electrogenerated on the Ti/PtOx–IrO_2 electrode with nitrogen gaseous being postulated to be the main by-product of ammonia electrolysis (Kapałka et al., 2010a). In general, during the electrochemical process of ammonia, nitrogen gas was the most favorable reduction product. One of the problems is the generation of nitrate, which needs to be further treated.

Although electrochemical method has been investigated and used to deal with ammonia issue, most researchers mainly focused on the anode effect on ammonia removal. However, few of them paid attention to the effect of cathode which may play an important role in the by-products (NO_3^--N, NO_2^--N and chloramines) generated during the process of electrochemical ammonia oxidation. On the other hand, some researchers found that the cathodes such as Cu/Zn and Fe had high efficiency on nitrate and nitrite removal. Therefore, it is possible to decrease the production of side products by employing cathode with high nitrate and nitrite reduction ability.

From previous study, ammonia could be efficient removed by Ti/RuO_2-Pt anode via electrochemical oxidation process (Wang et al., 2012). To compare with previous studies in order to design a better treatment system and study the effects of different anodes on experimental results simultaneously.

In present study, an efficient electrochemical ammonia oxidation system was designed with various cathodes (Ti, Cu/Zn, Fe) and Ti/IrO_2-Pt anode. The effect of different cathodes on the reduction efficiency of ammonia to nitrogen gas and the formation of by-products during the electrochemical process are studied in 2017, at Zhejiang Ocean University labs. The optimum operating conditions are also discussed, to enhance the selectivity of ammonia to nitrogen gas and to remove the by-products simultaneously.

Materials and methods

Electrochemical apparatus

The experiments are carried out in undivided cells using Ti, Fe and Cu/Zn plates as cathodes and Ti/IrO_2–Pt anode, respectively for the treatment of synthetic ammonia solution with anodic ammonia oxidation and cathodic reduction rates being compared. During the experiments, the influence of initial chloride ion concentration, current density, temperature and initial pH are investigated and assessed. The concentrations of ammonia, nitrite, nitrate, chloramine, and dissolved metals are determined with standard methods. The current efficiency (include the average current efficiency (ACE) and the instantaneous current efficiency (ICE), reaction kinetics, oxidation rate and one-way analysis of variance are used to analyze and assess this ammonia removal process.

The average current efficiency (ACE) and the instantaneous current efficiency (ICE) are calculated using *Equations 1* and *2*, respectively (Comninellis and Pulgarin, 1991; Van et al., 2004):

$$ACE = 3FV\left[\left(NH_4^+ - N\right)_0 - \left(NH_4^+ - N\right)_t\right]/14I_t \quad \text{(Eq.1)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_56655680
© 2018, ALÖKI Kft., Budapest, Hungary

$$ICE = 3FV\left[\left(NH_4^+ - N\right)_t - \left(NH_4^+ - N\right)_{t+\Delta t}\right]/14I_{\Delta t} \quad \text{(Eq.2)}$$

where $(NH_4^+\text{-}N)_0$, $(NH_4^+\text{-}N)_t$ and $(NH_4^+\text{-}N)_{t+\Delta t}$ are the concentration of NH_4^+-N (mg/L) at times zero, t and t + Δt (min), respectively, I is the current density (A), F is the Faraday number (96,485 C/mol), t is the time (min), V is the volume of the electrolyte (L), 3 is the number of exchanged electrons for the electrochemical oxidation of ammonia, and 14 is the molecular mass of ammonia (g/mol).

Batch experiments were conducted in an apparatus at room temperature (about 23.0-26.0 °C). An undivided and unbuffered electrochemical cell was designed in our lab with a networking volume of 400.0 mL. The 400.0 mL electrolysis cell was made of acryl plates with four outer spots for the electrodes assembled. Three metal plates include Cu/Zn (Cu: 62.2 wt.%; Zn: 37.8 wt.%), Ti and Fe plates of 75.0 cm^2 (15.0 cm × 5.0 cm) were used as the cathode respectively with Ti/IrO_2–Pt (TohoTech company, Japan) as the anode at the same area. A distance of 8.0 mm was set between the two electrodes. The immersed areas of the anode and cathode in the treated solution were the same and calculated as 50.0 cm^2. A DC power with a voltage range of 0–50.0 V and current range of 0–5.0 A was employed as a power supply. Test synthetic ammonia solutions were prepared using $(NH_4)_2SO_4$ and distilled water to give a final concentration of 100.0 mg/L with no Cl^- ion. In the solution, free ammonia concentration is only 0.0198 mg/L. The NaCl dosage of 0 g/L, 0.5 g/L, 1.0 g/L, 2.0 g/L (w/v) were added into the synthetic ammonia solutions to investigate the effect of influencing factors (sodium chloride dosage, current density, temperature and initial pH value). The current density was varied from 5.0 mA/cm^2 to 50.0 mA/cm^2, and the initial pH value was adjusted from 3.0 to 11.0 by NaOH (0.1 M) or H_2SO_4 (0.1 M). 0.5 g/L Na_2SO_4 was added in all solution as supporting electrolyte. At different intervals, 1.5 mL of sample was drawn from the electrochemical cell for analysis. The electrolysis was ceased when either 90.0% of initial ammonia was converted or 2 h elapsed.

Analysis

The concentrations of ammonia and nitrate were determined by spectrophotometer (DR/4000U Spectrophotometer, USA) by standard methods (Clesceri and Eaton, 1998). Nitrite was analyzed by ion chromatography (Yokogawa IC7000, AS9-HC column). Total nitrogen (T-N) was determined with a T-N, T-P autoanalyzer (Autoanalyzer 3, Bran+Luebbe). Dissolved copper and zinc contents in the filtered samples were detected using plasma emission spectrophotometer equipment (ICAP-575, Jareruasshu). Surface morphology of electrodes was characterized ex-situ by atomic force microscopy (AFM) (Digital Instruments, DimensionTM3000, USA). Mono-, di- and tri-chloramines were determined by the colorimetric DPD method (Clesceri and Eaton, 1998). All the other analyses were done according to standard methods (Clesceri and Eaton, 1998).

Results and discussion

Influence of NaCl dosages

In the present experiment, as NaCl plays an important role on not only the ammonia oxidation rate but also the formation of the by-product nitrate, the performance of electrochemical ammonia oxidation with different NaCl dosage was investigated.

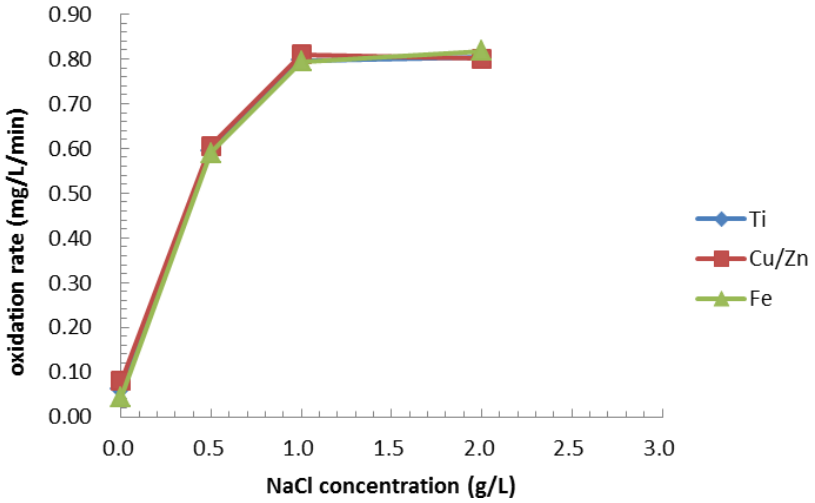

Figure 3. *Influence of NaCl concentrations on the ammonia oxidation rate. Anode: Ti/IrO_2-Pt, cathode: Ti, Fe, Cu/Zn, 30.0 mA/cm^2, respectively*

The results showed that without chloride ion, the ammonia removal efficiencies were 0.08, 0.1 and 0.05 with Ti, Cu/Zn and Fe as cathode employed, respectively. Meanwhile, the different amounts of nitrate formation during the electrochemical oxidation of ammonia can be attributed to the difference of the cathodes in the absence of NaCl, in which Cu/Zn cathode showed the lowest by-product formation. Cupro-zinc materials were well-known for their good corrosion resistance. Moreover, zinc has a good electroactivity while copper displays a good activity of electroreduction. As a result, a synergistic effect of alloying Zn with Cu could be expected. From the observed results, it can be concluded that Cu/Zn cathode is more suitable for ammonia removal than Ti and Fe cathodes in the absence of NaCl because of its high selectivity for ammonia oxidation to nitrogen gas. The effect of varying Cl^- concentration on ammonia-N and nitrate-N removal was also shown. The results indicated that these three cathodes exhibited almost the same performance of ammonia removal after 60 min electrolysis under NaCl addition. In the presence of 0.5 g/L NaCl after 120 min electrolysis, ammonia-N decreased from 100 mg/L to 25.4 mg/L, 25.3 mg/L and 26.1 mg/L respectively with Ti, Cu/Zn and Fe as a cathode. It is clear that the ammonia-N was significantly decreased compared with that in the absence of NaCl, which proved the key role of indirect oxidation during electrochemical oxidation of ammonia (Deng and Englehardt, 2007). Meanwhile, nitrate-N increased from 0 to 2.0 mg/L, 1.5 mg/L and 4.0 mg/L respectively, and no nitrite was detected through the experiments. In the presence of 1.0 g/L and 2.0 g/L NaCl, the ammonia decreased sharply, implying that in the presence of chloride ions, hypochlorite ions may be formed and then oxidize the ammonia and by-product presumably to nitrogen gas (Li et al., 2009) as listed in *Equations 3–7*.

For the indirect oxidation, in the presence of chloride ion, oxidizing hypochlorite ion will be formed during the electrolysis

$$2Cl^- \rightarrow Cl_2 + 2e^- \quad \text{(Eq.3)}$$

$$Cl_2 + H_2O \rightarrow HClO + H^+ + Cl^- \quad \text{(Eq.4)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_56655680
© 2018, ALÖKI Kft., Budapest, Hungary

$$HClO \rightarrow ClO^- + H^+ \quad \text{(Eq.5)}$$

The hypochlorite acid formed during the electrolysis would efficiently oxidize the ammonia, which is assumed to be oxidized into nitrogen gas and nitrate.

$$2NH_4^+ + 3HClO \rightarrow N_2 + 3H_2O + 5H^+ + 3Cl^- \quad \text{(Eq.6)}$$

$$NH_4^+ + 4HClO \rightarrow NO_3^- + H_2O + 6H^+ + 4Cl^- \quad \text{(Eq.7)}$$

Stated, above 90% of removed ammonia was assumed to transform into N_2 gas with NaCl addition, which was similar to another report (Kim et al., 2005). The production of N_2 could be calculated as equal to the loss of N element according to the N conservation law (Xiao et al., 2009). Simultaneously, intermediate nitrate ions were formed in the water. On the contrary, the by-product formation had different results. The nitrate formation could come from not only the indirect oxidation of ammonia by HClO but also by hydroxyl radicals. The by-product formation generated by Ti and Fe increased during electrolysis while it increased for the first period and then decreased finally under Cu/Zn cathode condition. As Cu/Zn cathode exhibited high reduction ability, the NO_3^- concentration was the lowest. Mácová and Bouzek (2005) found that brass is containing Zn higher than 35 wt. % and lower than 41 wt. % will significantly influence the kinetics of current density, and higher electrocatalytic activity of Cu/Zn than both Cu and Zn was observed.

It can be concluded that ammonia oxidation rate was increased with the increased dosage of NaCl, while nitrate formation was different with various cathodes, which suggested that the cathode and chloride ion concentration can be optimized in the ammonia solution during electrolysis process with effective ammonia removal and relatively low amount of by-products left in the solution. Therefore, the electrochemical process in the presence of chlorides showed a higher capacity and selectivity in ammonia transformation into nitrogen gas (Xiao et al., 2009) In this study, the optimum NaCl concentration was 1.0 g/L and the best cathode was Cu/Zn cathode. As the combination of Ti/IrO_2-Pt anode and Cu/Zn cathode showed a good performance for ammonia oxidation, the influence of several other factors, such as current density initial pH and temperatures were also studied.

Influence of current density

Figure 4 shows that current density had some effect on the removal of ammonia and the nitrate-N production. In this work, current densities ranged from 5.0 mA/cm^2 which is the minimum required to achieve effective oxidation of ammonia (Cossu et al., 1998).

The ammonia concentration decreased from 100.0 mg/L to 80.9 mg/L, 59.3 mg/L, 23.2 mg/L, 0.0 mg/L in 120 min respectively (*Fig. 4a*). This observation is in agreement with the previous report that an increase in current density improves ammonia-N treatment efficiencies under the same charge loading. The possible reason is that the increased current density during electrochemical oxidation could enhance chlorine generation, which was responsible for subsequent removal of pollutions (Deng et al., 2007).

Figure 4b shows the variation of nitrate-N during electrolysis at different current densities. The final concentration of nitrate-N decreased with the increase of current

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_56655680
© 2018, ALÖKI Kft., Budapest, Hungary

density. The nitrate-N increased from 0 to 2.6 mg/L, 2.4 mg/L, 1.3 mg/L, 2.4 mg/L, 3.3 mg/L and 2.8 mg/L in 120 min, respectively. Ammonia oxidation rate has been reported to be linearly by current density (Vanlangendonck et al., 2005), which is in agreement with the present experiments. A similar tendency was obtained in the present experiments. At lower current density, less amount of hypochlorite acid was produced, which was not enough to oxidize all the ammonia present in the solution.

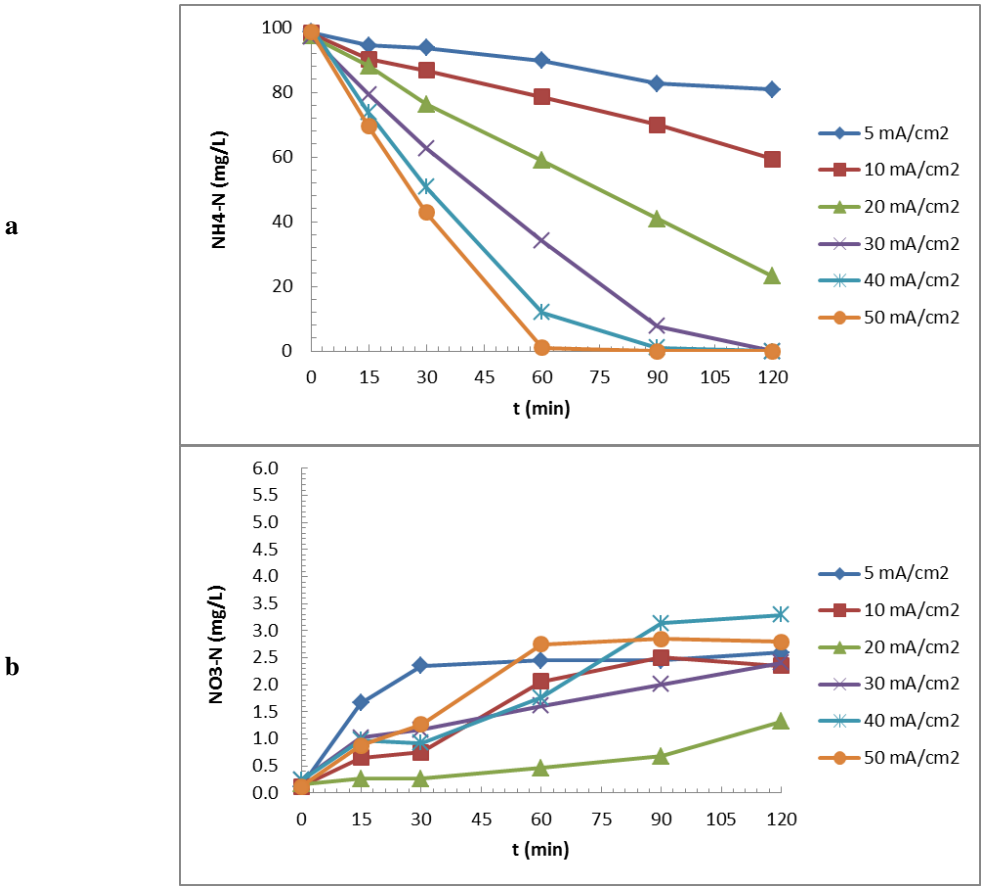

Figure 4. *The concentration of ammonia (a) and nitrate (b) concerning reaction time at different current densities. Anode: Ti/IrO_2-Pt, cathode: Cu/Zn, 1.0 g/L NaCl*

And from *Figure 5,* the ammonia oxidation rate almost increased with current density increased from 5.0 to 50.0 mA/cm^2. This enhancement could be attributed to more chlorine generated responsibly for subsequent removal of pollutions (Deng et al., 2007).

The impact of current density on both ICE and ACE during electrolysis are also investigated (data not shown). At a higher current density, the ICE and ACE decreased rapidly as the duration of electrolysis increased. Initially, the ammonia concentration and chloride ion concentration were high, and the electrical energy was mainly consumed by the ammonia oxidation. With the electrolysis progressed the electrical energy was mainly consumed by oxygen evolution and chlorate formation, thus resulting in a decrease in current efficiency.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_56655680
© 2018, ALÖKI Kft., Budapest, Hungary

Therefore, in the present experiments, to remove all of the ammonia with the consideration of ACE and ICE, the optimum current density was determined at 30.0 mA/cm^2.

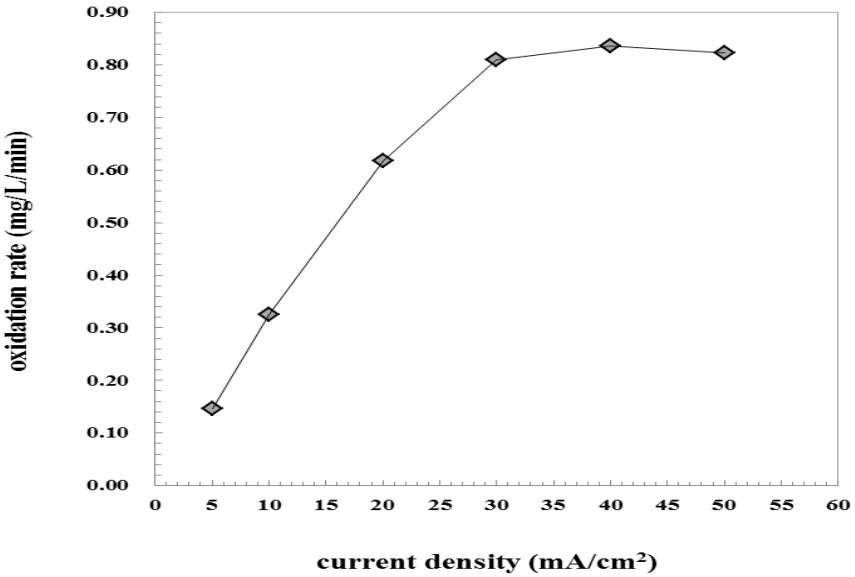

Figure 5. *Effect of current density on ammonia oxidation rate under 1.0 g/L of NaCl condition*

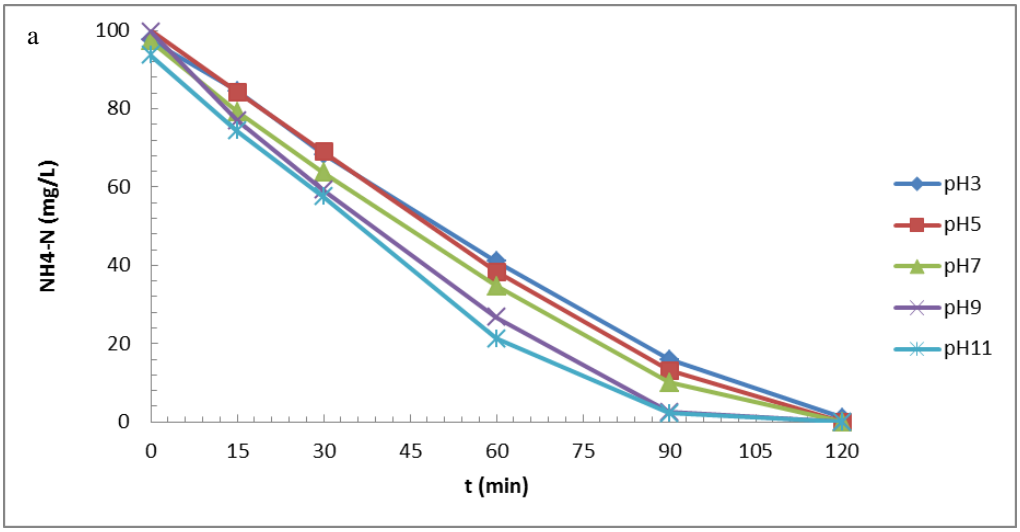
Influence of initial pH

Figures 6 and *7* present the ammonia oxidation rate under different initial pH conditions. Initial pH of 3, 5, 7, 9 and 11 were tested.

The ammonia decreased from 100.0 mg/L to 1.0 mg/L and 0 mg/L in 120 min, respectively under initial pH 3.0, 5.0, 7.0, 9.0 and 11.0 conditions. The oxidation rates were almost 0.8 mg/L/min.

The results of one-way analysis of variance ($p = 0.991$ for NH_4-N and 0.541 for NO_3-N, > 0.05, data not shown) confirmed that electrochemical treatment is independent of initial pH. This result agrees with Lin and Wu (Lin and Wu, 1996), but different from Kapałka et al. (2010b, 2011).



http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_56655680
© 2018, ALÖKI Kft., Budapest, Hungary

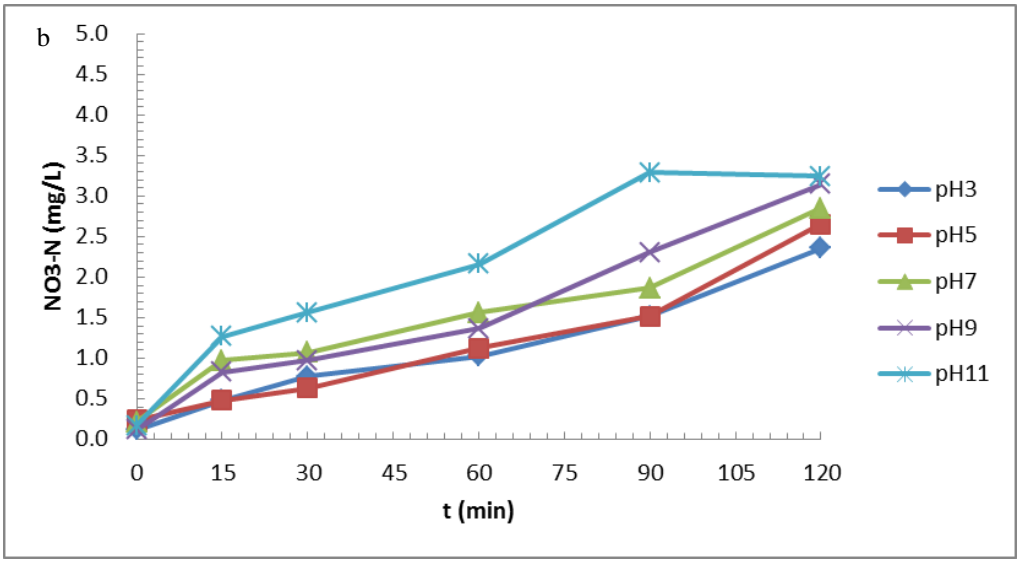


Figure 6. *The concentration of ammonia (a) and nitrate (b) VS time at different initial pH. Anode: Ti/IrO$_2$-Pt, cathode: Cu/Zn, 1.0 g/L NaCl, 30.0 mA/cm^2*

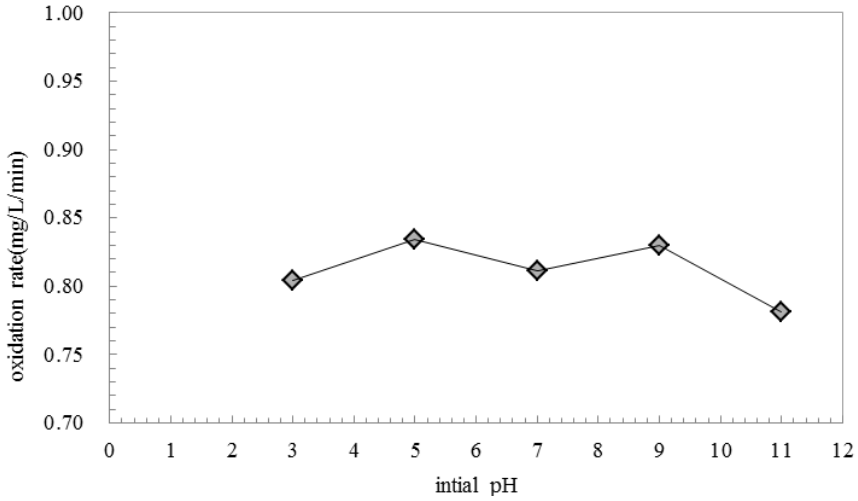

Figure 7. *Electrochemical NH_4^+-N removal as a function of pH under a current density of 30.0 mA/cm^2 and 1.0 g/L of NaCl*

Which can be explained by previously report, in a weak alkaline environment, the circulation of $Cl^- \rightarrow Cl_2 \rightarrow ClO^- \rightarrow Cl^-$ could be formed, making efficient use of chlorine. In a strong alkaline environment, ClO_3^- was present and competes with Cl^- for electrons, decreasing the removal rate (Wang, 2000). The mechanism for the ammonia removal at anode was like the "breaking point reactions" and a stepwise process, and the reaction at cathode was hydrogen evolution reaction.

Influence of temperature

Figure 8 shows the variation of ammonia-N and nitrate-N during electrolysis at different temperature control conditions. As it was difficult to maintain high temperature throughout experiments, the temperature was only set to be at uncontrolled

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_56655680
© 2018, ALÖKI Kft., Budapest, Hungary

and 25.0 °C. Under the uncontrolled temperature condition, the temperature of the treated solution increased from 25.0 to 41.2 °C after 120 min electrolysis with all of the ammonia being destroyed. Under the controlled temperature (25.0 °C) condition, ammonia oxidation was a little slower. This was mainly due to different pH changes in the electrolyte at different temperatures during the electrolysis (data not shown). The pH varied because of the various reactions occurred during ammonia oxidation process. Moreover, increasing temperature could increase the rate of diffusion and the capability of adsorption. Consequently, the ammonia oxidation rate increased when the temperature was increased from 25.0 to 41.2 °C.

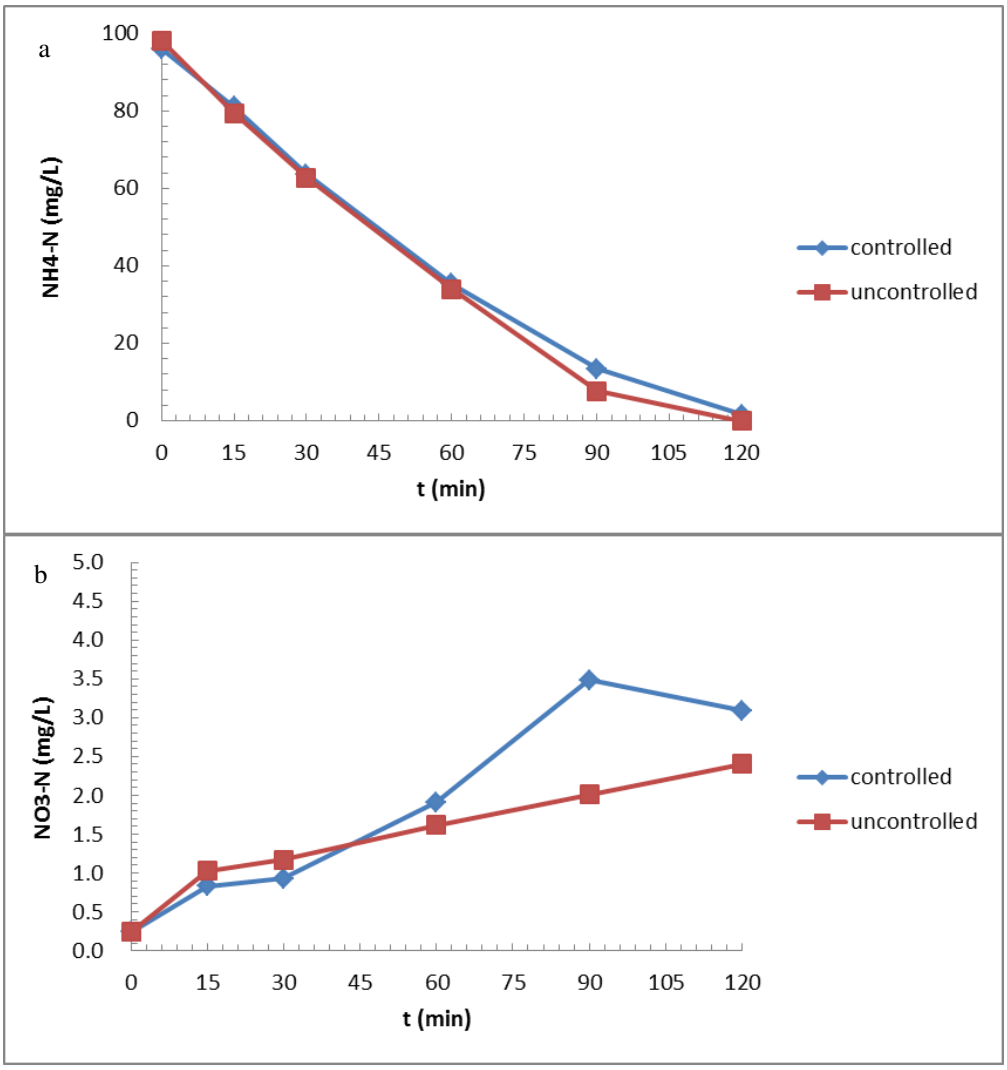

Figure 8. *The concentration of ammonia (a) and nitrate (b) concerning time at temperature control methods. Anode: Ti/IrO_2-Pt, cathode: Cu/Zn, 1.0 g/L NaCl, 30.0 mA/cm^2. The final temperature of the uncontrolled condition is about 41.2 °C*

In addition, ammonia in aqueous solution can exist in two forms: un-ionized form (NH_3) and/or ionized form (NH_4^+) (Körner et al., 2001). Compared these two forms of ammonia, the unionized one is much easier to be oxidized. These two forms of ammonia established an equilibrium following *Equation 8* (Lin and Wu, 1996).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_56655680
© 2018, ALÖKI Kft., Budapest, Hungary

$$NH_3 + H_2O \leftrightarrow NH_4^+ + OH^- \quad \text{(Eq.8)}$$

Under the uncontrolled condition, with increasing temperature, larger amount of NH_3 formed then subsequently oxidized on the electrode, which also increased ammonia oxidation rate.

The enhancement of ammonia oxidation could also be attributed to either the accelerated diffusion of ammonia from the bulk solution through the diffusive layer to the electrode surface (mass-transfer effect) or the rapid electro-oxidation reactions (activation effect).

In general, increasing temperature could enhance ammonia oxidation rate in several ways; the uncontrolled condition was a little favorable for electrochemical oxidation of ammonia.

Mass balance of nitrogen

Under the optimal condition, the mass balance of nitrogen in each treatment system is shown in *Figures 9* and *10*. The initial mass of ammonia nitrogen in the solution was 100 mg/L. The concentrations of ammonia, nitrite, nitrate and chloramines were determined during the electrolysis as listed in *Table 1*. It can be seen that the ratio of ammonia transferred into nitrogen gas was the highest in Cu/Zn cathode system, 97.34% and the others were 94.91% 94.38% in Ti and Fe cathode systems, respectively. This result indicated that the activity of the Cu/Zn electrode is relatively higher concerning the oxidation of ammonia ions and reduction of nitrate and nitrite.

Table 1. *Final concentrations of N species under different cathode conditions with 30.0 mA/cm^2 and 1.0 g/L NaCl in 120 min*

Cathode	Nitrate-N (mg/L)	Nitrite-N (mg/L)	Chloramine-N (mg/L)	Ammonia-N (mg/L)
Cu/Zn	2.40	0.00	0.24	0.00
Ti	4.08	0	0.24	0.92
Fe	4.52	0	0.00	1.16

Kinetic studies

$$ln\left(\left[NH_4^+ - N\right]_0 / \left[NH_4^+ - N\right]_t\right) = K_t \qquad \text{(Eq.9)}$$

where $[NH_4^+\text{-}N]_0$ and $[NH_4^+\text{-}N]_t$ respectively correspond to the initial ammonia concentration and the concentration after a period of reaction, and K is the reaction rate constant.

Application of *Equation 9* to the experimental data produces straight line plots as shown in *Figure11*. These data can be represented by pseudo first-order kinetics. However, when the NaCl concentration is at low levels (0.0 g/L, 0.5 g/L), the fitness was not good, possibly caused by diffusion and consumption of Cl^- ions during the electrochemical process.

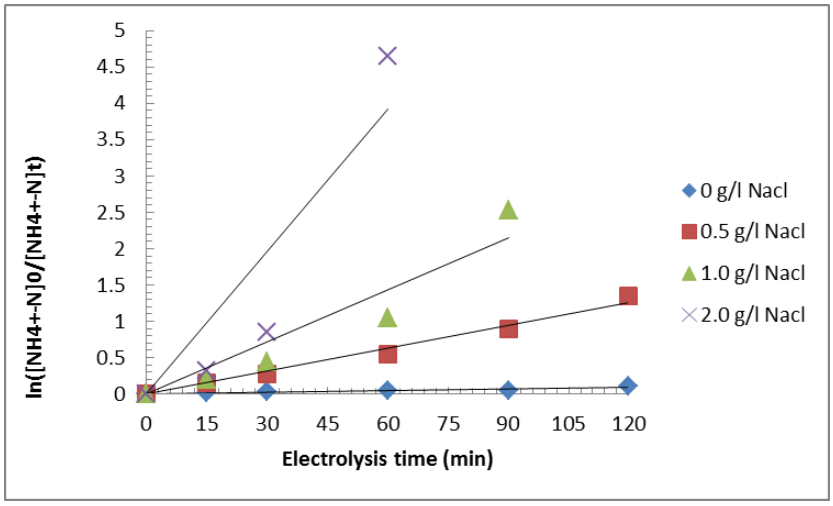

Figure 11. *Pseudo-first-order kinetic model of the electrochemical treatment data, with a current density of 30.0 mA/cm^2*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_56655680
© 2018, ALÖKI Kft., Budapest, Hungary

The kinetic rate coefficients were determined from the slopes of the straight lines under each set of operating condition (data not shown). The values of the kinetic rate coefficients obtained at different NaCl concentrations ranged between 0.01-0.07 min^{-1}. Higher values of correlation coefficients (R^2 = 0.84-0.98) confirmed the hypothesis of the pseudo first-order reaction of ammonia oxidation. The result also indicated that ammonia could be completely removed if appropriate conditions provided.

Analysis of electrode surfaces and the electrochemical solution

Analysis of the electrolyte after electrolysis for 2 h at the current density of 30.0 mA/cm^2 revealed that the concentrations of copper and zinc in the electrolyte were less than 0.2 and 1.5 mg/L, respectively, which are allowable limits for National Secondary Drinking Water Regulations (EPA 816-F-09-0004, May 2009). The low concentrations of Cu and Zn observed in the solutions may be attributed to limited corrosion of the electrodes under constant potential conditions.

As Ti/IrO_2–Pt anode and Cu/Zn cathode system had the best performance for ammonia oxidation in the presence of NaCl; the AFM investigation was carried out. The surface roughness of the anode had no change after electrolysis, implying that the Ti/IrO_2–Pt anode was stable for ammonia oxidation.

Conclusions

In this work, we have investigated the electrochemical ammonia removal system. To complete electrochemical oxidize of ammonia and reduce the formation of by-products, cathodic reduction of by-products, and anodic oxidation of ammonia was investigated in an undivided cell using Ti/IrO_2-Pt plate as an anode and three plates as a cathode for treatment of the synthetic ammonia solution respectively. It can be concluded:

(1) The ammonia-N decreased from 100.0 mg/L to 0.0 mg/L in the presence of 1.0 g/L NaCl after 120 min electrolysis at the current density of 30.0 mA/cm^2 with Cu/Zn cathode and Ti/IrO_2–Pt anode. No nitrite was detected in the treated solutions. Dissolved copper and zinc were 0.2 mg/l and 1.5 mg/l, respectively. The concentration of chloramine was 0.24 mg/l. About 97.34% of initial TN was transformed into nitrogen gas in Cu/Zn system, indicating that Cu/Zn cathode has good performance on by-production reduction.

(2) Initial pH had no obvious effect on electrochemical ammonia removal.

(3) Cu/Zn cathode possessed the highest ammonia oxidation rate (0.81 mg/L/min) and reduction rate of by-product (0.849 mg/L/min). The ammonia oxidation rates with Cu/Zn cathode was higher than that with Ti and Fe cathode. The nitrate formed during electrolysis with Cu/Zn was the lowest than that with other cathodes. The reason why the nitrate-N concentration was the lowest with Cu/Zn cathode was that because of its high reduction ability

(4) It was a little favorable for electrochemical oxidation of ammonia under uncontrolled temperature condition.

(5) The data obtained from the experiments could be represented by pseudo first-order kinetics.

From above, the mechanism of ammonia electro-oxidation on Cu/Zn cathode and Ti/IrO_2–Pt anode and formation of N_2 as a final product was indicated, that ammonia is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

oxidized through several steps to various nitrogen compounds, which was in accordance with previous reports, as *Equation 10*.

$$\begin{matrix} NH_3 \rightarrow NH_2OH_{ads} \rightarrow NO_x \\ \downarrow \\ N_2 \end{matrix} \quad \text{(Eq.10)}$$

In the present study, the ammonia was completely removed with less amount of by-products using Cu/Zn cathode and Ti/IrO_2-Pt anode electrochemical system.

Present experiments confirmed that the order of oxidation ability of those two anodes was Ti/IrO_2–Pt > Ti/RuO_2–Pt. The possible reasons are listed as follows:

(1) High oxidation ability of the Ti/IrO_2–Pt lead to more amounts of hydroxyl radicals and hypochlorite ion formed than at Ti/RuO_2–Pt anode, and they could lead to the passivation of the cathode, which resulted in the slightly lower ammonia oxidation rate.

(2) As it is likely that, the presence of Cl^- ions affected the performance of each electrode. Experimental data showed that the higher oxidant generation of FAC (Free available chlorine) under Ti/IrO_2-Pt anode condition than the other anode was particularly observed.

(3) On the other hand, previous studies indicated that EAN (anode potential) of Ti/IrO_2–Pt electrode was lower and electrocatalytic activity toward chlorine evolution was higher which was confirmed by Szpyrkowicz et al. (2005).

In general, Ti/IrO_2-Pt anode had highest oxidation ability by various pathways, which combined with Cu/Zn cathode exhibited good performance on ammonia oxidation that could be employed for practical use in the future.

(Received 13th Jun 2018; accepted 1st Aug 2018)

Abstract. Tree species display wide range of heterogeneity in their size, type, dormancy and growth of seed. Data about variation in germination under natural conditions and tree growth in connection with mentioned attributes is of immense value to understand tree distribution and forest stand management. Studies dealing with tree seed germination can enable successful nursery operations and healthy seedling production. This may also increase the seedlings' establishment in the forest restoration activities on destructed sites through native plant species. Successful germination is not only critical for plantlet establishment but also necessary for crop yield. As seed detaches from mother plant it desiccates continuously and selects suitable environment for germination activity. To understand the low germination rate in *Cyclobalnopsis gilva* molecular aspects of germination has been elucidated well with the integrated studies of proteomic, transcriptomic molecular biology. In this review, common and different aspects of seed germination including metabolic activation, transcription and translation regulation, have been discussed. This review will help to understand the transcriptomic and proteomic interaction of *C. gilva* which will be helpful to save the forest ecology and solve the problem of woody plants with low germination rate all over the world.
Keywords: *environment, woody plants, forest, metabolic activation, transcription, translation*

Introduction

Seed germination comprises of three interlinked processes, such as (I) rapid water uptake, (II) plateau phase and (III) post-germination. Phase (I) starts with the water absorption which helps in the breakdown of starch, proteins, and lipids along with the continuity of glycolytic and oxidative pentose phosphate pathways (Howell et al., 2007; Macovei et al., 2011). Phase II involves mitochondrial synthesis (Howell et al., 2007) and translation of stored mRNA (Dinkova et al., 2011; *Fig. 1*). Phase III follows the elongation of embryonic axes leading to radicle growth. Previous research studies have explained seed germination with considerable progress from more than two decades. However, there are many small circles of seed germination, which demands more

exploration for the proper understanding of mutual linkages between various pathways (He and Yang, 2013).

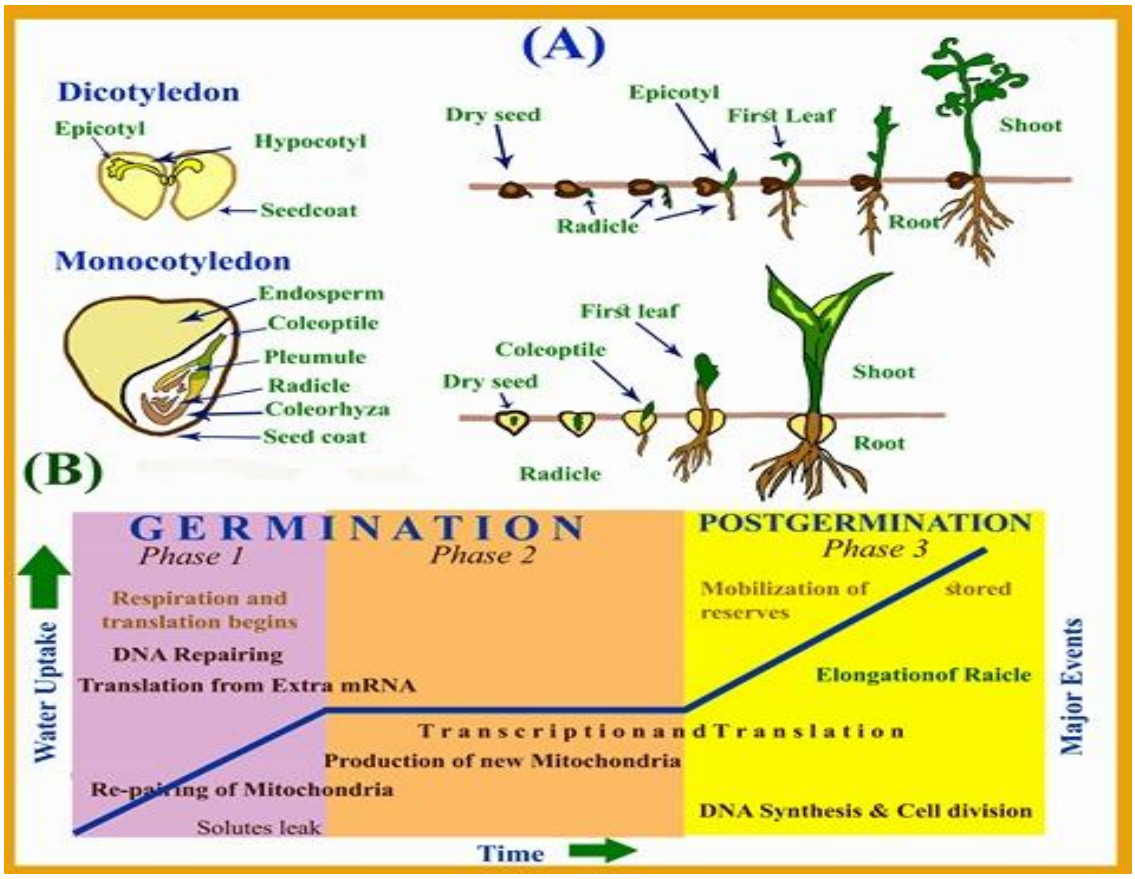

Figure 1. *Following imbibition, seed germination could be divided into three major steps. First of all, rapid uptake of water occurs which results in biosynthesis of mRNA. Second step includes more important activities which involves reactivation of metabolism, mobilization of stored reserves, loosening of cell wall, repair of cell structure and coleoptile enlargement. Again rapid uptake of water occurs during the last step, upon which respiration and TCA recovers, cell multiplication, radical emergence and seedling establishment initiates*

In Arabidopsis, barley and rice more than ten thousand stored mRNA and transcripts have been identified and several studies confirmed that mRNA are stored during seed maturation (Rajjou et al., 2004; Nakabayashi et al., 2005; Kimura and Nambara, 2010; Okamoto et al., 2010; Radchuk et al., 2007). Until now, the confirmed transcriptomes from whole dry seeds have presented the diverse type of transcripts according to their genetic and physiological parts like the embryo and endosperm (Le et al., 2010). Furthermore, the transcriptional theory was genuinely authenticated by Kimura and Nambara (2010). Seed germination depends upon the variation in physio-chemistry of different parts of seeds i.e. embryo, endosperm seed coat and interaction among them (Nonogaki et al., 2000). Embryo is a vital part of the seed, as it contains genetic information required for triggering the seed germination process (Sheoran et al., 2005). There are several enzymes involved in metabolic pathways during seed germination and that stored during seed maturation (www.seed-proteome.com) (Rajjou et al., 2004; Fujino et al., 2008; Gallardo et al., 2001). Okamtao (2010) reported that during

© 2018, ALÖKI Kft., Budapest, Hungary

imbibition transcriptome profile in germinating seed changes and even these changes are tissue specific. During early germination, transcripts are noticed to share similar or common but highly abundant cis-acting elements in their respective gene promotor followed by high expression pattern (Marcus and Feeley, 1964; Dure and Waters, 1965; Comai and Harada, 1990). Degradation of stored mRNA is associated with a change in expression of a gene (Comai and Harada, 1990; Nakabayashi et al., 2005; Howell et al., 2009; Preston and Hileman, 2009). The mechanisms involved in seed germination, numerous broad-spectrum omics studies have been conducted across the globe, involving transcriptomic approaches (Holdsworth et al., 2008; Sghaier-Hammami et al., 2009a, b). Productivity and survival of woody plants is continuously affected by multiple stresses (Pinheiro et al., 2014). Plants growth is negatively affected by surrounding biotic and abiotic stress agents that cause physical and biological dysfunctions and plants differ in their ability to overcome these stresses. Aside from the huge proteomics data available for woody plants, limited information is available on seed germination. Until now, *Fagus sylvatica* is among the limited plants for which attempts has been made to know the proteomic changes associated with seed germination (Pawlowski, 2007), similarly *P. dactylifera* (Sghaier-Hammami et al., 2009a, b), *J. curcas* (Yang et al., 2009) and *P. campanulata* (Lee et al., 2006) are some other examples. Depending upon seed dormancy woody plants have four categories (Gendreau and Corbineau, 2009) that are physical, mechanical, morphological and embryo dormancy. Fukumoto and Kajimura (2001) reported the poor regeneration of Cyclobalnopsis sp is due to insect damage of seeds and deer grazing of regenerating seedlings which are threatening the successful regeneration of Cyclobalnopsis sp. Transcriptome and proteomic interaction of woody plants during the seed germination studies has been ignored till now. *Cyclobalnopsis gilva* a woody plant has low germination rate as compared to other plants (Meiqing et al., 2012). It belongs to *Fagaceae* family and because of its hardness it is used in the furniture industry. (Zaynab et al., 2017). It is native in the southeastern part of China (*Fig. 2*). Among evergreen broad leaves, Cyclobalanopsis is one of an abundantly found woody tree which is a good biological filter that reduces environmental pollution (Deng et al., 2014). Being efficient natural cleaners, trees can help to overcome environmental pollution (Seth et al., 2003). Leaves with hairy, spiny and waxy surface can easily absorb gaseous form of pollutants while particle forms of pollutants can be trapped by twigs, branches and tree stems. Trees reduce carbon oxides, disintegrate waste materials and fix nitrogen in atmosphere. Trees act as pollution sinks and metabolize heavy metals and absorb toxic gases from the surrounding environment (Yang et al., 2017). There are no studies reported transcriptome and proteome changes analysis during seed germination of *C. gilva.* The basic purpose of this study/review is to describe transcript and protein change during the complex mechanisms of seed germination of *C. gilva*.

Transcription and translation activation

Gene expression changes dramatically at proteomic as well as transcriptomics level as seed imbibes water (*Fig. 3*) (Holdsworth, 2008). Weitbrech et al. (2011) reported that these alterations in gene expression are related to germination. It is considered that transcription is not going on in fully ripened seed, but mRNAs which are essential for germination have already been stored (Howell, 2009). Large number of mRNA species are present in fully ripen seed. Over 12000 mRNA have been found in mature seeds of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_56815692
© 2018, ALÖKI Kft., Budapest, Hungary

Arabidopsis. He et al. (2011) in rice embryo, about 17000 mRNA have been found (Howell, 2009). In rice and Arabidopsis α-amanitin, a transcription inhibitor has found to delay germination but not totally block it (Rajjou, 2004). It looks that transcription inhibitors have greater role to play in seedling establishment than in germination (He et al., 2011). These results suggest that factors assuring the germination speed are synthesized in de novo transcription. High increase in transcription occur in rice embryo after 3 to 12 h of water absorption which results in increased secondary metabolites production that are involved in cell wall, amino acids, carbohydrates metabolism (Howell, 2009). Rice and Arabidopsis germination was diminished in the presence of translation inhibitors which showed that instead of transcription, translation is prerequisite of germination (Rajjou, 2004). New protein synthesis in Arabidopsis starts 8 h after imbibition. That is why it is proposed that stored mRNAs are utilized for this protein synthesis. For metabolites activation and mobilization of reserves translation of stored mRNAs was important in both rice and Arabidopsis seeds (Rajjou, 2012, 2006). In maize seeds in vitro incubation experiments demonstrated that eIF(iso)4E is required for translation of stored mRNAs (Dinkova et al., 2011). Arabidopsis double mutant i4g1/i4g2 knocked out for eIFiso4G1 and eIFiso4G2 (responsible for stored mRNA translation) showed diminished germination rate and long seed viability (Lellis, 2010). Form this experiment it was clear that cereal seeds and Arabidopsis possess similar mode of translation for stored mRNA.

Figure 2. *Presence of C. gilva in the southeastern ecological region of China*

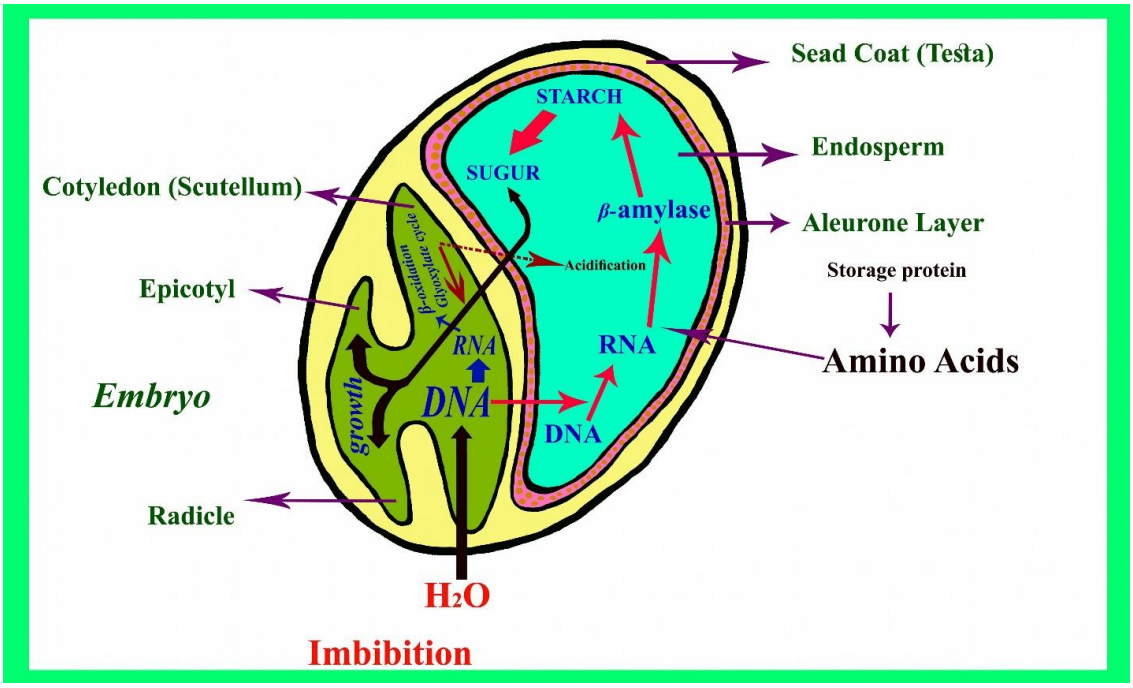

Figure 3. *Molecular processes occurring in embryo and endosperm during C. gilva seed germination*

Role of translation in seed germination

Previous observation inferred that upon imbibition radicle protrude out of seed coat in Arabidopsis seed in the presence a specific, potential inhibitor of DNA-dependent RNA polymerase "α-amanitin", this showed that seed germination is not limited to de novo transcription (Rajjou, 2004). To speed up the germination vigor, de novo synthesis of transcripts encoding proteins and enzymes involved in GAs biosynthesis and involved in germination sensitivity to this hormone is important because germination uniformity and speed is strongly affected under absence of these transcripts. In contrast, under the presence of translation inhibitor "cycloheximide" Arabidopsis germination was totally blocked (Rajjou, 2001). These results highlight the importance of protein synthesis especially from the stored RNA templates in seed for the completion of germination. As seed store RNA and proteins during maturation on source plant, role of these stored elements is clear from these results and for Arabidopsis seed germination potential is planned during seed maturation. For germination, other studies have also identified the core role of translation. During germination of mature seeds high contribution of stored mRNA has been confirmed by transcriptome analysis (Nakabayashi et al., 2005). The study conducted by Nakabayashi et al. (2005) elaborated the importance of protein synthesis during early germination stages, as 2% to 3% genes showed upregulation while evidence was also provided by ribosomal proteins coding genes and translation initiation and elongation factors.

Recent analysis of sugarbeat (*Beta vulgaris* L.) seed proteome identified 758 proteins reconstructing and inferring their detailed metabolic status (Catusse et al., 2008). Seeds are prepared for germination mainly during maturation on plan as indicated by sugar beet seeds, which are prepared to mobilize their reserves including starch, proteins, phytate and triglycerides during germination as occur in Arabidopsis and they also

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_56815692
© 2018, ALÖKI Kft., Budapest, Hungary

identified proteins not mentioned in seeds. Promisingly, data highlight that sugar beet seeds have opportunity to initiate translation either by using cap-independent mechanism or conventional way of cap-dependent mechanism. It is clear that during some events of cell life like during stress conditions or viral infection and mitosis, cell compromises its standard way of translation i.e. 5-end cap-recognition of mRNA while at the same time some mRNA use cap-independent mechanism of initiation as congregation initiation site for initiation factor (Baird et al., 2006). A model is suggested by these findings. In this model germinating seed has two pools of mRNA comprising of de novo synthesized mRNA and stored mRNA and during germination these pools allow their recruitment by either of two initiation pathways (Catusse et al., 2008). In maize seed, during embryonic axis elongation, stored mRNAs were likely to use cap-independent mechanism for translation initiation (Dinkova et al., 2005).

Comparison of the seed transcriptome and proteome

Comparison of several proteome and transcriptome studies carried out in the same environmental conditions and sampling points, showed little correlation between functional gene classes at proteomics and transcriptomics level (Gallardo et al., 2002; Ogawa et al., 2003; Chibani et al., 2006; Carrera et al., 2008). Germination vigor can possibly change the abundance of RNA present in seed for germination completion, some functions associated with establishment of seedling (translation after germination completion), for observation of changes in protein profiles, proteomic approaches are not sensitive enough. Up till now it is also vague that changes in seed dormancy status are controlled by translational or post-translational regulations (Holdsworth et al., 2008). Gene expression study is critically important to understand the molecular network involved in germination regulation as the list of genes regulated in imbibed seeds obtained through either proteomic (Chibani et al., 2006) or transcriptomic (Cadman et al., 2006) approaches showed similarities. Integration of information from proteomic and transcriptomic studies will be the key objective for further post-genomic research. Favorably, some proteomic and transcriptomic based studies under similar time essays and growth conditions are helping to integrate the information from different studies (Cadman et al., 2006; Chibani et al., 2006; Carrera et al., 2008).

Due to less germination rate of woody plants proteomic studies of seed germination are getting more importance (Zaynab et al., 2017; Canovas et al., 2004). It is difficult to examine woody plants due to laborious sample preparation and high concentrations of resins, tannins and phenolic compounds (Sebastiana et al., 2013). In a study, *P. dactylifera* L. (Date palm) proteomic studies for seed development and germination were done by Sghaier-Hammami et al. (2009) and they reported that carbohydrates, the major storage reserves are stored in early seed development which are used during initial stages of seed germination.

Comprehensive information regarding access amount of some functional protein types related to seed ripening, dormancy and germination have been provided by the proteomic analysis of germinating seeds. Many other studies have also shown the proteome changes related to dormancy and germination status (Gallardo et al., 2001, 2002; Job et al., 2005; Chibani et al., 2006; Oracz et al., 2007), regarding this information seed biology is a prominent host of plant proteomics. Proteomics is a strategy for global analysis that provides information on a multitude of processes in complex events, such as germination (Gallardo et al., 2001). Despite the increasing

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_56815692

interest in plant proteomics, studies on woody plant seed germination are still very limited. To date, the only attempts to understand proteome changes during the germination of woody plants were carried out in *Prunus campanulata* (Lee et al., 2006), *Fagus sylvatica* (Pawlowski, 2007), *Acer platanoides* (Pawlowski, 2009), *Jatropha curcas* (Yang et al., 2009), *Phoenix dactylifera* (Sghaier-Hammami et al., 2010, 2009b) and *Araucaria angustifolia* (Balbuena et al., 2011). Only a limited number of reports about proteomics in woody plant seed germination have been published. Lu et al. (2016) conducted a study to determine the mechanisms involved in seed dormancy breaking of M. sieboldii to better understand the anatomical and translation bases of seed germination in this species and they reported that a small subunit of legumin precursor, ADP-glucose pyrophosphorylase and aspartic proteinase dominate the seed proteome of M. sieboldii. Such studies not only provide information regarding the protein abundance in dry stored seeds and imbibed seeds but also elaborate the post-translational modifications for proteome expression. Gallardo et al. (2001) reported the proteome changes related to imbibition germination while Chilbani et al. (2006) studied the imbibed ripened seeds. Rajjou et al. (2004) noticed that germination in alpha-amanitin treated transparent testa (tt) of mutant seeds was not blocked concluded that transcription was not important for germination. On the other hand, cycloheximide was a potential inhibitor of radicle emergence. If transcription was important for expression of genes involved in synchronization and speed of germination was answered by the α-amanitin treatment. Seeds treated with α-amanitin showed great germination potential, but germination rate was slow and less sensitive to GA application and the level of several key proteins for germination (malate synthase) (Eastmond et al., 2000) were very low in treated seeds. Chibani et al. (2006) reported great difference in protein profiles of after-ripened and imbibed seeds of accession CVI. In dormant seeds lack of germination was not associated with less de novo protein production because 35S methionine incorporation quantification showed the same incorporation level in after-ripened and dormant seeds (Carrera et al., 2008). Exogenous ABA application greatly lowered the germination potential in after-ripened imbibed seeds, but it did not alter dormancy at proteomic level (Chibani et al., 2006). 35S methionine incorporation in ABA treated after-ripened imbibed seeds were greater that non-treated and dormant seeds, this indicated that ABA treatment does not hinder RNA translation protein abundance was also high in treated seeds. Both proteomic and transcriptomic studies showed that instead of seed dormancy ABA treatment use another way of inhibiting germination. This is not surprising because physiologically ABA does not reduce germination potential but only delay it (Muller et al., 2006). It is very likely that ABA application to un-germinated seeds just like drought and salinity causes increased ABA production, these responses have already been observed in germinating seedlings (Lopez-Molina et al., 2002).

Post-translational control of seed germination

A growing number of evidence indicates that large changes in redox state of protein occur as seed germinates. In dry cereal seeds proteins are present in oxidized (S-S) form in embryo and starchy endosperm, upon imbibition these are converted into sulfhydryl (-SH) or reduced form (Buchanan and Balmer (2005)). Thioredoxin (Trx), a regulatory protein seems to play core role in redox conversion. Trx cause reduction enzymatically in the presence of NADPH and facilitates reserves mobilization during germination in

three ways i.e. enhancing protein susceptibility and sensitivity to proteolysis by reducing them, enhancing breakdown of stored proteins and starch as it inactivates disulfide proteins inhibiting specific proteases and amylases and it activates enzymes functioning in germination (*Fig. 3;* Buchanam and Balmer, 2005). This issue has recently been investigated in barrel clover (*Medicago truncatula*) (Alkhalfoui, 2007). Role of Trx in monocotyledons and dicotyledons seed germination have been proved. It can be summarized that in dry and fully mature seeds oxidized proteome keep seed metabolically dormant, which is activated. It can be summarized that oxidized proteome in metabolically dormant seed is by redox reaction in protein bisulfide bridges in the presence of specific Trx during seed germination. Given the large number of proteins affected (more than 100) Alkhalfioui (2007), post-translational mechanism offers an efficient and simple way of controlling complex pathways critical in seed germination. It follows, that investigation of targets like post-translational modifications becomes an emerging question. As post-translational changes may become key regulators of cell activity upon imbibition, so this question is importance increasingly. Carbonylation of proteins by reactive oxygen species may be another oxidative change. In several model systems carbonylated proteins accumulation is referred to aging, but it is not for Arabidopsis where germination rate is high, and seedlings are vigorous. Results indicates that changes in protein carbonylation patterns may occur to nullify the ROS produced in germinating seeds by recovery of metabolic processes. Job et al. (2005) conducted a study in which it is suggested that carbonylation of proteins stored in seed is to facilitate the protein mobilization at time of seed germination. Jatropha and other woody plants store the metabolic reserves as starch, proteins and lipids in embryo and endosperm (Yang et al., 2009). Triacylglycerol (TAG) the major form of lipids is the storage reserve of oilseed plants. TAG is broken down by lipases to release fatty acids which are further catabolized in glyoxilate cycle and β-oxidation. Seed germination and development mechanism of woody plant *A. angustifolia* was studied by Balbuena et al. (2011). Their study showed the differential expression of proteins in germinated and mature embryos which suggests the activation of robust metabolic pathways, translation initiation and stress regulation, overall indicates active degradation metabolism.

Conclusion and perspectives

Like any other field of plant science seed biology is of importance and attracting attention of plant biologists. Previous studies have suggested complicated signalling network and gene expression regulation are involved in seed germination. Plants may share same molecular mechanisms as transcription and translational activation, phytohormone behavior, radicle protrusion etc. however different plant species possess distinct mechanisms, especially for metabolism activation and reserves mobilization. Furthermore, cross-talk among environmental factor signalling pathways and phytohormones during germination is spurious up till now. With the advent of omics era, molecular pathways underlying the germination are becoming more elaborated. For example, during germination, role of functional proteins and specific signalling components in rice and Arabidopsis have been identified by proteomic and phosphoproteomic studies. However, still much information is required to understand the germination process. Nevertheless, in future integration of newly emerging techniques including ChIP-sequencing, proteomic and transcriptomic techniques and imaging will contribute to understand the process how different signals conciliate seed

germination. To better understand the underlying mechanisms of desiccation tolerance and intolerance, the physiological responses described require research at the metabolomic and transcriptomic levels in detail.

Abstract. Lake Basin pollution has become an important environmental problem, exploring its landscape pattern of land use and eco-environment characteristics is of great significance for environmental pollution control. Through the analysis of the landscape pattern indices of diversity, evenness, dominance and fragmentation of the three lake basins in Yunnan province of China, and based on the evaluation results of the ecological environment of the lake basins, to explore the relationship and characteristics between the landscape pattern of land use and its ecological environment. Research indicates: (1) According to the analysis of landscape pattern of land use in the basin, the level of landscape diversity and evenness in the Fuxian Lake Basin is the highest, followed by the Erhai Basin. However, the lowest is in the Dianchi Basin; the degree of landscape fragmentation in the Dianchi Basin is the highest, followed by the Fuxian Lake Basin, and the lowest in the Erhai Basin. (2) According to the results of the ecological environmental quality assessment, Dianchi Basin is the worst, while the Erhai Basin and Fuxian Lake Basin are better, and the Fuxian Lake Basin is the best. (3) The landscape pattern of land use in the basin is closely related to the quality of the ecological environment. Basins with good ecological environment quality have a relatively high degree of diversity and evenness, and relatively low fragmentation; in the basins with poor ecological environment, the degree of evenness and diversity of landscape are relatively low, and the degree of landscape fragmentation is relatively high.
Keywords: *plateau lake basin, remote sensing interpretation, land use; landscape pattern index, ecological environment evaluation*

Introduction

Along with the rapid development of social economy and urbanization process accelerated, environmental quality is declining, population is increasing and the environmental problems are increasingly prominent, the land use / cover change and ecological environment research have become a hot topic in the world. The research content mainly includes the land use change rule (Rao, 2015; Yang, 2016; Sharma, 2017; Kumar, 2017), mechanism (Zhang, 2012; Fu, 2012; Martyn et al., 2017), driving force (Li, 2014; Cattarino, 2014; Chai, 2016; Yuan, 2016; Wenban-Smith, 2017), landscape spatial pattern and so on (Xu, 2012; Yu, 2016; Liu, 2015; Lamine, 2018), the research on landscape pattern of land use mainly in provincial (Li, 2005; Zhang, 2009), municipal (country) regions (Ge, 2016; Wang, 2015; Hassan, 2017), a typical river basin (Feng, 2010; Chen, 2009; Mehrian, 2016) as the scale, abundant research results have been achieved. In the above studies, the longitudinal analysis of different phases in the same region is the main research, and the landscape pattern of land use and ecological

© 2018, ALÖKI Kft., Budapest, Hungary

environment were often studied separately, and the research on the relationship and characteristics between landscape pattern of land use and ecological environment in different lake basins was relatively insufficient.

According to "The Environmental Status Bulletin of Yunnan Province in 2015" (Yunnan Environmental Protection Department, 2016), the water quality of Lugu Lake Basin and Fuxian Lake Basin in the nine great plateau lake basins of Yunnan Province in China was excellent, the water quality in the Erhai Basin was good, and the Dianchi Basin was heavily polluted, and land use is closely related to lake pollution. This study selected the Dianchi Basin, Erhai Basin and Fuxian Lake Basin as the research object, the relationship and characteristics between landscape pattern of land use and ecological environment in the three major lake basins were analyzed, which is of great significance for optimizing landscape structure of land use and controlling lake water environment pollution.

Materials and methods

General background of the study area

In order to study the relevance and comparability, this article referred to the two major factors of socio-economic development level and lake pollution degree. The Dianchi Basin (capital of the provincial capital, heavy pollution), the Erhai Basin (prefecture-level city, good water quality) and the Fuxian Lake Basin (County Town, Type I Water Quality) are selected as the research area to explore the characteristics of land use landscape and ecological environment quality in the three major lake basins (*Fig. 1*).

The total area of the Dianchi Basin is 2891.07 km^2. The entire basin's terrain gradually decreased from north to south. With the rapid development of social economy, the rapid expansion of urban built-up areas in Kunming, the landscape pattern of land use in the lake basin has undergone major changes, and the landscape has presented a trend of fragmentation and the development of complex boundaries (Zhang, 2013).

The total area of the Erhai Basin is about 2609.07 km^2, which is second only to Dianchi Basin in the plateau lakes of Yunnan Province. The area along the lake is flat and the periphery is dominated by mountains. The type of land use in the basin is dominated by woodland, grassland and paddy fields. Economic and social development has had a certain impact on the land use structure of the Erhai Basin (Li, 2011).

The total area of the Fuxian Lake Basin is 690.03 km^2. The north of the lake is a basin, with fault cliffs or fault block mountains on the east and west sides, and alluvial plains on the south (Kang, 2011). Since the 1980s, unreasonable development of human activities have caused some damage to the land use structure of the lake basin. However, in recent years, with the emphasis on the ecological environment of the lake basin, the land use structure has gradually been optimized and the lake has always been Class I water quality (Wu, 2002).

Data sources

Part of the research data is from Landsat OLI remote sensing image data from the three major lake basins. The shooting time was March 2015, the line number of Dianchi Basin, Fuxian Lake Basin and Erhai Basin are 43, 43 and 42, respectively, and the band number is 129, 129 and 131, respectively. According to the classification standard of land use status (GB/T 21010-2007), combined with land use status, land use types are

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

divided into the dry land, paddy fields, garden lands, forest land, grass land, construction land, water area and unused lands eight types. Used spatial information technology (GIS/RS) and ERDAS software, based on the correction and enhancement processing of remote sensing images in the three lake basins, training samples were selected, supervised classification was conducted, and data such as land use type and area were further extracted. The other part comes from environmental protection agencies and their websites in Yunnan Province, Kunming City, and Dali Prefecture, as well as relevant data released in the "Yunnan Province Environmental Status Bulletin", "Kunming City Environmental Status Bulletin" and "Dali Prefecture Environmental Status Bulletin".

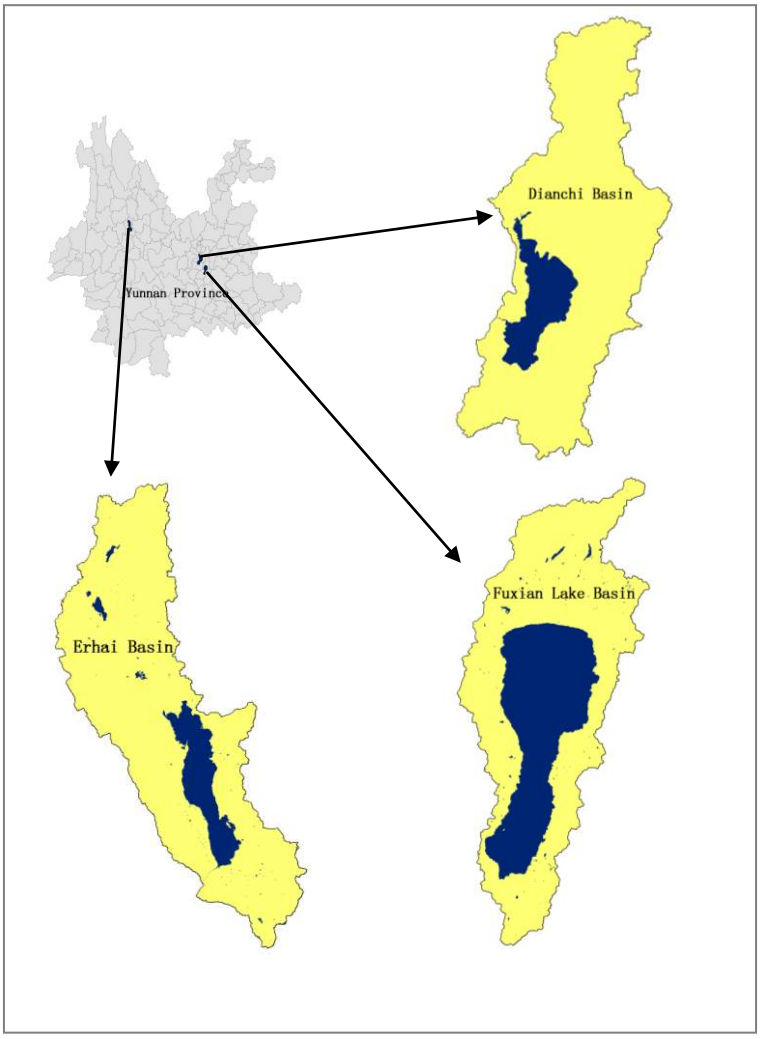

Figure 1. *Study areas*

Research methods

Analysis method of characteristics of land use landscape pattern

Based on the analysis methods of landscape ecology on quantitative structure, the land use diversity, evenness, dominance and fragmentation index of the three lake

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_56935704
© 2018, ALÖKI Kft., Budapest, Hungary

basins were obtained, and the characteristics of land use landscape patterns were analyzed (Liu et al., 2008). The formula is as follows:

- Diversity index (*Eq. 1*)

$$SHDI = -\sum_{i=1}^{m} \left(p_i \ln p_i \right) \quad \text{(Eq.1)}$$

In the formula,, "*SHDI*" is the diversity index, "P_i" is the ratio of landscape plaque type "*i*", and "*m*" is the landscape type.

- Evenness index (*Eq. 2*)

$$SHEI = \frac{H}{H_{\max}} = \frac{-\sum_{k=1}^{n} P_k \ln\left(P_k\right)}{\ln\left(m\right)} \quad \text{(Eq.2)}$$

In the formula,, "*SHEI*" is the evenness index, "*H*" is the measured diversity index, "H_{max}" is the maximum diversity index, and "*m*" is the landscape type.

- Dominance index (*Eq. 3*)

$$LDI = H_{\max} + \sum_{i=1}^{m} P_i \ln\left(P_i\right) \quad \text{(Eq.3)}$$

In the formula,, "*LDI*" is the dominance index, "H_{max}" is the maximum diversity index, "P_i" is the ratio of landscape plaque type "*i*", and "*m*" is the landscape type.

- Fragmentation index (*Eq. 4*)

$$LFI = \sum N_i / \sum A_i \quad \text{(Eq.4)}$$

In the formula,, "*LEI*" is the fragmentation index, "N_i" is the number of plaques in class "*i*", and "A_i" is the total area of class "*i*".

The method of ecological environment evaluation

- Build an evaluation system

Referring to the "Technical Specifications for Eco-environmental Status Assessment" (HJ 192-2015) (Ministry of Ecological and Environment of the People's Republic of China, 2016), published in 2015 by the Ministry of environmental protection, and combined the geographical features of the three lake basins, the evaluation indexes were selected according to the principles of objectivity, comprehensiveness, evaluability, independence and hierarchy. Then the Analytic Hierarchy Process (AHP) was used to determine the degree of association between the adjacent level evaluation indexes in the structural model. For indexes that belong to the same level, the above-mentioned index elements are the criteria. We constructed the pairwise judgment matrix by "1-9 scale method", compared the importance of the evaluation indicators, and calculated the relative weight values until it passed the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_56935704
© 2018, ALÖKI Kft., Budapest, Hungary

consistency check (CR < 0.1000). Because the selection of each index is extensive and the directions of the indicators are inconsistent, in order to eliminate the influence of the unit of measure, dimension and magnitude differences on the evaluation results, and make the indexes comparable and in the same direction, the linear data is used for non-dimensional treatment of the initial data (*Eqs. 5* and *6*). The evaluation indicator system for the ecological environment of the three lake basins is shown in *Table 1,* and the classification criteria for the evaluation results are shown in *Table 2*.

Index dimensionless processing formula:

$$Y = \frac{X}{X_{\max}} \text{ (Positive indicators)} \quad \text{(Eq.5)}$$

$$Y = \frac{X_{\min}}{X} \text{ (Negative indicators)} \quad \text{(Eq.6)}$$

In the formula, "X" is the original value of a certain evaluation factor, "X_{max} "is the maximum value of a parameter, and "X_{min}" is the minimum value of a parameter.

Table 1. *Evaluation index system of ecological environment in three lake basins*

Target layer	Rule layer	Direction	Weight	Index layer	Weight
Ecological environment quality index (EI)	Biological abundance index (A1)	Positive	0.1589	Arable land ratio (A11)	0.1799
				Forestland area ratio (A12)	0.2965
				Grassland area ratio (A13)	0.2965
				Construction land area ratio (A14)	0.0700
				Wetland area ratio (A15)	0.1112
				Unused area ratio (A16)	0.0460
	Vegetation coverage index (A2)	Positive	0.1589	Forestland area ratio (A21)	0.5695
				Grassland area ratio (A22)	0.3331
				Arable land ratio (A23)	0.0974
	Water network density index (A3)	Positive	0.0967	Water resources/Total area (A31)	0.4934
				Wetland area/ Total area (A32)	0.3108
				The length of the river/Total area (A33)	0.1958
	Soil erosion index (A4)	Negative	0.2409	Severe erosion area ratio (A41)	0.6370
				Moderate erosion area ratio (A42)	0.2583
				Slight erosion area ratio (A43)	0.1047
	Pollution load index (A5)	Negative	0.3447	COD/Total annual precipitation in the region (A51)	0.3000
				NH3—N/Total annual precipitation in the region (A52)	0.3000
				SO2/Total area (A53)	0.3000
				Solid waste emissions/Total area (A54)	0.1000

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

Table 2. *Classification criteria for evaluation results of ecological environment*

Level	Index	Status
Excellent	EI ≥ 0.75	Vegetation coverage, biodiversity, and ecological conditions are the best
Good	0.55 ≤ EI < 0.75	Vegetation coverage, biodiversity, and ecological environment are better
General	0.35 ≤ EI < 0.55	Vegetation coverage, biodiversity, and ecological conditions are normal
Poor	0.20 ≤ EI 〈 0.35	The vegetation coverage is poor, with severe drought and less rain, fewer species, and poor ecological environment
Worst	EI < 0.20	Ecological environment and its bad conditions

- Establish a comprehensive evaluation model

Individual indicators include biological abundance index, vegetation coverage index, water network density index, soil erosion index, and pollution load index, which are the composite of different basic indicators of each criterion level. Every single index reflects ecological environmental quality from different aspects, and the calculation of the single index adopted the method of the multi-factor linear weighting function, the calculation formula is as follows (*Eq. 7*):

$$B_i = \sum_{j=1}^{n} Gj * Wj \quad \text{(Eq.7)}$$

In the formula, "B_i" is every single index,, "G_j" is the index score corresponding to each specific evaluation index, and "W_j" is the weight of corresponding evaluation index.

The single-item index evaluated the priority of ecological environment quality in a certain aspect, and a comprehensive evaluation must be conducted to fully reveal. The formula is as follows (*Eq. 8*):

$$B = \sum_{i=1}^{n} Bi * Wi \quad \text{(Eq.8)}$$

In the formula, "B" is the total evaluation score, "B_i" *(i = 1, 2, 3)* is the individual index, "W_i" is the weight corresponding to the basic indicators of each criterion level, the standard value of each indicator is weighted and averaged on a layer-by-layer basis to obtain a composite index.

Results

Through remote sensing image interpretation, land use remote sensing classification maps of three lake basins were obtained (*Fig. 2*), and landscape pattern index is shown in *Table 3*.

Table 3. *Land use landscape pattern index of three lake basins*

Basins	Diversity index	Evenness index	Dominance index	Fragmentation index
Dianchi Basin	1.2966	0.6663	0.6493	0.1780
Erhai Basin	1.3569	0.6973	0.5890	0.0616
Fuxian Lake Basin	1.3852	0.7119	0.5607	0.1167

© 2018, ALÖKI Kft., Budapest, Hungary

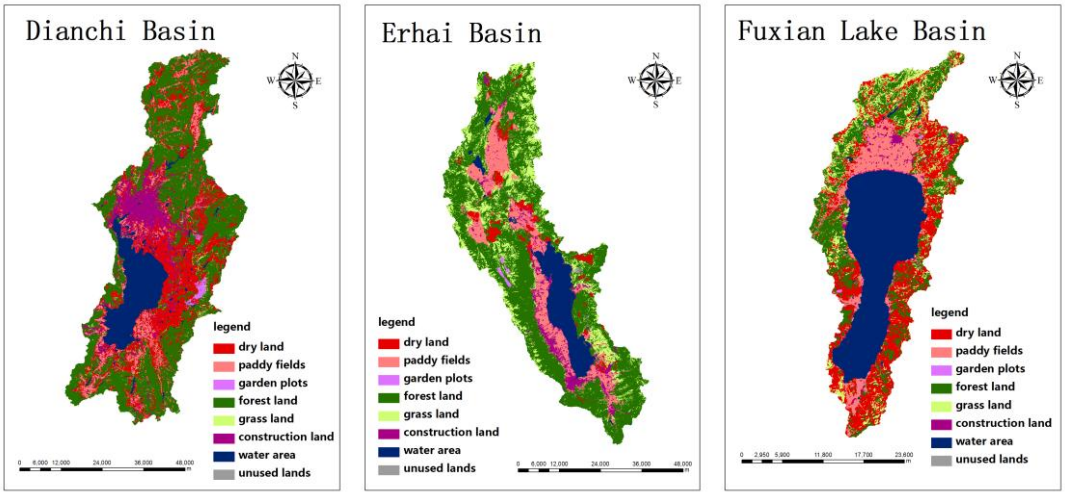

Figure 2. *Classification map of land use in the three major lake basins*

Analysis of landscape pattern characteristics of land use

According to *Table 3,* the landscape pattern of the three lake basins was analyzed horizontally horizontally, that is, the different indexes of the same basin were analyzed, and the results were as follows:

(1) In Dianchi Basin, the diversity index and evenness index were the smallest, while the dominant index and fragmentation index were the largest, indicating that the diversity of landscape structure of land use in Dianchi Basin was the worst, the landscape types were unevenly distributed, and the degree of landscape fragmentation was the most serious;

(2) In addition to the lowest fragmentation index in the Erhai Basin, the diversity, evenness, and fragmentation index are all in the middle level and are closer to the Fuxian Lake Basin. Therefore, overall, the diversity of land use landscape structure in the basin is relatively good. The type distribution is more uniform, and the landscape type is divided into smaller segments with the best connectivity.

(3) The diversity index and evenness index of the Fuxian Lake Basin are the largest, the dominance index is the lowest, and the fragmentation index is at the intermediate level. Based on the comprehensive analysis, the land use landscape structure of the basin is the simplest, and the level of human disturbance is the lowest.

The landscape pattern of the three major lake basins was analyzed longitudinally, that is, the same index of different watersheds is analyzed. The results are as follows:

(1) The order of diversity index which is Fuxian Lake Basin > Erhai Basin > Dianchi Basin, 1.3852, 1.3569, and 1.2966, respectively. The diversity of landscape structure of land use in Dianchi Basin was the lowest, the landscape diversity was poor, and the coordination of various landscape types was low. The diversity of landscape structure of land use in Fuxian Lake Basin was the highest, and the diversity of landscape was well maintained. The degree of coordination is high; the diversity of the Erhai Basin is between the two.

(2) The ranking of evenness index which is Fuxian Lake Basin > Erhai Basin > Dianchi Basin, which is 0.7119, 0.6973, and 0.6663, respectively. The dominance index ranking is Dianchi Basin > Erhai Basin > Fuxian Lake Basin, which are 0.6493, 0.5890,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_56935704
© 2018, ALÖKI Kft., Budapest, Hungary

and 0.5607, respectively. It showed that the balance of land use landscape structure in Dianchi Basin is poor, and the distribution of land use types is uneven. This is mainly due to the fact that the proportion of forest land and cultivated land in the basin is large, which greatly improves the dominance of the overall landscape. The balance of land use structure in the Fuxian Lake Basin is relatively good, with a balanced distribution across the regions; the landscape evenness in the Erhai Basin is located between the two.

(3) Fragmentation index ranking which is Dianchi Lake Basin > Fuxian Lake Basin > Erhai Lake Basin, which is 0.1780, 0.1167, and 0.0616, respectively. The result showed that the landscape pattern of land use in Dianchi Basin has the highest degree of fragmentation, and the landscape is the most severely fragmented. This is mainly because the Dianchi Basin is located in a karst landscape area and the degree of rocky desertification is relatively deep, resulting in serious landscape fragmentation; The higher degree of fragmentation of land-use landscape structures in the Fuxian Lake Basin is because the basin is located in the central part of the central basin of the central Yunnan basin and the watershed of the Zhujiang River system. The surrounding area is mostly eroded by fault blocks, and the terrain is undulating, scattered and distributed on both sides of the lake. There are 61 sub-watersheds, and special geological conditions have caused great fragmentation of the terrain of the Fuxian Lake Basin. The fragmentation of land use landscape structures in the Erhai Basin is the lowest.

The evaluation results of the ecological environment of the three lake basins

According to *Table 4,* the "*EI*" indexes of the Dianchi Basin, the Erhai Basin, and the Fuxian Lake Basin are 0.5628, 0.7274, and 0.7413, respectively. They are all between 0.55 and 0.75. It showed that the three lake basins have good vegetation coverage, good biodiversity, and good ecological environment.

Table 4. *Evaluation results of ecological environment in the three lake basins*

Evaluation index	Dianchi Basin	Erhai Basin	Fuxian Lake Basin
Biological abundance index (A1)	0.7431	1.0000	0.9624
Vegetation coverage index (A2)	0.6811	1.0000	0.6010
Water network density index (A3)	0.1608	0.1519	1.0000
Soil erosion index (A4)	1.0000	0.9345	0.2135
Pollution load index (A5)	0.2322	0.4926	1.0000
Ecological environment quality index (EI)	0.5628	0.7274	0.7413

Comparative analysis showed that the "*EI*" index is the lowest in the Dianchi Basin, and the ecological environment is the worst in the three lake basins. The "*EI*" index of Erhai Basin is slightly lower than that of Fuxian Lake Basin, which is larger than the Dianchi Basin, and its ecological environment is better than that of the Dianchi Basin, which is slightly inferior to Fuxian Lake Basin. The "*EI*" index is the highest in Fuxian Lake Basin, and the ecological environment is better than the other two lake basins.

Comprehensive analysis of the landscape pattern of land use and eco-environment characteristics

The comprehensive analysis was made on the landscape pattern index of land use and ecological environment index in the three lake basins. The Dianchi Basin landscape

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_56935704
© 2018, ALÖKI Kft., Budapest, Hungary

diversity index and evenness index were the smallest, while the dominance index and fragmentation index were the largest, the ecological environment index was the smallest, and the fragmentation degree of the Erhai Basin was the smallest. In addition to the lowest fragmentation index in the Erhai Basin, the other indices are all in the middle level. The landscape diversity index and evenness index of the Fuxian Lake Basin are the largest, the dominance index is the smallest, the fragmentation index is small, and the ecological environment index is the largest (*Fig. 3*).

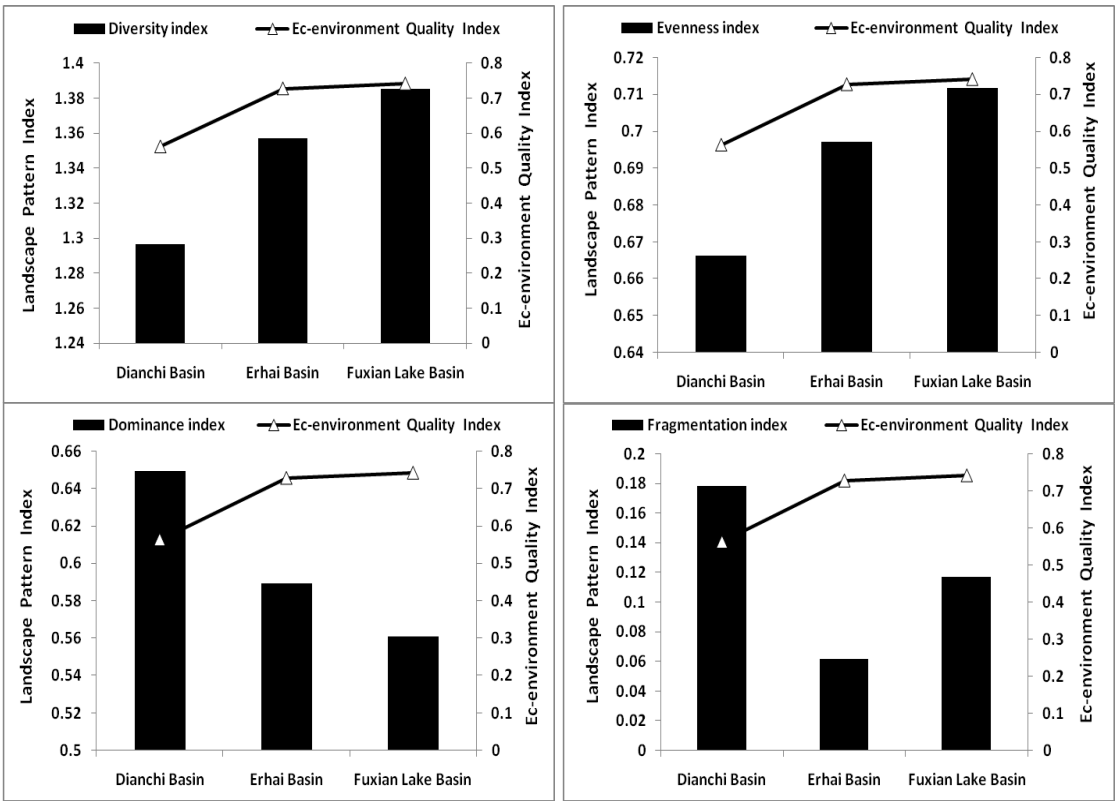

Figure 3. *Landscape pattern index and eco-environment quality index of land use in the three major lake basins*

Through comparison, it is found that the landscape patterns of land use in the three lake basins are closely related to the status of the ecological environment, and the landscape diversity and evenness of the basins with good ecological environment quality are relatively high, and the degree of landscape fragmentation is relatively low. On the contrary, in the basin with poor ecological environment, the degree of diversity and evenness of landscape is relatively low, and the degree of landscape fragmentation is relatively high.

Based on the analysis of the socio-economic development level of the three lake basins, the landscape pattern of land use and eco-environment characteristics of the three lake basins are related to the socio-economic development level of the lake basins. The Dianchi Basin with the highest level of economic development has the lowest landscape diversity. The distribution of landscape types is the lowest, the degree of landscape segmentation is the highest, and the quality of ecological environment is the lowest. The degree of landscape diversity and landscape types in the Erhai Basin and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_56935704
© 2018, ALÖKI Kft., Budapest, Hungary

Fuxian Lake Basin with a lower level of economic development are relatively evenly distributed. The degree of landscape fragmentation is relatively low, and the quality of ecological environment is the best.

Discussion

At present, there are many researches on the landscape pattern of land use, and the results are relatively fruitful, but mainly based on the study of landscape patterns in different phases of the same study area, and the lateral contrast analysis between different regions of the same time phase is less, most of them take city, county and other areas as the research scale, and few studies take plateau lake basin as the object. This study conducted a comparative analysis on the landscape pattern of land use and eco-environment characteristics among different plateau lake basins in Yunnan Province of China, which can provide scientific basis for optimizing the landscape pattern of land use and protecting the ecological environment. Because the factors affecting regional landscape pattern of land use and ecological environment quality are complex, involving natural conditions such as climate, topography, vegetation, hydrology, and socio-economic factors such as population and economic level, this study is only a brief description from the macro aspect, the next step will focus on the driving factors that affect the landscape pattern and the ecological environment of different basins, so as to make the research more perfect and scientific.

Conclusion

(1) From the analysis of the land use landscape pattern of the lake basins, the degree of landscape diversity and the degree of evenness are the highest in the Fuxian Lake Basin, followed by the Erhai Basin, and the lowest is the Dianchi Basin; the fragmentation of the landscape is highest in the Dianchi Basin and followed by the Fuxian Lake Basin. The lowest is the Erhai Basin.

(2) According to the results of the ecological environmental quality assessment, Dianchi Basin is the worst, while the Erhai Basin and Fuxian Lake Basin are better, and the Fuxian Lake Basin is the best.

(3) The landscape pattern of land use in the basin is closely related to the quality of the ecological environment. Basins with good ecological environment quality have a relatively high degree of diversity and evenness, and relatively low fragmentation; in the basins with poor ecological environment, the degree of landscape evenness and diversity are relatively low, and the degree of landscape fragmentation is relatively high.

The landscape pattern of land use is closely related to the ecological environment, unreasonable land use is one of the important factors of lake pollution, therefore, the relationship between land use and lake water quality should be further explored on the basis of this study, so as to better alleviate the pollution and improve the ecological environment of the lake basins from the perspective of land use.

Abstract. A novel, rapid low-density solvent based dispersive liquid-liquid microextraction has been developed for extraction and preconcentration of silver nanoparticles (AgNPs) prior to flame atomic absorption spectrometry analysis. In this study, water samples were first treated with acetonitrile/water (80:20, v/v) which was then utilized as disperser solvent in the dispersive liquid-liquid microextraction process along with using 1-octanol as extractant. An enrichment factor of 57 is obtained, and the recoveries of AgNPs spiked into environmental samples are in the range of 96.7 to 108%. A low limit of detection (LOD) of 6.5 μg/L is achieved using flame atomic absorption spectrometry (FAAS) for quantification. The relative standard deviation (RSD) is 2.1% (n = 9). This proposed method provides an efficient approach for the analysis and tracking of AgNPs in the environmental water samples.

Introduction

Metallic nanoparticles are of high importance in current materials research, with potential applications in biomedicine, energy conversion, imaging, or as pigments (Khaligh et al., 2015; Hartmann et al., 2013). Engineered nanomaterials (NMs) have already yielded a variety of commercially available products including cosmetics, antimicrobials, suntan lotions, paints, stain-resistant clothing and remediation products (Mirzaei et al., 2013). The rapid growth in the commercial use of AgNPs will inevitably increase silver exposure to the general population (Ghaedi et al., 2013). AgNPs may penetrate the skin (Ghaedi et al., 2015) via textile or wound dressing contact, be inhaled from some spray medicine, or ingress into the female genital tract by incorporation into female hygienic products or medical implants (Habila et al., 2015), and it is also toxic to human cells (Altunay et al., 2015; Fan et al., 2012; Choi et al., 2011). Therefore, it is important from an analytical point of view to develop sensitive and economical methods for determination of trace silver nanoparticles.

Because of the complexity of the matrices and trace amounts of metal ions residues in practical samples, sample preparation is necessary and often plays a vital role in the overall analytical scheme (Lambropoulou et al., 2007). In the past few years, a diversity of extraction methods, including liquid-liquid extraction (LLE) (Fernández-Gutiérrez et al., 1998), stir bar

© 2018, ALÖKI Kft., Budapest, Hungary

sorptive extraction (SBSE) (Van et al., 2007), solid-phase micro extraction (SPME) (Beltran et al., 2003) and solid-phase extraction (SPE) (Gil-García et al., 2006), have been developed for sample preparation. A wide range of applications hitherto bears testimony to the fact that they are portable and effective for sample preparation. However, for most of these methods, considerable time and organic solvent are needed for analytes to be extracted into the organic phase or onto the sorbent. In order to increase the throughput for sample pretreatment, the development of time saving and high efficient microextraction techniques has drawn much attention (Ding et al., 2013).

Dispersive liquid-liquid microextraction (DLLME) has been brought up as an exciting microextraction technique in 2006 (Yu et al., 2014; El-Shahawi et al., 2013; Rezaee et al., 2006). In this procedure, a mixture of high density organic solvent (serving as extraction solvent) and water miscible polar dispersive solvent (dispersive solvent) is rapidly injected into an aqueous sample to form an emulsion consisting of fine droplets of the extraction solvent, dispersive solvent, and water. Due to the extraction solvent being highly dispersed in the aqueous phase, the surface area between extraction solvent and sample solution is infinitely large, thus speeding up the extraction. While, the main disadvantage of DLLME is that the extraction solvent is generally limited to solvents with higher density than water in order to be sedimented by centrifugation, typically chlorinated solvents such as chlorobenzene, chloroform, and tetrachloromethane, all of them are potentially toxic to humans and the environment. To date, CPE has already successfully been applied for the quantification of Au-NPs in water samples in combination with electrothermal atomic absorption spectrometry (ET-ASS) (Hartmann et al., 2013). However, ET-AAS measurement, which background absorption signal is large, the relative sensitivity and sample in homogeneity more serious, analytical precision is poor.

In this study, the possibility of AgNPs enrichment by DLLME was considered. A new microextraction method combined with flame atomic absorption spectrometry (FAAS) was developed for separation, enrichment and determination of AgNPs in environmental waters. Factors affecting the extraction efficiency, such as pH, concentration of extractant, extraction time, and nature of the extractant were studied and optimized.

Materials and methods

Materials

All chemicals used were analytical grade or better and all solutions were prepared in deionized water. 1-hexanol, 1-heptanol, 1-octanol, 1-nonanol, 1-decanol and decanoic acid were obtained from the Aladdin Reagent Corporation (Shanghai, China). Tannic acid, sodium carbonate , Ammonium sulfate , hydrochloric acid, silver nitrate, ethanol and sodium thiosulphate, all purchased from (Aladdin, China).

Equipment

A pHSJ-4A pH meter (Shanghai, China), vortex agitator (Shanghai, China) and SK5210LHC ultrasonic instrument (Shanghai, China), centrifuge (Shanghai, China) and flame atomic absorption spectrometer (AA6300, Shimadzu, Japan) were used.

Synthesis of AgNPs nanoparticle

Preparation of $AgNO_3$ solution and tannic acid solution, 0.100 mol/L Na_2CO_3 solution with deionized water; amount of 200 mL tannic acid solution at three mouth bottle

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_57055714
© 2018, ALÖKI Kft., Budapest, Hungary

thermostatic water bath heating, and stirring; adding 5 mL Na_2CO_3 solution to tannin reduction; after 10 min, A certain amount of volume $AgNO_3$ solution, with the constant pressure drop funnel the dropwise added to the above mixture. Three mouth bottle solution color from colorless to light yellow gradually, orange, red, and finally turned a deep red or red brown, continue stirring heating 30 min, obtained the AgNPs. The AgNPs concentration of the solution was determined by FAAS.

Extraction procedure

DLLME of AgNPs step

A 4 mL AgNPs sample solution placed in 10 mL long tapered glass centrifuge tube was adjusted to pH 3.0 with diluted HCl, and then 40 μL of 1 M $Na_2S_2O_3$ and 80 μL of 1-octanol (as extraction solvent of DLLME) were added to the acetonitrile/water (80:20, v/v) extract (used as disperser solvent) and the mixture was diluted to 40 mL by deionized water in a 50 mL vial with conical bottom. Then, the tube was sealed and swirled on a vortex agitator at 2000 rpm for 30 s to accelerate the formation of the fine droplets of the extraction solvent and to enhance the transfer of the analytes. The supernatant aqueous phase can then easily be removed by decanting. The droplet was dissolved in 2 mL of ethanol and transferred to FAAS measurement.

Results and discussion

Optimization of the DLLME conditions

Parameters that commonly affect the DLLME efficiency, such as sample pH, the type and volume of extraction solvent, salt content, equilibration time were investigated.

pH plays an important role on metal chelate formation and subsequent extraction. To optimize the extraction conditions for the nanoparticles pH was varied between 1 and 7 using hydrochloric acid for pH adjustment while the other experimental variables remained constant. The highest extraction efficiency was achieved at pH 3.0 (*Fig. 1*) while the replicate times n = 6. So, pH 3.0 was selected as the optimum for further experiments.

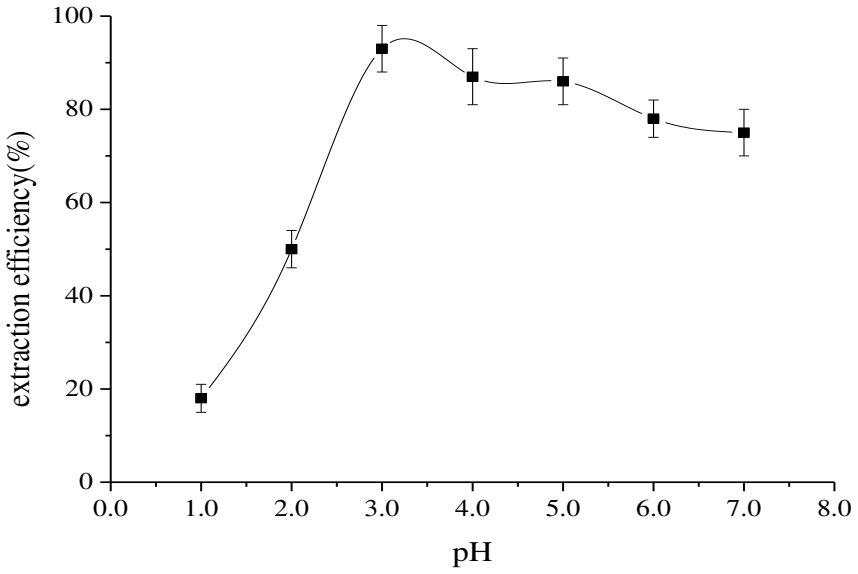

Figure 1. *Effect of pH on DLLME of AgNPs*

Selection of the disperser solvent

The applicability of several organic solvents including MeOH, MeCN, EtOH, MeOH 80% and MeCN 80% was investigated in the preliminary experiments taking into account that they should be used as primary extracts of the analytes from real water samples must then act as disperser solvent in DLLME process. *Figure 2* shows the recoveries of the whole procedure of all extraction solvents tested. The results revealed that the maximum extraction efficiency was achieved by MeCN/water (80:20 v/v).

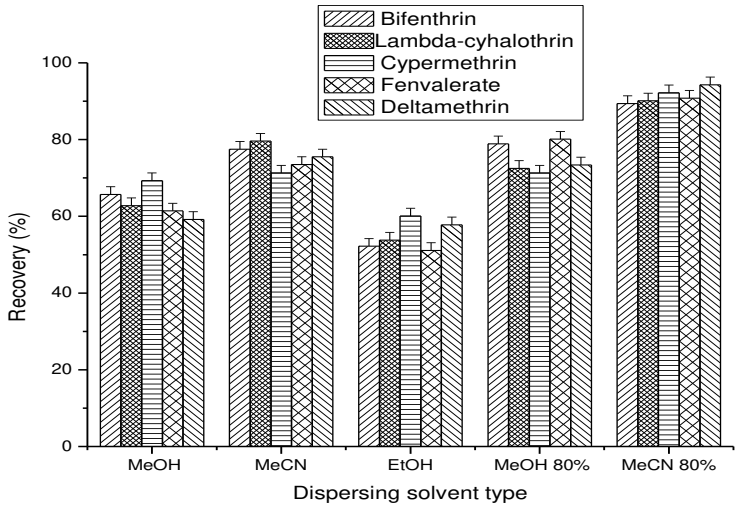

Figure 2. *Effect of dispersing solvent*

To study the volume effect of disperser solvent, it was varied from 4 to 12 mL in the interval of 2 mL while extraction solvent was kept at 80 µL. The obtained results showed that the extraction efficiency increased with increasing the volume of MeCN 80% up to 10 mL and then dropped down slightly above 10 mL due to the increased solubility of AgNPs in the aqueous phase and decreasing the distribution ratio.

Therefore 10 mL MeCN 80% was selected as both the extraction solvent of AgNPs from environmental samples and as disperser solvent in DLLME for subsequent experiments.

In this study $Na_2S_2O_3$ as a masking reagent to cover the interference of Ag^+. When $Na_2S_2O_3$ was added, thiosulfate ions and silver ions generated thiosulfate (*Fig. 3*), which is soluble in water. Therefore, silver ions can be eliminated to the detection of AgNPs.

$$Na_2S_2O_3 + 2Ag^+ = 2Na^+ + Ag_2S_2O_3\downarrow$$

$$Ag_2S_2O_3 + 2Na_2S_2O_3 = Ag_2Na_4(S_2O_3)_3$$

Figure 3. *The reaction of sodium thiosulfate with* Ag^+

Selection of extraction solvent

Selection of appropriate extraction solvent is of great importance in microextraction technique in order to obtain efficient extraction. For the LDS-DLLME, the extraction

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_57055714
© 2018, ALÖKI Kft., Budapest, Hungary

solvent should meet the following requirements: (1) be immiscible with aqueous solution (2) able to extract the analytes, and (3) possess low toxicity. To avoid the use of more highly toxic solvents such as trichloromethane, tetrachloromethane, tetrachloroethylene, chlorobenzene etc., five low density organic alcohol including 1-hexanol (density, d = 0.819 g mL^{-1}), 1-heptanol (d = 0.820 g mL^{-1}), 1-octanol (d = 0.821 g mL^{-1}), 1-nonanol (d = 0.827 g mL^{-1}), and 1-decanol (d = 0.828 g mL^{-1}) were evaluated as extractants. Among them a stable cloudy solution and good extraction recovery were observed with 1-octanol. The fine droplets of 1-octanol afford larger surface area to contact with the water sample and can be completely absorbed by MNPs after magnetic separation, so that higher extraction performance can be attained. As can be seen, 1-octanol has higher extraction recovery than those obtained by other extraction solvents for the AgNPs.

Effect of extraction solvent volume

The volume of extracting solvent is an important parameter which can influence the occurrence of the cloudy state and efficiency of extraction process. To investigate the volume effect of 1-octanol, different quantities of 1-octanol (50-100 μL) were used. Observably, too little 1-octanol may lead to low recoveries and the extraction efficiency was improved with the increase of 1-octanol volume. As shown in *Figure 4,* the recoveries for each of the AgNPs increased from 55-63% to 86.8-109.1% in the range of 50-80 μL of 1-octanol. The highest recovery was obtained when 80 μL of 1-octanol was used for the extraction. Therefore, the volume of 80 μL of 1-octanol was selected as an optimum solvent volume for further studies.

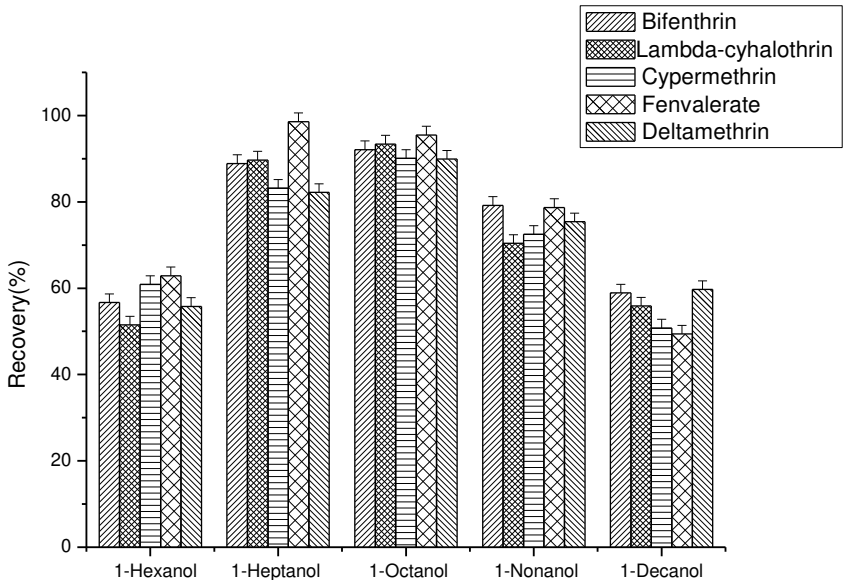

Figure 4. *Selection of extraction solvent*

Effect of equilibration time

In DLLME extraction, equilibration time is defined as an interval time from the occurrence of cloudy solution and before addition of magnetic adsorbents. The effect of extraction time on the adsorption was investigated from 0-120 s. The result showed that

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_57055714
© 2018, ALÖKI Kft., Budapest, Hungary

equilibration time has no influence on extraction efficiency. It is well-known that vortex process is an effective way to enhance mass transfer from aqueous phase to the extraction phase. Consequently, short time was required for extraction. Generally, 30 s of extraction time was enough to achieve high extraction recovery, and prolonged extraction time did not contribute significantly to an increase in extraction recovery. Thereby, vortex time of 30 s was selected.

The high viscosity of the so prepared surfactant rich phase made it necessary to dissolve the sample prior to sample introduction to FAAS. Ethanol appeared to be a feasible solvent since it readily dissolves the surfactant rich phase and it prevents degradation of the enriched nanoparticles.

Evaluation of the preservation of the nanoparticle size distribution

To gain an insight in the size distribution of the nanoparticles in real samples it is necessary to know whether the size distribution of Ag-NPs is changing during the extraction procedure or not. This was studied using TEM for imaging of the particles before and after DLLME. As shown in *Figure 5,* the size of particles that underwent the extraction process is more or less identical to the size before DLLME treatment. Thereby we conclude that the size distribution is not affected by the presented method. This supports the results of Yang et al. (2017) that studied CPE for metal nanoparticles. This finding is especially important because the size determination of nanoparticles is an important issue in current research. DLLME samples of Ag-NPs can therefore be used for size determination after pre-concentration.

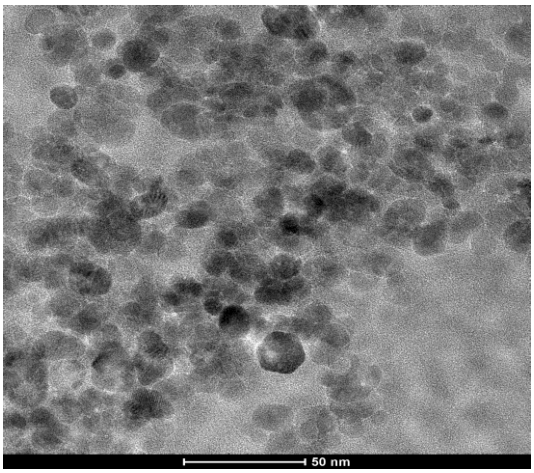

Figure 5. *TEM images of synthesized AgNPs*

Analytical features

The analytical characteristics of the method were evaluated under the optimum experimental conditions (*Table 1*). The enrichment factor (EF), relative standard deviations (RSD) and limits of detection (LOD) are effective factors to evaluate a developed analytical method. With the optimized system, the calibration graph of AgNPs was linear in the range of 10-1000 μg/L. The calibration equation is $A = 7.9 \times 10^{-2}$ C + 0.003 with a correlation coefficient of 0.9999, where A is the absorbance and C is the Ag concentration in μg/L. The detection limits, defined as the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_57055714
© 2018, ALÖKI Kft., Budapest, Hungary

concentration equivalent to three times the standard deviation of the reagent blank, for AgNPs was 6.5 μg/L. The relative standard deviation for AgNPs was 2.1% (n = 9). The relative recoveries of AgNPs in water samples at the spiking level of 3-20 μg/L ranged from 96.7 to 108%. There are many reasons, such as instrument fluctuations, operating errors, etc., so the calibration curve will appear quantitative. Recovery rates of 80% to 120% are generally considered normal. The enhancement factor, defined as the ratio of slope of preconcentrated samples to that obtained without preconcentration, was 57 for AgNPs.

Table 1. *Analytical characteristics of the method*

Parameter	Analytical feature
Linear range (μg/L)	10-1000
R^2	0.9999
Limit of detection (μg/L)	6.5
RSD (%) (n = 9)	2.1
Enrichment factor	57
Pre-concentration time (min)	<10
Recovery (%)	96.7-108.0

Effect of foreign ions

To regard of the high sensitivity of FAAS, the interference connected with the DLLME procedure was studied. Due to cations may react with AgNPs and lead to the decrease of extraction efficiency.10 mL sample solution containing Ag^+ and other ions were prepared and treated with the developed procedure. The tolerance limit was defined as the foreign ion concentration causing a change in the absorbance of less than ±5%. *Table 2* shows the concentration of the interferential ions, the recovery is tolerable.

Table 2. *Effects of the matrix ions on the recoveries of the examined metal ions*

Ions	Concentration (ug/L)	Recovery (%)	
		Pd	Ag
Na^+	10×10^3	105.0	104.1
K^+	10×10^3	104.2	104.8
Cl^-	10×10^3	103.5	102.2
Ca^{2+}	10	99.1	101.1

Analysis of real samples

To further evaluate the applicability of the proposed method, real environmental water samples were analyzed and the recoveries were determined by spiking 3-20 μg/L AgNPs. The WWTP water sample was obtained from our laboratory (Bijie, China), the river water sample from LiuCang Qiao River (Bijie, China). As shown in *Table 3,* the obtained recoveries of AgNPs were in the range of 96.7-108%, which was satisfactory with regard to the low spiking level. No significant difference between recoveries for samples with or without filtration was observed, suggesting that the presence of natural particles in the samples had no significant effects on the DLLME of AgNPs at concentrations 20 μg/L. This result indicates that FAAS can be adopted to identify and quantify the AgNPs content in environmental samples.

Table 3. *Determination and identification of AgNPs in environmental waters by the proposed method*

Sample	AgNPs added (μg/L)	AgNPs found (μg/L)	Recovery (%)
River water	0	*ND	–
	5	4.9±0.3	98.0±0.6
	10	10.8±0.5	108.0±5.0
	20	20.5±0.6	102.5±3.0

Conclusion

In the present study, a new microextraction technique, based on dispersive liquid-liquid microextraction (DLLME) was developed for determining AgNPs in environmental water samples. $Na_2S_2O_3$ was added into the extraction system as a masking reagent of Ag^+ to prevent its extraction into the 1-octanol rich phase. The extraction could be achieved within 2 min and good extraction efficiencies were obtained. Such facile separation is essential to improve the operation efficiency which avoiding time-consuming centrifugation or freezing or manual collection of extractant.

In addition, there are many reasons, such as instrument fluctuations, operating errors, etc., so the calibration curve will appear quantitative. Recovery rates of 80% to 120% are generally considered normal. The type of sample and matrix does not affect the detection of AgNPs. This proposed method provided a simple approach for quantification of AgNPs in environmental water samples.

(Received 22nd Jun 2018; accepted 9th Aug 2018)

Abstract. The world's non-renewable energy resources continually decline and therefore there is an urgent need to seek and use any available renewable energy sources. An alternative to conventional fuels can be the usage of plant biomass for energy purposes. This particularly relates to plants with C4 photosynthesis, a large increase in biomass, low habitat requirements, and high resistance to diseases and pests. All these characteristics are met, among others, by switchgrass which in many countries occurs as a common wild plant. In agricultural production, switchgrass does not pose many agronomic problems; moreover, it is a very durable plant that can be used in one stand for even 10 years and can be grown in all soils, even contaminated ones. Effective use of switchgrass for bioethanol, biogas or syngas production provides measurable ecological benefits and in the long term offers a chance to maintain a sustainable national energy balance, given the continuously shrinking non-renewable fuel resources. Due to the multifaceted use of this plant and a number of features important from the point of view of the power generation industry, it is worth having a closer look at the possibility of spreading the cultivation of this species.
Keywords: *Panicum virgatum, cropping, biomass, combustion and co-firing, biofuels*

Introduction

Switchgrass (*Panicum virgatum* L.) belongs to the *Poaceae* family. It is native to North America where it occurs naturally from the Atlantic coast to the Rocky Mountains within the area between 55°N (southern Canada) and 30°N (northern Mexico) (Lewandowski et al., 2003; Wullschleger et al., 2010). This is a perennial grass with erect stems, often with a reddish tinge, and a height from 0.5 to 2.7 m. The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

inflorescence is a branched panicle with a length from 15 to 50 cm. Switchgrass has a very well-developed root system that reaches a depth of even 3 meters (Moser and Vogel, 1995; Christian and Elbersen, 1998; Vogel et al., 2011; Kibet et al., 2016). It is a species with C4 photosynthesis (Hatch-Slack cycle) and due to this it can carry out this process even four times more efficiently compared to C3 type plants (Gołaszewski, 2011; Wang et al., 2012).

Due to the different morphological characteristics and habitat preferences, two ecotypes of this species are distinguished: the lowland ecotype and the upland ecotype (Bals et al., 2010; Casler, 2012; Young et al., 2012). Lowland ecotypes reach a height of more than 3 m, usually grow in clumps in wetland areas, and have thick stiff stems with a large number of branches. Upland ecotypes are shorter, occur in dry areas, have thinner stems with a lower number of branches compared to lowland switchgrass, and form characteristic sods; they are more recommended for growing in a cooler climate (Christensen and Koppenjan, 2010; Casler, 2012).

The first attempts to grow switchgrass began in the 30s and 40s of the 20th century in the USA where many switchgrass cultivars have been bred, including several cultivars also adapted to European climatic conditions: 'Cave-in-Rock', 'Kanlow', and 'Alamo' (McLaughlin and Kszos, 2005). In the United States, this species is recommended for sodding in degraded areas and is grown as an erosion prevention plant. Moreover, switchgrass has the ability to clean soils and waters by removing excess nutrients (N, P) originating, among others, from fertilization. Switchgrass filter strips decrease the amount of reactive phosphorus and reduce the chemical oxygen demand (COD) in surface runoff water, which protects surface waters against eutrophication (Sanderson and Adler, 2008). Switchgrass is used for phytoremediation because it exhibits the capacity to accumulate toxic substances from soils, in particular heavy metals and residues of crop protection chemicals (Chen et al., 2012; Zorer Çelebi and Zorer, 2018). The capacity of switchgrass for significant soil carbon sequestration contributes to a reduction in total environmental CO_2 balance (Liebig et al., 2008; Adkins et al., 2016). This plant is also an excellent growth and living habitat for wildfowl and mammals, in particular in the so-called ecotone zones between forest and crop fields. It is also a very impressive and beautiful ornamental grass sown in gardens and parks (Dudkiewicz and Bolibok, 2011; Elbersen et al., 2013).

At the beginning of the 90s of the last century, an attempt was also made to use switchgrass as an energy crop. The U.S. Department of Energy, among others, conducted research on the use of biomass of this species for energy purposes. Also in Europe, switchgrass arouses an increasingly greater interest as a productive and durable 'energy' species resistant to adverse environmental conditions (Bals et al., 2010; Sanderson and Adler, 2008; Wullschleger et al., 2010). Due to the multifaceted use of this plant and a number of features important from the point of view of the power generation industry, it is worth having a closer look at the possibility of introducing and spreading the cultivation of this species (Bocian et al., 2010; Pszczółkowski et al., 2012).

Plantation establishment and management

Sowing of switchgrass

Switchgrass seeds are very small (depending on the cultivar, 500-1000 seeds·g^{-1}) and characterized by very short viability and low germination capacity. The field emergence

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_57155743
© 2018, ALÖKI Kft., Budapest, Hungary

rate is about 50% (Schmer et al., 2006). To increase their germination capacity, switchgrass seeds should be stratified by subjecting them to low temperatures or NaClO. The recommended seeding depth is from 0.5 to 2.0 cm (Sanderson et al., 2012). In wet areas, it is recommended to grow switchgrass with a row spacing of 60-90 cm, while in dry areas 90-120 cm (Majtkowski, 2006). It has been shown that switchgrass germinates better and besides the growth of seedlings is more intensive after application of selected strains of Cyanobacteria, which have the ability to fix atmospheric nitrogen, as a biofertilizer (Chojnacka et al., 2010). Switchgrass is not resistant to low temperatures and this is why it should be sown in areas with mild winters. Its seeds sprout best in a soil with a pH ranging 6-8 (Hanson and Johnson, 2005).

The field under switchgrass should be very carefully prepared. Switchgrass can be sown in no-till or conventional cultivation practices. No-till allows you to set up switchgrass plantations on fields with a large slope and in areas with low rainfall (Drinnon et al., 2014; Sadeghpour et al., 2014b). Moreover, according to Ashworth et al. (2015) intercropping selected legumes in switchgrass may enhance forage quality and yield, reduce fertilizer costs, and emissions/runoff to air and groundwater.

Plantation evaluation in terms of emergence

The first evaluation of the condition of a plantation is conducted after 6-10 weeks from the date of its establishment. At this time, the number of seedlings per 1 m^2 should be from 100 to 200. The second evaluation of the condition of the plantation is made at the end of the first growing season. To conclude that the plantation has been successfully established, there should be 10-30 plants per m^2 (Douglas et al., 2009). Due to intensive tillering, plants growing at a lower density in the first year will produce a larger number of stems in the next years.

Weed control

One of the major factors that ensure optimal growth and development of switchgrass intended for energy production is to eliminate or at least reduce weed infestation of a plantation, mainly in the first year (Miesel et al., 2012). The slow growth rate of switchgrass (during the first month) and the late time of its sowing (the second decade of April and the beginning of May) promote weed competition. The greatest noxiousness of weeds is observed during the period from emergence to the 8-10-leaf stage of switchgrass (Boydston et al., 2010; Anderson et al., 2014).

Switchgrass badly bears cutting (especially in the first year of cultivation) and damage that can occur during mechanical weed control treatments and therefore mechanical and physical methods are not recommended in switchgrass cultivation. Chemical weed control in switchgrass crops is limited by the small range of agents recommended for use in non-agricultural crops used for energy purposes. The effect of such weed control is partial, since predominantly the annual (mono- and dicotyledonous) species are well destroyed, whereas the perennial deep-rooted species are poorly destroyed and in the next year (during the plant establishment period) they reappear, very frequently with double intensity. Furthermore, inappropriately selected herbicides can produce the following adverse effects: decreased field germination capacity, damage of switchgrass plants, and their reduced biomass (Sekutowski et al., 2009; Boydston et al., 2010; Anderson et al., 2014). A year before the establishment of a switchgrass plantation, it is recommended to use different herbicides that contain in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_57155743
© 2018, ALÖKI Kft., Budapest, Hungary

their composition mainly glyphosate (following Smeets et al., 2009). According to Bullard and Metcalfe (2001), the optimal rate of glyphosate in switchgrass cultivation is 2.5 $kg \cdot ha^{-1}$. To control dicotyledonous weeds, herbicides with bentazon and 2,4-D can also be used (Samson, 2007; Christensen and Koppenjan, 2010; Scordia et al., 2015). In the professional literature, there is little information and few recommendations concerning weed management in switchgrass plantations using foliar herbicides. The present author's research conducted since 2008 shows that it is possible to use selectively and safely various foliar herbicides recommended for use in cereal, maize or green crops (*Table 1*).

Table 1. *Exemplary active substances of herbicides used in the cultivation of switchgrass. (Own results not published)*

Active substance	Application date	F		Weed management	
		I	II	Monocotyledons	Dicotyledonous
Iodosulfuron-methyl-sodium; Mesosulfuron-methyl	T-3	2-3 (CH)	1-2	+	+
Thifensulfuron methyl; Chlorsulfuron	T-3	2 (CH)	1	+	+
MCPA	T-3	1	1	-	+
2,4-D; Dicamba	T-3	1	1	-	+
Clopyralid; Fluroxypyr; Triclopyr	T-3	1	1	-	+

F – phytotoxicity – sensitivity to the active substance of the herbicide in a 1-9 scale, where: 1 – no effect on switchgrass, 9 – complete destruction of switchgrass; I – 7 days after application of the active substance of the herbicide; II – 28 days after application of the active substance of the herbicide; CH – leaf chlorosis; T-3 – 3-5 switchgrass leaves

Switchgrass insects

Switchgrass is genetically varied and generally resistant to many insects and hence pests usually do not pose a problem in growing switchgrass. Damage caused by insects can be much greater when switchgrass monocultures are grown on large production fields (Sanderson et al., 2012). The most common insects found were Coleoptera, Hemiptera, Diptera and Hymenoptera (Parrish and Fike, 2005; Holguin, 2010).

In the northern states of the USA, Prasifka et al. (2010) recorded the occurrence of *Blastobasis repartella* on a wildly growing switchgrass. Larvae of this moth feed on young tillers of switchgrass. In South Dakota (USA) Boe and Gagne (2011) discovered on switchgrass new species of gall midge. Sometimes plantations of switchgrass can be damaged by grasshoppers and crickets (*Orthoptera*) (Parrish and Fike, 2005; Branson et al., 2006; Holguin, 2010).

Management of pests in grasses involves mainly chemical control. With high pest incidence, insecticides based on malathion and carbaryl, insect growth regulators and pyrethroids are used (Holguin, 2010).

Switchgrass diseases

In wet locations, switchgrass can be infected by fungal diseases, but lowland types are more resistant to rust than upland ones. Especially young plantations can be sometimes attacked by various diseases (Vogel et al., 2011; Uppalapati et al., 2013).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_57155743
© 2018, ALÖKI Kft., Budapest, Hungary

Rust is the biggest problem in growing switchgrass. Two species of rust fungi, *Uromyces graminicola* and *Puccinia emaculata*, are known to infect switchgrass (Gustafson et al., 2003; Zale et al., 2008; Sanderson et al., 2012; Uppalapati et al., 2013). Rust can be controlled by fungicides, however, some of them negatively affect the quality of the raw material obtained. Hagan and Akridge (2013) achieved the best results by applying azoxystrobin and myclobutanil. A very good way to protect the plantation against rust is also the cultivation of varieties resistant to these pathogens (Gustafson et al., 2003).

Switchgrass may also be attacked by diseases such as: anthracnose (*Colletotricum navitas*), smuts (*Tilletia maclaganii*), Phoma leaf spot (*Phoma spp.*), and *Fursarium* root rot (*Fusarium spp.*), sharp eyespot (*Rhizoctonia cerealis*), leaf spot (*Colletotrichum graminicola*), bunt (*Tilletia pulcherrima*), spot blotch and root rot (*Bipolaris spicifera*) (Vogel, 2004; Carris et al., 2008; Crouch et al., 2010; Vu et al., 2011). In Iowa (USA) Thomsen et al. (2008) estimated yield losses from *Tilletia maclaganii* of 2-40% in switchgrass fields. Leaf spot is caused by fungi from the genus *Bipolaris*. This disease reduces seed germination and yield of switchgrass biomass, particularly if a susceptible cultivar is seeded over a wide area. Control measures against leaf spots include developing resistant cultivars and fungicidal seed treatments (Krupinsky et al., 2004). According to research of Steward et al. (2015) viral diseases raised by Panicum mosaic virus and its satellite virus should be considered important pathogens of switchgrass and serious potential threats to biofuel crop production efficiency.

Fertilization

Switchgrass does not have high soil requirements. Even though it prefers soils with a neutral pH, but it also grows well in slightly acidic and alkaline soils. It can be grown on light or medium cohesive, moderately salinated and agriculturally unsuitable soils (Evanylo et al., 2005; Kabała et al., 2010; Quinn et al., 2015).

Switchgrass is characterized by low nutrient requirement. Bullard and Metcalfe (2001) think that NPK fertilization should be used at the stage of plantation establishment and the fertilizer rates proposed by them are as follows: 80 kg NH_4NO_3 (28 kg $N \cdot ha^{-1}$), 40 kg P_2O_5 (17.5 kg $P \cdot ha^{-1}$), and 60 kg K_2O (49.8 kg $K \cdot ha^{-1}$). Sokhansanj et al. (2009) as well as Christensen and Koppenjan (2010) claim that in the first year of plantation nitrogen fertilizers are not recommended to be applied because weeds characterized by higher biomass increase could suppress the slowly growing young seedlings of switchgrass. Over the plantation lifetime, nitrogen fertilizers are applied to increase biomass yield, but the need to use phosphorus and potassium is determined by the content of these nutrients in the soil (Sanderson et al., 1996; McLaughlin et al., 2002). Nitrogen fertilization also has a beneficial effect on the content of lignin in biomass (Withers, 2010). According to Samson (2007), nitrogen fertilization at a rate of 50-60 kg $N \cdot ha^{-1}$ is appropriate to obtain optimal biomass production in switchgrass, whereas higher rates may reduce its yield. The nitrogen rate that will positively affect switchgrass yield depends on many factors, among others, climatic conditions and the productivity of switchgrass cultivars (An et al., 2018). Thus, in some studies yields have been observed to increase at higher nitrogen rates than those applied by Samson (2007). For example, based on the literature data Gunderson et al. (2008) report that lowland and upland ecotypes reach the maximum yield under nitrogen fertilization at rates of 90 and 100 $kg \cdot ha^{-1}$, respectively. Kering et al. (2012), Giannoulis et al. (2016) and Alexopoulou et al. (2017), on the other hand, observed an

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_57155743
© 2018, ALÖKI Kft., Budapest, Hungary

increase in switchgrass biomass production at a nitrogen doses of 135 kg·ha^{-1} and 80, 160, 240 kg·ha^{-1} and 75, 150 kg·ha^{-1}, respectively. Nitrogen rate should be adjusted depending on the level of this nutrient in the soil (Mitchell et al., 2014). In planning nitrogen fertilization, biomass harvest date should also be taken into account (Miesel et al., 2017). If harvest is to be carried out after the end of the growing season (the first ground frost), the applied nitrogen rate should be lower than in the case of an earlier harvest date (Mitchell et al., 2016). Generally, moderate nitrogen rates under particular soil conditions are entirely sufficient and allow high switchgrass yields to be obtained (Thomason et al., 2004).

Switchgrass is characterized by efficient use of both potassium and phosphorus. Information can be found in the literature which shows that these two elements have effect on biomass yield quantity and quality but also information which proves that they can do not affect the yield of switchgrass. The effect of using K and P fertilizers on the yield of switchgrass depends on the content of these macroelements in the soil. In general, on soils with a deficiency of N and P, switchgrass reacts positively to fertilization of K or P. However, this beneficial effect is not observed on soils that are rich in K and P (Muir et al., 2001; Kering et al., 2012; Shield et al., 2012; Kering et al., 2013). Some studies indicate that the use of multi-ingredient fertilizer increases the yield of switchgrass. Ameen et al. (2018) showed that the fertilizer mixture of N, P, and K (NPK) caused increase in biomass yield of switchgrass compared with the PK, NK, and NP treatments. Mohammed et al. (2015) showed that mixture fertilizer NPK significantly increased biomass yield of switchgrass (by 49%) compared to the control treatment. In turn, calcium fertilizers should only be used when the soil pH is below 5 (Bates et al., 2008).

Good results were obtained using organic cattle manure (CM) and poultry litter (PL) fertilizers on the switchgrass. It was found that these fertilizers increased biomass yield significantly to the extent of 30 and 23% compared with combined chemical fertilizer (12.9 Mg·ha^{-1}) (Mohammed et al., 2015).

Biomass yield and harvest

In the first and second year of cultivation, biomass productivity reaches from 33 to 66% of the maximum production level (McLaughlin and Kszos, 2005). It is only in the 3rd year of plant growth that the biomass production reaches 100% productivity on light soils, whereas on heavy soils this occurs 2-3 years later. Due to this, in the first year switchgrass is usually not harvested, nor is animal grazing recommended, in particular in plantations established in a cooler climate (Christensen and Koppenjan, 2010). From the year in which the optimal productivity is reached, in properly managed switchgrass plantations yields can be maintained at a constant high level for more than 10 next years (Mitchell et al., 2008, 2016; Monti et al., 2009a; Sokhansanj et al., 2009).

The annual switchgrass yield is from several to over a dozen Mg of dry matter (DM) per hectare, though it may exceed 20 Mg DM·ha^{-1} and even more than 30 Mg DM·ha^{-1}, depending on environmental and agronomic factors as well as the cultivar, ecotype and plantation age (Gunderson et al., 2008; Smeets et al., 2009; Hattori and Morita, 2010). Generally, lowland species are characterized by higher yields than upland cultivars. A review of literature data by Heaton et al. (2004) shows that the average annual yield is 10 Mg DM·ha^{-1}. In Poland, the average yield of switchgrass grown on a light soil in the area of Wrocław in the period 2004-2006 was 7.16 Mg DM·ha^{-1} (Dradrach et al., 2007).

© 2018, ALÖKI Kft., Budapest, Hungary

Switchgrass productivity is significantly dependent on the amount of rainfall during the growing season and is higher on well-irrigated soils (Kimura et al., 2015).

Harvest date and frequency depend on climatic and soil conditions, switchgrass ecotype and the future use of biomass harvested (Casler and Boeb, 2003; Jiang et al., 2014). Potentially, switchgrass can be harvested once or several times during the growing season or once after the end of the growing season. In the case of several harvests, a larger amount of nutrients, in particular nitrogen, is removed with the yield (Prieto et al., 2017; Wang et al., 2018). For this reason, plantation operating costs increase due to the need to replenish soil nitrogen at higher nitrogen fertilizer rates. Moreover, each successive harvest requires equipment for biomass cutting and transport, which generates additional economic costs (Christensen and Koppenjan, 2010). A single harvest during the growing season (e.g. in the middle of August or at the turn of summer and autumn) allows a high biomass yield to be obtained (Vogel et al., 2002; Lemus et al., 2008). A late autumn harvest gives a relatively high yield, but the productivity can be lower by 10-20% compared to an earlier harvest (Vogel et al., 2002). But a frequent harvest adversely affects the condition of plants and plantation longevity (Fike et al., 2006; Lee et al., 2014b). It should be stressed that after the end of the growing season nutrients from the aboveground parts of switchgrass plants are transported to the roots (Anderson et al., 2013; Lindsey et al., 2013; Wayman et al., 2014). That is why a single harvest after the end of the growing season is more appropriate in the context of good overwintering of the rhizome (following Mitchell and Schmer, 2012). A spring harvest (before plant growth begins) causes the lowest losses in reserve nutrients (Adler et al., 2006; Samson, 2007; Guretzky et al., 2011; Gamble et al., 2015), but the yield harvested during this period is lower than the yield obtained from an autumn harvest (Adler et al., 2006; Cherney et al., 2018). Yield losses result, among others, from dry and brittle leaves of switchgrass plants being blown away by strong winds. Most frequently, the harvest is carried out once a year, though in the case of upland ecotypes grown in a warmer climate a high yield is also obtained with two biomass harvests per year (Fike et al., 2006).

The harvest is carried out using one-stage technology (simultaneous cutting and grounding) or two-stage technology (first the cutting operation, then grounding). It should be indicated that the grounding operation is important when switchgrass biomass is used for energy purposes. In the case of biomass to be burned or subjected to thermochemical conversion, low moisture, ash, nitrogen, potassium and chlorine contents are also of major importance (Lindsey et al., 2013; Liu et al., 2014; Sadeghpour et al., 2014a; Gorlitsky et al., 2015). It is essential that the values of these parameters are lowest in spring-harvested biomass (*Table 2*) (Adler et al., 2006; Zegada-Lizarazu et al., 2010; Lee et al., 2014b; Cherney et al., 2018). During the summer period, the plant water content is about 70%, at the end of autumn it decreases to about 40% (following Sokhansanj et al., 2009), while in spring-harvested biomass it can be from several to over a dozen percent (Adler et al., 2006; Samson, 2007; Sadeghpour et al., 2014a). It is worth mentioning that a low plant water content facilitates harvest as well as storage and pelletization of the material harvested. But biomass with a water content of > 20% can be stored only for a short time and its drying is costly (Sokhansanj et al., 2009). Harvest at a later time seems to be less favorable when the biomass will be subjected to enzymatic hydrolysis (bioethanol production) because the biomass harvested during this time contains more lignin which hinders this

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

process (Lindsey et al., 2013; Aurangzaib et al., 2016; Serapiglia et al., 2017). However, this component increases the energy value of biomass (Williams et al., 2016).

Table 2. *The ash and selected elements content in switchgrass depending on the harvest date. (Adler et al., 2006)*

Harvest date	Ash	N	K	Cl
	% dry matter			
	Experience plots

Spring	2.26	0.40	0.07	0.01

Switchgrass is harvested using conventional farming equipment. It is mowed at a height of 10-15 cm from soil surface and the cut biomass is baled into round or rectangular bales that are stored in a dry place isolated from the ground. To reduce storage losses, biomass with a moisture content > 18% should be field dried before it is baled (Garland, 2008; Monti et al., 2009b; following Mitchell and Schmer, 2012).

The use of biomass for energy purposes

The growing problem of greenhouse emissions and the increasing demand for energy have enhanced the interest in energy sources alternative to fossil fuels. Biomass is an appropriate energy source that can provide in a short time transportation fuels such as biodiesel and bioethanol. Bioethanol is one of the most known biofuels that can be a substitute for petrol (Alvira et al., 2010). The possibility of using first generation bioethanol, produced from maize, wheat, sugar beet, sugar cane, etc., has been studied thus far (Bai et al., 2010). Nevertheless, the production of biofuels from food raw materials arouses a lot of controversy and therefore second-generation biofuels are used, which are produced from lignocellulosic substrates (e.g. switchgrass, straw). Switchgrass biomass can be converted to useful energy by direct combustion or during the production of liquid (bioethanol) and gaseous biofuels (syngas, biogas) (Sanderson et al., 2006; Alvira et al., 2010; Schmer et al., 2014).

Combustion and co-firing of switchgrass

Switchgrass biomass can be used in the burning process as a stand-alone fuel or can be co-fired with coal. However, the use of switchgrass as the only source of fuel or in a mixture with coal in high capacity power plants is not common or economically beneficial. This is due to slagging and contamination of the combustion systems (Karlsson et al., 2015). The reason for this adverse phenomenon is the presence of potassium, calcium, magnesium, chlorine and silicon in biomass in amounts larger than in coal (Qin et al., 2006; Antunes and de Oliveira, 2013). The higher the potassium and sodium content, the lower the biomass ash melting point and as a result of this the greater the slagging and the boiler corrosion. Gaseous chlorine and hydrogen chloride are the main corrosion factors of power boilers, but the action of HCl on boiler metal

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_57155743
© 2018, ALÖKI Kft., Budapest, Hungary

jest less dangerous than that of Cl_2. Chlorides, especially potassium and sodium chlorides, released during biomass burning condense on the surface of the boilers and superheater tubes. Then, in a reaction of the chlorides with iron oxides present in the deposits or SO_2 that occurs in flue gas, chlorine and hydrogen chloride are formed, respectively. The solid products of these reactions, on the other hand, are melted into a glassy viscous layer that captures non-volatile elements (Ca, Si and Mg) from which silicates are formed with lower melting points than in the case of chlorides, which increases the risk of corrosion (Hardy et al., 2009; Kumar et al., 2017).

The effectiveness of switchgrass biomass burning is also dependent on ash and moisture content. The composition and calorific value of switchgrass are shown in *Table 3*. A relatively high ash content in switchgrass is due to the higher proportion of leaves, which can contain 3 times more ash than the stems, in the biomass of this plant (*Table 4*) (Madakadze et al., 1999; Hu et al., 2010; Vamvuka et al., 2010). Ash reduces the calorific value of biomass. A high moisture content of biomass also results in a reduced calorific value and this content should not be more than 23% (Lewandowski and Kicherer, 1997). In the biomass burning process, nitrogen content is also important, since it affects NO_x emissions (Elbersen, 2001). According to Lewandowski and Kicherer (1997), the nitrogen content in dry matter should be < 10 $g \cdot kg^{-1}$ DM (dry matter).

Table 3. *The composition and calorific value of the biomass of switchgrass*

Research shows that burning switchgrass biomass mixed with coal can bring ecological benefits, such as reduced emissions of some atmospheric pollutants and an increase in biomass heating rate during this process (Kumar et al., 2017). Switchgrass and coal can be co-fired in pulverized coal-fired boilers (which are commonly used in Polish power plants and combined heat and power plants) as well as in fluidized beds. Co-firing in pulverized coal-fired boilers requires the biomass to be converted into a homogeneous material with a grindability similar to that of coal. This is due to the fact that the co-firing process is preceded by biofuel grinding in coal mills, which are structurally unsuitable for co-milling of coal with raw biomass (Zuwała et al., 2014). During the combustion of a coal and biomass mixture in fluidized beds, on the other

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

hand, pollutants are deposited on the coils of the secondary superheaters of the boiler which hinder its operation (Hycnar, 2006). It should be added that the risk of chloride corrosion in the co-firing process is not high if the percentage of biomass in the fuel stream does not exceed 10% (Hardy et al., 2009).

Bioethanol production from switchgrass

Switchgrass is considered a good substrate to produce bioethanol because of its biomass yield, high carbohydrate content, good adaptation to various soil and climate conditions, and low agricultural requirements for its production. Preferred ecotypes for bioenergy applications is lowland ecotypes. This is due to the fact that the biomass yield is higher compared to lowland ecotypes (Dien et al., 2013). In studies Dien et al. (2013) the higher content of carbohydrate occurred in upland ecotype and increased with harvest maturity.

The process of bioethanol production is based on the fermentation of monosaccharides (pentoses and hexoses) that are formed as a result of enzymatic hydrolysis of the polysaccharides (cellulose and hemicelluloses) contained in switchgrass biomass. Cellulose and hemicelluloses, together with lignin, are the major components of the lignocellulose polymer which is not very susceptible to enzymatic hydrolysis due to its complex structure (Lee et al., 2014a; Williams et al., 2016; Zabed et al., 2017). In the lignocellulosic complex, lignin is the most difficult to hydrolyze, mainly due to the presence of carbon-carbon bonds and ether-type bonds in its structure, while the hemicelluloses are relatively easiest to hydrolyze. Moreover, the lignin and hemicelluloses surrounding the microfibers of the cellulose effectively impede the degradation of this polysaccharide by the cellulosic enzymes (Waramit et al., 2011; Umezawa, 2018).

Individual varieties of switchgrass differ in the content of carbohydrates and their individual fractions. Studies on biomass composition of five switchgrass genotypes, selected from twenty-two as the best yielding, were carried out by Min et al. (2017). Biomass composition was analyzed for total carbohydrate polymers (glucan + xylan + arabinan), total lignin (acid-soluble lignin + acid-insoluble lignin) and total extractives (water-soluble extractives + ethanol-soluble extractives) contents. The SWG 2007-2 genotype switchgrass had the highest amount of total carbohydrate polymers and the lowest amount of total lignin; therefore, this genotype is the most promising switchgrass line for the bioconversion to produce biofuel through sugar platform route. On the other hand high ratio of [water soluble carbohydrates + starch + cellulose]:hemicellulose showed that biomass of switchgrass stems and whole aboveground part (2.39 and 2.40) could be highly valuable feedstock for liquid biofuel production (Butkutė et al., 2013).

Thus, to reduce the resistance of lignocellulose and its fractions (in particular cellulose and lignin) to enzymatic action, the biomass structure and chemical composition should be changed (Rijal et al., 2012). These effects can be achieved through biomass pretreatment using the following methods: mechanical (grinding, milling), chemical (decomposition using acids (H_2SO_4, HCl) and bases (NaOH, KOH, $Ca(OH)_2$) as well as ammonium and ozone), thermal (in which steam heating, for example, is used), and also biological (the use of microorganisms to degrade or digest the cellulose and lignin) (Xu et al., 2011; Larsen et al., 2012; Karp et al., 2015; Loow et al., 2016; Sharma et al., 2016; Chen et al., 2018; Rajendran et al., 2018). Acid hydrolysis or base hydrolysis is relatively cheap and commonly used methods of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

chemical biomass pretreatment. The study of Rijal et al. (2012) showed the beneficial effect of acid or base pretreatment as well as of grinding and heating in a pellet mill on the efficiency of enzymatic hydrolysis of switchgrass biomass.

The process that follows pretreatment is enzymatic hydrolysis designed to convert the cellulose and hemicelluloses to fermenting sugars, which include glucose and xylose. This method uses the complexes of three enzymes (cellulases and hemicellulases) which are produced by microorganisms and which have a synergistic effect during the hydrolysis of cellulose (endo-β-1,4-glucanases, exo-β-1,4-glucanases, and β-glucosidase) and hemicelluloses (endo-β-1,4-xylanases, exo-β-1,4-xylanases and β-xylosidase). These polysaccharides are hydrolyzed to monosaccharides. The glucose derived from the hydrolysis is usually subjected to fermentation using strains of the yeast *Saccharomyces cerevisiae* and the bacterium *Zymomonas mobilis*. But xylose is converted by other yeasts, such as *Pachysolen tannophilus, Candida shehatae,* and *Pichia stipitis* (following Zabed et al., 2017). However, problems have been noted with the use of xylose-fermenting yeasts due to their low tolerance to ethanol, slow fermentation rate and difficulties with adjusting the reaction conditions (Keshwani and Cheng, 2009). Therefore, strains of bacteria such as *Escherichia coli* and *Zymomonas mobilis* have been modified in recent years using genetic engineering. Nevertheless, the fermentation capacity of these strains is not sufficiently effective. Genetically modified strains of *Sacharomyces cerevisiae* are currently used in the process of biomass conversion to ethanol, which is common for xylose and glucose (Balan et al., 2012).

The results of studies on the efficiency of ethanol from switchgrass biomass, with reference to other biomass resources, using in process *Sachcaromyces cerevisiae* are presented by Guragain et al. (2014) (*Table 5*).

Table 5. *Ethanol production at shake flask level using fermentation of biomass hydrolyzed using S. cerevisiae. (Guragain et al., 2014)*

Type of biomass	Ethanol yield ($g \cdot g^{-1}$ glucose consumed)	Productivity ($g \cdot l^{-1} \cdot h^{-1}$)	Ethanol yield ($g \cdot g^{-1}$ pretreated biomass)	Ethanol yield ($g \cdot g^{-1}$ raw biomass)
Switchgrass	0.492 ± 0.003	2.17 ± 0.039	0.16 ± 0.0029	0.10 ± 0.003
Wheat straw	0.492 ± 0.003	2.87 ± 0.003	0.22 ± 0.0002	0.12 ± 0.003
Miscanthus	0.489 ± 0.007	2.27 ± 0.030	0.17 ± 0.0022	0.10 ± 0.001
Sorghum bagasse	0.494 ± 0.005	2.80 ± 0.081	0.21 ± 0.0061	0.13 ± 0.003

Productivity was measured for 15 h of fermentation at 30 °C and expressed as gram of ethanol produced per liter per hour

The yeast *Saccharomyces cerevisieae* only ferment hexoses and are not able to use pentoses contained in biomass. Therefore, other microorganisms that do not have this negative trait are used for the fermentation of sugars and are competitive to *S. cerevisa* strains in terms of the amount of ethanol produced (Kurylenko et al., 2014). Abdullahi et al. (2017) studied the effect of N fertilization and acidic switchgrass biomass hydrolysis on ethanol yield. Pre-treatment was carried out with HCl (concentrations of 3, 4 and 5%). *Saccharomyces cerevisiae* and Gram-negative *Zymomonas mobilis* were used in the fermentation process. The microorganisms were used singly and in combination. The beneficial effects of nitrogen doses of 50 and 75 kg $N \cdot ha^{-1}$ and treatment with 4% acid on the content of reducing sugars in the hydrolyzate were found.

The most ethanol was obtained when the hydrolyzate was fermented using the combination of *Saccharomyces cerevisiae* and *Zymomonas mobilis*.

Hydrothermal pretreatment is recommended for grass biomass (Alvira et al., 2010; Kim et al., 2011). As a result of the hydrothermal degradation of lignocellulosic biomass, liquid and solid fractions containing useful bioproducts of the depolymerisation of complex sugars can be obtained. Kim et al. (2011) showed that the content of glucose and xylose in switchgrass biomass processed by hydrothermolysis was higher than after the following pre-treatment methods: AFEX (ammonia fiber exolosion), SAA (soaking aqueous ammonia), lime and dilute sulfuric acid. According to Suryawati et al. (2009) temperature 200 °C and time10 min are the best conditions for the hydrothermolysis of switchgrass. Under these conditions, Suryawati et al. (2008) reported an increase in glucan content from 36.6 to 56.6% (dry basis) and a reduction in the xylan content from 21.0 to 2.4% (dry basis) in the solid fraction of switchgrass.

The most problematic step in the biochemical method of obtaining ethanol is the hydrolysis. It is related to the fact that simple sugars which are the end products of enzymatic hydrolysis inhibit the activity of enzymes: cellulases and hemicellulases. For complete hydrolysis of lignocellulose polysaccharides, the sugars released should be directly (in the same tank) transformed by fermenting organisms into ethanol. It is possible in the process of simultaneous saccharification and fermentation (SSF process) (Kurylenko et al., 2014). Faga et al. (2010) conducted research on fermentation of switchgrass biomass using the SSF process. For the pretreatment of biomass, hydrothermolysis (water in the subcritical state, temperature 200 °C, holding time 10 min, 10% (w/w) solids loading) was applied. The following yeast strains were used for the fermentation: *Kluyveromyces marxianus* IMB 1, IMB 2, IMB 3, IMB 4 and IMB 5 (culture at 45 °C) and *Saccharomyces cerevisiae* D_5A (culture at 37 °C). The fermentation process was carried out for: 72 h (*K. marxianus* IMB 1, IMB 2, IMB 4 and IMB 5), 96 h (*K. marxianus* IMB 3) and 7 days (*S. cerevisiae* D_5A). The effect of buffer pH on bioethanol production by *S. cerevisiae* D_5A was also investigated. It was found that in 96 and 120 h of fermentation, the strains IMB 3 and *S. cerevisiae* D_5A were characterized by a higher yield of ethanol production in relation to other *K. marxianus* strains. In the final fermentation stage, the bioethanol production efficiency for IMB 3, IMB 1, IMB 5 strains was at a similar level, but lower than for IMB 3 and *S. cerevisiae*. With the lowering of the pH from 5.5 to 4.8, reduction of ethanol production by *S. cerevisiae* D_5A was observed. Research Sykes et al. (2016) indicate that ethanol efficiency method is significantly reduced by the use of biomass switchgrass infected with rust.

Bioethanol from switchgrass biomass can also be obtained without pre-treatment, which reduces the costs of the process. Chung et al. (2014) proposed the use of a genetically modified strain of *Caldicellulosiruptor bescii* for fermentation. Genetic modification consisted of among others on the introduction of a gene responsible for coding the enzyme allowing ethanol synthesis. A gene isolated from *Clostridium thermocellum* was used for this purpose. The degree of biomass processing using the *Caldicellulosiruptor bescii* recombinant was about 30% and 1.7 moles of ethanol was obtained from each one mole of glucose. Fu et al. (2011) and Yee et al. (2014) studied the production efficiency of bioethanol from biomass of genetically modified switchgrass. Transgenic switchgrass was characterized by a decreased expression of the COMT (Caffeic acid O-methyltransferase) gene, which is responsible for the coding of one of the key enzymes in the lignin biosynthetic pathway. As a result, with the use of

© 2018, ALÖKI Kft., Budapest, Hungary

Clostridium thermocellum, a greater production of bioethanol from transgenic switchgrass biomass in relation to unmodified biomass was obtained.

Ethanol yield from switchgrass biomass from field-scale production ranged from about 2300 to 3500 $L \cdot ha^{-1}$ in depends on biomass yielding (Schmer et al., 2008). Net Energy Yield (NEY) of this biofuel ranged from 50 to more than 75 $GJ \cdot ha^{-1}$. However the complex technological process of bioethanol production from lignocellulosic feedstocks involves significant costs. Moreover, the technology of producing liquid biofuels from this type of biomass has not been fully identified. In particular, the economic aspect is a barrier to the production of second generation biofuels being quickly spread. Energy inputs on the production and processing of switchgrass under the U.S. conditions are 50% higher than the energy generated from the ethanol produced from this crop (Pimentel and Patzel, 2005).

Conversion of switchgrass biomass to gaseous fuels

In spite of the continuous development of bioethanol production from woody feedstocks, the reaction costs are still high, while the variation in biomass composition requires the selection of appropriate hydrolyzing enzymes. Thus, more practical and less costly possibilities of using biomass are sought. One of them is the production of gaseous fuels (Boateng et al., 2006).

Biomass-derived gaseous fuels can be obtained using various processes, including among others: thermal process (gasification and pyrolysis (*Table 6*)) and biochemical: anaerobic digestion. The former one is high-temperature conversion of biomass to gaseous fuels under the influence of a gasifying agent. On the other hand, pyrolysis is a process that does not require access of external oxidizing and reducing agents and hence can be a stand-alone process or one of the stages of gasification or combustion (Piechocki et al., 2010). The pyrolysis products are: non-condensable gases (CO, CO_2, CH_4, and H_2), bio-oil (liquid) and bio-char (solid). Depending on the time of pyrolysis, the yield of these products varies. As a result of gasification synthesis gas (syngas) is produced, whose main components are as follows: H_2, N_2, H_2O, CH_4, CO and CO_2. The amount and composition of the synthesis gas varies depending on the conditions of the gasification process (Damartzis and Zabaniotou, 2011; Sarkar et al., 2014). Lower heating value (LHV) of gases which produced in gasification and pyrolysis of switchgrass biomass are respectively: 4 $MJ \cdot Nm^{-3}$ and 5.9 $MJ \cdot kg^{-1}$ (Elbersen, 2001).

Table 6. *Thermal conversion products of switchgrass biomass. (Elbersen, 2001)*

Product	Gasification	Pyrolysis
H_2	5%	-
CH_4	3%	5%
CO	11%	32%
Other	tar	Bio-oil, charcoal

Pyrolysis can be carried out in a reactor equipped with a mechanism that provides the flow and simultaneous mixing of the feedstock (e.g. a rotating drum reactor or a screw reactor). The syngas production efficiency is higher and the quality of syngas is better when biomass harvested at later dates is pyrolyzed (Boateng et al., 2006). Subsequently,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_57155743
© 2018, ALÖKI Kft., Budapest, Hungary

through catalytic conversion bioethanol can be obtained from the synthetic gas derived using this method.

In studies by Boateng et al. (2007) with the use of a fluidized-bed reactor, the bio-oil efficiency was over 60% by mass and the energy conversion efficiency was in the range of 52%-81%. He et al. (2009) studied the effect of feedstock moisture contents and pyrolysis temperature (T) on the yield and physicochemical properties of the obtained bio-oil. It was shown that under conditions: moisture of 10% and T = 450 °C, moisture of 15% and T = 550 °C, the obtained bio-oils were characterized by the best physical properties. In addition, experience has shown that by modifying only two parameters of the pyrolysis process, it is possible to significantly affect the efficiency and properties of the obtained biofuel.

According to Boateng et al. (2007), Bridgeman et al. (2007) and He et al. (2009) the chemical composition of bio-oil made from switchgrass is dominated by oxygen compounds, mainly acids, alcohols, ketones, phenols and furans. The mentioned compounds and the presence of water give the hydrophilic character of bio-oil, which limits its useful properties. It should be noted that the water must be separated if the bio-oil is used to produce fuels (Imam and Capareda, 2012). The aqueous phase contained in bio-oil is attempted to be used for the production of hydrogen by means of microbial electrolysis (Borole and Mielenz, 2011). The presence in char and bio-oil of mainly derivatives of phenols, furans and cyclopentanones was also reported by Pilon and Lavoie (2013), who studied the switchgrass pyrolysis at temperatures 300, 400 and 500 °C and in the atmosphere of two different gases: N_2 and CO_2. The studies also showed the variability of biochar and bio-oil shares as well as their calorific value as a function of temperature and type of inert gas. In the process conducted at 500 °C, less biochar was obtained than at temperatures of 300 and 400 °C in both N_2 and CO_2 environments. At 300 °C and in a CO_2 atmosphere the char content was higher than at this temperature in the N_2 environment. The calorific value of biochar at 300 °C and in the CO_2 atmosphere showed a lower calorific value than at the same temperature under the N_2 atmosphere (22.2 vs. 24.5 $MJ \cdot kg^{-1}$). In turn, the calorific value of bio-oil at the temperature of 300 and 400 °C was similar in both atmospheres (~15 $MJ \cdot kg^{-1}$) and at a temperature of 500 °C it was higher in the atmosphere of CO_2.

Research Mohamed et al. (2016) indicate that the use of catalysts in the pyrolysis process can improve the quality of bio-oil obtained from switchgrass biomass. The catalysts were used individually (K_3PO_4; clinoptilolite; activated carbon) and in a mixture (K_3PO_4 + clinoptilolite; K_3PO_4 + bentonite). It was found that bio-oils obtained in the presence of catalysts (K_3PO_4 (10, 20, 30 wt.%), clinoptilolite (20 wt.%), combinations (10 wt.% K_3PO_4 + 10 wt.% clinoptilolite, 10 wt.% K_3PO_4 + 10 wt.% bentonite, 10 wt.% K_3PO_4 + 10 wt.% bentonite) were characterized by lower water content and viscosity in relation to bio-oil obtained without the use of catalyst. The presence of catalysts also positively influenced the quality parameters of biochar, including composition, surface area and porosity. The variability of bio-oil properties (including viscosity, pH, calorific value) obtained from various tests makes it impossible to determine the appropriate quality standards, which in turn is a barrier to the use of this product on an industrial scale (He et al., 2009).

To gasify switchgrass biomass, fluidized bed boiler technology is most recommended, since fluidized bed boilers can use biofuels with a low volume density and a low ash melting point. In the process of switchgrass gasification using this technology, only light tar fractions are formed and boiler slagging does not occur.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_57155743
© 2018, ALÖKI Kft., Budapest, Hungary

However, a disadvantage of this gasification method is the high carbon content in ash (Elbersen, 2001).

Methods of pretreatment of biomass, ie torrefaction and densification, may lead to obtaining syngas with better properties. Torrefaction is a high-temperature drying process in which a solid fuel (biocarbon) with improved properties towards the raw biomass is obtained. The basic methods of biomass densification are: briquetting and pelleting. Densification increases the volume density of biomass, which increases its usefulness for energy purposes. Sarkar et al. (2014) studied switchgrass biomass gasification, which was pre-treated with torrefaction (at 230 and 270 °C), densification (pelleting) and combined treatment: torrefaction and densification. Gasification was carried out at 700, 800 and 900 °C. The oxidizing agent was air. An increase in H_2 and CO concentrations in the synthesis gas and its lower heating value (LHV) with increasing temperature was observed. The largest amounts of produced H_2 (0.03 $kg \cdot kg^{-1}$ biomass) and CO (0.72 $kg \cdot kg^{-1}$ biomass) showed synthesis gas (LHV = 5.08 $MJ \cdot m^{-3}$) obtained at 900 °C. This gas came from biomass gasification, which was subjected to a combined treatment.

Research Pasangulapati et al. (2012) indicate that the content of cellulose, hemicellulose and lignin in the switchgrass biomass affects the quality of gas obtained as a result of thermal conversion. According to the authors, higher content of cellulose and hemicellulose in relation to lignins results in a higher proportion of CO and CO_2 than CH_4 in the produced gas. Switchgrass and wheat straw in comparison to other biomass tested (eastern red cedar and dry distilled grains with solubles (DDGS)) were characterized by the highest efficiency of coal conversion: 94 and 95%, respectively. In the studies of Torreiero et al. (2018) biomass gasification process (*Nicotiana glauca, Panicum virgatum, Elytrigia elongata*) was tested. It was shown that the conversion efficiency of carbon from switchgrass biomass was the highest: 80% (oxidizing agent: air) and 91.3% (oxidizing agent: enriched air).

The syngas obtained from switchgrass biomass can be subjected to bacterial fermentation to produce bioethanol. For this purpose is best suited a syngas with a high content of carbon monoxide and hydrogen and small content of tar. Fermentation of syngas occurs with the use of anaerobic microorganisms, including from the genus *Clostridium*. According to Tanner (2008) the fermentation of syngas results in the production of 30% more bioethanol in relation to the biochemical conversion method using the same amount of biomass. Pardo-Planas et al. (2017) conducted simulation studies on the optimization of gasification of biomass with steam to a syngas rich in carbon monoxide and hydrogen. The paper analyzed the values of fuel-air equivalence ratio (ER) and molar ratio of steam to biomass (SBR) and the influence of their value on the quantity and percentage composition (CO and H_2 content) of the produced syngas. It was shown that in simulated conditions the efficiency of synthesis gas conversion to ethanol was 63.5%. According to the authors, the hybrid method, ie the combination of gasification with fermentation, is a promising method for producing bioethanol from switchgrass biomass.

Qian et al. (2013) studied the effect of biomass type (switchgrass, sorghum straw and red cedar) and fuel-air equivalence ratio ER (0.20, 0.25 and 0.28) on the physicochemical properties of char obtained as a result of gasification. It was shown that with the increase of the ER index, the following char parameters increased: Brunauer-Emmett-Teller (BET) surface area and ash content, while the content of moisture and fixed carbon decreased.

Gaseous fuel from switchgrass biomass can be also obtained in the biochemical conversion process: anaerobic digestion (AD). In this process, microorganisms participate, which under anaerobic conditions convert organic substances of the raw material into biogas. The main components of biogas are: methane and carbon dioxide. The usefulness of switchgrass biomass for biogas production results from its chemical composition. Especially some of switchgrass germplasm could be of interest for biogas producers: biomass of octoploid switchgrass ecotype No. 64 by chemical composition was similar to that of reed canary grass, which is characterized by high energy potential (Butkutė et al., 2013). It should be also noted that the solid fraction of post-fermentation residue can be used for the production of solid biofuels, which increases the energy and economic efficiency of the project (Czekała et al., 2018).

Anaerobic fermentation is a labile process whose normal course depends on many factors, including the content of lignins in the substrate. Lignins are resistant to biodegradation (hardly decomposed by methane bacteria) and therefore cause low methane production and reduce process efficiency. In order to use switchgrass biomass more efficiently for the synthesis of methane, pre-treatment is carried out by various methods: mechanical, chemical, thermal or biological (Rodriguez et al., 2017). These methods are similar to those used at the initial preparation stage for the production of bioethanol. Literature data demonstrate the effect of pre-treatment on the efficiency of methane production from switchgrass biomass (Frigon et al., 2012; Papa et al., 2015; Capecchi et al., 2016). Biological methods of pre-treatment, i.e. ensiling and the use of enzymes, are an alternative to physical and chemical methods due to the less onerousness for the environment. For the production of biogas to be possible throughout the year, the maintenance of switchgrass biomass is necessary. One of the treatments for the preservation of biomass is its ensiling (Bélanger et al., 2012). This process not only allows the biomass to be stored for a long period of time without loss, but also to ensure that physico-chemical composition remains unchanged during storage. The stability of the composition of switchgrass biomass is extremely important when it is used for the production of biogas (Herrmann et al., 2011). This composition, however, is altered due to side reactions, e.g. secondary fermentation, which may occur in the ensiling process. The production of silage is based on the metabolic processes of lactic acid bacteria. Therefore, in order to improve the stability of aerobic silage, it is recommended to use microbiological preparations containing strains of lactic acid bacteria. In view of the further use of ensiled biomass for the production of biogas, absolutely heterofermentative bacterial strains (eg, *Lactobacillus buchneri, Lactobacillus brevis*) are particularly useful (Liu et al., 2016). Under anaerobic conditions, the strains of these bacteria ferment simple sugars, both pentoses and hexoses, among others to lactic acid and acetic acid. Lactic acid is a biomass conservation factor in the ensiling process. Whereas, acetic acid is a component that methane bacteria use in the production of biomethane in methane fermentation. In order to obtain good quality silage, both bacterial and bacterial-enzymatic inoculum are used. Kupryś-Caruk (2017) investigated the effect of the addition of bacterial preparations Lactosil and 11CH4 on the quality of silage and biogas production, among others from switchgrass. Both preparations contained heterofermentative lactic acid bacteria and differed in the absence of homofermentative bacteria (11CH4). It was found that silages made with the addition of both Lactosil and 11CH4 were characterized by a higher content of lactic acid in relation to the control. The content of acetic acid was higher in silage with the addition of Lactosil, and the lower in silage with the preparation 11CH4 compared to silage

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_57155743
© 2018, ALÖKI Kft., Budapest, Hungary

made without the addition of these preparations. Significant more biogas was obtained from silage with the addition of 11CH4, which contained the least hemicelluloses and lignins. The problem of the effect of additives on the quality of silage and biogas yield was also investigated by Zhao et al. (2017). In the conducted experiment, the authors demonstrated a positive effect of the combined addition of the strain of *Lactobacillus brevis* and the xylanase enzyme on the volume of biogas production from switchgrass silage. The xylanase enzyme breaks down the lignocellulose hydrolytically into products that are used by the strain of *Lactobacillus brevis*. The use of this enzyme resulted in lowering the lignin content, which positively affected the quality of the obtained silage. Another way to optimize biogas production is to use mixed fermentation feeds, i.e. prepared on the basis of two types of substrates. One of the most common practices of this type is the mixing of plant biomass with manure. Due to the buffering properties of manure, the risk of lowering the pH in the fermenter and consequently stopping the fermentation process is reduced. Ahn et al. (2010) studied the effect of co-fermentation of manure with switchgrass silage on biogas yield in thermophilic conditions (55 °C). For mixture of switchgrass silage with swine manure, a 53% volatile solids reduction (VS) and a biogas yield of 0.373 L $CH_4 \cdot g^{-1}$VS were noted. However, for the other two mixtures (silage of switchgrass + dairy manure and silage of switchgrass + poultry manure) the reduction rates of VS and biogas yields were clearly lower: 9.3%, 0.028 L $CH_4 \cdot g^{-1}$VS and 20%, 0.002 L $CH_4 \cdot g^{-1}$VS, respectively. It should be noted that the higher share of ensiled biomass in the batch, the more acidification of the digester and the complete refraction of the process may occur. This is due to both the low pH of the silage and the production in the digester with the wrong composition and proportion of the substrate mixture of larger amounts of volatile fatty acids (VFA) (Thamsiriroj et al., 2012). In the studies of Ahn et al. (2010) high concentration of VFA was observed during fermentation of mixtures (silage of switchgrass + dairy manure and silage of switchgrass + poultry manure), which was maintained until the end of the process. The methane bacteria could not digest the accumulated acids, which led to acidification of the fermenter and a decrease in biomethane production capacity from these mixtures. For this reason, it is important to determine the right ratio of substrates used and to select the optimal initial loading of the digester with the charge of organic compounds. In addition, the content of dry matter in the digester, which has a significant influence on the yield of biogas, depends on the proportion of substrates in the mixture. Zheng et al. (2015) investigated the effect of various manure dairy farm to biomass relation to methane production in mesophilic conditions. The substrates were mixed in the following total solid ratios (TS): 4:0, 3:1, 2:2, 1:3 and 0:4. It was found that the co-digestion mixture with the ratio of 2:2 substrates showed the highest efficiency of methane production (158.6 mL $CH_4 \cdot g^{-1}$VS). In comparison to the monofermentation of manure and switchgrass, the increase in methane production was 74.5% and 18.3%, respectively.

Among vegetable raw materials, maize is most commonly used in biogas installations. Research of Barbanti et al. (2014) shows that the production capacity of methane from switchgrass biomass is lower (217 mL $CH_4 \cdot g^{-1}$VS) in relation to maize production (316 mL $CH_4 \cdot g^{-1}$VS). This is due to the higher content of structural carbohydrates and lignins in swtchgrass biomass in relation to maize biomass (Barbanti et al., 2014). The data provided in the literature also indicate differences in the production of biogas from switchgrass resulting from fluctuations in the composition and volume of its biomass yield. These characteristics are influenced by the variety,

habitat and climate conditions of the crop and the applied agrotechnics. It seems therefore justified that varieties of switchgrass intended for biogas should be selected in terms of the same indicators as in the case of maize. These indicators include the highest possible dry matter content·ha^{-1}, low ash content, and lignin and the ability to ensilage (BiogasMagazine, 2012). Selection of varieties with the use of agrotechnics corresponding to local conditions and optimally selected parameters of methane fermentation should result in intensification of biogas production.

Summary

In the world, switchgrass is a species that is used more and more frequently for energy purposes. This species has many positive traits that make this plant very attractive and worthy of spreading. From the agricultural point of view, an enormous advantage of switchgrass is that it has low soil and fertilization requirements; switchgrass is also characterized by high resistance to diseases and pests and thereby it is relatively easy and cheap to grow. Moreover, it exhibits great durability and high biomass productivity over a long period of time and due to this it can be used in a given field for even 10 years without a significant decrease in yield. When switchgrass is used as an energy crop, it is possible to produce bioethanol, biogas (biomethane) and synthesis gas. Biomass of this species can also be co-fired with coal. The effectiveness of these processes is dependent on the moisture content, the ash content and composition as well as the lignin content in switchgrass biomass.

Abstract. In this study ZnO/ZnS/CuS heterostructure have been controllably synthesized through a microwave-assisted synthesis and cation exchange. The compounds ZnO, ZnO/ZnS and ZnO/ZnS/CuS were characterized by X-ray diffraction (XRD), scanning electron microscopy (SEM), ultraviolet-visible (UV-vis) and Raman. It is found that the crystal structures obtained were Hexagonal Wurtzita for ZnO, hexagonal Wurtzita for ZnS, and hexagonal covellina for CuS. In comparison of ZnO and ZnO/ZnS the results show that ZnO/ZnS/CuS heterostructure has a higher photocatalytic activity under visible light, because its photocatalytic properties increase, helping to separate the electron-hole. These ZnO/ZnS/CuS efficiently decompose organic dyes such as methyl orange and methylene blue upon visible light conditions. Degradation rates can reach 31% and 71% during 240 min of treatment, respectively. The experiments revealed that the ZnO/ZnS/CuS decomposes methylene blue much faster than methyl orange.
Keywords: *semiconductors, photocatalysis, water treatment, KOH, pollutant*

Introduction

In recent years, environmental problems have generated a greater concern for society, due to the excessive growth that companies have presented, which means an increase in the number of pollutants they are producing. An exhaustive research of new techniques has been developed for water treatment; that they are no only low cost, but friendly to the planet (Chaudhuri, 2017). In the search for these new techniques, photocatalysis plays a fundamental role mainly due to its different applications, such as environmental remediation (Ahmad et al., 2016) and hydrogen production (Okemoto et al., 2018).

Of the photocatalysts most widely used, it includes TiO_2 (Liu and Li, 2014), ZnO (Liu et al., 2015) and ZnS (Wan et al., 2014). The semiconductor materials, either type p or n-type (Zhang and Jaroniec, 2018), play a fundamental role due to their different properties such as the great potential as a photocatalyst, its low cost, high

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

surface area and low toxicity (Park, Kim, et al., Photoinduced charge transfer processes in solar, photocatalysis based on modified TiO_2 2016), because the energy gap is small, An electron can be excited from the valence band to the conduction band, and then an electron-hole pair is generate producing oxidation-reduction reactions, taking advantage of the photocatalytic efficiency of these semiconductor materials.

The ZnO is a wide band gap semiconductor material, with a large surface area, photosensitivity, a high exciton binding energy of (60 mV), and a band gap of 3.37 eV that belong to II-VI group. ZnO is an important photocatalyst due to the rapidity to produce electron-hole pairs, but it has an important disadvantage as a photocatalyst, since it only can be activated in UV light $\lambda < 385$ nm, therefore, several attempts have been made to improve the absorption capacity of the structures based on ZnO.

To improve the photocatalytic performance of ZnO and to be able to accept visible light, heterostructure are fabricated with other semiconductor material for enhanced their photocatalytic activity (Basu et al., 2014) and its advantage is based on the fact that each of its compounds plays an individual role in the absorption of photons (Zhu et al., 2008).

ZnS with a wide band gap is another well-known photocatalytic, that has a band gap of 3.72 eV belongs to II-VI group semiconductor. However, as the ZnO is restricted to the ultraviolet range. To extend the photoresponse of ZnO/ZnS (Li et al., 2014). It has been shown that there is an efficient coupling between the ZnS and the CuS. Cus is capable of activating zinc oxide and zinc sulphide in the visible region, thus improving the separation of electron-hole pairs (Paria and Reiser, 2014).

Thus, in this study the ZnO/ZnS/CuS was synthesized by microwaves, expanding the light absorption range and ZnO/ZnS/CuS can absorb photons from the range of the solar spectrum taking advantage of the main source of renewable energy that counts (sunlight).

Materials and methods

Materials

Zinc di-hydrated acetate ($Zn(O_2CCH_3)2(H_2O)$, 100%, J. T. Baker), potassium hydroxide (KOH, 85%, CIVEQ), thioacetamide (C_2H_5NS, 99%) and cupric nitrate ($Cu(NO_3)_2 \cdot 2.5H_2O$),98%,CIVEQ). The solutions were prepared with deionized water and ethanol (C2H6O, 99.5%, Meyer). For the evaluation of the photocatalytic activity, methyl orange ($C_{14}H_{14}N_3NaO_3S$, Meyer) and methylene blue ($C_{16}H_{18}C_lN_3S$, CIVEQ) were used.

Synthesis of ZnO

In a typical synthesis 4.4506 g of $Zn(O_2CCH_3)2(H_2O)$ and 720 µL of deionized water was dissolved in 50 mL of ethanol, the solution was under constant stirring at 30 RPM. After 5 min of stirring the pH was modified with potassium hydroxide (KOH) to pH 8. The mixture was then transferred to a vial which was sealed and heated to 130 °C by microwave irradiation for 15 min. After cool down the mixture was filtered and washed with deionized water and acetone at least three times, in order to eliminate residual precursors, finally was dried for 24 h at 80 °C in an electric hot air oven.

DOI: http://dx.doi.org/10.15666/aeer/1605_57455756
© 2018, ALÖKI Kft., Budapest, Hungary

Synthesis of ZnO/ZnS

0.050 g of ZnO previously synthesized, and 0.041 g of thioacetamide C_2H_5NS was dissolve in 40 mL of deionized water. The solution was stirred with an ultrasonic bath for 20 min, then the solution was transferred to a vial which was sealed and irradiated with microwaves for 30 min at 650 W. After cool down the mixture was washed with deionized water and acetone for three times, and finally dried in an electric hot air oven for 24 h at 90 °C.

Fabrication of ZnO/ZnS/CuS

The synthesis method of the ZnO/ZnS/CuS heterostructure was similar to that reported by Can Lu (Lu and Otros, 2016). ZnO/ZnS/CuS was synthesized by cation exchange. 0.0139 g of ZnO/ZnS and 0.0317 g of copper nitrate $Cu(NO_3)_2 \cdot 2.5H_2O$ was dissolve in 20 ml of deionized water. The solution was kept under constant stirring in an ultrasonic bath, at 80° C during 4 h. The precipitate obtained was washed and dried for 24 h in an electric hot air oven and then pulverized.

Characterization

In order to know the crystal structure and its phases, the powders were studied using a Rigaku diffractometer (XRD), with Cu-Kα radiation (λ = 1.544 Å) over the range of 2 θ between 20° and 80°. The average crystallite size was calculated using the Scherrer equation (*Eq. 1*), which is described below;

$$\beta = \frac{k \times \lambda}{B \times \cos\theta} \qquad \text{(Eq.1)}$$

where, λ is the wavelength, k is a constant (shape factor of the diffraction peak), β is the average crystal size, θ is the peak position and B is the full width at half maximium intensity (Patterson, 1939).

The Surface morphology of powders was characterized by using a scanning electron microscopy (SEM) JEOL microscope model JSM-7100F with 10 kV acceleration voltage and a working distance WD. of 9.8 mm. The powders of ZnO, ZnO/ZnS and ZnO/ZnS/CuS were adhered to a double-sided carbon tape for the correct taking of micrographs at magnifications of 1500x, 20,000x, 25,000x, 50,000x and 100,000x.

The optical properties were obtained using UV-Visible spectrophotometer SHIMADZU model UV-2600, with a R-928 photomultiplier over the range of 185 to 900 nm. The band gap was calculated by the modified function of Kubelka-Munk (F(R)*hv) 1/2, and the calculation of F (R) (*Eq. 2*).

$$F(R) = \frac{1-R^2}{R \times 2} \qquad \text{(Eq.2)}$$

where R is the diffuse reflectance and $F(R)$ is the absorbance (Choudhury, 2013).

Raman spectra of the samples were recorded with a HORIBA sciencific spectrophotometer model XploRA PLUS in a spectral range of 100 to 800 cm^{-1} with a 532 nm laser.

Photocatalytic test

The photocatalytic activity of ZnO, ZnO/ZnS and ZnO/ZnS/CuS were evaluated using Methyl Orange (10 mg/l) and Methylene Blue (10 mg/l) as an organic pollutant using a Halogen FTK lamp 120 V, model 54875 placed at 10 cm.

0.0249 g of photocatalyst was added in 60 ml of the dye, and kept in an ultrasonic bath in the dark to establish the absorption-desorption equilibrium. After 30 min, an aliquot were removed and centrifuged at 4000 RPM for 25 min to separate the powders from the solution. The irradiation of visible light was started with the remaining dye in constant agitation at 180 RPM, at 28 °C. Aliquots were taken every 30 min and centrifuged with the same conditions mentioned above. The degradation was monitored by UV-Vis absorption spectroscopy in the range of 340-600 nm for Methyl Orange, and 500-750 nm for Methylene Blue. The measurements were made during 240 min. The degradation efficiency of the dyes was calculated with the degradation efficiency equation (*Eq. 3*).

Degradation efficiency

$$ED(\%) = \frac{A_0 - A_t}{A_0} \text{ x } 100 \qquad \text{(Eq.3)}$$

where A_0 is the initial absorbance of the dye and A_t is the absorbance of the dye at a time t (Alvi et al., 2017).

Results and discussion

The X-ray diffraction pattern was performed for the samples of ZnO, ZnO/ZnS and ZnO/ZnS/CuS (*Fig. 1*).

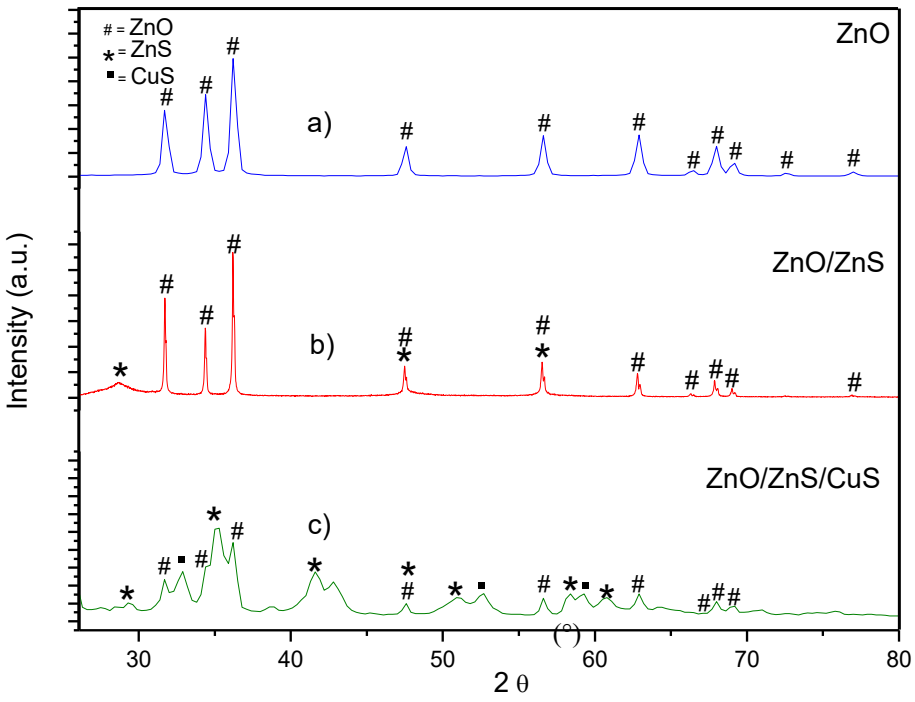

Figure 1. *XRD patterns of the ZnO, ZnO/ZnS and ZnO/ZnS/CuS*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_57455756
© 2018, ALÖKI Kft., Budapest, Hungary

The ZnO crystallizes in a hexagonal wurtzite phase (JCPDF 89-7102), and the average crystallite size is 21 nm. The compound ZnO/ZnS shows the characteristic peaks of both compounds ZnO and ZnS; checking the obtaining of the hexagonal Wurtzite phase for ZnO (JCPDF 89-7102), and the appearance of zinc sulfide (JCPDF 72-0162) for the Wurtzita Hexagonal phase. Finally, the X-ray diffraction pattern of the heterostructure ZnO/ZnS/CuS is corrobored with the peaks of the coveline phase of CuS (JCPDS 74-1234).

The ZnO powders have an irregular morphology of semi-spherical shape and agglomerations, with particles ranging from 205 to 702 nm in diameter (*Fig. 2*), this morphology is characteristic of the materials prepared by the microwave-assisted method (Kajbafvala et al., 2012; Sooksaen and Chuankrerkkul, 2017).

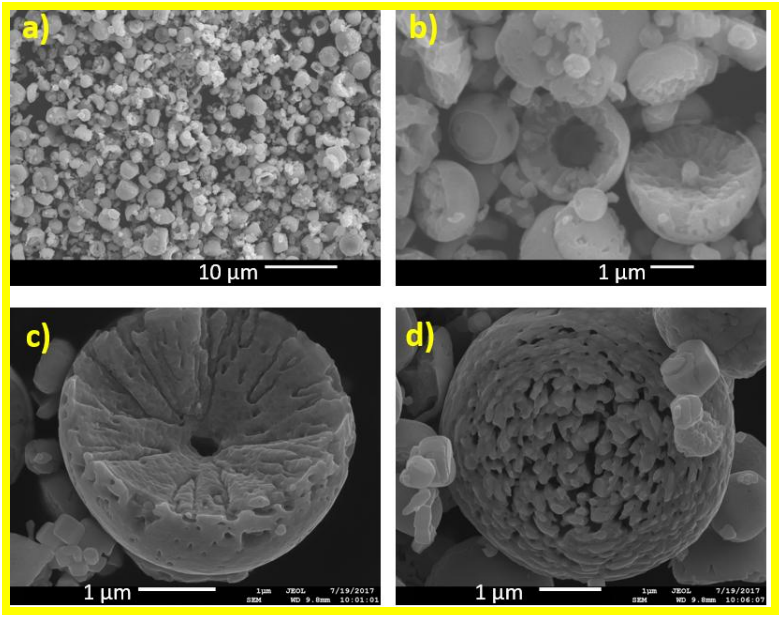

Figure 2. *SEM images of ZnO a) 2 500x b) 15 000x c) 25 000x d) 20 000x*

The SEM images of ZnO/ZnS after adding TAA and do not show variation with respect to the micrographs for ZnO (*Fig. 3*). Semi-spherical forms are presented with the formation of small spherical assembled particles, the size of these particles varies from 677 to 1400 nm in diameter.

Finally, the ZnO/ZnS/CuS heterostructure have a variation in the morphology with respect to the micrographs for ZnO, and ZnO/ZnS in which the circular morphology prevailed, varying for them to elongated forms with 380 nm in length (*Fig. 4*), which coincides with the morphology reported for this compound (Lu et al., 2016).

The optical absorbance was performed for the samples of ZnO, ZnO/ZnS and ZnO/ZnS/CuS (*Fig. 5*). The absorption Edge value of ZnO was obtained at 470 nm wich coinciding with the absorption edge values of the ZnO (3.37 eV). For ZnO/ZnS is possible to observe two edges values of absorption which is associated with the electronic interaction between the ZnO and ZnS with the increase of ZnS in the surface of ZnO (Jia et al., 2013) however no significant changes of the absorption increase above 400 nm are observed. For the ZnO/ZnS/CuS the absorption edges of the heterostructure have been significantly improved allowing the absorption of light in the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

visible region (400-800 nm), which implies that the sample has a good activity photocatalytic in visible light (Lu et al., 2016).

The band gap was calculated with the modified function of Kubelka-Munk (F(R)*hv) 1/2 as a function of the photon energy (hv), It shows the band gap value of the ZnO of 3.18 eV which is similar to the value reported for the ZnO (Munirah et al., 2017). The band gap 3.17 eV of the ZnO/ZnS/CuS is significantly decreased compared with to individual ZnO, so that the increase of the surface of the ZnS over the ZnO produces a decrease in its band gap (Torabi and Staroverov, 2015), in the same way the value obtained from the band gap for the ZnO/ZnS/CuS is 3.09 eV (*Fig. 6*).

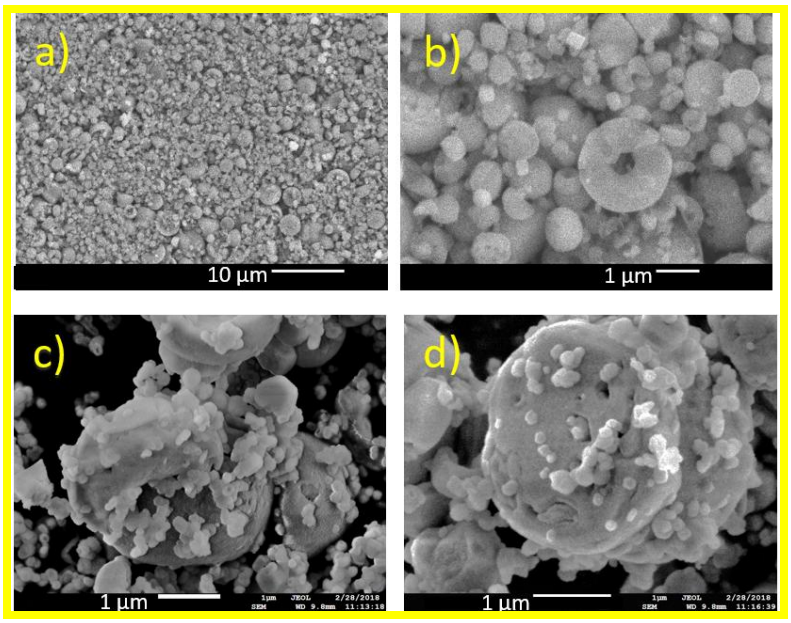

Figure 3. *SEM images of ZnO/ZnS a) 2 500x b) 15 000x c) 25 000x d) 20 000x*

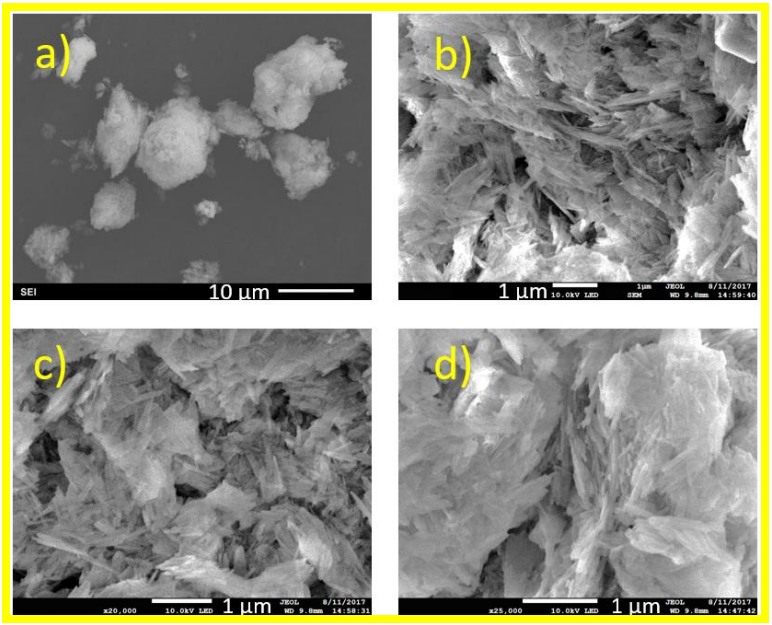

Figure 4. *SEM images of ZnO/ZnS/CuS a) 2 500x b) 15 000x c) 25 000x d) 20 000x*

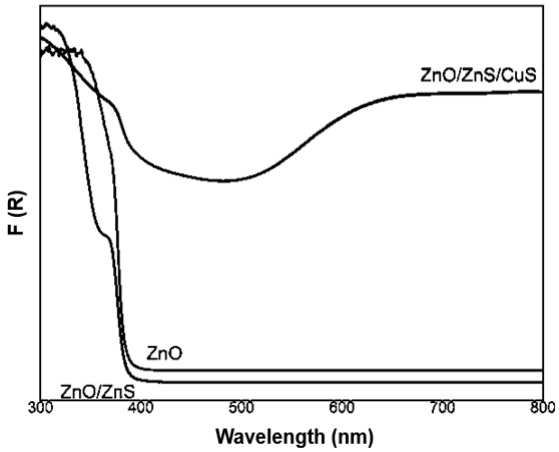

Figure 5. *Plot of absorbance vs wavelength ZnO, ZnO/ZnS and ZnO/ZnS/CuS*

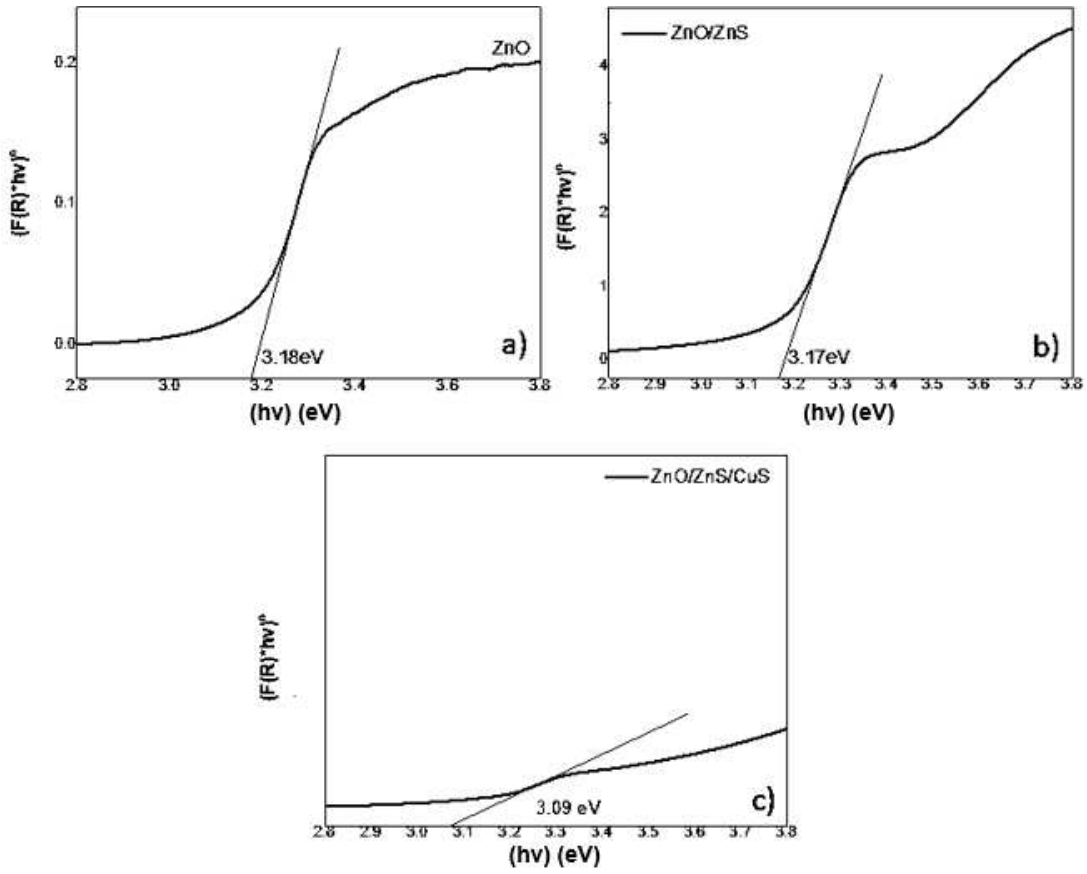

Figure 6. *Band gap of a) ZnO, b) ZnO/ZnS and c) ZnO/ZnS/CuS*

To confirm the formation of the compounds, raman scattering analyzes were performed for the ZnO, ZnO/ZnS and ZnO/ZnS/CuS samples (*Fig. 7*). Zinc Oxide ZnO, where the location of the vibrational modes located at 105, 385, 445, 585 and 663 cm^{-1} are associated with the vibrational active modes of the Wurtzite phase of ZnO (Ruiz et al., 2011) the dominant peak at 445 cm^{-1} is attributed to high-frequency phonons from

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_57455756
© 2018, ALÖKI Kft., Budapest, Hungary

oxygen atoms (Fletcher et al., 2014), and E1 (LO) mode at 585 cm^{-1} is associated with interstitial zinc and oxygen vacancies, the $E2_L$ peak at 105 cm^{-1} is associated with the vibrations of the zinc (Scepanovic et al., 2009), the vibrational mode $E2_{high}$ - $E2_{low}$ at 337 cm^{-1} is associated with multifononic processes (Londoño-Calderón et al., 2012) and finally the vibrational mode A_1TO at 385 cm^{-1} is associated with intrinsic defects (Sundara Venkatesh et al., 2016), for the ZnS the additional presence of two resonant raman lines is observed in 217 and 350 cm^{-1} that correspond to the active vibrational modes of the ZnS, the spectrum shows the dominant peak in 350 cm^{-1} identified as a mode T2 (LO) of first order [20] (Milekhin et al., 2012), the LO mode in 217 cm^{-1} is attributed to the second order of raman scattering (Fairbrother et al., 2014). The heterostructure ZnO/ZnS/CuS locates the characteristic peaks that are associated with the presence of ZnO, ZnS and CuS and the appearance of the new peak that denotes the presence of the coveline phase of CuS at 165 cm^{-1} and 465 cm^{-1} (Baert et al., 2013).

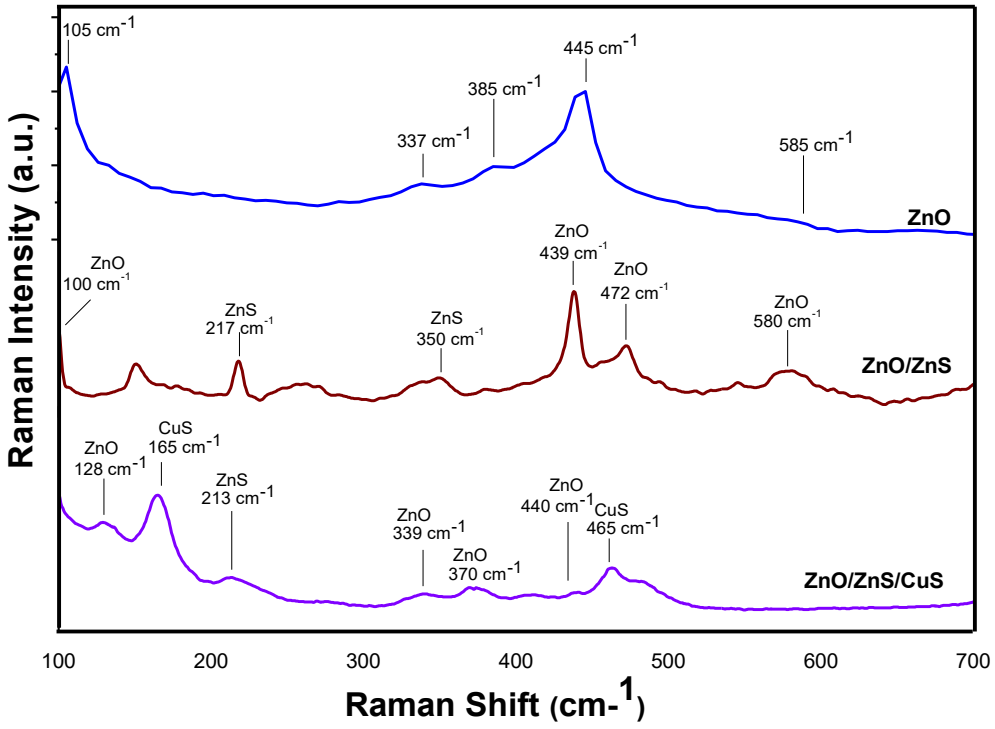

Figure 7. *Raman spectra of ZnO, ZnO/ZnS and ZnO/ZnS/CuS*

The photocatalytic test was performed with the degradation of MB (methylene blue), and MO (methyl orange). The test was prepared with 0.0249 g of photocatalyst and a concentration of 10 ppm of each of the dyes with the use of a lamp in the range of visible light. As mentioned in the methodology aliquots were taken every 30 min to measure its dye concentration during 240 min of reaction.

The UV-Vis absorption spectra show the degradation for the MB and MO dye with the time exposed to visible light radiation for ZnO/ZnS/CuS at a specific wavelength of 464 nm and 664 nm respectively (*Fig. 8*). As seem the aborbance intensity gradually decreased over time, according to what was reported by Lu et al. in 2016 this improvement can be attributed to the formation of the heterostructure constituted by the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_57455756
© 2018, ALÖKI Kft., Budapest, Hungary

three semiconductors ZnO, ZnS and CuS with which it is possible to reduce the recombination of the electron-hole pair due to the difference of their band gap (Liu et al., 2014).

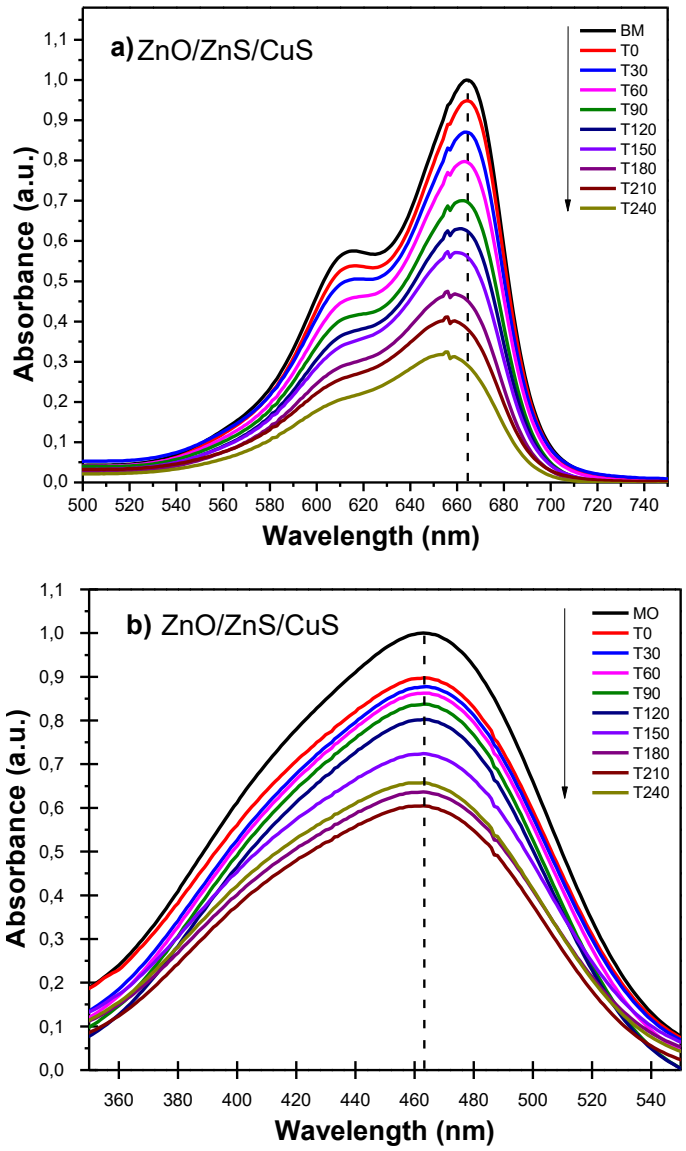

Figure 8. *Photocatalytic decomposition of a) methylene blue and b) methyl orange*

With the data obtained from the UV-Vis and applying the formula of the degradation efficiency (*Eq. 3*) to these values, it is established that the photocatalytic degradation of the MB increased by ~ 57% of its efficiency for the pure ZnO at ~ 61 with ZnO/ZnS and up to ~ 71% for the ZnO/ZnS/CuS heterostructure under visible light irradiation during 240 min of reaction and the photocatalytic degradation efficiency of MO increased from ~ 5% for ZnO to ~ 16% ZnO/ZnS and up to ~ 35% for ZnO/ZnS/CuS under the same conditions.

Figure 9 shows the values of the degradation of methyl orange and methylene blue in terms of $C/C_{0,}$ where C is the concentration of MB/MO at time t and C_0 is the initial concentration of MB/MO.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_57455756
© 2018, ALÖKI Kft., Budapest, Hungary

All samples of heterostructures exhibit greater photocatalytic activity than pure ZnO. The synthesized ZnO/ZnS/CuS showed high photocatalytic activity in methylene blue MB (~ 71%) unlike orange of methyl NM (~ 35%), this because the hydroxyl radicals play an important role in the breakdown of the anionic anionic dye orange methyl, while in cationic dyes such as methylene blue are involved in controlled reactions on the surface, resulting in the formation of intermediates that generally compete with the degradation of the original dye in solution (Li et al., 2014) than ZnO/ZnS and ZnO powders according to the exposure time (*Fig. 9*).

The difference of efficiencies in the degradation of contaminants is valid since each material is capable of degrading an organic compound efficiently or less efficiently due to the parameters that control the photocatalytic reactions such as temperature and pH (Scuderi et al., 2014).

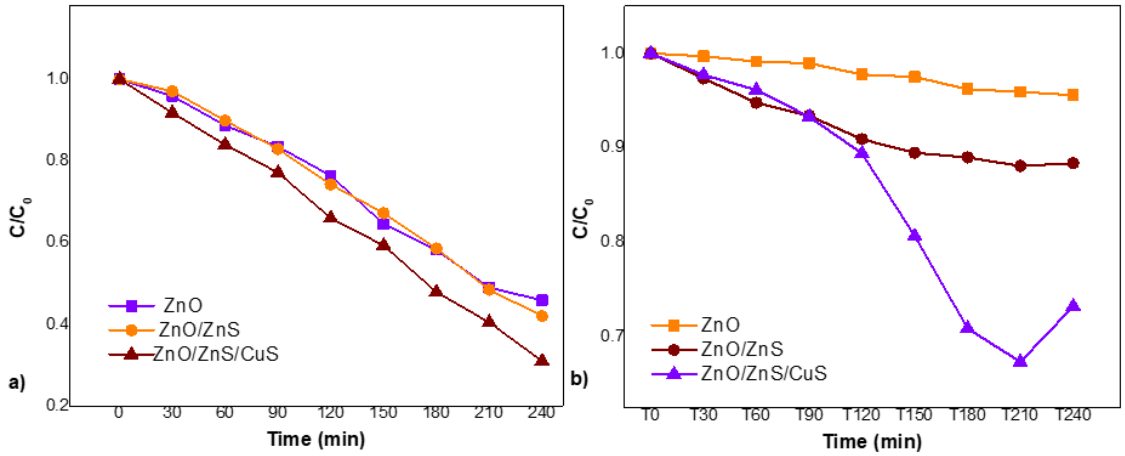

Figure 9. *Photocatalytic decomposition of a) methylene blue and b) methyl orange*

Conclusions

In this work, the ZnO/ZnS/CuS heterostructure was synthesized by microwave-assisted synthesis and cation exchange, which considerably modified its band gap. The ZnO/ZnS/CuS heterostructure can effectively decrease the recombination and exhibit a better photocatalytic activity in visible light compared to ZnO compared to the dyes analyzed in this study. We could also say that the heterostructure has a selective effect on the type and structure of the dye. It is recommended to modify the pH of the initial ZnO to improve the efficiency in the degradation, as well as to perform photocatalytic tests with mixed dyes.

Acknowledgements. The research group appreciates Edith Ponce Recinos for his support in the measures of SEM.

Abstract. The present study was designed to analyze the concentration of tropospheric NO_2 over Saudi Arabia for a decade from 2005-2014 based on observations from satellite borne Ozone Monitoring Instrument (OMI). The spatial analysis has identified two hotspots: Jeddah and Riyadh. The result of temporal analysis shows increase of 1.45%, 3.15% and 3.10% per year over Saudi Arabia, Jeddah and Riyadh respectively. The Linear Regression analysis and Analysis of Variance (ANOVA) have been performed to analyze the relationship between meteorological parameters, seasons, years and concentration of NO_2. The results show that temperature and NO_2 are moderately correlated whereas wind and humidity give negative correlation. The major causes of elevated NO_2 over the hotspots are road traffic and the fossil fuel combustion for electrical power generation.
Keywords: *tropospheric NO_2, OMI, spatiotemporal analysis, Saudi Arabia, hotspots*

Introduction

Anthropogenic activities play a very important role in changing the atmospheric composition. It would be very disastrous for the whole ecosystem. Nitrogen dioxide (NO_2) is a very harmful for human beings and their environment. Nitrogen dioxide is an eminent air pollutant due to its strong influence on the chemistry and quality of atmosphere. It helps to normalize the ozone concentration in troposphere and also affects the amount of hydroxyl (OH) ions. The increase in anthropogenic activities especially fossil fuel burning, vehicular traffic and industrial production has enhanced the amount of NO_x in the atmosphere. Identification of the areas rich in this and other pollutants may be the first step to clean the environment. Satellite Remote Sensing (SRS) has now become a useful technique for air pollution monitoring by measuring the pollutants concentration within the study area. This technique helps to assess large scale coverage with uniformity of averaged measurements.

The main objective of the present work was to identify the NO_2 hotspots and analyze their spatial and temporal patterns over Saudi Arabia by using SRS technique. Saudi Arabia is the biggest Arab state in Arabian Peninsula, Western Asia with an area of 2.1 million km^2.

Review of literature

Satellite data is more appropriate and recent for different emissions. Hence it could be compared with in situ measurements (Zohary and Spiegel-Roy, 1975; Hayn et al., 2009; Kgosiesele, 2010; Lamsal et al., 2010; Sheel et al., 2010; Kloog et al., 2012; Khan, 2012; Khanum et al., 2013a). Satellites provide a high-coverage alternative to ground-based measurements. Many studies (Lennon et al., 2000; Hayn et al., 2009; Kumar and Stohlgren, 2009; Khan et al., 2010) provide useful assessment trends for air pollution especially for NO_2. It is observed that human activities produce approximately 75% NO_x, whereas combustion of fossil fuel contributes about 50% (Leyequien et al., 2007; Jeschke and Strayer, 2008). The tropospheric NO_2 columns derived from satellite have been used to evaluate chemical transport models (Zyrichidou et al., 2013), to study long term changes in anthropogenic emissions of NO_x over developing areas (Khanum et al., 2013b; Yang et al., 2013) and to examine the spatio-temporal patterns of NO_x emissions on global and regional scales (Yuan et al., 2015). In some recent studies these measurements have already been used to provide top down estimates of land surface NO_x emissions via inverse modeling on the global scale (Martin et al., 2003; Jaegle et al., 2005; Lin et al., 2010; Miyazaki et al., 2012). Due to rapid urbanization and industrialization air quality degradation is a serious threat to Saudi Arabia. (Yost et al., 2008; Taheri, 2010; Joly et al., 2004) have provided the temporal and spatial distribution of air pollutants specially NO_x and O_3 for Jeddah using ground based data.

Methodology

Study area and its meteorology

The research has been carried out in Saudi Arabia (16.5 to 32 °N and 35 to 55.6 °E) with population 26.9 million. Its geography is mostly dominated by BSh and BWh (Koppen climate classification types for dry climate, BSh for steppe hot desert and BWh for true hot deserts) There are no water bodies like rivers, ponds or lakes. The central plateau is the major topography from Red Sea to Persian Gulf. Meteorological data have been collected from www.wunderground.com. In general desert climate is dominated in Saudi Arabia with major difference of day and night. The summer temperature is usually found to be >45 °C and winter temperatures do not fall below 0 °C. The precipitation is negligible. The detailed meteorological parameters like maximum and minimum temperature, wind speed and pressure have been taken in account during the analysis of hotspots regarding NO_2.

Satellite data

Tropospheric NO_2 data have been collected from Ozone monitoring instrument (OMI) onboard NASA's satellite Aura. OMI uses spectral range of 270–500 nm (Levelt et al., 2006a, b). Its spectral resolution is about 0.5 nm (Zyrichidou et al., 2013). The data collected is for the past decade (2005-2014). Differential optical absorption spectroscopy (DOAS) analysis has been used to obtain tropospheric NO_2 column with spectral range 405–465 nm spectral range (Yu et al., 2014; Ellis, 2015). NASA's online user's manual for OMI products (Giovanni, 2014) has been consulted for further data analysis and filtering. The collected data of NO_2 column (OMNO2d.003, level–3) is screened for 0–30% cloud cover and binned spatially at 0.25 × 0.25 degrees (Slee and Feliciano, 2015). There is an uncertainty of 0.1×10^{15} molecules/cm^2 in dataset for

tropospheric NO_2. The tropospheric NO_2 data is compared with in situ data and bottom up emission inventories.

The satellite sensor data is compared with Global Ozone Monitoring Experiment (GOME-2) sensor data from January to December 2013. Both these sensors operate in sun-synchronous orbits, with 13:30 and 10:00 local time crossing at equator, respectively (van Noije et al., 2006). GOME-2 located on board MetOp-A satellite is the first of a series of three identical instruments which will provide more than 15 years of space-borne UV/visible observations of the atmosphere (Munro et al., 2000). The GOME-like nadir viewing spectrometer covers the spectral range between 240 and 790 nm at 0.2–0.4 nm resolution, has a ground pixel size of 80 × 40 km^2 and overpasses the Equator at 09:30 LT in the descending node (Callies et al., 2004). With its large swath of 1920 km, GOME-2 provides near global coverage every day. For this purpose Doha, capital city of Qatar, is considered due to limited data availability over Saudi Arabia. Doha has been considered due to its similarity with Saudi Arabia regarding climate and industrial activities. Both places have hot desert climate with long summers. *Figure 1* shows the time series of both sensors datasets. The time series shows good consistency between mean values of OMI (4.0×10^{15} molecules/cm^2) and GOME-2 (5.04×10^{15} molecules/cm^2) data. It is observed that the both datasets are positively correlated ($r = 0.534$).

Anthropogenic NO_x emissions have been obtained from Emissions of atmospheric Compounds & Compilation of Ancillary Data (ECCAD) web site available at http://eccad.sedoo.fr. These NO_x emissions have been estimated by Monitoring Atmospheric Composition and Climate (MACC) and megaCITY-Zoom for the Environment, CityZEN (Granier et al., 2011; ul-Haq et al., 2017). MACCity anthropogenic NO_x estimates are largely based on emissions from residential, transportation, agricultural, industrial, energy, waste and shipping sectors. Atmospheric Infrared Sounder (AIRS) instrument suite aboard the NASA Earth Observing System satellite Aqua provides the distribution of atmospheric trace gas constituents including ozone (Pagano et al., 2010). We have used monthly averaged and gridded AIRS O_3 product.

Analysis of data

Time series plotting techniques have been used for Data analyses, especially for determining the seasonal and monthly trend of NO_2. These trends over two cities were further explored with Pearson's correlational analysis. Analysis of significant factors associated with concentration of NO_2 was carried out through General Linear Model (ANOVA.). The concentration of NO_2 for two sites has been compared between years, months and seasons. SPSS 20.0 version has been used for this purpose.

Results

The yearly averaged column value of NO_2 is found to be 1.1680×10^{15} molecules/cm^2 with increasing trend of 1.45% per year over Saudi Arabia (*Table 1*).

Table 1. *Descriptive analysis of OMI-NO_2 column ($\times 10^{15}$ molecules/cm^2) over the study area and hotspots during 2005-2014*

	N	Range	Minimum	Maximum	Mean	Std. deviation
Saudi Arabia	3637	2.09	0.28	2.37	1.1680	0.29215
Jeddah	3344	9.99	-0.55	9.43	3.0616	1.18307
Riyadh	3230	11.49	-0.06	11.44	3.0828	1.41565

Two NO_2 hotspots have been identified within the study area as shown in *Figure 2*.

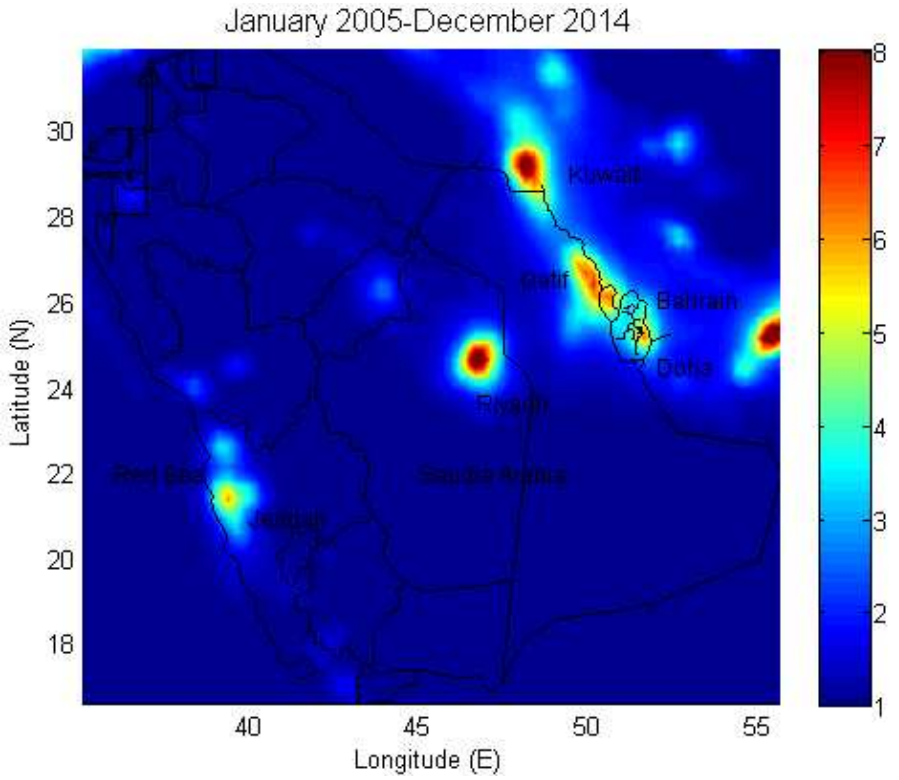

Figure 2. *OMI-NO_2 mean concentration ($\times 10^{15}$ molecules/cm^2) over the study area and two hotspots from 2005 to 2014*

The yearly averaged column value of NO_2 is found 3.06×10^{15} molecules/cm^2 with increasing trend of 3.15% per year over Jeddah and 3.06×10^{15} molecules/cm^2 with increasing trend of 3.10% per year over Riyadh. These elevated values can be seen throughout the year as shown in *Figure 3*.

The overall trend is found higher in higher percentile. An increasing trend also found year after year both in Jeddah and Riyadh (*Table 2*).

Table 4 highlights the effect size of NO_2 concentration for seasons and years over two hotspots Riyadh and Jeddah. Eta square η^2 for both one-way and multiway ANOVA from General Linear Model and then Univariate analysis has been calculated.

Figure 4 shows that Range of NO_2 concentration is higher over Riyadh whereas it found lower for Jeddah for the same reason. The NO_2 Range is high for Riyadh with 7.79×10^{15} molecules/cm^2 than Jeddah with 4.69×10^{15} molecules/cm^2. The seasonal temperature difference of 8 °C and 20 °C has been found for Jeddah and Riyadh respectively. The regression analysis shows that for every one degree increase in temperature tropospheric concentration of NO_2 over Riyadh increased by 0.15, which represent 0.36 standard deviation. F (1, 2388) = 327 had an associated probability level of $p < 0.001$, while for Jeddah increase in one degree in temperature will increase the value of NO_2 by 0.06.

Table 4. *Comparison between the measured NO_2 values of the sites and years and seasons through ANOVA*

Source	df	Mean square	F	Sig.	Partial eta squared
Season and NO_2_Jeddah	3	60.873	45.217	.000	.039
Year and NO_2_Jeddah	9	19.028	14.073	.000	.037
Season and NO_2_Riyadh	3	191.015	104.477	.000	.089
Year and NO_2_Riyadh	9	29.484	15.298	.000	.041

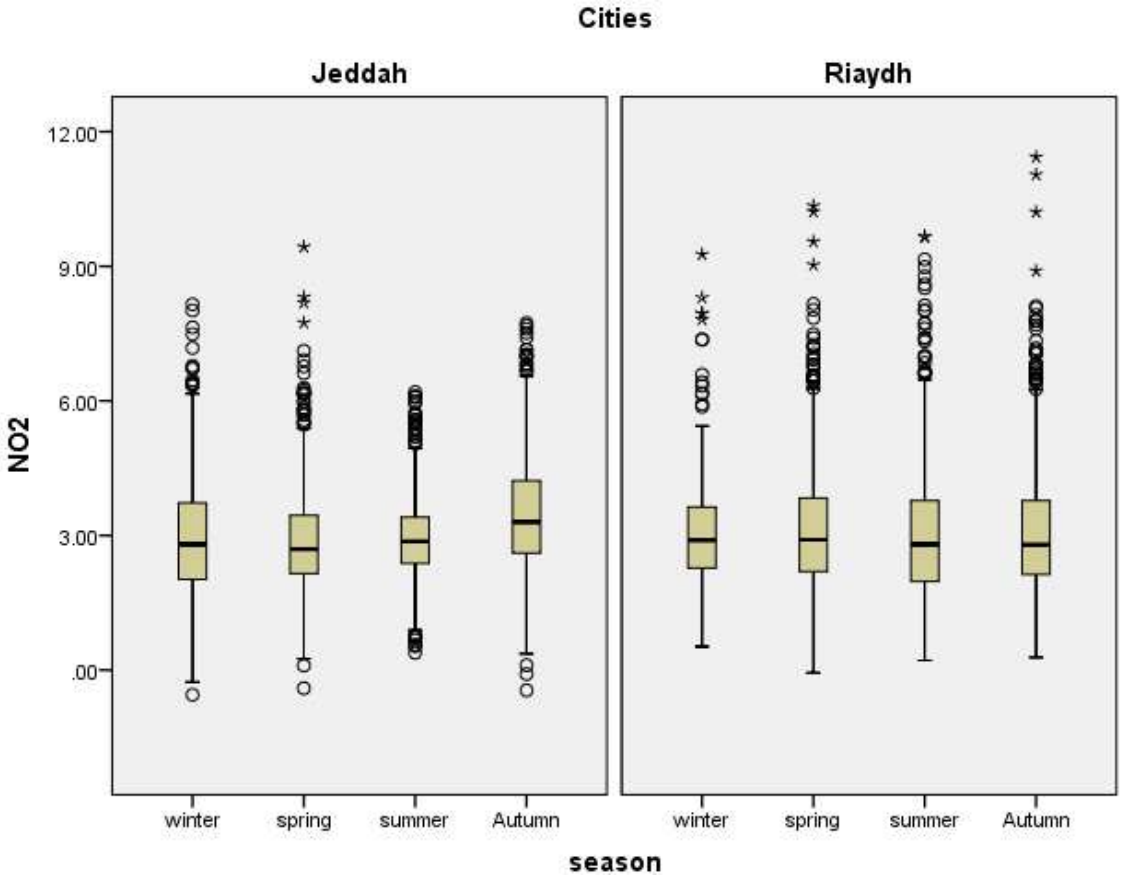

Figure 4. *Concentration of NO_2 ($\times 10^{15}$ molecules/cm^2) in different seasons over hotspots during 2005-2014*

The activities regarding electricity consumption, fossil fuel burning in automobiles and electrical power generators have been noticed at the peak during summer months. Therefore, high concentration of NO_2 has been found both in summer and autumn. The highest value found in Riyadh, i.e. mean 3.41×10^{15} molecules/cm^2 (Std. Dev = 1.25 whereas in Jeddah highest value found in autumn, i.e. mean = 3.39×10^{15} molecules/cm^2 (Std Dev = 1.19) (*Figure 5*).

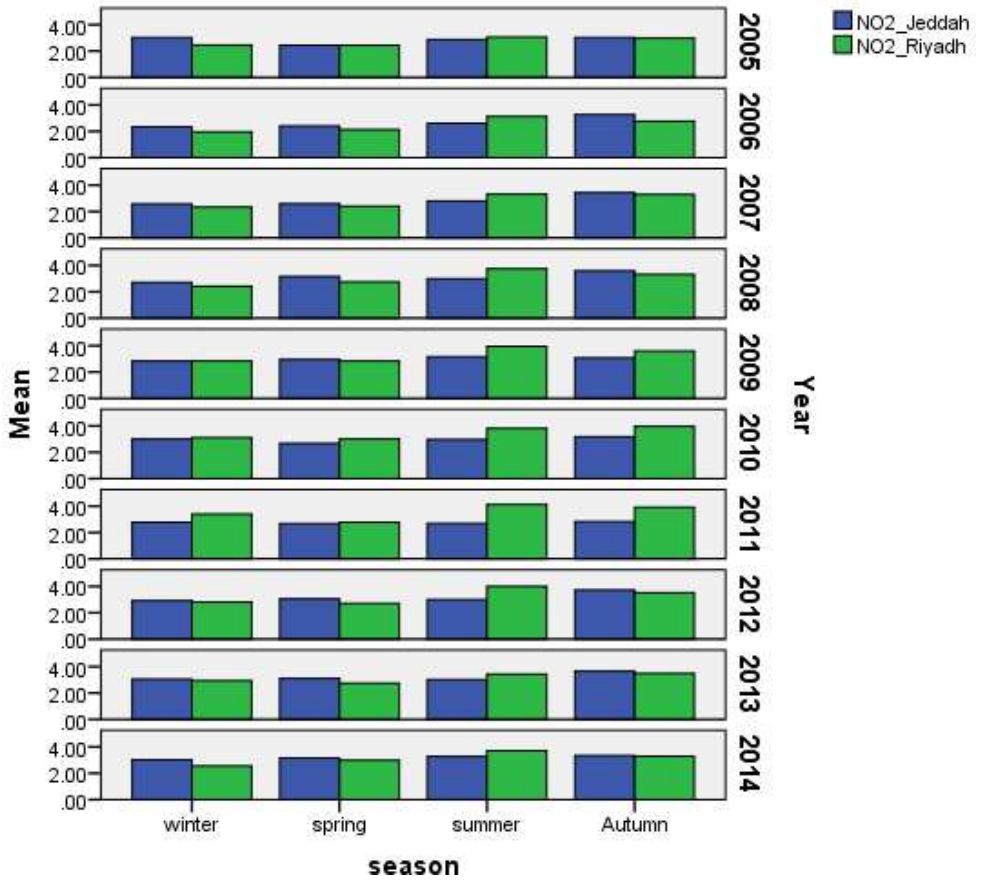

Figure 5. *Seasonal mean variations of NO_2 ($\times 10^{15}$ molecules/cm^2) over hotspots during 2005-2014*

An overall correlation between OMI tropospheric NO_2 and AIRS tropospheric ozone is found $r = 0.21$ during 2005-2014. Also spatial mapping of correlations between OMI tropospheric NO_2 and AIRS tropospheric ozone has been presented in *Figure 6* during 2005-2014. The correlations have been observed to be ranging from $r = 0.6$ to $r = –0.8$. Most of the northern parts of Saudi Arabia are found with higher positive correlations compared to southern parts largely due to more population and economic activities.

Discussion

The results show yearly averaged column value of NO_2 has been increased annually by 1.45%. This increasing trend is in close agreement with previous regional study by (Zohary and Spiegel-Roy, 1975). In Saudi Arabia the consumption of oil (million barrels per day) has increased 60.9% from 1996 to 2006 (EIA, 2008). This increase has contributed to increased levels of NO_2 in the atmosphere. The increase in Saudis' manmade activities contribute significantly to this trend. The most prominent sources of pollution are motor cars, factories and oil refineries. The number of private vehicles was found large because of weak public transportation system in Saudi Arabia (Kaba et al., 2007). According to Arab News (2014) an increase of 6% in motor vehicles from 2012 has been recorded.

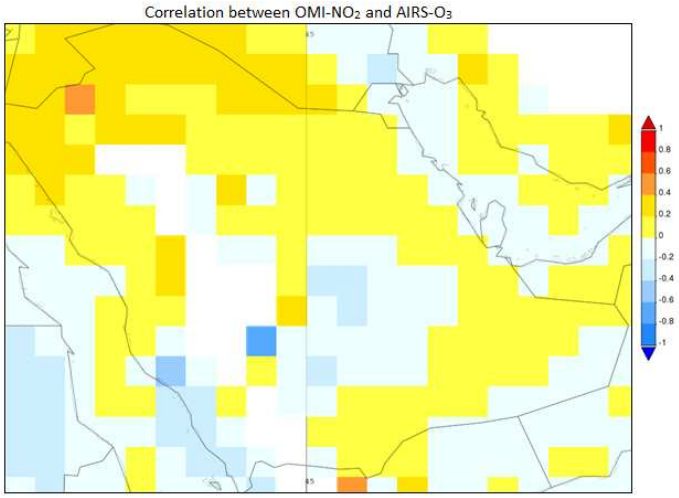

Figure 6. *Spatial map of correlation between OMI observed NO_2 and AIRS retrieved tropospheric ozone over Saudi Arabia during 2005-2014*

EDGAR (Emission Database for Global Atmospheric Research) data has shown 9.4% increase in NO_x emissions in Saudi Arabia (EDGAR, 2010) during 2005–2008 and has identified major sources with significant annual increase in various emission categories, i.e. public electricity and heat production (18.3%), manufacturing industries and construction (15.03%), manure man- agreement (6.93%), direct soil emissions (1.78%). Average oil industrial production growth rate was found 20% from 2010 to 2015 (Arab News, 2014).

Two cities, Jeddah and Riyadh, of Saudi Arabia have been identified with remarkable concentration of NO_2. Many studies have already identified these two cities as important source of NO_2 (Boersma et al., 2004, 2007; Bowler, 2014). Jeddah lat (20.6, 22.1 °N) long (38.9, 40 °E) has comparatively warm and humid climate with mean temperature 29 °C, mean humidity 54%, mean sea level pressure 1008 mb, 57% humidity and 10.9 km/hour wind speed. Precipitation is negligible. Winds blow in north east direction. The winds mostly come from Red Sea. In summers, dust storms blow from the Arabian Peninsula to Jeddah.

Riyadh lat (24.4, 26 °N) long (46.1, 48 °E) is capital city of Saudi Arabia. It has hot desert climate with increased seasonal range of temperature, i.e. 35 °C (mean temp 27.5 °C). The mean sea-level pressure is 1013 mb, and mean humidity value is 25%.

The reason behind higher concentration of NO_2 over Jeddah and Riyadh can be Industrial and vehicular emissions. Their combined effect gives Jeddah a serious air pollution problem. Many old cars cause serious air pollution in the city due to poor maintenance and improper check of regulations and then the industrial area of the city contribute further to environment (Kadi, 2009). Concentrations of heavy metals, gaseous air pollutants and particulate emissions far exceed internationally acceptable standards (Al-Jeelani, 2008; Hassan et al., 2013). Other important reasons of NO_2 emission in both Jeddah and Riyadh are incinerators, oil refineries, cement and electrical power plants. In Riyadh, sand rock quarries and crushers contribute significantly to NO_2 emission (Salama et al., 2011). The sprawling pattern of the cities, such as Riyadh and Jeddah, also contributes to emissions through long trips to work. Al-

© 2018, ALÖKI Kft., Budapest, Hungary

Ahmadi and Al-Zahrani noted that NO_2 concentrations in Jeddah and Riyadh might be caused by vehicle emissions and urban activities (Kaba et al., 2007).

The correlation between OMI NO_2 and MACCity anthropogenic NO_x from sum sectors including residential, transportation, agricultural, industrial, energy, waste and shipping sectors is (r = 0.78 and slope 0.942) over Saudi Arabia during 2005-2014.

The results show positive correlation between temperature and NO_2 and negative correlation with mean humidity, cloud cover and wind speed for both hotspots (*Table 3*). The literature supports these results as life time of NO_2 is 3-10 hours and may be remain for 5 to 10 days only when humidity level is low (Papes, 2007). The tropospheric NO_2 reacts with OH radical and removed from the atmosphere by converting into nitric acid (HNO_3) in day timings (Oindo et al., 2002). The relationship between NO_2 and temperature is discussed by (Moreno-Amat et al., 2015), that with the increase in temperature a significant increase in HNO_3 has been found. However, no significant correlation has been found between these two variables (NO_2 and Humidity) for Jeddah, a coastal city due to higher and constant level of humidity and less temperature variations over coastal city of Jeddah.

As the results showed, seasonal effects are remarkable for both hotspots. Analysis of variance (*Table 4*) showed a main effect of seasons on NO_2 concentration over Riyadh ($p = .000$, $\eta p^2 = 0.08$) and Jeddah ($p = .000$, $\eta p^2 = 0.03$), whereas for years it gives Riyadh ($p = .000$, $\eta p^2 = 0.04$) and Jeddah (($p = .000$, $\eta p^2 = 0.03$). It means seasonal effect is 8% for Riyadh and 3% for Jeddah. The difference in years for NO_2 concentration was found 4% for Riyadh and 3% for Jeddah. Maximum mean values of NO_2 have been found in summer and autumn and comparatively low values are observed in spring and winter. As far as Jeddah is concerned it is one of the major cities of Saudi Arabia and the largest after Mecca. It serves as a major platform for air, road and marine transport. It has also main airport for pilgrims for Hajj (Bowler, 2014). In 2013, 17 million people as tourist enter in Saudi Arabia where its 40.6% approximately 6.9 million were on religious purpose (Ellis, 2015). The highest value of NO_2 found in autumn and early winter reveals the fact that from 2005-2014 the Hajj season came between October and January. *Figure 5* shows a remarkable increase in concentration of NO_2 over Riyadh in summer and autumn 2011. It may be due to heavy transport movement of approximately 1000 Saudi troops (Slee and Feliciano, 2015) to handle the Bahrain uprising and unrest due to the protests in Saudi Arabia especially in Riyadh.

Conclusion

Tropospheric NO_2 has been studied over Saudi Arabia with the help of satellite based OMI data. Two hotspots Jeddah and Riyadh have been identified. The spatiotemporal analysis showed that there was significant increase in NO_2 level from 2005-2014. The NO_2 patterns were also analyzed with the help of meteorological parameters. The results showed positive correlation with temperature and negative correlation with wind speed, humidity and cloud cover. A detailed analysis to assess the relationship of NO_2 with other atmospheric pollutants such as CO, Ozone, SO_2 and aerosols over Saudi Arabia is recommended for future studies with special emphasis on Hajj season.

(Received 8th Oct 2017; accepted 27th Feb 2018)

Abstract. Germination behaviour plays an important role for seedling regeneration and the sustainable development of population in arid and semiarid areas. The objectives of the study were to explore germination characteristics of *Anabasis aphylla* and *Haloxylon ammodendron* under low temperature conditions and their ecological significance in Junggar basin of China. We combined the Logistic function and the thermal time equation, and used non-linear regression to estimate the base temperature and the thermal time for germination of both species. Germination experiments were carried out in the illumination incubators with 6 temperature gradients (20/15 °C, 15/10 °C, 10/5 °C, 5/2 °C, 2 °C and 2/-3 °C) for 15 days. Final germination percentages of the two species were not obviously different and were higher than 90% in different temperature treatments, and low temperature only inhibited germination speed. Moreover, germination percentages of the two species surpassed 50% in the eighth day under low temperature conditions. The base temperature and thermal time of *A. aphylla* was 0.54 °C and 9.89 °C, while *H. ammodendron* was 0.79 °C and 7.26 °C, respectively. The results showed that the two desert species adapted to the low temperature habitat and took advantage of humid soil conditions to grow in the snow-melting period.
Keywords: *seed germination, desert plant, snow-melting, base temperature, thermal time model, harsh habitats*

Introduction

Germination is a crucial stage in the life cycle of plants, however, this stage is highly unpredictable over space and time (Tlig et al., 2008). In germination experiments, temperature is an important and determining factor regarding the time of germination (Khan and Ungar, 1998). In general, it is thought that germination starts above 10 °C (Huang et al., 2003; Tobe et al., 2000). However, several researchers suggested that some species could germinate under low temperature conditions (Sun, 2015; Han et al., 2011; Körner, 2003; Shimono and Kudo, 2005; Zhang, 2010). For example, Shimono and Kudo (2005) actually observed that seedlings of *Peucedanum multivittatum* had already emerged at the time of snow-melting in the snow-bed habitat. However, limited information is available for seed germination at low temperature (Huang et al., 2003). So, it is significative for desert seeds to germinate during snowmelt period.

As a result of long-term adaptation to the environment, the majority of plant seeds have a specific requirement of base temperature (T_b) and thermal temperature value for triggering germination (Steadman et al., 2004). When the ambient temperature reaches the base germination temperature, seeds can become receptive to the thermal temperature, once the thermal temperature reaches the specific value for a given species, the seeds can germinate (Steinmaus et al., 2000). Depending on the accumulation process of environmental temperature during seed germination, the thermal time model

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_57715780
© 2018, ALÖKI Kft., Budapest, Hungary

can quantify the influence of external environment on seed germination in a certain degree (Liu et al., 2011). The process of seed germination is related to the accumulation of environment temperature, only the thermal time accumulated to a certain extent can promote seed germination, thermal time is generally considered to be accumulated when the environment temperature exceeds the base temperature of seed germination, and for seeds of the same species the base temperature is constant (Dahal et al., 1990). Thermal time models were derived for germination and shoot emergence using a range of sub-optimal and optimal temperatures (≤ 20 °C) for each provenance, this temperature range was selected as these models assume that there are linear relationships between rate and temperature (Finch-Savage and Whalley, 2006).

Haloxylon ammodendron and *Anabasis aphylla* are two shrubs of Chenopodiaceae, mainly distributed in northwest of China. *H. ammodendron* has many characteristics of adapting to drought, salinity, poor nutrition, strong wind, sand movement, and high light intensity (Huang et al., 2003). As an important component of old Mediterranean flora, it widely spread in Junggar basin, northeast of the Tarim basin and other desert areas on a range of soils and is a representative psammophytic species (Wang et al., 2014). *H. ammodendron* is a precious biological resource in the arid desert region. Besides its ecological value, *H. ammodendron* also has great economic value. *A. aphylla* population mainly distributes in diluvial fan, lowland among dunes, Gobi and hillside, and presents staggered distribution with *H. ammodendron* population in the desert–oasis ecotone (Wang et al., 2015). Several investigations have been conducted on germination and community traits of *H. ammodendron* and *A. aphylla* (Huang et al., 2003; Wang et al., 2014, 2015; Chu et al., 2014a, b). *A. aphylla* plays an important role in saline-alkali land, rehabilitated fissure and windbreak and sand fixation in the desert area, and has a certain significance for maintaining the water and soil safety of the alluvial fan in the foreland. It has a good application for the follow-up industrial development of returning farmland to forestry prospect. In Junggar basin, the habitats are harsh, coupled with improper human exploitation, so the habitats are further destroyed, and the seedlings of various plants are naturally difficult to be regenerated. *H. ammodendron* and *A. aphylla* are the dominant species in this area and can survive in this harsh environment. Studies have shown that temperature of Junggar basin increased in early April, resulting in the rapid drying of the shallow layer of soil, which is not conducive to the growth of *H. ammodendron* seedlings (Huang et al., 2008). In the field, our observations show that a large number of *H. ammodendron* and *A. aphylla* seedlings germinate during the snow-melting period in March. Therefore, studying the adaptability of desert plants at low temperatures is of great significance to ecological construction.

The objective of this study was to explore the characteristics and ecological adaptation of seed germination under low temperature conditions. It is necessary to understand seed germination in adaption to harsh environment, and also to study the evolution of plant life history.

Materials and methods

Experimental materials and habitat conditions

Fresh and matured seeds of *H. ammodendron* and *A. aphylla* were collected in the desert on the southern edge of the Junggar basin in Xinjiang (45°22′43.4″N, 84°50′32.5″E; altitude is 843 m). The annual mean temperature varies from 5 to 9 °C, and minimum winter temperature varies from -30 to -41 °C and maximum summer

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_57715780
© 2018, ALÖKI Kft., Budapest, Hungary

temperatures are 30–40 °C. Snow-melting appears at the end of winter, together with the rainfall that occurs in summer and annual precipitation amounts from 100 mm to 250 mm. Annual potential evaporation is greater than 2000 mm (Wang et al., 2014). In Junggar basin, the snow-melting period is about 10 days in March, the average daytime temperature is higher than 0 °C and the maximum temperature is basically maintained at 7-14 °C, while the minimum temperature is below 0 °C. So, during the snow-melting period, the surface of the soil is repeatedly frozen and thawed (*Fig. 1*).

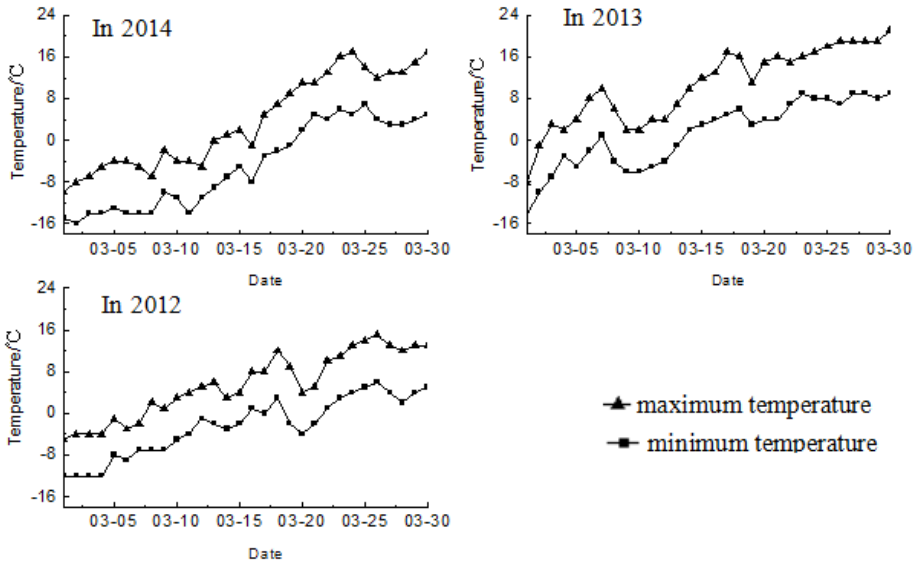

Figure 1. *Temperature conditions of the snow-melting period in the study area*

The seeds of both species are similar in shape and have perianth segments. The seed of *H. ammodendron* is larger than *A. aphylla*, and both seed is gray or black (*Fig. 2*). Its average diameter is 2.13 mm and 1.88 mm, while thousand seed weight is 1.90 g and 1.45 g, respectively. It was found through preliminary experiments that seeds of both species could germinate at 2 °C (*Fig. 3*).

Experimental methods

Experimental design of germination under different temperatures

Germination experiments were carried out in Petri dishes (9 cm in diameter) on two layers of filter paper (GB/T1914-93, Hangzhou Xinhua Paper Ltd., China) moistened with 10 ml of distilled solution. The variable temperatures of day and night were in control of 20/15 °C, 15/10 °C, 10/5 °C, 5/2 °C, 2 °C and 2/-3 °C individually. All Petri dishes were kept in an illumination incubator with 12 h photoperiod (LRH-250-G Illuminating Incubator, Guangdong Medicine Apparatus Manufactory, Guangdong, China) and freeze temperature were conducted in Ronshen Refrigerator (BCD-232YMB/X1). For all treatments (6 temperature gradients), four replicates of 40 seeds each were used in the experiment. Germinated seeds were recorded daily for 15 days. Seed was considered to have germinated with the emergence of the radicle (Chu et al., 2014b).

Experimental design of thermal temperature model

Based on the thermal time model standard, 5 constant temperature gradients were set up experimentally. For all treatments, four replicates of 40 seeds each were used for testing. Germination trials were carried out in Petri dishes with two layers of filter paper, the number of seed germination was recorded every 12 h. In the process of seed germination, the thermal time ($\theta_{T(g)}$) needed for the germination percentage of g is calculated by the following formula (*Eq. 1*):

$$\theta_{T(g)} = (T - T_b)t_g \quad \text{(Eq.1)}$$

T is temperature of the experiment, T_b is the base temperature of seed germination, T_g is the number of days required to accumulate the germination percentage of g.

By using the Logistic function (*Eq. 2*) curve fitting, the relevant parameters m, k, b and the base temperature (T_b) of seed germination can be obtained.

$$g = \frac{m}{1 + e^{-k(T - T_b)t + b}} \quad \text{(Eq.2)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_57715780
© 2018, ALÖKI Kft., Budapest, Hungary

By using the thermal time to achieve the germination percentage of g to estimate the thermal time value of seed germination, $\theta_{T(50\%)}$ was calculated by *Equation 3* and fitting results *m, k, b* and $g = 50\%$.

$$\theta_{T(g)} = \frac{1}{k}(b + \ln\frac{g}{m-g}) \quad \text{(Eq.3)}$$

Data analysis

Excel 2016 was used to analyze the experimental data. SPSS 19.0 software was used to make significant variance analysis of germination index, and non-linear fitting Logistic function to get the parameters of thermal temperature, and utilize Origin 8.5 to draw the graph.

Results

Seed germination characteristics of two desert species

As a whole, with the decrease of temperature, germination speed of *H. ammodendron* and *A. aphylla* seed increased slowly. Germination periods of high temperatures (20/15 °C and 15/10 °C) were less than 7 days while low temperatures (5/2 °C, 2 °C and 2/-3 °C) were more than 11 days. The experiment ended on the 15th day, the germination percentage of both species tended to be stable at a certain level, and the low temperatures slowed down the seed germination speed (*Fig. 4*). The initial germination time of *H. ammodendron* and *A. aphylla* increased with the decrease of temperature, and the germination index decreased gradually, but the final germination percentage was over 90% with no significant difference (*Table 1*).

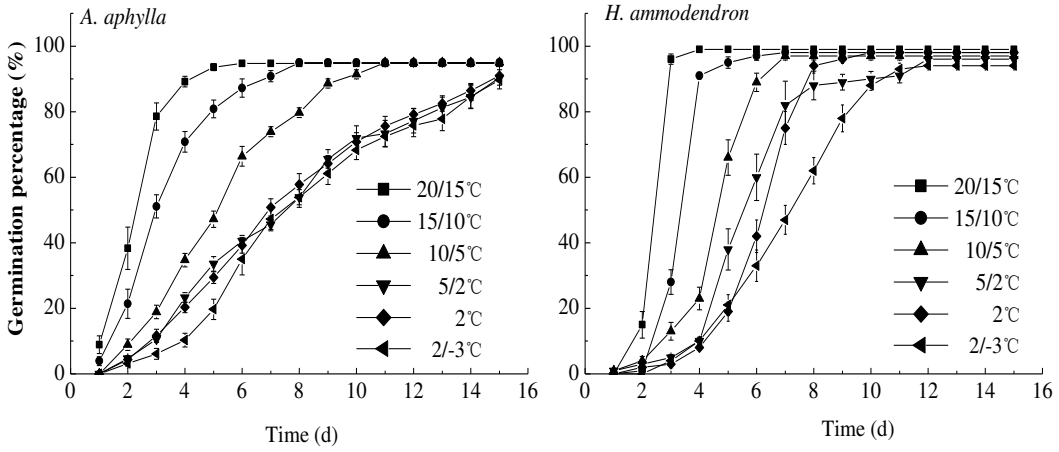

Figure 4. *Seed germination percentages of A. aphylla and H. ammodendron*

Thermal temperature model analysis of two desert species germination

The parameter estimates *m*, *k*, *b*, T_b (±standard error) obtained by fitting the Logistic equation (*Eq. 2*) are shown in *Table 2*. According to the above formula (*Eq. 3*), the relationship between cumulative germination percentage and thermal temperature of *H. ammodendron* was obtained, which is $\theta_{T(g)} = \frac{1}{0.90}(6.18 + \ln\frac{g}{0.85-g})$. *A. aphylla* is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_57715780
© 2018, ALÖKI Kft., Budapest, Hungary

$\theta_{T(g)} = \frac{1}{0.37}(3.36 + \ln\frac{g}{0.87 - g})$. When the cumulative germination percentage g = 0.5, the thermal temperature of *H. ammodendron* is 7.26 °C, *A. aphylla* is 9.89 °C. The base temperature of both species is low, both at about 0 °C. The determination coefficient R^2 is 0.94 (*Table 2*).

Table 1. *Seed germination characteristics of A. aphylla and H. ammodendron ($p < 0.05$)*

Treatment (°C)	Final germination percentage (%)		Initiate germination time (h)		Germination index	
	Species1	Species2	Species1	Species2	Species1	Species2

Means within a column at each treatment with the same letter are not significantly different. Species1 is A. aphylla and Species2 is H. ammodendron

Table 2. *Non-linear regression analysis results and the average value of thermal time $\theta_T(50\%)$*

Species	*m*±SE	*k*±SE	*b*±SE	T_b±SE (°C)	$\theta_{T(50\%)}$ (°C d)	R^2
H. ammodendron	0.85±0.012	0.90±0.117	6.18±0.775	0.79±0.065	7.26	0.94
A. aphylla	0.87±0.013	0.37±0.040	3.36±0.340	0.54±0.114	9.89	0.94

m, k, b and T_b are the values of parameter estimates. *m:* the approximate final germination percentage; *k:* the rate of increase in germination percentage; *b:* the value related to the lag in germination; T_b: the base or minimum temperature for germination; $\theta_{T(50\%)}$: the median thermal temperature. R^2 and SE are the coefficient of determination and standard error of parameter respectively

Discussion

The research indicates that the majority of seeds germinated optimally in the temperature range of 10–20 °C, in this temperature range, seeds have a high germination percentage, short initial germination time and high germination index (*Table 1*). But soil humidity was not suitable for seed germination of both species when soil surface temperature surpassed 10 °C in the field (Huang et al., 2008). In Junggar basin, the most of desert species can utilize snow-melting water that is available to better germination and seedling survival before the desiccation of early spring (Huang et al., 2009). In the short snow-melting period (12–15 days), air temperature usually is under 15 °C and the soil surface temperature is less than 5 °C (Sun, 2015). Therefore, germination under the low temperature condition has important ecological implications in plant adaptation to drought stress in arid and semi-arid zones. Meanwhile, both species have a lot of seeds germinated in snow-melting period.

In Junggar basin, the research of Han et al. (2011) showed that the snow melted in early spring, during which the maximum air temperature was maintained at 0–15 °C and the relative humidity was 50–60%, and the seeds of *Anabasis elatio* germinated on the

© 2018, ALÖKI Kft., Budapest, Hungary

mother plants and developed into viviparous seedling. Similarly, *Suaeda physophora* can germinate at 10 °C and even at 0 °C from field observation (Li and Zhang, 2007). The phenomenon was consistent with the results from Huang et al. (2003). The results of Zhang et al. (2010) showed germination percentage of *H. ammodendron* and *Haloxylon persicum* was over 80% under 2 °C. In addition, Sun (2015) suggested desert seeds started to germinate only two days when snow melted at the average daily temperature (day/night) of 3.5 °C (6.7/-0.5 °C) and a soil volumetric water content of 24.2%. Therefore, seed germination under low temperatures was a common behaviour for desert plants.

Junggar basin is one of the driest regions of the Eurasian continent. The annual evaporation is 10 times greater than the annual precipitation in the region (Song et al., 2006). The soil may dry up quickly after short periods of rainfall or snowmelt, resulting in a substantial rise in the mortality rate of desert plant seedlings (Huang et al., 2009). So, early germination is of significant importance. Low temperatures only slowed down germination speed in the snow-melting period, and weak salt and high humidity conditions were favourable to desert plant germination in early spring (Chu et al., 2014). Compared with the time of seed germination of different species, seed of early germination was found to provide the advantage for seedling emergency. The seedlings with a longer growth period were as better competitors, gained more nutrition and had a higher precompetitive survival than those with shorter growth period (Körner, 2003; Shimono and Kudo, 2005; Huang et al., 2008; Gornish et al., 2015).

The base temperature of seed germination may be an adaptive feature of plants, and species germinated under low temperatures have a relatively low base temperature (T_b) (Steinmaus et al., 2000). In previous studies, the T_b of temperate species is between 0-4 °C (Angus et al., 1980; Hur and Nelson, 1984; Moot et al., 2000). In this study, *A. aphylla* and *H. ammodendron* are temperate species, and their base temperature was 0.54 °C and 0.79 °C, respectively. This is consistent with previous studies. In the same temperature conditions, species with low base temperature can quickly germinate (Ross and Harper, 1972). Trudgill (2005) showed that germination adapted to low temperature environment requires higher thermal temperature and lower T_b than those adapted to warm environment. Liu et al. (2011) studied the base temperature and thermal temperatures of 12 Compositae species in the Qinghai–Tibet plateau, the base temperatures of the 12 Compositae species ranged from -1.4 to 1.5 °C with an average around 0 °C, and the average thermal temperature was 94.5 °C. Similarly, Larsen (2005) showed that the base temperature for Danish *Festuca rubra* was 2.7 °C and the thermal temperature was 60 °C. In this study, the base temperature of both species was about 0 °C, thermal temperature was 9.89 °C and 7.26 °C, respectively, compared with the previous results. The thermal temperature of the two species was lower than the thermal temperature of other species when the base temperature was similar, indicating that the species in this study not only could germinate at a low temperature, but also thermal temperature was low. In the early spring short snow-melting conditions, plant seeds will quickly germinate and occupy the habitat, with the time and space advantages, this is the result of long-term adaptation to environmental conditions. Therefore, with a consistent water supply in early spring, the seed can tolerate low temperatures to germinate, because of the available water from the melting snow, more heat and nutrients accumulated that are essential for the survival of the seedlings at later stages.

Conclusions

The final germination percentage of both species had no significant difference in 6 temperature gradients, and low temperature only slowed down germination speed. The base temperature and thermal temperature of both species were low. Therefore, seed germination of *H. ammodendron* and *A. aphylla* requires less energy, and this is conducive to early germinate for desert seed. The two species have opportunistic strategies for germination, and they can germinate quickly with short-term low temperature and snow water conditions.

Prospect

Seed germination is a crucial stage of plant life cycle, which directly determines establishment and regeneration of plant population. In arid and semi-arid areas desert species have formed some peculiar strategies of germination adapted to the harsh habitat. We found that desert species represented by *H. ammodendron* and *A. aphylla* have the characteristic of germination during snowmelt period. At present, there have been a lot of research studies on the physiological and ecological aspects of both species at low temperatures. However, few research studies have been done on the molecular level. Therefore, we are also carrying out molecular study. This study is expected not only to explore the anti-freezing pathway and mechanisms of the two species, but also to find some new anti-freezing substances, which will provide some ideas for gene engineering research of anti-freezing for desert plants.

Abstract. To evaluate the effect of different resources and methods of silicon (Si) and zinc (Zn) application on agronomic traits, nutrient uptake and grain yield of rice (*Oryza sativa* L.), a field experiment was conducted as a randomized complete block design with 16 treatments and three replications in Noor region, Mazandaran province, Iran in the crop year of 2015-2016. The experimental treatments included the different resources and forms of Si and Zn application as nanoparticles (NPs) foliar application and soil application of the elements. The results indicated that grain and straw yields were increased in response to application of Si and Zn fertilizers. All fertilized treatments had significantly higher yields than the control, although yields did not differ significantly between the fertilized treatments. The experimental treatments significantly affected the yield components, Si, Zn and N concentrations in the plant tissue. The combined application of Si and Zn by both methods, either via NPs foliar application or soil application resulted in an increase in the grain and straw yields, yield components and Si, Zn and N concentrations in rice grain and straw. According to the results of this research, the combined application of Si plus Zn, especially by NPs foliar application, is appropriate for increasing the production of the rice crop in Noor Region of Iran.
Keywords: *crop yield, foliar application, rice, soil application, silicon, zinc*

Introduction

Silicon (Si) and zinc (Zn) as macro and micronutrients, respectively have a key role in improving growth and increasing grain yield of plants, and their deficiency can make a serious problem for crop production, especially in the case of rice. Silicon is the second most abundant mineral in the soil (Kafi and Rahimi, 2011), that is a useful nutrient for healthy growth and sustainable production of rice (Tamai and Ma, 2008). Silicon has a dual effect on the plant and soil system, which, by being absorbed in the plant, makes the plant more resistant to pests, diseases and environmental stresses, and, on the other hand, led to soil fertility by improving water, physicochemical properties of soil and maintaining the nutrients in available form for the plant (Meena et al., 2014). Soil silicon has several benefits for rice including the reduction of the adsorption of heavy metals such as Pb (Jianguo et al., 2015), Cd (Lin et al., 2016), and As (Wu et al., 2015), resistance to salt stress (Mahmoud et al., 2017), increasing the extent of photosynthesis, the improvement of performance, the prevention of lodging (Jeer et al., 2017), as well as the reduction of the negative effects of ultraviolet radiation on the

DOI: http://dx.doi.org/10.15666/aeer/1605_57815798
© 2018, ALÖKI Kft., Budapest, Hungary

physiological processes of photosynthesis and transpiration (Lou et al., 2016). The modern silicon fertilizers (nano-SiO2) easily penetrate into the leaves and create a thick silicate layer on the leaf surface (Meena et al., 2014). Silicon plays an important role in increasing the activity of antioxidant enzymes and enhancing the content of osmolites, in contributing to the resistance of abiotic and biotic stresses in plants (Amiri et al., 2014). Reports indicated that the use of Si increases the grain yield of rice by increasing the number of whole spikelets (Mobasser et al., 2008) and the number of fertile tillers per hill (Ghasemi Mianaei et al., 2011). Other researchers reported that the Si application significantly increased the tiller number and Si concentration in the plant (Zia et al., 2017). Cuong et al. (2017) reported that increase in Si application, increases the Si absorption and other nutrients such as nitrogen, phosphorus and potassium in rice biomass (grain + straw) compared to control.

Zinc, after nitrogen and phosphorus, is the most important nutrient that limits the grain yield of rice (Yakan et al., 2000), and is a global concern for human nutrition (Farooq et al., 2018). Zinc as a cofactor of antioxidant enzymes such as catalase and peroxidase plays an important part in plant protection and ultimately improves yield (Samart et al., 2017). Zinc has an important role in several physiological processes of the plants such as protein synthesis, enzyme activation, gene expression and carbohydrate metabolism (Chang et al., 2005; Qiao et al., 2014). Studies have shown that zinc improves the absorption of other nutrients such as potassium, phosphorus and iron for the plant (Amirjani et al., 2014). It has been reported that the application of nano-ZnO in the rates of 25 and 50 $mg.l^{-1}$ improves the rice growth (Upadhyaya et al., 2014), but in higher concentrations due to the creation of toxicity by the accumulation of this element in the plant lead to reduction in plant growth and biomass (Boonyanitipong et al., 2011; Chen et al., 2015). The improvement of zinc concentration and enhancement of rice grain yield by Zn supply through soil (basal) + 2 foliar applications have been reported in the results of other investigators (Saha et al., 2017). In a study, which the effects of zinc were evaluated by two methods of foliar application and soil application on yield and yield components of rice, reported that the number of fertile tillers, number of grains per panicle, 1000-grain weight, grain yield, harvest index and grain Zn concentration significantly increased compared to control using both methods (Farooq et al., 2018). Sudha and Stalin (2015) found that zinc application in soil with its foliar application significantly increased the agronomic and physiological traits.

The problem of accessibility to nutrients such as Si and Zn by usual methods results in an increase in the attention to the use of modern methods for application of these elements in recent years. Nanotechnology is one of the most modern methods in agricultural practices. The most important of its applications in different aspects of agriculture, that is in the water and soil section are the use of nano-fertilizers for plant nutrition (Mazlomi et al., 2012). Nanofertilizers are more effective in improving plant nutrition, increasing the efficiency of nutrient use, and protecting plants from environmental stresses than conventional fertilizers (Wang et al., 2015). The Maximum use of production sources, especially with the nano-fertilizers application, and enhancing photosynthesis efficiency can reduce the environmental risks associated with the excessive application of chemical fertilizers (Sepehri and Vaziri Amjad, 2015). Although nanotechnology in agriculture is less developed due to lower investment compared to other sectors, nanotechnology is very effective in improving agricultural production (Huang et al., 2015).

Therefore, the aim of the present study was to evaluate the effects of Si and Zn by applying different resources and methods to improve yield components, nutrient uptake and grain yield of rice.

Materials and methods

Experimental site

The field experiment was conducted during crop year of 2015-2016 in Noor region, Mazandaran province, Iran, located at 36° 46'N latitude, 52° 28'E longitude and 71 m above the sea level (*Fig. 1*). The meteorological data recorded during rice-growing seasons are presented in *Table 1*. The physical and chemical properties of the soil in the experimental site are shown in *Table 2*.

Experimental layout, design and treatments

This experiment was designed as a randomized complete block design with 16 treatments and 3 replications, thus there were 48 equal plots in size of 10 m^2 (5 m × 2 m). The experimental treatments characteristics are presented in *Table 3*.

The land preparation practices were performed according to the conventional procedure, so that the land was disk-ploughed in late February and the complete practices including puddling and leveling were carried out in mid-May. An indica rice (Oryza sativa L.) cultivar Tarom Hashemi was used as plant material for the present research, which is an early rice cultivar that usually used by farmers in the north of Iran. The seed of rice cultivar Tarom Hashemi was obtained from the Rice Research Institute, Mazandaran, Iran. Rice seedlings were transplanted at a spacing of 20 cm× 20 cm with four seedlings per hill in mid-May, and harvested in mid-August. For all treatments, phosphorus and potassium fertilizers were applied as basal at the rate of 70 kg ha^{-1} as triple superphosphate and 100 kg ha^{-1} as potassium sulfate, respectively. Urea was applied as nitrogen fertilizer uniformly for all the plots at the rate of 150 kg ha^{-1} in three equal splits (one third at the time of transplanting, one third at the tillering stage and one third at the heading stage). For soil application, silicon and zinc fertilizers were applied as basal at the rate of 400 kg ha^{-1} as calcium silicate and 40 kg ha^{-1} as zinc sulfate, respectively. For foliar application, nano-SiO_2 and nano-ZnO in the concentration of 50 mg L^{-1} was applied in four stages of plant growth (early tillering stage, middle tillering, panicle initiation and full heading stage) in plots. Nanofertilizers used in the experiment were products of US Research Nanomaterials, Inc (*Table 4*). In order to control the weeds during growing stages, manual weeding was performed twice on days 14^{th} and 28^{th} after transplanting, and for its chemical control, Butakler's herbicide was applied in the concentration of 3.5 L ha^{-1} a week after transplanting. Furthermore, in order to

control *Chilo suppressalis,* diazinon insecticide (10% granule) was used at a rate of 15 kg ha^{-1} at the peak of tillering and heading stages (*Fig. 2*). The rice striped stem borer, *Chilo suppressalis*, is one of the most serious sources of damage to rice growth and production in Asia, northern Africa, and southern Europe (He et al., 2014).

Figure 2. *Photos of experimental field and fertilizer treatments application in growth stages of rice*

Sample preparation and Si, Zn and N analysis

During the flowering stage of the plant, chlorophyll content of flag leaf was measured using chlorophyll meter (SPAD-502, Minolta, Japan). At maturity, determination of plant height and panicle length were performed by measuring 12 plants in each plot. The number of fertile tillers per hill was determined by counting from 12 hill per plot, number of filled and unfilled grains per panicle were determined by counting from 20 panicles per plot and 1000-grain weight was determined by counting and weighing 10 samples of 100 seed. Grain and straw yields were determined by manually harvesting each plot (2 × 2 m^2), separating grains from straw and drying samples in an oven at 70 °C for 48 h. Grain and straw samples were weighed with 14% moisture content and calculated based on kilograms per hectare.

Si concentration in plant samples (grain and straw) was determined by Yoshida method (Yoshida, 1975). Zn concentration in plant tissue was determined by Atomic Absorption Spectrophotometer (AAS) method (Emami, 1996). The N concentration in grain and straw was measured by micro-Kjeldahl method (Emami, 1996). Mobilization efficiency index (MEI) of Si, Zn and N was calculated as *Equations 1, 2* and *3:*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_57815798
© 2018, ALÖKI Kft., Budapest, Hungary

$$Si\ MEI = \frac{\text{Si concentration in grain (\%)}}{\text{Si concentration in straw (\%)}} \quad \text{(Eq.1)}$$

$$Zn\ MEI = \frac{\text{Zn concentration in grain (mg.kg}^{-1}\text{)}}{\text{Zn concentration in straw (mg.kg}^{-1}\text{)}} \quad \text{(Eq.2)}$$

$$N\ MEI = \frac{\text{N concentration in grain (\%)}}{\text{N concentration in straw (\%)}} \quad \text{(Eq.3)}$$

where Si = silicon, Zn = zinc, N = nitrogen, and MEI = mobilization efficiency index.

The mobilization efficiency index of the elements was calculated to determine the amount of transmission of these elements from straw to grain and their accumulation in grain.

Statistical analysis

The data were statistically analyzed using MSTATC software. Randomized complete block design was used for data analysis. The mean comparison was performed using the least significance difference (LSD) test at 5% probability level. A simple linear regression was used to determine the relationship between the concentrations of Si and Zn in grain and straw with N concentrations in rice plant tissue and its yields.

Results

Grain and straw yields

In this study, grain and straw yields were increased in response to application of Si and Zn fertilizers. All fertilized treatments had significantly higher yield than the control, although its yield did not differ significantly between the fertilized treatments. The maximum grain yield (4502 kg ha^{-1}) and straw yield (5933 kg ha^{-1}) were obtained by the application of T13 (nano-SiO2 + nano-ZnO) and T16 (nano-SiO2 + nano-ZnO + calcium silicate + zinc sulfate) treatments, respectively. However, the combined application of Si and Zn had better effect in increasing grain and straw yields compared to individual application of each element (*Table 5*). There was a positive and significant linear correlation between rice grain and straw yields with the Si and Zn concentration in grain and straw at a probability level of 1%, such that by increasing Si concentration in grain and straw (R^2 = 0.1588 and R^2 = 0.0714, $P < 0.01$, respectively), and Zn concentration in grain and straw (R^2 = 0.1749 and R^2 = 0.2173, $P < 0.01$, respectively), grain and straw yield increased (*Fig. 3*).

Plant height and panicle length

In this research, the plant height did not differ significantly comparing experimental treatments. While, the panicle length was significantly affected by the evaluated treatments. The panicle length was significantly increased by combination of both methods of NPs foliar application and soil application in different treatments, but the maximum panicle length (26 cm) was obtained by the foliar application of nano-SiO_2 + nano-ZnO (T13), while the minimum panicle length (21.67 cm) was obtained in the control or no fertilizer application (*Table 6*).

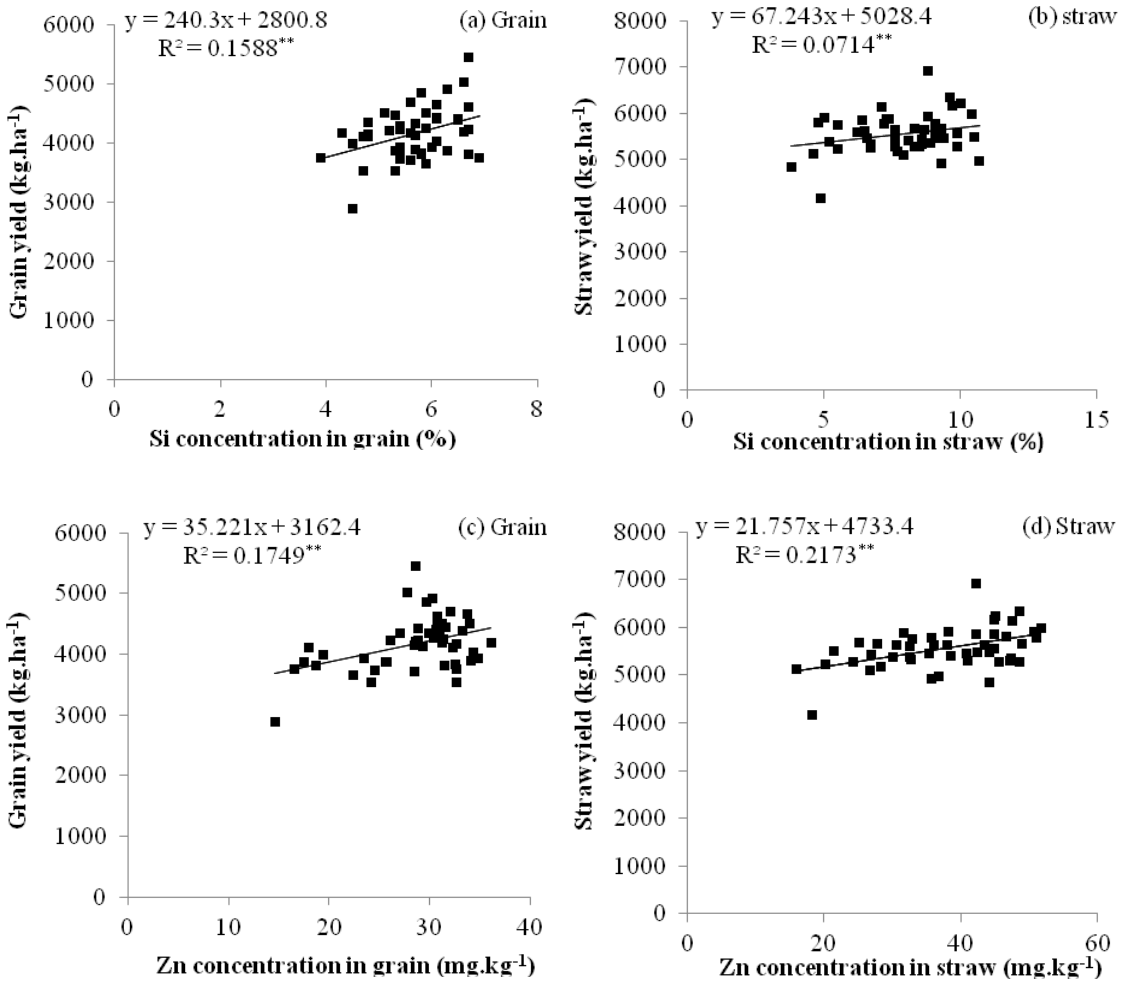

Figure 3. *The relationship of Si concentration in grain (a) and straw (b) with grain and straw yields of rice, correlations of Zn concentration in grain (c) and straw (d) with grain and straw yields of rice under the influence of experimental treatments*

Fertile tiller number per hill

Si and Zn application significantly increased the number of fertile tiller per hill. The maximum fertile tiller number per hill (18.47 tiller) was obtained by simultaneous foliar application of nano-SiO_2 + nano-ZnO (T13), and this trait was reduced under control condition by 28.9% (*Table 6*).

Filled and unfilled grain number, 1000-grain weight

The results of this experiment showed that the number of filled and unfilled grains per panicle were significantly affected by the experimental treatments. The highest number of filled grains per panicle (100 whole grain) was obtained by combined application of nano-SiO_2 foliar spray + calcium silicate soil application (T6), and with no fertilizer application (control), the trait was reduced by 18.4%. Also, the lowest number of unfilled grain per panicle was observed in the treatments of T6 and T14. The effect of experimental treatments was not significant on 1000-grain weight (*Table 6*).

Chlorophyll content of flag leaf

By Si and Zn application the chlorophyll content of flag leaf improved compared to the control, such that the maximum chlorophyll content (38.00) was obtained by T16 treatment application, whereas without applying Si and Zn, this trait was reduced by 7.8% (*Table 6*).

Si concentration in grain and straw

A significant increase in Si concentration in plant tissue was observed by NPs foliar application and soil application of elements. Mean comparison indicated that the Si concentration in grain (6.40%) and straw (9.80%) of rice was significantly increased by combined application of Si and Zn in both methods of NPs foliar application and soil application (T16). The lowest Si concentration in grain and straw of rice was observed in the control or no fertilizer application (T1). The application of T9 treatment increased the Si mobilization efficiency index (1.01) because of the better transfer of Si from straw to seed and consequently its accumulation in grain (*Table 7*).

Zn concentration in grain and straw

The effect of experimental treatments was significant on Zn concentration in rice plant tissue. However, by combined application of Si and Zn in the form of soil and foliar application, Zn concentration was increased in grain and straw. The maximum Zn concentration in grain (32.90 $mg.kg^{-1}$), was obtained by treatments of T16, while the maximum Zn concentration in straw (48.80 and 48.50 $mg.kg^{-1}$) was obtained by

N concentration in grain and straw

The N concentration in grain and straw was increased by Si and Zn application. The NPs foliar application and soil application of Si and Zn significantly improved the N concentration in plant tissue compared to control. The maximum N concentration in grain was obtained by treatments of T14, T15 and T16. Also, the T15 and T16 treatments had the highest N concentration in rice straw. The maximum N mobilization efficiency index in rice plant was observed by T1 treatment or control (*Table 9*). There was a positive and significant linear correlation between N concentrations in plant tissue with the Si and Zn concentration in grain and straw at a probability level of 1%, such that by increasing Si concentration in grain and straw (R^2 = 0.0655 and R^2 = 0.1859, $P < 0.01$, respectively), and Zn concentration in grain and straw (R^2 = 0.1902 and R^2 = 0.4708, $P < 0.01$, respectively), N concentrations in grain and straw increased (*Fig. 5*).

Discussion

The increase of the grain and straw yields with simultaneous application of Si and Zn can be attributed to the positive and synergistic effects between silicon and zinc, which by increasing the Si and Zn uptake, as well as increasing the fertile tiller number per hill lead to an increase in yields. There were synergistic interactions between Si and Zn, which ultimately has contributed to increased absorption of these elements in the plant tissue (Ghasemi et al., 2014). In the present study, in terms of an increase in yields, the NPs foliar application slightly is better than soil application of these elements. The micronutrients in the form of nanoparticles are effective in producing and increasing the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

product yield (Reynolds, 2002). Amrullah et al. (2015) stated that nano-SiO_2 is superior over conventional silicon fertilizer. Gradual release of nutrients during growth stages of the plant by nano-ZnO application increases growth and rice yield (Yuvaraj and Subramanian, 2014). Cuong et al. (2017) reported that by adding silicon, rice grain yield was improved due to increasing growth, yield components, and better absorption of nutrients. Silicon application, especially at reproductive stages increases the chlorophyll content, the number of fertile tiller per hill, percentage of filled spikelets, and finally improves rice grain yield (Tamai and Ma, 2008). Zinc application by both methods foliar application and soil application is suitable for improving grain yield and increasing profitability in various systems of rice production (Farooq et al., 2018). Saha et al. (2017) revealed that zinc supply through soil + 2 foliar application caused the greatest increase in zinc concentration in rice grains by producing optimal grain yield, which confirms the results of the present study.

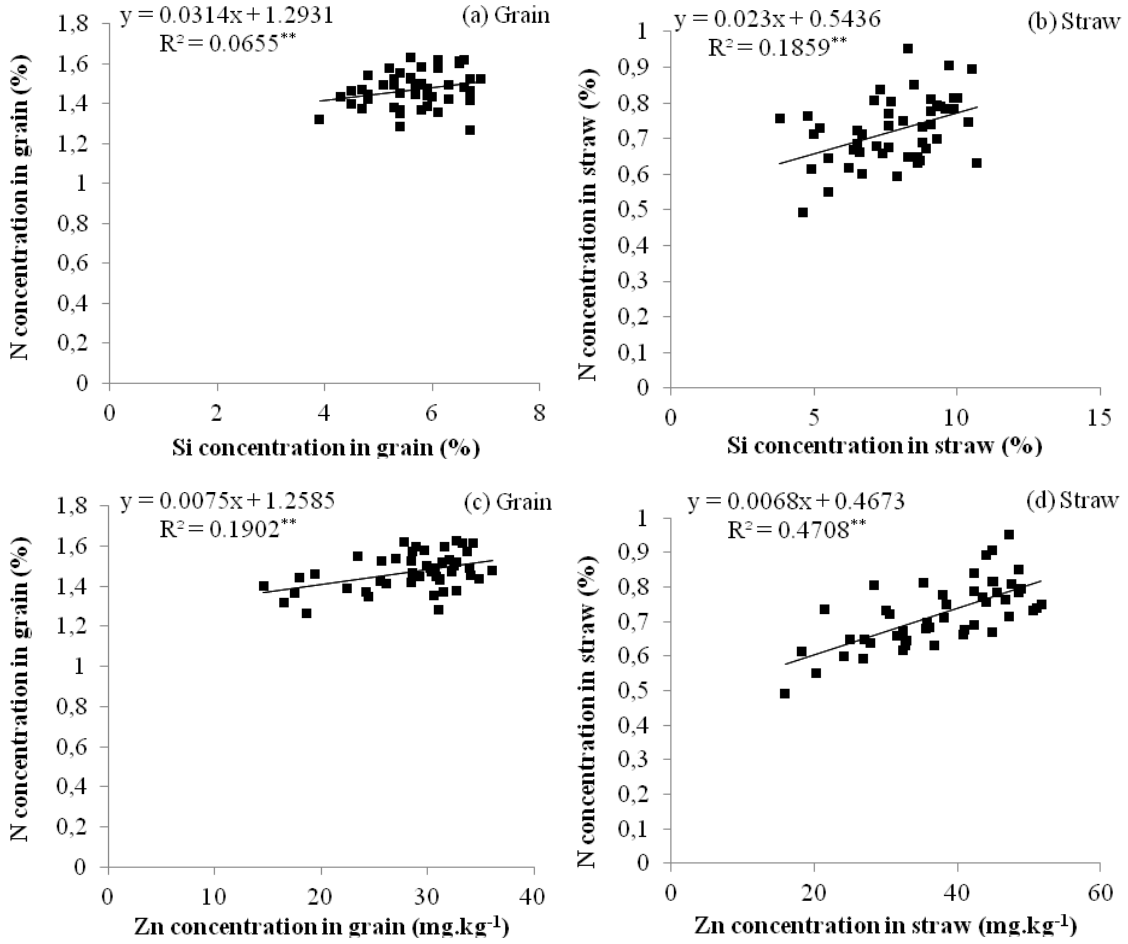

Figure 5. *The relationship of Si concentration in grain (a) and straw (b) and N concentration in grain and straw of rice, correlations of Zn concentration in grain (c) and straw (d) with N concentration in grain and straw of rice under experimental treatments*

It seems that the soil application of Si and Zn was less effective in improving panicle length than NPs foliar application, although it increased the trait compared to control. Although panicle length does not directly have a role in the calculation of grain yield, it

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_57815798
© 2018, ALÖKI Kft., Budapest, Hungary

is considered as one of the yield evaluation attributes (Jalali et al., 2015). Ghasemi Lamraski et al. (2014) reported that foliar application of nano-SiO_2 caused a 1.4% increase in the panicle length compared to non-silicon application. According to Kamari et al. (2014) by foliar application of nano-ZnO significantly increased the panicle length of triticale.

By combined application of Si and Zn in both methods used, the number of fertile tillers per hill significantly increased compared to individual application of Si and Zn. Zia et al. (2017) reported that the proper use of silicon has been effective in increasing the number of rice tillers, such that the application of 3 mM of silicon caused a 19% increase in the number of tiller compared with the control. Application of zinc in both methods of soil and foliar application due to increased zinc concentration in plant leads to an increase in the number of effective tillers per square meter (Farooq et al., 2018). The supply of silicon and zinc by the plant through NPs foliar application increased the number of fertile tillers per hill compared to the soil method. In similar results, the researchers by studying different sources of silicon in the methods of soil and NPs foliar application reported that the maximum fertile tiller number per hill was obtained by nano-SiO_2 foliar application for two crop years (Yazdpour et al., 2014a). The positive effect of zinc on increasing the number of fertile tillers per hill was quite evident over silicon so that in all treatments where zinc fertilizer was used to forms of NPs foliar application and soil application, the fertile tiller number was improved compared to silicon application, although using both elements increased the number of the fertile tiller per hill.

Reduction of the number of filled grains per panicle with no fertilizer application could be due to the lack of availability to nutrients and the reduction of photosynthetic seed distribution, but this trait was increased with the addition of Si and Zn. The result showed that the number of filled grains per panicle significantly increased in treatments where silicon was used. Cuong et al. (2017) reported that the number of grains per panicle was increased by increasing silicon application. The silicon application in the reproductive stages of rice had a very positive effect on the improvement of the number of filled grains per panicle (Lavinsky et al., 2016), which confirms the results of this experiment. According to Tamai and Ma (2008), among the yield components, the percentage of filled spikelets was more affected by silicon fertilizer.

The grain size in rice is controlled by its shell, which shows that why the extent of 1000-grain weight changes is not high (Saha et al., 1998). Reports indicate that the 1000-grain weight was not affected by different concentrations of silicon (Yazdpour et al., 2014a), which is consistent with the results of the present research. In contrast, a piece of research showed that the zinc application from different sources had a significant effect on thousand grain weight of rice (Shivay et al., 2016).

By combined application of Si and Zn in both methods of NPs foliar application and soil application, the chlorophyll meter value increased compared to the separate application of these two element. Nano-Si has an important role in increasing the chlorophyll content of rice leaves (Wang et al., 2015). It was reported that application of nano-Zn oxide did not significantly affect the photosynthetic pigment content of different varieties of rice, but it protected photosynthetic pigments such as chlorophyll a and b in plant cells by improving the antioxidant enzymes activities (Samart et al., 2017). Zinc foliar application at the tillering stage of rice led to an increase in gene expression, carbonic anhydrase enzyme activation, improvement of the photosynthesis process and increase in relative chlorophyll concentration per unit leaf area (Qiao et al.,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_57815798
© 2018, ALÖKI Kft., Budapest, Hungary

2014). Several reports have been presented by investigators regarding the effects of Si (Ranganathan et al., 2006) and Zn (Kabeya and Shankar, 2013) on increasing the chlorophyll content of plants, which is consistent with the results of this study.

In the present research, Si application increased the Si concentration in grain and straw of rice, and Zn application plus Si led to higher concentrations of Si in rice tissue. Reports indicated that the Zn application in the root increases the Si concentration in root and shoot (Mehrabanjoubani et al., 2015). Zia et al. (2017) found that by increasing silicon consumption from 0 to 3 mM, the Si concentration in root and shoot was increased by about 48 and 42%, respectively. According to Yazdpour et al. (2014b) the highest Si concentration in rice was obtained by nano-Si foliar application in both years of study.

The Zn concentration in grain and straw was improved in all treatments in which Zn fertilizer was used to both methods of soil application and NPs foliar application. It has been reported that the zinc concentration in rice grains increased by 47% compared to control, when zinc fertilizer was applied through soil (basal) + foliar application at maximum tillering and flowering stages (Saha et al., 2017). Zinc application using four different methods (foliar application, soil application, seed priming and seed coating) significantly increased grain zinc concentration in various systems of rice production at two different sites (Farooq et al., 2018). Although the combined application of Si and Zn in soil application method led to an increase in grain and straw Zn, the effect of combined application of elements by NPs foliar application method was greater than soil application. Si application by methods of soil application and NPs foliar application individually or in a combination of two methods could not significantly increase the grain and straw Zn concentration, but the Si application plus Zn significantly increased zinc concentration in rice tissue due to the synergistic interaction of these two elements. Similar to the results of this experiment, in previous studies the increase of Zn concentrations in rice plant tissue by the nano-Si application was reported (Wang et al., 2015).

In this research, it seems that role of Zn in improving N concentration was slightly more than Si, although both elements were effective in improving N concentration. The Zn application increases the accumulation of amino acids and nitrogen metabolism in plant tissue (Sudha and Stalin, 2015). Reports indicate that the N uptake was improved by Zn application in two growing seasons (Kumar Naik and Kumar Das, 2008). The researchers revealed that there was a positive and significant linear relationship between the amount of silicon absorption and the uptake of nitrogen in rice plant (Cuong et al., 2017). According to Yazdpour et al. (2014b) the maximum N concentration and protein content of rice were obtained by the foliar application of nano-Si.

Conclusion

In this research, we investigated the effects of different resources and methods of silicon and zinc application on agronomic and physiological traits, as well as the grain and straw yield of rice in Mazandaran province. The results revealed that the application of Si and Zn in both methods of NPs foliar application and soil application had a positive effect on agronomic traits and seed yield, although the influence of Zn fertilizer on grain and straw yields improvement was slightly more than Si fertilizer. Also, in both methods, the foliar application of nanoparticles had better efficiency than soil application of the elements due to the small size of the particles and the ability to absorb

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

more of the elements by the plant. By combined application of Si and Zn, many physiological characteristics such as the Si, Zn and N concentrations in rice plant tissue, yield components and grain and straw yield of rice improved compared to separate application of each elements and control. The main reason for this increase could be synergistic effects between the two elements of silicon and zinc, such that the silicon caused the balance of nutrients in the plant and was a good supplement with zinc in improving the nutrients uptake and increasing grain yield.

Therefore, given that the simultaneous application of silicon and zinc, especially by foliar application of nanoparticles provides the nutrient required for the plant and improves grain production of rice, this fertilizer treatment is recommended for use in soils similar to the one used in this experiment.

Future extensions of this study for future research: It is recommended to investigate the quality of rice produced in the cultivar studied in these treatments. The experimental treatments on late rice varieties can be also studied. Moreover, the germination characteristics of seeds produced in these treatments, as well as the effect of these treatments on the absorption efficiency of the main elements of NPK can be evaluated. Also, the effects of other nano-fertilizers such as nano-MgO and nano-Ag in combination with the nanoparticles used in this experiment, as well as the effects of other fertilizer sources containing silicon and zinc such as potassium silicate and zinc chelate on physiological traits, rice growth and yield can be investigated. Besides, the absorption of other essential nutrients such as P, K, S, Ca, Mg, Fe, Cu, Mn, B, as well as heavy metals such as Cd, As and Pb in rice grains can be measured in order to determine the health status of rice seeds because rice seeds are fed by humans. Finally, the effects of silicon and zinc both in the form of nanoparticles and conventional method on rice grain yield by a foliar application can be studied.

Abstract. Phytosociological studies help to understand extent of biological invasion. Multiple analyses of ecological parameters at different locations derive general explanations of impact on species diversity in plant communities. Current study assessed the impact of *Parthenium hysterophorus* (an annual weed of great significance in Pakistan and worldwide) invasion on native vegetation in Pothwar region of Pakistan. The approach used for the study was random samplings with two categorical factors: invaded and non-invaded under same habitat conditions. Differences in number of species (S), abundance (N), species richness (R), evenness (J'), Shannon diversity index (H') and Simpson index of dominance (λ) were compared between invaded and control plots by t-test series. Control plots harbored by average of 0.9 more species per 10 m^2. The control category was more diverse (H' = 1.73) than invaded category (H' = 1.53). The higher value of species richness in control plots shows the heterogeneous nature of communities and *vice versa* in invaded plots. The lower value of index of dominance in invaded plots shows less sample diversity than in the control ones. At multivariate scale, ordination (nMDS) and ANOSIM showed significant magnitude of differences between invaded and control plots in all sites. The most effected site by *Parthenium* invasion was Jhelum followed by Attock, Rawalpindi, Chakwal and Islamabad. The decrease in diversity indices in invaded over control sites indicated less productive plant communities due to *Parthenium* invasion. This makes *Parthenium* a candidate of consideration for appropriate control measures.
Keywords: *invasion impacts, diversity indices, multivariate analysis, diversity conservation, PRIMER*

Introduction

There has been a rapid acceleration in the number and rate of plant invasions attributed to increased dispersal of exotics and expansion of disturbed habitats associated with rapid human population growth (Collier and Vankat, 2002). The introduction of invasive plants may change the structure and function of ecosystem, e.g., alterations in succession, species composition, biomass, net primary productivity and nutrient cycling (Charles and Dukes, 2007; Dassonville et al., 2008). Invasive species may also deplete available resources. Other studies have shown changes at population, community and landscape levels (Collier and Vankat, 2002; Qureshi et al., 2014). Consequently, studying the community level impacts of the invader identifies its

© 2018, ALÖKI Kft., Budapest, Hungary

potential effects and provides valued information for management and nature conservation strategies (Hejda et al., 2009).

Plant invasions deplete native species diversity, alter community composition and effect ecosystem processes thus cause ecological and economic imbalance (Kunzi et al., 2015). Exotic plants coexist in relative harmony in native habitat but competitively exclude neighbors in recipient communities. Various studies have provided data on the effects of exotic invasive plants on declining indigenous diversity and altering native community composition. These studies assumed different mechanisms that generate substantial invasion impacts. Among these processes are allelopathy, competition, and alteration of native ecosystem characteristics (Odat et al., 2011). Direct competition with native flora may result in monocultures of exotic species, e.g. *Parthenium hysterophorus* in Pakistan, Australia and India and *Psidium cattleianum* in Mauritius (Dogra et al., 2010). In different parts of the world, 80% of endangered species are threatened by alien invasive species (Pimentel et al., 2005).

Parthenium is an aromatic, annual herb native to Mexico, southern United States and South & Central America. It was inadvertently introduced to many countries and now has become a troublesome rangeland and agricultural weed in parts of Africa, Asia, Australia and the Pacific Islands (*Fig. 1*). Because of its status in the world, it is documented among world's top ten worst weeds (Tamado and Milberg, 2000; Khan et al., 2014). *P. hysterophorus* is assumed to move in to India along food grains trade in from USA. It then has spread to sub-continent (Nath, 1988). It is supposed to enter Pakistan via road links where automobiles cross at many places every day. In Pakistan, *Parthenium* weed was stated in the 1980s from Gujarat, Punjab (Razaq et al., 1994). Since then, it has spread rapidly all through to Islamabad, Punjab Province and parts of Khyber Pukhtunkhwa. *Parthenium* affects biodiversity, crop production and human and animal health (Shabbir, 2013). It grows in a range of habitats. Wide environmental adaptability, drought tolerance, photo and thermo-insensitivity, high seed production, small and light weighted seeds adept of long distance travel via water, wind, birds, animals and vehicles, longevity of seeds in soil seed banks, strong competition and allelopathy contribute to its invasiveness (Khan et al., 2014; Hassan et al., 2012; Shabbir and Bajwa, 2006).

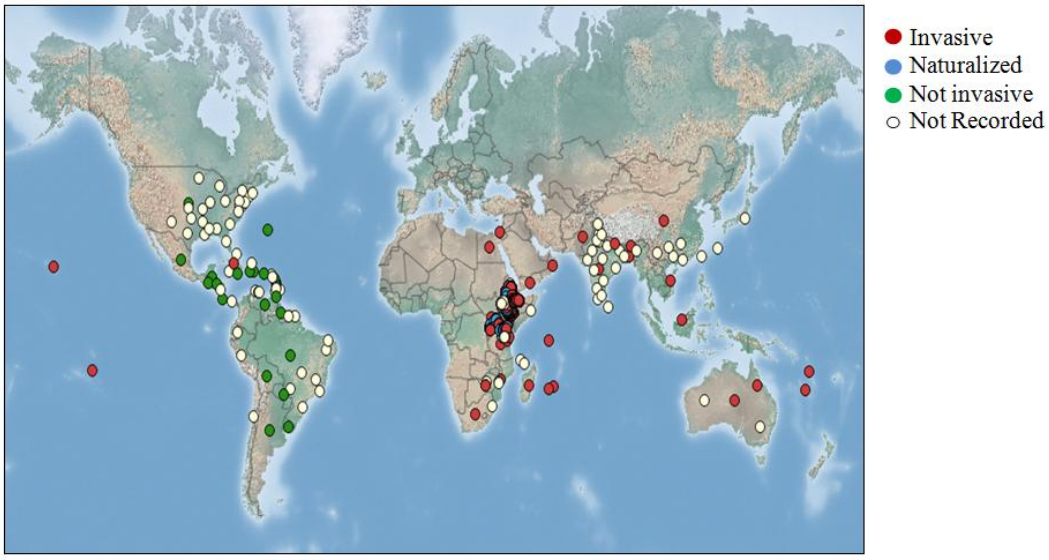

Figure 1. *Distribution map and invasion status of Parthenium weed around the globe*

Parthenium is one of the worst weeds presently known in Pakistan. No previous study is reported from Pothwar region regarding its ecological impacts. The current study was carried out to find out (1) what is the effect of *Parthenium* weed on ecological diversity indices in different districts of Pothwar region (assuming each district as 'site'); (2) do the effects on diversity differ between different sites (districts) in the area?

Materials and methods

Study area

Pothwar is a north-eastern plateau in Pakistan, making the northern part of Punjab. It edges Azad Kashmir (the western parts) and Khyber Pakhtunkhwa (southern parts). Pothwar Zone extends from 32.5°N to 34.0°N latitude and 72°E to 74°E longitude and lies between the Indus and Jhelum River. The plateau expanses from salt range northward to the foothills of Himalayas. The Pothwar region embraces Jhelum, Islamabad, Attock, Rawalpindi and Chakwal districts (*Table 1*). Total area of Pothwar region is 28488.9 km^2. (Rashid and Rasul, 2011). Pothwar region has an extreme climate with hot summers and cold winters. Weather is divided into four seasons: Cold (December-March); Hot (April-June); Monsoon (July-September) and Post-Monsoon season (October-November). This area gets an average annual rainfall of 812 mm, about half of which occurs in the Monsoon months (July-September). The mean maximum temperature rises till the month of June and then falls appreciably with advent of rains, being coldest in January (14.62-18.7 °C). Average temperatures range from 14 °C in January to 37 °C in June (*Fig. 2*). The region has broadly four types of soil: loess, river alluvium, residual and piedmont alluvium. Due to dynamic climate and combination of hills and plains, Pothwar region is rich in biodiversity. Native vegetation is characterized by open patches of grasses and forb species. *Albizia lebbeck* (L.) Benth., *Acacia modesta* Wall., *Abies pindrow* (Royle ex D. Don) Royle, *Cassia fistula* L., *Cedrela toona* Roxb. ex Rottler, *Dalbergia sissoo* Roxb., *Dodonaea viscosa* Jacq., *Ficus religiosa* L., *Ficus benghalensis* L., *Melia azedarach* L., *Olea cuspidata* Wall. Ex G. Don., *Zizyphus jujuba* Mill. and *Zizyphus nummularia* (Burm. f.) Wight & Arn. are principle species in the region (Shabbir et al., 2012; Ghufran et al., 2013).

Table 1. *Coordinates of study sites*

District	Coordinates
Jhelum	32.94°N, 73.72°E
Islamabad	33.73°N, 73.09°E
Attock	33.76°N, 72.36°E
Rawalpindi	33.59°N, 73.04°E
Chakwal	32.93°N, 72.85°E

Experimental design

Field work was carried out during July-August (being the maximum growth period of plants), 2016. The effect of invasion was studied in each of five districts (Attock, Chakwal, Jhelum, Islamabad and Rawalpindi). Ecological indices for selected invaders

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_57995813
© 2018, ALÖKI Kft., Budapest, Hungary

were calculated and compared at various sites. The sampling technique was random. For each district six invaded and six non-invaded paired vegetation plots (each 3.16 × 3.16 m in size, i.e., 10 m^2 in area) were sampled. Based on visual observations, plot of invaded vegetation ('invaded plot') where the invader showed dominance was considered as 'treatment' and a second vegetation plot, usually 0.5-1 km apart from treatment, where invader has no dominance ('non-invaded plot') was considered as the "control". The estimated density of the weed in the area across locations was 4/m^2. In all, a total of 60 vegetation plots were sampled (consisting of six paired samples per district, and hence 30 treatments; 30 controls for the entire Pothwar region) (*Fig. 3*). Within each randomly chosen plot (10 m^2 in area), all vascular plant species in control and invaded plots were identified to species level.

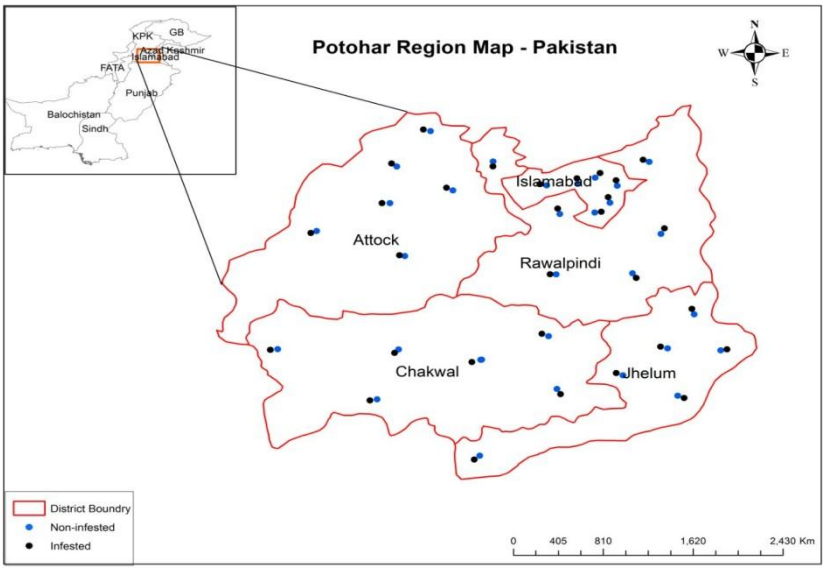

Figure 3. *Distribution of plots for impact analysis of Parthenium hysterophorus in Pothwar region*

Data analyses

Species frequency data were created and invasion impacts of *P. hysterophorus* on local flora were assessed by calculating and comparing ecological indices including Margalef's index of richness, Shannon–Weaver index of diversity, Simpson index of dominance and index of evenness for control and invaded sites (Magurran, 1998). These parameters were calculated as (*Eqs. 1, 2, 3* and *4*):

$$\text{Margalef's index of richness (R)} = \frac{S-1}{\ln N} \quad \text{(Eq.1)}$$

N = Total number of individuals; S = Total number of species.

$$\text{Shannon-Weaver index of diversity } (H') = -\sum_{i=1}^{S}\left(\frac{n_i}{N} \times ln\frac{n_i}{N}\right) \quad \text{(Eq.2)}$$

N = Total number of individuals of all species; n = Actual number of individuals of one species.

$$\text{Simpson index of dominance } (\lambda) = 1 - \frac{\sum_{i=1}^{S} n_i(n_i-1)}{N(N-1)} \quad \text{(Eq.3)}$$

N = Total number of individuals of all species; n = Number of individuals of one species.

$$\text{Index of evenness } (E) = \frac{H'}{lnS} \quad \text{(Eq.4)}$$

H' is Shannon's index; S = Number of species.

Rarefaction curves were plotted to determine if sampling was adequate in each district using observed, Coleman's, Jackknife, Bootstrap and Chao2 models in PRIMER v. 7 (Clarke and Warwick, 2001). All gave comparable results; consequently only that of real (observed) data are presented. Data were then subjected to univariate and multivariate analyses of non-metric multidimensional scaling procedure (Clarke and Gorley, 2015). Data were log transformed to achieve criteria of normality (evenness and Simpson index of diversity). For invasion impact analysis, diversity indices including total number of species (S), abundance (N), species richness (R), species evenness (J'), Shannon index of diversity (H′) and Simpson index of dominance (λ) were calculated for control as well as for invaded plots. The above ecological indices were subjected to analysis of variance (ANOVA) with invasion status and districts as factors using IBM SPSS v. 21. Differences between ecological indices for five districts were individually tested for significance between invaded and control plots by multiple comparisons tests of t-test. Data were further analyzed for species assemblages by non-metric multidimensional scaling (nMDS) in two-three dimensions with invasion status (control, invaded) as factor using PRIMER V.7 software. nMDS was used to ordinate the similarity of data between site categories (invaded, control) based on Bray-Curtis dissimilarity matrix following log-transformation of species abundance data due to zero species count in some plots. The range of clustering of sites and locations in response to invasion were assessed by analysis of similarity (ANOSIM) and similarity percentage (SIMPER). ANOSIM relates mean difference of ranks between and within groups, generating the Global statistic (R). The values of Global statistic (R) range from -1 to +1. Values near 0 and negative values demonstrate similarity among groups. Values impending +1 indicate a strong dissimilarity among groups (Clarke and Warwick, 2001; Osunkoya et al., 2017). SIMPER identified species contributed most to average dissimilarity between groups (invaded and control plots). This technique calculates average impact of each species contributing to dissimilarity between groups (Clarke and Warwick, 2001). Values of percentage similarity between groups range between 0 to 100, with 100 stating maximum similarity.

Results

To assess sampling completeness, rarefaction curves plotting cumulative number of species as a function of sampling effort were used which indicated that sampling was reasonably complete (*Fig. 4*). A total of 56 plant species from 50 genera were documented during the study (*Table 2*). A total of 56 species were recorded in control plots compared with 37 in infested plots. Mean species diversity and richness/quadrat was higher in control plots (*Fig. 5*).

Comparisons of ecological indices showed significant difference across districts and invasion status. *Parthenium* invasion exhibited variable impact across five districts by reducing species number per plot (S) and abundance (N) up to a maximum of 40% in Attock. Control plots harbored on average 6.033 ± 1.75 (mean ± SD, n = 30) species. This was greater than that observed in the invaded plots (5.133 ± 1.83) and the difference was statistically significant (t = 2.09, df = 29, p = 0.045). A total of 181 and 154 individuals were recorded in control and invaded plots respectively. Similarly, abundance in control and invaded plots differed by 3.7 ± 3.83 (mean±SD, n = 30) and the difference was significant (t = 4.34, df = 29, p < 0.0001). Control plots also exhibited higher values of species richness by a difference of 0.15 ± 0.51, species evenness by 0.019 ± 0.02; Shannon index of diversity by 0.2 ± 0.34 and Simpson index of dominance by 0.22 ± 0.35 (*Table 3*).

Table 3. *Analysis of variance (ANOVA) of invasion impacts and district on diversity indices of local plant community*

Ecological index	SUMMARY ANOVA			Mean (±SD)	
	District (D)	Invasion status (IS)	D×IS interaction	Control (30)	Invaded (30)
No. of species (S)/10 m^2	**	**	***	6.033±1.75	5.133±1.83
Abundance (N)/10 m^2	**	***	**	14.4±3.81	10.70±3.86
Species richness (R)	**	NS	***	1.87±0.49	1.62±0.53

Simpson index of dominance (λ)	**	**	***	1.72±0.29	1.50±0.42

***P ≤ 0.001; **P ≤ 0.02; *P ≤ 0.05; NS (not significant) P > 0.05

For individual district, native flora differed significantly in species density (S), abundance per plot (N), species evenness (J') and Simpson index of dominance (λ) but not in overall species richness (R) and Shannon index of diversity (H'). *Parthenium* invasion had significant impacts on all ecological indices except species richness (R) at site 1 (Attock). For site 2 (Chakwal), only abundance was affected significantly. For site 3 (Islamabad) invasion impacts were not significant only on native species abundance. Species evenness (J') was non-significant for site 4 (Jhelum) while for site 5 (Rawalpindi) the only index significantly affected by *Parthenium* invasion was species evenness (J') (*Table 4*).

Table 4. *Student's t-test for significance of differences between control and invaded plots at different sites*

Site	Number of species (S)	Abundance (N)	Species richness (D)	Species evenness (J')	Shannon index of diversity (H')	Simpson index of dominance (λ)

The ordination (nMDS) and ANOSIM showed significant magnitude of differences between species composition of invaded and control plots in all sites with global R values of 0.876 (p = 0.002), 0.519 (p = 0.002), 0.598 (p = 0.002), 0.907 (p = 0.002) and 0.759 (p = 0.002) for Attock, Chakwal, Islamabad, Jhelum and Rawalpindi, respectively (*Fig. 6*). The greatest dissimilarity between invaded and control plots was noticed by Jhelum.

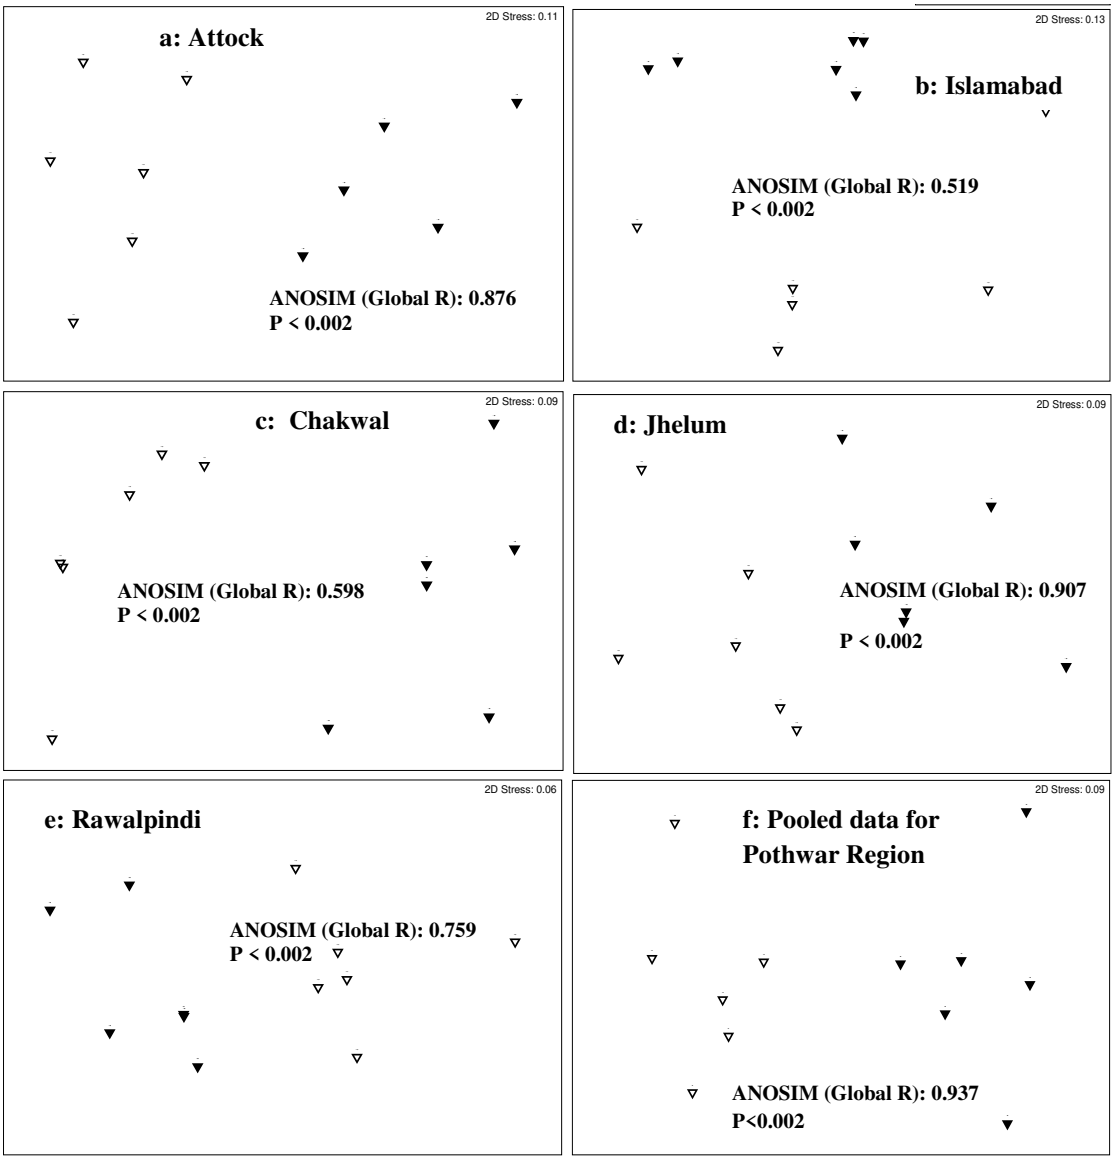

Figure 6. *Multidimensional scaling (MDS) ordination and analyses of similarity (ANOSIM) results of invasion status data for Pothwar region, Pakistan (open symbols are for control, uninvaded plots, and closed symbols are for invaded plots)*

Similarity percentage (SIMPER) analysis of data suggested those species contributing most to average dissimilarity between control and invaded groups. This analysis also computed average contribution of species causing dissimilarity. Few top species separating invaded plots from non-invaded plots (control) for analysis are enlisted in *Table 5*. *Tephrosia purpurea* and *Lathyrus aphaca* were found in control

Discussion

Parthenium weed exerts significant impact on natural communities by displacement of native species and hence exert discrepancy in natural ecosystems. This discrepancy results in formation of its large monocultures. In present study, comparisons of ecological indices across invaded and control plots indicated significant differences in the study area. These findings are in-line with other studies on this alien invasive weed, in which indicated strong effects of the invader on ecosystem properties, e.g., in grazing and wastelands of district Attock (Riaz and Javaid, 2011), district Hafizabad, (Riaz and Javaid, 2010) and Islamabad, Pakistan (Shabbir and Bajwa, 2007).

The results show modifications in vegetation composition of invaded and control plots. Analysis of variance among invaded and control plots showed significant decrease in ecological indices across site and invasion status. These results are consistent with other studies on invasive species indicating their negative effects on bio-diversity and ecosystem properties (Manchester, 2000; McNeely, 2001; Grice, 2006;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

Borokini et al., 2011; Jeschke et al., 2014; Panetta and Gooden, 2017). In our study, despite the negative effect of *P. hysterophorus* on species composition, species evenness of control and invaded plots was not significantly different. That is contradiction to above-mentioned studies; however, a few studies have shown that invasive species pose little or no effect on species diversity (e.g., Martin, 1999; Hejda and Pysek, 2006; Timsina et al., 2011). It is reported elsewhere that *Parthenium* invasion enriches compositional diversity but may result in extinction of native species (Nigatu and Sharma, 2013).

Wide environmental adaptability, drought tolerance, photo and thermo-insensitivity, high seed production and short life cycle (being an annual), small and light seeds capable of long distance travel via water, wind, birds, animals and vehicles, longevity of seeds in soil seed banks, strong competition and allelopathy contribute to the invasiveness of Parthenium weed (Shabbir and Bajwa, 2006; Hassan et al., 2012; Khan et al., 2014). Allelopathy especially plays important role in the invasion of this weed. The major allelopathic compounds found in *P. hysterophorus* are, gentisic, o-coumaric, p-coumaric, ferulic, vallinic, caffeic, salicylic acid, p-hydroxybenzoic and trans-cinammic acids and sesquiterpene lactone etc. (Borah et al., 2016). These allelochemicals are supposed to reduce native seed germination, allowing the weed to pre-empt space and establish monocultures.

Parthenium invasion exhibited variable impacts in five sites by reducing species number per plot (S), abundance (N), species richness (R), species evenness (J'), Simpson index of dominance (λ) and Shannon index of diversity (H'). The trend of decrease in ecological indices in invaded plots is similar to invasion studies on *P. hysterophorus* from Australia, Ethiopia, Nigeria, Tanzania and India (Grice, 2006; Kilewa and Rashid, 2012; Seta et al., 2013; Borokini et al., 2011; Abdulkerim-Ute and Legesse, 2016). The most effected site by *Parthenium* invasion was Jhelum followed by Attock, Rawalpindi, Chakwal and Islamabad. The lowest invasion impacts in Islamabad compared to other sites are probably because of management practices in the area being its importance as metropolitan region of Pakistan while highest dissimilarity in invaded and control plots in Jhelum is possibly due to the saline soil of the area (Anonymous, 2017).

The ordination (nMDS) and ANOSIM showed significant magnitude of differences between species assemblages of invaded and control plots. The difference was significant for all of five study sites but the greatest dissimilarity between invaded and control plots were noticed by Jhelum. It was reported that the *Parthenium* plant has a higher survival rate in higher level of soil salinity (Upadhyay et al., 2013), a condition inimical to establishment of many native plant species. Consequently the higher invasion impacts in Jhelum are possibly due to its saline soil (Anonymous, 2017).

SIMPER analysis showed dominance of fewer species in invaded plots than in control. These were *Tephrosia purpurea* and *Lathyrus aphaca.* Possible reason for their presence in invaded plot may be due to their aggressive nature as weeds in their own right. Perhaps higher contribution values of Fabaceae weeds is due to competition potential with *Parthenium* as suggested by Belachew and Tessema (2015); Gnanavel (2013). There is an urgent need of appropriate control measures including the use of proven biological control agents for this weed in Pakistan as done elsewhere around the globe/world, e.g., Australia and South Africa (Kaur et al., 2014; Strathie et al., 2011).

Conclusion

The increased occurrence of invasion around the world poses a major threat to indigenous diversity. Plant invasions in novel areas deplete species diversity, alter indigenous community composition, affect ecosystem processes and thus cause huge ecological and economic imbalance. Invasive species studied in the past revealed that the effects of invasion are complex and can permanently alter the function and structure of communities, cause local annihilations and changes in ecosystem processes. Invasion by alien plant species affect the composition and dynamics of species on a wide scale and have great impact on ecosystem functions. The decrease in ecological diversity indices in invaded over control sites in present study indicated that plant communities become less productive due to *Parthenium* invasion, hence it is a threat to plant diversity of invaded areas. There is an urgent need of appropriate control measures including the use of proven biological control agents for this weed in Pakistan.

(Received 29th Apr 2018; accepted 5th Jul 2018)

Abstract. Organic carbon is an important component of soil that influences soil fertility, biological activity, food security, and climate change. One of the important issues in soil science is the establishment of empirical relationships between different soil properties. The objectives of this research were to investigate the influence of different factors on soil organic carbon, such as total nitrogen, clay content, calcium carbonate equivalent and pH, for soils from various geomorphologic settings in the Damavand Region in Northwest Tehran, Iran. Regression models were developed for prediction of the organic carbon content of soils characteristics in this region. Lower SOC concentrations were measured for plateau soils (~4.92 g kg^{-1}), associated with lower plant biomass and reduced temperatures at higher elevations. In contrast, soils from River Alluvial Plain regions, which are currently utilized for gardening, had the highest organic carbon content (~22.05 g kg^{-1}). For all landform types (i.e., alluvial fan (irrigated farming lands), plateau (Rangeland), and River Alluvial Plain soils (garden)), SOC had positive and significant relationship with total nitrogen ($r = 0.962$, $p < 0.01$). Simple linear regression, multiple linear regression, and nonlinear regression models were also developed for describing the relationship between SOC and landforms physical and chemical characteristics.
Keywords: *physiographic characteristics, regression models, soil properties*

Introduction

Current investigation attempted to enhance the amount of organic carbon captured in soils. Organic matter is one of the most important indicators of soil quality. Recent efforts have been made to increase the carbon storage capacity of soils, having a positive effect on biological activity, fertility and productivity (Baldock et al., 2010). The sequestration of carbon in soil has the potential to offset greenhouse gas emissions (i.e., CO_2, CH_4, and N_2O) associated with climate change (Xun et al., 2010). Practical methods to increase carbon sequestration of particular research were developed. This requires an understanding of the influence of different land-management practices (e.g., tillage) on soil organic carbon (SOC) (Gaiser et al., 2008), which is complicated by the fact that SOC is affected by climate, soil type, vegetation type, topography and land drainage, as well as land management practice (Gami et al., 2009).

Zhao et al. (2017) researched the impact of shifts in land use on SOC in an agro-pastoral ecotone of Inner Mongolia. Li et al. (2016) estimated the impact of land use change on SOC sequestration in China from 1985 to 2005. However, the effect of shifts in land use on carbon budget in China's arid and semi-arid regions, such as the Shiyang River Basin, has received little attention, which limits our understanding of the mechanisms by which land use change affects the carbon cycle. Poeplau and Don (2015) showed that planting cover crops during winter and tilling them into the soil as additional carbon input can significantly enhance soil C on croplands.

It is important to identify the relationships between SOC and landscape features and to assess the amount and spatial variability of carbon storage in soils. Physiographic

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_58155824
© 2018, ALÖKI Kft., Budapest, Hungary

characteristics such as altitude, slope and aspect have an influence on the efficiency of carbon sequestration in different regions. Wang et al. (2010) showed that landscape characteristics influenced SOC. They measured lowest organic carbon accumulation in elevated areas and identified a significant negative relationship between SOC and elevation ($r = –0.429^{**}$). The same relationship also found a significant negative correlation between SOC and slope ($r = –0.195^{**}$).

Heidari et al. (2010) suggested that the highest levels of carbon are found in areas that have moderate rainfall and low elevation. These factors are unaffected by human activities (i.e., tillage), and have suitable climatic conditions (i.e., temperature and precipitation) so that the growth period is not limited. While the ability to estimate carbon sequestration in a wide range of environments is essential, this has been limited by the complexities of soil characteristics and environmental conditions (Padilla et al., 2010).

Topography is one of the most important factors affecting the amount of organic carbon in soils, but this is not a simple relationship. For example, Senthilkumar et al. (2009) found that the influence of topography on organic carbon storage varied between different agricultural systems. This was attributed to the accumulation of plant residues that affect SOC content in the uppermost 0–30 cm depth of the soil. Soil organic carbon also varies with slope, due the influence of leaching, soil erosion, vegetation, and other physical properties such as soil texture (Boulal and Macpherson, 2010).

Geostatistical methods provide a way of studying and predicting the spatial variability of SOC based on relationships with other soil properties and landscape characteristics (Zhang and McGrath, 2004). These relationships can be expressed as regression models (Vasques et al., 2010), developed using parameters that measured in the field, or for which data already exist (Sarmadian et al., 2010). Motallebi et al. (2011) also estimated soil hydraulic properties (e.g., bulk density, calcium carbonate content, and sand–silt–clay fractions) for a semi-arid region using similar models. However, few studies have examined the spatial patterns of SOC and its relationship with the physiographic properties in semi-arid regions (Heidari et al., 2010; Parvizi et al., 2010).

The objectives of this research were to: (i) investigate the influence of physical and chemical characteristics (e.g., total nitrogen, equivalent calcium carbonates, clay content and pH) on SOC and (ii) develop regression models between SOC and different landform types in the Damavand Region of Tehran, Iran.

Materials and methods

Study area

The Damavand Region is located in northeast of Tehran in Iran (*Fig. 1*), covers about 6272 ha at 35°35’55”–35°40’37”N and 51°59’11”–52°11’33”E. The climate is predominantly dry and cold, with a mean annual precipitation of 322 mm and a mean annual temperature of 11.6 °C (1999–2010 data) (Climatic Data Center, 2010). Height above sea level varies between 1800 and 2200 m. The main landforms of the region are “alluvial fans, River Alluvial Plains, and plateaus” and soils classified as Entisols and Inceptisols using the USDA soil classification system (Keys to Soil Taxonomy, 2010).

A digital elevation model (DEM) of the region was developed in Arc-GIS from a topographic map (1:25,000 scale). Physiographic characteristics (slope, altitude, and aspect) were classified using the DEM, and landform units were subsequently

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_58155824
© 2018, ALÖKI Kft., Budapest, Hungary

determined. Landform units were determined by overlaying the slope, hypsometric and aspect maps.

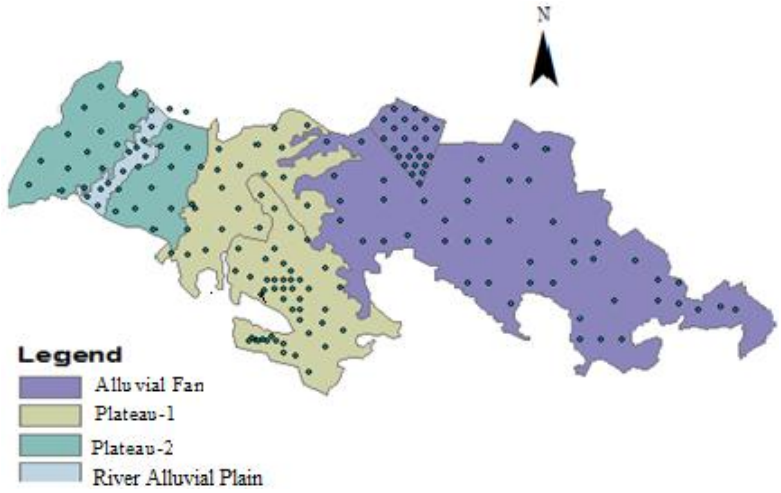

Figure 1. *Landform types and sampling sites in the Damavand Region of Tehran, Iran*

Dividing the slope according to the irrigation management division and determining the height adjustment according to the type of cover and management changes. Nine elevation classes (1820-1900 m, 1900-1950 m, 1950-1985 m, 1985-2020 m, 2020-2045 m, 2045-2075 m, 2075-2110 m, 2110-2150 m, 2150- 2200 m), four slope classes (0-5%, 5-12%, 12-25%, > 25%), and four aspects (north, south, west, east) were defined. ETM+ satellite images (from 2002), Indian Remote Sensing (IRS) satellite images (from 2007), and Moderate Resolution Imaging Spectroradiometer (MODIS) satellite images (from 2010) of the region were analyzed to delineate land type boundary from Rs and using GIS software. The use of remotely sensed data from satellite imagery or aerial photography has become commonplace in soil management studies (Karl and Maurer, 2010).

Soil sampling

Soil samples were collected from 0-25 cm soil depth, for each land unit. Sampling was done with a shovel of about 2 kg. Average slopes of alluvial fan 0-5% and clay loam texture, Plateau 1: average slopes 5-8% and silty clay loam texture, Plateau 2: average slopes 8-12% and sandy loam texture, River Alluvial Plains: average slopes 0-5% and loam texture. They were classified based on the relative area under each soil type, land use, slope, aspect, and elevation class. The plateau was divided into two groups due to the type of cover and management. The total number of 1607 sites was initially classified. According to the Minimum Decision Area (MDA) (*Eq. 1*), areas less than 10 ha were merged with neighbor polygons, reducing the number of sites by 160, as follows:

$$MDA(hac) = 1.6cm^2 \times 10^{-8}(hac.cm^2)(Scalefactor.mm^{-1}) \quad \text{(Eq.1)}$$

Sampling sites were located in the field using GPS in October 2010. At each sampling location, three separate points (approximately 10 m apart) was sampled at 0–

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_58155824
© 2018, ALÖKI Kft., Budapest, Hungary

30 cm soil depth. These three individual samples were combined to form a single bulk sample for each site. Samples were sealed in plastic bags and transported to the laboratory. At each location, recorded the latitude longitude, landscape position, slope class, aspect, elevation, land cover, and land management practice.

Laboratory analysis

Soil samples were air-dried and sieved in the laboratory to retain the <2 mm fraction. Soil pH was measured in a 1:1 suspension of soil and distilled water (McLean, 1982). Soil texture was measured using hydrometer method (Bouyoucos, 1962). Soil organic carbon was determined using the Walkey–Black method (Walkley and Black, 1934). Bulk density (BD) was measured using standard paraffin wax procedures. (USDA, 1995). Total Nitrogen (TN) was determined using the Kjeldahl method (USDA, 1995). Calcium carbonate equivalent (T.N.V), was measured using the Acidimetric method, which involved neutralization of the sample by a titrated acid. Back-titration using a base that used to determine CaCO3 content (USDA, 1995). Particle size distribution was determined using the hydrometer method (Gee and Bauder, 1979).

Statistical analysis

Descriptive statistical parameters for SOC were determined, including the mean, median, skewness, kurtosis, standard deviation, variance, coefficients of variation, maximum and minimum. Pearson correlation coefficients (r) were estimated for all possible paired combinations of the response variables to generate a correlation coefficient matrix. Kolmogorov–Smirnov tests showed that the data were not normally distributed; consequently, non-parametric tests were used. The Kruskal–Wallis test was used to assess differences in SOC between land units (Mills and Cowling, 2010). Simple linear regression, multiple regression, and simple nonlinear regression methods of predicting SOC were assessed. The limiting stepwise regression was applied on the input variables to prevent internal regression.

The performance of the regression models were evaluated by cross validation, where estimated and observed values are compared at each of the observed value location. Reliability of the models evaluated with an independent dataset. Estimated and observed values were compared using two criteria: mean absolute error (MAE) and mean bias error (MBE) (*Eqs. 2* and *3*):

$$MAE = \frac{1}{n}\sum_{i=1}^{n}\left|z^*(x_i) - z(x_i)\right| \quad \text{(Eq.2)}$$

$$\mathrm{MBE} = \frac{1}{\mathrm{n}}\sum_{\mathrm{i}=1}^{\mathrm{n}}\left(\mathrm{z}^*(\mathrm{x_i}) - \mathrm{z}(\mathrm{x_i})\right) \quad \text{(Eq.3)}$$

where z*(xi) is the value to be estimated at the location of xi, z (xi) the known value at the sampling site xi and n is the number of sites.

Geostatistical analysis was also used to infer the spatial variation of SOC at each site. The spatial distribution of SOC was predicted by the IDW method. In this study, the geostatistical analyses were produced with GIS software ArcGIS (version 9.3).

Results

The results showed that there are significant differences of the Kruskal-Wallis ($p < 0.01$) test between soil organic carbon contents of the four land types (*Table 1*).

Table 1. *Comparing SOC among land forms ranks*

Landform-code	N	Mean rank
Alluvial fan (irrigated farming lands)	54	89.62
Plateau1 (dry farming)	56	66.29
Plateau2 (rangeland)	30	44.12
River alluvial plain (garden)	12	146.08
Total	152	

The highest SOC was measured in River Alluvial Plain soils (mean SOC = 22.04 g kg^{-1}), followed by alluvial fan soils (mean SOC = 7.75 g kg^{-1}), plateau 1 soils (mean SOC = 6.17 g kg^{-1}), and plateau 2 soils (SOC = 4.92 g kg^{-1}). The mean SOC value for the study area was 7.73 g kg^{-1} (*Table 2*).

Table 2. *Descriptive analysis of soil variables*

Parameter	Land type				
	Total area	Alluvial fan	Plateau 1	Plateau 2	River alluvial plain
Mean	7.74	7.750	6.170	4.920	22.05
Median	6.93	6.840	5.830	4.620	22.10
Variance	2.55	6.539	2.710	5.800	20.60
Std. deviation	5.05	2.980	1.650	2.410	4.54
Skewness	2.42	2.282	0.422	0.447	1.22
Kurtosis	6.57	6.539	-0.022	-0.684	2.56
Min	0.91	3.695	2.920	0.914	16.25
Max	33.16	20.222	10.210	9.250	33.16

To explain the spatial variability of SOC, the Inverse Distance Weighting (IDW) method was used. The organic carbon content was low for soils sampled from several sites in the study area, which was the main factor in their low fertility status. The distribution of organic carbon in the upper profile (0–30 cm) of soils is shown in *Figure 2*.

The results showed that soil organic carbon ranged from 0.1% to 3.2% (1–32 g kg^{-1}) in the study area. Organic carbon was very low in the some part of plateau with SOC < 4 g kg^{-1} and higher SOC > 16 g kg^{-1} in the all part of River Alluvial Plain.

The area under each land form had normal distribution (Kolmogorov-Smirnov test). Except total area and alluvial fan, the data distributed abnormal. Based on the result of this table, soil organic carbon was significantly positively correlated with %N ($r = 0.962^{**}$, $P < 0.01$) in total area. In general, the value of N significantly affected SOC for all landform classifications (*Table 3*).

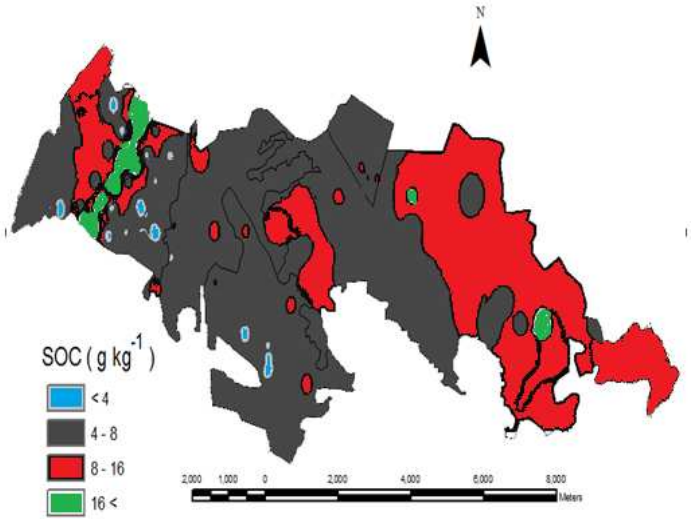

Figure 2. *Distribution of organic carbon in the study area*

Table 3. *Pearson correlations among soil physical, chemical variables and organic carbon in land form classification*

Land type	Total area	Alluvial fan	Plateau 1	Plateau 2	River alluvial plain
Variable	%N %T.N.V pH	%N	%N	%N Clay	%N
r	0.962** 0.407* -0.447*	0.893**	0.609*	0.730** 0.838**	0.960**
n	152	54	56	30	12

**Correlation is significant at the 0.01 level (2-tailed)
*Correlation is significant at the 0.05 level (2-tailed)

Linear and nonlinear regression equations to predict SOC from physiographic variables are shown in *Table 3*. For all landform types, TN had the highest correlation with SOC. There were significant differences between the types of landform ($r = 0.99^{**}$, $p < 0.01$). For each landform, two linear regression model and one nonlinear regression model were developed to predict SOC. In all equations, all or one of the independent variables such as TN, Clay, pH, Bd was used (*Table 4*).

Comparing nonlinear models in all land types, indicate that cubic models has highest coefficient of multiple determination (*Table 4*), and it is fitted for predicting SOC. Estimating regression models in each land type indicated, the models had not any over estimation or under estimation because MBE index was nearly zero (*Table 5*).

MAE value was greater in River Alluvial Plain than any other land types; which means high error in that location. Measured and predicted values were compared using the t-student test. Results showed no significant difference between them in each land type. This means that predicted models is approved and the relationship is reliable.

The significance level of coefficients in each land type for regression models was determined: for River Alluvial Plain, alluvial fan and total area; Correlation coefficient is significant at the 0.01 level. For Plateau 1 and Plateau 2; Correlation is significant at the 0.05 level. Standard Error was calculated 1.01, 0.33, 0.5 and 0.61 for River Alluvial Plain, alluvial fan, Plateau 1 and Plateau 2, respectively.

Discussion

The Pearson's linear correlation analysis revealed a significant positive relationship between SOC and total nitrogen. The highest organic carbon contents measured in soils from the highest storage of N accumulation. It can be assumed that that TN affected SOC status significantly. It assumed that TN has a positive benefit in maintaining and restoring the SOC quality and quantity for cropland in the study area. In similar research, Parvizi (2010) showed that physical variables and land use type can identify carbon sources. In that research, regression models were developed in forestry with a higher coefficient.

In some land types, there was significant correlation between clay and SOC; it is assumed clay protects organic matter from decomposition and runoff. For instance, Kasel et al. (2011) investigated that across north-central Victoria in south-eastern of Australia, mean rates of SOC accumulation in whole soils were greater increase under

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_58155824
© 2018, ALÖKI Kft., Budapest, Hungary

the N-fixing trees. There was poor correlation between SOC and clay content across sites due to the clay mineralogy.

Differences in accumulation of SOC may also be related to physiographic condition such as slope, aspect, elevation, land use, the structure of root systems that could contribute to SOC distribution.

Soil organic carbon originates primarily from plants, thus vegetation and land use history is one of the most important driving factors of SOC (Jafarian and Kavian, 2013; González et al., 2010; Strickland et al., 2010). Accurate and reliable estimates of SOC storage in landscapes and land use are critical to the development of effective policies and strategies to mitigate atmospheric and climate change (Sylvia et al., 2016; Lufafa et al., 2008; Zhao et al., 2010). This research was provided where these findings were used to create a reference of regression models. This information was found to be valuable in supporting the evaluation of SOC field surveys, which are increasingly becoming available. I would also recommend to search on available topographic and management variables to develop models to estimate soil organic carbon.

Conclusion

Soil organic carbon in the land forms of the study area was abnormal, and had an arithmetic mean of 7.7 g kg^{-1}. The highest organic carbon content (22.04 g kg^{-1}) was in River Alluvial Plain region that has lowest elevation, and include river surrounded by river sediment. This fertility area was used for garden utilization. These results explained relationships between organic carbon and land types and land use attributes. In some parts of alluvial fan, including cropland utilization, the level of soil organic carbon (7.75 g kg^{-1}) could be explained by the input of litter, organic manure, decomposition and loss by the soil erosion. Addition of chemical fertilizer and manure could increase SOC in topsoil. Chemical fertilizer can increase root production of crops and products' yield, subsequently increasing organic residue input into the soil.

(Received 10th May 2018; accepted 5th Jul 2018)

Abstract. *Haemonchus contortus* is a highly pathogenic nematode that causes haemonchosis in ruminants. As *H. contortus* is reported to be resistant to anthelmintic drugs, biological control might be the alternative approach. The study was conducted in Pakistan on different parameters to control *H. contortus* biologically by fungi. *Alternaria alternata, Fusarium oxysporum, Aspergillus niger, Trichoderma harzianum* and *Ochroconis gallopava* were isolated from the feces and abomasa of infected domestic sheep (*Ovis aries*) and goats (*Capra aegagrus hircus*). Different concentrations of the extracted spore-free cultures of these fungi were applied on eggs, larvae and adults of *H. contortus* for eggs hatching inhibition assay, larval mortality assay and adult mortality assay. In eggs hatching inhibition assay, the higher concentrations i.e. 100% and 50% of *A. alternata, F. oxysporum, A. niger, T. harzianum* and *O. gallopava* caused 100% inhibition of eggs. In adult mortality assay, all the culture filtrates caused no mortality in the first and second hour while in the third hour of the post treatment mortality varied with concentrations. In larval mortality assay, higher concentrations i.e. 100% and 50% of *T. harzianum* and *A, niger* caused 100% mortality of L_3 larvae of *H. contortus.* All the extracted spore-free cultures significantly caused eggs hatching inhibition. Higher concentrations of *Trichoderma* and *Aspergillus* significantly caused larval mortality (100%) while adult mortality assays were dose and time dependent and insignificantly caused adult mortality of *H. contortus.*
Keywords: *nematode parasite, haemonchosis, biocontrol, fungal extracts, egg hatch assay, adult mortality assay*

Introduction

Livestock plays an important role in the economy of Pakistan. Agriculture contributes 21% in national gross domestic product (GDP) in which share of livestock is 11.9%. The estimated population of domestic sheep (*Ovis aries*) was 29.1 million while domestic goats (*Capra aegagrus hircus*) were 66.6 million during 2013-14. According to a survey in Pakistan, about 45000 tons of meat was obtained from sheep during the year 2013-2014 (Economic Survey of Pakistan 2013-2014). Small ruminant livestock are highly susceptible to gastrointestinal nematodes (GINs). Among GINs, *Haemonchus contortus*, member of the family Trichostrongylidae (Radostits et al., 2006), is a highly pathogenic nematode parasite that causes haemonchosis in sheep and goat, an infection characterized

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_58255835
© 2018, ALÖKI Kft., Budapest, Hungary

by anemia, protein deficiency, bottle jaw and digestive disturbances throughout the world (Getachew et al., 2007; Bowman et al., 2009). It is estimated that an infected sheep with 5000 *H. contortus* worms may lose 250 ml blood/day. Life cycle of *H. contortus* takes about 21 days to complete. *H. contortus'* life cycle is direct i.e. without the involvement of secondary host. Every adult female parasite lays between 5000-10,000 eggs/ day which are passed out in the feces (Hepworth, 2006) as shown in *Figure 1.*

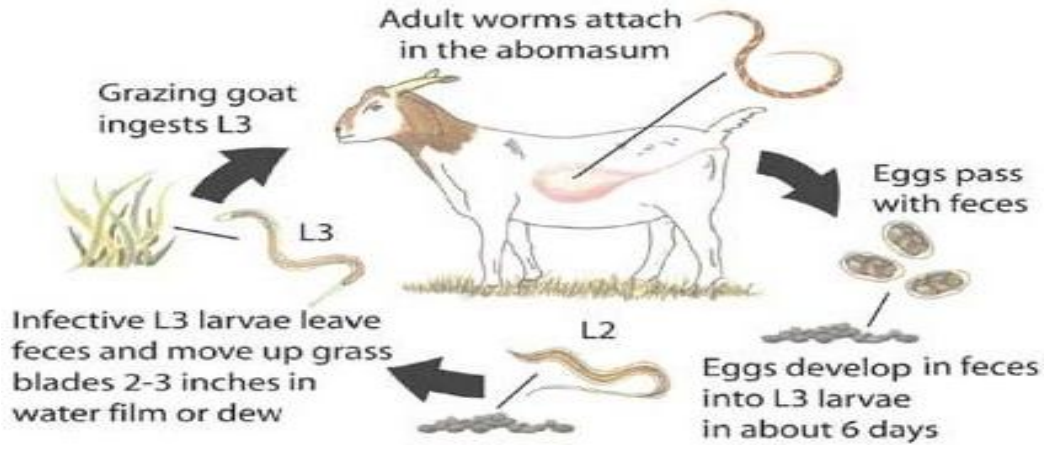

Figure 1. *Life cycle of Haemonchus contortus. (Courtesy: pinterest.com)*

As *H. contortus* is reported to be resistant to anthelmintic drugs (Miller et al., 1987; Sangster, 1999; Jackson and Coop, 2000) biological control might be the alternative approach. Many fungal species have been isolated from nematodes in which *Duddingtonia flagrans* has proven to be the most effective nematode-destroying fungus (Larsen et al., 1997) whose spores are found to survive while passing through the gastro-intestinal tract of grazing livestock (Hertzberg et al., 2001). *Trichoderma, Fusarium* and *Acremonium* have ovicidal effect on *Toxacara canis* ova (Maia Filho et al., 2011).

The present study was carried out in the light of previous work done to isolate and identify fungi from the feces of infected sheep and goats to evaluate the fungal filtrates' abilities of suppression the population of *H. contortus* on eggs hatching level, larval developmental level and adult level. These fungal extracts can be used as biological control against this parasite as a spray on grazing pastures or can be fed to animals in the form suspensions or pellets. Moreover, all fungi investigated in this study are of less toxigenic nature to animals' health so making them more suitable candidates for the purpose of the study.

Materials and methods

This research work carried out in laboratory of the Department of Microbiology, Kohat University of Science and Technology, Kohat, Pakistan.

Sampling

100 fecal samples of rectum from live goats and sheep and 100 abomasa samples from freshly slaughtered goats and sheep were collected from different areas of Kohat-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_58255835
© 2018, ALÖKI Kft., Budapest, Hungary

Pakistan (33°34'47.1"N 71°26'29.3"E). The samples were analyzed for the detection of eggs (fecal samples) and worms (abomasa samples) of *H. contortus* as shown in *Table 1*. All the samples were processed in the department of Microbiology, Kohat University of Science and Technology Kohat, Pakistan.

Table 1. *Samples collected and analyzed for the detection of eggs and worms of H. contortus*

Ruminants	Fecal samples	Positive (eggs seen)	Negative (no eggs)	Abomasa	Positive (worms seen)	Negative (no worms)
Goats	50	37	13	50	34	16
Sheep	50	31	19	50	41	9
Total	100	68	32	100	75	25

Haemonchus contortus (eggs, adults and larvae)

Eggs of *H. contortus* were identified and concentrated from fecal samples by simple test tube floatation method (Dryden et al., 2005), Mac Master counting chamber (Soulsby, 1968) and isolation of eggs from feces as described by (Hubert and Kerboeuf, 1992). Adult worms were collected from abomasa based on their typical barber pole appearance of female worms in a clean container as shown in *Figure 2*. Collected worms were washed with distilled water and concentrated in a container having freshly prepared phosphate buffer saline (PBS). Third stage larvae (L_3) were cultivated from the eggs recovered from adult female worms following the protocol of (Amarante, 2011) with slight modification. The L_3 were morphologically differentiated and identified as described by (Van Wyk et al., 2004).

Figure 2. *Harvesting worms from abomusam*

Fungi (isolation, identification and extraction)

All positive fecal and abomasa samples were processed for the isolation of fungi. One-gram samples' contents were serially diluted and poured on Sabouraud dextrose agar (SDA) media for fungal growth. After 72 h, the grown colonies were sub cultured to isolate pure cultures. For identification, both colony morphology and microscopic characteristics were deeply compared with the identification keys provided by (Navi et al., 1999) and (Larone and Larone, 1987). Among many other isolates, *Alternaria*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_58255835
© 2018, ALÖKI Kft., Budapest, Hungary

alternata, Fusarium oxysporum, Aspergillus niger, Trichoderma harzianum and *Ochroconis gallopava* were the main isolates present in all positive samples. So these fungi were selected for fungal extracts.

For extraction, fungi in broth media were incubated in a shaker incubator for 7 days at 25 °C in dark. After 7 days, they were filtered by common Whatman filter papers and the filtrates were again filtered through Millex HA syringe driven filters (0.45 µm). Different concentration i.e. 100%, 50%, 25%, 12.5% and 6.25% were made from each in phosphate buffer saline (PBS) and distilled water separately. Final filtrates were tested on potato dextrose agar (PDA) and SDA media to confirm the absence of fungal spores.

Egg hatch assay (EHA)

EHA was performed in triplicate following the protocol of (Coles et al., 1992) with slight modification. Isolated eggs were dissolved in 15 ml distilled water with concentration adjusted to 100-200 eggs/75 µl. Then 75 µl egg suspension was added to each well of a 24-welled titration plate having 2.5 ml of each concentration. For positive control, 0.025 mg/ml of Oxfendazole (Glaxo-welcome) was prepared in 0.3% dimethyl sulfoxide (DMSO). Wells having egg suspension and 2.5 ml tap water with no extracts were used as negative control. The plate was incubated at 25 °C for 48 h. After 48 h, one drop of Lugol's oil was added to stop the reaction. Then the plate was observed under 10X of inverted microscope as shown in *Figure 3*. The percent hatching inhibition was observed as:

$$\text{Hatching Inhibition } (\%) = \frac{P_{\text{HI}}\text{Test}}{P_{\text{HI}}\text{Total}} \times 100$$

P_{HI}Test = number of unhatched eggs, P_{HI}Total = number of unhatched eggs + number of hatched eggs.

Adult mortality assay (AMA)

In AMA, ten worms were treated in triplicate to each filtrate concentration at room temperature. 25 µg/ml of Closantel was used as positive control. Phosphate buffer saline with worms and no fungal extracts were used as negative control. After each one hour of post treatment, all the plates were observed to check the mortality till all worms were dead in negative control. Because adult worms cannot survive without host longer than 9 h. The percent mortality was calculated as:

$$\text{Adult Mortality}(\%) = \frac{P_{\text{AM}}\text{Test}}{P_{\text{AM}}\text{Total}} \times 100$$

P_{AM}Test = number of dead worms, P_{AM}Total = number of dead worms + number of live worms.

Larval mortality assay (LMA)

One ml of L_3 larval suspension containing 10 larvae were added in triplicate to each well of titration plate having 2.5 ml of fungal filtrates. Negative control well received

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_58255835
© 2018, ALÖKI Kft., Budapest, Hungary

only one ml L_3 suspension and 2.5 ml phosphate buffer saline while positive control well received one ml L_3 suspension and 2.5 ml closantel (25 µg/ml). The plate was incubated at room temperature for 3 h. After 3 h, the plate was observed under 10X of inverted microscope. Percent mortality was calculated as:

$$\text{Larval Mortality}(\%) = \frac{P_{\text{LM}}\text{Test}}{P_{\text{LM}}\text{Total}} \times 100$$

P_{LM}Test = number of dead larvae, P_{LM}Total = number of dead larvae + number of live larvae.

Figure 3. *H. contortus' eggs under inverted microscope*

Statistical analysis

Data obtained from bio-assays i.e. EHA, AMA and LMA were analyzed by ONE Way ANOVA and TWO-Way ANOVA through Statistix version 9 and GraphPad Prism version 5 software. The p values <0.05 was considered significant.

Results

Egg hatch assay

After three days' incubation, the effect of different concentration of all fungal filtrates on eggs, were observed as shown in *Figure 4*. Higher concentrations i.e. 100% and 50% of all filtrates caused 100% inhibition while inhibition by lower concentrations varied from specie to specie. There were 100% and no inhibition (0%) in positive and negative control respectively.

Adult mortality assay

All concentrations of fungal filtrates treated with adult worms caused no mortality in the first three hours of post treatment. After three hours, the results were dose and time dependent and caused insignificant percent mortality as shown in *Figure 5*.

results showed that all the tested fungi significantly affected all stages of *H. contortus*. Pairwise comparison of fungi showed that all fungi have equal significant effect on eggs of *H. contortus* while the significance of efficacy on adults and larvae varies from fungal to fungal species as shown in *Figure 7*.

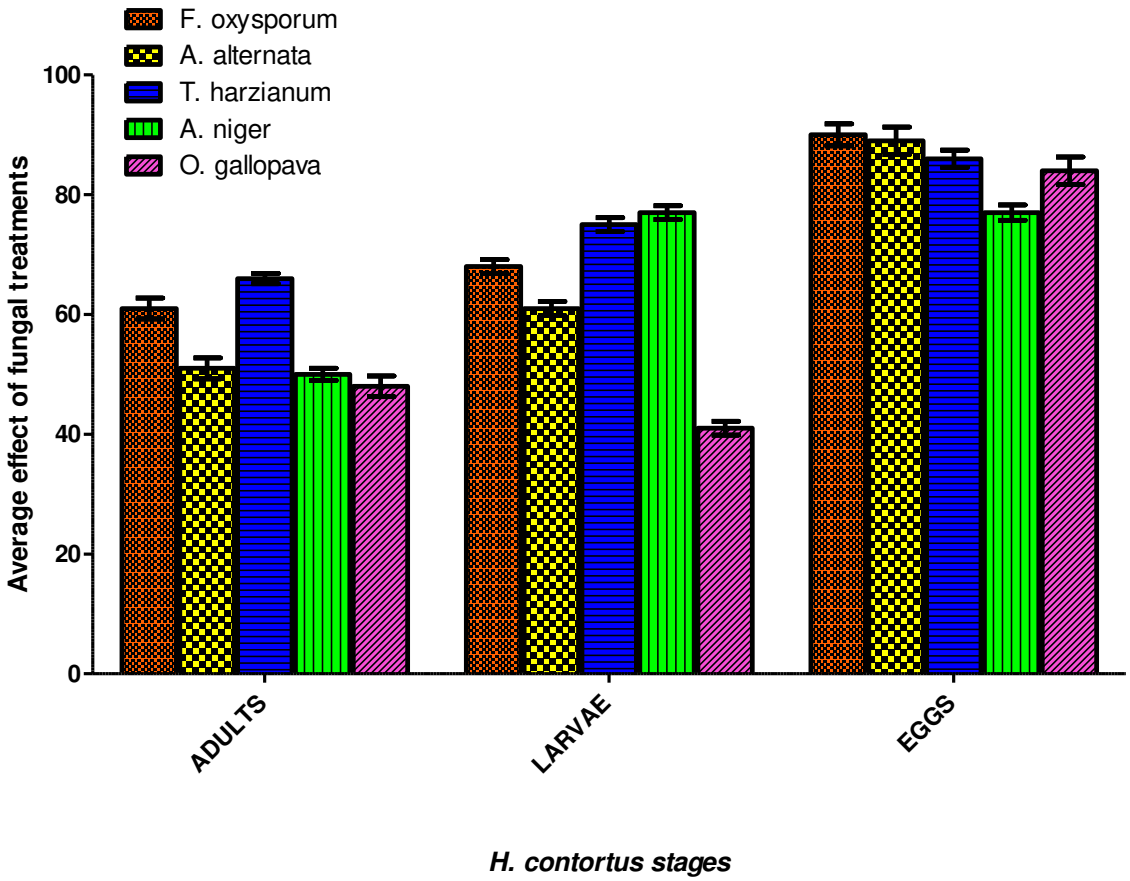

Figure 7. *Average effect of fungal treatments on adults, larvae and eggs of H. contortus*

Discussion

To control *Haemonchus contortus*, common anthelmintics are applied but not enough to erase this parasite completely as it is reported to be resistant to all three broad spectrum families of anthelmintics viz. benzimidazole, lmidazothiazole and ivermectin and against drugs with narrow spectrum of activity such as salicylanilides anthelmintics (Kaplan and Vidyashankar, 2012). Keeping in view the importance of this blood sucker, there is need of alternative methods other than common anthelmintics to prevent sheep and goats from this highly dangerous nematode parasite. Biological control is an environment friendly alternative approach towards these nematodes. Among the microorganisms that parasitize on nematodes, fungi hold an important position in continuously eliminating parasitic nematodes (McSorley et al., 2008). About 70 genera and 200 species of fungi have been investigated that they are associated with nematode parasites. Till now, only a few of them are successful biocontrol agents (Nordbring-Hertz et al., 2011).

In the present study, it was tried to investigate the fungal abilities biologically to suppress the *H. contortus* population on eggs hatching, larval and adult levels. Fungi

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

were isolated from the feces of small ruminants and different concentrations of culture extracts were made from the isolated fungi. The spore-free cultures were applied on eggs, L_3 larvae and adult worms of *H. contortus* to find out the percent inhibition and percent mortality. The results demonstrated that the higher concentrations i.e.100% and 50% of all the extracted spore-free cultures of *A. alternata, F. oxysporum, A. niger, T. harzianum* and *O. gallopava* showed 100% eggs hatching inhibition of *H. contortus.* For the first time these fungi were applied on eggs of *H. contortus* although in previous studies many other nematophagous and filamentous fungi such as *Arthrobotrys oligospora, A. musiformis, Cladosporium spp, A, flavus* and *Duddingtonia flagrans* were treated with *H. contortus* eggs and showed similar results (Maia Filho et al., 2011). Also, different plant extracts have been reported previously to affect the biology of the parasitic eggs in the same ratio (Hounzangbe-Adote et al., 2005).

Adult worms of *H. contortus* in this study were treated with different concentrations i.e. 100%, 50%, 25%, 12.5% and 6.25% of the extracted spore-free cultures. The results were dose and time dependent as compared to a similar study conducted on animals grazing on pastures where *D. flagrans* was present which showed 97% efficacy of the fungus against this nematode parasite (Maria et al., 2011). Another study conducted by Chandrawathani and colleagues (Chandrawathani et al., 2003) in which they fed sheep during 24 days with either mineral blocks containing a dose of 500,000 chlamydospores/kg bw/day or pellets with the same fungal dose, and obtained a reduction in adults of *H. contortus* of >95% in the first case and 98% in the second case.

The third stage larvae (L_3) of *H. contortus* in the present study were treated with different concentrations of each extracted spore-free cultures for three hours. After three hours, it was observed that higher concentrations i.e. 100% and 50% of the *Trichoderma harzianum* and *Aspergillus niger* caused 100% mortality in the L_3 larvae while the mortality caused by lower concentrations of extracts varied from species to species. These results resemble a recent study conducted in Iran by Zarrin and colleagues in which they demonstrated that some saprophytic fungi spread in the environment can be effective in reducing the number of third stage larvae of *Trichostrongylidae* family. However, the rate of mortality was different because of the fungal species and isolates. They concluded that there was a considerable decrease in larvae population by *Cladosporium spp.* (98.8%), *Trichoderma spp.* (98.5%), and *Aspergillus spp.* (96.7%) culture. Their results indicated great potential of using appropriate saprophyte fungi for biological control of *H. contortus* larvae in sheep (Zarrin et al., 2015). A similar study conducted on stage 3 larvae of *H. contortus* by Ivonneet al., 2011 investigated that mortality of infective larvae (L_3) by *A. oligospora* was 90.3%, *A. musiformis* was 97%, and *M. thaumasium* was 62.3% (Ivonne et al., 2011). Also, Menduza De Gives and Vazquez-prats investigated that *A. oligospora, Monacrosporium acermatoum* and *A. robusta* caused mortality of the population of *H. contortus* infective L_3 larvae with 93.30%, 95.70% and 10.10%, respectively (Mendoza-De Gives and Vazquez-Prats, 1994).

Conclusion and recommendations

From the study, it is concluded that higher concentrations of all the extracted spore-free culture filtrates from the isolated fungi significantly caused eggs hatching inhibition. Higher concentrations of *Trichoderma harzianum* and *Aspergillus niger* significantly caused larval mortality (100%) while adult mortality assays were dose and

© 2018, ALÖKI Kft., Budapest, Hungary

time dependent and insignificantly caused adult mortality of *Haemonchus contortus*. Keeping in view the importance of this problem and encouraging results obtained from the study, there is need to explore the chemistry of the fungal filtrates to find out their active compounds and their mechanism of actions (both *in vitro* and *in vivo*). The effects of these fungi at molecular level like DNA damage and genetic alterations in *H. contortus* need further explorations.

(Received 25th May 2018; accepted 1st Aug 2018)

Abstract. Bi_2MoO_6/kelp biochar (BKB) nanocomposite has been obtained by a combination of pyrolysis and solvothermal method. The synthesized sample was characterized by X-ray diffraction (XRD), scanning electron microscopy (SEM), UV-vis diffuse reflection spectroscopy (DRS) and Fourier transform infrared (FT-IR) spectra. The specific surface area and pore volumes of BKB nanocomposite with the mass ratio of Bi_2MoO_6 to kelp biochar of 0.25 (BKB-0.25) were 210.918 m^2/g and 0.2449 cm^3/g, respectively, indicating that the as-prepared nanocomposite had wide specific surface area and porous structure. Moreover, the photocatalytic tests exhibited that the highest photocatalytic degradation efficiency obtained by BKB-0.25 under visible light irradiation for 60 min was 61.39%, which was up to 13 times higher in comparison with pure Bi_2MoO_6. This showed that the photocatalytic degradation data fitted well with pseudo-first-order model. The unique features of BKB nanocomposite suggested that it may have a great potential for dyes removal from liquid effluents.
Keywords: *kelp biochar, photocatalyst, adsorption activity, nanocomposite, removal efficiency*

Introduction

Methylene blue (MB), a cationic type model dye compound, is widely used in industries such as paper, leather, cosmetics and pharmaceutical industries (Wang et al., 2018; Velanganni et al., 2018). Residues of dye without proper treatment will do harm to both human health and ecological safety (Abdelwahab and Emh, 2018; Liu et al., 2017; Ghosh and Bandyopadhyay, 2017; Fan et al., 2016). The most common methods have been used for wastewater treatment such as chemical oxidation, microbiological degradation, electrochemical treatment, adsorption, etc, but they are limited to some kinds of dyes due to many reasons. Being effective and attractive, the photocatalytic technique is a promising way for the treatment of dyes and organic compounds from aqueous effluents.

Nanostructured photocatalysts have gained worldwide attention currently, due to their potential application in environmental purification and solar energy conversion

© 2018, ALÖKI Kft., Budapest, Hungary

(Zhang et al., 2006; Zhang et al., 2007; Umapathy et al., 2015). Recently, Bi_2MoO_6 has been one of the excellent photocatalysts for the degradation of organic compounds under visible light irradiation, which has excellent intrinsic properties, such as, dielectric nature, catalytic behavior and luminescence with a typical E_g of about 2.6 eV (Zhang et al., 2011). However, the photocatalytic performance of Bi_2Mo_6 is still far from satisfactory due to the high recombination rate of photogenerated electron–hole pairs and potentially poor surface chemistry, which limits the application of Bi_2MoO_6 catalysts (Yan et al., 2015). It has been demonstrated that complex or hierarchical hetero-nano-structures with high performance can be achieved to facilitate the separation of photo-generated electron–hole pairs and further improve the photocatalytic activity (Shang et al., 2010; Li et al., 2016; Chen et al., 2015; Cao et al., 2011). Among them, Bi_2MoO_6-based composites, such as MoS_2/Bi_2MoO_6, $BiOI/Bi_2MoO_6$ and Bi_2MoO_6/TiO_2 have been proved to have higher photocatalytic activity.

Biochar materials obtained from waste biomass (gasification or pyrolysis) show better performance in adsorption of organic pollutants from water owing to their low cost, economically feasible, developed porosity, wide specific surface area and abundant functional groups (Enniya et al., 2018; Jian et al., 2018; Yang et al., 2017). Macroalgae has been promising biomass resources for the production of activated carbon with a high adsorption capacity (Rathinam et al., 2011; Yu et al., 2015; Son et al., 2018; Lee et al., 2018; Ross et al., 2018). However, the present transformation and utilization of seaweed are mainly in the production of fertilizers, industrial gums (phytocolloids), and bio-materials for medical applications, which limits the utilization of this raw material for the production of adsorption and carrier material (Haykiri-Acma et al., 2013; Yu et al., 2017; Joonhyuk et al., 2014).

In this work, a novel Bi_2MoO_6/kelp biochar nanocomposite by using the abundant and available kelp was fabricated by a combination of pyrolysis and solvothermal method, which exhibited an enhanced photocatalytic activity in the visible light irradiation. Therefore, the as-prepared sample may be expected to effectively degrade organic pollutants in water, which could realize the value-added use of kelp biomass.

Materials and methods

Materials

The fresh kelp was collected from a local food market in Zhoushan, Zhejiang. Bi $(NO_3)\cdot 5H_2O$, $Na_2MoO_4\cdot H_2O$, Methylene blue (MB, $C_{16}H_{18}N_3SCl$), glycol, ethanol (>99.7%) and hydrochloric acid were analytical grade and had been obtained from Sinopharm Chemical Reagent Co., Ltd. China.

Preparation of carbon

45 g of dried kelp powder was pyrolyzed in a tubular furnace under nitrogen flow (100 mL min^{-1}) up to 800 °C with a rate of 10 °C/min, and the final temperature lasted for 3 h (Wang et al., 2016; Aravindhan et al., 2007; Aravindhan et al., 2004; Rathinam et al., 2011). The carbonized residue was allowed to cool down to room temperature in a furnace under the same gas flow. Then, it was removed from the furnace and stored in an air-tight sample vessel (Choi et al., 2014; Yu et al., 2017; Afonso et al., 2018).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_58375847
© 2018, ALÖKI Kft., Budapest, Hungary

The obtained black solid was mixed with KOH powder with the mass ratio of 1:3. Then the mixture was also pyrolyzed in that tubular furnace under nitrogen flow (100 mL min^{-1}) up to 800 °C with a rate of 10 °C/min. The residence time of the final temperature would reduce to 2 h. This cooled sample was immersed in the deionization water and then heated in a water bath at 80 °C. The sample was washed with 0.1 mol/L HCl to neutrality, then filtered and washed with deionization water three times, and finally dried at 73 °C overnight.

Preparation of Bi_2MoO_6–kelp biochar nanocomposite

In a typical case, 0.363 g $Bi(NO_3)_3$•$5H_2O$ and 0.0907 g Na_2MoO_4•$2H_2O$ were dissolved in 7 mL ethylene glycol. Then, 0.1016 g kelp biochar was dispersed into 20 mL ethanol under magnetic stirring for 60 min to form a homogeneous solution, which was slowly added into the $Bi(NO_3)_3$•$5H_2O$ and Na_2MoO_4•$2H_2O$ mixed solution, stirring for 12 h. The resulting mixture was transferred into a 50 mL Teflon-lined stainless steel autoclave, heated to 160 °C and maintained for 24 h. Then, the autoclave was cooled down to room temperature. The obtained sample was washed with deionized water and ethanol to remove any ionic residual, then dried at 73 °C for 12 h. The as-fabricated sample was denoted as BKB-2.25. According to this method, the Bi_2MoO_6/kelp biochar composite with different mass ratios of 0.25, 0.75, 1.25 and 1.75 were synthesized and named as BKB-0.25, BKB-0.75, BKB-1.25 and BKB-1.75, respectively. For comparison, pure Bi_2MoO_6 was prepared by adopting the method in the absence of kelp biochar.

Characterization

Composition and morphology of the samples were investigated by scanning electron microscopy (SEM, Hitachi S-4800, Japan), and X-ray diffraction (Ultima IV X-Ray Diffractometer, Rigaku Corporation, Japan) in the range of 2θ = 10–80°. The surface functional group were analyzed by Fourier transform infrared spectra (FTIR, Nicolet 5700, Thermo Corp., USA). UV–vis spectrophotometer (UV-4100, Shimadzu) was used to analyze the optical properties of the as-fabricated materials in the wavelength range of 200–1000 nm by the diffuse-reflectance spectroscopy (DRS). The specific surface areas of the samples were measured with a Micromeritics ASAP 2010 instrument and analyzed by the BET method.

The removal efficiency of MB

The adsorption experiments of MB were investigated by adding 0.01 g as-fabricated samples to 50 mL MB solutions (80 mg/L) in Erlenmeyer flasks which were stirred in the dark for 4 h to ensure the dye and sample to reach adsorption-desorption equilibrium.

The photocatalytic activity of BKB composite was evaluated by photodegradation of MB solution under visible light (λ > 420 nm) irradiation. To obtain the needed irradiation photo source (14 V, 16 A, 15 cm), a 300 W xenon lamp (FSX-300, NBeT Group Corp. Beijing) was used as a visible light source. Moreover, 2 mL of suspension was collected followed via centrifuging to move the remained photocatalysts at specific illumination intervals. And the obtained clear solution was measured at 665 nm via a UV–vis spectroscopy (UV 2600, Shimadzu). The adsorption

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_58375847
© 2018, ALÖKI Kft., Budapest, Hungary

capacity of BKB composite was calculated according to *Equation 1* as follows (Chen et al., 2016):

$$\text{Adsorption capacity (mg/g)} = (C_0\text{-}C_e) \times (V/m) \quad \text{(Eq.1)}$$

where q_e is equilibrium adsorption capacity of the BKB composite, mg/g; C_e and C_0 are the equilibrium and initial concentration of MB concentration, mg/L; V is the volume of the solution, L; M is the mass of the BKB composite, g.

The photocatalytic degradation of BKB composite was calculated according to *Equation 2* as follows (Geng et al., 2017):

$$\text{Degradation} = [(A_0 - A_1) / A_0] \times 100\% \quad \text{(Eq.2)}$$

where A_0 is an initial photocatalytic degradation of methylene blue, A_1 is an absorbance measured at the irradiation time.

Results and discussion

Characterization of as-prepared samples

The specific surface area and pore volumes of BKB composite are listed in *Table 1*. It can be seen that the specific surface area and pore volumes increase with the decrease of Bi_2MoO_6 content. Particularly, the maximum values BKB-0.25 obtained are 210.918 m^2/g and 0.2449 cm^3/g, respectively, which may be beneficial for the enhancement of sorption capacity. The nitrogen adsorption isotherms for BKB-0.25 suggests the V isotherms with a hysteresis loop at $P/P_0 > 0.4$. Moreover, the slit between adsorption and desorption curves may be due to the presence of stacking holes. The pore size distribution of BKB-0.25 also exhibits the significance of mesopores with pores mainly in the range 2-20 nm (*Fig. 1*).

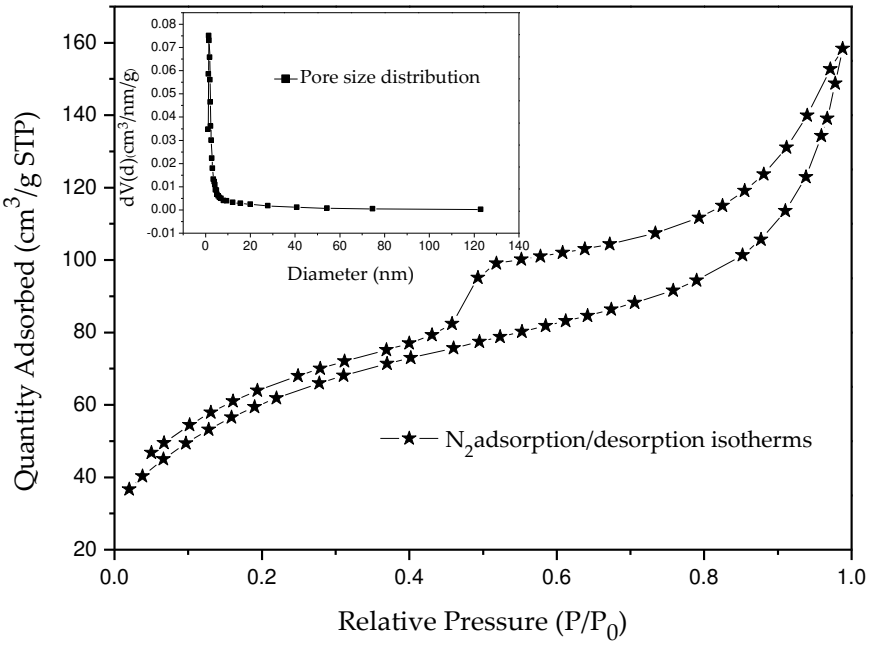

Figure 1. *Nitrogen sorption isotherms of BKB—0.25 with corresponding pore size distribution*

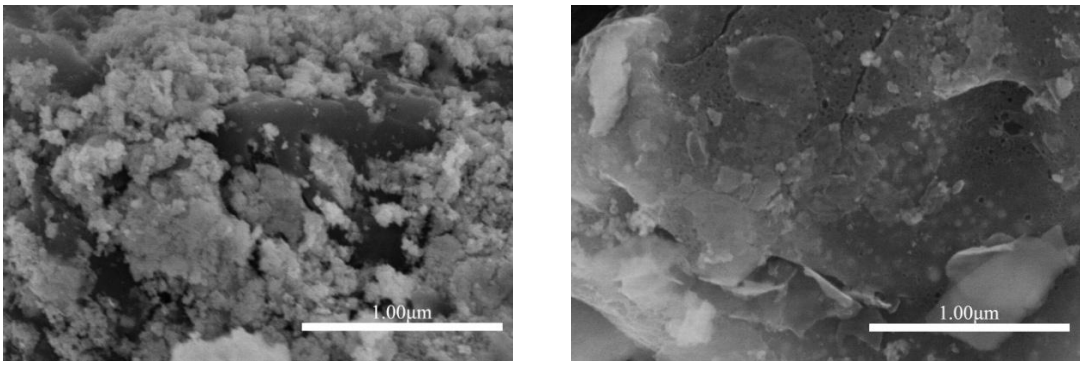
Table 1. *Specific surface area parameters of BKB composite*

Composites	BET (m^2/g)	Total pore volumes (cm^3/g)	Average pore diameter (nm)
BKB-0.25	210.918	0.2449	4.645
BKB-0.75	168.731	0.2032	4.817
BKB-1.25	105.936	0.1549	5.850
BKB-1.75	41.528	0.1066	10.27
BKB-2.25	35.793	0.1150	12.86

As shown in *Figure 2a,* kelp biochar has a very smooth surface. And surface morphologies of BKB-0.25 (*Fig. 2b*) shows the presence of uneven structure, which suggests that Bi_2MoO_6 nanoparticles successfully grow on the surface of kelp carbon.



a **b**

Figure 2. *Surface morphologies of (a) kelp biochar, (b) BKB-0.25*

Figure 3 shows the FT-IR spectrum of the kelp biochar and as-prepared Bi_2MoO_6/kelp biochar composite to investigate their chemical structures. The spectrum of pure Bi_2MoO_6 contains some strong characteristic bands such as Mo = O (~ 842 cm^{-1}) stretching vibration and the absorption at 743 cm^{-1} is attributed to the tetrahedral stretching vibration of Mo (VI)—O groups. However, a band at 580 cm^{-1} may be due to the bending mode of the MoO_6. Characteristic absorption bands are all observed on the as-prepared composite, indicating the presence of Bi_2MoO_6 grown on kelp biochar materials.

Information concerning the crystal structure and phase analysis of the as-fabricated materials are shown in *Figure 4*. The XRD patterns of pure Bi_2MoO_6 and BKB composite exhibit that diffraction peaks at about 2θ = 23.3°, 28.1°, 32.3°, 35.8°, 46.7°, 55.3° and 58.2° could be perfectly indexed to the (111), (131), (200), (151), (062), (331) and (191) crystal planes of orthorhombic Bi_2MoO_6 (JCPDS76-2388) respectively. This indicates that BKB composite is successfully synthesized.

A comparison of the UV–vis diffuse reflectance spectra of pure Bi_2MoO_6 and BKB composite are shown in *Figure 5*. The pure Bi_2MoO_6 exhibits a weak absorption in the visible light with range absorption edges located at 478 nm. For the BKB heterostructures, there is an enhanced absorbance in the visible-light region (λ > 400 nm) with different contents of kelp biochar added. The optical absorption edge of composite is gradually red shifted when increasing the content of kelp biochar. The

The removal efficiency of MB

Adsorption tests

The adsorption of methylene blue on the composite is implemented for 4 h under dark conditions without exposure to visible light illumination, and the results are represented in *Figure 6*. The increased adsorption percentage from 0.6625% to 45.28%, indicated that the adsorption will increase with the decrease of Bi_2MoO_6 content. The equilibrium adsorption capacity of MB on different Bi_2MoO_6/Kelp biochar composite is shown in *Table 2*. It can be seen that the maximum adsorption capacity obtained by BKB-0.25 is consistent with the BET results.

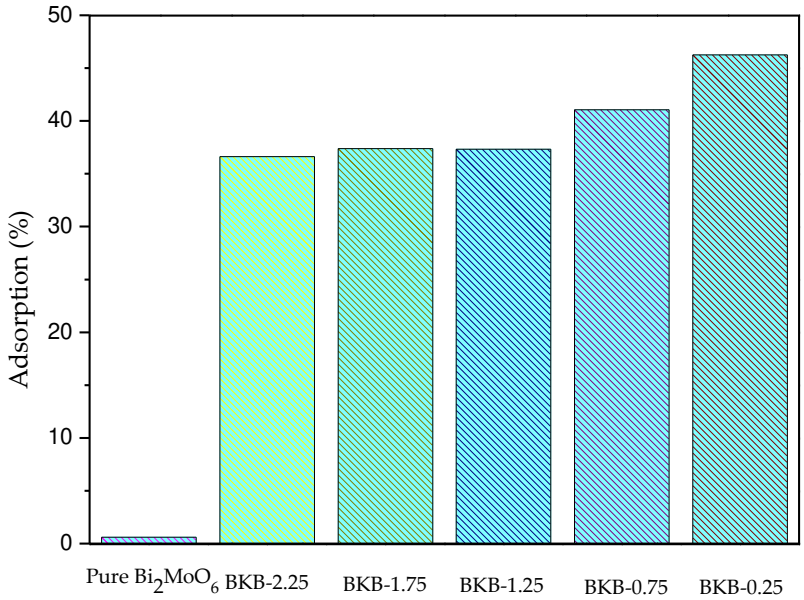

Figure 6. *Adsorption of MB for BKB-0.25, BKB-0.75, BKB-1.25, BKB-1.75, BKB-2.25, and pure Bi_2MoO_6*

Table 2. *Equilibrium adsorption capacity of MB on samples*

Catalysts	q_e (mg/g)
pure Bi_2MoO_6	2.65
BKB-2.25	143.4
BKB-1.75	146.4
BKB-1.25	146.2
BKB-0.75	160.75
BKB-0.25	181.1

Photodegradation texts

On the other hand, photodegradation texts are implemented to evaluate the photocatalytic efficiency of samples under visible light irradiation. As we can see in *Figure 7,* the Bi_2MoO_6/Kelp biochar composite may have a better photocatalytic performance than pure Bi_2MoO_6. Moreover, the photocatalytic activity of the composite is remarkably enhanced with the increasing of kelp biochar content added. Significantly, BKB-0.25 composite exhibits the best catalytic activity, while the percent of MB degraded (out of total MB) is 16.11%. For comparison, blank tests are carried out at the identical conditions except for the absence of either irradiation or photocatalyst.

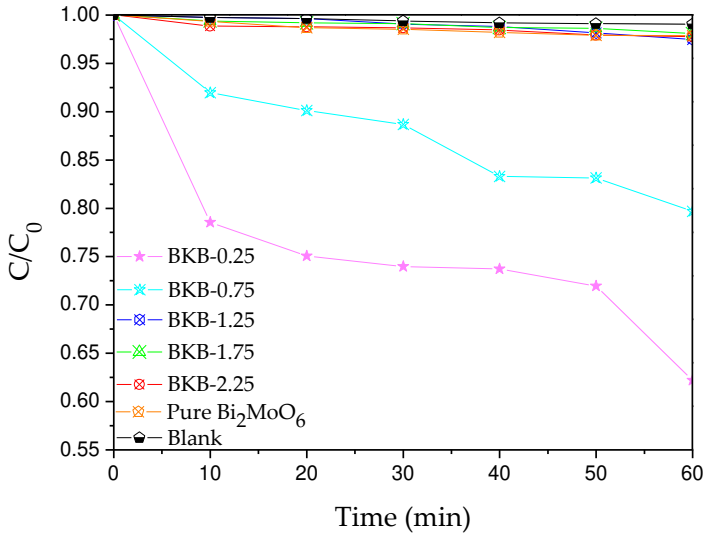

Figure 7. *Degradation efficiency of MB for BKB-0.25, BKB-0.75, BKB-1.25, BKB-1.75, BKB-2.25, and pure* Bi_2MoO_6

The photocatalytic degradation process of MB is studied on the basis of pseudo-first- order kinetic model, which can be expressed by *Equation 3* (Liu et al., 2017):

$$-\ln(C_t / C_0) = kt \qquad \text{(Eq.3)}$$

where k is apparent rate constant; C_0 is initial dye concentration in mg/L; C_t is the concentration of dye in mg/L at different time intervals.

DOI: http://dx.doi.org/10.15666/aeer/1605_58375847
© 2018, ALÖKI Kft., Budapest, Hungary

Figure 8 shows that photocatalytic degradation processes have the good consistency with pseudo-first-order kinetic model. Moreover, pure Bi_2MoO_6 only shows a low degradation rate of 0.00045 min^{-1}. As for the BMB composite, the mass ratio of kelp biochar could greatly influence the degradation rate increasing from 0.0003 min^{-1} to 0.0082 min^{-1}. Moreover, the maximum value is 0.0082 min^{-1} obtained by BKB-0.25, which is up to 18.22 times higher in comparison with pure Bi_2MoO_6. As it is shown in *Figure 7,* the order of the MB removal efficiency is BKB-0.25 > BKB-0.75 > BKB-1.25 ≈ BKB-1.75 ≈ BKB-2.25 > pure Bi_2MoO_6. The enhanced degradation efficiency may be attributed to the synergetic effects of effective absorption as well as the heterojunction constructed between Bi_2MoO_6 and kelp biochar.

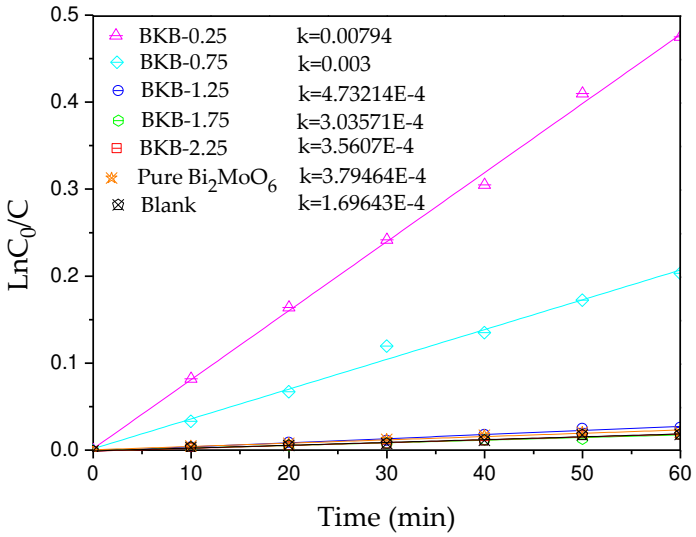

Figure 8. *Kinetic process of MB degradation for BKB-0.25, BKB-0.75, BKB-1.25, BKB-1.75, BKB-2.25, and pure Bi_2MoO_6*

Conclusions

In summary, a novel BKB composite has been successfully prepared via combining the pyrolysis and solvothermal method. As shown in the work, BKB nanocomposite exhibits superior removal efficiency of MB compared with pure Bi_2MoO_6, and the best degradability can be obtained by BMB-0.25 composite the best degradability. The total removal efficiency of MB on BMB-0.25 is 61.39%, which was up to 13 times higher than pure Bi_2MoO_6. Consequently, the novel composite materials with enhanced photocatalytic activity are promising candidate materials for environmental remediation.

Abstract. From the early Quaternary, external factors such as climate change have altered the surface of the earth. The climatic changes have led to increase or decrease of glacier in highlands of Iran. The Alvand Mountain with an altitude of 3500 m is one of Iran's highlands, which is located in Hamedan Provence. In order to the equilibrium line altitude (ELA) estimate during the last glacial maximum (LGM) in Alvand Mountain, this paper has used five methodological approaches such as Wright, slope–direction (SD), curvature coefficient (CC), the accumulation-area ratio (AAR), and terminus to head altitude ratio (THAR). After estimating ELA through the aforementioned methods, ELA in the northeast and southwest slopes were compared. According to the ELA estimates require the identification of Quaternary glacier circuses. The cirques in southwest slopes had an altitude between of 1700 to 2900 m and in northeast slopes had an altitude between of 2000 to 3400 m. The estimation of ELA of the whole study area turned out to be 2294 m. In the SD method, the average ELA in the northeast and the southwest slopes was 1960 and 2491 m, respectively. In the CC method, the ELA of the northeast and the southwest slopes was 2167 and 2099 m, respectively. The results of ELA analysis indicate that there are differences between the northeast and southwest slopes. According to Wright and CC methods, ELA in the northeast is higher than the southwest slopes, which is against the natural order of the environment. ELA estimated by AAR and SD methods in the northeast slopes is lower than in the southwest slopes. According to these two methods, there is about 500 m difference between the ELA of the northeast and southwest slopes. In this paper, in addition to the ELA, the water and ice equilibrium line altitude (WIELA) have been estimated. The field observation of the moraines revealed that WIELA during LGM was located at 1680 and 1776 m in the northeast and southwest slopes, respectively.
Keywords: *Alvand, curvature coefficient, glacial Quaternary, slope-direction, Wright*

Introduction

The Quaternary period represents the past 2.58 million years and is officially subdivided into the Pleistocene and Holocene epochs, with the base of the Holocene aging 11,700 calendar years before 2000 AD (Head and Gibbard, 2014). The Quaternary is characterized by repeated cycles of cold-warm climatic oscillations as the Earth alternated between glacial and retreating continental modes. Glacial –interglacial climate changes during the Quaternary were largely controlled by cyclic variations in the amount of solar radiation, or solution received in middle to high latitudes of the northern hemisphere (Bondarenko et al., 2013). The study of glaciers is of great importance for understanding and predicting global environmental changes (Knight, 2006). Climatic cold phases and future changes can be predicted by investigating the glacier advances (Abramowski et al., 2006; Solomina et al., 2004). Due to the different

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

nature of glaciers depending on the areas and their physiographic features, the various evidence is remarkable for glacier processes (Stroeven et al., 2013). As glaciers move across the Earth's surface, they erode and transport sediments. Ice sheets and glaciers are, therefore, powerful agents of erosion that are manifested in the grandeur of, e.g., glacial cirques and valleys (Jafari, 2013). Landforms resulted from glacial erosion are mostly detected in an area where the summits are 300-400 m higher than those of the equilibrium line altitudes (ELA) during the Quaternary cold periods (Zomorodian, 2012; JedariEivazi, 2011). The ELAs are the elevation across the glacier where the annual net balance is zero. "The equilibrium line indicates the position where, over a period of one year, accumulation of snow is exactly balanced by ablation" (Benn and Lehmkuhl, 2000). ELA is a statistical concept representing the line dividing the accumulation and ablation zones. The ELA of glaciers is particularly sensitive to changes in summer temperature and winter precipitation (Ohmura et al., 1992; Paterson, 1994; Nesje and Dahl, 2000; Osmaston, 2005). The ELA of a glacier separates the accumulation zone (where the annual mass balance is >0) from the ablation zone (where the annual mass balance is <0). These changes are commonly summarized by the fluctuations in the ELA (the dividing line between a glacier's accumulation and ablation areas). There is substantial controversy regarding the interpretation of changes in mountain glacial extent during the last glacial maximum (LGM). The LGM is in the Quaternary history when world glaciers reaching their maximum integrated volume (Clark et al., 2009). The LGM was the period when the Scandinavian, Irish, British and Laurentide ice sheets were at their maximum extent, coinciding with the period of lower sea level (approximately 130 m relative to the current sea level) (Yokoyama et al., 2000).

Review of literature

Regarding the context of this study, the geographical position of Iran and its climate limited the extension of continental glaciers. In fact, Iran's geographical position, i.e. 25 to 40 N and its arid and semi-arid climate have put a limitation on the formation of glaciers. Vaziri (2003) estimated the ELAs of present glaciers in some high mountains of Iran, including Damavand (5610 m), Alamkouh (4850 m), Sabalan (4811 m), Oshtorankouh (4090 m), and Zardkouh (4221 m). Several researchers have estimated the ELA of the glacier Quaternary, some of them are referred to in *Table 1*.

Many geomorphologists have studied the late Quaternary glaciers of Iran using Wright method. This method affects the topography and altitude of mountain sinusitis (The mountain knick point). In regions which mountain sinusitis is higher than ELA, the recognition of cirques becomes troublesome. This ends with not being able to estimate the exact ELA. In order to solve this problem, various methods have been compared in this article (Slope-direction (SD), curvature coefficient (CC), altitude- ratio (AR), accumulation-area ratio method (THAR) and Wright methods during the LGM to estimate ELA).

Materials and methods

The study area of this research is known as Alvand batholith. It is located in the vicinity of Hamedan province, Iran, with an area of 1375 km^2. This batholith belongs to the Quaternary and has been created by igneous masses. This area is made up of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_58495868
© 2018, ALÖKI Kft., Budapest, Hungary

intrusive granite rock, shale, siltstone, and schist of the Jurassic. It is surrounded from two directions: from the northwest by Khodabandehlu, Sanandaj, and Chehelcheshmeh Mountains, and from the southeast by Rasund Highlands and Vafs Mountains in the Central Province. The mountain is oriented to NW–SE directions and divides Hamedan Province into northern and southern halves. The Alvand Batholith is located between 48°–48.6°E and 34.5°–34.85°N. The highest and the lowest parts of the study area had 3574 and 1700 m altitude, respectively (*Fig. 1*).

Various methods of reconstructing ELAs have been critically reviewed (Meirding, 1982; Benn and Evans, 1998; Porter, 2001; Kaser and Osmaston, 2002; Osmaston, 2005). In order to reconstruct ELA, Wright, slope- direction (SD), curvature coefficient (CC), altitude- ratio (AR), and accumulation-area ratio method (AAR) methods were employed in this project. To this end, cirques altitude and extent of the glacier tongues were determined in both northern and southern slopes. The topographic 1: 50,000 scale maps were provided, and the study area was also divided into 28 sub-basins. All this information was recorded through direct observations and field surveys. In the next step, the results of the field surveys and Quaternary landform processes were considered together and combined with the geomorphological, topographic, and geological results.

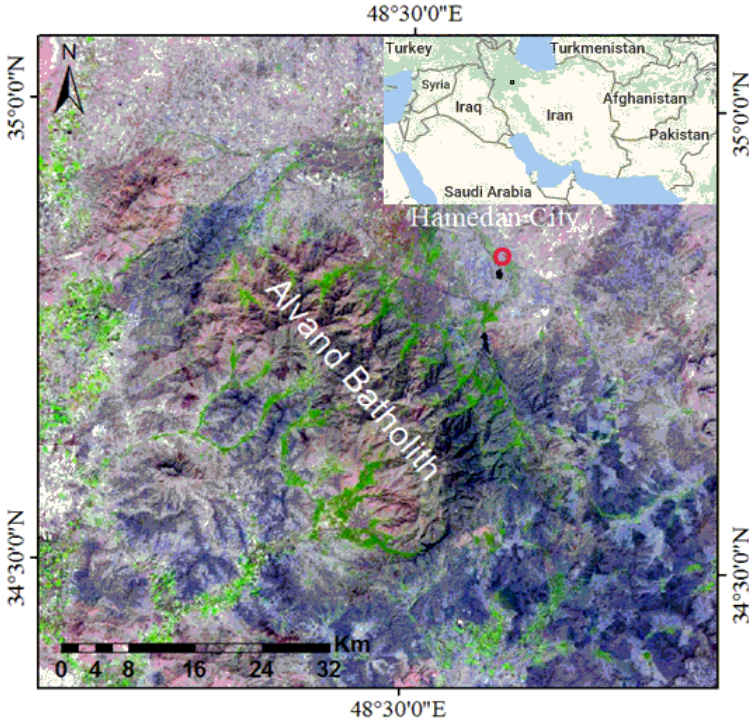

Figure 1. *The position in the study area*

Wright method

This method estimates ELA by determining the location and altitude of 60% of cirques above the line. Above this, the annual snowfall is more than the melting of annual, and below this altitude, the snowfall is less than the melting of annual. For estimating ELA, the altitude of identifying cirques is sorted based on descending order. Then the number of cirques is multiplied to 60% (*Eq. 1*) (Ramesht and Nematollahi, 2005; Ramesht and Shahzeidi, 2011; Ghahroudi Tali et al., 2013; Abtahi, 2014). The gained number represents a numerical line of cirques in which ELA is located. In the following, X shows the number of rows and N is cirques number (Porter, 2001).

$$X = N \times 0.6 \qquad \text{(Eq.1)}$$

The northeast and southwest slopes of sub-basins are separated using topographic maps, and cirques are determined in each slope.

Slope-direction (SD) method

Mountainous topography is constructed through a variety of interacting processes. In addition to other geomorphic processes, in many mountainous region's topography has been affected by glacier erosion (Headley and Ehlers, 2015). Among several factors, which influence ELA location, two important factors are determinate in SD Method. One of these factors is mountains' slope direction. A shady mountain slope will have a lower ELA than the one which receives more solar energy. Wind is another factor because it produces snow drifts on the leeward side of mountain ranges. In the middle latitudes of the Northern Hemisphere, ELA is lower on the north (shaded) and east

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

(leeward) slopes. Consequently, the most significant glacier development in this region is on north-facing and east-facing slopes (Petersen et al., 2008).

The principal reason for naming this method as SD is that ELA is estimated based on differences between mountain slope and their directions; besides these two elements, the latitude and longitude of the pikes must be calculated. This method depends on the solar elevation angle which varies according to the direction and slope of the mountains. In order to apply this method in Iran's context, appropriate equation was defined according to the prevailing geographical direction in 16 polygons. Which was determined considering the 16 Iran climate stations, and 8 acquisitions were defined in 16 geographical directions (Jafari, 2013). The reason why 8 equations were used for 16 directions is that the solar elevation angles in symmetric directions were equal. For example, the solar elevation angles are similar to each other in the southwest to southeast or in the northwest to northeast provided that the amount of slope is equal. Slope value is estimated by using 30 m Digital Elevation Mountain (DEM) of the area, and aspect is determined along with the main mountainous region. To this end, the slope maps were prepared separately for the northeast and southwest slopes. Based on slope maps, *Equation 2* was used to estimate the average slope in percent.

$$S = \frac{\Sigma(s.x)}{A} \qquad \text{(Eq.2)}$$

In this equation S is the average slope (%), *s* is the slope of each pixel, x is the area of each pixel in the slope map, and A is the total area. Jafari (2009) has estimated 144 equations in main and secondary directions on the basis of the slope and 16 Polygon Radiometers of Iran (*Table 2a* and *b*) (Moayeri et al., 2011).

For Alvand Mountain, polygonal equations of Hamadan in the northeast and southwest have been used based on the direction of the slopes. Placing the calculated slope of the northeast slopes in *Equation 3* and the southwest slopes in *Equation 4,* the annual average temperature was estimated for the related slope (Moayeri et al., 2011).

$$T = 10.84 - 0.11S \quad \text{(Eq.3)}$$

$$T = 11.27 + 0.09S \quad \text{(Eq.4)}$$

In the above equations, *T* is temperature in degrees Celsius, and *S* is the average slope in percentage. The estimated temperature in a thousand is multiplied, and the result is divided by the lapse rate of the region. Then the altitude of the base station is obtained. The estimated number is the contemporary ELA. According to the ELA estimated by Wright method and assuming zero temperature °C, the contemporary temperature estimated for altitude was deducted from the temperatures estimated for the northeast (*Eq. 3*) and southwest slopes of the relationships (*Eq. 4*), and the result was multiplied in thousand and divided by the lapse rate of the region, resulting in the altitude of the base station. The estimated number is the ELA. Therefore, determining the altitude is necessary where the temperature (slope and specific direction) is equal to zero. *Equation 5* was applied for this purpose.

$$H = \frac{T.1000}{Lr} + hs \quad \text{(Eq.5)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_58495868
© 2018, ALÖKI Kft., Budapest, Hungary

In this equation, *H* is altitude, *Lr* is the environmental temperature drop per thousand meters, and *hs* is the altitude of the base station.

Curvature coefficient (CC)

Consideration of the contour line as the characteristics of topographic maps is an important step in the study of geomorphologic processes. Extensive glacial landforms related to valley glaciation are found in the study area, including glacial valleys, cirques (*Fig. 2A* and *B*), erratic block (*Fig. 2C*), Drumlin (*Fig. 2D*), and terminal moraines (*Fig. 2E* in southwest and F in northeast slope). Glacial valleys have distinct U-shaped cross-profiles, usually with a distinctive cirque at the valley head (Fu et al., 2013).

Figure 2. *Glacial landforms in the Alvand Mountain*

Steep mountain streams carve valleys in cross section that resemble the letter V (CC closer to zero). Since glaciers are much thicker than streams, they erode the sides as well as the bottom of these valleys, bowing the cross-sectional shape out to a U-shaped glacial trough (Gabler et al., 2017: 391) (CC is closer to one).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_58495868
© 2018, ALÖKI Kft., Budapest, Hungary

The contour line in different slopes of Alvand Mountain was determined by 30-m DEM. The mountain valleys were divided into 28 sub-basins by drawing a line along the mountain sinuosity on topographical maps 1.50000 (*Fig. 3*).

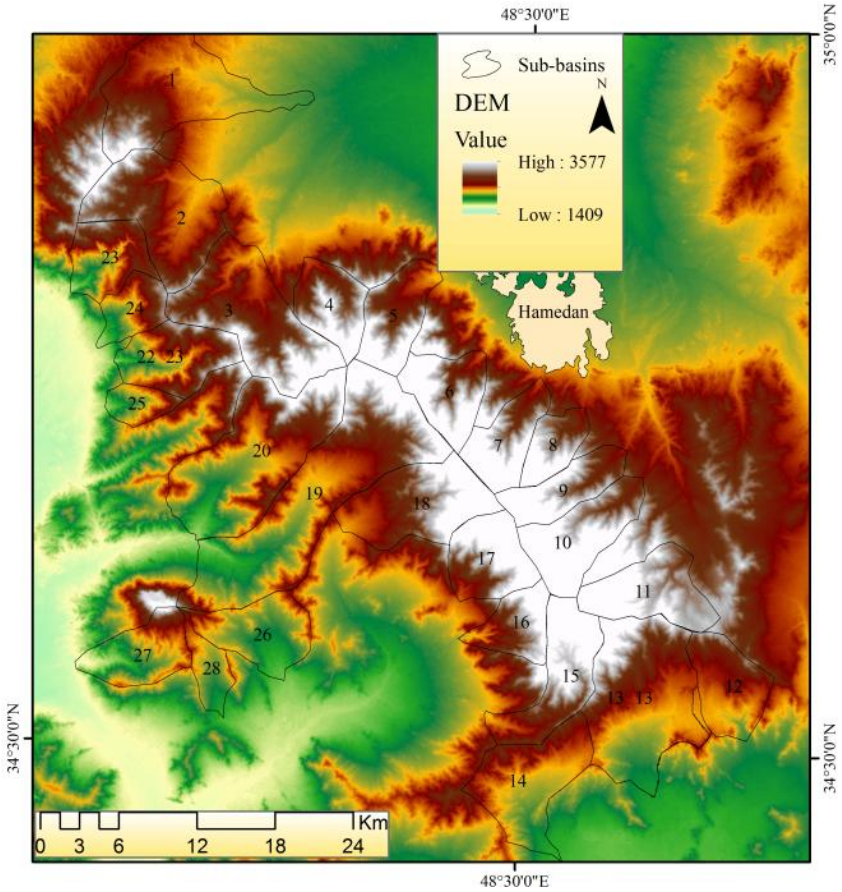

Figure 3. *Sub-basin of Alvand Mountain*

For further analysis, the contour lines with 50 m intervals were selected along the main stream. From the peak toward the lowlands, the first contour line with no straight form was selected, and later the length of the part which were located in the watershed was measured. Then, *Equation 6* was used to estimate CC (Jafari and Rostamkhani, 2015).

$$CC = \frac{a}{b} \qquad \text{(Eq.6)}$$

CC is the ratio between the aerial (a) and the actual distance of a curve (b) within a valley. Estimated values vary between 0 and 1. Thus, the estimated coefficient in a contour with low intensity and frequency in the process during the set time will be closer to 1, and if the processes mostly occur along the thalweg, the estimated coefficient will be closer to 0. Investigation of the linear relationships between the estimated coefficients and altitude implies the ascending and descending distribution of the coefficients with respect to altitude. The altitude of this trend change was considered as the ELA.

Altitude-ratio (AR) and accumulation-area ratio method (AAR)

In the median-altitude variant of altitude-ratio method, ELA lays midway in the altitude between the head of the glacier (Ah) and the terminus (At). In the terminus-head altitude ratio (THAR) approach, the THAR equals the ratio of the altitude difference between the terminal and the ELA divided by the total altitude range of the glacier. ELA can be estimated by adding the altitude of the terminus to the product of the total altitude range and an assumed THAR. The use of accumulation-area ratio (AAR) method is based on the ratio of the accumulation area (Sc) to the total area of the glacier (where *Sa* is the ablation area). Empirical studies suggest that a steady-state (SS, when the mass balances 0) AAR of 0.65±.15 is appropriate for more temperate, relatively debris-free glaciers. The surface topography of the former glacier is reconstructed based on glacial-geologic data. ELA value is obtained from glacier's area-altitude distribution (here depicted as a cumulative curve) and an assumed AAR (*Fig. 4*).

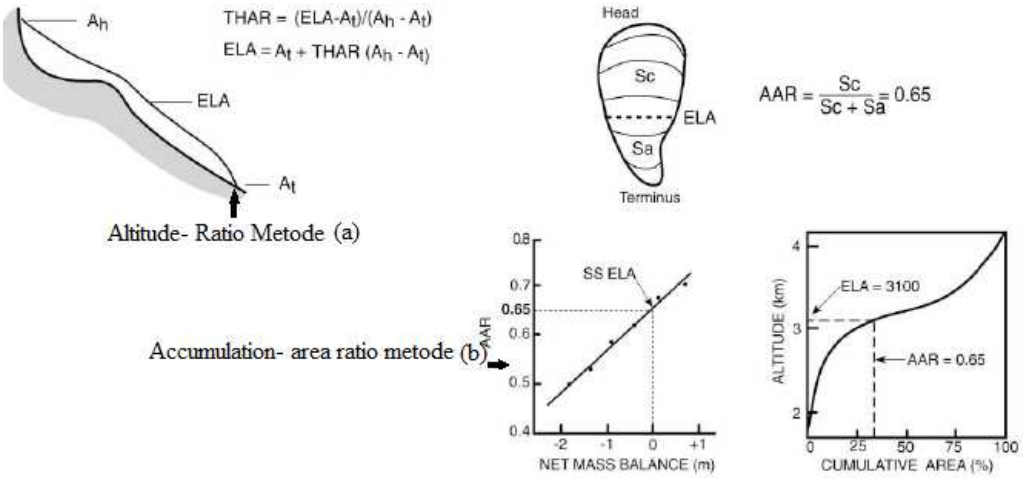

Figure 4. *AR and AAR method used to derive past equilibrium-line altitudes in the tropics. (Adopted from Porter, 2001)*

Results and discussion

ELA estimation of Alvand Mountain by Wright method

Iran's Alvand Mountain, which is above 3500 m and possess different forms of cirques, is one of the ancient glacial cirques in mountainous regions and can be employed for estimating ELA. In the study area of this research by studying the topographical maps the numbers and positions of cirques were determined through the contour lines. Accordingly, ELA for Alvand Mountain were estimated. Then the number of cirques was separately identified in both northeast and southwest slopes and their ELA was estimated. Investigations revealed that cirques in the southwest slope (100 cirques) have been decreasing at an altitude between 1700 to 2900 m, and their number has been decreasing up to 2300 m. Whereas cirques in the northeast slope (162 cirques) have been decreasing at an altitude between 1900 to 3300 m, and their number has been decreasing up to 2200 m. According to Wright Method, ELA was estimated at 2294 m for the entire study area of this research. Also, ELAs of 2404 and 2246 m were estimated for northeast and southwest slopes, respectively (*Fig. 5*).

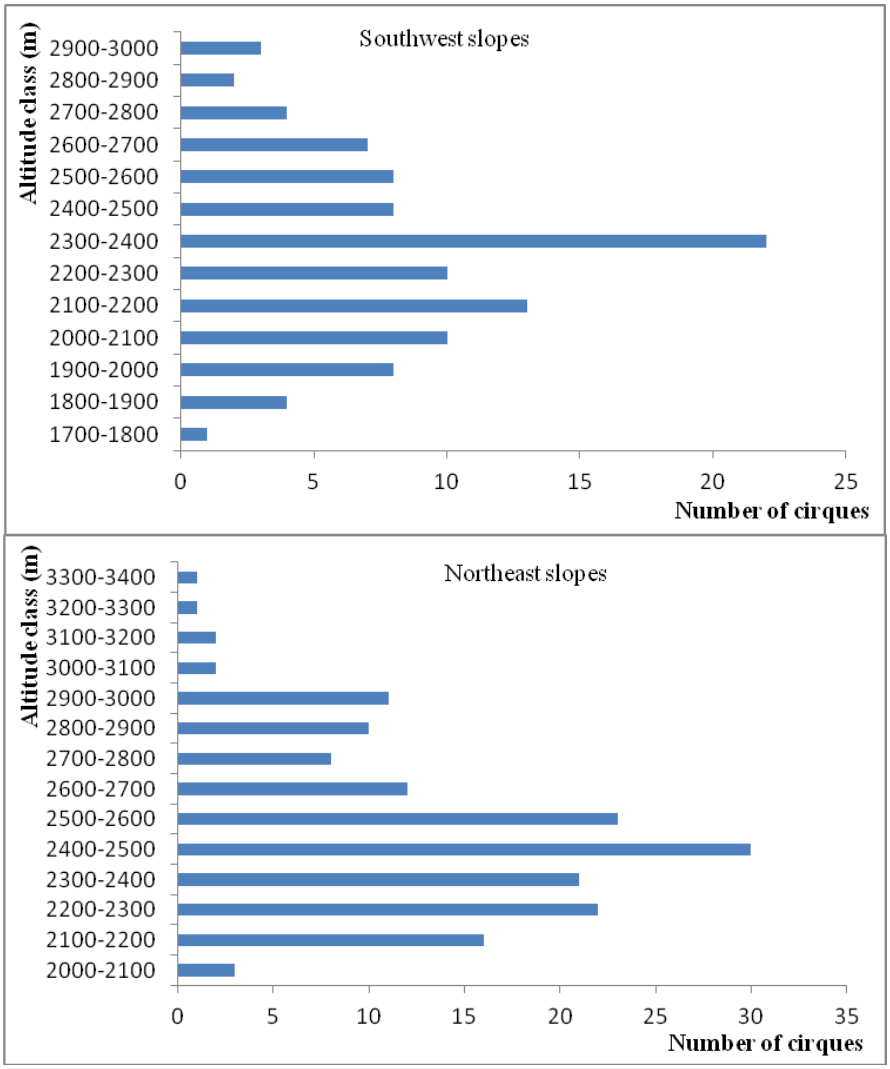

Figure 5. *The distribution of cirques altitude at northeast and southwest slopes*

ELA estimation of Alvand Mountain by slope-direction method

The amount of slope is very important in the Slope-Direction (SD) method. The GIS estimated average slope for northeast and southwest were 10.035% and 13.73%, respectively. The calculated slope was placed in *Equations 3* and *4* and eventually their temperatures were estimated. Estimated temperatures were placed in *Equation 5* and their altitude was obtained.

$$T = 10.84 - 10.035(0.11) \qquad T = 9.74^{0}C$$

$$T = 11.27 + 0.09(13.73) \qquad T = 12.5^{0}C$$

Contemporary ELA in northeast slopes:

$$X = \frac{9.74(1000)}{5.2} = 1873.07 + 1741.5 = 3614$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_58495868
© 2018, ALÖKI Kft., Budapest, Hungary

Contemporary ELA in southwest slopes:

$$X = \frac{12.5(1000)}{5.2} = 2403.84 + 1741.5 = 4145$$

ELA in northeast slopes:

$$T = 9.74 - 8.5 = 1.14^0C \; X = \frac{1.14 \times 1000}{5.3} = 219.03 + 1741.5 = 1960$$

ELA in southwest slopes:

$$T = 12.5 - 8.5 = 3.9^0C \; X = \frac{3.9 \times 1000}{5.3} = 735.84 + 1741.5 = 2491.5$$

ELA will be achieved using *Equation 5*. Thus, the average ELA was obtained at 1960 and 2491 m for northeast and southwest slopes, respectively, which were about 530 m higher in southwest slopes.

ELA estimation by CC method

In this method, GIS software was used to draw the mountain sinuosity on topographical maps of 1.50000. The mountain valleys were separated into 28 sub-basins. In all sub-basins, the contour lines with 50 m intervals were selected along the main stream. From the peak toward the lowlands, the first contour with no straight form was selected, and the length of part located in the basin was measured (b). Then, *Equation 6* was used to estimate CC. CC is the ratio between the aerial (a) and the actual (b) distance of a contour in a valley. Fitted values of the linear regression between the estimated coefficients and altitude denote the ascending and the descending distribution of the coefficients with respect to the altitude. The altitude at which this trend change was considered to be the lowest point of the CC, the altitude of which matches ELA. The CC status at low altitude was also examined with respect to the dominant peak in the basin. To evaluate the geomorphologic processes over time, curvature coefficients were compared in all sub-basins using *Equation 6*. Linear regression was fitted between altitude, as an independent variable, and curvature, as a dependent variable. The results show that CC had specific trends in most sub-basins. The estimated CC was close to 1 on the slopes, and it decreased with increasing altitude (*Figs. 6* and *7*). With increasing distance from the basin outlet, first the coefficient reached with minimum and then increased again.

As it is evident in *Figures 6* and *7,* the lowest altitude of CC (0.31) is located at 2500 m altitude (No. 19, Shahrestaneh Valley) and the maximum value of this coefficient (0.8) is located at 3300 m altitude. The amount of this coefficient reduces from the mountain peak up to 2400-2500 m, and it increases again toward the basin outlet (*Table 3*). This process is also affected by the topography of the region. The altitude of these changes was estimated 2400 m in northeast slopes and 2400-2500 m in southwest slopes in most of the sub-basins. As the peak altitude reduces, the lowest amount of the coefficient shifts toward the lower altitudes. *Table 3* indicates the lowest altitude diagrams for each sub-basin. Where the sub-basins' slope direction is inclined north, the lowest altitude in the diagrams is expected to be in sub-basins number 4, 6, 8,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_58495868
© 2018, ALÖKI Kft., Budapest, Hungary

9, 10, 11, 16, 17, 20, 22, 27, 26, and 28. For example, the minimum altitude located at sub-basin number 26 (1750 m) with estimated weigh value of 96° tends toward the north. The maximum altitude at sub-basin number 7 (2450 m) with estimated weigh value of 179° completely tends toward the south.

Roughness within the basin will be affected by the solar elevation angles. Air masses will also affect the region and precipitation currents in different forms, the outcome of which will be reflected in contour lines. Consequently, Quaternary glacial processes had greater impacts on the northeast slopes. In comparison with the southwest slopes, the lowest altitude was located at a lower altitude.

14	1650-2300	1850	28	1800-2200	1800

In order to estimate the altitude variations, they were classified into four classes of 3500, 3400, 3200, and 2800 m. A linear relationship was fitted between the altitude of the mountain peaks, as an independent variable (X), and the lowest altitude, as a dependent variable (Y) (*Eq. 8*). According to this equation, it can be expressed that the low altitude increases by about 51 m for every 100 m altitude. The sub-basins were classified into seven groups based on the dominant geographical direction in the main valley. Also, the average lowest altitude (the altitude at which the CC varies) and the average CC were estimated in the same directions for each group (*Table 4*). To estimate the relationship between the average geographical direction and the average lowest altitude, *Equation 8* was used and *Equation 9* was applied to estimate the CC and the average lowest altitude.

$$Y = -1.0968x + 2242 \quad \text{(Eq.8)}$$

$$Y = -0.0004x + 1.227 \quad \text{(Eq.9)}$$

Accordingly, it was revealed that as the sub-basins' geographical direction stretches toward the north, the lowest altitude increases in the curvature coefficients (*Table 3* and *Eqs. 8* and *9*). This altitude was estimated at 2242 and 2044 m for the valleys that completely lean towards the south. This represents the glacial impact on the northeast and southwest slopes, which varies according to the environmental conditions. The

accumulation of glaciers emanated from the cirques above the ELA indicates a better condition in the topography of southwest slopes. Hence, the lower altitudes move toward the lower altitudes in comparison to the northeast slopes. Although the southwest slopes of Alvand Mountain have lower CC altitude, its CC value is much lower for the glacial processes were less effective on the highlands. Accordingly, the average lowest altitude was 2130 m in the entire area, and 2000 and 2146 m in the northeast and southwest sub-basins, respectively.

The matter and energy distribution have been usually uniform from the Mountain peak down to the slopes. In the V-shaped valleys, the CC became close to zero. In the glacial valleys, although the glacier thickness increases, the concentration of the matter and energy did not occur in the thalweg. By investigating CC in the 28 sub-basins of Alvand Mountain, it was revealed that the descending trend of the CC was expected to the point where matter and energy (glacial ice) are concentrated, and later from that altitude, the CC is increasing. In the sub-basin, where the slopes lengths are considerable (the southwest slopes), the lowest altitude of the CC varies based on the highest peak in the area. In the valleys that the highest peaks are more than 3400 m, the altitude of change CC is between 2400 and 2500 m. As if the tallest peak in the sub-basin is less than 3400, the altitude of change CC decreases.

ELA estimation by AR and AAR Method

For estimating ELA of Alvand Mountain via AR and AAR Method, a profile of cirques' floor was detected by global mapper software. If the profile is a concave, landform is considered as cirque. In field observation, the beginning literate moraines were determined. Their record was positioned by GPS and the data transferred to GIS. Through field observations, cirque number 42 was detected in northeast slope, cirque number 25 was detected in the southwest, and *At* was estimated. To obtain altitude and determine Ah in the profile (*Fig. 8*), ELA was estimated and translated into equations related to THAR and AAR. Based on AAR method, the estimated ELA for northeast slopes is 2297 m and for southwest slopes is 2727 m.

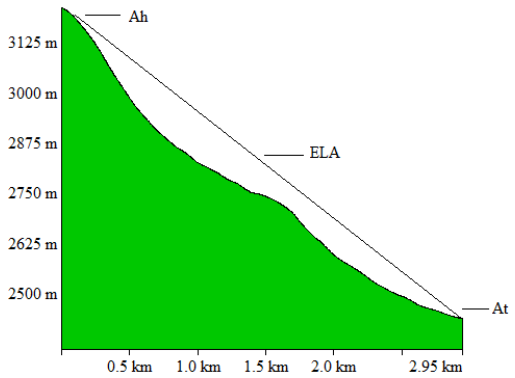

Figure 8. *sample of profile in Alvand Mountain*

Water and ice equilibrium line altitude (WIELA)

Values of erratic block and paleo-climates have been investigated as archive of historic glacial activity and as ice glaciers, respectively (Millar and Westfall, 2008). Large terminal moraines mark the outer limit of the ice sheet. In some places, the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_58495868
© 2018, ALÖKI Kft., Budapest, Hungary

terminal moraine is a single ridge; in other places, it may be a series of sub parallel ridges. There may be a large sandar (outwash plains) leading away from the terminal moraines wherever sub glacial or supra glacial streams emerge from the ice margin. The terminal moraines can be used to reconstruct the size of the ice sheet at its maximum extent (Bennett and Glasser, 2009: 367). There are moraine terminals around Alvand Mountain that can be used to estimate the WIELA in the longest glacial period in the Quaternary. For this purpose, several major paths of the erratic block were chosen in the northeast and southwest slopes and their expansion was investigated. Field survey revealed that the WIELA in the longest glacial period in the southern slopes was placed at 1680 m, and erratic block evidence has been detected in northeast slopes (1776 m). In the middle latitudes of the Northern Hemisphere (like Iran), the most suitable places for the cirques are topographical hollows facing northeast. The most extensive glacier of the Alamkouh is located on the northeast side and constitutes permanent glacial (Zomorodian, 2012).

In this regard, consideration of environmental gradients and topographical conditions (features that affect the ice flow velocity and moves WIELA to the lowlands) is highly recommended. The greater the slope, the greater the increase in glacier flow velocity is. Thus, it takes more time to achieve a balance between the flows and melt velocity. The second feature is the topography on the front side of the mountain that will accumulate more ice and consequently, be thicker and faster ice flow in favourable conditions. As a result, it limited the lateral extent of ice and prevented melting. These two features indicate the slope of the southwest slopes leads to ice accumulation and valley glacier formation. Although there is no appropriate condition for the glacial formation in the northeast slopes, the valleys come together after the mountain knick. Hamedan topographical similarities with a large cirque (with a radius of 3.3 km) imply that if the glacier tongues were fed well and accumulated, it could not overflow for the low slope gradient. The existence of the erratic block in different parts of Hamedan is an evidence for this claim (*Fig. 9*).

Conclusion

Wright method is often used for estimating the Quaternary ELA of the Iranian mountains. Four methods have used to test this method in an Alvand Mountain (SD, CC, AAR and THAR). The ELA of Alvand Mountain estimated using the Write method indicates that the ELA of the northeast slopes is above the ELA of the southwest slopes. While, given the position of Iran in the temperate region of the northern hemisphere, the ELA in the northeast slopes should be in lower heights than the southwest slopes. The ELA estimated using the CC method in the northeast slopes is 68 meters above the southwest slopes, such a difference, like the Wright method, cannot be accepted with regard to environmental conditions. The non-conformance of ELAs estimated using Wright and CC methods with environmental conditions is due to differences in altitude of mountainous sinusitis in two northeast and southwest slopes. The sinusitis elevation in the northeast slopes is 2000 m and 1700 m in the southwest slopes. The 300 m difference of the sinusitis altitude has led to the identification of the cirque up to 1700 m in the southwest slopes and its identification up to 2000 m in the northeast slopes. The identification of the cirques at different heights of the two slopes led to estimate a lower ELA in the northeast slopes compared to the southeast slopes. The beginning of the pediment at an altitude of 2000 m in the northeast slopes in the Cc method has led to a higher ELA estimation of northeast slopes compared to southwest slopes. In the Cc method, the ELA is estimated based on the contour line forms. The result is that these two methods cannot be used for ELA estimation in areas where sinusitis height is above the maximum expansion of the Quaternary glacial. Estimated ELA for northeast slopes by the SD method is 513 m lower than the estimated ELA on the southwest slopes. Such a difference is justifiable with regard to the sun's altitude angle in the northeast slopes. The ELAs Estimated through both AAR and THAR methods were similar. That is why the AAR method is just presented. The ELA estimated using the AAR method in the northeast slopes is 430 m lower than the estimated ELA of southwest slopes (*Fig. 10* and *Table 5*). The results of using SD and AAR methods for ELA estimation are consistent with the findings of Jafari (2013), Moayeri et al. (2011), and Ramesth (2002). Therefore, these two methods can be used to estimate ELA.

Table 5. *The comparisons of ELA in Alvand Mountain*

Method	Total	Northeast slope	Southwest slope
CC	2138	2167	2099
Wright	2294	2404	2246
SD	2226	1960	2491.5
AAR	2512	2297	2727

In addition to the ELA, WIEA has been also estimated in the present study. WIEA was detected using erratic blocks. The WIEA estimated in the southwest slopes was 1680 m and on the northeast slopes was 1780 m. Glacial's tongues in the southwest slopes than the northeast slopes have flowed until a lower altitude. The reason is due to the differences between the topography of the pediment of the southwest and northeast slopes. The topography of the southwest slopes causes glacial's tongues to be connected and creates a glacial valley. Whereas, the topographic conditions of the pediments of the northeast slopes have led to the creation of a glacial sheet (ice sheet) instead of a glacial valley. The flow velocity in the glacial sheet is less than the flow velocity of the glacial valley due to the less thickness. As a result, in the maximum expansion of the WIEL, the topographic conditions of the pediment were more effective than the direction of mountain slopes.

Abstract. The essence of all external morphogenesis processes depends on the governing climatic conditions of the time. Evidence suggests that the climatic conditions of the world and, consequently, external morphogenesis processes have undergone changes throughout the life of the earth. There are U-shaped valleys, cirques, local names and lake evidence around the Qala'ehchai Basin, which can be a reason for the quaternary glacier process. The glacier process of the region is approved by evidence such as the cirques and snow-line. For identification of glacier cirques, curve of the values extracted from DEM and Pari topographic map of 1: 50,000 scale is used. The quaternary snow-line is obtained using two methods of Wright and Porter. To identify pseudo-cirques, allometric method for the three parameters of length (L), width (W) and height difference (A) of the cirque, linear regression analysis in Excel software, and lithology study of main cirques have been used. Based on the highest snow-line calculated by Porter method (2425 m), all the lakes are situated above the height of the quaternary water and the ice equilibrium line. Field evidence and lithology of the region indicate that glaciers that are originated from high altitudes and well fed enter marl deposits by exiting the igneous area and resistant sediments. Glaciers in marl sediments create U-shaped valleys with a linear flow. After the treatment of glaciers, the necessary conditions for the creation of lakes are provided. The granulometry of the sediment sample suggests that when the location of the sediment is closer to the bank of the lake, its profile is similar to lake sediments and when its location is far from the center or bank of the lake, its profile is somewhat between glacial-lake sediments.

Introduction

The essence of all external morphogenesis processes depends on the governing climatic conditions of the time. Evidence suggests that the climatic conditions of the world and, consequently, external morphogenesis processes have undergone changes throughout the life of the earth. The long-term climatic data of the regions as well as the tracing of geomorphic evidence of climate change have not only been a nodule to many of the problems regarding the how of past lives, but also have raised a radical transformation in sociologists' perception of the evolution of human societies and have called some of their definitive findings for a serious reconsideration (Ramesht, 2001). The morphological effects of very old climatic changes, with the exception of the quaternary, used in various issues of geology and old geography, are either lost or fossilized (Jedari Eyvazi, 2013). Quaternary is the fourth, last, and youngest period that is so short unlike other geological periods. The existence of multiple climatic changes has led to the importance of studying this period (Martin et al., 2008). The emergence of humans and the recurrence of glacial and inter glacial periods are two important features

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

of the quaternary period; in this period, two different glaciers and inter glacial climates are dealt with (Seif and Abtahi, 2013). The quaternary period, which began with the advent of continental glaciers from the polar regions, ended with the melting of the continental glaciers. After that, the post-glacial period was replaced. In Iran, the beginning of the post-glacial period has been estimated to be 10,000 years ago (Zomorodiyan, 2012). At the end of the Ice Age, global changes were made in atmospheric conditions with the global retreat of ice-covered plates and glaciers. As a result of the warming of the air and the increase in evaporation in rainfall, most of the lakes, covering many plains and plain areas in the midst of the mountains and current desert areas of the planet were dried up (Klinsley, 2009). Some believe that these lakes are caused by a tensile regime after compression, another group attribute them to the anticline bending of the Mirror toward Masha, and eventually, some other consider non-domesticated births as their cause (Oskooi and Omidian, 2013). The size of the lakes and altitude of aridity and water equilibrium line during the quaternary have been a function of snow-line altitude and ice and water equilibrium line altitude (Ramesht, 2004). The snow line is a linear boundary above which snow does not change, i.e. the snow remains in a cumulative state for a long time and does not turn into water above this line (Chinn and Whitehouse, 1980). Aside from lakes that simultaneously remain with ice until the formation of a part of the coast, there are also lakes that are formed when the glacier or ice field decoys. Thus, water in the ditch creates a lake with the wall of valleys on the iceberg. These lakes are slightly filled up until they flow to the surrounding area from the lowest point (Gresswell, 1958).

During the glacial periods, the lower regions of the water and ice line equilibrium have had high rainfall and lower temperatures than the current conditions. Therefore, this positive equilibrium of water and water, resulting from the melting of upstream ice, caused the formation of lakes whose banks are known as the aridity and water equilibrium line (Abtahi, 2013). Existing evidence in nature show that the conditions governing the past climate differ from today. In addition to the climate, the conditions of dehydration and hydrological cycles in basins depend on the physiographies and geological conditions. River entry or discharge does not depend only on the climate of the region, but the position of the lake relative to the basin makes sense of the increase in the entry because nutrition and energy are meaningful when there is a life (Velayati, 1995). Hollows and lakes are the lowest part of the basin and planar surfaces that are the result of stagnant waters. In other words, lagoons, lakes, reservoirs and sedimentation mechanisms in them lead to the formation of smooth surfaces with fine texture (Ramesht, 2013).

In addition to the presence of U-shaped valleys, cirques and local names of the mountains such as the Gharghalan (Permanent snow) around the Qala'ehchai Zanjan Basin, which are evidence of the sovereignty of the quaternary glacial process, there is a lake called Khandaghlo that still retains its identity. In fact, this lake, with greater water in the past, is another reason for the governance of the morphogenesis system of the quaternary glaciers in the region. In addition to Khandaghlo Lake, the reflection of landforms with simple and sometimes closed contour lines along with convergent drains, single-point elevations and two-way drain in topographic maps with a scale of 1:50,000 was evidence of the abundance of such lakes in the past, which are now largely destroyed and have lost their independence. In addition to the climatic changes in the quaternary, the change in the level of Ghezelowzan, including the Qala'ehchai, and the dominance of backward erosion in the region has played an indelible role in the

© 2018, ALÖKI Kft., Budapest, Hungary

destruction of the lakes in the region. Investigation of this issue can be very important in introducing the region, which is likely to be called the Finland of Iran, and encouraging environmentalists, paleontologists and, in particular, paleoclimatologists for further study of the region.

Literature review

According to the studies of Russell (1889) and Longmore and Heijnis (1999) on the lakes of the past, lunar periods coincided with the ice age. Walter Goldthwait (1908) reconstructed extinct aqueducts and glaciated lakes in the Michigan Lake Basin and used field evidence, and concluded that in Michigan and Wisconsin, rock cuts at the current levels of Michigan lake are severe, but stretch of the old coastline, which was 5 to 25 miles further away from the current surface, is partially or completely destroyed. In a study entitled fluctuations and changes in the cold stages of large lakes, including Larness affected by the Agassis and Barlow ice currents, Lewis and Anderson (1989) concluded that during the second period of frost and after its end, ice currents caused the discharge of the lake from the frozen state and flooded with the flow of the glacier down the lake, increasing the flow velocity. Olvmo and Johansson (2002) evaluated the importance of stone and lithological structure in deep weathering before glaciation and glacial erosion on the landforms of the West Coast of Sweden using satellite imagery, accurate mapping and frequent field observations, and concluded that the direction of ice and pre-glacial landforms is aligned with the forms engraved on the rocks of the area. Glassera and Bennettb (2004) argue that landforms of glacial erosion are the basis of paleo glaciology. Cossart et al. (2008) analyzed the slope instability of the glaciers in the mountainous areas of the Durranz Basin, in southeastern France, using field evidence, geographic information system, and spatial pattern combination, and concluded that large stones in avalanche of rock are related to the stress of the pressure; these avalanches are due to the rock breaking during the glacial period, where rocks become unstable with the slope after the glaciation and appear as avalanches. Bao et al. (2009) studied coverage of surface tensile stresses in the past Neo-Proterozoic 2 ice lake in Svalbard. Sundal et al. (2009) explored the evolution of the ultra-glacial lake across the Greenland plate. Bajracharya and Mool (2009) discovered the behavior of glaciers and the explosion of lagoons in ice lakes in the study of glacial and ice lakes in the Nepalese region of Everest. Askari Chawardi (2009) investigated lake of the Jajrood valley during the quaternary period and concluded that one of the factors causing the formation of lakes is the transfer of glacial deposits in the quaternary period, their density at the margin of Jajrood valley, landslide occurrence during the glacial and tectonic periods. Bolch et al. (2011a) identified a dangerous ice lake in North Shian and concluded that climate change and global warming have the potential to create an increasing number of glacial lakes, and the flooding of these lakes also causes serious damages and risks. In another study, Bolch et al. (2011b) studied the evolution of ice lakes along the Hindu Kush mountain range between 1990 and 2009 using Landsat satellite imagery and concluded that in eastern Nepal, India and Bhutan, lakes are larger and more numerous; however, glacier in the Hindu Kush (50%) and Karakorum (30% contraction) is associated with the loss of ice in the western part of Hindu Kush Himalaya. With a study on the potential volume of the Himalayan lake flood based on satellite imagery, the angle of stagnation on the lake bank, and estimation of the volume of flood on more than 2000 lakes, Fujita et al. (2013) found that there are 794 lakes lacking Steep Lakefront Area; meanwhile, the volume of the lake was identified as

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

10 million m^3 of ice. Jananeh, and Rajabi (2016) studied the effects of the quaternary period on Iranian seas and lakes and found evidence that the sea and lake levels had been up and down during glacial quaternary periods. In addition, they asserted that changes in Iran's sea and lake levels during glacial periods are quite similar to changes in the global scale and that there is evidence of existence of lakes in today's deserts, but there are different views on their extent and depth. The glaciers are the origin of the formation of most lakes, and alone contribute to the formation of lakes more than any other factor. These types of lakes are not too deep and are caused by glacial factors. Kiani et al. (2016) assessed the ecological vulnerability of climate change in Abarkuh Basin, concluding that the change in the ratio of environmental parameters occurs during cooler periods and all of the thresholds of transit stability and general state of environmental systems are on the verge of collapse. Ghiyas Abadi et al. (2014) stated that Gohar Lake is the only mountainous lake with glacial Paternoster species in Iran. Entezari et al. (2015) studied the geomorphology of climate change in the Gorganroud Basin during the quaternary period and compared two maps of the current and quaternary periods, showing a temperature difference of 9.4 °C. They also showed that the cool and humid climates are in the fourth quarter. Studies on the Paleolithic in Iran go back to the work of French Democrats (1907); while discovering some rocky devices in the Pleistocene sediments in the Caspian Basin, it is stated that Iran was covered by mountain glaciers and lakes during this period. Some of the Iranian researches on glaciation and glaciers include Ramesht (2004), Tahoni (2004), Yamani et al. (2007), Rezvani et al. (2010), Ghahroudi Tali (2011), Amirahmadi et al. (2011), Abtahi (2013), Parizi et al. (2013), Jafari and Asghari Serkansrudi (2014), and Shamsipour et al. (2015).

Materials and methods

Study area

Several lakes in the quaternary have been created by glaciers or glacial treatment. These lakes have been created by rill erosion or sedimentation of glaciers or due to the creation of a moraine dam. The Ombilics and the Verrous are also places that have spawned in glacier valleys, creating permanent and temporary lakes. Posture, on the one hand, and proper rainfall feeding, on the other hand, have led the glacier cirques to become small and scattered lakes so that the high cirque lakes are the result of the melting of the upstream snow and downstream cirque lakes are due to the overflow of the upper cirque lake (Derruau, 2011). The Qala'ehchai Basin is one of the regions in Iran that has well retained evidence of glacial lakes. The Qala'ehchai is one of the sub-basins of Ghezelowzan Basin, originating from the northeastern slope of Belquis Mountain and joining Ghezelowzan from the western-eastern direction near the village of Moshampa. The Ghezel Owzen joins the Caspian sea through Sefidrud, and pouring into the lake of the Manjil dam. Khandaghlo Lake is one of the lakes alive in Zanjan Province in highlands near Belquis Mountains. Basin area is over 618,400 m^2 and has a length of over 3150 m. Its maximum depth is 5-6 m and its average depth is 1.5 m. The main lithology of deposits is marl. The altitude of Khandaghlo Lake is 1600 m and it is under the influence of the adjacent glacial system. The lithology and climatic conditions of the Qala'ehchai Basin have led to the formation of closed basins, some of which have been ruptured and destroyed. However, they can have water for some times of year through proper management. The geographical area of the Qala'ehchai Basin is located about 47° 15' to 47° 30' east and 36° 45' to 37° north latitude. The total area is 780 km^2

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_58695891
© 2018, ALÖKI Kft., Budapest, Hungary

and its average height is 2220 m above sea level. This basin is limited from the west to Takab Provance, from the east to Hesar-Moshampa Department, from the south of Mahneshan Township, and from the north to Miyaneh Township (*Fig. 1*). This basin is a part of the Khoy–Mahabad Zone (Nabavi, 1976) in terms of geological structure and it is located in the intersection of Sanandaj-Sirjan, Alborz-Azerbaijan and Central Iran zones. This area is composed of metamorphosed rocks of schist, marl, gneiss and amphibole, with the northwest-southeast trend in the middle sections of the Ghezelowzan Basin. The higher altitudes are 3330 m in Belquis Mountain and 3208 m in Ghebleh Dagh Mountain. These rocks are directly covered by non-sorting Oligo-Miocene sediments. It seems that metamorphic rocks of the Precambrian to Paleozoic period from the second to the middle of the terrain constitute high altitudes with no sediments on them, a slight potential deposition may have been demolished due to high altitude and erosion. Generally, the rocks in the studied area are Precambrian metamorphic rocks, Late Precambrian sedimentary rocks, previous Cambrian and Cambrian-Ordovician, Paleozoic metamorphic rocks, Diorite intrusive masses, Granodiorite and Gracie volcanoes, Oligo-Miocene volcanic rocks, Pliocene, and quaternary sediments from below upwards, respectively (The Iran Geological Survey).

Extrusive basalt disturbs the region's morphology and is resistant to erosion, which does not easily react to corrosive factors. It is unevenly distributed on the marl and gypsum sandstone, periodic andesite lava of marl, and red sandstone with gypsum, been greatly expanded in the southwest region with layers of the travertine spring deposited horizontally. The sediments of this unit can be considered equivalent to the upper red formations in Qom area. It is also distributed on the periodic conglomerate unit of marl and sandstone with gypsum horizons, being expanded to the west-southwest of the basin. Geomorphologic and hydrological conditions of the area, such as the existence of marl between the sandstone and conglomerate layers in vast areas of the basin, together with the low topographic conditions reflected in topographic maps of 1:50,000 scale farther away from the current river bed indicate that many parts of the region have had more equilibrium conditions during the quaternary. Disturbances of faults and over thrusts are seen in Takht-e-Solayman Mountains and west of Qala'ehchai. These faults are perpendicular to the Qala'ehchai River. The most important fracture in the Ghirgeh-Chahar Tagh fault is in the north west-southeastern trend that crosses the middle sections of the area (*Fig. 2*).

Methods

To study quaternary changes, Digital elevation model (DEM) was extracted from satellite images with resolution 30 m from ASTER of the year 2017. The topography layer was prepared using ARC GIS software. The glacial process of the region was proven by evidence such as cirques and snow-line frontiers. For identification of glacier cirques, curve of the values extracted from DEM and Pari topographic map of 1: 50,000 scales is used. The curved line indicates the glacial process that is reflected as a fan in the impassable valleys. Also, the quaternary snow-line was obtained using Wright and Porter methods. The method of elevation of the cirques floor is one of the five methods Porter has proposed to reconstruct the equilibrium line at low latitudes. The use of this method depends on the number, geographic direction, the altitude classes and the percentage of cirques. Floor altitudes were measured as the single lowest DEM grid cell within each cirque. Latitude and longitude were measured from the centre point of each cirque; and the aspect was measured as the outward direction of each cirque's median axis (Evans, 1977; Evans and Cox, 1995; Barr and Spagnolo, 2015). In Wright's method, by multiplying the number of glacier cirques in 0.6, the number of rows of cirques in descending from in terms of height is obtained. This altitude is the height of the quaternary equilibrium line altitude (ELA). This method estimates ELA by determining the location and altitude of 60% of cirques above the line. For estimating ELA, the altitude of identifying cirques is sorted based on descending order. Then the number of cirques is multiplied to 60% (*Eq.1*). The gained number represents a numerical line of cirques in which ELA is located. In the following, X shows the number of rows and N is cirques number.

$$X = N \times 0.6 \qquad \text{(Eq.1)}$$

The existence of pseudo-cirques led to the determination of the three parameters of length (L), width (W), a height difference of cirque (A) through allometric method and linear regression analysis in Excel software and lithologic study of main cirques in order to determine the correct snow-line.

Geologic maps of the Mahneshan at 1: 100,000 scales were used. The topography is reconstructed with respect to the equilibrium environments in the topographic maps. Two-way drains and single-point elevations along with closed contour lines on topographic maps indicate the abundance of lake in the past. Using the pixel to code software, the areas where such evidence was seen were digitalized and the past

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

topography of the region was reconstructed with the help of digitalized data in the Surfer software through the Kriging interpolation. The watershed and basins were drawn and lake area was reconstructed with Generate watershed extension in the Global Mapper software. The converging radial drainage channels represent a lake. To verify and document the previous lakes, sediment sampling was implemented in areas where there was the possibility of lake in the simulation of previous topography. In this way, sediment samples were taken from places where there were old terraces. In the laboratory, the granulometry operation was carried out through the following steps: 1- Sample washing; 2- Sample placement in the oven device for 24 h; 3- Detachment of dried sediment after the operation of shiker for 15 min; 4- Weighing each of the remaining samples in each of the sieve's pieces; 5- Plotting the frequency table based on the obtained data; and finally, 6- Drawing the cumulative curve graph in Excel software and matching each of the obtained graphs with the curve of the lake sediment.

Quantitative relationships were applied to the data resulting from the granulometry of the sampled sediments. Using these relationships, sediment status was analyzed in terms of standard deviation (σi), mean size (Mz), skewness (SKi) and kurtosis (KG). The final analysis of the data was done according to the values of *Table 1*. In addition, the final analysis was done by comparing the data of other samples with the data's Peri Lake sediment sample, the only live evidence from past lakes.

Results and discussion

Many of the lakes that were in the glacial period have been torn apart after being overflowed or absorbing large quantities of water, and have been ruined by the dominance of various erosions. One of the major factors affecting the destruction of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_58695891
© 2018, ALÖKI Kft., Budapest, Hungary

lakes is the change in the base level that results in the collapse of the river system, causing phenomena such as gullies. These gullies or so-called gully erosion snatches and captures the rivers. There are many other lakes that have not been completely destroyed or eroded. There is evidence around these basins indicating that they were lakes in the quaternary. Among the evidence that can be seen in the field vision is the alluvial terrace left by the lake after passing wet and dry periods. Based on their own characteristics, such as texture, structure, color and thickness, these terraces are of particular features. Existence of other evidence on topographic and geological maps is of great help in identifying the lake. These evidences are as follows (*Fig. 3*): 1. Closed and hole-like contour lines; however, these holes should be detected from the contour line of mountain peaks and volcanoes; 2. Rivers that have been deformed to two-way canals; 3. Single altitude points in the between contour line; 4. To entity material of sediments of past terraces in geological maps.

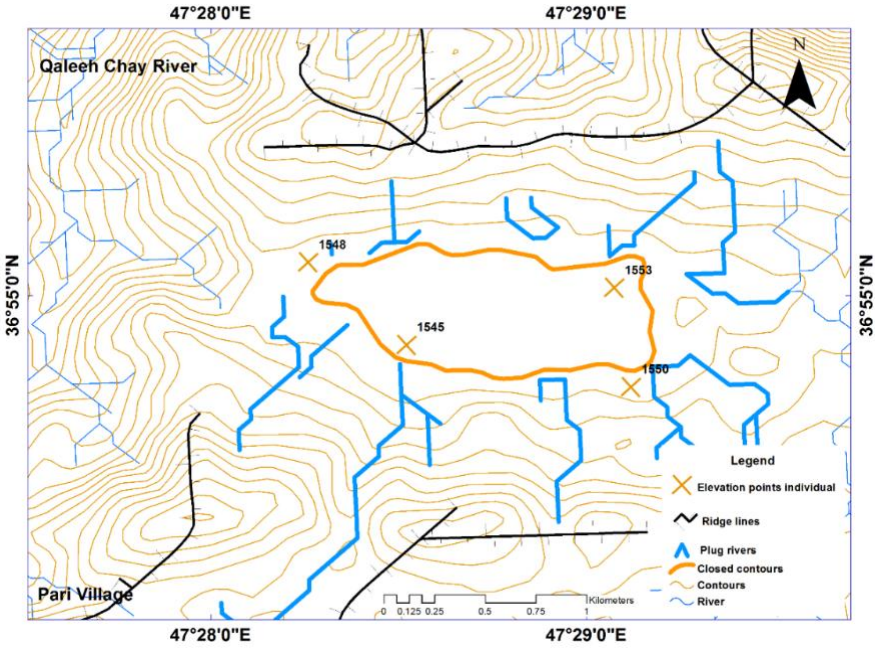

Figure 3. *Evidence of the existence of a lake on a topographic map*

Allometry of the cirques

Detecting glacial effects in mountainous areas is one of the important tasks to be achieved by the remaining evidence. The most important pattern resulting from glacial erosion is the glacial cirques. From a spatial point of view, any hole-like area holds snow and is called a snow house. However, not all holes and amphitheatres are glacial cirques. On the other hand, it is necessary to consider several factors including lithology. Effects of cirques do not remain in loose sediments such as marl, clay and conglomerate for a long time, and they are pseudo-cirques that cannot be attributed to the cirque. For a better study of the cirques and separation from pseudo-cirque, the cirque allometry, i.e. obtaining parameters such as length, width, floor area, height of the peak overlooking the cirques, and slope of the cirque, is done. Usually, in a cirque space, there is a high correlation between the special parameters of the cirque. Otherwise, correlation is reached to higher than 50% by eliminating liars that are

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_58695891
© 2018, ALÖKI Kft., Budapest, Hungary

pseudo-cirques. After finding glacial cirques, their height was accurately calculated. The cirques were sorted by height in a descending order and the total number of cirques was multiplied by 0.6, and the altitude of the number of the row obtained in the descending order was considered as the quaternary snow-line elevation. Accordingly, the snow-line of the study area was 2364 m above sea level. The corrected snow-line after allometry of glacial cirques also averaged 2354.7 m. Snow-line correctly to suit the paper (Seif and Ebrahimi, 2014) was a linear relationship between the length, width and height of the cirques confidence R2 above 90% for solidarity cirques evaluated. Using the cirque floor method of Porter, the frequency of the cirques was determined in geographical directions and snow-line elevation was obtained after performing the necessary analyses. Snow-line elevation was 2354.7 m above the sea level in the Wright method and it was 2425.12 m in Porter's method, with a difference of 70 m (*Table 2*) (*Fig. 4*).

Table 2. *Data Porter's method for determining snow-line*

© 2018, ALÖKI Kft., Budapest, Hungary

average temperature is considered to be 7.3. In fact, the minimum quaternary temperature reduction is considered to be 7.3 °C.

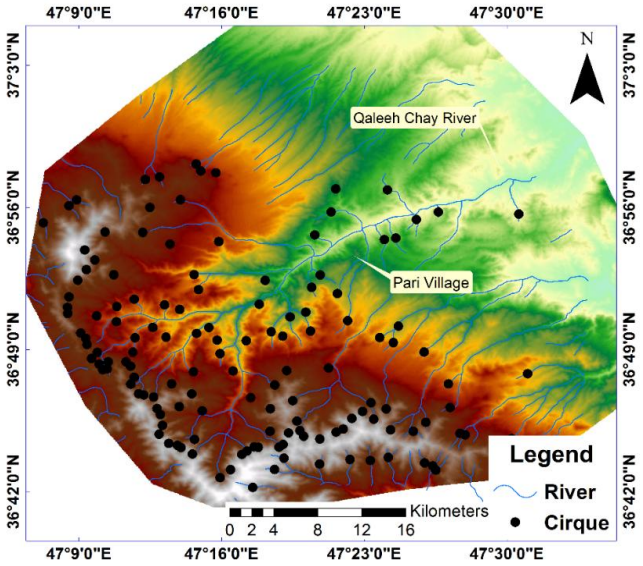

Figure 4. *Scattering of glacial cirques in the study area*

Topographic reconstruction

The base level of Ghezelowzan River Basins and Sub-basins has considerably changed during the quaternary period. The base level changes basically led to the formation of various morphogenesis and processes, such as the capture phenomena. In the capture of a river, the river changes into another direction. Stream capture, river capture, river piracy or stream piracy is a geomorphological phenomenon occurring when a stream or river drainage system or watershed is diverted from its own bed, and flows instead down the bed of a neighbour stream. The changes in the base level of Ghezelowzan River were about 200 m (*Fig. 5*). Base level changes have changed the flow of river processes and the dominance of gully erosion. The domination of gully erosion in the headwaters of the basin changes the alluvial process in pluvial process. In clay and silt lands in stagnant waters, in the case of running water, the form of the contour lines is expressed as the claw sinusoidal. Depending on the degree of erosion of these surfaces, the sinusoidal contour lines tend to be medial and claw-like. On topographic maps, wherever the gradient of the earth is very low, single elevation points are plotted instead of plotting the contour lines. This indicates that the intended level has evolved in the process of functioning of stagnant water. This is because very slow slopes have been developed in the bed of stagnant waters and secondly, the sediments will be fine-grained since the lake's environments and stagnant waters are low-energy and provide conditions for sedimentation with a diameter of less than 0.15 mm. In addition, convergent radial channel lines at these levels suggest the existence of past lakes. Drawing profiles (*Fig. 6*) Perpendicular to Qala-ehchai River on the left and right banks of the river showed that there were terraces of the same height with common ground, common slope and common morphology. Placing the longitudinal and transversal profiles on the region and the probability of existence of lake focuses attention on the terraces of the same height on both sides of the Qala-ehchai River.

Figure 5. *Drop down to Qala-ehchai River base*

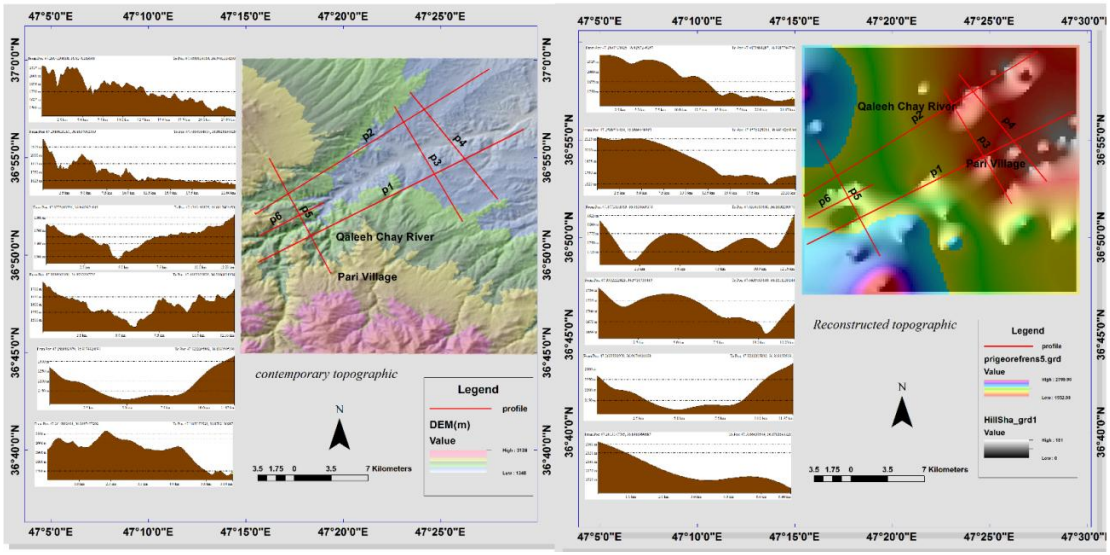

Figure 6. *Location and schematic figure of profiles in the studied area in both quaternary and contemporary conditions*

For further study of the reconstruction of the entire topography of the region, the height of these terraces was the basis of analysis and reconstruction of the total topography was done accordingly (*Figs 7* and 8). An examination of the old terraces of the entire area during the quaternary topographic reconstruction suggests that the lake's conditions and closure of the area still retain their original status. In the drawn profiles, the average depth of erosion in profiles 1 to 6 was 140, 115, 80, 225, 110 and 150 m, respectively. Border of lake was also drawn assigning banks to each river. After simulating the topography of the quaternary, the previous profiles drawn on the topography were drawn on the reconstructed topography in the same direction. In this way, the altitude of eroded land levels was detected and quaternary lakes were reconstructed.

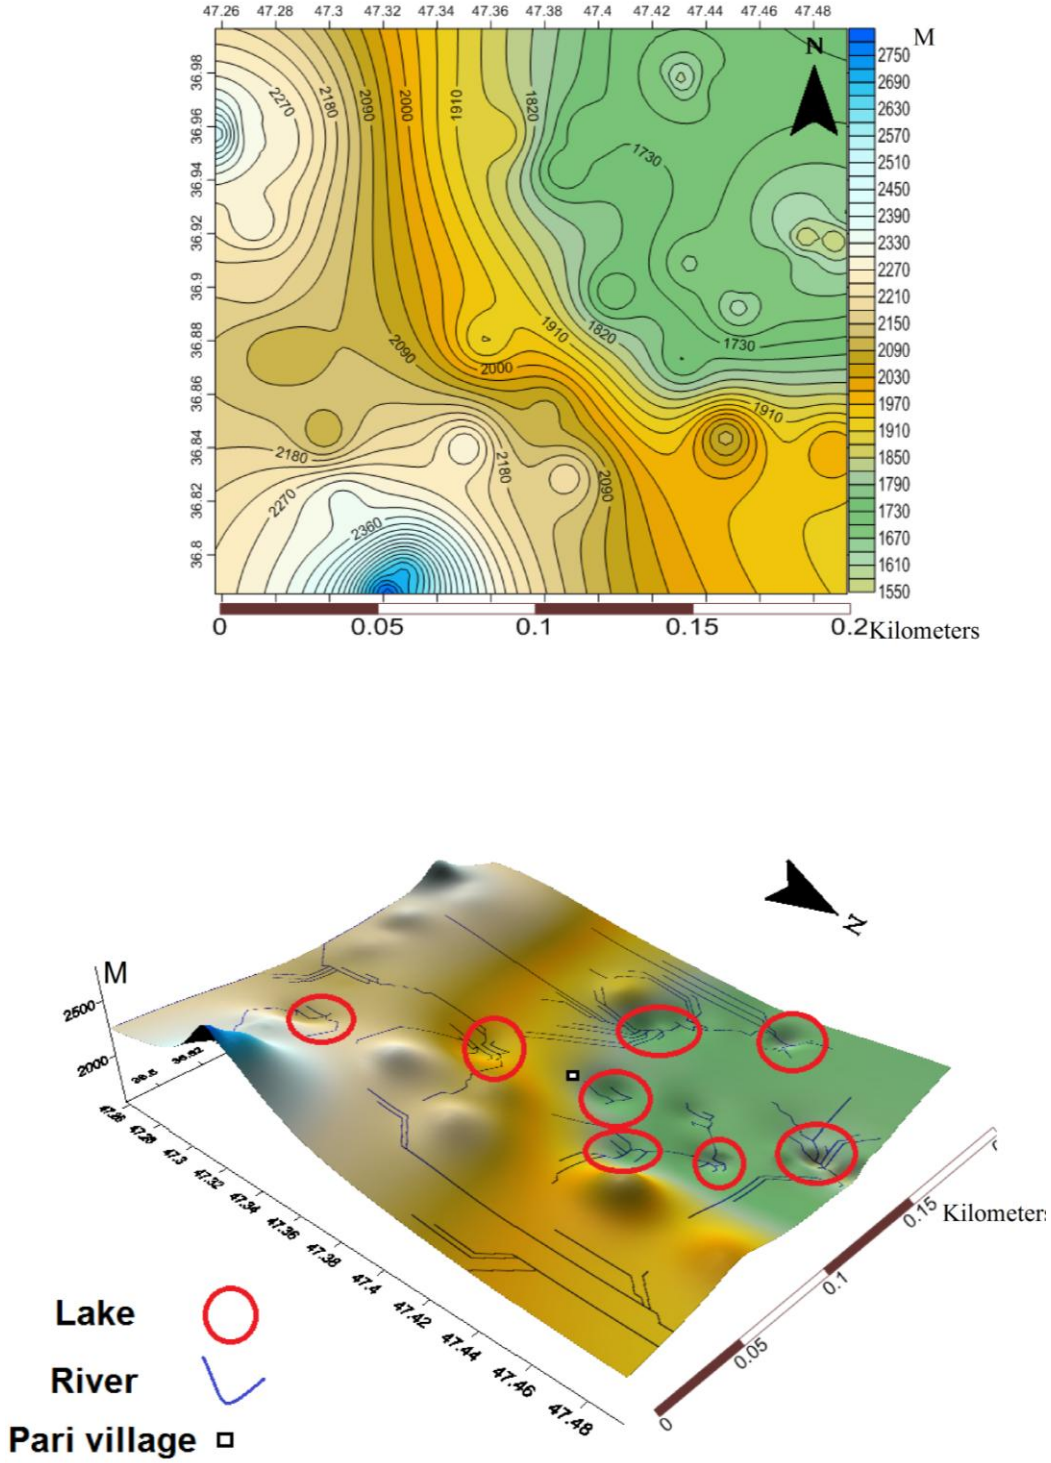

Figure 8. *Reconstructed topographic and 3D maps*

Given that the morphogenesis system in the quaternary was glacial and the study area was dominated by various lakes, it can be said that the glacial plates caused pouring erosion and created a number of lakes in one direction. The lakes have also been torn and drained on their left side. In the profile shown in *Figure 7,* this can be completely seen (*Fig. 9*).

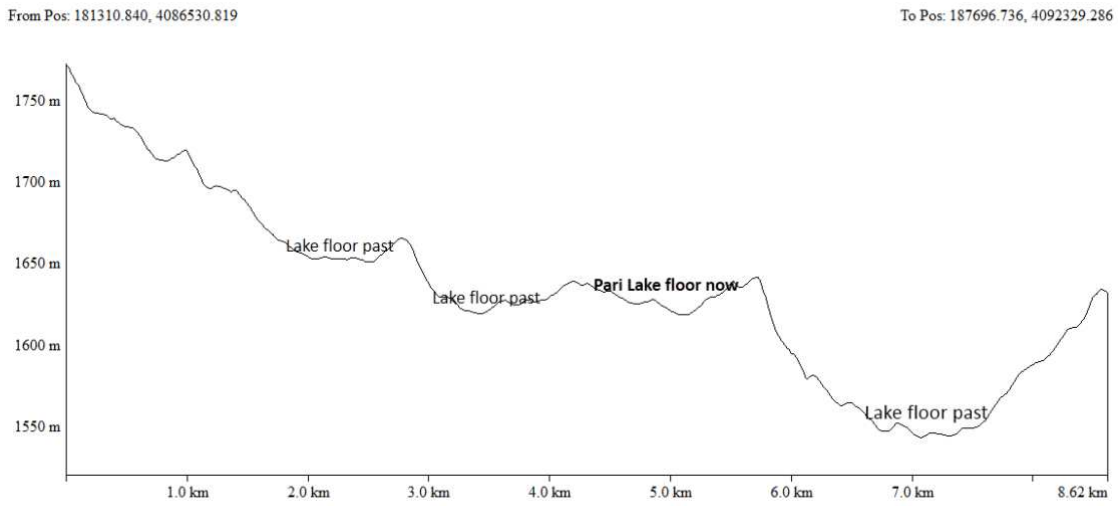

Figure 9. *Transversal profile in the quaternary*

The granulometry of sediments

Controlling slope over a long period of time in the plane causes exposure to air and physical and chemical weathering. The value of slope is also different in different bed rocks. This means that in a resistant formation, the slope undergoes fewer changes. In the study area, using a 30-meter DEM, a gradient map was obtained (*Fig. 10*). It turned out that the slopes of up to 5% are almost smooth and are considered as plain. On the direction map, the slopes of up to 5% are called highlands. However, given that lakes have transformed from hole-like shape into a flat form over time, they indicate past lakes in the quaternary period. In addition to topographic maps, more environmental documentations, the best of which is granulometry of sediments, are required for proving that the area under study was a lake during the quaternary period. For this purpose, 14 specimens of sediment in 9 points with different geographical coordinates were transferred from the profiles to the laboratory environment (*Fig. 11*). After selection and initial washings, a specified amount of each specimen was weighed and granulometry started using a Shaker between sieves number 20 to 230. The remaining sediment in each sieve was weighed and the graph was finally plotted. Based on the location of the sediments, three samples were taken at different depths with respect to the apparent change of sediment type near Khandaghlo Lake, which is currently one of the lakes in the region; although it has become independent due to a change in the base level of Qala'ehchai River and the upstream basin waters are not naturally directed to the lake, part of the water of Qala'ehchai goes to its centre by creating an artificial pond and it is used for agricultural and fish farming purposes. Profiles 1, 2, 3 belong to sediment condition of this part of the basin. These profiles were used as control profiles for the analysis of other profiles because them granulometry indicates lagoon coastal sediments. The change in these three profiles indicates the uniform distribution of grains in different sieves, and more than 60% of the sediments remain in the sieves receiving the finer grains. In other areas, it was not possible to identify the exact river bank due to changes in the use of the rivers and the diversion of the rivers, but it was attempted take samples from the nearest potential bank (*Fig. 12; Table 3*).

Profiles 1-3 and 2-3, taken from the same location with the farthest distance to the centre, are known as the Polygon of Lake and are very similar to the profiles provided by researchers such as Mahmoudi and Moghimi (2011) for glacier deposits, which is evidence that the area was a glacier during cold quaternary periods. Rest of the profiles (4, 5, 6, 7, 8, and 9) are affected by lake-glacier process, which indicates that the environment is affected by the glacier-lake process and that the polygon of the sediment lake shows a tendency to be glacier when being taken away from the centre.

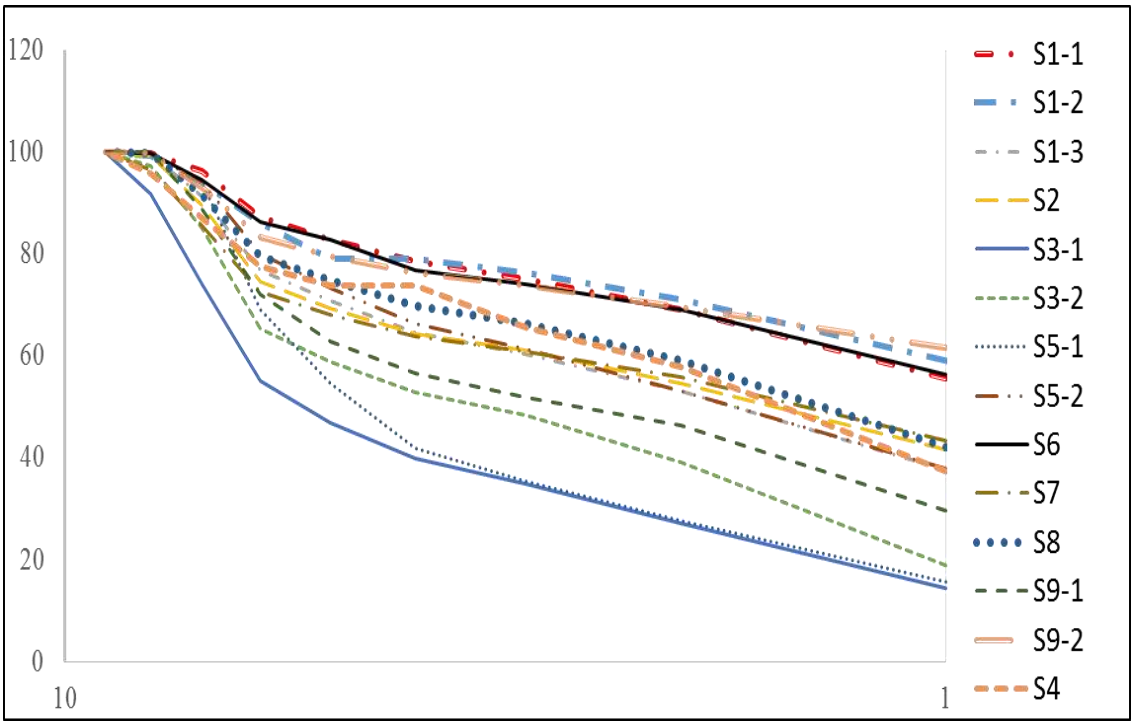

Figure 12. *Plot of different sediment samples*

The granulometric results of the data and the relationships in *Table 1* show that, in terms of the Mz index, all samples are coarse grains and are divided into two groups of medium sand and coarse sand. In terms of Q1 index, the sediments fall into two very poorly sorted and poorly sorted groups, and only one sample has been moderately sorted. The Ski index subdivides the sediment into four groups. Most of the samples are located in the mediums positively skewed group of the fine particles. Two samples of asymmetric sediments are very positively skewed toward coarse particles and granularity. A large asymmetric sample is symmetrically skewed toward fine particles. In the KG index, the whole sediment sample was divided into two very platykurtic and leptokurtic groups. According to the data in *Table 4,* it can be said that most of the collected grains correspond to very slight differences with the precipitates taken from the Peri Lake. Accordingly, the condition of the lake is confirmed by past sampling sites.

The quaternary glacial processes of Iran have been exposed to various geographic and environmental conditions. Until now, moraines, U-shaped valleys, and cirques or mountain snow flats have attracted attention of many glacier researchers. Evidence of the quaternary glacial lakes was less considered. The topographic and geomorphological

conditions of the Qala'ehchai Basin and the adjacent basins indicate that the streams flow out of the mountains to the plains in the wide and U- shaped valleys. U-shaped valleys were shaped due to the glacier flow in the quaternary cold periods. Investigating Qala'ehchai Basin as a typical basin on the west of the Ghezelowzan river from Mahneshan to Miyaneh shows that there is evidence of geomorphological effects of eight lakes from the quaternary period. Glacier lakes are not caused by the deposition of the terminal moraines or by the exploration of the glacier in the cirques, but rather they are formed by the glacier flow in marl sediments. Glacier flow in the marl sediments has created U-shaped valleys that have become independent basins, creating small and shallow lakes with the withdrawal of the glacier. By changing the base level of the Ghezelowzan River during the quaternary and overcoming the decreasing erosion on its branches, small basins have lost their independence and have been evacuated in Ghezelozen River. Several field surveys in different areas affected by the quaternary glacier in Iran indicate that the areas around the Qala'ehchai Basin are the only area that has kept the effects of glacial lakes. Studies of quaternary climate change in Khandaghlo Lake, as a remaining ecosystem since then, can be a nod to many quaternary issues.

Table 4. *Computed grain size parameters and their verbal terms for outcrops from study areas*

Sample and figure number	Mean size (MZ)	Sorting (Q1)	Skewness (Ski)	Kurtesis (KG)
1-1	0.3 coarse sand	1.5 poorly sorted	2.266 mediums positively skewed	0.2 very platykurtic
1-2	0.17 coarse sand	2.015 very poorly sorted	1.19 mediums positively skewed	0.45 very platykurtic
1-3	0.94 coarse sand	2.48 very poorly sorted	5.15 mediums positively skewed	0.63 very platykurtic
2	0.9 coarse sand	1.57 poorly sorted	0.25 symmetrical skewed	0.65 very platykurtic
3-1	1.43 medium sand	1.14 poorly sorted	-1.1 negatively skewed	0.70 platykurtic
3-2	1.53 medium sand	1.31 poorly sorted	0.657 very positively skewed	0.72 platykurtic
4	1.75 medium sand	1.07 poorly sorted	0.58 very positively skewed	0.69 platykurtic
5-1	1.33 medium sand	0.971 moderately sorted	0.325 very positively skewed	0.69 platykurtic
5-2	0.56 coarse sand	1.125 poorly sorted	5.67 mediums positively skewed	0.43 very platykurtic
6	0.6 coarse sand	1.8 poorly sorted	1.31 mediums positively skewed	0.85 platykurtic
7	0.37 coarse sand	1.51 poorly sorted	2.17 mediums positively skewed	0.61 very platykurtic
8	0.51 coarse sand	2.28 very poorly sorted	2.75 mediums positively skewed	0.68 platykurtic
9-1	0.76 coarse sand	1.22 poorly sorted	1.87 mediums positively skewed	0.59 very platykurtic
9-2	0.83 coarse sand	2.52 very poorly	1.22 mediums	1.33 lepokurtic

		sorted	positively skewed	

Conclusion

In the east of the western highlands of Zanjan Province, landforms are either closed or semi-closed basins. Their geomorphological evidence at first sight brings a land like the land of thousands of lakes in Finland to mind. Khandaghlo Lake is the only remaining lake in this region. In this area, where the altitude varies from 1600 to 1900 m, there are convergence centres in the waterway network that are sometimes cut off from one side and water has been discharged. In order to have a standard profile, three sediment samples were taken at different depths from the lake bank; Granulometry of sediments indicate their homogeneous distribution. The snow-line height according to Wright, and Porter methods was 2357 and 2425 m. If the highest snow-line height estimated by the Porter method is taken into account, it is noteworthy that all lakes are above the quaternary water and the ice equilibrium line since the height of the water and the ice equilibrium line is 1042 m below the snow-line height based on the findings. On this basis, the quaternary water and ice equilibrium line is less than 1400 m, with the lower lakes with a height of nearly 1600 m above it. Field evidence and lithology of the region indicate that glaciers that are originated from high altitudes and well fed enter marl deposits by exiting the igneous area and resistant sediments. Glaciers in marl sediments create U-shaped valleys with a linear flow. They contribute to the creation of lakes in two ways: Lakes closest to the water and the ice equilibrium line have been established for the glacier valley terminal, such as the glacier and the terminal moraine. The rest of the lake has been created due to explorative erosion in long-tailed valleys as a result of further dredging of the lake bed. The granulometry of taking samples indicates that the profile of the sediments taken from the lake bank or its centre is more similar to the lake sediments, and their profile becomes of lake-glacial sediments by going away from the centre or bank of the lake. Of the 780,000 m^2 of the total area of Qala'ehchai, about 96,000 m^2 (12%) includes the identified 8 lake beds. Khandaghlo Lake, as an evidence of the lakes of the quaternary period, owes its existence to an artificial canal that transfers part of the water of the Qala'ehchai to the lake. With regard to climate change over the last few decades, the study of climate changes and quaternary ecological conditions has an important role to play in environmental planning. A detailed study of the climate change aspects of the region can provide important solutions for managing global warming. On the other hand, given the tourist boom, the introduction of these places is of particular importance in attracting tourists.

Abstract. A natural channel differs from a prismatic one by its rich variability. Regulated rivers have a geometrically regular shape that is not suitable for the instream biota. The morphology of a regulated river is the main cause of habitat changes. The article provides the results of research that was focused on assessing the impact of a channel's morphology on the instream habitat preferences by ichthyofauna. In the article the ichthyofauna is represented by brown trout (*Salmo trutta m. fario*). During the years 2015 and 2016, research was carried out for 13 reaches of mountain watercourses in Slovakia. These reaches were geodetically measured, and a hydraulic model was created. The ichthyological survey was focused on the fish's habitat preferences. A set of data was created from the results that was statistically evaluated by cluster analysis, and the correlation relations for the abiotic and biotic characteristics of the watercourses were evaluated. The individual evaluations provide mutually compatible results. It can be concluded from the results that bioindications by fish provide reliable results in relationship to the changes in habitats in regulated rivers. There was an unambiguous statistical correlation in the preferences of brown trout in the regulated and natural rivers.
Keywords: *brown trout, suitability curves, RHABSIM, river regulation effect*

Introduction

In most cases, the regulation of rivers has always been and is still oriented towards flood protection. Often, such implementation has been unilaterally aimed at increasing the capacity of the channel, so that the variability of the channel's morphology was replaced by a prismatic shape. Such modifications significantly altered the natural morphology of the channel. Natural habitats that create favorable conditions for biota during minimum flows have disappeared in regulated rivers. Therefore, a whole set of methodologies that assess the consequences of changes in rivers has been developed.

Modelling of the biological variables of a stream was used for this purpose. This method enable an assessment of the suitability of the microhabitat of a reach (Copp, 1992; Bockelmann et al., 2004), the organization of aquatic communities (Townsend and Hildrew, 1994) or the anthropogenic impact on a watercourse (Shuler and Nehring, 1994; Shields et al., 1997).

A key aspect of these methodologies is to identify and assess the links between the hydromorphological, physical-chemical and biological states of streams (Conallin et al., 2010; Galie et al., 2017).

Along with the quality of streams and biotic interactions, morphological characteristics form a basis for assessing the availability of a habitat (Carnie et al., 2016; Gibson and Pasternack, 2016). When restoring the regulations that were aimed only on flood protection, it is important to be able to predict the response of the biota to the restoration measures. Therefore, the modelling of the impact of the morphology on a river's ecosystem requires a systematic and repeatable analysis of the impacts of the habitat characteristics of the stream on its suitability (Galbraith et al., 2016; Turner et al., 2016), the organization of aquatic compartments (Piniewski et al., 2016), and any anthropogenic changes in the stream (Santiago et al., 2016). This is the methodological framework for an environmental assessment of the effects of changes in streams (climatic, morphological, quality of water, etc.), on the quality of the aquatic habitat that are based on the Instream Flow Incremental Methodology – IFIM (Bovee, 1982; Bovee et al., 1998).

The impact of changes of the quality of a habitat is determined by bioindications. Research shows that freshwater fish are good indicators of morphological changes in streams and of biotic integrity in freshwater ecosystems (Pont et al., 2006; Cheek et al., 2016; Roni et al., 2014). They also respond sensitively to changes in the temperature and flow (Avery-Gomm et al., 2014). Due to their mobility, which they also have in their old age, and sensitivity to biotope changes, fish are suitable for assessing a river's ecological integrity (Keeley et al., 2015; Booker and Dunbar, 2004).

Information about the impact of channel characteristics on the quality of a habitat is important. This problem was solved by Holm et al. (2001), when he created three different suitability curves of flow velocity at three different flow rates for juvenile Atlantic salmon (*Salmo salar*) under laboratory conditions. Holm's study focused on fish habitat preferences in terms of changes in flow, depth and velocity (see also Marsili-Libelli et al., 2013; Ayllón et al., 2009; Macura et al., 2016).

Intensive discussions are ongoing among water managers, ichthyologists and hydrobiologists. Nowadays, these specialists believe that the success or failure of any restoration project depends on understanding of river biotopes (Zhang et al., 2016) and continuous stream monitoring.

In view of this trend, the results in this article are aimed at assessing the impact of the river regulation on the quality of the aquatic habitat, which is indicated by ichthyofauna.

At present, it can be said that the success or failure of any restoration project does not only depend on continuous river monitoring; it also particularly depends on a design based on a high-quality forecast of the reaction of the biotope to the restoration interventions that will be needed. This procedure minimizes inappropriate restoration measures in a stream. In accordance with this trend, the

© 2018, ALÖKI Kft., Budapest, Hungary

results presented in this article are aimed on the impact of river regulation on the quality of an aquatic habitat that is mainly indicated by brown trout.

Materials and methods

From the point of view of the restoration of a river, it is important to quantify its design parameters. It is important to focus on the summer season. Minimum flows along with high temperatures create the highest load factors for the biota. Therefore, the summer period can be considered as a design condition for assessing the quality of a habitat or for the design of appropriate parameters for restoration measures for a river (Carlson et al., 2015; Macura et al., 2016).

The main objective was to determine the effect of the morphology of a river on the habitat preferences of the ichthyofauna, which in this article is represented by brown trout. The following methodology was selected:

- Selection of the reference reaches
- Ichthyological survey and hydrometric measurements
- Topographic measurements of the reference reaches
- Statistical evaluation of the characteristic parameters of the aquatic habitat
- Modelling of the quality of the aquatic habitat
- Effect of the flow velocity and channel depth on the suitability of the river habitat

Reference reaches of the rivers

For this study smaller mountain and piedmont streams were selected for the following reasons:

- Mountain streams have more characteristics in common, so the negative effects of their regulation are also common in many areas. Therefore, it can be expected that the results obtained could be generalized
- Mountain streams are in the upper sections of a river basin. Their length is relatively short, so the pollution load is low, and the water quality is usually suitable for the full use of the restoring effect on the stream and its surroundings.
- River regulations mainly affect the morphology of a stream. The good water quality of the selected reaches of mountain and piedmont streams does not alter the impact of the morphology on the quality of the aquatic habitat.

The reference reaches with a river basin of a size of 10-100 km^2 were selected from a whole database of reference reaches by a selective method in the environment of ArcView GIS. From the point of view of the rock complexes, a flysch was selected. At this selection stage, the river basin database contained 265 river basins that fulfilled the previous conditions. In the first phase, streams where hydrological stations are located were selected. Based on the ArcView GIS analysis, a physical survey of the streams was performed, and suitable representative reaches for ichthyological and hydrometrical field measurements were selected. The Teplička, Lesnianka, Petrovička, Zázrivka, Veselianka, Kľačianka, Hybica, Lipnik and Kamienka reaches, which are located in the Váh River basin in Slovakia, were selected (*Fig. 1* and *Table 1*).

Ichthyological survey

An ichthyological survey of the selected reaches was oriented towards determining the suitability curves of the individual fish species. The data were obtained by electro fishing, similarly as in Lamouroux et al. (1999). An electrofishing device (Hans-Grassl ELT62IIHI) with the possibility of a choice of electric parameters was used to capture the fish. The parameters of the electrofishing device were determined based on the conductivity of the water and the fish species but were also based on the sensitivity of the fish to the electric current similarly as in Scholten (2003). Each part where the individual species were found has been described (Lambert and Hanson, 1989). At the capture point of each fish, the depth of the flow, the microhabitat characteristics, and the flow rate, which was measured by a set of hydrometric propellers, were recorded; three hydrometric propellers were placed on one rod. The velocities were measured as standard in the following depths of water (d): 0.2d, 0.4d, 0.8d. Using these measured flow velocities, the mean vertical velocity was derived. Based on the mean vertical velocity, the suitability curve was created. The ichthyological survey was carried out in July 2015 and June 2016. *Table 2* shows the number of fish caught in particular reaches.

Topographic measurement of the reference reaches

The topographic measurement of the various reaches was adapted to the requirements of the hydraulic modelling. The cross-section profiles were measured by levelling. The water level was fixed in characteristic profiles to stable points that accelerate the measurement of the water level mode at other flow rates. The topographic and hydrometric measurements were carried out in September 2015 in a period of minimum flow rates.

Modelling of the quality of the aquatic habitat

Based on the technical interventions in the stream, the quality of the aquatic habitat was assessed by the Instream Flow Incremental Methodology (IFIM). This method is used for an analysis of the relationship between the flow rate and biotic components of an environment, while this relationship is a continuous function of the flow rate (Williams, 2001; Lopes et al., 2004). The IFIM methodology (Bovee et al., 1998) is traditionally considered to be state of the art despite persistent criticism (Rosenfeld and Ptolemy, 2012). Based on this methodology, a number of models have been created. The Riverine Habitat Simulation Model (RHABSIM) was used. It is an interdisciplinary decision-making system that helps landscape engineers consider the benefits and consequences of different water management solutions. This model is widely used not only in the region of its creation (Payne, 1998) but also in many European countries (e.g., the U.K., Norway, and France, and often with certain modifications). A very good overview of the overall philosophy, history, development and background of the IFIM, including a comprehensive list of the literature, can be found in Stalnaker et al. (1995). The model contains data from the biotic and abiotic areas. The abiotic parameters are the width, depth and surface area of the channel, the velocity of the flow, and the hydraulic characteristics in relation to the flow and morphology of the channel. The biotic information is mainly represented by bioindicators (fish) in the form of suitability curves. The relationship of the basic characteristics of the channel (depth and flow velocity) was statistically evaluated in the first phase.

Results

Statistical evaluation of the characteristic parameters of the aquatic habitat

At the point of the capture of each individual fish of the species, the depth and flow velocity were measured. The flow velocity and depth of the stream preferences were indicated by three fish species, i.e., the brown trout (*Salmo trutta m. fario*), Alpine bullhead (*Cottus poecilopus*) and Eurasian minnow (*Phoxinus phoxinus*). A graph of the habitat preferences for the individual fish species (*Fig. 2*) was developed. According to *Figure 2,* there is no significant difference between habitat preferences of individual fish species.

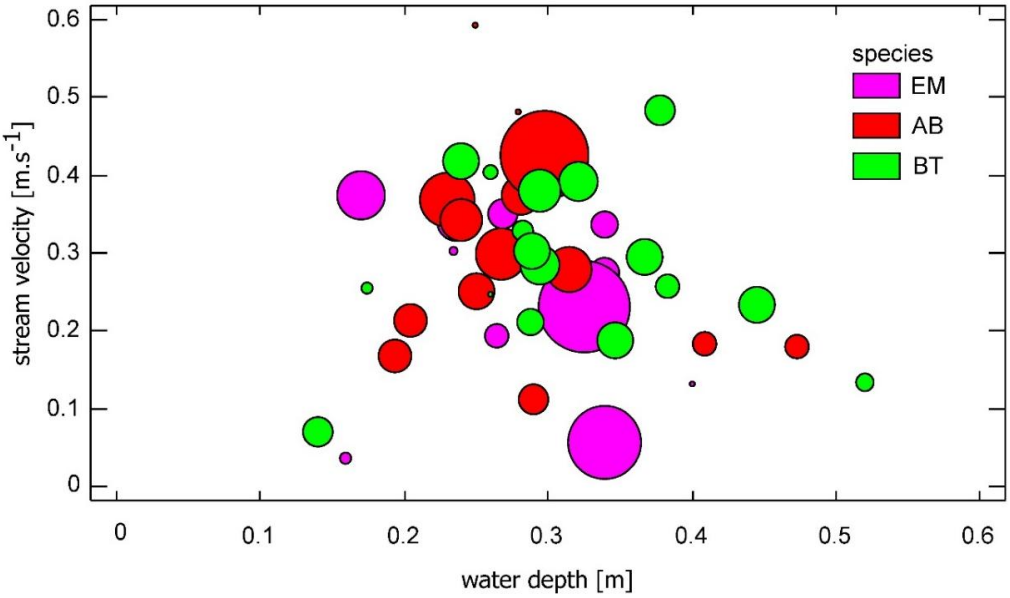

Figure 2. *The graph shows the presence of the Eurasian minnow (EM), Alpine bullhead (AB) and brown trout (BT) at individual depths and flow velocities*

For the next analysis the cluster method of the furthest neighbour was used. (Horváth and Gregušová, 1999).

The file was divided into two subsets, i.e., regulated and natural streams, to verify the cluster analysis results. Data on the depth, flow velocity and number of individual fish species were used as variables. Specifically, the brown trout was singled out. The number of complete cases in the cluster analysis was seventeen for the brown trout. *Figure 3* clearly shows the process of the merging of the objects into clusters. The objects that were joined at the bottom of the chart are similar; those objects that are linked at the top are different. Two clusters were created:

1) Hybica N, Veselianka N, Kamienka N, Lesnianka N, Lipnik N, Teplička N and Kamienka R, which can be described as a cluster of natural (N) reaches.

2) Hybica R, Petrovička R, Petrovička N, Teplička R, Kľačianka R, Zázrivka N, Lesnianka R, Lipník R, Veselianka R and Zázrivka R, which can be described as a cluster of regulated (R) reaches.

On a vertical axis, the distance between the individual objects is displayed where this distance is defined as the centroid distance of the two clusters. Centroid is a vector of diameters (each coordinate is the diameter of the respective coordinate objects in the

© 2018, ALÖKI Kft., Budapest, Hungary

cluster). The method was derived by R. R. Sokal and C. D. Michener (1958) based on the geometric concepts and the degree of disparity of the two clusters was expressed as the Euclidean distance of their drawings.

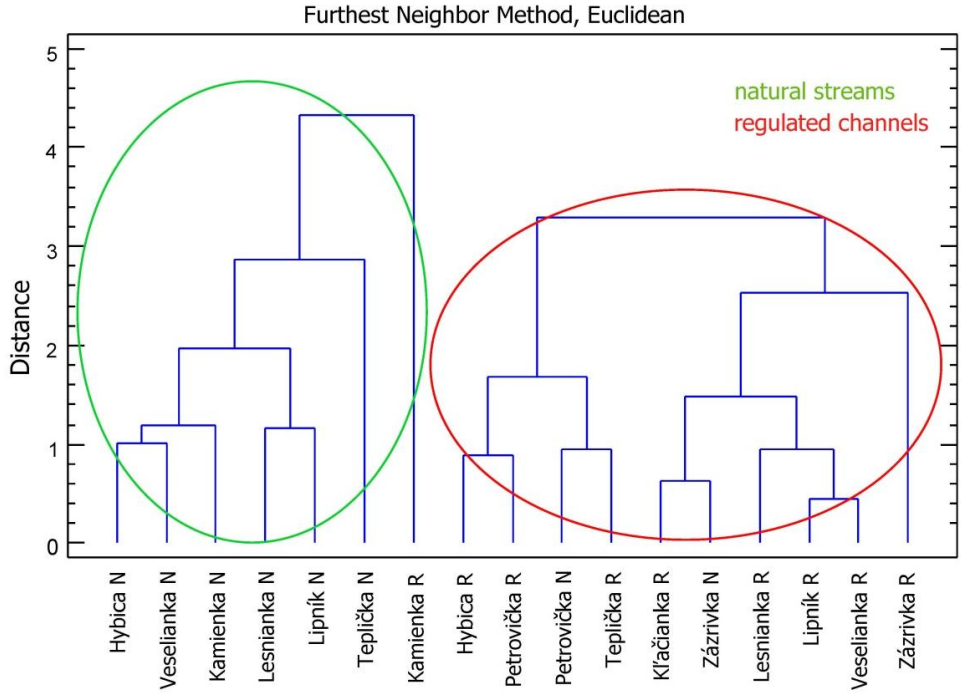

Figure 3. *Dendrogram of brown trout. The vertical axis represents the distance between the individual objects. Stream condition: N - Natural stream, R - Regulated reach*

This division is not perfect because the regulated reach of Kamienka is included in the group of natural reaches, but it is attached at the top of the dendrogram, which shows a certain difference from this group. Also, there are two natural reaches in the cluster of regulated reaches. The reason for this classification is the fact that the morphology of these reaches is poorly variable and therefore little different from the regulated reach.

Figure 4 shows the division of the individual reaches into clusters that focus on the distance between the objects. The objects located at the edge of the cluster are the most remote and therefore the least alike. This difference is evident in the Kamienka flow.

The next analysis will be based on the preference of the brown trout as expressed by the suitability curves that are the basic input to the RHABSIM model.

Derivation of the suitability curves

In the RHABSIM model, the basic parameters of a river habitat are divided into abiotic and biotic parameters. The biotic parameters are represented by fish as a bioindicator of the quality of the habitat of an aquatic flow area. The relation between abiotic and biotic characteristics is represented by the suitability curves of the individual fish species. Specifying the suitability curves is most challenging part of the RHABSIM model. Each species of fish (or other bioindicator) prefers certain combinations of abiotic environmental parameters. These parameters, for example, can be the flow velocity, depth, cover possibilities for the fish, type of bottom substrate, or water

© 2018, ALÖKI Kft., Budapest, Hungary

temperature or quality. The suitability curves for the depth and flow velocity are the most typical and most used curves. These curves are continuous since the parameters of the depth and flow velocity can be interpolated between each computational node of the model. It is necessary to emphasize that a change in flow also changes the suitability curves, similarly as in the work of Jager and Pert (1997). Therefore, during each ichthyological survey, the flow is determined using the hydrometry, and the suitability curve is recalculated to Q_{365}. The suitability curves of all the reference reaches for the depths are shown in *Figure 5* and for the flow velocity in *Figure 6*.

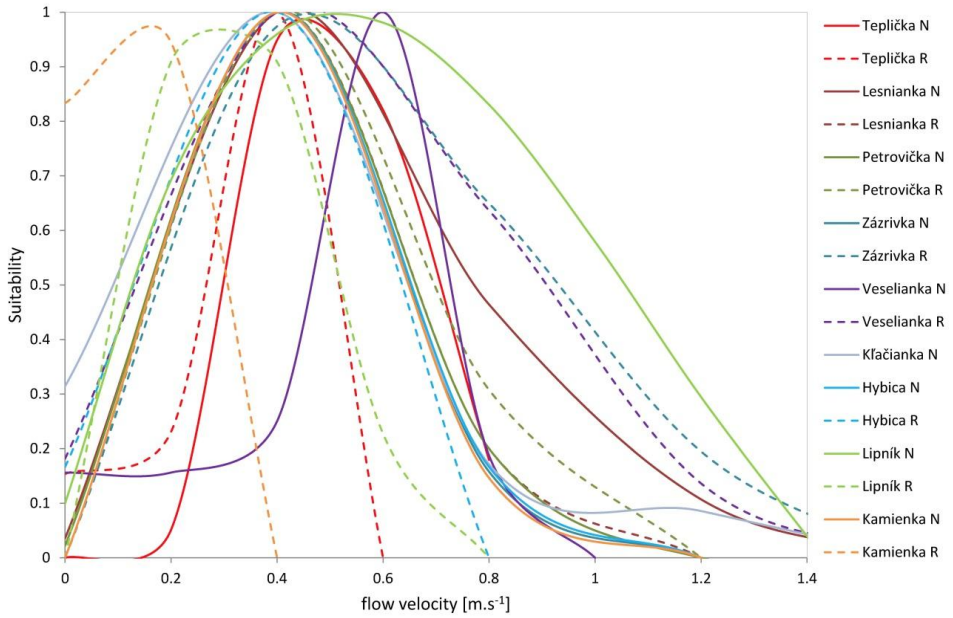

Figure 6. *Suitability curves for the velocity for the brown trout in the reference reaches of the stream*

Relationship between the abiotic and biotic characteristics of the stream

The previous evaluation is only based on the basic characteristics of the stream depth and flow velocity along with the occurrence of the representative fish species. Further, the morphological and hydraulic characteristics of the channel were assessed in relation to the fish preferences of the habitat, which are represented by suitability curves. The morphological and hydraulic characteristics of the channel are represented by the constant of the geometric and dynamic similarity M (*Eq. 1;* Grišanin, 1981):

$$M = \frac{R(g.B)^{\frac{1}{4}}}{Q^{\frac{1}{2}}} \qquad \text{(Eq.1)}$$

where:
R the hydraulic radius [m]
g the gravitational acceleration [$m.s^{-2}$]
B the channel width at the water level [m]
Q the flow [$m^3.s^{-1}$]
M a more detailed description of this parameter (dimensionless) is given in Grišanin (1981).

The peaks of the suitability curves were compared, i.e., the location with the largest occurrence of the given species at a certain depth and flow velocity. These values are listed as the velocity parameter (P_v) and the depth parameter (P_d). An important factor was the selection of a suitable representative fish species. Brown trout, which occurred in all the observed streams, is the most representative, and is very responsive to the morphology of the stream, was selected.

© 2018, ALÖKI Kft., Budapest, Hungary

To evaluate the correlation relationship, the Pearson's correlation coefficient *r* was used. The interpretation of *r* is a very common problem. According to Cohen (1988), the following evaluation of the correlation ratio is stated: A correlation below 0.1 is considered trivial, 0.1 - 0.3 small, 0.3 - 0.5 mean, and above 0.5, large. The correlation of 0.7 - 0.9 is often referred to as very large, and 0.9 - 1 is almost perfect. P_v and P_d were tested to *M* (*Table 3*).

Table 3. *Comparison of the Pearson correlation coefficient (r) for the brown trout between the following variables: velocity parameter (P_v), depth parameter (P_d), the M-factor*

	P_v-*M*	P_d-*M*
r All the watercourses	0.06	0.14
r Regulated channels	0.64	0.28
r Natural channels	0.13	0.52

The correlation coefficient *r* was not confirmed in the case of the file created by all the flows (P_v - M = 0.06 and P_d - M = 0.14). Therefore, the file was divided into two files: regulated streams and natural streams. In both files, the same parameters were correlated (*Table 3*). For the regulated streams the relationship between P_v and *M* equals 0.64, which can be characterized as a large degree of dependence; for the P_d and *M* relationship = 0.28, which indicates an indirect relationship. For natural flows, the relation P_d and M = 0.52, i.e., shows a strong dependence, and for the P_v and *M* relationship = 0.13, which is a small dependence.

Discussion

There is plenty of information about the effect of river regulation on ichthyofauna (Bovee, 1982, 1986; Booker and Dunbar, 2004; Parasiewicz and Walker, 2007). Most fish species prefer certain combinations of water depth, flow velocity, bedding material and hiding possibilities. Information about the influence of water flow rate and depth of water on habitat preference is also sufficient, for example in Macura et al. (2016) or in Wilding et al. (2014) where the authors stated that for several years, eco-hydraulic research has been focused on the effects of velocity and depth on the channel habitats of fish and other aquatic species. Applications of many models, such as IFIM, have shown that the water current can provide a series of speed and depth combinations that support a wide variety of species during their lifetime.

Previous studies have confirmed the correlation between suitability curve characteristics and flow hydraulics, particularly in relation to depth and water velocity (Macura et al., 2012; Davey et al., 2011). The flow velocity and the depth of water are the basic hydraulic characteristics that are interconnected. Therefore, the article analyzes the impact of the hydraulic flow on the quality of the aquatic habitat. Flow Hydraulics is represented by a constant of geometric and dynamic similarity *M* and the preference of the habitat by ichthyofauna is represented by P_d and P_v.

The results presented in *Table 3* can be explained in relation to the morphology of the channel and the habitat preference of the brown trout as follows:

The brown trout does not have a suitable habitat in regulated rivers during small flows. Trout is only present in a regulated river during migration (in the summer it is a

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_58935907
© 2018, ALÖKI Kft., Budapest, Hungary

food migration), when trout is guided by the flow velocity. This responds to the strong correlation of P_v and M.

In natural streams trout prefer cover places with a sufficient depth. The velocity of the flow is not decisive in areas with greater depths, as there is usually a low velocity in these areas. This matches with the significant correlation of P_d and M. The evaluated results directly confirmed the sensitivity of trout as a bioindicator to habitat parameters that are dominant in the characteristic reaches.

The results of the statistical evaluation show a clear division. Overall, it can be said that the basic stream characteristics indicated by the brown trout clearly divided the whole set for the regulated and natural streams.

Even in this case it has been confirmed that trout is a suitable bioindicator of the environment because it responds sensitively to changes in flow rates and flow depths (Hooper, 1973; Shirvell and Dungey, 1983; Reiser and Wesche, 1976; Macura et al., 2012, 2018).

Conclusion

Based on the current research results on the selected reference reaches of mountain watercourses in Slovakia, it follows that the changes caused by the topography of the channel and flow rates are well described by the relationship between the fish population and the characteristics of the habitat. The results from the cluster analysis and correlation analysis show the same trends. In particular, it can be said that the brown trout sensitively responds to abiotic characteristics such as the channel's morphology, flow velocity and depth and the biotic characteristics represented by the suitability curves.

Using these results it is possible to evaluate the impact of the proposed restoration measures. Such a process will greatly contribute to the quality of the restoration of the stream.

Abstract. Culture media affects the yield and quality of tomato. Knowledge about the tomato yield formation in response to culture media is still needed. The purpose of this study was to investigate the effect of culture media on yield, growth, photosynthetic capacity and antioxidant enzyme of different tomato varieties. A greenhouse experiment was conducted at the Baiyun Experimental Base of Guangdong Academy of Agricultural Sciences, Guangdong, China, three culture media treatments viz. soil culture cultivation treatment, substrate cultivation treatment and hydroponics cultivation treatment were applied. Four represented tomato varieties viz. Xinxing 101, Jinbaolai, Kaidi and Xiariyangguang were used as materials. The result showed that, the substrate cultivation and hydroponics produced higher yield than soil culture treatment due to higher dry weight accumulation, fruit weight, and net photosynthetic rate at seedling stage and mature stage. The yield showed significant correlation with individual fruit weight ($R^2 = 0.8205$, $P < 0.01$), net photosynthetic rate in leaves at seedling stage ($R^2 = 0.7189$, $P < 0.05$). The SPAD value and antienzyme activity vary among different planting patterns, cultivars and growth stages. Further study to observe the quality of tomato fruits and nutrition of the tomato plant under different culture media is needed.
Keywords: *antioxidant capacity, culture cultivation, plant growth, photosynthetic ability, tomato, yield formation*

Introduction

Tomato is an important vegetable crop worldwide which ranks next to spuds in terms of the planted area whilst ranks first as a processing crop (Mehdizadeh et al., 2013). It is susceptible to pest and disease while water management and nutrient supply could significantly affect tomato's health (Salokhe et al., 2005). However, this problem could be solved in greenhouse condition which has been known as a protected cultivation (Pires et al., 2011). Recently tomato is suitable for facility cultivation for its high yield and quality requirement and precise management for pest and disease control (Xie et al., 2017). Greenhouse farming, one of the famous agriculture systems, is widely used to create and maintain a stable and suitable environment to optimize the crop production in

order to maximum profits (Abou-Hadid et al., 1994). For facility cultivation of tomato, the culture media is one of the most important key factors that affecting the yield and quality of tomato for the cultivated culture media are different in physicochemical properties such as water-retaining property, nutrient preserving capability, heat retaining property, gas permeability and so on (Liu et al., 2006).

A previous study revealed that different nitrogen forms in media culture had significant effects on tomato's photosynthetic rate, plant growth, root vigor and leaf water content (Yang, 2003). Previous report demonstrated that silicate application in culture media affected tomato fruits and silicon content (Lee et al., 2002). Furthermore, supplementing the nutrient solution with NaCl was able to decrease the yield of tomato significantly (Korkmaz et al., 2016). Thus, it is commonly recommended to select appropriate cultivated culture media for the tomato growth and to improve plant establishment and enhance yield.

Photosynthesis is the basis of crop yield and has a significant correlation with both the yield and fruit quality of tomato (Xu et al., 2001). Regarding to photosynthetic traits, different growth culture media will have effect on net photosynthetic rate, transpiration rate, stomatal conductance and Intercellular carbon dioxide. A previous report showed that culture on sugar medium enhances photosynthetic capacity and high light resistance of plantlets grown in vitro (Tichá et al., 2010). The study of Chen (Chen et al., 2009) demonstrated that tomato assimilation products were enhanced in organic substrates compared with the soil control while the photosynthetic rate and intracellular CO_2 concentration were higher in organic substrate cultivation. Ghoreishy et al. (2018) found that tomato grown in culture media which using composted wheat residue had better fruit yield, chlorophyll, and vitamin C contents. In addition, Hydroponics is also a modern agriculture technique which uses nutrient solution for crop production and a report demonstrated that hydroponic greenhouse system is only system which could meet the food requirements of our needs (Khan, 2018).

However, effect of culture media on yield, growth, photosynthetic capacity and antioxidant enzyme of different tomato varieties is still unknown. Here, we studied the effect of culture media viz. soil culture cultivation treatment, substrate cultivation treatment and hydroponics cultivation treatment on yield, growth, photosynthetic capacity and antioxidant enzyme of four represented tomato varieties viz. Xinxing 101, Jinbaolai, Kaidi and Xiariyangguang.

Materials and methods

Tomato plant growth condition

A greenhouse experiment was conducted from 2016 to 2017 at the Baiyun Experimental Base of Guangdong Academy of Agricultural Sciences, Guangdong, China. Four popular tomato cultivars were used in this study, two of them were large fruit tomato cultivar (Xinxing 101 and Jinbaolai), the other two were small fruit tomato (Kaidi and Xiariyangguang), these four cultivars can be planted in spring, autumn or winter and is provided by the Modern Demonstration Garden of Guangdong Academy of agricultural Sciences. The seeds of the tomato cultivar were sown at March 15th and the seedlings were transplanted at April 22nd. Two seedlings were transplanted to each foam box, the foam box (Length × Width × Height = 59.5 cm × 36 cm × 45 cm) purchased from Guangzhou Xinyinfa Foam Products co. LTD. The climatic conditions

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_59095919
© 2018, ALÖKI Kft., Budapest, Hungary

applied during plant growth period was 30 ± 5 °C in air temperature and 70 ± 20% in air humidity.

Experimental design

The tomato cultivars were growing under three culture media: I) Soil culture filled the foam box with 80 kg soil. II) Substrate cultivation, filled the foam box with 20 kg substrate (vermiculite: pearlite: ceramsite: turfy earth = 1:1:1.5:3). III) Hydroponics, filled the foam box with 85 L nutrient solution, the nutrient solution containing $Ca(NO_3)_2 \cdot 4H_2O$ 590mg·L^{-1}, KNO_3 404 mg·L^{-1}, KH_2PO_4 136 mg·L^{-1}, $MgSO_4 \cdot 7H_2O$ 246 mg·L^{-1}, $MnSO_4 \cdot H_2O$ 2.13 mg·L^{-1}, H_3BO_3 2.86 mg·L^{-1}, $ZnSO_4 \cdot 7H_2O$ 0.22 mg·L^{-1}, $CuSO_4 \cdot 5H_2O$ 0.08 mg·L^{-1}, and $(NH_4)_6Mo_7O_{24} \cdot 4H_2O$ 0.02 mg·L^{-1} (Lv et al., 2010). For the soil culture and substrate cultivation treatment, each foam box was irrigated with 400 ml of the nutrient solution every two days. For the hydroponics treatment, the nutrient solution kept constant volume.

Sampling and measurements

Fruit weight and yield of tomato

The mature fruit was harvest during November 2016 to February 2017, the fruit numbers per was calculated, the individual fruit weight and yield was investigated.

Dry weight of tomato plants

At harvest stage, three represented plants in each treatment were harvested, the plants were separated into stem and leaves, the different plant parts were oved- dried at 80 °C to constant weight for measurement of dry weight of tomato plant.

SPAD value and net photosynthetic rate (Pn) in leaves

The SPAD value and net photosynthetic rate (Pn) in leaves was measured at seedling stage (2016-08-26), flowering stage (2016-10-21) and mature stage (2017-01-20). Three represented plants in each treatment were selected for the measurement of SPAD value and Pn. For SPAD value, the SPAD value was detected by using the SPAD-502 reading meter (KONICA MINOLTA, Japan). The Pn (μmol·m^{-2}·s^{-1}) was measured using LI-6400 (LI-COR, USA). Measurement was conducted in the morning (9:30 - 11:30) in each stage.

Superoxide dismutase (SOD), peroxidase (POD), catalase (CAT) activity in leaves

The fifth leaf from the top of the seven tomato plants were sampled for the measurement of antienzyme activity. The leaves were immediately put in liquid nitrogen and stored at -80 °C (for biochemical assays).

Fresh leaf samples were crushed in liquid-nitrogen and homogenized in 3 ml of 50 mM sodium phosphate buffer (pH 7.8) and the homogenates were centrifuged at 10,000 g for 15 min at 4 °C and the aliquot of the supernatant was used to investigate the enzymatic activities. The SOD activity was measured by detecting the inhibition of photochemical reduction due to nitro blue tetrazolium (NBT) (Foyer, 1987). The POD activity was measured by using guaiacol method (Foyer, 1987). The CAT activity was investigated according to the procedures of Foyer (1987) by recording the decomposition of H_2O_2 at A240.

Statistical analysis

Pots were arranged in randomized complete block design (RCBD), the data were analyzed by using a statistical software (SPSS 13.0), the mean value among the different culture media treatments within one variety was separated by LSD method at $P < 0.05$ level. Correlation analyses among yield and other parameters were computed and represented by using Excel 2010.

Result

Yield of different tomato varieties

Compared to control (soil culture treatment), the hydroponics treatment increased fruit number per plant for all the varieties, while the substrate cultivation increased fruit number per plant in Xinxing101, Jinbaolai, and Kaidi. The substrate cultivation and hydroponics treatment remained statistically similar in individual fruit weight in Xinxing 101, whilst significant increase in Jinbaolai was detected as compared with control (soil culture treatment). In addition, the hydroponics treatment dramatically increased individual fruit weight in Kaidi and Xiariyangguang, but substrate cultivation did not differ from soil culture condiction in individual fruit weight. The yield of tomato showed substantial changes in Xinxing101, Jinbaolai and Kaidi with an increase of 64.87, 77.61, and 48.59%, respectively for substrate cultivation treatment as compared with soil culture treatment. Moreover, compared to control, all tomato cultivars showed significant improvement in hydroponic treatment, with a percentage increase of 107.41, 58.28, 73.19, and 120.29% in Xinxing101, Jinbaolai, Kaidi, and Xiariyangguang, respectively (*Table 1*).

Table 1. *Effect of culture media on yield of different tomato varieties*

Varieties	Culture media	Fruit number per plant	Individual fruit weight ($g \cdot fruit^{-1}$)	Yield ($g\ plant^{-1}$)	Yield change relative to soil culture (%)
Xinxing101	Soil culture	199	5.02±0.05ab	1000.68±83.94b	—
	Substrate cultivation	307	5.38±0.10a	1649.83±111.81a	64.87

© 2018, ALÖKI Kft., Budapest, Hungary

dry weight in Jinbaolai significantly differed among culture media. The substrate cultivation (63.33%) and hydroponics treatment (128.88%) recorded significant higher stem dry weight than the soil culture treatment. Hydroponics treatment induced a significant improvement in leaf dry weight by 97.89% (*Table 2*).

Table 2. *Effect of culture media on dry weight of different tomato varieties*

Varieties	Culture media	Stem dry weight (g)	Stem dry weight change relative to soil culture (%)	Leaf dry weight (g)	Leaf dry weight change relative to soil culture (%)
Xinxing101	Soil culture	23.03±1.97a		36.78±7.89a	
	Substrate cultivation	32.89±5.63a	42.81	38.05±8.67a	3.45
	Hydroponics	31.05±2.36a	34.80	37.44±4.87a	1.80
Jinbaolai	Soil culture	18.19±1.63c		22.71±4.15b	
	Substrate cultivation	29.71±1.41b	63.35	25.46±2.16b	12.09
	Hydroponics	41.27±5.31a	126.90	44.94±2.30a	97.87
Kaidi	Soil culture	30.72±2.43a		33.83±3.31a

	Substrate cultivation	31.90±3.02a	39.05	26.92±3.92a	43.99
	Hydroponics	24.20±4.59a	5.49	29.88±5.82a	59.86

Different lowercase letters within one variety represent significant difference at $P < 0.05$ level

Photosynthetic capacity of different tomato varieties

Compared to CK, the substrate cultivation and hydroponics treatment improved the net photosynthetic rate in leaves in Xinxing 101. The net photosynthetic rate in leaves in Jinbaolai, Kaidi, and Xiariyangguang were increased at seedling and mature stage as compared to CK. At flowering stage, compared with CK, the net photosynthetic rate in leaves was significantly decreased under substrate cultivation treatment, while dramatically increased under hydroponics treatment for Jinbaolai and Xiariyangguang. For Kaidi, the net photosynthetic rate in leaves at flowering stage was significantly decreased. The Pn in the varieties in response to different culture media showed similar trend at seedling stage and mature stage, while vary among culture media at flowering stage (*Table 3*).

The SPAD value in leaves of Xinxing101 was not affected by culture media at seedling stage and mature stage, only hydroponics treatment showed significant reduction in SPAD value at flowering stage as compared to CK. For Jinbaolai, substrate cultivation treatment induced significant reduction in SPAD value at seedling stage, while significant reduction in SPAD value at flowering stage and mature stage was detected for hydroponics treatment. Compared to CK, the culture media (substrate cultivation and hydroponics treatment) did not affected the SPAD value in leaves at seedling stage and mature stage, while significantly decreased SPAD value in leaves at flowering stage (*Table 4*).

Antioxidant enzyme of different tomato varieties.

Compared to CK, the substrate cultivation treatment significantly decreased SOD activity in leaves at mature stage for Xinxing101 and Kaidi, and at seedling stage for Xiariyangguang. Significant enhance in SOD activity in leaves at mature stage for Xiariyanguang was detected as compared to CK. The hydroponics treatment dramatically reduced SOD activity in leaves at all the stage for Xinxing 101 and Kaidi, and at mature for Jinbaolai and Xiariyangguang as compared to CK (*Table 5*).

For Xinxing101, compared with CK, substrate cultivation treatment significantly reduced POD activity in leaves at seedling stage and mature stage, hydroponics treatment improved POD activity in leaves at seedling stage significantly, but significantly reduced POD activity in leaves at mature stage. For Jinbaolai, compared with CK, significant reduction in POD activity was investigated for substrate cultivation treatment at both seedling stage and mature stage, while hydroponics treatment significantly reduced POD activity at flowering stage and mature stage. Substrate cultivation treatment significantly reduced POD activity in leaves in Kaidi and Xiariyangguang as compared to CK. Compared with CK, significant reduction in POD activity in leaves at flowering stage and mature stage was recorded for hydroponics treatment (*Table 6*).

Discussion

Soilless culture mainly includes water culture, fog culture and substrate culture, among which substrate culture is the most important form of soilless culture. The main function of culture media is to support and fix plants, and provide a stable and coordinated water, gas and fertilizer environment for the crops (Liu et al., 2006). In the traditional sense, soilless cultivation mainly relies on nutrient solution to supply the total value nutrients needed by crops, and the nutrient content of cultivation matrix is often ignored whilst in fact, various organic substrates are rich in nutrients. In this study, we observed higher yield was recorded in both substrate cultivation and hydroponics than soil culture. This result agreed with the study of Tzortzakis (Tzortzakis and Economakis, 2008) which found that tomato grown in special substrate had higher yield and better fruit quality. There are several factors which effected yield and photosynthesis. The researches of Zhu (Zhu et al., 2012) showed that the interaction of water and fertilizer affected photosynthetic capacity and yield significantly in tomato plants. And in our study, the substrate cultivation and hydroponics indeed had some differences in net photosynthetic rate compared with soil culture. Meanwhile, early study proved that the net photosynthetic rate was a limited factor for yield, dry matter and fruit quality (Whitehead and Singh, 1997). Our research evidenced the view again by showing a significant positive correlation between yield and net photosynthetic rate in leaves at seedling stage.

In addition, we also found that the hydroponics treatment and substrate cultivation treatment reduced the activity of SOD or POD in leaves for some tomato cultivars in some stage. SOD and POD anti-oxidative enzymatic which have significant roles in osmo-regulations and often help to quench ROS while maintaining cellular structures and functions (Kong et al., 2017). For example, SOD dismutases superoxide radical when POD involved in scavenging H_2O_2 (Sairam et al., 2000). The changes in activity of SOD and POD might suggest that the environment of substrate cultivation and hydroponics was more stable and less environmental stresses for tomato and thus the tomato could had higher dry weight accumulation, fruit weight, and net photosynthetic rate.

In recent years, with the development of ecological agriculture and sustainable circular agriculture, greenhouse tomato in media culture develops rapidly. We would suggest that the substrate cultivation and hydroponics is benefit for tomato growth because they produced higher yield as a consequences of higher dry weight accumulation, fruit weight, and net photosynthetic rate at seedling stage and mature stage.

Conclusion

The substrate cultivation and hydroponics produced higher yield than soil culture treatment due to higher dry weight accumulation, fruit weight, and net photosynthetic rate at seedling stage and mature stage. The yield showed significant associate to fruit weight ($R^2 = 0.8205$, $P < 0.01$), net photosynthetic rate in leaves at seedling stage ($R^2 = 0.7189$, $P < 0.05$). The SPAD value and antienzyme activity vary from different planting patterns, cultivars and growth stages.

Abstract. Soil organic carbon decomposition is regulated by soil physical and chemical properties, such as soil nitrogen (N) and soil substrate quality. In this study, soil samples from both N fertilization and control plots were collected at two depths in a *Larix gmelinii* plantation to determine if N addition elicits consistent responses in microbial respiration in bulk and rhizosphere soil, and to determine the temporal and spatial dynamics of soil organic carbon decomposition. Soil bulk and rhizosphere microbial respiration were determined using the NaOH solution absorption method. Soil microbial biomass was determined by a modified $CHCL_3$ fumigation-extraction method. The greatest soil bulk and rhizosphere microbial respiration occurred in July. Soil rhizosphere microbial respiration was higher than bulk respiration at 0–10 cm and 10–20 cm. The biggest reductions in soil microbial respiration induced by fertilization were 15.0% (bulk) and 19.6% (rhizosphere) at 0–10 cm in July, and 6.4% (bulk) and 7.9% (rhizosphere) at 10–20 cm in September. Fertilization did not influence the rhizosphere priming effect except for at 10–20 cm in May. Structural equation modeling revealed that soil microbial biomass carbon (MBC) and nitrogen (MBN) contributed directly to soil microbial respiration. Moreover, soil total N and organic carbon content were associated with soil microbial respiration through MBC and MBN. These results suggest that N fertilization suppresses soil organic carbon decomposition by decreasing soil microbial biomass, while C input induced by root exudates determined the rhizosphere priming effect, not soil microbes in the rhizosphere.
Keywords: *soil microbe, rhizosphere, soil N availability, soil organic carbon decomposition*

Introduction

Soil is a large organic carbon pool ($1.5 \cdot 10^{18}$ g of C), containing twice the total C in the atmosphere (Schlesinger, 1997). The decomposition of soil organic carbon occurs via the microbial assimilation process known as soil microbial respiration, which is one of the most important processes in global carbon cycling (Schimel and Schaeffer, 2012), response to the primary decomposed ability of new carbon associated to soil by plant (Schlesinger, 1997). Therefore, the decomposition ratio of soil C pools is regulated by soil physical and chemical properties (Xu et al., 2016). Soil nutrient availability, particularly that of nitrogen (N), has been suggested as a key driver of soil organic carbon decomposition (Zhou et al., 2014), such that the soils with a high C:N ratio showing lower decomposition rates (Xu et al., 2016). Recent studies have shown that nitrogen addition reduced soil microbial respiration induced by the negative effects of N application on soil microbial abundance and composition (Zhang et al., 2018), as well as that of soil microbial activity by shifting the metabolic capabilities of soil bacterial communities (Ramirez et al., 2012). These results suggest that N addition slows soil organic carbon decomposition by decelerating microbial mineralization. Therefore, a better

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_59215932
© 2018, ALÖKI Kft., Budapest, Hungary

understanding of soil microbial responses to N addition is critical to predicting soil carbon sequestration in terrestrial ecosystems.

Soil substrate quality controls the soil organic carbon mineralization and efficiency of soil organic carbon microbial assimilation (Manzoni et al., 2008, 2012), with a higher substrate quality leading to higher microbial assimilation, large microbial biomass (Blagodatskaya et al., 2011), and a higher ratio of microbial carbon to soil organic carbon (Xu et al., 2014). Plant root exudates and other labile root-derived rhizodeposit are important substrates for soil microbes (Haichar et al., 2014). For example, the soil adjacent to roots has larger C mineralization rates than bulk soil in undisturbed temperate forest sites (Phillips and Fahey, 2007). A meta-analysis showed that input of labile organic C to the rhizosphere can stimulate soil organic carbon decomposition by 59% (Huo et al., 2017), and this process may be regulated by changes in the size and composition of the microbial community (Dorodnikov et al., 2009; Talbot et al., 2008). This is likely because there is 14–31% higher microbial biomass (Blagodatskaya et al., 2014) and an order of magnitude higher microbial activity and abundance in the rhizosphere than in bulk soil (Kuzyakov and Xu, 2013). However, few studies have investigated the rhizosphere soil microbial activity when there is no more ongoing labile organic C input under N addition.

Therefore, the present study was conducted to determine if N addition elicits consistent responses in microbial respiration in bulk and rhizosphere soil, and to determine the temporal and spatial dynamics of soil organic carbon decomposition. To accomplish this, soils were collected from a larch plantation (*Larix gmelinii*) during the growing season and incubated under laboratory conditions. We expected that soil microbial activity under N fertilization would mitigate any increases in soil organic carbon decomposition induced by rhizosphere microbes. We also hypothesized that changes in microbial biomass would result in concurrent changes in soil microbial respiration.

Materials and methods

Study site

This study was conducted at the Maoershan Experimental Station (127°30'–127°34'E, 45°21'–45°25' N) of Northeast Forestry University, Heilongjiang Province, China (*Fig. 1*).

This region is characterized by a cold, temperate-zone, continental monsoonal climate. The average annual temperature is 2.8 °C, with average daily air temperatures ranging from -19.6 °C (January) to 20.9 °C (July). The mean annual precipitation is 723 mm, with 66% (477 mm) occurring in June, July and August. Additionally, the mean annual evapotranspiration is 1,094 mm. The soil (Hap-Boric Luvisol) is usually frozen to a depth of 1 m in winter (December–April). More details about the soil in the region are given by Wang et al. (2006).

Experimental design

The experiment was designed to test the fertilization treatment effects on soil and plantations. *L. gmelinii* and *Fraxinus mandshurica* with representing 65% and 10% of conifer and hardwood plantations are both dominant species in natural forests of Northeast China and key commercial plantation specie. Two plantations were established in 1986 by planting 2-year-old seedlings using a 1.5–2.0 m planting grid. The experiment was arranged in a randomized design in each plantation in May of 2002, and all plots were 20 m×30 m. Each stand had two N (NH_4NO_3) fertilization treatments, control plots (0 g $N \cdot m^{-2} \cdot y^{-1}$) and fertilized plots (10 g $N \cdot m^{-2} \cdot y^{-1}$), and each treatment was applied in triplicate. The fertilizer was applied continuously on the 15th of each month from 2003 until sampling year (2014) in amounts set based on soil temperatures (*Table 1*). All measurements were performed after the fertilizer had been applied for two weeks. In the present experiment, only the *L. gmelinii* plantation of the parent experiment was sampled.

Table 1. *Soil temperature at different soil depth of research site*

Season	Soil temperature different depths (°C)			Fertilizer amount (%)
	5 cm	10 cm	20 cm	
May	12.50	9.70	8.70	15.25
June	19.50	17.20	16.30	21.00
July	22.30	20.60	19.90	27.50
August	22.10	21.00	20.80	21.00
September	14.60	16.00	14.60	15.25

Soil sampling

Six soil samples were collected from each plot using soil cores with a 6 cm inner diameter at depths of 0–10 cm and 10–20 cm in May, July, and September of 2014. Samples were separated into bulk and rhizosphere soil. To accomplish this, rhizosphere soil was collected from the soil tightly adhering to fine roots (<2 mm in diameter) as described by Wang and Zabowski (1998). Briefly, the soil not tightly adhering to roots was first removed by gently shaking the roots, then tightly adhered soil was collected by putting the roots into a paper bag and vigorously shaking them. Bulk samples were obtained from pooled soil by mixing thoroughly after fine root and rhizosphere soil removal. Soil samples were transported to the research station in a cooler (~4 °C), then sieved (<2 mm) to remove stones, coarse and fine roots and stored at 4 °C.

Soil microbial biomass

Soil microbial biomass was determined by a modified $CHCL_3$ fumigation-extraction method (Vance et al., 1987). The C and N content that were K_2SO_4-extracted from the $CHCL_3$-fumigated and unfumigated soils were estimated using a TOC-VCPH analyzer (Shimadzu, Tokyo, Japan), and soil microbial biomass C (MBC) and soil microbial biomass N (MBN) were calculated using extraction factors of 0.45 and 0.54, respectively (Brookes et al., 1985; Vance et al., 1987).

Soil microbial respiration

The microbial (basal) respiration (including bulk and rhizosphere soil) was determined based on the soil CO_2 emissions over a 10 d incubation period. Briefly, 20 g soil samples adjusted to 60% of the water holding capacity were incubated in 1000 cm^3 gas-tight jars at 20 °C ± 2 °C. The CO_2 was then absorbed by NaOH solution (0.05 M) and CO_2 was determined by single end-point titration with HCl following addition of 400 µl of 0.5 M $BaCl_2$, and precipitated as barium carbonate, after which the amount of CO_2 was calculated (Bekku et al., 1997; Phillips and Fahey, 2007).

Soil properties

Soil total C and N were determined using a FlashEA 1112 elemental analyzer (Thermo Finnigan, Italy). Soil pH was measured in a 1:5 soil: water solution using a FiveEasy pH meter (Mettler-Toledo Ltd., Mississauga, Canada). Soil NO^-_3-N and NH^+_4-N were extracted using 2 M KCl and were determined with an 8500 series flow injection autoanalyzer (Hach Company, Loveland, USA).

Data analysis

Repeated measures ANOVA was conducted to assess the effects of fertilization on soil microbial respiration using the SPSS statistical software 11.5 (SPSS Inc., Chicago, USA). When the results of ANOVA demonstrated a statistically significant difference, Tukey's test was conducted to assess the effects of fertilization treatments. A $P < 0.05$ was considered to indicate statistical significance.

Structural equation modeling (SEM) was used to evaluate the general hypothesis that soil microbial biomass (C, N), soil organic carbon, total N, NO_3^--N, NH_4^+-N and pH influence soil microbial respiration in response to fertilizer application. We constructed an a priori model including possible causal relationships among predictors. Those eight predicators in the initial model were treated as observed variables. Mardia's test was then used to estimate the multivariate normality of the dataset, and the model fit was assessed using the χ^2-test, comparative fit index (CFI), and root mean square error of approximation (RMSEA). Analyses were performed with the SPSS AMOS 21.0 software (SPSS Inc., Hong Kong, China) using the robust maximum likelihood estimation procedures.

Results

Soil microbial respiration

Soil bulk and rhizosphere microbial respiration showed similar seasonal dynamics as soil temperature, with the greatest respiration rate occurring in July (*Fig. 2*). Soil

microbial (bulk and rhizosphere) respiration varied with soil depths. Specifically, the surface (0–10 cm) soil microbial respiration rate was about 4.0 times (bulk: 3.1–4.9) and 3.9 (rhizosphere: 3.1–4.6) greater than that at 10–20 cm ($P < 0.05$). Soil rhizosphere microbial respiration was 6.6% (control) to 6.8% (fertilized) and 10.0% (fertilized) to 11.7% (control) higher than the bulk respiration at 0–10 cm and 10–20 cm ($P > 0.05$), respectively. Additionally, the priming effects were positive, being about 6.7% and 10.9% at 0–10 cm and 10–20 cm (*Fig. 2; Table 2*).

Effect of fertilization on soil microbial respiration

Fertilization decreased soil bulk and rhizosphere microbial respiration, while its effects on soil microbial respiration varied with sampling time and soil depth (*Fig. 2; Table 2*). The greatest reductions in soil microbial respiration induced by fertilization of 15.0% (bulk) and 19.6% (rhizosphere) occurred in July at 0–10 cm, and by 6.4% (bulk) and 7.9% (rhizosphere) at 10–20 cm in September (*Fig. 2; Table 2*). Fertilization did not influence the rhizosphere priming effect at 0–10 cm and 10–20 cm during the growing season except during May at 10–20 cm (*Fig. 2*).

Relationship between soil properties and soil microbial respiration

Structural equation modeling revealed that the predictors explained 88% of the variation in soil microbial respiration (Rmic) (*Fig. 3*). Soil MBC and MBN contributed directly to soil microbial respiration, and the response of soil microbial respiration to MBC and MBN differed. Soil total N (STN) and organic carbon (SOC) content were associated with soil microbial respiration through MBC and MBN. It should be noted that fertilization influenced soil microbial respiration indirectly through soil NO^-_3-N and pH.

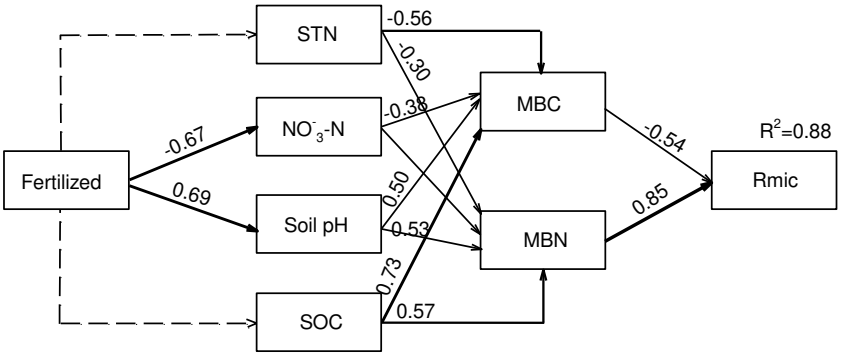

Figure 3. *Structural equation model relating fertilization on soil microbial respiration ($\chi 2$ = 14.385; df = 28; P = 0.695; CFI = 1.000; RMSEA = 0.000). Discussion

Soil microbial respiration

Soil microbial respiration showed significant seasonal and soil depth effects. Specifically, the respiration rate was 2.04–4.87 μgC·g^{-1} soil·h^{-1} and 1.90–4.27 μgC g^{-1} soil·h^{-1} in rhizosphere and bulk soil, respectively, which is consistent with the results of other studies (Ananyeva et al., 2008; Olsson et al., 2005). These seasonal dynamics differed from those of the MBC and MBN (*Table 3*). This likely occurred because of interspecific competition between plants and microbes for nutrients (Kuzyakov and Xu, 2013), especially for N. In July, soil conditions are beneficial to both soil microbes and plant growth. Soil microbes showed higher respiration rate, indicating they were taking more nutrients for their own and plant growth, leading to decreased biomass accumulation (*Fig. 2; Table 3*). Soil microbes might utilize available N more effectively than plants in the short-term, while plants might be more competitive in the long run (Kuzyakov and Xu, 2013). Moreover, temporal dynamics of soil microbial biomass are associated with alternating periods of microbial death and growth, which has important consequences for soil nutrient dynamics and soil microbial biomass turnover (Wardle, 1998). The soil microbial respiration rate decreased with declining soil microbial biomass turnover, leading to the accumulation of soil microbial biomass in September (*Table 3*). Finally, soil microbial biomass and activity determined the soil microbial respiration rates (Xu et al., 2017). A higher soil microbial metabolic quotient (qCO_2),

© 2018, ALÖKI Kft., Budapest, Hungary

which is defined as the microbial respiration per unit of microbial biomass, indicates higher respiration consumption of carbon and lower construction carbon. The results of the present study showed that the qCO_2 value in July was higher than in May and September at depths of both 0–10 and 10–20 cm (*Table 4*). In general, if microbes are more active during that period, cumulative maintenance respiration should be greater, and the population size should be lower (Brown et al., 2004).

Fertilization effect

Soil nitrogen availability strongly influences the growth and abundance of soil organisms. The addition of N has been shown to affect microbial growth, abundance and composition, as well as soil microbial activity (Bowden et al., 2004; Phillips and Fahey, 2007; Zhang et al., 2018), which is consistent with our finding that fertilization decreased soil microbial respiration (*Fig. 2*). There are several explanations for these results. First, N fertilization decreased the number of colony forming units of bacteria, fungi, and actinomycetes in our research plot by 98%, 63% and 61%, respectively (Jia et al., 2009). Because the number of colony forming units of soil microbes was positively related to soil pH (Compton et al., 2004), which declined from 5.18 (control plot) to 4.35 (fertilized plot) in this larch plantation. Moreover, the SEM results revealed that fertilization influenced soil microbial respiration indirectly through soil pH. Second, N fertilization decreased soil microbial biomass (*Table 3*). Soil MBC and MBN contributed directly to soil microbial respiration (*Fig. 3*). Because soil microbial biomass turnover was fast under lower soil pH, it would be slower under higher pH

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

(Wardle, 1998). Third, the soil microbial respiration metabolic quotient (qCO_2) is increasingly being used as an index of ecosystem development and disturbance (Wardle and Ghani, 1995). Nitrogen fertilization increased qCO_2 by 42% (the average of the growing season) at both 0–10 and 10–20 cm. The increasing qCO_2 indicates that microbes invested more in consuming carbon instead of construction carbon. These findings suggested that soil microbes may change their strategy by increasing the function per unit of soil microbial biomass in high nutrient soil. Therefore, N fertilization decreased microbial respiration because of reduced microbial demand for mining of soil organic carbon for N uptake.

Rhizosphere effect

Soil organic carbon is the source of soil microbial respiration. In rhizosphere soil, organic C derived from living roots consists of soluble and insoluble forms of organic C such as sugars, organic acids, mucilage, sloughed cell walls and root hairs, providing a carbon- and energy-rich environment (Haichar et al., 2014). This can suppress soil organic carbon decomposition by 50% or stimulate it by 380% during incubation in soil without plants (Cheng et al., 2014). Therefore, rhizosphere microbial communities, biomass, activity and abundance are distinct from those not affected by living roots (Blagodatskaya et al., 2014; Garland, 1996). The soil microbial community and biomass in the rhizosphere have been shown to be higher than in bulk soil. For example, Gram-negative, Gram-positive and fungal PLFA abundance in rhizosphere were higher by 45.4%, 33.3% and 66.7% than in bulk soil, and the average rhizosphere microbial biomass was 3.5 times more than that of bulk soil in a previous study (Paterson et al., 2007). The root exudates and other rhizodeposits can influence physical, chemical, biological and environmental interactions between plants and soils (Cheng et al., 2014; Kuzyakov and Blagodatskaya, 2015), and it is estimated that the quantity of C released in soil via root exudates ranges from 50 to 1500 μg g^{-1} soil d^{-1} (Cheng, 1996; Jones and Darrah, 1993; Meharg and Kilham, 1991; Trofymow et al., 1987), which may induce higher microbial abundance and diversity and faster microbial growth in rhizosphere soil (Berg and Smalla, 2009; Paterson et al., 2009). Moreover, exudation rates were shown to be positively correlated with organic carbon decomposition in the rhizosphere (Yin et al., 2014). Furthermore, the amount of soil microbial biomass was not closely related to priming (Liu et al., 2017). In the present study, no significant priming effects were observed (*Fig. 4*), even though the average rhizosphere soil respiration was 6.4% (4.0–7.1%) and 11.7% (1.9–18.5%) higher than that of bulk soil at depths of 0–10 and 10–20 cm (*Fig. 2; Table 2*). These findings differ from the previous studies, which showed significantly higher basal respiration in the rhizosphere than root-free soil after glucose addition (Blagodatskaya et al., 2014). Our findings suggest that the C input induced by root exudates determined the occurrence of rhizosphere priming, not soil microbes in the rhizosphere.

The priming effect did not differ significantly between the control and fertilized (except for in May at 10–20 cm) plot in this study (*Fig. 4*). This may have been because there was no ongoing new C input in the present study. Indeed, a previous study showed that N fertilization decreased the decomposition of old and stable soil organic carbon, but did not affect newly deposited C (Zang et al., 2017). However, soil nutrient availability is one of the factors controlling priming effects between soil depths. Greater priming has been observed in low nutrient soils compared with high nutrient soils (Dimassi et al., 2014), which may explain why the rhizosphere effects in July and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

September were higher at 10–20 cm than at 0–10 cm (*Fig. 4*). Another reason may be the lower MBC at 10–20 cm soil, because soils with a higher MBC showed less priming compared to those with a lower MBC (Wang et al., 2015). These results suggest that microbes from deeper soil were less dependent on the C input derived from roots.

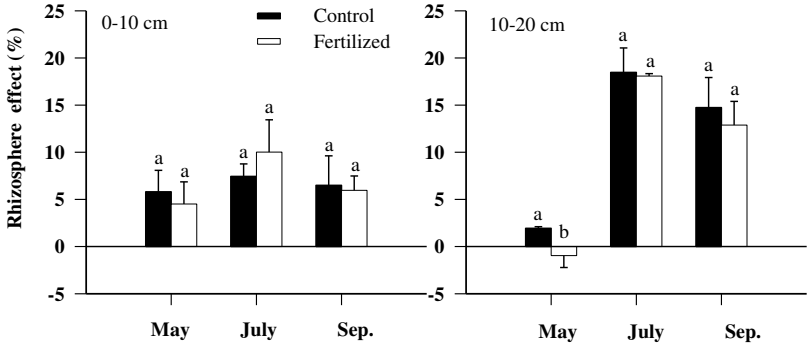

Figure 4. *Effect of N fertilization on rhizosphere effect at surface and subsurface layer*

Conclusion

In summary, there was no significant rhizosphere priming effect when there was no ongoing new C input to soil, even though soil rhizosphere microbial respiration was higher than bulk respiration. Nitrogen fertilization decreased soil bulk and rhizosphere microbial respiration, but did not influence the rhizosphere priming effect. Soil microbial biomass carbon and nitrogen contributed directly to soil microbial respiration. Moreover, soil total N and organic carbon content were associated with soil microbial respiration through soil microbial biomass. These results suggest that it is not the soil microbes in the rhizosphere that determined the occurrence of rhizosphere soil organic carbon decomposition (priming effect). Soil microbes may change their strategy for mining soil organic carbon under higher soil N availability.

Abstract. Microbial diversity in rhizospheric soil plays a vital role for sustainable crop production and maintenance of soil quality. The aim of this study was to evaluate microbial diversity in rhizosphere of Triticeae species by denaturing gradient gel electrophoresis (DGGE) and DNA sequencing technique and to select suitable varieties being introduced to Shanxi province to improve soil quality and crop production. In the experiment, there were nine introduced varieties of Triticeae crops and one local breeding winter wheat variety (S1, Shannong 129, white grain, middle-gluten). The nine Triticeae varieties included six common wheat varieties, one durum wheat variety (S8, Yavaros F9), one rye variety (S9, rye 4R) and one triticale variety (S10, taisi 1). The six common wheat varieties were: Yannong 19 (S2, white grain, middle-gluten, winter), Huaimai 18 (S3, white, middle-gluten, half-winter), Yumai 34 (S4, white, high-gluten, spring), Shannong zixiaomai (S5, purple, middle-gluten, winter), Heixiaomai 031244 (S6, black, high-gluten, winter), Wumai 202W22 (S7, black, high-gluten, spring). Results showed that the rhizospheric bacterial and fungal community varied with Triticeae genera and wheat varieties. Huaimai 18 stimulated the increase of uncultured bacterium and *Nabis ferus*, while Shannong 129 stimulated the increase of uncultured *Chloroflexi bacterium*. Bacterial diversity was higher in rhizosphere of Heixiaomai 031244, whereas, fungal diversity was relatively higher in Huaimai 18. Hence, our study implies that, Huaimai 18, Yannong 19, and Heixiaomai 031244 could be planted in Shanxi province to develop high quality wheat variety resources and rye 4R as a feed crop for planting structure adjustment.
Keywords: *bacterial community, rhizobial fungal, common wheat, rye, triticale, durum wheat, DGGE*

Introduction

Soil microbes are an important component of soil fertility and play critical roles in ecosystems and influence many important ecosystem processes such as organic matter mineralization, humus formation and decomposition, carbon-nitrogen cycling, soil formation, plant nutrient acquisition and so on (Li, 1993), although they are very small parts of the soil composition (Jia et al., 2004b). Especially in terrestrial ecosystems, soil microbes make important contributions to plant productivity and diversity. Van der Heijden et al. (2008) showed that mycorrhizal fungi and nitrogen-fixing bacteria were

© 2018, ALÖKI Kft., Budapest, Hungary

responsible for about 5-20% (in grassland and savannah) to 80% (in temperate and boreal forests) of all nitrogen, and up to 75% of phosphorus, that was annually acquired by the vegetation.

Crop roots spread widely in farmland soil, forming special soil microbial habitat and affecting soil fertility and nutrient circulation (Jia et al., 2004a). Guriguis et al. (1969) had divided farmland soil into rhizosphere and non-rhizosphere soil. The bioactivity of rhizosphere soil was significantly higher than that of non-rhizosphere soil during crop growth period (Takuya, 1990). Organic matter of rhizosphere soil came from crop roots, which could account for about 30% of plant photosynthetic products (Martin, 1977). The amount of rhizosphere soil microbial carbon accounted for about 3 percent of the total soil organic carbon (Joergensen, 2000). The ratio of rhizosphere and non-rhizosphere soil microbial biomass (R/S) was in turn bacterial > fungus > actinomycetes (Lou, 1962; Chen, 1990). Rhizospheric microbes can stabilize soil structure, accumulate organic residue, fix nitrogen, and remove toxin (Doran and Zeiss, 2000; Gomes et al., 2003; Sainia et al., 2004; Wakelin et al., 2008). Also, rhizospheric microbial species and their populations can considerably maintain crops healthy and improve crop growth (Acosta-Martínez et al., 2010; Aira et al., 2010). There were a few relevant reports about the effects of these factors, such as soil type and properties, soil nutrition, cropping system, cultivating management practice, varietal differences within a species, plant age, plant species, and plant genotype (Mar et al., 2000; Xu et al., 2009; Buyer et al., 2010; Teaumroong et al., 2010; Piromyou et al., 2011) on rhizospheric soil microbial diversity as one of the most sensitive biological indicators for monitoring soil quality changes (Brock, 1987; Niemi et al., 2001). However, very few reports were published about rhizospheric soils' microbial diversities when a number of wheat resources were introduced into a particular area.

Wheat (*Triticum aestivum* L.) is one of the most important crops due to having the biggest cultivated area and yield as well as having the widest geographical distribution in the world (FAOSTAT, 2017). In China, the planting area and yield of wheat is next to that of rice. Shanxi Province, located at the eastern edge of loess plateau, is one of the main provinces of wheat production in China. According to wheat ecological quality regionalization, Shanxi province belongs to strong-gluten and middle-gluten wheat producing area in China (He et al., 2006).

Grain quality is determined by the environment and interaction between environment and genotype (Kaya and Akcura, 2014). Grain quality of wheat is characterized by a number of physical and compositional properties and threshold requirements are set according to end-use requirements. For instance in wheat whole-grain physical properties such as size and shape, grain protein content and protein composition is also an important quality measure which defines nutritional and end-use properties of dough mixing, dough strength and effect the efficiency of the bread making process and product quality (Nuttall et al., 2017).

Based on wheat quality classification of the National standard of the People's Republic of China (GB/T 17320-2013), the average protein content of wheat grains in Shanxi has reached above 14% which is in accordance with the protein content of strong-gluten quality, but the average wet gluten content is up to 28%-30% which was between the strong-gluten and middle-gluten range and cannot meet the wheat standard for making bread for which wet gluten content should be ≥ 32% (Ma et al., 2016). Therefore, in order to further improve the quality of wheat varieties in Shanxi Province, it is necessary to introduce some high-protein and high-wet gluten varieties from other

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_59335954
© 2018, ALÖKI Kft., Budapest, Hungary

regions (Xiyong et al., 2012). Xia et al. (2014) reported that grain qualities such as protein content and wet gluten content of six wheat varieties from Huanghuai wheat region were improved significantly compared to those of local variety Shannong 129 after late sowing in Jinzhong wheat region, Shanxi province. Ma et al. (2016) showed that Wumai 201W22 and Wumai 203W2 contain high-protein (≥14%) with high-gluten (≥32%) and high-protein (≥14%) with middle-gluten (30%-32%), respectively, while the local Shannong 129 contains middle-protein (13.4%-14%) with lower-gluten (<30%) after late sowing in Jinzhong wheat region. Juanjuan et al. (2016) studied the genetic potential and wheat quality in Jinzhong, Shanxi province and reported that Heixiaomai 031244 was higher-protein and middle-gluten (30-32%), however, Wumai 202W22 was low-yield with middle-protein (13.4-14.0%) and lower-gluten, and there was only Jinmai84 which was middle-yield with lower-protein (≤13.05%) and lower-gluten (≤30%). Shannong129 of the local breeds was higher-yield with middle-protein and lower-gluten. Besides, Shanxi is also an important livestock and poultry production area, such as pig, cattle, sheep, chick, but feed crops are mainly oats and corn. In order to enrich feed crop resources, it is necessary to introduce some other feed crops, such as rye and triticale.

Soil microbes could be a critical factor affecting grain quality because they are important regulators of plant productivity. The cultivar selection can also affect soil microbial diversity (Nelson et al., 2008; Yang et al., 2016). Therefore, rhizosphere soil microbial diversity was hypothesized to be significantly different among different varieties of Triticeae crops. To validate our hypothesis, in our study, we have chosen ten different varieties of Triticeae crops, which are of high quality and variable in chromosome ploidy, grain color, overwintering, gluten, and source. They include four varieties of common winter wheat (Shannong 129, Yannong 19, Shannong zixiaomai and Heixiaomai 031244), one variety of common half-winter wheat (Huaimai 18), one variety of rye (rye 4R), one variety of triticale (taisi 1), two varieties of common spring wheat (Yumai 34 and Wumai 202w22), and one variety of durum wheat (Yavaros F9). Using the method of PCR-denaturing gradient gel electrophoresis (PCR-DGGE) of the V3 region of 16S or the V1-V2 region of 18S ribosomal DNA (rDNA) (Yang et al., 2016), we preliminarily compared the similarity and diversity of rhizosphere soil microbes (bacteria and fungi) in the above Triticeae crops, collected general (occurring in all soils) and specific (occurring in some soils only) bands of their DGGE gel, and then sequenced the 16S or 18S rDNA fragments to examine the microbial species and to determine detailed microbial community changes among rhizospheric soils of ten Triticeae crop varieties.

Materials and methods

Field site description

The experiment was conducted in the experimental field of Shanxi Agricultural University in Taigu County, Shanxi Province, China (*Fig. 1*). The experimental field is located at 37°25' N and 112°35' E and continuously planted with winter wheat many years, one time per year. The winter wheat variety Shannong 129, which was bred by Shanxi Agricultural University in 2009, previously had been planting in the experimental field for many years. The field soil was medium loam; soil samples of cultivated horizon (20 cm) contained total nitrogen of 1.80 g kg^{-1}, organic matter of 12.6 g kg^{-1}, available N 53.6 mg kg^{-1}, available P 9.6 mg kg^{-1} and exchangeable K

137.5 mg kg^{-1}, which were measured by the methods as previously described (Lü et al., 2002; Yang et al., 2016). The winter wheat in the fall and the spring wheat in the spring are planted one time per year in the field.

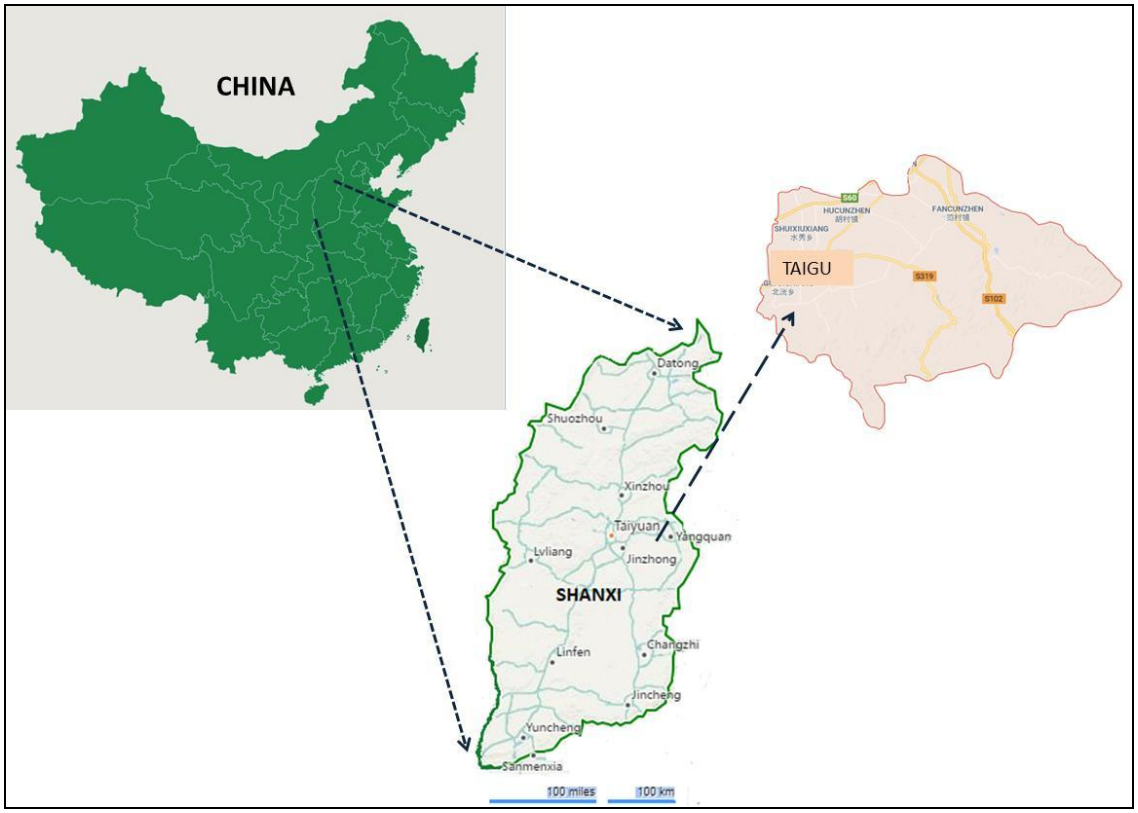

Figure 1. *Map of experimental region in China*

Triticeae species and varieties

Four kinds of Triticeae crops, belonging to common wheat, durum wheat, rye and triticale, respectively, were introduced in the experiment. The characteristics of each variety were summarized in *Table 1*. Common wheat is one of the main food crops planted in Shanxi province and is divided into winter, semi-winter and spring wheat according to vernalization. Winter wheat is often sown in the fall of current year and harvested in the summer of the following year, especially must pass through the vernalization stage (low temperature of 0-5 °C, short-day) and then enter the reproductive growth period (including heading, flowering and grain filling stages). Spring wheat is often sown in spring and harvested in summer this year without overwintering stage. Semi-winter wheat is also sown in fall but its cold resistance is less than winter wheat's. Rye is a feed crop with high yield and high nutritional value, being sown in fall and harvested in summer like winter wheat. Triticale is a new artificial combination species, which is produced by using the sexual hybridization technology and doubling hybrid chromosomes numbers from Triticum and Secale. Durum wheat belongs to Triticum and is usually used for improving wheat grain quality in breeding because both the protein (average 15%) and wet gluten (average 35%) content of its grains are higher than those of common wheat (average 14% and 30%, respectively). Like spring wheat, durum wheat is also sown in spring and harvested in summer. Nine

different varieties of above the Triticeae crops selected for this study were planted because of their high qualities in the Jinzhong region of Shanxi province, China (Xia et al., 2014; Liu et al., 2015; Ma et al., 2016; Su et al., 2017). The local breeding variety Shannong 129 was chosen as control.

Experimental design

In the experiment, randomized block design was adopted to plant the ten varieties above mentioned. Ten varieties made up a block group in random order, in triplicate, that is to say, in total three block groups, which were named as A, B, and C groups, respectively. The distance between two adjacent blocks was 60 cm, and the distance between two adjacent varieties was 40 cm. Each variety was planted four rows, row-length 5 m, row-space 20 cm, planting area 4 m^2 (4.20 m × 5 m), planting-depth 5 cm and planting density 300 grains per row. The seven of winter and semi-winter varieties (Shanong 129, Yannong 19, Shannong zixiaomai, Heixiaomai 031244, rye 4R, Taisi 1 and Huaimai 18) were sown on September 30, 2012, and the remaining three of spring varieties (Yumai 34, Wumai 202w22 and Yavaros F9) were sown on February 26, 2013. During the entire development period, common field management was used for each variety. At the mature stage (June 30, 2013), rhizospheric soil samples from the 0-20 cm soil layer were taken to complete microbial community diversity analysis for each variety.

Soil sampling

For the ten varieties of Triticeae crops, soil samples were collected at three different sampling sites of three block groups (A, B and C) at the maturity stage (*Fig. 2*).

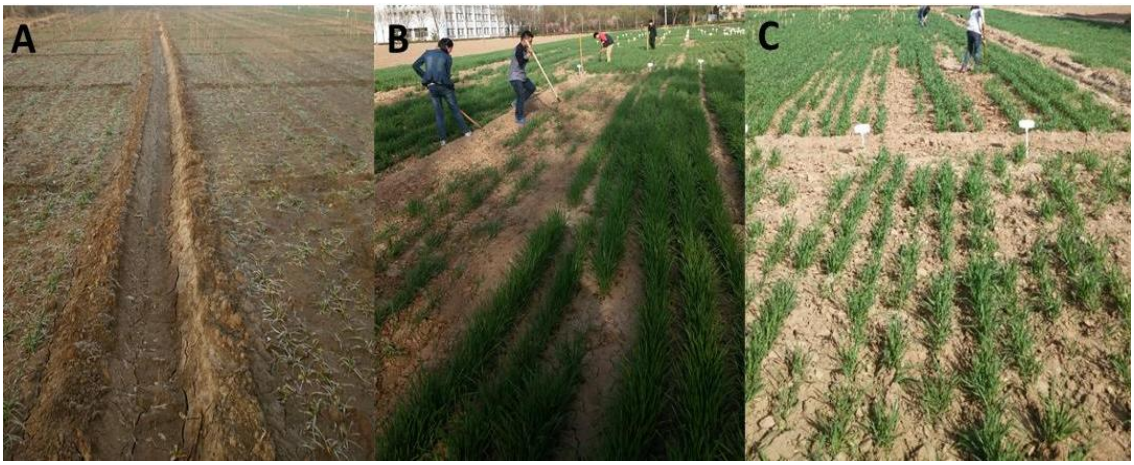

Figure 2. *Sampling sites for soil collection at Shanxi province, China*

The Triticeae crops having different sowing and flowering time but the maturity time was almost consistent, therefore, samples were collected at maturity stage. Considering the effect of the side row, three random sampling points were chosen from two rows in the middle for each sampling site (such as A) with a minimum distance of 2 m between individual sampling points. An 8-cm diameter soil auger was used to drill a suitable hole into the ground around the crop roots for the soil samples from the 0-20 cm layer. In the sterile petri dishes, the roots were taken out and shaken gently to remove non

rhizospheric soil to collect the soil remaining on the roots as rhizospheric soil. Every variety had nine random single samples of rhizospheric soil. By thoroughly mixed the nine samples to reduce the spatial difference in soil and sieved by a 2 mm sieve, respectively, the composite samples representing each Triticeae crop variety were obtained, collected in sealed individual plastic bags, and stored at -20 °C until DNA extraction was performed in the lab (*Table 1*).

Table 1. *Characteristics and rhizosphere soil samples of ten varieties of several Triticeae crops in the experiment*

Crops	Varieties	Chromosome ploidy	Grain color	Varietal characteristic	Source region	Rhizosphere soil samples
Common wheat	Shannong 129	Hexaploid	Red	Winter	Middle of Shanxi, China	S1
Common wheat	Yannong 19	Hexaploid	White	Winter	Shandong, China	S2
Common wheat	Huaimai 18	Hexaploid	White	Half-winter	Jiangsu, China	S3
Common wheat	Yumai 34	Hexaploid	White	Spring	Henan, China	S4

PCR-DGGE microbial community analysis

The PCR-DGGE technique, separating the DNA of different sequence by the concentration gradient of the denatured agent of polyacrylamide gel, and providing community composition as well as information about the dominant species in the community by analyzing the sequence of excised bands (Yang et al., 2016), is suitable for investigating the spatiotemporal changes of species population, has the characteristics of repeatability and simple operation, and can be used to analyze multiple samples simultaneously. Therefore, it is feasible to use the PCR-DGGE technique in this experiment. To investigate microbial community diversity in the rhizospheric soil of Triticeae crops, PCR-DGGE) of the V3 region of 16S or the V1-V2 region of 18S ribosomal DNA (rDNA) was performed. Species of the complex microbial community were assayed by a genotypic fingerprinting approach using the PCR-DGGE technique. Each composite soil sample was divided in triplicate, and then total DNA was extracted directly from the soil according to the E.Z.N.A.™ Soil DNA Kit protocol (Omega Bio-Tek).

PCR amplification of 16S rDNA V3 hypervariable region for bacteria

The PCR amplification of the 16S rDNA V3 hypervariable region for bacteria (about 250 bp PCR product) was performed in 50 μL of reaction mixture by universal bacterial specific primers F338-GC (5'-CGCCCGCCGCGCGCGGCGGGCGGGGCGGGGGCACGGGGGGCCTACGGGAG GCAGCAG-3') and R518 (5'- ATT ACC GCG GCT GCT GG -3') on a C1000-Touch Thermocycler (Gene Amplification PCR System, Bio-Rad, USA) using the touchdown PCR method, which increases specificity of PCR reactions and uses a cycling program in which the annealing temperature is gradually reduced (e.g. decrease 0.5 °C /each cycle). The thermal cycling scheme was as follows: initial denaturation at 94 °C for 5 min, 20 touchdown cycles of denaturation at 94 °C for 1 min, annealing at 65 °C (reduced 0.5 °C per cycle) for 1 min, and extension at 72 °C for 3 min, followed by 10 cycles of denaturation at 94 °C for 1 min, annealing at 55 °C for 1 min, and extension at 72 °C for 3 min, and a final extension period at 72 °C for 10 min. The compositions of the PCR reaction mixture and the examination of the PCR products consulted the reference (Yang et al., 2016) with a minor modification.

PCR amplification of 18S rDNA V1-V2 region for fungus

Similar to bacteria, the target part of the 18S rDNA V1-V2 region (about 450-bp PCR product), which is the most suitable region for detecting fungal diversities in soil using DGGE analysis, was amplified by universal fungal specific primers Fung-GC (5'-CGCCCGCCGCGCCCCGCGCCCGGCCCGCCGCCCCCGCCCCATTCCCCGTTAC CCGTTG-3' and NS1 5'-GTAGTCATATGCTTGTCTC-3'). The PCR mixture compositions were the same as the bacterial fragment amplification above, except for the universal primers (1 μL of Fung-GC (10 μM) and 1 μL of NS1 (10 μM)) and product checks. DNA samples were amplified by PCR using the following thermal cycling scheme: initial denaturation at 94 °C for 3 min, 40 cycles of denaturation at 94 °C for 1 min, annealing at 50 °C for 1 min, and extension at 72 °C for 1 min, followed by a final extension period at 72 °C for 10 min.

DGGE analysis

Gels for the DGGE of PCR products (300 ng) carried out using a D-Code Mutation Detection System instrument (Bio-Rad, USA) were prepared, run for 8.0 h at 120 V and 60 °C in 10% (w/v) polyacrylamide, and visualized by the UVI Gene Genius Bioimaging System (*Figs. 1* and *2*) according to the reference (Yang et al., 2016). Soil samples used in the study were labelled as in *Table 1*.

DGGE gel bands recovery

Some bands in DGGE gel (bands indicated by yellow arrows in (*Figs. 3* and *4*), no matter general (occurring in all soils, such as band No. 13 in *Fig. 2*) or specific (occurring in some soils only, including bands No. 1-15 in (*Fig. 3*) as well as bands No. 1-12 and 14-15 in (*Fig. 4*) bands, were identified using direct sequencing of PCR products recovered from the gel by the SK1135 UNIQ-10 Column Kit (Shanghai Sangon Biological Engineering Technology & Service Co., Ltd., P. R. China). The target genes were re-amplified with the original primer sets (F357 5'-CCTACGGGAGGCAGCAG -3', R518 5'- ATTACCGCGGCTGCTGG -3' for

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_59335954
© 2018, ALÖKI Kft., Budapest, Hungary

bacteria; and fungi; 5'-CATTCCCCGTTACCCGTTG-3', NS1: 5'-GTAGTCATATGCTTGTCTC-3' for fungi), and the expected fragments (about 250 bp for bacteria and about 450 bp for fungi) were obtained. The PCR mixture compositions and reaction conditions were the same as above. The PCR products were recovered using the SK1131 UNIQ-10 Column Kit. All reactions were performed in triplicate.

Cloning and sequencing

The target fragments were TA ligated to Takara pMD®18-T vector. According to the methods of published document (Yang et al., 2016), DNA sequencing of one 16S rDNA or 18S rDNA fragment was performed step by step. In the end, we compared these partial 16S and 18S rDNA sequences with sequences deposited in the GenBank database using Blast (http://blast.ncbi.nlm.nih.gov/). The new DNA sequences had been submitted to GenBank with accession numbers MF673132-MF673161.

The DNA sequence results of bacteria and fungi are given in *Attachments 1* and *2*. The similarity values of BLASTN results are in *Table 3* and accession numbers shown in *Attachment 3*.

Statistical analysis of DGGE patterns

Digitized DGGE images were analyzed by Quantity One software (Bio-Rad, USA). The Shannon diversity index (H) and Simpson's (D) index as mathematical measurements have been commonly used to characterize species diversity in a community (Du et al., 2016). DNA bands in gels were identified by Quantity One software (Bio-Rad, USA). Both Shannon diversity index (H) and Simpson's index (D) were calculated based on the number and relative intensities of DGGE bands. The Shannon (H) and Simpson's (D) index were calculated as follows:

$$H = -\sum(P_i)(\ln P_i),$$

$$D = 1 - \sum P_i^2,$$

where p_i is the proportion of i th phylotype.

To further understand the differentiation among DNA fragments from rhizosphere soil samples, the UPGMA (unweighted pair group method with arithmetic means) dendrograms of DGGE band profiles for bacteria and fungus (*Figs. 5* and *6*) were constructed using the clustering algorithm baseetd on the Dice similarity coefficient (*Tables 3* and *4*). The data of diversity index among ten varieties was statistically analyzed by ANOVA program of SAS9.1.3 software. A probability value (P) of < 0.05 was considered statistically significant.

Results

PCR–DGGE analysis of soil samples for ten varieties

In the DGGE gel, DNA fragments of the same length, but with different base-pair sequences, could be separated (Muyzer et al., 1993). The electrophoresis band pattern provided a profile of microbe diversity in rhizosphere soil samples. It is commonly assumed that these profiles and quantitation of peaks (bands) reflects the structure of the community. Concretely speaking, in each lane of the DGGE gel, the visualized

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_59335954
© 2018, ALÖKI Kft., Budapest, Hungary

intensities of DNA bands could respond to relative microbe biomass, and the number of DNA bands might reflect the genetic diversity of microbe community in rhizosphere soil samples. The greater the band number, the more diverse the microbial community is. These individual bands represented different gene fragments or different stable structural conformations of either the bacterial 16S rDNA V3 hypervariable region or the fungal 18S rDNA V1-V2 region. The relative intensity of each band and its position most likely represent the relative abundance of a particular species in the microbial community. Firstly, PCR-DGGE analysis was performed to investigate the microbe diversity of each Triticeae crop variety. The DGGE profiles indicated different bands' patterns for different soil samples (*Figs. 3* and *4*). As seen from DGGE profiles of PCR products of 16S rDNA V3 region in *Figure 3*, it was different in the bands' patterns from soil samples S1-S10 of different varieties, such as the location, intensity and number. Some strong and unique bands were observed in bacterial DGGE patterns of some varieties, while they were not detected in other varieties (*Fig. 3*). For example, Huaimai 18 soil of S3 had bands shown as code number 7, 8 and 10, while other varieties had no such bands. Bands 14 and 6 were observed in Shannong 129 soil of S1 and Yannong 19 soil of S2, respectively. Band 2 was found in rhizosphere soil samples from all crops except Shannong129 (S1). The bands shown as code number 1, 11 and 15 were found in rhizosphere soil samples of Yannong 19, Huaimai 18, and Yumai 34.

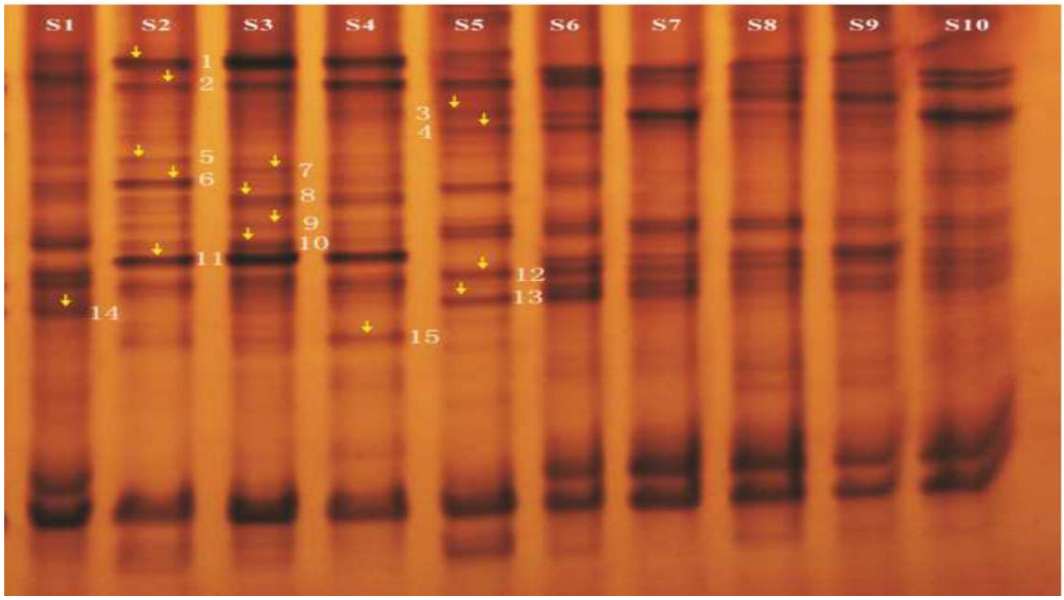

Figure 3. *DGGE analysis of bacterial community profiles of 16S rDNA PCR amplification products of rhizospheric soil samples S1-S10 of 10 different Triticeae crops*

The same situation occurred in fungal DGGE patterns of soil samples of different Triticeae crops. As shown in *Figure 4*, Yumai 34 soil of S4 was observed to show bands 2 and 8 compared to other Triticeae varieties soil; only Shannong zixiaomai soil of S5 was observed to show bands 1 and 3; band 9 was specific to the rhizosphere soil sample of Huaimai 18; band 13 was observed in all rhizosphere soil samples; Shannong 129 and Yumai 34 did not contain the band labeled as code number 15 (*Fig. 4*). The results revealed that the compositions of rhizospheric soil microbial communities including both bacteria and fungi were different among the ten varieties of Triticeae crops.

Taisi 1	S10	0.573±0.004c de	1.78±0.06 f	0.722±0.009 c	3.31±0.13 f

The indices of all soil samples were represented by the mean values with standard deviation and were compared by Duncan's multiple comparison. Different lowercase letters in the same column indicate significant difference ($P < 0.05$)

Diversity indices of the soil bacterial and fungal communities were significantly different among the varieties of soil samples S1-S10 ($P < 0.05$) of Triticeae crops. These findings were mostly consistent with band patterns observed in the DGGE profiles (*Figs. 3* and *4*) and revealed that the diversity of rhizospheric soil bacterial and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_59335954
© 2018, ALÖKI Kft., Budapest, Hungary

fungal communities was significantly affected by different varieties of Triticeae crops ($P < 0.05$). Reports have that 'interband' regions were considered as a potential source for less dominant members of natural microbial communities, and indicate that including such members might be a better fit for the use of Shannon index. Our study results showed that the Shannon index of a variety was high and its Simpson index was also high, and the differences of Shannon index between the varieties were greater than those of Simpson index (*Table 2*).

The Shannon index was more suitable than the Simpson index for reflecting microbial community diversity. Among the ten soil samples in this experiment, Heixiaomai 031244 (S6) had the highest bacterial diversity indices, followed by rye 4R (S9) and Shannong 129 (S1). The lowest diversity was shown in Yavaros F9 (S8) (*Table 2*). However, in terms of fungal community diversity, Huaimai 18 (S3) had the highest diversity indices, followed by Yannong 19 (S2), Yumai 34 (S4), Heixiaomai 031244 (S6), rye 4R (S9) and Taisi 1 (S10). The lowest level of diversity was exhibited in Shannong 129 (S1). To further understand the differences among microbial community structures of each sample, we constructed a UPGMA dendrogram with the 16S rDNA and 18S rDNA fragments (about 250 bp and 450 bp, respectively) and community Dice Coefficient for samples S1-S10 (*Figs. 5* and *6*, *Tables 3* and *4*).

Even though the diversity indices of microbial communities in some rhizospheric soil samples such as S9 and S10 in the fungus community were similar to each other, as seen in *Table 2,* the population structures of microorganisms in these soil samples were different as indicated in *Figure 5* or *Figure 6*. In the bacterial community of rhizospheric soil samples, five main clusters were detected in the condition of a Dice Coefficient of 0.53 (*Fig. 5*). in the condition of a Dice Coefficient of 0.78, only S6 (Heixiaom 031244) and S7 (Wumai 202W22) were clustered into a group (*Fig. 5*). The two varieties were black and high-gluten common wheat, but S6 is winter wheat but S7 is spring wheat. In the condition of a Dice Coefficient of 0.69, S2 (Yannong 19) and S4 (Yumai 34) were also clustered into a group. The two varieties were white and high-gluten common wheat, but S2 is winter wheat but S4 is spring wheat. In the condition of a Dice Coefficient of 0.66, S2, S4 and S3 (Huaimai 18) were further clustered into a group. Huaimai 18 was a white, middle-gluten and half-winter common wheat variety. In the same manner, in the condition of a Dice Coefficient of 0.53, the above-mentioned five varieties were clustered a group. The control of Shannong 129 (red and middle-gluten) was significant different with above-mentioned five varieties in the bacteria community structure. It inferred that bacteria community structure of wheat varieties could be related with grain color as well as grain quality. Besides, in the condition of a Dice Coefficient of 0.60, the durum wheat S8 (Yavaros F9) and triticle S10 (Taisi 1) were clustered into a group.

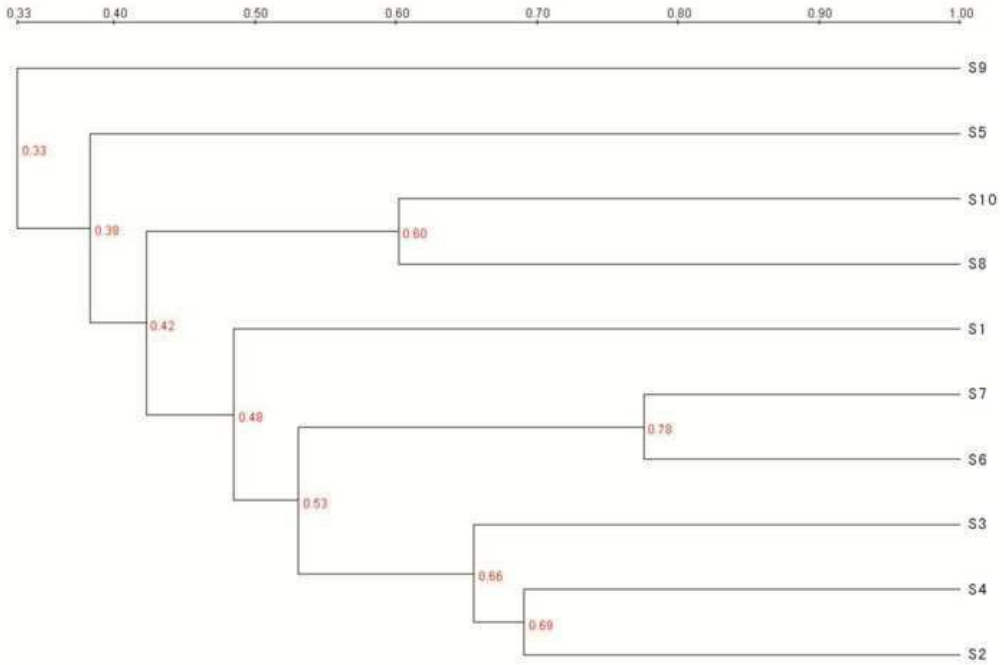

Figure 5. *UPGMA dendrogram constructed with DGGE profiles of bacterial 16S rDNA PCR amplification products from rhizospheric soil samples S1-S10 from different varieties of several Triticeae crops*

So, in the similarity level of 0.53, five main clusters were detected. One cluster was found in S3, S2, S4, S6 and S7. Another cluster was observed in S8 and S10. Besides, S9 (rye 4R), S5 (Shannong zixiaomai) and S1 (Shannong 129) stood in three clusters,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_59335954
© 2018, ALÖKI Kft., Budapest, Hungary

respectively. However, in terms of a Dice Coefficient of 0.48, S1, S2, S3, S4, S6 with S7 could form a new cluster. If the Dice Coefficient was 0.42, the above-mentioned new cluster and S8 as well as S10 furthermore composed a bigger cluster. Till a Dice Coefficient of 0.33, all of ten varieties stood in only one cluster. On the contrary, when the Dice Coefficient was greater than 0.78, ten varieties had 10 clusters. Similarly, in the condition of a Dice Coefficient of 0.51, six main clusters were found in the fungal community of rhizospheric soil samples (*Fig. 6*). These included a cluster formed by S6 and S5 with S3, a cluster shared by S9 and S7, a cluster containing S8 and S10, and else three clusters formed by S1, S2 and S4, respectively. The larger the Dice coefficient, the more clusters. In contrast, the smaller the Dice coefficient, the less clusters. When the Dice Coefficient was 0.44, S2, S3, S5 & S6 formed a cluster. When the Dice Coefficient was 0.39, S7, S8, S9 & S10 form a cluster. When the Dice Coefficient was 0.29, above mentioned the two clusters formed a new cluster. Ten varieties were clustered into 10 classes when the Dice Coefficient was greater than 0.56 (*Fig. 6*). Just the opposite, ten varieties were clustered into one class when the Dice Coefficient was less than 0.17. Therefore, the changes in bacterial and fungal community structure were distinct in different varieties of Triticeae crops.

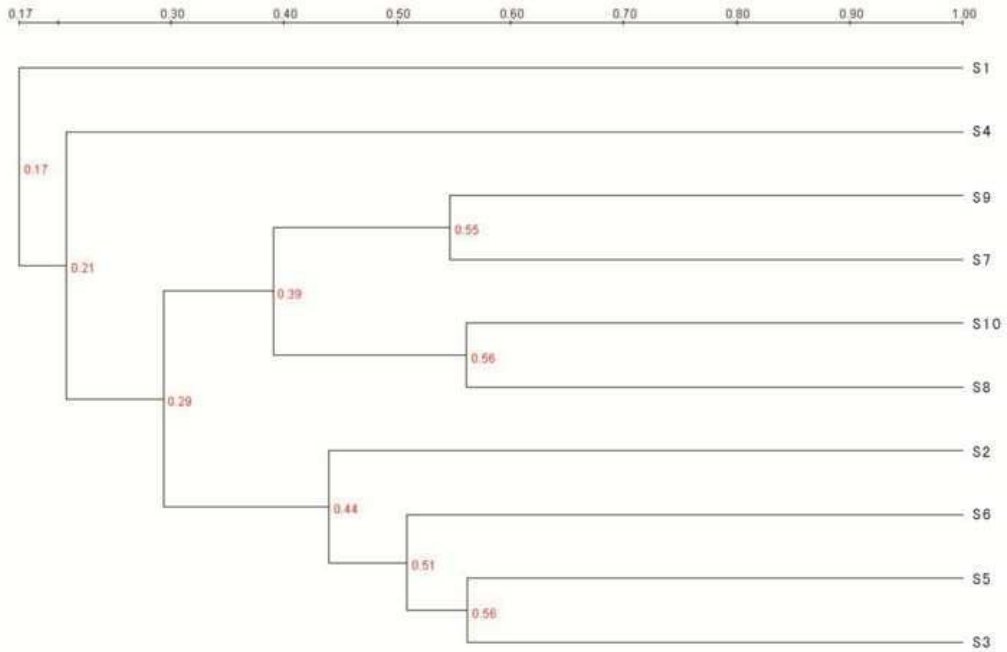

Figure 6. *UPGMA dendrogram constructed with DGGE profiles of bacterial 18S rDNA PCR amplification products from rhizosphere soil samples S1-S10 from different varieties of several Triticeae crops*

Bacterial and fungal community changes in different rhizospheric soil samples

To identify the microbial species in each sample, 15 common and specific excised bands were selected from bacterial and fungi DGGE gels of rhizosphere soil samples, respectively (*Figs. 3* and *4*). The PCR product was recovered from each excised band. Following the sequencing of all PCR products, the sequences obtained were compared with public DNA database sequences by BLASTN on the NCBI web server. The results of sequence comparisons were shown in *Tables 5* and *6*.

© 2018, ALÖKI Kft., Budapest, Hungary

fungi were detected only in certain crops. For example, uncultured *Chloroflexi* bacterium was detected in Shannong 129 (S1), while uncultured *Sphingobacteriales* bacterium was detected in Shannong zixiaomai (S5) and Heixiaomai 031244 (S6) only. *Nabis ferus* and *Xylariales* sp. were detected only in the rhizosphere soils of Huaimai 18 (S3) and Yumai 34 (S4), respectively. *Xenillus tegeocranus* was detected in Shannong 129 (S1), Yannong 19 (S2), Huaimai 18 (S3), and Shannong zixiaomai (S5), but not detected in the rhizosphere soils of other samples. By identifying the microbial species from different samples, our research demonstrated that the effects of different Triticeae crops on bacterial and fungal community diversity in rhizospheric soils were obvious.

In addition, we found some common bands in soil samples of some different varieties, which indicated there were similarities among the populations of microorganisms that existed in these rhizospheric soils. In the bacterial community, there was one common band coded the number of 2 (*Flavobacterium phragmitis*) in other nine varieties except Shannong 129 (*Fig. 3*). The else bands were specific in some varieties. For example, the uncultured *alpha proteobacterium* (band code 1 in *Fig. 3*), *Flavobacterium phragmitis* (band code 2 in *Fig. 3*), uncultured bacterium (band code 11 in *Fig. 3*), and *Bdellovibrio* sp. (band code 15 in *Fig. 3*) were commonly found in rhizospheric soil samples of common wheat crops, including Yannong 19, Huaimai 18 and Yumai 34 (S2, S3 and S4 in *Fig. 3,* respectively). As for the fungal community, there was only one common band coded the number of 13 (uncultured *Eukaryote*) in all soil samples (*Fig. 4*). The uncultured *Eukaryote* (band code 15 in *Fig. 4*) was common across all crops except Shannong 129 and Yumai 34 samples (S1 and S4 in *Fig. 4,* respectively). *Xenillus tegeocranus* (band code 5 in *Fig. 4*) was found in rhizospheric soil samples of common wheat crops, including Shannong 129, Yannong 19, Huaimai 18 and Shannong zixiaomai (S1, S2, S3 and S5 in *Fig. 4,* respectively). These common microorganisms indicated that there were some shared characteristics among wheat varieties.

Discussion

The climate features of Shanxi province provide natural and long-standing advantages such as adequate sunlight, moderate mean temperature, large temperature difference between day and night and abundant seed resources for wheat production (Tian et al., 2013). However, drought, a major Shanxi's climate characteristic, on the one hand is beneficial to accumulate protein during grain filing period, and on the other hand is responsible to limit the growth and development of wheat and has resulted in a continuously decreasing planting area of wheat in recent years. The planting area of wheat is currently about 720,000 hectares in Shanxi province, which is not enough to meet market demand. In addition, Shanxi wheat is supposed to contain the protein content of more than 14% on the average, however its wet-gluten content (28%-30% on the average) is lower than that of a large quantity of high quality wheat flour (more than 30%) for processing bread or dumpling. Therefore, it is necessary to introduce high-quality wheat varieties and improve local wheat variety quality for meeting consumer demand. In addition, the Shanxi provincial government has proposed to adjust the agricultural planting structure, which is to reduce the planting area of corn and increase that of feed crops to develop livestock and poultry production.

Previous evidence has shown that wheat cultivars were involved in shaping the rhizosphere by differentially altering the bacterial community (Aaron et al., 2017). The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

differences in microbial communities observed on different wheat lines showed that wheat breeding could affect rhizospheric communities (Aaron et al., 2017). Yang ZP (one of the authors) had studied the number of rhizosphere soil microbial populations (including bacterial, fungi and actinomycetes) with that of non-rhizosphere soil of 24 crops in north China using the plate culture method. The results revealed that the microbial population of rhizosphere soil was significantly higher than that of non-rhizosphere soil, which was consistent with previous studies (Lou, 1962; Chen, 1990; Takuya, 1990). Besides, in the previous studies by author, 120 varieties from different wheat areas were introduced and planted to Jinzhong wheat area of Shanxi province. Some of the varieties, which were suitable for local ecological climatic conditions and of higher yield-quality than others were selected. For reasons mentioned above, in this experiment, rhizosphere soil was regarded as research object to compare the differences between the introduced varieties from other wheat region and local varieties of Shanxi in rhizosphere soil microbial diversity. Triticeae varieties including nine introduced high-quality wheat / rye / triticale varieties and one local variety (Shannong 129 as control) were selected for preliminarily investigating rhizospheric soil bacterial and fungal community diversity in the Jinzhong region. This study was also conducted for providing theoretical basis for further analyzing the correlation of these indices with grain protein as well as wet-gluten contents to evaluate whether rhizospheric soil microbial community diversity can be used as an accessory ecological indicator on the basis of grain yield and quality for screening varieties. Shannong 129 is a local breeding late maturity winter wheat variety belongs to the northern area of China, and planted widely in the Shanxi wheat region region and fit to the local ecological environment conditions. The other varieties were introduced from other different wheat production regions. In order to expand Triticeae crop resources in Shanxi province, these high quality Triticeae crops were introduced and further investigated their microbial community structures compared with Shannong 129.

Rhizospheric soil is of great importance to plant health and soil fertility. The plant can affect its rhizospheric microbial communities by releasing root exudates (Glick, 1995; Kourtev et al., 2003; Andersen and Winding, 2004;), which are made up of saccharides, organic acid, amino acid, phenolic compound etc (Xiong et al., 2002). The amount and types of root exudates as well as allelopathy differ between crop species. Root exudates could provide a large amount of nutritional energy, stimulate species-specific shifts in the soil microbial community, and make changes to microbial community distribution (Xiong et al., 2002; Welbaum et al., 2004; Singh et al., 2007; Xu et al., 2009; van Dam and Bouwmeester, 2016). A general role for root exudates is becoming evident in repelling or attracting pathogenic or beneficial organisms, inhibiting growth of competing plant species, and altering soil properties (Bais et al., 2006; Weston et al., 2012). For instance, in terms of three hydroponic plants including *Ipomoea aquatica, Chlorophytum comosum* and *Oenanthe javanica,* the effects of organic acid in their root exudates on bacteria were not different, a positive effect on some bacteria, such as ammonifying and denitrifying bacteria and an inhibitory effect on others such as nitrobacteria and nitrosobacteria (Zhu and Cheng, 2011).

Previous studies have showed that plants could “shape” the microbial communities in their rhizosphere by attracting beneficial microorganisms that in turn could suppress the growth of pathogenic microbes either through direct competition or by priming the plant’s own defenses (Marschner et al., 2004; Miao et al., 2004; Doornbos et al., 2012; Aaron et al., 2017; Schlemper et al., 2017). In our study, it was founded that there were

© 2018, ALÖKI Kft., Budapest, Hungary

differences in the community structures of rhizospheric soil organisms (*Figs. 3* and *4*) and the diversity indices (*Table 2*) among wheat varieties, indicating that different varieties of wheat could obviously cause shifts in the composition of dominant populations about rhizospheric microbial communities through DGGE profiles. This conclusion is consistent with previous research (Miao et al., 2004), which showed that numbers of three main species of rhizospheric microbes were much more different after planting different crops on unused soil 2 m below ground.

Generally thought is that the larger the Shannon's index, the more diverse will be the components of microbial population. Similarly, the larger the Simpson's index, the richer will be the number of microbial population. Our results indicated that the Shannon's index and Simpson's index of Heixiaomai 031244 were highest among the bacterial communities in rhizospheric soils of ten varieties ($P < 0.05$). This suggested that Heixiaomai 031244 was the most beneficial variety for improving the diversity and abundance of bacterial communities in rhizospheric soils. The second variety was rye 4R. Similarly, the Shannon's index and Simpson's index of Huaimai 18 the highest among the fungal communities in rhizospheric soils of ten varieties ($P < 0.05$). Huaimai 18 was the most beneficial variety for increasing the diversity and abundance of fungal communities in rhizospheric soils, followed by Yannong 19 and Yumai 34. This suggests that Heixaomai 031244 and Huaimai 18 could be the two best species of seven common wheat varieties introduced into the Jinzhong region of Shanxi province according to Shannon's and Simpson's indexes. The rye 4R was second only to Heixiaomai 031244 in terms of bacterial community diversity. Yannong 19 and Yumai 34 were just behind Huaimai 18 in terms of fungal community diversity. It could be introduced to the Jinzhong region as a feed crop in planting structure adjustment.

Microbial species recognition by cloning and sequencing 16S rDNA or 18S rDNA fragments showed that crop species could stimulate specific microbial species while also causing the loss of others, thereby affecting rhizospheric soil microbial communities (Yang et al., 2016). Our study observed significant stimulation of uncultured bacterium (code No. 8, 7 and 10 in *Table 5,* respectively) and *Nabis ferus* (code No. 9 in *Table 6*), as well as the loss of uncultured *Sphingobacteriales* bacterium (code No. 4 in *Table 5*) and *Xylariales* sp. (code No. 2 in *Table 6*) in Huaimai 18. In addition, our studies hinted a relatively strong species-specific pattern on rhizospheric soil microbial community structure. Uncultured *Chloroflexi* bacterium was only found in the rhizosphere soil growing Shannong 129. Uncultured *alpha proteobacterium, Flavobacterium phragmitis,* uncultured bacterium, and *Bdellovibrio* sp. were observed in common wheat including Yannong 19, Huaimai 18 and Yumai 34. Uncultured eukaryote (code No. 13 in *Table 6*) was found in all experimental samples. The wheat cultivar-associated microbes identified in this work could provide beneficial services to their hosts, such as the utilization of organic matter, the degradation of hydrocarbons, and the cycling of respiratory sulfur and nitrogen (Chen et al., 2016; Dombrowski et al., 2017). Observable differences in microbial species of Triticeae crops in the present work could be related to root exudates which select and increase microbes associated with mineral mobilization and nutrient responsive metabolisms, such as nitrogen, sulfur and phosphorus (Aaron et al., 2017). Root exudates are intrinsic factors of rhizospheric effects. There is evidence to suggest that microbes are recruited through root exudates, and the greatest release may occur during the reproductive stages (Zhang et al., 2009; Lakshmanan et al., 2013). For example, Neal et al. (2012) demonstrated a central role in root exudates of maize, as a semiochemical below ground for recruitment of plant-

DOI: http://dx.doi.org/10.15666/aeer/1605_59335954
© 2018, ALÖKI Kft., Budapest, Hungary

beneficial rhizobacteria during the relatively young and vulnerable growth stages of maize. Plant hosts could benefit from these microbes with improved growth, drought and salt tolerance, and protection against soilborne pathogens (Kasim et al., 2013; Glick et al., 2014; de Boer et al., 2015). More interestingly, many uncultured organisms were observed when these Triticeae crop varieties were introduced into the Jinzhong region. In that way, in the course of wheat production, what might be the material cycle process that these specific microbial species or uncultured organisms could be mainly involved in? What would be dominant microbial populations? These issues will be further discussed in the future.

It is worth mentioning that the rhizospheric bacterial diversity of Shannong 129 was higher than that of Huaimai 18 (S3) or Yannong 19 (S2), while fungal diversity was much lower as above mentioned (*Table 2*). However, our previous studies showed that the grain qualities of Shannong 129 were lower, but its grain yield was higher than that of Yannong 19, whereas both the grain yield and qualities of Shannong 129 were higher than those of Huaimai 18. Considering Huaimai 18 and Yannong 19 have more than 60% similarity in bacterial community structure and a similar quality of grain, we speculate that various dominant and functional organisms enhanced in these two varieties (Uncultured *alpha proteobacterium, Flavobacterium phragmitis,* uncultured bacterium, *Pantoea* sp., *Bdellovibrio* sp., *Xenillus tegeocranus,* and uncultured eukaryote) imply a potential relationship between the yield increase of crops and microbial diversity.

Conclusion

Our study highlighted that variation of rhizospheric soil microbial community diversity is related to different Triticeae varieties. Among the ten experimental varieties, Heixiaomai 031244 was the most beneficial to improving the diversity and abundance of bacterial communities in rhizospheric soils, and Huaimai 18 was the most beneficial to increasing the diversity and abundance of fungal communities in rhizospheric soils. Different wheat varieties across wheat regions could induce an increase in some functional and uncultured rhizospheric soil organisms, such as uncultured *alpha proteobacterium, Flavobacterium phragmitis,* uncultured bacterium, *Bdellovibrio* sp., uncultured *Sphingobacteriales* bacterium, uncultured *Acidobacteria* bacterium, *Nabis ferus* and uncultured *Eukaryote,* suggesting some potential relationship between crop yield increase and microbes in new wheat varieties when compared with local original wheat variety. Our study strongly suggested that Huaimai 18, Yannong 19, and Heixiaomai 031244 could be considered for introduction to the Jinzhong region to develop high quality wheat variety resources for Shanxi. Additionally, rye 4R could be introduced to the Jinzhong region as a feed crop in planting structure adjustment. Further studies should be conducted to examine the exact mechanisms of these uncultured rhizospheric organisms and their interactions with specific crop species. Further to find whether these microorganisms affect grain quality formation and accumulation will be discussed in a follow-up study.

(Received 17th Jun 2018; accepted 22nd Aug 2018)

Abstract. Tourist vandalism has been a common phenomenon in different countries and regions with the rapid development of tourism industry. It is deteriorating the quality of recreational environment, and hazarding the safety. Current researches implied that the unified understanding of the concept of vandalism had not yet formed, basic theoretical framework research was still weak and the antecedent factors of vandalism and its generating mechanism had not been paid enough attention to, which greatly affected the management of tourist vandalism. Therefore, adopting the extended Theory of Planned Behavior (TPB) perspective, this paper constructs the theoretical model of tourist vandalism. Then, using Structural Equation Models (SEM), taking tourists from Mainland to Taiwan as the case study, combined with questionnaire data, the study seeks to examine the influence factors of vandalism and its generating mechanism. The study found out that: (1) past behavior has significant positive effects on behavior intention, while subjective norm and perceived behavioral control have no significant positive effect on behavior intention; (2) past behavior has a significant positive effect on behavior intention, while subjective norm and perceived behavioral control have no significant positive effects on behavioral attitude; (3) environmental awareness has a significant positive effect on behavioral attitude, subjective norm, past behavior, while has no significant positive effect on perceived behavioral control. To conclude, environmental awareness and past behavior are applied to understand tourist vandalism and makes contribution to the tourist vandalism literature. Consequently, the paper suggests that family, schools and the educational institution should provide targeted training to outbound tourists to guide their attitude and clarify the concept of tourist vandalism and its negative influences through establishment of vandalism list to help tourists recognize and avoid vandalism in the future.
Keywords: *environmental awareness, Mainland, Taiwan, structural equation models*

Introduction

With the rapid development of tourism, Tourist vandalism has become widely discussed in various countries and regions (Bhati and Pearce, 2016). Whether vandalism is caused by independent tourists or group tourists, intentional or unintentional, accidental or repeated acts, it damages the surrounding environment and resources quality, public or private property, recreational safety, etc. Tourist vandalism greatly increases the management costs of tourism destinations. The annual repair costs due to tourist vandalism were up to 79.2 million US dollars in National Parks of USA and the cleaning and maintenance reached the amount of 18.8 million US dollars (Johnson et al., 1996); 10% of the annual budget for recreation forest in Beth, Canada is used to recover the damages caused by tourists; 9% of the total annual budget accounts for cleaning and maintenance for Yangmingshan Park in Taiwan area (Yang et al., 2013).

Obviously, tourist vandalism has always been one of the main factors to worsen the quality of recreational environment and safety (Chang et al., 1995).

Different disciplines have different understanding of tourist vandalism. Social behavioral studies mainly recognize tourist vandalism from the perspective of social behavior standards, legal provisions, and moral deviations; Environmental Psychology perceives the message of vandalism from the surrounding environment and personal psychological attitudes; Environmental Ethology focuses on the interaction between environmental information and vandalism from the emotions and attitudes of tourists response to the environment; Recreational behavior theory emphasizes the influence of physical and psychological needs and external human, social, and natural factors, and determines the intention to vandalism through the cognitive process of the surrounding environment (Kaplan, 1983). Based on the definition of different disciplines, the concepts similar to tourist vandalism include tourist deviant behavior (Mills et al., 1978), dysfunctional behavior (Daunt et al., 2012), depreciative behavior (Ibitayo et al., 1996), misbehavior (Fullerton et al., 2004), uncivilized behavior (Li et al., 2002), etc. These similar concepts have, to a certain extent, outlined the current state of negative impact of tourist behavior on the natural and humanistic social environment of tourism destinations. However, these concepts have not reflected the degree of harm caused by tourist negative behavior, and whether it constitutes a crime or not. This is not conducive to tourists' understanding and control of their negative behaviors.

Some scholars have pointed out that tourist behavior is a comprehensive manifestation of a series of psychological and physical behaviors formed by interaction between tourists and the new environment. It can be expressed by the equation $B = f(P,E)$, that is, tourist behavior is shaped by personal and environmental factors (Lewin, 1951). Based on the above equation, this paper defines tourist vandalism as tourists' improper behavior that violated social norms resulted from inadequate or excessive stress on the changes when tourists engaged in recreational activities, in an unconventional context. Although the behavior may not necessarily constitute a crime, it does harm the natural and human social environment of the tourist destination (Bhati and Pearce, 2016) Typical tourist vandalism includes graffiti, littering, throwing food to animals, damaging the vegetation, snapping off coral, noise making, improper dressing code, damaging recreational property, etc. (Chang et al., 1995).

After reviewing the relevant domestic and foreign literatures of tourist vandalism, it has been found out that academic attention focused on vandalism behaviors of tourists (Weaver, 2006), theoretical basis (Bhati, 2014), influential factors (McCaghy, 2008), motivation (Crotts, 2003), behavioral control (Cohen, 1973), etc. Foreign researchers and researchers form Hongkong and Taiwan have made fruitful achievements on the characteristics of tourist vandalism (Chang et al., 1995), macro (social, economic and environmental design) and micro (physiological, developmental, psychological) influential factors (Chang et al., 2003; Hou et al., 1998; Huang et al., 2016), Environment design ecological explanations of vandalism, Human ecological explanations of vandalism, Behavioral ecological explanations of vandalism, Integrative ecological explanations to vandalism, Cohen typology, situational crime, environmental design, technical and non-technical preventive approaches (Bhati and Pearce, 2016) etc. But Chinese scholars have not yet reached uniformed understanding on the concept and research subject of tourist vandalism (Li, 2012). Due to the sensitive topics of tourist vandalism, the complexity of classification, and the difficulties in obtaining survey data, researchers are more likely to adopt obscure words like uncivilized behaviors,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

inappropriate behaviors to replace the word vandalism, which leads to weak basic of theoretical researches. The current research mainly focuses on the influential factors and motivations of uncivilized behavior, with the research achievements scattered in areas such as outbound tourism (Qiu, 2016) and ecotourism (Gao, 2003), which indicates the huge gap with foreign researches. It is urgently necessary to unify conceptual understanding of tourist vandalism and construct psychological and environmental science research paradigms, so as to promote the breadth and depth of the research.

Based on Theory of Planned Behavior (TPB) in psychology, this study expands the model to construct a framework of tourist vandalism. Taking the tourists visiting Taiwan as an example, the Structural Equation Models (SEM) is adopted to verify the influencing factors and mechanisms of vandalism. Furthermore, the study proposes counter measures to promote the in-depth study of tourist vandalism in theory and practice.

Literature review and research hypothesis

Theory of planned behavior

Theory of Planned Behavior (TPB), a derivative theory of Reasoned Action (TRA), was proposed by Ajzen to explain the process of individual decision-making (Ajzen, 1991). TPB holds the idea that human behavior is the result of deliberate planning, which can explain how people change their behavior patterns. TPB also can be used to predicate human behavior. In the 185 studies of Armitage and Conner (2001), TPB can explain 39% of behavior intention and 27% of behavior variance, so it is often used in the study of tourist behavior, such as tourist low-carbon travel decisions (Bamberg et al., 2003), ecological choices (Greaves et al., 2013; Kaiser, 2003), intention to participate in low-carbon tourism (Hu, 2014), green hotel consumption options (Xie, 2016), and pro-environmental behavior (López-Mosquera, 2016), etc. TPB has a better explanation for tourist behavior intention (Lin et al., 2016; Qiu, 2016).

In TPB, Attitude toward the behavior (AT) is a determinant factor of behavioral intention (BI). Salient Beliefs are cognitive and emotional foundations of attitude toward the behavior (AT), Subjective norm (SN), and Perceived behavioral control (PBC) (Ajzen, 1991). TPB assumes that behavioral intention covers the motivation for behavior. It reflects people's willingness to try or plan to work hard for something, that is, the stronger a person's intention to act, the more likely the action will happen (Duan, 2008). TPB further assumes that behavioral intention is mainly determined by AT, SN, and PBC (Cui, 2010). Lin et al. (2016) constructed a conceptual framework of tourist civilized behavioral intention and civilized behavior attitude based on TPB. It was found that there was a significant positive correlation between tourists' attitudes, travel times and tourist civilized behavioral intention; and there was a significant positive correlation between tourists' jobs, educational background, travel times and tourists' civilized behavior attitude.

Based on above description, the following hypothesis is proposed:

H1. The behavioral attitude has a positive effect on tourist's intention of vandalism.

Xie (2016) studied the decision-making mechanism of consumers choosing to stay in a green hotel based on TPB. The study proposed that behavioral attitude is the most important factor. Subjective norms not only directly affect behavioral intentions, but also indirectly influence behavioral intentions through behavioral attitudes and perceived behavioral control. Qiu (2017, 2016) introduced moral norms and local

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_59555969
© 2018, ALÖKI Kft., Budapest, Hungary

attachment based on TPB, and constructed a model of outbound tourists civilized behavior intention mechanism. It is confirmed that subjective norms, perceived behavior control, moral norms, and local attachment all indirectly affect the intentions of outbound tourists civilized behavior through behavioral attitudes. Meanwhile, subjective norms not only directly affect behavioral attitudes, but also indirectly affect behavioral attitudes through moral norms; behavioral attitudes are the most important factor in driving intentions of outbound tourists' civilized behaviors. Based on the above discussion, the following hypotheses can be proposed:

H2. Subjective norms have a positive effect on tourist's intention of vandalism.

H3. Perceived behavioral control has a positive effect on tourist's intention of vandalism.

H4. Subjective norms have a positive effect on tourist's attitude toward vandalism.

H5. Perceived behavioral control has a positive effect on tourist's attitude toward vandalism.

H6. Perceived behavioral control has a positive effect on subjective norms of tourist's vandalism.

Past behavior and behavioral intentions

"More than 90% of people's daily activities are habitual behaviors" (Li, 2007). Ajzen (1991) suggested adding past behaviors to perceived behavioral control of TFB which could better predict behavior. Ouellette and Wood (1998) pointed out that past behaviors had an impact on future behaviors in two phases. Good behaviors repeatedly occur in a specific behavioral context. The frequency of past behaviors reflects the habit strength and has direct influence on future performance (Ouellette and Wood, 1998). Christina et al. (2004), after studying the tourist littering behavior, pointed out that there was a very significant relationship between past behavior and behavioral intentions for those who did not have recycling habits. Compared with behavioral attitudes, subjective norms, and perceived behavioral control variables, past behaviors can better explain behavioral variances, and people's past behaviors mainly influence their behaviors through intermediary variables such as behavioral attitudes and behavioral intentions (Ajzen, 2005). Therefore, it is necessary to include tourists' past vandalism into the theoretical framework of tourist vandalism and put forward the following hypothesis:

H7. Past behaviors have a positive effect on tourist's intention of vandalism.

H8. Past behaviors have a positive effect on tourist's attitude toward vandalism.

H9. Past behaviors have a positive effect on the subjective norms of tourist's vandalism.

H10. Past behaviors have a positive effect on perceived behavioral control of tourist's vandalism.

Environmental awareness and behavioral intention

Environmental Awareness (EA), also known as "Ecological Awareness", "Environmental/ Ecological Literacy" or "Environmental/Ecological Concern" (Dunlap et al., 1978). Though there is no uniformed definition at home and abroad (Roth, 1992), a common sense still exits that EA reflects relationship between man and nature (Hwang, 2000). According to the B = f(P,E) formula, environmental awareness is one important factor influencing tourist vandalism. Many tourists may think their vandalism reasonable, and make excuses for their behavior, or they are completely unaware of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_59555969
© 2018, ALÖKI Kft., Budapest, Hungary

their mistakes (Chang et al., 2003). Studies have shown that tourists with better environmental awareness would have incentives to protect the environment (Hwang et al., 2000). Wang (2010) applied TPB to the study of the relationship between environmental awareness and environmental behavior of tourists, and found out that there was a significant correlation between environmental awareness and environmental behavior of tourists. The key factors of environmental awareness influencing environmental behavior had been identified. Lin et al. (2014) surveyed that there was a significant positive correlation between the environmental awareness and tourists' behavior. Based on Widegren (Bamberg, 2003), Corral-Verdugo et al. (2008) and other related research results, the following research hypotheses are proposed:

H11. Environmental awareness has a positive effect on tourist's attitude toward vandalism.

H12. Environmental awareness has a positive effect on tourist's past vandalism.

H13. Environmental awareness has a positive effect on subjective norms of tourist's vandalism.

H14. Environmental awareness has a positive effect on perceived behavioral control of tourist's vandalism (*Fig. 1*).

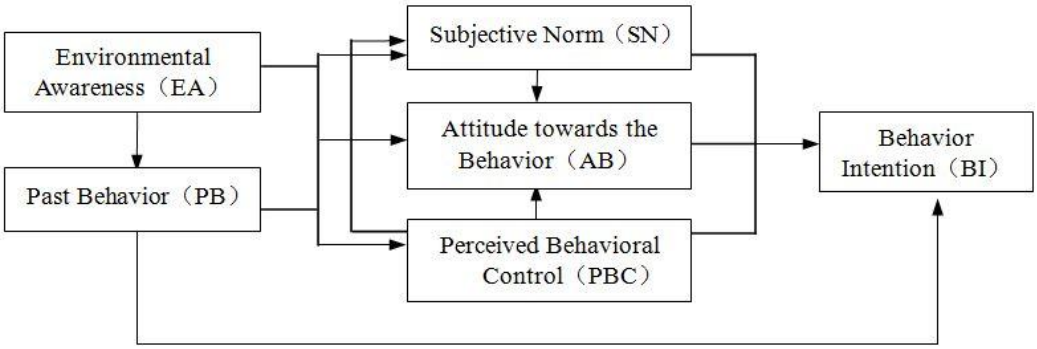

Figure1. *Conceptual framework of vandalism intention*

Methodology

Research methods

Based on the tourist vandalism and environmental awareness scale, the questionnaire was divided into two parts: the demographic characteristics of tourists and the main body of the questionnaire. The demographic characteristics of tourists include the tourist's place of residence, age, gender, monthly income, occupation, educational background, and travel times. Tourist vandalism includes "graffiti, littering, throwing food to animals, damaging the vegetation, snapping off coral, noise making, improper dressing code, damaging recreational property" (Xu, 2014). Questionnaire topics cover tourists' attitude toward vandalism, subjective norms, perceived behavioral control, past vandalism, environmental awareness, and vandalism intentions. The questions refer to Bamberg and Ajzen (2003), Gao (2003), Li (2007), Dunlap (1978, 2008), Luo (2007) in TPB and environmental awareness measurement (*Table 1*). The questionnaire was measured by 5-points Likert-type scale, and the respondents were asked about their level of agreement. In order to avoid hurried responses from the visitors, the fuzzy options of "don't know" and "general" were removed and respondents were required to make choices, with actual scores ranging from 1 to 4 points.

Table1. *Questionnaire of vandalism*

Variable	Measurement index	Mean	Standard deviation
Attitude towards the behavior (AB)	AB1 It's fine to have vandalism in Taiwan	3.03	0.883
	AB2 It's allowed to have vandalism in Taiwan	2.93	0.965
	AB3 It's reasonable to have vandalism in Taiwan	3.11	0.919
Subjective norm (SN)	SN1 My family and relatives believe that I can have vandalism in Taiwan	2.96	0.972
	SN2 My friends believe that I can have vandalism in Taiwan	2.85	0.882
	SN3 My relatives and family believe that I can have vandalism in Taiwan	2.88	0.880
Perceived behavioral control (PBC)	PBC1 It is entirely up to me to make vandalism in Taiwan	2.84	0.981
	PBC2 There is no control to make vandalism in Taiwan	2.91	0.962
	PBC3 I could behave like a vandalist anytime in Taiwan	2.76	0.983
Behavior intention (BI)	BI1 How likely does vandalism occur in Taiwan?	2.80	0.874
	BI2 How willful does vandalism occur in Taiwan?	2.87	0.884
	BI3 At what probability does the vandalism occur in Taiwan?	2.80	0.873
Past behavior (PB)	PB1 Vandalism happened last time I visited Taiwan	2.93	0.950
	PB2 Vandalism happened a lot last time I visited Taiwan	3.01	0.898
Environmental awareness (EA)	EA1 Natural self-regulation is strong enough to withstand the effects of modern industrial society	2.24	0.905
	EA2 Humans can develop and change the natural environment in order to meet their own needs	2.32	0.859
	EA3 Humans will eventually understand natural laws to fully control the natural world	2.28	0.876

Descriptive statistics of the questionnaires were collected by SPSS22.0 software to obtain the mean scores and standard deviations of each test topic. Correlation analysis was carried out on each test topic to obtain the correlation coefficient. Based on this, factor analysis was conducted to obtain the KMO value of the questionnaire and the factor loadings of each item. Reliability analysis was conducted to obtain the Cronbach's α coefficient of each variable and each item.

This study investigated the influence mechanism of tourist vandalism. To test the proposed model, the statistical tool Amos22.0 was used to conduct Structural Equation Models (SEM) analysis. Combined with the questionnaire data, the hypothetical model was fitted and tested, and was modified by removing insignificant path links.

Composite reliability was assessed by *Equation 1,* and the average variance extracted (AVE) values were acquired by *Equation 2*.

$$CR = \frac{\left(\sum_{i=1}^{k} \lambda_i\right)^2}{\left(\sum_{i=1}^{k} \lambda_i\right)^2 + \sum_{i=1}^{k} e_i} \quad \text{(Eq.1)}$$

$$AVE = \frac{\sum_{i=1}^{k} \lambda_i^2}{\sum_{i=1}^{k} \lambda_i^2 + \sum_{i=1}^{k} e_i} \quad \text{(Eq.2)}$$

In *Equations 1* and *2, k* means the number of measured corresponding factors, λ_k means the true variance, and e_k means error variance.

Data collection

Considering the diversity of tourists, representativeness of tourist vandalism, and availability of data, this study takes Chinese tourists who are visiting Taiwan as an example (*Table 1*). Taiwan could make a typical case. Chinese traditional culture is deeply penetrated into the society of Taiwan. On the other hand, Taiwan had been under Japan's rule for 50 years, and it is also westernized. Due to the political and historical reasons, Chinese visitors visiting Taiwan can be regarded as domestic tourism in theory, but it is actually viewed as outbound tourism in practice. Therefore, it is meaningful to take Chinese visitors visiting Taiwan as an example to study the influence factors and mechanism of tourist vandalism, which will contribute a lot to the prevention of tourist vandalism in domestic and outbound tourism.

This study chose to cooperate with the Hong Kong, Macao and Taiwan Affairs Offices of the Fujian Provincial Tourism Administration from September to October of 2017, peak time of mid-autumn holiday, to conduct a questionnaire survey at Fuzhou Changle International Airport and Pingtan cruise to Taiwan. A simple random sampling method was adopted. 200 questionnaires were issued each month. 5 copies had been sent to each Taiwan tour each time. 400 questionnaires were distributed to backpack tourists, 367 were returned and with a final example of 316 (79% response rate).

Data analysis and research results

Demographic characteristics description

This study measured 17 items and the 400 sample size estimate by Cochran method. Also, structural equation analysis is used to assess the overall fitness of the model and examine the statistical significant of each hypothesis (Wu, 2009). 316 respondents were mainly from Fujian Province, only 27.53% respondents were non-Fujian Province tourists. 51.90% were female. They are predominately young, with 37.97% in their 20s and 52.53% in their 30s. Most respondents received bachelor degree (44.93%) or got education to senior middle/professional college (35.44%). 58.86% of respondents monthly earned 2000-3999 yuan. In terms of the occupation of tourists, most of them work for public institutions (41.14%), corporate staff (33.23%) and civil service (14.87%); 77.22% of respondents visited Taiwan for the first time, and 22.15% tourists visited Taiwan for the second time; 84.18% of respondents visited Taiwan by group

tour, only 15.82% chose independent travel. The sample data satisfy the assumption of normal distribution as each indicator's skewness are between -0.60 and 0.842, the corresponding the absolute value is less than 3; the kurtosis are between -0.127 and 1.002, the corresponding absolute value is less than 8 (Wu, 2009).

Common method variance

Harman's single-factor test was used to perform exploratory factor analysis on the variables of interest. The results showed that the variance interpretation ratio of the first unrotated factor was only 39.79% and less than 50%, indicating that CMV was Acceptable range; the maximum correlation coefficient of all variables is 0.85, less than 0.90, the CMV of the displayed data is not obvious. Therefore, the common method bias of survey data is not a pervasive issue.

Reliability and validity test

Using SPSS22.0, we scrutinized the overall reliability was 0.923, and the Cronbach's alpha value of each latent variable was between 0.783 and 0.923 (*Table 2*), which exceeded acceptable thresholds of 0.7, thus indicating that the scale was reliable.

Table 2. *Reliability and validity test of the scale*

Latent variables	Measurement index	Factor loading	t-value	Cronbach's α	C.R.	AVE
Attitude towards the behavior (AB)	AB1	0.931	-	0.906	0.914	0.780
	AB2	0.777	18.705			
	AB3	0.933	27.542			
Subjective norm (SN)	SN1	0.806	-	0.889	0.896	0.742
	SN2	0.879	18.055			
	SN3	0.896	18.486			
Perceived behavioral control (PBC)	PBC1	0.946	-	0.932	0.913	0.778
	PBC2	0.798	19.827			
	PBC3	0.895	25.463			
Behavior intention (BI)	BI1	0.955	-	0.911	0.934	0.825
	BI2	0.863	24.351			
	BI3	0.904	27.374			
Past behavior (PB)	PB1	0.876	-	0.853	0.854	0.746
	PB2	0.851	17.321			
Environmental awareness (EA)	EA1	0.747	-	0.783		
	EA2	0.689	10.579		0.783	0.547
	EA3	0.780	11.336			

In terms of construct validity, first, we completed the reviews of literature to gain each construct. Second, we employed the pilot studies and the factor analysis method was adopted. For structural validity, the factor with the eigenvalue greater than 1 was retained. The cumulative variance contribution rate was 75.32%, the KMO was 0.885, and the Bartlett's sphere test had a significance of 0.000. The normalized load values

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_59555969
© 2018, ALÖKI Kft., Budapest, Hungary

corresponding with each latent variable are between 0.689-0.946, all loadings and corresponding t-value is between 10.579 to 27.542, the composite reliability is between 0.783-0.934, and the average variance extracted (AVE) for each scale is between 0.547-0.825. Each AVE exceeded Fornell and Larcker's (1981) suggested minimum value of .50, which indicates convergence validity was good.

Analysis of the goodness fit indexes suggested good model fit(X^2/df = 2.473, Root Mean Square Residual [RMR] = 0.041, Root mean square error of approximation [RMSEA] = 0.068, goodness-of-fit indexes [GFI] = 0.914, TLI = 0.952, normed fit index [NFI] = 0.940, Incremental Fit Index [IFI] = 0.963, comparative fit index [CFI] = 0.963). The fit statistics shows that the overall research model provides a good fit with the data (Wu, 2009).

Structural equation models analysis

Using Amos22.0, The fit index met the corresponding requirement (X2/df = 2.456, RMR = 0.041, RMSEA = 0.068, GFI = 0.914, TLI = 0.952, NFI = 0.940, IFI = 0.963, CFI = 0.963), and supported nine hypotheses (H1, H4, H6, H7, H9, H10, H11, H12, H13), while H2, H3, H5, H8, H14 have been rejected (*Table 3*).

Table 3. *Result of hypothesis test*

Hypothesis path			Path coefficient	t value	Result
H1 : AB	→	BI	0.259**	2.636	Support
H2 : SN	→	BI	-0.003	-0.028	Denial

***P < 0.001, **P < 0.01, *P < 0.05. AB: Attitude towards the behavior, SN: Subjective norm, PBC: Perceived behavioral control, BI: Behavior intention, PB: Past behavior, EA: Environmental awareness

The model has been modified by removing insignificant path links (Wu,2009). The corrected fit index was: X2/df = 2.358, RMR = 0.043, RMSEA = 0.066, GFI = 0.914, TLI = 0.955, NFI = 0.939, IFI value = 0.964, CFI = 0.964. Meanwhile, the post-correction fit index was good and the initial model has been improved. The revised model was more concise than the initial model (*Fig. 2*).

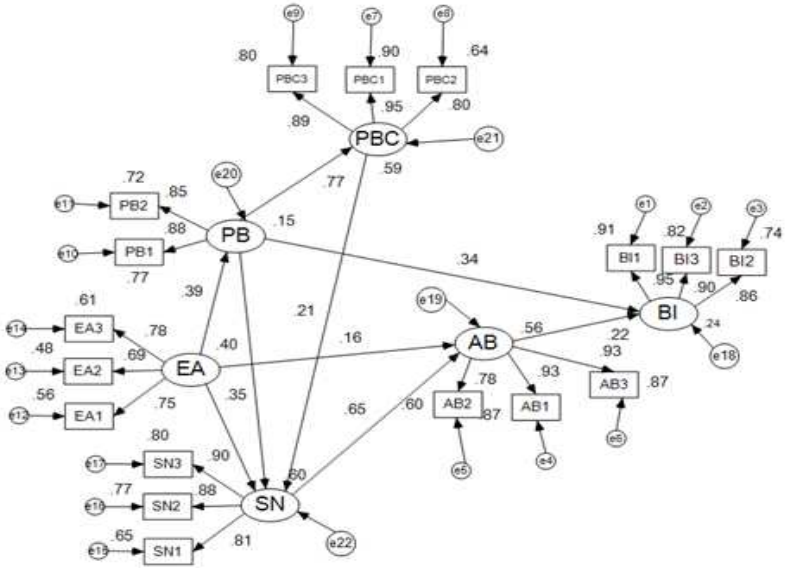

Figure 2. *Map of vandalism intention of tourists from Mainland to Taiwan. (AB: Attitude towards the behavior, SN: Subjective norm, PBC: Perceived behavioral control, BI: Behavior intention, PB: Past behavior, EA: Environmental awareness)*

Conclusions and discussions

Conclusions

First, tourist's attitudes toward vandalism and past vandalism have a significant positive effect on behavioral intentions, which is consistent with the original assumptions of theoretical models of planned behaviors. The results also reflect in Lin's (2016) research on the formation mechanism of the tourists to Taiwan civilized behaviors intention and the findings of Qiu (2017) on the influencing mechanism of civilized tourists behavior intentions. The coefficient of influence on the behavioral intention of the past behavior (0.34) was significantly higher than that of the behavioral attitude on the behavioral intention (0.22). It shows that tourists past vandalism would significantly influence their intention to repeat their vandalism.

Second, the subjective norms of tourist vandalism and perceived behavioral control have no direct positive influence on behavior intentions, which explains that the attitude of peers and the willingness of tourists to act vandalism have not directly positive affected their vandalism intention, while they indirectly influence behavioral intentions through behavioral attitudes. This proves Qiu's (2017) study on perceived behavior control of the civilized tourists' behaviors indirectly affecting behavioral intentions through behavioral attitudes. When the subject of the study is macroscopic, vague, and does not have much to do with tourists' own interests, such as ecotourism behaviors, civilized tourist behavior, and green purchasing behavior, the approval attitude of the peers has a direct positive effect on tourists' behavior intentions. On the opposite, when the subject of the study is quite sensitive and more related to the interests of tourists, like, graffiti, littering, throwing food to animals, snapping off the vegetation and coral, noise making, improper dressing, damaging recreational property and other vandalism, then the attitudes of the peers do not have a direct positive effect on the tourist behavior intentions. And the approval attitude of the local residents of the tourism destination may become an important factor that directly affects tourist vandalism intention. The

© 2018, ALÖKI Kft., Budapest, Hungary

positive effects of perceived behavioral control on behavioral attitudes are not significant, but they indirectly affect behavioral attitudes through subjective norms. This is different from the results of Qiu (2017) research that these two variables are multi-influenced. It shows that the attitudes of the peers have a positive impact on the tourist vandalism, furthermore affects the behavioral attitudes and behavioral intentions.

Third, past behavior has positively influenced behavioral intentions, subjective norms and perceived behavioral control, but the positive impact on behavioral attitudes is not significant. The findings are basically consistent with Ajzen's (1991) expansion research on the TPB, while are not consistent with the findings of Li (2007). Past behavior has a significant positive effect on behavioral intentions, but the impact on behavioral attitudes is not significant, possibly due to the Face issues. Tourist vandalism are kinds of sensitive and negative behaviors, although tourists respond positively. However, in decision-making process of specific behavioral intentions, they are deeply influenced by past behaviors, and may deliberately avoid the choice of true behavioral intentions.

Fourth, environmental awareness has positive influence on past behaviors, subjective norms, and behavioral attitudes, but the impact on perceived behavioral control is not significant. This is consistent with Lin's (2014) findings of significant correlation with environmental awareness and tourism behavior, and has deepened the research on the mechanism of environmental awareness affecting tourism behavior. There are mainly two ways how environmental awareness influences behavior intentions: one is indirect influence on behavioral intentions by past behavior; the other is indirect influence on behavioral intentions through subjective norms and behavioral attitudes. Thus, environmental awareness is an important latent variable for outbound tourist vandalism. In addition, the direct impact of environmental awareness on perceived behavioral control is not significant. The reason is that environmental awareness reflects the tourists' opinions on the relationship between people and nature, which can directly affect behavior intentions and the behavior itself. Therefore, through the direct influence on the past behavior, it will indirectly affect the perceived behavioral control.

In conclusion, based on the conceptual formula $B = f(P, E)$, this study further defines the connotation and extension of tourist vandalism, and provides a theoretical basis for the study of vandalism behaviors of domestic and foreign tourists. Furthermore, variables such as environmental awareness and past behaviors are introduced into the modified tourist vandalism intention model, which further verifies the reliability of the planned behavior theory to explain the mechanism of tourist vandalism, and further clarifies the influence mechanism of environmental awareness on past behaviors, subjective norms, and behavioral attitudes. This study has important reference significance for the study of the mechanism of tourist vandalism. It also promotes the perfection of the theory and application of planned behavior theory in Chinese context.

Discussions

In 2016, the number of Chinese outbound tourists reached 122 million, and the tourists spent 109.8 billion US$ while traveling abroad (Qiu, 2017). The huge outbound tourism market is not only for tourist's personal leisure and holiday activities, but also bears its social awareness and responsibility. Based on the above research, we can unify the individual consumption behavior of outbound tourists and social responsibility from the following three aspects. Such managerial implications foster broader implications for public policy makers. That is, while it may be beneficial for service companies to

© 2018, ALÖKI Kft., Budapest, Hungary

train employees in methods of misbehavior management and deterrence, from a public policy perspective it would appear fruitful to educate customers.

(1) Face the urgent needs of scientific research on tourist vandalism. Tourist vandalism is not a unique phenomenon to China's outbound tourists. The developed countries have experienced various degrees of vandalism during the rapid development of tourism. The key is how to propose appropriate governance programs through scientific research to change the personal vandalism of a few tourists as soon as possible to avoid the formation of group phenomenon. The best reference is Japan's approach to vandalism of outbound tourists in the 1980's. Therefore, there is an urgent need to clarify the concept and characteristics of tourist vandalism in the Chinese context, and establish a black list of outbound tourist behaviors for different tourist destinations. According to the government notices of "20 uncivilized behaviors of domestic and outbound tourists", based on the content and nature of tourism activities, it can be broadly divided into three categories: illegal acts, violations of social moral acts, and uncivilized acts. Among them, violations of social morality and uncivilized behavior are the main body of tourist vandalism.

(2) Correct attitude towards tourist vandalism. Attitude consists of three dimensions: perception (belief, knowledge and understanding), emotion (likes and dislikes), and behavior (participation). Attitude is an important factor affecting the behavioral intention (Zhang, 2018). In recent years, the publicity and education of the media and governments made a significant drop of outbound and domestic uncivilized behavior. This study found that behavioral attitudes are significantly affected by environmental awareness and subjective norms. In addition to the publicity and education of the media, knowledge of correct attitudes towards tourist vandalism should be incorporated into the education of family and schools, so that the society can understand the contents and harms of the vandalism, and make tourists ashamed of vandalism.

(3) Avoid repetition of past vandalism. People always act specific behaviors in a certain way, and as long as such behaviors have occurred in the past, the possibility of repetition is very high (Chang, 2003). The study realizes that past behavior is one of the important factors that influence behavioral intentions. Besides establishing a negative list of vandalism of outbound tourist destinations, we must know the occurrence probability of vandalism and how to make outbound tourists avoid those behaviors. It was reported by "United Daily News" that in the past ten years illegal touching and throwing food to animals, littering, and urination anywhere were the typical tourist vandalism in Taiwan. These behaviors should be targeted and educated before trip.

In addition, the study also found out that past behavior was significantly affected by environmental awareness. Under the economic reform, China is undergoing a structural adjustment of industries, and people's environmental awareness is changing from the mainstream social paradigm (DSP) to the new ecological paradigm (NEP). That is to say, Chinese has changed from simply pursuit of GDP and economic benefits to integration sustainable development of economic, environmental and social benefits. Although tourists' environmental awareness at this stage is weak in human exceptionalism (Lin et al., 2014), they can be trained and educated.

(Received 20th Jun 2018; accepted 22nd Aug 2018)

Abstract. This study was conducted on sediment and overlying water samples from Mogan Lake, an important recreational area, in April, July and October 2015 and January 2016. The noteworthy data for this study were presented as follows: a) Sediment adsorption/desorption characteristics dependent on phosphate concentration, temperature and time were determined using models, and the relevant parameters were derived. b) Sediment equilibrium phosphate concentrations (EPC_0) and the critical dissolved phosphorus in the overlyingwater were estimated. Presentation of the research data is as follows: a) Phosphorous adsorption in the sediment samples was theoretically between 421 mgP kg^{-1} and 1,001 mgP kg^{-1}, and phosphorus sorption efficiency was estimated at 0.21-1.92 L mg^{-1}. Based on the Langmuir Model, the mean maximum adsorption capacity obtained for the July samples was significantly higher than that obtained for October ($p < 0.05$). Moreover, regarding the very low degree of sediment phosphorus desorption (<1%), it can be concluded that sediment does not behave as a desorbant material for phosphorus. b) Considering the EPC_0 values (5.5×10^{-3} and 46.6×10^{-3} mg L^{-1}), when the overlying water SRP concentrations fall below 0.008 mg L^{-1} in October and 0.046 mg L^{-1} in July, there will be a risk of phosphorus flux from the sediment to the lake water. Considering the overlying water SRP values reported for Lake Mogan, monitoring them in the months of October and July will prove to be decisive in predicting the internal phosphorus load of the lake.
Keywords: *adsorption, desorption, Freundlich model, Langmuir model, phosphorus, sediment*

Introduction

Phosphate sorption (adsorbtion/desorbtion) between the sediment and the sediment porewater is one of the mechanisms controlling phosphate exchange between the sediment and the overlying water in aquatic ecosystems. In determining the sediment's role as either a trap or a source of phosphorus, sediment phosphate adsorption is recognized as one of the most important components of long-term phosphate retention mechanisms especially in shallow lakes (Wang and Li, 2010; Zhang et al., 2012). Long-term estimates of sediment phosphate adsorption are important in determining phosphate pollution and suitable restoration techniques in lakes. The measurement of the most recent phosphate concentration in lake water is not restricted to the lake's phosphate intake and the measures taken to reduce its phosphate level; it can also be determined using the phosphate sorption rate. Kinetic models of sediment phosphate adsorption are defined by Langmuir isotherm (a rational basis) and Freundlich isotherm (an empirical equation) these are generally used in determining the rate of the chemical reaction and the effective factors following the calculation of the equilibrium phosphate concentration (Huang et al., 2011). The above models are often excellent at describing

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_59715985
© 2018, ALÖKI Kft., Budapest, Hungary

adsorption, which are simply numerical relationships used to curve-fit data. Langmuir and Freundlich equations, widely and well used to explain the K adsorption, took into account the quantity, intensity and capacity factors which are important for estimating the sediment nutrient amounts (Wang et al., 2017).

The equilibrium phosphate concentration (EPC_0) is the state of aquatic systems in which adsorption and desorption values between the sediment and the overlying water are equal. It is an important parameter used for determining internal phosphate loading potential following a reduction in external phosphate loading or for measuring the level of phosphorus release and/or retention (Palmer-Felgate et al., 2011; Zhijian et al., 2012). If the equilibrium phosphate concentration is greater than the SRP value of the overlying water, phosphate release from the sediment into the overlying water occurs (Wang and Li, 2010; Wang et al., 2012; Jin et al., 2013; Tang et al., 2014).

Lake Mogan is an important recreational area for metropolitan Ankara, Turkey. It is under environmentally protected status as the 'Golbasi Specially Protected Area' since the major source of phosphorus in the area is wastewater containing detergents and fertilizers applied in the surrounding agricultural areas. Lake Mogan is an important recreational area due to its proximity to the city of Ankara, and studies have been conducted on the interaction between eutrophication and sediment in the lake (Pulatsü et al., 2008; Topçu and Pulatsü, 2008; Pulatsü and Topçu, 2009).

This study, being the pioneer one regarding the determination of sediment phosphate sorption characteristics, was conducted in Lake Mogan in April, July, and October 2015 and January 2016 with the aims of: a) deriving parameters for the use of kinetic and thermodynamic models for adsorption/desorption features of sediment phosphates in terms of concentration, temperature and time, and b) estimating the critical total dissolved phosphate concentration for the overlying water by calculating the sediment's equilibrium phosphate concentration (EPC_0).

Materials and methods

Study area

Lake Mogan is located 20 km south of Ankara on the Ankara-Konya road. It is an alluvial lake fed in large part by rain and also by more than five large and small streams (Boşgelmez et al., 2005). Detailed locations of the sampling stations in Mogan Lake are shown in *Figure 1*. Because the eastern littoral area's lakebed is covered with stones, the two stations were placed near the lake's western shore, where the lakebed is more suitable for collecting sediment samples. The area surrounding the sampling stations is covered with rooted aquatic macrophytes and is under the effects of intense negative development and pollution from anthropogenic sources.

Sediment sampling and analyses

All sediment samples were collected from the surface sediment (0-20 cm) in April, July, October 2015 and January 2016 with Van Veen Grab. Prior to mixing and splitting the sediment samples, they were taken to the laboratory in sealed plastic bags, which were put in iceboxes. After that these samples were air-dried, homogenized by grinding, and finally passed through a 0.5 mm sieve. The overlying water was grained by siphoning from the water located 10 cm above the sediment sampling locations. The mean depth of the sampling stations vary between 2.20 and 2.80 m. The supernatants of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_59715985
© 2018, ALÖKI Kft., Budapest, Hungary

overlying water were filtered through Whatman GF/C filters and then analyzed for SRP as ascorbic acid method according to standard analytical procedures (APHA, 2005). Two samples were obtained from each station and dublicate sub-samples were used for every sample in all analyses.

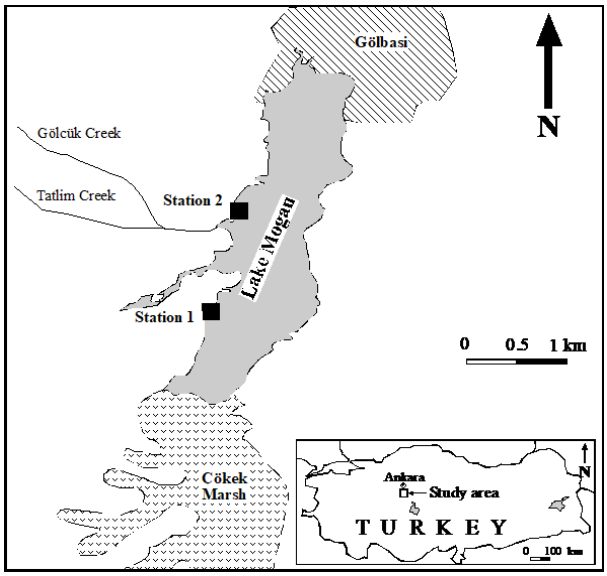

Figure1. *Study site and sampling stations (■: Station 1: 39°46'07" N 32°47'03" E; Station 2: 39°45'33" N 32°47'05" E) in Mogan Lake*

Adsorption procedures

Phosphorous adsorption studies were performed for various temperatures (277, 289, 295 and 300 K). The change of adsorption by phosphorous concentration was investigated for the range of 0.1-10 mg L^{-1} by considering previous investigations related to the seasonal change of phosphorous release in Mogan Lake by Pulatsu et al. (2008) at 277, 289, 295 and 300 K. 0.2 g fractions of sediment samples exemplified for July and October were added in screw-cap centrifuge tubes containing 20 mL of 0.1-10 mg L^{-1} phosphorous equivalent KH_2PO_4 (Ca ≈ 0.4-40 mg L^{-1}) solutions at studied temperatures. Two drops of 0.1% chloroform to inhibit bacterial activity. The samples were let to equilibrate for 24 h in temperature controlled water bath with gentle agitations. The solution and solid phases were separated by centrifugation at 4000 rpm for 15 min. Solutions were filtered and the phosphorous contents were determined by the APHA procedures (2005). This prescription was also applied for investigations enquiring the effect of time (kinetics) at 277 and 300 K and temperature (thermodynamics) at 289, 295 and 300 K on phosphorous adsorption at constant phosphorous concentration (2 mg L^{-1}). The solid and solution interaction was 24 h for the temperature effect whilst that was variable from 10 min to 36 h for the kinetics.

Calculation of phosphate desorption

The experimental processes of desorption measurement (change of desorption with concentration, thermodynamic, and kinetic), the 'desorbant (sediment)–phosphorus equilibrium solution' balance in the system, the 'phosphorus' concentrations were measured with spectrophotometric methods.

Data evaluation

The adsorbed amounts 'Q' (mg kg^{-1}) were calculated by *Equation 1* where 'C_0 and C_e' were phosphorous concentrations (mg L^{-1}), 'V' was solution volume (L), and 'm' was the mass of adsorbent (kg).

$$Q = \frac{(C_0 - C_e)xV}{m} \quad \text{(Eq.1)}$$

The concentration dependence of adsorption was evaluated with reference to the compatibility of experimental data (Q vs. C_e) to Langmuir, Freundlich and Sips models (*Eqs. 2–4*) in which X_L (mg kg^{-1}) and K_L (L mg^{-1}) were monolayer adsorption capacity and a constant energetically related to the adsorbate affinity to adsorbent. According to Langmuir model the active adsorptive centers were homogeneously distributed over the surface; the amount of adsorbate filling of these centers completely was X_L.

$$Q = \frac{X_L K_L C_e}{1 + K_L C_e} \quad \text{(Eq.2)}$$

Freundlich model was description of adsorption exponentially related to the surface heterogeneity '$0 < \beta < 1$' where 'a' was Freunlich capacity constant associated with adsorption intensity.

$$Q = aC_e^{\beta} \quad \text{(Eq.3)}$$

'K_s' and 'a_s' were the model constants and 'β_s' was known to be Sips exponent. This model explained that the isotherm was compatible to Freundlich model at low adsorbate concentrations, the compatibility shifted to Langmuir at high concentrations. The equation defines Langmuir model at $\beta_s = 1$ (Foo and Hameed, 2010; Baybaş and Ulusoy, 2011).

$$Q = \frac{K_s C_e^{\beta_s}}{1 + a_s C_e^{\beta_s}} \quad \text{(Eq.4)}$$

These models were commonly considered in obtaining adsorption characteristics of any sorbents and of sorption processes. The obtained parameters were used as references for comparison of e.g. adsorption dependence on sorbents and/or processes. According to Wang et al. (2012), Langmuir model should be further evaluated by taking into account of the contribution natively adsorbed exchangeable phosphorous (NAP) to adsorption process (*Eq. 5,* where C^0_e denotes equilibrium concentration of exchangeable phosphorous i.e. the concentration in desorption equilibrium by fresh water). EPC_0 (zero phosphorous concentration) as the threshold concentration referring the release of phosphorous from the reservoir sediment back into the water when 'EPC_0 > Soluble Reactive Phosphorous (SRP)' can be foreseen after NAP by *Equation 6*.

$$NAP = \frac{X_L K_L C_e^0}{1 + K_L C_e^0} + C_e^0 \frac{V}{m} \quad \text{(Eq.5)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_59715985
© 2018, ALÖKI Kft., Budapest, Hungary

$$EPC_0 = \frac{NAP}{K_L(X_L - NAP)} \quad \text{(Eq.6)}$$

The adsorbed amounts calculated by *Equation 1* with reference to the phosphorous contents of solutions taken by time intervals were evaluated in view of the compatibility of adsorption to pseudo-first and -second order models (*Eqs. 7* and 8) where 'Q_t' (mg kg^{-1}) defines the adsorbed amounts at time 't (h)', 'Q_1 and Q_2' are the theoretical adsorptions obtained from the compatibilities. The adsorption rate constants are referred by 'k_1 (h^{-1}) and k_2 (mg^{-1}.kg h^{-1})' for first and second order kinetics (Ho and McKay, 1999).

$$Q_t = Q_1(1 - e^{-k_1 t}) \quad \text{(Eq.7)}$$

$$\frac{t}{Q_t} = \frac{1}{k_2 Q_2^2} + \frac{t}{Q_2} \quad \text{(Eq.8)}$$

Time required reducing initial phosphorous concentration to its half i.e. the time passed reaching half of the maximum adsorption 't1/2 (h)' and the initial adsorption rate 'H ($mg.kg^{-1}.st^{-1}$)' are given by *Equations 9–12* for pseudo first and second-order kinetics models.

$$t_{1/2} = 0.693/k_1 \quad \text{(Eq.9)}$$

$$H_1 = k_1 Q_1 \quad \text{(Eq.10)}$$

$$t_{1/2} = 1/k_2 Q_2 \quad \text{(Eq.11)}$$

$$H_2 = k_2 Q_2^2 \quad \text{(Eq.12)}$$

Adsorption activation energy, EA (J mol^{-1}) is calculated by Arrhenius equation (*Eq. 13*) rearranged for rate constants (k_{T1} and K_{T2}) obtained for two different temperatures where 'T' and 'R' are temperature in Kelvin scale (K) and ideal gas constant (8.314 J mol^{-1} K^{-1}) respectively (Winzor and Jackson, 2006).

$$\ln \frac{k_{T2}}{k_{T1}} = -\frac{E_a}{R}\left(\frac{1}{T_2} - \frac{1}{T_1}\right) \quad \text{(Eq.13)}$$

Further evaluation of the kinetics by Weber-Morris Model (*Eq. 14;* k_i is the rate constant for the model) provides information for the nature of adsorption, i.e., the process most effective on adsorption and its kinetics amongst mass transfer/diffusion, adsorption by surface precipitation or electrostatic attraction between adsorbent and adsorbate, and intrapartical diffusion could be proposed.

$$Q_t = k_i \sqrt{t} \quad \text{(Eq.14)}$$

Adsorption thermodynamics is evaluated by Gibbs-Helmotz and van t'Hoff equations (*Eqs. 15* and *16*) for which the values 'ln K_T' (distribution coefficient

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

obtained from the ratio of the amount adsorbed to equilibrium concentration after the solid-solution interaction is ceased, $K_T = Q_T/C_T$) vs. '1/T' for the studied temperatures is firstly depicted to figure out the changes in adsorption entropy (ΔS, J $mol^{-1}K^{-1}$) from the intercept and enthalpy (ΔH, J mol^{-1}) and from the slope. Adsorption free energy (ΔG, J mol^{-1}) is then calculated.

$$\ln K_T = -\frac{\Delta H}{R}\frac{1}{T} + \frac{\Delta S}{R} \quad \text{(Eq.15)}$$

$$\Delta G = \Delta H - T\Delta S \quad \text{(Eq.16)}$$

Results

The experimental isotherms and adsorption parameters

Figures 2 and *3* show the compatibility of concentration dependence of phosphorous adsorption to Langmuir and Freundlich models. Sips models is not provided in the figures to avoid chaotic view. The parameters derived from the compatibilities to all three models considered are presented in *Table 1*.

[1]mg kg^{-1}
[2]L mg^{-1}
*Means are significantly different

Although the results of compatibility of experimental isotherms to all adsorption models considered were significant with coefficient of variations of $R^2 \geq 0.936$ ($p < 0.05$) the best fits were obtained for the Sips (*Table 1*). This could be attributed to the theoretical considerations of the model which is combination of both Langmuir and Freundlich models. The mean of maximum adsorption values obtained for the defined temperatures for samples collected in July was 819 ± 81 mg kg^{-1} as it is significantly different ($p < 0.05$) from those collected in October (530 ± 48 mg kg^{-1}). This should be attributed to the heat activation of the sediment as depending on the weathering, i.e., the sediment of Mogan is subjected to heat a prolonged period of time in summer. In fact

the mean of temperatures reached were 25.25 ± 0.03 °C in July and 10.23±0.05 °C in October. The significance of the adsorption mean values also imply that the studying of adsorption at changing temperatures is not much effect on adsorption capacities because of the interaction time of solution and sediment in batch experiments is not enough (24 h) to change temperature associated sediment feature. The experiments to recover the phosphorous adsorbed on the sediments samples by distilled water proved that the adsorption is not reversible so that the corresponding amounts with phosphorous concentrations in recovery solutions were <1% of the adsorbed quantities.

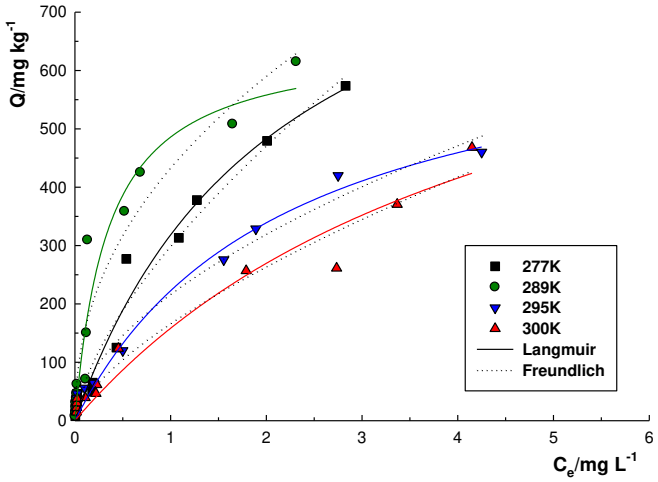

Figure 2. *The experimental isotherms for various temperatures obtained for adsorption of phosphorous on sediments sampled in July and its compatibility to Langmuir and Freundlich models. Table 2 provides results relevant to NAP and EPC_0. The comparison of the magnitudes of NAP with that of X_L values predicated that contribution of NAP to adsorption process is not considerable for any of the studied conditions. The values of EPC_0 were in the range of 0.004-0.012 mg L^{-1} for the sediments sampled in both seasons which is less than the values of SRP 0.018 ± 0.009 and 0.039 ± 0.003 mg L^{-1} for July and October sediments respectively.

Adsorption kinetics

Time dependence of phosphorous adsorption on sediment samples were investigated to evaluate the adsorption with reference to pseudo first and second order models of the kinetics for sediments sampled in July and October for two different temperatures. The compatibility of experimental data to the models from which the parameters were obtained are presented in *Figure 4*, and *Table 3*.

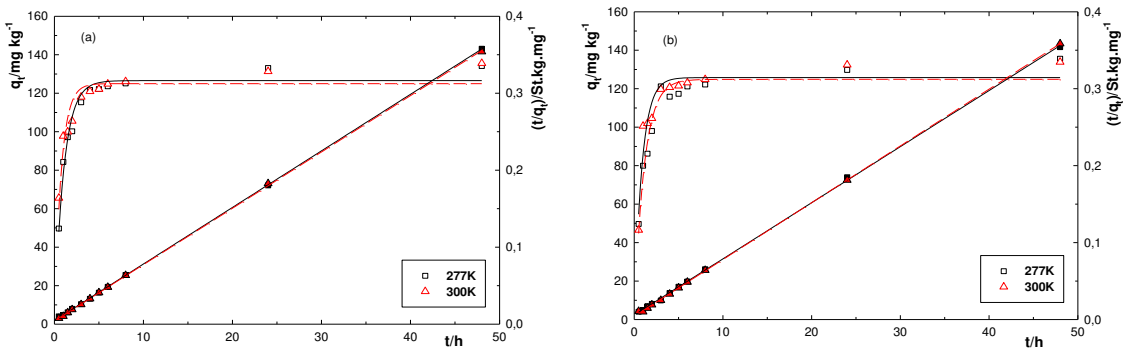

Figure 4. *The compatibility of experimental data for July (a) and October samples (b) at 277 and 300 K to pseudo-first (i vs. qt) and second order (t vs. t/qt) kinetic models;' t' and 'qt' refer the time elapsed after the solid-solution contact as hour and adsorbed amounts calculated for time 't' as mol kg-1 (C0 = 2 mg L-1, m/V = 0.25g/20 mL)*

[1]mg kg^{-1}
[2]The adsorbed amounts experimentally determined 6 and 48 h after adsorbent–adsorbate contact
[3]h^{-1}
[4]h
[5]$mg^{-1}.kg.h^{-1}$
[6]Initial adsorption rates as $mg.kg^{-1}$ h^{-1}

As seen from the table that the phosphorous adsorption kinetics obeyed more significantly to second order model ($R^2 \geq 0.999$) than that to the first order model. This was also consistent with closeness of the values for Q_2 (the adsorbed amounts found from second order model) and Q_{exp} (the adsorbed amounts after experimental equilibrium). Adsorption rate constants proved that the increasing temperatures increase the adsorption rates k_2 (300 K)>k_2 (277 K), although this was not significant for P adsorption on the Mogan Sediments at the studied conditions. From the comparison of Q_{max} and Q_2 values, it was obvious that P adsorption completed in a few hours after adsorbent-adsorbate contact. In fact that the values of $t_{1/2}$ (time elapsed up to half of the completion of adsorption) showed that half lives were about 0.6-0.8 h with high initial adsorption rates ranging between 169 mg kg^{-1} h^{-1} and 242 mg kg^{-1} h^{-1}. Similar trends were also seen from the parameters derived from first order model. The adsorption activation energy was calculated and evaluated under thermodynamics section because of energetically relevance of the subjects.

The adsorption kinetics of P was further evaluated with reference to Weber-Morris model to figure out the physicochemical nature of adsorption for which the graph of Q vs. $t^{0.5}$ was obtained by using all the data obtained from the adsorption kinetics to signify the figure's pattern which could be considered with two parts (*Fig. 5*). The profile of graph was typical for adsorption of species to an adsorbent with chemical feature; otherwise, the pattern is with a straight linearity passing through the origin for adsorptions with physical nature.

Adsorption thermodynamics

Temperature dependence of P adsorption on Lake Mogan sediments studied for 289, 295 and 300 K for both sediment samples of the July and October. The obtained data were evaluated with reference to Gibbs-Helmotz and van t'Hoff equations for which the linearity of 'ln K vs. 1/T' depiction was considered (*Fig. 6*). The values acquired from slop and intercept of the linear relation ($R^2 \geq 0.974$) were used to calculate Gibbs free enthalpy of the adsorption. The results were exhibited in *Table 4*. Because of its energetical relevance, the activation energy of the adsorption derived from the kinetics studies was also represented in the table.

Table 4. *Thermodynamic parameters for adsorption of P to sediment samples*

	ΔH (kJ mol^{-1})	ΔS J mol^{-1}K^{-1}	ΔG_{298K} (kJ mol^{-1})	R^2	E_a (kJ mol^{-1})
July	-68.1	-188	-12.1	0.979	2.9
Oct	-60	-164	-11.1	0.974	11

ΔH, ΔS and ΔG are of the state functions and represent the energetically changing overall adsorption process which here refers to the changes in not only P adsorption alone but also in the contributions made by all other interactions in adsorption medium (such as P hydrolysis/hydration of P ions, water and sediment contents interaction, and many others) to the process. The results demonstrated that overall adsorption process was exothermic (ΔH < 0) with decreasing entropy (ΔS < 0), and spontaneous (ΔG < 0) under enthalpy influence (ΔH-ΔS <0). The energy released after adsorption is not big enough to form a covalent bonding (ΔH ≈ 200 kJ mol^{-1}) but it is sufficient to identify the presence of highly strong interactions between P species and sediment surface via electrostatic attractions This should also further evidence for the occurrence of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_59715985
© 2018, ALÖKI Kft., Budapest, Hungary

adsorption is via surface precipitation. Activation energy, the threshold to be overcome for the adsorption did not have considerable impact opposing to the adsorption at studied temperatures. However the value of Ea for July samples significantly lower than that for October samples because of the heat activation of the sediment during summer season as discussed above, as concordant with the results of ΔH found for the same seasonal sediments.

The phosphorus desorption for all the sediment samples under different temperature applications in both months were all calculated at less than 1%, these values were not taken into consideration.

Discussion

Langmuir and Freundlich's equations were used in order to estimate the phosphate adsorption in the sediment of Lake Mogan. The equilibrium phosphate concentration was determined using the mentioned kinetic models, and the rate of the chemical reaction during the adsorption process was measured. During the research, the effects of four different temperatures (277 K, 289 K, 295 K, 300 K) reflecting the natural conditions of phosphate sorption in the sediment of Lake Mogan were taken into account, and thus, measurements were taken during the months of October and July.

As reported by Huang et al. (2011), since shallow lakes are often isothermal, their sediments are sensitive to temperature changes, and the initial rates of sediment phosphorus adsorption are in direct proportion to the temperature. The constant values for the phosphorus adsorption rate in Lake Mogan for October and July were estimated at between 169-277 mg kg^{-1} h^{-1} and 216-242 mg kg^{-1} h^{-1} at temperatures of (k) 277 K and 300 K, respectively. The fact that these values for the lake sediment increased in direct proportion to the increase in temperature was in accordance with the above-mentioned research findings.

According to Wang et al. (2009) in a study on Three-Gorges Reservoir (China), the phosphate adsorption rate from the sediment reached its peak within six hours, and the maximum phosphate adsorption amount was 0.15-0.402 mgP g^{-1}. The kinetic characteristic of P-sorption in sediment is described by the Elovich model in sediment of Dongting Lake (Zhu and Yang, 2018). The rapid stage of P adsorption occurs within 60 min, and then, slow P sorption appears between 60 and 240 min. The P-sorption amount of sediment changes smaller after 240 min. The phosphate adsorption rate in Lake Mogan was at 90% within six hours that takes longer than Zhu and Yang (2018) and the maximum phosphate adsorption amount was estimated at 421-1001 mgP kg^{-1}. While the phosphate adsorption rate in this study resembles that reported in Wang et al. (2009), the extremely high maximum phosphate adsorption amounts in the Three-Gorges Reservoir were found to be lower (137.79-1975.50 mg kg^{-1}) in another study undertaken in the same reservoir by Zhang et al. (2012). In that study, the phosphate sorption activity in the sediment was determined to be 47.341-230.88 L kg^{-1} (Zhang et al., 2012). Lake Mogan's sediment phosphate sorption activity (0.21-1.92 L mg^{-1}) is higher than the findings of the above study.

Lai and Lam (2008) revealed sediment phosphate adsorption/release and the factors affecting this mechanism in Hong Kong's eutrophic Mai Po Marshes. The study's estimated EPC_0 values were lower than the overlying water's SRP concentrations, and the sediment phosphate release level under aerobic conditions was found to be, on average, 9.4 mg m^{-2} day^{-1}. The EPC_0 values in Lake Mogan were similar to the findings

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_59715985
© 2018, ALÖKI Kft., Budapest, Hungary

of Lai and Lam (2008) in that they were found to be lower than the overlying water SRP concentrations. When the EPC_0 and the overlying water SRP concentrations were examined in the present study, it was suggested that internal phosphate loading from the sediment has a lower effect on the current nutrient level of the lake than the external phosphate load.

In Cry et al.'s (2009) study of oligomesotrophic Opeongo Lake (Canada), when the highest estimated EPC_0 values in the sediment (5 $\mu gP\ L^{-1}$) and the unmeasurable level of SRP values in the overlying water were considered, it was dertermined that there was a phosphate reserve in the sediment. In Nansi Lake (China), kinetic and adsorption/desorption isotherms were detected in the sediment and the equilibrium phosphate concentration and phosphate release potential were estimated, and it was determined that EPC_0 < SRP (Li et al., 2012). The fact that the estimated EPC_0 values in Lake Mogan were found to be lower than the SRP concentrations measured in the overlying water shows agreement with the reports of the above researchers.

In a study examining the details of phosphate adsorption at the sediment-water interface in Fushi Reservoir (China), sorption isothermic experiments were defined using the Langmuir and Freundlich models. When comparing the EPC_0 values with the overlying water SRP values, it was emphasized that the higher EPC_0 values facilitated phosphate release from the sediment, and that the sediment played a role as a phosphate source (Wang et al., 2012). Shoja et al. (2017), in their study of Ekbatan Reservoir (Iran), found that the EPC_0 value was much higher than the SRP concentration and that, despite the high adsorption capacity of the sediment, phosphate release from the sediment could occur. The fact that the estimated EPC_0 values in Lake Mogan are lower than the SRP concentrations found in the overlying water, unlike the findings of Wang et al. (2012) and Shoja et al. (2017), points to phosphorus adsorption in the sediment.

According to Fang et al. (2017) the role of particle morphology of clay minerals in P adsorption were studied. They revealed that Sips model can provide a better prediction than the Langmuir model, especially for kaolinite and hematite minerals and performs improvements as compared to the Langmuir model. This better performance could be attributed to the consideration of particle morphology reflected in the heterogeneity coefficient γ and adsorption capacity Q_m. The fact that the correlation coefficients calculated for the Sips model in Lake Mogan were greater than the values found for the Langmuir and Freundlich models shows the heterogenous behavior of the low phosphorus concentrations on the sediment surface in line with the researchers below. This finding supports the case for high adsorption levels in the lake. Moreover, during the research period, the low phosphorus concentration in the overlying water and the phosphorus fractions undergoing irregular changes in the sediment (Topçu and Pulatsu, 2017) concur with the finding that the sediment's phosphorus adsorption mechanism behaves heterogeneously.

Wang and Li (2010) studied the phosphorus adsorption and desorption mechanism in sediment samples obtained from six different sources in America (canal, ocean, coastal, river, marsh and lake). The estimated NAP and EPC_0 values in the canal and lake sediments were found to be higher than in the other sources. The phosphorus adsorption values in the sediment were calculated in order as Coastal>Marsh>Ocean. In the scope of the research it was reported that the desorption potential of the coastal and marsh sediment samples was extremely low. The fact that the phosphorus desorption value in Lake Mogan, one of Turkey's important wetlands, was found to be lower than 1% supports the high phosphorus adsorption value (907 mg kg^{-1}) and the low NAP (4.8-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_59715985
© 2018, ALÖKI Kft., Budapest, Hungary

11.7 mg kg^{-1}) and EPC_0 (5.5×10^{-3}-46.6×10^{-3} mg L^{-1}) values determined for the sediment. Our findings concur with Wang and Li's (2010) report stating that high values for adsorption in the sediment are effective at keeping desorption at low levels.

Tang et al. (2014) reported that the values for the energy released through phosphorus adsorption (Ea) are in inverse proportion to the calculated phosphorus adsorption in the sediment. The fact that the phosphorus adsorption energy (Ea) values reported in Lake Mogan were lower for the samples taken in July than those taken in October supports the finding that phosphate adsorption values were calculated to be at a maximum in July. Prevalence of ΔH with a high magnitude is generally evidence for the high adsorption energy affinity of P to the sediment. The results of the thermodynamics experiments demonstrated that overall, the adsorption process was exothermic ($\Delta H < 0$) with decreasing entropy ($\Delta S < 0$), and spontaneous ($\Delta G < 0$) under the influence of enthalphy (ΔH-$\Delta S < 0$). The high-magnitude values of ΔH signal strong interactions between phosphorus species and the sediment surface via electrostatic attraction. Adsorption activation energy did not have a significant impact on adsorption resistance at the temperatures in this study.

Experimentally obtained isotherms for phosphorus adsorption onto Lake Mogan sediments were well compatible to all three adsorption models considered ($R^2 \geq 0.936$; $p < 0.05$). Based on Langmuir the Model, the mean of maximum adsorption capacity obtained for July samples was significantly higher than that obtained for October samples ($p < 0.05$). This was attributed to heat activation of July samples due to the exposure of sunlight. The adsorbed phosphorous was not recoverable by distilled water. The comparison of EPC_0 and SRP values signified that the soluble phosphorous do not release from the sediment into the lake water.

The adsorption kinetics comply with the second order model with a high significance ($R^2 \geq 0.999$). Phosphorous adsorption completed in a few hours after adsorbent-adsorbate contact with a period of 0.6-0.8 h with high initial adsorption rates (169-242 mg kg^{-1} h^{-1}). The overall adsorption process was surface precipitation with a high mass transfer to the boundary layer after evaluation of the kinetics with reference to Weber-Morris model.

Conclusions

The sediment's equilibrium phosphate concentration value is used in estimating the phosphorus concentration in the overlying water, which may negatively affect the nutrient value of a lake. With this study, it has been scientifically proven through laboratory research that there may be a risk of phosphorus release from the sediment when the overlying water SRP concentration for October of 0.008 mg L^{-1} falls below the July value of 0.046 mg L^{-1}. Accordingly, considering the overlying water SRP values reported above for Lake Mogan, monitoring them especially in the months of October and July will prove to be decisive in predicting the internal phosphorus load of the lake.

Abstract. This study was conducted to evaluate the effects of combination of ethylene diamine tetra acetic acid (EDTA) with arbuscular mycorrhizal fungi (AMF) on arsenic (As) phytoremediation using maize plants in pot experiment with four treatments (Control, EDTA, AMF, and EDTA+AMF). The results showed that lone addition of EDTA significantly increased exchangeable As concentration in the rhizosphere soil, and thus, enhanced plant uptake of As in shoots and roots. However, it markedly inhibited the root colonization, plant growth, and antioxidant enzyme activity. Consequently, As biological enrichment factor was the lowest because of reduced plant dry weight, although the plants possessed the highest As extraction efficiency. Unlike EDTA, AMF alone had a positive effect on root colonization, dry matter accumulation, and antioxidant enzyme activity, whereas negative effects of AMF on exchangeable As content in the rhizosphere soil and As uptake in shoots and roots were observed. However, using EDTA-AMF combination, maize plants simultaneously exhibited significantly higher exchangeable As extraction efficiency and biological enrichment factor, which were beneficial for the remediation of heavy metal-contaminated soil. Therefore, it is concluded that the EDTA-AMF combination could be regarded a promising choice for phytoremediation of heavy metal-polluted soil.
Keywords: *EDTA, AMF, heavy metal, hyperaccumulator, phytoremediation, soil remediation*

Introduction

Soil becomes polluted when potentially toxic substances are released in amounts exceeding their permissible levels, and reaching prohibitively high concentrations, which affect normal ecosystem functions (Meier et al., 2012). According to most legislative schemes, soil may require remediation if the concentration of one or more metals exceeds the specified threshold level in the soil profile (Meier et al., 2012). Regarding the increasing need to combat heavy-metal pollution, various strategies for soil remediation, mainly mechanical or physicochemical methods, including soil washing, vitrification, thermal treatment, excavation and confinement of soil, and so on, have been used to treat contaminated soil in recent decades (Bhargava et al., 2012; Sarwar et al., 2017). These techniques are usually expensive, require technical expertise and disturb the soil, occasionally rendering the land useless as a medium for further events such as plant growth (Marques et al., 2009). Therefore, mechanical and physicochemical treatments are not applicable on a large scale.

In contrast, phytoremediation is proposed to be efficient, cost-effective, with greater public acceptance, environmental-friendly and sustainable technology from remediation of metal contaminated soils (Pandey, 2012; Sinha et al., 2013; Shabir et al., 2018). In these techniques, plant roots absorb metals from the soil and accumulate them into their

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_59875999
© 2018, ALÖKI Kft., Budapest, Hungary

vegetative parts which are then harvested, and thereby metal is removed from the site of contamination (Shabir et al., 2018). The prerequisite for phytoremediation is that the plants must be genetically capable of growing in soils with high concentrations of metals, and have ability to accumulate metals in their shoots and roots without toxicity to their metabolic processes (Seth, 2011; Tang et al., 2012). The known plants meeting these requirements are called hyperaccumulators. However, growth and biomass production of hyperaccumulators are slow, and consequently, phytoremediation requires several years to reduce soil metal concentrations to an acceptable levels (McGrath and Zhao, 2003). This long duration is a drawback of metal-polluted soil remediation. Nevertheless, owing to preferred occurrence in residual forms, and strong binding with non-biotic or biotic ligands in soil, or inclusion within the crystal lattices of primary or secondary soil minerals, heavy metal bioavailability in soils is actually reduced (Charriau et al., 2011; Echevarria et al., 2006; Shahid et al., 2012). Additionally, the relatively low solubility and phytoavailability of heavy metals in soil is unfavorable for phytoremediation.

To compensate for the relatively small biomass of hyperaccumulators and low metal availability in soil, one alternative scenario has been hypothesized, wherein the plant selected for remediation can have large biomass production, and a chelating agent combined with soil amendment is used. This hypothesis is infact based on the concepts that (1) high plant biomass can enhance metal extraction from polluted soil, (2) chelating agents are used to improve the mobility, solubility, and bioavailability of heavy metals in the soil solution phase, and (3) amendment is applied to increase plant tolerance to heavy metal stress.

Actually, ethylene diamine tetra acetic acid (EDTA) is widely used as the most efficient and effective chelating agent to extract metals from contaminated soil. After soil application, EDTA transfers the metal sorption and precipitation equilibrium toward the enhanced dissolution of heavy metals owing to metal-EDTA complex formation (Goel and Gautam, 2010; Hadi et al., 2010). However, certain researchers reported that there was no significant effect of EDTA on metal uptake by plants, and in certain cases, even negative effects of EDTA application were observed (De La Rosa et al., 2007; Tomé et al., 2009). These contradictory findings indicate that the effect of EDTA on heavy-metal uptake varies with soil type, plant variety, heavy metal concentration and soil pH.

Arbuscular mycorrhizal (AM) fungi (AMF) can develop extensive extraradical hyphal networks, which explore the soil to a greater extent, absorb nutrients from a large vacinity, and translocate them to the roots of host plants. Therefore, they are considered intermediary between soil nutrients and host plants. Moreover, AMF shows great potential for use in phytoremediation due to (i) their ubiquity in the soil environments, and (ii) the development of several strategies enabling host plants to tolerate high metal concentrations in the soil (Hildebrandt et al., 1999; Janousková et al., 2005). Nevertheless, the role of AMF in phytoremediation is still not completely understood. Many studies have demonstrated that AMF promote phytoextraction, causing an increase in metal translocation to shoots (Davies et al., 2001; Trotta et al., 2006). However, other researchers have showed that AMF develop mechanisms that only enable metal accumulation within plant roots, and prevent metal translocation to the shoots (Citterio, 2005; Giasson et al., 2005). To the best of our knowledge, research investigating role of EDTA or AMF in phytoremediation of metal contaminated soils

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

© 2018, ALÖKI Kft., Budapest, Hungary

are scarce, whereas no solid data set exists regarding their combined application for the aforementioned purpose.

With growing concern about remediation techniques for heavy metal-polluted soil, Knowledge of the processes and factors behind the combination of EDTA and AMF for enhancing the phytoremediation of heavy metal-polluted soil is crucial to evaluate and manage the outcomes of this technique. Therefore, this study aimed to highlight the role of the combination of EDTA and AMF in the phytoremediation of soil contaminated with arsenic (As), and additionally, to possibly provide new insight into the remediation of heavy metal-polluted soil.

Material and methods

Experimental design

The experiment was based on a randomized complete block design with three replications, and included four treatments. (i) Control: no EDTA and no AMF, (ii) EDTA: EDTA alone, (iii) AMF: AMF alone, and (iv) EDTA + AMF: EDTA-AMF combination.

AMF inoculum and domestication

The AMF inoculum *Glomus versiforme* was isolated from uncontaminated fluvo-aquic soil at the Yantai Institute, China Agricultural University, Thereafter, a pot culture was prepared with *Trifolium repens* L. grown in a sterilized soil-sand mixture at 1:9 contaminated with arsenic (As) at 50 mg kg^{-1}. After 90 days, chopped root pieces of *T. repens* along with soil were defined as the inoculum, containing a mixture of AM spores, colonized root pieces, AM mycelia, and 700–750 spores per 100 g of inoculum.

Pot culture experiment

To explore the objective as outlined above, an indoor pot experiment was conducted under controlled conditions in a greenhouse at the Yantai Institute, China Agricultural University. For this purpose, plastic pots were used with height and surface diameter of 30 and 23 cm, respectively. Soil used in this study had 6.44 pH (soil:water, 1:2.5), 2.1% organic matter, 140 mg kg^{-1} available nitrogen, 58 mg kg^{-1} Olsen phosphorus, 158 mg kg^{-1} available potassium, and 5.2 mg kg^{-1} total As. After collection from the field soil was air-dried, and then sterilized at 121 °C for 25 min. Required amounts of $Na_2HAsO_4 \cdot 7H_2O$ (50 mg kg^{-1} of soil) were dissolved in 1000 ml of distilled water, and then sprayed onto the soil. Subsequently, the soil was mixed thoroughly, and each pot was filled with 25 kg of the soil. The pots were incubated for 60 days to improve the balance of As in the contaminated soil. During incubation, moisture in the pots was maintained roughly at pot capacity. As was allowed to penetrate deep into the pots via watering, and then, transferred to the soil surface by volatilization, and thereby, was distributed uniformly in the soil. Regarding the AMF, 100 g of inoculum was uniformly introduced at a depth of 3 cm. Thereafter, 5 seeds of maize (*Zea mays* L. 'Denghai-3622') were sown in each pot. Before sowing the seeds were surface-sterilized with 0.5% NaClO solution, subsequently washed several times with distilled water, and allowed to germinate at 28 °C for 48 h. Seven days after emergence, maize were thinned to 3 plants per pot. In each pot, soil moisture was maintained daily at 70% of the pot capacity with distilled water based on weight, and amount of nutrients were added

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_59875999
© 2018, ALÖKI Kft., Budapest, Hungary

according to chemical analysis and plant requirements. Fifty days after emergence EDTA (5 mmol kg^{-1}), prepared in distilled-deionized water, was sprayed on the soil surface as per treatment plan

Data collection and analytical methods

From each pot, maize plants were harvested at 65 days after germination to estimate shoot and root biomass. Shoots were clipped with a pair of scissor at ground level (Shah et al., 2016). To harvest the roots, the whole soil clump from the pot was taken out and placed in a container filled with cold water. After 2 h of soaking, the clump was manually divided into 6 pieces. These pieces were taken out of the container one by one and placed on a 0.5 mm mesh frame to separate roots from soil with a jet of tap water and then, with deionized water as described by Shah et al. (2013). Percentage root colonization by AMF was calculated using the gridline intersect method after staining the roots with trypan blue (Koske and Gemma, 1989). The activities of superoxide dismutase (SOD) and catalase (CAT) in fresh shoots and roots were measured as described by Beauchamo and Fridovich (1971) and Aebi (1974), respectively. The remaining parts were dried in an oven at 80 °C for 48 h, and then weighed to obtain dry matter of shoots and roots. As concentrations in the dried plant materials were determined by inductively coupled plasma atomic emission spectrometry (ICP-AES) (Yang, 1986). Rhizosphere soil was collected following the procedures described by Wang and Zabowski (1998). Classification of the heavy metal species in the dried soil was performed using continuous extraction (Yang et al., 2003). The extraction efficiency of the heavy metal and biological enrichment factor were calculated using *Equations 1* and *2,* respectively.

$$\text{Extraction efficiency } (mg\ g^{-1}) = \frac{\text{shoot heavy metal uptake}}{\text{root dry weight}} \quad \text{(Eq.1)}$$

$$\text{Biological enrichment factor} = \frac{\text{amount of heavy metal in plant}}{\text{amount of heavy metal in soil}} \quad \text{(Eq.2)}$$

Statistical analysis

Values of the collected data are expressed as means of the three replicates. Effects of EDTA, AMF and their combinations were tested using analysis of variance (ANOVA). Means were compared among the treatments using the LSD (least significant difference) test at the 0.05 probability level.

Results

Percentage root colonization

Results revealed the significant effects of AMF on the extent of root colonization (*Fig. 1*). Mycorrhizal colonization was not observed in the control and EDTA treatments, due to the lack of mycorrhizal inoculation. However, plants treated with AMF alone and EDTA-AMF combination showed high colonization rates. In the former case, percentage root colonization was 1.6 folds higher than in case of EDTA-AMF combination.

Dry weights of maize shoots and roots

Dry weight of maize shoots and root are shown in *Figure 2*. Dry weights of both shoots and roots were significantly influenced by application of AMF and/or EDTA. The highest dry weights of both shoots and roots were observed in AMF and least in case of EDTA. Results revealed 53, 119, and 21% higher shoot dry matter yield from AMF treatment as compared to Control, EDTA, and EDTA-AMF, respectively. The respective increased fractions in case of roots dry matter were 63, 122, and 27%. Furthermore, the results indicated that EDTA application seriously inhibited dry matter accumulation in shoots as well as roots and the values were even lower than the control.

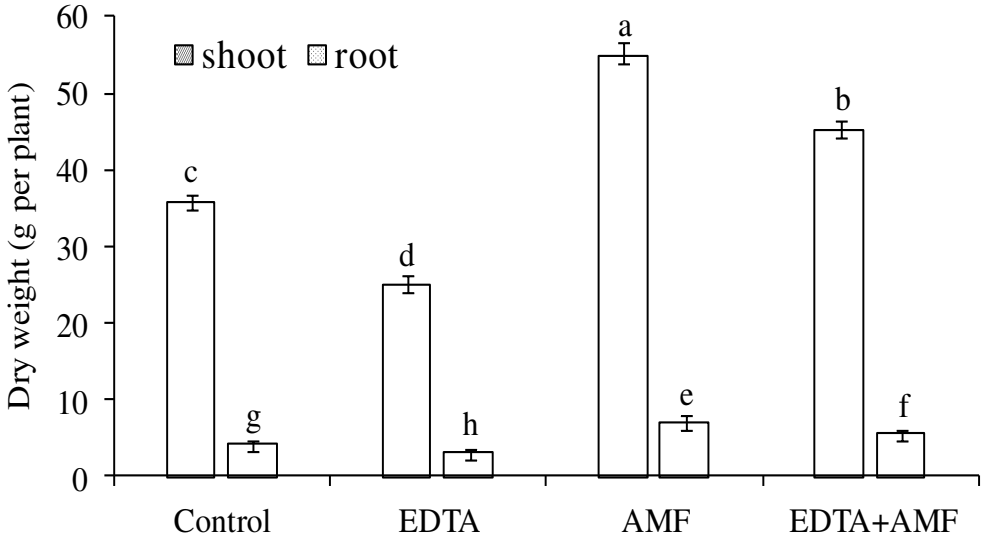

Figure 2. *Dry weight in shoot and root affected by AMF and EDTA application. All the values are the mean of triplications. Different letters above columns indicate significant differences between means by LSD at 5% level*

As concentrations in maize shoots and roots

Results revealed greater total plant As accumulation from AMF, EDTA and their combination as compared to the control (*Table 1*). Among these treatments total As accumulation followed the order EDTA> EDTA-AMF>AMF>Control. Out of the total As accumulation, greater fractions ended up in roots irrespective to the treatments. For the shoots, the highest value was observed in the plants treated with EDTA alone, and the lowest value was observed in the AMF-inoculated plants. Compared with EDTA alone, there was a decrease in As concentration in the plants treated with the EDTA-AMF combination; however, statistical analysis revealed no difference. For the roots, the highest value was similarly observed in the plants treated with EDTA alone; however, the lowest value was observed in the control plants. Moreover, the results indicated that increase in As concentration was larger in the roots than in the shoots, and there were significant differences between them.

Table 1. *Changes in average As concentration (n = 3) in shoot and root of maize plants. Different letters following the means indicate significant differences between means by LSD at 5% level*

Treatment	As concentration (mg kg^{-1})		
	Shoot	**Root**	**Total**
Control	4.16 b	92.07 d	96 d
EDTA	7.58 a	258.72 a	266 a
AMF	3.88 c	168.49 c	172 c
EDTA+AMF	7.25 a	220.93 b	228 b

Enzyme activity

Results revealed a significant effect of AMF, EDTA, and their combination on SOD and CAT activities as compared to the control (*Fig. 3*). SOD and CAT activities in the shoots and roots were significantly improved after AMF application and respectively increased by 37 and 30%, as compared to the control plants. This increased fractions in case of AMF-EDTA combination was 29 and 16%. In contrast, sharp inhibition of both these enzymes was observed in plants receiving EDTA only (*Fig. 3*). Consequently, SOD and CAT activities in the shoots decreased by 17% and 30% respectively, as compared with the control plants. Similar trend was observed for the roots; however, the increase in CAT activity was evidently larger than that in SOD activity (*Fig. 3*).

Relative change in As in different species

Figure 4 shows the relative changes if As speciation as affected by the addition of AMF, EDTA and their combination. We found that the ratio of different species to total As exhibited different changes in the rhizosphere soil. When EDTA was added alone, exchangeable As content increased to 13%, which was 1.72 times greater than control, 2.7 times that AMF alone, and 1.8 times than the EDTA-AMF combination. However, the contents of all the other As forms in the EDTA treatment decreased as compared to the other treatments. Although the exchangeable As content in the rhizosphere soil treated with AMF alone was the lowest, the contents of carbonate As, Fe-Mn-bound As, and organic-bound As increased by 71%, 63%, and 16% as compared to the control.

DOI: http://dx.doi.org/10.15666/aeer/1605_59875999
© 2018, ALÖKI Kft., Budapest, Hungary

Whereas the respective increased fraction was 212, 160, and 31% than EDTA alone, and 15, 26 and 9%, as compared with EDTA-AMF combination. Compared with AMF alone, the EDTA-AMF combination caused slight decreases in the contents of carbonate As, Fe-Mn-bound As, organic-bound As, and residual As, equivalent to the increase in exchangeable As content. The residual As was the greatest among all the As species, irrespective to the treatment.

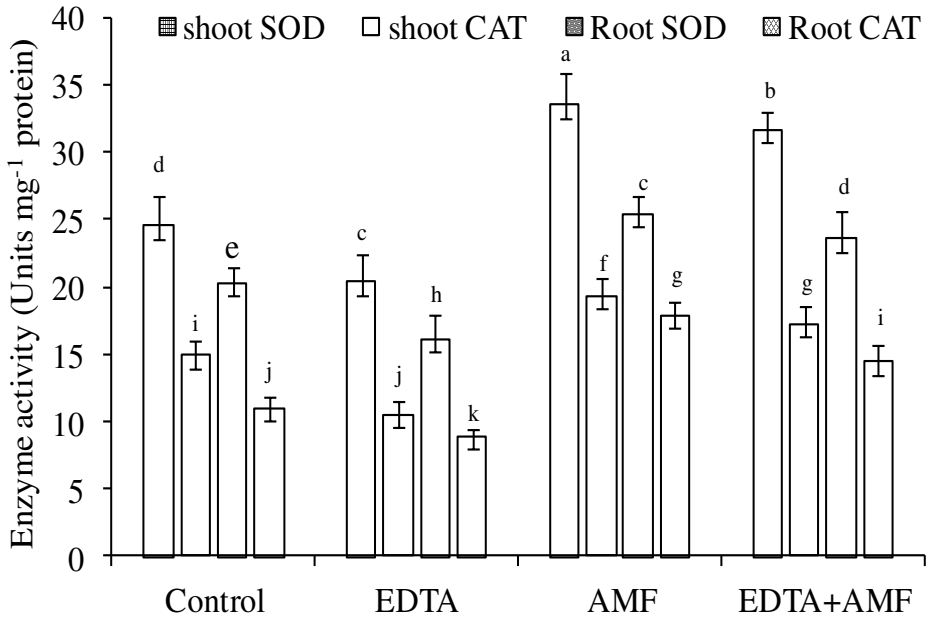

Figure 3. *Enzyme activities of SOD and CAT in shoot and root affected by AMF and EDTA application. All the values are the mean of triplications. Different letters above columns indicate significant differences between means by LSD at 5% level*

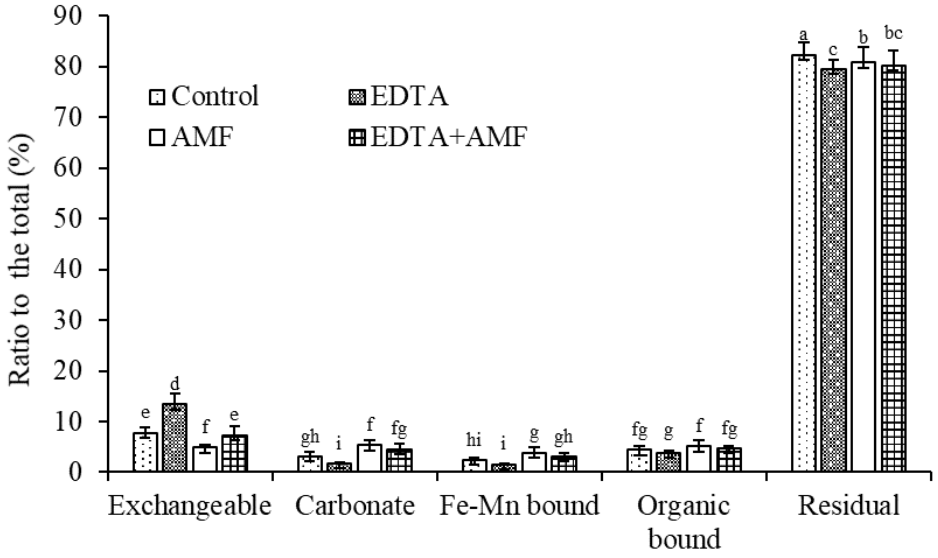

Figure 4. *Relative change of As in different speciations as affected by AMF and EDTA application. All the values are the mean of triplications. Different letters above columns indicate significant differences between means by LSD at 5% level*

As extraction efficiency and biological enrichment factor

As extraction efficiency is shown in *Table 2* and followed the order EDTA ≥ EDTA + AMF > Control > AMF ($P < 0.05$). The order of As biological enrichment factor was EDTA + AMF > AMF > EDTA > Control. The As extraction efficiency of maize plants treated with the EDTA-AMF combination was 1.71, and 1.95 folds greater that of the control, and AMF-treated plants, respectively, whereas the values were almost similar to that of EDTA Similarly, As biological enrichment factor was 2.84, 1.54, and 1.11 times greater than that of the control, EDTA-treated, and AMF-treated plants, respectively.

Table 2. *Average As extraction efficiency and biological enrichment factor (n = 3) in maize plants. Different letters following the means indicate significant differences between means by LSD at 5% level*

Treatment	As extraction efficiency (mg g^{-1})	As biological enrichment factor (%)
Control	0.0347 b	0.0403 d
EDTA	0.0600 a	0.0743 c
AMF	0.0304 c	0.1029 b
EDTA+AMF	0.0593 a	0.1145 a

Discussion

Mycorrhizal colonization

Percentage root colonization is an important factor indicating the establishment of mycorrhizal associations by plants. This study showed that AMF application alone was favorable for mycorrhizal colonization, whereas the EDTA-AMF combination was observed to exert inhibitory effects to AMF survival (*Fig. 1*). These results were in line with some earlier studies who reported that EDTA addition to soil decreases the viability and number of AMF in the rhizosphere soil, although it is not lethal to the fungus (Marques et al., 2008; Tanwar et al., 2013).

Plant dry weight

Figure 2 shows that the order of the dry weights of both shoots and roots was AMF > EDTA + AMF > Control > EDTA. EDTA treatment alone considerably decreased dry weight, probably because of the added phytotoxicity of EDTA and the heavy metal. Moreover, *Figure 2* indicates that biomass accumulation in the mycorrhizal plants with and without EDTA treatment tended to increase. Various mechanisms have been reported to demonstrate that mycorrhizae can help plant species colonize metal-contaminated sites by improving P uptake by the plant, and thus, well-nourished plants show better growth (Lin et al., 2007; Tabrizi et al., 2015). Furthermore, AMF can effectively bind As to their cell walls, immobilize As in the fungal biomass, and subsequently improve plant tolerance to the metal-contaminated environment (Garg and Chandel, 2010; Joner et al., 2000). The positive effect of mycorrhizae on dry matter accumulation was partly offset by EDTA; the dry weight of plants treated with the EDTA-AMF combination was lower than that of the AMF-treated plants, yet significantly higher than that of the EDTA-treated plants.

As uptake and transport

Roots are the first organs to be exposed to metal toxicity, and therefore, greater As accumulation was observed in the roots than in the shoots for all treatments. This might be regarded a strategy for preventing further metal translocation to the shoots and evidence of the operation of a potential tolerance mechanism in the root cells (Khudsar, 2008). It is well known that EDTA addition to contaminated soil can bring metals into solution through desorption of sorbed species and dissolution of precipitated compounds, thus maintaining their bioavailability for plant uptake (Marques, 2009; Norwell, 1984). Moreover, because of their neutral charge, metal-EDTA complexes are not blocked or bound by carboxyl groups or polysaccharides on the rhizodermal cell surface (Shahid et al., 2012). Therefore, root As concentration was the highest with the EDTA treatment (*Table 1*).

Xu et al. (2009) indicated that metal-EDTA complexes are transported through the apoplastic pathway, causing several-fold-stimulated metal translocation from roots to aerial plant parts, in agreement with our finding that, shoot As concentration was higher with the EDTA treatment than with other treatments. Extraradical hyphae of AMF can restrict heavy metal transport from soil to aboveground plant organs, and thus, may serve as a filter/biological barrier against heavy metal transport to plant shoots (Gaur and Adholeya, 2004; Schutzendubel and Polle, 2002). Therefore, shoot As concentration was observed to be minimum when AMF was applied alone. Although As was mainly retained in the root through immobilization by efficient mycorrhizal symbiosis, root As concentration with AMF alone was significantly lower than those with EDTA alone and EDTA-AMF combination, because of improved As uptake by EDTA.

Relative change in different As species

When EDTA was added to the soil, the ratios of the carbonate, Fe-Mn-bound, and organic-bound forms to total As were the lowest in the rhizosphere soil among all treatments, and the following mechanisms were mainly highlighted to explain this decrease caused by EDTA: (1) EDTA can decrease soil pH (Chen et al., 2004). Carbonates are sensitive to pH, and decrease in pH triggers As release from carbonate minerals; (2) EDTA destabilizes the weak bond between metal ions and Fe-Mn oxides and organic matter, and releases the metal ions from these substances (Luciano et al., 2013). EDTA generally increases the exchangeable fractions of heavy metals in soil by forming soluble complexes with them, and this organic molecule is capable of releasing metals linked with different soil particles (Jean-Soro et al., 2012; Udovic and Lestan, 2009). These may be the reasons for the increase in exchangeable As content and decrease in residual As content in the rhizosphere soil after EDTA application alone.

Figure 4 indicates that AMF application had a negative impact on exchangeable As content in the rhizosphere soil; however, it had a positive impact on the contents of carbonate-bound As, Fe-Mn-bound As, organic-bound As, and residual As. The decrease in exchangeable As content and increase in bound As contents were beneficial to maize growth under As stress. The benefits conferred by the mycorrhizosphere for plant growth are: (1) metal ions are bound to extraradical mycelia, which form a dense network of up to several meters of hyphae, and have an unusually high metal sorption capacity (Janoušková and Pavlíková, 2010); (2) binding of metal ions to chitin in the fungal cell wall reduces metal concentration in the mycorrhizosphere soil (Göhre and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1605_59875999
© 2018, ALÖKI Kft., Budapest, Hungary

Paszkowski, 2006); (3) AMF have high affinity for heavy metals, and are particularly suitable for fixing metal in the rhizosphere soil (Göhre and Paszkowski, 2006). These phenomena clearly explain the decrease in exchangeable As content and increase in bound As contents after AMF application alone. The ratio of exchangeable As to total As with the EDTA-AMF combination was evidently higher than that with the control and AMF alone, yet lower than that with EDTA alone, which was mainly because of mycorrhizal inhibition and EDTA promotion of EDTA-As chelation.

Enzyme activity

Under stress induced by As at 50 mg kg^{-1}, the activities of both SOD and CAT increased significantly with AMF alone and EDTA-AMF combination; however, activities of both enzymes decreased with EDTA alone, in both shoots and roots, compared with the control (*Fig. 3*). Increase in enzyme activity is actually a defense mechanism activated by the AMF relationship wherein the metal-induced production of reactive oxygen species increases under metal stress, and activated SOD and CAT are responsible for scavenging the excessively accumulated reactive oxygen species to reduce oxidative stress (Saraswat and Rai, 2011). Concerning EDTA alone, the decrease in enzyme activity might be related to the increase in As bioavailability promoted by EDTA, which may result in enzyme inactivation.

As extraction efficiency and biological enrichment factor

Different responses of As extraction efficiency and biological enrichment factor are presented in *Table 2*. The decrease in extraction efficiency with AMF alone and EDTA-AMF combination indicated that the growth dilution effect was likely to be an important protective mechanism provided by AMF (Zhang et al., 2005). However, the significant increase in biological enrichment factor with AMF alone and EDTA-AMF combination may be attributed to higher dry weight conferred by AMF and higher metal bioavailability facilitated by EDTA. Although EDTA application alone showed the highest extraction efficiency among all the treatments, biological enrichment factor was lower, excluding the control, because of growth inhibition caused by higher metal bioavailability.

Conclusions

We found that lone application EDTA significantly increased As extraction efficiency. However, it reduced plant yield, root colonization and antioxidant enzymatic activity. On the other hand, sole use of AMF, increased root colonization, maize dry matter yield and antioxidant enzyme activities, whereas decreased As extraction efficiency. Combine application of EDTA and AMF utilized the advantages of both EDTA and AMF to enhance As desorption from soil, improve the tolerance of maize plants to As stress, and increase As accumulation in shoots and roots. Thus, it showed a promising option for the remediation of heavy metal-polluted soil. This study warrants further investigations to optimize proportion of combination between AMF and EDTA. Moreover, the time and cost required for the phytoremediation of metal-polluted soil using maize should be considered.

(Received 26th Jun 2018; accepted 31st Aug 2018)

Abstract. Many spider mite species are polyphagous and live together. They are significantly harmful pests for agricultural crops. Acaricides and insecticides are commonly used to control *T. urticae*. Spider mites can rapidly develop resistance to pesticides. Organic control may be considered as an alternative and environment-friendly approach. Three native plants essential oils were isolated by hydrodistillation technique hydro distillation in a Clevenger type apparatus. In this study, *Thymbra spicat*a L. (Labiatae), *Laurus nobilis* L. (Lauraceae) and *Myrtus communis* L. (Myrtaceae) plants have been tested for their essential oil's repellency effect. Essential oils of these three plants were compared for 48 h at four different doses (0.1, 0.5, 1 and 2 ml/l). We observed repellency effect all does and for all essential oils, whereas *M. communis* was proven to be a stronger repellent compared to *L. nobilis* at 2 ml/l.
Keywords: *control, essential oil, repellency effect, Tetranychus urticae, Tokat, Turkey*

Introduction

The two-spotted spider mites, *Tetranychus urticae* Koch. (Acarina: Tetranychidae), are about 0.5 mm in size, with reddish or greenish body color. The adult female body bears 12 pairs of dorsal seta. Two-spotted spider mites (TSSM) were initially described as a European species by Tuttle and Baker in 1968. *T. urticae* is a significant proliferous polyphagous pest, commonly controlled by pesticides in Turkey and other countries. This mite has more than 1200 known host plants (Zhang, 2003). Pesticides pose serious risks for the environment, non-target-organisms and also human life. Tetranychidae has developed resistance against 80 different acaricides to date (Darp, 2004; Miresmailli et al., 2006; Vanpottelberge et al., 2009). *T. urticae* has developed resistance to many insecticides and acaricides (Ay and Gürkan, 2005; Dermauw et al., 2013). Eventually, its control has become problematic in many regions of the world. Several researchers have focused on alternative methods to overcome the negative impacts of conventional pesticides. Essential oils and plant extracts are among the alternative methods against pests and spider mites. Plant essential oils have toxic effects on pests through contact, ingestion and fumigation; in addition, plant essential oils or their constituents have significant behavioral effects on pests, especially as repellents (Akhtar et al., 2010). Another study investigated repellency effects of plant extracts obtained from weeds and essential oils of 53 different plants on *T. urticae* (Kawka and Tomczyk, 2002). The use of plant extracts and essential oils in pest control could be an effective alternative compared to pesticides. Essential oils and their contents such as terpenoids, alkaloids and flavonoids are effective in pest control (Grodnitzky and Coats, 2002). EOs are used antibacterial, antifungal and insecticidal (Chang and Cheng, 2002). Furthermore, plant essential oils have minimal direct and/or indirect effect on predators or the ecosystem (Isman, 2006). Black thyme (*Tthymus spicata*) grows wild in some Eastern

Mediterranean countries and Turkey (Kizil, 2010); its essential oil contains 60-80% of carvacrole. It is belongs to the Lamiaceae family. Thyme has been studied as repellents (Rajkumar and Jebanesan, 2005). *Laurus nobilis* is also a major source of essential oil and its leaf essential oil was reported to be rich in 1.8-cineole (Baydar, 2009). *L. nobilis* is a important plant of used in foods, drugs, and cosmetics. Laurus leaves and essential oils are used for antimicrobial and insecticidal activities (Patrakar et al., 2012). *Myrtus communis* (myrtle) is grows wild and cultivated. It is widespread throughout the Mediterrian region of Anatoloia-Turkey. *Myrtus* leaves and fruit of the plant contain mirtenol, cineol and terpenes. The main constituents of *M. communis* oil are 1.8-cineole, myrtenyl acetate, myrtenol and limonene (Traveset et al., 2001). The myrtle essential oil observed toxicity fumigation of lepidoptera and coleoptera species (Ayvaz et al., 2010; Tayoub et al., 2012).

This article reports repellency effects of essential oils obtained from flowers, stems and leaves of *T. spicata*, *L. nobilis* and *M. communis* against two-spotted spider mites, and positions them as an alternative to pesticides.

Material and methods

Mites culture

Two-spotted spider mites were obtained from a colony maintained at the Plant Protection Department, Tokat Gaziosmanpaşa University (GOP), Turkey. Mites were grown in a climate chamber at 26 ± 1 °C, 60-80% of relative humidity (RH) and 16 h of light and 8 h of dark (LD) photoperiod.

Material collection and processing

T. spicata, L. nobilis and *M. communis* were collected from around the campus area of GOP University during the summer season in June-August 2016 (Location 40.3339, 36.4769). Fresh plant parts were air-dried in the shade at room temperature and then grounded. Essential oils were extracted from a 100 g mixture of stems, flowers and leaves using a Clevenger-type apparatus within 2 h. The essential oils were later stored in sealed vials at 4 °C until the time of analyses (as previously performed by Cosimi et al., 2009).

Repellency effect

During the trial, same age ten adult female mites were transferred into 3 cm bean leaf disks as nutriment and then placed in 9 cm Petri dishes. We tested four different concentrations (0.1, 0.5, 1 and 2 ml/l) of essential oils of *T. spicata*, *L. nobilis* and *M. communis*. They were dissolved in water containing 0.3% Tween 20 and were diluted to the targeted doses. Leaf discs (30 mm diameter) were cut from *P. vulgaris* leaves. In the repellency assay, half of leaf discs were immersed in water containing 0.3% Tween 20, which served as control and the other half of the leaf discs were immersed in each essential oil solution for 20 s before drying in room temperature for 30 s. Afterwards, leaf discs were put in Petri dishes; ten adult females (1-2 day old) of *T. urticae* were placed on the center of each leaf disc. Cotton saturated with water was added in the Petri dishes in order to maintain the leaf turgor and avoid escape of mites.

Plates were then sealed with parafilm to prevent any loss of essential oils. Each treatment was repeated for three times. The number of mites on treated leaves (half of

© 2018, ALÖKI Kft., Budapest, Hungary

the leaf) and untreated leaves (the other half of the leaf) were counted at 2, 24 and 48 h post treatment respectively and repellency index was calculated by RI = (C – T / C + T) × 100 (Pascual-Villalobos and Robledo, 1998). In this formula RI stands for repellency index, T is the number of mites in treatment group and C is the number of mites in the control group.

Phytotoxicty test

Based on a study by Miresmailli and Isman (2006), essential oils of three test plants were tested on rose shoots (*Rosa damascena* Mill) using 1% solution (300 ml) consisting of essential oil, distilled water and Triton X. Each plant's essential oil (30 ml solution) was sprayed on rose shoots by using a handle sprayer, while control rose shoots remained unsprayed. Shoots were prepared in a glass flask filled with tap water (500 ml) under laboratory condition maintained at 26 ± 1 °C and 16 h of light and 8 h of dark (LD) photoperiod. Results were recorded after a treatment 24 using a scale between 0 to 4. Each treatment was replicated three times.

Data analysis

The repellency effects were analyzed by one-way analysis of variance (ANOVA) and significant differences between mean values were found by Tukey test using SPSS version 19.0. P-value < 0.05 was regarded as a significant difference.

Results and discussion

The repellent activity of three different plant essential oils tested at various concentrations after 2, 24 and 48 h post exposure period are presented in *Table 1*. *T. spicata* was found to have the lowest repellency effect at 49.9% in 2 h and 45.8% after 24 and 48 h. We also observed that the repellency effects of essential oils on adult mites would increase with time regardless of the concentration level.

Table 1. *Repellency effects of three plants' essential oil on Tetranychus urticae*

Time (h)	Concentration (ml/l)	Repellency effect (% ± SE)		
		Laurus nobilis	*Myrtus communis*	*Thymbra spicata*
2	0.1	76.9±11.98a	79.16±12.50a	49.99±08.90a
	0.5	75.00±10.44a	79.16±16.59a	70.83±11.67 a

24-h repellency effects of *L. nobilis* and *M. communis* at 0.5 ml/l concentration on adult females of two-spotted spider mites were recorded as 66.6% and 75% respectively, which was statically significant ($P < 0.05$). The repellency effect of *T. spicata* at the lowest concentration (0.1 ml/l) was found to be lower than *L. nobilis* and *M. communis* at the end of 2, 24 and 48 h and there is no difference statistically. In addition, no significant difference was found between the repellency effects at 2 h and 48 h, when applying 0.1 ml/l concentration. At 2 h, in all three plant essential oil treatments, the effect of 0.1 and 2 ml/l concentrations were statistically within the same range. The highest repellency effects were observed at the and of 48 h with *M. communis* and *T. spicata* essential oil on *T. urticae* adults as 95.8% and 91.6% respectively. Furthermore, the highest repellency effect on adult mites identified as 95.8% with 2 ml/l concentration of *M. communis* at the 48 was found to be statistically different from other groups ($F = 01.50$, d.f. = 3, $P < 0.05$). Regardless of duration, the repellency effects of all three tested essential oils on *T. urticae* adults changed with the changing concentration. Eventually, *M. communis* essential oil was observed to have highest repellency effects as compared to other test plant essential oils on *T. urticae* in 24 and 48 h exposure ($P < 0.05$).

Essential oils contain several biochemicals including acids, alcohols, aldehydes, ketones, esters, phenols, terpenes and sesquiter penes. Essential oils are used as antifeedant, antiviral, acaricidal, antimicrobial, antioxidant, antifungal, contact and repellent (Isman, 2000, 2006). In this study, we demonstrated repellency effects of essential oils from three plants belonging to Lamiaceae family against two-spotted spider mite. There is no observed any phytotoxic effect on bean plants.

Previously, different concentrations of essential oils from 14 species of Lamiaceae were shown to cause mortality and induce repellency in adult females of the carmine spider mite, *T. cinnabarinus*. (Mansour et al., 1986). Other studies also confirm repellency effect of *M. communis* essential oil against two spotted spider mites (El-Zemmity et al., 2006). In another repellency effect study, four different concentrations of rose essential oil, geraniol and citronellol were applied to *T. urticae* and results confirmed repellency effects of essential oils on the mites (Yorulmaz-Salman and Erbaş, 2014). In a repellency trial on *T. urticae* with essential oils of *Origanum vulgare* L, *Micromeria fruticosa* L. And *Nepeta racemosa* L. of the Lamiacea (mint) family, highest motalily rate was observed at 2 µl/l concetration, and it also increased with time. (Çalmaşur et al., 2006). Another study in greenhouse conditions with essential oils obtained from *Cuminum cyminum* and *Origanum syriacum* var *bevanii* revelaed fumigant effects on *T. cinnabarinus* and *Aphis gossypii* (Tuni and Sahinkaya, 1998).

Conclusion

In conclusion *M. communis* essential oil showed stronger repellency effect on TSSM adults at the highest concentration (2 ml/l) in comparison to *L. nobilis* and *T. spicata* essential oils. We concluded that all three plant essential oils can be used to control *T. urticae*. The repellency effects of *T. spicata*, *L. nobilis* and *M. communis* essential oils on TSSM adults in all concentrations increased with time. However, it is necessary to perform experiments with these three plant essential oils under the greenhouse conditions and compare results with laboratory results. As a final note, at given concentrations, the tested essential oils were not detected to have any phytotoxic effect on the plants.
